This book compiles the abstracts from the 36th annual meeting of the Society of Environmental Toxicology and Chemistry – Europe (SETAC Europe), conducted from 17–21 May 2026 in Maastricht, the Netherlands.

The abstracts are reproduced as submitted by the author and accepted by the scientific committee. They appear in order of abstract code and alphabetical order per presentation type. The poster spotlight abstracts are included in the list of poster abstracts. The presenting author of each abstract is high-lighted in bold.

The information in this abstract book reflects the status of the abstracts as was on 22 April 2026.

No part of this publication may be reproduced, stored in a retrieval system, or transmitted in any form or by any means, electronic, electrostatic, magnetic tape, mechanical, photocopying, recording, or otherwise, without permission in writing from the copyright holder. SETAC Europe's consent does not extend to copying for general distribution, for promotion, for creating new works, or for resale. Specific permission must be obtained in writing from SETAC for such copying. Direct all inquiries to SETAC Europe.

Society of Environmental Toxicology and Chemistry Europe (SETAC Europe)

About SETAC

In the 1970s, no forum existed for interdisciplinary communication among environmental scientists, biologists, chemists, toxicologists, managers, engineers or others interested in environmental issues. The Society of Environmental Toxicology and Chemistry (SETAC) was founded in North America in 1979 to fill the void and quickly saw dynamic growth in the Society's membership, meeting attendance and publications.

A unique strength of SETAC is its commitment to balance the scientific interests of government, academia and business. The Society by-laws mandate equal representation from these three sectors for officers of the World Council and Geographic Unit Boards of Directors and Councils, and in the composition of committees and other society activities. The proportion of members from each of the three sectors has remained nearly equal over the years.

The Society is concerned about global environmental issues. Its members are committed to Environmental Quality Through Science®, timely and effective communication of research, and interactions among professionals so that enhanced knowledge and increased personal exchanges occur. Therefore, SETAC publishes two globally esteemed scientific journals and convenes annual meetings around the world, showcasing cutting-edge science in poster and platform presentations. Because of its multidisciplinary approach, the scope of the science of SETAC is broader in concept and application than that of many other societies.

SETAC's growth is reflected in the founding of Geographic Units around the world. SETAC Europe was established in 1989 as an independent organisation, followed by SETAC Asia-Pacific in 1997 and SETAC Latin America in 1999. In 2002, the four existing organisations joined together under the governance of the SETAC World Council. SETAC Africa is the most recent Geographic Unit, which was adopted in 2012. As evidence of international acceptance of the SETAC model and of the great interest at the local level, regional chapters and branches have emerged in a number of countries.

SETAC publishes two journals, *Environmental Toxicology and Chemistry* (ET&C) and *Integrated Environmental Assessment and Management* (IEAM). ET&C is dedicated to furthering scientific knowledge and disseminating information on environmental toxicology and chemistry, including the application of these sciences to risk assessment. Integrated Environmental Assessment and Management focuses on the application of science in environmental decision-making, regulation and management, including aspects of policy and law, and the development of scientifically sound approaches to environmental problem solving. Together, these journals provide a forum for professionals in academia, business, government and other segments of society involved in the use, protection and management of the environment for the enhancement of ecological health and human welfare.

SETAC books provide timely in-depth reviews and critical appraisals on scientific subjects relevant to understanding a wide range of contemporary topics pertaining to the environment. These include any aspect of environmental chemistry, toxicology, risk assessment, risk management or environmental policy.

SETAC has two administrative offices, in Pensacola, Florida, USA, established in 1992, and in Brussels, Belgium, established in 1993.

1.01 Advancements in Data-Driven Ecotoxicology: Integrating Data and Innovative Methods

1.01.T-01 AIVIVE: Quantitative Comparison of Uncertainty in Hazard Characterization Using Traditional Animal Studies Versus New Approach Methodologies (NAMs) Leveraging AI-Driven Data Extraction

Ana Fernandez Agudo¹, Irene Aguado Orquillas², Davide Lugli², Jose V. Tarazona¹, Maria del Carmen Gonzalez-Caballero¹ and David Perez del Rey¹, (1)Institute of Health Carlos III (ISCIII), Spain, (2)UPM, Spain

Traditional chemical hazard assessment relies largely on in vivo studies summarised into point estimates such as NOAELs, EC values and benchmark doses (BMDs), which obscure underlying variability, uncertainty and mechanistic context. In contrast, New Approach Methodologies (NAMs), including high-throughput in vitro assays, omics platforms and computational tools, offer pathway level insight but remain difficult to integrate into regulatory frameworks due to heterogeneous data structures and uncertain comparability with traditional endpoints.

To address this gap, we propose an AI-enabled framework, using locally trained LLMs based on BioMistral, explainable AI (XAI) and aligned pipelines, to extract, harmonise and compare toxicological information from in vivo studies, NAM datasets and established resources such as ToxCast/Tox21 and AOP-Wiki. This supports large-scale cross-modality comparison of dose-response patterns and mechanistic concordance across chemical groups, aligning with current efforts to advance data-centric, non-animal toxicology.

A multilayer workflow retrieves and standardises traditional and NAMs derived data. Bioactivity datasets from CompTox follow ToxCast/Tox21 and PARC ontologies. In parallel, advanced NLP/LLM tools extract full dose-response information and metadata from scientific literature and regulatory dossiers, enabling reconstruction of experimental variability. Curated data are integrated into a semantic Knowledge Graph following FAIR principles.

The AI-driven extraction system successfully recovers study descriptors, dose-response datapoints and mechanistic annotations across heterogeneous formats, enabling harmonised datasets suitable for comparative modelling. Integration with ToxCast/Tox21 profiles and AOP-linked evidence yields mechanistic fingerprints consistent with established toxicodynamic frameworks. The harmonised dataset enables preliminary uncertainty evaluation and mechanistic clustering to explore whether chemicals sharing NAMs-derived pathway activation profiles exhibit coherent biological effects.

This work establishes a mechanistically grounded, uncertainty aware AI framework that enhances comparability between traditional and NAMs based evidence, supporting broader regulatory integration of NAMs and contributing to reduced reliance on animal testing in next-generation risk assessment.

1.01.T-02 Bio-QSARs: Enhancing Ecotoxicity Predictions by Exploiting Chemical and Biological Information

Jochen Zubrod¹, Maxime Vaugeois² and Nika Galic³, (1)Zubrod Environmental Data Science, Germany, (2)Syngenta Crop Protection LLC, United States, (3)Syngenta AG, Switzerland

Practical, legal, and ethical considerations necessitate the development of methods to replace animal experiments, commonly known as new approach methodologies (NAMs). Among these, machine learning (ML)-based quantitative structure-activity relationship (QSAR) models are a key component. Recently, we introduced the Bio-QSAR concept for multispecies aquatic toxicity regression tasks, enabling cross-chemical and cross-species predictions by integrating both chemical and biological descriptors. Here, we present extensions to the first-generation Bio-QSAR models that markedly expand the scope, data foundation, and performance of the initial approach.

First, training datasets were enlarged by approximately 20-fold, extending from pesticides to the broader chemical landscape and from freshwater organisms to aquatic species in general, while allowing for flexible test durations. Model training employed Gaussian Process Boosting, an algorithm combining tree boosting with mixed-effects modeling, to handle both fixed and random effects. We tested training Bio-QSARs using different

sources of biological information besides Dynamic Energy Budget (DEB) parameters by including, among others, taxonomic distances. The models achieved unprecedented predictive power, with R^2 values on independent test sets of up to 0.922 for fish and 0.905 for invertebrates. Applying SHapley Additive exPlanations (SHAP) in combination with a multicollinearity correction rendered the models fully explainable. Novel applicability domain (AD) approaches based on principal component analysis and feature importance improved predictive power and robustness by reducing outlier frequency. Next, we incorporated curated in-house toxicity data (~1,500 data points) into fish Bio-QSAR training, which further expanded the feature space, yielding higher predictive performance (AD-filtered $R^2 = 0.934$), and markedly fewer extreme outliers (0.4%). Our enhanced Bio-QSARs demonstrate flexible cross-chemical and cross-species prediction capabilities that meet OECD criteria for regulatory application. Current work focuses on extending the Bio-QSAR framework to algae and terrestrial plant species, paving the way toward a unified, multispecies modeling platform. These explainable, regulation-ready models hence hold promise to benefit a range of applications in environmental risk assessment as well as research and development of chemicals.

1.01.T-03 Data-Driven Mechanistic Forecasting of Species-Specific Chemical Sensitivity Using Docking-Derived Molecular Features

Rama Krishnan¹, David Spurgeon², Stephen James Short², Bruno Campos³, Claudia Rivetti³, Claire Peart³ and Peter Kille¹, (1)Cardiff University, United Kingdom, (2)UK Centre for Ecology & Hydrology, United Kingdom, (3)Safety, Environmental and Regulatory Sciences (SERS), Unilever, United Kingdom

Understanding cross-species susceptibility to chemicals remains a key challenge in environmental risk assessment (ERA), which still relies on a few model species and assumes others respond similarly. Conventional toxicity testing is slow and costly, limiting biodiversity coverage. To move from assumption to mechanism, we developed a framework that starts at the molecular initiating event (MIE) within an Adverse Outcome Pathway (AOP) and extends to organism and population effects. As proof of concept, we analysed chlorpyrifos and chlorpyrifos-oxon across non-model taxa by comparing their interactions with acetylcholinesterase (AChE) orthologs, linking variations in binding dynamics to susceptibility predictions and enabling more mechanistic ERA.

Molecular docking revealed consistently stronger target engagement for chlorpyrifos-oxon compared to chlorpyrifos, with protein-ligand interaction fingerprints aligning with empirical sensitivity rankings. When converted into calibrated susceptibility scores and compared with species sensitivity distributions, the framework identified known sensitive lineages such as cladocerans and amphipods, while highlighting plausible outliers among fish where toxicokinetics and barrier properties likely attenuate target-level effects. This defines a mechanistic link from molecular trigger to risk-relevant outcomes, distinguishes cases where strong target binding does not result in high sensitivity, and minimises false-negative classification of vulnerable species.

We then scale this logic to a broader endocrine axis. Using curated ecdysone receptor (EcR) orthologs from >1,200 arthropods, we simulate binding of synthetic diacylhydrazine (DAH) agonists and embed these signals in an EcR activation pathway. The evidence resolves hotspot clades, ranks DAHs above steroidal agonists in predicted affinity, and nominates early-warning biomarkers tied to molting transcriptional programs. The output is a regulatory-scale, traceable species–compound prioritisation to guide testing, monitoring, and mitigation. Limitations remain, coarse docking physics, uneven omics coverage, incomplete toxicokinetics; but the framework is modular and ready to absorb better receptor dynamics, metabolism, and additional off-target receptors. Combined, this framework provides mechanistically anchored evidence for New Approach Methodologies (NAMs) and Next-Generation Risk Assessment (NGRA), linking molecular triggers to ecological effects.

1.01.T-04 Ruleless Reaction Prediction with Transformers utilising Enzyme Context

Liam Brydon-Brown¹, Tobias Olenyi¹, Tim Lorschebach² and Joerg Wicker¹, (1)University of Auckland, enviPath Limited, New Zealand, (2)enviPath limited, Germany

Enzyme-catalysed reactions are common in many areas, including pharmaceutical metabolism and agricultural chemical biodegradation. Analysing and predicting how these reactions occur is increasingly important for identifying toxic by-products and achieving regulatory approval. Incorporating enzyme information into these predictions has been shown to improve prediction capabilities. However, existing methods require knowledge of the enzyme to perform prediction, and in many situations, especially biodegradation, the complexities of the reaction environment mean the exact enzymes are not known. In this presentation, we propose a hierarchical multi-label classifier and associated evaluation framework to predict the enzyme commission number a

chemical compound reacts with. Our method achieves a hierarchical F1-score of up to 93.2%, outperforming existing methods. Additionally, we present an ablation study on the effects of including enzyme information for product prediction.

1.01.P Advancements in Data-Driven Ecotoxicology: Integrating Data and Innovative Methods

1.01.P-Mo001 CRANE-DB: A Curated Dataset and Variability Analysis for Avian Acute Toxicity.

Syarifatun Nisa Nurdhy¹, M. Amine Aouini¹, Mark D Jankowski² and Jo Nyffeler¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)U.S. Environmental Protection Agency, United States

Bird populations across Europe are declining despite their essential role in ecosystem services, with pesticide and fertilizer use identified as major drivers. Avian acute toxicity testing therefore remains central to pesticide risk assessment for non-target organisms. Although acute dietary testing has been waived and replaced with acute oral testing, this method remains low-throughput. At the same time, interest in New Approach Methods (NAMs) is increasing to reduce animal use, yet their implementation in avian toxicity studies is limited. A key barrier is concern about their relevance to in vivo data, making high-quality curated in vivo datasets crucial for NAMs development.

We curated avian acute oral toxicity data from the Toxicity Values Database (ToxValDB, v9.5), the Pesticide Properties Database (PPDB), and the U.S. Environmental Protection Agency (EPA) Office of Pesticide Programs (OPP). Records were restricted to oral LD50 values with 14-day observation according to Organization for Economic Co-operation and Development Test Guideline 223. ToxValDB entries were manually checked against original sources to extract missing substance purity information, new LD50 values (lethal dose causing 50% mortality) and correct reporting errors. PPDB was limited to high-quality regulatory entries, and substance purity information was harmonized. Duplicates were removed within and across databases based on identical CASRN (CAS Register Number), species, LD50 value, purity, and qualifier.

Variability in LD50 values for compounds with multiple datapoints was assessed using median absolute deviation (MAD) and LD50 max/min ratios (>3 and >10). The effects of purity and the use of more than one species on variability were evaluated using Generalized Linear Mixed Models.

We retrieved 506, 466, and 889 records from ToxVal, PPDB, and OPP, respectively. After curation and de-duplication, our dataset contained 1671 entries covering 811 CASRN, which we named CRANE-DB. Majority of our records (55.2%) were from Northern Bobwhite, followed by 28.2% Mallard Duck. Nearly half of our entries (48.5%) have 2 or more LD50 within one CASRN. Furthermore, we examined LD50 variability within CASRN and found that low substance purity and cross-species testing significantly increase variability ($p < 0.05$). Purity effects were more pronounced within same species. These curation and analysis highlight CRANE-DB value as a more robust benchmark for developing NAMs in avian toxicity.

1.01.P-Mo002 Threshold of Toxicological Concern (TTC)- refining ecological TTC using Enhance Database of Fragrance Chemicals.

Aurelia Lapczynski¹ and Scott E. Belanger², (1)Research Institute for Fragrance Materials, United States, (2)Stream Wise Ecotox, LLC, United States

The Threshold for Toxicology Concern (TTC) is a well established and accepted concept in human health safety. Its purpose is to rapidly screen and assess data poor materials and mixtures by establishing an exposure concentration below which negligible risk is expected. The ecological threshold of toxicologic concern (ecoTTC) was created back in 2015 (Belanger et al. 2015) and proposed as a means to summarize larger amounts of ecotoxicity data with the purpose of Predictive No Effect Concentration (PNEC) extrapolation. Leveraging database with computational tools (Ecotoxicological Information System, EnviroTox; Connors et al. 2019) ecoTTC allows the prediction of 5th percentile PNEC for ecosystems using ecotoxicity data extrapolated to individual PNEC for individual compounds. Since TTC has been used by Research Institute for Fragrance Materials (RIFM) to screen fragrance materials in human health assessments, an effort began to develop an ecoTTC for fragrance materials. A review of available ecotoxicological data in the RIFM database as well as

additional literature including Europea Chemicals Agency (ECHA) registration database was used to derive ecological Thresholds of Toxicologic Concern (ecoTTC) and Chemical Toxicity Distributions (CTD). For the purpose of this project the following ecoTTC assessments and comparisons were made: material alone versus supplementation by EnviroTox; groupings based on chemical class, Verhaar Mode of Action (MOA) and MOATOX MOA classification, groupings based on various bands of log Kow, etc. In addition US-like and European-like ecoTTC assessments were evaluated. A total of 1094 ecotoxicity studies of all types were summarized covering 424 fragrance materials and results from analysis are going to be reported during the presentation.

1.01.P-Mo003 Integrating Ecotoxicity Evidence: A Meta-analysis of Pharmaceutical and Personal Care Product Effects on Freshwater Fauna

Anita Tarandek¹, Sandra Hudina², Marina Veseli¹, Ivan Senta¹, Antonia Smolić¹, Jelena Bujan¹, Ana Previšić³ and Antica Čulina¹, (1)Ruder Boskovic Institute, Croatia, (2) University of Zagreb, Croatia, (3) University of Zagreb; Collaborative Research Centre 1357 Microplastics, University of Bayreuth, Croatia

Pharmaceuticals and personal care products (PPCPs) are increasingly detected in freshwater ecosystems due to their widespread use and incomplete removal during wastewater treatment. These chemicals include psychoactive substances, antibiotics, anti-inflammatory drugs, hormones, chemotherapeutic drugs, fragrances, preservatives, UV filters, plasticizers etc. Numerous studies report effects on survival, growth and reproduction in non-target freshwater organisms. However, the synthesis of such studies that would summarise the overall evidence of these effects has not yet been conducted. We thus conducted a systematic review and meta-analysis to integrate ecotoxicity evidence across freshwater taxa. Our main aims were to quantify the overall effects of environmentally relevant PPCP exposures on fitness of freshwater fauna, and to test several hypotheses on the variation in the magnitude of the effects. Fitness was defined as any direct or indirect endpoint associated with the survival or reproductive output of an organism. We identified 92 relevant peer-reviewed experimental studies and openly available datasets on 27 species. We calculated two effect sizes, log response ratios (lnRR) to estimate changes in mean trait values and log variance ratios (lnVR) to evaluate shifts in trait variability. Meta-regression models were used to assess moderators such as developmental stage, sex, exposure duration and environmental conditions on the magnitude of the effects. Additionally, we identified taxonomic and geographic gaps to provide directions for future studies. Finally, we assessed whether the included studies influenced policy or regulatory attention by exploring their alternative impact metrics. Our work provides a comprehensive quantitative synthesis of PPCP effects on freshwater animals. By integrating heterogeneous ecotoxicity data, our findings support improved prioritisation of PPCPs and strengthen the evidence base for environmental risk assessment and regulatory decision-making.

1.01.P-Mo004 Curation of REACH Acute and Chronic Fish Toxicity Data and Assessment of Models Predictive Performance

Panagiotis Karamertzanis¹, Heidi Ekholm², Aliisa Yli-Tuomola², Anna-Maija Nyman², Kostas Andreou², Romanas Cesnaitis², Salvador Moncho Escrivá², Vincent Bonnomet² and Wim De Coen², (1)No Affiliation, Finland, (2)European Chemicals Agency (ECHA), Finland

Under REACH, both acute and chronic fish toxicity data are required for the hazard and risk assessment of substances manufactured or imported at 10 ton/y or more, yet experimental testing is resource-intensive and often complicated by substance properties (e.g. low solubility). Hence, it is important to maximize the use of already generated data, e.g. to validate alternative in vitro and in silico methods, establish the relative species sensitivity and assess the role of fish acute and chronic studies in hazard assessment.

We constructed high-quality reference datasets fish toxicity by extracting and rigorously curating experimental studies from REACH registration dossiers, with AI-assisted algorithmic curation applying strict criteria for study reliability, guideline adherence, and molecular structure assignment. Acute and chronic effect levels were standardised and categorised into scenarios reflecting test design and data quality. The dataset comprises approximately 700 substances with LC₅₀ values derived from high-quality short-term fish toxicity, fish embryo, or fish cell line assays. These values were obtained through concentration - response modelling based on analytical verification of concentrations. For long-term toxicity, the dataset includes NOEC/EC₁₀ values for

around 250 substances, generated using tests such as the fish early-life stage toxicity test, juvenile growth test, life cycle toxicity test, short-term embryo and sac-fry stage test, or fish sexual development test, all conducted under equally rigorous reliability criteria.

As a first use of the reference datasets, we assessed the accuracy and applicability domain coverage of predictive models, including Vega, ECOSAR, iSafeRat, T.E.S.T., ISIDA and KATE. Models were benchmarked for their ability to predict effect concentrations and regulatory classification thresholds both globally and within chemical subspaces using spectral clustering. Several models demonstrated reasonable predictive accuracy for in-domain chemicals. For acute toxicity 80-90% of the LC50s were predicted within 1 log unit. For chronic the performance was lower and with a much smaller applicability domain coverage. The analysis shows promise for using modelling in aquatic toxicity hazard assessment, but also highlights limitations due limited applicability domain, algorithm variance and bias and confounding factors, such as solubility limitations, that are not always and sufficiently accounted for by current models.

1.01.P-Mo005 Time to Shine: Illuminating How Ecotoxicology Laboratory Lighting Modulates the Circadian Metabolome

Ryan Lester¹, Steve Melvin¹ and David J. Beale², (1)Griffith University, Australia, (2)Commonwealth Scientific and Industrial Research Organisation (CSIRO), Australia

Organisms rely on circadian clocks to optimise their metabolism, ensuring energy availability matches metabolic need and preventing contradictory metabolic processes from operating simultaneously (e.g. synthesis and degradation). The circadian clock regulates diverse metabolic processes like sleep and wakefulness, appetite and gut motility, and a suite of behavioural and physiological phenomena. In animals whose habitats are exposed to sunlight, light is generally the dominant signal for setting the circadian clock. Human studies show that limited access to the right quality and quantity of light is a major contributor to poor metabolic health. Thus far, there has been very little investigation into how indoor lighting affects the circadian metabolism of laboratory animals, despite often similar light quality to human-inhabited indoor spaces. In this study, we exposed Eastern mosquitofish (*Gambusia holbrooki*) to the typical fluorescent lights found in an environmental toxicology laboratory as well as light-emitting diodes (LEDs) with a spectral power distribution mirroring sunlight, and programmed with a simulation of sunrise and sunset. We used nuclear magnetic resonance and liquid chromatography-mass spectrometry metabolomics and lipidomics to investigate the effects of these lighting schemata on the fish's metabolic health. We ran a parallel field study to investigate which laboratory lighting schemata led to the most natural circadian metabolome. Using these data, we elucidated ways to improve laboratory design for animal health, to maintain circadian entrainment that reflects natural metabolic oscillations of wild fish, and to mitigate inadequate light quality as a confounding variable with sensitive multiparameter omics studies.

1.01.P-Mo006 A multi-task neural network approach for predicting toxicokinetics in freshwater crustaceans

Wei-Yu Chen¹, Chia-Yun Chiang¹ and Wei-Chun Chou², (1)National University of Tainan, Taiwan (Greater China), (2)University of California, Riverside, United States

This study develops a multi-task neural network-assisted toxicokinetic (TK) model to predict time-varying internal concentrations of organic compounds in freshwater crustaceans (water fleas and amphipods), particularly when compound-specific TK information is limited. The work includes: (i) establishing a comprehensive database of TK data for pharmaceuticals, pesticides, PFAS, and other organic contaminants; (ii) developing machine learning (ML)-assisted quantitative structure-activity relationship (QSAR) methods to identify physicochemical, biological, and environmental descriptors and to predict uptake (ku) and elimination (ke) rate parameters; and (iii) integrating these predicted parameters into a mechanistic TK model to form an ML-assisted TK framework. To stabilize variance and reduce the influence of extreme values, TK parameters were transformed prior to modeling, resulting in robust predictive performance in the transformed space. Because transformed values only reflect the learning space of the model, original-scale TK parameters were reconstructed for downstream TK simulations. Although uptake rates span several orders of magnitude, which naturally leads to larger absolute errors, especially for highly bioaccumulative compounds, the model still produces reliable predictions for both TK parameters in the original scale. SHAP analysis showed that life stage,

exposure duration, and dissolved organic matter strongly influence both k_u and k_e , while certain chemical descriptors contributed more prominently to elimination, indicating slightly greater sensitivity to intrinsic molecular properties. Validation demonstrated that the ML-assisted TK model captures time-varying internal concentrations and key TK features for most compounds, including peak concentration, time to peak, and overall exposure (AUC), with only a few cases showing poor agreement. Overall, this approach integrates chemical knowledge, biological context, and experimental data to fill critical TK data gaps and provides a mechanistically meaningful foundation for downstream TK applications.

1.01.P-Mo007 From Variability to Validation: A Bayesian Approach for Evaluating Alternative Fish Toxicity Tests

Kristin Connors, Spiro Stilianoudakis and Kathleen McDonough, Procter & Gamble, United States

Regulatory environmental toxicology relies on experimental results from a handful of standardized toxicity tests including the fish acute toxicity assay (e.g., OECD 203, EPA OPPTS 850.1075). Several animal alternative assays have been developed to replace the acute fish toxicity (AFT) assay including the fish embryo toxicity (OECD 236) test, RTgill cell cytotoxicity assay (OECD 249), as well as computational approaches. These new approaches must be easily transferred to new labs, statistically robust, reproducible, reliable, and “accurate”. Implicit in this, is understanding the inherent variability of traditional acute fish toxicity (AFT) studies, which has been largely unknown, and widely taken for granted. In this work, we developed a Bayesian hierarchical linear model applied on a curated database of over 1,000 historical AFT results. We leveraged our bespoke Bayesian model to both gain inference on the primary sources of variability in AFT studies and to derive a robust and statistically principled global margin of error (MOE) on LC50 endpoints, providing a quantitative benchmark against NAM-derived toxicity values. When applied across chemicals and species, our framework demonstrated that FET endpoints generally fall within the expected range of AFT variability, supporting their use as scientifically credible alternatives. Together, these findings provide a transparent, data-driven foundation for assessing NAM reliability and set the stage for reproducibility-based performance criteria in future validation and regulatory decision-making.

1.01.P-Mo008 Application of Statistical Causal Discovery to Development of Adverse Outcome Pathway

Kyoshiro Hiki¹, Thong Pham², Michio Yamamoto³, Takehiko Hayashi⁴ and Shohei Shimizu³, (1)University of Tokyo, Japan, (2)Shiga University, Japan, (3)The University of Osaka, Japan, (4)National Institute for Environmental Studies (NIES), Japan

The adverse outcome pathway (AOP) framework has evolved as a promising tool for organizing mechanistic toxicology information, providing a structured representation of the biological key events (KEs) that link a molecular initiating event (MIE) to adverse outcomes (AO) at higher levels of biological organization (e.g., death, reproductive impairment). Most published AOPs are still developed by expert judgment, although several semi-automated techniques have recently been proposed. Consequently, KE selection and causal directions are often inferred manually, and the resulting networks can be incomplete and subjective. As the volume of mechanistic toxicology data grows and the number of chemicals increases, there is an urgent need for data-driven approaches that can propose new AOP structures and verify existing ones. Statistical causal-discovery (SCD) methods offer such a data-driven solution. These algorithms infer causal structure directly from data, by imposing tractable assumptions that restrict the search space of possible causal graphs. However, ecotoxicology data often has challenges for SCD applications, such as missing data and violation of SCD algorithm assumptions.

As a proof-of-concept application of SCD to AOP development, we applied a linear non-Gaussian acyclic model (LiNGAM), a representative SCD method, to three types of ecotoxicology datasets: (1) bivariate dose–response relationships, (2) bivariate response–response relationships, and (3) a multivariate dataset with a known causal structure. Missing data were addressed through multiple imputation followed by causal estimation using DirectLiNGAM, a direct method for estimating LiNGAM. DirectLiNGAM identified correct causal directions with high statistical reliabilities in three of four bivariate dose-response cases, even when assumptions such as linearity and non-Gaussianity were partially violated. In contrast, response–response cases did not yield a single dominant direction, likely due to the limited number of replicates. In the multivariate case, the inferred graphs closely resembled the expert-curated causal graph, achieving high recall (0.50–0.75), despite relatively

low precision (0.31–0.40). These results demonstrate the utility of SCD, combined with multiple approaches, in identifying relevant key events, revealing missing links, and refining existing AOPs and quantitative AOP (qAOP) networks under realistic ecotoxicological constraints.

1.01.P-Mo009 Comprehensive Transcriptomic Response Index for Decoding Nanomaterial-Induced Pulmonary Responses

Viacheslav Muratov, Karolina Jagiello and Tomasz Puzyn, University of Gdańsk, Poland

Engineered nanomaterials (ENMs) are commonly used in various industrial fields. Such widespread application has raised numerous concerns about the ENMs' safety. Currently, toxicogenomic studies play a central role in the ENMs hazard evaluation. However, omics datasets remain highly dimensional, which complicates their analysis and predictive modelling. In this work, we aimed to address this problem by developing a new transcriptomic response index (TRI). TRI compresses complex transcriptomic space, including hundreds of differentially expressed genes (DEGs), into a single predictive variable, while preserving linear interpretability with respect to gene-level contributions. Thus, we propose a biologically meaningful method in computational nanotoxicology that significantly contributes to new approach methodologies (NAMs) by reducing the need for animal testing to perform mechanism-based predictions.

We utilized previously published in vivo exposure data for titanium dioxide nanoparticles (TiO₂-NPs) and multi-walled carbon nanotubes (MWCNTs). The resulting datasets included transcriptomic responses following mouse inhalation exposure to TiO₂-NPs (621 differentially expressed genes, DEGs) and MWCNTs (5167 DEGs), alongside ENMs' physicochemical properties. We used principal component analysis (PCA) to estimate TRI based on the compressed transcriptomic data. Then we applied ridge regression to link the TRI to the inhaled ENMs properties. The amount of DEGs covered by TRI was defined based on the machine learning (ML) model robustness. The resulting ML models successfully approximate and predict over 5000 DEGs for MWCNTs (99.9% of the entire DEGs space, $Q^2_{\text{test}}=0.78$) and ~272 DEGs (~44% of the DEGs space, $Q^2_{\text{test}}=0.79$) for TiO₂-NPs datasets. Across this space, TRI links the expression of DEGs from Saa, Ccl, Cxcl, and other immune-related gene families to the properties of inhaled ENMs. The estimation of this relationship significantly contributes to the understanding of the mode of action of the pulmonary pathologies induced by ENM inhalation.

In line with SETAC's overarching objectives, our study advances the adoption of data-driven and mechanistically informed methodologies for chemical safety assessment by demonstrating a robust NAM-aligned omics endpoint for ENM hazard evaluation that interprets complex transcriptomic data and enhances mechanistic understanding of ENM-induced effects.

1.01.P-Mo010 A Review of Quantitative Structure–Activity Relationship Approaches to Predict Avian Acute Toxicity

M. Amine Aouini, S. Nisa Nurdhy and Jo Nyffeler, Helmholtz Center for Environmental Research (UFZ), Germany

Acute avian toxicity is assessed in vivo for all pesticides to be registered. It requires at least 30 birds per chemical and species, following OECD TG (Organisation for Economic Co-operation and Development Technical Guidelines) 233 and USEPA (United States Environmental Protection Agency) 850.2100 guideline, respectively. To reduce animal suffering, replacing these studies with New Approach Methods (NAMs) is desirable. In silico tools, particularly quantitative structure activity relationship (QSAR) approaches, offer a high-throughput and low-cost alternative. Several QSAR models for avian acute toxicity exist, yet none has been adopted in regulatory practice. In this study, we reviewed existing QSAR models based on ecotoxicological criteria (scope of the study, bird species, adherence to OECD guidelines, observation duration), modelling aspects (feature engineering, data pre-processing, algorithms), and model performance (statistical evaluation, applicability domain, biological plausibility). For four models, we attempted to re-implement the code and (1)

reproduce the published data and (2) run the model on our own, larger set of in vivo data (over 800 chemicals). Of fifteen publications initially considered, five were excluded for not addressing acute toxicity. For the ten remaining publications, the main limitations were: (i) no disclosure of training datasets (chemical features and in vivo data), (ii) insufficient reporting of model details for re-implementation, (iii) small datasets (10–50 chemicals), and (iv) misleading performance metrics, with high accuracy but poor sensitivity, indicating a limited ability to detect toxic compounds. We successfully replicated the reported results for most studies when using the preprocessed data files provided by the authors. However, recreating the full workflow from scratch often failed due to missing data, reliance on paid software, or random variation in feature selection algorithms. Despite multiple attempts, no QSAR model for acute avian toxicity is yet suitable for broad regulatory use. Insufficient methodological detail remains a key barrier, which could be mitigated by adhering to established QSAR reporting guidelines (e.g., OECD Nos. 69 and 386). Expanding the dataset of available in vivo toxicity values would further support model development and help pave the way toward regulatory application.

1.01.P-Mo011 Decoding ER α -azole derivative interactions to evaluate environmental health risks through computational and experimental models

Rajesh Kumar Pathak¹, Da-Hyun Jeong², Vikas Kumar³, Hee-Seok Lee² and Jun-Mo Kim⁴, (1) University of Rovira i Virgili, Spain, (2) GreenTech-based Food Safety Research Group, BK21 Four, Chung-Ang University, Korea, Republic of, (3) University of Rovira i Virgili; Pere Virgili Institute for Health Research (IISPV), Spain; German Federal Institute for Risk Assessment (BfR), Germany, (4) Chung-Ang University, Korea, Republic of

The widespread use of azole fungicides in agriculture is essential for crop protection, yet it has raised significant environmental and public health concerns owing to their potential endocrine-disrupting properties. This study investigates the molecular-level interaction of selected azoles with the estrogen receptor alpha (ER α) to elucidate their capacity to interfere with the receptor's native function. Our integrated computational approach began with molecular docking of the azoles alongside the native agonist estradiol (E2) and the antagonist 4-hydroxytamoxifen (OHT). The binding affinities of the resulting complexes were quantified using MM/GBSA analysis. The top five azole candidates were further characterized through ADMET profiling, density functional theory (DFT) calculations, molecular dynamics simulations (MDS) and post-simulation MM/GBSA calculations to visualize the dynamics of complex stability and interaction patterns. Furthermore, experimental validation using a BRET-based assay demonstrated that these azoles significantly suppressed E2-induced dimerization of cytosolic ER α . As expected, OHT exhibited a potent inducing effect. Collectively, these results underscore the need for focused strategies to mitigate the reproductive risks posed by azoles and to support environmental health.

1.01.P-Mo012 Intraspecies Correlation Estimation (ICE) Models for Acute-to-Chronic Toxicity Prediction of Insecticides to Daphnids, Chironomids, and Honeybees

Dhruv Savaliya¹ and Lennart Weltje², (1) Georg-August University Göttingen, Germany, (2) BASF, Germany

In silico methods, such as quantitative structure activity relationships (QSARs) are mostly limited to predicting acute toxicity values. In this work we aim to predict chronic toxicity values using the interspecies correlation estimation (ICE) method. However, we applied the existing ICE methodology within and not between species, hence as intraspecies and not interspecies models.

To develop the models, regulatory acute and chronic toxicity data on insecticides were collected for water fleas (*Daphnia magna*; OECD TG 202 and 211), non-biting midges (*Chironomus* sp.; OECD TG 235 and 219) and honeybees (*Apis mellifera*; OECD TG 213/214 and 245) from publicly available regulatory documents and databases. These data are typically of high quality and derived often from GLP studies following OECD testing guidelines. Following the methodology described in the US EPA's Web-ICE manual (V4.0) only bound values were retained. The statistical correlation of log-transformed toxicity values was analyzed by Spearman's test. Thereafter, additional (statistical) criteria from the Web-ICE manual were applied for selecting robust ICE models.

We identified robust acute-to-chronic intraspecies correlation estimation models for daphnids, chironomids, and two for honeybees: one on basis of the contact and one on basis of the oral test. The chronic bee test in the robust ICEs was the 10-d adult honeybee test (for the larval chronic test, no robust intraspecies correlation models were identified).

So, with the identified robust intraspecies models for insecticides, we can predict the chronic outcome, i.e., NOEC or NOEDD, on basis of the acute test endpoint, i.e., EC50 or LD50. For honeybees it has the additional advantage that prediction of endpoints can be done all year round, as opposed to the testing which is seasonally limited. The developed intraspecies models can be used in addition to other in silico tools such as QSARs and

interspecies estimation models to obtain a more comprehensive toxicity profile of insecticides in early stages of development.

1.01.P-Mo013 Uncovering Early Transcriptomic Biomarkers of Toxicity in Zebrafish Embryos Exposed to Chemical Mixtures

Santiago Gómez-Herrera, Janan Gawra, Anna Jurado, Victoria Osorio and Laia Navarro-Martin, Institute for Environmental Assessment and Water Research, IDAEA-CSIC, Spain

Zebrafish (*Danio rerio*) is widely used in toxicology as it combines vertebrate biological complexity with highthroughput practicality. Its human-like genome, rapid development, and transparent embryos allow assessment of chemical effects across biological scales. These features make zebrafish embryos particularly suitable for detecting early transcriptional changes that occur before visible toxic effects appear. However, despite the growing number of studies, the interpretation of chemical-induced transcriptomic changes remains fragmented across compounds and experimental settings, limiting the identification of consistent molecular signatures and hindering predictions of mixture toxicity.

To identify transcriptome-level biomarkers linked to chemical contaminants exposure, a comprehensive data collection was conducted to compile RNA sequencing datasets from zebrafish embryos exposed during the first five days post-fertilization. Seventy-nine studies were selected from public repositories, selecting 2739 datasets involving 201 compounds. These datasets were standardized for gene annotation and classified based on compound class, physicochemical properties, concentration, exposure duration, developmental stage, and mode of action. The Association Plot (APL) tool in R is being applied to explore gene–response relationships across exposure categories, providing an integrative view of transcriptional patterns.

We hypothesize that early-life exposure to diverse chemicals triggers specific transcriptomic responses in zebrafish embryos, involving genes related to developmental signalling, energy metabolism, and cellular homeostasis that may serve as early biomarkers of chemical stress. Preliminary results reveal comparable transcriptional trends across contaminants, with shared biomarker candidates such as *cyp2k18*, linked to xenobiotic metabolism, and *angptl3*, involved in lipid homeostasis and thyroid/steroid hormone regulation related to endocrine-disrupting compounds. Moreover, certain genes (e.g., *cyp19a1b*) show consistent associations across experiments regardless of concentration or exposure windows like in Bisphenol A and other estrogenic compounds datasets, validating *cyp19a1b* as maker of estrogenicity. These transcriptomic patterns offer valuable insights for assessing the combined effects of chemical mixtures and may support future efforts to predict mixture toxicity in aquatic ecosystems.

1.01.P-Mo014 Fish Reproductive Toxicity Testing: From Historical In Vivo Data to Alternative Cell-Based Predictions

Vid Modic¹, Stephan Fischer², Roman Li³, Katharina Klotz², Kristin Schirmer³ and Anze Zupanic¹, (1)National Institute of Biology, Slovenia, (2)aQuaTox-Solutions GmbH, Switzerland, (3)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Chemical safety evaluation serves to safeguard ecosystems while enabling society to utilize the beneficial applications of chemical compounds. Conventional assessments remain animal-based, where animals, such as fish, are commonly sacrificed in studies to characterize chemical toxicity. Such approaches present both ethical challenges and practical limitations—they cannot match the pace of chemical innovation or provide sufficient mechanistic insight for the thousands of substances requiring evaluation. Alternatives to these tests are therefore urgently needed. Our aim is to establish an integrated assessment framework utilizing immortalized fish cell lines coupled with predictive computational approaches, enabling chemical reproductive toxicity evaluation without animal testing. Building on our prior work showing that Rainbow trout (*Oncorhynchus mykiss*) cell cultures demonstrate capacity to predict impacts on fish survival and growth, we extended this methodology through the CRACK-IT challenge – SAFE: Innovative Safety Assessment of Fish adverse Effects – supported by the UK NC3Rs, to address adult fish reproductive toxicity. Initially, we constructed a multistage

computational pipeline identifying critical molecular biomarkers underlying fish reproductive toxicity. We tested these biomarkers in fish cell lines through systematic exposure to known reproductive toxicants, negative control chemicals, and compounds with ambiguous toxicity profiles, establishing gene expression profiles. We subsequently compiled all publicly available data on reproductive endpoints, test chemicals, and gene expression patterns into a comprehensive reproductive toxicity database for adult fish. Through machine learning approaches, we leveraged existing in vivo gene expression and chemical data to predict reproductive endpoints, particularly fecundity. Additionally, we investigated potential methodologies for predicting chemical reproductive toxicity from in vitro gene expression patterns. The compiled database—integrating information from ECOTOX, EnviroTox, and the scientific literature—serves as a comprehensive, publicly accessible resource consolidating current knowledge on adult fish reproductive toxicity. It establishes a solid foundation for the development of alternative testing strategies, advances mechanistic insight into reproductive toxicity, and contributes to the 3Rs principles by reducing dependence on animal studies.

1.01.P-Mo015 Beyond Regulatory Testing: Data-driven Mechanistic Insights into the Effects of the Anti-Diabetic Pharmaceutical Metformin in Fish

Luigi Margiotto-Casaluci¹, Samuel K Maynard² and Stewart Owen³, (1)King's College London, United Kingdom, (2)Environmental Protection, Global Sustainability and SHE, Operations, AstraZeneca, United Kingdom, (3)AstraZeneca, United Kingdom

Metformin, one of the most widely prescribed anti-diabetic medicines globally, is routinely detected in aquatic environments, prompting concerns regarding its potential effects on fish. Despite extensive research activity, interpretation of metformin's ecotoxicological significance remains challenging due to heterogeneous study designs, endpoints, and reporting practices. Here, we present the first comprehensive, data-driven meta-analysis of metformin effects in fish, synthesising 1,375 datapoints from 28 peer-reviewed studies involving over 14,000 fish. We quantify effect size, direction, and statistical significance across key endpoints including survival, growth, reproduction, and hormone biomarkers, and evaluate concentration–effect concordance.

Across the dataset, 65% of all observations - and 84% of regulatory-relevant observations - showed no statistically significant effect. Reported effect concentrations varied over several orders of magnitude, with limited dose–response agreement between studies. Meta-analysis did not identify consistent adverse effects at concentrations below the regulatory predicted no-effect concentration (1,000 µg/L). While a subset of studies suggested potential reproductive impacts, quantitative synthesis across multiple reproductive endpoints did not support a consistent adverse outcome pathway.

This work illustrates both the challenges and opportunities of integrating non-regulatory data into chemical risk assessment. By combining effect-size quantification, directionality analysis, and transparent reporting of non-significant findings, we provide a scalable and reproducible data-driven framework for strengthening next-generation ecotoxicology and supporting more nuanced regulatory decision-making.

1.01.P-Mo016 Derivation of Dynamic Energy Budget Parameters of *Heterocypris incongruens* Using High-Throughput, Standardized Ecotoxicological Test Conditions

Angel Daniel Ceballos Ramirez¹, Mark Hodson¹, Elma Lahive², Thomas G. Preuss³ and Daniel Harrison Burkow³, (1)University of York, United Kingdom, (2)MacLean Building, United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Bayer Research & Development Services LLC, Germany

One of the major obstacles in the creation of new Dynamic Energy Budget (DEB) models in small aquatic invertebrates is the derivation of parameters associated with endpoints such as growth and reproduction, due to the difficulty of measuring changes in mass over a period of time. Recent advances in high-throughput ecotoxicological tests have demonstrated growth, reproduction and survival can be measured simultaneously, however, they are constrained to *Daphnids* and their application to other aquatic invertebrates has not been proved yet.

Therefore, an experiment was designed to derive DEB parameters in an ostracod species not often used in Environmental Risk Assessment.

To derive the DEB parameters in *Heterocypris incongruens*, individual organisms were purchased as resting eggs

from MicrioBio Tests Inc. (Mariakerke, Ghent, Belgium) and hatched per the provider's instructions at 25°C. They were kept in Elendt M7 media prepared according to OECD D. magna reproduction test and kept in four different incubators at 15, 20, 25 and 30°C with a 16:8 light dark cycle. The *H. incongruens* individuals were deposited into 24 well microtiter plates (83.3922, Sarsted AG & Co, Nurnbrecht, Germany) with one individual per well. At each temperature, organisms were separated into cohorts of 12 individuals and fed six different feeding regimes of *Selenastrum capricornutum* plus Tetra® fish food concentrated at 5g/L, as done in available literature. Organisms were cultured in 2ml of media and changed to a new well plate every four days before scans to remove molts and keep food levels stable.

Survival was tracked every other day, and growth and reproduction was tracked every four days, coinciding with media changes.

Images of individual ostracods in their wells were taken with the Cell Imager Cell3iMager (CC-5000, SCREEN holdings Co. Ltd., Kyoto, Japan) every four days. To ensure an in-focus image was obtained, bracket scans at multiple heights were used.

Parameter derivation will be done with the DEBtool software package.

Preliminary analysis of the data show that temperature has the greatest impact in reproduction and survival, and effects in growth being present at both different temperatures and feeding regimes, with the DEB parameter derivation currently ongoing.

Results of this study could demonstrate the generation of a novel DEB under conditions similar to those of a standardized ecotoxicological test, facilitating the integration of these models into regulation.

1.02 Beyond Exposure: Epigenetic Mechanisms, Omics Integration, and AI for Long-Term Environmental Impact

1.02.T-01 Parental Exposure to the Toxic Dinoflagellate *Alexandrium minutum* Affects Offspring DNA Methylation in the Pacific Oyster *Magallana gigas*

Adeline Marzari¹, Natacha Clairet², Hugo Koechlin¹, Hélène Hégaret¹, Caroline Fabioux¹ and Guillaume Rivière², (1)LEMAR, France, (2)MERSEA, France

Blooms of the toxic dinoflagellate *Alexandrium minutum* are recurrent on the French coasts, sometimes reaching high concentrations ($>10^7$ cells. L⁻¹). This microalgae can produce paralytic shellfish toxins (PSTs) but also uncharacterized bioactive extracellular compounds (BECs), often associated with harmful effects on marine organisms. The Pacific oyster *Magallana* (=Crassostrea) *gigas*, an important commercial species, is regularly exposed to *A. minutum* during its reproductive period. Studies demonstrated effects of direct exposure to *A. minutum* on oyster gametes and early life stages. Furthermore, parental exposure during gametogenesis also affects gametes, reducing their quality and fertilization potential, as well as offspring, reducing larval size and survival during settlement. Nevertheless, the molecular mechanisms underlying these intergenerational effects remain unknown. In recent years, epigenetic mechanisms, mainly DNA cytosine methylation, have attracted growing interest due to their role in transmitting life traits across generations. Environmental factors experienced by parents, whether biotic or abiotic, can modify DNA methylation, which in turn may shape phenotypic plasticity of offspring. During gametogenesis in mammals, DNA methylation undergoes reprogramming in both female and male gametes. Different timing of stress exposure could therefore imprint distinct DNA methylation marks in the germline, potentially transmitted to subsequent generations. In this study, we exposed a first generation of adult oysters (F0) to *A. minutum* (AM89BM strain) during gametogenesis: either at the initiation or the mature stage. We monitored larval development and settlement, and sequenced spat methylomes (F1), targeting 5-methylcytosine (5mC) and 5-hydroxymethylcytosine (5hmC) modifications. While no major effects were observed at the phenotypic level in adults and their offspring, 5mC and 5hmC showed differences in the overall variance of methylation levels between conditions. Spats from exposed or non-exposed broodstock displayed differential methylation at several cytosine locations. Most of them belonged to genes related to the structural constituent of chromatin and nucleosomes, involved in genome reorganization. These epigenetic modifications may contribute to genomic flexibility and thereby participate in allowing organisms to adjust to their changing environment.

1.02.T-02 Multigenerational exposure and epigenetic regulation in duckweed (*L. minor*) under chronic radiation: non-standard responses informing future AOPs

Nele Horemans, Luca Boldrini, Pol Laanen and Gustavo Torqueto Duarte, Belgian Nuclear Research Center (SCK CEN), Belgium

Chronic, multi- and transgenerational exposure to ionizing radiation remains insufficiently represented in current environmental risk frameworks, which are largely derived from acute laboratory studies. To address this gap, we investigated long-term stress responses in the freshwater macrophyte *Lemna minor*, a model organism with rapid clonal propagation enabling multi-generational assessment. Plants were exposed for six weeks (~19 generations) to external gamma radiation (0.5–480 mGy/h), Sr-90 (40–4,000 Bq/L), Cs-137 (40–40,000 Bq/L), or combined radionuclide treatments. Weekly subsampling enabled kinetic analyses of growth, photosynthesis, antioxidative enzyme activity, transcriptomics, and epigenetic regulation, including DNA methylation via whole genome bisulphite sequencing.

Results revealed dose- and time-dependent responses across all exposure scenarios. Growth showed transient hormetic effects, while biochemical and molecular endpoints indicated acclimation and adaptation processes. Stress responses differed by radiation type: gamma exposure induced persistent transgenerational effects maintained even after recovery, supported by gene expression changes linked to DNA methylation. Sr-90 exposure triggered early antioxidant responses and promoted epigenetic machinery at later stages, whereas Cs-137 showed enhanced photosynthetic activity under comparable dose rates indicating plant coping mechanisms. These divergent mechanisms highlight radiation-type specific pathways of plant stress adaptation. The consistent underlying stress responses observed across generations suggest potential destabilization of populations under chronic exposure, underscoring the need to incorporate long-term and epigenetic endpoints into quantitative Adverse Outcome Pathways (AOPs). Our findings will contribute to refining plant AOPs in the AOPwiki, extending current frameworks beyond acute exposure scenarios to better support environmental radiation protection.

1.02.T-03 Decoding Neurobehavioral Disruption: Multi-omics Insights in Cadmium and Ciprofloxacin-Exposed Seabass

Juliette Bedrossiantz¹, Janan Gawra¹, João Raio², Paula Medina³, Nerea Sanchis³, Vitória Pereira³, Fátima Brandao², Demetrio Raldua¹, Joana Luisa Pereira⁴, Patrícia Pereira², Mercedes Blázquez³ and Laia Navarro-Martin¹, (1) Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (2) University of Aveiro, Portugal, (3) Institute of Marine Sciences (ICM-CSIC), Spain, (4) Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal

Cadmium (Cd) and ciprofloxacin (CIP) are emerging aquatic contaminants with neurotoxic potential. Cd, a trace metal from industrial and agricultural sources, and CIP, a fluoroquinolone antibiotic resistant to water treatment, can induce oxidative stress and disrupt neuronal functions. This study assessed their neurotoxicity in juvenile seabass (*Dicentrarchus labrax*) following 21-day dietary exposure to environmentally relevant concentrations. Fish were fed diets containing Cd (100 or 10 mg·kg⁻¹) or CIP (10 or 1 mg·kg⁻¹). Brain samples were analyzed for epigenetic (DNA methylation), transcriptomic (RNA-seq), antioxidant defenses, oxidative damage, neurotransmission (acetylcholinesterase activity), and behavior. Both contaminants reduced brain glutathione levels, increased AChE activity, and altered locomotor behavior, including reduced swimming activity, increased freezing episodes, and higher social cohesion—indicative of anxiety-like responses. Oxidative stress markers showed treatment-specific patterns: Cd increased SOD activity and lipid peroxidation, while CIP caused glutathione depletion without major changes in SOD. These findings suggest Cd and CIP impair neural signaling and antioxidant balance, leading to behavioral dysfunction that may compromise ecological fitness. Epigenetic and transcriptomic analyses are underway to link molecular alterations with observed phenotypes,

highlighting the need for integrating advanced approaches to assess subtle neurotoxic effects of contaminants in aquatic organisms.

1.02.T-04 Epigenetic Insights from DNA Adductomics: Early Indicators of Environmental Stress?

Giulia Martella¹, Juliane Hollender², Corina Meyer¹, Miriam Langer³, Dominik Züger⁴ and Bianca Lucchini¹,
(1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)University of Applied Sciences Muttens (FHNW), Switzerland, (4)University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Switzerland,

High-resolution DNA adductomics offers a powerful approach to detect early molecular alterations induced by environmental contaminants, yet its application in ecotoxicology remains limited. Here, we established an HRMS-based, non-target DNA adductomics workflow to characterize environmentally induced DNA modifications in *Gammarus pulex* and applied it to evaluate temporal and spatial patterns upstream and downstream of a wastewater treatment plant (WWTP) between 2021 and 2025.

DNA was enzymatically digested and analyzed using LC-HRMS with non-target acquisition, automated MS/MS fragmentation, and in-silico fragmentation-based molecular annotation. In parallel, water samples were screened for ~50 contaminants, including pesticides and pharmaceuticals. The WWTP underwent major upgrades during the study period, a biological upgrade in 2023 and an activated-carbon-based chemical treatment upgrade between 2023 and 2024.

The adductomics workflow detected several hundred DNA adducts across individuals, covering diverse chemical classes and biological processes. Approximately 15 statistically significant features were selected for Partial Least Squares Discriminant Analysis (PLS-DA), providing strong discriminatory power for identifying exposure-related patterns. The multi-year dataset revealed substantial annual variability, with the most pronounced upstream–downstream differences observed in 2025. Downstream organisms exhibited elevated overall adduct burdens, driven particularly by increases in epigenetically relevant adducts such as methylated and hydroxymethylated nucleosides. Although activated carbon treatment reduced the general chemical burden in the water column, a heavy stormwater overflow event occurred during organism collection, and this short-term disturbance was not fully captured by routine chemical monitoring. In contrast, the adductome profiles may reflect this episodic exposure, indicating that DNA adductomics could be sensitive to complex and transient environmental influences.

Overall, this work demonstrates that non-target DNA adductomics provides early, mechanistically interpretable molecular endpoints capable of resolving subtle exposure differences that conventional chemical analysis may miss. By linking environmental gradients to molecular damage and epigenetic alterations, DNA adductomics supports next-generation environmental risk assessment, particularly in systems influenced by multiple and dynamic stressors.

1.02.T-05 Detection of transcriptomic biomarkers for environmental stressors in *Paracentrotus lividus* embryos using machine learning approaches

Alexandre Schönemann¹, Juan Bellas¹ and Juan Ignacio Bertucci², (1)Spanish Institute of Oceanography (IEO-CSIC), Spain, (2)Spanish Institute of Oceanography - Spanish National Research Council (IEO-CSIC), Spain

The sea urchin *Paracentrotus lividus* provides a robust model for studying the effects of environmental stressors. *P. lividus* embryos were exposed to the pharmaceutical citalopram (CIT) and the biocide triclosan (TC) within a global change scenario that included elevated temperature and sea water acidification, using a factorial design. Transcriptomic profiles were generated by RNAseq and analyzed using a sparse Partial Least Squares Discriminant Analysis (sPLS DA) model reinforced with bootstrapping to identify genes that discriminate each experimental condition.

Machine learning (ML) techniques proved useful in analyzing RNA-seq data from complex experimental designs, and allowed the identification of discriminant biomarkers with specific stressor-dependent expression

patterns. The sPLS-DA model identified 42 biomarkers for thermal stress, 24 biomarkers for CIT exposure and 15 biomarkers for TC exposure. Furthermore, specific biomarker sets associated with the interactions between global change stressors and contaminants were identified. Specific primers were designed and used in qRT PCR to validate the biomarker discovery tool.

The increasing accessibility of omics analyses, in terms of both methodology and cost, is driving a rise in the complexity of data analysis and interpretation. In ecotoxicology, RNAseq analysis has paved the way for performing omic factorial experiments, which are essential for investigating the interactions between multiple environmental conditions and contaminants, an ecologically relevant strategy crucial for addressing current and future contamination scenarios. This methodology identifies more robust biomarkers than classical differential expression analyses, prioritizing those with high exclusivity for a particular experimental condition. Although this study focused on two contaminants and two stressors, the methodology is scalable to include additional treatments and replicates, which would yield more robust discriminant biomarkers and enable the model's predictive capacity for class assignment.

Disclaimer/Disclosure:

This work was partially funded by the European Union's Horizon-CL6-2023-ZEROPOLLUTION-01 through the CONTRAST Project (grant agreement No. 101135037-CONTRAST-Horizon CL6-2023) and by the Spanish Government (Ministry of Science and Innovation) through ECO-MIND (CNS2023-145567).

1.02.P Beyond Exposure: Epigenetic Mechanisms, Omics Integration, and AI for Long-Term Environmental Impact

1.02.P-We001 Exposure to Tetrabromobisphenol A Reprograms Hepatic Lipid Metabolism Both in Mothers and Their Offspring

Xuan Ma¹, Yujie Liu², Quanquan Guan² and Yankai Xia², (1)*The Affiliated Wuxi Center for Disease Control and Prevention of Nanjing Medical University, Wuxi Center for Disease Control and Prevention, Wuxi Medical Center, Nanjing Medical University, China, China (Mainland),* (2)*State Key Laboratory of Reproductive Medicine, Center for Global Health, School of Public Health, Nanjing Medical University, Nanjing, China, China (Mainland)*

Tetrabromobisphenol A (TBBPA) is one of the most used brominated flame retardants, and its environmental exposure has raised extensive attention about potential health hazards. Previous studies have suggested its lipid metabolism toxicity, but its effect on mothers and offspring and the underlying mechanism remains unclear. In this study, TBBPA concentrations in serum from mice exposed to different doses and 971 mid-pregnancy women were detected via HPLC-LTQ-MS to determine an environmentally relevant dose. C57BL/6J mice were then subjected to daily TBBPA exposure (0.2 mg/kg-bw/day) during pregnancy and lactation. Serum biochemistry and multi-tissue H&E staining (liver/adipose/intestine/placenta) were used to assess systemic lipid metabolism in dams and offspring. For mechanism analysis, liver transcriptome, histone modifications (H3K4me3/H3K27ac) and RNA polymerase (RNAPolII), as well as metabolome were detected via RNA-seq, CUT&Tag, and LC-MS, respectively. The results showed that mid-pregnancy (GD12.5) was a maternal sensitive window, with increased fasting blood glucose, liver/adipose coefficients, hepatic lipid deposition/inflammation, reduced free fatty acids, and FoxO pathway enrichment (downregulated *Mfsd2a/Acot2*) indicating lipid reprogramming; while offspring only displayed mild hepatic inflammation with sex-specific lipid metabolism patterns. Epigenetically, offspring had abnormal hepatic H3K4me3/SETD4 levels, with redistribution of H3K4me3/H3K27ac/RNAPolII at lipid metabolism-related gene promoters binding FOX factors. These findings demonstrate environmentally relevant maternal TBBPA exposure disrupts maternal lipid metabolism via FoxO signaling and induces sex-specific offspring metabolic perturbations through SETD4-mediated H3K4me3 remodeling. This work provides a scientific basis for TBBPA safety limits, highlights gestational/lactational exposure management, and advances understanding of early-life chemical-induced metabolic reprogramming via epigenetics.

1.02.P-We002 The transcriptome and epigenome of the marine calanoid copepod *Acartia clausi* after short-term cadmium exposure

Ilias Semmouri¹, Albano Pinto², Ana Beatriz Rodrigues², Robbe Paepen¹, Ana Rita Guimarães², Joana Luisa Pereira³ and Jana Asselman⁴, (1)*Ghent University, Belgium,* (2) *University of Aveiro, Portugal,* (3)*Centre for Environmental and Marine Studies (CESAM) & University of Aveiro, Portugal,* (4)*Blue Growth Research Lab (BGRL), Ghent University, Belgium*

Recent evidence indicates that environmentally driven epigenetic modifications can exert persistent effects on gene transcription across multiple generations. These findings underscore the importance of examining the consequences of pollutants to better understand their long-term impact on populations. Cadmium, a trace metal with no essential biological role known, is particularly harmful due to its high toxicity, persistence, and bioaccumulation potential. Herein, we assessed the potential link between phenotypic endpoints, (behaviour and enzymatic) DNA methylation and transcriptome wide changes as a response to short-term (48 h) cadmium exposure (238.8 µg/L, corresponding to the pre-estimated immobilization EC20) of the marine copepod *Acartia tonsa*, a zooplankton species with a key role in pelagic systems and widely recognized as a model organism in ecotoxicology. Oxidative stress and damage were evaluated by measuring glutathione S-transferase (GST) activity and lipid peroxidation using the TBARS assay, while genotoxicity was assessed through DNA damage analysis with the comet assay. Post-exposure swimming behavior of *A. tonsa* was further examined using automated video tracking. Epigenetic changes were assessed through quantification of global 5-mC DNA methylation and whole-genome bisulfite sequencing (WGBS). We also sequenced the transcriptome and studied differences in the copepod's gene expression as the molecular processes underpinning the studied phenotypic effects. Global 5-mC DNA methylation levels showed a slight decrease in exposed copepods, indicating a trend toward global hypomethylation. Phenotypically, this was associated with a marked rise in genotoxicity, a significant increase in GST activity, and elevated oxidative damage. From the obtained gene expression data, we aimed to identify the most active metabolic pathways and we tried to place these results into a broader context of observed physiological activities. Next, we constructed gene-co-expression networks, identified hub genes and we tried to obtain a mathematical relationship between these networks/hub genes and the phenotypic characteristics of interest. As such, we aim to identify epigenetic mechanisms that can be consistently anchored to phenotypic changes and to provide a molecular basis for adverse outcome pathways for toxicity caused by stressors such as cadmium in copepods.

1.02.P-We003 Integrating Transcriptomic Insights to Predict Long-Term Impacts of Emerging Contaminants Under Climate Stressors

Juan Ignacio Bertucci, Alexandre Schönemann and Juan Bellas, *Spanish Institute of Oceanography - Spanish National Research Council (IEO-CSIC), Spain*

Pharmaceuticals and personal care products (PPCPs), such as citalopram (CIT) and triclosan (TC), are increasingly detected in marine ecosystems at environmentally relevant concentrations, raising concerns about their ecological impact. Concurrently, climate change drivers such as ocean warming (OW) and ocean acidification (OA) may interact with chemical stressors, producing complex biological responses. This study assessed phenotypic and transcriptomic effects of CIT and TC, alone and combined with OW and OA, on larvae of the sea urchin *Paracentrotus lividus*, a sentinel species in ecotoxicology.

Fertilized eggs were exposed for 48 h post-fertilization to EC₁₀ concentrations of CIT (46.70 µg/mL) and TC (98.92 µg/mL), under control and climate change scenarios (OA: +126 µmol/kg DIC; OW: 24 °C). Growth endpoints were measured at the pluteus stage, and RNA-seq analysis identified differentially expressed genes ($|\log_2FC| \geq 1.5$; $p_{adj} \leq 0.01$) and enriched pathways.

Phenotypically, OA intensified CIT and TC toxicity, reducing larval growth by up to 50%, whereas OW mitigated or reversed these effects. Combined OW+OA conditions neutralized growth alterations, suggesting non-linear interactions. Transcriptomic profiles revealed substantial molecular perturbations even when morphology remained unaffected. CIT alone dysregulated genes linked to metabolism, development, and apoptosis; OA alone had minimal impact, while OW altered transcriptional regulation and morphogenesis. CIT combined with OA or OW triggered broader responses involving energy metabolism, stress signaling, and transcriptional control. TC exposure disrupted cilium assembly, glutathione metabolism, and cytoskeletal organization, with complexity increasing under OW and OA. Multi-stressor scenarios produced the most complex profiles, affecting pathways related to oxidative stress, protein metabolism, and calcium signaling, indicating compromised homeostasis.

These findings highlight that low-level PPCP contamination can interact with climate stressors to elicit significant molecular effects, challenging single-stressor risk assessment paradigms. Omics biomarkers emerge as sensitive tools for early detection of sublethal impacts, advocating for their integration into predictive models. Future research should explore cross-taxa patterns and long-term ecological consequences to inform adaptive management strategies under accelerating anthropogenic pressures.

1.02.P-We004 Integrative Analysis of Physiological, Epigenomic, and Transcriptomic Changes in *Phaeodactylum tricornutum* Exposed to Cadmium and Ciprofloxacin

Robbe Paepen¹, Ilias Semmouri¹, Albano Pinto², Ana Rita Guimarães², Silja Frankenbach², Jana Asselman³ and Joana Luisa Pereira⁴, (1)Ghent University, Belgium, (2) University of Aveiro, Portugal (3)Blue Growth Research Lab (BGRL), Ghent University, Belgium, (4)Centre for Environmental and Marine Studies (CESAM) & University of Aveiro, Portugal

In recent years, epigenetic research has demonstrated that mechanisms such as DNA methylation and histone modifications play pivotal roles in regulating gene expression and mediating environmental adaptation in several microalgae. However, surprisingly few studies have investigated how environmentally driven epigenetic modifications affect diatom physiology and stress-response. To address this gap, we investigated physiological, transcriptomic, and epigenomic changes in the marine pelagic diatom *Phaeodactylum tricornutum*, a model organism in ecotoxicology, following sustained exposure (96 h) to either cadmium (0.293 mg L⁻¹) or ciprofloxacin (0.202 mg L⁻¹), concentrations corresponding to pre-estimated EC₂₀ values based on growth inhibition. Both pollutants were selected due to their documented potential to induce epigenomic alterations: cadmium, a non-essential trace metal, is persistent and bioaccumulative, while ciprofloxacin, a fluoroquinolone antibiotic, has been shown to inhibit histone demethylases and alter methylation patterns in mammalian systems. Oxidative stress and damage were assessed via glutathione S-transferase (GST) activity and lipid peroxidation (TBARS assay), while genotoxicity was evaluated using the comet assay. Epigenetic changes were quantified through global 5-mC DNA methylation analysis and whole-genome bisulfite sequencing (WGBS). Transcriptomic profiling was performed to identify differentially expressed genes and enriched metabolic pathways, which were integrated with the obtained physiological data to elucidate molecular mechanisms underlying observed phenotypic effects. Gene co-expression networks were constructed to identify hub genes and explore their relationships with stress-related traits.

Our results revealed a significant increase in global 5-mC DNA methylation in cadmium-exposed cells, indicating a trend toward hypermethylation, whereas ciprofloxacin exposure did not induce significant changes at the global level. In the transcriptomic analysis we focused on interpreting changes in the key pathways involved in metal detoxification, oxidative stress response, and chromatin remodeling. Network analysis identified candidate hub genes potentially linking epigenetic regulation to the stress phenotypes. These findings provide novel insights into the epigenetic basis of diatom stress responses and contribute to the development of molecular frameworks for adverse outcome pathways (AOPs) relevant to marine ecotoxicology.

1.03.A Bridging Innovation and Interpretation: New Approach Methodologies (NAMs) and 3R Alternatives in Environmental Toxicology

1.03.A.T-01 Adaptation of fish hepatocytes improves the cytotoxicity assessments of substances requiring biotransformation: The curious case of allyl alcohol

Maria T. Hultman, Malcolm Reid and Adam Lillicrap, Norwegian Institute for Water Research, Norway

The 96-hour acute fish toxicity (AFT) test is required for chemical hazard assessment, however ethical concerns drive efforts toward implementing alternatives that support the 3Rs (replace, reduce, refine). In 2021, the OECD adopted a fish cytotoxicity test using *Oncorhynchus mykiss* gill cells (RTgill-W1), promoted as a promising alternative to AFT. Despite this progress, full replacement remains difficult for chemicals that require metabolic activation. Allyl alcohol is a notable example, as it must be biotransformed into the toxic metabolite acrolein to induce cytotoxicity. Limited toxicity in RTgill-W1 has been linked to insufficient metabolic enzyme expression, including *aldh8a*, a limitation also observed in zebrafish embryos. Thus, there is a need for metabolically competent in vitro models that can reliably assess such substances. Primary hepatocytes (HEP) show high metabolic capacity and therefore may enable more accurate assessment of metabolically activated chemicals. While commonly used in in vitro bioaccumulation studies (e.g., OECD 319A), their broader potential for acute ecotoxicity remains underexplored. Here, we evaluated metabolic activation and cytotoxicity in rainbow trout HEP exposed to allyl alcohol and its metabolite acrolein. Hepatocytes were isolated using a two-step perfusion method, and incubated at 15 °C for 24 or 48 h with 0.03–100 mg/L allyl alcohol or 0.3–50 mg/L acrolein in 24-well plates (500,000 cells/mL). Cytotoxicity was assessed following OECD TG 249 using three endpoints: cell membrane integrity (CFDA-AM), metabolic activity (Alamar Blue), and lysosomal stability (Neutral Red). Media were collected post-exposure for chemical analysis, and EC₅₀ values were determined using log-linear regression. Hepatocytes exhibited concentration-dependent toxicity for both chemicals across all endpoints and exposure durations. Toxicity profiles were highly similar, with allyl alcohol only slightly more potent; EC₅₀

values differed by less than seven-fold. Sensitivity to allyl alcohol was ~1000-fold greater than reported for zebrafish embryos and comparable to 96-h acute toxicity values in the EPA fathead minnow database. These findings suggest that hepatocytes biotransform allyl alcohol into acrolein within 24 h. Overall, rainbow trout HEP represent a metabolically competent *in vitro* model for acute toxicity and provide a valuable complement to RTgill-W1, supporting future reduction and potential replacement of AFT testing.

1.03.A.T-02 Cellular Diversity Behind Ecotoxicogenomics: Single-Cell and In Vitro Insights into Mycophenolic Acid Exposure in Rainbow Trout Gills

Owen Trimming¹, Peter Kille¹, Charles Tyler², Andrew Ross Brown² and Stewart Owen³, (1)Cardiff University, United Kingdom, (2)University of Exeter, United Kingdom, (3)AstraZeneca, United Kingdom

Pharmaceuticals pose unique ecotoxicological assessment challenges, being designed to elicit specific receptor-mediated effects. RNA sequencing is therefore an appropriate tool for environmental risk assessment (ERA), revealing both pharmacological mode of action (MoA) and off-target effects. The growing list of active pharmaceutical ingredients makes vertebrate testing ethically questionable, driving adoption of animal alternatives such as the rainbow trout epithelial gill cell line RTgill-W1. Combining cell culture with transcriptomics can generate mechanistic insights more ethically, but systematic differences between *in vivo* and *in vitro* models (particularly gene expression profiles) must be considered. Importantly, the RTgill-W1 culture is a single cell type, and an intact gill contains a range of cells with varied function.

The work presented is a case study of the immunosuppressant drug mycophenolic acid (MPA) both *in vivo* (rainbow trout gill) and *in vitro* (RTgill-W1). MPA functions by binding to inosine-5'-monophosphate dehydrogenase (IMPD) and inhibiting purine synthesis. This disproportionately depletes T and B cells, which (unlike other cell types) rely on *de novo* purine synthesis and cannot switch to alternative synthesis pathways. Given that MPA targets immune cells specifically, single cell sequencing analysis was employed to evaluate the diversity of cells within a rainbow trout gill. This data revealed 20 cell types within the rainbow trout gill tissue: including a lymphocyte population which is key to the MPA MoA. Here it was hypothesised that the unicellular RTgill-W1 cell line will not accurately represent the predicted immunosuppressant effect of MPA *in vivo*.

In the *in vivo* results, the expression of immune system related genes was significantly down regulated in all exposure conditions, which may make the fish more vulnerable to other stressors in aquatic environments. This immunosuppressant effect was notably not observed in the *in vitro* results, however developmental genes were suppressed in both the cultures and the intact gills at higher MPA concentrations. This cell cycle interference could reduce the gills capacity for growth and structural remodelling, which is important for its role as an environmental protective barrier for fish. Our case study exposure reveals the necessity to consider the greater complexity of the cell types contained in the intact gill when considering the utility of cell lines, such as RTgill-W1, in ERA.

Disclaimer/Disclosure:

The research presented was funded by The UK Research and Innovation Natural Environment Research Council (UKRI NERC). This work was part of the ECORISC Centre for Doctoral Training in case partnership with AstraZeneca, with primary supervision at Cardiff University. The *in vivo* fish exposures were conducted at the UK Home Office regulated Aquatic Resources Centre at The University of Exeter, with funding from PREMIER (Prioritisation and Risk Evaluation of Medicines in the EnviRonment).

1.03.A.T-03 Risk-based prioritization of persistent and mobile chemicals using new approach methodologies (NAMs)

Maxim Carlier¹, Abishek Laxmanan Ravi Shankar², Todd Gouin³, Sylvia Escher², Majorie Van Duursen¹ and Timo Hamers¹, (1)Vrije Universiteit, Netherlands, (2)Fraunhofer Institute for Toxicology and Experimental Medicine (ITEM), Germany, (3)TG Environmental Research, United Kingdom

Persistent and mobile chemicals are of growing concern as they can accumulate and travel large distances from their point of emission. These chemicals can pollute water resources that are used for the production of drinking water. For many persistent and mobile chemicals used and produced in Europe, no or limited data is available on toxicity. As traditional *in vivo* toxicity testing raises concerns regarding limited testing capacity, high costs and animal welfare, novel strategies are required to prioritize chemicals for further toxicity testing, or for efficiently allocating funds for prevention or mitigation efforts.

Within the ZeroPM project, we have developed a low-tier risk-based prioritization matrix using *in vitro* and *in silico* new approach methodologies (NAMs). In this matrix, the combined estimations of exposure and hazard

are used to determine the priority of each chemical. The exposure estimate is based on measured groundwater concentrations calculated to free human plasma concentrations using physiology-based kinetic models, reflecting a worst-case exposure scenario. The hazard is estimated by testing the chemical in in vitro bioassays and deriving benchmark concentrations which were calculated to free medium concentrations using a virtual in vitro distribution model. As a proof-of-concept, the matrix was used to prioritize 9 triazine, 16 triazole and 11 PFAS compounds classified as persistent and mobile. Given the data-richness of these compounds, the predictive value of the NAMs could be evaluated with toxicokinetic and toxicodynamic in vivo data. Based on the known toxicity of the test chemicals, the in vitro methods focused on endocrine disrupting properties, liver toxicity and developmental toxicity.

In general, the hazard estimates based on in vitro data were more conservative than based on in vivo data. When comparing toxicological benchmark concentrations to exposure estimates, PFOA was the only tested high priority chemical. PFOS and PFHxS were prioritized after PFOA, based on lower exposure concentrations, that were <1% of the toxicological benchmark concentration. Chemicals as difenoconazole and fenbuconazole had similar ranges of toxicological benchmark concentrations as PFOS and PFHxS, but were categorized as lower priority chemicals due to their lower exposure estimate. This study demonstrated the applicability of a NAM-based prioritization matrix, but also highlighted the importance of accurate exposure estimations.

1.03.A.T-04 Next Generation Hazard Assessment of Legacy and Alternative Phthalate Plasticizers Using New Approach Methodologies within an Integrated Approaches to Testing and Assessment (IATA) Framework

Chaein Chong, Donghyeon Kim, Gaeul Yang, Hyeonwoo Kim, Siyeol Ahn and Jinhee Choi, University of Seoul, Korea, Republic of

Regulatory restrictions on legacy phthalates have driven the introduction of alternative plasticizers; however, their safety profiles remain poorly characterized. Combined with reduced animal testing, this underscores the need for structured frameworks integrating diverse mechanistic evidence to evaluate data-poor chemicals efficiently. This study applied an Integrated Approaches to Testing and Assessment (IATA) framework to comparatively evaluate developmental and reproductive toxicity of legacy and alternative phthalates, assessing how multiple New Approach Methodologies (NAMs) can collectively inform hazard potential and reduce uncertainty.

We integrated evidence from regulatory in vivo reports, literature-derived in vitro assays, high-throughput screening from ToxCast, and artificial intelligence-based predictions. These datasets were organized through adverse outcome pathway (AOP) networks related to male reproductive toxicity. Both qualitative evidence mapping and quantitative human-equivalent dose estimation using high-throughput toxicokinetics were conducted, with findings compared to traditional animal study outcomes.

Legacy phthalates exhibited strong and consistent toxicity signals across multiple evidence streams, whereas alternatives showed weaker or inconsistent activity, reflecting lower hazard potential and substantial data gaps. Quantitative comparison demonstrated that NAMs-derived doses can approximate traditional reference values but remain limited by metabolic coverage gaps and incomplete endpoint representation.

This study demonstrates feasibility of NAMs-informed IATA for comparative phthalate assessment. For data-rich legacy compounds, NAMs provided complementary mechanistic information, reducing uncertainty; for data-poor alternatives, NAMs identified signals guiding prioritization and precautionary actions. The approach underscores the importance of integrating methods within AOP frameworks under FAIR principles and developing tiered testing strategies. Continued expansion of mechanistic datasets and refinement of extrapolation models will strengthen hazard evaluation for chemical substitution and regulatory decision making.

1.03.A.T-05 European Seabass (*Dicentrarchus labrax*) Hepatic Spheroids: a Novel in Vitro Model to Decipher Biotransformation and Mechanisms of Action of Chemical Contaminants

Soizig Le Garrec¹, Isabelle Leguen², Yann Aminot¹, Aourell Mauffret¹, Olivia Terceve³, Thibaut Larcher³, Thibaut Leger⁴ and Audrey Barranger⁵, (1)French Institute for Ocean Science (IFREMER), France, (2)MARBEC Université de Montpellier, France, (3)INRAE Oniris, UMR 703, PanTher, APEX, France, (4)Toxicology of Contaminants Unit, Fougères Laboratory, French Agency for Food, Environmental and Occupational Health & Safety (ANSES), France, (5)CCEM, French Institute for Ocean Science (IFREMER), France

The marine chemical exposome encompasses thousands of legacy and emerging contaminants, along with their transformation products, whose toxicity, modes of action and biotransformation remain only partially characterised in marine organisms. In this context, in vitro New Approach Methodologies (NAMs) are increasingly promoted to generate mechanistic data while reducing dependence on in vivo testing. Among these, three-dimensional (3D) liver models such as hepatic spheroids are gaining attention thanks to their better conservation of tissue architecture and metabolic functions than conventional two-dimensional (2D) monolayers, making them particularly suitable for studying chemical contaminant biotransformation and mode of action. In this study, the aim was to develop and characterise a 3D hepatic model from primary liver cells of European seabass (*Dicentrarchus labrax*), a marine teleost of high ecological and economic importance. Hepatic spheroids were generated and benchmarked against both the native liver and classical 2D hepatic cultures. The model was characterised using biometry, cell viability, histology and expression of key liver genes. Seabass hepatic spheroids remained viable over more than a month and retained more pronounced hepatic features than 2D cultures, supporting a more stable and liver-like phenotype. To evaluate their functional relevance for chemical contaminant fate and effects, spheroids were exposed to the model polycyclic aromatic hydrocarbon pyrene. Biotransformation capacity was demonstrated in both 2D and 3D cultures, including activation of Phase I and II metabolism. Ongoing proteomic analyses are further refining the phenotype of seabass hepatic spheroids relative to the parent organ and 2D cultures, and are being used to investigate pyrene modes of action across culture formats. Overall, our results support this 3D hepatic model as a species-relevant in vitro system. The ability to generate more than 70,000 spheroids from a single fish liver highlights its potential for higher-throughput toxicological analyses and a substantial reduction in the number of animals required in marine ecotoxicology.

1.03.B Bridging Innovation and Interpretation: New Approach Methodologies (NAMs) and 3R Alternatives in Environmental Toxicology

1.03.B.T-01 Mechanistic Insights into 6PPD-Quinone Toxicity using Brain- and Gill-derived Rainbow Trout (*Oncorhynchus mykiss*) Cell Lines as New Approach Methodologies (NAMs)

Anna Toso¹, Sara Isabel Bastos Gonçalves¹, Thibault Masset², William Dufey¹, Alan J Bergmann³, Mihai-Ovidiu Degeratu¹, Ksenia J Groh¹, Etienne Vermeirssen³, Florian Breider², Benoît J.D. Ferrari⁴ and Kristin Schirmer¹, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Swiss Federal Institute of Technology Lausanne (EPFL), Switzerland, (3)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Switzerland, (4)Ecotox Centre, Switzerland

6PPD-quinone (6PPD-Q), formed through the environmental oxidation of the tire antioxidant 6PPD, has been identified as the primary driver of urban runoff mortality syndrome (URMS), responsible for the mass mortality of Coho salmon. However, the cellular and molecular pathways underlying its toxicity remain poorly characterized. To address this knowledge gap, we employed our well-established cell-based toolbox, consisting of rainbow trout (*Oncorhynchus mykiss*) cell lines derived from different tissues and serving as relevant New Approach Methodologies (NAMs). In vitro cytotoxicity assays (OECD TG 249) revealed tissue-specific effects: 6PPD-Q was highly toxic to RTbrain cells but not to RTgill-W1 cells, derived from brain and gill tissue, respectively. Surprisingly, IPPD-Q - derived from the tire additive IPPD - showed no toxicity in RTbrain cells at the tested concentrations.

To investigate the mechanisms underlying these tissue- and chemical-specific responses, we performed RNA sequencing (Illumina NovaSeq X platform) and global proteomic analysis (nanoLC-MS/MS) after 24 h of exposure. Differentially Expressed Genes (DEGs), identified via DESeq2, and subsequent Gene Ontology (GO) analysis revealed both shared and tissue specific responses to 6PPD-Q: genotoxic and oxidative stress pathways were upregulated in both cell lines, whereas inflammatory/immune response were uniquely upregulated in RTgill-W1 and neuronal function/ion channel regulation uniquely in RTbrain. Comparison of 6PPD-Q vs IPPD-Q exposure in RTbrain cells showed downregulation of detoxification pathways along with activation of metabolic and stress responses in 6PPD-Q treated cells, potentially explaining its higher toxicity compared to

IPPD-Q. Preliminary proteomic analysis identified several differentially expressed proteins (DEPs), with GO terms broadly consistent with transcriptomic findings. RNA sequencing and global proteomic analysis highlight pathways that may underlie tissue-specific responses and the mechanisms of action of 6PPD-Q. Next steps include validating key genes by RT-qPCR, expanding toxicity endpoints (e.g., ROS formation), and quantifying internal concentrations to assess cellular bioaccumulation. Overall, these results support the growing potential of fish cell lines as NAMs for mechanistic toxicology of tire additives, paving the way toward more predictive and ethically aligned environmental risk assessment of these emerging contaminants.

Disclaimer/Disclosure:

The work presented here was funded by the World Business Council for Sustainable Developments (WBCSD) Tire Industry Project (TIP), a global CEO-led initiative undertaken by leading tire manufacturing companies. The study design, execution, interpretation, and manuscript preparation were conducted solely by the authors.

1.03.B.T-02 Development of Fish Cell-based Reproductive Toxicity Assays

Roman Li¹, Katharina Klotz², Vid Modic³, Kristin Schirmer¹, Anze Zupanic³ and Stephan Fischer²,
(1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland,
(2)aQuaTox-Solutions GmbH, Switzerland, (3)National Institute of Biology, Slovenia

Chronic fish toxicity data, which include reproductive toxicity endpoints, are required by regulators such as EFSA, ECHA, and EMA. Tests to obtain these data demand substantial numbers of animals, and time and money. Within the framework of the NC3Rs CRACK IT Challenge “SAFE”, we initiated the development of in fish cell line-based bioassays that can predict chemical impact on fish reproduction.

As the first step in this endeavour, we have developed a computational pipeline to identify 372 potential biomarkers of reproductive toxicity in fish (based on in vivo data) and tested their basal expression in chemically exposed permanent rainbow trout (*Oncorhynchus mykiss*) cells derived from liver and testis (in vitro). In the second step, we exposed the cell lines to four chemicals with known reproductive effects in fish (17 β -estradiol, 17 β -trenbolone, fadrozole, and flutamide) and two chemicals with no known reproductive effects (saccharin and sodium dodecyl sulphate). In the third step, we used the newly generated in vitro data to train machine learning (ML) algorithms. The amount of in vitro data, however, constrained model performance, indicating that more data is required. To temporarily overcome this limitation, we generated synthetic data comprising 34 additional treatments and achieved >70% model accuracy.

This proof-of-concept study demonstrated that (1) measuring biomarkers in cultured fish cells and interpreting the data with ML algorithms is a promising approach for predicting fish reproductive toxicity, and (2) expanding the dataset with approximately 30 additional chemical tests would enhance model performance to a robust and reliable standard, as well as build further confidence in this suite of assays, define their applicability domain, and advance them toward formal validation.

As a next step, we plan to incorporate cell lines derived from other organs, such as the brain and ovary, to achieve broader coverage of tissues involved in reproduction. Ultimately, we envision this work to evolve into a modular in vitro/in silico assay for fish reproductive toxicity, positioned within the framework of the fish invitrome and animal replacement strategies more broadly.

1.03.B.T-03 In Vitro Transcriptomic Points of Departure (tPODs) for 42 diverse chemicals in a human (Caco-2) and fish (RT-Gill) cell line

Niladri Basu¹, Ke Xu¹, Kritika Mittal², Geoff Hodges³, Bruno Campos³ and Claudia Rivetti⁴,
(1)McGill University, Canada, (2)Natural Resource Sciences, McGill University, Canada, (3)Unilever, United Kingdom, (4)Safety, Environmental and Regulatory Sciences (SERS), Unilever, United Kingdom

Transcriptomic points of departure (tPODs) have emerged as of scientific and regulatory interest, and there is increased interest in advancing the tPODs approach using cell lines. Towards this, we have developed the ‘TPD-seq’ workflow which links microplate-based exposure methods involving cell lines, with a commercially available RNA-seq kit, with a cloud-based bioinformatics tool (ExpressAnalyst.ca). To date the TPD-seq workflow has been applied to study positive/negative control chemicals routinely used in toxicological studies as well as 6PPD-quinone which is a chemical of immediate regulatory concern. To assess the scalability of the TPD-seq workflow, here it was applied to rainbow trout (*Oncorhynchus mykiss*) gill (RTgill-W1) and human intestinal epithelial cells (Caco-2) exposed to 42 chemicals of varying properties. Cells were exposed in a concentration-dependent manner (0-1000 μ M, spaced on a semi-log scale), following which cytotoxic and transcriptomic responses were measured and compared. Bioinformatics analysis yielded tPOD values. For Caco-

2 cells, the number of reads per sample was about 2-42 million, with 80-98% being mapped to genes. The number of differentially expressed genes (DEGs) across the chemicals was in the thousands, with gene BMDs ranging from 10 – 3,271. The tPODmode values ranged from 0.03 - 62 µM. Transcriptomics analysis for the RTgill-W1 cells is ongoing. Thus far, as like Caco-2, two methods for differential expression analysis (DESeq2 versus the Williams trend test) did not significantly affect tPOD results. 3,4-dichloroaniline (DCA) which was used as a positive control across multiple exposures resulted in tPODmode ranging from 0.01 to 0.03 µM (repeated four times). Thus far the TPD-seq workflow is generating cytotoxicity data, tPOD values, and lists of genes and potentially impacted biological pathways for a fish and human cell line. It is interesting to note that molecular/tPOD data can be derived for many chemicals that are not deemed cytotoxic. The derivation of this data was rapid and efficient compared to traditional animal-based methods, while also returning tremendous biological (molecular) information.

1.03.B.T-04 Evaluating the Protectiveness of High-Throughput Transcriptomics Data from fish cell lines for Environmental Risk Assessment

Claudia Rivetti, Jacob Collins, Geoff Hodges and Bruno Campos, Unilever, United Kingdom

The accelerating pace of chemical innovation necessitates efficient, mechanistically informative approaches for environmental safety assessment. Traditional animal-based toxicity testing is increasingly challenged by ethical, logistical, and scientific limitations, driving the adoption of New Approach Methodologies (NAMs). High-Throughput Transcriptomics (HTTr) offers a promising solution by enabling rapid evaluation of chemical bioactivity in vitro. This study evaluates whether transcriptomic points of departure (tPODs) derived from zebrafish cell lines are protective of apical endpoints observed in aquatic species. Forty-two chemicals were tested in ZFL (liver) and ZEM2S (embryonic fibroblast) cell lines using the TempO-Seq platform and analysed via gene-level and signature-based dose-response modelling. When converted to predicted external water concentrations using quantitative in vitro-in vivo extrapolation (qIVIVE), tPODs were generally protective compared to in vivo effect concentrations curated in the ECOTOX Knowledgebase. Benchmark comparisons revealed that HTTr-derived PoDs demonstrate conservatism with median in vivo values, supporting their utility for screening-level hazard assessment. Furthermore, integration of biological pathway analysis and cross-species susceptibility tools demonstrated the potential for extrapolating chemical effects beyond the tested taxa. These findings underscore HTTr as a scientifically robust and ethically preferable approach for advancing environmental risk assessment, while highlighting the importance of multi-cell-type strategies to capture tissue-specific responses.

1.03.P Bridging Innovation and Interpretation: New Approach Methodologies (NAMs) and 3R Alternatives in Environmental Toxicology

1.03.P-Tu001 Assessing the environmental safety of microbial pesticides: Opportunities to apply the 3Rs *Amy Marriott and Natalie Burden, NC3Rs, United Kingdom*

Microbial pesticides are an expanding class of crop protection products, increasingly developed for global markets as sustainable alternatives to conventional chemicals. To achieve worldwide registration, environmental data packages must satisfy diverse regulatory requirements across multiple jurisdictions. These requirements often differ in scope and interpretation, leading to duplicative testing and, in some cases, unnecessary vertebrate studies that add limited scientific value. Such practices raise concerns in terms of addressing the 3Rs (Reduction, Refinement and Replacement of animal use) and regulatory efficiency.

Current ecotoxicology test guidelines were designed for chemical substances and are often unsuitable for living

microorganisms, which exhibit unique properties such as infectivity and persistence. This misalignment creates challenges for study design, interpretation, and waiver justification. While some regions allow flexibility, approaches remain inconsistent, and opportunities to apply the 3Rs may not be fully maximised.

This poster will summarise the work the expert NC3Rs Ecotoxicology Working Group are carrying out to scope the global regulatory landscape for microbial pesticide ecotoxicology testing priorities and identify opportunities for better harmonisation and application of the 3Rs. Key opportunities include developing fit-for-purpose guidelines, promoting weight-of-evidence strategies, best practices for study waivers and integrating new approach methodologies (NAMs) to reduce reliance on vertebrate testing. By embedding 3Rs principles into evolving frameworks, the sector can support innovation in microbial pesticide development while maintaining robust environmental protection.

1.03.P-Tu002 Building AOPs for Developmental and Reproductive Toxicity in a 3R Paradigm: PFAS Case Study in *C. elegans*

Wouter Bakker, Nynke Kramer and Samantha Hughes, Wageningen University and Research (WUR), Netherlands

A limitation of cell-based in vitro toxicity assays is that they cannot capture downstream key events for systemic toxicity endpoints, as multiple cells and tissues are involved in the adverse outcome. To complement these cell-based assays, *Caenorhabditis elegans* offers a promising whole-organism 3R approach to adverse outcome pathways (AOP) development for toxicity testing. Despite its potential, *C. elegans* has not yet been widely applied to the study of key event relationships (KERs) within AOPs. Per- and polyfluoroalkyl substances (PFAS) represent a timely case study for developing AOPs in the context of developmental and reproductive toxicity (DART) using *C. elegans*.

In this study, we exposed *C. elegans* for 1–6 days to increasing concentrations of two prototypical, data-rich PFAS: perfluorooctanesulfonic acid (PFOS) and perfluorodecanoic acid (PFDA). We assessed upstream and downstream key events associated with DART, including gene expression changes, embryonic lethality, development, brood size and daily reproductive output. Using RNA-seq, expression of DART-related genes was significantly downregulated at low micromolar concentrations, while more downstream key events were perturbed at higher concentrations. When concentration–response relationships were expressed using nominal exposure concentrations, PFDA appeared significantly more potent than PFOS for each measured endpoint. For example, a clear dose–response relationship was observed for total brood size, with EC₅₀ values of 104 µM and 40 µM for PFOS and PFDA, respectively.

However, we also analytically measured internal concentrations of both PFAS in the worms after exposure using LC-MS/MS. When concentration–response relationships were expressed as internal worm concentrations, PFOS and PFDA showed more similar potencies as developmental toxicants, suggesting they act on the same AOP. The internal EC₅₀ was 3 mM for PFOS, while the EC₅₀ for PFDA was 1.5 mM, much higher than the nominal concentrations suggest. These data demonstrate that both PFAS substantially accumulate in *C. elegans* and that PFDA accumulates to a greater extent than PFOS, which can be explained by its higher lipophilicity. Our study demonstrates a clear, similar reproductive toxicity, across biological levels of organisation, following exposure to PFOS and PFDA.

1.03.P-Tu003 Surveying Regulatory Ecotoxicology Practices: Trends and 3Rs Opportunities in Contract Research Organisations

Amy Marriott and Natalie Burden, NC3Rs, United Kingdom

The UK National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) leads a programme to advance the application of the 3Rs in regulatory ecotoxicology testing. This work is supported by the NC3Rs Ecotoxicology Working Group, which includes experts from regulatory agencies, contract research organisations (CROs), the pharmaceutical, consumer products and (agro)chemical industries, and academia. In collaboration with this group, we conducted a survey of CROs to capture current practices in regulatory ecotoxicology testing and identify opportunities and barriers for implementing 3Rs approaches within standardised test guidelines used for safety assessment.

Building on a previous survey conducted in 2016, this survey examined how in vivo testing trends have evolved, where new approach methodologies (NAMs) are being applied, and where refinement and reduction strategies are already in use. Respondents also highlighted challenges and drivers for wider adoption of existing

3Rs approaches. The findings provide a benchmark for current testing practices and will inform future NC3Rs projects and priorities. By comparing these insights with historical data and tracking changes over time, this work aims to support evidence-based strategies to reduce vertebrate use in ecotoxicology while maintaining robust regulatory decision-making.

1.03.P-Tu004 Exploring Cross-Species Chemical Sensitivity Analysis of Alternative Model Organisms, Using Bayesian Methods, to Evaluate Their Potential to Inform Chemical Hazard Assessment

Isabelle Kavanagh, University of Birmingham, United Kingdom

Historically, regulatory toxicology has relied on vertebrate species for chemical safety assessment, yet ethical and legislative pressures are accelerating the transition towards non-animal approaches. A major barrier to this shift is that traditional point estimates provide limited insight into uncertainty and hinder robust comparison of sensitivity across taxa. Probabilistic methods such as Bayesian Benchmark Dose (BBD) modelling address these limitations by generating full posterior distributions that characterise both the magnitude and uncertainty of chemical effects.

This study investigates whether BBD distributions can reveal patterns of cross-species chemical sensitivity that may reflect evolutionary relationships. Using immobilisation dose–response data from the PrecisionTox project for five biomedical relevant model species, the analysis will evaluate whether similarities in shape, location, and overlap of posterior distributions are consistent with shared ancestry or divergence between major taxonomic groups. Framing chemical sensitivity as a continuous probabilistic phenotype provides a robust basis for comparative analysis and supports evaluation of alternative model organisms as potential replacements for traditional vertebrate species.

BMD10 posterior distributions were generated for a set of 29 chemicals from the PrecisionTox database tested across all of the five species. These distributions were used to assess cross-species sensitivity rankings, uncertainty, and overlap in responses. Planned analyses will apply phylogenetic reconstruction to the posterior distributions, examining variability across the full species set and comparing reconstructed vertebrate and invertebrate nodes. This will enable assessment of whether inferred toxicity distributions for the ancestral vertebrate lineage differ from or overlap with those of ancestral invertebrates. This approach contributes to the 3Rs and supports broader regulatory use of alternative test species.

Preliminary results show strong agreement in species sensitivity rankings across chemicals, with several vertebrate–invertebrate pairs displaying identical rank orders. Whole organisms, including *C.elegans* and *Daphnia magna*, demonstrated comparatively narrow posterior distributions, suggesting lower uncertainty than human cell assays for the endpoints examined. These findings indicate that distributional phenotypes may capture biologically meaningful similarities across taxa.

The dataset used was generated by the PrecisionTox project.

1.03.P-Tu005 Enabling the Next Generation of Avian NAMs: Data Curation, Model Evaluation, and Mechanistic Pathways Forward

Chloé Prunier¹, S. Nisa Nurdhy², Carlo Romoli³, M. Amine Aouini², Erik B Muller³, Mark D Jankowski⁴, Jean Viallet¹ and Jo Nyffeler², (1)Inovotion, France, (2)Helmholtz Center for Environmental Research (UFZ), Germany, (3)ibacon GmbH, Germany, (4)U.S. Environmental Protection Agency, United States

New Approach Methods (NAMs) offer opportunities to reduce animal testing, but their use in avian acute toxicity remains limited due to fragmented data, uncertain predictive performance, and the narrow reliance on a few standardized test species (quail, duck). These domestic models do not capture the physiological and ecological diversity of the ~10,000 extant bird species, raising concerns about the ecological relevance of current assessments. To support the development of more representative, mechanism-informed alternatives, we compiled and evaluated available *in vivo* data and assessed existing computational and experimental approaches.

We curated acute toxicity records from three major databases, obtaining 1,671 high-quality entries for 811 chemicals. Uncertainty analysis showed substantially less experimental noise than in mammalian datasets, providing a strong basis for evaluating NAM performance.

We reviewed Quantitative Structure–Activity Relationship models for avian toxicity; ten models met inclusion

criteria but were constrained by small or undisclosed training sets, limited transparency, and poor sensitivity to highly toxic chemicals. A targeted literature search identified two promising experimental approaches—avian cell cultures and the embryonated egg model—but both suffer from scarce data, lack of standardized protocols, and species-specific variability that further highlights the limitations of using domestic species as universal surrogates.

The literature provided NAM-derived LD₅₀/EC₅₀ values for 72 chemicals, with only two overlapping adult bird LD₅₀ data. Curation also identified a larger DT-40 chicken bursal cell-line dataset (75 chemicals). To explore extrapolation from NAMs to adult birds, we developed a simplified TKTD model using the GUTS framework. Applied to DT-40 cytotoxicity data, predictions were unreliable for neurotoxicants, likely due to missing mechanistic targets. Overall, DT-40 data poorly predicted avian acute toxicity, and hydrophobicity alone did not explain variability.

This work identifies key data gaps and methodological limitations while providing the most comprehensive quality-screened in vivo dataset available. By integrating this resource with systematic evaluation of computational and experimental approaches, we outline a path toward species-appropriate NAM platforms and mechanistically informed TKTD models, supporting reliable and regulatory-ready alternatives to adult bird acute toxicity testing.

1.03.P-Tu006 High-Throughput Determination of Structure-Activity Relationships in Organophosphate Ester Protein Binding

Jolie Miller, Hui Peng, Pranav Nair, Zhipeng Cheng and Kevin Zhu, University of Toronto, Canada

Organophosphate esters (OPEs) are a class of contaminants characterized by a pentavalent phosphorous and three ester groups, used commonly as flame retardants, plasticizers, and pesticides. The toxicity of OPEs varies significantly depending on their structural differences (e.g., aryl, alkyl, or halogenated ester side chains). However, structure-dependent toxicity assessments remain limited, largely due to the scarcity of reliable data. Moreover, more than 700 OPEs with diverse chemical structures are currently in production worldwide, underscoring the need for high-throughput approaches to evaluate their structure–activity relationships and potential impacts on human health.

To achieve this, we have synthesized a diverse array of >250 OPEs using ligands from alkyl, aryl, chlorinated, and brominated ester side chains used commonly in OPEs. Syntheses were characterized via 31P NMR and high-resolution mass spectrometry. The protein bindings of the synthetic OPEs were assessed in a high-throughput affinity selection mass spectrometry (AS-MS) assay adapted from our recent study. The synthesized chemicals were incubated with purified protein targets of OPEs before bioactive compounds were pulled out by tagged proteins, washed, eluted, and detected by mass spectrometry. The selected protein targets included FABP1, a recently identified binding target for tri-aryl OPEs with high structural selectivity along with six other nuclear receptors reported to have affinity for OPE binding. Interestingly, when correlating calculated XLogP of synthetic OPEs with FABP1 binding, an inverted U shape structure-activity relationship could be found. Differences in OPE binding affinity between FABP1 and various nuclear receptors will be further investigated to determine whether binding trends persist across different types of proteins. Collectively, this study developed a high-throughput new approach methodology for establishment of structure-activity relationships within a chemical class, which can be further extended to prioritize the most bioactive compounds.

1.03.P-Tu007 Defining Applicability Domains for the OECD 249 Fish Gill Cell Line Assay: Systematic Evaluation of Membrane-active Substances

Anika Dreier¹, Dennis Becker², Christine Landsberg¹, Lydia Hanschmann¹, Dirk Scheerbaum¹ and Christian Maeßl¹, (1)Noack Laboratorien, Germany, (2)Clariant, United States

As environmental risk assessment still relies heavily on animal testing, new approach methodologies (NAMs) are being developed in line with the principles of the 3Rs (Replacement, Reduction, Refinement). The OECD 249 fish gill cell line assay represents a promising alternative, where rainbow trout RTgill-W1 cells are exposed to test substances for 24 hours. Cell viability is quantified using three fluorescent dyes targeting different metabolic pathways, complemented by visual microscopic evaluation of the cell monolayer.

Our research evaluated membrane-active substances (surfactants) using this approach. While the three fluorescent dyes typically represent distinct cellular metabolic pathways to identify specific MOAs, our

fluorescence data suggested membrane interactions that could have been overinterpreted without complementary analysis. The microscopic evaluation revealed that cells and membranes were clearly damaged, indicating that relying solely on fluorescence data would have led to false positive interpretations of the specific interaction mechanisms. This finding demonstrates the essential role of microscopic assessment in preventing misinterpretation of fluorescence data, particularly for membrane-active substances where cellular damage may confound endpoint-specific signals.

We observed that specific chemical properties lead to distinct cell interactions, explaining previously identified inconsistencies in in vitro to in vivo result correlations across substance groups. These substance specific differences must be systematically identified to define the applicability of the OECD 249 test and its limitations. These findings would provide valuable insights for the regulatory acceptance of alternative methods in environmental risk assessment and could facilitate the transition away from animal testing. Our work contributes to the ongoing refinement of NAMs for more ethical, efficient, and predictive ecotoxicological assessments.

1.03.P-Tu008 Improving Chronic Fish Toxicity Prediction by Fish Early-Life Stage Data analysis and guided development of predictive alternative models

Nadia Katherine Herold¹, Stefan Scholz², Jürgen Arning³, Gerd Maack³, Susanne Walter-Rohde³, Daniel Faber⁴, Sebastian Schmidt⁵, Volker Strauß³, Tobias Pamminger⁶, Eric Bruns⁵ and Christopher Fassbender⁷, (1)No Affiliation, Germany, (2)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (3)German Environment Agency (UBA), Germany, (4)Bayer CropScience AG, Germany, (5)Bayer Research & Development Services LLC, Germany, (6)Early Environmental Safety, Bayer AG, Monheim am Rhein, Germany, (7)PETA Science Consortium Int. E.V., Germany

Chronic fish toxicity data are required by many regulations for environmental risk assessment and hazard classification. Typically, this information is provided from animal tests, mainly the fish early-life stage test (FELST; OECD Test Guideline 210). FELST is one of the most animal-consuming tests in ecotoxicology, with over 23,000 fish used annually in Europe. The LIMIT-FELST project aims to reduce the number and severity of FELST studies through predictive computational and experimental alternatives. We apply a tiered strategy where full concentration–response FELSTs are replaced by single-concentration limit tests informed from computational and experimental models. To develop this approach, we curated a database of FELST studies from public literature, ECHA, and other regulatory dossiers. Each entry was screened for TG210 compliance, and preference was given to studies reporting both no observed (NOEC) and lowest observed effect concentration (LOEC) value for survival and growth. For studies lacking direct survival LOECs, estimates were derived from growth endpoints via regression analysis. This yielded a dataset covering >500 substances. A key step in the data analysis was comparison of effects to the predicted baseline toxicity (i.e., hydrophobicity-driven intrinsic toxicity). We extended an existing baseline toxicity model (Scholz et al. 2018, ETC 37, 955-969) by adding more presumed narcotic compounds and using the dissociation-corrected lipid–water distribution coefficient (D_{lipW}) as descriptor of hydrophobicity. The expanded dataset confirmed the previously established regression for narcotic chemicals, increasing confidence in its use and enabling identification of compounds deviating from baseline toxicity. These were often associated with specific modes of action such as mitochondrial respiration inhibition, kinase signaling interference, endocrine disruption, or redox cycling. We hypothesized that these modes of action can be identified in an alternative testing approach, with similar sensitivity as in the FELST. Therefore, test systems like fish embryo morphology and behavior, cell-based assays, and transcriptomic profiling will be explored to support identification of limit concentrations without effects in full FELSTs. While ultimately the approach aims at a full replacement, the LIMIT approach has the advantage of being compliant with recent regulatory guidelines. The LIMIT approach could reduce animal use by up to 60%.

1.03.P-Tu009 Exploring the Applicability of the OECD TG 249 Fish Cell Line Acute Toxicity Assay in Environmental Hazard and Risk Assessment of Cosmetic Product Ingredients

Kyle Roush¹, Helena Villuendas Garcia², Roman Li², Christopher Fassbender³, Ryan Heisler⁴ and Amelie Ott⁴, (1)Procter & Gamble, United States, (2)aQuaTox-Solutions GmbH, Switzerland, (3)PETA Science Consortium Int. E.V., Germany, (4)International Collaboration on Cosmetics Safety (ICCS), United States

The OECD Test Guideline 203 fish acute toxicity test has historically provided data for environmental risk assessment, hazard classification, and regulatory decision-making. However, its reliance on live fish has driven a shift toward alternative methods that align with the 3Rs principles and evolving regulatory expectations. Among these, the OECD TG 249 assay, based on the RTgill-W1 fish gill cell line, represents a key innovation that enables the prediction of acute fish toxicity without the use of vertebrates.

As OECD TG 249 becomes more widely applied, efforts are increasingly focused on refining our understanding of its domain of applicability. Characterizing these boundaries is essential for defining how and when OECD TG 249 can be appropriately used in hazard and safety assessment, screening, and as part of integrated approaches to testing and assessment (IATAs). Seral initiatives are helping to map the OECD TG 249 assay's performance across diverse substance classes, identify conditions where concordance with in vivo outcomes is strongest, and develop guidance for interpretation within regulatory frameworks.

Building on these advancements, the International Collaboration on Cosmetics Safety (ICCS) has initiated a project focused on cosmetic ingredients, a category characterized by high chemical diversity. By carefully choosing test chemicals from diverse functional classes and physicochemical properties, the project seeks to further clarify TG 249's applicability domain. Comparing OECD TG 249 results with existing high-quality in vivo data will seek to evaluate how accurately the in vitro assay predicts toxicity across various chemical classes, whilst also identifying those classes that need further evaluation and consideration. These learnings and the data generated through this comparative assessment can then be incorporated into existing risk assessment frameworks to ensure the appropriate application of this assay in supporting the safe use of cosmetic ingredients in consumer goods.

1.03.P-Tu010 A Next-Generation High-Throughput In Vitro Exposure System for Early Hazard Ranking and Comparative Toxicity Assessment of Cigarette Smoke and Heated Tobacco Aerosols

Jonas Daniel¹, Amy Zimmermann-Klemd², Luisa Wende Wolf², Fabiola Susanna Emser², Marie Follo³, Rainer Trittler⁴, Barbara Rothen-Rutishauser⁵, Peter Deibert⁶, Carsten Gründemann² and Manuel Garcia-Käuffer⁶,
(1)Institute for Environmental Research (IFER), RWTH Aachen University, Germany, (2)Translational Complementary Medicine, University of Basel, Switzerland, (3)Lighthouse Core Facility, University of Freiburg, Germany, (4) University of Freiburg, Germany, (5)BioNanomaterials, Adolphe Merkle Institute, University Fribourg, Switzerland, (6)Institute for Exercise- and Occupational Medicine, Medical Center - University of Freiburg, Germany

Reliability and reproducibility of in vitro toxicological procedures for assessing the hazard potential of complex aerosols are determinant to cope with the innovations in molecular biology. The tools available for simulating exposure of epithelial lung cells are constantly being refined, but there are still no standards – or none have been agreed. This study contributes to close this gap by examining a novel high throughput exposure system that is designed to provide comprehensible exposure data, based on air-liquid interface and continuous flow technology. Using reference cigarette smoke and heated tobacco aerosol emissions, A549 cells grown in 96-well insert microplates were exposed to 11 aerosol concentration levels plus a vehicle control in eight technical replicates each, yielding 96 data points in a single batch. The consistency between nominal aerosol dose metrics and the elicited biological responses (cytotoxicity, genotoxicity, immunomodulation), confirms accuracy and reproducibility. Comparison between both emission classes, supported by chemical analyses, confirmed the transferability of the methodology, providing relative toxicity equivalents that enable an effect-based ranking of tobacco products. The feasibility of high-content approaches such as in situ γ -H2AX (genotoxicity) analysis also indicates an extended scope of application beyond conventional screening purposes. A unique combination of precise aerosol conditioning, uniform dosing and an unprecedentedly low background noise qualifies the high throughput exposure system for providing valuable dose-response data. A high degree of approximation to lung physiology can be derived, which is certainly not a matter of course in the context of continuous-flow exposure, particularly considering the novel microplate format.

1.03.P-Tu011 Contribution of the Ionic Fraction to the Toxicity of Soluble Metallic Nanomaterials

Mariia Goncharova¹, David Hernandez-Moreno¹, Rocío Fernández-Saavedra², Ana Isabel Cardona², Laura Molinero², Ana Valdehita¹, Jose María Navas¹ and María Luisa Fernández-Cruz¹, (1)National Institute of

One of the key challenges in studying the toxicity of partly soluble nanomaterials (NMs) is determining whether the observed toxicity is primarily caused by released ions or by the nanoparticles themselves. Because the solubility of NMs varies with the physicochemical properties of the test medium, and the duration of the experiment, it is important to assess solubility in each specific test.

Therefore, the aim of this study was to investigate the solubility of some metal-based NMs and to assess the contribution of released ions to their overall toxicity.

For this purpose, partly soluble metallic nanomaterials differing in size, shape, and surface coating were investigated: Ag (stabilized with citrate), 10 nm; CuO, 15-20 nm, (PlasmaChem); CuO, <50 nm, (Sigma-Aldrich); Cu, 25 nm; Cu, 50 nm; Cu, 100 nm, (IoLiTec); ZnO NM-110, 42 nm; ZnO NM-111, 34 nm (JRC repository).

NM toxicity was assessed following the OECD Test Guideline No. 249, which evaluates the cytotoxicity in the fish cell line RTgill-W1 applying three assays. The Nanogenotox protocol was used to obtain stable dispersions. Solubility was evaluated following the recommendations of OECD Guidance Document No. 318, using centrifugal ultrafiltration with Amicon 3 kDa filters. Concentrations of the soluble fraction relative to the total NM amount were measured at 0 and 24 h by ICP-MS. In parallel with NM toxicity testing, the toxicity of the corresponding metal ions was assessed by applying their soluble salts (AgNO₃, CuCl₂, ZnSO₄) under identical conditions.

Among the tested nanomaterials, CuO NMs showed the lowest solubility, followed by ZnO, and then Ag and Cu NPs. NMs that are more soluble exhibited greater toxicity. Comparative analysis of NM and ion toxicity revealed that ions accounted for most of the toxicity detected in Ag and Cu NPs (>90% of the toxicity attributed to the ion fraction). However, for ZnO and CuO, this contribution amounted only to 25–30% and 6–30%, respectively. Thus, the toxicity of these substances was predominantly driven by the nanoparticles themselves.

1.03.P-Tu012 Using Fathead Minnow Fish Embryo Tests to Parameterize Mechanistic Models for Environmental Risk Assessment Refinement

Daniel Harrison Burkow, Daniel Faber, Yvonne Wolf, Christoph Paul Linder, Markus Ebeling and Jutta Agert, Bayer CropScience AG, Germany

New approach methodologies (NAMs) are increasingly used in environmental risk assessment to reduce reliance on live animal testing. Fish embryo toxicity tests (FET) show promise as proxies for acute live-animal fish tests and could be extended to early life stage (ELS) tests under the right assumptions. Mechanistic models serve as intermediates to bridge the acute-to-chronic gap but require suitable data to estimate relevant endpoints.

This study explores how growth and survival data from embryos exposed to a substance can be used to calibrate the toxicokinetic–toxicodynamic module of a Dynamic Energy Budget model. A modified FET protocol (OECD 236) was conducted on fathead minnow, extending test duration and incorporating destructive sampling for daily length measurements. Fathead minnow embryos are protected by a semi-permeable chorion. For most substances, permeability is unknown and estimates strongly influence extrapolation accuracy. The DEB model was calibrated on FET test endpoints and parameter values from the AddMyPet database, with TKTD parameters validated against an existing 33-day ELS study to estimate chorion permeability.

This approach could become an animal-free replacement for ELS endpoints with the right chorion permeability data and already shows utility combining growth data from the modified FET protocol with existing ELS observations to parameterize a mechanistic model for tier 2c refinement. This work demonstrates a novel approach to combine environmental risk assessment data and mechanistic models to expand refinement options in ecological risk assessments.

1.03.P-Tu013 2-Ethylhexanol induces cardiotoxicity and molecular neurobehavioral impairment in *Daphnia magna*

Kojo Eghan, Sangwoo Lee and Woo-Keun Kim, Korea Institute of Toxicology, Korea, Republic of

The abundance of 2-ethylhexanol, which is a common plasticizer and solvent component, in aquatic ecosystems poses potential ecological risks. This study investigated the sublethal effects of 2-ethylhexanol on *Daphnia magna* by assessing physiological, biochemical, and molecular markers related to heart function and nervous system behavior. *D. magna* were treated with 1.11, 3.33, 10, and 30 mg/L of 2-ethylhexanol for 48 h. The endpoints assessed were cardiac and thoracic limb function; swimming behavior; neurochemical marker levels, such as acetylcholinesterase (AChE) and dopamine (DA); oxidative stress enzyme activity, including catalase (CAT), superoxide dismutase (SOD), and total nitric oxide (NO); and gene transcription associated with cardio- and neurotoxicity. Dose-dependent inhibition of cardiac rhythm and thoracic limb activity was also evaluated. Dysregulation of the transcription of the genes associated with cardiomyopathy, *sgcd*, *tmp3*, and *adcy5_1*, was observed. *D. magna* exhibited neurobehavioral disruptions, characterized by a reduction in body contact time and an increase in turn angle, supported by decreased dopamine levels and suppressed acetylcholinesterase activity. The oxidative stress response involved increased levels of CAT, NO, and SOD, with SOD demonstrating consistent upregulation at all concentrations. Significant changes in neurotoxicity-related genes (*drd2*, *slc6a3*, and *slc6a6*) highlighted the mechanistic connections to neurotransmitter dysregulation. These physiological, biochemical, and transcriptional alterations demonstrated that 2-ethylhexanol caused cardiotoxicity and neurobehavioral impairment in *D. magna* owing to oxidative stress. These ecological risks may disrupt predator-prey dynamics in aquatic ecosystems. Thus, reassessing the environmental safety thresholds of chemicals and identifying *Daphnia magna* as a sensitive model is essential for assessing sub-organismal toxicological effects.

[Acknowledgment] This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products Program, funded by Korea Ministry of Environment (MOE) (2022002980005, 1485019201) and the Korea Institute of Toxicology (KIT) Research Program (no. 2710008763, KK-2501-01).

1.03.P-Tu014 Can Environmental RNA be Used to Assess Stress in Macro-organisms in the Field?

Kyoshiro Hiki, *University of Tokyo, Japan*

Environmental nucleic acids (eNA), including both environmental DNA (eDNA) and environmental RNA (eRNA), have emerged as powerful tools for ecological monitoring. Unlike DNA, RNA is synthesized only for active genes in response to environmental changes and developmental processes. This characteristic makes the analysis of functional eRNA genes uniquely suited to providing physiological insights, such as information on reproduction, development, and stress responses, which cannot be inferred through eDNA analysis alone. However, the majority of studies focusing on functional gene detection remain confined to laboratory settings with a limited range of taxa.

In this study, I re-analyzed two published metatranscriptome studies on microbes that applied shotgun RNA sequencing to non-laboratory conditions, aiming to demonstrate that functional genes can be detected in environmental samples as eRNA released from macro-organisms. The re-analysis based on data from an aquaculture facility and an aquarium revealed that functional genes, such as *tlr4*, *lrp12*, and *elov11*, were detected as eRNA from Pacific oyster, whale shark, zebra shark, and green sea turtle. This result highlights the feasibility of using eRNA to assess biological processes, including immune responses and fatty acid metabolism. Despite these successes, challenges such as the dominance of microbial RNA, low sequencing depth, and RNA degradation were identified. This study provides a foundational direction for developing eRNA analysis as a non-invasive tool for ecological monitoring and the management of aquatic organisms in non-laboratory environments.

1.03.P-Tu015 Toxicity of biohybrid and fossil fuel fumes to *Drosophila melanogaster*

Lena Benner, *Carla Müller and Thomas Backhaus, RWTH Aachen University, Germany*

To support the transition away from fossil fuels, bio-hybrid fuels are being developed as potential replacements for conventional gasoline and diesel. One promising candidate is a ketone–ester–alcohol–alkane (KEAA) blend composed of ethanol, methanol, pentane, 3-methylbutanone, ethyl acetate and methyl acetate. In addition to engine performance, reduced toxicity is a critical consideration for the deployment of new fuels, particularly because human and environmental exposure to fuel vapors might occur during refueling, production, and

transport. Currently, standardized inhalation toxicity studies use vertebrate species (rats) to assess toxicity of volatile or gaseous pollutants. However, in order to minimize animal experimentation (3R principle), alternatives using invertebrate species need to be developed. Insects are considered especially sensitive to airborne contaminants due to their extensive tracheal respiratory system. Therefore, we established an acute inhalation toxicity assay using the fruit fly *Drosophila melanogaster*.

Adult *D. melanogaster* (strain OregonR) were exposed to concentration-series of KEAA and fossil-fuel vapors (gasoline E5). Water and acetone were used as negative and positive control, respectively. Mortality could be observed within one hour with LC50 values of 12.3 g/m³ and 23.8 g/m³ air for KEAA and gasoline (preliminary data), respectively.

Flies proved to be more sensitive to both pollutants than human lung cells (A549) in an air-liquid interface test setup, and reacted equally fast. The new biotest is versatile, easy to maintain and can be easily adapted to different insect species.

This work was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy – Cluster of Excellence 2186 „The Fuel Science Center” – ID: 390919832.

1.03.P-Tu016 Potentials of Metabolomics-Based Early Indication of Drug-Induced Liver Injury (DILI) using In vitro and In vivo Methods

Tae-Young Jeong and Dahyeon Hwang, Hankuk University of Foreign Studies, Korea, Republic of

Hepatotoxicity persists as a leading cause of post-market drug withdrawal, undermining the success of pharmaceutical development despite rigorous verification processes. Drug-induced hepatotoxicity, also known as drug-induced liver injury (DILI) is assessed through in vitro and in vivo screening in preclinical phase. Currently, the evaluation of chronic toxicity remains heavily dependent on in vivo models. Given the limitations associated with animal testing—including interspecies differences, extensive time requirements, and ethical issues—there is a growing demand for alternative testing methods. In vitro assays also take a relatively long period and harvests exposed cells that limit observation of time- and physiology-dependent cellular and molecular responses. Therefore, in this study, we applied extracellular metabolomics, a non-destructive methodology, to a traditional cytotoxicity assay. Our hypothesis was that changes in abundance of liver cell-derived biomolecules will be correlated with the magnitude of subsequent hepatotoxicity. We additionally expected that whether a drug is DILI or not could be predictable from the metabolomic profile patterns. HepaRG cell line was used for this experiment. Five DILI and non-DILI pharmaceutical substances were respectively selected, and exposure tests were conducted at concentrations showing high and low degree of hepatotoxicity. The exposed cells and the cell culture media were sampled 5 days later, pretreated, and analyzed using LC-QTOF-MS. Additionally, zebrafish embryo exposure testing was conducted to assess the correlation between in vitro metabolic signatures and in vivo toxicity at 72 hours post-fertilization (hpf). For this assessment, each compound was tested at its respective LC50 concentration. As results, we identified biomolecular differences in abundance for both intra- and extra-cellular, between the control and exposure groups. Furthermore, potential intracellular biomarkers for hepatotoxicity were identified through analysis of major metabolic pathways of biomolecules exhibiting significant differences between the groups. We also observed consistency between in vitro and in vivo results. These findings contribute to the basis for discovering potential extracellular biomarkers that can indicate DILI and non-DILI hepatotoxicity. At the same time, the study reveals the promises and limitations that require further studies.

1.03.P-Tu017 Fish Cell Lines in Pesticide Risk Assessment: Acute Toxicity and Bioaccumulation

Kehinde Olajide, René Schönenberger, Marco Enrique Franco, Ksenia J Groh and Kristin Schirmer, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Environmental legislation requires rigorous chemical risk assessment before market authorization to safeguard aquatic ecosystems. Traditional approaches rely on toxicity tests that evaluate impacts on survival and bioaccumulation, yet these methods are resource-intensive and depend heavily on the use of live fish. Emerging alternatives, particularly fish cell line systems, offer to reduce and replace animal testing while being amenable to delivering mechanistically relevant data. The RTgill-W1 cell line, derived from rainbow trout gills, has gained international regulatory relevance through its adoption as OECD Test Guideline 249 for determining acute fish toxicity and can additionally be applied to investigate toxicokinetic processes, such as bioaccumulation.

In this study, we assessed the acute toxicity and bioaccumulation of three organic pesticides —trifloxystrobin, tebuconazole, and tembotrione— using RTgill-W1 cells. In vitro EC50 values aligned well with corresponding in vivo LC50 values for acute toxicity, with differences of less than one order of magnitude. Bioaccumulation

was quantified using kinetic depletion and steady state models and compared with in vivo estimates. Taking trifloxystrobin as an example, chemical analysis shows significant elimination in cell-containing exposures compared with controls, and biotransformation products could be identified, demonstrating the ability of the cell line to biotransform this pesticide. These findings indicate that fish cell line assays can capture both acute toxicity and bioaccumulation processes relevant to regulatory assessment. Future work will expand these evaluations to environmentally relevant temperatures and to gill cell lines from multiple fish species to investigate interspecific sensitivity differences.

1.03.P-Tu018 Validation of the tFET: Enhancing the OECD 236 Fish Embryo Toxicity Test with Novel Endpoints to Assess Thyroidal Hormone System Disruption by Chemicals

Benedikt Luckner, Patricia Marini, Laura Wanner and Stefan Josef Hoeger, IES - Innovative Environmental Services Ltd., Switzerland

Endocrine-disrupting chemicals pose significant risks to human and environmental health, as even low concentrations can severely imbalance physiological homeostasis in organisms, affecting both individuals and populations. Current ecotoxicological assessments, such as the OECD 231 Amphibian Metamorphosis Assay or OECD 248 *Xenopus* Eleutheroembryonic Thyroid Assay (XETA), evaluate thyroid-disruptive properties but require testing on protected animal life stages, raising ethical concerns.

An implementation of further endpoints surrogate for thyroidal disruption into existing TGs such as the OECD 236 Fish Embryo Acute Toxicity Test (FET), designed as an acute toxicity test in fish but limited to non-protected life stages bares the potential to reduce the need for multiple tests and hence to spare resources and animals in line with the 3Rs principle and sustainability. In a collaborative project of academic and industry partners (ERGO Project), an expanded thyroid FET (tFET), with novel endpoints that assess disruptions of the hypothalamic-pituitary-thyroid axis has been designed and shall be validated for regulatory use in ecotoxicological hazard assessment.

Participating in the validation process of this modified OECD236 guideline, we will validate the test design and selected surrogate endpoints, e.g. the posterior swim-bladder inflation, changes in the eye histopathology and measuring of thyroidal-related hormone levels in exposed organisms. To minimize systemic toxicity interference, chemical concentrations will be capped at the maximum tolerated dose, defined by the 96-hour LC10 following OECD 236 guidelines.

Initial progress includes the identification of potentially suitable substances, pretesting, determination of appropriate concentration ranges based on 96-hour LC10 values and evaluation of the workflow and protocols regarding technical feasibility and practicability in exemplary trials.

1.03.P-Tu019 Filling in the gaps to support the application of alternative methods (OECD TG 236 and 249) to replace acute fish toxicity testing

Kristin Schirmer¹, Pia Talja², Shoko Furuno², Marta Sobanska², Panagiotis Karamertzanis², Simon Gutierrez³, Laure Chabot⁴, Stephan Fischer¹ and Flavio Marchetto², (1)aQuaTox-Solutions GmbH, Switzerland, (2)European Chemicals Agency (ECHA), Finland, (3)Ricardo-AEA Ltd, Spain, (4)Ineris, France

Information on acute fish toxicity is a data requirement under several EU legislations dealing with environmental safety of chemicals around the world. Historically, standardised in vivo testing has been used to fulfil such data needs, for example using the OECD test guideline (TG) 203. Ethical and practical reasons are promoting alternative methods, such as tests on fish embryos (OECD TG 236) or a fish gill cell line (OECD TG 249), adopted in 2013 and 2021, respectively. Replacement of the in vivo acute fish test for regulatory purposes requires a systematic comparison with the alternatives as far as data availability across methods allows, especially to identify areas of chemical space where over- or under-prediction of toxicity may occur.

The European Chemicals Agency (ECHA), with the support of a consortium composed of aQuaTox-Solutions, INERIS and Ricardo, ran a project to gather OECD TG-compliant data for the in vivo and the two alternative assays to analyse their concordance and to further advance knowledge on the applicability domain of the OECD TGs 236/249. Specific focus was on the areas of chemical space where these methods offer an equal or higher level of protection to fish and where uncertainties on the applicability still remain due to technical limitations or biological implications. Data on tests performed according to OECD TG 203 and stored in the International Uniform Chemical Information Database (IUCLID) were curated for comparison as a reference. Data generated using OECD TGs 236 and 249 were collected through a literature search from peer-reviewed journals, reports from research projects and publicly available databases. Information was harmonised and recorded using a tailor-made template.

Statistical analyses were performed on substances with data available from studies covering all three considered TGs. These analyses included regressions comparing effect levels between assays and enrichment analyses to

identify effect level ratios that deviated significantly from one. The substances were partitioned according to their physicochemical properties and their expected mode of action to determine for which substances and under which conditions one test may be more conservative than another. We will present the types and characteristics of substances for which the applicability of the alternative assays has been demonstrated, as well as those for which it has not yet been demonstrated and for which additional information is needed.

1.03.P-Tu020 Deriving Effect-Based Trigger Values in Human Serum Using Non-Target Suspect Screening Data, Reference Doses, and Toxicokinetic Modelling

Maria Margalef¹, Beate Escher², Martin Scholze³, Nora Bouftas⁴, Solène Motteau⁵, Maria König⁶, Maria Valente⁷, Yanying Ma⁷, Peter Cenijn⁴, Jean-Philippe Antignac⁵, Marja Lamoree⁴, Anne Marie Vinggaard⁷ and Timo Hamers⁴, (1)A-LIFE (Environment & Health), VU University Amsterdam (VU), Netherlands, (2) Helmholtz Centre for Environmental Research - UFZ, Netherlands, (3)Brunel University, United Kingdom, (4)VU University Amsterdam (VU), Netherlands, (5)LABERCA, Oniris, INRAE, France, (6) Helmholtz Centre for Environmental Research - UFZ, Germany, (7)National Food Institute - Technical University of Denmark, Denmark

We encounter a multitude of chemicals in daily life. Thus, it is vital to understand the internal exposure to chemical mixtures in human biomonitoring to better assess the impact of chemical pollution on health. Effect-based bioassays provide integrated biological readouts that captures the cumulative effects of all chemicals with similar sites of action present in a sample, making them powerful tools for mixture exposure assessment. Yet, the high sensitivity of these high-throughput assays can lead to overestimation of the effects of chemical mixtures on human health because also endogenous chemicals may trigger effects in these assays.

To differentiate between acceptable and unacceptable bioassay responses to the mixture of contaminants found in human samples, we need effect-based trigger values (EBTs) for bioassay responses. Establishing such EBTs remains challenging due to the complexity of human exposure profiles, the diversity of chemical signatures in serum, and the lack of comprehensive quantitative datasets that reliably link observed bioactivity to internal concentrations (e.g. blood levels) and health-based reference values. This limitation highlights the need for innovative strategies to derive scientifically robust benchmarks.

Our novel strategy for deriving EBTs for human serum combines high-resolution mass spectrometry-based non-target and suspect screening data of pooled serum extracts, with established reference doses from regulatory bodies (e.g., EFSA, ECHA), and toxicokinetic modelling. This workflow estimates internal concentrations corresponding to health-protective external exposure limits. By aligning bioassay responses with these modelled internal thresholds, we establish EBTs that reflect realistic exposure scenarios and regulatory guidance rather than arbitrary effect levels. This integration accounts for mixture effects, uses non-quantitative analytical data, and prioritizes chemicals driving observed bioactivity enhancing interpretability for risk assessment.

The application of this workflow to human serum samples demonstrates that EBTs derived through combined chemical-biological modelling can provide accurate and context-specific benchmarks compared to conventional effect-based approaches. This strategy offers a pathway for harmonizing state-of-the-art chemical occurrence data, bioassay outcomes, and regulatory standards in human biomonitoring programs, supporting improved health protection and evidence-based decision-making.

1.03.P-Tu021 Biological Effects of Microcapsules 3

Yukiyo Okazaki, Soramu Komeyama and Norihisa Tatarazako, (1)Ehime University, Osaka University, Japan

Microcapsules are small particles that encapsulate chemicals in an inner core. Similar in size to microplastics, they enable controlled and sustained release. The environmental fate of the encapsulated chemicals depends on the capsule matrix, which can slow degradation, enhance stability, or increase mobility, thereby altering hazard profiles.

On the other hand, these properties can be advantageous in aquatic ecotoxicity testing. Microencapsulation stabilizes degradable chemicals and reduces volatility, allowing evaluation of substances otherwise difficult to test with standard waterborne methods. It also shifts exposure in aquatic organisms from dermal or branchial absorption to oral intake, offering new insights into toxicokinetics and toxicity.

To address these challenges, we propose a Chemical Delivery System (CDS) that delivers chemicals to fish via microcapsules (MCs), particularly those unsuitable for waterborne administration. This approach creates

exposure conditions more comparable to mammalian studies.

In this presentation, we report our investigation of the chemical load per microcapsule and present the results of toxicity assays conducted using this microcapsule-based exposure system.

1.03.P-Tu022 Bioaccumulation Assessment Using New Approach Methodologies for Difficult Substances

Pauline Remuzat¹, Kai Benjamin Paul², Marianne Matzke², Virginie Burosse¹ and Jamie Marshall², (1)Blue Frog Scientific SAS, France, (2)Blue Frog Scientific Limited, United Kingdom

Screening for bioaccumulation traditionally relies on surrogate metrics such as octanol-water partition coefficient (log Kow), which has been widely used and accepted for decades and underpins many quantitative structure-activity relationships ((Q)SARs) models.

However, the accuracy of the log Kow for the bioaccumulation assessment is limited to certain substance classes and primarily reflect one accumulation mechanism – partitioning into storage lipids. For substances such as surfactants, ionisable compounds, or per- and polyfluoroalkyl substances (PFAS), bioaccumulation may involve alternative mechanisms, including specific biological binding interactions and depuration processes.

To address these limitations and improve bioaccumulation assessment for a broader range of substance, including difficult test substances, we have developed a non-animal bioaccumulation testing strategy combining up to five in chemico / in vitro assays, followed by in silico predictions. The tests include:

- 1) Log Kow - to account the partitioning to storage lipids;
- 2) Octanol/air partition coefficient (Koa) - to account for air-breathing organisms;
- 3) Membrane liquid/water partition coefficient (Kmw) - to avoid the estimation of lipid interactions using Kow;
- 4) Bovine serum albumin (BSA) solution/water partition coefficient (Kbsa) - to account for protein binding accumulation processes;
- 5) Determination of in vitro intrinsic clearance in rainbow trout liver cells (OECD 319A RT-HEP) - to account for biotransformation processes.

Each test aids in the removal of specific uncertainties related to substances that may accumulate via other processes than that indicated by log Kow. These data can inform weight-of-evidence approaches and/or serve as input for the BAT “Bioaccumulation Assessment Tool” QSAR model, improving accuracy of intermediate property predictions (e.g. biotransformation) / BCF predictions compared to Kow-based estimates alone. Incorporating these parameters into modelling software increases the precision, accuracy and predictability in an in vitro - in vivo extrapolation (IVIVE) approach.

The testing strategy proposed permits robust conclusion on bioaccumulation under PBT (Persistent, Bioaccumulative, Toxic) assessment regulatory frameworks. Here we present a case study and outline in which specific instances these tests are of value.

1.03.P-Tu023 Establishing Hemocyte Cell Cultures from Parhyale hawaiiensis: A Key Step Toward New Approach Methodologies (NAMs) in Marine Ecotoxicology

Giovanna Rodrigues de Melo¹, Paula Rocha² and Gisela Umbuzeiro¹, (1) State University of Campinas (UNICAMP), Brazil, (2) São Paulo State University, Brazil

Toxicology and ecotoxicology rely on model organisms to assess chemical and environmental hazards. However, the traditional use of vertebrates raises ethical concerns, encouraging the development of New Approach Methodologies (NAMs), such as in vitro cell culture systems. Despite advances with insect cell lines, marine invertebrate cell cultures remain scarce. The amphipod *Parhyale hawaiiensis* is a promising model organism, yet no established cell culture system exists for this species.

This study aimed to develop primary hemocyte cultures of *P. hawaiiensis* to support NAM-based assays. Adults were maintained under controlled salinity, temperature, and feeding conditions at the Laboratory of Ecotoxicology and Genotoxicity (LAEG) of the Universidade Estadual de Campinas (UNICAMP). Hemolymph was extracted using glass capillaries and cultured in Leibovitz's L-15 medium supplemented with FBS, antibiotics and Red Sea Salt to adjust salinity. Cultures were maintained in 96-well plates at 26 °C and

monitored daily.

Establishing this culture presented significant challenges due to the organism's very small size, which limits the volume of hemolymph obtained and makes it difficult to maintain sufficient cell numbers. Even so, results demonstrated the successful formation of primary cultures: cells adhered to the plate surface within 4 hours and remained viable for up to two weeks with medium replacement. This achievement represents an important milestone for the application of NAMs in marine ecotoxicology and provides the foundation for developing a continuous cell system for this amphipod.

We are currently optimizing the visualization of adhered cells using confocal microscopy, aiming at fluorophore staining and future structural characterization. As next steps, we plan to compare adverse effects on cultured hemocytes and also on those derived from exposed animals using different contaminants to strengthen the use of these cultures as a robust tool within NAMs.

The authors acknowledge the financial support from FAPESP (Grant 23/10693-5), which was fundamental for this research.

1.03.P-Tu024 Checklist-based quality criteria for generating and reporting acute fish cell line data in the FACT database.

Christoph Schuerl¹, Marion Revel¹, Gilly Stoddart², Christopher Faßbender² and Kristin Schirmer¹, (1) Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)PETA Science Consortium Int. E.V., Germany

The RTgill-W1 fish cell line assay, a bioassay that is validated and standardized as the OECD Test Guideline (TG) 249, has shown great promise as an alternative method to fish acute toxicity testing (e.g., OECD TG 203). Despite its rigorous validation and adoption as ISO standard 21115 and OECD TG 249, its uptake is facing barriers such as reluctance in regulatory acceptance, often due to a lack of understanding and confidence in using the data, and some data not being publicly available. This could be helped by a comprehensive characterization of the assay's applicability domain, i.e., the chemical space in which the assay can be expected to perform reliably, which, however, requires an overview of all available data.

To collect all available fish cell acute toxicity data, we created the Fish Acute Cell Toxicity (FACT) database as a continuously updated resource. Currently, the FACTdb contains toxicity (cell viability) data on over 100 chemicals represented through EC50, EC10, and non-toxic concentrations (NtC) values, calculated using a consistent analysis workflow. In the process of data curation, it became evident that even with such a standardized assay, there is still variation in how the assay is conducted and the data is reported. This often leaves questions regarding the validity and suitability of the data for inclusion into the database. Accordingly, we created checklist-based quality criteria that sensitize users towards key elements of data generation and reporting. This checklist follows the OECD guidance document 147 requirements "on the Generation, Reporting and Use of Research Data for Regulatory Assessments". It therefore requires information across the categories of chemical properties, experimental setup, and validity criteria. The checklist serves as a quality assessment before data are entered into the FACT database. It assigns guideline adherence levels from 1 to 3: Level 1 indicates full compliance with OECD TG 249, Level 2 reflects adherence with some deviations (e.g., alternative plate formats), and Level 3 concerns relevant research data (e.g., other fish cell lines).

We aspire for the combination of the checklist and FACT database to strengthen both the confidence of the regulatory community in how to best conduct the assay, improve the reporting quality of generated data, motivate further uptake of the assay, and help towards higher regulatory acceptance by further characterization of the evolving applicability domain.

1.03.P-Tu025 Catching the Risk: Leveraging New Approach Methodologies to Address Acute Fish Toxicity in Plant Protection Product Assessments

Yvonne Wolf, Elena Adams, Daniel Faber, Sarah Hartmann and Eric Bruns, Bayer AG CropScience, Germany

In the European Union (EU), the authorization of plant protection products (PPPs) and their active substances involves a comprehensive evaluation of environmental risks to various taxonomic groups. One of the

requirements is assessing the acute toxicity towards fish (Commission Regulations (EU) 283/2013 and 284/2013). Concurrently, there are ongoing initiatives aimed at reducing or completely eliminating vertebrate testing within the EU and other regions. Over recent decades several New Approach Methodologies (NAMs) have been developed to predict the acute toxicity towards fish such as the fish embryo toxicity assay (FET, OECD TG 236) and the rainbow trout gill cell line assay (RTgill W1, OECD TG 249). However, these alternative methods have yet to be integrated into the registration process for PPPs as is already done or under development within other legislations (e.g., REACH, cosmetics, German wastewater treatment assessment). In a recent publication, we found that the risk assessment for less than 10 % of the active substances registered in the EU in 2022 was primarily based on the acute risk towards fish in an aquatic first-tier assessment (Adams et al., 2025). In a subsequent step we assessed the modes of action (MoAs) of these substances and identified various MoAs that potentially cause a higher acute toxicity towards fish. Our research focuses primarily on the substance classes that have shown an increased acute risk to fish, rather than on those classes that have demonstrated no or only a low acute risk for fish compared to other aquatic endpoints. Ultimately, the goal of this research is to develop a tiered approach to cover fish acute toxicity starting with NAMs and only conducting vertebrate tests as a last resort to ensure ecological safety. By focusing on critical substance classes, we aim to better understand the utility of NAMs in ecotoxicological risk assessments as these might not be covered by NAMs. Preliminary results from FET assays with *Danio rerio* demonstrate a significant overlap in effect concentration ranges with results from acute fish tests. Further findings will be presented at the conference, contributing to the ongoing discussion on the integration of NAMs into the legislation framework of PPPs risk assessment.

1.03.P-Tu026 Machine Learning-Enhanced High-Content Screening Platform for Genotoxicity Assessment in Human HepaRG Cells

Yiping Xu¹, Peiyu Jiang¹, Mei Ma¹ and Kaifeng Rao², (1)Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, China (Mainland), (2)Key Laboratory of Environmental Aquatic Chemistry, State Key Laboratory of Regional Environment and Sustainability, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, China (Mainland)

The assessment of chemical-induced genotoxicity remains a critical challenge in safety evaluation, particularly given the limitations of conventional methods, which often lack metabolic relevance and multimodal integration. To address this, we developed a high-content screening (HCS) platform combining immortalized human HepaRG cells—capable of intrinsic metabolic activation—with machine learning (ML) for mechanism-based genotoxicity classification.

HepaRG cells were cultured in 96-well plates and exposed to 24 mode-of-action (MOA)-characterized genotoxic agents (16 clastogens, 8 aneugens) across nine concentrations. A triplex fluorescent staining protocol (Hoechst 33342, ethidium bromide/acridine orange) enabled high-content imaging of nuclear morphology, apoptosis, and membrane integrity. From >1,000 fields per well, 51 phenotypic parameters were extracted, including micronucleus (MN) counts and morphometric features. A three-tier feature selection process narrowed these to 13 discriminative parameters for ML modeling.

Three algorithms—Random Forest (RF), Support Vector Machine (SVM), and Gradient Boosted Decision Trees (GBDT)—were benchmarked. SVM achieved the best performance with 75.5% test accuracy and an AUC-ROC of 0.895, effectively distinguishing clastogenic from aneugenic mechanisms. The optimized pipeline was applied to predict MOA for 27 plastic additives with unknown genotoxicity profiles, yielding consistent multi-model predictions for 89% of compounds.

This integrated approach offers a physiologically relevant, high-throughput, and interpretable platform for mechanism-based genotoxicity assessment, overcoming key limitations of existing methods.

1.03.P-Tu027 Zinc- and Copper-Containing Metal Fumes Inhibit Inflammatory Responses in THP-1-Derived Human Macrophages

Jan Steffens¹, Sabrina Michael², Katharina Kuth³, Henner Hollert⁴, Miriam Du Marchie Sarvaas³, Andrijana Nestic⁵, Thomas Kraus³ and Ralf Baumann⁵, (1)Institute for Translational Medicine, Medical School Hamburg, Germany, (2)Institute of Hygiene and Environmental Medicine, University Hospital RWTH Aachen University,

Germany, (3)Institute for Occupational, Social and Environmental Medicine, University Hospital RWTH Aachen University, Germany, (4)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Germany, (5)Institute for Translational Medicine, Medical School Hamburg, Germany

Occupational exposure to metal fumes increases the risk of severe pneumonia among metal workers, though the immunological mechanisms remain unclear. This study investigated whether zinc oxide (ZnO) and copper oxide (CuO) particles suppress human macrophage inflammatory responses to bacterial pathogens. Human THP-1-derived macrophages were differentiated by exposure to phorbol 12-myristate 13-acetate for 48 h and subsequently exposed in vitro to bacterial pathogen-associated molecular patterns (PAMPs): lipopolysaccharide (LPS; 2 or 20 ng/mL), lipoteichoic acid (LTA; 100 or 1000 ng/mL), or peptidoglycan (PGN; 1000 or 3162 ng/mL), with or without 2 µg/mL CuO/ZnO particles generated by metal inert gas soldering. Particles were nanosized (40 to 250 nm) with a predominantly spherical morphology as observed by scanning electron microscopy. The elemental composition primarily consisted of 49.42% Cu and 47.27% Zn, as measured by inductively coupled plasma mass spectrometry. Energy-dispersive X-ray spectroscopy confirmed the elemental composition, and oxidation states were inferred from oxygen detection and the known properties of CuO/ZnO. TNF and IL-6 mRNA expression was quantified by qPCR 4 h post-exposure (n=5), and secreted protein levels were assessed by electrochemiluminescent immunoassay after 24 h (n=3). PAMP stimulation induced a dose-dependent increase in TNF and IL-6 mRNA and protein, which was significantly inhibited by 2 µg/mL CuO/ZnO particles. Inhibition was more evident with TNF than with IL-6. Particle exposure with CuO/ZnO only significantly suppressed TNF protein secretion, while IL-6 was unaffected. Cell viability remained high (97.5%) at 2 µg/mL, with an IC50 for cytotoxicity of 6.7 µg/mL. These findings indicate that CuO/ZnO particles can inhibit key macrophage immune responses to bacterial stimuli, providing a potential mechanistic explanation for the increased risk of severe pneumonia among metal workers, supporting current pneumococcal vaccination recommendations for occupationally exposed individuals, and highlighting the value of exposure limits and preventive measures.

1.03.P-Tu028 Can gene expression be used to detect endocrine activity in zebrafish embryos?

Yana Andreevna Streletsova¹, Hannes Armin Reinwald², Steve Uwa Ayobahan³, Sebastian Eilebrecht⁴ and Tobias Pamminer⁵, (1)Bayer CropScience AG, Germany, (2)Bayer Research & Development Services LLC, Germany, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Early Environmental Safety, Bayer AG, Monheim am Rhein, Germany

Endocrine disrupting compounds (EDCs) are substances that can interfere with the normal functioning of the hormonal systems, posing a potential risk to both wildlife and human health. To be classified as EDCs, compounds must exhibit endocrine activity at the relevant receptor or enzyme and as a consequence, cause population-relevant adverse effects in either the exposed organism or its offspring. Current regulatory frameworks make use of a range of in vivo assays in adult vertebrate species to assess both aspects of endocrine disruption. However, the ethical concerns associated with animal suffering have generated increasing cross-stakeholder momentum to align regulatory approaches with the 3Rs principles (Refinement, Reduction, and Replacement of animal experiments) and to reduce dependence on animal-based test systems. According to European Directive 2010/63/EU regarding the protection of animals used for scientific purposes, zebrafish embryos model are not considered as a protected life stage up to 120 hours-post-fertilization (hpf), as the embryos are not capable of independent feeding at this stage. This research investigates the potential of fish embryos as a non-animals alternative model for assessing the endocrine activity of chemicals across three EAS modalities. The focus of this study is to determine whether the key components of the sex endocrine system in zebrafish are expressed and functional during the early developmental period up to 96 hpf, which is essential for generating a reliable transcriptional response associated with endocrine activity.

1.03.P-Tu029 Predicting Pulp and Paper Mill Effluent Toxicity Using the RTgill-W1 Assay

Jack Salole¹, Lisa N. Taylor² and Joanna Wilson¹, (1)McMaster University, Canada, (2)Nautilus Environmental Company, Canada

Around the world, regulatory programs are demanding a shift from traditional vertebrate-based toxicity test methods to alternative approaches. In Canada, this was introduced in legislation aiming to phase out whole animal vertebrate toxicity testing by 2035. As these tests use millions of vertebrates to inform several regulatory programs, the development of replacements is desperately needed. One of the most extensively used regulatory tests exposes rainbow trout (*Oncorhynchus mykiss*) to industrial and municipal effluents to determine their compliance with national and provincial legislation. Our research explores an alternative approach, based on the OECD 249 and ISO 21115 methods, that uses cell viability indicators in a rainbow trout gill cell line (RTgill-

W1) to assess the acute toxicity of effluent samples. Using pulp and paper mill effluents from 5 unique sources, we assessed the robustness of RTgill-W1 assay to detect effluent toxicity through reference toxicant testing in non-toxic effluents (n = 42) and control media (n = 54) backgrounds. The sensitivities of both test methods were assessed using effect-causing effluent samples (n = 20). In all of these effect-causing effluents, the RTgill-W1 assay performed similarly to the rainbow trout test and proved generally more sensitive to pulp and paper mill effluent. We also determined the use of this assay as a tool to identify common toxicants of pulp and paper mill effluents to demonstrate its potential for investigative testing. This research provides critical information about the sensitivity of a potential replacement to the most widely used test in effluent regulations globally.

1.03.P-Tu030 Long-term In Vitro Exposure Strategy to Study Micro- and Nanoplastic Carcinogenicity

Irene Barguilla¹, Javier Gutiérrez-García¹, Raquel Egea², Penny Nymark³, Alba Garcia-Rodriguez¹, Boris Guyot⁴, Véronique Maguer-Satta⁴, Ricard Marcos¹, Laura Rubio Lorente¹ and Alba Hernández¹, (1)Autonomous University of Barcelona (UAB), Spain, (2)Genetics and Microbiology, Autonomous University of Barcelona (UAB), Spain, (3)Karolinska Institute, Sweden, (4)Cancer Research Center of Lyon (CRCL), France

Human populations are increasingly exposed to many environmental pollutants over long periods, which may lead to carcinogenic impacts. Traditional animal assays cannot support the large testing needs for such agents, which highlights the need for human-relevant in vitro approaches based on new approach methodologies. This work addresses this challenge by applying a long-term in vitro exposure strategy combined with multiple transformation biomarkers to evaluate chronic effects of airborne micro- and nanoplastics, a widespread pollutant with growing concern for human health.

We exposed human bronchial epithelial cells continuously for 30 weeks to PET particles representative of real-life exposure scenarios. The micro- and nanoplastics size, morphology and stability were characterised, and cell uptake was confirmed. Our exposure strategy enables time-resolved assessments; therefore, key biomarkers of transformation were examined at mid and late stages, including DNA damage, anchorage-independent growth, and invasion capacity. Transcriptomic profiling at three time points provided mechanistic insight into progressive cellular changes.

Cells showed no early effects, but after 30 weeks clear transformation features emerged. Genotoxicity appeared only at the latest stage, suggesting it may be a consequence rather than an initiating event. Growth in soft agar and invasive behaviour also increased only after long-term exposure, indicating a progressive acquisition of malignant traits. Gene expression analyses confirmed these trends: the number of altered genes rose over time, many linked to cancer pathways. Notably, genes associated with epithelial–mesenchymal transition and lung cancer were strongly upregulated, supporting the phenotypic evidence and pointing to mechanisms related to oncogenic activation.

Overall, this study demonstrates that chronic exposure to PET particles can induce progressive transformation in human lung cells. The approach reproduces realistic long-term conditions and uncovers effects that short-term assays would miss. These findings strengthen the case for considering chronic low-dose exposure to micro- and nanoplastics in risk assessment and illustrate how long-term in vitro models can advance carcinogenicity testing and mechanism-based evaluation of emerging pollutants.

1.03.P-Tu031 Development of Biocide-Specific Quantitative Structure-Activity Relationship(QSAR) model to Predict Developmental Toxicity to Zebrafish Embryos

Gyumin Kang¹, Hyun Kil Shin² and Ki-Tae Kim¹, (1)Seoul National University of Science and Technology, Korea, Republic of, (2)Korea Institute of Toxicology, Korea, Republic of

Objective: The objective of this study was to develop a Quantitative Structure–Activity Relationship (QSAR) model to predict the acute toxicity of biocides to zebrafish embryos.

Methods: We produced developmental toxicity of 74 biocides by using zebrafish embryo. Among them, except for inorganics and mixture compounds the calculated median lethal concentration (LC50) values of 42 biocides were used as the dataset for QSAR model development. Chemical space analysis using a Tanimoto heat map, LC50 distribution, and Structure-Similarity Activity Trailing (SimilACTrail) confirmed that the dataset was suitable for fingerprints and descriptors were calculated as input features. The molecular features were split into training and test sets at an 8:2 ratio using the Kennard–Stone algorithm, and a genetic algorithm was applied to identify optimal feature combinations for predicting LC50 values. Finally, a Multiple Linear Regression (MLR) model was developed, and its predictive performance was evaluated using R^2 , root mean square error (RMSE), and 5-fold cross-validation (CV).

Results: Toxicity testing showed that 73 individual biocides (98%) caused embryonic mortality with a median lethal concentration ranging from 0.73 to 58.82mM. The diversity of chemical structures and LC50 distribution confirmed that the dataset was appropriate for model development. The SimilACTrail map showed that toxicity is largely structure-driven, with one chemical pair highlighting chlorine as a key determinant. Toxicity testing showed that 73 individual biocides (98%) caused embryonic mortality with a median lethal concentration ranging from 0.73 to 58.82mM. The diversity of chemical structures and LC50 distribution confirmed that the dataset was appropriate for model development. The SimilACTrail map showed that toxicity is largely structure-driven, with one chemical pair highlighting chlorine as a key determinant.

Conclusion: The developed fingerprint-based QSAR model demonstrated strong predictive performance, indicating its suitability for assessing biocide toxicity. Both the fingerprint-based interpretation and the SimilACTrail analysis consistently showed that biocides containing halogen atoms exhibit greater developmental toxicity in zebrafish embryos. This study demonstrates a solid and reliable QSAR framework for biocide toxicity evaluation with clear applicability for regulatory assessment and chemical screening.

1.03.P-Tu032 Defining the Domain of Applicability: A Case Study to Increase Confidence in Toxicogenomic Tools for Ecological Risk Assessment

Stephanie B Kennedy¹, Melissa Marie Heintz¹, Lauren Brown¹, Chloe Louise Fender¹, Markus Hecker², Sarah A. Hughes³, Jonathan Naile⁴ and Paul DeLeo⁵, (1)ToxStrategies, United States, (2)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (3)Shell Global Solutions (US) Inc, United States, (4)Shell Global Solutions International BV, (5)Regulatory and Scientific Affairs, American Chemistry Council (ACC)

Toxicogenomics offers a powerful means to characterize the molecular effects of environmental chemicals, often with reduced animal testing. Its use in human health assessment has grown rapidly in the last decade. In contrast, applications in ecological risk assessment remain limited, and uncertainty remains regarding how toxicogenomic responses translate to ecologically relevant outcomes. The objective of this research was to increase confidence in, and advance the application of, toxicogenomic approaches within ecological risk assessment.

A landscape review was conducted to evaluate current toxicogenomic applications in ecological assessments and to identify existing regulatory considerations. The primary focus of research among identified applications was the development and evaluation of ecological transcriptomic points of departure (tPODs). Although regulatory agencies are beginning to consider toxicogenomic data within weight-of-evidence evaluations, no formal ecological risk assessment frameworks currently incorporate these data. The review identified three key research gaps: (1) alignment between qPCR-based and whole-transcriptome tPODs; (2) ability of transcriptomic approaches to resolve species-sensitivity differences; and (3) concordance of in vitro and in vivo transcriptomic responses.

To address these gaps, a case study was designed using unpublished RNA sequencing and EcoToxChip qPCR datasets from fathead minnow and rainbow trout exposed to ethinylestradiol during early life stages. Comparative analyses will evaluate sensitivity, reproducibility, and variability across technologies, species, and exposure durations, and assess concordance with established apical effects and reference values. EcoToxChip data generated by a contract research organization will also assess feasibility outside academic and governmental settings.

The case study will address the performance and limitations of transcriptomic new approach methods (NAMs),

inform best practices for their use, and support their broader application in ecological assessments. Collectively, this work strengthens the evidence base needed to incorporate toxicogenomics into ecological risk assessment, and identifies priority areas for future research, including cross-trophic evaluations and applications in chemical grouping and read-across.

1.03.P-Tu033 Are Spheroids or Organoids the Real Game-Changers for Micro(nano)plastics Health Impact Studies?

Carolina Frazão, Mónica Almeida, Isabel Lopes and Miguel Oliveira, University of Aveiro, Portugal

Plastics have emerged as one of the most impactful alterations on the planet. Since their introduction in the 1950s, production has increased, reaching 430.9 million tonnes in 2024. Poor end-of-life management and the widespread use of single-use plastics have contributed to their accumulation in the environment, where they degrade into micro(nano)plastics (MNPs). These smaller particles have high bioavailability, with numerous studies, mainly with aquatic organisms, reporting adverse effects on reproduction, immunity, metabolism, and behaviour. Such findings raise concern about possible impacts on humans, who may be exposed through ingestion of contaminated food and beverages, inhalation of airborne particles, and dermal contact. Recent studies have proven that humans are incorporating (e.g., detection in blood) and releasing (faeces) these particles. However, current knowledge of their effects on humans remains limited and is largely based on rodent studies or 2D in vitro cultures, both of which present uncertainties due to species-specific physiology or the simple nature of monolayer systems.

Advanced 3D human cell culture models may help overcome these limitations. Spheroids and organoids, for example, are multicellular structures that better reproduce tissue architecture and cellular interactions, offering more physiologically relevant platforms without the ethical constraints of animal or human experimentation. Their use is particularly valuable given the diversity of MNP characteristics (e.g., polymer type, size, shape, surface charge, age, and chemical additives) that can influence their toxicity.

This study aims to integrate and increase current knowledge on the relevance of 3D systems for MNP research, highlighting their advantages and limitations with a focus on human models. Two approaches were used. First, a literature review of studies investigating MNP effects on human health. Second, in vitro experiments using human cell lines (e.g., HEK293T) exposed to fossil-based polymers (e.g., polymethylmethacrylate) and bio-based polymers (e.g., polylactic acid) in both 2D and 3D cultures (spheroids). Overall, data show that 3D systems provide enhanced biological relevance and improved predictive power for human risk assessment of micro(nano)plastics.

1.03.P-Tu034 Predicting Acute Fish Toxicity with the RTgill-W1 Cell Line Assay: New Insights and Regulatory Applications using Fragrance Chemicals as Case Studies

Heike Laue¹, Lu Hostettler², Tina Haupt², Karen Jenner³, Gordon Sanders¹ and Andreas Natsch², (1)Givaudan International SA, Switzerland, (2)Givaudan Suisse SA, Switzerland, (3)Givaudan UK Ltd, United Kingdom

The RTgill-W1 cell line assay was recently adopted as an OECD Test Guideline (TG) 249 and several studies have been published demonstrating its usefulness to predict acute toxicity to fish as a non-animal alternative to the conventional approach (OECD TG 203). Here we present new insights on the accurate prediction of in vivo LC50 values, and regulatory applications using fragrance chemicals as case studies.

According to TG 249, the predicted LC50 is equal to the lowest EC50 among three cell viability endpoints based on geometric mean measured concentrations. As an alternative, regression equations based on 38 fragrance chemicals translating the EC50 (metabolic activity endpoint) and measured concentrations (arithmetic mean, geometric mean) to the LC50 was developed by plotting EC50 against the corresponding in vivo LC50 values. In this study, the two approaches were applied for the fragrance chemicals used previously and for 11 additional chemicals as test set and compared to in vivo LC50 data. Both approaches can predict LC50 values accurately, yet the regression approach is more conservative. In addition, TG 249 was applied for the assessment of aquatic toxicity on 30 newly tested fragrance chemicals and two cosmetic ingredients including chemicals tested for regulatory purposes. For animal welfare reasons, nine in vivo studies required for regulatory dossiers were performed using the threshold approach and were in line (within a factor of 3-times) with predicted LC50 using the TG 249. A good agreement of predicted LC50 by the RTgill-W1 cell line assay and QSARs was observed (n=5) and in vitro data were also applied for five read-across studies. For three poorly water-soluble (< 1 mg/L) fragrance ingredients, effects on the RTgill-W1 cell line were evaluated using water saturated solutions demonstrating no effects at saturation. In conclusion, the TG 249 is a valuable tool to predict LC50 values for hydrophobic (highest log Kow 6.6) and volatile fragrance ingredients including complex substances (multi-constituent, UVCB) and has been successfully applied for REACH registrations to avoid animal testing. This

presentation will clearly demonstrate that fragrance molecules of broadly varying physico-chemical characteristics and differing chemistries fit well within the domain of applicability of the OECD TG 249.

1.03.P-Tu035 Mechanism-Informed PFAS Toxicity Classification Using Integration of Transcriptomics and Computational Platforms

Eun Ki Min¹, John K. Colbourne², Pu Xia³, Seohyeon Yeo¹ and Ki-Tae Kim¹, (1) *Seoul National University of Science and Technology, Korea, Republic of*, (2) *School of Biosciences, University of Birmingham, Canada*, (3) *School of Biosciences, University of Birmingham, China (Mainland)*

PFAS comprise thousands of chemicals, necessitating a grouped management strategy; however, even classification approaches are limited due to scarce toxicological data. We aimed to evaluate the utility of multi-dimensional information from chemical structure, bioactivity, and transcriptomics for classifying the developmental toxicity of PFAS in zebrafish embryos. We further integrated them to enhance classification performance and identify potential biomarkers for mechanism-anchored classification. A total of 15 PFAS were classified by developmental toxicity in zebrafish embryos. Those Chemotype, ToxCast, and transcriptomics data were collected from the ToxPrint Chemotyper, CompTox Dashboard, and GSE252004 respectively. To evaluate classification performance of individual- and integrative data, five machine learning algorithms were employed, and unsupervised analyses were employed to validate classification performance. Individual platforms showed poor performance (maximum accuracy ? 0.53). Integration of 44 selected features achieved perfect classification with high generalization (permutation mean ? 0.93). Further optimization identified 12 features: one structural feature (bond:COH_alcohol_pri-alkyl), two ToxCast assays (keratin 8/18, deiodinase-1), and nine pathways including NOD-like receptor signaling, endocytosis, mitochondrial ATP synthesis, and proteostasis. These features showed revealed toxicity-specific mechanisms: high-toxicity PFAS disrupted immunity and energetics; moderate-toxicity perturbed endocytic pathways; low-toxicity triggered adaptive and receptor-mediated program. We demonstrated that multi-platform integration efficiently classified developmental toxicity of PFAS and provided the corresponding potential biomarkers. This new approach could be applied to regulatory prioritization of data-poor PFAS and their mechanism-anchored grouping.

1.03.P-Tu036 High-Throughput C. elegans Toxicity Screening as a 3R-Aligned Whole-Organism Platform for Chemical Prioritisation

Scott Glaberman¹, Tobias Pamminer², Erik Andersen³ and Timothy Crombie⁴, (1) *University of Birmingham, United Kingdom*, (2) *Early Environmental Safety, Bayer AG, Monheim am Rhein, Germany*, (3) *Johns Hopkins University, United States*, (4) *Florida Institute of Technology*

High-throughput screening (HTS) using *Caenorhabditis elegans* represents a promising 3R-aligned whole-organism approach for early-tier chemical evaluation. Combining short life cycles, low cost, and exceptional genetic tractability, *C. elegans* allows rapid assessment of developmental, behavioural, and mechanistic endpoints that are challenging to capture in cell-based assays and impractical in vertebrate tests. This review synthesises current HTS platforms—including microfluidics, behavioural phenotyping, large-particle flow-based sorting, and image-based developmental assays—and evaluates their suitability for screening, prioritisation, and integration into modern New Approach Methodologies (NAMs).

Image-based HTS platforms exhibit the strongest cross-species concordance, showing close alignment with apical toxicity endpoints in fish and aquatic invertebrates. Behavioural HTS systems complement these assays by revealing neuroactive and sublethal effects at low doses, leveraging conserved neurotransmitter pathways and characterised neurodevelopment. We also highlight considerable intraspecific variation across wild *C. elegans* strains, demonstrating the importance of genetic diversity for capturing realistic ranges of chemical susceptibility and enhancing the generalizability of HTS results.

We outline the key technical and biological considerations required for broader adoption of nematode HTS, including feeding regimens, media effects, evaporation and absorption artefacts, and the need for dose-setting strategies that reliably capture full concentration-response curves. Persistent gaps—particularly limited overlap between nematode HTS and mammalian datasets—underscore the need for coordinated testing and development of shared chemical reference panels. When combined with the AOP framework, these comparative datasets will help clarify when nematode responses reflect conserved mechanisms relevant across taxa.

By integrating whole-organism biology with scalability and low animal-use burden, *C. elegans* HTS offers a compelling 3R-supportive alternative for chemical prioritisation and screening. We provide recommendations

for harmonisation, validation, and future investment to establish nematode-based HTS as a robust component of next-generation risk assessment.

1.03.P-Tu037 Enhancing Chemical Design with New Approach Methodologies: Evaluating Predictive Ecotoxicology Models for Structurally Similar Chemicals

Bianca Stadelmann¹, Natalia Karadimitriou¹, Lisa Annie Baumann², Antonia Praetorius¹ and Milo Leon de Baat¹, (1)Institute for Biodiversity and Ecosystem Dynamics (IBED), University of Amsterdam, Netherlands, (2)Vrije Universiteit, Netherlands,

The Safe and Sustainable by Design (SSbD) concept is a pre-market innovation approach aiming to minimise adverse human and environmental impacts from a chemical's inception in the design process. The integration of computational prediction models into design processes addresses the need to efficiently assess, compare and narrow down the number of candidate chemicals. A key challenge for the implementation of this is the need for reliable predictive models for chemical hazard indicators. This study evaluated the capabilities of existing in silico models for predicting the ecotoxicity of 17 selected structurally similar triazine compounds, including four known persistent, mobile, and toxic (PMT) chemicals. Acute toxicity data for *Daphnia magna* and *Danio rerio* (zebrafish) embryos were experimentally generated following OECD test guidelines 202 and 236. Quantitative Structure-Activity Relationship (QSAR) models from ECOSAR (US EPA EPISuite) and VEGA HUB modelling suites relevant to these endpoints were selected for analysis. Requiring only a chemical structure as input, QSAR models have high potential for efficient integration into chemical design processes. The performance of the models for structurally similar chemicals was evaluated by comparing the predicted effect concentrations with the experimental data, as well as ranking the toxicity of the chemicals based on experimental and in silico data. The study is currently being expanded to include additional computational models, such as machine learning approaches applying harmonised datasets. This will contribute to a broader, more comprehensive evaluation of available predictive models. Preliminary results from this study show variability in the predictive accuracy of the currently included models, indicating a need for their improvement before they can be effectively integrated into SSbD workflows. The conclusions of this study provide important guidance on which models can already be applied in chemical design contexts, contributing to the integration of new approach methodologies (NAMs) into early chemical design processes, supporting the development of safer chemicals.

1.03.P-Tu038 Advancing Fish-Specific Immunotoxicology through NAMs: Can Non-Immune Zebrafish Cell Lines Detect Drug-Induced Immunomodulation?

Gian Hobbs¹, Stewart Owen², Christer Hogstrand¹ and Luigi Margiotta-Casaluci¹, (1)King's College London, United Kingdom, (2)AstraZeneca, United Kingdom

Immunotoxicity is increasingly recognised as a regulatory priority in environmental risk assessment; however, assessing the effects of chemicals on the fish immune system remains heavily reliant on in vivo studies. Our previous in vivo work has shown that several immunomodulatory pharmaceuticals elicit comparable immune responses in fish and humans, demonstrating conserved mechanisms but also highlighting the need for scalable, animal-free approaches. Yet the absence of established fish immune cell lines restricts the development of higher-throughput immunotoxicology NAMs. Given the documented sensitivity of non-immune cell types to immune stimuli, we tested the hypothesis that the fibroblast-like zebrafish ZF4 line could detect drug-induced immunomodulatory activity and serve as a mechanistically informative platform for fish-specific NAMs.

Using TNF α as an anchor reference immunostimulant, we characterised early and late responses in ZF4 cells through IL-6 secretion assays, high-content cell-painting morphological profiling, and RNA-seq-based transcriptomic analysis. This data revealed rapid IL-6 release, distinct phenotypic fingerprints, non-monotonic morphological patterns, and time-resolved transcriptional changes, indicating that ZF4 cells can sense cytokine-mediated perturbations despite their non-immune origin. Building on this foundation, we expanded the approach to a broader panel of cytokines representing diverse inflammatory states, alongside a selected set of pharmaceuticals with known immunomodulatory activity in mammals.

In this presentation, we will discuss the ability of ZF4 cells to discriminate across cytokine- and drug-induced immune-relevant perturbations, and evaluate their potential application as a scalable, high-content NAM for fish immunotoxicology. By integrating cytokine benchmarks, drug-induced phenotypes, and multimodal readouts, this work provides a case study illustrating how non-immune fish cell lines could contribute to IATA-compatible assays and help reduce reliance on traditional in vivo immunotoxicity studies.

1.04 Bridging Science and Policy: The Role of Adverse Outcome Pathways in Research and Regulatory Practices to Support Next Generation Risk Assessment

1.04.T-01 Neural crest cell impairment as a conserved developmental target of retinoid signalling disruption: evidence from zebrafish

Audrey Phan¹, **Eva Bundinská**², **Elise Pesce**³, **Lisa Annie Baumann**⁴ and **Klára Hilscherová**², (1) *Masaryk University, France*, (2) *Masaryk University, Czech Republic*, (3) *VU University Amsterdam (VU), France*, (4) *VU University Amsterdam (VU), Amsterdam, Netherlands*

Retinoic acid (RA) signalling plays a conserved and fundamental role in vertebrate embryogenesis, and its disruption can lead to developmental toxicity with ecological and population-level implications. Although several AOPs addressing retinoid signalling have recently emerged, mechanistic links between receptor overactivation and defects in sensitive progenitor populations, i.e. neural crest cells (NCCs), remain underrepresented. NCCs are multipotent, migratory population essential for craniofacial, ocular, connective-tissue, cardiovascular and peripheral nervous system formation, placing them at the centre of developmental processes vulnerable to RA signalling disruption. Understanding NCC-specific impacts is critical for improving predictive assessment of chemicals interfering with RA signalling pathway. This study investigated (1) how NCC impairment contributes to RA-induced developmental defects and (2) identified early transcriptional biomarkers. Sox10:eGFP (NCC-marker) zebrafish were exposed from 3 hpf to ATRA (RAR agonist), BMS493 (RAR inverse agonist), UVI3003 (RXR antagonist), or diclazuril (RAR/TR antagonist), alone or in co-exposure. NCC migration pattern was assessed by time-lapse fluorescence microscopy (11-13 hpf), and NCC abundance by FACS isolation of sox10:eGFP⁺ cells at 19 hpf. Transcriptional responses were characterised via RNA-sequencing and Gene Set Enrichment Analysis. Craniofacial and ocular morphology was evaluated in 5 dpf wild-type larvae. RAR overactivation altered early NCC migration patterns and increased cell abundance. Affected pathways included cranial skeletal development, heart valve morphogenesis, connective-tissue organisation, epithelial tube formation, and forebrain regionalization. Co-exposure with BMS493 or diclazuril fully rescued transcriptional and cellular effects, enabling the identification of key NCC-related genes. Corresponding ATRA-induced morphological defect (craniofacial malformation, microphthalmia, retinal pigment epithelium thinning) were also rescued, directly linking RAR overactivation to NCC impairment and its downstream outcomes. Together, these findings establish NCCs as a central and conserved developmental target of retinoid signalling disruption. The resulting NCC-linked transcriptional signatures represent promising biomarker candidates and support the development of mechanistically anchored predictive assays for assessing chemicals that interfere with retinoid signalling.

1.04.T-02 From Theory to Practice: Employing EcR Agonism AOP for In Vitro Screening Assay

Rebeka Darmati¹, **Rama Krishnan**², **Samantha Hughes**¹, **Peter Kille**³, **Paul Carmichael**⁴, **Bruno Campos**⁴ and **Nico van den Brink**¹, (1) *Wageningen University and Research (WUR), Netherlands*, (2) *Cardiff University, Cardiff, United Kingdom*, (3) *Cardiff University, United Kingdom*, (4) *Unilever, United Kingdom*

Advances in molecular biology, in vitro assays, and computational modelling are transforming Environmental Risk Assessment (ERA) by providing mechanistic data that enhances our understanding of chemical effects across biological levels. Traditional ERA approaches have largely relied on in vivo studies assessing apical endpoints in a few representative species. A drawback is that such studies provide limited insight into underlying molecular mechanisms and the extrapolation of results to ecosystems is challenging. To address these limitations and align with evolving regulatory and ethical goals to reduce animal testing, New Approach Methodologies (NAMs) enable a more mechanistic understanding for next generation ERA. Integrating in vitro and in silico methods within Adverse Outcome Pathway (AOP) frameworks allows mechanistic data to be connected to higher level biological outcomes, supporting predictive and quantitative hazard assessments. To contribute to this shift, we have developed an in vitro assay based on the Ecdysone Receptor (EcR) Agonism AOP (AOP4) using *Drosophila melanogaster* embryonic (S2) cell line. Ecdysone is an insect hormone regulating development and metamorphosis. However, since EcRs are conserved and thus found in non target species such as pollinators, understanding receptor mediated responses is crucial for a robust hazard assessment. We characterise gene expression responses to the natural ligand for several early key events in AOP4 and to several synthetic EcR agonists for short term and continuous exposure scenarios. This confirmed the initial key events of AOP4 in a concentration and time dependent manner. Utilising molecular docking simulations, we explore how chemical structure influences EcR binding affinity and

activation dynamics, linking receptor level perturbations to transcriptional and functional responses. These mechanistic insights strengthen AOP development and inform model parameterisation for in vitro–in vivo and cross-species extrapolation. Together, we show how combining experimental and computational approaches advances the integration of molecular evidence into predictive ERA frameworks and the early screening of chemicals. Using this approach, it is possible to improve biological realism in predictive ecotoxicology in a mechanistic and ethically sustainable manner, ultimately improving precision and robustness of ERA.

1.04.T-03 Integrating point of departure and structural equation modelling to AOP development: A case study of diuron toxicity in microalgae

Li Xie¹, Walter Zobl¹, Mei He², You Song¹, Lei Tian² and Knut Erik Tollefsen¹, (1)Norwegian Institute for Water Research, Norway, (2)Yangtze University, China (Mainland)

Adverse Outcome Pathways (AOPs) and their quantitative extensions (qAOPs) provide structured frameworks to understand toxicological mechanisms, thereby supporting risk assessments. However, quantitative data for key event relationships (KERs) are often limited. This study used multiple points of departure (POD), including No Observed Effect Concentration (NOEC), Lowest Observed Effect Concentration (LOEC), Benchmark Dose (BMD) and half-maximal effective concentration (EC50), combined with structural equation modelling (SEM) to verify and quantify the causal relationships within AOP frameworks. The case study involved *Chlamydomonas reinhardtii* exposed to Diuron, analysis of dose-response data for PSII inhibition, photosynthesis, mitochondrial membrane potential (MMP), ATP content, and growth at different exposure durations. Most endpoints exhibited clear dose-response patterns, with sensitivity increasing over time. A conceptual AOP was developed based on the new experimental evidence and supporting literature. As expected, BMD-based PODs of molecular events (e.g., PSII inhibition) occurred at lower concentrations and earlier than downstream events such as MMP, ATP and growth. The SEM verified the proposed AOP and quantified the KER to support qAOP construction. Additionally, the SEM identified supplementary mechanisms, such as MMP disruption, contributing to growth inhibition. This work proposes a hybrid framework combining POD-based analysis and SEM to strengthen qAOP development.

1.04.T-04 Multi-level Analysis of effects in *D. leopardus* male tree frogs of Fukushima prefecture - Towards fueling the ‘repro-toxicity cAOP’ with wildlife responses.

Léa Dasque¹, Magali Floriani¹, Catherine Labbe², Clément Car¹, André Gilles³, Nathalie Mondy⁴, Daniel Orjollet¹, Virginie Camilleri¹, Isabelle Cavalié¹, Kenji Nanba⁵, Hiroko Ishiniwa⁵, Jean-Marc Bonzom¹, Olivier Arman¹ and Sandrine FRELON¹, (1)ASNR, France, (2)INRAE, Rennes, France, (3)INRAE Recover, France, (4)UCBL LEHNA, France, (5)IER, Japan

The growing release of persistent pollutants in the environment has increased the need to better assess effects on wildlife. To do so, Adverse Outcome Pathways (AOPs) aim to describe a sequence of causally linked events, called Key Events (KE), from the Molecular Initiating Event (MIE) to an Adverse Outcome (AO) at a relevant biological scale, usually population for the Ecological Risk Assessment (ERA). While most of AOP included in AOP-Wiki are based on model organisms, with much of the knowledge acquired at the individual or sub-individual level (a few extending to a population effect), it is nevertheless important to consolidate these patterns of adverse effects on wildlife remaining in a contaminated environment over several generations, and undergoing long-term chronic exposure.

While in 2022, a consensus AOP through six species attempted to highlight the main steps of radio-induced reprotoxicity from laboratory experiments, our study proposes to analyze the biological reproductive responses of male tree frogs during the breeding season, across a dose gradient in Fukushima. Three biological levels, i.e. molecular (RNAseq analysis), cellular (Transmission Electron Microscopy analysis) and individual (sperm parameters such as motility and sperm density) were analyzed on adult testis samples, in order to describe the current observable effects attributable to long-term exposure to radionuclides following the Fukushima accident, and draft a putative ‘radio-induced reprotoxicity’ AOP from in natura derived data.

The results observed in frogs from radio-contaminated areas underline key events already highlighted by the consensus AOP drafted in 2022. More specifically, DNA damage response, oxidative stress and sperm count decrease for males were correlated to the radiation dose. Importantly, these effects, were robust even by controlling for genetic lineage, considered as a confounding factor.

This study highlights that the application of multi-scale experiment on a wild species was able to detect ongoing functional changes on reproductive parameters of a wild species. This comprehensive study on tree-frogs from the Fukushima prefecture is particularly interesting as it enables to fuel a consensus AOP already established with different other taxa. If the results of our work remain correlative, they demonstrate that integration of

molecular analyses with functional assessments can be developed on wild species, increasing the ecological relevance of AOP.

1.04.T-05 Adverse Outcome Pathway Network-Based Approach for the Evaluation of Thyroid Hormone System Disruption for Human Health and Environmental Regulatory Hazard Assessment

Lucia Vergauwen¹, Sabrina Tait², Lola Bajard³, Natalia Bulawska⁴, Arno Gutleb⁵, Ellen Hessel⁶, Klara Hilscherova⁷, Henrik Holbech⁸, Dominika Kowalska⁴, Jiri Novak³, Nafsika Papaioannou⁹, Elisavet Renieri⁹, Alessandra Roncaglioni¹⁰, Dimosthenis Sarigiannis⁹, Anita Sosnowska⁴, Annick van den Brand⁶, Miriam Jacobs¹¹ and Dries Knapen¹, (1)University of Antwerp, Belgium, (2)Istituto Superiore di Sanità, Belgium, (3)Masaryk University, Czech Republic, (4)University of Gdańsk, Poland, (5)Luxembourg Institute of Science and Technology, Luxembourg, (6)National Institute for Public Health and the Environment (RIVM), Netherlands, (7)RECETOX, Masaryk University, Czech Republic, (8)University of Southern Denmark (SDU), Denmark, (9)Aristotle University of Thessaloniki (AUTH), Greece, (10)Istituto di Ricerche Farmacologiche Mario Negri IRCCS, Italy, (11)United Kingdom Health Security Agency (UKHSA), United Kingdom

Thyroid hormones (THs) regulate growth, development, and metabolism across vertebrates, making thyroid hormone system disruption (THSD) a critical concern for human and environmental health. Regulatory identification of endocrine disruptors (EDs), such as chemicals inducing THSD, requires evidence of adversity, endocrine activity, and a biologically plausible link, increasingly supported by adverse outcome pathways (AOPs). Over 50 THSD-related AOPs are available/under development (with 7 AOPs endorsed and published by the OECD), forming a cross-species AOP network that underpins mechanistic understanding and informs Integrated Approaches to Testing and Assessment (IATAs). The OECD Conceptual Framework (CF) guides ED assessment by structuring relevant methods into five Levels from *in silico* to *in vivo*. Important challenges remain in the availability and regulatory application of methods for THSD assessment. Notably, no validated *in vitro* assays are currently available at CF Level 2 for THSD mechanisms. In parallel, environmental ED assessment currently relies on amphibian testing, as fish assays capable of adequately addressing the thyroid (T) modality are still lacking at CF Levels 3-5.

In the framework of the European Partnership on the Assessment of Risks from Chemicals (PARC), we collected recent advances in an inventory of 108 methods relevant to THSD, including *in vivo* Test Guidelines, statistically validated *in silico* models, validation efforts for *in vitro* assays, and the validation of thyroid-sensitive endpoints as additions to existing OECD Test Guidelines using fish early-life stages. These efforts align with EU initiatives to phase out animal testing for chemical hazard assessment and implement Next Generation Risk Assessment (NGRA). We propose a modular AOP network-based IATA model integrating mechanistic and effect-level information across CF Levels to support regulatory hazard assessment for both human and environmental health under a One Health framework. In a case study on resorcinol, we demonstrate how emerging methods complement traditional data to strengthen weight-of-evidence for ED classification. By mapping gaps and priorities, this work advances the integration of New Approach Methodologies (NAMs) into chemical safety assessment, supporting a future update of OECD Guidance Document 150 and EU legislative goals for sustainable, NAM-based testing strategies.

1.04.P Bridging Science and Policy: The Role of Adverse Outcome Pathways in Research and Regulatory Practices to Support Next Generation Risk Assessment

1.04.P-Tu039 Mapping Disease-Linked AOPs to Inform Bioassay Selection for Chemical Hazard Assessment

Sarah Stevens¹, Jane Muncke² and Beate Escher¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Food Packaging Forum, Switzerland

Modern societies produce and use thousands of chemicals but most lack appropriate hazard assessment, and likely contribute to the global burden of noncommunicable diseases. Current regulatory toxicity testing is slow, resource-intensive and relies on animal studies focused on apical endpoints. New Approach Methods (NAMs)

offer faster, mechanistically informative, and animal-free testing strategies. However, a systematic selection of biologically relevant endpoints that comprehensively reflects human disease pathways affected by chemical exposures remains a key gap to be filled. Here, we leveraged Adverse Outcome Pathways (AOPs) to identify critical molecular and cellular key events across the six clusters of disease framework – encompassing major noncommunicable diseases linked to chemical exposure. We extracted information from 487 AOPs (AOPwiki, v2024-10-01) and applied filtering criteria, resulting in 284 AOPs manually mapped to the disease clusters. AOP networks for each cluster were constructed, and degree centrality was calculated to assess key events importance within disease networks. The 284 AOPs mapped to one (76%), two (20%), or more (4%) disease clusters, with networks containing 24–90 AOPs. The three most frequently occurring molecular and cellular key events across all clusters were: cytotoxicity (6/6 clusters), oxidative stress (6/6 clusters), and mitochondrial dysfunction (4/6 clusters). These effects are involved in multiple biological pathways and align with oxidative stress being identified as an "umbrella" key characteristic of toxicants. Receptor-mediated key events also showed high connectivity, with aryl hydrocarbon and estrogen receptor appearing in multiple cluster, confirming the importance of receptor-mediated effects and endocrine signalling as toxicants' key characteristics. Other highly connected key events were cluster-specific, such as triglyceride accumulation in metabolic diseases, hence can be informative for detection of specific effects. Building on this analysis, high-throughput cell-based assays covering critical endpoints can be selected, integrating the key characteristics of toxicants framework to ensure coverage beyond current AOP limitations. A panel of 10–15 multiplexed assays meeting criteria for simplicity, robustness, and high throughput could enable efficient screening of single chemicals or their mixtures. Future work will validate this approach by testing diverse chemicals in a selected bioassay panel.

We acknowledge funding by the Initiative and Network Fund of the Helmholtz Association, project “Co-Creation process for the modernization of chemical hazard indicators – CoModHaz” KA-TCP-20.

1.04.P-Tu040 Revealing sublethal effects of *Protoceratium reticulatum* on mussels (*Mytilus edulis*) by adverse outcome pathway (AOP) network approaches

Wenxin Liu¹, Ilias Semmouri¹, Filip Van Nieuwerburgh¹, Colin Janssen¹, Pu Xia² and Jana Asselman³,
(1)Ghent University, Belgium, (2)University of Birmingham, United Kingdom, (3)Blue Growth Research Lab (BGRL), Ghent University, Belgium

Harmful algal blooms (HABs) are being reported with increasing frequency worldwide. The bloom-forming dinoflagellate *Protoceratium reticulatum* is a major producer of yessotoxins (YTXs), which have been detected in shellfish globally, yet their toxicity to both shellfish and humans remains insufficiently understood. *Mytilus edulis* plays a key role in marine ecosystems which contributes to marine biodiversity, water quality, and energy flow. Its ecological importance makes it a valuable bioindicator for assessing environmental changes and coastal ecosystem health. Moreover, as a widely consumed seafood species, *M. edulis* represents a direct exposure pathway for marine toxins to enter the human food chain. In this study, we investigated the effects of *P. reticulatum* on *M. edulis* under environmentally relevant bloom conditions. Adult mussels were exposed for six days to diets containing 0% (control), 10%, 50% and 100% *P. reticulatum* supplemented with the non-toxic algae *Tisochrysis lutea* based on carbon-equivalent contents. Transcriptomic analysis revealed that *M. edulis* were significantly affected on gene level. At the individual level, the ingestion rate, O₂ consumption and NH₄⁺ production rate were significantly reduced both for gene-level and pathway level. Benchmark doses (BMDs) were derived at both the gene and pathway levels and integrated with adverse outcome pathway (AOP) networks. Overall, our findings demonstrate that short-term exposure to bloom-level *P. reticulatum* can affect mussel physiological and molecular responses, providing new insights for ecological risk assessment of harmful algal blooms.

1.04.P-Tu041 Early Warning of Aquatic Ecological Risks for Trifluoromethanesulfonimide: Oxidative Stress - Driven Adverse Outcome Pathways and Toxicity Thresholds

Jinlin Jiang¹, Hao Zhang² and Tao Long¹, (1)Nanjing Institute of Environmental Sciences, Ministry of Ecology and Environment, China (Mainland), (2)Hohai University, China (Mainland)

The latent ecotoxicological effects of emerging contaminants (ECs) necessitate the development of early warning systems. Trifluoromethanesulfonimide (TFSI), a lithium battery electrolyte additive, has been recognized as a contaminant of emerging concern. This study established a “mechanism prediction - biological validation - threshold derivation - risk assessment” framework to enable ecological risks early warning for TFSI,

with extensibility to ECs. Network toxicology predicted NFKB1 and PTGS2 as key targets of TFSI, with psoriatic arthritis (PsA) identified as a TFSI-associated disease. By reverse translation of PsA pathogenesis, we predicted adverse outcome pathways (AOPs) of TFSI based on the AOP-Wiki network and screened biomarkers for validation. Cross-species validation in zebrafish models demonstrated dysregulated expression of GCH1/NFKB1/IL34 concomitantly driving dose-dependent oxidative damage and biphasic behavioral alterations, biochemical analysis identified the brain as the target organ. A novel Hormesis model was constructed, which revealed that after correction, EC10 and EC50 resulted in reductions of 90.59 % and 91.37 %, respectively, compared to the traditional model. The combined threshold EC10 overall was derived as 1154.48 ng/L. Risk assessments revealed potential aquatic ecological risks in multiple regions worldwide, a conclusion further supported by risk probabilities quantified through the quantitative adverse outcome pathway (qAOP) model. This work comprehensively uncovered the latent ecotoxicological effects of TFSI, offering theoretical substantiation for addressing regulatory gaps spanning from its initial environmental release to risk manifestation.

1.04.P-Tu042 AI-Assisted Development of a Comprehensive Adverse Outcome Pathway Network for Oxidative Stress

You Song, Li Xie, Knut Erik Tollefsen and Walter Zobl, Norwegian Institute for Water Research, Norway

Oxidative stress is a central mechanism in (eco)toxicology, linking reactive oxygen species (ROS) formation to cellular dysfunction and adverse organism-level outcomes. Despite its importance, existing Adverse Outcome Pathways (AOPs) capture only parts of this biology, limiting their use for mechanistic assessment, chemical grouping, and interpreting new approach methodology (NAM) data. This work aimed to develop a comprehensive, mechanistically coherent AOP network (AOPN) for oxidative stress-mediated chronic toxicity using a hybrid AI-human workflow that accelerates evidence gathering, integration, and evaluation. An iterative process combined expert oversight with multiple AI tools, including AOP-helpFinder, ChatGPT, and S2CIE. Work began with assembling a conceptual AOPN linking excessive ROS production to reduced growth. AI tools supported initial assessments of biological plausibility and helped refine or harmonize key events (KEs) with those in the AOP-Wiki. A KE-derived search-term library enabled AI-assisted retrieval of relevant literature and mechanistic data from in vitro high-throughput screening resources such as ToxCast. Because searches still produced large literature sets, a second-stage screening of abstracts used AI ranking complemented by expert review. Evidence was evaluated across taxa, including fish, humans, invertebrates, and primary producers. Criteria for the stressor domain were applied flexibly due to limited overlap in stressors across the network. Collected evidence was assessed for biological plausibility, empirical support, and essentiality through a structured weight-of-evidence evaluation performed by human experts. The hybrid workflow increased the speed, consistency, and transparency of AOPN development. AI tools efficiently retrieved mechanistic studies spanning redox biology, mitochondrial energetics, and genotoxicity, while experts resolved inconsistencies, confirmed causal directionality, and ensured alignment with OECD AOP development principles. The resulting oxidative stress AOPN integrates 15 KEs and multiple converging pathways, capturing major processes such as lipid peroxidation, protein oxidation, oxidative DNA damage, and mitochondrial uncoupling. The network reflects established oxidative stress biology as well as under-represented linkages revealed through AI-assisted exploration, providing an expanded mechanistic framework to support regulatory application.

1.04.P-Tu043 Practical Strategies for Translational Modelling-Enabled qAOP Development Using Existing Scientific Evidence

You Song¹, Henrieta Hlisnikova², Deepika Deepika³, Anna Beronius⁴, Vikas Kumar³, Johanna Zilliacus⁴ and Jannicke Moe¹, (1)Norwegian Institute for Water Research, Norway, (2)Institute of Environmental Medicine, Karolinska Institutet, Sweden, (3)Institut d'Investigació Sanitària Pere Virgili (IISPV), Spain, (4)Institute of Environmental Medicine, Karolinska Institutet, Sweden

Quantitative Adverse Outcome Pathways (qAOPs) offer a mechanistic and structured approach for predicting regulatory-relevant adverse effects from molecular and cellular perturbations measured using new approach methodologies (NAMs). A major barrier to developing qAOPs is the limited availability of complete in vivo datasets needed to parameterise quantitative relationships. When such data are incomplete, translating in vitro responses into in vivo key events or adverse outcomes becomes essential and requires robust translational

modelling. This work presents practical strategies and a stepwise workflow for qAOP development that leverages existing scientific evidence rather than relying solely on new experimental studies. The workflow was developed within the EU MERLON project, which aims to enhance quantitative AOP frameworks, support endocrine disruptor assessment and increase the use of human-relevant NAMs. The workflow integrates three core components: (i) systematic data mining and evidence extraction from peer-reviewed literature and in vitro high-throughput screening databases, covering dose-response and time-course data across human and murine systems; (ii) translational modelling using physiologically based toxicokinetic (PBTK)-enabled quantitative in vitro-to-in vivo extrapolation (qIVIVE) to translate in vitro bioactivity into internal concentrations relevant for in vivo key events; and (iii) probabilistic modelling using Bayesian Networks (BN) to represent quantitative key event relationships (qKERs), support qAOP network construction and propagate uncertainties transparently. Initial application shows that, although extensive evidence exists across biological and chemical domains, the information is fragmented, heterogeneous and requires careful evaluation before use in quantitative modelling. Nevertheless, several qualified datasets were identified and used to construct preliminary qKERs. A critical need for dose translation of high-throughput screening data was also identified and will be addressed through targeted qIVIVE for selected prototype chemicals. Overall, this work illustrates practical strategies for making best use of existing scientific evidence in qAOP development. The workflow provides a transparent path for integrating disparate data sources, enabling translational modelling and supporting future quantitative AOP development to advance mechanistically informed risk assessment of endocrine disruptors.

1.04.P-Tu044 Molting inhibition in *Calanus finmarchicus* after exposure to the chitin synthesis inhibitor teflubenzuron

Celine Våga¹, Bjørn Henrik Hansen², Li Xie³, Dag Altin⁴ and Knut Erik Tollefsen³, (1)Norwegian University of Life Sciences, Norway, (2)SINTEF, Norway, (3)Norwegian Institute for Water Research, Norway, (4)BioTrix, Norway

Chitin synthesis inhibitor teflubenzuron, are widely used in marine aquaculture to control parasitic salmon lice. However, these compounds may also harm non-target species like *Calanus finmarchicus*, a keystone copepod in Arctic and boreal ecosystems. With growing environmental stress from climate change and pollution, it is critical to understand the mechanisms behind such impacts to improve ecological risk assessments.

This study explored the effects of teflubenzuron on *C. finmarchicus*, using Adverse Outcome Pathway (AOP) 360, “Inhibition of chitin synthase 1 leading to increased mortality,” as a knowledge organizing framework. Over a seven-day exposure, we assessed mortality, development, morphology, and gene expression linked to molting processes in the copepod.

Teflubenzuron exposure at 0.012 µg/L caused significant mortality, disrupted development, and led to visible deformities. It also altered the expression of genes involved in molting and chitin metabolism. However, no significant changes in *chs1* gene expression were detected at concentrations between 0.001 and 0.012 µg/L. Thus, we could not directly link *chs1* inhibition to the observed effects as described in AOP 360. Further studies are needed to clarify the molecular mechanisms related to teflubenzuron toxicity and validate AOP 360's relevance for *C. finmarchicus*.

We thank the EMBRC-ERIC Laboratory for Low Level Trophic Interactions at NTNU SeaLab for access to the *Calanus finmarchicus* culture.

1.05 Crawling Through Challenges: Emerging Trends in Ecotoxicology for Amphibians and Reptiles

1.05.T-01 Bufadienolide Toxins in Common Toad Skin and Their Link to Population Status

Sarah Devliegere, Siegrid De Baere, Ellen Blomme, Andrea Barbi, Dries Bonte, An Martel, Frank Pasmans and Siska Croubels, Ghent University, Belgium

The European common toad (*Bufo bufo*) is facing gradual population declines likely driven by multiple stressors. As a chemical defence against predators and pathogens, the common toad produces toxins called bufadienolides. Increased toxin production can be considered as a general stress response, as relative toxin

levels were previously found to be increased in populations exposed to anthropogenic stressors, such as environmental contaminants. However, these levels were only assessed in a semi-quantitative way. Therefore, we aimed to develop an analytical method for the quantitative determination of 5 major bufadienolide toxins in the skin of road-killed toads, in order to link population status to differences in toxin levels between populations. A suitable analysis method was developed and validated to quantify 5 bufadienolide compounds in toad skin samples of both non-declining (n=10) and declining populations (n=10) in Flanders (Belgium). As declining populations are assumed to be exposed to severe stressors, we expected to find a correlation between increased toxin levels and population decline. The sampling of road-killed toads was carried out during spring migration (February-March 2024 and 2025) as an alternative to sacrificing live animals from populations which are already facing a decline in abundance. Dorsal skin samples (1-2 g wet weight) were freeze-dried and homogenized using a bead mill. Subsamples (20 mg dry weight) were analysed using a solid-liquid extraction procedure and Ultra High Performance Liquid Chromatography-Tandem Mass Spectrometry (UHPLC-MS/MS). A preliminary data analysis of a subset of samples (n=300) indicates that concentrations are slightly, although not significantly, higher in declining populations. Increasing sample size (n=700) will provide a more accurate and representative estimate of the populations and allow for more robust statistical analysis. Differences in toxins concentrations will be linked to population status using generalized linear mixed effects models. Furthermore, we will explore inherent variability due to age, body size and sex, as well as patterns in toxins composition linked to geographical distribution of the populations. The association of bufadienolide toxin levels and population status indicates that toxin levels could potentially be used to identify declining populations. This will aid in prioritizing urgent conservation actions to conserve an ecologically valuable amphibian species.

1.05.T-02 Preliminary Overview of the Direct and Indirect Effects of Chemical Contamination on Amphibians in the Interface Between Water and Land in Agricultural Landscapes

Manuel Ortiz Santaliestra¹, Araceli Gort Esteve² and Ana Maria Lemos-Marques³, (1)Institute for Game & Wildlife Research - Spanish National Research Council (IREC - CSIC), Ciudad Real, Spain, (2)Institute for Game & Wildlife Research - Spanish National Research Council (IREC - CSIC), Spain, (3)University of Castilla-La Mancha (UCLM), Spain

Amphibians are the most threatened vertebrate group, one that is uniquely sensitive to the threat posed by chemical contamination, currently one of the main drivers behind the loss of biodiversity. Contributing to this group's vulnerability to chemical contaminants are not only amphibian's particular characteristics, but also the lack of regulation to adequately protect them. Current regulatory efforts are inefficient mainly due to being supported by limited and fragmented Environmental Risk Assessments (ERAs), which is especially alarming in the context of pesticide use in agricultural landscapes for the amphibian species that depend on this habitat. The current ERA framework severely neglects amphibians, not only by not acknowledging them as an individual vertebrate group, but also by contemplating the aquatic and the terrestrial environments in separate assessments, which overlooks the reality of these animals' life cycle, notorious for its flow between both compartments. Furthermore, different chemicals each have their own separate ERA, which also fails to take into account that, in real-life conditions, amphibians can be exposed to varying chemical mixtures by multiple exposure routes. The present work aims to shed light on the risks posed by the flow of pesticides from agricultural lands in central Spain to nearby ponds, for the amphibian populations developing in these ponds; and clarify the role of amphibians as mediators of the return of contaminant's undesirable effects from the aquatic to the terrestrial compartment. After one season (of two) of surveying and sampling food availability, diet composition, susceptibility to diseases, body condition and reproductive output populations of *Hyla molleri*, *Pelobates cultripes* and *Pleurodeles waltl* in eight field ponds, located in the watershed of neighbouring cultivated fields, this study sheds a much-needed light on the general fitness of these animals in the wild. At the same time, it highlights the potential that the conservation of amphibians has, to serve as a tool to break the regulatory silos currently dominating the elaboration of ERAs. Funded by the Horizon Europe project SYBERAC (ref 101135213).

1.05.T-03 Amphibian Body Burden Dynamics: A Refined Mechanistic Model for Dermal Pesticide Uptake from Soil

Valentin Mingo¹, Klaus Hammel², Elena Adams³, Lucas Garcia⁴, Joachim Ulrich Kleinmann⁴, Marina Lauck⁵, Thomas G. Preuss², Chunming Sui⁶, Lennart Weltje⁷, Arnd Weyers² and David Heckmann⁸, (1)Corteva Agriscience, Germany, (2)Bayer Research & Development Services LLC, Germany, (3)Bayer AG CropScience, Germany, (4)BASF, Germany, (5)Corteva Agriscience, (6)BASGlobal Agricultural Solutions, BASF, Germany, (7)Agricultural Solutions - Ecotoxicology, BASF, Germany, (8)Bayer CropScience AG, Germany

Amphibians may be exposed to pesticides in terrestrial scenarios, but at the same time additional animal testing for use in environmental risk assessment (ERA) is discouraged, especially in the context of next generation risk assessment (NGRA). New Approach Methodologies (NAMs) like data-driven in silico approaches can be used to fill this gap. In their terrestrial life stages, the permeable skin of amphibians and their close contact with treated soils suggest that dermal absorption may be a relevant exposure route. Building on the model by Mingo et al. (2024), we present a refined mechanistic toxicokinetic (TK) model that simulates dermal pesticide uptake from soil into amphibians, aiming to provide robust internal concentration estimates and support ERA strategies that do not require additional in vivo testing.

The presented model advances the original one-compartment framework by introducing a two-compartment system that explicitly couples soil and amphibian compartments in a modular approach. It simultaneously integrates key processes such as diffusive and advective uptake, metabolism, excretion, and soil degradation, thereby enabling a dynamic mass balance and more realistic exposure scenarios. For example, body burdens for animals moving in a landscape can now be predicted.

Model validation against empirical data from 815 anurans exposed to 13 pesticides demonstrated robust predictive performance, with 79.8% of predictions conservatively overestimating measured internal concentrations. Sensitivity analyses identified key parameters influencing model output, and scenario simulations illustrated the impact of ecological behavior (e.g., movement patterns) and soil dissipation processes on internal body burdens.

This work advances the mechanistic understanding of dermal pesticide uptake in amphibians, thereby improving future screening approaches and ERA. The refined model offers a transparent and adaptable tool to evaluate amphibian exposure under realistic field conditions, enabling ERA efforts while minimizing the reliance on new animal testing.

1.05.T-04 Impact of multiple stressors on amphibian population dynamics – insights from spatially explicit population modelling

Joachim Ulrich Kleinmann¹, Chiara Accolla², Amelie Schmolke³, Lennart Weltje⁴ and Pernille Thorbek⁵, (1)BASF, Germany, (2)Waterborne Environmental Inc., (3)RIFCON GmbH, Germany, (4)Agricultural Solutions - Ecotoxicology, BASF, Germany, (5)BASF, United Kingdom

Amphibians are widely recognized as a vulnerable vertebrate group, yet the drivers of their population declines are complex and multifactorial. While plant protection products (PPPs) often receive considerable attention in ecological risk assessments, other stressors—such as habitat fragmentation, disease, climate variability, and roadkill—can exert equal or greater influence on population viability.

To address these interactions, we developed a spatially explicit, individual-based population model for the common toad (*Bufo bufo*). The model can be applied to address multiple stressors because it integrates ecological and toxicological data, simulates both aquatic and terrestrial life stages, and explicitly represents movement across heterogeneous landscapes. Individuals progress through realistic life phases—from eggs to tadpoles, metamorphosis, juvenile stages, and adulthood—while moving between breeding ponds, summer habitats, and overwintering sites. This structure enables scenario-based evaluations of how landscape configuration and multiple stressors (e.g. traffic) jointly shape population dynamics. Initial simulations demonstrate that landscape structure strongly influences habitat use and spatial distribution. When breeding ponds are surrounded by agricultural areas, individuals disperse widely, whereas proximity to natural habitats promotes concentrated occurrence near ponds. These patterns are likely to affect exposure potential, roadkill and ultimately population dynamics. Simulations showed that a disconnection of the summer habitat and the breeding pond resulted in considerably higher roadkill probability.

Our modeling approach provides a robust framework for assessing cumulative effects of stressors such as PPP exposure, habitat change, and traffic. By capturing spatial heterogeneity and life-history processes, it supports more ecologically realistic risk assessments and informs targeted conservation and management strategies.

1.05.T-05 From Fish to Frogs: Leveraging Fish Toxicity Data to Predict Chronic Pesticide Effects on Aquatic Amphibian Life Stages

Elena Adams¹, Eric Bruns¹, Lennart Weltje², Katherine K. Coady³, Julie Brodeur⁴ and Dominic Englert¹, (1)Bayer AG CropScience, Germany, (2)Agricultural Solutions - Ecotoxicology, BASF, Germany, (3)Bayer AG CropScience, (4)National Scientific and Technical Research Council (CONICET), Canada

Numerous studies have shown that acute fish toxicity data can predict acute toxicity of pesticides to larval aquatic life stages of amphibians. However, chronic toxicity comparisons have been limited due to insufficient amphibian data. With an expanded database, we compared the chronic sensitivity of aquatic amphibian life stages and fish using apical endpoints from amphibian metamorphosis assays (AMAs) and fish Early Life Stage (ELS) tests for 90 pesticides. Through this comparative analysis, we aimed to derive an interspecies correlation model to predict chronic sensitivity in larval aquatic amphibian life stages based on established fish ELS endpoints.

Apical endpoint data (No Observed Effect Concentrations; NOECs for survival, body weight, and length) were extracted from publicly available registration documents or, in a few cases, from unpublished study reports. Statistical correlations between NOECs (and in addition, between Maximum Acceptable Toxicant Concentrations, MATC) were assessed using Pearson's correlation coefficient. Additionally, AMA responses were compared to their respective counterparts in the ELS test using paired t-tests. For substances where the AMA-NOEC was not directly covered by the respective ELS-NOEC, a stepwise approach was employed to contextualize the results within the EU aquatic risk assessment framework. Using multiple linear regression, we derived an interspecies extrapolation model to predict a chronic surrogate endpoint for larval aquatic amphibian life stages.

Notably, 741% of ELS endpoints were unbound, while 775% of AMA-NOECs were unbound, highlighting the variability in chronic toxicity data. Although the AMA's design limits its use for deriving quantitative NOECs, results indicate that the AMA was equally or more sensitive than the ELS test for most pesticides, with significant correlations observed between the endpoints of both systems. After contextualizing the results within the EU risk assessment framework, the chronic sensitivity of amphibians could be covered for 99% (89/90) of the investigated substances.

The derived interspecies correlation model demonstrated that for 72% of the pesticides, the predicted endpoints were either over-protective or within a factor of three of the observed values, suggesting a reasonable alignment with actual toxicity data. Further validation, considering other pesticides and amphibian species (e.g. from literature data) is planned.

1.05.P Crawling Through Challenges: Emerging Trends in Ecotoxicology for Amphibians and Reptiles

1.05.P-We005 Development of minimally invasive protocols for biomarker detection in amphibians using saliva samples – from laboratory to field application

Loïc Cattin¹, Laurent Boualit², Brigitte Guillet³ and Nathalie Chèvre², (1)IDYST, Faculty of Geosciences and Environment, University of Lausanne, 1015 Lausanne, Switzerland, (2)IDYST, Faculty of Geosciences and Environment, University of Lausanne, Switzerland, (3)Former affiliation : Centre de Ressources Biologiques Xenopes, Université de Rennes, France

Global biodiversity is declining, with amphibians being the most threatened group of vertebrates. Among the key drivers of this decline is exposure to anthropogenic contaminants such as pesticides, heavy metals, fertilizers and pharmaceuticals. Biochemical biomarkers are valuable tools for detecting such exposure and assessing sublethal stresses in both lab and field settings. To measure biomarkers, traditional methods require exposing living organisms to pollutants and rely on invasive sampling—typically resulting in the death of the test subjects. However, in recent years, particular attention has been paid to the 3Rs principle, which aims to replace, reduce and refine animal use in science. In this context, the development of alternative methods to measure biomarkers is essential. As an example, recent studies have successfully explored saliva sampling as a minimally invasive approach for biomarker detection in reptiles. Building on this approach, the present study explores the potential of using saliva as a matrix for biomarker analysis in amphibians under both laboratory and field conditions.

Laboratory work was conducted on African clawed frog (*Xenopus laevis*) and field work was conducted on Swiss populations of alpine newt (*Ichthyosaura alpestris*). Protocols were developed to test three enzymatic biomarkers: EROD, GST and AChE. Liver samples from *Xenopus laevis* were also analysed to compare detection rate with saliva, as this organ is a standard tissue in ecotoxicological assessments. All three biomarkers were detected in liver samples, whereas only EROD and GST could be detected in saliva samples for both

species. The detection rate of EROD and GST was above 90% in *Xenopus laevis* for both saliva and liver samples, whereas it reached considerably lower levels in saliva samples from *Ichthyosaura alpestris*. This pilot study proposes two new minimally invasive protocols to measure EROD and GST activity in amphibians using buccal swabs, contributing to more ethical and sustainable approaches in ecotoxicology. It also highlights the challenge of applying laboratory-developed protocols to field samples.

1.05.P-We006 High-Content Imaging in Amphibian Cell Lines: A Novel In Vitro Platform for Chemical Hazard Characterization

Luisa Reger and Jo Nyffeler, *Research Unit Chemicals in the Environment, Helmholtz Centre for Environmental Research - UFZ, Germany*

Amphibians represent the most threatened vertebrate group globally, with chemical pollution recognized as a major contributor to their decline. Yet, despite their high sensitivity, amphibian-specific New Approach Methods for chemical screening are largely lacking. Image-based in vitro assays, such as Cell Painting (CP), are increasingly applied in chemical safety assessment because they detect morphological perturbations across multiple subcellular compartments, enabling the characterization of subtle cellular responses beyond overt cytotoxicity. However, the ecological relevance of such assays is currently limited by the absence of test systems for taxa that are disproportionately affected by environmental contaminants.

Here, we present what is, to our knowledge, the first implementation of the CP assay in two amphibian cell lines, establishing a foundation for expanding high-content imaging to more ecologically relevant taxa. We optimized the assay in two *Xenopus laevis* - derived cell models: carcass fibroblasts (XTC-2) and epithelial kidney cells (A6 CCL) using a 384-well format to enable high-throughput screening. Both lines were exposed for 24 h to a 12-point concentration range of 24 well-characterized CP reference compounds, as well as a set of chemicals with documented in vivo toxicity across diverse amphibian species. Multiplexed staining captured nuclear, RNA, endoplasmic reticulum, Golgi, and cytoskeletal compartments, generating high-dimensional phenotypic profiles. The reference compounds enabled the identification of distinct compound-specific phenotypic signatures.

To evaluate interspecies differences, the same chemical set was profiled in the human A549 lung carcinoma cell line. Potency estimates were comparable between amphibian and human cells for a substantial fraction of active compounds; however, several chemicals - including cytarabine, rapamycin, actinomycin D, and docetaxel - exhibited more than an order-of-magnitude difference in activity across species.

Collectively, these results demonstrate the feasibility of CP in amphibian cell systems and introduce the first amphibian-origin in vitro assay capable of high-throughput screening of chemicals. This work advances the development of ecologically relevant mechanistic test systems and increases the translational value of high-content imaging for environmental risk assessment.

1.05.P-We008 Developmental, Physiological and Metabolic Impacts of Sublethal Delorazepam Exposure in *Xenopus laevis* Tadpoles

Carla Quintaneiro¹, Sara Costa¹, Chiara Fogliano², Chiara Motta², Rosa Carotenuto², Bice Avallone² and Isabel Lopes¹, (1)CESAM, University of Aveiro, Portugal, (2)Department of Biology, University of Naples Federico II, 80126, Naples, Italy, Italy

Benzodiazepines, psychotropic drugs, have become a significant group of pharmaceutical pollutants. Their widespread use for anxiety and depression, increasing during the COVID-19 pandemic, has resulted in greater environmental discharge. Wastewater treatment plants cannot entirely remove these compounds, leading to their frequent detection in surface waters. Although developed for human therapeutic purposes, their interaction with conserved GABAergic pathways raises concerns for non-target aquatic vertebrates. Delorazepam (DLZ), a long-acting benzodiazepine, remains ecotoxicologically poorly understood. This study examined the sublethal effects of environmentally relevant DLZ concentrations on early developmental stages of the non-target amphibian *Xenopus laevis*. Tadpoles at Nieuwkoop-Faber stage 46 were exposed for 72 hours to 0.01, 0.1, 1, and 10 mg/L DLZ. Endpoints included mortality, feeding rate, swimming behaviour, growth (body length and weight), heart rate, energy reserves (proteins, lipids, glycogen), and biochemical markers linked to neurotoxicity (acetylcholinesterase, ChE), detoxification (glutathione peroxidase, GST), oxidative stress (catalase, CAT; lipid peroxidation, LPO), and energy production (lactate dehydrogenase, LDH; electron transport system activity, ETS). Exposure to 10 mg/L DLZ caused 85% mortality. At lower concentrations, physiological and biochemical parameters showed dose-dependent changes, but overall survival was not significantly affected. Heart rate and weight remained stable despite reduced feeding rate. Energetic reserves were depleted at 1 mg/L, indicating increased metabolic costs; this is supported by elevated ETS and LDH activities, reflecting enhanced aerobic and anaerobic energy production. Increased antioxidant and detoxification enzyme activities suggest activation

of cellular defence mechanisms. Regarding behaviour, DLZ altered swimming activity: total distance travelled increased while time spent swimming decreased, resulting in higher speed. This may be related to increased ChE activity, which indicates neurotoxicity, although the changes were not statistically significant. The results indicate that DLZ affects various biological processes in *X. laevis*, including behaviour, energy metabolism, and redox balance, even at low concentrations. These findings emphasise the ecological dangers that benzodiazepines present to amphibians and underscore the necessity for better pharmaceutical wastewater management.

1.05.P-We009 Benchmarking Bio-Based DGEVA Versus DGEBA: Developmental and Behavioral Toxicity in Amphibian Larvae

Sara Costa¹, Cátia Venâncio¹, Ana Lopes¹, Rafaela Maria Tavares Reis¹, Laura Carvalho¹, Camille Chatard², Samuel Malburet² and Isabel Lopes¹, (1)CESAM, University of Aveiro, Portugal, (2)Specific Polymers, France

Epoxy resins are widely used in coatings, adhesives, and composites worldwide, with bisphenol A diglycidyl ether (DGEBA) being one of the most commonly used precursors. However, concerns regarding bisphenol A (BPA) derivatives, including environmental persistence and endocrine disruption, have led to the search for bio-based alternatives. Diglycidyl ether of vanillyl alcohol (DGEVA) is a promising candidate derived from lignin-based monomers; however, its ecotoxicological effects remain poorly characterized. Diglycidyl ether of vanillyl alcohol (DGEVA), derived from lignin-based monomers, is a promising candidate, but its ecotoxicological effects remain poorly characterized.

In this context, the present work aimed at a comparative assessment of the toxicity of the commercially available DGEBA and the bio-based monomer DGEVA in *Xenopus laevis* tadpoles, to evaluate the potential of bio-based resins as safer alternative. Tadpoles were exposed to a range of nominal concentrations (0.79 to 100 mg/L, with a dilution factor of 2,) of each compound. Assays were carried out for 72 h, at 23 ± 1 °C in the dark with continuous aeration. Mortality, body weight, growth rate, and feeding activity were measured as key developmental and behavioral endpoints.

The results indicated that DGEBA caused higher mortality than DGEVA; the former compound induced 100% mortality, after 24 h of exposure, at concentrations of 100 and 50 mg/L. The LC50 and LC20 values were for 10.4 and 6.7 mg/L DGEBA and for 29.9 and 17.7 mg/L DGEVA, respectively. No significant differences were found in weight, despite the reduced feeding rate at the lowest concentrations (0.78 mg/L in DGEBA and 0.78 and 1.56 mg/L in DGEVA). Relatively to morphometry, tadpoles showed no significant differences relative to the control, except for a significant increase in total length and body width at 0.78 mg/L in DGEBA, and an increase of total and tail lengths at 25 mg/L of DGEVA.

Overall, these findings contribute to understanding the potential trade-offs of substituting conventional petroleum-based epoxies with bio-based analogs.

1.05.P-We010 Effects of dermal exposure to pesticides on skin structure and function of amphibian terrestrial stages

Samuel González-López¹, Nuria Serrano¹, Daniele Marini², Sara Costa³, Isabel Lopes³ and Manuel Ortiz Santaliesra⁴, (1)IREC (UCLM-CSIC-JCCM), Spain, (2)Università degli Studi di Perugia, Italy, (3)CESAM, University of Aveiro, Portugal, (4)Institute for Game & Wildlife Research - Spanish National Research Council (IREC - CSIC), Ciudad Real, Spain

Amphibians are especially susceptible to dermal exposure to plant protection products (PPP) because they lack tegumentary protective that limit the uptake of these substances. Amphibian skin plays diverse physiological functions, so the direct contact of PPP with it may not only result in a quick absorption, but also come along with direct toxicity through effects on those functions. The aim of this study was to determine how dermal exposures of amphibian post-metamorphic stages to PPP active ingredients and formulations resulted in pesticide accumulation in the skin and affected its structure and physiological, namely immunological, function. We exposed post-metamorphic Iberian waterfrogs via overspray to six active ingredients (a.i.) or their formulations, using two doses: the labelled spray application rates and an increased rate that varied between 3 and 10 times the labelled rate depending on the a.i. solubility. Skin secretions were collected after seven days to quantify concentration and antimicrobial capacity of skin peptides. Exposure to the flupyradifurone formulation Sivanto Prime lowered peptide concentrations and tended to reduce their ability to inhibit the growth of a pathogenic *Aeromonas caviae* bacteria. Also at day 7 post exposure, froglets were euthanised to measure pesticide residues in skin and conduct a histological assessment of the epidermis at the lateral plicae. Flupyradifurone, azoxystrobin and tebuconazole formulations led to higher PPP accumulation in froglet skins than a.i. The epidermal index indicative of skin thickness was increased after exposure to azoxystrobin and α -cypermethrin, with stronger effects caused by formulations, whereas effects of metrafenone and fluzifop-p-butyl on this

index were detected only after the exposure to the a.i.. The results of the study evidence that formulations play a major role in the effects of PPP on amphibian skin following overspray, that lipophilicity drives effects on epidermal histological structure and that some substances may compromise the immune function of the skin by reducing both the total amount and the antibacterial efficacy of skin peptides.

1.05.P-We011 Why Size Matters: Clarifying the Calculation of Anuran Body Surfaces

Arnd Weyers¹ and Valentin Mingo², (1)Bayer AG, CropScience, Germany, (2)Corteva Agriscience, Germany

Amphibians have a moist and permeable skin, enabling exchange of gases and water with the environment, while also acting as a potential route of exposure to environmental contaminants. Therefore, the correct estimation of surface area for amphibians is highly relevant for estimating exposure to contaminants. Recently, some proposals have been made to address risk of pesticide exposure to amphibians, typically focusing on anurans (frogs and toads) as most widely distributed and occurring in agricultural landscapes. A publication often used in these proposals is Hutchison et al. (1968), titled “Relation of body size and surface area to gas exchange in anurans”, describing the respiratory function of amphibian skin. In their publication, the authors measured the surface (skin) area of different anuran species and derived an allometric relationship to body weight. The equation has been incorrectly applied in a number of scientific and regulatory documents about pesticide exposure of anurans.

When comparing results of different equations that are proposed to estimate pesticide overspray area of frogs and hence their exposure, we noted up to 10-fold differences in results that were difficult to explain. Also the allometric equation had been applied without considering the log scale for surface area (SA in cm²) and body weight (bw in g) as originally published.

This work highlights and aims at correcting a repeated error in different scientific and regulatory publications assessing amphibian exposure to pesticides, e.g. by overspray during pesticide application. Incorrect application of the Hutchison et al. (1968) equation (i.e. failing to de-logarithm the first term of the equation) leads to a ca. 10-fold underestimation of total surface area and a 3-fold underestimation of dorsal surface area of anurans. To estimate anuran dorsal surface area explicitly in pesticide overspray exposure assessments we recommend using the simpler Weltje et al. (2017) ellipse equation (which could also be used as a starting point for ventral contact with soil) as a practical approximation.

1.06 Crossing Scales in (Eco)toxicology: Using Multi-Omics to Understand and Predict Physiological and Ecological Responses

1.06.T-01 Connecting the Dots: data-driven clustering of mechanisms of action based on molecular signatures of gene expression profiles in zebrafish embryos.

Fatma Marghany¹, Hannes Armin Reinwald², Cimin Kalali³, Julia Alvincz⁴, Pragma Thapaliya⁴, Jule Bäcker⁴, Christoph Schaefer⁴, Henner Hollert⁵ and Sebastian Eilebrecht⁴, (1)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Bayer Research & Development Services LLC, Germany, (3)University of Münster, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany

In order to utilize the potential of recently accessible OMICs data in the context of ecotoxicology, this study employs the connectivity mapping (Cmap) approach on 32 chemical substances, belonging to 10 different modes of action (MoAs) in zebrafish embryos. The 32 chemicals were clustered by their transcriptome profiles. Furthermore, a comprehensive strategy was formulated for the execution of Cmap on zebrafish embryo transcriptome data, encompassing the evaluation of the performance of various Cmap models. The vector-based scoring (Pearson's correlation) revealed overall higher accuracy than the aggregation-based scoring (GSEA). Additionally, higher accuracy was achieved using a smaller gene input size in Cmap. Furthermore, GSEA was performed to map the chemical substances at the functional level and inspect the functional signatures of the given MoA. Finally, a random forest model was applied to the transcriptome profiles of *Danio rerio* exposed to chemicals, to define unique molecular signatures for each MoA. This study represents a significant step towards integrating the existing knowledge of single molecular responses with the objective of deriving data-driven

biological conclusions about the ecotoxic MoA of chemicals. Additionally, the defined molecular signatures provide a potential cost- and time-effective MoA prediction strategy.

1.06.T-02 Spatial Multi-Omics to Advance Toxicity Assessment of Tributyltin in Zebrafish Embryos

Laia Navarro-Martin¹, Albert Menéndez-Pedriz², Liliya Sokalchuk Sokalchuk², Michiel Vandenbosch³, Melissa Diogo Faria², Alba Julia², Marina Bellot⁴, Cristian Gómez-Canela⁴, Carlos Barata Dr⁵, Ron Heeren³ and Joaquim Jaumot², (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (2)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (3)Maastricht MultiModal Molecular Imaging (M4I), Institute Division of Imaging Mass Spectrometry, Maastricht University, Netherlands, (4)Ramon Llull University, Spain, (5)Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Tributyltin (TBT), a widely used antifouling agent, remains a pervasive marine pollutant with endocrine-disrupting and neurotoxic properties. To elucidate early neurotoxic mechanisms, zebrafish embryos (*Danio rerio*) were exposed to environmentally relevant TBT concentrations (3?nM and 30?nM) for 24?h at 4?dpf. A spatial multi-omics framework integrated MALDI-MSI lipidomics, MERFISH-based transcriptomics, and phenotypic assays. Cryosectioned larvae (7?µm) underwent MALDI-MSI lipid profiling at 15?µm resolution using timsTOF fleX, followed by multivariate analyses. Spatial transcriptomics employed MERSCOPE® with a 1,000-gene panel, clustering via Seurat. Phenotypic endpoints included LC-MS/MS neurotransmitter quantification, behavioral assays (escape and visual motor responses), and chromatic preference tests. TBT induced dose-dependent lipid disruptions in brain, eye, and tail regions, predominantly affecting glycerophospholipids (>60%), alongside sphingolipids and sterols. Approximately 20–25% of lipids showed coordinated dysregulation, more pronounced at 30?nM. Transcriptomic analysis identified 36 cell clusters and 218 DEGs (FDR?<?0.05) in neural tissues, largely downregulated and linked to neuronal communication, neurodevelopment, lipid metabolism, and stress pathways. Notochord DEGs implicated morphogen signaling, reinforcing CNS patterning disruption. Multi-omics integration revealed impaired neuronal differentiation, myelination, and activity-dependent signaling, with lipid remodeling (PC, PE, DG), sterol/HexCer accumulation, and Ca²⁺-linked stress converging with apoptosis activation. Behavioral deficits, altered color preference, and monoaminergic neurotransmitter imbalance confirmed functional consequences. TBT disrupts zebrafish neurodevelopment through coordinated molecular and phenotypic alterations. Spatial multi-omics uncovered lipid remodeling and neurodevelopmental gene downregulation validated by behavioral impairments. These findings underscore the value of advanced spatial omics in environmental hazard assessment and regulatory frameworks.

1.06.T-03 Meta-Metabolomics to Unravel Biopesticide-Induced Structural, Functional and Adaptive Responses in Benthic Microbial Communities

Fanny CHARRIER¹, Chloe Bonnineau¹, Justine Montgillard², Melissa Eon¹, Isabelle Batisson², Hermine Billard², Antoine Capizzo², Miriam Florit², Joan Artigas³ and Nicolas Creusot¹, (1)National Research Institute for Agriculture, Food and Environment (INRAE), France, (2)University of Clermont Auvergne, France, (3)Agence Comptable Service Facturier, University of Clermont Auvergne, France

Faced with growing concern about the environmental and health impacts of pesticides, biopesticides emerge as a less hazardous alternative. Nevertheless, there is paucity of knowledge about their actual effect on non-target species. In particular, the response and further tolerance of microbial communities—key actors in aquatic ecosystem structure and functioning—to these « natural » chemicals remains poorly understood. To address this gap, meta-metabolomics is a cutting edge approach by providing a snapshot of the molecular/biochemical responses of microbial communities exposed to biopesticides.

This study aims to elucidate the responses and tolerance mechanisms of leaf-associated microbial communities exposed to kasugamycin, a biosubstance with antifungal and antibacterial properties. To this end, an untargeted metabolomic approach was combined with functional (enzymatic activity, respiration), structural (biomass) and adaptive (Pollution-Induced Community Tolerance) analyses to map and understand the different responses and

metabolic pathways affected during a 28-day chronic exposure .

Results showed a decline in bacterial density and community respiration, accompanied by an increase in fungal biomass and a stimulation of β -glucosidase activity under kasugamycin exposure. Tolerance to kasugamycin emerged in pre-exposed communities only at day 7. Metabolomic profile analysis revealed significant effects of both time and kasugamycin concentration. The metabolite classes most affected by kasugamycin were peptides and amino acids. These shifts likely confirmed that kasugamycin disrupts protein synthesis, in accordance with its known mode of action on prokaryotes.

This work represents a major step forward in microbial ecotoxicology by applying untargeted metabolomics to benthic microorganisms, providing an integrated picture of exposure and molecular responses at the community level. Metabarcoding will complement these analyses by revealing taxonomic composition and diversity.

Ongoing annotation of metabolites and pathways, along with further investigation of the lipophilic fraction, will help to elucidate the cascade of reactions leading to structural and functional responses and tolerance (i.e. eco adverse/tolerance outcome pathways) acquisition in leaf litter exposed to a biopesticide. Ultimately, this approach may allow the identification of molecular descriptors that could serve as biomarkers to support the monitoring and protection of aquatic ecosystems.

1.06.T-04 Ecotoxicity and mechanism of antifouling paint particles on Pacific white shrimp

Lia Kim, Jung Woo Lee, Seung Geun Ye, Haemi Kim and Youn-Joo An, Konkuk University, Korea, Republic of

The antifouling paint particles (APPs) have emerged as one of the microplastics. But there are limited studies of APPs on living organisms, so this study aimed to evaluate the ecotoxicity and toxicological mechanism of APPs on aquatic ecological receptor. Pacific white shrimp (*Penaeus vannamei*) were exposed to APPs collected from the hydro-blasting effluent of dry-dock and toxicological symptoms and mechanism were analysed. *P. vannamei* got growth inhibition and changes in molting patterns. The organ damages (exoskeleton, hepatopancreas, and intestine) were observed. By using multi-omics analysis, we found that APPs induced disturbances in membrane transport and amino acid metabolisms, which eventually caused irreversible disability of tissue-organism level on shrimp. As *P. vannamei* are valuable ecological receptors and food source for human, this result suggests the potential risks of APPs on marine ecosystems and needs for food source management from APPs contaminations.

1.06.P Crossing Scales in (Eco)toxicology: Using Multi-Omics to Understand and Predict Physiological and Ecological Responses

1.06.P-Tu046 Developing Non-lethal Bio-dosimetry Techniques Using Fathead Minnow (*Pimephales Promelas*) Proteomics and Metabolomics

Spencer Hang¹, Erico Oliveira Pereira², Theresa Warriner¹, Kirk Atkinson¹ and Denina B.D. Simmons¹, (1)Ontario Tech University, Canada, (2)University of Toronto, Canada

With the looming threat of climate change, governments around the world have begun investing in alternative energy sources to replace fossil fuels, with a significant emphasis on nuclear energy. Small modular reactors (SMRs) can replace fossil fuel usage. In addition, they can be used in small, remote communities for electricity generation, desalination, and heating. However, while still novel, there is limited knowledge of the effects that SMRs might have on their surrounding environment. While there is literature on the effects of ionizing radiation to fish, most studies have focused on acute, single-exposure developmental toxicity above 1 Gy, with limited results on the effects of lower levels over long-term, chronic exposures. Our study aims to fill that literature gap by investigating the effects of ionizing radiation on the proteome and metabolome of the fathead minnow (*Pimephales promelas*). We will sample across multiple tissue types, including mucus, plasma, gill, skin, and muscle. We expect to see changes in protein concentrations related to reactive oxygen species, pigmentation and sex hormones. These results can be used to develop non-lethal bio-dosimetry programs for the surrounding environment of SMRs, enabling consistent monitoring while reducing stress on sample organisms and providing additional data for risk assessors.

1.06.P-Tu047 Non-Invasive Biofluid Profiling for Detecting Low-Dose Radiation Exposure Using Omics Analysis

Erico Oliveira Pereira, Spencer Hang, Theresa Warriner, Kirk Atkinson and Denina B.D. Simmons, Ontario Tech University, Canada

To mitigate carbon emissions and meet global energy needs, nuclear power has increasingly been suggested as a complementary solution in the pursuit of low-carbon energy sources. Among the new facilities and technologies to be soon operational are small modular reactors (SMRs). They are designed to be pre-made and transported for installation close to industrial facilities, as well as in remote areas, such as lakes and the ocean. Therefore, exposure to low-dose radiation is likely to occur in a range of species, including fish and humans. In this study, we aimed to establish alternative non-invasive biodosimetry approaches using omics analysis. For the fish component of the study, we exposed fathead minnows to low and high ionizing (gamma) radiation for periods that would result in doses of 0.1 and 1 Gy, respectively. For the long-term 0.1 Gy exposure, we used coin-sized Cesium-137 sources with fish exposed for 7 days. Meanwhile, a gamma ray irradiator system was utilized for the higher dose of 1 Gy over a period of 2 hours (shorter term). Fish mucus samples were collected with paper tissues and analyzed for protein and metabolite biomarkers using untargeted mass spectrometry (MS)-based analysis. We also collected human saliva from radiation workers (potential exposure group), administrative workers (negative control) and patients undergoing radiation-based diagnostic procedures (positive control). The saliva samples were processed, and quantification of proteins and metabolites was performed using the same MS-based approaches as for fish mucus. Bioinformatics tools will be used for the identification of biomarkers of exposure as well as for understanding impacts on specific pathways. We predict that responsive biomarkers will be associated with DNA damage as well as oxidative stress responses. Given the potential of an increase in low-dose radiation exposure for both wildlife and humans, the identification of biomarkers of exposure could strengthen routine health monitoring and screening programs for nuclear sector workers, as well as improve environmental monitoring efforts.

1.06.P-Tu048 Slippery Science – Fish Mucus for Non-invasive Biomonitoring

Denina B.D. Simmons, Amy Del Vecchio, Raina Mackenzie Kerr Hubley, Cristina Henriques, Keisha Ann Deoraj, Urvi Pajankar, Kylee Ronnenberg and Theresa Warriner, Ontario Tech University, Canada

Fish epidermal mucus is one of the first lines of defence against chemical, physical, and biological stressors. Acting as a natural, semi-permeable barrier, fish epidermal mucus plays a critical role in its immunological and protective function due to its mechanical and biochemical properties. As such, fish epidermal mucus is a repository of numerous innate and acquired components of immunity. Fish epidermal mucus is produced and sloughed off constantly, allowing for its non-invasive collection with relative ease compared to other methods (i.e., blood and tissue sampling).

We aimed to develop methods to identify and measure proteins in fish epidermal mucus, for low-impact monitoring of threatened and/or protected wild fish populations. We optimized two sampling methods that can be used in lab and remote field environments. We also characterized the types of proteins we could find in mucus to better understand its practical application for fish health studies. We refined our collection methods to work on different species and sizes of fish that occupy different environments.

All mucus, plasma, and tissue samples were analyzed using liquid chromatography tandem high resolution full scan mass spectrometry (Agilent 1260 Infinity LC with 6545 QTOF), and data were processed using Agilent Spectrum Mill (Version B.04.01.141), Skyline 20.2 (MacCoss Lab Software), and Metaboanalyst 5.0 software. We will present the results from our method development and optimization, and then compare mucus proteins from four species of fish (Rainbow trout, Lake sturgeon, Fathead minnow, and Bluntnose dace). Finally, we will demonstrate how the mucus proteome adequately informed our understanding of the toxicological effects from three different laboratory exposure studies (Ni²⁺, Benzalkonium chloride, and PFAS).

1.06.P-Tu049 Investing Gut-Brain Axis disruption and Neurotoxicity Following Nanoplastic Exposure in Adult Zebrafish (*Danio rerio*)

Minji Kim and Sang Don Kim, Gwangju Institute of Science and Technology (GIST), Korea, Republic of

Nanoplastics (NPs) are increasingly recognized as common contaminants in aquatic ecosystems, where they can accumulate in organisms and affect multiple physiological systems. The gut-brain axis (GBA), which links gut microbial composition and intestinal barrier function to central nervous system activity, is thought to be highly sensitive to environmental stressors. However, the mechanisms by which chronic NP exposure disrupts gut homeostasis and contributes to neurotoxicity through the GBA remain insufficiently understood.

This study aims to explore whether NP-induced gut dysbiosis contributes to neurotoxicity via the GBA in adult

zebrafish (*Danio rerio*). Adult male zebrafish are being exposed to 1 mg/L NPs under controlled laboratory conditions. Following exposure, behavioral assessments are conducted, after which intestinal tissues, gut contents, and brain samples are collected for molecular and microbiological analyses. Gut microbiota composition is assessed using 16S rRNA sequencing, while RT-qPCR and ELISA will be used to evaluate intestinal barrier gene expression, neuroinflammatory markers, and related protein mediators. We hypothesize that NP exposure will shift gut microbial composition, weaken intestinal barrier function, and trigger neuroinflammatory responses, leading to changes in behavior. This work is expected to provide mechanistic insights into how NP exposure affects systemic health, emphasizing the role of the GBA in linking gut disturbances to neural outcomes. These findings may inform ongoing discussions in ecotoxicology and public health regarding the impacts of micro/nanoplastic pollution.

1.06.P-Tu050 Brain Metabolic Responses of Honey Bees (*Apis Mellifera*) Exposed to Coumaphos and Fipronil Using UPLC-Q-TOF/MS

Yoonjeong Jeon, Sung-Gil Choi, Won Noh, Jinwoo Park, Dae-Wook Kim and Jong-Hwan Kim, Korea Institute of Toxicology, Korea, Republic of

Honey bees (*Apis mellifera*) serve as keystone pollinators essential for agricultural productivity, biodiversity maintenance, and overall ecosystem stability. However, recent global declines in honey bee abundance and diversity have raised substantial concern, with the widespread use of pesticides in agricultural and natural ecosystems identified as a major contributing factor. Among these pesticides, coumaphos, a synthetic organophosphate used to manage Varroa mite infestations within colonies, and fipronil, a phenylpyrazole employed to control agricultural pests, have both been shown to adversely affect honey bees. Evidence indicates that coumaphos exposure can detrimentally impact honey bee physiology and behavior, including increased cellular damage, impaired olfactory learning, and reduced foraging activities. Similarly, fipronil disrupts bees' communication and foraging activity, ultimately increasing colony vulnerability.

In the present study, honey bee colonies were provided with feeding solutions containing coumaphos or fipronil for either 1 day or 10 days to examine the effects of each pesticide. The exposure concentrations of coumaphos and fipronil were determined based on literature surveys identifying concentrations detected in pollen and honey within colonies. Both pesticides had negative effects on honey bee nursing performance over 10 days of exposure, including reductions in the number of bees and the duration of nursing behavior. To better understand nursing behavior changes in bees exposed to each pesticide, we conducted comparative metabolic profiling of honey bee brains following exposure to coumaphos or fipronil using UPLC-Q-TOF/MS.

The results revealed that the levels of 73 and 69 metabolites were altered after exposure to coumaphos and fipronil, respectively. Among these altered metabolites, coumaphos significantly affected key metabolites related to NAD⁺-dependent signaling, whereas fipronil exposure caused changes in metabolites involved in arginine and proline metabolism. These findings provide new insights into the potential mechanisms through which individual exposure to coumaphos or fipronil disrupts nursing behavior in honey bees, underscoring their risks to colony health.

1.06.P-Tu051 Comparative Toxicometabolomics and Proteomics of Insecticide Abamectin in Honeybee

Junghak Lee¹, Yoonjeong Jeon¹, Sung-Gil Choi¹, Jeong-Han Kim² and Jong-Hwan Kim¹, (1)Korea Institute of Toxicology, Korea, Republic of, (2)Department of Agricultural Biotechnology and Research Institute of Agriculture and Life Sciences, Seoul National University, Korea, Republic of

Abamectin, an insecticide, has been used widely to control mites, nematodes, and various insect pests in crop. In order to investigate the toxicological mode of action of abamectin on insects, the honeybee was selected as the representative insect, utilizing an integrated multi-omics approach combining targeted metabolomics (GC-MS/MS) and toxicoproteomics (LC-HRMS). Honeybees were exposed to sub-lethal concentrations of 0.115 ng/uL for the low-exposure group and 1.15 ng/uL for the high-exposure group based on the 48-h LD50 value (0.0023 ug/bee) under controlled conditions.

For metabolomics, samples were extracted with 80% methanol and the extract was prepared with TMS derivatization for GC-MS/MS. The targeted MRM mode detected 239 metabolites, and non-targeted LC-HRMS was also used. Statistical analysis (PLS-DA, VIP, ANOVA) identified biomarkers. Pathway analysis (MetaboAnalyst 5.0) revealed significant disruption in core functions: Citrate Cycle (TCA cycle), Tyrosine metabolism, Phenylalanine/tyrosine/tryptophan biosynthesis, Alanine/aspartate/glutamate metabolism, and Ascorbate/aldarate metabolism. For proteomics, proteins were extracted with 0.1 M phosphate buffer and digested using the FASP method. LC-HRMS identified 670 proteins, and 32 proteins were selected as significant biomarkers through volcano plot. The integrated multi-omics evidence confirms that abamectin

exposure perturbs fundamental metabolic and biochemical networks in honeybee. The omics study proves that it can identify the mode of action and toxicological mechanisms in detail over simple LD50 values.

1.06.P-Tu052 Assessing the Impact of Fluorescent Polyethylene Terephthalate and Phenanthrene on the Blue Mussel by Omics Approaches

Zahra H.H. Alfahmi^{1,2}, Raul Martin Hilder Nine², Adam Stevens³, Cyrill Bussy⁴, Bart van Dongen⁵ and Holly A. Shiels², (1)Division of Biology, Faculty of Basic Science, University College Adham, Umm Al-Qura University, Saudi Arabia, (2)Division of Cardiovascular Sciences, Faculty of Biology Medicine and Health, University of Manchester, United Kingdom, (3)Manchester Academic Health Sciences Centre, Royal Manchester Children's Hospital and the Institute of Human Development, University of Manchester, United Kingdom, (4)Division of Immunology, Immunity to Infection and Respiratory Medicine, School of Biological Sciences, University of Manchester, United Kingdom, (5)University of Manchester, United Kingdom

Microplastics (MPs) are a threat to aquatic life in part because they can act as carriers of pollutants by adsorbing them to their surface and contributing to bioaccumulation. Environmental metabolomics could offer meaningful information on the biochemical response to exposure to evaluate the impact of multi-contamination on marine biota without any a priori information. Hence, the goal of this study was to investigate the accumulation and effects of single and combined exposures on metabolomic signatures in the marine bivalve *Mytilus edulis*. Blue mussels were exposed for 7 days to PET mixture with sizes of (300-500 µm, 150-300 µm, 80-150 µm and 40-80 µm), with and without the polycyclic aromatic hydrocarbon (PAH) phenanthrene (Phe) (0.5 mg/L), which is dominant component of crude oil. PET was quantified using Pyrolysis-gas chromatography-mass spectrometry (Py-GC-MS); Phe was quantified using GC-MS both were found to accumulate at higher levels in digestive gland (DG) tissue compared to other organs haemolymph (HL) and gill. We investigated the metabolic profile of HL and DG using non-targeted metabolomics through the utilisation of GC-MS and liquid chromatography-mass spectrometry (LC-MS). Between exposed and non-exposed groups, we identified 35 distinct metabolites in mussel HL by GC/MS, and in the DG we used a combination of GC-MS/LC-MS and found 80 and 75 distinct metabolites, respectively. We applied univariate (ANOVA $P < 0.05$), and multivariate (PCA and PLS-DA/sPLS-DA) statistical analyses on the data sets. We identified the metabolites that drive the differences across treatment groups in HL, namely uracil and citric acid. In DG, the most unique biomarkers were glycolic acid and taurine metabolites revealed by GC-MS, and 1-Hydroxy-2-Naphthoate metabolites detected by LC-MS. Our study demonstrates the suitability of metabolomics analysis to reveal metabolic perturbations in the HL and DG tissues of *Mytilus edulis* following exposure to environmental toxicants. Integrated HL-DG metabolomics (GC-MS and LC-MS) revealed a coherent biomarker panel through sPLS-DA, with the combined-exposure group exhibiting the strongest metabolic enrichment and the most distinctive biomarker profile. These findings offer a better understanding of the impacts of combined PAH and MNPs pollution on the health of blue mussel populations from pollutants.

1.06.P-Tu053 Assessing the linkages between Vitellogenin Amino Acid and Protein Sequences to Selenium Developmental Toxicity Thresholds among Fish

Theresa Warriner and Denina B.D. Simmons, Ontario Tech University, Canada

Vitellogenins are a family of lipo-proteins found in females in many oviparous species. Synthesized in the liver, vitellogenins are then transported to unfertilized eggs, where they are cleaved into multiple, smaller egg yolk proteins to prepare for egg fertilization. As a result, the transfer of vitellogenin from female to offspring can be a pathway in which environmental substances can influence egg and progeny quality. Selenium is an essential element that is required in low concentrations for the amino acid selenocysteine (by substituting selenium for sulphur in cysteine). However, when organisms have an excess of selenium, selenomethionine becomes abundant (by substituting selenium for sulphur in methionine), which can negatively impact protein sequence, structure, and function. Studies investigating selenium toxicity have shown that parental exposure in fish can lead to decreased hatching rates and increased offspring mortality and developmental deformities. We propose that vitellogenin may be a vehicle of selenium into unfertilized eggs, and that the selenium toxicity thresholds in a species may be regulated by the abundance and sequence of vitellogenin and other egg proteins. To determine whether vitellogenin amino acid and protein sequences correlate with selenium toxicity thresholds, we used liquid chromatography tandem mass spectrometry (LC MS/MS) to examine the vitellogenin sequences in representative fish species (with varying selenium toxicity thresholds). We will present 1) the abundance of cysteine and methionine in vitellogenin sequences and in other egg proteins, 2) the abundance of vitellogenin isoforms across different fish species and correlate these abundances with established selenium toxicity thresholds. This project may provide evidence for a mechanism for selenium toxicity.

This work is funded through a grant from the Selenium Working Group of the North American Metals Council (NAMC SWG).

1.06.P-Tu054 Male-biased gut dysbiosis following environmentally relevant benzalkonium chloride exposure in fathead minnows (*Pimephales promelas*)

Milena Esser¹, Raina Mackenzie Kerr Hubley², Shreya Sehrawat¹, Denina B.D. Simmons² and Karen A. Kidd,¹
(1)McMaster University, Canada, (2)Ontario Tech University, Canada

Quaternary ammonium compounds (QACs) are widely used antimicrobial chemicals in household and industrial products. Given their microbial-targeting properties, their release into aquatic environments raises concerns about potential impacts on microbial communities, including the gut microbiomes of aquatic organisms. Yet, the impacts of QACs on these communities remain poorly understood.

To investigate these impacts, we exposed male and female fathead minnows (*Pimephales promelas*) to environmentally relevant concentrations (0.5-15 µg/L) of benzalkonium chloride (BAC), one of the most widely used QACs, for 28 days in flow-through tanks under controlled conditions. Following exposure, fish guts were dissected, DNA extracted, and microbial communities were profiled via amplicon sequencing of the V3-V4 region of the 16S rRNA gene on an Illumina MiSeq platform, generating 300 base pair paired-end reads for a total read length of 600 base pairs per fragment.

Control fish showed no significant sex differences, indicating that baseline gut microbiomes were intrinsically similar. In BAC-exposed males, PERMANOVA analysis indicated a significant shift ($R^2 = 0.22$, $F = 3.01$, $p = 0.007$) in overall gut community composition in response to BAC exposure. In BAC-exposed males, *Enterococcus* (including *E. gilvus*) was significantly reduced, while *Peptostreptococcaceae* showed a significant increase with increasing BAC concentration. *Enterococcus* are facultative anaerobes that produce lactic acid via homofermentative metabolism, supporting gut homeostasis and colonization resistance. *Peptostreptococcaceae* are obligate anaerobes that ferment peptides and amino acids to produce short-chain fatty acids (SCFAs), including acetic, butyric, isobutyric, caproic, and isocaproic acids. The observed shift may therefore alter the balance of fermentation products in the gut, potentially affecting SCFA composition and related microbial functions. In comparison, female gut microbiomes showed no significant changes, reflecting resilience to BAC-induced perturbation, which may be mediated by host-protective mechanisms such as hormonal regulation or immune modulation.

Overall, these findings demonstrate that BAC exposure can induce sex-specific gut microbiome dysbiosis, with males particularly susceptible, which may predispose exposed fish to impaired gut function and negative health outcomes, highlighting the ecological and physiological risks of BAC contamination in aquatic environments.

1.06.P-Tu055 Assessing the Applicability of Sediment Metabolomic Biomarkers for Quantifying Phytoplankton Damage under Chemical Spill Incidents.

Yejin Bang¹ and Tae-yong Jeong², (1)Hankuk University of Foreign Studies, Korea, Republic of,
(2)Environmental Science, Hankuk University of Foreign Studies, Korea, Republic of

Damage to phytoplankton, the primary producers in aquatic food webs, caused by chemical accidents results in a severe loss to aquatic ecosystems; however, the extent of damage to algae has not been calculated during the regulatory damage assessment process. To address this issue, our previous study simulated chemical spill conditions by exposing algae to river water and sediment contaminated with chemical hexamine. We subsequently applied non-targeted metabolomics using LC-QTOF-MS to analyze the sediments mixed with dead algae. The results demonstrated that biomolecules detected from sediment can reflect population-level damage of algae and even approximate the timing of death. To evaluate the applicability of this methodology, we expanded the experiments to different conditions: two algal species, three chemicals, and three different water stream samples. To find metabolites that indicate algal mortality irrespective of experimental conditions, we performed cluster analysis and pattern hunter based correlation analysis. As a result, we identified approximately 40 tentatively annotated metabolites that consistently exhibited increased or decreased abundance in chemically impacted samples, even when algal species, chemical type, or sampling location differed. Among these metabolites, a lignan glycoside-like compound and an isoquinoline-derived compound exhibited condition-independent responses under all tested scenarios. Therefore, this study, as an extension of our previous work, provides evidence that certain metabolites may serve as broadly applicable, non-algae species-specific, non-chemical-specific, and non-location-specific biomarkers for assessing phytoplankton damage resulting from chemical exposure. The findings presented here demonstrate the feasibility and broad applicability of sediment metabolomics as a framework for evaluating phytoplankton damage under chemical spill scenarios.

1.06.P-Tu056 Multiple stressor effects in freshwater invertebrates – lessons learned from transcriptomics
Marie Brasseur¹, Ralf Bernhard Schaefer², Florian Leese³ and Christoph Mayer⁴, (1)Ecotoxicology, University of Duisburg-Essen, Germany, (2)University Duisburg-Essen (Uni DUE), Duisburg, Germany, (3)University of Duisburg-Essen, Germany, (4)Leibniz Institute for the Analysis of Biodiversity Change, Bonn, Germany

Stream ecosystems and their associated biodiversity are threatened by multiple anthropogenic stressors such as pollution, overexploitation and hydromorphological degradation. Traditionally, these stressor effects are quantified at the population level through changes in organismal abundances. While this provides valuable insights in stressor-induced structural alterations of biological communities, stressor effects at the individual level i.e., sublethal effects, are often neglected in multiple stressor studies. However, they may represent early warning signals before biodiversity loss manifests. We used RNA-Sequencing to profile the transcriptomic stress responses in multiple stream macroinvertebrate species exposed to various chemical and physical stressors. Specifically, we aimed to unveil stressor-induced molecular response mechanisms linked to pesticide exposure, fine sediment deposition, reduced discharge and salinization. We found that in several cases, transcriptomic responses to single and combined stressor exposure were in line with previously detected stressor effects at the population level such as the antagonistic interaction between fine sediment deposition and reduced flow velocity in the amphipod *Gammarus fossarum*. At the same time, transcriptomic data revealed stressor effects that would have remained unnoticed when focusing on abundance data alone. Further, we detected stressor-induced mechanisms at the functional genomic level that were unexpected, such as an altered expression of genes involved in development in insect larvae exposed to the insecticide chlorantraniliprole. These findings underscore the complexity of multiple stressor dynamics, highlighting that an improved mechanistic understanding of multiple stressor effects is urgently required. We here demonstrate one possibility to achieve this, namely to combine transcriptomics with ecological experiments, allowing us to synthesize stressor effects that are consistent across different experimental settings, organismic groups and ecological scales.

1.06.P-Tu057 A Developmental Self-Organising Map of the Zebrafish Embryo Transcriptome
Paul Michaelis, Janet Krüger, Julia Nöth, Stephan Schreiber and Wibke Busch, Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Chemical risk assessment is constrained by the scale of untested compounds and the limited interpretability of static toxicogenomic designs. Zebrafish embryos offer a tractable vertebrate system, but their rapidly shifting transcriptional states require models that capture developmental context. A developmental reference model was built to characterise transcriptome dynamics across zebrafish embryogenesis. Five RNA-sequencing datasets covering fertilisation to 120 hours post-fertilisation were integrated, yielding more than 250 samples across 49 timepoints. Gene-wise temporal expression was modelled using generalised additive models, capturing non-linear profiles and accounting for inter-study variation. These profiles served as input for a 60×60 self-organising map that arranged genes by similarity in developmental timing. The resulting topology represented coordinated expression waves and produced clusters enriched for discrete biological functions, forming a coherent transcriptional atlas of early zebrafish development. In an initial analysis, we projected a dataset of zebrafish embryos exposed to the angiogenesis inhibitor SU4312 onto the devSOM. Depending on the timepoint of observation, distinct regions of the map are regulated, indicating that chemically induced transcriptional responses are strongly dependent on developmental stage rather than occurring as uniform stress signals across time. The developmental self-organising map therefore provides a framework for interpreting toxicogenomic signatures in the context of embryonic progression, improving mechanistic resolution and supporting comparative analyses across datasets.

1.07 Daphnia- Advances, Problems, & Historic, Novel and Interdisciplinary Approaches

1.07.T-01 Bridging the Gap: Using High-Throughput Ecotoxicological Tests to Facilitate Chemical Extrapolations in the Standard Dynamic Energy Budget Theory for *Daphnia magna*
Angel Daniel Ceballos Ramirez¹, Mark Hodson², Elma Lahive³, Thomas G. Preuss⁴ and Daniel Harrison Burkow⁵, (1)University of York, York, United Kingdom, (2)University of York, United Kingdom, (3)MacLean

Building, United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)Bayer AG, Germany, (5)Bayer Research & Development Services LLC, Germany

Current ecotoxicological endpoints, both in tests and effect modelling, focus primarily on survival and reproduction, forgoing growth due to difficulties in its measurement. However, novel approaches to ecotoxicological testing have demonstrated that the three endpoints can be measured simultaneously in *Daphnia magna*, and potentially other organisms. As these tests differ to standardized approaches due to their experimental design, it is important to understand the observed differences in lethal and sublethal endpoints. To bridge the gap between standardized test results and high throughput techniques, data obtained from high throughput ecotoxicological tests that closely replicate those of the OECD *Daphnia* reproduction test No. 211 were compared to the original data used in the approval process for two neonicotinoid pesticides (Acetamiprid and Thiacloprid). Data for a third neonicotinoid chemical (Imidacloprid) was also available, and an extrapolation of lethal and sublethal endpoints with mathematical reasoning was derived using endpoint data available in literature.

Using the Dynamic Energy Budget (DEB) Standard Toxicokinetic-Toxicodynamic (TK-TD) model, best fits were found for the high throughput data in DEB parameters, modes of action and TK-TD parameters. The original data for the chemicals was then used as inputs for the DEB TK-TD model and the predicted endpoints were compared. Results point to the high throughput model underestimating or overpredicting survival and reproduction in most cases. However, when growth data was available, the predicted endpoint closely matched the original report. For the extrapolation to Imidacloprid, applying a conversion factor to the TK-TD parameters for Acetamiprid and Thiacloprid resulted in the predicted growth and reproduction endpoints closely matching the original ones.

This study highlights the differences in modelling high throughput and regular standardized testing, demonstrating that the observed differences in sublethal endpoints can be explained by DEB modelling. However, for lethal endpoints, more studies are necessary to understand the differences between the two types of testing.

1.07.T-02 Molecular Docking On *Daphnia Magna* Methoprene Tolerant Receptor As A Predictive Approach For Potential Environmental Endocrine Disruptors

Luna Grimault, Zara Msoili and Laure Garrigue-Antar, Leesu (ENPC), France

Molecular docking is a computational method predicting molecular binding modes. This *in silico* approach usable for environmental contaminants virtual screening allows putative binding mode identification before experimental testing. In this study, molecular docking was applied to the Methoprene-tolerant receptor (Met), the juvenile hormone receptor in insects and crustaceans. Met is naturally activated by methylfarnesoate in crustaceans, but can be disrupted by pesticides like fenoxycarb, severely impacting the reproduction of non-target species like *Daphnia magna*. Daphnids are key primary consumers in aquatic ecosystems, thus understanding Met activation and identifying interacting compounds is essential for ecotoxicological risk assessment. A previous study tested the ability of 28 environmental chemicals to activate Met *in vitro*. Based on these results, we evaluated the tested compounds' interactions with Met using molecular docking, with the aim of validating an approach for screening a large number of environmental contaminants to identify potential endocrine disruptors. We also tested our approach on furosemide (FUR), a pharmaceutical contaminant and two of its metabolites, pyridinium of furosemide (PYR) and saluamine (SAL) which presented significant toxicity at environmentally relevant concentrations (ng/L).

The 3D structure of *D. magna* PAS-B domain (ligand binding site of Met) has been modelled using AlphaFold DB and the screening box was designed based on previous studies. Flexible docking was run on the 28 compounds studied *in vitro*, FUR, PYR and SAL. Docking results were assessed by 15-day reproduction assays on *D. curvirostris* with FUR, PYR, SAL and mixtures.

Docking results indicate that *in vitro* active compounds have low binding energies, consistent with favorable interactions with Met. However, some inactive compounds showed similarly low energies. Most of these false positives contain chloride atoms, which may form halogen bonds with Met *in silico* only considering that none of the active compounds contain chlorides. FUR and PYR which also contain chlorides, displayed low binding energies, suggesting potential interactions with Met. However, like SAL, they showed little to no impact on *D.*

curvirostris reproduction in vivo. Assays on *D. magna* will soon be performed to confirm these results. Additional docking and interaction analysis with Met are ongoing to improve mechanistic understanding and enable broader-scale applications.

Disclaimer/Disclosure:

This work is supported by the OPUR 6 program (2024-2029) led by Leesu - L.G. is a recipient of a doctoral grant from the French Ministry of Higher Education and Research.

1.07.T-03 Genome Editing *Daphnia* as a Tool for Understanding Endocrine Disruption

Hajime Watanabe¹, Lichi Hsieh², Fransiscus Jason Wiguna³, Nikko Adhitama³ and Yasuhiko Kato⁴, (1)Osaka University, Japan, (2)The University of Osaka, Taiwan (Greater China), (3)The University of Osaka, Indonesia, (4)The University of Osaka, Japan

Juvenile hormone (JH) regulates essential biological processes in arthropods, including reproduction, molting, and sexual differentiation. However, in non-insect crustaceans such as *Daphnia magna*, the JH-producing organ and regulatory mechanisms remain poorly characterized, making it difficult to assess how environmental contaminants disrupt JH-mediated physiology. The objective of this study is to establish genome-edited *D. magna* lines capable of visualizing JH biosynthesis in vivo, and to utilize them for evaluating endocrine disruption caused by juvenile hormone analogs (JHAs).

To identify the JH-producing organ, we generated a TALEN-based intron knock-in strain in which Achilles fluorescent protein is bicistronically expressed from the juvenile hormone acid o-methyltransferase (JHAMT) locus, a key enzyme in the sesquiterpenoid biosynthesis pathway. Reporter expression was confirmed in F1 offspring. Fluorescence localization revealed a previously unidentified bilateral JH-producing organ located posterior to the brain in juveniles, suggesting an endocrine secretion route that mediates multiple physiological functions.

To evaluate endocrine disruption, we examined fenoxycarb toxicity using time-course exposure and transgenic imaging. A vasa:H2B-GFP strain enabled direct visualization of ovarian cell integrity. Fenoxycarb exposure significantly reduced fecundity and induced apoptotic nuclear abnormalities in developing oocytes, demonstrating that JHA-induced reproductive impairment is mediated through oocyte cell death.

In conclusion, genome-edited *D. magna* strains enable real-time visualization of endogenous JH signaling and provide mechanistic insight into endocrine disruption by JHAs. These tools strengthen the utility of *Daphnia* as a sensitive and biologically relevant model for environmental risk assessment of endocrine-disrupting chemicals in aquatic ecosystems.

1.07.T-04 Understanding the Impacts of Exposure to Ten Pesticides and Their Mixtures in *Daphnia pulex*: a Transcriptomics Approach

Eduarda Santos¹, Jake Bowley¹, Rob McFarling¹, Sarah Woodsford¹, Connor Crilly¹, Jonathan Ray Newman², Ceri Lewis³, Aaron Jefferies⁴, Greg Paull¹ and Anke Lange¹, (1)University of Exeter, United Kingdom, (2)GPC Expenses, Environment Agency United Kingdom, United Kingdom, (3)Biosciences, University of Exeter, United Kingdom, (4)University of exeter, United Kingdom

Freshwater systems are highly diverse environments supporting an important component of the world's biodiversity but are highly vulnerable to environmental stress, including that associated to chemical exposures. In river catchments affected by farming, some of the most common contaminants are pesticides. Given the complex nature of the chemical contamination present in these environments, it is challenging to assess to what extent organisms in these ecosystems are affected by chemical exposures. As a result, for many of the chemicals present in freshwater systems, their impact on freshwater invertebrates is poorly understood. We aimed to develop and apply a transcriptomics approach to determine the mechanisms of toxicity of 10 common pesticides, alone and as part of mixtures, to better understand their impacts on the health of freshwater invertebrates. To do so, we used the *Daphnia pulex* as a model system due to its well characterised genome and history of use as an ecotoxicology model. We combined exposure experiments with transcriptomics (RNA-Seq in a NovaSeq S4 Illumina platform) over time to determine the adverse effects of each individual chemical alone and as part of binary and complex mixtures. Our data revealed specific mechanisms of action for each chemical with commonalities also encountered, in particular for molecular pathways associated with response to stress and recovery. Gene Set Enrichment Analysis for the mixtures showed some degree of concordance between the molecular pathways affected by individual chemicals and the mixtures showing that the effects of chemicals alone can predict some, but not all, the outcomes of complex mixtures. We are now expanding our analysis to include weighted correlation network analysis in order to uncover global trends across all the dataset.

1.07.T-05 Different pasts, different responses: How Daphnia react to cyanobacteria exposure?

Ivo Filipe Magalhães Pinto¹, Luísa Azevedo² and Sara C. Antunes³, (1)ICBAS; CIIMAR; UMIB; FCUP, Portugal, (2)UMIB; ITR, Portugal, (3)CIIMAR, FCUP, Portugal

Freshwater ecosystems are increasingly threatened by cyanobacteria, which compromise water quality and affect aquatic organisms. *Daphnia*, a key genus in freshwater food webs, often coexists with cyanobacteria, facing physiological stress that can drive adaptation or tolerance. This study aimed to integrate the morphological and genetic identification of *Daphnia* and cyanobacteria from Portuguese reservoirs and evaluate how different field *Daphnia* populations respond to cyanobacteria through feeding performance and biomarker analyses. Two Portuguese reservoirs were selected: Rabagão (bloom-free) and Aguieira (bloom-prone) to collect water samples and *Daphnia* individuals. Cyanobacteria and *Daphnia* species were isolated and taxonomically and genetically identified. Feeding inhibition assays were conducted with *Daphnia magna* and field *Daphnia* spp. exposed to cyanobacteria cell concentrations (cells/mL): 7.5×10^7 (medium risk), 1.5×10^7 (high risk), 3.0×10^7 (high risk), and 1.2×10^7 (very high risk), according to World Health Organization guidelines. Additionally, biomarkers related to oxidative stress, neurotoxicity, and energy metabolism were evaluated. Three *Daphnia* species were identified: *D. longispina* and *D. middendorffiana* associated to Rabagão and *D. galeata* and *D. middendorffiana* to Aguieira. *Microcystis aeruginosa* and *Aphanizomenon flos-aquae* were identified only in Aguieira, while Rabagão showed no bloom-forming species. *D. magna*, *D. middendorffiana* (from Rabagão) and *D. galeata* (from Aguieira) exhibited feeding inhibition under cyanobacterial exposure, though feeding rates increased with cyanobacteria concentration. Antioxidant enzyme activity (e.g. catalase) was enhanced, as well as oxidative damage, acetylcholinesterase inhibition, and altered energy metabolism after *Daphnia* spp. was exposed to cyanobacteria. Populations from the bloom-prone reservoir (*D. galeata*) displayed stronger physiological adjustment and distinct biomarker profiles, suggesting higher cyanobacteria tolerance. These findings highlight that cyanobacteria can impair *Daphnia* even at concentrations posing human health risks, and that exposure history influences tolerance and physiological responses to bloom conditions.

1.07.P Daphnia- Advances, Problems, & Historic, Novel and Interdisciplinary Approaches

1.07.P-Mo017 Assessing Sublethal Effects of Nanomaterial-Enhanced Magnesium Oxychloride Cement (MOC) Composites on *Daphnia magna* Through Feeding and Biomarker Responses

Bárbara Salazar Diogo¹, Jana Kofronova², Ondřej Jankovský³, Radek Vurm⁴ and Sara C. Antunes⁵, (1)ICBAS/CIIMAR, Portugal, (2)Department of Environmental Chemistry, University of Chemistry and Technology, Prague, Czech Republic, Czech Republic, (3)Department of Inorganic Chemistry, University of Chemistry and Technology Prague, Czech Republic, Czech Republic, (4)Faculty of Environment, Jan Evangelista Purkyně University, Ústí nad Labem, Czech Republic, (5)FCUP/CIIMAR, Portugal

Magnesium oxychloride cement (MOC) is considered a more environmentally friendly alternative to conventional cement. Unfortunately, some of its properties limit its potential applications. Therefore, the possibility of incorporating various additives to improve its properties is being investigated (e.g. reducing hydrophilicity and increasing strength). One option for these additives are nanomaterials, such as multi-walled carbon nanotubes (MWCNT), oxidised multi-walled carbon nanotubes (MWCNT-ox), graphene oxide (GO) or graphene (G). Although these compounds can improve properties, they may have a toxic effect on organisms relevant to the environment, such as the microcrustacean *Daphnia magna*. This study investigated the impact of these materials on the feeding behaviour of *D. magna* after 24 hours exposure at concentrations of 10, 50 and 100 mg/L. Biomarkers associated with cholinergic neurotransmission (acetylcholinesterase – AChE activity), oxidative stress (glutathione-S-transferase – GSTs activity) and lipid peroxidation (thiobarbituric acid reactive substances – TBARS levels) were quantified to evaluate the effects on a sub-individual level. In terms of feeding, a significant increase was observed, especially at the highest tested concentrations after exposure to MOC, MOC-MWCNT-ox and MOC-GO, whereas a decrease in feeding rates was recorded following MOC-G exposure. Regarding neurotransmission, only 50 and 100 mg/L of MOC-GO cause a significant increase in

AChE activity. All the tested compounds caused significant differences in GSTs activity, suggesting an activated enzymatic response after exposure to these stressors. Although these significant responses observed, the results indicate that enzymatic activity was sufficient to prevent lipid peroxidation, as no oxidative damage was detected. These findings demonstrated that while the incorporation of nanomaterials may enhance the physicochemical properties of MOC, these additives can also amplify or modify its toxicity toward aquatic organisms. Given the ecological importance of *D. magna* and its role in freshwater ecosystems, these results highlight the need for careful evaluation of MOC-based materials to prevent potential environmental impacts across trophic levels.

1.07.P-Mo018 Behavioral Analysis of Freshwater Invertebrates – A Deep-Learning Approach for 3D Movement Analysis

Frida Pallapies and Linda Weiss, Ruhr-University Bochum, Germany

Global change significantly impacts freshwater ecosystems, contributing to biodiversity loss and ecosystem instability. Disregarding the type of stressor, one of the first adaptations of organisms to changes in the surrounding environment is behavioral. Analysing these behavioral changes still remains challenging, but in the recent years the multitude of computational-assisted methods have become increasingly important. However these analytical approaches are often semi-automatic, thus subjective and prone to errors, requiring a time consuming manual correction. Most of the approaches are only focusing on the organism used in the specific laboratory, making it hard to transfer the software to other labs. Additionally only few of them are designed to analyse movement of smaller organisms such as invertebrates and even less are able to analyse movements in the three dimensional space. However this is crucial for the analysis of organisms living in aquatic systems. Here we present a concept for novel approach to analyse sublethal effects of different stressors on the behavior of different freshwater invertebrates, mostly focusing on *Daphnia* spec. Within this workflow, a deep learning-based 3D analysis software is set to be developed, in order to be able to objectively assess even the smallest differences. Therefore general parameters, such as velocity, depth selection as well as neighbor distances will be recorded. Additionally organism specific movement parameters will be analysed. Through the implementation of a fully automatic software, results will be deterministic, thus reproducible and independent of the experimenters experience. The software will mostly be trialed for multiple stressor experiments analysing the effects of psychotropic drugs, such as antidepressants and changes in temperature. However, through the development of an open source software, we will generate a system that is easily applicable to data and experiments from other labs, thus creating a platform of reliable data, with reproducible and comparable results. The software thus offers great potential in studying the effects of different stressors on aquatic organisms, increasing the impact of behavioral freshwater research.

1.07.P-Mo019 Clone-specific responses of *Daphnia magna* to combined warming and contaminant mixtures

Natacha Saez¹, David Boukal¹ and Claire Duchet², (1)University of South Bohemia, Czech Republic, (2)Faculty of Science, University of South Bohemia, Czech Republic

Freshwater ecosystems such as lakes, ponds and pools represent only 1% of the Earth's surface but are dramatically exposed to multiple natural and anthropogenic stressors. Climate warming and chemical contaminants are among the most prominent stressors, increasingly contributing to major biodiversity losses and changes in ecosystem functioning over the last decades.

While the individual effects of warming and contaminants on freshwater ecosystems are relatively well studied, little is known about their combined impacts on aquatic invertebrates, especially when contaminants occur as complex mixtures rather than single compounds. *Daphnia magna*, a model freshwater organism, is commonly used in ecotoxicological studies, but inter-individual variability in response to combined stressors has received limited attention until recently. Moreover, toxicity tests are typically conducted with monoclonal laboratory populations that do not fully reflect the standing genetic variability of natural populations composed of multiple

clones. As a result, standard tests may lead to biased estimates of population-level responses to realistic environmental change.

The present study tests how different clones originating from a single *D. magna* population respond to predicted future warming scenarios and environmentally relevant mixtures of pesticides and pharmaceuticals under laboratory conditions. Individuals were hatched from resting eggs collected in a local pond and maintained in laboratory culture for a year. Chronic toxicity tests were conducted in the laboratory to measure survival, individual growth and reproduction of three clonal lines under two temperature regimes (22°C and 26°C) and four contaminant treatments: control, pesticide mixture, pharmaceutical mixture and the greater mixture of both contaminants. Contaminant concentrations were chosen to reflect environmentally relevant 'worst-case' levels commonly detected in local aquatic environments. Each treatment was replicated 15 times. The measures of individual-level responses were then used to estimate long-term effects of the stressors on the population growth rate of each clonal line.

This work aims to provide insights into inter-individual variability in response to multiple stressors and improve our understanding of how freshwater invertebrate populations may respond to the combined pressures of climate change and chemical pollution.

1.07.P-Mo020 Effects of the antiparasitic veterinary drug ivermectin on *Daphnia magna* including transcriptomic fingerprinting

Lena Kosak¹, Benedikt Ringbeck², Sebastian Eilebrecht³, Frederik Meyer⁴ and Mirco Bundschuh⁴,

(1)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (3)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Rhineland-Palatinate Technical University Kaiserslautern-Landau, Germany

Antiparasitic agents are used as veterinary pharmaceuticals e.g. in livestock, and may be released into the environment with potential toxicity to non-target organisms. These active substances can disrupt ecological balance, affect environmental integrity with potential consequences for biodiversity. Ivermectin is an anthelmintic, belonging to the avermectin substance group and is mainly used to treat several types of parasitic infections of livestock and pets. Ivermectin may enter the environment directly through faecal excretion of livestock grazing on fields or using manure as fertilizer. Run-off caused by rainfall events can then lead to the entry into nearby small water bodies. Ivermectin blocks the neurotransmitter γ -aminobutyric acid in invertebrates, thereby inducing paralysis and death of parasites as well as in non-target organisms. In several terrestrial and aquatic invertebrates high ecotoxic potential with effect levels down to the ng/L range was already shown for ivermectin. Even though there are indications of adverse effects on several invertebrates, there is a lack of reliable studies on the effect of ivermectin on the model organism *Daphnia magna* with regard to chronic effects. Therefore, we performed a GLP study to investigate the effects of ivermectin on the reproduction of *D. magna* following OECD test guideline 211. Based on pre-tests targeting acute toxicity (immobilization), we performed the test in a concentration range of 1 - 15 ng/L. In this study, the endpoints immobility, growth, and reproduction, as well as day of first reproduction were evaluated. To confirm the exposure concentrations in this low concentration range, a UHPLC-MS/MS method with a limit of quantification (LOQ) of 0.3 ng/L was developed and validated following SANTE 2020/12830 guideline. In addition, a second short term exposure study (48 h) will be performed to investigate transcriptomic changes hinting at potential further adverse effects in juvenile daphnids. This test aims at identifying potential additional toxic modes of action (MoA) of ivermectin in invertebrates. Furthermore, it is intended to assess the transcriptomic point of departure (tPOD) for comparison of effect thresholds to the regulatory acute and chronic tests.

Overall, these investigations help to understand the toxicity of ivermectin to invertebrates, as well as toxic MoA, and contribute to a better understanding of its potential ecological impacts.

1.07.P-Mo021 Growth Measurements as a Phenotypic Endpoint for the Assessment of the Impact of Pollutants on Water Fleas – An Online and AI Assisted Approach

Flavia Melati Chiappara¹, Anne Leung¹ and Konstantinos Grintzalis², *(1)Dublin City University, Ireland, (2)Dublin City University (DCU), Ireland*

The rise in anthropogenic pollution is exerting profound negative effects on both environmental systems and human health, having become the leading cause of death worldwide, surpassing all major diseases. The urgency of tackling these environmental challenges and gaining mechanistic information about anthropogenic contaminants commonly found in the environment is leading to the widespread use of Novel Approach

Methodologies, towards more predictive and holistic methods in chemical risk assessment. In this context, the cladoceran *Daphnia magna* has been widely employed as a bioindicator species in effect-based monitoring approaches, largely due to its ecological importance within freshwater food chains. Phenotypic endpoints have been proven to be sensitive, effective and inexpensive tools to assess pollution levels and the effects of xenobiotic compounds present in freshwater at low but environmentally relevant and biologically active concentrations. Size and growth measurements are important physiological characteristics and represent good sublethal toxicity markers in ecotoxicological studies. The research for an effective standardisable method is leading towards the miniaturisation and automation of phenotypic assays. This study focuses on the development of a growth assay using size measurements as an approach to monitor the impact of pollutants on daphnids. The method was optimised using a low volume and higher volume approach and with different amounts of algae as food to identify the best working conditions. The final method was developed in a small-case volume and was applied to test cigarette extracts. Images of the animals were taken using different instruments (stereoscope, magnifying lenses for phone camera), to assess resolution and aim for improved method portability, and the size measured using a combination of manual (Image J) and automated software (Image Measurement, QuPath). In this context, Artificial Intelligence has been proven to be a useful tool in toxicology due to its predictive and automated capabilities. This study implemented growth assays by developing an AI script for automated size measurements, to improve the efficiency of phenotypic assays in daphnids and their role as non-invasive and rapid screening tools for pollution assessment and early detection systems.

1.07.P-Mo022 Impact of Age and Nutritional Status on Effects in *Daphnia* Acute Studies

Thomas Moser, Katrin Weber, Nathalie Schwalbach and Elsa Wendling, Eurofins Aquatic Ecotoxicology GmbH, Germany

Keywords: *Daphnia magna*, acute test, age, nutritional status, multiple stressors, toxicity endpoints

Acute toxicity tests with *Daphnia magna* (OECD test guideline 202) are currently conducted with juvenile daphnids which should be no more than 24 h old. This means that the age of the animals at the start of the test can differ between 0 and 24 h.

Further, according to the guideline, the daphnids are not fed during the 48-h exposure period, but no information was provided in the guideline regarding the feeding status of the daphnids prior to the start of the test. However, in the light of more precise and comparable results it needs to be questioned whether the age of the test organisms and their nutritional status at test start can have an impact on the sensitivity and thus the resulting EC50 values.

To evaluate possible impacts of the age of the daphnids and their nutritional status at test start acute toxicity tests with *Daphnia magna* (OECD 202) were conducted with three narrowly defined age classes (0 – 4 h, 4 – 8 h and 8 – 12 h). Tests included daphnids that did not come into contact with food prior to exposure and such daphnids which had access to food prior to exposure. All age groups with both nutritional statuses were tested with lambda-cyhalothrin and prothioconazole. EC50 values of the tests runs with the three different age groups in the different nutritional status were compared to evaluate possible differences and thereby impacts of age and nutritional status on results of toxicity tests with *Daphnia magna*.

1.07.P-Mo023 Improving micro-/nanoplastics (MNPs) ecotoxicity assessment: A harmonised ecotoxicity testing approach with *Daphnia magna*

Dana Kühnel¹, Eberhard Kuester¹, Andreas Mattern² and Mbuyiselwa Moloi¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Helmholtz Center for Environmental Research (UFZ), Germany

Micro- and nanoplastics (MNPs) are emerging contaminants of global concern, yet their ecological risks remain poorly defined due to limitations in current toxicity testing. Standard assays with *Daphnia magna*, a keystone grazer and regulatory model species, typically employ pristine, monodisperse polystyrene MNPs and focus on endpoints such as immobilisation or reproduction. This simplified approach neglects the freshwater cladoceran *Daphnia magna*'s ecological function, fails to capture the diversity and weathering of environmental plastics, and generates fragmented datasets that hinder meta-analysis and robust risk evaluation. To address these shortcomings, a tiered framework for MNP ecotoxicological assessment using *D. magna* that integrates ecological relevance, mechanistic insight, and systematic data harmonization is proposed. The framework progresses from acute endpoints (mobility, behaviour) to chronic assays (growth, reproduction, population dynamics), multigenerational studies (offspring quality, ephippial investment, sex ratio, transgenerational resilience), and mechanistic investigations employing omics and epigenetics. A central principle across all tiers

is environmental realism, operationalised through the inclusion of MNP characterization, heterogeneous and weathered MNPs, diverse polymer chemistries, MNP physicochemical heterogeneity, and co-occurring environmental stressors. By systematically linking life-history traits with molecular and transgenerational endpoints under realistic exposure scenarios, the framework provides a more comprehensive understanding of MNP effects at both organismal and population levels. Importantly, it establishes protocols for endpoint selection, exposure duration, and test material characterisation, thereby improving comparability and reproducibility across studies. Adoption of this approach will help bridge the gap between laboratory testing and ecological risk assessment, enhancing predictive capacity on plastic pollution risks.

1.07.P-Mo024 Integrated assessment of *Daphnia magna* condition: applications in culture management and ecotoxicological testing

Sizenando Nogueira Abreu¹, Fatima Jesus², Rui Escadas Martins¹ and Miguel Oliveira e Silva¹, (1)Univ. Aveiro, Portugal, (2)University of Aveiro, Portugal

Daphnia magna is used widely as a standard ecotoxicological indicator organism, and protocols exist for its use in assessing the toxicity of substances under acute and chronic experimental conditions. The objectivity of bioassay results largely depends on the level of “reliability” of the test cultures used. Even though reliability of *Daphnia magna* tests being ensured through standard protocols and quality control measures, such as those defined by the OECD, the biota response may vary due to the overall condition of the cultures used to start the experiments. Hence, the condition/fitness of the cultures plays a relevant role in ecotoxicological assessment. For this purpose, it is useful to assess the reproduction in *Daphnia* cultures, as well as size distribution and individual fitness. Moreover, some multigenerational testing for ecological risk assessment might consider the use of multiple organisms in a single replicate, likely resulting in several individuals of different sizes in each replicate. In this case, it is also useful to apply a method allowing a fast, non-destructive count of *Daphnia* offspring, as well as their size distribution and individual fitness.

The aim of our study is to discuss the feasibility of using an automated, rapid, and non-destructive technology (D-counter) to evaluate *D. magna* condition (reproduction, size and “fitness” of individual organisms) under conditions of high density and a large fraction of juveniles, using light detectors. This is particularly relevant in cultures (to assess the overall condition of the culture) and in multigenerational experiments using multiple individuals per replicate. The D-counter device has already been tested for assessing the number and size of individual daphnids and, hence, the novelty of the present study is the assessment of daphnids “fitness”. Results were obtained applying the automated device D-Counter and using *D. magna* cultures maintained under laboratory conditions, as defined by the OECD protocols. The evaluation of individual “fitness” was obtained as the ratio between the observed opacity of every single organism divided by its estimated length. In *Daphnia*, animal width changes with nutritional status and growth within instar, while length changes only during moulting. Thus, estimation of individual “fitness”, besides evaluating overall culture condition, also allows an integrated characterization of every organism, improving comparability and reliability.

1.07.P-Mo025 Novel New Approach methodologies in *Daphnia magna* to monitor neurological hazardous contaminants: from lab to field, from single to chemical mixtures

Carlos Barata Dr¹, Hugo Moro¹, Alba Julia¹, Benjamin Pina², Juliette Bedrossiantz³, Irene Romero Alfano⁴ and Cristian Gómez-Canela⁵, (1)Department of Environmental Chemistry, IDAEA-CSIC, Barcelona, Catalonia, Spain, Spain, (2)Environmental Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (3)Environmental Toxicology, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (4)Department of Analytical and Applied Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (5)Ramon Llull University, Spain

New Approach Methodologies (NAMs) in chemical hazard assessment refer to scientific methods, technologies, or approaches that provide information on chemical safety without relying on traditional animal testing. NAMs thus include existing standardized and novel bioassays with the aquatic crustacean *Daphnia magna*.

Concomitant with the extension of life, there is an increasing concern for neurological disorders. Humans as well as biota are exposed to complex chemical cocktails in the environment, being neurological active contaminants part of them. Thus there is a need to identify neurological hazardous chemical cocktails in the field. Here we present experimental results showing that the *D. magna* can be used as a neurological model to assess chemical mediated neurological defects following exposures during embryonic stages, that *D. magna* is also a good neurological model to study how gut dysbiosis affects the central nervous systems and cognition, and how it is possible to detect chemicals that may promote Parkinson using *D. magna* locomotion kinematics.

Finally, we propose a framework to identify neurological active hazardous chemicals in the field.

1.07.P-Mo026 Similar Metabolomic Responses of *Daphnia magna* to Insecticides with Different Modes of Action.

Marelize Marsay¹, Paul van den Brink² and Victor Wepener¹, (1)North-West University, South Africa, (2)Wageningen University and Research (WUR), Netherlands

Daphnia magna is used as an aquatic macroinvertebrate model species for laboratory toxicity testing to identify chemical hazards and assess chemical risks. The Adverse Outcome Pathway framework enables the understanding of how a contaminant's mode of action affects an organism and where these effects occur. This framework is based on the principle that if a contaminant results in a similar molecular initiating event, a cascade of key events downstream will follow a similar pathway. It can be expected that a similar pathway and adverse outcome can then be expected. These outcomes can include respiration, swimming behaviour, and reproduction, just to name a few. This study aimed to investigate the effect of two insecticides with different modes of action on the metabolic profile of *Daphnia magna*. This study applied an untargeted metabolomics-based approach to identify metabolites and metabolic pathways affected after exposure to imidacloprid and deltamethrin. Daphnids were exposed for 48 hours to sublethal concentrations of 25.5 mg/L imidacloprid and 0.4 µg/L deltamethrin. These concentrations are based on 30% of the LC50 for each insecticide. Metabolomic profiling revealed disruptions in the amino acid, carbohydrate, and lipid metabolism, where both insecticides disrupted overlapping pathways that are energy related and oxidative stress. Deltamethrin caused a much stronger metabolic impact, with more metabolites significantly affected in specific pathways. While imidacloprid mainly altered carbohydrate, sugar, and general energy metabolism, deltamethrin severely disrupted amino acid, nitrogen, glutathione, and nucleotide pathways. This indicates a more intense oxidative and cellular stress response. Overall, both pesticides target similar metabolic systems regardless of the mode of action which will result in similar adverse outcomes. Nevertheless, deltamethrin induces more severe pathway-level disturbances at significantly lower concentrations.

This work is based on the research supported by the NRF-NUFFIC (Grant Number: 120207).

1.07.P-Mo027 Susceptibility of *Daphnia magna* to immune-stimulating and immune-suppressing effects of pharmaceuticals

Anja Coors, Miriam Hoen, Marc-Christopher Reinnig and Matthias Findeiß, ECT Oekotoxikologie GmbH, Germany

Within the world of human-use pharmaceuticals, immune-stimulants and immune-suppressants are used to support the human immune system, e.g. to fight off viruses, or to suppress immune reactions that would e.g. lead to the rejection of transplanted organs. Environmental organisms exposed to pharmaceuticals targeting the immune system may not only show signs of general toxicity, but also could be affected by specific immunotoxic effects. The innate immune system specifically is evolutionary highly conserved, and represents the key defence mechanisms of invertebrate organisms lacking an adaptive immune system. While the current environmental risk assessment for human-use pharmaceuticals requires a targeted analysis for pharmaceuticals with specific modes of action, immune-related specific effects are not explicitly mentioned. In addition, there are no established test guidelines for investigating such potential effects in invertebrates. In this presentation, we demonstrate the use of an invertebrate host-parasite model, involving *Daphnia magna* as host, for investigating the influence of an immune-stimulant as well as an immune-suppressant on the outcome of the host's battle with its bacterial endoparasite *Pasteuria ramosa*. We observed that both pharmaceuticals influenced the host-parasite interaction in a way that is in agreement with the intended use of the pharmaceuticals in human patients. These results demonstrate that *D. magna* is a suitable model for studying immunotoxicity in invertebrates and, secondly, that pharmaceuticals targeting components of the innate immune system can have specific effects in exposed invertebrate organisms.

1.07.P-Mo028 The impact of tobacco extracted compounds on daphnids

Emma Rowan and Konstantinos Grintzalis, Dublin City University (DCU), Ireland

There is a growing global recognition of the devastating effects of pollution, which remains one of the most pressing environmental challenges of our time. Among its many sources, tobacco pollution represents an overlooked contributor with serious ecological consequences. While the health impacts of smoking are widely acknowledged, the environmental burden of tobacco production, consumption, and waste is equally alarming. Discarded cigarette butts, which constitute one of the most common forms of litter worldwide, can persist in the environment for up to fifteen years. During this time, they release a complex mixture of toxic chemicals including nicotine, heavy metals, and polycyclic aromatic hydrocarbons into surrounding soils and water bodies. This leaching process contaminates aquatic ecosystems, threatens wildlife, and contributes to the broader issue of chemical pollution. Addressing tobacco pollution, therefore, requires not only public health interventions but also improved waste management and policy measures to mitigate its long-term environmental impact. Current pollution assessments primarily focus on the detection of chemicals in the environment to estimate water quality; however, these methods are often descriptive and insufficient for understanding ecological impacts. This limitation underscores the need for effect-based methods as more sensitive tools for risk assessment. Daphnids are key species in molecular ecotoxicology and serve as effective indicators of environmental health.

In this study, we employed a combination of phenotypic and holistic approaches to investigate the impact of extracts from tobacco on these aquatic organisms. Integrating assessments of toxicity, growth, survival, feeding behaviour, and key enzymatic activities revealed distinct molecular and physiological responses, which serve as “molecular fingerprints” of exposure to tobacco-derived contaminants. This comprehensive approach highlights the potential of the water flea as a sensitive bioindicator to assess ecological risks from tobacco pollutants, acting as an equivalent to a “canary in the coal mine” for freshwater ecosystems.

1.07.P-Mo029 The short-term Juvenile Hormone Activity Screening Assay (JHASA): intra-laboratory findings and statistical issues.

Bruna ANDREOTTI DA SILVA AMARAL¹, Sarah ODDOUX¹, Florence DEVAL¹, Veronica Gonzalez-Andres², Aymeric Bellemain¹, Monika Ratte³ and Benjamin Daniels³, (1)Rovaltain Research Staphyt, France, (2)Rovaltain Research Staphyt, Spain, (3)ToxRat Solutions GmbH & Co.KG, Germany

Juvenile hormones (JHs) play crucial roles in the developmental and reproductive processes of *Daphnia magna*. Several studies have demonstrated that JHs and their analogs, such as the insect growth regulators pyriproxyfen and diofenolan, are involved in sex determination. Exposure to these compounds induces the production of male neonates in subsequent broods of *D. magna*. Consequently, the production of male offspring is a relevant endpoint for detecting endocrine-disrupting chemicals (EDCs) with JH activity. The OECD Test Guideline 253, “Short-term Juvenile Hormone Activity Screening Assay in *Daphnia magna*”, was developed to screen substances for short-term JH activity and detect their endocrine-disrupting potential. In this assay, *Daphnia* aged 10–17 days are exposed until their second reproduction, and the sex of the offspring from this brood is recorded. If male offspring are produced in treated groups and none in controls, the substance is considered “active” without the need for statistical analysis.

In this study, two molecules known to act as juvenile hormone analogs in *D. magna*, pyriproxyfen and diofenolan, were tested. Preliminary OECD TG 202 assays were conducted to determine the EC₅₀ values for each substance (0.283 mg/L for pyriproxyfen and 0.328 mg/L for diofenolan). To avoid acute effects, half the EC₅₀ was used as the maximum concentration in the definitive assay. Three concentrations were tested for pyriproxyfen (30, 70, and 140 µg/L) and five for diofenolan (10, 20, 41, 82, and 172 µg/L).

In the definitive tests, no males were observed in the controls, whereas a high proportion of males appeared at low concentrations of both substances. The sex ratio effect was evident from the lowest dose tested, and reproduction decreased with increasing concentration.

Beyond the results of our study, we identified some issues with the statistical approach recommended in the TG when a dose-response curve is based on more than three treatment levels. These issues relate to the recommended procedure for calculating ratios, the use of arcsin transformation regardless of sample size, and the explicit advice against using the Cochran-Armitage test, despite this being a powerful method for analyzing quantal data, including extrabinomial variance.

Our findings confirm the sensitivity of *D. magna* to JH analogs and highlight the need for refinement of OECD 253's statistical recommendations to ensure correct data interpretation in endocrine disruption screening.

1.07.P-Mo030 To What Extent Can the Fungicide Azoxystrobin Affect the Uptake and Elimination of Copper in *Daphnia magna*?

Marius Schmitt¹, Kayawe Valentine Mubiana², Karel Viaene³, Ronny Blust² and Karel De Schamphelaere¹,
(1)GhEnToxLab, Ghent University, Belgium, (2)University of Antwerp, Belgium, (3)ARCHE Consulting, Belgium

Copper (Cu) is essential for a well-functioning metabolism in almost all living organisms. However, like most essential metals, Cu can cause toxicity when internal concentrations exceed essential needs. To a certain extent, organisms can regulate their internal Cu concentrations to ensure homeostasis and avoid toxicity. In aquatic systems, metals often occur as mixtures with other chemical micropollutants, both organic and inorganic. The uptake and elimination processes of metals have been extensively studied in many aquatic organism's but less is known about how these processes can be affected by the presence of organic substances.

We investigated the extent to which the presence of the fungicide azoxystrobin affects the uptake and elimination of Cu in *D. magna*. Azoxystrobin is a mitochondrial respiration inhibitor that affects the organism's energy metabolism. Based on its MoA, we hypothesised that azoxystrobin may cause an increased uptake and decreased elimination of Cu in *D. magna*. The study employed a stable isotope (⁶⁵Cu) approach to determine the uptake rate over a 72-h period and the elimination rate after 24 h of elimination. In the uptake phase, *Daphnia* were sampled every 2h for 12h, after 24h, 48h and 72h and internal ⁶⁵Cu concentrations were measured. In the elimination experiment, *Daphnia* pre-exposed for 48h to ⁶⁵Cu were transferred to clean medium and sampled every 2h for 10h and after 24 h. Per time point, three replicates of 10 individuals (5-6 days old) were sampled. Based on earlier chronic reproduction tests, the effect concentrations (EC) of copper of 5% and 25% effect were used in this study. The tested treatments were ⁶⁵Cu alone, azoxystrobin alone, a binary mixture of ⁶⁵Cu-azoxystrobin and a control treatment. A two-compartment model was applied to derive uptake and elimination rate constants. The differences between uptake and elimination rate constants of Cu alone and in the presence of azoxystrobin were interpreted. Preliminary results indicate that the presence of azoxystrobin increased ⁶⁵Cu uptake rates. These findings allow a deeper understanding of the interactions metal-organic mixtures have on organisms like *D. magna*. In the future these results will be used to optimize toxicokinetic models to enhance the predictions of internal metal concentrations in mixture situations with organic substances.

1.07.P-Mo031 Water fleas as “canaries in the coal mine” for the detection of cigarette-derived pollution in the environment

Izabela Antepowicz and Konstantinos Grintzalis, School of Biotechnology, Dublin City University, Ireland

Smoking is a leading global habit with implications for human health and the environment. While the adverse health effects of smoking have been extensively studied, the environmental impact of cigarette-derived pollutants remains underexplored. The waste produced from discarded cigarette filters takes up to fifteen years to decompose and leach out toxic chemicals in aquatic environments. Various analytical techniques employed in water monitoring identify contaminants, however, these methods are inadequate to provide early predictions and capture the underlying mechanisms for the observed effects in the ecosystem. This limitation highlights the need for comprehensive approaches in pollution assessment. Consequently, there is growing support from effect-based methods that assess the responses of key species, such as daphnids to pollutants. Daphnids are critical freshwater organisms that serve as valuable indicators of ecosystem health. In the context of New Approach Methodologies, daphnids provide significant advantages due to their alignment with the principles of the 3Rs (Reduce, Refine, Replace) and their conserved toxicity responses to more complex organisms, in phototoxicological studies. Our research focuses on the impact of smoked cigarette and e-cigarette filters on the

physiology and metabolism of neonates and four generations of *Daphnia magna*, followed by analysis of filter extracts to assess their chemical composition. By integrating phenotypic endpoints, such as growth, feeding and reproduction, with metabolic fingerprints, we aim to provide deeper mechanistic insights into the actions of these pollutants. Ultimately, identifying metabolic disruptions can yield more sensitive assessment metrics, allowing us to capture the mechanisms of action more accurately. This enables timely predictions of pollution hotspots, facilitating proactive management strategies to mitigate environmental damage before it becomes irreversible.

1.08 Democratization of Big Data: Live Demonstrations of Computational Platforms and Data Resources to Advance Chemical Safety Assessment

1.08.T-01 Navigating Chemical Spaces with COMPASS: Standardized Visualization of Chemical Data Sets

Jose Andres Cordero Solano¹, Jasmin Hafner², Kathrin Fenner³ and Kerstin von Borries⁴, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Environmental Chemistry, University of Zürich, Switzerland, (4)Technical University of Denmark (DTU), Denmark

Chemical safety assessments are often limited by missing data needed to describe environmental fate, exposure, and effects on human and ecosystem health. Data-driven prediction methods using machine learning and artificial intelligence offer promising ways to fill these data gaps by estimating chemical properties directly from molecular structures. However, because these models rely on existing data, their reliability is restricted to chemicals similar to those included in their training sets. Currently, there is no standardized reference to compare the applicability of different models across the wide range of chemicals in use. To address this, we developed COMPASS (COMParative chemical Space Systems), a user-friendly application that visualizes reference chemical spaces for marketed chemicals and four application-oriented domains: pharmaceuticals, pesticides, PFAS, and natural products. These reference chemical spaces were created using well-curated reference lists and visualized through t-distributed stochastic neighbor embedding (t-SNE), which maps the high-dimensional structure of each domain into an intuitive two-dimensional space. The developed interactive tool enables users to explore chemical diversity and overlap across data sets. Model developers can use it to assess how representative their training data are and identify chemical domains where prediction reliability may be limited. Experimental researchers can use it to prioritize data generation for underrepresented compounds, while tool users can compare the applicability of different models within a given chemical space. By supporting more transparent and harmonized applicability assessments, the tool can strengthen confidence in chemical predictions and support iterative improvements in both data coverage and model representativeness across diverse chemical domains.

1.08.T-02 AMIRA: Animal-free Mechanistic Inference for Risk Assessment

Richa Malik¹, Bruno Campos², Claudia Rivetti³, Luigi Margiotta-Casaluci¹ and Christer Hogstrand⁴, (1)King's College London, United Kingdom, (2)Unilever, United Kingdom, (3)Safety, Environmental and Regulatory Sciences (SERS), Unilever, United Kingdom, (4)King's College London, ., United Kingdom

Environmental Risk Assessment (ERA) of chemicals is essential for regulatory approval and environmental protection. This traditionally requires testing across taxonomic groups of algae, crustaceans, and fish to determine the most sensitive species. With regulatory bodies drafting roadmaps to phase out animal testing in line with the 3Rs principle, it has become essential to learn from existing *in vivo* vertebrate data to inform the development of predictive models and support future risk assessments. Previously, we have shown that vertebrates exhibit higher sensitivity than invertebrates and algae for only 10% of chemicals in acute toxicity studies and 16% in chronic toxicity studies, indicating that data from algae and invertebrates may often be sufficient to establish environmental quality standards. Existing ecotoxicity databases do not offer a framework for systematically comparing inter-species and species-sensitivity patterns across chemical classes and taxa while also integrating mechanistic information.

To address this gap, we developed an interactive web application, AMIRA, that integrates ecotoxicity data across the entire chemical landscape, combining the U.S. EPA ECOTOX Knowledgebase (>10,000 chemicals, 6,395 species) with a curated dataset of 205 pharmaceuticals. Users interested in inter-species sensitivity can access harmonised acute and chronic toxicity datasets for, respectively, 631 and 674 chemicals. These represent chemicals with data from vertebrates and algae or invertebrates, enabling meaningful cross-taxon comparisons. AMIRA also enables users to identify chemicals that are more, less, or similarly sensitive within selected taxonomic groups by comparing statistical summaries and applying uncertainty factors. This approach facilitates

the identification and prediction of chemicals for which testing in non-vertebrates could replace fish studies without compromising environmental protection goals.

By integrating inter-taxa sensitivity patterns with pathway-based insights, AMIRA will support the mechanistic understanding of why species may be more sensitive to given chemical classes, enabling the prioritization of chemicals based on regulatory-relevant mechanisms of action and enable predictive modelling of untested chemicals rooted in biology. Interactive demonstrations at the session will showcase the potential of curated, interoperable datasets to accelerate ethical, efficient, and mechanistically informed chemical safety assessments.

1.08.T-03 PULSE: A Pilot UVCB (Substances of Unknown and Variable Composition, Complex Reaction Products or Biological Materials) Library for Substance Prioritization

Julie Krzykwa¹, Erin Maloney², Marc Fernandez³, Lilly Cesh³, Caitlin Tejowinoto³, Emma Schymanski⁴ and Sandrine Estelle Deglin⁵, (1)HESI Global, Washington, United States, (2)Shell Global Solutions International BV, Netherlands, (3)Environment and Climate Change Canada (ECCC), Canada, (4)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg, (5)HESI Global

Substances of unknown or variable composition, complex reaction products, and biological materials (UVCBs) account for a significant portion of chemicals registered globally and pose challenges for risk evaluation. To address these issues, the UVCB committee of the Health and Environmental Sciences Institute (HESI Global) has been developing a tiered, exposure-based framework to support UVCB prioritization. The initial tier (Tier 0) emphasizes basic characterization to identify potential exposure concerns, but this step depends heavily on the availability of fundamental compositional, exposure, and other data—information that is often sparse or inconsistent in public sources.

To help fill this gap, the HESI UVCB Committee developed PULSE, a Pilot UVCB Library for Screening and Evaluation. PULSE compiles Tier 0 information for 109 UVCBs selected from the Canadian Domestic Substances List and the OECD PFAS inventory. Data were collected across nine categories essential for initial assessment, including identifiers, structural descriptors, whole-substance ecotoxicity, constituent information, physicochemical properties, environmental fate, manufacturing and use data, registration status, and analytical metadata. Publicly accessible regulatory dossiers, chemical databases, scientific literature, and industry documents served as data sources. Since UVCB data are often incomplete or conflicting, it was very important that each source was assigned a qualitative reliability score to ensure transparent interpretation.

Data completeness varied substantially. Identification information was generally robust, while structural, physicochemical, and fate data were frequently partial or presented as ranges. Constituent data were limited for many substances, reflecting broader challenges such as inconsistent CAS mappings, limited public reporting, and the incompatibility of complex mixtures with single-compound database structures.

This pilot effort demonstrates the feasibility and value of a structured Tier 0 UVCB database. PULSE supports rapid screening, prioritization, and read-across within the developing UVCB framework and highlights areas where improved reporting and collaboration are needed to fully realize the database's potential.

1.08.T-04 envPath: Transformer-based Biotransformation Pathway Prediction and Open APIs for Regulatory Workflows

Tobias Olenyi¹, Liam Brydon-Brown¹, Tim Lorschebach² and Jörg S. Wicker¹, (1)University of Auckland, envPath Limited, New Zealand, (2)enviPath limited, Germany

Experimental pathway elucidation relies on long-term laboratory studies that are resource-intensive, time-consuming, and costly to scale. As a result, risk assessors and regulators often lack complete information on transformation processes, limiting their ability to identify persistent or hazardous transformation products.

enviPath addresses these challenges by combining pathway prediction models with an open, expert-reviewed database. The new transformer-based model is trained on curated biotransformation data and complements rule-based systems by proposing plausible transformations and pathway structures, including for chemistries with limited rule coverage. Alongside prediction, envPath serves as registry for curated transformation data—such as recent PFAS-focused datasets; reducing fragmentation and enabling users to search, retrieve, and compare deposited reactions with model-generated pathways. A redesigned web interface supports intuitive exploration of pathways and transformation records, while a documented REST API enables integration into automated screening, prioritization, and modelling workflows.

In this live demonstration, participants will walk through representative assessment tasks using both the interface and API: predicting pathways for candidate substances, identifying potentially persistent transformation products, retrieving relevant deposited reactions, and exporting results for downstream analysis or dossier preparation. Attendees will also have the opportunity to discuss practical use cases and future feature needs directly with the developers.

1.08.P Democratization of Big Data: Live Demonstrations of Computational Platforms and Data Resources to Advance Chemical Safety Assessment

1.08.P-Mo032 High-Throughput Screening and Structure–Activity Relationship Analysis of ER α -Targeted Toxicity for Emerging Pollutants

Yuchao Song¹, **WenHui Qiu²**, **Chunmiao Zheng¹** and **Yongguan Zhu³**, (1)Eastern Institute for Advanced Study, Eastern Institute of Technology, China (Mainland), (2)Guangdong-Hong Kong Joint Laboratory for Soil and Groundwater Pollution Control, School of Environmental Science and Engineering, Southern University of Science and Technology, China (Mainland), (3)State Key Laboratory of Urban and Regional Ecology, Research Centre for Eco-Environmental Sciences, Chinese Academy of Sciences, China (Mainland)

The estrogen receptor alpha (ER α) plays a critical role in mediating endocrine-disrupting effects of emerging pollutants, which puts higher demands on the classification and categorization of chemicals may have strong affinity based on computational prediction. In this study, we combined virtual screening and quantitative structure–activity relationship (QSAR) modeling to identify and predict the high ER α -affinity emerging contaminants. Firstly, a curated dataset of more than 150,000 emerging contaminants from the EPA and PubChem data sets were screened using molecular docking to determine binding affinities with ER α . Compounds with favorable binding energies (lower than -5.0 kcal/mol) were further analyzed for ER α -compound interaction. Here, machine learning-based QSAR models were then developed to capture the ER α -compound interaction using molecular parameters. Through expertise assistance and rigorous modeling methodology, an accurate and robust Extreme Gradient Boosting (XGBoost) model was established and key molecular structures influencing the binding energy were identified through SHAP analysis, including phenolic, stilbene, and halogenated aromatic motifs. The combined workflow enabled the identification the chemicals with potential of high binding energy with ER α . The predictions demonstrated the good generalization of ML model which was subsequently validated by in vitro experiments. This integrative approach offers a rapid and mechanistically informed strategy for the high-throughput screening emerging pollutants and prioritizing candidates for experimental assessment.

1.08.P-Mo033 The FACT database: A comprehensive collection of fish acute cell toxicity data.

Christoph Schuer¹, **Marion Revel²**, **Gilly Stoddart³**, **Christopher Fassbender³** and **Kristin Schirmer¹**, (1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)PETA Science Consortium Int. E.V., Germany

One of the barriers towards broader acceptance of New Approach Methods (NAMs) is a lack of confidence into, and understanding of, the capabilities of these assays. Such limitations are often due to the fact that not all relevant data is publicly available and an associated unclear definition of the applicability domain of the assay. The RTgill-W1 cell line acute toxicity assay is an alternative method for fish acute toxicity that has been validated and standardized as OECD Test Guideline 249. Its results have been shown to strongly correlate with fish acute mortality. In order to strengthen the confidence in this method and to characterize the continuously expanding applicability domain of the assay, we created the FACT (Fish Acute Cell Toxicity) database as a collection of currently available viability data from tests using fish cell lines. The database aims to be a comprehensive collection of available cell viability data associated with OECD TG 249. The data is collected through a standardized workflow that includes the assessment and rating of adherence to OECD TG 249. Thus, data is labeled as fully adherent, adherent with some deviations (e.g., different plate formats), or as relevant research data with a clear link to OECD TG 249. To reduce variability in the analysis of the data, concentration-response curves are created and visualized through a coherent and consistent method. Publicly available data is made available through the user interface of the database, which can be searched using the chemical name and a range of chemical identifiers, as well as filtered by experimental properties and OECD compliance level. Data can be exported as Excel or CSV file. Non-public data can be included but are only used internally to continually characterize the applicability domain of the assay. Each data point can be browsed individually through a detailed view. All data can further be explored without computational expertise through the

accompanying FACTexplorer dashboard that provides an overview and summary statistics of the data contained at any point in time. This effort aims to strengthen the confidence in the utility of fish cell lines for chemical hazard assessment through showcasing the breadth of toxicity data and applications.

1.08.P-Mo034 WATCH: A comprehensive WATER CHEMISTRY dataset for German freshwater systems

Theresa Piana¹, Ariane Moulinec², Andrea Sundermann³, Ralf Bernhard Schaefer² and Elisabeth Berger⁴,
(1)Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, Landau, Germany, Germany,
(2)Research Center One Health Ruhr, University Duisburg-Essen, Germany, (3)Senckenberg Research Institute and Natural History Museum Frankfurt, Germany, (4)Department of Electrical and Industrial Engineering, University of Applied Sciences Landshut, Landshut, Germany, Germany

Freshwater ecosystems are among the most biodiverse and valuable habitats on Earth, providing vital ecosystem services to both humans and wildlife. However, they are also among the most threatened ecosystems globally, with biodiversity declines exceeding those of marine and terrestrial systems. European policies, including the Water Framework Directive (WFD) and the Habitats Directive, seek to mitigate these threats by mandating ecological and chemical monitoring of surface waters which is why by 2006 all German federal states established water quality monitoring networks to comply with the WFD, resulting over time in the large-scale generation of georeferenced chemical and ecological data.

Despite this wealth of data, challenges persist due to fragmented data storage, inconsistent parameter terminology, varying measurement protocols originating from Germany's decentralized federal system. Limited accessibility further impedes comprehensive nationwide assessments and integrated freshwater management. To address these issues, we developed the WATCH database (WATER CHEMISTRY dataset for German freshwater systems), compiling data from all German federal states obtained from diverse institutional, governmental, and research organizations. WATCH encompasses data from over 23,000 sites, includes more than 1,500 chemical, physico-chemical, hydrological, and selected biological parameters, covering a timespan from 1929 to 2025, with the core dataset spanning from 2000 to 2020 for all states.

By unifying data from the different sources, WATCH provides immediate access to harmonized data, eliminating time-consuming requests and standardization efforts, enabling large-scale evaluations of pollutant loads, identification of contamination hotspots, assessment of policy effectiveness, and modelling of land use and climate change impacts. It establishes a foundation for evidence-based freshwater management, supporting ecological conservation, restoration, and sustainable governance across Germany.

1.08.P-Mo035 Predicting Environmental Persistence with PEPPER

Jose Andres Cordero Solano¹, Moritz Salz², Jasmin Hafner³ and Kathrin Fenner⁴, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)University of Zurich, Switzerland, (3)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (4)Environmental Chemistry, University of Zürich, Switzerland

Predicting environmental persistence of chemicals is a key aspect in developing Safe-and-Sustainable-by-Design chemicals, in screening substances for potential environmental risk in chemical regulation, and to parametrize exposure models. We have developed two models to predict persistence endpoints from chemical structure: (i) The Wastewater Treatment Plant (WWTP) breakthrough model, a Random Forest regressor trained on over 1000 chemicals with reported WWTP breakthrough data, and (ii) the soil primary biotransformation half-lives model, a Gaussian Process Regressor trained on half-lives observed for ~900 pesticides and pesticide biotransformation products in soil simulation studies. Both models have been fully validated and published, and they are implemented within the PEPPER (Predict Environmental Pollutant PERsistence) framework. Importantly, half-life and breakthrough predictions come with confidence scores to distinguish reliable from less certain predictions.

To make PEPPER models freely and easily accessible to the public, we provide an intuitive user interface at <https://pepper-app.streamlit.app/>. The web application can be used to predict persistence endpoints for single chemicals, or for batches of chemicals. The PEPPER source code is available on GitHub

(<https://github.com/FennerLabs/pepper>), and the PEPPER library can be easily installed via PiPy for a seamless integration into any Python workflow or software. We hope that our prediction tool proves useful to regulators, industry, and academia alike.

1.09.A Fish Model Species in Human and Environmental Toxicology

1.09.A.T-01 Architecture and validation of a scalable, modular, 3Rs compatible workflow to predict acute and chronic effects of plant protection products in fish

Tobias Pamminger¹, Sebastian Schmidt², Yvonne Wolf², Zhenglei Gao³, Daniel Faber⁴, Laura Franz² and Thorsten Leicher⁴, (1)Early Environmental Safety, Bayer AG, Monheim am Rhein, Germany, (2)Bayer Research & Development Services LLC, Germany, (3)Data Science, Bayer CropScience AG, Germany, (4)Bayer CropScience AG, Germany

Effective pest management is essential to protect crop yields and food quality under changing climate and agronomic conditions. Chemical plant protection products provide potent, scalable, and cost effective pest management options for farmers worldwide. However, non target organisms can come into contact with these products, which can result in adverse effects. To minimize effects on non target species (including fish), the environmental safety characteristics of candidate molecules must be characterized and, where needed, optimized early during product development. Traditional in vivo fish toxicity tests are time consuming, costly, ethically challenged, and require large quantities of test compounds, making them difficult to scale to the number of candidate molecules under consideration in early stage development.

To address this challenge and advance the next generation of sustainable plant protection products, we have developed a modular, scalable, in vivo free fish screening strategy. By integrating high throughput testing and computational methods into a single workflow, we can now make reliable predictions of acute and chronic effects in fish without the need for vertebrate in vivo studies. In this presentation, we describe the workflow's components and architecture and present results from our initial validation exercise covering 160 molecules with well characterized in vivo effects in fish.

We find that our workflow is well suited to predict both acute and chronic effects in fish for a wide range of plant protection products. In contrast to previous publications, we observe that empirical non vertebrate testing methods tend to underestimate acute effects of plant protection products on fish. For chronic effects, both applied models perform well overall, but tend to underestimate the toxicity of some insecticides.

We discuss the strengths and challenges of developing an in vivo free screening strategy and outline next steps to expand the workflow's capabilities. In summary, our approach enables the selection, optimization, and de-risking of candidate molecules without reliance on in vivo fish studies, aligning with Bayer's commitment to the 3Rs principles.

Disclaimer/Disclosure:

All authors are employed by Bayer Crop Science, a manufacturer and supplier of plant protection products. The authors are committed to advancing the adoption of New Approach Methodologies (NAMs) in both research and development as well as regulatory contexts, in alignment with Bayer's 3R (Reduce, Refine, Replace) principles.

1.09.A.T-02 Comparative Analysis of Testis and Brain Transcriptomes in Guppies Exposed to Legacy (Perfluorooctanoic Acid) and Emerging (GenX) PFAS

Rebecca Zgheib¹, Edoardo Pietropoli¹, Alessandro Devigili², Mery Giantin¹, Andrea Barbarossa³, Anisa Bardhi³, Mauro Dacasto¹, Clelia Gasparini² and Marianna Pauletto¹, (1)Department of Comparative Biomedicine and Food Science, University of Padova, Italy, Italy, (2)Department of Biology, University of Padova, Italy, (3)Department of Veterinary Medical Sciences, Alma Mater Studiorum University of Bologna, Italy, Italy

Per- and polyfluoroalkyl substances (PFAS) are highly persistent contaminants, and growing concerns surround the long-term effects of both legacy compounds, such as perfluorooctanoic acid (PFOA), and newer alternatives such as GenX (trademark name for the ammonium salt of hexafluoropropylene oxide dimer acid). Mechanistic evidence remains limited, particularly for sensitive tissues involved in reproduction and behaviour. This study compared the chronic effects of environmentally relevant levels of PFOA and GenX on the transcriptomes of the testes and brains of adult male guppies (*Poecilia reticulata*). Male and female guppies were exposed for 90 days to PFOA or GenX (1 µg/L). Whole-body concentrations were measured at the end of the experiment, and transcriptomic profiles of the testis and brain were generated using high-throughput RNA sequencing and

differential expression analysis. The aim was to identify tissue-specific molecular pathways responsive to each PFAS and assess whether legacy and emerging compounds trigger similar or distinct mechanisms. PFOA accumulated substantially in fish (bioconcentration factors 3.77–8.30), whereas GenX showed no measurable bioaccumulation. In the testis, GenX altered 22 genes linked to epithelial structure (*krt4*, *cdh17*), osmoregulation, and hormonal signalling (*prlr*), whereas PFOA elicited a modest differential expression in genes. In the brain, GenX triggered a pronounced down-regulation (77 down-regulated genes) of neuroendocrine and stress-related genes (e.g., *prl*, *cga*, *lhb*, *pomc*, *map3k15*), whereas PFOA produced a more heterogeneous effect involving genes associated with synaptic activity, calcium-binding proteins, and lipid metabolism. These findings suggest that GenX may have a greater transcriptomic impact than PFOA under chronic exposure, even in the absence of bioaccumulation. The distinct tissue-specific responses observed across the hypothalamic–pituitary–gonadal axis highlight potential reproductive and behavioral consequences following chronic exposure. This work provides new mechanistic insight into PFAS toxicity and supports improved ecological and human health evaluation.

Disclaimer/Disclosure:

This study has received funding from the University of Padova (call STARS@UNIPD2021; "AsTER - Assessing Toxicity Of An Emerging PFAS On Reproduction And Cognition: Behaviour And Molecular Mechanisms")

1.09.A.T-03 The Effect of Thyroid Hormone System Disruption on Neurodevelopment in Zebrafish Early Life Stages

Ellen Vandeputte, Phuong Ngoc Thi Mai, Lucia Vergauwen and Dries Knapen, University of Antwerp, Belgium

Thyroid hormone system disruption (THSD) is a major contributor to developmental neurotoxicity (DNT), with adverse outcome pathways linking THSD to impaired neurodevelopment and deficits in cognition, learning and memory in mammals. DNT research has primarily focused on rodent models but zebrafish offer a promising alternative due to rapid brain and central nervous system development within 72 hours post fertilization (hpf) and high conservation of these processes across vertebrates. They also exhibit learning and memory capabilities from early life stages. Additionally, literature shows considerable evidence in the linkage between THSD and DNT in fish. Here, zebrafish embryos were exposed to a known neurotoxicant, chlorpyrifos (CPF), and 6-n-propylthiouracil (PTU), a model THSD compound, from <1 to 120 hpf to assess THSD-related neurobehavioral effects. Learning and memory was evaluated using a Y-maze and custom T-maze assay, both based on spontaneous alternation behavior (SAB, i.e. the animal's tendency to alternate turn direction in consecutive turns). By closing one arm of the T-maze, the animal should choose to explore the other arm on the next trial, which requires proper memory. Data from T-maze and Y-maze, general neurotoxicity tests [spontaneous tail coiling (STC) and touch-evoked escape response (TEER)] and gene transcript analysis was combined to investigate whether THSD impairs learning and memory in zebrafish eleutheroembryos. No preference was observed for the previously free or blocked arm among negative controls for both CPF and PTU, raising the question whether eleutheroembryos exhibit SAB at this age. However, additional control runs with both arms open indicated that 66.67% of eleutheroembryos did exhibit SAB at 120 hpf. Interestingly, both maze assays show that exposed larvae prefer the arm they already visited. CPF exposure led to gene transcript effects on myelin (significant increase in *mbpa* transcript levels and a significant decrease in *sox10*) and pallium (significant decrease in *ascl1a* and *emx1*) related genes. PTU exposure downregulated *mbpa* and *gpr17* - both associated with myelination - and *emx2*. Given that CPF is known to impair learning and memory, and PTU elicits similar behavioral and gene transcript patterns, it is plausible that PTU also disrupts learning and memory. Overall, this work evaluated whether THSD affects the neurobehavioral system and supports the suitability of zebrafish as a model organism for DNT studies.

1.09.A.T-04 High Content Zebrafish Embryo Screening of chemicals and their mixtures

Stefan Scholz¹, Wibke Busch¹, Riccardo Massei, Dr¹, Gloria Chidiebere Ajugwo² and Emmanuel Ogwu Chukwu¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Goethe University Frankfurt, Germany

Understanding how complex chemical mixtures effect organisms remains a major challenge in environmental risk assessment. Mixtures often show combined effects that are difficult to predict. Using the zebrafish embryo model this work addresses whether hydrophobicity-driven baseline toxicity dominates in mixtures of specifically acting chemicals, and whether concentration addition (CA) and/or independent action (IA) models can be also be used to predict sublethal effects. To investigate these questions, we combined specificity assessment with High-Content Zebrafish Embryo Screening using automated imaging and behavioral analysis. Two hundred chemicals were tested across multiple developmental, behavioral, and morphological endpoints, and concentration-response models were generated using a KNIME workflow with embedded R scripts. Of the 200 chemicals screened, 118 produced effects below baseline toxicity predictions, allowing the modeling of concentration-response curves and estimation of EC50s. 34 compounds exhibited toxic ratios (TR) > 10, i.e. provoking mortality below the predicted hydrophobicity-driven baseline toxicity Twenty-six compounds produced sublethal effects well below lethal concentrations or when no mortality was observed in the tested range of concentrations. From these compounds, ten high-TR chemicals with diverse modes of action and similar concentration-response slopes were selected for mixture testing. A mixture was designed to achieve equitoxic contributions of the individual test compounds at the predicted LC50 for the assumption of IA. Therefore, the ratios of individual compounds were based on the modelled LC10 values. Experimental mixture responses are compared with CA and IA predictions. A mass-balance model is applied to evaluate the relation of the mixture effects to the predicted baseline toxicity using predicted internal membrane concentrations. This study demonstrates that High-Content Zebrafish Embryo Screening, combined with specificity assessment, provides a strong foundation to advances prediction of mixture effects and supporting mixture risk assessment.

1.09.B Fish Model Species in Human and Environmental Toxicology

1.09.B.T-01 Evaluating Steatosis Induction by Endocrine-Disrupting Chemicals in a Zebrafish Larval Model

Roeland Jackson¹, Nikita Korpel¹, Juliette Legler² and Jorke Kamstra¹, (1)Utrecht University, Netherlands, (2)Institute for Risk Assessment Sciences, Utrecht University, Netherlands

Metabolic dysfunction–associated steatotic liver disease (MASLD) is the most common chronic liver disorder, affecting about 25% of the global population. The disease ranges from simple steatosis to metabolic dysfunction–associated steatohepatitis (MASH) and can progress to cirrhosis and hepatocellular carcinoma. Although MASLD is strongly linked to obesity and type 2 diabetes, many non-obese and lean individuals also develop the condition, suggesting that additional factors influence its onset and progression. Emerging evidence implicates endocrine-disrupting chemicals (EDCs) as potential contributors, though the underlying mechanisms remain poorly understood. To address this gap, we assessed the ability of ten EDCs to induce steatosis in a zebrafish larval model.

Transgenic zebrafish embryos expressing a liver-specific fluorescent reporter, Tg(fabp10a:EGFP), were exposed to non-developmentally toxic concentrations of EDCs from 5- to 9-days post-fertilization (dpf). Liver development and lipid accumulation were then evaluated using a neutral lipid dye and fluorescent microscopy. Preliminary results indicate effects on both liver-specific lipid content and liver development. However, our data indicate that none of the tested EDCs induced a steatotic phenotype at 9-dpf; p,p'-dichlorodiphenyldichloroethylene could only increase liver-specific lipids after 5-day exposures, whereas benzo[a]pyrene reduced liver-specific lipid content after both 5- and 9-day exposures. Furthermore, exposures to triphenyl phosphate and perfluorooctanoic acid increased fluorescence of the transgenic reporter linked to an intracellular lipid transporter at 9-dpf, suggesting disruption of lipid metabolism, while not showing any effect after only 5-day exposures. These findings highlight the importance of assessing these endpoints beyond the 5-dpf window. Ongoing studies are assessing the effects of 9-day EDC exposures combined with high-caloric diets, as well as liver-specific gene expression of MASLD-related genes at 5-dpf, to further elucidate the role of EDCs in MASLD initiation and progression.

This project has received funding from the Horizon Europe research and innovation program of the European Union (EDC-MASLD project, grant agreement No 101136259).

1.09.B.T-02 Multiple Endocrine Activities of Bisphenol Mixtures in Brain and Intestine of Zebrafish Embryos: Implications for Hazard Assessment

Florian Geffroy¹, Nathalie Hinfray¹, Selim Ait-Aissa¹, Benjamin Piccini¹, Xavier Coumoul², Cléo Bodin³ and François Brion¹, (1)INERIS, Ecotoxicology of substances and environments (ESMI) unit, France, (2)Université Paris Cité, Inserm UMR-S 1124 HealthFex, France, (3)INERIS, Experimental Toxicology and Modeling (TEAM) Unit, France

Mixtures of endocrine-disrupting chemicals remain a major challenge for hazard and risk assessment, as current regulations underestimate their risks by assessing substances individually. In vitro mechanism-based assays are widely used to address this issue, yet in vivo tissue-specific endocrine responses to chemical mixtures remain poorly studied.

Herein, we aimed to determine whether bisphenol mixtures elicit tissue-specific endocrine effects in zebrafish embryos, focusing on receptor-regulated genes in the brain (cyp19a1b, regulated by zERs) and intestine (cyp3a65, regulated by zPXR, zAhR2 and zGR).

We first assessed the estrogenic and metabolic activity of 11 bisphenols using two transgenic zebrafish embryo assays: the EASZY assay (OECD TG 250), reporting brain expression of cyp19a1b, and the EMERGE assay, targeting intestinal expression of cyp3a65. All bisphenols except TCBPA induced cyp19a1b in the brain, and several also targeted cyp3a65 in the intestine, confirming their estrogenicity and revealing additional intestinal metabolic activity.

Based on single compound concentration-response data, we assessed a binary mixture of BPB and BPC using a ray design, and tested a six-bisphenol mixture at equipotent and environmentally relevant ratios. For the binary mixture, chemical analysis confirmed nominal concentrations and exposure stability. The BPB-BPC mixture produced additive effects on cyp19a1b and cyp3a65 expression in brain and intestine, respectively. For the six-bisphenol mixture, additive responses were observed at equipotent ratio in EASZY, while the mixture at environmentally relevant ratio led to two-fold lower effective concentrations than predicted by the concentration-addition (CA) model, suggesting a weak synergy.

By expressing median concentrations of the six bisphenols in European surface waters as BPA-equivalents, an interpretable and regulation-relevant metric, an estrogenic activity of 14.7 µg BPA-Eq/L was quantified, below the BPA freshwater environmental quality standard (129 µg/L) but above that for drinking water (2.5 µg/L). Together, these findings highlight the relevance of transgenic zebrafish embryos to capture endocrine activity of mixtures of compounds with similar modes of action in specific target cells and organs, while considering whole-organism toxicokinetics. This approach, combining biological assays with predictive models such as CA, supports improved mixture hazard assessment into a regulatory context.

1.09.B.T-03 Assessing Molecular Responses to Groundwater-relevant Contaminant Mixtures in Zebrafish Eleutheroembryos: A Transcriptomic Approach for Effect-Directed Analysis

Lyen Marie Marcelo Castro¹, Sotonye Dere-Biemgbo¹, Santiago Gómez-Herrera¹, Liliya Sokalchuk Sokalchuk¹, Marta Casado¹, Anna Jurado¹, Laia Navarro-Martin² and Victoria Osorio¹, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (2)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

As climate change exacerbates droughts, cities like Barcelona will increasingly rely on alternative water sources such as urban groundwater (UGW). However, UGW quality is compromised by wastewater and freshwater intrusion carrying pharmaceuticals, pesticides, and other micropollutants. This complex mixture may pose health risks poorly captured by single-chemical assessments, highlighting the need for effect-based monitoring and mechanism-focused tools. The zebrafish eleutheroembryo model provides a whole-organism perspective to detect sublethal and developmental effects, and, when combined with omics, reveals early molecular responses

and disrupted pathways. Transcriptomics in particular stands out for its sensitivity and genome-wide coverage, making it ideal for mixture toxicity assessment. Integrating transcriptomic biomarkers into effect-directed analysis (EDA) may enhance its sensitivity to help identify key toxicity drivers within complex mixtures. In this study, we exposed zebrafish embryos to a synthetic mixture of 77 organic compounds found in Barcelona's UGW, including pharmaceuticals, pesticides, herbicides, and industrial chemicals at concentrations ranging from 0.2 to 251 µg/L. Mortality and swim bladder inflation were recorded at 5 dpf, and transcriptomic analysis was performed on embryos from non-lethal doses. Target genes related to key toxicological pathways were analyzed using RT-qPCR. Mortality increased sharply at higher exposures, exceeding 80% above 33 µg/L. Swim bladder inflation emerged as a highly sensitive endpoint and was impaired at all concentrations, ranging from 30–63% inflation compared to controls (90±11%), with effects observed at environmentally relevant concentrations in Barcelona's UGW. While no significant changes were observed in genes related to thyroid disruption, neurodevelopment, and organ development, genes involved in xenobiotic metabolism responded markedly, including significant *cyp2k18* upregulation at 15 µg/L, preceding the onset of mortality. Non-monotonic responses were evident at intermediate doses in mortality, swim bladder inflation, and gene expression. RNA-Seq is currently being performed to identify additional sensitive biomarkers for EDA, and further work will expose eleutheroembryos to fractionated mixtures to validate the toxicants driving these effects. Ultimately, this approach aims to provide a sensitive, mechanistic tool for assessing complex mixtures in environmental monitoring.

1.09.B.T-04 Zebrafish (*Danio rerio*) as a New Approach Methodologies (NAM)-model for Thyroid Hormone System (THS) Disruption-mediated Developmental neurotoxicity (DNT) – A case study with Methimazole

Pernille Ambus Kjær, Henrik Holbech, Sina Volz and Anna Paulsen, SDU, Denmark

Thyroid hormones (THs) are essential for brain development and neurodevelopmental processes, particularly myelin formation within nerve cells. Consequently, endpoints sensitive to developmental neurotoxicity (DNT) are critical when assessing the thyroid hormone signaling (THS)-disrupting potential of chemicals. Current DNT evaluations rely on rodent guideline studies (OECD TG 426 and TG 443), which are resource-intensive and require large numbers of animals, limiting chemical coverage and leaving no validated methods for environmental hazard assessment. In line with the 3Rs and the EU's roadmap to phase out animal testing, there is growing emphasis on developing New Approach Methodologies (NAMs). Zebrafish (*Danio rerio*) have emerged as a promising model in ecotoxicology and NAM development, as they are considered non-protected animals until free-feeding begins at 5 days post fertilization (dpf).

To address the need for sensitive NAM endpoints, we investigated methimazole (MMI) as a model THS-disrupting chemical and hypothesized that MMI would induce neurotoxic effects and brain developmental alterations through THS mechanisms. We present preliminary results on brain morphology changes following exposure to four sublethal concentrations of MMI. Quantitative analysis revealed significantly smaller brain size in 33-day-old zebrafish compared to controls (Student's t-test, $p = 0.0064$), with the optic tectum also significantly reduced ($p = 0.00002$). In contrast, no significant effects were observed at 5 dpf for either brain size or optic tectum. These findings suggest that zebrafish eleutheroembryos cannot predict brain alterations occurring at later life stages under the tested conditions. A full dataset will include additional brain regions such as the telencephalon, diencephalon, and myelencephalon.

We also confirmed THS disruption in both 5 dpf and 33 dpf zebrafish, evidenced by significant upregulation of the *tpo* gene. Transcriptional analyses of THS-related genes (*dio1*, *dio2*, *dio3a*, *thraa*, *thrb*) and DNT-relevant genes (*mbp*) will be presented, alongside immunohistochemical staining of thyroid follicular cells and myelin basic protein to evaluate the sensitivity of additional DNT markers.

1.09.P Fish Model Species in Human and Environmental Toxicology

1.09.P-Mo036 Dietary Exposure to Bisphenol E Increased Abundance of Nocardia in Zebrafish Gut Microbiome

Michaela Vykypllova, Barbora Zwinsova, Lucie Blahova, Hana Dufkova, Petra Borilova Linhartova and Ondrej Adamovsky, Masaryk University, Czech Republic

Bisphenol A (BPA) is known for endocrine-disrupting effects and can alter immune responses and the gut microbiome, highlighting the need to evaluate its alternatives. Bisphenol E (BPE) is increasingly used as an alternative to BPA in consumer products, yet its biological effects remain largely unexplored. In this study, we investigate how long-term dietary BPE exposure affects intestinal microbial communities in zebrafish (*Danio rerio*).

Adult zebrafish (n=100) were exposed for 30 days to feed containing BPE, at 500 µg/kg (Low) or 5000 µg/kg (High), reflecting environmentally relevant and worst-case scenario. Intestinal content was collected, and the gut microbiome community structure was analyzed by 16S rRNA amplicon sequencing. Functional shifts in microbial metabolic production were also predicted.

Sequencing data revealed a statistically significant dose-dependent increase in the relative abundance of *Nocardia* species, including *N. asteroides*, *N. neocaledoniensis*, and *N. rhizosphaerihabitans* ($p < 0.001$, Kruskal-Wallis test). *Nocardia* are opportunistic pathogens causing nocardiosis, chronic granulomatous disease in fish, associated with gut dysbiosis, intestinal tissue damage and immune activation. Nocardiosis causes high mortality and has resulted in severe economic losses in aquaculture. Predicted functional changes in microbial metabolites were not statistically significant. However, genomic analyses of *Nocardia* spp. revealed high biosynthetic potential. *Nocardia*'s metabolites, including siderophores, may modulate surrounding microbiota and promote dominance of pathogenic *Nocardia*.

Although the overall gut microbiome community remained comparable across exposure groups, the robust increase in *Nocardia* reveals a biologically relevant shift that may have significant implications for gut health and host-microbiota interaction. This study provides the first evidence of microbiome alterations linked to BPE exposure, suggesting potential implications for fish health and immune regulation. The findings highlight the need for further evaluation of BPA substitutes which may contribute to risk assessment.

1.09.P-Mo037 Perfluorooctanesulfonamide-induced epiboly delay is associated with decreased ATP production within zebrafish embryos

John Hoang, Nicholas Jimenez, Keivon Faizi, Qibo Xiang, Emma Fencel, Rebecca E Yates, Jay Gan and David C. Volz, University of California, Riverside, United States

Per- and polyfluoroalkyl substances (PFAS) have been widely used within various industrial processes and consumer products, such as food packaging and fire-fighting foams. PFAS persistence within environmental media has led to ubiquitous exposure in humans and wildlife. We previously conducted a high-content toxicity screen of 38 different PFAS within the first 72 h of zebrafish development. This screen identified perfluorooctanesulfonamide (PFOSA) as the most potent developmental toxicant among the 38 PFAS tested. At non-lethal concentrations, exposure to PFOSA from 0.75 to 6 h post-fertilization (hpf) – a developmental window that includes cleavage, blastulation, and early-gastrulation – resulted in a concentration-dependent delay in epiboly (epiblast cell migration) by 6 hpf. Therefore, for this study, we determined whether 1) PFOSA delays epiboly similar to Cytochalasin B (CCB), a potent actin polymerization inhibitor, by inhibiting actin polymerization within the yolk, as epiboly progression is reliant on yolk-associated actin networks, and 2) PFOSA-induced effects are associated with a decrease in embryonic ATP, as PFOSA is a potent uncoupler of oxidative phosphorylation in vitro. To accomplish these objectives, we employed zebrafish embryo-based chemical exposures, liquid chromatography-mass spectrometry, phalloidin-based staining of F-actin, laser-scanning confocal microscopy, mRNA-sequencing, and luminescence-based ATP assays. Although PFOSA and CCB induced a similar magnitude of epiboly delay beginning at 4 hpf following initiation of exposure at 0.75 hpf, PFOSA did not, contrary to CCB, significantly decrease yolk-associated actin within embryos. Using

mRNA-sequencing, we found that, consistent with chemical-specific differences in actin polymerization effects, PFOSA-exposed embryos were also transcriptionally different from CCB-exposed embryos. Moreover, phenotypically matched, PFOSA-exposed embryos at 6 hpf were transcriptionally similar to vehicle-exposed embryos at 5 hpf, and PFOSA delayed the maternal-to-zygotic transition (MZT) beginning at 5 hpf. Finally, PFOSA-induced epiboly delay was associated with decreased ATP levels in vivo, an effect that was partially mitigated by co-exposure to exogenous ATP. Overall, our findings suggest that PFOSA exposure during early embryonic development decreases ATP production in vivo without affecting actin polymerization, an effect that was associated with PFOSA-induced delays in epiboly and the MZT.

1.09.P-Mo038 New approach methodologies for aquatic toxicity testing – Omics enhanced Fish Embryo Test (E-FET)

Sebastian Eilebrecht¹, Mounir Bouhifd², Wim De Coen², Fabian Essfeld¹, Panagiotis Karamertzanis², Claire Elisabeth MacKenzie³, Anna-Maija Nyman², Benedikt Ringbeck⁴, Marta Sobanska² and Tomasz Sobanski², (1)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)European Chemicals Agency (ECHA), Finland, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany

The REACH regulation requires chronic fish toxicity testing, such as the Fish Early Life Stage (FELS) test, which is resource-intensive and reliant on a high number of vertebrate animals. To support the development and regulatory uptake of animal-free new approach methods (NAMs), this study examined whether transcriptomic points-of-departure (tPODs) derived from zebrafish embryos can serve as protective and predictive indicators of chronic toxicity for 16 industrial chemicals with differing modes of action and sensitivity profiles. Using an enhanced Fish Embryo Toxicity test (E-FET) for each substance zebrafish embryos were exposed to five sublethal, analytically confirmed concentrations spanning the NOEC–LOEC range reported from FELS studies. Subsequent transcriptomic profiling, including RNA sequencing, differential gene expression analysis, and benchmark dose (BMD) modeling via DRomics, enabled the derivation of gene-level concentration–response relationships and tPOD values. The majority of chemicals that induced growth or survival effects in FELS also produced clear, concentration-dependent transcriptional alterations in the embryos, and the resulting tPODs generally mirrored FELS NOECs, with particularly strong alignment for substances primarily affecting growth. Chemicals that produced no observable effects in FELS similarly showed no transcriptomic signal in the E-FET, supporting the relevance and sensitivity of the tPOD approach. For two substances, tPOD derivation was not possible due to rapid degradation in the test medium resulting in insufficient exposure, underscoring the necessity of rigorous test concentration validation and application testing - particularly for substances with low solubility, high adsorption, or instability. These findings further indicate that semi-static exposure designs may be inadequate for certain chemical classes and that alternative systems should be considered to ensure stable exposure conditions. Collectively, the study provides strong evidence that zebrafish embryo tPODs can serve as early, protective indicators of chronic fish toxicity, while also highlighting current methodological limitations and the need for broader chemical evaluation to fully substantiate their utility for regulatory decision-making.

1.09.P-Mo039 Identification of Biomarkers for Immunosuppression in PAMP-challenged Zebrafish Embryos using Transcriptome Analyses

Kirsten Germing¹, Elke Eilebrecht¹, Sebastian Eilebrecht², Martina Roß-Nickoll³, Joachim Kurtz⁴ and Christoph Schaefer¹, (1)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)RWTH Aachen University, Germany, (4)University of Munster, Germany

It is assumed that in stressed ecosystems, pathogens exert strong pressure on populations. In addition, the organisms in the environment are exposed to a high number of environmental pollutants. The ecotoxicological hazard and risk assessment of chemicals do not include the identification of effects regarding the immunocompetence of organisms. However, studies indicate that chemicals can induce various effects on immune related parameters of organisms. Immunotoxic effects of chemicals that impair the immunocompetence of organisms could influence host-pathogen-interactions and could pose a significant threat to the stability of ecosystems. Thus, the regulatory authorities claim that methods must be developed to identify immunotoxic modes of action (MoA) of chemicals.

The project aims at the identification of reliable markers for the MoA of immunomodulatory chemicals in zebrafish (*Danio rerio*). For this, the classic zebrafish embryo toxicity test was adapted and the chemical exposure is followed by an immune challenge, which enables the investigation of chemical effects in the activated immune system. In a first step, a suitable Pathogen-associated-molecular-pattern (PAMP) that induces an immune system activation, was identified. In four independent experiments the PAMP flagellin was shown to induce a specific and reproducible immune response.

In the main experiments, freshly fertilized zebrafish eggs are exposed to a chemical for 48 h followed by an immune challenge via flagellin injection. After 3 h, the RNA of the exposed embryos is extracted and a transcriptome analysis is performed. In the first experiment with the immunosuppressive drug clobetasol propionate (CP) as exposure chemical, the flagellin treatment as well as the CP-treatment affected mostly genes involved in immune processes. The differentially expressed genes (DEGs) of the PAMP exposure were compared to the DEGs of CP-PAMP and sorted into hyper (stronger differential expression in CP-PAMP than in PAMP treatment), hypo (lower differential expression) and non-responsive genes (consistent expression). Interestingly, the hypo-responsive genes which are mostly involved in immune processes reveal an additive effect of CP and PAMP, indicating that CP suppressed the immune system activation by flagellin.

The data of all five experiments will serve to identify reliable markers for immunosuppressing MoA after immune system activation, which could be integrated into classic ecotoxicity testing.

1.09.P-Mo040 Integrating Molecular and Behavioral Endpoints to Assess neurotoxicity of BPA Alternative Compounds

Angela Centeno¹, Maria Santos de Sousa e Costa², Marta S. Monteiro², Liliya Sokalchuk Sokalchuk³, Joselyne Caceido¹, Valerie S Langlois⁴, Ines Domingues⁵ and Laia Navarro-Martín⁶, (1)Institute for Environmental Assessment and Water Research, IDAEA-CSIC, Spain, (2)University of Aveiro, Portugal, (3)IDAEA-CSIC, Spain, (4)National Institute for Scientific Research (INRS), Canada, (5)CESAM - Department of Biology, University of Aveiro, Portugal, (6)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Understanding the link between molecular endpoints and phenotypic outcomes is crucial in ecotoxicology to establish adverse outcome pathways and better predict environmental risk. This study aims to identify correlations between molecular-level responses and behavioral impairments following contaminant exposure. Thus, transcriptomic changes and alterations in locomotory behavior in zebrafish (*Danio rerio*) early life stages were assessed after exposure to BPA and BPA alternatives BPAF and BPZ. Furthermore, the sensitivity of two exposure protocols was compared: a continuous 120-hour exposure starting at ~ 3 hours post-fertilization (hpf), and a shorter 24-hour exposure at 96 hpf larvae. The shorter exposure targets a stage when the chorion is no longer present, potentially reducing confounding effects that may occur during early embryonic exposure. We hypothesize that the 24-hour larval exposure may demonstrate equal or greater sensitivity due to direct contaminant interaction without the protective chorion barrier. Results from this comparative approach will inform best practices for zebrafish toxicology testing. This work will further enhance our understanding of BPAF and BPZ mechanisms of action and consequent threats for ecosystem health.

Disclaimer/Disclosure:

This work was supported by the European Partnership for the Assessment of Risks from Chemicals (PARC), funded by the European Union's Horizon Europe research and innovation programme under Grant Agreement No. 101057014

1.09.P-Mo041 Toxic Legacies: Ecotoxicity of Phenylarsenical Chemical Warfare Agents and Their Transformation Products in Freshwater and Brackish Model Organisms

Alischa Helena Becker¹, Noora-Kaisa Rantanen², Raisa Turja³, Harri Kiljunen², Hanna Hakulinen², Henner Hollert⁴ and Sarah Johann⁴, (1)Goethe University Frankfurt, Germany, (2)Finnish Institute for Verification of

the Chemical Weapons Convention (VERIFIN), Finland, (3)Finnish Environment Institute (SYKE), Finland, (4)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany

Approximately 50,000 tons of chemical warfare agents (CWAs) were dumped in the Baltic Sea after the World Wars, which was considered the most efficient and safest disposal method at the time. Progressive corrosion of metal shells and casings results in the release of CWAs into the environment. Originally designed to cause physiological harm to humans, CWAs also pose a significant threat to aquatic ecosystems. Current environmental risk assessment of CWAs is primarily based on in silico analyses and a limited number of in vivo studies, with a predominant focus on intact CWAs. However, emerging evidence highlights that transformation products can also be considerably toxic to exposed biota. Given the rather scarce knowledge on CWAs and their transformation products toxicity, it is essential to develop a customized, multi-level bioassay battery for a holistic ecotoxicological assessment. Arsenic-containing agents are among the most commonly dumped CWAs. This project aims to evaluate the ecotoxicological effects of the CWA-related phenylarsenicals Clark 1 and phenyl(dichloro)arsine and their methylated transformation products methyldiphenylarsine oxide, methylphenylarsinic acid and dimethylphenylarsine oxide. All CWAs selected have previously been detected in Baltic Sea sediments. Freshwater and marine model organisms spanning different trophic levels are used (*Danio rerio*, *Gammarus fossarum*, *Oryzias melastigma*, *Gammarus oceanicus*). By extending beyond traditional freshwater test species, this approach aims for a more ecologically representative toxicity profile for marine and brackish ecosystems. To evaluate early developmental alterations and to establish acute toxicity thresholds, the fish embryo toxicity (FET) test (with *D. rerio* & *O. melastigma*) was conducted in accordance with the OECD No. 236 guideline. FET-derived thresholds are furthermore used to define non-lethal, yet biologically and environmentally relevant effect concentrations for neurotoxicity testing, addressing a relevant mode of action. Systemic identification of neurotoxic pathways is achieved by linking key events at the biochemical, tissue and organismal level with state-of-the-art techniques. Expected outcomes include novel insights into neurobehavioral effects, particularly locomotor impairment in early life stages of *D. rerio*. Ultimately, this research seeks to enhance ecosystem-based risk assessments and drive more effective environmental management strategies for sea-dumped CWAs.

1.09.P-Mo042 Chronic Fish Toxicity Case Studies toward a Best Practice Guidance Document

Adriana Wigh¹, Bruno Campos², Noémie de Croze³, Kyle Roush⁴, Takahiro Suzuki⁵, Lauren Brown⁶, Stephanie B Kennedy⁷, Markus Hecker⁸, Ryan Heisler⁹ and Amelie Ott⁹, (1)Henkel AG & Co. KGaA, Germany, (2)Unilever, United Kingdom, (3)L'Oréal, France, (4)Procter & Gamble, United States, (5)Kao Corporation, Tokyo, Japan, (6)ToxStrategies, Inc., United States, (7)ToxStrategies, United States, (8)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (9)International Collaboration on Cosmetics Safety (ICCS), United States

Chronic fish toxicity data form part of aquatic safety assessments and are mandated under frameworks such as EU REACH. However, traditional in vivo methods rely heavily on animal testing, are resource-intensive and provide limited information on a few model organisms to protect the environment holistically. In line with the European Commission's roadmap to phase out animal testing and priorities highlighted by ECHA in their KARC 2025 document, there is growing momentum to implement New Approach Methodologies (NAMs) within Next Generation Risk Assessment (NGRA) for chronic aquatic toxicity.

This International Collaboration on Cosmetics Safety (ICCS)-led project aims to address standard information requirements for chronic fish toxicity by evaluating the applicability of NAMs through multiple case studies focused on cosmetic ingredients. Insights from these case studies will be consolidated into an ICCS best practice guidance document to help regulatory and industry safety assessors.

The work is driven by a tiered approach: starting with identification of data gaps and developing solutions to support safety assessments and regulatory registration dossiers (e.g., under REACH), ultimately progressing towards applying environmental Next Generation Risk Assessment (NGRA).

The ICCS project is closely aligned with case studies led by other organizations, ensuring cross-fertilisation of approaches and harmonisation of data integration strategies. Together, these efforts aim to inform and shape future OECD Integrated Approaches to Testing and Assessment (IATAs) for chronic aquatic toxicity, promoting global regulatory acceptance of NAM-based frameworks.

The poster will provide an initial project overview and outline planned case studies to foster discussion and collaboration with the SETAC community. Ultimately, this work supports regulatory acceptance of NAMs and NGRA, advancing environmental protection anchored on modern science.

1.09.P-Mo043 Advancing Safety Assessment of Redox Flow Battery Electrolytes Using Zebrafish and Aquatic Models: Multi-Endpoint Toxicological Insights

Andrea Weiner¹, Ander Arbelaiz¹, Idoia Ibarburu¹, Stefan Spirk² and **Arantza Muriana¹**, (1)BBD BioPhenix SL (Biobide), Spain, (2)Institute of Bioproducts and Paper Technology, Graz University of Technology and Ecolyte GmbH, Austria

Following the initial findings presented previously, this study expands the toxicological and ecotoxicological evaluation of quinone-based redox-active compounds used in flow battery systems. A multi-endpoint strategy was employed using new alternative models—Danio rerio, Daphnia magna, and Raphidocelis subcapitata—to assess developmental toxicity, endocrine disruption, and environmental impact. In the case of zebrafish, the protocols were extensively validated at Biobide. The ecotoxicological studies conducted are based on internationally recognized guidelines, such as the OECD Test Guidelines 201 and 202 for acute tests in algae and daphnia.

Four structurally distinct aminoquinones were tested. All compounds showed signs of teratogenicity in zebrafish embryos, with MHQ-DMA and MHQ-Morph classified as likely teratogenic based on teratogenic index values. In contrast, AQDS-Na was considered non-toxic under the tested conditions. Thyroid disruption assays revealed no goitrogenic effects for most compounds, except for MHQ-DMA, which induced a statistically significant reduction in thyroid fluorescence. Bioavailability analysis showed low internal absorption (<10%) in zebrafish larvae, suggesting that observed effects may be driven by surface interactions or indirect mechanisms rather than systemic exposure.

Ecotoxicological assays demonstrated that AQS-Na, MHQ-DMA, and MHQ-Morph were toxic to Daphnia magna, causing significant immobilization at low concentrations. All four compounds inhibited algal growth in Raphidocelis subcapitata, with EC50 values in a comparable range, indicating consistent toxicity across species. These results highlight the importance of integrating multiple biological endpoints to comprehensively assess the emerging battery materials' safety profile. The findings support the application of Safe- and Sustainability-by-Design (SSbD) principles in the development of next-generation energy storage technologies.

KW: teratogenicity, thyroid disruption assay, ecotoxicology, Zebrafish, Daphnia magna, Raphidocelis subcapitata, NAM.

1.09.P-Mo044 Analyzing the Metabolic Effects of Nitrobenzene Exposure in Japanese Medaka (Oryzias latipes) with Consideration of Spawning Cycle

Jaehyeon Park¹ and Sang Don Kim², (1)School of Earth Science and Environmental Engineering, Gwangju Institute of Science and Technology (GIST), Korea, Republic of, (2)Gwangju Institute of Science and Technology (GIST), Korea, Republic of

For impact investigation of chemical accidents in Korea, National Institute of Chemical Safety suggest the criteria for calculating damage scale. However, based on the current standards, the damage can be recognized only visually identifiable damaged fish. As a result, there is no standard for assessing the damage to fish that were near the accident site but did not die, even though they may have been affected by chemicals invisibly. Therefore, it is crucial to establish accurate standards for distinguishing fish damaged by chemicals. We chose nitrobenzene as an experimental chemical, because it is a highly toxic chemical to fish and showing a lot of usage in Korea. Therefore, this research investigates the impact of nitrobenzene on fish metabolism, particularly in Japanese medaka (*Oryzias latipes*), considering their spawning cycle. We selected a sampling method to acquire samples from both the control and experimental groups as a singular entity, involving the concentration and measurement of extracorporeal metabolites released into the media over a designated time interval. We sampled four times a day in accordance to verify metabolic changes, which are characterized by daily ovulation. In this study, an investigation of the impact of both the spawning cycle and nitrobenzene exposure on the extracorporeal metabolites of medaka was undertaken. distinctive identification of metabolites that exhibited a notable decrease after nitrobenzene exposure, as compared to their pre-exposure state, indicated an encompassing influence on the spawning cycle. Using the Mummichog pathway analysis algorithm, we identified significant pathways in our dataset. As a result, pathways found to be affected by nitrobenzene were, in order, the steroid synthesis pathway, xenobiotics metabolism, and lipid synthesis. Subsequently, we identified biomarkers to differentiate changes attributed to the spawning cycle and those induced by nitrobenzene exposure.

1.09.P-Mo045 Automatization of the EASZY assay (OECD TG N° 250): A Robust Imaging Platform for the screening of Environmental Endocrine Active Substances

Typhaine BRINGEL¹, Cyril Turies², François Brion² and Noémie de Crozé¹, (1)L'Oréal, France, (2)INERIS, France

The TG OECD N°250 (EASZY assay), adopted in 2021, described a mechanism-based screening method designed to detect environmental endocrine active substances acting as agonists through estrogen receptors (ERs) to induce the expression of the ER-regulated cyp19a1b expression in transgenic tg(cyp19a1b:GFP) zebrafish embryos(1).

In this transgenic model, the GFP expression faithfully reports the endogenous cyp19a1b expression within the brain allowing to quantify in a noninvasive way the expression of this gene using fluorescence imaging.

The standard EASZY assay protocol involves exposing fertilized embryos (up to 4 hours post-fertilization (hpf)), to test substances for a period of 96 hours. Following this exposure, the fluorescence in the brain of the exposed organisms is measured using a fluorescence microscope (2). This imaging step presents a practical challenge. It required the manual positioning of each 96 hpf fry to obtain a clear dorsal image of the brain. This manual process is time-consuming and could introduce variability into the results inconsistent fry orientation. To improve this step, we applied an automated imaging strategy. This system integrates a VAST Bioimager (Union Biometrica Inc.) combined with a fluorescent microscope. The VAST Bioimager greatly facilitates precise and reproducible positioning of individual zebrafish fry through its rotative capillary mechanism. Additionally, we adapted the EASZY ImageJ macro to enable the analysis of Z-stack images, ensuring objective data extraction from the acquired fluorescent images.

Validation of this automated methodology was conducted using the 11 compounds from the OECD inter laboratory validation Assay (4). Our results indicate that the automated assay demonstrates sensitivity comparable to that of the established manual intercalibration study. A significant advantage of this automation is the improved reproducibility in fry positioning. This led to a measurable decrease in the standard deviation associated with the quantification of fluorescent intensity across batches of 24 fry exposed to identical experimental conditions.

In summary, the automated imaging method described here offers several key benefits for the OECD250 EASZY assay. It provides time savings in the imaging workflow, ensures a more reproducible positioning of the fry, while reducing the variability of GFP quantification which increase the statistical robustness of the data.

1.09.P-Mo046 Long-term toxicity to fish : building a weight of evidence approach

Yannick Bayona, Giacomo Grassi and Véronique Poulsen, L'Oréal, France

Different chemical regulations worldwide require that information on fish ecotoxicity is provided. This includes long term effects on fishes, depending on specific requisites, which have been historically derived from in vivo chronic toxicity assays, using juveniles or adult fishes. In line with the 3R objectives and the European Directive on the protection of animals used for scientific purposes, this use-case presents a weight of evidence (WoE) approach to assess the long-term ecotoxicity to fish, as an alternative to in vivo fish chronic studies. We propose an approach combining available information and generating additional data to build a robust WoE to cover long term toxicity to fish. To do so, we integrate a range of acute ecotoxicity endpoints, both already available and generated ex-novo, including the acute fish embryo toxicity assay (OECD TG 236), the RT-Gill assay (OECD TG 249) and historical fish acute toxicity data (OECD TG 203). In parallel, we leveraged information from the Endocrine Disruption test EASZY (OECD TG 250), in which additional observations were collected, such as morphological and physiological traits, as an indication of potential sublethal effects. The approach also includes interspecific effects comparison to complement fish data, such as ecotoxicity studies covering short- and long-term effects on freshwater invertebrates and algae. A Quantitative Structure Activity Relationship (QSAR) is also used to predict the chronic fish ecotoxicity as well as the identification of specific mechanisms of action based on chemical structure. Finally, the molecular properties that may drive specific physico-chemical behaviour (hydrophobicity, ionicity) are included in the approach. The rationale is built upon the analysis of acute-to-chronic ratios (ACRs), interspecies correlations, physicochemical properties, and sublethal effects, as a mean to cover long term toxicity to fish. We propose to develop a framework based on a range of lines of evidence to support whether chronic fish effects are expected or not, also providing an overview of the strengths and limits of our approach. Ultimately, by proposing a synthetic approach, we strive to contribute to

paving the way towards a comprehensive framework to determine when chronic fish testing could be considered necessary or conversely avoided for regulatory assessment.

1.09.P-Mo047 Developmental Toxicity and Transcriptional Changes in Zebrafish Embryos following Exposure to PM2.5 Extracts

Su-Bok Joung¹, Eunhye Kim², Taeyeon Kim¹, Hyejin Shin¹ and Kyungho Choi², (1)Seoul National University, Korea, Republic of, (2)School of Public Health, Seoul National University, Korea, Republic of

Particulate matter $2.5 \mu\text{m}$ (PM2.5) is a major environmental concern in Korea, despite national regulations and seasonal management policies. Its health effects, particularly during winter, remain a significant issue. In this study, we examined the developmental toxicity of PM2.5 using a dechorionated zebrafish embryo model, focusing on phenotypic changes and transcriptional alterations in thyroid and neuronal genes. PM2.5 samples were collected from December 2024 to February 2025 in Korea, representing high-concentration winter exposure scenarios. PM extracts were prepared using an organic solvent mixture, diluted in E3 medium containing 0.01% dimethyl sulfoxide, and applied to embryos from 4 hours post-fertilization (hpf) to 5 days post-fertilization (dpf). Morphology and gene expression were assessed. PM2.5 exposure caused developmental abnormalities in a concentration-dependent manner. Embryos at the highest exposure level (300 $\mu\text{g/mL}$) exhibited marked pericardial edema, reduced body length, shortened jaw structure, and smaller eye size. The thyroid-related gene *dio2* and the neural development gene *mbp* were downregulated, indicating disruption of endocrine balance and neurodevelopmental processes. These findings suggest that Korean PM2.5 extracts can induce developmental toxicity and impair thyroid-mediated neurogenesis. Chemical analysis identified abundant ionic species, including NO_3^- , SO_4^{2-} , and NH_4^+ . Further studies are needed to identify specific toxic constituents in the PM extracts and to understand the consequences of transcriptional changes in key genes in zebrafish.

This research was supported by Particulate Matter Management Specialized Graduate Program through the Korea Environmental Industry & Technology Institute (KEITI) funded by the Ministry of Environment (MOE).

1.09.P-Mo048 Modelling Chronic Toxicity to Fish Considering Data Uncertainty

Chanita Kuseva¹, Stela Kutsarova¹, Ksenia Tankova¹, Daniela Nedelcheva¹, Marin Georgiev¹, Atanas Chapkanov¹, Ovanes Mekenyan¹ and Terry W Schultz², (1)Laboratory of Mathematical Chemistry (LMC) Prof. Assen Zlatarov Burgas State University, Bulgaria, (2)The University of Tennessee, College of Veterinary Medicine, United States

Chronic toxicity to fish is a crucial regulatory endpoint; however, experimental NOEC studies are costly and time-consuming and raise ethical concerns. This study develops two complementary *in silico* methods for predicting chronic fish toxicity while explicitly accounting for data uncertainty. Approach 1 creates acute-to-chronic QSAR models based on an enhanced Verhaar mode-of-action (MoA) and adds alerts for protein and estrogen receptor reactivity. Linear regressions were derived for MoA1–MoA3; however, due to limited data and regulatory considerations, MoA4 and MoA5 were excluded. MoA1 and MoA2 were later integrated into a model supported by mechanistic, structural, and parametric applicability domains. Approach 2 uses a two-step read-across/trend-analysis workflow that first assigns compounds to the augmented Verhaar MoA and then finds structural analogs for prediction. Variability in experimental NOEC values was modeled using a Gaussian distribution ($\sigma = 0.67$), while QSAR prediction uncertainty was represented with Student-t distributions. Together, these methods provide chemical-specific uncertainty ranges for NOEC estimates. Internal 1000-fold cross-validation demonstrated strong model performance. Correlations between acute and chronic toxicity were high for MoA1 and MoA3 ($R^2 = 0.84$) and acceptable for the combined MoA1+MoA2 model ($R^2 = 0.74$). Predicted NOEC distributions were transformed into probabilistic GHS chronic hazard categories, enabling grey-zone classification when uncertainty prevents definitive categorization. All workflows were implemented in the QSAR Toolbox. By integrating experimental and model uncertainties, this approach enables probabilistic GHS classification rather than fixed categories, reflecting real data variability and reducing misclassification risk. This better reflects the variability of real data and lowers the risk of misclassification. These workflows also support 3R principles (Replacement, Reduction, and Refinement) by offering transparent, reproducible, and robust alternatives to chronic fish testing, suitable for preliminary hazard screening and regulatory prioritization.

1.09.P-Mo049 Challenges in Applying OECD 210 Validity Criteria: Refinement Opportunities

Annemiek Feijen-Stens¹, Maria Blanco-Rubio Ph.D², Marcel Migchielsen¹, Mira Wenker¹, Sarah A. Hughes³,

Carla Bol¹ and **Marlly Guarín**², (1)Charles River Laboratories, Den Bosch-NL, Netherlands, (2)Shell Global Solutions International BV, Netherlands, (3)Shell Global Solutions (US) Inc, United States

The OECD Test Guideline (TG) 210 for the Fish Early-Life Stage (FELS) test is the standard method recommended under Annex X of the European Union REACH Regulation for fulfilling the long-term fish toxicity requirement. It specifies strict validity criteria and minimum fish numbers to ensure robust data. However, practical implementation often reveals challenges in fulfilling these criteria without compromising animal welfare or data integrity.

This presentation explores critical gaps in the application and interpretation of OECD 210 validity items, focusing on embryo quality, vague or inconsistent definitions of malformation, and their implications for study validity. The current guidance lacks clarity regarding acceptable levels of malformation in embryos and larvae and their relationship with final survival outcomes, as referenced in TG 210 paragraph 29 on abnormal appearance. These uncertainties frequently result in inconsistent validity assessments across laboratories and, in some cases, unnecessary repetition of animal testing. Additionally, such inconsistencies could lead to ecotoxicity data that misrepresent actual hazard potential, resulting in unreliable risk assessments and regulatory decisions.

Through analysis of fish embryo studies in fathead minnow (*Pimephales promelas*) and zebrafish (*Danio rerio*), we identify examples of sublethal findings and humane endpoints that illustrate the limitations of current validity criteria. Specifically, we highlight how clearer definitions of malformation thresholds (expressed as acceptable percentages), refined humane endpoints for euthanasia, and improved consideration of sublethal effects with potential or non-potential for regeneration could enhance both data quality and animal welfare. We propose that revision of the OECD 210 guideline should include explicit, evidence-based validity parameters that integrate malformation rates with survival and abnormal appearance criteria, while incorporating humane endpoints to minimise animal suffering. These refinements would improve the consistency of test interpretation across laboratories, reduce the need for repeated testing, and better align regulatory practice with the 3Rs principles of replacement, reduction, and refinement.

By identifying these opportunities, this work aims to support the scientific and regulatory dialogue on updating OECD 210 validity criteria to ensure robust, ethical, and reproducible fish early-life testing under regulatory requirements.

1.09.P-Mo050 The SEASON Project: How Will Climate Change Affect the Risk Associated With Sediments Contaminated With Organic and Inorganic Pollutants?

Marina Ricarte¹, Rudolf Aro¹, Ingrid Ericson Jogsten¹, Jana K. Geuer¹, Maria Larsson¹, Nikolai Scherbak², Viktor Sjöberg¹, Leo Yeung¹, Stefan Karlsson¹ and Steffen H. Keiter¹, (1)Man-Technology-Environment Research Center, Sweden, (2)Örebro Life Science Centre, School of Science and Technology, Örebro University, Sweden

Sediments are both a sink and a source of various organic and inorganic pollutants. In the SEASON project we aim to investigate how environmental changes (temperature, pH, and remobilization) affect the fate, availability, and toxicity of these pollutants. Additionally, by investigating how these changes influence sediment processes and microbial communities, we will develop models to predict the impact of these pollutants on aquatic ecosystems under climate change conditions.

The SEASON project consists of four different subprojects, three of which focus on studying the effects of metals, PFAS, and pollutant mixtures. These subprojects consist of various in vivo and in vitro assays, as well as aquatic microcosm simulations that can regulate climate change related parameters. The fate, bioavailability, and toxicity of pollutants in sediment will be studied, including microbiome and chemical analysis. The aim of the fourth subproject is to refine and develop predictive models for improved risk assessment under climate change conditions.

Zebrafish embryos have been used to investigate teratogenicity, developmental toxicity, behavioral changes, and

gene expression alterations caused by contaminated sediments using a contact assay. Based on these results, two sediments will be chosen for conducting the microcosm studies, in which various toxicological effects in adult zebrafish, including reproduction and behavior, will be assessed. Changes in temperature and pH will mimic climate change conditions, while remobilization events will be introduced to simulate heavy rain events. Microbiome analysis will be performed using different sequencing technologies not only on sediment samples, but also on fecal and intestinal samples from the fish. Chemical analyses will quantify PFAS, metals, and their speciation throughout the study. Effect-directed analysis (EDA) will be used to identify key toxicants in sediments used for microcosm studies. The subsequent creation of a predictive model will increase the understanding of the impact of climate change on sediment contamination and aquatic ecosystem health.

The SEASON project is funded by the Swedish Knowledge Foundation (Dnr. 20240010)

1.09.P-Mo051 Characterization of Thyroid Transmembrane Transporters in the Brain: Advancing the Utility of Zebrafish Embryos for Thyroid Hormone System Disruption Studies

Nora Karlsson¹, Nathalie Hendriks², Peter Cenijn², Elise Pesce³, Majorie Van Duursen², Lisa Annie Baumann⁴ and Timo Hamers², (1)VU University Amsterdam (VU), Sweden, (2)VU University Amsterdam (VU), Netherlands, (3)VU University Amsterdam (VU), France, (4)VU University Amsterdam (VU), Amsterdam, Netherlands

Transmembrane transporters at the blood-brain and brain-cerebrospinal fluid barriers are vital regulatory components of the intricate thyroid hormone (TH) system allowing for adequate supply of THs to the developing brain. Disruption of these transport systems can impair neurodevelopment in the embryonic brain and lead to adverse, irreversible outcomes in affected organisms. Improved mechanistic insights and better testing systems for endocrine disrupting chemicals (EDCs) targeting TH transport are therefore critical to protect human and environmental health.

A wide range of mammalian TH transmembrane transporters (THTMTs) belonging to the group of solute carrier proteins have previously been characterised in rodent models, overexpression cell lines and recently in a novel choroid plexus organoid model. These THTMTs belong to the families of monocarboxylate transporters (e.g. MCT8, MCT10), organic anion transporters (e.g. OATP1C1), and cationic amino acid transporter (e.g. LAT1, LAT2).

To study chemical effects on THTMTs, interspecies differences and in vitro to in vivo extrapolations are an ongoing challenge. While human cell-based models are preferred for studying human THTMT disruption in vitro, these models lack the in vivo complexity of a whole-organism vertebrate model.

Zebrafish (*Danio rerio*) embryos seem to be a promising model for studying THTMT dysregulation, with the potential to bridge the gap between in vitro work and studies of higher vertebrate organisms. In contrast to rats, MCT8 deficient zebrafish larvae display a phenotype similar to that of human patients with MCT8 mutations, suggesting conservation of important thyroid transport functions. Still, the expression patterns and spatial distribution of THTMTs in zebrafish remain largely unexplored.

In this recently started PhD project, the initial focus is on characterizing zebrafish orthologs for known human THTMTs. Gene expression pattern in zebrafish embryos will be assessed by qPCR, and their spatial localisation in the embryonic brain will be mapped via in situ hybridisation. This foundational characterisation will support future investigations of the impact of potential TH disruptors in different transgenic zebrafish lines.

1.09.P-Mo052 Rethinking Chronic Fish Toxicity Testing: Case Studies Toward an Integrated Approach to Testing and Assessment

Heike Laue¹, Michelle Rau Embry², Gordon Sanders¹, Mathijs Smit³ and Lucy Wilmot⁴, (1)Givaudan

International SA, Switzerland, (2)HESI Global, (3)Shell Global Solutions International BV, Netherlands, (4)ECETOC, Belgium

Assessment of aquatic toxicity is a cornerstone of environmental hazard and risk assessment under various regulatory frameworks. Chronic fish toxicity data are often required, with fish serving as a representative predator species for the pelagic environment. The Fish Early Life Stage (FELS) test (OECD Test Guideline 210) is the standard method for generating such data. However, the FELS test involves the use of hundreds of vertebrate animals, raising ethical and regulatory concerns, and typically relies on a limited number of standard species, creating uncertainty regarding the protection of more sensitive or threatened species.

In line with the EU REACH Regulation's requirement to make full use of existing information before conducting new vertebrate tests, there is growing interest in approaches that combine existing data and non-animal methods. These include the integrated use of read-across, acute fish toxicity data, non-vertebrate test methods (e.g., Daphnia assays), and New Approach Methodologies (NAMs) such as *in silico* predictions and *in vitro* fish cell line assays. Such approaches can strengthen predictive power in hazard and risk assessments while supporting the goal of reducing vertebrate testing.

Although tiered testing frameworks and integrated testing strategies (ITS) for fish toxicity exist, practical examples and a dedicated Integrated Approach to Testing and Assessment (IATA) for chronic fish toxicity are still lacking. Concurrently, new *in vitro* methods for assessing chronic fish toxicity are under development.

A group of experts coordinated by ECETOC are developing a series of case studies to explore how existing data, including non-vertebrate methods and NAMs, can be integrated to conclude on chronic fish toxicity. The case studies aim to cover a range of chemical types, uses, and industry sectors, as well as different regulatory contexts, such as risk assessment and classification and labelling. The intention is to assess data-rich and data-poor substances, and some case studies may include existing FELS data. This presentation will provide information on the case study substances, their regulatory and scientific context, and initial findings from the ongoing work.

The outcomes from this work are expected to inform regulatory and industry decision-making, potentially contribute to the development of OECD guidance, and support the broader European Commission Roadmap toward phasing out animal testing in chemical safety assessment.

1.09.P-Mo053 Distinct ecological risks associated to geogenic and smelting metal contamination.

Marisa Narciso Fernandes¹, Maira Rodrigues Lima², Iara da Costa Souza², Anieli Maraschi², Julieta Griboff³, Magdalena Monferran⁴, Daniel Wunderlin³, Caroline Souza², Silvia Matsumoto⁵ and João Batista Fernandes², (1)*Ciências Fisiológicas, Federal University of São Carlos (UFSCar), Brazil*, (2)*Federal University of São Carlos (UFSCar), Brazil*, (3)*National Scientific and Technical Research Council (CONICET), Argentina*, (4)*National University of Córdoba, Argentina*, (5)*Federal University of Espirito Santo, Brazil*

Metals and metalloids in aquatic ecosystems pose ecological threats to resident biota. This study evaluated 27 metal/metalloids in the water, sediment, and gills of *Oreochromis niloticus* collected in two coastal lagoons (Maembá and Carapebus) impacted by metallurgical activities and an aquaculture facility (Alegre) influenced only by natural geogenic inputs. The following were analyzed in the gills: the antioxidant enzymes superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), glutathione reductase (GR), and glutathione-S-transferase (GST); the non-enzymatic defense molecules glutathione (GSH) and metallothionein (MT); oxidative stress biomarkers (lipid peroxidation, protein carbonylation, and DNA strand breaks); histopathological lesions; and the density of mucous cells (MC). The concentrations of the metals/metalloids varied in the water and sediment of all sites. The gills of fish from the Maembá and Carapebus exhibited high concentrations of Al, V, Cr, Zn, and Sr; high SOD, CAT, GPx and GR activities; GSH depletion; pronounced oxidative damage (protein carbonylation and DNA strand breaks); extended histopathological lesions; and a high density of MC. The gills of fish from Alegre showed high levels of Fe, Ba, Rb, and Ce; elevated MT; and only focal histopathology; they could clearly be differentiated from the samples from impacted lagoons. This study provides novel evidence that metallurgical activities (smelting) can chemically modify metals and thus enhance their biological impact compared with natural geogenic sources. The combined use of biochemical and morphological biomarkers allowed for effective discrimination of different effects revealing distinct ecological risks associated with metal/metalloid contamination of different origins in aquatic ecosystems

1.09.P-Mo054 Integrating New Approach Methodologies to Inform Chronic Fish Hazard: A HESI Case-Study

Julie Krzykwa¹ and *HESI Global Next Generation EcoRisk Committee Alternatives to Chronic Fish Testing Working Group²*, (1)*HESI Global, Washington, United States*, (2)*HESI Global*

Regulatory demands for chronic fish early-life stage (FELS; OECD TG 210) data are increasing across sectors, yet default FELS testing can be resource-intensive and require substantial numbers of animals. Multiple new approach methodologies (NAMs) relevant to chronic aquatic toxicity have been developed and, in some cases, standardized (e.g., fish embryo and gill cell assays, hepatic biotransformation), but practical guidance for integrating these data into fit-for-purpose decisions remains limited. The HESI Alternatives to Chronic Fish Testing Working Group is developing a flexible, weight-of-evidence framework to evaluate when confidence in NAM-based evidence is sufficient to meet chronic fish data needs, and when in vivo chronic fish testing remains necessary. The framework is organized in two phases: (1) prioritizing whether chronic fish toxicity testing is needed given external and internal exposure potential and existing evidence; and (2) if chronic data are required, integrating diverse lines of evidence to estimate chronic endpoints and associated uncertainty. Potential key lines of evidence that could be incorporated into the framework include physicochemical and environmental fate data, in silico predictions (e.g., QSARs), acute-to-chronic ratios, invertebrate chronic data, existing in vitro assays (e.g., RTgill, fish embryo toxicity test), available mechanistic high-throughput data (e.g., ToxCast), and emerging endpoints such as transcriptomic points of departure.

To demonstrate feasibility and identify framework roadblocks, we are applying the approach to case studies. The chemicals of interest for case studies are selected based on the availability of robust in vivo chronic data and NAM data, enabling direct comparison of NAM-informed conclusions with in vivo ELS outcomes.

Ongoing analyses will evaluate how lines of evidence can be integrated together and how uncertainty shifts with data availability and agreement. Expected outputs include a transparent decision workflow and documented case studies to support consistent, chronic fish hazard and risk assessments.

1.09.P-Mo055 Assessment of (Neuro)developmental Effect Signatures of Organophosphate and Neonicotinoid Pesticides Using Zebrafish High-Content Morphology and Behavior Analysis

Prosper Ashibudike Opute¹, **Stefan Scholz²** and **Tamara Tal²**, (1)*University of Benin, Nigeria*, (2)*Helmholtz Centre for Environmental Research GmbH (UFZ), Germany*

Legacy organophosphates and modern neonicotinoids are still used globally despite region-specific restrictions. For many of these compounds, a knowledge gap exists regarding their potential developmental or neurodevelopmental effects, particularly during early life stages. This is further challenged by the frequent co-occurrence of pesticide mixtures in the environment, with scarce monitoring and mechanistic toxicity information available. To address this gap, we employed New Approach Methodologies (NAMs) using the zebrafish embryo as an alternative model. The aim of the study is to generate comprehensive, developmental toxicity and neurotoxicity fingerprints that can be compared to an existing reference library to predict underlying mode of action information. Zebrafish embryos were exposed to chlorpyrifos-oxon (CPO) from 0 to 4 days post-fertilization (dpf). At 4 dpf, automated imaging was performed, and a suite of morphological endpoints were quantified using FishInspector. Exposure to 0.03-5 μ M of CPO resulted in a range of concentration-dependent developmental toxicity effects. Quantitative analysis of morphological endpoints revealed a specific signature, characterized by pronounced reductions in swim bladder area ($AC_{50} = 0.15 \mu$ M), eye area ($AC_{50} = 4.93 \mu$ M), and a concomitant increase in yolk sac area ($AC_{50} = 0.95 \mu$ M). In contrast, mortality remained low (~25%), even at 5 μ M and there were no significant changes in heart rate, arrhythmia, or blood circulation. Morphology assessments and neurobehavioural profiles, captured with the VAMR assay, which assesses locomotor activity, startle responses, habituation learning, and memory retention at 5 dpf, will be performed for a range of organophosphate and neonicotinoid compounds. The next phase of this study will focus on prioritized organophosphates and neonicotinoids to compare potential class-specific morphological and behavioral fingerprints.

1.09.P-Mo056 Development of a Zebrafish Metabolome Atlas from Different Transgenic Lines with a Focus on Steroid Hormones and Lipids to Unravel the Effects of Endocrine Disruptors

Emilie Daut¹, **Sophie Otto¹**, **Nathalie Hendriks¹**, **Elise Pesce²**, **Manuel Heinzelmann¹**, **Lisa Annie Baumann³** and

Pim Leonards¹, (1)VU University Amsterdam (VU), Netherlands, (2)VU University Amsterdam (VU), France, (3)VU University Amsterdam (VU), Amsterdam, Netherlands

Zebrafish (*Danio rerio*) embryos are a well-established and important model in the research of endocrine disrupting chemicals (EDCs). They have many advantages like the homology to the human genome and a very high number of genes that can also be associated to human diseases. Furthermore, the simplicity of creating transgenic lines allows for even more focused and accessible research on specific biomarkers in (eco)toxicological and metabolomic studies including endocrinology. Moreover, these transgenic zebrafish are increasingly used for the assessment of EDCs in research and in a regulatory context. For example, different established and currently validated OECD test guidelines use transgenic fish lines to assess EDC-specific effects in embryonic life-stages. In the context of new approach methodologies (NAMs) and the EU roadmap for phasing out animal experiments, these models gain increasing importance. However, basic differences between zebrafish lines remain insufficiently described. To investigate if there are detectable and significant variances in the early life stage metabolome between different transgenic lines we compared various metabolite levels (lipids, steroids, neurotransmitters) of the wildtype line, a triple-transgenic line tg(eno2:GFP), gfap:mCherry, mbp:mCitrine (nervous and glial cells) and the tg(tg:mCherry) (thyroid follicles) line at multiple timepoints up to 5 days post fertilization. Samples of embryos were extracted and analysed using liquid chromatography combined with high resolution mass spectrometry. Based on the results we will focus on one of these lines to further explore how metabolites, incl. hormone levels differ throughout early life development. Embryos will also be exposed to EDCs to study how metabolite levels are influenced at different concentrations, and to increase our understanding of the mechanism of action.

This PhD project is part of the EU project “NeXED”, which is funded by the European Union’s Horizon Europe Research and Innovation programme, under the Marie Skłodowska-Curie Action (Grant Agreement number 101168892).

1.09.P-Mo057 Defining the EATS Effectome: A Review of Biomarkers Triggered by EATS Model Chemicals

Marta Ferreira da Silva and Henrik Holbech, Southern University of Denmark, Denmark

Model endocrine disrupting chemicals, characterized by their specific modes of action (MoA), are commonly used to study endocrine activity and adversity to support method development within the EATS pathways. However, increasing evidence shows substantial cross-over between endocrine systems, as well as secondary effects non-directly correlated with the endocrine modality of the chemical in question, challenging the assumption that these chemicals act on isolated pathways. Zebrafish exposed to compounds traditionally classified as estrogenic have been shown to influence thyroid histopathology, while thyroid hormone system disrupters have been reported to affect male reproductive development. This illustrates the complexity of endocrine interactions and the need for more integrated evaluations, particularly relevant in zebrafish, a widely used vertebrate model for studying endocrine disruption across multiple levels of biological organization. The aim of this study is to identify and synthesize endocrine-sensitive biomarkers and phenotypic endpoints reported for standard EATS model chemicals in zebrafish. To achieve this, we are conducting a structured literature review combined with analysis of existing Adverse Outcome Pathways (AOPs) associated with these chemicals. The review focuses on mapping commonly observed molecular, cellular, physiological, and developmental effects, identifying biomarkers and endpoints that appear pathway-specific versus those that reflect broader endocrine crosstalk, and highlighting inconsistencies or gaps in current evidence. By integrating available findings with AOP frameworks, this work will provide an overview of how EATS model chemicals manifest across different biological levels in zebrafish and evaluate the extent to which these markers reliably reflect specific or multiple endocrine pathways. This synthesis aims to support the refinement of endocrine biomarkers/endpoints, improve interpretation of results in zebrafish models, and help prioritize areas where additional mechanistic research is needed.

1.09.P-Mo058 Refinement of Fish Embryo Toxicity Test To Assess Ecotoxicological Effects of Nanoparticles

Alessandra Lama, Pamela Floris, Patrizia Bonfanti, Anita Colombo, Maurizio Gualtieri and Paride Mantecca, Research Centre POLARIS, Dept. of Earth and Environmental Sciences, University of Milano-Bicocca, Italy, Italy

The Fish Embryo Acute Toxicity (FET) test (OECD 236/2013) with the zebrafish (*Danio rerio*) is designed to determine acute toxicity of a wide range of chemicals on fish embryos' development and survival. This study assesses the contribution of the FET test to the evaluation of potential hazards and toxicity of sonochemically produced Zinc oxide nanoparticles (ZnO NPs), which are widely used as additives in various materials. One of the key benefits is its antimicrobial activity, mainly due to the redox properties of elemental zinc in nano form. Given that the fate, transport, and toxicity of NPs are heavily influenced by their intrinsic physicochemical properties and water chemistry parameters—such as pH, ionic strength (IS), and natural organic matter—we investigated how IS affects the properties and toxicity of ZnO NPs. ZnO nanopowder was dispersed in standard and diluted FET solutions; the latter having different IS, all comparable to that of freshwater. The Dynamic Light Scattering (DLS) technique assessed the NPs' hydrodynamic behaviour and surface charge, while Inductively Coupled Plasma–Optical Emission Spectroscopy (ICP-OES) analysed dissolution. Zebrafish embryos at 3 hours post fertilization (hpf) were exposed to increasing concentrations of freshly prepared ZnO NPs until 96 hpf. Lethality was recorded every 24 hours, hatching was evaluated from 48 hpf, and malformations and morphometric parameters were analysed at 96 hpf.

The results show that the simulated low-IS improved the suspensions' stability by decreasing the NPs' hydrodynamic size compared to standard IS conditions. These physicochemical changes may improve the ZnO NPs bioavailability for developing tissues, increasing the lethal and teratogenic potential of them, evidenced by higher rates of lethality and malformations. Conversely, the inhibition of embryo hatching—the main effect observed under standard test conditions—was partially alleviated under low-IS, as indicated by nearly a tenfold increase in the effect Concentration on Hatching (HC50).

These findings corroborate that the tolerance of zebrafish embryos to various IS media allows refining the FET test to match optimal NPs dispersion to enhance bioavailability and thus increase test sensitivity.

1.09.P-Mo059 Zebrafish to observe vascular responses associated with preeclampsia risk

Inhye Lee¹, Kyungho Choi¹ and Kyunghye Ji², (1)Department of Environmental Health Sciences, Seoul National University, Korea, Republic of, (2)Department of Health, Environment, and Safety, Yongin University, Korea, Republic of

Preeclampsia is a pregnancy disorder characterized by early disturbances in vascular regulation and kidney function. Experimental models capable of detecting these biological features are essential for assessing environmental influences on maternal risk. Zebrafish retain conserved angiogenic and kidney filtration pathways, and PFAS exposure has been epidemiologically linked to increased preeclampsia risk. Based on this evidence, zebrafish were used to examine vascular and kidney-related phenotypes following PFOA and PFOS exposure. Adult zebrafish were exposed to PFAS for 21 days. Fertilized eggs collected on days 7 and 14 were maintained under the same exposure conditions for 96 hours. Larval blood flow and heart rate were assessed using DanioScope, and vessel diameter was quantified with ImageJ to estimate relative vascular pressure. Gene expression related to angiogenesis and kidney filtration was evaluated in larvae and adult tissues. Larvae derived from exposed adults exhibited early functional alterations in vascular activity. Blood flow speed increased at the highest concentration, accompanied by elevated estimated pressure, whereas heart rate was unchanged. Body length decreased at the highest exposure level, indicating developmental stress. In adult gonadal tissue, angiogenesis-related genes showed decreased *vegfa* and increased *eng* expression. Exposed females also exhibited reduced gonadosomatic index, suggesting compromised reproductive condition. These findings demonstrate that zebrafish can detect early vascular and developmental phenotypes relevant to preeclampsia and support their utility for evaluating environmental chemicals that may influence maternal vascular risk.

1.09.P-Mo060 Towards Non-Lethal Ecotoxicology: Validation of a Non-invasive Biomarker Approach for Assessment of Benzo[a]pyrene Exposure in *Salmo trutta*

Coline Louvet¹, Patrice NOURY¹, Laura Garnero¹, Léa GOBILLOT², Valérie HAMELET², Lucía Viñas³, Emilie Réalis-Doyelle² and Carmen GONZÁLEZ-FERNÁNDEZ¹, (1)INRAE Lyon-Grenoble Auvergne Rhône-Alpes, Riverly unit, ECOTOX team, 69100 Villeurbanne, France, (2)Pôle ECLA (OFB, INRAE, USMB), France, (3)Oceanographic Centre of Murcia, Instituto Español de Oceanografía, Spain

Fish populations are experiencing a marked decline due to multiple environmental pressures, particularly chemical pollution. A challenge emerges consisting of finding reliable biomarkers to assess the physiological state of fish exposed to toxic stress using less invasive matrices. In this context, this study aims to apply non-invasive biomarkers, based on the analysis of biomarkers in skin mucus and serum, for comparison with those traditionally analysed in internal organs, to study the effects of pollution on fish. An experiment was therefore conducted on Brown Trout (*Salmo trutta*), exposed to benzo[a]pyrene (BaP), a genotoxic polycyclic aromatic hydrocarbon and common combustion by-product that contaminates aquatic environments and severely compromises fish health. To evaluate the relevance of these non-invasive approaches for monitoring responses associated with oxidative stress, detoxification, and immunity, fish received a single intraperitoneal BaP injection (at concentrations of 0.5 mg/kg or 10 mg/kg). A panel of biomarkers, including Ethoxyresorufin-O-deethylase (EROD), Glutathione S-Transferase (GST), Superoxide Dismutase (SOD), Carboxylesterase (CE), and bactericidal activity was subsequently analysed in the liver and mucus at different exposure times: 72 hours and 7 days after injection. The results confirmed significant BaP bioaccumulation in the liver and a strong hepatic EROD induction at 7 days, thereby validating the accumulation and the activation of Phase I detoxification pathways. Furthermore, BaP exposure increased the CE and SOD activity in the mucus, suggesting that oxidative stress can be detected via this non-invasive matrix. Nevertheless, other biomarkers, such as GST and bactericidal activity, showed no significant modulation. These observations reveal that non-invasive matrices reflect key physiological changes, often with a divergent temporal dynamic compared to the liver. These results confirm the relevance of BaP as a contaminant model and highlight the value of mucus as non-invasive matrix. They represent a promising tool for assessing the effects of pollution on fish, allowing relevant physiological information to be obtained without resorting to invasive methods.

1.09.P-Mo061 Reproductive toxicity of tributyl phosphatate (TBP) and its underlying mechanisms in zebrafish and fathead minnows

Ba Reum Kwon, Amos Agyei, Aigerim Abdimanova, HyeonYoung Choi and Bryan W. Brooks, Baylor University, United States

Due to the phase-out of polybrominated diphenyl ethers (PBDEs) in the global market, the use of organophosphate esters (OPEs) has increased as an alternative flame retardant. Among OPEs, tributyl phosphatate (TBP) is widely used in various applications, including building materials, electronics, textiles, and furniture, to prevent the ignition and spread of fires and protect human life and property. Due to its lipophilicity, TBP can persist in the environment and bioaccumulate, raising potential health concerns for both humans and aquatic organisms. Experimental studies have shown the sex hormone and neuroendocrine-disrupting effects of OPEs; however, toxicological information on TBP is largely limited. In the present study, we aimed to investigate the reproductive toxicity of TBP and its underlying mechanisms, with a particular focus on gonadal lipid metabolism and sex steroid biosynthesis, using two model fish species: the fathead minnow (*Pimephales promelas*) and the zebrafish (*Danio rerio*). Following OECD Test Guideline 229, adult breeding pairs of both fathead minnows (FHM) and zebrafish (ZF) were exposed to TBP at nominal concentrations of 0, 0.03, 0.3, and 3 mg/L for 21 days. Fecundity and gene expression changes related to lipid metabolism and steroidogenesis were measured. The number of cumulative eggs produced significantly decreased in a concentration-dependent manner in both adult FHM and ZF following 21-day exposure to TBP. This reproductive decline could be explained by the altered gene expression of gonadal steroidogenesis, i.e., *3bhsd*, *17bhsd*, *11b2hsd*, *cyp17*, and/or *cyp19a* in the gonads of both adult FHM and ZF. Moreover, the gene expression of *ppar?*, *srebp1*, and/or *srebp2*, which are critical for fatty acid and glucose metabolism, was disrupted in the gonads in both species, suggesting a metabolic disruption could partly explain the reduced fecundity. Overall, our results indicate that exposure to TBP may impair reproductive function by disrupting steroidogenesis and gonadal lipid metabolism in both FHM and ZF. Considering the environmental persistence and bioavailability of TBP, further research is needed on its long-term and transgenerational effects to understand its ecological risk.

1.09.P-Mo062 A Mechanistic approach to regulatory compliant Quantitative Structure-Activity Relationship modelling for chronic fish

Paul Thomas, Maxime Edelblout and Floriane Larras, KREATiS SAS, France

Of all the studies in environmental toxicology, the chronic fish test is probably the hardest to replace and in doing so, would save the highest number of vertebrate animals.

QSARs have long been seen as “screening” tools with limited capacity to directly replace experimental studies let alone chronic ones. Nevertheless, the release by the OECD of the QAF (5 principles for model validation and 4 principles for prediction validation) reduces uncertainty in predictions. The QAF aided in the production of far more accurate models that can serve as stand-alone replacements to experimental guideline studies.

High accuracy QSARs have been created combining two approaches:

1) mechanisms of toxic action (MechoA), similar to Molecular Initiating Events (MIE) are inextricably linked to two keystones: on one side, structural features and on the other, biological matrix interactions. More than one structural group can have the same mechanism of action (thus, the same toxicological impact).

2) The use of the chemical activity approach relating the external metric “water solubility” to the toxicity endpoint (EC10) using only data that was rigorously validated internally to create “High Accuracy QSARs”. These models, in the KREATiS iSafeRat® model suite may thus be better termed Quantitative Mechanism-Activity Relationships or “QMARS”.

Original fears that chronic QSARs were not possible due to unaccounted for metabolic impact on the test substance in long term studies were rejected as such metabolism was inherently included in the training set data. At this stage the iSafeRat® Platform boasts only 4 QSARs for fish chronic predictions. However, as these are related to 4 MechoA sub-Classes, and each sub-class contains multiple structural groups, the diversity of structures for which accurate predictions of chronic fish toxicity can be made is extremely high, covering thousands of REACH registered substances for which chronic data are currently absent.

While in silico methods cannot replace all chemicals (e.g. nanoparticles, UVCBs where potentially bioavailable constituents are unknown), the use of a reliable model like the QMARS of the iSafeRat® platform can serve as a stand-alone replacement or as part of a weight of evidence approach with confidence when falling within the applicability domain of the model, significantly reducing testing for the majority of chemical substances and ultimately for biocides, agrochemicals and pharmaceuticals as the science progresses.

1.09.P-Mo063 Assessment of Macrophage Counts in Tg(mpeg1) Zebrafish Following PFAS Exposure

Sarah Elise Smebakk Nilsen¹, Elena Katharina Nicolay², Jan Ludvig Lyche¹, Oddvar Myhre³, Tamara Tal² and Selma Hurem¹, (1)Norwegian University of Life Sciences, Norway, (2)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (3)Norwegian Institute of Public Health, Norway

Per- and polyfluoroalkyl substances (PFAS) are contaminants of emerging concern increasingly found in the environment and human exposure pathways. Many PFAS can cross the placental, and blood brain barriers, resulting in developmental exposure. Macrophages are central elements of innate immunity, contributing to both homeostasis and immunomodulation. Microglia are resident macrophages in the Central Nervous System that play a key role in neurodevelopment, immune responses, synaptogenesis, and the maintenance of neural circuits. Disruptions in their function during critical developmental windows can impact both immune and neural outcomes underscoring the need for an understanding of their potential impact on the developing immune and nervous systems during chemical exposure. To address this gap, we assessed the impact of PFAS exposure on macrophage count and morphology in the whole body and head region using the (mpeg1:mCherry) zebrafish, which express an mCherry fluorophore under the control of the macrophage-specific mpeg1 promoter. Exposure levels were based on concentrations previously measured in the blood of Scandinavian populations (1x or 1000x the human blood concentration (HBC)). Zebrafish embryos were exposed from 0-4 days post fertilization (dpf) to 1000x HBC of either PFOA, PFHxS, PFNA, PFDA, PFUnDA, or 1x HBC of either PFOS or a ratio-based mixture of all six PFAS. The potential effect on macrophage numbers was compared to the solvent control (0.1% dimethyl sulfoxide) and to dextran sodium sulfate (DSS, 0.18%), a potential positive control which was previously shown to increase macrophage numbers. To quantify macrophages and evaluate morphology, embryos were anesthetized and embedded in agarose. High-Content Images were acquired as z-stacks over three tiles covering the entire larva using an ImageXpress Confocal HT AI system, enabling automated quantification of macrophages with a bespoke Python-based analysis pipeline. Analysis is underway and will quantify total body macrophages, and head region macrophages in ratio to whole body counts after exposure. Preliminary results show that exposure to 0.18% DSS increased whole body macrophage numbers relative to the solvent control, and a trend towards lower numbers following PFNA exposure (1000x HBC). Taken together, this approach will reveal whether exposure to single PFAS or a representative mixture results in reduced macrophage numbers, potentially indicative of dampened immune function.

1.09.P-Mo064 Use of RTL W1 Liver Cell Line in a Testing Platform to Monitor

Biotransformation/Degradation and for Mode of Action Studies for Nanomaterials; A Case study using Boron nitride (BN)

Mona Connolly¹, Elena García Sánchez¹, Ana Valdehita¹, Emmanuel Flahaut² and Jose María Navas¹, (1)INIA CSIC, Spain, (2)CNRS, CIRIMAT, University of Toulouse, France

The RTL W1 cell line from rainbow trout liver holds the potential to be used as a test system for long term studies on biotransformation/degradation because it has relevant metabolic capacities, and one can assess the extent to which a potential toxicant activates specific pathways or induces key metabolic enzymes in a bid to try to identify the real mode of action. The importance of performing longer term experiments in such cellular models lies in the fact that materials such as nanomaterials can change (transform/degrade) over time within these biological systems. Depending on the extent of this transformation/degradation, effects could either be driven by the pristine material “per se”, the transformed material or indeed any degradation products. This information is important for a complete understanding of the hazard, to determine what is driving effects and the ultimate biological fate of these materials. In this study the RTL W1 cell line was used to investigate the role of the aryl hydrocarbon receptor (AhR)/cytochrome P450 1A (CYP1A) biotransformation pathway activation in the cellular processing of nanotubes and nanosheets of boron nitride (BN) following 24h, 72h and 7 days exposure. After 7 days the nanosheets remained intact in cellular vesicles with no obvious transformation or degradation, while in cells exposed to nanotubes there was evidence of membrane piercing and much smaller transformed nanotubes in the cytoplasm. The AhR dependent CYP1A-catalyzed 7-ethoxyresorufin-O-deethylase (EROD) activity assay revealed increases in activity and increased gene expression of *ahr* and *cyp1a1* were measured in RTL W1 cells following exposure to the BN nanotubes, implicating activation of the AhR/CYP1A signaling pathway in the cellular processing of this material. On the other hand BN nanosheets did not increase EROD activity nor gene expression levels at any exposure time. Increased reactive oxygen species (ROS) were also measured following BN material exposure suggesting oxidative processes are also involved in the mode of action. This investigation using the RTL W1 liver cell line is the first to confirm the activation of this important biotransformation pathway by nanotubes of BN (or its degradation products). Such a platform is useful for nanomaterial biodegradation/transformation testing and to identify potential AhR/CYP1A pathway activation in the mode of action for other aromatic like nanostructures or degradation products.

1.09.P-Mo065 Rainbow Trout Alevin (RTA) Assay: Comparisons of transcriptomic points of departure with fish chronic toxicity data

Niladri Basu¹, Emily Boulanger², Hugo Marchand¹, Kritika Mittal³, Ke Xu¹, Rebecca Dalton, Ph.D.⁴, Florence Pagé-Larivière⁵, Doug Crump⁶ and Jessica Head², (1)McGill University, Canada, (2)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (3)Natural Resource Sciences, McGill University, Canada, (4)Ecological Assessment Division, Environment and Climate Change Canada (ECCC), Canada, (5)Environment and Climate Change Canada (ECCC), Canada, (6)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada (ECCC), Canada

There is regulatory, scientific, and ethical interest in the development of alternatives to vertebrate animal toxicity tests. The objective of this study was to establish a high-throughput test method for embryo-larval fish that could yield data comparable to both fish acute (i.e., 96-hr LC50s) and chronic (i.e., long-term, sub-lethal) toxicity tests; here, we focus on the ability of this test to help predict fish chronic toxicity. Rainbow trout alevins (~1 day post-hatch) were placed in individual wells (24-well plates) and exposed for 24 hr to 12 different concentrations per chemical. To date, 39 chemicals with diverse physical and chemical properties have been studied, including negative controls (fish medium water or 0.5% DMSO). To eliminate the need for a range-finding test, test concentrations were based on a tapered design which included an LC50 push zone (10- and 100-fold higher than the empirical LC50s listed in the U.S. EPA ECOTOX Knowledgebase), transcriptomic point of departure (tPOD) zone (six concentrations below the LC50 range on a half log10 basis), and baseline zone (10- and 100-fold lower concentrations). Mortality during transport, rearing, hatching, and experimental phases were all lower than guidance from OECD236. To ensure repeatability of the results, copper sulfate was studied four times and yielded consistent LC50 values. For most chemicals, putative LC50 values were obtained, and these tend to correlate with 96-hr LC50 values (fish acute toxicity). Sequencing data have been obtained for 33 chemicals. Bioinformatics analysis of these data using ExpressAnalyst shows that the number of gene benchmark doses ranges from 113 to 2118 across the dataset, with an average of 733 per chemical. For

each chemical, a tPOD (either mode, 10th percentile, or 20th gene) was calculable, with tPOD mode values ranging from 0.008 to 1,500 mg/L. Currently we have fish chronic toxicity data for 15 chemicals, with a statistical association between the tPODs data obtained here (i.e., 24 hour assay with fish embryos) and fish chronic toxicity data (i.e., whole animal studies that are at least 21 days in duration). The findings thus far are promising in terms of establishing a new test method, though work continues to expand our sequencing efforts to yield more tPOD data, test more compounds, expand the fish acute/chronic data, and continue discussions between academic and government partners.

1.10 From Mechanistic Insights and Innovation to Regulation: Integrating Behavioural Endpoints, AOPs and NAMs into Next Generation Environmental Risk Assessment

1.10.T-01 Every data point matters – maximising value for regulatory toxicology

Kristin Schirmer¹, Stephan Fischer², Willem Bastiaan Ravenhorst², Laure Chabot³, Simon Gutierrez⁴, Melanie Fischer⁵, Marion Revel⁵ and Christoph Schuer¹, (1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)aQuaTox-Solutions GmbH, Switzerland, (3)INERIS - Verneuil-en-Halatte, France, (4)Ricardo-AEA Ltd, Spain, (5)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

When New Approach Methodologies (NAMs) achieve the quality seal of the Organisation for Economic Co-operation and Development's (OECD) test guideline (TG) programme, they move a crucial step closer to regulatory use. Indeed, regulatory agencies, such as the European Chemical Agency, expect data submissions to build on OECD TG compliant performance, including following Good Laboratory Practice, which usually requires a Contract Research Organisation environment.

However, academic laboratories also frequently benefit and apply OECD TG and are free to publish the achieved results. Such academically derived data sets can comprise an invaluable resource not only to the scientific community but to regulatory toxicologists as well. This is especially true for newly developed OECD TG, where rapidly growing data sets can promote confidence building, enhance knowledge about the applicability domain, and identify needs for further developments. Yet, to count in a regulatory science context, these data must be reported in a way that key elements and validity criteria can be traced.

As developers and distributors of knowledge on OECD TG that aim to substitute toxicity testing using fish, we are continuously screening academic reports and publications – here with regards to OECD TG249 (Fish Cell Line Acute Toxicity - The RTgill-W1 cell line assay) as example. We noted two principal digressions in the open literature that create hurdles for application in the regulatory space: (i) incomplete reporting of essential experimental details; (ii) alterations to the procedure that make it difficult to judge whether the changes impact the predictive ability of the assay as a surrogate for the acute fish LC50 as intended. These findings motivated us to create a template that encompasses details with respect to test substance information, in vitro assay performance and validity criteria. We envision this template to serve several important causes, including structured reporting and facilitated entry into databases, such as the Fish Acute Cell Toxicity database (FACTdb).

Taken together, academic laboratories can contribute a great deal toward the mainstreaming of OECD TG featuring NAMs. When following the TG exactly as developed whenever possible, paying particular attention to key experimental details and criteria for validity, and reporting them accordingly, the data can be of direct and instrumental use for regulatory science.

Disclaimer/Disclosure:

The development of the FACTdb is supported by PETA Science Consortium International e.V.. Continuous maintenance and expansion is currently ensured through financial support by UTOX at Eawag (Swiss Federal Institute of Aquatic Science and Technology), the European Partnership for the Assessment of Risks from Chemicals (PARC; Grant Agreement No. 101057014), and by the Swiss National Research Programme “Advancing 3R—Animals, Research and Society” (NRP 79), project number 407940_206439.

1.10.T-02 Mode of Action Assessment in *Raphidocelis subcapitata* by Complementing the OECD 201 Test with Transcriptomics

Melina Schöpker¹, Fabian Essfeld², Benedikt Ringbeck³, Karsten Schlich⁴ and Sebastian Eilebrecht², (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (4)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology

(IME), Germany

The growing number of chemicals worldwide increases the need for risk assessment and investigation of their environmental effects on organisms in order to protect the earth's ecosystems. For this purpose, it is very helpful to understand the effects of substances at the molecular level. The combination of ecotoxicological tests and transcriptome analysis makes it possible to identify and understand the modes of action (MoA) of substances in non-target organisms at the gene expression level. The aim of this study was to combine the workflow of the Algal growth inhibition test (OECD Test Guideline (TG) 201) with transcriptome analysis to gain insight into the MoA of substances in the freshwater microalga *Raphidocelis subcapitata* (R. subcapitata).

The toxicity test in R. subcapitata, according to OECD TG 201, was followed by transcriptomics and provided insights into the molecular effects of two substances, the photosynthesis-inhibiting herbicide bentazone and the zinc oxide nanoparticle NM-110, which is widely used in products such as sunscreens for its UV-absorbing properties. Several range finding tests were performed to determine low effective concentrations (e.g. EC5 and EC20). Main tests based on these concentrations and subsequent RNA extraction using a newly established RNA extraction protocol for R. subcapitata formed the basis for the subsequent gene expression analysis. Combined with an overrepresentation analysis, these analyses showed that exposure to low effective concentrations of each substance (Bentazone: EC5=9.96 mg/L, EC20=24.2 mg/L; NM-110: EC5=0.033 mg/L, EC20=0.041 mg/L) resulted in a large number of differentially expressed genes compared to the unexposed control. The molecular effects observed could be partially related to the MoA described in the literature for each substance. Comparative analysis indicated different MoA for the two substances. However, both substances shared a common link to the generation of reactive oxygen species and thus also to oxidative stress.

In conclusion, this study could positively contribute to a better understanding of the molecular effects and MoA of the two substances, bentazone and the zinc oxide nanoparticle NM-110, in R. subcapitata. The development of an RNA extraction protocol for the alga was fundamental for this. The results of this study also provide a basis for further screening approaches with other chemicals.

1.10.T-03 Sweet but Toxic? An Ecotoxicological Hazard Assessment of the Artificial Sweetener Acesulfame using Toxicogenomics

Alexandra Loll¹, Fabian Essfeld², Henner Hollert³, Benedikt Ringbeck⁴ and Sebastian Eilebrecht²,
(1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (4)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany

Acesulfame (ACE) is widely used as an artificial sweetener, primarily in food and beverages. Due to its chemical stability and water solubility, it remains unmetabolized and is not fully removed during wastewater treatment, resulting in environmental persistence and mobility in aquatic systems. Despite recognition as an emerging contaminant for years, a comprehensive environmental risk assessment is still lacking, as regulation for food additives does not require it. Aligned with the goals set by PARC, this project investigates the ecotoxicological effects of ACE via toxicogenomics. Three aquatic model organisms of different trophic levels were exposed to analytically verified concentrations ranging from environmentally relevant levels (10 µg/L) to the upper limit used in substance evaluation (100 mg/L). Following a tiered testing approach in line with next generation risk assessment, standardized acute toxicity tests (OECD) were combined with transcriptomics. Statistically significant changes in gene expression were observed in all organisms. Functional analyses indicated oxidative stress as the dominant effect in zebrafish, while lemna exhibited several stress and defense responses. Notably, environmentally relevant concentrations of ACE affected neuroendocrine pathways in daphnids and cluster analysis showed transcriptomic similarity to pyriproxyfen, a known developmental disruptor. To connect molecular findings with regulatory endpoints, a chronic toxicity test with daphnia at low concentrations is planned. As juvenile hormone mimics typically impair moulting in daphnia, population-level effects may be expected. In prior higher-concentration tests, systemic effects might have masked endocrine disruptions.

In summary, this study underscores that ACE induces stress-related transcriptional changes across aquatic model organisms and reveals early signs of neuroendocrine disruption in daphnids. For a food additive not previously considered in environmental risk assessments, these findings are concerning. The results exemplify how OMICs approaches can advance hazard assessment by sensitively identifying sublethal effects with potential long-term consequences. Building on the daphnia results, transcriptomics indicate that chronic testing at environmentally relevant concentrations is warranted, thereby linking molecular and population-level effects and promoting more efficient, animal-friendly hazard assessment.

1.10.T-04 Comparative Behavioral Screening of Environmental Chemicals in *Daphnia magna* and *Drosophila melanogaster*

Pu Xia¹, Lautaro Gandara², Tayebah Soltanighias¹, Justin Crocker² and John K. Colbourne¹, (1)Centre for Environmental Research and Justice (CERJ), The University of Birmingham, United Kingdom, (2)European Molecular Biology Laboratory, Germany

The increasing presence of neuroactive chemicals in the environment poses significant risks to the developing nervous systems of humans and wildlife. Behavioral endpoints represent early and sensitive indicators of neurotoxicity and ecological impairment, yet they remain insufficiently integrated into regulatory ecotoxicology frameworks. To advance the application of behavior within New Approach Methodologies (NAMs), we performed a cross-species behavioral screen of 200 environmentally relevant chemicals using *Daphnia magna* and *Drosophila melanogaster* as complementary model organisms.

High-throughput behavior tracking platforms were used to quantify locomotor activity under sublethal exposure conditions across three concentrations per chemical. A machine learning-based algorithm was developed to benchmark and extract quantitative behavioral features. Behavioral signatures demonstrated strong reproducibility across exposure levels and experimental replicates. Chemical clustering based on locomotor phenotypes revealed organophosphate pesticides as consistently neuroactive across both species, while additional compounds produced species-specific behavioral disruptions, reflecting differences in neurophysiology and exposure susceptibility.

These results highlight the feasibility and value of behavior-based NAMs for comparative neurotoxicity screening and chemical prioritization, and support the broader use of behavioral endpoints in ecologically relevant and mechanism-informed hazard assessment.

1.10.P From Mechanistic Insights and Innovation to Regulation: Integrating Behavioural Endpoints, AOPs and NAMs into Next Generation Environmental Risk Assessment

1.10.P-We012 EthoCRED: A Framework to Guide Reporting and Evaluation of the Relevance and Reliability of Behavioural Ecotoxicity Studies

Michael Grant Bertram¹, Marlene Ågerstrand² and Tomas Brodin¹, (1)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Stockholm University, Sweden

Behavioural analysis has been attracting significant attention as a broad indicator of sub-lethal toxicity and has secured a place as an important subdiscipline in ecotoxicology. Among the most notable characteristics of behavioural research, compared to other established approaches in sub-lethal ecotoxicology (e.g. reproductive and developmental bioassays), are the wide range of study designs being used and the diversity of endpoints considered. At the same time, environmental hazard and risk assessment, which underpins regulatory decisions to protect the environment from potentially harmful chemicals, often recommends that ecotoxicological data be produced following accepted and validated test guidelines. These guidelines typically do not address behavioural changes, meaning that these, often sensitive, effects are not represented in hazard and risk assessments. Here, we propose a new tool, the EthoCRED evaluation method, for assessing the relevance and reliability of behavioural ecotoxicity data, which considers the unique requirements and challenges encountered in this field. This method and accompanying reporting recommendations are designed to serve as an extension of the “Criteria for Reporting and Evaluating Ecotoxicity Data (CRED)” project. As such, EthoCRED can both accommodate the wide array of experimental design approaches seen in behavioural ecotoxicology, and could be readily implemented into regulatory frameworks as deemed appropriate by policy makers of different jurisdictions to allow better integration of knowledge gained from behavioural testing into environmental protection. Furthermore, through our reporting recommendations, we aim to improve the reporting of behavioural studies in the peer-reviewed literature, and thereby increase their usefulness to inform chemical regulation.

1.10.P-We013 Scaling Up Biomonitoring: Eukaryotic Community-Wide 18S Profiling Enables to Identify Priority Taxa Across Upstream–Downstream Pollution Gradients

Vanessa de Almeida Moreira¹, Karel Viaene², Jana Asselman³, Charlotte Nys², Lara Van De Merckt⁴, Marnix Vangheluwe², Hugo Waeterschoot⁵ and Karel De Schamphelaere¹, (1)Ghent University, Belgium, (2)ARCHE Consulting, Belgium, (3)Blue Growth Research Lab (BGRL), Ghent University, Belgium, (4)AV DE TERVUEREN 168, Eurometaux, Belgium, (5)EUROMETAUX, Belgium

The Water Framework Directive, among others, requires the monitoring of biodiversity or ecosystem structure. Conventional environmental biodiversity monitoring relies on a few indicator groups of organisms with a proven history of sensitivity to contamination (e.g., diatoms). However, the targeted species only provide an incomplete picture of the community's full taxonomical range and its diverse contaminant response profile. Additionally, biodiversity indices are routinely calculated based on monitoring data because they condense complex community structure into simple values. However, biodiversity indices can mask important ecological features such as taxonomic turnover, functional replacement, and stressor-driven shifts, all essential to understand the effects of contaminants. To complement these conventional metrics, we applied eukaryotic 18S metabarcoding as a holistic screening tool to detect community-wide responses to local metal pollution along a stream (Grote Nete - GN, Belgium). Baskets containing five stones were installed at each site during 8 weeks for later biofilm collection. Biofilm DNA was extracted for metabarcoding sequencing (18S rRNA) and further taxonomic assignment using SILVA 138. We coupled overall richness and Shannon diversity (ANOVA)—considering all species without phylum-level distinction—with phylum-level diversity metrics and ALDEx2-based differential abundance testing to assess site-level contrasts between upstream and downstream locations. Among the 48 phyla detected in GN, Shannon diversity significantly differed for 3 groups (e.g., Ascomycota), and richness for 3 others (e.g., Porifera)—post hoc Tukey, indicating changes in the internal structure of these phyla—such as shifts in taxa evenness. While ALDEx2 paired-site comparisons revealed significant upstream–downstream shifts for more than 10 groups (e.g., Blastocladiomycota), reflecting changes in the dominance of these phyla, as pollution-driven selection and competitive displacement cause some groups to become more prevalent while others decline.

Our findings reveal that 18S rRNA gene metabarcoding survey rapidly and effectively diagnoses eukaryotic groups most affected by metal pollution and efficiently prioritizes group-specific assays for ongoing targeted monitoring (e.g., ITS genetic region for Blastocladiomycota), complementing regulatory programs and improving early detection of pollution-driven ecological change.

1.10.P-We014 Aligning the REACH Revision with the EU Roadmap to Phase Out Animal Testing for Stronger Environmental Protection

Jen Hochmuth¹, Vera Engelbrecht², Mandy Veillette², Gilly Stoddart¹ and Julia Baines¹, (1)PETA UK, United Kingdom, (2)PETA Germany, Germany

The REACH revision marks a critical moment to reshape chemical safety assessment in the European Union. The EU has committed to ending animal testing for chemical safety assessments – a pledge driven by the Chemicals Strategy for Sustainability (CSS), the European Parliament's 2021 resolution concerning the CSS, and the Commission Roadmap towards phasing out animal testing for chemical safety assessments in response to the EU Citizens' Initiative "Save Cruelty Free Cosmetics – Commit to a Europe Without Animal Testing". To translate this commitment into practice, the revised legislation must establish non-animal approaches as the standard for chemical safety assessments.

Non-animal approaches based on mechanisms of action can assess risks across a wider range of species, offer greater ecological relevance and support more timely and informed regulatory assessments. These methods help overcome the well-established limitations of tests on animals and hold the promise of equal or higher environmental protection while reducing reliance on animal testing.

To deliver this shift, key reforms are required to modernise the governance of chemical safety assessment. We propose introducing the concept of information objectives by defining information on intrinsic properties of substances that must be generated and assessed against clearly defined objectives that serve the overarching protection goal, rather than relying on standard information requirements based on prescribed test mandates. Building on this foundation, the revision should strengthen the legal requirement that tests on animals be used only as a last resort. In addition, we recommend that registration, testing proposals, and compliance checks systematically prioritise non-animal approaches, thereby enhancing transparency, preventing redundant testing, and enabling the wider use of existing evidence. The revision should also advance the development, implementation and regulatory integration of innovative environmental safety methods and be supported by an independent expert committee to ensure consistent, science-based evaluation across all processes.

Together, these reforms would future-proof environmental assessments and improve regulatory consistency, enabling the European Union to honour its commitment to ending animal testing while advancing scientific innovation and strengthening environmental protection.

1.10.P-We015 Immunomodulatory In-vitro Effects of Realistic Environmental Pollutant Mixtures on Innate Immunity

Elena Hommel, Niklas Wojtysiak, Beate Escher and Georg Braun, Helmholtz Center for Environmental Research (UFZ), Germany

Humans are continuously exposed to complex mixtures of chemicals, including endocrine-disrupting compounds (EDCs), which are increasingly associated with the growing incidence of non-communicable diseases. The immune system, which is interconnected with the endocrine system, plays a fundamental role in maintaining overall health, yet remains an overlooked target in toxicology. Due to the complexity of immune cell interactions, data on immunotoxic effects are still limited, and current OECD test guidelines are sparse. In vitro bioassays offer promising approaches for evaluating immune-related health endpoints, including inflammation, antiviral response, immune cell proliferation and general stress responses, that reflect overall innate immune system function. Essential transcription factors and receptors covering those health endpoints are NF- κ B (nuclear factor kappa B), IRF (interferon regulatory factor), AP-1 (activator protein 1), AhR (aryl hydrocarbon receptor) and PPAR γ (peroxisome proliferator-activated receptor gamma). The inhibition of such signaling pathways is rarely evaluated in current screening strategies. We tested representative mixtures of pan-European chemical exposure (including PFAS, PAHS, Phenols, Pesticides and Phthalates) in a test battery covering these endpoints in agonism and antagonism mode. We observed antagonistic effects of the mixtures and their individual components at realistic concentration ratios, exemplify the interference of NF- κ B (four out of six tested mixtures), IRF (four out of six tested mixtures), and PPAR γ (2 out of six mixtures). Our results highlight the applicability of in vitro bioassays to screen realistic mixtures of chemicals for the capability to disrupt health-relevant molecular processes and to explore how chemicals act together in mixtures.

1.10.P-We016 Developmental Neurotoxicity mediated through Endocrine Disruption in Fish: A Systematic Review

Simone Fibiger Sørensen and Henrik Holbech, University of Southern Denmark, Denmark

Developmental neurotoxicity (DNT) is defined as “chemical-induced interference with normal development of the nervous system, which, if uncompensated, may lead to adverse effects on nervous system structure and/or function” (OECD). Endocrine-disrupting chemicals (EDCs) can interfere with hormonal signaling pathways that are critical for brain development, such as thyroid and estrogen systems in vertebrates. Disruption during sensitive developmental windows may lead to long-term behavioral and physiological effects. However, the mechanistic interaction between endocrine disruption (ED) and DNT remain unclear. Regulatory agencies emphasize the need for Adverse Outcome Pathway (AOP)-based frameworks to assess DNT, as these approaches integrate mechanistic evidence across biological levels and support predictive, regulatory-relevant testing strategies.

This systematic review aims to identify knowledge gaps and evaluate the credibility of existing evidence and approaches for studying endocrine disruption-mediated DNT in vertebrate fish. This will be achieved by using a systematic review approach to evaluate factors including study design parameters, chemical identity, exposure conditions and neurodevelopmental endpoints assessed. Preliminary insights suggest that most studies focus on transcriptional analysis and behavioral endpoints, while morphological and molecular endpoints are less investigated. This implies a knowledge gap regarding mode of actions (MoA) on key events placed between molecular initiating events (MIEs) and adverse outcomes, as intended in the Adverse Outcome Pathway (AOP) framework. This highlights the need for both transcriptional analysis, molecular markers, morphology and behavioral endpoints, to improve mechanistic understanding and ensure relevance for regulatory decision-making.

Our review provides a foundation for development of robust testing strategies, and prioritizing research to address critical uncertainties in DNT assessment in fish mediated through endocrine pathways.

1.10.P-We017 C. elegans as a Model Organism to Complement the OECD Developmental Neurotoxicity In Vitro Battery

Molly Cooper, University of Birmingham, United Kingdom

Only a small fraction of chemicals on the market have been fully evaluated for developmental neurotoxicity (DNT). Current *in vivo* test guidelines (OECD TG 426 and TG 443) are not mandatory in international regulatory frameworks and remain costly, time-consuming, and often insensitive to subtle neurodevelopmental effects. As a result, there are large data gaps for industrial and agricultural chemicals, underscoring the need for faster and more predictive DNT screening approaches.

In 2023, the OECD published guidance on interpretation of data from the *in vitro* battery (IVB), a set of 17 cell-based assays that target key neurodevelopmental processes. While the IVB represents major progress toward NAM-based DNT testing, important endpoints remain insufficiently covered, including whole-organism responses, learning and behaviour, metabolic and endocrine interactions, and systemic compensatory mechanisms. Integrating a whole-organism model with the IVB could therefore strengthen mechanistic interpretation and improve detection of DNT hazards.

The nematode *C. elegans* offers a promising complementary model due to its conserved neurodevelopmental pathways, well-characterised nervous system, genetic tractability, and suitability for rapid, high-throughput behavioural assessment. An image-based platform capable of detecting changes in behaviour may identify whole-organism level DNT effects not measurable by cell-based assays, therefore providing more comprehensive screening that supports efforts to advance NAMs in chemical safety assessment.

This project will test a subset of the positive and negative control chemicals used in the IVB, enabling nematode behavioural endpoints to be benchmarked against existing IVB data. This comparison is essential for validating the behavioural platform and demonstrating how whole-organism responses may complement DNT-relevant endpoints not captured by the current IVB. Furthermore, incorporating strain variation in this platform will better reflect genetic diversity and support the assessment of population-level differences in susceptibility, while also helping refine DNT-relevant AOPs. Together, these advances position *C. elegans* as a valuable whole-organism tool to address current gaps in the OECD DNT IVB and to accelerate the transition toward predictive, ethical, and efficient DNT testing strategies.

1.10.P-We018 Development of an Automatic High-Throughput Behavioural Phenomics Platform for *Daphnia magna* Toxicity Screening

Matthew Barnard¹, Iestyn Stead², Luisa Orsini³ and Pu Xia¹, (1)University of Birmingham, United Kingdom, (2)Engineering, University of Birmingham, United Kingdom, (3)School of Biosciences, University of Birmingham, United Kingdom

Daphnia species, particularly *Daphnia magna*, are widely used sentinel organisms in freshwater ecotoxicology due to their ecological relevance, short generation time, clonal reproduction, and sensitivity to a broad range of chemical stressors. Their well-characterised physiology and transparent bodies make them ideally suited for mechanistic and behavioural studies. Although behavioural responses in *Daphnia* provide rapid, sensitive, and non-invasive indicators of sublethal stress, behavioural endpoints remain underutilised in regulatory frameworks, which still rely heavily on binary immobilisation outcomes and other low-resolution metrics.

To address this gap, we developed and validated a high-throughput behavioural phenotyping platform using *Daphnia magna*, designed to support reproducible and scalable chemical screening across multiple strains and treatments. We established a ten, 24-well plate assay system integrated with environmental stabilisation measures and automated video tracking. The platform is designed for automated acquisition of behavioural data including immobilisation, speed and frequency of locomotion, and spatial positioning, using behavioural tracking software and analytical workflows. Multiple clonal lines of *Daphnia magna* from distinct environments are being incorporated to allow assessment of genotype-dependent behavioural variability both under controlled conditions and during stress response.

We aim to establish whether the platform can generate consistent behavioural profiles over 48hr exposures and whether behavioural endpoints offer earlier or more nuanced detection of chemical stress than conventional acute exposure endpoints. Future integration with transcriptomic profiling will enable mechanistic interpretation of behavioural phenotypes in relation to pathways and processes of toxicological relevance.

Overall, the vision system is intended to accelerate next-generation ecotoxicological assessment by improving sensitivity, mechanistic relevance, and throughput, with the longer-term goal of supporting chemical screening and risk assessment across diverse *Daphnia* genotypes.

1.10.P-We019 Evaluation of Patulin-Induced Neurotoxicity: Effects on Neurotransmitters, Neural Damage, Behavior, and Mechanisms in *Caenorhabditis elegans*

YU-NING HSU and Chia-Cheng Wei, Institute of Food Safety and Health, National Taiwan University, Taiwan (Greater China)

Patulin (PAT), a mycotoxin mainly produced by *Penicillium expansum*, is commonly found in moldy fruits, vegetables, and grains, especially apples and apple-based products. Due to its heat and acid stability, humans are frequently exposed through fruit juices and infant foods. PAT is known to cause multiple toxic effects, including acute nausea, vomiting, and gastrointestinal discomfort, and long-term exposure may damage the kidney, liver, and immune system. However, studies on its potential neurotoxicity are relatively limited, and the underlying mechanisms remain unclear. Therefore, this study uses *Caenorhabditis elegans* to determine whether PAT induces neurotoxicity and how it affects neurotransmitters and physiological behaviors.

We evaluated developmental, locomotion, and feeding endpoints under various PAT concentrations. The results showed that PAT significantly inhibited worm growth at 50-90 μ M, reduced head thrashing at 0.1-90 μ M, and markedly decreased pharyngeal pumping at 10-90 μ M.

In *C. elegans*, head thrashing is controlled by head neurons involving serotonin and dopamine, and pharyngeal pumping is primarily regulated by serotonin. To assess serotonergic function, we performed an egg-laying assay, reflecting serotonin- and neuropeptide-regulated vulval muscle contraction, and found that PAT significantly reduced egg laying at 10-90 μ M.

Overall, PAT disrupts head thrashing, pharyngeal pumping, and egg laying, suggesting a specific impairment of serotonergic neurons. We will further explore the molecular mechanisms linking neurons and neurotransmitters to define the in vivo neurotoxic profile of PAT.

1.10.P-We020 Cocaine Pollution Alters the Movement and Space Use of Atlantic Salmon (*Salmo salar*) in a Large Natural Lake

Jack Andrew Brand¹, Daniel Palm², Daniel Cervený¹, Marcus Michelangeli¹, Aneesh Bose², Erin McCallum¹, Gustav Hellström², Jerker Berglund Fick³, Bryan W. Brooks⁴, Tomas Brodin⁵ and Michael Grant Bertram⁵, (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Swedish University of Agricultural Sciences, Sweden, (3)Umeå University, Sweden, (4)Baylor University, United States, (5)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden

Cocaine and its metabolites are increasingly being detected in aquatic environments worldwide. While previous research has demonstrated that environmental concentrations of these neuroactive substances can affect brain function, behaviour, and energetic traits in various species, this research has exclusively been conducted under simplified laboratory conditions that fail to capture real-world complexity. As a result, how cocaine pollution affects animal behaviour and movement in the wild is not known. Here, we combine novel slow-release chemical implants with acoustic telemetry tracking to reveal how environmentally realistic levels of cocaine and its main metabolite benzoylecgonine affect movement and space use of Atlantic salmon (*Salmo salar*) smolts in a large natural lake (Lake Vättern, Sweden). Both cocaine and benzoylecgonine exposure increased weekly movement rates of fish in the wild, with this effect being particularly pronounced in the benzoylecgonine treatment group. Further, benzoylecgonine increased dispersal and large-scale space use within the lake relative to controls. Our results demonstrate that environmental levels of illicit substances like cocaine and its metabolites can modify animal behaviour and space use in the wild, with potential consequences for species and community ecology.

1.10.P-We021 From gasoline to green fuels: Uncovering neurotoxic effects in developing zebrafish

Angelina Miller¹, Katja Schröder¹, Danilo Vasilkevic¹, Caitlin Steindorf¹, Pedro A. Inostroza², Henner Hollert³, Martina Roß-Nickoll¹ and Thomas Backhaus¹, (1)RWTH Aachen University, Germany, (2)Biological and Environmental Sciences, RWTH Aachen University, Germany, (3)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany

Climate-neutral mobility is becoming increasingly important as the European Union plans to ban new fossil-fuel combustion vehicles by 2035. Yet millions of existing combustion vehicles will remain in use, making bio-hybrid fuels (produced from renewable feedstock's, CO₂, and green hydrogen) a promising transitional option. Despite their sustainability potential, their toxicological profiles remain insufficiently understood. Conventional fossil fuels, such as gasoline, are known to cause adverse health effects, especially negative neurological outcomes including headaches, hyperactivity, and even sedation. Given this evidence, it is important to assess whether bio-hybrid fuels may similarly affect the nervous system during production, transport, use, and accidental release.

Here, we evaluated neurodevelopmental effects of the bio-hybrid fuel blend KEAA in zebrafish embryos (*Danio rerio*), alongside gasoline as a reference fuel and caffeine as a neurotoxic positive control. Neurobehavioral endpoints (spontaneous coiling, touch-evoked escape response, and light/dark locomotor activity) were assessed up to 120 hpf and complemented by morphological measurements.

KEAA induced clear, concentration-dependent neurobehavioral alterations, including early coiling deficits and reduced escape responses at low concentrations. Caffeine did not affect coiling, but reduced escape behavior at later stages. Gasoline water-accommodated fractions similarly impaired coiling and caused the strongest reduction in escape responses among the tested substances. KEAA additionally produced morphological alterations, most notably reduced body length and eye size, whereas caffeine did not elicit strong morphological changes. Gasoline-related morphological effects are currently under evaluation.

This work underscores the importance of integrating apical, behavior-based endpoints into early-stage safety assessment of emerging alternative combustion fuels using the zebrafish model. This approach is particularly valuable when evaluating complex or previously uncharacterized mixtures, as behavioral readouts provide sensitive indicators of subtle or unexpected effects that can subsequently be explored through more mechanistic methods such as transcriptomics or proteomics.

1.10.P-We022 Towards animal-free environmental safety assessment for petroleum UVCB: challenges and adaptations within the EU Roadmap to phase out animal testing

Maria Blanco-Rubio Ph.D¹, Louise Camenzuli², Lenny Kamelia¹ and Daniela Holland², (1)Shell Global Solutions International BV, Netherlands, (2)Exxon Mobil, Belgium

The European Commission (EU) has launched a Roadmap to phase out animal testing across 15 chemical legislations, setting short-, mid-, and long-term milestones (EC 2023, EC 2024) to advance with the application of New Approach Methodologies (NAMs) to ecological risk assessments without animal testing. Although NAMs offer significant potential in this paradigm shift, their applicability domain must be carefully considered, particularly for complex chemistries such as petroleum substances, known as substances of Unknown or Variable Composition, Complex Reaction Products, and Biological Materials (UVCBs). The petroleum UVCB substances pose specific challenges for NAMs implementation, including undefined specific molecular structures, compositional variability, and the presence of a very large number of constituents, making them difficult to be fully characterized. Their analytical and inherent variable complexity, including low solubility in aqueous solution, high hydrophobicity and volatility, combined with their nature as non-intentional mixtures, difficult the use of some in vitro dosing and modelling strategies.

This poster will identify key adaptations required to enable a feasible transition for petroleum substances within the EU Roadmap to phase out animal testing, including: (i) reducing animal testing through robust read-across approaches; (ii) achieving regulatory acceptance of existing NAMs for testing UVCB; (iii) advancing in vitro dosing strategies for complex substances; (iv) integrating legacy in vivo data to inform mechanistic models; and (v) tailoring New Generation Risk Assessment (NGRA) frameworks to address UVCB-specific challenges. These adaptations will be structured with the three key elements of the EU Roadmap including short-term priorities focus on compliance and minimizing animal use; mid-term goals emphasize in vitro and in silico integration; and long-term objectives aim for full replacement of animal testing through adapted NGRA paradigms.

By addressing these scientific and regulatory hurdles, the chemical industry can accelerate the transition towards an animal-free environmental safety assessment, ensuring the use of robust scientific methods to protect aquatic ecosystems.

Key words: EU Roadmap, New Approach Methodologies, NAMS, petrochemical substances, UVCBs

1.10.P-We023 Addressing a Regulatory Blind Spot in Traditional Ecotoxicity Methods

Vanessa de Almeida Moreira, Qiyun Zhang, Ph.D. candidate and Karel De Schampelaere, Ghent University, Belgium

Environmental risk assessment still focuses on traditional regulatory endpoints (e.g., mortality, reproduction), while pollutant effects on host-associated microbiomes remain neglected. Thus, examining antibiotic-induced microbiome shifts in *Daphnia* sp. is not only relevant to organismal fitness but also a warning for the promotion of antibiotic-resistant bacteria (ARBs) and the spread of antibiotic resistance genes (ARGs) in the environment. Our purpose was to test whether fluoroquinolone antibiotics reshape the *Daphnia magna* microbiome in ways consistent with selection, even when effects on traditional *Daphnia* endpoints are minimal.

A chronic 21-day *D. magna* reproduction test was conducted following the OECD guideline 211 with

ciprofloxacin (CIP), ofloxacin (OFX), and new fluoroquinolones designed to have higher degradability through hydrolysis (e.g., ciprofloxacin-hemi). Bioassay concentrations ranged from 10 to 1,049 µg L⁻¹ of each antibiotic. After exposure, pooled samples (5 organisms per antibiotic concentration) were flash frozen and kept at -80 °C until DNA extraction. Full-length 16S rRNA genes were sequenced (27F/1492R, PacBio); reads were processed in QIIME 2 with DADA2 to obtain ASVs. R software was employed to identify differences between survival, reproduction, as well as to compute diversity and microbiome compositional profiles. Based on standard regulatory observations, no significant toxic effects regarding survival or reproduction were identified. For sensitive/tolerant taxa, we hypothesize that there is concentration-dependent microbiome restructuring with selection of resistant bacteria.

Microbiome-based research could complement traditional regulatory endpoints, capturing host-relevant mechanisms. This study employs molecular endpoints for next-generation environmental risk assessment, revealing how host-linked microbiome indicators can be integrated into decision-making by bridging innovation into the regulatory practice.

1.10.P-We024 Comparative Dietary Analysis in Small Mammals: Fecal vs. Stomach Content eDNA Metabarcoding in Herbivores and Insectivores

Christian Imholt¹, Eric Linster², Jens Jacob³, Ana Filipa Pereira Miranda¹, Kristof Brenzinger¹, Jan-Dieter Ludwigs² and Sabina Ramirez², (1)BASF, Germany, (2)Rifcon GmbH, Germany, (3)Julius Kühn-Institute, Germany

Dietary analysis is essential in European pesticide risk assessment for wild birds and mammals, as species-specific diets and foraging behaviors directly affect exposure estimates. Traditionally, such analyses relied on invasive stomach content examinations or visual inspection of fecal samples, both limited by methodological constraints. Environmental DNA (eDNA) metabarcoding offers a non-invasive alternative, enabling simultaneous host and diet identification from fecal samples. This study compares fecal-based eDNA metabarcoding for host identification to dietary profiles from stomach content samples in two model organisms: *Microtus arvalis* (herbivore) and *Sorex araneus* (insectivore).

Samples from twenty individuals per species were analyzed using high-throughput sequencing. Host identification utilized mitochondrial markers (12SV5 and COI), while diet composition was assessed using ITS2 and trnL for plants, and 12S_EW (earthworm-specific) and COI for animal prey. DNA extraction protocols were optimized, and bioinformatics pipelines enabled taxonomic assignment and diversity analyses. Comparative analyses included Venn diagrams, principal component analysis, Shannon diversity index, and richness metrics. Results showed that COI enabled unambiguous species-level assignment in both fecal and stomach content samples. For *M. arvalis*, ITS2 and trnL markers revealed a diet dominated by Poaceae and Fabaceae, with no significant differences between sample types. For *S. araneus*, earthworms were part of a diet alongside arthropods and mollusks; 12S was more sensitive for earthworm detection, though COI also detected earthworms. Substantial taxonomic overlaps and no significant differences in diversity or richness metrics were observed between fecal and stomach content samples.

Fecal eDNA metabarcoding proved to be a powerful, non-invasive tool for host and diet identification, overcoming ethical and methodological limitations of traditional methods. The findings support broader adoption of fecal-based eDNA analysis in wildlife studies and regulatory risk assessment, with recommendations for marker selection and sequencing strategies. Future work will focus on increasing sequencing depth and applying more specific primers to increase species detection, especially for arthropods. Integrating molecular approaches into environmental risk assessment frameworks is a promising option that offers scalable solutions for monitoring and assessing wildlife exposure.

1.10.P-We025 Ecotox: An Outlier or Way-out?

Oluwafemi Azeez Sarumi, RPTU University of Kaiserslautern-Landau, Germany

The world and scientists are making a push to tackle one of the fastest growing section of the earth planetary boundary - novel entities. Companies such as “A” and “B” take the lead in the production of chemical and chemical products. One notable example is the merger between “B” and “C”, accruing all assets, including the famous pesticide protection product - “D”, globally debated amid the continued use and acceptance in EU and rejection in the US, fortified with law suit amounting to millions of dollar in charges to affected individuals. Scientists such as “E” and “F” continue to lead research and scientific studies to unravel the earthly, human and environmental challenges caused by the proliferation of these chemicals. It has turned out that we are the problem of our present conditions, covered by greed, hard-work and dedication, especially involving early career scientists. Is Ecotox an outlier or a solution to the globally interconnected challenges of pollution, climate change and biodiversity loss? Time will definitely tell. Codes available upon request.

1.10.P-We026 Integrating Alternative and Refined Approaches to Bisphenol Toxicity in *Xenopus laevis*
Fábio Miguel Ribeiro Gomes, Miguel Oliveira and Isabel Lopes, University of Aveiro, Portugal

The increasing release of plasticizers into aquatic ecosystems raises concern for wildlife. Bisphenol A (BPA) is widely regulated due to its environmental persistence and bioaccumulation. Bisphenol S-methacrylate (BPS-MAE) has been proposed as a replacement, though its ecotoxicity remains poorly characterised.

Amphibians are highly susceptible to contaminants, yet the use of live organisms requires ethical consideration. Implementing the 3Rs (Replacement, Reduction and Refinement) is therefore essential to ensure ecologically relevant and ethically aligned testing approaches.

This work compares BPA and BPS-MAE toxicity in *Xenopus laevis* under a 3Rs-based framework. A6 cells were exposed for 12 and 96-h to assess (Replacement and Reduction) cytotoxicity (MTT), genotoxicity (Comet assay) and biochemical biomarkers (CAT, GST, LDH and TBARS). NF48 tadpoles were exposed for 96 h to determine LC₅₀ and EC₅₀ values, used to define sublethal ranges, followed by 12-h behavioural assays (Reduction and Refinement) using the HeMHAS and ZebraBox systems.

In vitro LC₅₀ values were 10.3 mg L⁻¹ for BPA and 27.5 mg L⁻¹ for BPS-MAE. The Comet assay showed significant DNA damage from 0.15 mg L⁻¹ BPA. In vivo, BPA was consistently more toxic than BPS-MAE (LC₅₀ = 12.1 vs. 18.1 mg L⁻¹; EC₅₀ = 9.0–10.5 vs. 17.3–20.3 mg L⁻¹). Behaviourally, BPA-exposed tadpoles aggregated in contaminated zones at 7 mg L⁻¹, while BPS-MAE induced significant avoidance from 9.3 mg L⁻¹. Reduced mobility under BPA exposure clarified this “false preference”, suggesting impaired escape capability. These results show that although BPS-MAE is less potent than BPA, it still induces toxicity across molecular, cellular, organismal and behavioural levels, and should not be regarded as a safe alternative. Integrating in vitro assays with refined behavioural endpoints demonstrates how 3Rs-oriented methodologies can deliver ethical and ecologically realistic assessments of emerging contaminants in amphibians.

1.10.P-We027 Developmental and behavioral effects of two synthetic glucocorticoids, fluticasone propionate and clobetasol propionate, in zebrafish embryos

Maxime Martinez¹, Florian Geffroy¹, Valentin Bourges², Benjamin Piccini², Sélim Ait-Aïssa¹, François Brion² and Nathalie Hinfray², (1)Ineris, France, (2)INERIS, France

Synthetic glucocorticoids have been used in human and veterinary medicine for decades to treat inflammatory pathologies including rheumatoid arthritis, asthma or Covid-19. High consumption of these pharmaceuticals combined with incomplete removal by water treatment plants result in the contamination of aquatic systems, at concentrations in the ng/L range in surface waters up to dozens of µg/L in worst cases in effluents. Despite their environmental occurrence, their effects on endocrine signaling in aquatic organisms remain understudied.

Glucocorticoids act through activation of the glucocorticoid receptor (GR), which is involved in the regulation of essential physiological processes such as stress response, immune functions, development and behavior. In the present study, we investigated the molecular, developmental and behavioral effects of two synthetic glucocorticoids, fluticasone propionate (FP) and clobetasol propionate (CP), in zebrafish embryos, using the fish embryo toxicity assay (OECD TG 236) and a dark-light transition assay (DLT) at 120 hpf.

FP and CP induced a precocious hatching of embryos (at concentrations > 1 µg/L) and developmental effect on swim bladder inflation, without affecting the survival of embryos at concentrations up to 100 µg/L. The expression of a GR-regulated gene, i.e., *fkbp5*, was also quantified in embryos. At the tested concentrations, a concentration-dependent increase of *fkbp5* gene expression was observed in zebrafish embryos exposed to FP or CP. In the DLT assay, FP and CP disturbed locomotor activity by increasing the total distance traveled during the dark phase and the time spent in movement during both dark and light phase, while decreasing the velocity of embryos. Altogether, these behavioral changes may result from the activation of the GR signaling pathway. In the present study, molecular, developmental and behavioral effects of two synthetic glucocorticoids were shown in zebrafish embryos, confirming that glucocorticoids are of concern for developing fish. Eventually, this study highlights the importance of considering the effects of chemicals, not only glucocorticoids, on the GR signaling pathway and their effects on development and behavior in fish.

1.10.P-We028 Behavioral Impact of Road Dust and Tire Wear Particle on Gammarids and Potential Functional Consequences

Zoé Arrigoni¹, Emmanuel Naffrechoux² and Emilie Réalis-Doyelle³, (1)EDYTEM - CARRTEL, France, (2)EDYTEM, France, (3)CARRTEL, France

Tire Wear Particles (TWPs), a major component of road dust (RD), pose a significant threat to aquatic ecosystems. Abrasion of tires on roads generates microplastic-like particles that are transported to freshwater ecosystems via storm runoff. While the lethal effects of TWPs have been established for some species like Coho Salmon, their sublethal impacts on other aquatic organisms remain poorly understood. Moreover, in a global climate change context, the effect of rising temperature coupled to pollution exposure is lacking. This study investigates the behavioral alterations in gammarids (*Gammarus fossarum*), a ubiquitous sentinel species, following long-term exposure to road dust contamination for two different temperatures (12°C and 16°C). Over 21 days, we measured weekly changes in activity levels (percentage of active time), swimming speed, distance traveled, and nearest neighbor distance (NND) using video tracking. Additionally, functional effects were assessed by quantifying stress enzyme and acetylcholine esterase. Our results demonstrate a noticeable decrease in distance traveled, speed, active time, and interaction with nearby neighbors after 21 days of exposure in contaminated gammarids at 12°C. Furthermore, we observed changes in stress enzyme activity between contaminated and control at 12°C. We hypothesize that these behavioral changes may be attributed to energy reallocation towards detoxification processes, potentially compromising energy available for essential activities like swimming. This reduced swimming capacity could increase predation risk and negatively impact gammarid population dynamics. Future research will focus on assessing the vulnerability of contaminated gammarids to predation cues and exploring the behavioral effects of TWPs on other aquatic species.

1.10.P-We029 Effects of Benzo[a]pyrene on Swimming Behaviour of Brown Trout Assessed Using Non-invasive Approaches

Coline Louvet¹, Bastien TALLONE¹, Emilie Réalis-Doyelle² and Carmen GONZÁLEZ-FERNÁNDEZ¹, (1)INRAE Lyon-Grenoble Auvergne Rhône-Alpes, Riverly unit, ECOTOX team, 69100 Villeurbanne, France, (2)Pôle ECLA (OFB, INRAE, USMB), France

Aquatic environments are increasingly impacted by chemical contaminants arising from human activities, among which benzo[a]pyrene (BaP), a widespread polycyclic aromatic hydrocarbon (HAP) generated by the complete combustion of organic materials, is of major concern. Behavioural analysis provides a sensitive method for detecting sublethal toxic effects in fish, making them valuable tools for ecological risk assessment. This study investigated the impact of BaP on the swimming behaviour of brown trout (*Salmo trutta*) with the aim of identifying locomotor alterations early warning signs of toxic stress. Juvenile brown trout received a single intraperitoneal injection of BaP (0.5 mg/kg or 10 mg/kg), and their swimming behaviour was quantitatively assessed four days post-exposure using non-invasive video tracking. Key parameters analysed included swimming speed, mean acceleration, total distance travelled, and overall activity level. This approach enabled the collection of reproducible behavioural data without inducing handling stress during observation. The results revealed a clear, dose-dependent reduction in locomotor activity following BaP exposure. Exposed trout exhibited lower swimming speeds, reduced acceleration, and shorter distances travelled. Beyond locomotor impairments, BaP exposure was associated with a suppression of anxiety-related behaviours, leading to decreased vigilance. These behavioural alterations suggest that exposed individuals may face an increased risk of predation in natural environments. Overall, this study highlights swimming behaviour as a valuable endpoint for detecting contaminant-induced functional impairments and contributes to improving ecological risk assessments in freshwater ecosystems.

1.10.P-We030 When Colours Meet Plastics: Behaviour Gets Messy

Valérie Pires, Mónica Almeida, Isabel Lopes and **Miguel Oliveira**, CESAM, University of Aveiro, Portugal

Growing demand for visually appealing food products has intensified the use of artificial food dyes (AFDs), many of which are now recognized as emerging contaminants. Concerns about their potential effects are shared by consumers, environmental scientists and food safety authorities, who increasingly emphasize the need for periodic re-assessments of their safety.

At the same time, the extensive use of plastics in food packaging and single-use applications contributes to the release of micro(nano)plastics (MNPs) into the environment, where they may interact with AFDs and potentially modulate their environmental fate, behaviour, and biological effects.

To explore these potential interactions, zebrafish (*Danio rerio*) embryos and larvae were exposed to some of the most widely consumed AFDs and model MNPs (e.g., polyethylene terephthalate, PET) at environmentally relevant concentrations, both individually and in combination, from early development up to 8 days post-fertilization. Throughout exposure, key developmental parameters (e.g., survival, hatching, malformations and heart rate) were monitored, and larval locomotor and stress-related behaviours (e.g., swimming performance) were assessed using a set of complementary behavioural assays.

Overall, both contaminants induced significant physiological and behavioural alterations even at relatively low concentrations. The co-exposure assays revealed that interactions between contaminants can modulate the effects observed in individual exposures.

These findings suggest that AFD–MNP interactions may play a key role in shaping toxicity during early fish development, highlighting the need to integrate co-exposure scenarios into future environmental risk assessments and regulatory evaluations. Ultimately, these results provide a timely contribution to understanding how emerging contaminants jointly influence aquatic organisms, with broader implications for consumer safety and ecosystem health.

1.10.P-We031 Zebrafish adaptive strategies across development: Integrating Behavioural, Physiological, and Transcriptomic Profiles

Carla Ferreira Melo¹, Brian Jonathan Young², Miguel Oliveira³, Laia Navarro-Martin⁴ and Melissa Diogo Faria², (1)CESAM, University of Aveiro, Portugal, (2)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (3)University of Aveiro, Portugal, (4)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Zebrafish were reared from early life stages to adulthood to investigate how individual coping styles emerge as adaptation strategies and how they persist across development. Of particular interest are bold and shy coping styles, because they represent fundamental behavioural strategies linked to stress responsiveness, fitness-related traits, and differential sensitivity to environmental challenges. At multiple ontogenetic stages, fish were phenotyped and sorted into bold and shy profiles using standardized behavioural criteria. Survival, growth trajectories, and sex ratios were quantified to determine whether personality type was associated with differential physiological or developmental patterns. Behavioural assessment was conducted using the light–dark test at each stage to evaluate consistency and divergence in coping styles through time. Following behavioural assays, individuals were sampled for transcriptomic analysis to link phenotype with underlying molecular signatures. RNA sequencing was performed to characterize gene expression patterns associated with coping style and developmental progression. These data provide a basis for identifying pathways potentially associated with behavioural differentiation and life-history variation. Preliminary observations suggest possible stage-specific behavioural and transcriptional distinctions between coping styles. This integrated approach advances the understanding of how behavioural phenotypes relate to developmental, physiological, and molecular traits in zebrafish.

1.10.P-We032 Night Lights, Broken Rhythms: ALAN Effects on Zebrafish Larval Sleep and Sensorimotor Behaviour

Maria S. Costa¹, Niki Tagkalidou², Ouweis Aljabasini², João L.T. Pestana³, Marta S. Monteiro³, Carlos Barata Dr⁴ and Demetrio Raldua⁵, (1)CESAM, University of Aveiro, Portugal, (2)Institute for Environmental Assessment and Water Research (IDAEA-CSIC), Jordi Girona, 18, Barcelona 08034, Spain, Spain, (3)University of Aveiro, Portugal, (4)Chemistry, Institute of Environmental Assessment and Water Research -

Artificial light at night (ALAN) is an emerging environmental stressor in urban aquatic ecosystems, capable of disrupting circadian regulation and altering behaviour through interference with melatonin-mediated pathways. Despite its global expansion, the behavioural consequences of ALAN, particularly in early life stages, remain understudied. In this study, zebrafish (*Danio rerio*) embryos were exposed to environmentally relevant ALAN intensities (1 and 10 lux) for seven days, and behavioural parameters associated with sleep regulation were evaluated to test whether ALAN exposure induces sleep deprivation. All behavioural assays were conducted during the daytime light phase, when zebrafish larvae are normally active, enabling the detection of potential compensatory sleep responses. Sleep-wake dynamics, including minutes of sleep per hour, and the number and length of sleep bouts, were quantified using Ethovision XT 16 software, providing a sensitive measure of circadian and neuroendocrine disruption. In parallel, the kinematics of the acoustic startle response (ASR) were analysed using the Zebra_K+ platform to evaluate changes in arousal threshold and short-term habituation, a neurobehavioural process associated with non-associative learning. Larvae exposed to 10 lux showed a significant increase in the number of sleep bouts, indicating fragmented sleep or altered arousal, whereas 1 lux increased total sleep duration despite unchanged immobility bout number. Moreover, larvae exposed to 10 lux showed a reduced ASR relative to controls with no changes in the habituation process, suggesting an increase in the arousal threshold but no alterations in cognitive function. Overall, our findings identify ALAN as a potential disruptor of neurobehavioural function during early development. These results reinforce the value of behavioural endpoints as sensitive early-warning indicators of neurotoxicity and highlight the need to integrate light pollution into ecological and regulatory assessment frameworks.

1.10.P-We033 Small Doses, Big Effects: Low Sertraline Levels as a Behaviour Modulator in Fish

Márcio Barreto, Carla Ferreira Melo, Miguel Oliveira and Isabel Lopes, University of Aveiro, Portugal

Antidepressants are widely prescribed pharmaceuticals, increasingly recognized as contaminants of emerging concern. These drugs enter aquatic systems through patient excretion and improper disposal, combined with limited efficiency of wastewater treatment plants in their removal. Designed to modulate conserved serotonergic pathways, SSRIs can act on molecular targets and potentially affect non-target aquatic organisms. In fish, serotonergic signalling regulates essential behaviours, such as social interaction, stress responses, and predator avoidance, which can be disrupted by neuroactive substances present in the environment. Sertraline (SER), a widely used SSRI, has been detected in surface waters worldwide, at concentrations ranging from low to several hundred ng L⁻¹, where it may induce physiological and behavioural alterations in animals. This study aimed to evaluate the effects of environmentally relevant concentrations of SER on behavioural and physiological responses of early-life stages of zebrafish (*Danio rerio*). Embryos were exposed from 4 hours post-fertilisation (hpf) up to 8 days post-fertilisation (dpf) to six SER hydrochloride concentrations (0.16–500 µg L⁻¹) prepared in a fivefold dilution series, plus a negative control (E3 medium only). Spontaneous tail coil movements were quantified as an early neurotoxicity biomarker (at 24 hpf), heart rate was assessed as a physiological endpoint (at 48 hpf), and swimming profiles under dark and light conditions (at 8 dpf) were assessed as behavioural endpoints. Overall, SER exposure increased heart rate at all tested concentrations, indicating potential effects on the cardiovascular system. Under dark conditions, a decrease in locomotor activity (total swimming distance and average speed) was observed at 100 and 500 µg L⁻¹ SER. Thigmotaxis-related endpoints (distance and time spent in the outer zone of the test arena), as well as the time spent inactive decreased at 500 µg L⁻¹. Larvae's stress response was also altered after exposure to 20, 100, and 500 µg L⁻¹ SER which induced reduced total distance swam and average speed, and increased inactivity during light-to-dark transition tests. Organisms exposed to 20 µg L⁻¹ showed decreases in time and distance spent in the outer zone of the arena during stress tests. These results highlight the potential of SER to induce behavioural alterations even at low concentrations, and the potential to alter stress-related behavioural traits during early development.

1.10.P-We034 Exploring In Vitro Testing for Comparative Cellular Toxicology: Challenges, Opportunities and Future Directions

Isabelle Kavanagh, University of Birmingham, United Kingdom

Inter- and intra-species variation in chemical sensitivity presents a key challenge for chemical safety assessment for both humans and the environment. Regulatory toxicology has traditionally relied on a limited set of model organisms, providing only a narrow representation of the susceptibility of species intended to reflect the vast biodiversity of our ecosystems. Evaluating the current use of in vitro systems to characterise cross-species cellular responses is therefore critical, as these approaches allow exploration of the cellular and mechanistic drivers of variation. Such insights can generate predictive information to support more protective and broadly applicable chemical safety assessments while reducing reliance on animal testing.

The first phase of this PhD project focuses on reviewing the literature of the current applications of in vitro testing in regulatory toxicology. This includes evaluating the choice and characteristics of commonly used cell lines, assessing their relevance across species, and highlighting methodological strengths, limitations, and opportunities for cross-species comparison. The review also examines the translation of laboratory-based findings into regulatory adoption, including successful examples where in vitro approaches have reduced reliance on whole-animal models, and identifies future directions for advancing in vitro methods for predictive toxicology.

This work establishes a foundation for subsequent comparative cross-species cellular toxicology, with standardised experimental designs across multiple species enabling quantification of cellular responses under consistent conditions. It will also provide a basis for integrating genetic and evolutionary perspectives, exploring how mechanistic variation aligns with species relatedness and informing more predictive, phylogenetically informed approaches to chemical safety assessment.

1.10.P-We035 Molluscan Nuclear Receptors and Their Ligands: What We Know, What We Don't, and What Comes Next

Yann Stehly and Elvis Genbo Xu, Southern Denmark University (SDU), Denmark

Nuclear receptors (NRs) regulate development, metabolism, and reproduction, yet current endocrine-disruptor assessment remains centered on vertebrate EATS pathways. Our literature review shows that mollusks retain some vertebrate-like NR complements (RXR, RAR, THR, PPAR), unlike many invertebrates, which have lost key receptors, and that RXR is the only well-characterized molluscan NR known to be directly activated by contaminants such as organotins. In contrast, RAR, THR, and PPAR show altered ligand binding, limited transcriptional characterization, and unresolved physiological roles, representing a major knowledge gap. Based on the results of our literature review, our next step will be to identify life-stage-specific NR responsiveness in *Lymnaea stagnalis* using endogenous and xenobiotic ligands, then investigate RXR crosstalk with partner receptors, and evaluate cross-phylo conservation using zebrafish. This research will deliver a mechanistic mapping of NR signaling in mollusks, clarify how endocrine disruptors act across taxa, and strengthen the biological relevance of future ecotoxicological assessment frameworks.

1.10.P-We036 Emerging mycotoxins and 3D HepaRG liver models: comparative mechanistic insights from mono- and tri-cultures in the context of New Approach Methodologies

Pierre-Jean Ferron¹, Kevin Hogeveen¹, Valérie Fessard¹, Ludovic Le Hegarat¹ and Zeineb MARZOUGUI², (1)French Agency for Food, Environmental and Occupational Health and Safety (ANSES), Fougères Laboratory, Toxicology of Contaminants Unit, France, (2)French Agency for Food, Environmental and Occupational Health & Safety (ANSES), France

Mycotoxins, secondary metabolites produced by various species of fungi, pose significant health risks to humans and animals. These toxins, which commonly contaminate foods such as cereals and fruits, are stable and resistant to degradation during food processing. Over the past few decades, thousands of mycotoxins have been identified and characterised. Only a limited number of these toxins are regulated, and emerging toxins remain unregulated due to insufficient toxicological data.

The MYCO3D project, funded by the Brittany Region, emphasises the application of New Approach

Methodologies (NAMs) to assess the hepatotoxic potential of emerging mycotoxins, including Enniatins A and A1, as well as Alternaria mycotoxins Alternuene and Tentoxin. Using HepaRG spheroids, our results show that Enniatins A and A1 induced significant toxicity, oxidative stress, disruption of mitochondrial transmembrane potential, and steatosis following 48 hours of treatment. Whereas a 3-day treatment with Alternaria mycotoxins at concentrations up to 100 µM did not induce any cytotoxic effect. However, a 10-day chronic exposure to Alternuene and Tentoxin, with media renewal every 48 hours, resulted in significant decreases in cell viability only in cells treated with Tentoxin.

To further examine the cytotoxic effects of mycotoxins, we utilised more sophisticated liver organoid models that include HepaRG cells, primary human macrophages, and LX-2 stellate cells. This advanced liver organoid system enables the evaluation of mycotoxins' effects on complex inflammatory and fibrotic processes. Unlike the monoculture model, organoids composed of HepaRG, macrophages, and LX-2 cells showed greater resistance to Enniatins, with cell viability staying above 40% even at the highest concentration tested (10 µM). To gain deeper mechanistic insights, a transcriptomic study has been carried out using the TempO-Seq™ technology from BioClavis (UK) to investigate the molecular pathways involved in mycotoxin cytotoxicity and adaptation responses. Results are currently being processed to identify differentially expressed genes, and the impacted pathways. An overview of the results will be presented, either as a poster or an oral presentation. Overall, our results show that, unlike Enniatin A and A1, Alternaria mycotoxins Alternuene and Tentoxin do not cause adverse effects. This statement will be further investigated upon transcriptomics data treatment.

This research was supported by the Brittany Region (Région de Bretagne). The funding agency had no role in the study design, data collection, data analysis, manuscript writing, or the decision to submit articles for publication.

1.10.P-We037 Assessing Toxicometabolomic Responses of Daphnia Magna to Pharmaceutical Mixtures in Municipal Wastewater Treatment Plants from Costa Brava (Catalonia, Spain)

Emma Moragrega-Knol¹, Cristian Gómez-Canela¹ and Carlos Barata Dr², (1)Department of Analytical and Applied Chemistry, School of Engineering, Institut Químic de Sarrià-Universitat Ramon Llull, Via Augusta 390, 08017 Barcelona, Spain, Spain, (2)Institute for Environmental Assessment and Water Research (IDAEA-CSIC), Jordi Girona 18, 08034 Barcelona, Spain, Spain

The increasing scarcity of freshwater highlights the urgent need to identify alternative sources. Wastewater represents a promising option but requires advanced treatments to remove wastewater-borne contaminants, particularly contaminants of emerging concern. Previous targeted chemical studies have shown that, although tertiary treatments enhance removal efficiency, they do not ensure the complete elimination of pharmaceutical residues. Based on this evidence, the present study aims to address the hypothesis that residual concentrations persisting after treatment are sufficient to trigger measurable biological effects in exposed organisms.

To evaluate this hypothesis, a comprehensive sampling campaign was performed to assess the efficiency of 14 wastewater treatment plants located along the Costa Brava (Spain) to remove pharmaceutical contaminants. At each facility, effluent samples were collected at two stages (secondary and tertiary treatment) to capture differences in removal performance. A multiscale approach was applied integrating the concentrations from chemical analyses with a set of behavioural responses in *Daphnia magna* including startle, habituation, basal locomotor activity, visual motor response and phototaxis. In parallel, metabolomic data was obtained from the exposed organisms via ultra-high-performance liquid chromatography coupled to tandem mass spectrometry (UHPLC–MS/MS) to characterise changes in key biochemical pathways.

Finally, data analyses were conducted using multivariate statistics (PCA, PLS-DA) followed by pathway enrichment studies to identify the affected metabolic processes. The obtained results revealed clear clustering patterns that distinguished wastewater effluents according to both treatment characteristics and local population pressures. Sites serving larger populations exhibited higher pharmaceutical loads and correspondingly stronger biological responses, while differences in treatment processes significantly influenced the magnitude and nature of observed effects.

Overall, this integrated approach provides novel insights into the ecotoxicological risks associated with wastewater reuse highlighting the urgent need for more advanced tertiary treatments and the importance of stricter regulations to minimize pharmaceutical contamination, particularly when effluents are reused for human-related applications. Even at trace levels, pharmaceuticals may compromise both ecosystem integrity and human health.

1.10.P-We038 Early Life Stress Rewrites the Script of Coping

Carla Ferreira Melo¹, Cristian Gómez-Canela², Emma Moragrega-Knol³, Irene Romero Alfano⁴, Melissa Diogo Faria⁵ and Miguel Oliveira⁶, (1)University of Aveiro, Portugal, (2)Ramon Llull University, Portugal, (3)Ramon Llull University, Spain, (4)Department of Analytical and Applied Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (5)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (6)CESAM, University of Aveiro, Portugal

Early-life stress (ELS) can shape animal behaviour and physiology, yet its influence on the development of coping styles remains poorly understood. In this context, the presence of the antidepressant paroxetine (PAR) in aquatic environments is concerning, as it acts on conserved serotonergic pathways that play a key role in behavioural regulation.

This study aimed to determine how ELS, caused by abiotic (AB) stressors or environmental levels PAR, affects later-life coping styles (bold vs. shy) in zebrafish. To address this question, zebrafish larvae were exposed to sequential abiotic (AB) stressors at key developmental stages (4-, 7- and 15-days post fertilization - hpf), while embryos were exposed to PAR during embryogenesis (up to 48 hpf). After stress exposure, AB and PAR fish were reared under optimal conditions until the juvenile stage (45 dpf). At this stage behavioural profiling, neurochemical analysis, gene expression, and cortisol measurements were used to assess long-term consequences of ELS. Results show that bold and shy fish differ intrinsically in activity levels and monoaminergic regulation, and that ELS modifies these coping styles without altering their overall proportion. The 15 dpf stage was the most sensitive to AB stress, with shy juveniles exhibiting more behavioural, neurochemical and endocrine alterations than bold counterparts. PAR effects were dose-dependent, with shy phenotypes more affected by high PAR and bold phenotypes by low PAR concentrations.

Overall, ELS generated distinct stress-modified sub-phenotypes within bold and shy categories, with shy fish higher susceptibility to long-term programming. These findings highlight phenotype-specific developmental plasticity and improve understanding of how early adversity and neurochemical pollutants shape behavioural coping strategies. More research is needed to explore the adaptive potential of these ELS-modified coping styles in response to environmental contaminants, particularly for shy individuals.

1.10.P-We039 Behavioral Alterations of the Amphipod Gammarus pulex During Toxicokinetic Processes: The Role of Receptor Binding

Juliane Hollender, Colette vom Berg and Clarissa von Au, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Insecticides can not only target specific pest species but also have an impact on non-target organisms, such as aquatic invertebrates. In regulatory environmental risk assessments, toxicokinetic-toxicodynamic (TKTD) models are accepted for predicting time-dependent biological effects. Toxicokinetic studies are crucial for understanding chemical uptake and elimination dynamics, whereas the impact of these chemicals (toxicodynamic) is mainly assessed using lethal endpoints (i.e., immobility and mortality). However, behavioral endpoints can often be observed at concentrations below the lethal threshold and can indicate sublethal stress.

To explore toxicodynamics and sublethal effects, we investigated the relationship between internal concentrations and behavioral alterations using two polar neuroactive insecticides: the neonicotinoid thiacloprid and the butenolide flupyradifurone, both targeting the nicotinic acetylcholine receptors (nAChRs). Toxicokinetic analysis (online-SPE LC-HRMS/MS) revealed an elimination resistant fraction

for thiacloprid suspected to irreversibly bind to the nAChR, while flupyradifurone was fully eliminated.

Behavioral responses, quantified as total distance moved, were continuously monitored during both the uptake and elimination phases over 7 days to identify toxicokinetic-related changes in movement patterns. Notably, thiacloprid exposure resulted in a decrease in locomotion during the uptake phase, as well as a suppression of the circadian activity rhythm with incomplete recovery relative to controls during the elimination phase, consistent with irreversible receptor binding. Additionally, short-term behavioral assays were conducted at the end of each phase under both environmentally relevant and effect-inducing concentrations, assessing concentration-dependent responses to alternating light and dark conditions.

Our findings demonstrate the practical applicability of behavioral ecotoxicological approaches to toxicokinetics. With this study, we aim to improve the mechanistic understanding of chemical-induced behavioral alterations during uptake and elimination, linking toxicokinetics with sublethal effects.

1.10.P-We040 The Rise of New Approach Methodologies (NAMs) for Environmental Safety Assessment of Chemicals: Current Status, Challenges, and Strategies for Broader Adoption of NAMs

Maria Christou¹, Anastasia Georgantzopoulou¹, Maria T. Hultman¹, You Song¹, Aina Charlotte Wennberg¹, Sophie Mentzel¹, Michelle Rau Embry², Amelie Ott³, Takahiro Suzuki⁴, Giacomo Grassi⁵, Kyle Roush⁶ and Adam Lillicrap¹, (1)Norwegian Institute for Water Research, Norway, (2)HESI Global, (3)International Collaboration on Cosmetics Safety (ICCS), United States, (4)Kao Corporation, Tokyo, Japan, (5)L'Oréal, France, (6)Procter & Gamble, United States

Traditional ecotoxicity testing relies heavily on vertebrate animal models, which are resource-intensive, low-throughput, and raise ethical concerns under the 3Rs principle (Reduction, Refinement, Replacement). New Approach Methodologies (NAMs) including in silico, in chemico, in vitro and ex vivo offer promising alternatives for environmental hazard assessment. While NAMs have gained traction in human health risk assessment, their regulatory acceptance for environmental safety remains limited due to technical, scientific, and policy barriers. This proposed platform presentation will present an overview of a literature review. The review's objectives were to: (1) systematically review the current state of NAMs for aquatic toxicity assessment, (2) identify gaps in NAM readiness and endpoint coverage, and (3) provide recommendations to accelerate regulatory acceptance and integration of NAMs into environmental safety frameworks.

A systematic literature review was conducted using PubMed followed by the SWIFT-Active Screener tool, focusing on NAMs applicable to aquatic organisms (fish, amphibians, marine mammals). The review excluded terrestrial and invertebrate models. Search terms considered within the scope of the review included in silico, in chemico, in vitro and ex vivo. While embryo assays are not considered a NAM by all geographical regions and stakeholders, information from existing embryo assays was also reviewed to reduce the reliance on protected vertebrate life stages.

The screening identified 4,275 unique articles; 1,310 included for full-text review. A database containing all the reviewed information is freely available and contains 18 metadata fields including for example the captured assay type, species, endpoints, and readiness level.

This review provides a comprehensive roadmap for transitioning toward animal-free environmental safety assessment. By addressing gaps in readiness, standardization, and mechanistic integration, NAMs can become central to next-generation risk assessment, supporting global initiatives to phase out vertebrate testing.

Disclaimer/Disclosure:

We would like to acknowledge the International Collaboration on Cosmetics Safety (ICCS) for funding this review and Scott Belanger for his valuable input to the project.

1.10.P-We041 Are Behavioural Ecotoxicity Endpoints Relevant at the Population Level? Evidence-Based Insights for Environmental Protection

Michael Grant Bertram¹, Marlene Ågerstrand² and Tomas Brodin¹, (1)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Stockholm University, Sweden

A substantial body of evidence exists demonstrating that exposure to environmental contaminants can alter animal behaviour. Moreover, methodological and technological advancements, as well as increasing standardisation, mean that behavioural ecotoxicity studies are more rigorous and reliable than ever before. Despite this, behavioural data are still seldom used in the risk assessment and regulation of chemicals. This is partly due to a lack of clarity among some stakeholders about whether changes in behaviour at the individual level result in population-level outcomes. To address this, we first consider the state of evidence within the field of behavioural ecotoxicology linking individual-level behavioural alterations with population-level consequences. We then assess the evidence from behavioural ecology and other neighbouring fields that supports this link. Further, we evaluate whether some behavioural endpoints are more easily tied to population-level changes than others. In this regard, we propose combining insights from two complementary ecological frameworks—the functional trait framework and the limiting traits framework—to evaluate which behaviours should be prioritised in ecotoxicological research and regulatory efforts. We contend that the link between behavioural changes and population-level outcomes is evident, with behavioural endpoints representing a highly valuable yet so-far underutilised line of evidence in applied environmental protection.

1.11.A From Molecules to Models: Integrating Mechanistic Insights and Quantitative Modelling into Predictive Ecotoxicology

1.11.A.T-01 In Vitro Hepatic Microsomal Michaelis-Menten Parameters In Biotransformation: Do They Scale Allometrically?

Luke Ockhuijsen¹, Ad M. J. Ragas² and Jan A.J. Hendriks¹, (1)Radboud University, Netherlands, (2)Environmental Science, Radboud University, Netherlands

Extrapolating xenobiotic biotransformation parameters between species is challenging due to species differences. At the organism level, pharmacokinetic rate constants are believed to scale allometrically to body weight with a power of $\frac{3}{4}$, akin to metabolic rate constants. However, the underlying contributing factors for biotransformation scaling are unclear. Altogether, this understanding builds up to predicting xenobiotic biotransformation through a quantitative in vitro to in vivo extrapolation (QIVIVE) approach, combining allometric scaling relationships related to liver physiology and in vitro xenobiotic biotransformation. This study explores the previously unexplored potential of allometric scaling for hepatic microsomal Michaelis-Menten parameters. Hepatic microsomal Michaelis-Menten parameters, viz., affinity (K_m), maximum velocity (V_{max}), and in vitro clearance (CL_{int}), were examined for the xenobiotic biotransformation enzymes Cytochrome P450 (CYP) and UDP-glucuronosyl transferase (UGT). To ensure validity, data for 74 mammals per substrate biotransformation pathway were collected through a literature search and available databases. Ordinary linear regressions per pathway for each parameter showed that only 10% of the regressions scaled statistically significantly to body weight. Averaging all scaling exponents of significant regressions revealed that hepatic microsomal Michaelis-Menten parameters are independent of body weight. The average scaling exponent for each Michaelis-Menten parameter did not deviate from 0. Therefore, differences in other factors like enzyme abundance or liver physiology between species might be contributors to the observed $\frac{3}{4}$ exponent for allometric scaling relationships of in vivo xenobiotic clearance. Characterisation of underlying mechanisms at an enzyme-substrate level might ultimately improve understanding and estimation of xenobiotic clearance for mammals in QIVIVE approaches.

1.11.A.T-02 MIE, Myself and IC50: The Importance of the Molecular Initiating Event for the Difference in Carbaryl Sensitivity of Aquatic Arthropods

Nick van Sabben¹, Giulia Cafiero¹, Ivo Roessink¹, Sanne van den Berg¹, Tobias Pamminger² and Nico van den Brink¹, (1)Wageningen University and Research (WUR), Netherlands, (2)Early Environmental Safety, Bayer AG, Monheim am Rhein, Germany

Species differ in their sensitivity to pesticides, but the mechanisms behind these differences are only partly understood. The sensitivity of an organism for a compound is the product of both toxicokinetics, what the organism does to the compound, and toxicodynamics, what the compound does to the organism. Although variation in toxicokinetic processes in aquatic arthropods has been linked to the interspecies differences in sensitivity to pesticides, the role and variation in toxicodynamic processes is less well characterised. Addressing this knowledge gap, we examine a key toxicodynamic component: the molecular initiating event (MIE). We characterize the difference in interaction at the MIE of the carbamate carbaryl in six aquatic arthropod species to better understand its role in driving the difference in sensitivity. The MIE of carbaryl is the binding and inhibition of acetylcholinesterase (AChE). Structural variation in AChE across species may influence this interaction. To quantify the interaction at the MIE, homogenised samples of six aquatic arthropod species were exposed to a range of carbaryl concentrations and AChE activity was measured using the Ellman method adapted for plate reader. We derived the half-maximal inhibitory concentration (IC50), the bimolecular rate constant and the decarbamylation rate. The sensitivity of the organisms was reflected by the effect threshold in a reduced General Unified Threshold Model of Survival (GUTS). For the tested species, the Effect Threshold showed a strong positive correlation with the IC50.

This indicates that the interaction between carbaryl and AChE at the MIE is an important driver of sensitivity. Additional tests will show whether (de)carbamylation rates will correlate even stronger with the sensitivity of the organisms. These results also show that in vitro (AChE inhibition) assays could potentially be used to predict species sensitivity to carbamates.

1.11.A.T-03 What's Really Stopping the Head-AChE? Implementing Enzyme Inhibition in TKTD Model for Carbaryl

Nick van Sabben¹, Giulia Cafiero¹, Annika Mangold-Döring², Nina Jansen¹, Tobias Pamminer³, Ivo Roessink¹, Nico van den Brink¹ and Sanne van den Berg¹, (1)Wageningen University and Research (WUR), Netherlands, (2)Environmental Risk Assessment team, Wageningen University and Research (WUR), Netherlands, (3)Early Environmental Safety, Bayer AG, Monheim am Rhein, Germany

Linking the adverse outcome pathways (AOP) framework with effect model approaches will enhance our ability to robustly extrapolate across different levels of biological organization. Due to their increasing acceptance in Environmental Risk Assessment (ERA) and their continuously growing application in the field, mechanistic effect models like toxicokinetic-toxicodynamic (TKTD) models, seem the most logical choice for this endeavor. Therefore, we implement a TKTD model for carbaryl and *Gammarus pulex*. Informing the model with in vivo AChE activity measurements enables us to explicitly model the toxicodynamic process that is assumed to be driving toxicity (i.e. AChE inhibition).

Our results confirm the inhibiting effect of carbaryl on the target molecule AChE in *G. pulex* and display its recovery dynamics which together drive the effect on the organism's survival. In the next step, we use the TKTD model to combine these quantitative measurements on the molecular level with data on internal concentrations and the survival of *G. pulex* exposed to carbaryl, enabling us to create a quantitative link across multiple levels of biological organization.

As the development of our TKTD model is informed by data from different levels and scales (i.e., toxicokinetics, enzyme activity, and individual survival), we provide a robust tool to assess the toxicity of carbaryl and other AChE inhibitors with high predictive power. In doing so, we provide a versatile contribution to advance towards predicting adverse effects in non-target species, based on molecular endpoints, thereby supporting the AOP framework.

1.11.A.T-04 Expanding the Chemical Domain of Applicability of a Cross Species Quantitative Adverse Outcome Pathway for Activation of the Aryl Hydrocarbon Receptor Leading to Early Life Stage Mortality

Justin Dubiel¹, Cameron Hunter Collins², Andreas N.M. Eriksson¹, Vann Lynne Boyte², Lauren Eagon², Fernando Calahorra-Nunez³, Jonathan Reid Sangiovanni⁴, Zhe Xia⁵, Gregg Tomy⁵, Danielle Philibert⁶, Benjamin Patrick de Jourdan⁶, Jessica Head⁷, Nicolas Bury⁸, Jon Doering² and Steve Wiseman¹, (1)University of Lethbridge, Canada, (2)Louisiana State University, United States, (3)University of Southampton, United Kingdom, (4)McGill University, Canada, (5)University of Manitoba, Canada, (6)Huntsman Marine Science Center, Canada, (7)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (8)Ocean and Earth Science, University of Southampton, United Kingdom

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental chemicals that induce toxicity by activating the aryl hydrocarbon receptor (AhR). Species differ dramatically in sensitivity to AhR activation by dioxin-like chemicals (DLCs) and PAHs. A predictive model linking AhR activation by DLCs to early life-stage mortality in birds and fish has been developed to aid in risk assessment, however this model is not applicable to PAHs. This research aims to 1) expand the domain of applicability of the existing model to PAHs and 2) use in silico approaches to explore molecular mechanisms underlying differences in species sensitivity to potentially incorporate in silico predictions into the model. A standardized in vitro reporter gene assay was used to develop species sensitivity distributions for transactivation of the AhR across species. To determine whether in vitro differences in sensitivity to AhR activation correspond with differences in sensitivity to early life-stage mortality, embryos of a subset of fish and avian species were exposed to PAHs by microinjecting into the yolk sac of embryos. Lastly, in silico analysis was performed to determine binding potential energies and investigate the role of receptor subdomains in differences in species sensitivity. Species differences in sensitivity to AhR activation by PAHs exceeded 500-fold and there is a strong and significant relationship between sensitivity to AhR activation (EC50) and sensitivity to early life-stage mortality in fish (LD50; $p = 0.007$, $R^2 = 0.86$) and

birds ($p = 0.007$, $R^2 = 0.91$). Adjustment factors were calculated for PAHs in birds and fish to enable predictions of PAH toxicity to be made using the existing predictive model. Predicted LD50s were within 3.9-fold of measured LD50s across birds and fish, on average. There is a significant correlation between the EC50 for activation of the zebrafish AhR2 by 22 structurally diverse ligands and *in silico* binding affinity ($p = 0.0002$, $R^2 = 0.57$) which suggests that this predictive model can be further expanded to generate predictions using *in silico* methods, however cross-species validations are ongoing. Due to the abundance of PAHs in the environment and practical limitations of performing traditional toxicity tests across numerous species, developing *in vitro* and *in silico* tools to assess these toxicities more efficiently could be essential for more objective ecological risk assessment of these chemicals.

1.11.A.T-05 When are Repeated Pesticide Exposures Independent? A Species-Specific Approach Using GUTS-based Depuration Times

Anna Huang, Jan Baas and Sanne van den Berg, Wageningen Environmental Research, Netherlands

Pesticide persistence inside organisms is far less understood than persistence in soil or water, yet internal elimination and recovery processes critically shape how organisms respond to repeated exposure pulses in agricultural landscapes. When elimination is slow, sequential applications can lead to carry-over toxicity, but current risk assessment frameworks focus mainly on external exposure declines and overlook internal toxicokinetics. This study therefore evaluates how recovery dynamics, quantified through toxicokinetic–toxicodynamic (TKTD) parameters, influence the minimum safe interval between applications of products containing the same active ingredient.

We conducted a targeted literature review of published TKTD parameters for pesticides, following PRISMA principles. Forty-one studies met all criteria, from which we extracted toxicokinetic rate constants across five TKTD model types and calculated the 95% depuration time (DRT_{95}) as a cross-model indicator of recovery. Data covered 36 chemicals and 75 species spanning 37 taxonomic orders.

DRT_{95} values varied widely across species and chemical classes. Cladocerans and some aquatic insects showed the longest recovery times, whereas fish typically exhibited faster elimination. Variation within taxa was often driven by chemical class: for example, amphipods showed slow recovery from neonicotinoids but rapid depuration of pyrethroids. These patterns highlight substantial differences in vulnerability to repeated pulses, even among closely related species.

Our findings demonstrate that DRT_{95} is a mechanistically grounded and broadly applicable metric for defining minimum intervals between applications of products sharing the same active ingredient. Active ingredients with long DRT_{95} values should be limited to single annual applications, and the combined use of multiple products containing the same active ingredient should be avoided to prevent internal carry-over. Compounds with short DRT_{95} values may allow multiple applications, but stacking within a single treatment remains inadvisable. By integrating internal toxicokinetics into guidance on application timing, pesticide regulation can better reflect the dynamics of real-world exposure and reduce unintended risks for non-target organisms. Future work should quantify whether mixtures of active ingredients require additional safety margins.

1.11.B From Molecules to Models: Integrating Mechanistic Insights and Quantitative Modelling into Predictive Ecotoxicology

1.11.B.T-01 Linking Biomarkers to Life-History Traits through Response–Response Approaches in Three-Spined Stickleback (*Gasterosteus aculeatus*) Exposed to Bisphenol S (BPS)

Blanche Goddyn, Anne Bado-Nilles, Grégoire Balluats, Ugo Iaria, Cyril Turies, Olivier Palluel and Rémy Beaudouin, INERIS, France

Freshwater ecosystems are increasingly threatened by complex mixtures of anthropogenic contaminants. Since monitoring all chemicals is unfeasible, integrative approaches are needed to evaluate mixture toxicity. Biomarkers provide a sensitive and mechanistic framework to link sub-individual alterations with higher biological responses. This study investigated the effects of bisphenol S (BPS), an emerging endocrine disruptor, on the three-spined stickleback (*Gasterosteus aculeatus*), focusing on response–response relationships between biomarkers and life-history traits.

Males and females were individually exposed for 40 days to 0, 1, 10, and 100 $\mu\text{g/L}$ BPS under controlled laboratory conditions. After 40 days, males were placed in isolated compartments with nesting materials and visual access to females for a 7-day nest-building test. Morphometric indices (HSI, GSI, NSI), biochemical biomarkers (hepatic lipid content, VTG, SPG, sperm mortality), and reproductive behaviour (nest-building) were assessed. Data were analysed using ANOVA or Kruskal Wallis tests, response–response regression

modelling, and Linear Discriminant Analysis (LDA).

In females, a significant increase in HSI at 100 µg/L BPS indicated an obesogenic response, while trends in GSI and oocyte counts suggested estrogenic activity. A four-parameter log-logistic model accurately described the relationship between GSI and mature oocytes, revealing reproductive dysfunction potentially linked to egg retention or abnormal yolk accumulation. In males, GSI decreased significantly at 100 µg/L BPS, and nest-building was delayed among individuals displaying extreme physiological profiles. The LDA score, integrating HSI, NSI, and GSI, efficiently identified these outliers and predicted nest-building performance.

Overall, this study demonstrates the relevance of response–response approaches to link physiological and behavioural responses under chemical stress. By integrating multivariate biomarker data, these methods enhance the predictive power of ecotoxicological assessments and support the development of mechanistic biomonitoring tools to improve ecological risk assessment of emerging contaminants such as BPS.

1.11.B.T-02 Temperature Effects on Species Sensitivity Distributions Across Aquatic Taxa

Lea Grenc¹, Leo Posthuma², Paul van den Brink³ and Jan A.J. Hendriks¹, (1)Radboud University, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands, (3)Wageningen University and Research (WUR), Netherlands

Human activities introduce a wide range of chemicals into aquatic environments, where they can affect aquatic organisms and disrupt ecosystem functioning. Ecological risk assessment frameworks aim to determine concentrations at which chemicals pose no or only minimal risk to the environment, often using the Species Sensitivity Distribution (SSD) approach. However, SSDs are generally based on standardised toxicity tests conducted at specific temperatures, even though aquatic species experience natural temperature variation. This study explores how SSDs vary with respect to the temperatures at which toxicity is assessed. Acute toxicity data for fish, crustaceans, and algae were obtained from the ADORE database. 22 chemicals with sufficient data were selected for analysis. The linear Arrhenius equation was used to assess the relationship between temperature and LC50 values for species chemical pairs. To investigate temperature effects on SSDs, LC50 values were grouped by test temperature, and separate SSDs and corresponding HC50 values were constructed for each chemical where data allowed. The Arrhenius equation was also applied to describe correlations between temperature and HC50.

Temperature did not show consistent significant effects on LC50 across all species chemical pairs. However, in most cases where statistically significant relationships were found, toxicity increased with rising temperature. SSDs constructed for individual chemicals were generally similar in shape but shifted to the left with increasing temperature, indicating higher sensitivity under warmer conditions. This pattern occurred only when the same species contributed to SSDs across all temperatures. When HC50 trends could be evaluated, their temperature responses were similar to those observed for LC50.

These results show that temperature can influence both species-level toxicity and community-level sensitivity estimates. Incorporating temperature as a modifying factor in SSD-based risk assessments could therefore improve their relevance under changing environmental conditions.

1.11.B.T-03 Mechanistic Modelling of Insecticide Effects on Lepidoptera using DEB-TKTD

Josef Koch¹, Simon Ewald Hansul¹, Eric Peterson² and Maxime Vaugeois², (1)gaiac eco assessment GmbH, Germany, (2)Syngenta LLC, United States

Current insecticide risk assessments for endangered Lepidoptera under U.S. regulatory frameworks (US EPA) rely on safety factors often derived from honey bee data, potentially leading to inaccurate risk characterization. To address this limitation, we are developing mechanistic effect models combining Dynamic Energy Budget (DEB) theory with toxicokinetic–toxicodynamic (TKTD) approaches. The DEB framework models animal life cycles in terms of energy allocations for growth, development, and reproduction, while DEB-TKTD models additionally incorporate chemical uptake, metabolism, and lethal and sublethal effects on DEB processes. In the first project phase, the painted lady *Vanessa cardui* was used as a model species. A recently proposed DEB variant for terrestrial holometabolous insects was refined to match the growth pattern of *V. cardui*. Insecticide effects on survival and growth of three larval instars under dietary exposure were analysed using the DEB-TKTD approach. Traditionally, (DEB-)TKTD models have mainly focused on aquatic species, where exposure can be described directly by the external water concentration. For terrestrial organisms, however, uptake kinetics require explicit reformulation. Here, we build upon the recently proposed BufferGUTS model and evaluate its applicability for integrating lethal and sublethal endpoints with diet-based terrestrial exposure metrics in DEB-TKTD.

The newly generated laboratory data show clear dose-response relationships for survival and growth, with a life stage-dependent sensitivity to the insecticide. Size-dependent toxicokinetics alone could not fully explain this pattern, so additional assumptions are being explored. Preliminary modelling suggests that assuming an independent effect-slope parameter for each life stage improves fits while keeping model complexity low. Plausible physiological modes of action (pMoA) are currently being evaluated to link damage to observed growth effects. We see the integration of sublethal and lethal endpoints as a particular strength of DEB-TKTD, and ongoing experiments will help refine the model structure and clarify sensitivity patterns. Overall, this work demonstrates both the feasibility and the added value of DEB-TKTD modelling for Lepidoptera. As additional endpoints and mechanisms are incorporated, the model is expected to provide a robust basis for future risk assessments.

1.11.B.T-04 Mechanistic Modelling of Aquatic Mesocosm Communities: Exploring Model Structures for Ecotoxicological Studies

Chuxinyao Wang¹, *Louis Sollinger², Lukas Kruckenfellner², Andreas Scheidegger¹, Peter Ebke² and Nele Schuwirth³*, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)MESOCOSM GmbH, Institut fuer Gewaesserschutz, Germany, (3)Systems Analysis and Modelling, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Mesocosms are controlled outdoor aquatic model ecosystems that enable the study of ecological responses to toxicants under environmentally realistic conditions. They capture both natural variability and the direct and indirect effects of chemical exposure at the community and ecosystem levels, making them valuable tools in higher-tier ecological risk assessment. However, the inherent complexity of mesocosm systems complicates the interpretation of observed community dynamics. Interacting biological processes, measurement uncertainty, and natural variability are confounded in the data, making it difficult to disentangle underlying mechanisms and to accurately understand the processes occurring within the mesocosms.

Mechanistic modelling provides a powerful tool, enabling better understanding of community dynamics and complex biological interactions. However, the level of detail required for such models to remain both interpretable and useful is still unclear. This research therefore aims to develop and compare versions of a mechanistic model that differ in the resolution of the food web and represent key ecological processes and food web interactions in control mesocosms without chemical treatment. Bayesian inference is applied to quantify uncertainty and enhance the interpretation of variability observed in mesocosm dynamics.

By systematically linking model complexity with predictive performance and uncertainty, this study aims to establish a framework for interpreting mesocosm observations with a quantitative approach. This work provides a foundation for future applications to toxicant exposure scenarios, ultimately improving environmental risk assessment by connecting experimental data with ecological understanding in mesocosms.

1.11.B.T-05 Quantifying the Effect of Biodiversity Loss to Freshwater Ecosystems by Linking Mean Species Abundance to Ecosystem Services

Venja Sandrine Anna Margit Schoenke¹, *Paul van den Brink², Leo Posthuma³ and Jan A.J. Hendriks¹*, (1)Radboud University, Netherlands, (2)Wageningen University and Research (WUR), Netherlands, (3)RIVM, Netherlands

Chemical pollution is among the five highest-ranked environmental drivers of biodiversity loss, with freshwater ecosystems among the most vulnerable. The emerging consequences of this loss remain insufficiently quantified due to the complexity of ecosystem responses. This work addresses this challenge by determining the loss of ecosystem services resulting from chemical stress-induced biodiversity loss.

As representatives of an ecosystem, we used data from three freshwater mesocosm experiments. The mesocosms were exposed to the fungicide carbendazim, the herbicide linuron, and the insecticide mixture of chlorpyrifos and lindane. To determine ecosystem services, ecosystem productivity was assessed through decomposition rates, photosynthetic activity, and macrophyte biomass production. These indicators were chosen to represent provisioning, regulating, and supporting ecosystem services. The mean species abundance (MSA) served as a metric of biodiversity. It was used to calculate the mean species abundance relationship (MSAR), which represents the loss of biodiversity as a function of chemical concentration. Functional models were then

applied to translate biodiversity decline into changes in ecosystem productivity.

It was shown that each chemical's mode of action resulted in distinct ecological responses and that ecosystem productivity decreases log-linearly with biodiversity reduction. The resulting loss of ecosystem services at the current hazardous concentration threshold for 5% of species (HC5) will be critically discussed to evaluate its safety for risk assessment. Furthermore, the implications of this loss at HC5 will be converted into monetary values to provide additional information to stakeholders. This approach enhances the integration of biodiversity-function relationships into environmental management and supports a more thorough evaluation of the impacts of chemicals on the environment.

1.11.P From Molecules to Models: Integrating Mechanistic Insights and Quantitative Modelling into Predictive Ecotoxicology

1.11.P-We042 Identification of Ecotoxicological Endpoints for Developing Predictive QSAR Models of Naphthenic Acids in Brazilian Produced Water

Marllon Robert dos Santos Valentim, Sarah Daflon, Alyne Moraes Costa and Juacyara Carbonelli Campos, School of Chemistry - UFRJ, Brazil

Produced water (PW) is the main effluent generated during oil and gas exploration; some of its constituents can cause damage to the aquatic environment, including naphthenic acids, phenols, BTEX, and PAH. In Brazil, according to the Brazilian National Oil Agency, 4.344 m bbl/d of oil equivalent were obtained in 2024; that production can generate between 17.38 m and 43.44 m bbl PW/d, which potentially may have a significant impact on the aquatic environment. In this context, quantifying the damage caused by PW compounds through ecotoxicology assays is crucial for determining effective strategies to treat this effluent. However, in recent years, the increasing concern about the impact and damage that these assays can cause to organisms has sparked a debate about reducing tests involving organisms, and it has encouraged the development of alternative methods for evaluating the effects that substances may have on the environment. QSAR models are crucial for determining ecotoxicology results without the need for additional assays using organisms. In this work, a strategy was developed to extract and filter data from databases to determine possible organisms and ecotoxicology endpoints with parallel curation on data to build a model to predict results of ecotoxicology tests to naphthenic acids present in Brazilian PW of the oil and gas industry. In the first step, many substances (658 compounds) were gathered with the QSAR Toolbox that were similar to the naphthenic acids chosen to be predicted. In the second step, data on organisms with more results for the substances collected in the first step were extracted, and then the two organisms with the most results were selected. In the third step, the ecotoxicology endpoints with more results were counted and ranked, and every not-conclusive result ($LC_{50} > 100$ mg/L) was removed. These steps demonstrated that *Daphnia magna* was the aquatic organism with the most compounds exhibiting ecotoxicological results for the model: EC5048h for mobility (76 compounds) and LC50 48h for mortality (49 compounds). *Raphidocelis subcapitata* was the second aquatic organism with more results: EC50 72h for growth rate (68 compounds), NOEC 72h for growth rate (64 compounds), and EC10 72h for growth rate (45 compounds). These five endpoints may provide applicable QSAR models to the naphthenic acids of PW. The following steps will be the collection of descriptor data, the development of models and the statistical validation of the results.

1.11.P-We043 Exploring Mechanisms of Species Sensitivity to AhR Activation using In Silico Approaches
Justin Dubiel¹, Fernando Calahorra-Nunez², Nicolas Bury³, Jon Doering⁴ and Steve Wiseman¹, (1)University of Lethbridge, Canada, (2)University of Southampton, United Kingdom, (3)Ocean and Earth Science, University of Southampton, United Kingdom, (4)Louisiana State University, United States

The aryl hydrocarbon receptor (AhR) transcription factor that is activated by a wide range of structurally diverse endogenous or exogenous ligands. Species differ dramatically in sensitivity to AhR activation by various ligands including dioxin-like chemicals (DLCs) and polycyclic aromatic hydrocarbons (PAHs). Sensitivity to AhR activation by DLCs in birds is determined by two key amino acids in the ligand binding domain, however due to the AhR of fishes being less conserved the mechanisms underlying species sensitivity in fishes are not well understood. This research utilized in silico molecular docking to characterize ligand-AhR interactions and binding affinity. To determine whether differences in in silico binding affinity correspond with differences in chemical potency, molecular docking with the AhR2 of zebrafish (*Danio rerio*) was performed for 22 ligands, including 7 DLCs, 1 heterocycle, 1 benzotriazol ultraviolet stabilizer, and 4 unsubstituted, 3 alkyl-substituted, and 6 halo-substituted PAHs with available in vitro data, which yielded a significant correlation between the in vitro EC50 for AhR2 activation and in silico binding affinity ($p = 0.0002$, $R^2 = 0.57$). To investigate whether differences in binding affinity correlate with species differences in sensitivity to AhR activation, molecular docking was performed with the AhRs of 9 phylogenetically diverse fish species. While there was no significant correlation between the EC50 for DLCs and binding affinity across species ($p = 0.11$, $R^2 = 0.36$) there was a significant correlation between EC50s for AhR activation and the size of the glutamine- and acidic-rich subdomains of the transactivation domain of the AhR ($p = 0.0005$, $R^2 = 0.65$). This suggests that both the ligand binding and transactivation domains of the AhR are involved in species differences in sensitivity to AhR2 activation by DLCs. Research is ongoing to generate data in additional species and with PAHs to investigate whether the same relationship is true for PAHs. Additionally, work is ongoing to characterize differences in binding position and specific amino acid interactions across species and ligands, and the role of the ligand binding and transactivation domains in driving differences in species sensitivity. This understanding could potentially be used to further improve predictive models and enable predictions about chemical toxicity using in silico approaches.

1.11.P-We044 Modelling Gene Expression Dynamics During Early Zebrafish Development to Explain Developmental Changes in Detoxification Capacity

Marie Große Holthaus¹, Florian Schunck², Andreas Focks³, Wibke Busch⁴ and Paul Michaelis⁴, (1)University of Osnabrueck, Germany, (2)Institute of Mathematics, University of Osnabrueck, Germany, (3)FB06/Institute of Mathematics, University of Osnabrueck, Germany, (4)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Molecular toxicokinetic-toxicodynamic (mTKTD) models dynamically link exposure to detoxification and lethality via the expression of stress regulator genes (e.g. *cyp1a*, *nrf2*). Currently, these models assume a constant baseline expression for fold-change calculation. However, during early zebrafish embryogenesis, gene expression is highly dynamic. A key event is the maternal-to-zygotic transition (MZT), during which the zygotic genome becomes transcriptionally active and gradually replaces maternally deposited factors. Consequently, stress regulator levels can vary significantly across early developmental stages, implying that the stress response is strongly dependent on exposure timing. Assuming a constant baseline may therefore overestimate the detoxification capacity at stages where stress regulator concentrations are naturally low.

To address this limitation, we developed a set of mechanistic transcription models that capture common expression patterns and incorporate MZT dynamics to generate biologically more profound baselines. Each model describes the total transcript abundance as the sum of maternal and zygotic contributions. Maternal transcripts dominate initially and decay without de-novo transcription, while zygotic transcripts are absent at first but accumulate after zygotic genome activation (ZGA). We explored two ZGA timing mechanisms assuming a maternal threshold or time-dependent activation. After ZGA, transcription either proceeds with zero-order growth or is repressed by a transcription factor. We compared these versions against a commonly used kinetic model.

We fitted and evaluated all models using an RNA sequencing dataset comprising more than 24,000 genes and 18 time points from 0 to 120 hpf using a Bayesian approach. Our results show that 58% of the genes can be described by at least one of the models. For *cyp1a* in particular, the early developmental stages are captured equally well by both the threshold and the timing model. Both models reproduce the initial decline and subsequent increase in transcript levels, whereas the standard kinetic model overestimates the early expression.

The simulated *cyp1a* baseline will be integrated into a recently published mTKTD model (GUTS-RNA-pulse) to assess the impact of exposure timing, comparing effects and detoxification capacity for exposure to diclofenac, diuron and naproxen at 2 hpf (pre-ZGA) and 24 hpf (post-ZGA).

1.11.P-We045 Molecular Insights into Caffeine Toxicity in the Freshwater Gastropod *Physa acuta*
Ahlam Mohamed-Benhammou, National University of Distance Education (UNED), Spain

Caffeine (CAF), a widely consumed psychoactive compound, has recently been recognized as an emerging environmental pollutant in freshwater ecosystems. Previously, it has been shown that relevant concentrations of CAF (5, 30, and 50 µg/L) alter behaviour, including locomotor activity, exploration patterns, and feeding patterns in the freshwater gastropod *Physa acuta*. Building upon these findings, the present study investigates the molecular mechanisms underlying these behavioural effects. Adult snails were exposed to the same CAF concentrations (5, 30, and 50 µg/L) for 24 hours and 7 days. The transcriptional activity of genes associated with the nervous system, as well as the glucocorticoid receptor (Cortisol), known to interact with CAF, was analyzed via RT-PCR. The target genes are: adenosine receptor 1 (A1AR), adenosine A2B receptor (ADORA2B), adenosine receptor A3 (ADORA3), acetylcholinesterase (AChE), glycine receptor subunit alpha 2 (GLRA2), dopamine receptor 1 (DRD1), dopamine receptor 2 (DRD2), serotonin receptor (HTR), ryanodine receptor (RyR), Glutamate Receptor NMDA 2B (GRIN2B), Hydroxysteroid 11-beta-dehydrogenase 1 (HSD11B), FMRFamide receptor (FMRFaR), sodium-dependent noradrenaline transporter (SLC6A2), and GABA Transporter 1 (SLC6A1). Given that the molecular pathways influenced by CAF in aquatic invertebrates remain poorly understood, this research aims to provide valuable insights into the molecular pathways modulated by CAF in freshwater invertebrates, thereby filling this gap. Additionally, the results of this study will contribute to a better understanding of its ecological impact and support environmental risk assessment efforts.

I want to thank my supervisor, José-Luis Martínez-Guitarte, for the critical reading of the manuscript, and the support to carry out this work.

1.11.P-We046 Measuring Detoxification In-Vivo: Validation of a General Esterase Substrate in Several Freshwater Invertebrates

Giulia Cafiero¹, Anna Huang¹, Tobias Pamminer², Paul van den Brink¹, Sanne van den Berg¹ and Ivo Roessink¹, (1)Wageningen University and Research (WUR), Netherlands, (2)Early Environmental Safety, Bayer AG, Monheim am Rhein, Germany

General esterase enzymes are a ubiquitous and essential superfamily that mediate neurotransmission and phase I metabolism through cleavage of esterase bonds. They are key for the detoxification of endogenous molecules and xenobiotics and are a promising target to gain mechanistic insight into toxicokinetic processes that could be leveraged to understand (eco)toxicological effects. While the activity of carboxyl/butyryl esterase enzymes has been measured in vitro for a few species-substrate combinations, in vivo assays have not yet been optimized for multiple species, nor validated for several chemical classes. In this study, we present the selection of a fluorogenic substrate for in vivo measurement of general esterase enzyme activity in several aquatic invertebrate species. Basal conversion activity of the substrate 4-methylumbelliferyl butyrate (4-MUB) to 4-methylumbelliferone (4-MU) is measured in vivo by exposure of six freshwater arthropods. The assay conditions are optimized based on the sensitivity of the substrate to pH, light intensity, and temperature. Our findings show that the 4-MUB substrate is mostly stable at physiological pH, in dark conditions and at room temperature. Each species is exposed for 4 hours to a range of 4-MUB concentrations (0 – 104 µM), with solution samples taken every hour. This allows measurement of the formation kinetics of the fluorescent product, 4-MU. The fluorescent units read by the spectrophotometer are converted to pmol/mg protein/hour of 4-MU by measuring the protein content of each species. Preliminary results show low variation in substrate affinity between species. The range of 4-MUB concentrations allowed to select an optimal substrate concentration for each species to be used for the synergism assay. To validate the metabolic activity of 4-MUB, a synergism assay is performed with a known esterase inhibitor, S,S,S-tributyl phosphorothioate (DEF). After assessing the toxicity limits of DEF, the species are pre-exposed to the inhibitor for 24h, and the metabolic activity is assessed with the 4-MUB assay. The results will give insight into the affinity of the substrate with the esterase system of the species. Selection and optimization of substrates like 4-MUB is fundamental to expand the suite of molecular tools in ecotoxicology. These tools help gain insights into the impact of chemical stressors on the detoxification capacity of aquatic invertebrates and into the understanding of toxicity determinants.

1.11.P-We047 Tire Wear Particles as an Oxidative Stressor: Antioxidant Enzyme Response in the Carpenter ants (*Camponotus* spp.)

Snehal Wasnik, Shuo Cheng and Jeffrey Cross, Institute of Science Tokyo, Japan

Tire wear particles (TWPs) constitute one of the largest sources of microplastic pollution in terrestrial environments, with global estimates at 6.1 million metric tons annually. Unlike conventional microplastics, TWPs represent a complex mixture of synthetic and natural rubber polymers with chemical additives including carbon black, zinc oxide, sulfur, and polycyclic aromatic hydrocarbons. Despite their environmental prevalence, research examining TWP impacts on terrestrial insects remains scarce. This study investigated oxidative stress responses of carpenter worker ants (*Camponotus* spp.) exposed to environmentally relevant TWP concentrations. Ants were maintained under controlled laboratory conditions and assigned to three treatment groups: control, 0.05% TWPs, and 0.50% TWPs, representing TWP levels in roadside soils. TWPs were mixed into the Bhastkar diet and fed to ants over 72 hours. Following exposure, antioxidant enzyme activities, including SOD, CAT, POD, and MDA, were measured. Results demonstrated distinct concentration-dependent oxidative stress patterns. SOD activity exhibited a biphasic response: 0.05% TWP exposure caused 19.4% activation, indicating compensatory antioxidant defense, while 0.50% TWP caused 20.2% suppression, suggesting enzyme system overwhelm. Lipid peroxidation increased dramatically, with MDA levels showing 6.3-fold and 18-fold increases at 0.05% and 0.50% TWP, respectively, indicating severe membrane damage. CAT activity was suppressed by 50% at both concentrations, highlighting catalase inhibition as a critical vulnerability. POD activity showed moderate, non-significant reductions. These findings demonstrate that environmentally relevant TWP concentrations induce severe oxidative stress in carpenter ants, characterized by catalase suppression, extreme lipid peroxidation, and biphasic SOD responses. The magnitude of antioxidant impairment at concentrations found in roadside soils suggests TWPs pose significant biochemical threats to terrestrial invertebrates. Given carpenter ants' keystone roles in forest ecosystems through nutrient cycling and decomposition, TWP pollution may have cascading effects on soil ecosystem functioning. This study provides critical baseline data for understanding TWP ecotoxicological impacts on terrestrial insects and highlights the need for investigation into long-term consequences and specific chemical constituents responsible for oxidative damage.

1.11.P-We048 Applying a Toxicokinetic-receptor Model to Explain Long-lasting Bioaccumulation of Neonicotinoids in Two Invertebrate Species

Clarissa von Au¹, Johannes Rath², Juliane Hollender¹ and Natsumi Maeda¹, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Uchem, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Neonicotinoids are an insecticide class whose polarity indicates a low potential for bioaccumulation. However, studies have revealed the tissue concentrations of gammarids to be significantly higher in the field than those derived from laboratory toxicokinetic studies. This demonstrates an environmental risk to non-target aquatic species and further highlights gaps in our understanding of the underlying bioaccumulation processes. An observed elimination resistance of neonicotinoids could be due to the irreversible binding to the nicotinic acetylcholine receptors (nAChRs).

To test this hypothesis, we performed toxicokinetic experiments with three neonicotinoids (i.e., Imidacloprid (IMI), Thiacloprid (THI), and Acetamiprid (ACE)) using two freshwater invertebrate species *Gammarus pulex* and *Hyalella azteca*. We further aimed to elucidate receptor–ligand interactions by examining competition experiments, as these compounds all selectively bind to nAChR but exhibit different affinities and efficacies towards the receptor.

Thus, first, we investigated long-duration kinetics (6 to 18 days) for each compound individually. Subsequently, we conducted sequential exposure experiments, comprising two uptake phases with paired compounds to assess displacement dynamics. Concentrations in the medium and extracts were determined using an online-solid phase extraction system coupled with liquid chromatography and high-resolution tandem mass spectrometry (online-SPE LC-HRMS/MS). Various experiments were used to calibrate and validate a two-compartment toxicokinetic-receptor model, including growth dilution and irreversible receptor binding. The model facilitated the mechanistic understanding of competitive binding at the different subunits of the receptor, explaining neonicotinoid bioaccumulation in aquatic invertebrates.

Altogether, the results emphasize that receptor binding as a cause for bioaccumulation should be considered in chemical risk assessments.

1.11.P-We049 Bayesian Species Sensitivity Distribution Modeling for Microplastics: Integrating Particle Properties and Species-Level Variations of Effect Concentrations

Yuichi Iwasaki¹, Kazutaka Takeshita², Koji Ueda¹ and Wataru Naito³, (1)National Institute of Advanced Industrial Science and Technology, Japan, (2)Toyo University, Japan, (3)Riss, National Institute of Advanced Industrial Science and Technology, Japan

Because of growing global concern about the environmental impacts of microplastic particles (MPs), scientifically defensible ecological risk assessments are increasingly required. However, such assessments remain challenging due to the diversity of MP properties, such as particle length and shape. In this study, we developed species sensitivity distributions (SSDs) for MPs using hierarchical Bayesian modeling, which accounted for species identity as well as the influence of MP properties on chronic no observed effect concentrations (NOECs). We also incorporated highest observed no-effect concentrations (HONECs) into SSD estimation by appropriately treating them as right-censored data. Using data from a recently updated ecotoxicity database, we analyzed two datasets excluding HONECs (21 species) and including HONECs (33 species). For the HONEC-excluded dataset, the best SSD model, selected based on the widely applicable information criterion, included size category (particle length <83 μm vs. $\geq 83 \mu\text{m}$) and fiber shape, suggesting that smaller particles and fibers were associated with lower chronic NOECs. For the HONEC-included dataset, the best model included particle length and shape (fragment and fiber), indicating that shorter particle lengths and non-spherical shapes were linked to lower chronic NOECs. Median estimates of the hazardous concentration for 5% of species (HC5) ranged from 0.06 $\mu\text{g/L}$ (fiber, <83 μm) to 111 $\mu\text{g/L}$ (non-fiber, $\geq 83 \mu\text{m}$) in the HONEC-excluded dataset. For the HONEC-included dataset, median HC5 estimates ranged from 0.003 to 167 $\mu\text{g/L}$ depending on particle length and shape, with considerable uncertainty in the estimates. Despite uncertainties in modeling, our SSD modeling framework provides a generalizable and data-informed approach to incorporating diverse MP properties and censored effect concentrations to improve ecological risk assessments for MPs as well as other substances.

1.11.P-We050 Trophic Transfer Impact of Combined Microplastics and Tire Particles in Three-Species Freshwater Food Chain

Kimheng Keang and Shuo Cheng, Institute of Science Tokyo, Japan

Microplastics (MPs) and tire particles (TP) are ubiquitous contaminants in aquatic ecosystems, posing complex ecological challenges through their persistence, heterogeneity, and potential for trophic transfer. While previous studies have explored single-species exposures, limited evidence exists on how these mixed polymeric pollutants propagate across multiple trophic levels. This study investigates the trophic transfer, physiological responses, and oxidative stress induced by combined microplastics and tire particles (MPsTP) in a three-species freshwater food chain: *Chlorella vulgaris*, *Daphnia magna*, and zebrafish (*Danio rerio*).

A simplified food-chain model was developed to simulate environmentally relevant exposure (1 mg/L) to MPs, TP, and their mixtures. The MPs comprised polypropylene, polyethylene, and polyethylene terephthalate particles and fibers representing dominant polymers in freshwater environments. *Chlorella vulgaris* cultures were exposed to MPs, TP, and MPsTP mixtures before being fed to *Daphnia magna*, which were subsequently consumed by zebrafish. Fluorescence microscopy confirmed ingestion, retention, and transfer of particles from microalgae to *Daphnia* and ultimately to zebrafish intestinal tissues, demonstrating efficient movement of synthetic particles through the trophic chain.

Biochemical assays revealed that zebrafish exposed via trophic pathways exhibited significantly elevated malondialdehyde (MDA) levels, indicating enhanced lipid peroxidation and oxidative stress, particularly in the MPs and TP groups. Total antioxidant capacity (T-AOC) remained stable, suggesting partial compensation through antioxidant defense mechanisms during short-term exposure. These results demonstrate that MPs and

TP induce sublethal oxidative imbalance at higher trophic levels, even at low concentrations.

This study provides direct experimental evidence that mixed microplastic and tire-derived contaminants are trophically transferred within freshwater ecosystems, eliciting oxidative stress responses in consumers. The findings highlight the mechanistic link between particle ingestion, physiological disruption, and potential ecological consequences, reinforcing the need for integrating trophic-level interactions into predictive ecotoxicology models. Understanding such pathways is crucial for advancing next-generation risk assessment frameworks addressing complex plastic pollution in aquatic food webs.

1.11.P-We051 Modelling the Life Cycle of the Painted Lady Butterfly *Vanessa cardui* Using the Dynamic Energy Budget Theory

Simon Ewald Hansul¹, Josef Koch¹, Eric Peterson² and Maxime Vaugeois², (1)gaiaeco assessment GmbH, Germany, (2)Syngenta LLC, United States

Mechanistic effect models combining Dynamic Energy Budget (DEB) theory with Toxicokinetic-Toxicodynamic (TKTD) approaches offer several advantages. They allow extrapolation from laboratory generated toxicity data to untested scenarios. Time-variable exposure and environmental conditions can be accounted for, and individual-level effects may be extrapolated to the population. In order for toxicity effects observed in the laboratory to be accurately reproduced in the DEB-TKTD model, it is important that the DEB reference model is first able to reproduce the control data sufficiently well. While there are predefined DEB model variants for many groups of organisms that can be fitted to control data (typically composed of literature data and control data from toxicity tests) with relative ease, holometabolous insects represent an underdeveloped group in this regard. The aim of this study was to develop a DEB model structure for the Painted Lady butterfly *Vanessa cardui* that can adequately represent the Lepidopteran life cycle, and to parameterize the model using literature data and newly generated laboratory data.

Building on recently developed DEB models for *Coccinella septempunctata* and *Chrysoperla carnea*, the butterfly's life cycle could be convincingly modeled with only a few modifications. For each new model adjustment, plausible assumptions were implemented separately into the model and compared with the data to make informed model decisions. For example, various assumptions about larval growth behavior were systematically investigated in this manner. Another key aspect was the explicit consideration of the prepupa phase, which was clearly evident in the data as a premature growth stop before pupation. For this purpose, several plausible model assumptions for an adjusted feeding rate, the rate of reserve mobilization, and the energetic investment in maturation during this phase were compared and evaluated. The final model is considered suitable as a reference model for the unstressed organism in DEB-TKTD. Its structure may serve as a reference for other species of Lepidoptera in the future. A DEB-TKTD analysis using this new model is presented in a parallel presentation.

1.11.P-We052 Linking PBK and DEB models for risk assessments: an example for the wood mouse

Thomas Martin¹, Torben Wittwer², Amelie Schmolke², Joseph Leedale³ and Nika Galic⁴, (1)Effect Modelling, Rifcon GmbH, Germany, (2)RIFCON GmbH, Germany, (3)Syngenta, United Kingdom, (4)Syngenta Crop Protection AG, Switzerland

In environmental risk assessment (ERA), laboratory data from test species are used to estimate potential risks of exposures to various species in the field. We present a linked physiologically based kinetics (PBK) and dynamic energy budget (DEB) model that addresses the challenge of extrapolating from laboratory test species to wild species under field conditions.

The PBK component simulates toxicant concentrations across organs and tissues over time, incorporating species-specific physiological parameters to capture interspecies differences in chemical kinetics. We parameterized and validated the PBK model using laboratory rat data for a herbicide, then adapted it for the wood mouse (*Apodemus sylvaticus*) using physiological parameters from the closely related laboratory mouse (*Mus musculus*).

The DEB component simulates effects on organism physiology and was calibrated with wood mouse-specific data on growth and reproduction. By linking PBK predictions of internal exposures to the disruption of

physiological processes in the DEB model, we can capture the herbicide's effects while assuming conservation of internal chemical effects between species.

This integrated PBK-DEB model, when incorporated into the wood mouse population model (APODEMUS), enables the estimation of population-level effects under field-relevant exposure scenarios. Our approach demonstrates how mechanistic modeling can facilitate cross-species extrapolation of exposure and effects beyond standard laboratory test conditions.

1.11.P-We053 Mechanistic Effect Modeling of Freshwater Mussels: The Role of Life-History in Stress-Driven Population Dynamics

Ines Haberle^{1,2}, Maxime Vaugeois³ and Valery Forbes¹, (1)Florida Atlantic University (FAU), (2)Ruder Boskovic Institute, Croatia, (3)Syngenta Ltd, United States

Assessing stress effects at the population level is crucial for informing ecological risk assessment and science-based management policies. However, determining these effects in laboratory or in-situ settings is challenging due to delayed responses, with impacts often becoming evident only after multiple generations. This is particularly challenging for imperiled taxa experiencing rapid declines driven by environmental and anthropogenic stressors, and whose persistence relies on timely interventions.

Even when individual-level effect data exist for a species of interest or a suitable surrogate, scaling these effects to the population level is not straightforward, and requires consideration of interacting mechanisms and stochasticity. Mechanistic effect models provide a framework to bridge these gaps and translate individual responses – driven by life-history traits – into more realistic population-level effects.

Our research develops a generalized individual-based population model (IBM) for freshwater mussels, a taxon experiencing global decline. This builds upon prior work that combined Dynamic Energy Budget (DEB) and life-history theory to capture sub-lethal individual effects of stressors across three mussel life-history strategies: opportunistic, equilibrium, and periodic.

The modeling approach integrates an individual DEB model into the IBM, parameterized for a representative species of each life-history category, to capture how changes in growth, maturation, and fecundity influence long-term population dynamics. The model is used to simulate a range of impact scenarios and physiological modes of action of a theoretical stressor, while accounting for realistic environmental drivers, inter-individual variability, and intra-specific competition.

Preliminary results show that population-level outcomes differ across life-history categories, even when individual-level responses appear similar. While population decline is evident in most scenarios, opportunistic species seem more resilient due to faster generation turnover, supporting quicker recovery once stress exposure is removed. Equilibrium species may be more vulnerable due to their longer generation times and lower fecundity. We highlight conceptual model, key decisions, structure, and implementation, and present simulation results for selected species. Finally, we discuss the limitations and potential of this framework in supporting ecological risk assessment and guiding conservation strategies.

1.11.P-We054 Assessing Effects on Lemna Growth under Toxicological Stress in the Funne Water Catchment

Khaled Brimo¹, Oliver Jakoby¹, Dirk Nickisch², Joachim Ulrich Kleinmann³, Mike Devin Fuchs⁴ and Sebastian Multsch³, (1)RIFCON GmbH, Germany, (2)Rifcon GmbH, Germany, (3)BASF, Germany, (4)RPTU University of Kaiserslautern-Landau, Germany

Understanding how plant protection products affect aquatic ecosystems remains a major challenge in environmental risk assessment. Landscape-scale modelling that integrates hydrological, exposure, and ecological processes offers one of the most advanced ways to refine surface water risk evaluations.

In this study, the toxicokinetic–toxicodynamic model for *Lemna* species within the xLandscape framework, originally based on the SETAC approach implemented in the CVAI package, was extended to account for water flow velocity as a growth-limiting factor influencing biomass dynamics. A sensitivity analysis has been conducted for nutrient availability of phosphorus and nitrogen, showing that both parameters are non-limiting factors due to increased level in surface waters in agricultural landscapes. The model was then applied and tested to capture how hydraulic conditions shape *Lemna* growth under toxicological stress at the catchment scale. Model simulations were conducted across the 54 km² Funne catchment in North Rhine-Westphalia, Germany, representing an intensively managed agricultural landscape. The modelling scenario was parameterized using monitoring data on product applications, land use, hydrography and hydrology. Derived landscape-scale EP50 values, representing the exposure reduction factor leading to a 50% growth inhibition, were evaluated across different application and management patterns improving our understanding of spatially distributed aquatic effects and their implications for regulatory risk assessment considering ecological habitat parameter such as flow velocity.

1.11.P-We055 Suitability of Delta log D to Predict pH-dependent Toxicity Differences Across Aquatic Organism Groups for Ionisable Substances

Stephan Brendel, Peter von der Ohe, Thomas Gräff and Marcus Hillebrand, German Environment Agency (UBA), Germany

Depending on ambient pH, ionisable substances occur as mixtures of neutral and ionic microspecies that differ in membrane permeability and thus in bioavailability and toxicity. In fish embryo acute toxicity tests, previous studies have evaluated the difference in the distribution coefficient log D between two pH conditions (i.e. delta log D) as descriptor of membrane passage and a predictor of pH-dependent changes in toxicity using the partitioning coefficient for octanol-water as a descriptor for the trans-membrane diffusion capability of organic chemicals. Although literature data for other organism groups indicate higher toxicity of the neutral form, the transferability of this simple delta log D model beyond fish embryos has not been systematically assessed. In this work, we compile published aquatic toxicity data for ionisable substances across several organism groups and pH conditions and derive delta log D for each test substance and pH combination. We analyse how well delta log D explains observed pH-specific differences in toxicity across taxa and substances. This provides a first quantitative insight into the applicability and limitations of the delta log D approach for predicting pH-dependent toxicity differences across aquatic organism groups.

To facilitate the consideration of pH-dependent toxicity in a regulatory context, we also present an open-source tool that models and visualises log D–pH relationships for monoprotic acids and bases based on experimentally derived log D values at defined pHs. This supports the use of delta log D as a simple, transparent predictor in extrapolating laboratory toxicity data to variable field conditions and may therefore help align risk assessments with environmental protection goals.

1.11.P-We056 Predicting Chemical Risks in a Changing Climate Through Model-Guided Study Designs.

Anthony Jeanpier Fow Esteves¹, Peter Vermeiren² and Sandrine Charles³, (1)Université Claude Bernard Lyon 1; CNRS, UMR 5558, Laboratory of Biometry and Evolutionary Biology, 69100 Villeurbanne, France. INRAE, Centre de Lyon-Grenoble Auvergne-Rhône-Alpes; UR RiverLy, Ecotoxicology Laboratory, 69100 Villeurbanne, France, France, (2)INRAE, Centre de Lyon-Grenoble Auvergne-Rhône-Alpes; UR RiverLy, Ecotoxicology Laboratory, 69100 Villeurbanne, France, France, (3)Université Claude Bernard Lyon 1; CNRS, UMR 5558, Laboratory of Biometry and Evolutionary Biology, 69100 Villeurbanne, France, France

Evaluating toxic effects is critical for chemical risk assessment. However, additional climate-change-induced stressors and dynamic exposure conditions are making this complicated. To meet this challenge, regulators are turning to predictive, mechanistic models, such as General Unified Threshold models of Survival (GUTS). However, laboratory toxicity tests have traditionally been designed for hypothesis testing or dose-response analyses, resulting in data that are not ideally suited to dynamic, multi-stress modelling. We aim to provide data- and theory-driven evidence on how to optimise ecotoxicology study designs to make them “model-ready”.

First, we identify the defining features of an optimal experimental design for dose-response and GUTS modelling. 216 time-resolved toxicity test datasets, complemented by meta-data from their source papers, are used to train a machine learning model. This enables us to identify which design choices (e.g., concentrations and replicates) predict more accurate and precise toxicity estimates (e.g., high goodness-of-fit and low coefficients of variation for the lethal concentration LC50). This will be compared with a theoretical D-optimality framework. We hypothesize that designs prioritizing concentrations over replicates will yield more robust data for modelling.

Second, we quantify the impact of design choices on GUTS model reliability. We conduct a sensitivity analysis selecting the most robust datasets and systematically subsampling them to mimic poorer designs. This includes a "Regulatory Test" in which the data is thinned to meet the minimum requirements of the OECD guidelines, and allow results of poorer designs to be interpreted while considering their experimental uncertainty.

Third, we demonstrate the real-world consequences of this uncertainty. GUTS models parametrised from both full- and thinned-datasets will be challenged using synthetic, time-varying scenarios that combine chemical exposure and climate stressors. We predict large uncertainty for the thinned-data model and more accurate and precise predictions for the full-data model.

This project produces a portfolio of recommendations that comply with the FAIR principles (Findable, Accessible, Interoperable, and Reusable) to help regulators and scientists in adapting experimental protocols, supporting the 3Rs approach (Refinement, Reduction, and Replacement) and strengthening the scientific basis for using predictive models in a changing climate.

1.11.P-We057 How Species Sensitivity Variation and Biotic Interactions Buffer Food Web Endpoints under Chemical Exposure

Xiaoxiao Li¹, Amy Rose Ockenden², Hana B Mayall², Lorraine Maltby² and Andrew Beckerman¹, (1)University of Sheffield, United Kingdom, (2)School of Biosciences, University of Sheffield, United Kingdom

Chemical pollution in aquatic ecosystems is an escalating global concern, yet our understanding of how complex networks of species interactions combine with variation in species sensitivities to determine community-level responses to chemical stress remains limited. In this study, we asked how species interactions and sensitivity determine biodiversity dynamics and community biomass. We constructed synthetic food webs that varied in their biotic interaction structure and complexity, and assigned empirically grounded patterns of sensitivity variation across multiple chemical target groups. We then simulated food web responses to sequential chemical perturbations and fitted shape constrained additive models to estimate three endpoint levels (5%, 50%, and 100% loss) for species persistence (biodiversity) and community biomass (ecosystem function). We found that the proportion of links among species (connectance) and maximum trophic level exert strong effects on both persistence and biomass at the 5% and 50% endpoints. Highly connected food webs tended to buffer early stage losses to chemicals, whereas higher maximum trophic levels were correlated with lower biodiversity and biomass under chemical stress, likely due to stronger trophic cascades. In contrast, variation in species sensitivities played a buffering role at the 100% endpoint compared to the 5% and 50% endpoints. Variation in species response to chemical stress (response diversity) substantially buffers against complete food web collapse. Together, these findings highlight the distinct roles of species-level sensitivity and food web structure in shaping biodiversity and biomass responses to chemical pollution.

1.11.P-We058 From Individual Traits to Food Web Effects: Predicting Contaminant-induced Impact on Theoretical Aquatic Food Webs Using Allometric Scaling

Anastasia Manjavidze, Bipul Pouydal and Jürg Spaak, University of Kaiserslautern-Landau, Germany

Chemical contaminants, stemming from human activities, are omnipresent in aquatic systems nowadays. Among many adverse effects, these chemicals may alter the body sizes of organisms. This may have important indirect effects on species interactions, as many predator-prey interactions are driven by body size differences. Therefore, such a change in an individual trait can indirectly affect the functioning of the entire food web. To get a better understanding of how these chemicals affect food-web properties, we first performed a meta-analysis and then simulated food-web models based on this meta-analysis.

After reviewing 3586 papers, we selected 38 that measured the body length and weight of aquatic organisms under exposure to different chemicals. We then derived a simple model on how chemicals affect the body size of species. Lastly, we used a trait-based food web model to simulate the effects of increased chemicals and ultimately assess their impact on the functioning of the entire food web.

We hypothesize that 1. increasing the concentration of a particular substance leads to changes in body weight and length. 2. These changes in body size affect species interactions and will hence affect the entire community

3. The most sensitive species are not necessarily the species most affected by the chemicals, but rather those that depend on the structure of the food web.

1.11.P-We059 Exploring Pesticide Effects on Biological Pest Control Through Ecological Modelling

Dana Bashkir¹, Louise Wipfler², Paul van den Brink¹ and Bas Buddendorf¹, (1)Wageningen University and Research (WUR), Netherlands, (2)Environmental Risk Assessment, Wageningen University and Research (WUR), Wageningen, Netherlands

The prospective environmental risk assessment of pesticides is shifting toward approaches that explicitly protect biodiversity and ecosystem services. Regulation of arthropod pests is one such service, with *Orius laevigatus* being a service providing unit for greenhouses and field crops. It preys on the western flower thrips, *Frankliniella occidentalis*, which rapidly develops insecticide resistance. Understanding the effects of pesticides on *O. laevigatus* is crucial for protecting this non-target species and maintaining biological control. Some earlier studies showed that pesticides reduce pest numbers only when natural enemies are absent. In modelling experiments, predators largely determine pest population levels, and increased predator mortality can increase pest densities. Whether these findings hold under higher ecological realism, with varying environmental conditions, and longer time scales, remains uncertain. This work explores the impact of insecticides on biological pest control under more realistic environmental conditions using an agent-based predator–prey model. The model represents *O. laevigatus* as individuals at different life stages with individual-based properties. Thrips are included as super-individuals to quantify pest control. Model processes include development, reproduction, dispersal, overwintering, and mortality. Predator–prey interactions include feeding by nymphs and adults. Pesticide effects are implemented using toxicokinetic-toxicodynamic modelling with a selected insecticide. Sensitivity analysis will examine how variation in parameter ranges influences predator and prey densities. All processes occur in a homogeneous space at 1 m² resolution and a time step of one day. We hypothesize that the results will be consistent with earlier studies: insecticide applications will either increase or not significantly change average pest densities when natural enemies experience additional mortality. Incorporating temperature dependence of processes and toxicity over time is likely to produce more context-dependent interactions and emergent behaviours, such as delayed pest outbreaks, altered seasonal population structure, and variable overwintering success. This work supports more ecologically grounded predictions of how pesticides influence biological pest control and will further provide a tool for evaluating impacts on the non-target arthropod species, helping the shift towards a more realistic environmental risk assessment.

1.12 In Vitro Tools and Biosensors for Assessing the Mixture Effects of Contaminants of Emerging Concern in Water

1.12.T-01 The Key Factor Toxicity: Development and Application of a Tool to Characterize the Toxic Pressure of Chemical Pollution in Surface and Drinking Water

Corine J. Houtman¹, Milo Leon de Baat², Sanne Brekelmans³, Yvonne van Oorschot³, Tessa E. Pronk⁴, Insam Al Saify⁵ and Leo Posthuma⁶, (1)Het Waterlaboratorium, Haarlem & Amsterdam Institute for Life and Environment (A-LIFE), VU University Amsterdam, Netherlands, (2)Chemical Water Quality & Health, University of Amsterdam (UVA), Netherlands, (3)Het Waterlaboratorium, Netherlands, (4)KWR Water Research Institute, Netherlands, (5)Waternet, Netherlands, (6)National Institute for Public Health and the Environment (RIVM), Netherlands

Understanding the effects of chemical mixtures in surface waters is crucial for protecting ecosystems and drinking water quality. Thousands of substances enter aquatic systems via wastewater, agriculture, and industry, forming complex mixtures whose combined effects are poorly addressed by single-compound monitoring. This knowledge gap limits risk prediction for ecology and human health.

To address this challenge, we developed the Key Factor Toxicity (KFTox) Instrument and webtool, integrating two complementary approaches: a Chemistry Track and a Bioassay Track. The Chemistry Track calculates mixture toxic pressure as multi-substance potentially affected fraction (msPAF) using species sensitivity distributions (SSD) of individual chemically monitored compounds and summarizes the results into five categories. The Bioassay Track measures biological activity through a panel of in vitro and in vivo assays, benchmarking the measured activities against effect-based trigger values for ecological and health relevance.

Both tracks provide intuitive, color-coded outputs.

A nine-month case study included surface water abstraction points, process water, and produced drinking water. Chemical monitoring covered >500 parameters; eight bioassays targeted general toxicity, endocrine disruption, oxidative stress, and receptor-mediated effects. The Chemistry Track indicated low toxic pressures, while the Bioassay Track revealed multiple activities exceeding trigger values—indicating possible risks not captured by the Chemistry Track. Each bioassay added unique, relevant information despite a deliberately limited set.

The tracks proved complementary: the Bioassay Track e.g. detected high AhR-mediated activity despite negligible PAH msPAF in the Chemistry Track, suggesting unmonitored AhR-agonists. Conversely, the Chemistry Track included metals and nutrients beyond the scope of the Bioassay Track. Combining both approaches therefore ensures a more representative water quality assessment.

The KFTox instrument offers a robust, integrated framework for assessing chemical water quality. It provides a practical framework for assessing toxic pressure in water systems and to prioritize mitigation measures, supporting the objectives of the EU Water Framework Directive.

1.12.T-02 A Pan-European Bioassay-Based Assessment of Endocrine Activities Across Multiple Environmental Compartments

Abd El Rahman El Mais¹, Elise CHATILLON¹, Sebastian Buchinger², Meike Hahn², Marina Ohlig², Andreas Schuettler², Jessica Reinmueller², Emmanuelle Maillot-Marechal¹, Olivier Palluel¹, Marina Grimaldi³, Beate Escher⁴, Maria Konig⁴, Julia Huchthausen⁴, Maria Margalef⁵, Timo Hamers⁵, Marja Lamoree⁵, Anna Bialk-Bielińska⁶, Tina Kosjek⁷, Georgios Niarchos⁸, Petra Příbylová⁹, Shazeeda Koonjan¹⁰, Kerstin Winkens Pütz¹⁰, Gunnar Thorsén¹⁰, Azziz Assoumani¹, Nina Huynh¹, Valeria Dulio¹, Katrin Vorkamp¹¹, Patrick Balaguer³ and Selim Ait-Aissa¹, (1)Institut National de l'Environnement Industriel et des Risques (INERIS), Verneuil-en-Halatte, France, France, (2)Fed Inst Hydrology (BfG), Dept G Qual Hydrol, Germany, (3)INSERM, U1194, Univ Montpellier, Inst Rech Canc Montpellier (IRCM), Montpellier, France, France, (4)UFZ-Helmholtz Centre for Environmental Research, Germany, (5)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands, (6)Department of Environmental Analysis, Faculty of Chemistry, University of Gdańsk, ul. Wita Stwosza 63, 80-308 Gdańsk, Poland, (7)Jožef Stefan Institute, 1000 Ljubljana, Slovenia, Slovenia, (8)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (9)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (10)IVL Swedish Environmental Research Institute, Valhallavägen 8, 11428 Stockholm, Sweden, Sweden, (11)Aarhus University, Denmark

Endocrine-disrupting compounds (EDCs) encompass a broad range of chemicals from diverse sources and remain a major challenge for environmental monitoring when using conventional target chemical analysis. In vitro bioassays provide a powerful complementary approach by detecting the endocrine activities, although they cannot identify causative substances. Within the Horizon Europe Partnership for the Assessment of Risks from Chemicals (PARC), an integrative approach of chemical analyses and a broad battery of in vitro bioassays has been applied to comprehensively characterize EDC contamination across multiple environmental matrices (surface water, air, and soil) in Europe.

In 2023-2024, coordinated sampling campaigns were conducted covering all European regions and diverse anthropogenic pressures (urban, industrial, agricultural, etc.). A total of 117 water, 42 soil, and 19 air samples were collected and processed using standardized extraction protocols. Water and soil extracts were analyzed with in vitro bioassays targeting nine human nuclear receptors, i.e., the Androgen Receptor (AR), Estrogen Receptor (ER), Glucocorticoid Receptor (GR), Mineralocorticoid Receptor (MR), Progesterone Receptor (PR), Aryl Hydrocarbon Receptor (AhR), Pregnane X Receptor (PXR), Peroxisome Proliferator-Activated Receptor Gamma (PPAR γ), and Retinoic Acid Receptor- α (RAR α), as well as the competition with thyroid hormone to bind its transport protein, Transthyretin (TTR). Air extracts were tested for AR, ER, AhR, PXR, and TTR. In water samples, fish receptors for selected endocrine modes of action (AR, MR, PR, AhR, PXR) were also included to explore potential interspecies differences. Defined quality assurance and control measures were implemented throughout sampling, extraction, and bioassay procedures.

Agonistic endocrine activities are widespread across surface water samples, following the order ER >> AR > PR, GR, MR, RAR α . TTR, PPAR γ , and PXR were detected at >80% of sites. Western and Eastern Europe showed the strongest responses, with some samples exceeding the proposed effect-based trigger values for ER and TTR. No clear link with anthropogenic pressures was found. Next steps include data interpretation for air and soil, and comparison with data from chemical analyses.

Overall, this study represents a large-scale pilot investigation of EDC contamination across multiple environmental compartments in Europe using an extensive battery of bioassays and novel modes of action.

1.12.T-03 Getting a Grip on Pesticide Mixture Toxicity Using Effect-Based Methods

Harry Boonstra¹, Milo Leon de Baat², Froukje Van der Meer¹, Anna Van der Veen¹, Harrie Besselink³, Ivo

Roessink⁴ and Michiel Kraak⁵, (1)Wetterskip Fryslân, Netherlands, (2)Chemical Water Quality & Health, University of Amsterdam (UVA), Netherlands, (3)BioDetection Systems BV, Netherlands, (4)Wageningen University and Research (WUR), Netherlands, (5)Sciencepark 904, University of Amsterdam (UVA), Amsterdam, Netherlands

Pesticides are widely used to enhance crop productivity, but their application leads to emissions that form complex mixtures in surface waters, posing risks to aquatic ecosystems. Effect-based methods, which capture the combined biological activity of chemical mixtures, offer a more realistic assessment of ecotoxicological hazards than evaluations of single substances. This study aimed to examine the suitability of various effect-based methods for assessing the toxicity of representative pesticide mixtures. Four mixtures (herbicides, insecticides, fungicides, and azoles) were formulated based on their occurrence in Frisian agricultural drainage ditches where pesticide levels frequently exceed environmental standards. Compounds were combined at their EC50 or at the highest feasible concentrations due to solubility constraints. Chemical analyses were performed to confirm stock solution concentrations. A battery of in vivo bioassays (algae, *Daphnia*, bacteria) and in vitro CALUX assays covering cytotoxicity, endocrine and metabolic disruption, oxidative stress, and genotoxicity were used to evaluate the potential toxicity of the mixtures. All in vivo assays showed clear effects. Insecticides were most toxic to *Daphnia* and bacteria, while herbicides caused strong algal responses, reflecting the expected sensitivity of these organism groups. Fungicides and azoles also induced substantial in vivo toxicity, even though their modes of action are not directed at the primary target organisms in the assays used, indicating non-target toxicity. The PXR, anti-AR, and anti-PR in vitro assays were the only CALUX assays that responded to the fungicide and azole mixtures. Herbicides and insecticides did not trigger activity in the applied in vitro assays. These findings highlight that fungicides may drive observed toxicity in the field and that current environmental risk assessment lacks an in vivo fungal bioassay to adequately capture their ecological impact. A multispecies fungal bioassay may therefore provide a valuable addition to future effect-based monitoring strategies. Here, we showed that effect-based methods are well-suited for assessing the toxicity of pesticide mixtures and represent a valuable tool in environmental monitoring. Toxic pressure from the fungicide and azole mixtures is captured by these methods, although a comprehensive risk assessment of fungicides requires an in vivo fungal bioassay to accurately reflect their ecological impact.

1.12.T-04 High-Throughput Receptor-Based Bioassay For Non-targeted Screening of Bioactive Contaminants in Water

Paul van den Brink¹, Tatiana Siniakova¹, Maurice Henquet¹ and Milou M. L. Dingemans², (1)Wageningen University and Research (WUR), Netherlands, (2)Institute for Risk Assessment Sciences, Utrecht University, KWR Water Research Institute, Netherlands

Biologically active micropollutants, including pharmaceuticals, hormone disruptors, and pesticides are increasingly detected in surface waters worldwide. Psychoactive pharmaceuticals are one of the most frequently detected group of water pollutants. Their persistence, low-dose bioactivity, and potential biotransformation raise concerns for aquatic ecosystems and human health. Their risk to the aquatic environment is generally assessed by a combination of chemical and biological analyses. Yet, these methods are often resource-intensive and time-consuming in practical application. As such, there is a need for a rapid, sensitive, and biologically relevant method capable of screening complex water matrices for a broad spectrum of bioactive compounds. One such innovation is multiplex receptor technology called “receptomics” developed by Wageningen University and Research. This platform uses a flow-cell sensor system to assess dozens of G-protein-coupled receptors (GPCR) activation in response to contaminants in water samples that acting like receptor’s ligands. Receptor’s activation provides a unique biological activity fingerprint enabling holistic assessment of bioactive contaminants (www.receptomics.com). The broad diversity of GPCRs allows screening pharmaceuticals in water samples. The receptor repertoire might be extended to include nuclear receptors or non-human GPCRs, namely, insect or zebrafish’s GPCR, increasing environmental relevance. The assay allows repeated measurements every five minutes, enabling rapid screening of both pure compounds and complex mixtures. As a proof-of-concept a psychoactive pharmaceutical was tested on a set of serotonin and muscarinic receptors. Already at 0.32 µM of the psychoactive drug- clozapine activated several muscarinic receptors. Although the tested concentrations exceed typical environmental levels, these results establish the biosensor’s capability to detect receptor-specific activity patterns of psychoactive pharmaceuticals, confirming that the platform can measure reproducible and biologically meaningful GPCR activation. The system is a sensitive, rapid, and high-throughput platform that can support water managers and drinking water companies to monitor water quality continuously. The developed system can also be used as an early warning system and as a screening tool to develop risk-driven measurement programs in the (drinking) water sector.

1.12.T-05 Combining Sample Fractionation and Pull-Down Assays for Identifying Thyroid Hormone Disruptors in Non-Targeted Screening of Complex WWTP Effluents

Petra Mikusova¹, **Zuzana Tousova¹**, Pavla Cetl², Marek Stiborek¹, Branislav Vrana¹, Andrea Vojs Staňová², Kateřina Grabicová², Roman Grabic² and Klara Hilscherova¹, (1)Masaryk University, Czech Republic, (2)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, Czech Republic

Micropollutants discharged from wastewater treatment plants continue to pose a significant challenge, as complex mixtures of chemicals can disrupt sensitive biological pathways, such as those involved in thyroid hormone transport. Transthyretin (TTR) is a key carrier of thyroxine (T4), and many environmental contaminants can interfere with TTR-T4 binding. Identifying the specific drivers of this disruption is challenging because environmental extracts contain thousands of co-eluting compounds that complicate non-targeted screening (NTS). Here, we combined effect directed analysis with an affinity-based pull-down assay to improve the identification of TTR-binding ligands in passive sampler extracts from a large municipal WWTP. Passive samplers deployed for 16 weeks provided time-integrated extracts, which showed strong TTR-binding inhibition. Primary HPLC fractionation distributed activity mainly into fractions F7 and F8 from the eleven collected ones. Secondary fractionation of these fractions again revealed broad activity across multiple sub-fractions, indicating contributions from many compounds with diverse physicochemical properties. While fractionation reduced sample complexity, activity remained widely distributed, limiting its ability to isolate causal chemicals.

To selectively capture TTR ligands, the original extract and active fractions were analyzed using a pull-down assay with His-tagged TTR. Non-targeted screening of eluates enabled the identification of 47 compounds with confirmed structures and demonstrated bioactivity. Several compounds were identified as novel environmental TTR ligands, while known ligands including diclofenac, LAS, and benzophenone-3 were also detected. Quantification and mass-balance evaluation showed that identified ligands explained only a minor portion of the observed activity, since number of features remained unidentified due to gaps in spectral libraries. Our study demonstrates that fractionation alone can be insufficient for resolving complex wastewater extracts, whereas the pull-down assay reliably enriches active ligands and significantly enhances identification. Combining both approaches provides a powerful strategy for uncovering thyroid-disrupting chemicals in environmental mixtures.

1.12.P In Vitro Tools and Biosensors for Assessing the Mixture Effects of Contaminants of Emerging Concern in Water

1.12.P-Mo066 Monitoring Endocrine Activities of Surface Waters Using Transgenic Zebrafish-Based Bioassays

François Brion¹, Alizée Desrousseaux², Valentin Bourges¹, Benjamin Piccini¹, Florian Geffroy², Elise CHATILLON², Abd El Rahman El Mais¹, Nathalie Hinfray¹ and Selim Ait-Aissa¹, (1)INERIS, France, (2)INERIS, Verneuil-en-Halatte, France

Over the past decades, numerous studies have reported the contamination of aquatic environments by endocrine-disrupting chemicals (EDCs), resulting in adverse health effects on sensitive aquatic species. Monitoring environmental endocrine activities has thus become increasingly important for assessing the quality of water bodies. In a previous study, we demonstrated the relevance of the EASZY assay (OECD TG250), which uses tg(cyp19a1b:GFP) zebrafish embryos, to quantify in vivo estrogenic activity (ER) in water samples collected across Europe. Estrogenic activities were correlated with in vitro responses and with EQS mixture risk assessment. Although relevant, the EASZY assay remains limited to ER-mediated activity. To refine EDC monitoring in water samples, the EASZY test design was expanded to include assessment of gene expressions, enzymatic activities regulated by other receptor signaling pathways such as Aryl Hydrocarbon Receptor (AhR), Glucocorticoid Receptor (GR), and Pregnane X Receptor (PXR). In addition, a novel zebrafish-based assay, EMERGE, using tg-(cyp3a65:GFP) zebrafish embryos, was applied to assess the effects of aquatic contaminants on intestinal expression of cyp3a65, a multi-receptor-regulated gene involved in the endogenous and xenobiotic metabolism. Twenty-six surface water samples were collected at the French national scale within the framework of the Horizon EU PARC project, and their organic extracts were tested at different relative enrichment factors (REF) in each bioassay.

Estrogenic activity in several surface waters was evidenced through their capacity to induce GFP in EASZY, in agreement with in vitro ER activities measured at the same sites. Weak dioxin-like AhR-mediated activities were also observed in some samples through their capacity to induce cyp1a expression and/or CYP1A activities. Notably, many environmental samples were active in EMERGE, leading to concentration-dependent inductions in intestinal GFP fluorescence driven by the cyp3a65 promoter, at levels close or similar to those of the positive control.

Overall, this study demonstrates that multiple endocrine activities can be monitored using zebrafish-embryo based-assays, enabling quantification of multi-endocrine activities and the identification of contaminated and hotspot sites. Further, the in vivo data will be compared to endocrine activities measured in vitro and chemical analysis of environmental contaminants measured at the same sites.

1.12.P-Mo067 Benchmarking Historical Data of Estrogenic Activity of Waters From Rio de Janeiro State Against Effect-based Trigger Values

*Allan Argolo, Esther Brasil, Giselle Gomes and **Daniele Maia Bila**, Universidade do Estado do Rio de Janeiro, Brazil*

The occurrence of estrogenic micropollutants in aquatic ecosystems is a widespread issue affecting societies across the globe. Considering the challenge of quantifying these substances at low concentrations, in vitro bioassays are well-established bioanalytical tools capable of capturing mixture effects in complex samples and thus complement chemical analysis in environmental monitoring. In the present study, historical data of estrogenic activity of several water matrices from Rio de Janeiro state, assessed using the Yeast Estrogen Screen, were compiled and benchmarked against proposed effect-based trigger (EBT) values. It included large rivers (n=55), urban streams (n=12), coastal lagoons (n=54), bay/sound waters (n=10), and tap waters (n=21) to a total of 152 samples investigated over the last decade. The contribution of suspended particulate matter (SPM) was also evaluated in selected surface waters. Estrogenic activity was very often (> 75%) detected in streams, bay/sound waters, lagoons and rivers, with estradiol-equivalents (EEQ) quantified in the ranges 3.47 – 189 ngE2/L, 8.96 – 76.9 ngE2/L, 1.49 – 65.4 ngE2/L and 0.28 – 82.9 ngE2/L, respectively, but was rarely observed in tap waters (9.5%, EEQ: 1.47 – 3.49 ngE2/L). Although the estrogenic activity of assessed tap waters was never below the proposed threshold for potable use of 12 ngE2/L in the YES assay, the various surface waters usually exceeded a calculated EBT value of 1,17. Moreover, the median concentration in coastal lagoons was around 10xEBT, whereas median concentrations in way waters and urban streams ranged between 10 times and 100 times higher than the EBT value, highlighting the elevated risk for the aquatic ecosystems. The fraction of EEQ associated with SPM in surface waters ranged from 10% and 90%, which shows a great contribution to the total estrogenic activity. Nevertheless, all samples evaluated for SPM already exceeded the EBT value through their dissolved fraction alone, suggesting that this assessment approach might be protective. The results reinforce a worrisome panorama for the investigated aquatic environments, especially in lentic and receiving waters.

1.12.P-Mo068 The Amphipod Ecdysone Receptor (EcR): New in vitro Approach for the assessment of arthropod endocrine disrupting chemicals and water biomonitoring

João Sousa¹, Anabelle Espeyte², Teresa Neuparth³, Rémi Recoura-Massaquant², Sarah Bancel², Nicolas Delorme², Arnaud Chaumot², L. Filipe C. Castro³, Miguel M. Santos³, Olivier Geffard Pr², Raquel Ruivo³ and Davide Degli Esposti², (1)CIIMAR, INRAE, Portugal, (2)INARE - National Research Institute for Agriculture, Food and Environment, France, (3)Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portugal

The ubiquitous presence of endocrine-disrupting chemicals (EDCs) in aquatic environments threatens wildlife, food webs, and water quality. By disrupting endocrine signaling pathways, these substances may impair the development, reproduction, and overall health of exposed organisms. Nuclear receptors (NRs) are a family of transcription factors, key in endocrine regulation, which are often ligand-induced and, thus, vulnerable to EDC effects. This susceptibility has guided the development of active molecules targeting specific NR-mediated pathways. However, lack of proper hazard characterization can put off-target species vulnerable to the action of EDCs and contaminants of emerging concern (CECs). The ecdysone receptor (EcR) is an excellent case study. The EcR alongside the retinoid x receptor (RXR) form a heterodimeric complex initially assumed to be

arthropod exclusive. This apparent group specificity has prompted the design of pest-control chemicals acting on ecdysone-induced pathways (e.g., insecticides). Yet, the elucidation of a broader EcR phylogenetic distribution may extend the action of such substances to off-target species. While vertebrate NR-based reporter gene assays (RGAs) are currently included in environmental risk assessment (ERA) frameworks (e.g., OECD, EPA, WFD), a striking knowledge gap still exists regarding NR-based assays for environmentally relevant invertebrate species, such as amphipods commonly used in biomonitoring. In this work, we address this gap by focusing on two ecdysone-related NRs (EcR and RXR) of the keystone amphipods *Gammarus fossarum* and *G. locusta*. Using luciferase-based assays, we characterized EcR:RXR function and screened putative EDCs. This approach allowed the identification of chemicals with potential EcR-modulating activity (e.g., diacylhydrazines). Additionally, to address the elusiveness of EDCs and mixture effects – key challenges in ERA – we further applied this mechanism-based approach to environmental extracts. For this, eighteen surface water samples from the French Water Agency's Rhône Méditerranée Corse monitoring network were processed by solid-phase extraction to obtain natural mixtures, among which four sites displayed EcR-agonistic activity. To our knowledge, this work provides the first proof of concept for in vitro detection of EcR-modulatory activity in natural water samples, aiming to improve current biomonitoring strategies.

1.12.P-Mo069 A bioanalytical and chemical approach for wastewater discharge: beyond detected chemicals for water quality assessment

Phoebe Lewis¹, Peta Neale², Hung Tan¹, John Leeder³, Elissa O'Malley², Mark P. Taylor⁴, Frederic Leusch² and Minna Saaristo⁵, (1)EPA Victoria, Australia, (2)Griffith University, Australia, (3)Leeder Analytical, Australia, (4)Department of Climate Change, Energy, the Environment and Water, Australia, (5)Environment Protection Authority Victoria, Australia

Targeted chemical analysis is widely used for water quality monitoring but has significant limitations, as it cannot detect unknown chemicals or account for mixture effects. To address these gaps, applying effect-based methods (EBM) are gaining interest. Here, we applied a battery of in vitro bioassays to wastewater influent and effluent from four wastewater treatment plants (WWTPs) in Victoria, Australia, as well as surface water upstream and downstream of the WWTPs, to assess the potential risks from mixture effects. The bioassays were complemented with targeted chemical analysis of over 600 chemicals. Our study shows that both the chemical and bioanalysis had higher chemical concentrations and effects in discharged effluent compared to surface waters, confirming WWTPs as key pollution sources. Though most WWTPs were able to remove over 80% of bacterial toxicity, photosystem II inhibition, estrogenic activity and oxidative stress response, one site had poor removal of estrogenic and aryl hydrocarbon (AhR) activity. This site also had a lower median chemical removal efficiency (40%) compared to the other WWTPs (72-88%). Surface water samples downstream of some of the WWTPs exceeded ecological effects-based trigger values (ecoEBTs), suggesting effluent discharge contributing to increased estrogenic and AhR activity, as well as oxidative stress. Despite the large number of detected chemicals, only a small fraction of the observed biological effects could be explained using iceberg modelling, highlighting the presence of unknown bioactive contaminants. These findings underscore the need for integrated chemical analysis with EBM to accurately assess water quality, and improve protection of aquatic ecosystems, worldwide.

1.12.P-Mo070 In Vitro Assessment of Chlorine and Monochloramine Reactivity During Gastrointestinal Digestion

Éliette Tavernier¹, Cécile Vignal² and Justine Criquet³, (1)Univ. Lille, CNRS, UMR 8516 - LASIRE, Laboratoire de Spectroscopie pour les Interactions, la Réactivité et l'Environnement F-59000 Lille, France and Univ. Lille, Inserm, CHU Lille, U1286 - INFINITE - Institute for Translational Research in Inflammation, F, France, (2)Univ. Lille, Inserm, CHU Lille, U1286 - INFINITE - Institute for Translational Research in Inflammation, F-59000 Lille, France, France, (3)Univ. Lille, CNRS, UMR 8516 - LASIRE, Laboratoire de Spectroscopie pour les Interactions, la Réactivité et l'Environnement F-59000 Lille, France and Institut Universitaire de France (IUF), France

Nowadays, disinfectants such as chlorine (HOCl) or monochloramine (NH₂Cl) are used to treat drinking water along the distribution network. However, little information is available on the impact of those oxidants on the gastrointestinal tract (GI). Here, we examine how they interact with digestive fluids along the GI, their degradation pathways and their potential to form new disinfection by-products (DBP) using an in vitro digestion protocol.

The simulation of treated water ingestion is performed using the INFOGEST in vitro model. This standardised method simulates salivary, gastric and intestinal digestion, using digestive enzymes: α -amylase, pepsin and pancreatin. In order to study the evolution of residual disinfectant concentrations during these phases, oxidant concentrations were quantified using the N,N-diethyl-p-phenylenediamine method after each stage. The results obtained were compared with kinetic simulations. Oxidant-digestive enzyme interactions were studied by HPLC-DAD/Fluorescence and the by-products formed by GC-MS/MS. An AGS (stomach) culture and a coculture of Caco2/HT29-MTX (intestine) were used to study toxicity of the DBP formed after digestion on both organs.

Findings show that after ingesting chlorinated water, sodium hypochlorite reacts with salivary ammonium to produce monochloramine, which partly oxidizes α -amylase. During gastric digestion, monochloramine further reacts with pepsin. Both HOCl and NH₂Cl are consumed by these interactions, leaving no detectable oxidant residuals after two hours. HPLC analysis confirmed these enzyme-oxidant interactions with different reaction rates, slower for NH₂Cl. As a result, active disinfectants rarely reach the intestine directly.

The implication is that while residual disinfectants are neutralized before reaching the intestine, their transformation products may pose a greater toxicological risk than the oxidants themselves. Ongoing work includes identifying these DBPs and determining their toxicity, as well as assessing if ingestion causes oxidative stress or inflammation in digestive cell cultures. It is important to note that such in vitro simulations simplify reality and do not account for factors like the gut microbiota or certain serum proteins. Nonetheless, this approach provides an initial framework for understanding the health impacts of drinking water disinfectants and their by-products.

1.12.P-Mo071 Thyroid hormone-Disrupting Potential of Wastewater Treatment Plant Effluents Across Europe: Insights from an In Vitro Bioassay Battery

Zuzana Touseva¹, Marie Smutná², Puja Kumari², Saskia Finckh³, Werner Brack⁴, Jiri Novak² and Klara Hilscherova², (1)Masaryk University, Czech Republic, (2)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (3)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (4)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany; Department of Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, Germany

Growing concern over contaminants in freshwater ecosystems requires advanced analytical techniques for their detection and quantification. Wastewater treatment plant (WWTP) effluents are a major source of endocrine-disrupting chemicals (EDCs), which can interfere with thyroid hormone regulation.

In this study, effluents from 20 WWTPs of varying capacities and employing different treatment technologies across 15 European countries were collected using on-site large-volume solid-phase extraction. The concentrated extracts were assessed using an in vitro bioassay battery targeting key mechanisms of thyroid hormone disruption (THD). The tested endpoints included sodium/iodide symporter (NIS) inhibition, thyroid peroxidase (TPO) inhibition, transthyretin (TTR) binding competition, thyroid receptor (TR) agonism and antagonism, as well as activation of the aryl hydrocarbon receptor (AhR), which is known to interact with thyroid hormone homeostasis.

Our results show that several WWTP effluents from different countries exhibited effects across multiple THD mechanisms-. Particularly pronounced activity was observed for the inhibition of, TPO and TTR binding assays, accompanied by AhR activation in many samples. These findings indicate that compounds with THD potential are widely present in treated wastewater across Europe. To assess potential drivers of the observed effects, we applied iceberg modeling combining measured target compound concentrations with their known effect potencies from the literature. Although a number of individual chemicals could be linked to parts of the observed bioactivities, the majority of the effects remained unexplained, indicating that substantial contributions likely stem from compounds outside the target list or from mixture interactions.

Overall, this study provides important new insights into the THD potential of WWTP effluents at the European scale and demonstrates the value of integrating bioassays with chemical analytical tools. The presence of EDCs capable of interfering with thyroid hormone regulation in treated wastewater emphasizes the need for more comprehensive monitoring frameworks and regulatory measures to better assess, manage, and mitigate environmental contamination.

1.12.P-Mo072 Assessing the Impact of Quaternary treatment at a Municipal Wastewater Treatment Plant on Surface Water Quality through a Multi-Level Evidence Approach.

Birte Raes¹, Eva Houben², Maarten De Jonge² and Birgit De Bock¹, (1)Aquaflin, Belgium, (2)Flanders Environment Agency (VMM), Belgium

Urban wastewater treatment plants (UWWTPs) in Flanders treat 88% of domestic wastewater, primarily targeting organic matter and nutrients. Yet residual micropollutants remain a challenge for achieving good chemical and ecological status under the Water Framework Directive. The revised Urban Wastewater Treatment Directive (2024/3019) now requires large UWWTPs and UWWTP's in sensitive areas to implement quaternary treatment for micropollutant removal in order to improve water quality in Europe.

In April 2025, the first full-scale quaternary treatment step in Flanders was commissioned at the Aartselaar UWWTP, which discharges into a small watercourse where effluent contributes approximately 50% of the river. The advanced treatment combines ozonation and granular activated carbon (GAC), both contributing to the reduction of micropollutants and associated toxic effects, with the extent of removal depending on operational conditions.

Aquaflin NV and the Flanders Environment Agency assess treatment efficiency and improvements in surface water quality through a multi-level evidence monitoring approach. Monitoring occurs at the UWWTP and in the receiving water upstream and downstream, enabling evaluation of both removal performance and ecological impact. Chemical analyses target a broad spectrum of micropollutants, including pharmaceuticals and pesticides. In addition to chemical monitoring, effect-based methods combining *in vitro* approaches (using CALUX bioassays) and *in vivo* approaches are applied to capture cumulative biological responses.

A reference monitoring phase prior to commissioning revealed that effluent discharge significantly affected downstream water quality, with increased pharmaceutical concentrations and endocrine-disrupting effects. With quaternary treatment now operational, first observations indicate that negative impacts identified during the reference phase can be reversed, supporting the role of advanced treatment in improving ecological water quality.

Disclaimer/Disclosure:

Part of the monitoring on the quaternary treatment performed by Aquaflin NV was carried out as part of the project Schone Waterlopen door O3G, funded by the Interreg Vlaanderen-Nederland program.

1.12.P-Mo073 From gene to behaviour: combined exposure of Mg-Al layered double hydroxide and Epirubicin on *Danio rerio* larvae

Diana Isabel Oliveira Carneiro¹, Daniel Alexandre Bruno², Madalena Filipa Moreira Vieira², Inês Lopes Pereira³, Érika Sousa², Vânia Calisto², Marta Gouveia Martins⁴, Susana Loureiro², Roberto Martins⁵ and Maria D Pavlaki², (1)CESAM & Department of Biology, University of Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)Nova University Lisbon, Portugal, (4)NOVA.ID.FCT, Portugal, (5)CESAM - Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal

Advanced technologies and drugs has led to an increase in emerging contaminants, including nanomaterials like layered double hydroxides (LDH) and antineoplastic agents (AA). LDH are 2D engineered nanomaterials with versatile properties, enabling their use in diverse fields (e.g., corrosion protection; environmental remediation). AA affects aquatic organisms at low concentrations and has been frequently detected in water bodies. LDH, as a drug vehicle for AA, may co-occur in aquatic ecosystems through contamination pathways. However, information regarding their single and combined effects remains limited. Our study evaluated the single and combined toxicity of Mg-Al LDH and epirubicin in zebrafish, assessing multiple endpoints, including embryo development, larval behaviour, DNA damage, biochemical changes, and alterations in gene expression. Single exposure to Mg-Al LDH (13-100 mg/L) caused no mortality or morphological alterations, indicating low acute toxicity. Epirubicin exposure resulted in an LC50=49.3 mg/L and a NOEC for malformations <11.5 mg/L. Mixtures showed no significant change in LC50 values with increasing LDH concentrations, suggesting LDH neither enhanced nor mitigated epirubicin acute toxicity. Epirubicin and M1–M2 mixtures (low LDH with the lowest and highest epirubicin concentrations) significantly increased catalase activity, reflecting activation of antioxidant defence, while mixtures with higher LDH concentration showed no significant effects. No

significant effects were detected for other biomarkers or locomotor behaviour. LDH caused no DNA damage, while epirubicin induced genotoxic effects at 92 and 206 µg/L. When combined with LDH (M1-M5), Tail DNA (%) remained <10%, suggesting LDH influence on epirubicin genotoxicity through adsorption, as confirmed by chromatographic analysis in the tested media. Gene expression analysis showed 100 mg LDH/L induced no change in tp53, catalase, or tbx5a, while 500 µg epirubicin/L caused downregulation of tp53 and catalase, consistent with oxidative stress. These patterns under mixed exposure support that LDH interacts with epirubicin, reducing its bioavailability through likely surface adsorption, thereby antagonizing its genotoxic effects. Overall, epirubicin exerted significant effects on zebrafish, while LDH showed low toxicity and reduced epirubicin effects when co-exposed, highlighting the importance of analysing combined exposures for environmental risk assessment of nanomaterials and drugs.

1.12.P-Mo074 Embedding Effect-Based Methods in Regulatory Water Quality Assessment: Dutch Practice and European perspective

Corine J. Houtman¹, Tineke Slootweg², Insam Al Saify³ and Milo Leon de Baat⁴, (1)Het Waterlaboratorium & Amsterdam Institute for Life and Environment (A-LIFE), VU University Amsterdam, Netherlands, (2)Het Waterlaboratorium, Netherlands, (3)Waternet, Netherlands, (4)Inst. for Biodiversity & Ecosystem Dynamics (IBED), University of Amsterdam, Netherlands

Bioassays, or effect-based methods (EBMs), directly measure biological activity caused by chemicals in water samples, capturing combined effects of known and unknown substances. EBMs complement chemical analysis and provide a more comprehensive assessment of water quality.

This work explores practical integration of EBMs into two key European legislative frameworks: the Drinking Water Directive (DWD) and the Water Framework Directive (WFD). It discusses examples of current applications in the Netherlands and the position of EBMs in Europe.

The current DWD, effective since 2023 (EU 2020/2184), introduced a risk-based approach (RBA) requesting monitoring (and subsequent risk management) with focus on emerging and catchment-specific contaminants to ensure that drinking water treatment sufficiently protects human health against harmful chemical effects. While EBMs are not explicitly required by the DWD, they offer significant value within this RBA as a safety net to detect new or re-emerging pollutants and assess biologically active – and thus possibly harmful – compounds. Dutch drinking water companies apply bioassays in this context, benchmarking responses against effect-based trigger values (EBTs). When EBTs are exceeded, effect-directed analysis (EDA) identifies causative compounds, enabling targeted risk management.

In September 2025, the European Commission announced EBMs will be incorporated into the WFD for surface waters, with mandatory monitoring of estrogenic activity for two years. Additionally, EBMs can be employed within the WFD to detect mixture effects and unknown pollutants that may hinder attainment of a 'good ecological status'. Therefore, a Dutch research consortium developed and applied the Key Factor Toxicity (KFTox) instrument, combining chemical and bioassay tracks to assess toxic pressure in water and its potential ecological impact.

These examples demonstrate that applying EBMs within regulatory water quality assessment is possible. Nevertheless, EU-wide implementation faces challenges, including standardization, cost, and consensus on EBTs. To address these, we initiated a European survey targeting stakeholders and experts in water management, research, and regulation. The survey aims to identify barriers and opportunities for EBM adoption, evaluate knowledge gaps, and explore strategies for harmonization. Outcomes will provide insights to guide policy development, supporting broader integration of EBMs into regulatory frameworks.

1.13 Integrating Chemical Pollution and Wastewater-Based Epidemiology into the One Health Framework

1.13.T-01 HydroFATE as a One Health Tool: Modelling Multi-Contaminant Risks from Different Sources and Across Scales

Heloisa Ehalt Macedo¹, Bernhard Lehner¹, Jim Nicell¹, Liza-Marie Beckers² and Wibke Busch³, (1)McGill University, Canada, (2)Aquatic Chemistry, German Federal Institute of Hydrology (BfG), Germany, (3)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Chemical pollution is a critical yet underexplored driver of health outcomes across the human–animal–environment interface, and comprehensive monitoring is often constrained by resource and analytical limitations. To address this gap, we present new applications of HydroFATE, a global contaminant fate model designed as an accessible screening tool for assessing chemical risks in surface waters. HydroFATE integrates spatially explicit pollution sources, hydrological connectivity, and chemical-specific parameters to enable rapid, scientifically robust assessments for stakeholders, including regulators, industry, and water managers. Within a One Health framework, we apply HydroFATE to case studies in collaboration with international partners, including modelling veterinary and domestic antibiotic pollution in Canadian waters and assessing the environmental risk of 80 chemicals representative of typical wastewater composition in European rivers. Despite the added complexity of these applications, HydroFATE retains its core strength as a streamlined platform for screening and prioritization. Initial results reveal overlapping contamination patterns that may exacerbate antimicrobial resistance and ecological stress, underscoring the importance of multi-contaminant approaches to risk assessment. Although development of a user-friendly interface is underway, the current framework already supports evidence-based policy development and proactive strategies for safeguarding water quality and ecosystem health. Ongoing efforts to expand HydroFATE's contaminant library and foster collaboration with government agencies, non-profit organizations, and industry stakeholders will further enhance its utility for integrated water management worldwide, ultimately contributing to the preservation of global water quality and the protection of interconnected human, animal, and environmental health.

1.13.T-02 Proactive public health – actionable data for notifiable diseases using wastewater-based epidemiology

Laura M Langan¹, Piyada Juntawong², Bonnie Oh², Yan Sun², MD ALAMIN³, Fallon Bain³, HyeongYoung Choi³, Kacie A. Kaneshiro³, Layla Lustri⁴, Charlotte Nwagwu³, Janelle Oldfather³, Audrey Robertson⁴, Victoria Salinas⁴, Olivia Sagvold³, Christine Snow³, Adam Wronski³, Bryan W. Brooks³ and Heidi K Bojes⁴, (1)University of South Carolina, (2)Texas Department of State Health Services, United States, (3)Baylor University, United States, (4)Environmental Epidemiology and Disease Registries, Texas Department of State Health Services, United States

Having been used to estimate lead times for SARS-CoV-2 infection surges, thereby facilitating early interventions to reduce spread, wastewater-based epidemiology and surveillance (WBE/WBS) has subsequently been used for many additional pathogens. Although reverse transcription-quantitative polymerase chain reaction (RT-qPCR), RT digital PCR (RT-dPCR) and RT digital droplet PCR (RT-ddPCR) are commonly used for WBE, differences among the platforms exist.

In this study, we employed RT-qPCR and RT-dPCR platforms for the comparative detection of vaccine (A genotype Edmonston) and wild-type (D8 genotype) measles RNA from wastewater in nearby cities separated by < 50 kilometers during the 2025 measles outbreak in Texas, USA, in addition to several other locations up to 30 – 1,400 kilometers from the outbreak location. In addition, as measles is also a mandatory notifiable disease, clinical testing for measles is required if patient present with symptoms consistent with measles. Each wastewater sample with a positive of D8 using PCR (n = 23), was also sequenced, with 22 samples being successfully sequenced. Of the successfully sequenced samples, 13 were used for phylogenetic tree reconstruction. Each of these 13 wastewater samples could be directly matched to a clinical genome, with seven wastewater samples having zero SNP differences to clinical cases, four wastewater samples having +1 SNP, and one showed -1 SNP. Of these 13 samples, three (> 20 %) provided early warning. Many of the influent samples led clinical genome confirmation by 9 – 19 days (i.e. detection in wastewater prior to clinical detection), although not all, with prolonged shedding also observed.

This study, a first to specifically connect individual clinical samples with population level wastewater surveillance, demonstrates a widening use case for WBE, providing actionable data for notifiable diseases, capturing transmission dynamics that extend beyond geographic boundaries.

1.13.T-03 A National-Scale Application of Wastewater Analysis to Monitor Plasticizer Exposure in Spain

Andrea Estévez Danta¹, Rosa Montes¹, Rosario Rodil¹, Iria González-Mariño², Sara Rodríguez-Mozaz³, Unax Lertxundi⁴, Lubertus Bijlsma⁵, Carlos Pagan-Galbarro⁶, Andreu Rico⁷, Eva Pocurull⁸, Ruben Rios-Quintero⁹, Vicente Andreu Andreu¹⁰, Rocío Bonansea¹¹, Ailette Prieto¹² and José Benito Quintana¹, (1)University of Santiago de Compostela, Spain, (2)University of Salamanca, Spain, (3)Catalan Institute for Water Research (ICRA), Spain, (4)Bioaraba Health Research Institute, Spain, (5)University Jaume I, Spain, (6)University of Balearic Islands, Spain, (7)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain, (8)University of Rovira i Virgili, Spain, (9)University of Cádiz, Spain, (10)Spanish National Research Council (CSIC), Spain, (11)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (12)University of Basque Country, Spain

The widespread use of plastics in the 20th century led to the incorporation of additives such as BPA and phthalates, later identified as endocrine disruptors. Their regulation prompted the introduction of alternative compounds (bisphenol S or F, terephthalates, di(isononyl) cyclohexane-1,2-dicarboxylate (DINCH)), whose toxicological properties remain insufficiently understood, highlighting the need for robust monitoring of both traditional and emerging plastic-related contaminants. Wastewater-based epidemiology (WBE) offers an efficient tool to assess population exposure through its metabolic biomarkers in wastewater. Although these compounds have been studied in several countries, data from Spain are limited and lack national coverage. Hence, this study investigates human exposure to 3 bisphenols and 11 plasticizers (from phthalate, terephthalate and DINCH families) by measuring their metabolites in influent wastewater collected in 2023 from 27 WWTPs across Spain, representing over six million inhabitants. Samples underwent solid-phase extraction and were analyzed by liquid chromatography coupled to tandem mass spectrometry. Then, concentration levels were transformed into population-normalized daily loads (PNDLs) applying the flow rate and the population served by the WWTP. Findings show that short-chain phthalates remain prevalent, with DEP indicating the highest overall exposure (~500 mg/day/1000 inhabitants) whereas in a northern region, DEHP dominated, exceeding 2000 mg/day/1000 inhabitants. Among phthalate alternatives, DEHTP reached levels comparable to its phthalate analogue, while DINCH appeared sporadically at < 100 mg/day/1000 inhabitants. For bisphenols, metabolites of BPA and BPS were detected in all samples, whereas BPF appeared in fewer than half of the cities. Generally, BPS exposure exceeded BPA (~200 vs. ~100 mg/day/1000 inhabitants), except for one northwestern city showing unusually high BPA levels.

1.13.T-04 Bridging Environment to Exposome: In Vitro Evidence for Chemical Mixture Propagation to Humans

Beate Escher¹, Martin Scholze², Maria Margalef³, Maria König¹, Maria Valente⁴, Timo Hamers⁵, Kostja Renko⁶, Marc Audebert⁷, Jungeun Lee¹, Laure Khoury⁸, Peter Cenijn⁹, Yanying Ma¹⁰, Andreas Treschow¹⁰, Leisa-Maree Toms¹¹, Christina Rørbye¹², Georg Braun¹, Solène Motteau¹³, Jean-Philippe Antignac¹⁴, Gaud Dervilly¹³, Marja Lamoree⁵ and Anne Marie Vinggaard¹⁰, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Brunel University, United Kingdom, (3)A-LIFE (Environment & Health), VU University Amsterdam (VU), Netherlands, (4)Technical University of Denmark, Denmark, (5)VU University Amsterdam (VU), Netherlands, (6)German Federal Institute for Risk Assessment (BfR), Germany, (7)Université de Toulouse, INRAE, INP-ENVT, INP-EI-Purpan, France, (8)Preditox, France, (9)Vrije Universiteit, Netherlands, (10)Technical University of Denmark (DTU), Denmark, (11)Queensland University of Technology, Australia, (12)Hvidovre University Hospital, Denmark, (13)LABERCA, Oniris, INRAE, France, (14)National Veterinary, Food and Food School of Nantes-Atlantique (ONIRIS), France

Synthetic organic chemicals are pervasive in the environment, forming complex mixtures with diverse toxic potentials. Their number, diversity, and co-occurrence pose major challenges for assessing risks to ecosystems and human health, particularly at low concentrations. In vitro bioassays are well-suited for evaluating both known and unknown mixtures. In the Panoramix project [1], we examined how environmental chemicals

propagate through food webs to humans. Samples from 5–10 European countries were pooled, covering wastewater influent and effluent (human waste and emissions), surface water and fish (aquatic and dietary exposure), and conventional and organic cow milk (terrestrial mammal exposure). Human dietary exposure was represented by drinking water, bottled water, milk, and fish, while breast milk, adult serum, and cord serum captured direct human exposure. All samples were extracted using harmonized protocols and analyzed with targeted and nontarget chemical screening [2]. Extracts and reconstituted mixtures of 24 commonly detected chemicals were tested in 22 in vitro bioassays covering neurotoxicity, thyroid disruption, reproductive toxicity, and genotoxicity. Most bioassays responded, with strongest effects in samples from higher trophic levels like fish and humans. Reconstituted mixtures conformed to concentration addition predictions, but accounted for only a fraction of the observed bioactivity—pointing to the presence of uncharacterized toxicants and underscoring the limitations of current analytical coverage. These findings illustrate how synthetic chemicals cross ecological and physiological boundaries, impacting ecosystems and human health alike, highlighting the value of in vitro tools and a One Health approach to integrated risk assessment. 1.13.T-05 Potential of Settling Basins to Record Quantitative Information about Public Health: History of Paris since 2018

Thomas Thiebault¹, Asif Mahmud², Sébastien Wurtzer³, Claude Le Milbeau⁴, Fabrice Alliot¹, Laurence Le Callonnec⁵, Laurent Moulin³ and Jeremy Jacob⁶, (1)Practical School of Advanced Studies (EPHE), France, (2)METIS, France, (3)Eau de Paris, France, (4)ISTO, France, (5)ISTEP, France, (6)LSCE, France

Settling basins in sewage networks mainly trap coarse particles that accumulate between cleanings. These deposits, though coarse, can archive contamination signals from wastewater. With the rapid development of wastewater-based epidemiology (WBE), which estimates community health and consumption from wastewater composition, this study explores whether sediments in an urban settling basin can serve as historical archives of both chemical and microbiological anthropogenic contamination.

We investigated the Marceau–Courcelles settling basin (northwestern Paris), a cylindrical underground structure receiving mixed wastewater and stormwater, not dredged since 2018. In 2024, four sediment cores (0.5–1 m) were collected and subsampled (48 samples) for grain size, total organic carbon (TOC), organic matter characterization (Rock-Eval), chemical contaminants (LC–MS/MS after ASE extraction), and microbial indicators quantified by digital (RT)-PCR (CrAssphage, *E. coli*, PMMoV, adenoviruses, noroviruses). Sediment stratigraphy and monitoring data allowed correlation between depth and time, reconstructing contamination trends from 2018–2024, including the COVID-19 period.

Twelve depositional layers (mostly winter) were identified, with lateral heterogeneity in sedimentation but similar geochemistry across cores. Sand dominated (70–90%), though TOC reached up to 9.5%, without clear correlation to grain size. Among 60 targeted molecules, 42 were detected (up to several $\mu\text{g g}^{-1}$), showing both vertical and lateral variability independent of in situ degradation. Statistical associations between parent compounds and metabolites (e.g., cocaine/benzoyllecgonine, caffeine/paraxanthine) suggest variations in wastewater inputs rather than diagenetic processes.

Microbiological markers showed variable behavior: *E. coli* and CrAssphage were irregular, whereas PMMoV, adenoviruses, and noroviruses displayed consistent patterns and NVG I/II ratios correlated with wastewater signals. SARS-CoV-2 was not detected, likely due to degradation.

Overall, sediments captured temporal variability in chemical and microbial markers, confirming their potential as retrospective WBE archives. The Marceau–Courcelles basin thus potentially functions as an urban observatory, archiving contamination and public health signals. These findings open perspectives for using urban sediment records to reconstruct past pollution and epidemiological trends, complementing real-time wastewater monitoring.

1.13.P Integrating Chemical Pollution and Wastewater-Based Epidemiology into the One Health Framework

1.13.P-We060 From Point Measurements to Integrated Assessments: How Decision Theory Supports Integration Over Multiple Objectives, Space, and Time

Nele Schuwirth, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Environmental assessments involve diverse objectives, temporal and spatial scales, making integration a major challenge. Multi-criteria decision analysis (MCDA), rooted in decision theory, provides a structured approach to address this complexity: By disaggregating overarching objectives into smaller components that can be assessed separately, it provides a framework to make wicked problems manageable. By aggregating the smaller components into holistic assessments, it facilitates synthesis. Its foundation in decision theory ensures that assessment procedures satisfy mathematical axioms essential for rational decision making.

As a framework to formulate, harmonize and integrate assessments, MCDA offers tools for elicitation, implementation and visualization. This facilitates information to be presented at different levels of detail, supporting a transparent communication tailored to specific management questions and audiences.

A key challenge for integration is selecting appropriate mathematical aggregation methods. This contribution examines their implications and provides practical guidance for choosing methods suited to specific contexts to prevent unintended consequences through informed methodological choices.

We illustrate applications of MCDA for integrated assessments in the scope of surface waters and at different scales. Examples include the integration over multiple pollutants and ecotoxicological endpoints for integrated water quality assessment, the integration of physical, chemical and biological modules into an ecological assessment of rivers at the reach scale, or the integration of spatial criteria for the prioritization of the removal of fish migration barriers at the catchment scale.

With the potential of MCDA to harmonize and integrate diverse data sources and indicators, it can support advancing One Health-oriented risk assessment and management frameworks.

1.13.P-We061 Impact of Widely Occurring Organic Micropollutants on Antibiotic Resistance in Clinically Relevant Bacterial Pathogens

Judit Háhn, Boróka Szilágyi, Sándor Szoboszlai, Balázs Kriszt and Edit Kaszab, Hungarian University of Agricultural and Life Sciences (MATE), Hungary

Antibiotics are widely used antimicrobial agents, but their extensive application exerts strong selective pressure on pathogens, contributing to the global rise of antibiotic resistance. Recent studies show that not only antibiotics but also non-antibiotic anthropogenic micropollutants can promote the development and spread of resistance genes. Given their global application and frequent environmental detection, we selected three pesticide active substances and three personal care product ingredients to evaluate their potential to induce resistance in environmental isolates of clinically relevant opportunistic pathogens.

The examined strains (*Escherichia coli*, *Acinetobacter johnsonii*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa* and *Stenotrophomonas maltophilia*) belonged to ESKAPEE-associated genera.

MIC experiments were preceded by cytotoxicity tests to determine sublethal micropollutant concentrations (<EC₁₀). Bacterial cultures were then exposed for 96 h to 10 mg/L micropollutants, followed by standardized MIC testing (EUCAST/CLSI). Resistance profiles of untreated “wild-type” strains served as references.

Our results show that the tested micropollutants frequently induced increased MIC values across all species. *E. coli* displayed 2–3-fold increases against ciprofloxacin; imipenem resistance emerged after exposure to benzophenone-3, glyphosate, and DEET. In *A. johnsonii*, all compounds induced ciprofloxacin resistance, and several caused up to fourfold MIC increases for piperacillin–tazobactam. In *K. pneumoniae*, all micropollutants triggered ciprofloxacin resistance, with glyphosate, benzophenone-3, and methylparaben showing the strongest effects. *P. aeruginosa* showed the most alarming pattern: nearly all micropollutants induced resistance to almost all tested antibiotics. In *S. maltophilia*, shifts in MIC values suggested altered susceptibility for multiple drug classes, including carbapenems and fluoroquinolones.

Our findings demonstrate that environmentally relevant micropollutants—though not antibiotics—can substantially contribute to the development of antibiotic resistance in facultative pathogenic environmental bacteria. These results highlight the critical role that non-antibiotic organic micropollutants may play in shaping resistance patterns in environmental bacteria, reinforcing their relevance within the One Health perspective.

1.13.P-We062 The AMR Multi-Stakeholder Partnership Platform: a global Quadripartite initiative to address the challenges of antimicrobial resistance by fostering collaboration between diverse stakeholders

Paola Grenni¹, Andrea Di Cesare², Sabiha Essack³, Francesca Latronico⁴, Yerkem Sembayeva⁴, Viola Convertito⁴ and Nelea Motriuc⁴, (1)Water Research Institute, Italian National Research Council (CNR), Italy, (2)National Research Council, Italy, (3)University of KwaZulu-Natal, South Africa, (4)Food and Agriculture Organization of the United Nations, Italy

Antimicrobial resistance (AMR) is a global health threat arising from the misuse of antimicrobials, leading to infections becoming harder to treat in humans, animals and contaminating the environment. This resistance threatens modern medicine, food security, social and economic stability, making common infections life-threatening and compromise medical procedures. As it spans borders and sectors, addressing AMR requires a collaborative, One Health approach involving all stakeholders to address the interconnectedness of humans, animals, plants and the environment. Despite decades of effort, governance remains fragmented, scientific knowledge is unevenly translated into policy, and inequities in access to antimicrobials fuel inappropriate use. In response, the Quadripartite organizations (FAO, UNEP, WHO and WOA) established in 2022 the AMR Multi-Stakeholder Partnership Platform (MSPP) to mobilize collective action, integrate underrepresented perspectives, and accelerate implementation of evidence-based solutions applying the One Health approach. The MSPP engages more than 300 entities, organized in 5 clusters and 13 Action Groups which are operational units, testing of practical interventions.

The MSPP elevates underrepresented stakeholder groups and sectors into global AMR decision-making processes, facilitating widespread stakeholder participation in the 2024 UN General Assembly High-Level Meeting on AMR and the Fourth High-Level Ministerial Conference in Jeddah. In 2025, it organized global consultations for the update of the Global Action Plan on AMR and the establishment of the Independent Panel on Evidence for Action against AMR (IPEA), enabling contributions from over 2,000 participants across sectors and regions. This approach exemplifies a multi-stakeholder governance model in which heterogeneity of expertise is treated as a strategic asset rather than a barrier to problem-solving.

The MSPP, in an era of declining trust in multilateral institutions, financial constraints and policy fragmentation, provides a structured mechanism for integrating scientific evidence, diverse experience and collective priority-setting into coordinated global action. By strengthening connectivity across sectors and disciplines, it contributes to a more resilient, equitable and effective response to one of the most pressing public health threats of the 21st century.

1.13.P-We063 Ecotoxicity of selected antimicrobial resistance (AMR) causing agents in potentially susceptible species

Hiroshi Yamamoto¹, Yusuke Oda², Haruna Watanabe², Takahiro Yamagishi², Kyoshiro Hiki³, Tomoko Sugiura², Akiko Nagao² and Koichi Ohno², (1)Health and Environmental Risk Division, National Institute for Environmental Studies (NIES), Japan, (2)National Institute for Environmental Studies (NIES), Japan, (3)University of Tokyo, Japan

While antimicrobial resistance (AMR) caused by the use of antibiotics in patients and livestock has attracted considerable attention, the ecotoxicological risks of AMR-causing agents remain a significant concern. In Japan, some macrolide antibiotics are considered among the highest-risk pharmaceuticals—second only to hormonal drugs—based on screening-level risk assessments. However, there are still substantial ecotoxicity data gaps for this group of chemicals, as toxicity testing with the standard three species (green alga, daphnid, and fish) is not required for human or veterinary medicines under current Japanese regulations.

Since 2002, we have conducted screening-level risk assessments for over 400 chemicals under the “Initial Risk Assessment of Chemicals” program of the Ministry of the Environment, Japan. Yet, only eight of these chemicals have been antimicrobials (e.g., clarithromycin, sulfamethoxazole). To address data gaps, we performed ecotoxicity tests not only with the standard three species but also with potentially susceptible organisms such as cyanobacteria, luminescent bacteria, and protozoa (*Tetrahymena* sp.). The results of these studies were presented at the 46th Annual Meeting of SETAC North America in Portland, OR, USA.

We subsequently shifted our focus to other antimicrobials considered potential contributors to AMR. For these substances, we conducted ecotoxicity tests using both the standard three species (green alga, daphnid, and fish) and the additional susceptible species (cyanobacteria, luminescent bacteria, and protozoa). Based on the newly

obtained ecotoxicity data and existing monitoring data, we also carried out screening-level risk assessments for these antimicrobials.

This research was supported by the Environment Research and Technology Development Fund (JPMEERF25S21230) of the Environmental Restoration and Conservation Agency (ERCA), provided by the Ministry of the Environment of Japan.

1.13.P-We064 Prevalence of Selected Antibiotic Resistance Genes in Agricultural Soils in Germany

Cecilia Diaz¹, Fabian Essfeld², Udo Hommen¹, Dimitrios Alexander Skodras¹, Marie Winter³, Karlheinz Weinfurter¹, Patrick Schröder⁴, Jens Schönfeld⁵, Pia Kotschik³ and Judith Klein¹, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)University of Osnabrueck, Germany, (4)Pharmaceuticals, German Environment Agency (UBA), Germany, (5)German Environment Agency (UBA), Germany

Growing concerns about the presence of antibiotic resistance genes (ARGs) in agricultural soils—especially due to inputs such as manure—have highlighted the need to better understand environmental reservoirs of antimicrobial resistance and their potential risk to human and animal health. In this context, soils from 63 agricultural sites across Germany were sampled between 2022 and 2024 and analyzed for a wide range of parameters, including soil physicochemical properties, contamination with plant protection products and pharmaceuticals, ecological variables, and the presence of ARGs. In addition to the agricultural sites, three reference sites retrieved from the German Environmental Specimen Bank were included in the ARG analysis to provide background levels for comparison. This integrated dataset allowed the assessment of potential links between ARG abundance and agricultural practices, chemical exposure, and soil characteristics across Germany. The study showed that a few ARGs were widespread across German agricultural soils. Genes conferring resistance to macrolide (ermB) and tetracycline (tetA) classes were most frequently detected. In contrast, genes associated with aminoglycoside resistance (aacC4 and aadA1) and trimethoprim resistance (dfrA1) were only sporadically detected. Genes from additional classes—including macrolides (ermA), trimethoprim (dfrA12), β -lactams (blaCTX-M1), quinolones/fluoroquinolones (qnrS), and polypeptide antibiotics such as colistin (mcr-3)—were not detected, indicating their low abundance or absence in analyzed soil samples. The class 1 integrase gene (intI1), as an indicator of mobile genetic elements, was present at nearly all sampled sites. Relative ARG abundances varied between sites and tended to be higher in soils with manure or digestate application. In contrast, reference sites—representing soils with minimal or no anthropogenic influence—generally exhibited lower ARG prevalence, suggesting that agricultural activities and organic fertilization contribute to the enrichment and spread of resistance genes in soil environments. Although direct causal relationships between antibiotic residues and ARG occurrence could not be established, the observed co-occurrence highlights the importance of evaluating together these factors when assessing the spread of antibiotic resistance in the environment.

1.13.P-We065 In Vivo Toxicity and Ecotoxicological Evaluation of a Bioactive Metabolite Derived from *Streptomyces nogalater* KNB14980

Seok-ki Min, Seon-yeong Yun and Seung-Hyun Yang Ph.D, Korea Testing & Research Institute, Korea, Republic of

Microbial-derived crop protection agents require comprehensive evaluation of their in vivo toxicity and ecological safety to ensure reliable field application. In this study, we investigated the in vivo and ecotoxicological properties of a bioactive metabolite (KNB14980 EM, 98% a.i.) produced by *Streptomyces nogalater* KNB14980 following standardized testing protocols.

Acute oral and dermal toxicity assessments, along with skin and eye irritation tests, were conducted in rodent and rabbit models. Oral administration of up to 2000 mg/kg in female Sprague–Dawley rats resulted in no mortality or treatment-related adverse effects. Dermal exposure at 4000 mg/kg induced only transient and fully reversible skin reactions. Skin and eye irritation tests in rabbits showed no evidence of corrosion or persistent damage, confirming the compound to be non-irritating.

Ecotoxicity was further examined through acute aquatic and pollinator assays. Danio rerio exhibited no abnormal responses, with 48-h and 96-h LC50 values exceeding 100 mg/L. Honeybee (*Apis mellifera*) oral and

contact exposure both yielded LD50 values greater than 100 µg a.i./bee, indicating low risk to pollinators. Collectively, these findings demonstrate that the metabolite possesses low acute in vivo toxicity, negligible irritation potential, and minimal hazard to aquatic organisms and pollinators. The results support its suitability as a safe and environmentally compatible microbial-based crop protection agent.

1.13.P-We066 Determining Potentially Misused Pharmaceuticals and Metabolites to Assess Usage Through Wastewater Analysis

Tin Županović, Karlo Jambrošić, Ivona Krizman Matasić, Senka Terzić, Marijan Ahel and Ivan Senta, Ruder Boskovic Institute, Croatia

Wastewater-based epidemiology (WBE) is a relatively new approach that provides insight into pharmaceutical consumption at the population level. Traditional methods rely on sales and prescription data, which can yield inaccurate results, especially for pharmaceuticals that are frequently misused. WBE can therefore serve as a complementary method to provide more accurate consumption figures.

The aim of this research is to develop and validate an analytical method for the simultaneous determination of 39 pharmaceuticals and their metabolites in wastewater, including anxiolytics, hypnotics, and phosphodiesterase type V inhibitors. The analysis will be conducted using ultra-high-performance liquid chromatography coupled to tandem mass spectrometry (UHPLC-MS/MS), with solid-phase extraction (SPE) enrichment.

After optimizing mass spectrometric parameters and chromatographic separation, the SPE procedure was developed and optimized. The target compounds were enriched from 10 mL raw wastewater samples using hydrophilic-lipophilic balance cartridges, with an average recovery of 90%. Method accuracy was also high (average trueness: 90%; average precision: 5%), and low detection limits were achieved. Enzymatic deconjugation experiments were conducted to assess the contribution of the conjugated forms of selected compounds, particularly benzodiazepines, while in-sample model experiments were performed to evaluate the stability of the target compounds. Most compounds were highly stable at both 4 °C and 25 °C over 24 hours, indicating negligible transformation during composite sample collection and short-term storage, confirming their suitability for WBE.

The developed method will be used to assess spatial and temporal trends in the consumption of selected pharmaceuticals in six Croatian regions using the WBE approach. These results will be compared with data on pharmaceutical consumption obtained through traditional methods to assess potential misuse.

1.13.P-We067 Informing Site Selection for Wastewater-Based Epidemiology with Social Vulnerability Indicators

Adam Wronski¹, Laura M Langan² and Bryan W. Brooks¹, (1)Baylor University, United States, (2)University of South Carolina

Though wastewater-based epidemiology (WBE) can be used to understand socioeconomic status, it may also be possible to identify disease susceptibility. We recently sampled the wastewater treatment plants (WWTPs) of two communities of similar size that vary notably in their socioeconomic status, with one community ranked among the healthiest in the state of Texas, USA, and having low social vulnerability, while the other community is ranked as moderately healthy with medium-high social vulnerability. When these samples were analyzed for 24 pharmaceuticals, wastewater tracers, and an illicit drug metabolite, we observed significantly ($p < 0.001$) higher consumption of pharmaceuticals and an illicit drug at the site with higher social vulnerability. Similarly, a growing body of work considers the influence of socioeconomic factors on the loading of pharmaceuticals to the environment from WWTP effluent discharges. To better understand this relationship across a gradient of urbanization and socioeconomic status, we selected 14 estuarine sites across the Gulf Coast of Texas, USA, collecting paired time-weighted composite and grab samples across two seasons. In both seasons, we identified a significant ($p < 0.05$) negative relationship between sum pharmaceutical mass load and county health ranking,

suggesting greater environmental loading of pharmaceuticals in healthier communities with low social vulnerability. This approach also shows the potential use of WBE methods to identify hotspots with high chemical loads and thereby inform environmental monitoring, assessment and management. A key issue that limits the application of much socioeconomic data to WBE is the relatively limited spatial resolution of data; for example, in the US, much data is reported only at the county or zip code level, limiting the usefulness of this data to derive insights about sewersheds that often contain only portions of counties or zip codes. To begin to close this data gap, we developed a sewershed-level social vulnerability index across all United States WWTPs; our ongoing studies are examining the utility of this approach by analyzing illicit drugs, wastewater tracers, and viral targets in several Texas WWTPs located across a gradient of socioeconomic conditions. This new sewershed social vulnerability index, which is based on census tract information (~4,000 people), presents an opportunity to spatially inform future environmental monitoring, assessment and management efforts.

1.13.P-We068 Assessment of population exposure to polycyclic aromatic hydrocarbons using wastewater-based epidemiological analysis

Katarzyna Styszko¹, Laura Węgrzyn², Karolina Cwynar², Zuzanna Prus², Dominika Uchmanowicz², Elżbieta Sochacka-Tatara³, Agnieszka Pac⁴ and Barbara Kasprzyk-Hordern⁵, (1)University of Science and Technology (AGH), Poland, (2)AGH University of Krakow, Poland, (3)Jagiellonian University Medical College, Chair of Epidemiology and Preventive Medicine, Poland, (4)Jagiellonian University Medical College, Chair of Epidemiology and Preventive Medicine, Poland, (5)University of Bath, Poland

Wastewater-based epidemiology (WBE) may be able to monitor public health emergencies by analyzing human urinary biomarkers in wastewater. This work proposes a novel approach utilizing WBE for the spatial and temporal evaluation of PAHs exposure using hydroxyl derivatives of PAHs. These are 1-hydroxynaphthalene, 2-hydroxynaphthalene, 2-hydroxyfluorene, 9-hydroxyfluorene, 9-hydroxyphenanthrene, 1-hydroxypyrene and 3-hydroxybenzo(a)pyrene. Most target markers were found at quantifiable concentrations in raw and treated wastewater. The total loads identified in raw sewage ranged from 88.33 g/day to 154.77 g/day during the summer period and from 137.66 g/day to 283.78 g/day during the winter period. The obtained results for the removal efficiencies of OH-PAHs indicate a seasonal dependency in their degradation. Removal efficiencies were higher in January compared to August. The results of the back calculations allowed to estimate that during the summer, on average, a resident of Krakow could absorb approximately 2.1 µg of the assessed OH-PAHs per day, while in winter, this value increased to 4.1 µg. This is close to the reported in the literature value that the total daily exposure to OH-PAHs is estimated at 3 µg/day. To the authors' knowledge, this is the first time wastewater profiling of OH-PAHs in wastewater for the evaluation of exposure to PAHs have been used, also their removal as well emission with effluent were determined.

1.13.P-We069 Unveiling the presence of 20 perfluoroalkyl substances in wastewater in Spain – a national inventory of household emissions

Andrea Estévez Danta¹, Rosa Montes¹, Rosario Rodil¹, Sandra Méndez¹, Iria González-Mariño², Sara Rodríguez-Mozaz³, Gorka Orive⁴, Lubertus Bijlsma⁵, Carlos Pagan-Galbarro⁶, Nuria Fontanals⁷, Ruben Rios-Quintero⁸, Andreu Rico⁹, Julian Campo¹⁰, MIREN LOPEZ DE ALDA VILLAIZAN¹¹, Néstor Etxebarria⁴ and José Benito Quintana¹, (1)University of Santiago de Compostela, Spain, (2)University of Salamanca, Spain, (3)Catalan Institute for Water Research (ICRA), Spain, (4)University of the Basque Country (UPV/EHU), Spain, (5)University Jaume I, Spain, (6)University of Balearic Islands, Spain, (7)University of Rovira e Virgili, Spain, (8)University of Cádiz, Spain, (9)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain, (10)University of Valencia, Spain, (11)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Per- and polyfluoroalkyl substances (PFAS) and specially perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkyl sulfonic acids (PFSAs) have been extensively manufactured for numerous industrial and consumer applications. Several studies have suggested that both acute and chronic health effects, including cardiovascular diseases, may be associated with PFAS exposure, prompting the European Commission to impose restrictions on their use. Hence, the occurrence and fate of PFAS in wastewater and during treatment has been a hot topic in the last years. Nonetheless, few studies have considered this problematic in Spain, while there are no investigations at national level, nor have put the focus on using wastewater data to assess emissions.

In this context, this study aims to provide a comprehensive assessment of the occurrence of 20 PFAS across Spain by analyzing influent wastewater samples from 27 wastewater treatment plants (WWTPs) collected in 2023, covering a population of over six million inhabitants. Samples were solid-phase extracted, injected in a liquid chromatography-tandem mass spectrometry system and PFAS concentrations were transformed into population-normalized daily loads (PNDLs) applying the flow rate and the population served by the WWTP. Eleven PFAS were positively detected in influent wastewater samples being, 7 PFCAs (from C4 to C10) and 4 PFSAAs (C4, C6, C8 and C9). The highest detection frequency was denoted for the PFCAs family, highlighting perfluorobutanoic, perfluoroheptanoic and perfluorooctanoic acid that were detected in all wastewater samples. Similar PNDLs were found for detected PFAS with perfluorobutanoic acid showing the highest PNDLs (median: 8.9 mg/day/1000inhabitants) followed by the two C6 PFAS (median of 3.8 mg/day/1000inhabitants and 3.2 mg/day/1000inhabitants for perfluorohexanoic acid and perfluorohexanesulfonic acid, respectively). Regional patterns showed minimal differences overall, except for four PFCAs, for which exposure levels were found to be twice as high in a central region of Spain (median: 21 mg/day/1000inhabitants). Hence, the national extrapolation of the total PFAS-related PNDLs daily discharged to Spanish WWTPs is estimated at 1.7 mg per inhabitant per day.

1.13.P-We070 UHPLC–MS/MS Analysis of Lifestyle and Dietary Biomarkers in Wastewater: Method Optimization, Biomarker Stability, and Multi-city Study

Karlo Jambrošić¹, Tin Županović¹, Ivona Krizman-Matasić¹, Senka Terzić¹, Marijan Ahel² and Ivan Senta¹,
(1)Ruder Boskovic Institute, Croatia, (2)Division of Marine and Environmental Research, Ruder Boskovic Institute, Croatia

Wastewater-based epidemiology (WBE) has become a powerful tool for assessing population exposure to illicit drugs and other lifestyle chemicals. However, its potential for evaluating dietary habits remains largely unexplored due to the vast number of food-related biomarkers. To address this, we developed a UHPLC–MS/MS method to quantify over 40 lifestyle and dietary biomarkers in wastewater. These analytes cover diverse classes: flavonoids (plant metabolites) and other food constituents, vitamins, artificial sweeteners, caffeine, nicotine and alcohol biomarkers, and the pharmaceutical metformin, including many not previously monitored in WBE.

A dual sample preparation workflow was optimized to accommodate the wide range of analyte concentrations: high-abundance compounds (e.g., caffeine, nicotine and alcohol metabolites, sweeteners, metformin) were quantified by direct injection of diluted wastewater, whereas low-abundance dietary biomarkers were enriched using solid-phase extraction on hydrophilic-lipophilic balance cartridges. All compounds were separated on a T3 HSS C18 column using an acidified water–acetonitrile gradient and detected by tandem mass spectrometry in multiple reaction monitoring mode. The method achieved excellent linearity ($r^2 \geq 0.99$), high recoveries (>80% for most analytes), and quantification limits low enough to ensure reliable determination.

Stability tests showed that most biomarkers remained stable at 4 °C for 24 h, whereas some, such as certain vitamins and polyphenols, degraded significantly during prolonged storage at –20 °C. These findings highlight the need for prompt analysis or consideration of analyte losses. The method was applied during the 2025 one-week autumn/winter sampling campaign, analyzing 24-h composite wastewater samples from 12 Croatian cities across six regions, and revealed spatial variations in lifestyle and dietary habits.

Our findings broaden the scope of WBE by enabling high-throughput monitoring of dietary biomarkers alongside traditional surveillance of substances of abuse and other lifestyle chemicals. Future work will assess the in-sewer stability of biomarkers to validate their robustness under sewer conditions, and an additional sampling campaign in spring will investigate seasonal differences in lifestyle and dietary habits.

1.13.P-We071 A temporal analysis of microbiome dynamics in activated sewage sludge aerated for 14 days in OECD 301 biodegradation tests

Thomas Wilkes, Jonas Lo and Julia Hunter, Labcorp, United Kingdom

Organisation for Economic Co-operation and Development (OECD) 301 guidelines provide the basic requirement for microbial counts from activated sewage sludge for each of the six tests under this guideline. The guideline also states that the activated sewage sludge may be kept aerated for up to seven days. However, the microbiome of activated sewage sludge is highly dependent on the domestic population from which it is derived, with several genera of bacteria present in greater abundance over a myriad of bacterial, fungal, viral, and protozoal genera. Such diverse microbial populations provide enzymatic and metabolic pathways for biodegradation studies, such as oxygenases, hydrolases, and dehydrogenases. As microbial diversity changes across the duration of activated sewage sludge aeration, studies have shown reductions in enzymatic expression. Therefore, the aim of the present study is to determine the change in microbiome profile, with an emphasis on bacterial communities, over a maximum of 14 days aeration, with colony forming unit (CFU) counts associated with respective OECD 301 tests throughout the 14 days. Metagenomic methodologies were employed to determine microbiome diversity, showing a significant alteration ($P < 0.001$) in bacterial diversity. Primary biodegradation species, such as *Pseudomonas fluorescens*, significantly increased ($P < 0.001$) in abundance up to day seven with greatest abundance on day four. Aerobic CFU counts indicated a consistent decline between days two and eight ($P < 0.001$), corresponding to the metagenomic diversity changes across the same time period. Post day eight, CFU counts increased to day 14, however, metagenomic data indicated such an increase of CFU counts was a migration away from typical biodegradation species. Therefore, based on both cell culture and metagenomic analysis, the present study is able to conclude that activated sewage sludge for OECD 301 tests would be more appropriately kept under aeration for a total of five days as opposed to the typical seven days in order to utilise the select key biodegradation bacterial species

1.13.P-We073 The Use of in vitro Bioassays To Assess the Endocrine Disrupting Potential of 4-tert-octylphenol via Estrogen Receptors Vital to the Regulation of Female Fertility.

Emma Adams, Yuling Xie, Thomas Stewart, Mark Muldoon and Lisa Connolly, Queen's University Belfast, United Kingdom

Alkylphenols (APs) are a family of compounds used in a wide range of commercial and industrial products. APs are commonly used to synthesise alkylphenol ethoxylate surfactants, which degrade in the environment back to APs such as 4-tert-octylphenol (4-t-OP). With no current widespread wastewater removal methods preventing its entry to the ecosystem, 4-t-OP is continually detected across many environmental matrices. Continual exposure to 4-t-OP is of concern due to its well documented estrogenic activity and association with reproductive toxicity. However, studies have mainly focused on reproductive effects in wildlife and in males, while the exact effects of 4-t-OP on female reproductive processes remain less understood, particularly regarding its ability to disrupt estrogen receptor (ER) activity which is vital to the regulation of fertility. Previous research has shown that 4-t-OP exposure triggers ER transactivation by utilising Reporter Gene Assay (RGA) cell lines expressing ER α and ER β respectively, but these results alone cannot convey how endogenous ER is affected in vivo, since both isoforms are usually co-expressed. To address this, we assessed the effect of 4-t-OP exposure on ER transactivation by measuring luciferase response using an RGA cell line (MMV-Luc) expressing both ER α and ER β , which mimics the in vivo scenario whereby these receptors communicate. Sample toxicity was monitored in the RGA using the MTT assay. The effect of 4-t-OP exposure on ER translocation was also measured by using U2OS cells stably expressing fluorescently tagged ER α and ER β respectively and imaged using High Content Analysis. Sample toxicity was controlled by monitoring pre-lethal cytotoxic effects in the same assay.

An increase in both ER translocation and transactivation in the presence of human relevant exposure levels of 4-t-OP was observed, indicating ER agonism, and extension beyond these levels revealed dose-response relationships, with translocation results showing a higher response for ER β .

In summary, 4-t-OP can disrupt ER receptor signalling. The correlation of results between both assays also validates the newer generation translocation assays which provide additional data output including sample toxicity control. These findings suggest that exposure may negatively impact female reproductive processes, highlighting the need to continue toxicological screening of commercially relevant compounds detected in the environment.

1.13.P-We074 One Health Insights Into Malathion Toxicity: Protective Effects of Thymoquinone and Diallyl Sulphide in Rats

Ali A Shati, Biology Department, King Khalid University, Saudi Arabia

Malathion, a widely used organophosphate insecticide, poses serious human and animal health concerns due to its ability to inhibit acetylcholinesterase and disrupt multiple biochemical and oxidative pathways. Understanding how natural bioactive compounds can mitigate pesticide-induced toxicity is essential within a One Health framework, where chemical exposures affect humans, animals, and shared environments.

This study aimed to evaluate the protective effects of thymoquinone (TQ) and diallyl sulphide (DAS) against malathion-induced oxidative and biochemical disturbances in rat cerebral, hepatic, and renal tissues. To address this challenge, rats were exposed to malathion with or without co-treatment using TQ or DAS for 30 days. Blood and tissue samples were subsequently collected to assess liver and kidney biomarkers, antioxidant enzyme activities, and oxidative stress indicators.

Malathion administration resulted in significant increases in serum AST, ALT, ALP, LDH, GGT, cholesterol, urea, creatinine, and 8-OHdG, along with reductions in total protein, albumin, triglycerides, and AChE. In parallel, malathion markedly elevated tissue malondialdehyde and nitric oxide levels while suppressing glutathione and antioxidant enzymes (GPx, SOD, CAT). Co-treatment with TQ or DAS significantly ameliorated these alterations, with TQ showing the most consistent restoration toward normal physiological ranges.

In conclusion, both TQ and DAS effectively mitigated malathion-induced biochemical and oxidative damage, likely by reducing reactive oxygen and nitrogen species and enhancing endogenous antioxidant defenses. These findings highlight the potential of natural protective agents in reducing pesticide-related health risks and underscore the relevance of integrating animal toxicity data into broader human and environmental health considerations within a One Health perspective.

1.13.P-We075 (Eco)toxicological effects of nanoengineered pesticides on humans and non-target biota

Evgenia Chaideftou¹, Willie Peijnenburg² and Hedwig Sutterlüty¹, (1)Medical University of Vienna, Austria, (2)Leiden University, Netherlands

Nanoengineered pesticides are novel chemical products that target pests with sufficient efficacy to maintain plant health. However, our knowledge regarding their environmental fate and exposure is still insufficient and we cannot reliably assess for instance potential accumulation across several biological organizations, and the potential ecotoxicological impacts. Several studies have already pointed out specific impacts at different scales of biological organization, but still it is not clear if and how this information could be utilized in a regulatory risk assessment framework. A systematic literature review was conducted to assess: (i) the advances in nanomaterial application in relation to classical pesticide use; (ii) if and which of the impacts on the organisms of the environment from nanomaterials used in pesticides, are assessed or sufficiently investigated to serve for regulatory risk or effect assessment schemes; (iii) if we should really focus on specific toxicological impacts following nano-based pesticide applications on the environment, that are supposed to have a limited exposure and thus limited effect on organisms; (iv) if and which of the impacts on organisms from nanomaterials used in pesticides, are assessed or sufficiently investigated to serve for regulatory risk or effect assessment schemes; and (v) the type of effects that have so far been detected in the available literature. Articles describing results of experimental research on toxic effects from nano-based pesticides on non-target biota were screened and gathered using the ASReview product developed by Utrecht University, and PRISMA guidelines on reporting towards meta-analyses. Impacts-related data are classified and analyzed. This review will enhance: (i) our understanding of the gaps that still need to be covered in the field of ecotoxicology for nano-pesticides, and (ii) our reporting of the available (eco)toxicological data from studies with organisms, for nano-enabled pesticides used in the agrochemical sector for plant protection. This advance would potentially minimize adverse effects on environmental and human health.

1.13.P-We076 Impact of E-cigarettes on Invertebrates in Aquatic Ecosystems

Noah Feiter¹ and Guido Gonsior², (1)No Affiliation, Germany, (2)GG Bio Tech Design, Germany

E-cigarettes, especially disposable e-cigarettes, have been less researched than traditional cigarettes. In addition to alkaloids, they contain heavy metals and complex chemical mixtures.

A student experiment has shown that not only does the mechanical destruction of the cigarettes pose a fire hazard, but also that significant amounts of the solutions remain in the sponge contained within them. Furthermore, the toxic effect appears to occur much more quickly than with normal cigarettes, as there is no release from the tobacco, but the harmful substances are already present in liquid form. This leads to significantly faster bioavailability. We present initial results from experiments conducted in cooperation with schoolchildren showing that e-cigarettes pose an environmental risk on invertebrates.

1.13.P-We077 Heavy metals analysis in selected wetlands in the Vaal Region, South Africa: A shift towards achieving Sustainable Development Goals

Mzimkhulu Ephraim Monapathi¹, Sekomeng Modise¹, Michael J Klink² and Ntefeleng Meno¹, (1)Vaal University of Technology, South Africa, (2)Natural Sciences, Vaal University of Technology, South Africa

Wetlands offer wide array of ecological, economic, and social benefits. However, these freshwater environments are gradually degraded and lost through anthropogenic activities, climate change and pollutants, including heavy metals globally. Heavy metals are toxic, persistent, and non-degradable contaminants that enter wetlands through human activities, threatening both aquatic organisms and humans. The present study aimed to analyse heavy metals in selected wetlands in the Vaal Region, South Africa. Using Nanocolor test kits with the 500D photometer, heavy metals were analysed from water samples collected at predetermined points, at the input and output along the wetlands during dry and wet seasons. Findings were compared with wastewater limit values applicable to the discharge of wastewater into water resources. Results for dry season (input: output) were as follows: Copper: 0.81; 0.72 mg/L, Lead (1.16; 0.84 mg/L, Silver (0.50; 0.30) and Zinc (0.50; 0.24). For wet season: Copper (0.46; 0.27mg/L), Lead (1.01; 0.89 mg/L), Silver (0.59; 0.25mg/L) and Zinc (0.48; 0.28mg/L). Low heavy metal concentrations at the outputs in both seasons in all sampled sites were indicative of reduced contamination along the wetlands. However, Copper, Lead and Zinc exceeded wastewater limit values applicable to discharges of wastewater into water resources. Even at low concentrations, heavy metals are a health risk to aquatic organisms and humans. The present study champions Sustainable Development Goals (SDGs) 3: Good health and well-being, SDG 6: Clean water and sanitation and SDG 15: Life on land. Although wetlands are considered natural wastewater treatment entities, wastewater effluent should be effectively treated before discharge into receiving water resources. Furthermore, wetlands should be protected to improve the water quality of receiving surface water environments, which often serve as primary sources of drinking water.

Keywords: Wetlands, Heavy metals, Wastewater, Sustainable Development Goals

1.13.P-We078 Are vulnerable insects sentinel species of chemical mixture threats in small streams? Resolving the debate around the German Kleingewässermonitoring (KGM)

Hanh Nguyen¹ and Ralf Bernhard Schaefer², (1)University Duisburg-Essen (Uni DUE), Germany, (2)University Duisburg-Essen (Uni DUE), Duisburg, Germany

Pesticide applications on agricultural lands contribute to the input of chemical mixtures into adjacent small lowland streams, where their toxic effects may impair biodiversity and ecosystem services that underpin One Health. A study on 101 small agricultural streams across Germany suggested that pesticides are the dominant stressor for vulnerable insects (Liess et al. 2021 Wat. Res.), whereas a recent study pointed to potential flaws in data analysis (Moore & Rathjens 2025 IEAM). These revolved around non-reproducibility of potential toxicity estimates, temporal mismatch of chemical and ecological monitoring and missing data. Given that the latter study did not resolve the issue of non-reproducibility and did not provide a comprehensive analysis of different decisions in data analysis, we aimed to resolve this issue through a reproducible re-analysis. We compared different methods of estimating potential toxicity in terms of toxic units. We were able to reproduce both the original results and those of Moore & Rathjens (2025). Irrespective of the method, we observed stronger associations between chemical mixtures and ecological metrics compared to individual substances. Moreover, associations with ecological metrics increased when both event-based and grab samples were included, which probably reflects that toxicity can occur during both dry-weather and rainfall periods, with one-third of sites exhibiting higher toxicity in dry-weather samples. When accounting for the temporal mismatch, the results still confirmed the primary hypothesis on negative association of pesticide mixture with sentinel species health. Across the gradient of agricultural land use (<20% to 100% coverage), the estimated potential mixture toxicity from pesticides was the dominant driver of declines in vulnerable insect species for most choices in data pre-processing. Our results demonstrate that the original conclusions of Liess et al. (2021) remain valid even when accounting for the points raised by Moore & Rathjens (2025). We discuss the role of freshwater insects as sentinel species integrating chemical mixture exposures over time and revealing ecosystem-level impacts.

Embedding such field-base evidence into integrated health frameworks might better safeguard freshwater biodiversity, ecosystem services and human health in an age of global pollution.

1.13.P-We079 Comparative Ecotoxicological Assessment of Nano-formulated and Conventional Copper-based Pesticides on Crop Plants, Freshwater Organisms and associated Microbiota: A One Health Framework

Thomas MOURA¹, Florian Chapeau¹, Van Xuan Nguyen¹, Marion Vivant¹, Frederic Candaudap¹, Camille Larue¹, Maïalen Barret¹, Laurence Chevalier², Lauris Evariste³, Eric Houdeau³, Bruno Lamas³, Laury Gauthier¹, Eric Pinelli¹ and Florence Mouchet¹, (1)Centre de Recherche sur la Biodiversité et l'Environnement (CRBE) Université de Toulouse, France, (2)Groupe de Physique des Matériaux, GPM-UMR6634, CNRS, Université de Rouen, France, (3)Toxalim UMR 1331, INRAE, Toulouse, France, France

Copper-based nanopesticides are increasingly used in agriculture because they are promoted as more efficient alternatives to conventional copper products due to their improved antibacterial and antifungal properties. Such formulations are applied to crops and can then be transported to adjacent freshwater ecosystems, creating a continuum of exposure for plants, non-target wildlife and associated microbiota. In this context, we evaluated the ecotoxic potential of the copper-based nanopesticide Kocide 3000® compared to the conventional formulation Kocide 2000®, from crop plants to freshwater organisms while considering associated microbiota. Tomato (*Solanum lycopersicum*) plant microcosms were subjected to a realistic foliar application scenario. In parallel, freshwater species representing distinct ecological niches were directly exposed in water to each copper formulation under controlled laboratory conditions. Beyond acute toxicity, we investigated developmental effects using *Chironomus riparius* and *Xenopus laevis* as holobiont models. In the terrestrial compartment, no phytotoxic effects were detected and neither formulation measurably altered the soil bacterial community composition. However, the nanopesticide caused a significant accumulation of copper in tomato fruits, indicating a potential dietary exposure route for humans. On aquatic organisms, analyses showed that all contaminants, induced toxicity at environmentally relevant concentrations (0.005 to 0.050 mg Cu L⁻¹). Regarding microbiota responses, both commercial formulations induced distinct shifts in bacterial taxa. In the gut microbiota of amphibian larvae, only the nanopesticide induced significant changes compared to the negative control at all tested concentrations. Finally, the differential and significant bioaccumulation potential of the nanopesticide in biological matrices suggests a higher risk of copper transfer through aquatic-terrestrial food webs, which could impact biodiversity. Together, these findings question the assumption that nano-formulations are safer alternatives and emphasize the need for further research into the mechanisms underlying the impacts of copper nanopesticides, as well as their broader ecological consequences following agricultural use. Overall, this multi-species, microbiota-informed approach illustrates how commercial pesticides can link environmental contamination, ecosystem health and potential human exposure within a One health framework.

Disclaimer/Disclosure:

This work was supported by the French Office for Biodiversity (grant OFB-22-1496), within the call for research projects “Plant protection products: from exposure to impacts on human health and ecosystems towards an integrated One Health approach”, funded by diffuse pollution fees from the Ecophyto II+ plan and conducted under the responsibility of the French ministries in charge of agriculture, ecological transition, health and research.

1.13.P-We080 Combined Low-Dose Toxicities and Interactions of Agricultural Toxicants in *Caenorhabditis elegans*: Epigenetics Insights

Yong-Shan Li¹ and Chia-Cheng Wei², (1)Institute of Environmental and Occupational Health Sciences, College of Public Health, National Taiwan University, Taipei 10055, Taiwan, Taiwan (Greater China), (2)Department of Public Health, College of Public Health, National Taiwan University, Taipei 10055, Taiwan, Taiwan (Greater China)

Combined toxicities are increasingly recognized as a critical environmental health concern. Under climate change, alterations in fungal contamination patterns and crop protection practices are likely to elevate the probability of co-exposure to multiple agricultural toxicants. This emerging reality highlights the necessity for continued investigation of toxicant mixtures to support cumulative impact assessment. However, most existing evidence is derived from in vitro assays, leaving a notable lack of long-term in vivo co-exposure data. In addition, potential interactions between toxicants complicate predictions of combined toxicities based solely on individual compound assessments. Given these gaps, a key challenge is determining whether toxicants interact in vivo and identifying the molecular pathways that connect mixture exposure to organism-level adverse

outcomes.

To address this, we applied an integrated experimental-computational approach using *Caenorhabditis elegans* (*C. elegans*). Long-term co-exposure interactions were assessed with the Chou-Talalay method using phenotypic endpoints, with mixture ratios defined by each toxicant's EC10 to analyze chronic interactions. Molecular responses were interpreted within an adverse outcome pathway (AOP) framework, emphasizing epigenetic initiating events associated with sustained low-dose toxicities. Preliminary results indicated that zearalenone (ZEN), a mycotoxin with estrogenic activity, and tebuconazole (TEB), a widely used triazole fungicide, synergistically affected body bending locomotor behavior in *C. elegans* at a 10% effect level. At this exposure level, the concentrations required to elicit comparable deficits were reduced by 2.4-fold for ZEN and 4.0-fold for TEB. The results also demonstrated that co-exposure to ZEN and TEB significantly affected the epigenetic regulatory mechanisms.

These findings indicate that mixture effects cannot be predicted from single-toxicant data alone, and that epigenetic AOP signatures providing a mechanistic basis for interpreting these interactions. The study advances mixture toxicology by delivering long-term in vivo evidence of low-dose co-exposure, a framework for interaction classification, and insights into molecular mechanisms underlying adverse phenotypes. These results can inform regulatory mixture assessments and improve cumulative exposure models for environmental protection.

1.13.P-We081 Synergistic Toxicity Induced by Co-exposure to Zearalenone and Deoxynivalenol in *Caenorhabditis elegans*

YUNG-CHUN LIU and Chia-Cheng Wei, Institute of Food Safety and Health, National Taiwan University, Taiwan (Greater China)

Mycotoxins are fungal secondary metabolites that are widely distributed in the environment and represent a significant global concern for both human and animal health. Among them, zearalenone and deoxynivalenol are commonly detected in grains such as wheat, corn, and barley, in food products and animal feed, and even in human urine. Furthermore, reports of the co-occurrence of zearalenone and deoxynivalenol have been increasing in recent years. Therefore, the interactions between these two mycotoxins, whether synergistic or antagonistic, warrant further investigation.

However, current studies are conducted under varying exposure concentrations and across different species, with inconsistent exposure durations and without rigorous approaches to clearly define synergistic or antagonistic interactions. Based on this background, the present study aims to investigate the interactive effects of developmental and reproductive toxicity induced by co-exposure to zearalenone and deoxynivalenol at various concentration combinations using *Caenorhabditis elegans* as a model organism. The interactions were evaluated with the Bliss independence model and the Chou–Talalay model, as these approaches were more consistent with the assumptions of our experimental design.

The results showed that, in terms of developmental toxicity, co-exposure to lower concentrations of zearalenone and deoxynivalenol (1.25 + 2.5 μ M) exhibited a synergistic effect, whereas higher concentrations (2.5-125 + 5-250 μ M) showed antagonistic effects. Regarding reproductive toxicity, lower concentrations of zearalenone and deoxynivalenol (1.25-25 + 2.5-50 μ M) produced synergistic effects, while higher concentrations (75-125 + 150-250 μ M) exhibited antagonistic effects. We further found that co-exposure to zearalenone and deoxynivalenol (1.25 + 2.5 μ M) also exerted synergistic toxic effects on mitochondrial dynamics, including fusion and fission processes.

In conclusion, these findings suggest a potentially high risk of low-dose co-exposure to mycotoxins. Based on these preliminary results, we will further focus on elucidating the underlying molecular mechanisms to understand how zearalenone and deoxynivalenol synergistically affect the reproductive and developmental systems in *C. elegans*.

1.13.P-We082 Safety Evaluation of Synthetic Compounds for Fire Blight Management: Environmental Fate and Ecotoxicity Assessment

Seon-yeong Yun, Seok-ki Min and Hoe-Gun Kwon B.S., Korea Testing & Research Institute, Korea, Republic of

Fire blight, caused by *Erwinia amylovora*, remains one of the most detrimental diseases affecting global pome fruit production, underscoring the need for effective and environmentally compatible management options. As part of the project “Field Application and Control System Development of Synthetic Compounds for Fire Blight Management,” we assessed the baseline safety profiles of four candidate compounds: pharmaceutical-derived bioactives (Azomycin, Enrofloxacin) and natural product–derived bioactives (Nifuratel, Nifuroxazide).

Partition-coefficient (n-octanol/water, log Pow) analysis indicated that all compounds were generally hydrophilic, suggesting minimal potential for environmental bioaccumulation. Enrofloxacin showed comparatively higher lipophilicity, which may contribute to enhanced surface persistence and potential field efficacy. Acute aquatic toxicity tests using *Danio rerio* revealed moderate toxicity for Azomycin and Nifuratel, and low toxicity for Enrofloxacin and Nifuroxazide. Biodegradability assays demonstrated partial degradability only for Nifuroxazide. Skin-irritation tests confirmed that all four compounds were non-irritants, indicating a favorable safety profile for agricultural handlers.

Collectively, these findings highlight that the candidate compounds exhibit low bioaccumulation potential and low-to-moderate aquatic toxicity, supporting their suitability for further development as fire blight control agents. Additional studies on chronic toxicity, soil microbial interactions, and environmental persistence are recommended to ensure comprehensive safety evaluation and sustainable application.

1.13.P-We083 Tier 1 Ecological Risk Assessment of Sulfa Drug Mixture Discharges from Livestock Facilities in Japan Using an RPF-Based Approach

Fujiko Ozawa¹, Takayuki Nakajima², Atsushi Yoshizawa¹, Hiroshi Yamamoto³ and Koichi Ohno¹, (1)National Institute for Environmental Studies (NIES), Japan, (2)Global Environmental Forum, Japan, (3)Health and Environmental Risk Division, National Institute for Environmental Studies (NIES), Japan

In recent years, the discharge of antimicrobial agents from livestock facilities into rivers has attracted considerable attention, as there are growing international efforts to substantially reduce the use of antimicrobials in agricultural and food systems in order to address environmental concerns. Sulfa drugs are among the most widely used veterinary antimicrobials in Japan, representing a diverse group of compounds with similar pharmacological and toxicological modes of action (MoA). Despite their extensive use, there is still insufficient monitoring data on environmental concentrations of sulfa drugs, and the actual discharge patterns from livestock operations remain poorly characterised.

This study aimed to evaluate the magnitude and possibility of ecological risks to aquatic organisms associated with the release of sulfa drugs into the environment from livestock facilities in Japan. To achieve this objective, it was necessary to assess the combined risk of multiple sulfa drugs with similar MoA that may be released simultaneously. Therefore, a Tier 1 risk assessment was conducted based on the WHO/IPCS framework for assessing combined exposure risks from multiple chemicals.

To estimate environmental concentrations, a simple yet transparent method was adopted: the discharge amount of each drug in each river segment was predicted using national sales data combined with available information on drainage volumes from individual farms. A higher-tier method with lower uncertainty - the relative potency factor (RPF) approach - was applied to assess the hazard. The RPFs of the sulfa drugs were estimated using a regression equation obtained from trend analysis of reliable ecotoxicity values and parameters related to the MoA. The risk assessment incorporated some biological metabolic processes.

The results of the Tier 1 assessment indicated that the combined exposure to the sulfa drug mixture revealed higher ecological risks than those identified in single-compound assessments. These findings emphasise the importance of monitoring water quality to identify all sulfa drug hotspots, and highlight the potential need for improved wastewater treatment for livestock facilities to mitigate the environmental risks associated with the mixture of sulfa drugs.

1.13.P-We084 A NAMs Approach for Hazard Assessment of Leachates of Environmentally Relevant Plastic Mixes Collected in the Southeastern Bay of Biscay

Antonio Pacheco¹, Nagore González-Soto², Isabella Gutiérrez-Zabala², Yann Combes³, Justine Receveur⁴, Emilie Dassié⁵, Stephan Le Floch⁴, Sophie Lecomte³, Jérôme Cachot³ and Miren P. Cajaraville², (1)University of the Basque Country, Spain, (2)University of the Basque Country (UPV/EHU), Spain, (3)University of Bordeaux, France, (4)CEDRE, France, (5)UMR EPOC 5805, Equipe EA, University of Bordeaux, France

Despite increasing micro and nanoplastic (MNP) research, limited information exists on toxicity of realistic environmental MNPs and their risk to human and environmental health. This is of special relevance in accumulation areas such as the Bay of Biscay. This study aims to assess the toxicity of environmental MNP mixes representative of plastics collected in beaches of the Southeastern Bay of Biscay and of MPs collected in

a SeaBin located at the port of Pasaia on selected fish and human cell lines. Beached plastics were collected once per season (2023-2024) in 4 beaches of the Bay of Biscay (Gorronatxe-Getxo, Alkolea-Mutriku, Murgita-Donostia and Tarnos-Baiona). Polymer composition of each item was identified by FTIR and items made of the same polymer were micronized up to <250 µm. Micronized polymers were mixed keeping the polymer proportion by weight to produce a MNP mix representative of each beach and all beaches (Bay of Biscay mix). For the SeaBin, MPs were collected during 1 week per month (March 2023-March 2024) using a 500 µm net. The MPs were sorted using milimetric paper and divided into 5 morphological categories. Polymer composition of 100 items per category was identified by FTIR. For toxicity assessment, filtered distilled water was added to each mix at 10 g/L, agitated (24h, 190 rpm, 18°C, darkness) and filtered (0.8 µm). Human intestinal Caco2 cells and fish RTL-W1 and RTG-W1 cells were exposed to 20-100% dilutions of each leachate for 24 h and cytotoxicity was assessed (Alamar or Deep blue). Then, cells were exposed to the first sublethal dilution to assess ROS production, integrity of the plasma membrane (PMI) and/or EROD activity. Metal and organic compounds were measured and the presence of NPs was checked by SEM. The Bay of Biscay and SeaBin mixes consisted mainly of polyethylene (PE), polyvinyl chloride, and polypropylene (PP) and PE, polystyrene and PP, respectively. Lead, phthalates and alkylphenols were detected in all leachates. By SEM, NPs were abundant in leachates from Gorronatxe and Bay of Biscay mix. For all cell lines, leachates of Bay of Biscay mix and SeaBin significantly decreased cell viability at 100% dilution. All leachates decreased PMI in Caco2 cells and increased ROS and EROD activity in fish liver cells. These results highlight the usefulness of NAMs approaches for toxicity profiling of complex mixtures such as environmental MNPs in order to assess their risks on human and environmental health.

1.13.P-We085 Longitudinal Differences in Microplastics in Amniotic Fluid between Mid- and Late Pregnancy and Exploratory Assessment of Perinatal Outcomes

Da Eun Jeong¹, Ha Lim Shin¹, Eun Bit Park¹, Hyo Jin Lee¹, Yunjeong Lee², Juyang Kim², Jaehak Jung² and Hyeon Ji Kim¹, (1)Department of Obstetrics and Gynecology, Seoul National University Bundang Hospital, Seoul National University College of Medicine, Gyeonggi-do, Republic of Korea, Korea, Republic of, (2)Korea Institute of Analytical Science and Technology, Korea, Republic of

Microplastics (MPs) have been increasingly detected in human biological samples, raising concerns about fetal exposure and potential impacts on pregnancy health. While previous studies have identified MPs in amniotic fluid and placenta, data describing gestational changes in intrauterine MP burden remain limited. Given that MPs may accumulate over time and potentially influence fetal environment, understanding how MP profiles differ across gestation is essential.

This study aims to evaluate how characteristics of MPs in amniotic fluid change from the mid-trimester (14-28 weeks) to the late-trimester (>28 weeks). Additionally, we explore whether MP burden is associated with pregnancy outcomes.

Under appropriate IRB approval and informed consent, amniotic fluid was obtained during clinically indicated mid-trimester amniocentesis and at cesarean delivery in late pregnancy. To prevent plastic contamination, all procedures were performed exclusively with cotton, glass, and metal instruments. MPs were detected using µ-Raman spectroscopy following extensive pre-processing to eliminate organic materials. Blank control tests were conducted to ensure that air, collection instruments, and pre-processing reagents were free of plastic contamination. We analyzed MP particle size, type, and concentration to evaluate gestational-age-related differences in intrauterine MP exposure. Pregnancy outcomes – including gestational age at delivery, birthweight, and neonatal clinical parameters – were explored in relation to MP burden. This study provides foundational evidence on temporal patterns of MPs in amniotic fluid and offers preliminary insight into their potential relevance to perinatal health.

1.13.P-We086 Assessing Chemical Pollution Through an Invasive Species: *Procambarus clarkii* as a Bioindicator in the Avigliana Lakes

Paolo Pastorino¹, Roberta Giugliano², Stefania Squadrone³, Serena Anselmi⁴, Camilla Mossotto¹, Valentina Ciccotelli⁵, Alessia Meriardi⁵, Tecla Bentivoglio⁴, Alessandra Maganza¹, Barbara Vivaldi⁵, Alice Gabetti¹,

Alessandra Griglione⁵, Giuseppe Esposito⁵, Antonia Concetta Elia⁶, Monia Renzi⁷ and Marino Prearo⁵, (1)IZSPLV - Experimental Zooprofylactic Institute of Piedmont, Liguria and Valle d'Aosta, Turin, Italy, (2)Istituto Zooprofilattico del Piemonte, Liguria e Valle d'Aosta, Italy, (3)IZSPLV - Experimental Zooprofylactic Institute of Piedmont, Liguria and Valle d'Aosta, Italy, (4)Bioscience Research Center srl, Italy, (5)Istituto Zooprofilattico Sperimentale del Piemonte, Liguria e Valle d'Aosta, Italy, (6)University of Perugia, Italy, (7)Life Sciences Department, University of Trieste, Italy

Invasive alien species are increasingly recognised as valuable bioindicators in environmental chemistry due to their high abundance, wide distribution, and resilience in contaminated habitats. The red swamp crayfish (*Procambarus clarkii*), a major invasive species in European freshwaters, has recently emerged as a promising model organism for assessing chemical pollution. This study investigated the occurrence of persistent and emerging contaminants in *P. clarkii* collected from the Great Lake of Avigliana (northern Italy), with the aim of evaluating its suitability as a freshwater bioindicator.

During the summer seasons of 2024-2025 crayfishes were captured using baited cylindrical creel traps. Individuals were euthanised by hypothermia and dissected to obtain muscle tissues for chemical analyses. Polycyclic aromatic hydrocarbons were quantified using HPLC-fluorescence detection; pesticides were analysed using GC-MS/MS; and rare earth elements (REEs) were measured via ICP-MS. Microplastics were extracted from the gastrointestinal tract and identified using micro-FTIR.

Among PAHs, only chrysene was detected in muscle tissue, with a mean concentration of $0.9 \pm 0.2 \mu\text{g/kg w.w.}$. All pesticide residues were below the limit of quantification. Mean total REE concentration was $0.0046 \pm 0.0061 \text{ mg/kg w.w.}$, with cerium and yttrium being the most abundant elements ($0.0215 \pm 0.0059 \text{ mg/kg}$ and $0.0117 \pm 0.0031 \text{ mg/kg}$, respectively). Microplastics were present in several individuals, ranging from 1 to 6 particles per crayfish, dominated by blue, black, and white fibres and fragments composed primarily of PET, PE, and PP. Particle sizes ranged from approximately 120 to 450 μm .

Chrysene is classified as a possible human carcinogen, and studies on other crustaceans indicate that concentrations in the microgram range may affect neuroendocrine and immune functions. In Italy, the regulatory limit for chrysene in soils is 5 mg/kg d.w. for agricultural areas, while only groundwater limits (5 $\mu\text{g/L}$) currently exist for freshwater systems. The ecotoxicology of REEs remains poorly understood; available studies report sublethal effects such as oxidative stress and reproductive impairment, potentially influencing growth and population dynamics. Overall, these results support the use of invasive crayfish as practical, informative, and ecologically relevant bioindicators for monitoring freshwater contamination, particularly in systems where native species are declining.

Disclaimer/Disclosure:

This study was partially funded by CIRCOLAQUA project (Italian Ministry of Health; code: IZS PLV 09/22 RC)

1.13.P-We087 The Potential of Invasive Alien Species to Serve as Bioindicators of Chemical Pollution

Paolo Pastorino¹, Giuseppe Esposito², Camilla Mossotto¹, Alice Gabetti¹, Alessandra Maganza¹, Antonia Concetta Elia³, Marino Prearo² and Christian Sonne⁴, (1)IZSPLV - Experimental Zooprofylactic Institute of Piedmont, Liguria and Valle d'Aosta, Turin, Italy, (2)Istituto Zooprofilattico Sperimentale del Piemonte, Liguria e Valle d'Aosta, Italy, (3)University of Perugia, Italy, (4)Bioscience, Aarhus University, Denmark

Invasive alien species (IAS) are increasingly recognized as valuable tools for assessing environmental pollution, complementing their better-known role as drivers of ecological change. Their broad distribution, resilience to stressors, and frequent dominance in degraded habitats make them suitable candidates for biomonitoring, particularly where native species are declining or protected. Recent studies show that IAS across multiple taxonomic groups, including plants, bivalves, crustaceans, fish, and mammals, can accumulate diverse contaminants such as trace metals, persistent organic pollutants, pharmaceuticals, PFAS, pesticides, and microplastics. Evidence from the last two years demonstrates that species like *Dreissena polymorpha*, *Corbicula fluminea*, *Procambarus clarkii*, *Lepomis gibbosus*, and *Myocastor coypus* reliably mirror local pollution patterns and in some cases support broad-spectrum contaminant monitoring. Despite this potential, several limitations constrain their wider implementation. Physiological and ecological differences between IAS and native species may lead to divergent bioaccumulation patterns, complicating risk assessments and reducing comparability across ecosystems. Furthermore, environmental variability, regulatory frameworks, and the ethical implications of relying on invasive populations require careful evaluation. Standardized protocols and integrative approaches, linking chemical analyses, biomarker responses, and molecular tools, are essential to ensure robust and ecologically meaningful applications. When incorporated into management or control actions, IAS may

simultaneously support pollution monitoring and contribute to invasive species mitigation. Overall, IAS represent an emerging yet underutilized resource for environmental chemistry, with strong potential to enhance contaminant surveillance while minimizing pressure on vulnerable native species.

1.13.P-We088 River water contaminated by a “cocktail” of chemicals: antimicrobial resistance and estrogenic effects

Paola Grenni¹, Ludovica Rolando², Alessandra Narciso³, Chiara De Carolis³, Luisa Patrolecco³, Jasmin Rauseo², Francesca Spataro², Ferenc Fekete⁴, Bernadet Khayer⁵, Karoly Törő⁵, Marta Vargha⁵, Katalin Monostory⁴ and Anna Barra Caracciolo³, (1)Water Research Institute, Italian National Research Council (CNR), Italy, (2)Italian National Research Council (CNR), Italy, (3)National Research Council, Italy, (4)Institute of Molecular Life Sciences, HUN-REN Research Centre for Natural Sciences, Hungary, (5)National Public Health and Pharmaceutical Center, Hungary

River waters can contain a mixture of legacy and emerging pollutants, including pharmaceuticals, and in particular antibiotics, which are of significant concern due to their potential impact on ecosystems and human health. These contaminants can derive from wastewater treatment plant (WWTP) discharges and may cause the disappearance or inhibition of specific microbial species involved in key ecosystem functions, while also promoting the spread of antibiotic resistance in natural microbial populations.

The Danube river was sampled over a 3-year period (2023-2025) in 2 seasons (spring and autumn) at selected sites inside and outside Budapest city. Various compounds were analysed, including antibiotics, metals, antipyretics, anti-inflammatories, hormones, anticonvulsants, insect repellents and disinfectants. The presence of several antibiotic resistance genes (ARGs) was also investigated. Finally, in line with the new Directive on water quality (COM(2022) 540 final), potential estrogenic effects were evaluated in river water samples using the Yeast Estrogenic Screen (YES) test.

Overall, the results showed diffuse pharmaceutical residual concentrations (e.g. antibiotics, antipyretics and anti-inflammatories) in all sampling points, with seasonal differences. Sulfamethoxazole and ciprofloxacin were the antibiotics detected at the highest concentrations in all three sampling points. ARGs were consistently present, with the highest levels associated with sulphonamides, although their occurrence was not directly correlated with antibiotic concentrations.

Because some estrogenic effects were observed in river water samples without a clear correlation to hormone concentrations, we further evaluated the estrogenicity of selected compounds (diclofenac, ibuprofen, paracetamol, acetylsalicylic acid), both individually and in mixtures at concentrations matching those detected in the river. Estrogenic activity of these substances, when tested individually, was observed only at high concentrations (250-1000 pM). However, when assayed in mixtures at low concentrations similar to those detected in the river water samples, they exhibited cumulative estrogenic activity. The estrogenic responses observed for the chemical mixtures highlight the importance of assessing this aspect in water samples, and suggest that estrogenicity may also be influenced by pollutants other than hormones, even when present at residual concentrations

1.14.P Navigating the Challenges of Difficult-to-Test Substances in Ecotoxicology and Environmental Fate Assessment

1.14.P-Mo075 How to Perform REACH Studies in a Smart Way? A Case Study with Industrial Chemicals on Aquatic Systems Highlighting Challenges and Solutions

Katrin Weber¹ and Marco Candolfi², (1)Eurofins Scientific, Germany, (2)Eurofins Aquatic Ecotoxicology GmbH, Germany

REACH-compliant ecotoxicological testing focusing on aquatic environments explores challenges and innovative strategies when conducting studies. The shift from testing plant protection products to a broader array of REACH-regulated substances has introduced significant analytical complexities. Unlike the simpler, smaller molecules traditionally analyzed for Plant Protection Products, many REACH substances are complex, poorly soluble, unstable or volatile, requiring adaptations in test setups and analytical methodologies.

The key challenges highlighted include difficulties in preparing stock solutions, maintaining accurate dosing, and handling substances that exhibit problematic behaviors such as biofilm formation, volatility, or instability. Traditional analytical methods (e.g. TOC analysis) are inadequate and proven to be insufficient under the stringent requirements of REACH regulations. Enhanced analytical techniques, such as HPLC, GC-MS, and LC-MS/MS are necessary for precise quantification, especially at very low concentrations.

To overcome these issues, a “smart testing” approach is advocated. This involves conducting feasibility studies

before the main biological assessments, leveraging in-depth analysis of the chemical properties to tailor testing methods. Emphasis is placed on method development, application approaches, enhanced communication and collaboration between regulatory bodies and testing facilities. The goal is to optimize test systems, reduce unnecessary studies, and ensure compliance while maintaining high standards of scientific rigor.

Adaptive testing strategies and robust analytical capabilities are important to meet the evolving requirements of REACH regulations, ultimately ensuring the environmental safety of industrial chemicals.

1.14.P-Mo076 Tackling pH-dependent Toxicity of Ionisable Organic Chemicals in Aquatic Risk Assessment

Florian Zindler, Exponent International, Germany

The characterisation of the toxicity of ionisable organic chemicals (IOCs) and related environmental risk assessments come with uncertainties, as the toxicity of IOCs towards non-target organisms can strongly vary depending on the physico-chemical properties of IOCs, their mode of action, the pH of the aqueous test medium, and the organism. Hazard endpoints of regulated chemicals from toxicity testing at specific pH values (of the test medium) can over- or underestimate the toxic potential of IOCs across environmentally relevant pH ranges (in soil and water) by up to three orders of magnitude. However, technical possibilities for testing or mathematical prediction of the actual toxicity of IOCs to non-target organisms are limited (as e.g. ecotoxicity testing may not be possible across wide pH ranges, while universal, generally accepted prediction models are not available). Consequently, in regulatory practice, pH-dependent toxicity of IOCs to non-target organisms is either subtly ignored or arbitrarily tackled by unrealistically high safety factors derived from simplified prediction models.

This case study evaluates the extent of pH-dependent differences of the toxic potential of IOCs in aquatic species and the relevance of generalised predictions of the aquatic toxicity of IOCs at different pH values. A dataset was compiled from peer-reviewed literature summarising endpoints from approximately 50 acute tests on the toxicity of IOCs (incl. pharmaceuticals, pesticides, industrial chemicals, and biocides) to fish, invertebrates, algae, and macrophytes, which were conducted in test media with varying pH. For each IOC, toxicity data determined experimentally at a selected pH value were used to predict the toxicity of the IOC at other pH values, and the model predictions were subsequently compared to corresponding experimental effect data (at the same pH). Our results show the suitability of the different models for generalised prediction of pH-dependent toxicity of IOCs in aquatic organisms. Additionally, it is discussed how ‘potential outliers’ (i.e., IOCs that were not adequately captured by the models) can be tackled using current OECD test protocols to ensure a protective aquatic risk assessment. The outcome of this case study highlights strengths and weaknesses of generalised predictions of the pH-dependent toxicity of IOCs and thus supports the improvement of aquatic risk assessments.

1.14.P-Mo077 Are fatty alcohols ‘difficult test substances’? Exploring the downsides of rapid biodegradability in combination with poor water solubility.

Trey Kucherka¹, Helen Jane Disley¹, Frank Seitz² and Erin Maloney³, (1)Vitis Regulatory, United Kingdom, (2)Sasol, Germany, (3)Shell Global Solutions International B.V., Netherlands

Fatty alcohols are a class of long-chain aliphatic alcohols that are commonly used as intermediates in the production of other common-use substances (e.g., surfactants) or as lubricants, process chemicals, laboratory chemicals, and solvents in commercial and industrial applications. Derived from petrochemicals, natural fats or oils, these substances are widely sold and manufactured - often registered under REACH at high tonnages (> 1000 tonnes per annum) in the European Union. Available environmental fate studies have demonstrated that these substances are highly biodegradable, with all registered C6 – C24 alcohols being classified as ‘readily biodegradable’. Further, available simulation studies demonstrate rapid mineralization in freshwater, sediment, soil, and sewage treatment plants. Rapid biodegradability is a desirable property for industrial and commercial chemicals as it lowers the environmental risk profile of a substance. However, this environmental fate behavior also introduces significant challenges for ecotoxicity testing. Moreover, when this property is combined with other inherent properties of these substances (e.g., poor solubility) – fatty alcohols can become very ‘difficult to test’ under chronic and acute exposure scenarios.

This poster aims to present some major challenges associated with conducting aquatic toxicity testing with fatty alcohols. Highlighting issues encountered during short- and long-term aquatic toxicity testing conducted with diverse taxa, we demonstrate how properties such as rapid biodegradability and poor solubility can introduce significant challenges when conducting these tests according to currently available guidance. We further discuss

successes and failures with adapted or alternative test methods, building evidence that can be used to inform future testing plans and strategies for similar substances. Finally, we put available test data in the context of environmental risk – raising the question of whether fatty alcohols are indeed ‘difficult test substances’ or whether toxicity testing requirements for such substances (e.g., highly biodegradable, potentially poorly soluble) should instead be adapted to better reflect likely environmental exposure scenarios.

1.14.P-Mo078 Beyond Dissolved Fractions: Rethinking Toxicity Assessment of Cationic Surfactants in Algal Test Systems

Liesa-Kristin Beuter¹, Jens Bietz², Janis Füller³, Marc Geurts⁴ and Dirk Scheerbaum³, (1)Nouryon Specialty Chemicals B.V., Sweden, (2)Clariant Produkte (Deutschland) GmbH, Germany, (3)Noack Laboratorien, Germany, (4)Nouryon Specialty Chemicals B.V., Netherlands

Cationic surfactants, particularly primary fatty amines (PFAs), present unique challenges in ecotoxicological testing due to their surface-active properties and strong adsorption tendencies. Traditional approaches to toxicity assessment rely on measured dissolved concentrations, with regulatory authorities increasingly demanding evaluation based solely on truly dissolved fractions. However, our research demonstrates this approach is fundamentally flawed for cationic surfactants in aquatic systems especially when algae or other organic matter are present (specifically alga toxicity and chronic daphnia studies). Using a radiolabeled PFA, we tracked substance distribution throughout an algal growth inhibition test, revealing that a significant amount of the total substance becomes bound to algal cells within 72 hours. As algal density increases during study duration, substance, initially bound to the glass surface, transfers from glass surfaces to algae, creating a dynamic redistribution system. Additional studies with non-radiolabeled PFAs of different chain-lengths confirmed that centrifugation, used to isolate truly dissolved fractions, introduces further methodological artifacts through adsorption to equipment surfaces, which is demonstrated in both types of study. Since cationic surfactants mainly exert toxicity through membrane disruption, the algae-adsorbed fraction actively contributes to observed effects rather than reducing its bioavailability. Both the concentration at the organism surface and in the surrounding medium significantly impact toxicity, with their combined effect determining the overall toxicological outcome. Our findings challenge current regulatory paradigms and demonstrate that for cationic surfactants, nominal concentrations based on carefully designed water-accommodated fractions provide more reliable metrics for toxicity assessment than truly dissolved concentrations, which substantially overestimate toxicity by underrepresenting the actual bioavailable amounts.

1.14.P-Mo079 Dosing of very hydrophobic chemicals in high-throughput microtiter plate-based in vitro bioassays

Eunhye Bae¹, Stefan Saretz¹, Juliane Ackermann², Anna Böhnhardt², Andreas Buser³, Luise Henneberger⁴, Arina Kremser¹, Eszter Simon³ and Beate Escher⁴, (1)UFZ-Helmholtz Centre for Environmental Research, Germany, (2)German Environment Agency (UBA), Germany, (3)Federal Office for the Environment (FOEN), Switzerland, (4)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

New Approach Methodologies (NAMs), including in vitro bioassays, have transformed and advanced next-generation chemical hazard and risk assessment. However, current in vitro bioassays predominantly operate within a narrow physicochemical window, mostly covering chemicals of moderate hydrophobicity (octanol-water partition constant $1 < \log K_{ow} < 5$). Hydrophobic chemicals ($\log K_{ow} > 5$) often face technical testing barriers such as solubility issues or precipitation in the microtiter-plate-based in vitro assays, resulting in frequent “nontoxic” outcomes simply because biologically effective doses in the cells cannot be reached. Serum-mediated passive dosing (SMPD) helps stabilize hydrophobic chemicals in small volume cell-based in vitro assays by supplementing the bioassay medium with colloids. Sorption to colloids increases apparent solubility, and the chemicals can desorb from the colloids and enter cells without depleting freely dissolved concentrations. The presence of colloids accelerate the uptake kinetics in the static exposure of microtiter (96- and 384-well) plates. However, SMPD still fails for (super)hydrophobic substances due to precipitation with floating microcrystals, which can be avoided by passive dosing into medium before dosing the saturated medium into bioassays. By swelling the silicone with a solvent solution of the chemical and evaporating the solvent, the chemical can be enriched over its PDMS solubility. This creates an oversaturated silicone containing microcrystals inside. During passive dosing, dissolution of these microcrystals replenishes medium concentrations, allowing the medium to be dosed at maximum solubility. This highest concentration in medium can then be serially diluted and applied to cells in microtiter plates. With sufficient serum protein, cellular uptake does not visibly deplete medium concentrations. We demonstrate this approach with a range of phenolic benzotriazole UV stabilizers and brominated flame retardants. It was possible to dose hydrophobic chemicals up to a octanol-water partition constant $\log K_{ow}$ of 8 but equilibrium was not reached for more hydrophobic

chemicals, indicating further optimization on the passive dosing is needed for chemicals with logKow > 8. The method is versatile and can be adopted to any cell exposure set up and is suitable for bioassay testing in high-throughput format, although sample preparation remains work-intensive.

Disclaimer/Disclosure:

We acknowledge funding by the Initiative and Network Fund of the Helmholtz Association, project “Co-Creation process for the modernization of chemical hazard indicators – CoModHaz” KA-TCP-20. All experiments were run on the CITEPro (Chemicals in the Environment Profiler) (bio)analytical platform funded by the Helmholtz Association.

1.14.P-Mo080 Addressing chronic aquatic toxicity test requirements for difficult to test surfactants

Rhiannon Smith¹, Rebecca Jayne Brown¹, Erin Maloney² and Jérôme Tisaun³, (1)wca environment Ltd., United Kingdom, (2)Shell Global Solutions, Netherlands, (3)ERASM (Cefic) Secretariat, Belgium

ERASM (Environment and Health – Risk Assessment & Management) commissioned a project to gather and synthesize data on properties which make surfactants difficult to test in chronic aquatic toxicity tests and solutions to optimise test performance. Data were collected through a search of published literature, including the Organisation for Economic Cooperation and Development (OECD) Test Guidelines and Guidance Document 23, and questionnaires were completed by contract research organisations (CROs) and industry representatives on their experiences with difficult to test surfactants.

Many surfactants require chronic aquatic toxicity testing under European Union (EU) Registration, Evaluation, Authorisation and restriction of Chemicals (REACH), but are difficult to test due to their surface activity. Many are also UVCBs (substances of Unknown or Variable composition, Complex reaction products or of Biological Origin), for which specific adaptations are necessary. Other key challenges include: poor water solubility, adsorption, rapid degradation, ionisation across the environmental pH range, volatility, and/or high background contamination. These challenges can mean ecotoxicity data may not meet reliability criteria or are difficult to interpret for regulatory purposes.

Adaptations for testing surfactants were considered based on: optimising solubility and dosing methods, modifications to the test design, adaptations based on the analytical method and reporting of results, and whether alternative ecotoxicology tests might be appropriate. Our findings show direct addition to be the most common dosing method, and most CROs avoided emulsions, solvents and generator systems. Potential modifications were identified to avoid formation of surface films and aggregation of particles, including changes to test vessels, test media and feeding regimes. Alternative tests, such as a 7 day Ceriodaphnia study instead of a 21 day Daphnia study, and waivers were also considered.

This review collects examples of potential solutions to challenges for chronic aquatic toxicity testing of difficult to test surfactants, in order to understand the feasibility, applicability and regulatory acceptability for future testing. The review identifies gaps in the available guidance and areas where challenges remain with testing surfactants. It also notes where potential solutions from guidance are not adopted.

1.14.P-Mo081 Beyond Standard Protocols: Chronic Fish Toxicity Assessment of UVCBs

Katharina Mayer¹, Stacey Webster² and Rosalinda Gioia², (1)Yordas Group, Germany, (2)Yordas Group, United Kingdom

Under EU REACH, regulatory authorities mandate long-term toxicity studies for poorly soluble substances to account for effects occurring at equilibrium. This poses challenges specifically for chronic fish toxicity testing as adherence to the 3R principle (Replace, Reduce, Refine) for animal testing is crucial. Generating reliable chronic data for Difficult-to-Test Substances (DTTS) and Substances of Unknown or Variable composition, Complex reaction products, or Biological materials (UVCBs) is challenging, as stable exposure is difficult to maintain. To address this, a battery of pre-tests is performed to optimise methodology. However, for registrants, the extent of work required to confirm technical feasibility can be difficult to assess. This submission aims to provide insightful discussions on the possibilities and limitations of chronic fish toxicity testing with poorly soluble UVCBs.

This submission will examine the testing strategies for two chronic fish toxicity studies (OECD 210) involving two very poorly soluble UVCBs with challenging properties (e.g., hydrolytic instability, adsorptivity, surface activity). The core strategy for both involved analytical method development and detailed ECHA-recommended pre-tests to determine solubility, stability, and optimal application, maximising success (Refine) and minimising animal use (Reduce).

For one poorly soluble UVCB, the full study was technically infeasible and could not be initiated due to

analytical limitations in accurately determining a stable, truly dissolved exposure concentration. For the second UVCB, successful stable exposure required strategic protocol adaptations informed by extensive pre-testing, including precise application control and rigorous analytical monitoring.

In conclusion, chronic fish toxicity testing of poorly soluble UVCBs requires significant upfront investment in adaptive methodology and analytical strategy. Although ECHA-guided adaptations and comprehensive pre-testing may improve success, our experience indicates that analytical limitations can render a chronic study scientifically unjustifiable and technically infeasible for some substances. These case studies underscore the need for increased regulatory guidance and acceptance of innovative testing approaches under REACH to better predict effort, assess feasibility, and improve the quality and regulatory acceptance of future chronic fish toxicity studies, thereby supporting regulatory toxicology and the 3R principle.

1.14.P-Mo082 Adapting the Fish Embryo Toxicity Test to Overcome Limitations in Aquatic Testing of Anticoagulant Rodenticides

Martina Fenske¹, Lavina Paesel², Emma Sinnwell³, Christel Möhlenkamp², Anton Friesen⁴ and Julia Regnery²,
(1)German Federal Institute of Hydrology (BfG), Germany, (2)Federal Institute of Hydrology (BfG), Germany, (3)Trier University, Germany, (4)Umweltbundesamt, Germany

Anticoagulant rodenticides (ARs) used for large-scale rodent eradication measures can contaminate small surface water bodies in particular following aerial dispersal of baits for wildlife conservation but also by accidental spills, leading to waterborne exposure of wild fish with potentially toxic effects. To date, studies on sublethal and lethal effects of ARs on fish are limited, especially regarding effects not directly linked to the known mechanisms of action of ARs. One reason is that ecotoxicity tests with ARs in fish are challenging due to their physicochemical properties such as low water solubility, adsorption, photolytic sensitivity, and potential ionizability. Another challenge is that their specific mode of action causes a delayed onset of symptoms. In our study, we aimed at overcoming some of the limitations of AR testing in aquatic species to further explore adverse effects of ARs on fish. Hence, zebrafish (*Danio rerio*) embryo toxicity tests were conducted with different AR active ingredients according to the OECD236 test guideline and extended by the assessment of sublethal morphological effects. Notably, substance specific adaptations were required to facilitate the application of these difficult-to-test substances. The exposure concentrations in the 96-multiwell-plates ranged from 0.1 to 7 mg/L. Aqueous AR concentrations in individual wells were monitored by LC-MS/MS and generally, showed good recovery of at least 80% after 96 hours in all treatment groups. While coumatetralyl and bromadiolone were equally toxic to the zebrafish embryos, observed morphological malformations varied, from chorda deformations and reduced head development to vascular defects and no heartbeat. For all tested ARs, a sudden increase in mortality was detected after hatching of the embryos, possibly indicating a protective function of the chorion. Effect thresholds (EC20-values) exceeded available predicted environmental AR concentrations in surface water. Yet, chronic effects must be considered due to the bioaccumulative properties of second-generation ARs. Therefore, we also investigated whether the known mechanistic effects of the tested ARs are linked to the developmental effects occurring in zebrafish embryos, and whether these early effects could substantiate evidence for presumed adverse outcomes for wild fish.

1.14.P-Mo083 The AFSA DIM Testing Project: When Animal Testing is Difficult, Impossible and Meaningless (DIM) and Implications for the REACH Regulation

Giorgia Pallocca¹, Maria Blanco-Rubio Ph.D², Paul Thomas³, Kevin Bonnot⁴, Sagar Thakali⁵, Kyle Roush⁶, Steve Gutsell⁷, Jay Dawick⁸, Xiaoling Zhang⁶, Anders Bergqvist⁹, Mojca Fuart-Gatnik¹⁰, Marlly Guarin¹¹, Jay Ingram¹, Aleksandra Mostrag-Szlichtyng¹², vicente aranda¹³, Martijn van Velthoven¹⁴, Marten Schults¹⁵ and Eva Serrano Candelas¹³,
(1)Humane World for Animals Euroe, United Kingdom, (2)Shell Global Solutions International BV, United States, (3)KREATiS SAS, France, (4)DSM-Firmenich SA, Belgium, (5)R&D, Kenvue, United States, (6)Procter & Gamble, United States, (7)Unilever, United Kingdom, (8)Innospec, United Kingdom, (9)GPC Regulatory, Sweden, (10)Merck Life Sciences, Germany, (11)Shell, Netherlands, (12)Merck Life Sciences, United States, (13)ProtoQSAR SL, Spain, (14)VelTox Strategy Consultancy, Netherlands, (15)IFF, Netherlands

The EU's REACH Chemicals Regulation Article 25 mandates that animal testing should be used only as a last resort. Adaptations of this standard (i.e. using animal test models) testing regime are described primarily through Annex XI. However, traditional in vivo testing remains common, often due to procedural rigidity and/or lack of understanding or proper application of regulatory framework, rather than scientific necessity. For regulatory ecotoxicological endpoints under industrial chemical legislation, an average of 21,070 animals per year have been used according to the ALURES Statistical EU Database.

The AFSA Collaboration launched a multi-phase project focusing on animal tests that are Difficult, Impossible, or Meaningless (DIM). DIM testing refers to cases where in vivo studies have been performed or requested when they are scientifically unfit, unjustified, technically infeasible, or irrelevant to real-world safety outcomes. Such tests often yield redundant, unreliable or unusable results, particularly for substances with physical-chemical properties that compromise standard protocols.

In this project we systematically reviewed registration dossiers and compliance decisions to quantify the prevalence of DIM tests identifying missed opportunities for scientifically sound, non-animal alternatives. The multidisciplinary expert group defined objective DIM criteria for substances (to be) tested and applied them to case studies across sectors, revealing recurring gaps in guidance clarity, methodological relevance, and procedural flexibility.

Initial evidence suggests that ecotoxicological endpoints seem to be most affected, with high animal use and limited regulatory value. Based on these insights, the project has formulated preliminary recommendations to improve the implementation of the last resort requirement, increase regulatory acceptance of novel methods, and clarify when standard animal tests are inappropriate. These include fostering collaboration between registrants and regulators, promoting substance-tailored and exposure-relevant testing strategies, strengthening the integration of toxicokinetics, ensuring scientific robustness across all data sources, and enhancing transparency and traceability of regulatory data.

This work highlights opportunities for a regulatory shift towards relevance-based, exposure-led safety assessment, rooted in robust non-animal methods while maintaining high standards for human and environmental protection.

Disclaimer/Disclosure:

The Animal-Free Safety Assessment (AFSA) Collaboration is a unique multi-sector partnership between non-profit, corporate, and philanthropic leaders working to advance acceptance and use of animal-free safety science as a gold standard across regulatory frameworks worldwide.

1.14.P-Mo084 Challenges Associated with Testing Calcium Fatty Acid Grease Thickeners for EU REACH *Lucy Kennelly, Rhianon Smith, Kate Roylance and Owen Green, wca environment Ltd., United Kingdom*

Calcium fatty acid salts are used as thickening agents for grease products, and are registered as a category under EU REACH (EC 1907/2006 on the Registration, Evaluation, Authorisation and restriction of Chemicals). The substances comprise monoconstituent substances and substances of Unknown or Variable Composition, Complex Reaction Products, or Biological Materials (UVCBs). A comprehensive testing programme is currently being conducted on this category in order to fill data gaps in the REACH dossiers. Calcium fatty acid salts are classed as difficult-to-test substances, and several associated challenges have arisen during the testing programme.

Calcium fatty acid salts have very low water solubility, which caused issues with obtaining suitable test solutions. For in vitro testing, difficulties were encountered with acquiring dosable solutions for some tests, as the test items were insoluble in all vehicles compatible with the test systems. The use of alternative vehicles is being investigated, including those not typically used in in vitro tests. These issues were encountered during human health genotoxicity testing; however it is anticipated that similar issues will occur for environmental in vitro tests that may be conducted in the future.

Issues have also arisen with developing suitable analytical methods for algae testing. As the test items are salts, an analytical method could not be developed for whole test items, so analysis was performed separately on the calcium and fatty acid components. The calcium component cannot be analysed due to high levels of calcium in the testing medium preventing the acquisition of meaningful results. Calcium is an essential element for algal growth so cannot be removed from the medium. For the fatty acids, difficulties arose in lowering the limits of detection (LOD) and quantification (LOQ) due to high background levels. Quantifiable levels for two substances could not be obtained, and therefore total organic carbon (TOC) analysis is included as a surrogate for fatty acid content but the low solubility means the concentrations may be <LOQ of the TOC analysis. This testing is currently ongoing so further updates will be included in the poster but nevertheless, this case study demonstrates some of the challenges associated with ecotoxicity testing of difficult-to-test substances, and some alternative strategies which can be applied to overcome these challenges.

1.14.P-Mo085 Difficulties with aquatic ecotoxicity testing of substances with constituents present in standard media: A case study with lithium fatty acid salts

Rhiannon Smith and Sylwia Kosmala-Grzechnik, wca environment Ltd., United Kingdom

Under EU REACH (EC 1907/2006 on the Registration, Evaluation, Authorisation and restriction of CHemicals), long-term toxicity testing on aquatic invertebrates is required if the substance has a water solubility <1 mg/L. The standard test for this endpoint is a 21-day *Daphnia magna* reproduction test following the OECD 211 test guideline.

The media recommended for the study are Elendt M4 or M7 media, both of which contain nutritional trace elements for the health of the organisms, which can impact the feasibility of analysis when testing substances which are, or contain, those same trace elements.

A case study is presented for various lithium fatty acid salts, where challenges were encountered with analysis during testing because lithium is present in the test media at 0.05 mg/L.

As the test items are salts, an analytical method could not be developed for the whole test items, so analysis was performed instead on the individual components of the test items, lithium and fatty acids. An analytical method was developed for the fatty acids, but it was not sensitive enough to measure them at the concentrations in *Daphnia* reproduction tests. The concentrations are also below the limit of detection for measuring total organic carbon as a surrogate for fatty acid content. Therefore, analysis focused on the metal.

Analytical methods are available for lithium (inductively couple plasma mass spectrometry; ICP-MS), but the metal is only a small proportion of these test items, so the relative lithium concentration is low at the concentrations used in the OECD 211 studies (concentration range of 0.020 to 0.045 mg/L Li at 1 mg/L nominal concentration of the test items; range reflects multiple lithium fatty acid salts). This means that the lithium concentration from the test items is difficult to distinguish from the background concentrations in the test media. As such, alternative methods are being investigated for testing and analysis, including use of modified or alternative test medium. One alternative being considered is ISO medium, which does not contain lithium as a trace element; however, as is not a standard medium for long-term testing with *Daphnia*, its suitability for the study needs to be confirmed. Therefore, trials are ongoing to culture *Daphnia* in ISO media to ensure suitable conditions before any testing is undertaken.

This case study demonstrates some of the challenges and strategies associated with ecotoxicity testing of difficult to test substances.

Disclaimer/Disclosure:

We would like to thank the European REACH Grease Thickeners Consortium (ERGTC) for allowing their work to be shared.

1.14.P-Mo086 Method Development Procedures for the Analysis of Complex Industrial Chemicals and UVCBs in Support of Ecotoxicology Studies

Stephen Brewin, Environmental Sciences, Labcorp, United Kingdom

Due to the evolving regulatory landscape for registration under REACH, environmental studies that were typically performed for crop protection chemicals are moving towards assessing a broader array of complex chemicals, including industrial chemicals, naturals, botanicals and chemicals of Unknown or Variable Composition, Complex Reaction Products or Biological Materials (UVCBs). The nature of these substances presents numerous challenges when also providing support for various study types, such as ecotoxicology studies, where difficulties in achieving the required levels of sensitivity to confirm application of the dose to the test media are frequently faced.

Many industrial chemicals present numerous analytical challenges, due to a variety of issues associated with their often varied and complex composition. Developing suitable analytical methods requires addressing several key considerations. For example, determining the nature of the analyte is particularly important, as a single component is more straight forward to quantify as the properties of the molecule can be considered when selecting and optimizing a suitable quantitation technique. However, a multiple component mixture (e.g. UVCB) consists of a range of components of differing chemical properties and abundance, often leading to a representative marker or even multiple markers being selected for quantitation. If possible, the development of a method that can monitor several marker components is desirable, to provide a more thorough representation of the test material.

A key challenge is selection of the most appropriate detection system that is sensitive enough to quantify the

required analyte concentration in the test samples for the supported studies. It may be that further method procedures are also required, such as sample concentration, but optimization of these steps is often difficult due to the unknown composition of the material as well as the chemical properties of the components that can be quantified.

This poster describes the typical stages of the development of an analytical method for the analysis of a complex chemical test item. It shows the approaches taken and the decisions made, demonstrating the step-by-step procedure of establishing a quantitative method, suitable to reliably quantify test samples generated in ecotoxicology studies.

1.14.P-Mo087 Enhancing ERAs for High LogP Substances: Partitioning to Air (KO/A), Cell membrane (KM/W), and Bovine serum albumin (KBSA/W)

Philip Rooney and Danny Wensley, Smithers, United Kingdom

Partition coefficients in octanol and water provide a rudimentary and overly generic value to describe a substances hydrophobicity. The endpoint (logPOW) of an OECD 107, 117 or 123 study is incorporated into modelling assessments to predict the behaviour of a substance in a wide range of environmental and biological scenarios; examples include its affinity to soil, sediment or sludge, the rate of transfer to water resources or bioaccumulation and elimination within a biological system. To varying degrees, LogP values derived from these regulatory studies are a fundamental, yet superficial input for persistent, bioaccumulation, mobility and toxicology assessments.

The environmental and human impact of emerging contaminants such per- and polyfluoroalkyl substances (PFAS), including PFOA, PFHxS and TFA with more extreme properties ($t_{1/2} < 12$ h, $\log\text{POW} > 6$ or $p_{\text{vap}} > 1$ kPa) require risk assessment and evaluation. The behaviour of these substance classes, deemed ‘difficult-to-test’, is not fully captured by conventional OECD guidelines. This poster details the development of bespoke GLP compliant partition co-efficient studies that investigate partition behaviour across three environmentally and biologically relevant environments: partition between air (KO/A), cell membrane (KM/W), and bovine serum albumin (KBSA/W).

These three coefficients are interconnected and work together to determine the overall distribution of a substance within a macro-scale environment and biological context.

1.14.P-Mo088 Navigating In Vitro Testing Challenges for Complex Hydrocarbon Substances: Improving Dosing and Exposure Characterization

Daniela Holland¹, Ming Kung², Megan Ruhmel², Aaron Redman², Biyao Han³ and Bryan Hedgpeth⁴,

(1)ExxonMobil Petroleum and Chemical, Belgium, (2)ExxonMobil Biomedical Sciences Inc., (3)ExxonMobil AP R&D Co., Ltd, Shanghai, China, China (Mainland), (4)ExxonMobil Corporation, United States

High-throughput in vitro (eco-)toxicology is central to next-generation risk assessment, yet substances with poor water solubility remain difficult to test reliably. Hydrophobic chemicals, including polycyclic aromatic hydrocarbons (PAHs) and complex hydrocarbon mixtures, may partition to media constituents and plastics, causing unstable exposure concentrations. This undermines conventional dose-response analyses based on nominal concentrations and complicates in vitro-to-in vivo extrapolation (IVIVE).

This work addresses the challenge of achieving reproducible and well-characterized exposures for hydrophobic substances in in vitro test systems that cannot be achieved/maintained using common media-miscible solvents such as DMSO. The influence of dosing strategies on bioactivity outcomes for PAHs tested individually and within a complex hydrocarbon substance was evaluated, by combining in vitro bioassays with partitioning modeling and analytical chemistry. The work showed that standard dosing techniques employed here often fail to maintain steady exposure, leading to variability and underestimation of bioactivity. Results demonstrate that conventional in vitro dosing approaches are inadequate for complex hydrocarbon substances with difficult to test properties. We identified opportunities for methodological refinement to stabilize exposure and accurately quantify bioavailable concentrations.

By improving dosing and exposure characterization, this work advances testing strategies for hydrophobic substances. These findings support more reliable hazard identification and strengthen IVIVE, with implications for regulatory assessments and broader application to difficult-to-test chemicals in environmental toxicology.

1.14.P-Mo089 Development of a non-radiolabelled mixture approach to obtain wastewater primary biodegradation half-lives for hydrocarbons according to the OECD 314B protocol

Yves Verhaegen¹, Thomas Hawkins Mr², David MV Saunders³ and Delina Lyon⁴, (1)European Fuel Manufacturers Association Division Concawe, Belgium, (2)Analytical Chemistry, Scymaris Ltd., United

Kingdom, (3)Shell Global Solutions International BV, Netherlands, (4)European Fuel Manufacturers Association Division Concawe, Brussel, Belgium

Biodegradation in wastewater treatment plants (WWTP) is the principal removal process for most widespread man-made organic chemicals. As such, estimation of WWTP biodegradation half-lives (HL_{bio}) is critical during the environmental exposure and risk assessment of chemicals. Unlike other environmental substance properties, HL_{bio} cannot be adequately predicted from general physico-chemical properties, such as the octanol-water partitioning coefficient. Instead, HL_{bio} is mainly determined by the presence or absence of rapidly biodegradable sub-structural features (chemotypes). To generate biodegradation data that could be used to develop predictive models, we have selected 68 commercially available hydrocarbons that represent the major chemotypes observed in typical petroleum/hydrocarbon UVCBs (Unknown or Variable composition, Complex reaction products, Biological materials).

To generate realistic WWTP HL_{bio}s, we are using the OECD 314B (activated sludge die-away test) test guideline, which simulates widely-used biological sewage treatment. The OECD 314B TG often requires radiolabeling of the (single) test chemical. However, to generate realistic WWTP HL_{bio}s in a cost-effective manner, we are developing an approach to test mixtures of the 68 commercially available hydrocarbons without radiolabelling.

A non-radiolabeled mixture of 5 representative hydrocarbons (n-decane, propylcyclohexane, 1,3-diethylbenzene, adamantane and diphenylmethane) was used for method development. Technical improvements to the standard protocol were required to 1) ensure stable oxygen concentrations throughout the test, 2) slow down and reduce rapid and substantial abiotic losses (volatilisation and formation of non-extractable residues) of the test chemicals, and 3) eliminate remnant biological activity in the abiotic control vessels.

This presentation shares the method development process and learnings. Once these technical challenges have been resolved, the improved 314B protocol will be applied to the remaining 63 representative hydrocarbons to generate primary biodegradation half-lives for all 68 chemicals. The primary biodegradation half-lives could in theory then be linked to the major chemotypes represented by those 68 chemicals, which would enable better predictive models.

1.14.P-Mo090 Passive Dosing for Identifying Microbial Degradation Products in Heating Oils

Jonas Daniel, M.Sc.¹, Felix Stibany², Katharina Mayer³, Andreas Schaeffer⁴ and Thomas Backhaus¹, (1)RWTH Aachen University, Germany, (2)gaia Research Institute, Germany, (3)Yordas Group, Germany, (4)Institute Environmental Research, RWTH Aachen University, Germany

Heating oil stored in tanks is prone to microbial degradation. Quantifying microbial activity in heating oil storage tanks requires significant time and fuel. In this study, we present a rapid and miniaturized system to assess microbial activity in heating oils using passive dosing. Passive dosing avoids the formation of micro emulsions often encountered while handling difficult liquid test chemicals like heating oils. These micro emulsions make it difficult to analytically measure the freely dissolved constituents. To solve this problem, silicone polymer O-rings were loaded with six different heating oils by means of passive dosing, followed by desorption of chemicals into the aqueous test medium to create water-accommodated fractions (WAFs) and additionally buffering losses due to sorption effects. WAFs were analyzed for aromatics, aliphates, alcohols, ester, ether and nitrogen compounds using GC-MS and compared to WAFs prepared from direct dosing experiments. GC analysis revealed a consistent WAF composition across both passive and direct dosing for all tested oils, with minor differences in xylene content. However, the absolute quantities varied considerably across oils. The substance breakdown showed a dominance of monoaromatic hydrocarbons, followed by diaromatics and heterocycles. Microbial activity in one heating oil was determined by measuring CO₂ in the headspace of a closed system. After microbial activity ceased, the aqueous test medium was extracted using silicone O-rings as passive samplers followed by GC-MS analysis to determine microbial degradation products. Except for indanes, all major substance classes were markedly reduced; xylenes were no longer detectable in one replicate. In addition, phenols appeared as intermediates in the degradation of benzenes. Shaking enhanced the release and bioavailability of heating oil components, while a reduced headspace volume allowed for quicker CO₂ detection. These results demonstrate the potential of passive dosing as a rapid, cost-effective method for evaluating the microbial degradability of heating oils.

1.14.P-Mo091 Examining biodegradation of a UVCB using distilled fractions

Paul G. Koster van Groos¹, Gail Bragin¹, Jolanta Zukowski¹, Lesheng Wang¹, Maria Likhogrud¹, Cary

Sutherland¹, Jay Patel¹, Louise Camenzuli² and Thomas Delfosse², (1)ExxonMobil, United States, (2)ExxonMobil, Belgium

Biodegradation is a key process affecting the environmental fate of chemicals. For organic chemicals, biologically mediated degradation can result in CO₂, a natural end-product of oxidation; and this process is commonly used to evaluate biodegradability with standardized tests. However, evaluating degradation solely through CO₂ evolution is challenging for UVCBs (Unknown or Variable composition, Complex reaction products, or Biological materials) because CO₂ does not indicate individual constituents that degrade.

We describe efforts examining the biodegradability of a UVCB substance that contains four main types of constituents observable through GC/MS evaluation. One of the four constituent groups is reasonably soluble, but solubilities of the other three constituent types are suggested to be much lower, which may limit bioavailability and biodegradation rates. To facilitate more detailed investigations, the UVCB substance was distilled into individual fractions generally covering each of the four constituent groups. Results from OECD 301F biodegradation screening of the whole substance and individual fractions are described, together with GC/MS analyses of the same. The GC/MS efforts provided further insights regarding the biodegradation that occurred, and also suggested that careful evaluation of whole substance information may provide valuable insights into the biodegradation of the individual constituent types. Overall, the results demonstrated that constituents degraded at different rates, with degradation of the most water soluble constituents occurring rapidly and completely. The extent to which mass transfer limitations due to solubility constraints limited biodegradation was not determined in this work but warrants further consideration.

1.14.P-Mo092 The Practicality of Adjusting pH to Comply with Pharmaceutical Testing Requirements *Tracey Jayne Goodband, Smithers, United Kingdom*

EMA Environmental Risk Assessment requirement guideline (2024), indicates that tests should be conducted at a stable pH consistent with the most bio-available form of the test chemical (usually the non-dissociated form or the form with the most neutral molecule species). However, what if the required pH is close to or outside the recommended pH values for the test species? How far should this be taken before the performance of the test is potentially compromised? And, how practical is this? This presentation will discuss the measures taken to perform a sediment-water chironomid test to the OECD 218 test guideline whilst also taking into consideration the requirements for pH adjustment. This will include initial considerations, the modifications performed during test set up, how effective these were, control performance, potential issues and how it is possible to modify testing in order to best achieve the ERA requirements whilst still maintaining the integrity of the test.

1.14.P-Mo093 Dietary exposure in ecotoxicological studies with fish - a different route for difficult substances

Matthias Teigeler¹, Jutta Mütter², Ulrike Schoebinger³ and Bettina Dudek⁴, (1)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)SynTech Research Group, Germany, (3)Syntech Research, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Ecotoxicological studies with aquatic species usually consider water as the dominant route of exposure. However, in case of difficult substance properties e.g. high lipophilicity or insoluble character, this induces technical challenges. An option might be to apply those substances via the food to ensure a full uptake. Currently, only the bioaccumulation test regimes provide an option for dietary exposure.

In our study, we aimed to assess potential long-term effects of a polymer on the biological performance of exposed fish. However, within an extensive pre-test program, it was not possible to achieve a constant exposure scenario via the water due to adsorption to surfaces and clogging of the polymer. Thus, it was agreed to choose the dietary application route.

Using experiences from fish metabolism and biomagnification studies, we modified the feed preparation procedures for small pelleted fish food. However, this was still not suitable to be used for larvae feeding as part of an Early life stage toxicity test (OECD 210), which is the usual setup for chronic fish toxicity. Instead, a Juvenile Growth test with rainbow trout, following OECD Guideline 215, did ensure a sufficient fish size already at test start.

Fish feed pellets with radiolabelled polymer at three different concentrations (i.e. 0.01, 0.1 and 1.0 % [w/w]) were produced. A pre-test using fish was applied to ensure feed acceptance. In the main-test, the fish were exposed to the test diet for 4 weeks in a flow-through system. Feed amounts were adapted considering the fish size increase during the study. To ensure a correct balancing of the radiolabelled test item, an extensive filter

system was installed to enable a thorough collection of test item as part of the system drain. In addition to the ecotoxicological assessment of the fish, the fish were prepared by excision of the inner organs after exposure. The separate measurements of radioactivity in fish tissue and intestines provided additional information about a possible intake of the test item by fish.

Finally, the study could successfully be conducted in line with the guideline requirements, confirming that a dietary exposure can also be implemented in ecotox testing.

The poster shows anonymised data and the developed test setup. The different project milestones and respective outcomes are illustrated.

1.14.P-Mo094 Assessing Repellent Effects in Bee Toxicity Studies

Sylviane Gony¹ and **Sophia Buschmann²**, (1)*Eurofins Agrosciences Regulatory Services, France*, (2)*Eurofins Agroscience Services Ecotox GmbH, Germany*

The recent EFSA guidance on pollinator risk assessment (EFSA, 2023) is not yet in force. However, its new approach for evaluating bee risk no longer relies on standard endpoints such as 48h-LD50 (acute toxicity), 10d-LDD50 (chronic oral toxicity), or NOED (larval toxicity). Instead, it focuses on using dose–response curves to determine a substance hazard to bees. In some cases, generating such curves can be challenging due to technical limitations, such as very low toxicity or poor solubility. Among these challenges, the repellent properties of a substance are particularly critical, as they may restrict effective exposure and be misinterpreted as reduced feeding motivation rather than a true avoidance response. Therefore, it is essential to demonstrate that the substance does not cause a sustained change in feeding motivation and that any observed decrease in feeding rate is due to a non-toxic, repellent-driven avoidance effect rather than a toxic mechanism. This demonstration should follow OECD testing guidelines without altering the study protocol in a way that could compromise regulatory validity.

For honeybee studies, this is relatively straightforward: the OECD TG 213 (acute oral toxicity) and TG 245 (chronic oral toxicity) designs (10 bees per cage) allow for choice tests by adding a second feeder—one with contaminated solution and one with uncontaminated sucrose. In contrast, bumblebee testing under OECD TG 247 (acute oral toxicity) uses single housing (one bee per Nicot® queen cage), permitting only one feeder and thus no choice between contaminated and uncontaminated solutions. To address this, a test was conducted with a fungicide formulation that previously showed a strong feeding rate reduction in a rangefinder, aiming to confirm that appetite was not durably affected, and that repellency was likely the cause for the observed reduction—without modifying the OECD TG 247 exposure design.

1.15 PFAS Across the Environment–Human Continuum: From Molecular Mechanisms to Disease-Relevant Outcomes

1.15.T-01 A One Health Perspective on PFAS Hazard: System-Level Immune and Neural Disruption in Ecological and Human Models

Davide Rotondo¹, **Davide Gualandris²**, **Antonio Calisi¹**, **Laura Lagostena³**, **Vittoria F Borriani¹**, **Konstantinos D. Papavasileiou⁴**, **Marcello Manfredi¹**, **Valeria Magnelli¹**, **Antreas Afantitis⁴**, **Iseult Lynch⁵** and **Francesco Dondero²**, (1)*University of Eastern Piedmont, Italy*, (2)*Department of Science and Technological Innovation, University of Eastern Piedmont, Italy*, (3)*Institute of Biophysics, CNR, Italy*, (4)*Entelos Institute, Cyprus*, (5)*School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom*

Per- and polyfluoroalkyl substances (PFAS) are globally persistent contaminants increasingly implicated in immune dysfunction and neurotoxicity, yet cross-species, mechanistic evidence integrating these endpoints remains limited. We applied a One Health toxicology framework combining human immune cells, a soil invertebrate model, and neuron-like cells to capture convergent PFAS effects on immune and nervous systems. Primary human PBMCs were exposed to PFOS (3–600 µM) under LPS or PHA stimulation and profiled by cytokine arrays and DIA-proteomics. PFOS did not induce overt cytotoxicity but caused marked, stimulus-specific immunomodulation: IL-6 and TNF-α were significantly suppressed in LPS-activated cells, while PHA-evoked Th1/Th2 and CD28 co-stimulatory pathways were repressed. Across conditions, CD48 was consistently downregulated and BAX upregulated, indicating impaired activation and a shift towards a pro-apoptotic phenotype.

Chronic exposure of *Eisenia fetida* to PFAS-contaminated soils (PFOS up to ~880 µg/kg) produced pronounced physiological disruption. Immune genes (Lysenin, CCF-1) showed non-monotonic regulation, catalase and phenol oxidase activities were significantly depressed, and acetylcholinesterase inhibition correlated with delayed escape responses, evidencing neuromuscular and immune impairment. Reproductive output was strongly reduced in high-PFAS soils, revealing ecologically relevant sub-lethal effects.

In S1 neuroblastoma cells, patch-clamp recordings showed that several emerging PFAS (PFMOPrA, PFMOBA, PDMDA, PFuDA, CH₃-PFO₃-3-6-9-TriDoA) significantly and reversibly decreased GABA-evoked currents after pre-treatment, whereas HFPO-DA consistently enhanced GABA responses without activating receptors per se. Docking analyses supported pore-region engagement for inhibitory congeners, consistent with functional modulation of GABA_A receptors.

Together, these data demonstrate that PFAS disrupt immune and inhibitory neurotransmission through distinct yet functionally convergent pathways across species. This integrated evidence base strengthens mechanistic support for PFAS-induced immunosuppression and neurofunctional alteration and underscores the need for cross-species risk assessment within a One Health perspective.

1.15.T-02 Early-life Hexafluoropropylene Oxide Dimer Acid (HFPO-DA or GenX) Exposure Disturbs Circadian Rhythms via DRP-1-dependent Mitochondrial Dysfunction in *Caenorhabditis elegans*

Yu-Hsuan Kuo and Vivian Hsiu-Chuan Liao, Department of Bioenvironmental Systems Engineering, National Taiwan University, Taipei 106, Taiwan, Taiwan (Greater China)

Poly- and perfluoroalkyl substances (PFAS) are widespread synthetic chemicals used in numerous consumer and industrial applications. They are globally detected in diverse environmental matrices and are associated with multiple toxic effects. Hexafluoropropylene oxide dimer acid (HFPO-DA, or GenX), an emerging PFAS introduced as a replacement for perfluorooctanoic acid (PFOA), remains insufficiently characterized in terms of its biological impact. Given the central role of circadian rhythms in organismal health, we examined whether HFPO-DA exposure disrupts circadian regulation in the model organism *Caenorhabditis elegans* and investigated the underlying mechanisms. We found that prolonged exposure to HFPO-DA or PFOA at 10 µg/mL disrupts circadian rhythms in *C. elegans*. HFPO-DA-induced circadian defects were accompanied by pronounced mitochondrial fragmentation and reduced mitochondrial membrane potential. We further demonstrated that HFPO-DA-induced mitochondrial damage and reactive oxygen species production depend on the mitochondrial fission regulator dynamin-related protein 1 (DRP-1). Moreover, HFPO-DA exposure exacerbated oxidative stress and reduced heat-stress resistance in a DRP-1-dependent manner. In silico molecular analyses supported these findings by revealing stable interactions between HFPO-DA and DRP-1. Collectively, our results show that long-term early-life exposure to HFPO-DA disrupts circadian rhythms through DRP-1-dependent pathways, impairs mitochondrial integrity, and diminishes stress resistance in *C. elegans*. Given the conserved nature of circadian and mitochondrial regulation, along with the increasing global use of HFPO-DA, our study highlights the urgent need to assess the long-term health risks associated with the emerging PFAS contaminant.

1.15.T-03 Toxicological effects of the emerging PFAS HFPO-DA in mussels exposed to salinity fluctuations: Implications for Future Coastal Ecosystem Health

Rosa Freitas¹, Claudio Bortot², Marta Barros Cunha¹, Tania Russo³, Carla Leite¹, Amadeu M.V.M. Soares¹, Gianluca Polese³ and Gianfranco Santovito², (1)CESAM, University of Aveiro, Portugal, (2)Department of Biology, University of Padova, Italy, (3)Department of Biology, University of Napoli Federico II, Italy, Italy

Poly- and perfluoroalkyl substances (PFAS) are highly persistent pollutants of growing environmental concern, particularly in transitional ecosystems. Among them, hexafluoropropylene oxide dimer acid (HFPO-DA, also known as Gen-X) has emerged as a replacement for legacy PFAS, yet its toxicity profile in marine organisms remains poorly characterised. At the same time, climate-driven salinity shifts, resulting from sea-level rise, extreme rainfall, and drought, are expected to act as major co-stressors for estuarine species and to modulate contaminant toxicity. To evaluate the interaction between HFPO-DA and salinity, the mussel *Mytilus galloprovincialis* was chronically exposed (28 days) to environmentally relevant HFPO-DA concentrations (10 and 100 ng/L) under three salinity regimes reflecting present and projected climatic conditions (20, 30, 40).

Metabolic, antioxidant, biotransformation, redox, neurotoxicity and histopathological endpoints were integrated using Principal Coordinates Ordination (PCO) and the Integrated Biological Response (IBRv2) index to characterise whole-organism stress responses. Results demonstrated that salinity is the primary driver of mussel responses, with HFPO-DA acting as a secondary modulator. At low salinity (20), IBR values were highest across treatments, but despite enhanced metabolism and strong activation of antioxidant and biotransformation pathways, no tissue or neurotoxic damage was detected. These findings suggest that osmotic stress primes defence capacity and temporarily masks HFPO-DA toxicity. Conversely, at hypersaline conditions (40), antioxidant and detoxification responses were largely constrained, and HFPO-DA exposure resulted in elevated lipid peroxidation, acetylcholinesterase inhibition, and marked gills and digestive gland lesions, indicating that high salinity intensifies HFPO-DA-induced cellular and tissue damage. At salinity 30, HFPO-DA alone was sufficient to induce a distinct metabolic and histopathological signature, particularly at 100 ng/L. Overall, this study reveals that HFPO-DA toxicity is strongly shaped by salinity, with contrasting biological outcomes according to climate-driven scenarios. These findings highlight the need to incorporate salinity variability into ecological risk assessment of emerging PFAS and reinforce the vulnerability of estuarine ecosystems to combined chemical and climate stressors

1.15.T-04 Protein-Mediated Modulation of PFOA and PFOS Mitochondrial Toxicity in Zebrafish Embryonic Cells (ZF4)

Timothy Prince Chidike Ezeorba¹, Emilie Brun¹, William A. Stubbings Dr¹, Jonathan Barlow², Mohamed Abou-Elwafa Abdallah Dr¹ and Iseult Lynch¹, (1)School of Geography, Earth, and Environmental Sciences, University of Birmingham, United Kingdom, (2)School of Sport, Exercise and Rehabilitation Sciences, University of Birmingham, United Kingdom

Per- and polyfluoroalkyl substances (PFAS) are environmentally persistent chemicals that accumulate in aquatic organisms and interact strongly with serum proteins, potentially altering their cellular bioavailability and toxicity. Understanding how protein binding influences PFAS-induced mitochondrial dysfunction is critical for refining in vitro hazard models and interpreting bioassay outcomes. This study investigated how protein presence in the medium modulates the mitochondrial toxicity of perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) in zebrafish embryonic cells (ZF4). Cells were exposed to several concentrations (100–1000 µM) of each compound in complete culture medium (CCM, with serum) or serum-free medium (NSM) for 24 h. Cytotoxicity was evaluated using metabolic (CKK-8) and cell-counting (Trypan Blue) assays, while mitochondrial endpoints were assessed using TMRM (membrane potential), MitoSOX Red (superoxide production), and Seahorse XF metabolic profiling. Intracellular PFAS accumulation was quantified by LC–MS to evaluate protein-mediated uptake differences.

Results revealed a pronounced protein-dependent modulation of PFAS effects as well as distinct mode of action differences between PFOA and PFOS. In serum-free conditions, both compounds but particularly PFOA, induced greater mitochondrial depolarization, elevated superoxide formation, and decreased coupling efficiency and basal respiration compared to the same exposures in the presence of serum. Seahorse profiling showed a shift toward glycolytic ATP production and reduced spare respiratory capacity, consistent with mitochondrial dysfunction, following exposure to PFOA that was enhanced under the serum-free conditions. LC–MS analysis confirmed approximately tenfold higher intracellular PFOA levels in NSM relative to CCM, linking enhanced bioavailability to stronger bioenergetic disruption. PFOS elicited comparatively milder effects under both serum-free and serum-containing conditions, despite its intracellular levels being > tenfold higher. These findings demonstrate that serum proteins substantially attenuate PFAS-induced mitochondrial stress by limiting cellular uptake and bioavailability. The data highlight the importance of medium composition when interpreting in vitro PFAS toxicity and the need to account for protein binding when translating cell-based results to environmental exposure scenarios.

1.15.P PFAS Across the Environment–Human Continuum: From Molecular Mechanisms to Disease-Relevant Outcomes

1.15.P-Mo095 Ecotoxicological Effects of Long-Chain PFAS in *Mytilus galloprovincialis*: Evidence Across Multiple Biological Levels

Marta Barros Cunha¹, Seila Diaz¹, Alessandro Nardi², Amadeu M.V.M. Soares¹, Ana Gil³ and Rosa Freitas¹,
(1)CESAM, University of Aveiro, Portugal, (2)Dipartimento di Scienze della Vita e dell'Ambiente, Università Politecnica delle Marche & NBFC, National Biodiversity Future Center, Italy, (3)CICECO, University of Aveiro, Portugal

Long-chain per- and polyfluoroalkyl substances (PFAS) are highly bioaccumulative and persistent in marine environments, posing a significant threat to aquatic organisms. This study investigated the biochemical, physiological, and histopathological effects of 4 long-chain PFAS (PFUnDA, PFDoA, PFTrIDA, and PFTeDA) on the mussel *Mytilus galloprovincialis*. The Integrated Biomarker Response (IBR) index was employed to combine metabolic, oxidative, detoxification, and neurotoxic biomarkers and provide an overall measure of organismal stress, enabling the visualization and comparison of biological responses across treatments and species. The results demonstrated that the longest-chain PFAS (PFTrIDA, PFTeDA) induced pronounced metabolic activation, reflected by enhanced electron transport system activity and respiration rate, accompanied by higher protein and lipid reserves and carbohydrates depletion. These energetic shifts intensified aerobic metabolism and higher energetic costs under chemical stress. The upregulation of antioxidant enzymes and total antioxidant capacity in response to increased lipid peroxidation suggests that the extent of oxidative damage exceeded the efficiency of the antioxidant defense system. Biotransformation enzymes displayed compound-specific modulation, with maximal activation under PFDoA and limited induction under longer-chain PFAS, suggesting constrained detoxification efficiency under high oxidative demand. Moreover, inhibition of acetylcholinesterase across all treatments indicated potential neurotoxic impairment. The histopathological analyses conducted in gills, digestive gland, gonad, kidney, and nervous tissue corroborated the biochemical results. Gills and digestive gland showed higher histopathological indices under longer-chain PFAS exposure, mainly characterized by digestive tubule atrophy, brown cell aggregates in primary tubule epithelia, fibrous tissue formation in connective areas, and enlarged central vessels in gills. No significant differences were observed in gonadal or adipogranular index. Kidney lipofuscin accumulation increased with PFAS chain length, and neural tissues exhibited greater necrosis. Overall, PFAS toxicity was chain length-dependent, with PFTrIDA and PFTeDA identified as the most disruptive compounds, eliciting oxidative, metabolic, and neurotoxic imbalances. These findings provide mechanistic insights into PFAS-induced stress in bivalves and support improved ecological risk assessment of PFAS.

1.15.P-Mo096 Effect of Equimolar PFAS Mixtures on *Eisenia fetida* Immune System

Davide Gualandris¹, Davide Rotondo², Candida Lorusso², Antonio Calisi² and Francesco Dondero¹,
(1)Department of Science and Technological Innovation, University of Eastern Piedmont, Italy, (2)University of Eastern Piedmont, Italy

Per- and polyfluoroalkyl substances (PFAS) are persistent soil contaminants, yet their effects on soil invertebrates remain comparatively understudied relative to aquatic species and human health models. Our laboratory has recently characterised the toxicity of individual PFAS congeners in *Eisenia fetida* following OECD Test 207 guidelines. However, environmental PFAS contamination rarely consists of single compounds; instead, it encompasses complex mixtures of legacy long-chain acids and emerging short-chain ether analogues. This raises a key toxicological question: do equimolar mixtures reproduce, attenuate, or amplify the sublethal responses observed for single compounds, or do they elicit qualitatively distinct biological outcomes?

To begin addressing this knowledge gap, we investigated the immune- and stress-related effects of an equimolar mixture composed of five PFAS: the long-chain legacy acid perfluorooctanoic acid (PFOA, C8), the short-chain perfluorobutanoic acid (PFBA, C4), and three emerging ether-PFAS—HFPO-DA (GenX, C6), PFMOBA (C5), and PFMOPrA (C4). Adult *E. fetida* were exposed on filter paper for 72 h to four nominal concentrations (0.6, 4.2, 31 and 229 µM). To disentangle mixture interactions, each PFAS was also tested individually at concentrations matching its proportion in the mixture, enabling direct comparison between combined and single-congener exposures.

Coelomic fluid was collected and separated into cellular and acellular fractions. In the supernatant, biochemical endpoints were quantified, including acetylcholinesterase (AChE), phenoloxidase (PO), and catalase (CAT), representing neurotoxicity, immunomodulation, and oxidative stress, respectively. The cellular pellet was used for amoebocyte morphometry, micronucleus scoring, and evaluation of cytological and genotoxic alterations. Furthermore, relative expression of CCF-1 and Lysenin, two genes involved in immune defence and stress responses, was assessed.

By integrating biochemical, cytological, and molecular biomarkers, this study aims to establish a comprehensive framework for interpreting the adverse outcome patterns potentially elicited by equimolar PFAS mixtures compared to their individual components. At this stage, the dataset allows us to define a robust experimental platform for mixture toxicity assessment; detailed interpretation of biological trends will require completion of ongoing analyses.

1.15.P-Mo097 Immunohistochemical Mapping of Neurotransmitter Systems in *Eisenia fetida* Exposed to PFAS

Antonio Calisi¹, Nicolò Baranzini², Laura Pulze², Davide Gualandris³, Davide Rotondo¹, Annalisa Grimaldi² and Francesco Dondero³, (1)University of Eastern Piedmont, Italy, (2)University of Insubria, Italy, (3)Department of Science and Technological Innovation, University of Eastern Piedmont, Italy

Per- and polyfluoroalkyl substances (PFAS) are persistent environmental contaminants whose sub-lethal effects on terrestrial invertebrates require sensitive mechanistic tools. *Eisenia fetida* is a relevant terrestrial model for neuroecotoxicology, yet methods capable of detecting PFAS-driven alterations in specific neurotransmitter systems remain limited.

We developed and applied a neurochemical histology workflow to evaluate the effects of two PFAS congeners—perfluorooctanoic acid (PFOA) and HFPO-DA (GenX)—on cholinergic, GABAergic, and serotonergic signalling in *E. fetida*. Adult worms were exposed to 0.06 µM and 229 µM of each compound, after which fixed and embedded organisms were serially sectioned for targeted immunohistochemical analyses. Cholinergic activity was assessed using Karnovsky's histochemical method for acetylcholinesterase (AChE). GABAergic modulation was examined using anti-GABA immunofluorescence, enabling quantification of GABA immunoreactivity in the circular muscle layer and peripheral neural structures. To expand the neurochemical panel, serotonergic innervation was characterised through anti-serotonin (5-HT) immunolabelling, allowing detection of serotonergic fibres and mapping of their spatial distribution under PFAS exposure. All imaging procedures were standardised for semi-quantitative comparison across treatments. Preliminary observations revealed detectable alterations in AChE, GABA, and 5-HT immunoreactivity in PFAS-exposed specimens relative to controls, confirming the sensitivity of this multiparametric histological platform in capturing PFAS-induced neurochemical shifts.

This methodological framework provides an expanded and reproducible approach to investigate neurotransmitter-level endpoints in soil invertebrates, offering finer mechanistic resolution and complementing traditional biochemical or behavioural assays in PFAS neuroecotoxicology.

1.15.P-Mo098 Exploring Native Fungal Communities for PFAS Tolerance in Contaminated Soils

Valentina Bonetto¹, Simonetta Sampò¹, Davide Rotondo¹, Davide Gualandris², Antonio Calisi¹ and Francesco

Dondero², (1)University of Eastern Piedmont, Italy, (2)Department of Science and Technological Innovation, University of Eastern Piedmont, Italy

Per- and polyfluoroalkyl substances (PFAS) are persistent environmental pollutants that pose significant ecological and human health risks due to their chemical stability and resistance to degradation. Among them, perfluorooctane sulfonate (PFOS) is the most prominent compound in our study area, a drill site with long term history of legacy PFAS contamination in Trelleborg, Sweden.

The goal of this study was to determine whether fungi native to PFOS-contaminated soils harbor adaptive traits enabling them to tolerate or even utilize PFAS compounds. We isolate and characterize fungal strains from the most contaminated soil sample (910 ppb sum of PFAS4 -sensu EFSA) and assess their growth on minimal PDA medium enriched with increasing concentrations of PFOS (10, 100, and 1000 mg/L).

Among the isolates, *Cladosporium cladosporioides* displays robust and consistent growth at all tested concentrations, suggesting a high level of tolerance to this contaminant. This observation aligns with previous literature reporting the genus's capacity to manage a variety of xenobiotic compounds. Based on these results, we select *Cladosporium cladosporioides* for preliminary chemical analyses on the culture medium. To evaluate the effect of fungal activity on PFOS concentrations, we perform LC-MS/MS analyses on culture media and fungal biomass after 30 days of growth. These analyses show a higher concentration of PFOS the medium closest to the fungal mycelium with the appearance of PFHxS, a shorter-chain PFAS, absent in control samples with no fungal growth. Meanwhile, only low levels of PFOS accumulate within the fungal biomass, which suggests that the fungus does not significantly internalize the contaminant but may instead be contributing to its transformation externally. These observations suggest a possible chain-shortening conversion of PFOS, supporting the hypothesis that fungi isolated from PFOS-contaminated environments may evolve adaptive or metabolic mechanisms to tolerate and potentially biotransform PFAS.

Our findings highlight the resilience and functional potential of native fungal communities in PFAS-polluted soils. Ongoing optimization of analytical protocols and molecular analysis will help confirm the identity and ecological relevance of the isolated strains, laying the groundwork for future applications of native fungi in sustainable bioremediation strategies targeting PFAS-contaminated environments.

1.15.P-Mo099 Neurofunctional and Transcriptomic Responses to the Hexafluoropropylene Oxide Analogues HFPO-DA and HFPO-TeA

Daide Rotondo¹, Davide Gualandris², Laura Lagostena³, Valeria Magnelli¹, Konstantinos D. Papavasileiou⁴, Antreas Afantitis⁵ and Francesco Dondero², (1)University of Eastern Piedmont, Italy, (2)Department of Science and Technological Innovation, University of Eastern Piedmont, Italy, (3)Institute of Biophysics, CNR, Italy, (4)Novamechanics, Greece, (5)Entelos Institute, Cyprus

Among the emerging ether-perfluoro analogues, hexafluoropropylene oxide dimer acid (HFPO-DA) and tetramer acid (HFPO-TeA) have been introduced as replacements for legacy PFAS, yet their potential neurotoxic properties remain poorly characterized.

In this study, we investigated their effects on neuronal homeostasis using S1 neuroblastoma cells with GABAergic features. We combined transcriptomic profiling, electrophysiological recordings of GABAA currents, cytotoxicity assays, and molecular docking.

Cytotoxicity testing revealed distinct profiles: in standard submarine culture conditions, HFPO-DA caused no changes in cell viability, whereas HFPO-TeA reduced viability at millimolar concentrations. These findings point to a lower cellular tolerance for HFPO-TeA.

Patch-clamp recordings showed that HFPO-DA (10 μ M) significantly and reversibly enhanced GABA-evoked currents without activating receptors on its own, suggesting a modulatory action at non-orthosteric sites. In contrast, HFPO-TeA, tested at reduced concentrations to preserve membrane integrity (0.5 μ M), did not affect GABA responses, indicating minimal acute interaction with GABAA receptor function.

Molecular docking revealed peripheral, non-occlusive poses for HFPO-DA, consistent with its lack of pore-blocking activity, whereas HFPO-TeA showed deep pore insertion in the closed state but retracted toward the channel exit in other states, a pattern that did not match its absence of current modulation.

Transcriptomic analysis (1 or 10 μ M) further revealed some compound-specific signatures. Although HFPO-DA and -TeA shared several enriched KEGG and GO pathways related to mitochondrial respiration, oxidative phosphorylation, ribosome biogenesis and proteostasis, -TeA elicits a far stronger, coherent and dose-dependent

activation of this program. It also triggered broader dysregulation of oxidative-stress- and mitochondrial-related pathways, including MAPK, apoptosis, and p53 signaling.

These findings reveal distinct neurotoxicological potential for HFPO-DA and HFPO-TeA. HFPO-DA acts as a mild and reversible modulator of GABAergic signaling with limited cytotoxic effects, whereas HFPO-TeA shows reduced cellular tolerance and induces transcriptional responses consistent with cellular stress. These results highlight divergent mechanisms for structurally related HFPO analogues and underscore the need for further studies to evaluate their long-term effects on neuronal systems.

1.15.P-Mo101 In Vitro Structure–Activity Relationships and Relative Potency Factors of PFAS: Integrating Hepato- and Immunotoxicity Endpoints for Improved Risk Assessment

Misha Vrolijk¹, Victor Amstutz¹ and Dick Sijm², (1)Department of Pharmacology and Toxicology, Faculty of Health, Medicine and Life Sciences, Maastricht University, Maastricht, the Netherlands., Netherlands, (2)Office for Risk Assessment and Research, Netherlands Food and Consumer Product Safety Authority (NVWA), Netherlands

Background: Per- and polyfluoroalkyl substances (PFAS) constitute a chemically diverse group of persistent pollutants for which toxicological data remain limited, particularly for emerging short-chain and fluorotelomer-based compounds. To support risk assessment of data-poor PFAS, we systematically investigated the structure–activity relationship (SAR) of thirteen PFAS, including perfluoroalkyl acids (PFCAs), perfluorosulfonic acids (PFSAs), and fluorotelomer alcohols (FTOHs), in human hepatocytes (HepG2) and immune cells (THP-1 monocytes/macrophages).

Methods and results: Across cytotoxicity assays and intracellular reactive oxygen species (ROS) assays, PFAS toxicity increased with carbon-chain length up to 8–10 carbons, while functional headgroups strongly influenced potency. PFCAs and PFSAs showed pronounced concentration-dependent cytotoxicity and ROS induction, whereas FTOHs were minimally toxic in HepG2 cells but exhibited marked immunotoxicity, underscoring clear cell-type specificity. Mechanistic analyses revealed that mitochondrial disruption acts as an early molecular initiating event, triggering ROS-generating cascades involving lysosomes and peroxisomes. In THP-1 macrophages, several PFAS altered cytokine responses by modulating TLR4-mediated signaling, supporting immunotoxicity as a particularly sensitive endpoint.

Significance: Using cytotoxicity- and ROS-based endpoints, we derived in vitro Relative Potency Factors (RPFs), revealing consistent potency rankings across PFAS subclasses. These RPFs provide a quantitative basis for grouping, prioritization, and read-across, demonstrating the feasibility of SAR-driven approaches for improving the risk assessment of both legacy and emerging PFAS. Collectively, our findings show that PFAS toxicity is structure-dependent, endpoint-specific, and cell-type-specific, supporting the integration of NAM-based SAR frameworks into regulatory evaluation.

1.15.P-Mo102 Enhancing Access to Human Biomonitoring Data in Europe: The Development and Utility of the European HBM Dashboard

Liese Gilles, Laura Rodriguez Martin, Caio Mescouto Terra de Souza, Stijn Baken, Gertjan Bisschop, Peter Stouthuysen and Eva Govarts, VITO, Belgium

HBM data serves as a crucial measure of internal concentration levels of exposure biomarkers found in human matrices, including urine and blood. As part of the Human Biomonitoring for Europe project (HBM4EU), the Flemish Institute for Technological Research (VITO) developed a comprehensive human biomonitoring (HBM) dashboard, launched March, 2021. Currently including data from over 100 studies covering 25 European countries. This dashboard continues to be actively maintained and updated under the auspices of the Partnership for Assessment of Chemical Risks (PARC) and aims to broaden access to HBM data by providing an intuitive platform for visualizing summary statistics derived from HBM datasets, fostering widespread community engagement. Users can explore exposure levels and trends in chemical exposure across European populations, with the ability to compare these levels against established health-based guidance values.

The dashboard ensures data consistency and reliability through standardized data collection methodologies, including predefined data templates, codebooks, data validation, derived variables and summary statistics tools (<https://hbm.vito.be/tools>) The dashboard presents key statistics i.e. (P05, P10, P25, P50, P75, P90, P95). An array of filters enables customized data exploration by criteria like sampling year, country, or target population.

Users can visualize summary statistics for specific stratifications, facilitating subgroup comparisons like sex or educational level.

The European HBM Dashboard represents a significant advancement in promoting transparency and accessibility in human biomonitoring. Its user-friendly interface and robust data visualization tools, make it a valuable resource for policymakers, researchers, and stakeholders in public health and environmental risk assessment. The dashboard, publicly accessible online at: <https://hbm.vito.be/eu-hbm-dashboard>, promotes informed decision-making and fosters engagement with HBM data.

1.15.P-Mo103 Extracellular Vesicles as Novel Indicators of PFAS-Induced Molecular Responses in Zebrafish Embryos

Csilla Pelyhe, Nina Mokrackova and Ondrej Adamovsky, RECETOX, Faculty of Science, Masaryk University, Czech Republic

Extracellular vesicles (EVs) are nanosized, lipid bilayered particles released by most cell types. They carry proteins, lipids, and nucleic acids from their parent cells, mediating intercellular communication. EVs can reflect exposure- or stress-induced alterations in cellular function, offering a potential insight into molecular responses to contaminants.

Zebrafish (*Danio rerio*) embryos are an established model for studying vertebrate development and toxicological mechanisms. Despite growing interest in extracellular vesicles, studies in zebrafish remain scarce, with only a few describing EVs under baseline conditions and none addressing exposure to environmental contaminants. This project aims to fill this gap by investigating how per- and polyfluoroalkyl substances (PFAS) modulate EV production and cargo composition in developing zebrafish.

PFAS are persistent synthetic chemicals widely used in industrial and consumer products. Owing to their extreme stability, they accumulate in the environment and organisms, where they can interfere with lipid metabolism, immune function, and cellular signaling.

The project aims to establish a workflow for isolating and characterizing extracellular vesicles from zebrafish embryos and to determine how PFAS exposure alters their size, abundance, and molecular composition. Embryos will be exposed to increasing concentrations of PFAS, and embryonic development will be assessed for potential morphological and physiological effects. EVs will be isolated and their morphology visualized by cryo-electron microscopy, while particle size and concentration will be measured by multi-angle dynamic light scattering, and small RNA profiling will be applied to assess PFAS-induced changes in EV cargo.

This study will provide in vivo insights into contaminant-induced modulation of EVs during vertebrate development. The outcomes are also expected to advance understanding of PFAS-mediated molecular communication and evaluate the potential of EVs as sensitive, mechanistically relevant biomarkers in aquatic toxicology.

1.15.P-Mo104 Placental ASCL2 Epimutations Link Prenatal Perfluorooctanoic Acid Exposure to Gestational Diabetes Mellitus

Sojin Park¹, Yehoon Jo², Sungkyoon Kim¹ and Jaehyoun Lee², (1)Department of Environmental Health Sciences, Graduate School of Public Health, Seoul National University, Korea, Republic of, (2)Institute of Health & Environment, Seoul National University, Korea, Republic of

Prenatal exposure to perfluorooctanoic acid (PFOA) is associated with an increased risk of gestational diabetes mellitus (GDM). The Achaete-scute family bHLH transcription factor 2 (ASCL2) plays a critical role in trophoblast differentiation during placentation; however, the mediating role of ASCL2 in disrupted glucose homeostasis following gestational PFOA exposure remains unclear. This study investigated whether PFOA-induced placental epimutations of ASCL2 contribute to GDM pathogenesis using a mouse model and a human birth cohort. Pregnant C57BL/6N mice were exposed to PFOA from embryonic day (E) 6.5 to E15.5, and placentas were collected at E16.5. Human placental specimens were obtained from participants in a Korean birth cohort. Placental mRNA expression levels of *Ascl2* and ASCL2 were assessed by reverse transcription-quantitative PCR (RT-qPCR). DNA methylation changes in the *Ascl2* differentially methylated region (DMR)

and the ASCL2 5'-end region were determined by bisulfite amplicon sequencing (BSAS) in mouse and human placental samples, respectively. RNA sequencing was conducted to profile transcriptomic programming in Ascl2- or ASCL2-upregulated placentas. Prenatal PFOA-exposed mice exhibited elevated maternal blood glucose levels and increased placental Ascl2 expression. In the human cohort, elevated placental ASCL2 expression was notably observed in GDM patients with significantly high maternal serum PFOA levels. Distinct methylation-expression relationships were found between species: positive correlations between Ascl2 expression and CpG methylation in the mouse Ascl2 DMR, whereas inverse correlations were observed in the human ASCL2 5'-end region. Transcriptomic profiling revealed distinct pathway enrichments between species: PFOA-exposed mouse placentas with elevated Ascl2 showed prominent enrichment of oxidative phosphorylation and cell proliferation pathways. In contrast, GDM human placentas with elevated ASCL2 exhibited glycolysis, mTORC1 signaling, and hormone response pathways, reflecting metabolic reprogramming characteristic of diabetic pregnancy. Our findings demonstrate that PFOA-induced placental ASCL2 epimutations are associated with maternal hyperglycemia in mice and GDM in humans. These results highlight critical species differences in placental responses to environmental exposures, and suggest that site-specific ASCL2 DNA methylation could serve as an epigenotoxic biomarker for detecting environmentally-induced GDM.

1.15.P-Mo105 Resolving The Unknown Toxicity of Novel Per- And Polyfluoroalkyl Substances (PFAS): ADONA, Gen-X and PFOSA

María Fernández-Rodríguez¹, Nerea Garcia-Velasco², Maddi Salvach Vilches³ and Belen Gonzalez-Gaya⁴, (1)University of the Basque Country (UPV/EHU), Research Centre for Experimental Marine Biology and Biotechnology, Spain, (2)University of the Basque Country, Research Centre for Experimental Marine Biology and Biotechnology, Spain, (3)University of Basque Country, Spain, (4)University of the Basque Country, Research Centre for Experimental Marine Biology and Biotechnology, Ikerbasque Found, Spain

The global production and widespread use of per- and polyfluoroalkyl substances (PFAS) have resulted in their continuous release into the environment, increasing their concentrations and generating ecotoxicological concerns. This scenario has driven the regulation of legacy PFAS and the subsequent development of new compounds by industry. Related toxicological research has thus largely centered on PFOS and PFOA, leaving other long-chain PFAS, such as the PFOS precursor PFOSA, and new-generation ones like ADONA and GenX less explored.

This study aims to evaluate the toxicological effects of these three under-studied PFAS through a battery of bioassays addressing different levels of biological complexity to clarify their potential environmental and human health impacts. The approach involves assessing effects on sea urchin embryo development, coelomocyte viability in polychaetes, marine bacteria bioluminescence, and human endocrine activity.

Results indicate that ADONA and GenX did not exert environmental impact at the tested endpoints. PFOSA affected sea urchin embryo development at concentrations above 5 mg/L, reduced coelomocyte viability at levels higher than 50 mg/L, and impaired bacterial bioluminescence starting at 5 mg/L, with significant effects at 50 mg/L. Regarding human-related endpoints, ADONA and GenX increased basal estrogenic activity under co-exposure with estradiol (50 ng/L) at concentrations above 50 mg/L, without affecting androgenic or thyroid receptors. PFOSA induced anti-estrogenic activity under estradiol co-exposure and showed anti-androgenic effects at concentrations above 50 mg/L, without influencing the thyroid receptor.

Overall, the findings provide the first reliable toxicological characterization of PFOSA, ADONA and GenX, indicating a toxicity ranking of PFOSA > GenX > ADONA. The multi-endpoint approach used in the present study generates mechanism-oriented evidence that helps bridge molecular actions with organism-level responses, as these pollutants disrupt vital functions. In addition, it provides an integrated overview of the impact of these persistent pollutants from a One Health perspective.

1.15.P-Mo106 Sniffing out PFOS: Mass spectrometry imaging for tissue-specific effects of contaminants
Rikke Poulsen¹, Emma M Field², Angela M Jackson³, Haley Kuecks-Winger², Anita Thambirajah, Ph.D.³, David Goodlett², Caren C. Helbing² and Helena Petrosova³, (1)University of Copenhagen, Denmark, (2)Department of Biochemistry and Microbiology, University of Victoria, Canada, (3)University of Victoria, Canada

Mass spectrometry imaging (MSI) is an exciting emerging technology that adds spatial information to mass spectrometry analysis, allowing mapping of both contaminants and endogenous biomolecules in the tissue. Where traditional mass spectrometry methods involves tissue homogenization, MSI preserves tissue heterogeneity and it is possible to look at extremely small tissues or tissue regions without contamination from the surroundings.

Here we utilized a representative of true frogs, the cosmopolitan tadpole model American bullfrog (*Rana* [Lithobates] catesbeiana), and MSI to identify hotspots of PFOS accumulation and look for associated tissue-specific effects in lipid composition. Premetamorphic tadpoles were exposed to PFOS (0, 10 and 100 µg/L) for 48 h. Tadpole heads were sampled for MSI and analyzed on a Bruker timsTOF fleX-MALDI-2

The results showed the tissue localization of PFOS – which notably localized to a specific neuroendocrine gland in the brain and to the olfactory epithelium. These same tissues exhibited a depletion in glycerophospholipids, with phosphatidylethanolamines (PEs) and phosphatidylglycerol (PGs) comprising the greatest number of PFOS-affected lipids. In the pineal gland, PFOS also induced depletion of the lipid PA (38:3); which has been shown to be important for brain development in mice.

The study exemplifies how MSI advances our analytical toolbox to support unbiased screening of contaminant distribution and their localized effects in biological compartments.

1.16.P The Extended Chemical Defensome: Novel Insights Into the Mechanisms of Defense Allowing Species to Cope With Chemical Pollution

1.16.P-Th001 Introducing the extended chemical defensome to emphasize mechanisms of defense as key research avenues to tackle priority questions in environmental toxicology

Marco Enrique Franco¹, Cristiano V. M. Araújo², Daniel Cervený³, Anna Koubová⁴, Bram Danneels⁵, Anders Goksøyr⁵ and Michael Grant Bertram⁶, (1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Institute of Marine Sciences of Andalusia (ICMAN-CSIC), Spain, (3)Swedish University of Agricultural Sciences (SLU), Sweden, (4)University of South Bohemia Ceske Budejovice, Czech Republic, (5)University of Bergen, Norway, (6)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden

In response to chemical exposure, organisms use specific regions of their genome coding for different defense mechanisms—this collection of genes is termed the “chemical defensome”. Specifically, genes associated with efflux transporters, transcription factors, antioxidant systems, and biotransformation pathways, among others, are expressed to reduce toxicity. These sub-individual processes are, for the most part, widely conserved across taxa and play a critical role in enabling organisms to cope with polluted environments. Additionally, behavioral responses—particularly spatial avoidance—should be recognized as an individual-level defense mechanism and incorporated into an extended chemical defensome framework. We therefore propose that expanding and reinforcing the concept of the chemical defensome beyond traditional studies at the genome level, as well as developing strategies to synthesize existing data, offers a valuable opportunity to link gene composition to physiological and behavioral responses, thereby addressing key research needs in environmental toxicology. These include: estimating the impact of chemical mixtures across different exposure scenarios, identifying the main drivers of intra- and interspecific sensitivity to pollution, and assessing large-scale ecological processes, such as biodiversity losses, in polluted habitats in a more integrated manner. In ecotoxicology and environmental risk assessment (ERA), understanding not only how chemical pollutants exert toxicity but also how organisms counteract these effects is essential. Thus, investigating chemical-induced shifts in defense mechanisms and strategically incorporating these data into ERA frameworks could improve predictions of adverse outcomes at higher levels of biological organization and inform more effective chemical management and regulatory strategies.

1.16.P-Th002 Microbial Components of the Host's Chemical Defensome

Anna Koubová¹, Eva Koutecká², Vladimír Žlábek¹ and Jiří Bárta², (1)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, Zátěží 728/II, CZ-389 25 Vodňany, Czech Republic, Czech Republic, (2)University of South Bohemia in České Budějovice, Faculty of Science, Branišovská 1645/31a, CZ-370 05 České Budějovice, Czech Republic, Czech Republic

Aquatic ecosystems are continually burdened with cocktails of micropollutants, including persistent organic compounds, pesticides, pharmaceutically active substances, and endocrine-disrupting chemicals, posing a hidden threat to fish health. Although laboratory studies have demonstrated the biochemical and metabolomic effects of these contaminants, their influence on the gut microbiome of wild fish, which is critical for immunity, metabolism, and overall health, remains poorly understood. This study evaluated the impact of wastewater treatment plant (WWTP) effluent on the intestinal microbiome of wild brown trout (*Salmo trutta* m. *fario* L.). Fish restocked downstream of an STP were compared with an upstream control group. Trout intestines were sampled after 6, 14, and 24 weeks. DNA extracted from intestinal contents was sequenced for 16S rRNA amplicons, clustered into zero-radius OTUs, and assigned taxonomy using Silva132. Taxonomic composition, microbial diversity, and functional potential were assessed. Upstream fish had a stable microbiome dominated by Firmicutes (249%), Actinobacteriota (224%), and Proteobacteria (222%), whereas downstream fish exhibited a variable microbiome dominated by Chlamydiota and enriched in *Ca. Rhabdochlamydia*, *Ca. Mesochlamydia*, and *Microcystis*, reflecting chemical contamination and potential toxic cyanobacterial influence. Downstream microbiomes showed higher diversity and unevenness, with functional shifts toward taxa adapted to antibiotics, biocides, and xenobiotics, including enhanced xenobiotic degradation, membrane/lipid remodelling, and tryptophan metabolism. The integration of microbiome, functional, and physiological data suggests that WWTP effluent exerts long-term selective pressure on brown trout, restructuring microbial communities and favouring pollutant-adapted, antibiotic-resistant, and opportunistic taxa. These microbiomes may serve as reservoirs of resistance genes and catabolic functions, creating an environment-host interface that facilitates the spread of adaptive traits through the aquatic food web. Such an adapted microbiome may potentially represent microbial components of the host's chemical defensome.

Disclaimer/Disclosure:

The research was supported by the Czech Science Foundation (project No. 20-04676X) and by the Ministry of Education, Youth and Sports of the Czech Republic, under the project "CENAKVA" (LM2023038).

1.16.P-Th003 Sex-linked Insecticide Selectivity in Mason Bees (*Osmia* spp.) is Driven by Differences in Cytochrome P450 Expression Profiles

Xingzhi Xiao¹, Ana R. Cabrera², Joshua Zuber², Niklas Hamaekers¹, Daniel R. Schmehl², Maria Teresa Almanza¹, Christian Maus¹, Julian Haas¹ and Ralf Nauen¹, (1)Bayer AG, Crop Science Division, R&D, Germany, (2)Bayer CropScience LLC, United States

Pollinator safety is a critical area for the evaluation and assessment of pesticide safety. Recently, attention has been focused on solitary bees as important group of pollinators, with *Osmia* spp. suggested as suitable laboratory toxicity testing species because of their availability and ease of handling. However, *Osmia* spp. and their physiology remain poorly understood in comparison to the honey bee *Apis mellifera* where decades of research have contributed to a solid knowledge of its physiology and potential determinants of pesticide sensitivity.

Recent studies have reported sex-linked insecticide sensitivity differences in certain *Osmia* species for which the mechanistic understanding remains limited. To address this knowledge gap, we investigated functional capacity and sex-linked differences in expression of cytochrome P450 monooxygenase genes, focusing on the CYP9 and CYP6AQ subfamilies commonly implicated in insecticide metabolism. Functionally recombinant expression of CYP9BU1 and CYP9BU2 of three *Osmia* species confirmed their detoxification capacity in vitro. qPCR revealed pronounced sex-biased transcription: Especially *O. lignaria* females exhibited consistently lower transcript abundance of CYP9 and CYP6AQ subfamilies, with reductions reaching a maximum of 10-fold compared to male counterparts, suggesting reduced detoxification capacity potentially linked to higher sensitivity towards certain insecticides. Subsequent RNAseq analyses were conducted to compare sex-specific transcriptomic profiles of a broader set of detoxification genes across *O. cornifrons*, *O. lignaria*, and *O. bicornis*. Such studies help to elucidate the physiology and sensitivity determinants of *Osmia* species used in toxicity testing, which in turn can help to inform the evaluation of toxicity data derived from such studies and how to integrate such data meaningfully in the evaluation of pesticides.

1.16.P-Th004 Persistent Organic Pollutants in the Barents Sea Marine Mammals: Habitat, Diet, and Biotransformation

Diogo Oliveira¹, **Heli Routti**², **Jenny Bytingsvik**³, **Filipe Castro**⁴, **Bram Danneels**⁵, **Aaron Fisk**⁶, **Anders Goksøyr**⁷, **Mikael Harju**⁸, **Tore Haug**⁹, **Kit Kovacs**², **Christian Lydersen**², **Audun Rikardsen**¹⁰, **Raquel Ruivo**¹¹ and **Pierre Blévin**³, (1)Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portugal, (2)Norwegian Polar Institute, Norway, (3)Akvaplan-NIVA, Fram Centre, Norway, (4)Interdisciplinary Centre of Marine and Environmental Research, University of Porto, Porto, Portugal, (5)Computational Biology Unit, Department of Informatics, University of Bergen, Norway, (6)University of Windsor, Windsor, Ontario, Canada, (7)University of Bergen, Norway, (8)Norwegian Institute for Air Research, Norway, (9)UiT - The Arctic University of Norway, Tromsø, Norway, (10)Institute of Marine Research, Tromsø, Norway, (11)Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Matosinhos, Portugal

Persistent organic pollutants (POPs) are human-made chemicals that organisms struggle to metabolize, and are thus ubiquitous in the environment as they persist and accumulate in animal tissues. Due to their traits, this particularly affects marine mammals: e.g., they have blubber, a layer of fat used for thermoregulation, in which POPs accumulate; they also usually occupy a high position in the food chain, which makes them susceptible to biomagnification. These animals are imperilled by POPs, and their health has been shown to deteriorate with increasing exposures, eventually leading to higher sickness and mortality rates. Organisms do have mechanisms to protect them from xenobiotics, the so-called chemical defensesome, despite its limited effectiveness against POPs. Usually lipophilic in nature, xenobiotics go through a series of oxidation and conjugation reactions that make them more hydrophilic, and thus easier to excrete from the organism. Here we assess the extent of POP accumulation in the marine mammals of the Barents Sea, using samples of blubber from 14 different species. Hierarchical clustering analysis of the samples grouped them by taxonomy, and the total amount of POPs in each taxonomic group followed a pattern of toothed whales > polar bears > walruses > seals > baleen whales. These results were cross-referenced with existing habitat and diet information for each species, and while these factors helped explain the found POP levels, they did not describe the whole picture. This indicates that additional factors could be vital determinants of pollutant accumulation. Thus, we looked into species-specific variations in biotransformation capacity - we quantified the number of genes in 14 subfamilies involved in crucial biotransformation reactions. Numbers of genes found for each subfamily followed similar trends in each taxonomic group, with polar bears > walruses > true seals > baleen whales > toothed whales. All these results combined made it evident that despite their prominent role, the chemical defensesome repertoire does not determine POP accumulation alone. To conclude, in this work we show how the interplay between environment and biotransformation capacity ultimately determines the differential accumulation of toxic compounds in the blubber, using the marine mammals of the Barents Sea as a case study.

Track 2: Ecotoxicology Becomes Stress Ecology: From Populations to Ecosystems and Landscapes

2.01 Aquatic and Terrestrial Plant Ecology, Ecotoxicology and Risk Assessment

2.01.T-01 Multiomics insights into wild flora molecular adaptation in the Chernobyl Exclusion Zone *Polina Volkova, Independent Researcher, Belgium*

Omic technologies are transforming our ability to understand the long-term consequences of low-dose chronic radiation exposure by moving beyond survival and morphology towards system-level changes in transcripts, proteins, and metabolites. By integrating field-based genomics, transcriptomics, proteomics and metabolomics, these approaches reveal fine-tuning of plant metabolism, signalling, and genome regulation that would remain invisible with traditional endpoints alone.

Comprehensive research on four plant species growing in the Chernobyl Exclusion Zone (*Trifolium repens*,

Achillea millefolium, *Vicia cracca*, and *Chelidonium majus*) using transcriptomics, non-targeted proteomics, and non-targeted metabolomics revealed that chronic radiation exposure drives nitrogen redistribution into stress-related metabolites and secondary compounds with antioxidant and defence functions. Moreover, altered TCA and glyoxylate cycles, suppression of some photosynthetic functions, accumulation of reactive oxygen species (ROS)-scavenging and phenolic metabolites, and signatures of biotin and redox imbalance, point to a tight rewiring of carbon metabolism and ROS homeostasis. Although species-specific reactions were revealed, enrichment of general abiotic-stress response networks, modulation of ROS-related systems (thioredoxin, glutathione), changes in photosynthesis-related genes, and deregulation of histones, heat-shock proteins, and transposable elements were core responses to chronic radiation. Hormone and signalling pathways, particularly abscisic acid-, auxin- and gibberellin-responsive genes, also appear as important integrators of the chronic radiation response, with little or no sustained induction of canonical DNA-repair genes. Together, these omics-based studies provide a more mechanistic, pathway-centred understanding of how plants cope with chronic low-dose radiation exposure and important insights into the adverse outcome pathways specific to ionising radiation in plants. Within the International Commission on Radiological Protection (ICRP) framework for environmental radiation protection, such mechanistic evidence can help refine endpoints for Reference Animals and Plants, supporting the selection of sensitive biomarkers and life stages.

2.01.T-02 Non-target terrestrial plant risk assessment: The implications for weed control in the EU

Joanna Davies¹, **Giovanna Meregalli²** and **Christoph Mayer³**, (1)Product Safety, Syngenta Ltd, United Kingdom, (2)Corteva Agriscience, Italy, (3)BASF, Germany

In 2024, the EU Commission mandated EFSA to update the risk assessment methodology for the assessment of active substances and plant protection products (PPPs) with respect to their potential effects on non-target arthropods other than bees, in-soil organisms and non-target terrestrial plants (NTTPs) outside of the treatment area. This process will require revision of the Specific Protection Goals and the associated Terrestrial Guidance Document that currently defines the risk assessment scheme for each organism class. EFSA has published a Scientific Opinion addressing the state of the science on the risk assessment of PPPs for NTTPs in 2014. This Opinion raises questions relating to risk assessment for NTTPs, including the suitability of endpoints for vegetative vigour on current test species to address potential effects on other plant species and effects on plant reproduction. In addition, it proposes increases in safety factors to address the uncertainty around these questions. These changes in risk assessment are predicted to limit the ability to register PPPs in the EU, increasing the need for higher-tier risk assessment solutions, such as ecological and landscape level modelling, and ultimately change the availability of PPPs to growers. Since 2014, the SETAC Plant Interest Group held two workshops, which lead to the initiation of research projects to investigate the issues of species sensitivity and plant reproduction. In addition, CropLife Europe has completed impact analyses to identify the likely consequences of proposed changes on the availability of PPPs to growers in the EU. Specifically, in this presentation, we will present findings related to:

- (a) the comparative sensitivity of wild and crop species
- (b) the comparative sensitivity of reproductive and vegetative endpoints
- (c) the impact of increased safety factors on the availability of herbicides in the EU
- (d) the consequences of reduced herbicide availability on weed control methods used by growers
- (e) the impact of these changes on broader socio-economic and environmental factors such as food production, farm costs and soil health.

The issues outlined in this presentation highlight that any future changes to PPP risk assessment will be accompanied by socio-economic trade-offs that need to be considered in light of the wider needs of growers and food production in the EU.

2.01.T-03 Overspray Exposure of Aquatic Plants: New Experimental Evidence and Implications for Risk Assessment

Bastian H. Polst¹, **Dick Belgers¹**, **Nina Jansen¹** and **Gertie Arts²**, (1)Wageningen University and Research (WUR), Netherlands, (2)Environmental Risk Assessment, Wageningen University and Research (WUR), Netherlands

Recent EU regulatory reviews, e.g., the glyphosate renewal, have explicitly identified a gap in current aquatic plant risk assessment, as direct foliar exposure scenarios are not yet considered. Although spray drift can result

in direct deposition of plant protection products on floating or emergent aquatic macrophytes, aquatic risk assessments still focus exclusively on exposure via the water phase. Conversely, non-target terrestrial plant (NTTP) assessments address foliar overspray but provide no clear evidence of their protectiveness for aquatic species facing comparable exposure routes. To address this regulatory gap, we conducted two dedicated overspray experiments with *Lemna minor* and *Glyceria maxima* using glyphosate.

For *L. minor*, foliar overspray caused substantially stronger effects than exposure via the growth medium. A risk assessment case study showed that while NTTP endpoints may appear protective at first glance, differing assessment factors and trigger values between terrestrial and aquatic frameworks lead to contrasting regulatory conclusions. For *G. maxima*, overspray resulted in strong growth inhibition and lethality at higher doses, whereas effects from exposure via the growth-medium were minimal, preventing derivation of EC50 values for that route.

Together, these findings demonstrate that foliar exposure represents a relevant and potentially critical risk pathway for aquatic macrophytes that is insufficiently covered by current regulatory approaches. The results highlight the need to re-evaluate the applicability of NTTP assessments for aquatic plants and to reconsider assessment factors resp. trigger values for this intermediate exposure scenario. Additional experimental data across aquatic and semiaquatic species will be essential to draw a robust conclusion on the risk assessment.

2.01.T-04 Aquatic Macrophyte Test Outdoors: Method to Derive a Species Sensitivity Distribution for Time-Variable Exposure

Steve Norman¹, Guido Gonsior², Rabea Christmann³, Maren Dill³ and Seamus Taylor⁴, (1)*RidgewayEco, United Kingdom*, (2)*Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany*, (3)*GG BioTech Design GmbH, Germany*, (4)*ADAMA, Germany*

Uncertainty regarding inter-species variation in sensitivity is reduced by testing multiple species. Towards this aim, 10 aquatic macrophyte species were simultaneously exposed to a herbicide in outdoor tanks for 14 days. Total Shoot Length, Fresh Weight (FW) and Dry Weight (DW) was quantified as in OECD Guideline 239. Growth Rate and Yield of control and treated plants were compared to calculate x% inhibitions for each peak concentration. These were used to derive EC50 values, a Species Sensitivity Distribution (SSD), and an HC5. The method will be presented as an example for potential use in higher-tier risk assessment of Plant Protection Products. The study was in July 2025 in Germany. Tanks were 5 m by 1 m wide. Test species were *Heteranthera zosterifolia*, *Egeria densa*, *Ceratophyllum demersum*, *Myriophyllum spicatum*, *Ranunculus aquatilis*, *Nasturtium officinale*, *Veronica beccabunga*, *Callitriche palustris*, *Mentha aquatica*, and *Lemna gibba*. Replicates per species followed OECD 239. There was one tank per concentration, each tank containing all species. Analysed peak concentrations were 0 (control), 0.0805, 0.238, 0.925, 2.50 and 9.17 µg herbicide/L in Smart and Barko medium. The test substance was dosed into each tank and the medium stirred. To elucidate time-variable exposure-profiles samples were analysed at eight time-points. According to OECD 239 a 2x increase in control fresh weight is sufficient to detect effects. The factor of control fresh weight increase ranged from 3.5 (*M. aquatica*) to 19.2 (*N. officinale*). The DT50 values ranged from 2.98 to 4.76 days. Based on inhibition of Growth Rate, *C. palustris* (FW EC50 0.537 µg/L) and *N. officinale* (FW EC50 0.973 µg/L) were most sensitive and *E. densa* (DW EC50 2.84 µg/L) least sensitive. The HC5 was 0.698 µg/L. The method was essentially the transfer of OECD Guideline 239 to outdoors, for multiple species. The method was valid in terms of good control growth and sensitive in terms of the organism response. In this example the range of sensitivities was relatively narrow, thereby reducing uncertainty with respect to inter-species variation. This method derives an HC5 - for a time-variable exposure - which could be used in higher-tier risk assessments described in EFSA Aquatic Guidance Document (2013).

2.01.T-05 The Prevalence and Acceptability of Mesocosm Studies Submitted for Macrophytes in Pesticide Risk Assessment

Isabel Navarro Law¹, Colin Brown¹, Jason Snape¹, Isabelle Durance², Melissa Reed³ and Michael Fryer⁴, (1)*University of York, United Kingdom*, (2)*Cardiff University, United Kingdom*, (3)*Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom*, (4)*Ecotoxicology, Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom*

Mesocosms can be used in higher tier aquatic risk assessments to assess the impact of Plant Protection Products (PPPs) on macrophytes. However, it is unclear whether these expensive and time consuming higher tier studies influence regulatory outcomes. This platform presentation will highlight common shortcomings in the experimental design of mesocosm studies, with the aim of maximising the regulatory value of future mesocosm studies. Fourteen mesocosm studies, which have been submitted for the regulatory risk assessments for macrophytes in the EU or GB, were identified and reviewed. Results show that only five of the 14 mesocosm studies were deemed acceptable by the regulatory authorities, suggesting that mesocosm studies are not currently being used to their full potential. Issues with the submitted studies include not following a realistic PPP exposure profile (including incorrect dose timings and dilutions), only using one macrophyte morphology, not leaving enough time for the macrophytes to establish and a lack of replicates which increases variability within treatments. *Glyceria maxima* and *Myriophyllum spicatum* were frequently the most sensitive macrophyte species, whilst dry weight was often the most sensitive and least variable endpoint. Even though mesocosms provide the opportunity for recovery and community responses to be observed, such information has not been used by regulatory authorities. Future regulatory mesocosm studies can build upon the shortcomings highlighted here, providing a greater chance of regulatory impact.

2.01.P Aquatic and Terrestrial Plant Ecology, Ecotoxicology and Risk Assessment

2.01.P-Tu058 Algae Species Sensitivity Distribution to Terbutylazine, Azoxystrobin, Copper and Their Mixture Effects

Emma Yenney¹, Zhaoxuan Luo¹ and Nina Cedergreen², (1)University of Copenhagen, Denmark, (2)Plant and Environmental Sciences, University of Copenhagen, Denmark

Chemical risk assessments to protect the freshwater algae community often rely on a single green algal species, despite natural communities containing hundreds of taxa with diverse functional traits. This study asks how sensitivity to common pesticides vary across ecologically relevant freshwater microalgae and whether chemical mixtures interact, altering toxicity.

This study tests species from green algae, diatoms, and cyanobacteria, representing differences in morphology, surface area to volume ratios, and photosynthetic pathways. Growth inhibition assays were conducted using modified standard OECD guidelines in 96-well microplates monitoring growth as increase in light absorbance at various timepoints over 48 hrs. Species were exposed to three surface-water contaminants: the herbicide terbutylazine, the fungicide azoxystrobin, and copper chloride, both individually and in binary mixtures. Preliminary results indicate clear variation in sensitivity among taxa and chemicals, with terbutylazine being the most potent chemical across species. For *R. subcapitata*, all binary mixtures produced a slight antagonist response. Species sensitivity distributions (SSD) will be constructed from the single chemical datasets to quantify community level risk.

These findings provide mechanistic insight into functional trait based differences in pesticide susceptibility and will inform future toxicokinetic-toxicodynamic (TKTD) modeling. Overall, the work supports more ecologically realistic pesticide risk assessments and improved protection of freshwater primary producers.

2.01.P-Tu059 Beyond Lemna and Myriophyllum – Validating Non-Standard Macrophyte Species

Theresa Graf¹, Rabea Christmann¹, Marcel Kahlke¹ and Guido Gonsior², (1)GG BioTech Design GmbH, Germany, (2)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany

Reference chemicals such as 3,5-dichlorophenol (3,5-DCP) are routinely used to verify the sensitivity of standard aquatic plant toxicity tests with *Myriophyllum spicatum* (OECD 239) and *Lemna gibba* (OECD 221). However, the responses of non-standard macrophytes to such benchmarks are still largely unknown. In this study, eight non-standard macrophyte species, including both monocotyledonous and dicotyledonous plants as well as free-floating, emergent and submergent species, were exposed to 3,5-DCP. Effect concentrations derived from standard tests with *Lemna gibba* and *Myriophyllum spicatum* were used as reference points to investigate whether the sensitivity of the various non-standard macrophyte species differs from that of the two standard species. The study supports the evaluation of additional macrophytes for potential inclusion in aquatic risk assessment and provides a reference-based framework, including a Species Sensitivity Distribution (SSD) for validating their use in future testing strategies.

2.01.P-Tu060 Chronic Effects of PFOA and Microplastics on Earthworms and Freshwater Snails: Ecotoxicological and Host-Parasite Outcomes

Lorena Oliveira Souza Soares¹, Evelyn Oliveira da Silva Nicolau¹, Fábio Veríssimo Correia², Ronaldo de Carvalho Augusto³ and **Enrico Mendes-Saggioro⁴**, (1)Laboratory for Environmental Health Assessment and Promotion, Oswaldo Cruz Institute, Brazil, (2)Department of Natural Sciences, Federal University of the State of Rio de Janeiro, Rio de Janeiro, Brazil, (3)Interactions Hosts-Pathogens-Environments, UMR 5244, University of Perpignan Via Domitia, CNRS, IFREMER, Perpignan, France, France, (4)Oswaldo Cruz Foundation (Fiocruz), Brazil

The intensification of human activities has increased the presence of persistent contaminants, such as perfluorooctanoic acid (PFOA), a perfluoroalkyl substance, and polyethylene (PE) microplastics, which can affect terrestrial and aquatic organisms. This study aimed to evaluate the chronic effects of these contaminants, individually and in combination, on organisms from different trophic levels and habitats: sublethal responses in the earthworm *Eisenia andrei* and survival, reproduction, and host-parasite interactions in the freshwater snail *Biomphalaria glabrata* and its parasite *Schistosoma mansoni*.

In terrestrial assays, *E. andrei* was exposed to PFOA in control soil following ASTM E1676-2, using environmentally relevant concentrations (125, 250, 500, and 1000 µg·kg⁻¹). Each replicate contained 10 organisms for 56 days. Monitoring included weekly biomass measurements, fortnightly sampling, and analyses of cytotoxicity, oxidative biomarkers, and enzymatic activity, allowing the identification of physiological and immune responses to the contaminant.

For *B. glabrata*, exclusively chronic assays were conducted. Snails were exposed to PFOA (3 µg·L⁻¹), PE (3.4 mg·L⁻¹), or the PFOA + PE mixture under controlled temperature, light, and water quality for 21 days, after which they were split into infected (with *S. mansoni* miracidia) and non-infected groups. Both groups remained under exposure conditions for up to 100 days, allowing prolonged monitoring of survival, reproduction, and, in the infected group, cercarial release.

Results in earthworms showed alterations in coelomocyte density and profiles, suggesting immune activation and possible physiological stress. Antioxidant enzymes were modulated, indicating redox system imbalances, while acetylcholinesterase activity revealed potential neurotoxic effects depending on concentration and exposure time. In *B. glabrata*, the PFOA + PE mixture reduced cercarial release, indicating interference in the parasite life cycle. Reproductive changes and survival variations were also observed, demonstrating prolonged effects of chronic exposure.

These findings show that PFOA and PE, alone or combined, induce complex physiological responses in different organisms, with ecotoxicological implications and potential impacts on host-parasite interactions. The results highlight the need for integrated assessments to understand environmental and health risks associated with persistent contaminants from a One Health perspective.

2.01.P-Tu061 CropLife Europe Proposal for Specific Protection Goals for Non-Target Terrestrial Plants Risk Assessment

Rena Jutta Irene Isemer¹, Giovanna Meregalli², Joanna Davies³, Christoph Mayer⁴, Thomas G. Preuss¹, Christine Mihan¹, Heidi Cunningham³ and Christian Bogen¹, (1)Bayer AG, Germany, (2)Corteva Agriscience, Italy, (3)Product Safety, Syngenta Ltd, United Kingdom, (4)BASF, Germany

To approve Plant Protection Products (PPPs) under Regulation (EC) No 1107/2009, the absence of unacceptable environmental effects must be demonstrated. Specific Protection Goals (SPGs) translate this General Protection Goal into practical guidance for Non-Target Organism risk assessments, including Non-Target Terrestrial Plants (NTTPs). As EFSA was mandated in 2024 to develop an NTTP Guidance Document, CropLife Europe experts have developed a proposal for SPGs for NTTPs to support this work.

The first step in setting SPGs is identifying ESS (Ecosystem Services) provided by NTTPs which are relevant for agriculture. According to EC guidance (2024), the relevant ESS assigned to NTTPs is the supporting service “habitat for species”. Protecting the ecological entity of NTTP communities ensures maintenance of this ESS. The ecological entity determines the attribute to be protected. For communities, it is proposed to protect plant species diversity and biomass. Biomass is a pragmatic attribute for the habitat function which can be addressed in testing and modelling and accordingly is preferred over species diversity. SPGs for NTTPs apply only off-field as requested by the EC mandate (2024). Accordingly, the main exposure route for NTTPs is via drift to areas beyond the field boundary. In addition, SPGs for the landscape level will be presented.

SPGs must be achievable under typical productive farming conditions. Typical agricultural practices such as soil tillage, mowing, or fertilizer-application can significantly impact NTTPs. Plant communities directly adjacent to arable fields are often species-poor and mostly contain species that are very abundant such as grasses. In this context, it has to be noted that the mandate to EFSA addresses common plant species of the agricultural landscape while rare and endangered species fall under other existing jurisdictions that are focused on

conservation. Accordingly, it is essential to take into account the baseline of what needs to be protected when setting SPGs. Otherwise, the translation of the SPGs into regulatory testing and a workable risk assessment is impossible.

SPGs for Non-Target Arthropods and soil organisms are also proposed and will be presented in separate posters at this conference.

2.01.P-Tu062 Data on 3,5-Dichlorophenol in Standard and Non-Standard Algae Species, an SSD Evaluation

Sara P. Cuellar-Bermudez¹, Gundula Gonsior¹, Maren Dill¹ and Guido Gonsior², (1)GG BioTech Design GmbH, Germany, (2)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany

The term algae usually refers to a group of photosynthetic microorganisms, including green microalgae, cyanobacteria, and diatoms. Algae are key in toxicological studies to measure the impact of substances on aquatic ecosystems. Several guidelines (OECD, ISO, OCSPP) serve as standardized procedures to evaluate specific species, namely the freshwater species *Raphidocelis subcapitata*, *Desmodesmus subspicatus*, *Navicula pelliculosa*, *Anabaena flos-aquae*, *Synechococcus leopoliensis*, and the marine species *Skeletonema* sp. and *Phaeodactylum tricornutum*. The chemical 3,5-Dichlorophenol (3,5-DCP) is used as a standard substance to determine effective concentrations (e.g., EC50), and some data is already available for a few of the species previously listed. In this study, we aimed to compare the effects of 3,5-DCP in standard species and additional non-standard species to determine how different the effective concentrations are among the species. We also provide an analysis of the validity criteria based on the different guidelines and the role of non-standard species in further toxicological studies.

2.01.P-Tu063 Development and Relevance of Overspray Tests for Aquatic Plants

Bastian H. Polst¹, Ruth Albuquerque², Eric Bruns³, Joanna Davies⁴, Graeme Last⁵, Amelia Griffith⁶, Kirsten McVean⁷, Joern Roesner⁸, Inge Van der Linden⁹ and Magali Solé¹⁰, (1)Wageningen University and Research (WUR), Netherlands, (2)BASF, United Kingdom, (3)Bayer Research & Development Services LLC, Germany, (4)Product Safety, Syngenta Ltd, United Kingdom, (5)Corteva Agriscience, United Kingdom, (6)Eurofins Agriscience Services, United States, (7)Noack Laboratorien, Sarstedt, Germany, (8)DHD-Consulting GmbH, Germany, (9)Federal Public Service (FPS) Health, Food Chain Safety and Environment, Belgium, (10)German Environment Agency (UBA), Germany

During the latest EU renewal of glyphosate, the risk assessment for aquatic plants from foliar exposure via spray drift could not be finalised. Current ecotoxicological studies on floating plants, such as *Lemna* spp., focus on exposure via the water phase (e.g., OECD TG 221) and may therefore not consider further and concurrent direct foliar/ contact exposure conditions from spray drift onto floating or emergent aquatic plants.

Conversely, the plant risk assessment already evaluates the risk of spray drift to non-target terrestrial plants (NTTP), e.g. OECD TG 227. However, it remains unclear whether the outcome of this assessment sufficiently covers the risk to aquatic plant species through similar foliar exposure. To clarify this issue and address the pending regulatory gap, a dedicated SETAC working group was established to: (1) develop a standardized protocol for an overspray test for the standard species *Lemna* sp., and (2) determine to what extent this exposure scenario is already covered by current NTTP risk assessment.

Here we present the group's progress, including (I) gap analysis and literature review, (II) protocol development, (III) key methodological issues for harmonized conducts and (IV) consideration of an interlaboratory validation. The proposed method builds upon OECD TG 221 principles while introducing controlled overspray application consistent with OECD TG 227.

Ultimately, this effort aims to establish a scientifically robust basis for assessing direct spray exposure to floating and emergent aquatic plants, thereby enabling a two-dimensional (2D) aquatic risk assessment comparable to the NTTP-approach in addition to the already established three-dimensional (3D) aquatic assessment. The resulting protocol may support future OECD guideline developments.

2.01.P-Tu064 Ecotoxicological evaluation of lead concentrations typical of Lithuanian shooting ranges using different functional groups

Gintare Sujetoviene, Diana Miškelytė, Austra Dikšaitytė, Giedrė Kacienė and Jurate Zaltauskaite, Vytautas Magnus University, Lithuania

Shooting ranges represent persistent point sources of lead (Pb) pollution, with soil concentrations in Lithuania frequently reaching levels capable of impairing terrestrial biota. To assess the ecological risks associated with such contamination, this study evaluated the effects of Pb-amended soils corresponding to concentrations

documented at Lithuanian shooting ranges. Soils were spiked with a gradient of Pb levels reflecting both average and hotspot. Ecotoxicity was assessed using earthworms, plants, and soil microbial activity, representing different trophic levels and functional groups within the terrestrial ecosystem. The study indicated concentration-dependent biological effects across all organism groups, with significant reductions in earthworm reproduction and plant root elongation at Pb levels corresponding to heavily contaminated Lithuanian sites. Microbial activity showed marked inhibition, particularly at concentrations aligning with shooting-range hotspots, underscoring Pb bioavailability as a key driver of toxicity. The combined chemical–biological approach highlights the importance of integrating bioavailability and organism-level effects for risk characterization. This framework supports improved ecological risk assessment of shooting ranges and informs management actions aimed at mitigating Pb exposure in terrestrial ecosystems.

2.01.P-Tu065 Ecotoxicological Test Protocol for the Assessment of Reproductive Endpoints in Non-Target Terrestrial Plants under Greenhouse Conditions

Andreas Duffner¹, Bianca Flickinger², Fernando Huerta³, Holger Teresiak⁴, Joanna Davies⁵, Lucia Privitera⁶ and Christine Mihan⁷, (1)Eurofins Agroscience Services Ecotox GmbH, Germany, (2)BASF, Germany, (3)Eurofins Trialcamp S.L.U., Spain, (4)Agro-Check, Germany, (5)Product Safety, Syngenta Ltd, United Kingdom, (6)AgroChemex Environmental Ltd., United Kingdom, (7)Bayer AG, Germany

Ecotoxicological testing of plant protection products (PPP) on non-target terrestrial plants (NTTPs) under greenhouse conditions is usually performed according to OECD 208 and OECD 227 guidelines. EFSA's 2014 Scientific Opinion highlighted a potential need to assess effects on plant reproduction and a new Guidance Document for Non-target terrestrial plants is currently being developed, likely adding complexity to current risk assessment approaches.

Literature reviews and experimental studies have examined the feasibility and relevance of reproductive endpoints. Results indicate that (a) assessment in selected species is technically possible, (b) there is no consistent evidence that reproductive endpoints are more sensitive than vegetative ones, and (c) sensitivity may vary depending on factors such as PPP mode of action or plant species.

When regulatory requirements demand evaluation of reproductive effects, the lack of a standardized protocol remains a major challenge. To address this, a SETAC Plant Interest Group working team compiled available data and practical experience to develop a greenhouse test protocol for reproductive endpoints in NTTPs.

Currently, comments from external reviewers are being analyzed to refine the protocol. The final version will be made openly accessible to ensure transparency and broad usability.

This poster will present the proposed protocol and highlight key challenges and considerations, including extended test duration, species and endpoint selection, and robust statistical evaluation. These aspects are critical for reproducibility, regulatory acceptance, and scientific relevance.

2.01.P-Tu066 Effects of Detergents on Macrophyte Standard Species

Marcel Kahlke¹, **Theresa Graf¹**, Rabea Christmann¹ and Guido Gonsior², (1)GG BioTech Design GmbH, Germany, (2)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany

Growing populations and increasing household consumptions are leading to higher use of laundry detergents, resulting in greater inputs of complex chemical mixtures into aquatic environments. Current EU regulations do not require full disclosure of all components, complicating ecological assessment. Furthermore, toxicity testing is typically only conducted on individual components rather than on the complete detergent formulation. Some substances are persistent and may negatively affect aquatic plants. Yet, regulatory assessments rely almost exclusively on *Lemna* species, while submersed macrophytes such as *Myriophyllum spicatum* remain largely overlooked. Therefore, we tested several commercial detergents, including eco-labelled products following current OECD macrophyte growth inhibition guidelines 239 and 221. Our results highlight the need for greater transparency in detergent composition and for macrophyte-specific endpoints in aquatic risk assessment. The work aims to improve understanding of macrophyte sensitivity to consumer product mixtures and to inform future discussions on ingredient transparency and aquatic risk assessment.

2.01.P-Tu067 Interactive Effects of Warming and Chemical Stressors on Freshwater Aquatic Ecosystems: Regulatory Integration and Applied Management Under Climate Change

We analyzed research from 2018 to 2025 on the impacts of pesticides and climate change on aquatic invertebrates, including mayflies, midges, and dragonflies in European surface waters. Results suggest effects on toxicity, chemical fate, community responses, and recovery, particularly within temperature ranges of 15–35°C. We furthermore compared current EU regulatory guidelines with climate data, revealing gaps in protection.

Climate warming and pesticide pollution pose combined, significant threats to aquatic ecosystems, emphasizing the importance of climate-informed risk assessments and sustainable farming practices. Elevated temperatures can increase the toxicity of insecticides through metabolic pathways, as indicated by Arrhenius coefficients, which are not yet incorporated into EU risk assessments. While the Water Framework Directive aims to establish pesticide standards, it currently overlooks temperature effects. Pesticides such as imidacloprid have been detected at concentrations exceeding regulatory limits, underlining the need for monitoring and supporting climate change mitigation. Temperature furthermore influences pesticide persistence via pathways including reduced oxygen, pH shifts, algal growth, and vapor pressure changes, affecting hydrolysis, degradation, photolysis, and volatilization, with some chemicals volatilizing more readily while others persist longer. Seasonal peaks in insecticide levels are driven by climate-dependent cycles of sorption and desorption, necessitating dynamic risk assessment approaches.

Phenological disruptions due to temperature changes can furthermore exacerbate chemical toxicity, potentially causing mismatches between insect emergence and habitat availability, which may threaten populations. Recovery of communities exposed to neonicotinoids is slow, with populations remaining depressed at concentrations above 1 µg/L for years and community structures permanently altered. Effective management across scales—such as riparian buffer zones and wetland restoration—can mitigate runoff and enhance resilience.

We therefore advocate policy updates to include mandatory chemical and biological monitoring, with future assessments incorporating climate scenarios, temperature-dependent toxicity, and heatwave impacts. Achieving the 2030 targets and EU standards requires integrated policies to reduce pesticide use, restore ecosystems, and adapt regulations to climate impacts.

2.01.P-Tu068 Multiscale Satellite–UAV Assessment of Vegetation Stress Following Chemical Exposure Events

*Sang Don Kim¹ and **DONG GEUN SONG²**, (1)Gwangju Institute of Science and Technology (GIST), Korea, Republic of, (2)School of Earth Science and Environmental Engineering, Gwangju Institute of Science and Technology (GIST), Korea, Republic of*

Chemical exposure incidents can cause rapid, spatially uneven damage to terrestrial vegetation. Conventional monitoring approaches often struggle to capture the full extent and severity of these impacts, which can lead to underestimation or misinterpretation of ecological risk. Field-based surveys are time- and labor-intensive, and when used alone they cover only limited areas. Remote sensing from a single platform can either miss fine-scale disturbance or lack the regional coverage needed to understand broader patterns. This study addresses these limitations by developing a multiscale framework that combines satellite imagery, such as Sentinel-2, with unmanned aerial vehicle (UAV) multispectral data to evaluate vegetation stress after chemical exposure. Satellite observations are used to describe broad-scale vegetation patterns before the exposure event or, if pre-event data are limited, to infer typical background conditions from nearby unaffected areas. From pre- and post-exposure images, key vegetation indices—the Normalized Difference Vegetation Index (NDVI), the Normalized Difference Red Edge index (NDRE), and the Green Chlorophyll Index (GCI)—are calculated to quantify changes in canopy condition. Index distributions are summarized using descriptive statistics, and threshold-based classes are applied to separate vegetation that appears unaffected, under stress, or clearly damaged. Comparisons across scales show that satellite data alone tend to underestimate or miss localized disturbances, such as edge effects along water bodies and small patch-level damage within fields, that are clearly visible in

high-resolution UAV imagery. Initial applications indicate that integrating satellite and UAV data improves both the spatial detail and the reliability of vegetation stress maps, with UAV data helping to validate and refine patterns derived from satellite images. The proposed framework links remotely sensed vegetation indices with spatial patterns of chemical impact and provides a practical tool for interpreting plant responses at the landscape scale, supporting plant ecotoxicology studies, ecological risk assessment, and more effective environmental management after chemical exposure events.

2.01.P-Tu069 Role of Mosses in Soil Organic Carbon Storage Under Heavy Metal Deposition in Coniferous Forests

Linee Goswami¹ and Ingrid Rijk², (1)Örebro University, Sweden, (2)School of Science and Technology, Örebro University, Örebro, Sweden

Traditional risk assessment methodologies often encounter difficulties due to the limited understanding of how metal pollutants impact soil ecosystems and their functions. Our study examines the long-term effects of, and recovery from, metal air pollution - specifically copper (Cu), zinc (Zn), and lead (Pb) - on soil organic carbon (C) storage within coniferous forests. The study area is located near a brass smelter in Gusum, Östergötland, Sweden, a site with a history of over 300 years of industrial activity. Notably, in 1982, the smelter was relocated 1 km away and its emissions were significantly reduced. Historically, the forests and their soils, including mosses, were thoroughly investigated from the 1970s up to 1994. This provides a unique opportunity to evaluate both the impacts of and recovery from prolonged heavy metal pollution. For this study, previously sampled sites in old-grown mixed coniferous forests were revisited. The research involved analysis of changes in moss and shrub cover, as well as the contents and isotopic signatures of organic carbon (C), nitrogen (N), and metals in soils, needles, and mosses.

Findings revealed that moss cover has shown signs of recovery and that contents of metals in mosses and the upper soil layers have decreased. However, persistent contamination remains evident in areas situated closer to 500 metres from the relocated smelter. Multivariate (Partial Least Squares regression - PLS) modelling highlighted the significant role of moss and shrub presence in total soil carbon storage and in the recovery process from air pollution.

This study is focused on improving methods for ecological risk assessment in metal-contaminated soils by employing site-specific strategies. This comprehensive onsite evaluation bridges a critical knowledge gap, as it challenges the common practice of removing contaminated soils without accounting for the ecosystem's inherent ability to recover from long-term metal pollution. Furthermore, the study underscores the vital role played by ground-covering mosses as a driver in ecosystem restoration and soil carbon dynamics within coniferous forests - an often-overlooked group of plants that are notably sensitive to metal contamination.

2.01.P-Tu070 Sensitivity of Aquatic Macrophytes to Copper: Comparing Functional and Structural Endpoints

Omar Orozco¹ and Nina Cedergreen², (1)University of Copenhagen, Denmark, (2)Plant and Environmental Sciences, University of Copenhagen, Denmark

This study assessed copper toxicity in six submerged macrophyte species representing diverse ecological traits and carbon acquisition strategies by comparing two endpoints: functional (oxygen production as a proxy for photosynthesis) and structural (relative growth rate). This work aimed to determine how endpoint selection (functional vs structural) and exposure duration shape the estimation of copper toxicity in macrophytes. Static 14-day tests were conducted with five copper concentrations (11–900 µg/L), and responses were

normalized to controls. Dose–response curves were modeled using a two-parameter log-logistic function to estimate EC_x values (EC₅₀). Species sensitivity distributions (SSDs) were then derived for both endpoints to calculate protective concentrations (HC₅). Functional indicators consistently exhibited earlier and stronger responses than structural ones. At day 7, oxygen production in the species *Elodea nuttallii* showed the highest sensitivity (EC₅₀ = 19 µg/L), while growth remained largely unaffected. By day 14, inhibition intensified across most species, confirming cumulative stress under static exposure. SSD analysis reflected these patterns: HC₅ values for oxygen were 22.7 µg/L (day 7) and 27.9 µg/L (day 14), compared to 38.2 and 72.2 µg/L for relative growth rate. These findings underscore the relevance of functional endpoints for early detection and their integration into ecological risk assessment frameworks.

2.01.P-Tu071 Terrestrial Eco-toxicological Effects of Typical Tire Rubber Antioxidants and Derivation of Their Environmental Criteria

Jinlin Jiang¹, Hao Zhang² and Tao Long¹, (1)*Nanjing Institute of Environmental Sciences, Ministry of Ecology and Environment, China (Mainland)*, (2)*Hohai University, China (Mainland)*

The tire rubber antioxidant N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD) and its transformation product, 6PPD-quinone (6PPD-Q), are emerging contaminants of concern. Although their toxicity toward aquatic organisms has been widely documented, their ecotoxicological effects on terrestrial species remain poorly understood, hindering the development of terrestrial environmental criteria due to a lack of relevant toxicological data. To address this gap, this study evaluated the toxicological effects and uptake-translocation mechanisms of 6PPD and 6PPD-Q in rice plants (*Oryza sativa*). In parallel, we compiled existing aquatic toxicity data for both compounds to derive their short- and long-term water quality criteria (WQC). Using both root and foliar exposure assays, we observed that 1 mg/L 6PPD and 0.5 mg/L 6PPD-Q induced significant phytotoxicity in rice, affecting key metabolic pathways and impairing growth traits. Subsequent analysis revealed that 6PPD exhibited a higher bioaccumulation potential in both roots and leaves. In contrast, 6PPD-Q showed limited translocation from shoots to roots under foliar exposure, with a pronounced tendency to accumulate in leaf tissues.

To supplement gaps in acute toxicity data for 6PPD-Q, we applied quantitative structure-activity relationship (QSAR) and interspecies correlation estimation (ICE) models. Using a species sensitivity distribution (SSD) approach, short-term and long-term WQC values were derived. The WQC for 6PPD were 26.02 µg/L (short-term) and 4.30 µg/L (long-term), suggesting an acceptable level of ecological risk. In contrast, the stringent WQC for 6PPD-Q — 0.20 µg/L (short-term) and 0.15 µg/L (long-term) — underscore its substantial ecological risk, highlighting an urgent need for regulatory attention.

2.01.P-Tu072 Testing Aquatic Macrophyte Growth Inhibition in 10 Species Simultaneously - Combining SSD and Time-variable Exposure Outdoors.

Guido Gonsior¹, Steve Norman², Seamus Taylor³ and Rabea Christmann⁴, (1)*Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany*, (2)*RidgewayEco, United Kingdom*, (3)*ADAMA, Germany*, (4)*GG BioTech Design GmbH, Germany*

Aquatic plants are sensitive to herbicides. Standard laboratory tests expose single species to constant concentrations of herbicide. Whereas our outdoor study focused on effects in multiple species for realistic time-variable concentrations. The study was based on OECD Guideline 239: Water-Sediment-Macrophyte Toxicity Test. Growth inhibition compared to controls was determined in 10 species for 14 days. The test established an EC₅₀ for each species and a Species Sensitivity Distribution (SSD) under realistic exposure. We present results showing that OECD validity criteria were satisfied, providing robust growth endpoints. Time-variable profiles were characterised by chemical analysis to enable comparison with FOCUS-modelled exposures in edge-of-field waters.

2.01.P-Tu073 The Effect Testing Toolbox for Non-Target Terrestrial Plant Risk Assessment: what is in and what is missing?

Sebastian Fellmann¹ and Rena Jutta Irene Isemer², (1)*Bayer AG, Germany*, (2)*Crop Science, Bayer CropScience AG, Germany*

The standard European environmental risk assessment (RA) for plant protection products in the area of Non-Target Terrestrial Plants (NTTPs) follows the Guidance Document on Terrestrial Ecotoxicology and is based on two OECD test methods (OECD 208&227). In 2014, the European Safety Authority (EFSA) published the Scientific Opinion addressing the state of the science on risk assessment of plant protection products for NTTPs where additional and/or higher tier testing options were discussed for their relevance for the NTTP RA. The list comprises pre-screening, open literature and efficacy data, and refined laboratory, semi-field and field studies. Testing reproductive parameters, non-crop (wild) species, and plant or species interactions were also discussed. No harmonized test guidelines are available for these additional studies. Since 2014, novel NTTP study designs have been developed that may support refining the RA and/or informing an NTTP reference tier. An NTTP Effect Testing Toolbox comprising laboratory bioassays, greenhouse studies, semi-field and field trials, and predictive modeling approaches was assembled. The present work provides a first attempt at systematically analysing the NTTP Effect Testing Toolbox regarding advantages and disadvantages of study designs based on whether they are fit-for-purpose, feasible, and proportionate. Some novel methods should be taken into account for the mandated Terrestrial Guidance Document review by EFSA. As the availability of harmonized test methods is key, this was evaluated as well and showed a gap for standardized methodologies for higher tier assessments and improved predictive modeling techniques, along with collaborative efforts for data sharing across Europe. We propose integrating intermediate tier testing and modeling methods to balance precision with ecological relevance. The size of the assessment factor used to address remaining uncertainties in the NTTP RA is expected to be discussed in the Terrestrial Guidance Document review by EFSA. To define an assessment factor, a reference tier for a sufficient number of plant species and plant protection products is needed. The NTTP Effect Testing Toolbox is evaluated regarding usability of the listed study designs to deliver a reference tier. Further work, involving all stakeholders, is needed.

2.01.P-Tu074 The Impact of Selected Chemicals on Various Species of Freshwater Alga and Cyanobacteria

Katarzyna Winiarska and Joanna Gilowska, Lukaszewicz Research Network - Institute of Industrial Organic Chemistry, Poland

The increasing number of chemical substances released into the environment poses a significant challenge for aquatic ecosystems. Many of these compounds can affect primary producers, disrupting ecological balance and food web dynamics. Algae, as key organisms in aquatic ecosystems, are highly sensitive to chemical stressors and serve as reliable indicators of environmental toxicity. They form the basis of the aquatic food chain, directly supporting herbivorous organisms.

In this study, we assessed the inhibitory effects of selected chemicals on the growth of freshwater green algae and cyanobacteria under controlled laboratory conditions. For each group, four chemical substances were tested using standardized growth inhibition assays. The No Observed Effect Concentration (NOEC) values were determined for all tested compounds, and concentration–effect relationships for yield and growth rate were analyzed to illustrate species-specific responses.

The tests were conducted in accordance with OECD Guideline 201 for algal growth inhibition, but using species other than those recommended in the guideline: *Synechococcus leopoliensis* (cyanobacteria), *Chlorella vulgaris* and *Tetrademus obliquus* (green algae). Our results revealed pronounced differences in tolerance between taxonomic groups, with cyanobacteria being less sensitive than green algae. These findings contribute to a better understanding of chemical stressors in aquatic ecosystems and support the development of more accurate environmental risk assessment strategies.

2.01.P-Tu075 The Intriguing Use of Plant Visual Injury Symptoms in Ecotoxicology

Pernille Thorbek¹, Ruth Albuquerque², Daniel E. Edwards³, Bianca Flickinger⁴, Christoph Mayer⁴ and Dhruvkumar Mukeshbhai Savaliya⁴, (1)Apd/EE, BASF, United Kingdom, (2)BASF, United Kingdom, (3)BASF, United States, (4)BASF, Germany

Current regulatory testing for non-target plants is based on the test guidelines from OECD and the OCSPP 850.4000 series.

Qualitative observations of plant visual injury (PVI) by the unaided eye have been included in non-target terrestrial plant (NTTP) and macrophyte studies for many years. PVI document observations of effects after treatment with plant protection products in addition to the standard quantitative parameters (weight, height etc.). Historically, PVI was developed for screening of plant health based on methodology evolved from Weed Scientists with deep expertise in PVI over an extensive range of terrestrial plant species. As PVI is quicker to assess than biomass / height, the Tier 1 OECD 208/227 (and respective OCSPP guidance) also use PVI for PPPs to determine if a Tier 2 study is required (>50% effect trigger). PVI provide evidence to support that

quantitative injury is indeed caused by the plant protection product and not unrelated stresses such as disease, insects or nutrient deficiency.

Recently, member states from the European Central Zone made requests for statistical calculation of ECx for NTTP PVI endpoints to be used in the risk assessment. This reflects a precautionary approach addressing the EU concern that existing quantitative endpoints potentially may not fully cover the risk to plants. However, statistical calculation of ECx PVI within the studies may create a mismatch with the OCPPTS 850.4000 series which generally considers visual ratings as qualitative data.

We understand that there is a great uncertainty about what the PVI results reported in NTP studies mean for plant health and how these results can best be considered in the risk assessment. However, while PVI ratings appear quantitative when expressed in percent damage, they are in fact closer to an ordinal scale and calculating ECx values from visual ratings may violate assumptions for dose-response models (which is the topic of a separate poster).

The main value of PVI ratings is that it can provide quick and valuable information for the interpretation of the study results. However, guidance and standardized, ring-tested procedures are missing for NTTP and aquatic macrophytes.

Therefore, the poster will focus the discussion on how PVI could be classified and contextualized alongside the quantitative endpoints of the studies for an improved assessment and use in risk assessment.

2.01.P-Tu076 The new OECD Test Guideline No. 239 - a Comparison with the Previous Version

Maren Dill¹ and **Guido Gonsior²**, (1)GG BioTech Design GmbH, Germany, (2)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany

The OECD test guideline 239 describes the water-sediment toxicity test with the rooted aquatic plant *Myriophyllum spicatum*. On June 25th in 2025 a revised version was published. Further, there are still ongoing discussions about additional parameters.

We present an historical insight based on the conducted ring tests and discuss the most relevant differences of the two versions.

2.01.P-Tu077 TKTD modeling of semi-static algae tests with time-variable herbicide exposure – data handling and evaluation of statistical endpoints

Natalie Albrecht¹, **Tido Strauss¹**, **Kim Rakel¹**, **Eric Bruns²**, **Jutta Hager²**, **Thomas G. Preuss²**, **Seamus Taylor³** and **Johannes Witt²**, (1)gaiac eco assessment GmbH, Germany, (2)Bayer AG, Germany, (3)ADAMA, United Kingdom

Ecotoxicological tests with planktonic algae are an integral part of an informed risk assessment of plant protection products (PPPs). Recent test developments now also allow the evaluation of toxic effects of time-variable peak exposures. Toxicokinetic-toxicodynamic (TKTD) models are increasingly being used to investigate and predict the effects of time-varying exposure concentrations of PPPs on aquatic organisms and can now also be applied to these refined algal tests.

We conducted peak exposure laboratory studies with the green alga *Raphidocelis subcapitata* exposed to the herbicide diflufenican, using a semi-static approach with a series of filtration and resuspension steps to examine exposure patterns with varying peak duration and intervals based on the OECD guideline 201 (Freshwater Alga Growth Inhibition Test). We applied the software tool ‘cvasi’ (calibration, validation and simulation of TKTD models in R) to evaluate the experimental algae data. Due to their exponential growth in unlimited tests, phytoplankton often show biomass increases over two orders of magnitude, raising the question of logarithmic data transformation.

We will show experimental results of a test series and the TKTD model calibration and validation outcome and discuss the effect of data transformation on different statistical model quality endpoints.

2.01.P-Tu078 Visual Injuries in Aquatic Plants: Gaps, Challenges, and Recommendations from a retrospective Assessment of Study Records

Katrin Kuhl¹, **Bastian H. Polst²**, **Gertie Arts²** and **Andreas Solga¹**, (1)Bayer AG, CropScience, Germany, (2)Wageningen University and Research (WUR), Netherlands

Visual injuries (phytotoxicity) in aquatic plants are gaining increasingly regulatory interest in the risk assessment of plant protection products. Yet a clear, validated evaluation scheme is still lacking. To support the development of new protocols, experimental approaches, and evaluation schemes, we analyzed existing registration study records available at Bayer AG, covering more than 500 GLP *Lemna*-studies dating back to the

1980s.

Our aim is to evaluate which types of phytotoxic effects have been observed, which assessment scales (qualitative vs. quantitative) were applied, and how severity and prevalence were recorded across studies. This allows us to identify evaluation schemes that have proven effective and robust, as well as reveal gaps in past and current assessment practices.

We found a general lack of quantitative data, likely caused by the omission of quantitative assessments in the respective test guidelines (e.g. OECD 221). Visual injuries were mostly recorded qualitatively and often without a clear indication of severity (e.g., slight, moderate, strong) or prevalence (e.g., number or share of affected fronds). In several cases, ordinal scales (e.g. for frond color: dark green, light green, yellow) were used without adequate context or differentiation to related injuries (e.g., chlorosis). Understanding these subtle differences is crucial for enabling a quantitative comparison with conventional (e.g., frond number, dry weight) endpoints. Based on these insights, we provide first recommendations towards a harmonized assessment framework for visual injuries in aquatic plants and highlight the need to relate visual injuries to ecologically relevant effects impacting growth and survival of aquatic plants. Upon completion, the assessment of our dataset will help to define standardized criteria for assessing visual injuries, enable quantitative evaluation of severity and prevalence, and improve consistency in future regulatory assessments.

2.01.P-Tu080 Investigating Alternative Treatment Strategies for Harmful Algal Blooms

Andrew Barrick¹, Ben Beck² and Tham C. Hoang¹, (1)Auburn University, (2)USDA-ARS, Aquatic Animal Health Research Unit, United States

Copper-based herbicides are commonly used to treat harmful algal blooms (HABs) as they are more effective and affordable than other treatment options. A limitation of copper is that it rapidly complexes with organic material in aquaculture ponds and precipitates into sediment. Over time, copper can accumulate and contaminate pond systems. This presentation outlines research conducted at Auburn University that explores alternative treatment approaches for treating cyanobacteria. This includes characterizing the efficacy of organic herbicides and developing high throughput testing to explore whether herbicides mixtures were more effective than copper sulfate. Two cyanobacterial genera, *Anabaena* and *Microcystis*, which commonly bloom were treated with 15 different herbicides to identify efficacy. Herbicide mixtures were tested using high-throughput screening to determine if mixtures were more effective than single herbicides alone. Results identified five alternative chemicals (bispiribac sodium, diuron, diquat, hydrogen peroxide, and penoxsulam) that reduced cyanobacterial growth with diuron and penoxsulam being effective at a low concentration for *Anabaena* and diuron being effective against *Microcystis*. Mixture studies demonstrated that most copper: organic herbicide mixtures were either antagonistic or additive and copper: diquat mixtures were synergistic. Results of the study suggested that diuron and penoxsulam may be effective alternatives to copper, however considerations need to be made regarding their environmental impact. The study also identified that while copper: diquat mixtures were more effective, increases in efficacy were likely not offset by the cost of the treatment approach when compared to copper.

2.01.P-Tu081 Toxic Effects of Ciprofloxacin and Sulfamethoxazole on Crustaceans, a Marine Diatom, and a Freshwater Plant

Marianna Pauletto, Edoardo Pietropoli, Rebecca Zgheib, Marco Selmo, Giacomo Melotto, Rosa Maria Lopparelli, Lorena Lucatello and Marco De Liguoro, Department of Comparative Biomedicine and Food Science (BCA), University of Padova, Italy

Pharmaceuticals are essential for human and animal health, but when excreted or improperly disposed of, they can harm the environment. Antibiotics like ciprofloxacin (CIP) and sulfamethoxazole (SMX) are particularly harmful as they persist in surface waters, where they can harm non-target organisms, including crustaceans, algae and aquatic plants. To provide a clearer understanding of the environmental impacts of these antibiotics, the present study investigates the toxicity of CIP and SMX on two primary consumers, the crustaceans *Daphnia magna* and *Artemia salina*, and two primary producers, the freshwater plant *Spirodela polyrrhiza* and the marine diatom *Phaeodactylum tricornutum*.

Experimental procedures followed OECD and ISO guidelines, when available, with species-specific adjustments. Toxicity tests included algal and duckweed growth inhibition, acute crustacean immobilisation with 10-day post-exposure follow-up, and embryo hatching assays. Endpoints measured encompassed growth, survival, morphological abnormalities, and frond/root metrics via microscopy and image analysis. CIP and SMX stability were confirmed by analysing drug-solution samples collected at the beginning and end of each assay. SMX inhibited *P. tricornutum* growth with an EC₅₀ of 2.69 mg/L²¹, while CIP had no effect. On *S. polyrrhiza*, EC₅₀s ranged 0.77–2.52 mg/L²¹ for SMX and 0.04–0.34 mg/L²¹ for CIP. *A. salina* was largely resistant, though embryos exposed to both antibiotics showed some non-lethal malformations. *D. magna* embryos were moderately sensitive, with EC₅₀s of 41.27 mg/L²¹ (SMX) and 95.93 mg/L²¹ (CIP) and malformations similar to those observed in the brine shrimp. CIP exhibited marked delayed toxicity in *D. magna* juveniles, with EC₅₀

dropping from 47.12 mg/L¹ at 48 h to 14.98 mg/L¹ after 10 days. Finally, both antibiotics slightly reduced daily growth.

Both antibiotics can impact aquatic organisms. *S. polyrhiza* appeared to be the most sensitive organism, while *P. tricornutum* was affected only by SMX. *A. salina* remained largely unaffected, whereas *D. magna* showed intermediate sensitivity. Environmental concentrations, especially of CIP, exceed predicted no-effect levels, highlighting ecological risks to freshwater ecosystems. These results underscore the need for sensitive plant endpoints, extended toxicity tests, and consideration of chronic and mixture exposures in future assessments.

2.02 Combining and Integrating Sustainability and Risk Assessment from Environmental, Social, and Economic Perspectives

2.02.T-01 Towards Robust Decision-Making in Safe and Sustainable by Design (SSbD): Current State and Recommendations for MCDA Integration

Nina van Dulmen¹, Marco Cinelli², Charles Corbett³, Carlos Felipe Blanco¹ and Jeroen Guinée¹, (1)Leiden University, Netherlands, (2)Decision Engineering for Sustainability and Resilience Laboratory, Leiden University College, Faculty Governance and Global Affairs, Leiden University, Netherlands, (3)Anderson School of Management, UCLA, United States

The Chemicals Strategy for Sustainability (CSS) outlines policies towards a toxic-free environment. It promotes Safe and Sustainable by Design (SSbD) as a pre-market approach to chemicals to deliver their essential functionality, but avoid potentially harmful volumes and properties at risk to human and environmental health.

Developing alternative chemicals, materials, or products under the SSbD paradigm requires comprehensive safety and sustainability assessment and the integration of potentially diverging stakeholder perspectives along the life cycle. Integrating decision-support methods like multi-criteria decision analysis (MCDA) is thus advocated, to support comprehensive evaluation over a broad range of criteria and potential trade-offs.

However, guidance is needed for decision-making in complex assessments encompassing a broad scope of chemicals, materials, or product life cycles, a potentially wide range of alternative designs, and numerous safety and sustainability criteria. This study adds to the foundation for future recommendations to guide the implementation of MCDA in SSbD assessments. By reviewing a set of 18 papers performing safety and sustainability assessments together with MCDA, we address the following question: How are various decision-making features (i.e., characteristics that define the MCDA process) present in current studies on safety and sustainability assessment in combination with MCDA, and which aspects require attention for the development and application of MCDA in the SSbD framework?

Our findings reveal six features that are notably essential to address, as, e.g., clearly defining the problem statement and the decision-maker, and justifying the set of criteria and alternatives, for selecting an appropriate MCDA method to the specific problem. At present, these features are insufficiently addressed in literature, and even methodologically unsound combinations of MCDA methods are used. These are main reasons for the call for dedicated guidance on SSbD-related problem characteristics, that are of importance for selecting an MCDA method to ensure suitable decision-making recommendations. Addressing the presented features could help charting the pathway towards methodologically aligned studies, sound results, and appropriate decision support.

In this presentation, we share our insights and outline key decision-making features. Additionally, we provide recommendations for adopting a more structured approach to MCDA in SSbD.

Disclaimer/Disclosure:

This work is part of the project Safe-by-Design Circular Products (with project number NWA.1437.20.106 of the research programme 'Towards a practical Safe-by-Design approach for chemical products and processes') which is (partly) financed by the Dutch Research Council (NWO).

2.02.T-02 Treating Safe and Sustainable-by-Design as a Multi-objective Optimization Problem – Mapping Tradeoffs Using Decision Spaces of Polyethylene Terephthalate and Polylactic Acid

Akshat Sudheshwar¹, Kealie Vogel¹, Tim Borner¹, Claudia Som¹, Roland Hirsch² and Bernd Nowack¹, (1)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (2)Technology & Society Laboratory, Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland

The European Commission's Safe and Sustainable-by-Design (SSbD) framework promotes the integration of human and environmental safety with holistic sustainability assessments. While research combining risk assessment (RA) and life cycle assessment (LCA) is well established, few studies have applied a multi-objective optimization problem (MOOP) approach. Thus, this work formally introduces the first SSbD-MOOP method and demonstrates its application through a case study.

In the case study, a hypothetical product designer compares fossil-based polyethylene terephthalate (PET) and bio-based polylactic acid (PLA) as material options. Over 35,000 lifecycle scenarios were simulated, evaluating sustainability via global warming potential and safety via plastic pollution impacts according to the PPI100 method. The analysis revealed lifecycles with trade-offs between safety and sustainability, as well as scenarios that optimize both through end-of-life recycling. To ensure meaningful material-level comparisons, the study introduces the concept of SSbD decision spaces, highlighting the role of PLA's potential biodegradability when assessing its relative performance to PET. For product designers, this analysis yields several practical recommendations: material choice and end-of-life strategies are critical; circularity should be prioritized; biodegradable polymers should also be recycled; landfill-only markets should be avoided for PLA; and materials should be matched to specific use requirements.

Compared to traditional LCA-RA integration methods, the SSbD-MOOP approach provides a distinct advantage by visually mapping all possible safety and sustainability trade-offs, supporting more informed decision-making. This represents the first structured attempt to embed MOOP within the SSbD framework, with future refinements encouraged to broaden its applicability across diverse innovation contexts.

2.02.T-03 Assessment of Functional Alternatives to Fluorinated Foam Blowing Agents in Insulation Materials

Romain Figuière¹, Olivier Kirik², Rahul Aggarwal³, Gregory Peters³ and Ian Cousins², (1)Department of Environmental science, Stockholm University, Sweden, (2)Stockholm University, Sweden, (3)Chalmers University of Technology, Sweden

By taking the example of the substitution of fluorinated gases used as foam blowing agents in insulation materials as a case study, here we aim to apply and adapt a well-known multi-criteria decision analysis (MCDA) method used for chemical alternatives assessment known as the multi attribute utility theory (MAUT) approach. The functional substitution approach was followed to define the functions delivered by fluorinated gases in insulation materials, and the ZeroPM alternatives database was used to identify functional alternatives. Data on environmental impacts along the life cycle, and the technical performance of the identified alternatives were collected based on previous literature reviews on insulation materials. The MAUT approach was used to compare the different alternatives. Four decision-making scenarios were defined in order to illustrate the flexibility of the MAUT method for the assessment of functional alternatives. Overall, 32 alternative materials to polyethene foams (also known as polyethylene foams) and extruded polystyrene foams containing fluorinated gases were identified. 9 insulation materials were shortlisted for further evaluation based on the amount of data available. Overall, alternatives ranked better than polyethene foams and extruded polystyrene foams in every decision-making scenario tested in this study, suggesting that suitable and safer alternatives to fluorinated gases used in insulation foams can be identified. This work highlights how the choices made by the decision-maker to develop a MAUT model influence the final ranking of the alternatives being evaluated. This might be highly relevant in a regulatory context as the availability of suitable alternatives is a critical part in the decision-making on bans of harmful substances. Although promising in the field of alternatives assessment in a regulatory context, further work is needed to develop appropriate guidance for using MAUT methods to identify suitable alternatives to substances of concern.

2.02.T-04 Are Larger Companies More Sustainable? Quantifying Scaling Relationships Between Company Size And Environmental Indicators

Jie Xiong, Félix Leiva, Louise Schreyers, Steef Hanssen, Birka Wicke and Jan A.J. Hendriks, Department of Environmental Science, Radboud Institute for Biological and Environmental Sciences, Radboud University Nijmegen, The Netherlands, Netherlands

Jie Xiong¹, Félix P. Leiva¹, Louise J. Schreyers¹, Steef V. Hanssen¹, Birka Wicke¹, A. Jan Hendriks¹

¹Department of Environmental Science, Radboud Institute for Biological and Environmental Sciences, Radboud University Nijmegen, 6525 AJ Nijmegen, The Netherlands

E-mail contact: jie.xiong@ru.nl

Quantifying the environmental impact of companies, such as CO₂ emissions, is crucial for assessing their sustainability. Understanding the relationship between company size and environmental indicators can help estimate sustainability impacts. While the importance of "scaling up sustainability" is widely recognized, the fundamental question of how to estimate the sustainability for companies of varying sizes remains. We used data from 14,342 companies worldwide and characterized the scaling relationships for four company size indicators (e.g., revenue, assets, and employees) and 13 environmental indicators (e.g., raw material, CO₂ emission, and total waste). The slopes and coefficients were estimated based on the mixed-effect model. For most environmental indicators (nine out of 13), scaling exponents did not significantly differ from one, indicating that small and large companies perform equally per unit of revenue (€). In addition, accounting for the economic sector of companies improved the explanatory power of the model. This shows that sector-specific characteristics are key in estimating environmental indicators based on company size. This system thinking perspective can hopefully help organizations systematically navigate development interventions involved in tackling scales.

2.02.P Combining and Integrating Sustainability and Risk Assessment from Environmental, Social, and Economic Perspectives

2.02.P-We089 Early-Stage Sustainability Assessment for Bio-Based Benzoxazines Using LCA and Safety Screening

Mariana Ochodkova¹, Leila Bonnaud², Aart Van Vuure³ and Karel Van Acker¹, (1)SAM Research Group, Department of Materials Engineering, KU Leuven, Belgium, (2)Materia Nova, the Innovation Center in Materials of the University of Mons, Belgium, (3)Composite Materials Group, Department of Materials Engineering, KU Leuven, Belgium

Bio-based materials offer a promising and sustainable alternative to materials derived from non-renewable resources, reducing the dependence on fossil fuels. However, it is essential to assess their sustainability during the early design stages to ensure they deliver lower environmental impacts than conventional fossil-based products.

This study demonstrates the integration of life cycle assessment (LCA) into the ecodesign of novel bio-based benzoxazine resins, supporting their development under a Safe and Sustainable by Design (SSbD) approach. First, a hotspot analysis of predominantly fossil-based benzoxazine formulations was conducted to identify key environmental impact drivers and prioritise redesign efforts. Next, a screening of promising bio-based feedstock chemicals was performed to evaluate their environmental profiles and select sustainable candidates for new formulations. Finally, environmental impact data were combined with chemical safety considerations to establish the first iteration of the SSbD framework for benzoxazine resins.

The results reveal potential environmental benefits of bio-based chemicals compared to fossil-based counterparts when substituting fossil-based chemicals with bio-based alternatives, while also highlighting possible trade-offs and critical knowledge gaps that must be addressed to achieve truly safe and sustainable formulations. This work contributes to advancing bio-based resin development by embedding environmental and safety considerations into early-stage design. The research was carried out within the Horizon SSSUCHY-Next project (grant agreement No. 101157517), which aims to develop sustainable and circular high-performance bio-based composites.

Disclaimer/Disclosure:

The research was carried out within the Horizon SSSUCHY-Next project (grant agreement No. 101157517).

2.02.P-We090 Advancing Integrated Sustainability Assessment of chemicals: combining LCA, Risk Analysis and Tools for Safer Industrial Processes

Simone Marzeddu, Fortunata Barone, Giuseppe Granato and Emiliano Panieri, Hazardous Substances Section, Service for environmental education and training and for the technical coordination of Directorate activities (DG-TEC), Italian Institute for Environmental Protection and Research (ISPRA), Italy

Industrial sectors face increasing pressure to align with climate neutrality and pollution prevention targets for 2030 and 2050. Achieving these goals requires methodologies that integrate environmental sustainability assessment with chemical risk management, ensuring compliance with regulatory frameworks such as REACH (Reg. EC 1907/2006) and CLP (Reg. EC n. 1272/2008) and the EU Chemicals Strategy for Sustainability (CSS). This work presents a technical approach for embedding sustainability principles into industrial decision-making by combining Life Cycle Assessment (LCA), hazard-based risk assessment, and sustainable platforms for data integration. The proposed framework enables comparative evaluation of substances and technologic processes across multiple aspects based on the One Health approach and related implications.

Methodologically, the framework identifies prospective LCA to foresee impacts of emerging technologies, integrates Best Available Techniques (BAT) benchmarks, and applies predictive analytics also to support substitution strategies. Greentech plays a key role in harmonizing heterogeneous datasets, improving transparency, and reducing uncertainty.

The case of chemical sector demonstrates how this integrated assessment can identify trade-offs between environmental performance and regulatory compliance, guiding also the adoption of Safe and Sustainable by Design (SSbD) principles. Results highlight critical implementation challenges, including data interoperability, methodological harmonization, and alignment with policy objectives.

In addition to presenting the methodological framework, this contribution introduces the Special Issue “Towards Sustainable Industrial Processes by 2030 and 2050: Technologies, Regulations and Implementation Challenges”, which aims to address research and case studies on regulatory drivers, technological innovation, and environmental implications of the sustainable transition.

Disclaimer/Disclosure:

The authors declare that there are no conflicts of interest. This work was conducted within the institutional framework of ISPRA, without any specific external funding or sponsorship.

2.02.P-We091 Integrating LCA-RA Methods for Environmental Sustainability Assessment of Pharmaceuticals: Supporting Safe and Sustainable by Design and Decision-Making

Chenyue Zhang¹, Rosalie van Zelm¹, Caroline Moermond² and Ad M. J. Ragas¹, (1)Department of Environmental Science, Radboud Institute for Biological and Environmental Sciences (RIBES), Radboud University, Heyendaalseweg 135, 6525 AJ Nijmegen, Netherlands, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands

The ambition to green the pharmaceutical sector requires a system to assess the environmental sustainability of pharmaceutical products. Such a system could build upon existing assessment methods such as Life Cycle Assessment (LCA) and Risk Assessment (RA). LCA focuses on comparative metrics to quantify upstream and midstream environmental burdens, including climate change, resource use, and human toxicity, while RA uses absolute metrics to evaluate exposure, persistence, bioaccumulation, and (eco)toxicity of pharmaceuticals. Stakeholders from regulatory agencies, industry, and healthcare emphasize the need for a transparent and scientifically robust framework that supports decision-making in product development, regulatory review, procurement, and health system planning.

The EU TransPharm project has developed a harmonised Environmental Sustainability Assessment Framework that combines elements of LCA and RA methods, recognizing that both life-cycle impacts and (eco)toxicological risks are critical for comprehensive evaluation. Its modular design allows adaptation of system boundaries, impacts, and aggregation levels to diverse decision contexts, while also providing general guidance for broader applications. The framework should support future implementation of Safe and Sustainable by Design approaches and be compatible with Multi-Criteria Decision Analysis.

The framework is built on three methodological pillars: Goal Definition, System Boundary Mapping, and Impact Quantification. Goal Definition distinguishes assessments at product level, therapeutic strategy level, or process optimization level, guiding selection of functional units, data requirements, and modelling assumptions. System Boundary Mapping aligns cradle-to-gate, gate-to-gate, cradle-to-grave, or use-to-EoL scopes with LCA

and RA requirements. Impact Quantification integrates LCA impact categories with RA metrics to evaluate trade-offs across sustainability, safe objectives. Applied to pre-screened research questions, comparison of products, evaluation of treatment options, and optimization of processes, the framework integrated LCA-RA methods advances environmental sustainability assessment in pharmaceuticals while fostering innovation, regulatory alignment, and responsible patient care. To demonstrate its applicability, the presentation will show assessment results comparing batch and continuous production, also region-specific environmental risk comparisons for selected pharmaceuticals.

Disclaimer/Disclosure:

This work was financially supported by the European Union's Horizon Europe Research and Innovation program (grant agreement No. 101057816, TransPharm project (Transforming into a sustainable European pharmaceutical sector)).

2.02.P-We092 Defining Minimum Data Quality for Decision-Making with Integrated Sustainability Assessment of Pharmaceutical Products: A Case Study on Anti-Inflammatory Drugs

Lowik Pieters¹, Tolga Ayeri², Muhammed Ayaj Ansar³, Martijn van Bodegraven⁴ and Rosalie van Zelm³,
(1)Centre for Sustainability, Environment and Health, National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Radboud University Nijmegen, Nijmegen, Netherlands, (3)Radboud University, Netherlands, (4)National Institute for Public Health and the Environment (RIVM), Netherlands

To prevent damage now and in the future, it is essential to make choices that reduce environmental impacts. This requires combining different assessment methods. The integration of life cycle assessment (LCA) and risk assessment is increasingly important for evaluating the environmental sustainability of pharmaceuticals, particularly as these evaluations may influence procurement, reimbursement, and (clinical) decision-making. However, the reliability and comparability of such integrated assessments depend critically on the quality and completeness of underlying Life Cycle Inventory (LCI) data and up-to-date impact assessment calculations. In the pharmaceutical sector, detailed primary data are often lacking in all life cycle stages, even for well-studied active pharmaceutical ingredients (APIs) like non-steroidal anti-inflammatory drugs (NSAIDs). As a result, sustainability assessments frequently rely on data from patents, literature, or other approximations.

This poster presentation examines to what extent such estimated LCI data are sufficient for robust (clinical) decision-making, using NSAIDs as a case study. We will apply new LCA methods developed in the EU Project TransPharm in the decision-making context by systematically testing impacts of patent-derived and other estimated LCI data, and by applying guidance for integrated assessment of pharmaceuticals. This work shows how minimum LCI data quality requirements can be defined and validated for pharmaceuticals, specifying which uncertainties should be addressed and reduced in order to fit the purpose of the integrated assessment. The implications for decision-making based on multiple sustainability criteria and further harmonization of assessment approaches will also be discussed. By providing concrete case study results for multiple APIs, we aim to support the development of integrated assessment tools that are both scientifically robust and practically applicable for healthcare and policy decision-makers.

Disclaimer/Disclosure:

This work has received funding from the European Union's Horizon Europe research and innovation program under grant agreement N° 101057816 (<https://transforming-pharma.eu/>).

2.02.P-We093 An Integrated Environmental Risk Assessment Framework for Safe and Sustainable Design of Pharmaceuticals: When Lower Persistence Does Not Trade Off Efficacy

Qiyun Zhang, Ph.D. candidate¹, Pieter-Jan De Sutter², Jéssica Amorim³, Päivi Järvinen³, Caroline Moermond⁴, Morten Suk⁵, Klaus Kümmerer⁵, Kristof Demeestere⁶, Tiina Sikanen⁷ and Karel De Schamphelaere¹,

Pharmaceutical residues in freshwater environments are a global concern. In response, the European Union funded the project TransPharm (<https://transforming-pharma.eu/>) following the 'Benign by Design' concept for developing novel fluoroquinolone (FQ) antibiotics in order to mitigate the environmental persistence of traditional FQs. This study introduces an interdisciplinary framework for comparative environmental risk assessment (ERA), applied to a new FQ derivative, ciprofloxacin-hemi (CIP-hemi), in comparison to its conventional counterpart, ciprofloxacin (CIP). This framework integrates multiple dimensions, i.e., antibiotic efficacy, human pharmacokinetics, environmental degradability, and ecotoxicity to non-target organisms. By combining experimental data from microbial assays, in vitro safety tests, and ecological toxicity studies, with in silico physiologically based pharmacokinetic (PBPK) modelling, the framework aims to assess trade-offs between human health safety needs (i.e., therapeutic efficacy) and environmental protection (i.e., risk to freshwater ecosystems).

Using this framework, we show that – when the two antibiotics reach equivalent efficacy levels – the expected environmental risk to aquatic ecosystems (RQeco) caused by CIP-hemi exceeds that of CIP in most investigated scenarios. Although CIP-hemi degrades faster than CIP through hydrolysis in human urine, and shows lower ecotoxicity to the sensitive non-target organism *Microcystis aeruginosa*, the minimum inhibitory concentrations (MICs) of CIP-hemi are 17-71 times higher than those of CIP for clinically relevant pathogens. As a result, higher doses of CIP-hemi are required to achieve equivalent therapeutic outcomes, making the RQeco of CIP-hemi surpassing that of CIP. Only under highly specific conditions, i.e., intravenous administration at clinically unrealistic high doses, CIP-hemi shows the potential for lower risk than CIP regarding the spread of antimicrobial resistance (RQMIC).

Our study indicates that prioritizing degradability alone is not sufficient in designing environmentally safe and sustainable pharmaceuticals. Instead, the interdisciplinary approach developed in this study is essential to offer a more robust basis for identifying antibiotic derivatives that are both clinically effective and environmentally responsible.

2.02.P-We094 Life cycle risks and environmental Impacts of consumer products and their chemicals on human health and ecosystems: The integration of USEtox 3 within GLAM applied to BPA and alternatives in toys

Olivier Jolliet¹, Lei Huang², Julie Elleby³ and Peter Fantke⁴, (1)Technical University of Denmark (DTU), Denmark, (2)University of Michigan, School of public Health, Environmental health Sciences, United States, (3)Technical University Denmark (DTU), Denmark, (4)substitute ApS, Denmark

The ubiquitous presence of more than 100,000 chemicals in thousands of consumer products stresses the need for screening a broader set of chemicals. The USEtox model was first extended to enable user to calculate characterization factors for human and ecotoxicity exposure to chemicals during product use. Once USEtox is integrated within the Global Life Cycle Impact Assessment Method (GLAM) developed by the UNEP Life Cycle Initiative, it enables users to compare human toxicity and ecotoxicity impacts to other impacts of the considered product on human health (HH), ecosystem quality (EQ) and socio-economic assets (SEA), and to weight these using econometric and MCDA-based weighting factors. The approach is illustrated by studying the impacts BPA & alternatives in toys, comparing toxicity to other impacts of the toys production.

To cover a wide range of chemicals-products combinations, we developed complementary models for: a) the object interior model – for chemicals in toys & building materials, b) the food contact model, c) the object surface model, d) The skin surface layer for personal care products. Substance coverage was substantially extended for non cancer effects from less than 750 regulatory chemicals to experimentally derived data for more than 5000 chemicals.

We assessed the exposure to BPA and alternatives across representative toy archetypes, identifying dominant exposure pathways, and most impacting type of toys. The highest total BPA exposure mass for a child occurs between ages 6 and 11. Summing across age groups, the aggregate exposure mass of BPA for a child from 6 months to 11 years is estimated to be 13.4 mg. We also evaluated health risks by comparing exposure doses to toxicity benchmarks. None of the aggregate exposures exceeds the corresponding RfD. However, dermal exposure to BPA is only a factor of 4 lower than the RfD for rep/dev effects.

Taking the doll and teething ring as examples, we assess the life cycle impacts associated with toy production. Toxicity damages on human health expressed in DALYs can be substantial compared to all other human health relevant categories. Once USEtox is integrated into GLAM, it enables us to compare human toxicity and

ecotoxicity impacts to another 15 impact categories. This approach consistently operationalizes the inclusion of chemicals in products during use for LCA and shows that these exposures are substantial and can be higher than the impacts of toxics over the rest of the life cycle.

This study was funded by California Department of Toxic Substances Control Agreement Number 22-T5098.

2.02.P-We095 Environmental Indicator of Pesticide Uses

Louise Wipfler¹, Richard Folkersma², Peter Leendertse² and Johan Bremmer³, (1)Environmental Risk Assessment, Wageningen University and Research (WUR), Wageningen, Netherlands, (2)CLM Research and development, Netherlands, (3)Wageningen University and Research (WUR), Netherlands

How to make agriculture and horticulture more sustainable? This question is part of an extensive societal debate. A safe and sustainable production of food and ornamentals is asked for. This requires that farmers and growers use well informed crop protection strategies. The environmental indicator crop protection (EICP) is being developed to inform farmers and growers about the environmental impacts of their pesticide use and to enable the comparison of strategies. By making use of the extensively developed field of prospective risk assessment in the pesticide regulation, the methodology is drawn upon and consistent with the European Food Safety Authority guidelines. The EICP has been developed based on existing environmental risk assessment guidance and models, using the lower tier risk assessment of pesticides as the basis. The EICP is multidimensional and calculates impacts on non-target organisms including pollinators, in-soil organisms, aquatic organisms, birds and mammals and non-target arthropods. All risk indicators are expressed by an exposure toxicity ratio (ETR) per unit area of agricultural land. Only active ingredients and products are assessed that have been approved. Properties of the active ingredients of these products have been stored in a pesticide properties database. They can be selected by the user and the tool will thereafter quantify the impact for the relevant protection goals. The tool also includes options for impact reduction such as the use of drift reducing techniques.

The methodology of the EICP that was originally developed for the Netherlands will be extended for use to other countries (EU and worldwide). Also additional exposure routes will be added such as runoff and drainage. The further development of the tool is a joined effort of private sector and public parties and research organisations with the aim to make the tool available for farmers and other private sector parties. The EICP could also be further developed to support the comparison of pest control practices across countries and to feed into EU policy making and private sector initiatives. Given the potential impact of indicators on decision making, we envision that their development should ideally have a joined character focussing on the harmonisation of the indicator approaches. We highly welcome to discuss with other initiatives how to join forces in the further shaping of these type of farmer targeted indicators.

2.02.P-We096 Towards Balanced Solutions for Considering Safety and Sustainability Trade Offs at an Organisational Scale: The SUNRISE Solution

Stella Ivanova Stoycheva¹, Danail Hristozov², Lisa Pizzol³, Arianna Livieri⁴, James Baker⁵, Chara Agaoglou⁶, Dimitrios Grigoriadis⁶, Katharina Mayer⁷ and Alex Zabeo³, (1)Yordas Group, Bulgaria, (2)EMERGE BG, Bulgaria, (3)GreenDecision Srl, Italy, (4)Greendecision Srl, Italy, (5)Temasol, Switzerland, (6)Hypertech, Greece, (7)Yordas Group, Germany

Safety and sustainability trade-offs often occur in complex organisational activities such as implementing Safe and Sustainable by Design (SSbD) innovation processes. These are conflicts which emerge when improving one goal comes at the expense of the other. For example, safety may often require short-term resource use that can conflict with long-term sustainability goals. Such trade-offs are unavoidable and demand a sound balanced approach which can help solve conflicts when for example a product designed for safety uses more resources, and/or when prioritising one sustainability goal can negatively impact other. To develop a sound solution for this problem, we are informed by survey and interview methods to determine the factors affecting and influencing potential safety and sustainability trade-offs decision makers face. An analysis of relevant biases is performed to define cognitive defaults for various stakeholder groups (eg. industry, regulators, consultants, academia). The analysis of these defaults explains the underlying reasons why the stakeholders may choose between e.g., products that are potentially damaging but less expensive or more profitable. The analysis of cognitive biases is combined with discursive methods (structured dialogue), which is applied during the interviews phase of the study to stir reflections about social desirability and to systematically collect information about the perspectives, arguments and values of the engaged groups. Gender considerations in decision making processes are also examined in the study. The results of the elicited safety and sustainability trade-offs for the targeted stakeholders

will be used as a basis for defining weights for specific assessment criteria/indicators and impacts in the Horizon Europe SUNRISE project integrated approaches for impact assessment (www.sunrise-horizon.eu) of advanced materials and its digital e-infrastructure thereby presenting one of the first industry oriented balanced solution able to account for safety-sustainability trade-offs in complex decision making.

Disclaimer/Disclosure:

SUNRISE has received funding from the European Union's Horizon Europe Research and Innovation Programme under Grant Agreement No. 101137324.

2.02.P-We097 Development of a Social Life Cycle Impact Assessment Method Considering the Effects of Child Labour on Education

Teruya Suzuki¹, Shuning Chen² and Norihiro Itsubo¹, (1)Waseda University, Japan, (2)Hiroshima University, Japan

Although the global prevalence of child labour has shown a declining trend, approximately 140 million children remain at risk as of 2024. Sub-Saharan Africa accounts for over 60% of global cases, indicating persistent and severe conditions in the region (ILO, 2025). Conventional Social Life Cycle Assessment (S-LCA) approaches have primarily relied on qualitative indicators—such as occurrence frequency or country-level risk categories—to evaluate child labour. While useful for hotspot identification, these indicators have limited capability to support quantitative impact assessment or cross-supply chain comparison.

In this study, child labour is conceptualized as both a loss of educational opportunity and an increase in labour supply. Each aspect is monetized to evaluate the resulting change in human capital. This methodological design is grounded in the Impact Pathway Approach. The analysis targets child labour in the mineral extraction and crop production sectors across 140 countries covered by the GTAP database. Data sources include sector-specific child labour risk information from the Social Hotspots Database (SHDB), integrated with educational and labour statistics published by international organizations such as the ILO and UNESCO.

Specifically, labour hours are treated as the elementary inventory variable and are converted into midpoint indicators through existing risk factors and weighting schemes. A state-transition model capturing stakeholder behaviour and causal relationships is then applied to translate midpoint results into endpoint indicators expressed in life-year units. Finally, changes in human capital are estimated in monetary terms based on the Inclusive Wealth framework, integrating both educational loss and increased labour supply effects.

The study introduces a quantitative method that monetizes the impacts of child labour through changes in human capital, and in extending the assessment scope to 140 countries to enable international comparison using risk factors. This work expands practical applications of the Type II (Impact Pathway) approach within S-LCA and proposes a new framework for quantitative social impact assessment.

The results can be applied to quantify human capital changes attributable to child labour throughout entire supply chains, contributing to corporate and policy-level decision-making for social sustainability.

2.03 Ecological Context of Pollinator Risk Assessment: Challenges Becoming Threats?!

2.03.T-01 A step forward - Comparative tool evaluation under EFSA's 2023 Bee Guidance Document

Daniel Stengel¹, Christian Berg², Alexander Blakey³, Kate Brougham⁴, Elizabeth Collison⁵, Denisa Cupi⁶, Kirsten Henn⁷, Silvia Hinarejos⁸, Stefan Kroder⁹, Raymond Layton¹⁰, Johannes Lückmann⁷, Marcus Metz⁷, Mark Miles¹¹, Christof Schneider¹², Verena Taenzler¹³, Torben Wittwer⁷ and Mila Arabadzhieva¹⁴, (1)Rifcon GmbH, Germany, (2)Ecotoxicology, FMC Corporation, Germany, (3)Syngenta Ltd., United Kingdom, (4)Nufarm, United Kingdom, (5)Corteva Agriscience, United Kingdom, (6)Novonosis, Denmark, (7)RIFCON GmbH, Germany, (8)Sumitomo Chemical Co. Ltd., Spain, (9)ADAMA, Germany, (10)Gowan Company, United States, (11)Bayer AG, United Kingdom, (12)BASF, Germany, (13)Bayer AG, Germany, (14)CropLife Europe, Belgium

Pollinator protection is a critical component of sustainable agriculture and regulatory ecotoxicology. The EFSA Bee Guidance Document (2023) intends to introduce a harmonized framework for assessing risks to pollinators, emphasizing a tiered risk assessment with consideration of time-reinforced toxicity (TRT), mixture toxicity and sublethal effects. Due to its complexity and to simplify the usage, an online, browser-based calculator tool (B-

risk, beta version 1.0.0, first public version, published Nov. 2024) was developed in R by EFSA and published on the EFSA R4U platform.

After publication of EFSA 2023, the authors, on behalf of the CropLife Europe (CLE) bee sub-group, independently started the development of a calculation tool using R (Beexp). The aim was to facilitate a better understanding of the new bee GD and to demonstrate whether the calculations required under EFSA 2023 can be transparently reproduced and applied in the same way as intended by EFSA. Beexp provides all functionalities for screening and tier I risk assessments, assessments of TRT and mixture toxicity. Further functionalities are still in development.

We compared the outcome of the same risk assessment calculations of both tools to get an overview of possible differences. These comparisons highlight potential uncertainties in EFSA 2023 which if left open to interpretation may lead to inconsistencies in the application and evaluation of the new guidance.

It should be emphasized that Beexp is not intended to replace B-risk but rather was developed to verify the B-risk calculations in the absence of a published R code, and ensure consistent interpretation of EFSA 2023.

Beexp also adds a different approach to the workflow outlined by EFSA 2023. In its current state, the functionality of EFSA's B-risk is limited to scenarios fully aligned with the guidance data requirements.

However, in practice screening assessments often involve incomplete datasets, where flexibility is essential to support development of robust testing strategies. Beexp closes this gap by applying EFSA principles while offering enhanced adaptability for screening and higher-tier refinements. The tool enables risk characterization even if data does not fully meet EFSA's input requirements, thereby supporting early decision-making and iterative refinement.

The presentation will illustrate the tool's functionalities, provide the results of the comparison and outline further steps of development.

Disclaimer/Disclosure:

The work was funded by CropLife Europe (CLE) bee group which is a European organization which represents the crop protection sector. Their members are global companies, small and medium-size enterprises (SMEs) and national associations operating in conventional pesticides, biopesticides, plant biotechnology, and digital and precision agriculture.

2.03.T-02 Effects of simultaneous exposure through different routes

Jan Baas¹, Anna Huang¹, Dick Belgers¹, Marie-Claire Boerwinkel¹, Steven Crum¹, Annika Mangold-Döring², Arrienne Matser¹, Kas Swinkels¹ and Ivo Roessink¹, (1)Wageningen University and Research (WUR), Netherlands, (2)Environmental Risk Assessment team, Wageningen University and Research (WUR), Netherlands

In real life most insects will be exposed to pesticides through simultaneous exposure by different exposure routes. Exposure through contact with sprayed plant material, in combination with exposure through contaminated food, like plant material, pollen and/or nectar will be the general rule and not the exception for most species. Despite this, experimental data on the effect of different simultaneous exposure routes with a single compound or different compounds could not be found.

To get a better fundamental understanding, dedicated experiments were carried out with single exposure through food, through contact and a simultaneous exposure through both routes. The experiments were carried out with honeybees exposed to imidacloprid. Since we know that exposure concentrations in acute tests are not constant the data are interpreted with the BeeGUTS model, which is a Toxicokinetic Toxicodynamic (TKTD) model, that allows for an effects analysis with a time-dependent exposure and can take into account the specifics of a bee. The experiments were carried out with additional observations on effects at intermediate points in time to facilitate the analysis with a TKTD modelling approach.

It showed that the effect of the combined exposure could accurately be predicted for the different doses and timepoints by adding the different (time-dependent) doses, or by multiplying the survival probability of the independent tests.

2.03.T-03 Mapping Honeybee Colony Vulnerability: Integrating Landscape, Exposure, and Effect Modelling for Pollinator Health

Sascha Bub¹, Thorsten Schad², Vanessa Roeben³, Julian Heinrich³ and John Herrmann³, (1)Rhineland-Palatinate Technical University Kaiserslautern-Landau, Germany, (2)Landwerk eV, Germany, (3)Bayer AG, Germany

Pollinators are essential for ecosystem services, yet current risk assessment frameworks often rely on simplified scenarios that fail to capture the spatial heterogeneity of real-world landscapes. A major challenge in regulatory decision-making is understanding how specific landscape structures and hive locations drive local risks. To address this, we utilized the xPollinator model to generate vulnerability maps that integrate landscape composition, resource availability, and pesticide exposure profiles.

In this study, we applied the model to apple-producing regions in France to assess honeybee colony health under pesticide use patterns. The resulting vulnerability maps reveal distinct spatiotemporal variations in colony size, demonstrating that hive placement can be a critical determinant of colony survival. We observed that colonies situated near apple orchards faced lower survival probabilities, while those in diverse landscape contexts exhibited greater resilience.

These findings illustrate the potential of vulnerability maps to synthesize complex simulation data into interpretable spatial formats. Rather than offering a standalone solution, the study demonstrates how spatiotemporally explicit methods can support the exploration of high-risk zones and mitigation concepts. This approach aligns with ongoing efforts to integrate landscape-level analyses into pollinator risk assessment, offering a flexible way to visualize how landscape context might inform future scenario development.

Disclaimer/Disclosure:

xPollinator is open-source. This work was partly supported by Bayer AG

2.03.T-04 Modulation of the Effects of local Pesticide Use by Landscape elements on Wild Pollinators in an Agricultural plain

Thanh-Julie Nguyen, Sabrina Gaba and Florence Carpentier, INRAE, France

Wild insect pollinators play a crucial role in maintaining biodiversity and supporting agricultural ecosystems by ensuring the reproduction of flowering plants, yet their populations are declining worldwide. Among the main drivers of this decline are the intensive use of pesticides and the loss of habitats and floral resources. Certain landscape elements such as grasslands can reduce the negative effects of pesticides on wild bees. However the extent to which landscape composition can mitigate or amplify the effect of pesticides on wild pollinators remains largely unknown. The study aims to fill this gap by assessing how landscape elements affect the impact of pesticides on wild pollinator communities (hymenoptera, coleoptera, diptera, and lepidoptera). Over a five-year period, surveys of wild pollinators were conducted in oilseed rape (*Brassica napus*) fields in the Long-Term Socio-Ecological Research (LTSER) Zone Atelier Plaine & Val de Sèvre using two complementary sampling methods: pan traps and sweep nets. Detailed information on pesticide applications (molecules and dosage) was available through farmers' surveys and was used to quantify local pesticide pressure. Pesticides (insecticides, fungicides, herbicides) were modelled using risk-based variables such as Hazard Quotients (HQ) and diversity metrics based on the number of modes of action. Their effects on pollinator abundance, species richness, and diversity were analysed together with the percentages of grassland, woody elements, and organic farming within a 500 m radius. Interactions between landscape variables and pesticides were included to determine how landscape composition modifies pesticide effects. The siland method from Carpenter and Martin was applied to the same models to estimate simultaneously the distance and the effect of landscape variable without any prior assumption on the spatial scales of influence and therefore explore the hypothesis that the landscape variables can affect pesticide effects at different scales. Species richness and diversity were negatively influenced by insecticide and herbicide use whereas the presence of grassland increases pollinator abundance, while forest cover enhances species richness. The study highlights that these landscape elements were shown to mitigate pesticide-risk effects at different spatial scales on wild pollinators. These results emphasize the need to consider multiple distances when assessing their impact on pollinator diversity.

2.03.T-05 Modelling Population-Resource Relationships Using a Spatially Explicit SolBeePop

Harriet Gold¹, Nika Galic², Alice Johnston¹, Claire Brittain³ and Simon Potts⁴, (1)Cranfield University, United Kingdom, (2)Syngenta Ltd, Switzerland, (3)Syngenta Ltd, United Kingdom, (4)University of Reading, United Kingdom

Solitary bees are important members of wild pollinator communities, contributing to agroecosystem biodiversity and the pollination of crops and wild plants. The life cycle of univoltine solitary bees involves a short post-emergence activity period, during which females independently provision successive brood cells. Reproductive output is sensitive to landscape-level resource availability, but the relative roles of nesting and floral resources

in shaping natural population dynamics remain poorly resolved. Ecological models are essential tools for understanding and predicting context-dependent population responses to support land management strategies and ecological risk assessment. By synthesising available data and information on species ecology, models can also identify key knowledge gaps to guide empirical research and future model refinement. SolBeePop is an existing trait-based, spatially implicit population model for several species of solitary bee. Here, we extend SolBeePop to a spatially explicit framework incorporating both nesting and floral resources to predict relative population dynamics across heterogeneous landscapes. We characterise nesting and floral resources for six landscapes and test alternative implementations of resource selection, density dependence and dispersal for realistic simulation of spatially structured populations. Assessment of model versions will involve expert judgement and qualitative comparison of model outputs (e.g. carrying capacity, mean brood cells per female, proportion of nesting patches occupied) to empirical population patterns. Analysis of model outputs in relation to landscape metrics will reveal how population outcomes vary across a range of resource availability scenarios. The spatially explicit SolBeePop framework provides a foundation for future investigations into how natural population dynamics respond to the interactive effects of landscape composition and configuration, changing floral phenology, agricultural management practices and other stressors in agricultural landscapes. In addition, we demonstrate a systematic approach to developing and testing alternative model structures using multiple information sources when empirical data is lacking.

Disclaimer/Disclosure:

Harriet Gold is funded by UKRI BBSRC FoodBioSystems Doctoral Training Partnership (DTP), grant number BB/T008776/1 and CASE support from Syngenta.

2.03.P Ecological Context of Pollinator Risk Assessment: Challenges Becoming Threats?!

2.03.P-We098 The Revised EFSA bee Guidance (2023) Three Years on: An Industry Stakeholder's Perspective and Recommendations

Alexander Blakey¹, Christian Berg², Kate Brougham³, Elizabeth Collison⁴, Denisa Cupi⁵, Silvia Hinarejos⁶, Gwendolin Kraetzig⁷, Stefan Kroder⁸, Raymond Layton⁹, Mark Miles¹⁰, Christof Schneider¹¹, Verena Taenzler¹² and Mila Arabadzhieva¹³, (1)Syngenta Ltd, United Kingdom, (2)Ecotoxicology, FMC Corporation, Germany, (3)Nufarm, United Kingdom, (4)Corteva Agriscience, United Kingdom, (5)Novozymes, Denmark, (6)Sumitomo Chemical Co. Ltd., France, (7)ISK Biosciences Europe N.V., Germany, (8)ADAMA, Germany, (9)Gowan Company, United States, (10)Bayer Research & Development Services LLC, United Kingdom, (11)BASF, Germany, (12)Bayer Research & Development Services LLC, Germany, (13)CropLife Europe, Belgium

In 2024, Crop Life Europe (CLE) conducted a comprehensive impact analysis of the revised EFSA 2023 Bee Guidance Document. The assessment evaluated: 113 active substances/products (23 insecticides, 43 fungicides and 47 herbicides) based on 197 different uses (GAPs).

As an outcome of this analysis, CLE categorised elements of the EFSA 2023 Bee Guidance Document into four groups:

- Category 1: Ready for implementation in the short-term (<2 years)
- Category 2: Can be implemented in the medium term (within 3 years)
- Category 3: Further development required before implementation (>3 years)
- Category 4: Additional topics that would benefit from a joint industry, regulator and academia workshop

Our impact analysis of the revised EFSA Bee Guidance Document (2023) identifies several elements suitable for short-term implementation, including honey bee screening and Tier I risk assessment of predicted individual effects (PIE), exposure estimates for during-flowering contamination, and the application of dose-response models with extrapolation factors for surrogate LD50 values. In the medium-term, pre-flowering factors (PFF) are a welcomed addition, but require additional calibration aligned with BBCH growth stages, while the time-reinforced toxicity assessments (TRT) face practical hurdles meeting the ~10% mortality threshold at 100 µg/bee/day, even for substances of low toxicity. In the long-term, several aspects require further development, particularly the establishment of robust protection goals for non-apis species, the determination of reliable toxicity extrapolation factors (TEFs), and harmonised analysis and interpretation of non-Apis higher tier studies. Finally, our analysis identifies topics that would benefit from a joint industry, regulator and academia workshop assessment such as experience with the EFSA Bee Calculator Tool and the assessment of higher tier bee studies.

CropLife Europe recommends a stepwise implementation plan (roadmap), whereby some elements of the lower tier risk assessment for honey bees may be workable in the short-term with improvements to the EFSA Bee calculator tool. Other aspects of the guidance require further development prior to their implementation.

2.03.P-We099 Towards Harmonised First-Tier Pre-Flowering Factors in the European Food Safety Authority 2023 Bee Guidance: Linking BBCH Growth Stages to Application Timing

Elizabeth Collison¹, Ashley St. Clair², Kristi Tatsi¹ and Stefan Kimmel³, (1)Corteva Agriscience, United Kingdom, (2)Corteva Agriscience, (3)Corteva Agriscience, Germany

The European Food Safety Authority's revised guidance on the risk assessment of plant protection products for bees (EFSA, 2023) introduces a new parameter – the pre-flowering factor (PFF) – to estimate dietary exposure in lower-tier assessments. The PFF extrapolates residue concentrations in pollen and nectar from applications made during flowering to those made before flowering, based on the number of days between application and crop flowering onset. A key challenge is that this time interval is not typically specified on product labels or Good Agricultural Practice (GAP) descriptions, as it varies by region and season. In contrast, the crop growth stage (BBCH) at application is consistently reported. To address this, we propose using the AppDate model, already employed in environmental exposure assessments, to estimate application dates for crop BBCH stages 10–59 and the onset of flowering (BBCH 60). This enables calculation of the minimum interval between pre-flowering application and flowering, and thus the appropriate PFF. We present initial analyses for several bee-attractive crops to illustrate the approach. Our findings support the development of default first-tier PFF values for major crop groups, which could be agreed upon by regulatory authorities ahead of implementing the EFSA 2023 bee risk assessment framework.

2.03.P-We100 The Equivalence Testing Approach for the Statistical Analysis of Higher Tier Pollinator Studies: Recommendations and Challenges

Davood Poursina¹, Elizabeth Collison², Stefan Kimmel³, Kristi Tatsi² and Xiaoyi Sopko¹, (1)Corteva Agriscience, (2)Corteva Agriscience, United Kingdom, (3)Corteva Agriscience, Germany

The 2023 revised European Food Safety Authority (EFSA) bee guidance mandates a shift from difference to equivalence testing for higher-tier pollinator studies, creating significant new challenges for study design and the overall evaluation and interpretation of data for regulatory purposes. The core question is determining whether this new statistical framework is practically feasible, particularly concerning the number of replicates needed to demonstrate the equivalence. To address this, we evaluated the performance of three statistical models (t-test, two-way ANOVA, and a linear mixed-effects model with an autoregressive structure) using a comprehensive simulation study. We investigated the number of replicates required to achieve 80% statistical power to conclude equivalence under various scenarios, including different true effect sizes, background variances, and temporal correlations.

While it could be demonstrated that one model fits best for purpose in terms of efficiency and statistical power, the number of replicates required in all models to demonstrate robust and reliable equivalence is substantially greater than recommended in current test guidance. Even in a best-case scenario, demonstrating equivalence for a product with no true effect (0%) required 7 replicates, while a product with a 9% effect required over 600. We also found that reducing initial colony variability as one aspect of potential improvement had only a minor impact on the required number of replicates.

These results indicate that the number of replicates demanded by the equivalence testing approach may be unmanageable in typical semi-field study designs used for regulatory testing. Our work highlights a critical feasibility gap and urges caution in the regulatory implementation of this approach until it is clear that studies can be realistically designed and conducted to meet the statistical requirements for demonstrating acceptable risk.

2.03.P-We101 From Controlled Tests to More Realistic Exposure: Advancing Risk Assessment Tools for Solitary Bees Using Osmia Species

Claire MOLITOR, Olivier MAMET, Milan BOIZIAU and Fabien DEMARES, TESTAPI, France

Solitary bees such as *Osmia cornuta* and *Osmia bicornis* are increasingly recognised as relevant non-Apis pollinators for pesticide risk assessment. As global regulatory guidance moves toward broader pollinator protection, validated and operational methods reflecting solitary bee biology are still needed for consistent implementation across laboratories and semi-field facilities.

These protocols support ongoing guideline development by evaluating and improving two complementary

methodological approaches. In the laboratory, we implemented a chronic oral toxicity test following a draft guideline using a toxic reference (dimethoate) to verify test feasibility and stability of exposure conditions. The method yielded clear and repeatable dose-dependent effects for *O. bicornis*. For the second species, *O. cornuta*, expected toxicity patterns were also observed, although increased variability in survival and feeding behaviour indicates areas requiring procedural adjustments before routine regulatory use.

At the semi-field level, we contributed to an international ring-test assessing a tunnel-based protocol for *O. cornuta*. This design enabled the controlled evaluation of exposure and effects across the first generation, including metrics related to reproduction, nesting activity and offspring production. The ring-test demonstrated that the protocol is feasible and transferable across multiple facilities and captures endpoints relevant for future guidance. Based on our findings and conclusions, the determination and pertinence of the exposure period will be discussed.

Overall, these results advance the regulatory readiness of solitary bee testing by identifying robust methodological elements, highlighting species-specific considerations and informing the refinement of future guidance. Integrating these methods into risk assessment frameworks will support a more comprehensive and ecologically relevant evaluations of pesticide impacts on pollinator communities.

2.03.P-We102 Pesticide Risk to Pollinators in Agricultural Landscapes: Comparison of *Apis mellifera* and *Osmia bicornis* in Two Cropping Systems

Dominika Izabella Twaróg¹, Tomasz Kiljanek², Milena Goliszek², Alina Koch³, Ove Jonsson³, Maj Rundlöf⁴, Elżbieta Ziolkowska⁵, Barbara Jaśkowiec⁵, Agnes Sękowski⁵, Ryszard Laskowski⁵, Adam Tofilski⁶ and Agnieszka Bednarska⁷, (1)Institute of Nature Conservation, Polish Academy of Sciences, Poland, (2)National Veterinary Research Institute – State Research Institute, Poland, (3)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (4)Department of Biology, Lund University, Sweden, (5)Institute of Environmental Sciences, Jagiellonian University, Poland, (6)Faculty of Animal Science, University of Agriculture in Krakow, Poland, (7)Institute of Nature Conservation Polish Academy of Sciences (INC PAS), Poland

Arthropod populations, including key pollinators, are declining worldwide due to human-driven factors such as land-use change, intensive agriculture, and pesticide use. Understanding pesticide exposure in both managed and wild bees is crucial for safeguarding pollinator health and crop productivity. This study assessed pesticide residues in pollen collected from *Apis mellifera* hives and *Osmia bicornis* nests at agricultural sites with apple orchards or oilseed rape fields, varying in the proportion of semi-natural areas (1.7-18%; e.g., forest, extensively managed permanent grasslands, field borders) within a 1 km radius, with a bee hive or nest as the center points. Pollen from *A. mellifera* was sampled using pollen traps active for one day in spring at the peak of crop flowering (13th April for orchards and 30th April for oilseed rape) and in summer after crop flowering had ended (18th July for orchards and 27th June for oilseed rape). Pollen from *O. bicornis* nests was sampled at the end of their foraging season, representing thus pollen collected by the bees throughout the season, from early April to the end of May.

Among 120 pesticides analysed in pollen of both species, 48 were detected, including some banned in the EU (e.g., chlorpyrifos, carbendazim, thiophanate-methyl). Insecticide acetamiprid was found in all samples, and fungicides azoxystrobin, difenoconazole, fluopyram, tebuconazole, and trifloxystrobin were detected in at least 75% samples. Pesticide Risk Index (PRI) for pollen from each bee hive per season and PRI for each *O. bicornis* nest were calculated as the sum of the ratios of each detected pesticide concentration to its oral 48h LD50 for *A. mellifera*, to capture the combined hazard and exposure level to multiple substances. For all sites but one, PRI for *A. mellifera* was higher in spring, and for most sites PRI was higher for *A. mellifera*. PRI for *A. mellifera* calculated for spring or summer did not correlate with the PRI for *Osmia* (?0.4, Pearson correlation). Relations between the species-specific PRI and risk calculated based on crop structure and associated pesticide use will be discussed. We will also explore the potential mitigation effect of semi-natural areas in reducing exposure of bees to pesticides.

2.03.P-We103 Solitary bee (*Osmia bicornis*) larvae test- Testing different pollen sources

Stephen Patrick Vinall¹ and Bettina Wenzel², (1)IES - Innovative Environmental Services Ltd., United Kingdom, (2)No Affiliation, Switzerland

In May 2023, EFSA published its revised guidance on the risk assessment of plant protection products on bees (*Apis mellifera*, *Bombus* spp. and solitary bees). This updated the data requirements to include acute, chronic and larvae testing for all three groups. To date, some research has developed methods for feeding *Osmia bicornis* larvae under laboratory conditions (i.e. Sgolastra et al. 2015, Exeler et al. 2019), which can be used to evaluate the effects of plant protection products on the larvae. In this study, three different pollen sources were tested to evaluate their suitability as food for the developing larvae. The findings demonstrated that both pollen collected and provided for eggs by the parent *Osmia bicornis* and pollen collected by honeybees were suitable for larval development to pupation, but not pollen collected directly from oak tree (*Quercus* spp.).

2.03.P-We104 Pollinator Acute Contact Toxicity Tests in Overspray Design

Kirsten McVean¹, Joern Roesner², Jennifer Kraul² and Katja Maier³, (1)Noack Laboratorien, Sarstedt, Germany, (2)DHD-Consulting GmbH, Germany, (3)Noack Laboratorien, Germany

For some plant protection products applied by spraying, currently ongoing evaluations on EFSA- and member state level point out the need for a more realistic acute contact risk assessment of pollinator species by direct spraying or spray-drift exposure. While there are established standard protocols available to quantitatively address such risks (OECD 214, OECD 246) in general, no methodologies or basic technical guidance is agreed to capture the acute contact risk by the overspray route.

We herein present first investigations of our developed experimental setup to address exposure in an overspray scenario on laboratory scale. Handling of honey bees and bumble bees as well technical details on study conduct are discussed. Sensitivity of such an experimental setup is demonstrated by assessing the 24- and 48-hrs LC50 values of honey bees and bumble bees exposed to Dimethoate compared to OECD 214 and OECD 246 reference values, intra-laboratory historical control data as well as commonly used rates in semi-field trials' positive controls (e.g., OECD 75).

Our procedure allows to address the data request by some competent authorities even in the absence of an agreed guideline or testing protocol in an excellent scientific and regulatory-compliant way. Such a study design may serve as basis to fulfil the demand of additional exposure scenarios in the risk assessment.

2.03.P-We105 The Effects of Plant Protection Product in Chronic Oral Toxicity Test on Honeybees

Agnieszka Wojciech, Ecotoxicology Research Group, Łukasiewicz Research Network – Institute of Industrial Organic Chemistry, Poland

Plant protection products (PPPs) are only authorised for marketing after a thorough environmental risk assessment. The assessment requires a series of ecotoxicological tests on non-target organisms, including honeybees (*Apis mellifera* L.). OECD Guideline No. 245 introduces a chronic oral toxicity test on adult worker honeybees under laboratory conditions over an exposure period of 10 days. In the study, PPP with the active substance pyriproxyfen was used as the test item. Pyriproxyfen is a pesticide and insect growth regulator. Chronic exposure to bees of pyriproxyfen can reduce survival rates and impair behaviors critical for colony health. The study involves feeding bees a diet containing the test item for 10 days and monitoring sublethal effects, mortality and food consumption. Freshly emerged young worker bees are collected for testing. For a period of 10 days, bees are fed a 50% aqueous sucrose solution treated with the test item with ad libitum access. Every day, the feeders are removed, weighed, and replaced with new ones containing a fresh diet. The insects are observed for mortality and other behavioural effects (i.e. apathy, movement coordination problems) at daily intervals up to 10 days of exposure. The test lasts 10 days. Weights of the feeders are recorded every 24 hours (until the end of the test). On the basis of the weight differences after 24 h, the amount of the consumed treated diet is determined. In addition to the group exposed to the test item, a control group and a reference item group participate in the test in order to verify the precision of the test procedure and the sensitivity of the biological test system. The aims of the study is to determine the chronic oral toxicity of the test item to honeybees and to demonstrate that the median lethal concentration and median lethal dietary dose are higher than the test item concentration used for exposure. The test takes into account chronic exposure scenarios that are representative of real-life conditions where residues persist in bee food supplies or crops.

2.03.P-We106 Bumblebee (*Bombus* spp.) larvae test- Approaches and first achievements

Bettina Wenzel¹, Florine Ory¹, Agnes Zimmermann², **Stephen Patrick Vinal³**, Eleonora Kolari¹ and Magdaléna Cornement¹, (1)Innovative Environmental Services (IES), Switzerland, (2)Innovative Environmental Services, Switzerland, (3)Mambotox, United Kingdom

In May 2023, EFSA published its revised guidance on the risk assessment of plant protection products on bees (*Apis mellifera*, *Bombus* spp. and solitary bees). This updated the data requirements to include acute, chronic

and larvae testing for all three groups. To date, very little research has focused on artificial feeding of bumblebee larvae under laboratory conditions—a critical first step toward developing a standardized bumblebee larval test. Based on the available literature, efforts were made to establish a practical feeding regime that supports proper larval development while remaining feasible for routine laboratory work. First attempts at food compositions, amounts fed, daily feeding times, plates used to raise the larvae, and grafting techniques are described for our lab.

Although more trials would need to be done to confirm the findings, first results suggest that synchronization is most easily achieved by collecting egg packages from colonies and allowing them to hatch in a Petri dish. The eggs need to be collected from hives that are not too old, held at appropriate temperatures and are in an overall good state. Once synchronized, larvae are transferred to rearing plates and fed increasing amounts of two different artificial diets according to their age. If the overall amount of food given was too little, larvae did not have enough energy to pupate. If the overall amount of food was too much, larvae died from overfeeding/molding. Young larvae (1st and 2nd instars) survived best when fed once per day with daily increasing amounts not exceeding 8 µL baby diet/day. Older larvae (3rd and 4th instars) survived best when fed twice per day, with amounts of about 5-10 µL of the second feeding solution/feeding. Feeding should be stopped after 18 days or when first signs of spinning are noticed. The only hatching success was achieved in larvae which were transferred to fresh cups at the first signs of spinning (after defecation) and no further manipulation took place.

These first attempts provide a foundation for future development of a standardized guideline for bumblebee larval testing.

2.03.P-We107 Sensitivity difference between Summer and Winter honeybees

Jan Baas, Anna Huang, Dick Belgers, Marie-Claire Boerwinkel, Arrienne Matser, Kas Swinkels and Ivo Roessink, Wageningen University and Research (WUR), Netherlands

As bees in general and honeybees specifically are important for pollination of crops, the potential impact of plant protection products and other toxicants on this group has been investigated extensively. However the biology of a honeybee biology differs throughout the season. With the so-called winter bees having a longer lifespan (months) then summer bees (weeks). As a result, there has been some debate on whether summer bees and winter bees differ in their sensitivity towards pesticides.

Tests were conducted with Summer and Winter honeybees exposed to imidacloprid in an acute contact test. The tests were carried out according the OECD guideline for acute contact exposure. The data were interpreted with the BeeGUTS model, this is a Toxicokinetic Toxicodynamic (TKTD) approach based on the GUTS modelling framework, but with some adaptations made in the exposure part to take the specifics of a bee into account.

The data showed that winter bees are about a factor of seven more sensitive than summer bees. But the 48 hour LD50 values are more or less identical. The higher overall sensitivity of the winter bees is caused by the slower kinetics, so effects take longer to develop. This is not reflected in the 48 hr LD50 values but the 96 hr LD50s are already substantially lower for the winter bees. This again implies that comparing sensitivity based on LD50 values, without taking the development of effects over time into account may lead to false conclusions about the sensitivity of an exposed species.

2.03.P-We108 BeeGUTS Meets Joint Survival: Multi-Species Toxicant Response Modelling; Integrating beeGUTS and multiGUTS for Ecotoxicological Risk Assessment

Dirk Nickisch¹, Amelie Schmolke², Johannes Lückmann², Matthias Becher², Mark Miles³, Verena Taenzler⁴, David Schneider⁴, Heike Fremdt⁴, Dominic Englert⁴ and Thomas G. Preuss⁴, (1)Rifcon GmbH, Germany, (2)RIFCON GmbH, Germany, (3)Bayer Research & Development Services LLC, United Kingdom, (4)Bayer Research & Development Services LLC, Germany

Mechanistic effect modelling has become a vital approach for understanding ecotoxicological impacts, explicitly accounting for uncertainties and variabilities in environmental conditions and processes.

In this study, we combined two recently published TKTD approaches: the joint survival modelling framework for multiple species (multiGUTS; Singer et al. 2022) and the bee-specific BeeGUTS model (Baas et al. 2022). For the test substance Dimethoate, acute contact and acute oral studies were available for five bee species: the honeybee (*Apis mellifera*), bumblebee (*Bombus terrestris*), leafcutter bee (*Megachile rotundata*) and two mason bee species (i.e. *Osmia bicornis* and *O. cornuta*).

The objectives of this study were to evaluate whether the multiGUTS approach, previously applied to aquatic species, is also applicable to bees, and to assess whether oral toxicity can be predicted from acute contact tests.

Current results clearly indicate that the multiGUTS approach is suitable for Dimethoate and the tested bee species, and that it may enhance GUTS modelling for datasets with limited data points and enabling the prediction of mortality under untested exposure scenarios across species.

2.03.P-We109 BeeGUTSmet: Extending TKTD Modelling for Honey Bees by Integrating Metabolism and Bioaccumulation

David Schneider¹, Vanessa Roeben², Marion Zaworra¹, Kathrin Vogelsang¹, Kristin Raschke¹, Heika Sobczyk¹, Kai Becker¹ and Thomas G. Preuss¹, (1)Bayer AG CropScience, Germany, (2)Bayer AG, Germany

Toxicokinetic–toxicodynamic (TKTD) models are increasingly used in environmental risk assessment of insecticides for honey bees. The BeeGUTS model, based on the GUTS-RED framework, integrates acute and chronic toxicity data using a simplified structure that combines uptake, elimination, and damage into a single rate constant. While effective for many substances, this simplification assumes rapid equilibrium between external exposure and internal damage, which may not hold for compounds with distinct metabolic or bioaccumulative properties.

To address this limitation, we developed BeeGUTSmet, an extension that explicitly models internal toxicokinetics using experimentally derived metabolic half-lives. These values were obtained through in vivo dynamic Total Compound Balance (dTCB) assays, allowing us to simulate internal concentrations over time and separate toxicokinetic from toxicodynamic processes. This mechanistic separation enhances biological realism and enables more accurate predictions, particularly under chronic exposure conditions.

BeeGUTSmet was calibrated and validated using insecticides with a range of kinetic profiles—from rapidly metabolized to highly persistent. The model consistently improved predictions, where delayed mortality or bioaccumulation played a significant role. By integrating metabolism explicitly, BeeGUTSmet enhances the biological realism of TKTD modelling and strengthens its applicability across diverse exposure scenarios. Importantly, BeeGUTSmet complements the original BeeGUTS model rather than replacing it. By maintaining compatibility with existing regulatory frameworks while expanding applicability to substances where internal kinetics are critical, BeeGUTSmet represents a meaningful advancement in TKTD modelling for pollinator risk assessment. Its integration of metabolism as a central driver of internal dose supports more robust and reliable evaluations of long-term pesticide effects.

2.03.P-We110 BeeGUTSmet: Technical Implementation of an Extended TKTD Model for Honey Bees

David Schneider, Vanessa Roeben, Marion Zaworra, Kathrin Vogelsang, Kristin Raschke, Heika Sobczyk, Kai Becker and Thomas G. Preuss, Bayer AG CropScience, Germany

BeeGUTS is a toxicokinetic–toxicodynamic (TKTD) model developed for honey bee (*Apis mellifera*) risk assessment. It is based on the reduced General Unified Threshold Model of Survival (GUTS-RED) and provides a practical framework for integrating acute and chronic toxicity data. This approach has proven valuable for regulatory applications, offering a streamlined representation of uptake, elimination, and damage accrual through a single dominant rate constant.

However, certain compounds exhibit kinetic profiles that challenge this simplification, such as rapid metabolism or bioaccumulation. To address these cases, we developed BeeGUTSmet, an extended TKTD model that explicitly separates toxicokinetics from toxicodynamics. Internal concentrations are calculated using a physiologically structured approach with substance-specific elimination parameters, enabling metabolism to be represented mechanistically rather than implicitly.

In this poster, we highlight the technical implementation of BeeGUTSmet in detail, including its modular design for uptake and internal processing, and demonstrate how these refinements improve the ability to capture delayed effects and time-dependent mortality patterns under chronic exposure scenarios. Comparative evaluations indicate that this approach enhances predictive robustness across diverse exposure assumptions, supporting more reliable extrapolation beyond standard laboratory conditions.

By combining mechanistic accuracy with regulatory relevance, BeeGUTSmet strengthens the TKTD modeling toolbox for pollinator risk assessment and provides a pathway toward dynamic, scenario-based evaluations that reflect realistic exposure patterns.

2.03.P-We111 Development of Chemical and Crop Specific Honeybee GUTS Exposure Scenarios for Assessment of Time-reinforced Toxicity

Thomas Sinclair¹, Christof Schneider¹ and Pernille Thorbek², (1)BASF, Germany, (2)BASF, United Kingdom

Honeybee health is a critical component of sustainable agriculture, and regulatory frameworks increasingly require robust risk assessments for plant protection products. The EFSA 2023 Bee Guidance Document requires the assessment of Time Reinforced Toxicity (TRT) for different bee scenarios, which can be assessed using GUTS TKTD modelling. While the bee GD allows for the use of GUTS TKTD modelling to refine risk, it is not clear from the GD what refinement scenarios for risk assessment should be.

Here, we show how the EFSA bee GD methods for estimating exposure can be translated into exposure time series for use in GUTS modelling. This is demonstrated for annual and perennial crops as well as for active period (summer) and overwintering bees using a hypothetical compound.

The proposed methodology for developing exposure scenarios incorporates crop and chemical information including degradation, (multiple) application timings and methods, and residue dynamics in different matrices from a realistic hypothetical compound. The different bee scenarios consume different amounts of nectar and pollen, and we show how this can be parameterised.

Finally, a hypothetical but realistic case study shows how the parameterised GUTS model together with exposure profiles can be used to calculate margin of safety for refinement of risk.

2.03.P-We112 A Scenario-Based Analysis Using the Model SolBeePop: Exploring Impacts of Foraging Activity, Floral Composition, and Pesticide Exposure in Agroecosystems on Simulated Abundances of Solitary Bees

Ella Rothe¹ and Andreas Focks², (1)University of Osnabrück, Institute for Mathematics, Germany, (2)FB06/Institute of Mathematics, University of Osnabrueck, Germany

Agriculture is essential for human food security, but it also brings negative side effects such as increased homogenization of agroecosystems and in parts intensive pesticide use. This can not only affect human well-being but is under discussion as one reason of drastic declines in many pollinator species. One particularly affected and still under-researched pollinator group are solitary bees. Individual-based models are a promising tool to estimate population-level effects of landscape composition and pesticide exposure. In this study, the model SolBeePop_ecotox was used and expanded to include environmentally relevant factors influencing bee foraging behavior, focusing on two bee species, *Osmia bicornis* and *Megachile rotundata*. Environmental scenarios were developed based on real weather data and diverse floral resource availabilities representing treated crop cultures and retreat areas of natural plant species, i.e., flower strips. Those were combined with annually repeated applications of the insecticide dimethoate. The key metric for effect evaluation was the exposure level at which the simulated populations declined by 50% at six different time points within the simulated period of 15 years. Explicitly, the proportion of how many bees are foraging was derived from prevailing weather conditions, with the result that unsuitable weather in contrast to suitable conditions leads to decreased population survival but increased resilience towards pesticide exposure. Furthermore, the results show that pesticide-free flower strips generally improve the survival rate of simulated bee populations and, in particular, can increase their resilience against pesticide use, especially at high pesticide concentrations and in low-resource agricultural systems. Contrarily, mass-flowering crops and high-diversity polycultures already provide near-optimal foraging conditions and showed reduced effects when coupled with flower strips. Momentarily, the developed scenarios are based on an exploratory approach and future studies should confirm these findings by using real landscape structures and observed solitary bee abundances. This current work gives important insights on how to depict agricultural resources in an implicit way, further enhancing individual-based model understanding. Eventually, research like this will be fundamental for evaluating the protection of solitary bees.

2.03.P-We113 xPollinator – A Flexible Landscape Modelling Framework for the Assessment of Land Use and Pesticide Impacts on Pollinators

Thorsten Schad¹, Sascha Bub², Julian Heinrich³, Christopher M Holmes⁴ and Vanessa Roeben³, (1)Landwerk eV, Germany, (2)Rhineland-Palatinate Technical University Kaiserslautern-Landau, Germany, (3)Bayer CropScience AG, Germany, (4)Applied Analysis Solutions LLC, Germany

Demands for more holistic regulatory ecological risk assessment and risk management for plant protection products increasingly require higher-tier tools, such as landscape-scale models, to address real-world spatial and temporal variability in exposure and effects. Such approaches are inherently complex regarding, e.g., environmental conditions, agricultural practices, exposure and environmental fate processes, species ecology, or effects to organisms. Furthermore, landscape-scale models must manage large volumes of (geo-)data and deliver

interpretable results.

The open source xLandscape framework (<https://github.com/xlandscape>, Schad et al. 2024) provides a modular design for integrating such processes, models and data to manage such complexity. Modularity has advantages for collaboration, harmonization, flexibility, consistency, transparency, and validation. With respect to collaboration, scientists developing individual models (e.g., a new effect model) can build on existing modules and data and can thus focus on the problem at hand and domain of expertise.

With xPollinator we introduce a landscape-scale model to assess effects of pesticides on honeybee colonies. xPollinator is composed of land use, bee forage, pesticide use, exposure and effect modules and is based on the xLandscape framework. The BEEHAVEecotox model (Preuss et al. 2022) is integrated as a module to simulate honeybee hive development and effects of pesticide applications. The bee forage module of xPollinator allows to simulate nectar and pollen occurrence in space and time in real-world landscapes. Thus, effects of different land use and landscape structures on colony health can also be studied using a range of agricultural landscape scenarios.

The poster will present the concepts and technical implementation of xPollinator. Results from simulations illustrate its capability to simulate distinct impacts on honeybee colony dynamics (e.g., changes in colony size, honey production, overwintering survival) based on chemical application patterns, and how the model manages data complexity to yield consolidated, relevant endpoints for pollinator risk assessment on the landscape scale. An interactive, web-based interface (BeeView) allows for result visualization. xPollinator will be made public at GitHub.

Disclaimer/Disclosure:

xPollinator is open source. The development was partly supported by Bayer AG.

2.03.P-We114 Buzzing Toward Better Risk Assessment: Advancing Bee Effect Modelling with the ICPPR Bee Modelling Interest Group

Amelie Schmolke¹, Jeffrey Minucci², Vanessa Roeben³ and Johannes Lückmann¹, (1)RIFCON GmbH, Germany, (2)U.S. Environmental Protection Agency, United States, (3)Bayer CropScience AG, Germany

Mechanistic pesticide exposure and effects models have the potential to improve the efficiency and accuracy of environmental risk assessments for bees and other pollinators. Several models have been introduced or are under development, spanning organism-level effects (e.g., toxicokinetic-toxicodynamic models), colony models, and population models, for a range of taxa including honey bees, bumble bees, and non-Apis bees.

However, these models are not yet well integrated into actual risk assessment processes, and a number of challenges remain. In response, the Bee Modelling Interest Group was established within the International Commission for Plant-Pollinator Relationships (ICPPR), with the aim of improving the acceptability and usability of exposure and effect models in bee risk assessments.

The interest group provides a platform for exchange and discussion between stakeholders from different groups including regulators, industry, contract research organizations and academia. Within the interest group, three work groups have been created based on a survey of members' perceptions of the urgency and feasibility of various topics: (1) improving characterization of exposure pathways relevant for bees, (2) incorporation of sublethal effects in honey bee colony models, and (3) establishing a bee model inventory.

We will introduce the aims and activities of the ICPPR Bee Modelling Interest Group and its three active work groups. Through these collaborative efforts, we aim to accelerate the adoption of mechanistic models within regulatory frameworks, ultimately enabling more accurate and efficient pollinator risk assessments that better protect bee populations while supporting sustainable agriculture.

2.03.P-We115 AI-driven Image Analysis for Increased Accuracy and Precision of Honey Bee Colony Health and Productivity in Regulatory Field Studies

Ashley St. Clair¹, Vince Kramer¹, Elizabeth Collison², Stefan Kimmel³, Edward Pilling², Nitin Kandpal⁴, Kristi Tatsu² and Suchitra Patil⁴, (1)Corteva Agriscience, (2)Corteva Agriscience, United Kingdom, (3)Corteva Agriscience, Germany, (4)Corteva Agriscience, India

Accurate measurement of honey bee populations and colony health is crucial for ecological research and the regulatory crop protection product studies required by national authorities like the U.S. EPA and EFSA. Traditional visual estimation methods, such as the 'Liebefeld Method', for determining "colony strength" are subjective, leading to inconsistent data, often with a high margin for error. To address this, Corteva Agriscience has developed innovative artificial intelligence systems that replace manual estimation with automated image analysis. One AI-driven system automatically and precisely counts individual honey bees on hive frames,

consistently maintaining over 95% accuracy; an 18% increase in accuracy compared to traditional methods. A complementary tool assesses overall colony organization by tracking the distribution of in-hive resources such as nectar, honey, brood, and pollen. Together, these AI-driven systems provide a more reproducible, accurate, and consistent alternative to traditional methods, significantly reducing subjective bias and human error. These tools are currently undergoing Good Laboratory Practices (GLP) validation, with the goal of full implementation in regulatory semi-field and full-field studies. By providing more reliable and precise data, these systems will enhance the quality of environmental risk assessments on honey bees and support the safe use of crop protection products. This investment in AI-driven technology sets a new standard for pollinator safety research and represents a significant step forward in refining ecotoxicological safety testing, making it faster, more accurate, and more reliable.

2.03.P-We116 Quantifying Landscape-Mediated Bee Exposure Refinement: Deriving Landscape-Specific Refinement Factors (RFs) to Inform Regulatory Risk Assessment, per EFSA 2023 Guidance

Silvio Knaebe¹, Pierre Mack², Beatrice Portail² and Farnaz Faramarzi², (1)*Eurofins Agrosience Services US, Germany*, (2)*Eurofins Ecotox, Germany*

Regulatory risk assessments for Plant Protection Products (PPPs) in Europe often rely on conservative tunnel studies, leading to overestimations of bee exposure in real-world agricultural settings. Building on the 2023 EFSA Guidance on the risk assessment of PPPs on bees, this project addresses the critical need for field data to refine exposure estimates. The main objective is to quantify the dilution effect of agricultural landscape complexity on pesticide residues in honeybee-collected pollen and nectar. The research will employ a multi-site field study designed as a landscape complexity gradient, using worst-case tunnel studies as a crucial control. This setup will allow for the calculation of Landscape-Specific Refinement Factors (RFs). Using GIS analysis, key landscape metrics, such as the percentage of semi-natural habitat, will be identified and ranked as predictors of residue dilution. This work, which continues a successful preliminary study from 2024, aims to generate a first regulatory-relevant dataset for informing risk assessments and validating predictive models like BEEHAVE.

2.03.P-We117 How Pesticide Uses and Agricultural Landscape Interact to Produce a Landscape of Pesticides Affecting Pollinator Communities

Hugo Fabre, Aude Ernoul, Aurélien Ridet, **Cécile Sulmon** and Benoît Geslin, *Univ Rennes, CNRS, ECOBIO [(Ecosystèmes, Biodiversité, Evolution)], UMR, 6553, Rennes, France, France*

Maintaining pollinator communities across agricultural landscapes is a major issue for wild plant diversity and crop yields. Recent studies have shown a general decline in insect populations, especially in agricultural environments and pollinators are no exception. A major cause of this decline is related to intensification of agricultural practices which consists both of a simplification of the landscape and the widespread use of pesticides, particularly insecticides. Studies of the impact of pesticides on pollinating insects have mainly focused on local effects at field level. However, pollinators are affected by pesticides throughout their life cycle and exploit resources at the landscape level. These landscapes are not homogeneous: they vary in composition and configuration and they can modulate pesticide exposure, in particular by altering pesticide flows and fate. The aim of this project is to understand how landscape affects pollinator communities, while integrating cumulative pesticide uses in order to characterize the pesticide landscapes to which pollinators are actually exposed. To this end, the study focuses on pollinator communities and associated plant communities in permanent grasslands in Brittany. Although these habitats do not directly receive treatments, they are subjected to pesticide flows from the surrounding landscape. Pollinator's exposure is evaluated by quantifying pesticides in soils, floral resources and pollinators themselves, in addition to knowledge of agricultural practices in the surrounding landscape. These data have two main purposes. The first one is to have an overview of pesticide landscape exposures for pollinators collected in permanent grasslands. The second one is to evaluate pesticide contaminations in grasslands and the transfers of pesticides from soil to pollinators through floral resources in these habitats. The results obtained will provide essential information for assessing the risks to these communities in agricultural environments and understanding how the landscape can modulate these risks. They will also make it possible to propose a new scale for assessing pesticide-related risks.

Disclaimer/Disclosure:

This work and the doctoral fellowship of Hugo Fabre are associated to the PESTILAND project which benefited from the financial support of the French Organism for Biodiversity (OFB) as part of the Ecophyto II+ plan.

2.03.P-We118 Beyond Mortality: Preliminary Assessment of Sublethal and Lethal Effects of Technical and Formulated Fungicide on Pollinators

Benedetta Ponti, Claudia Ferrario, Elena Lattuada and Erica Tediosi, LabAnalysis, Italy

Pesticides are considered one of the leading causes of honeybee (*A. mellifera*) colony decline. While extensive research regarding the effects of herbicides and insecticides on honeybee has been carried out, the effect of fungicides on honeybees has received less attention, probably because their effects may not be apparent and are more difficult to diagnose due to their generally lower acute toxicity.

One of the main steps in estimating the risks of exposure to fungicides for pollinators is to understand how and to what extent bees are exposed to these active ingredients. Although fungicides are typically not considered acutely toxic to bees, some active ingredients with low toxicity may pose chronic risks to bees. Depending on the application method and purpose, bees may be exposed to fungicides orally, through contact, or by inhalation. Additionally, the composition of the honeybee gut microbiota is closely related to the diet and is therefore simultaneously exposed to fungicides. Therefore, in addition to evaluating the lethal effects in honeybees, it is equally important to assess potential sublethal and indirect effects, including the alteration of pollinators basic gut microbial communities.

In the present case study, we evaluate the effects of a fungicide commonly applied via seed-treatment coatings on pollinators, assessing both the technical and the formulated product. All relevant laboratory exposure routes were considered: acute contact and oral toxicity tests (*A. mellifera* and *Bombus terrestris*), chronic oral exposure (*A. mellifera*), and a repeated-dose larval toxicity test (performed only for the formulated product).

Results revealed differences in responses between the technical and the formulated product. Moreover, sublethal effects occurred only with the formulated product, including intestinal injury as indicated by fecal appearance.

As reported in literature, even in the absence of immediate mortality, exposure to fungicides can still affect bees in subtle but significant ways, such as altering the gut microbiota. For this reason, it would be useful to evaluate the real impact of fungicides on pollinators by introducing microbiota analysis during the laboratory tests and considering the extension of the test durations, at least for chronic oral exposure on honeybee, to assess potential long-term effects on bee health following exposure.

2.03.P-We119 Pollinator Risks of Neonicotinoid Residues in Maize Guttation: Toxicity and Ecological Implications

Cafer Turgut¹, Mustafa Kösoğlu², Melis Yalcin³ and Nalan Turgut⁴, (1)Istanbul University, Türkiye, (2)Egeaen Research Institute, Türkiye, (3)Aydın Adnan Menderes University, Turkey, (4)Agroquatro A.Ş, Türkiye

This study offers a thorough assessment of the ecotoxicological risks posed to honey bees (*Apis mellifera anatoliaca*) by neonicotinoid seed treatments—specifically thiamethoxam and clothianidin—used in maize (*Zea mays*) farming systems in Türkiye. Considering that honey bees often use guttation droplets as a water source, the research measures both the insecticide residue levels and the acute toxicity from guttation fluid collected from maize plants grown from treated seeds. Controlled bioassays with guttation droplets from thiamethoxam-treated maize showed that bee mortality exceeded 80% within the first four hours of exposure during the initial five days of guttation production. Although mortality decreased afterward, it remained above 50% through day 10. Cumulative mortality assessments at 24 and 48 hours indicated complete bee death by day 9 across all experimental replicates. Interestingly, guttation fluid collected after day 5 continued to cause more than 50% mortality within 48 hours, and droplets taken up to 72 hours caused significant lethal effects. Thiamethoxam exposure led to consistently high mortality (>80%) for nearly all guttation samples collected within the first 72 hours, while clothianidin caused similarly severe outcomes, often resulting in mortality rates between 80–100%. These results highlight the significant risk posed by neonicotinoid seed coatings in maize to pollinator health through guttation-mediated exposure routes and emphasize the urgent need for stronger regulatory oversight and further ecotoxicological research.

2.03.P-We120 Differences in Butterfly Sensitivity to Oral Exposure to Flupyradifurone – A Call for Broader Research on Pollinators

Dominika Izabella Twaróg and Agnieszka Bednarska, Institute of Nature Conservation, Polish Academy of Sciences, Adama Mickiewicza 33, 31-120 Kraków, Poland, Poland

Agricultural intensification, including widespread use of pesticides, is one of the main drivers of insect biodiversity decline. Currently, regulatory pesticide risk assessment for pollinators relies almost exclusively on toxicity tests on the honey bee (*Apis mellifera*), despite growing evidence that other pollinator species differ substantially in their sensitivity to pesticides. Butterflies, often overlooked in this context, constitute an ecologically important group of pollinators. They may facilitate cross-pollination and access deep floral

structures that are less frequently visited by bees.

This study aimed to determine LD₅₀ values for flupyradifurone administered orally via contaminated sucrose solution to adults of five butterfly species (*Papilio machaon*, *Pieris brassicae*, *Aglaia io*, *Gonepteryx rhamni*, *Polygonia c-album*), allowing for an early comparative assessment of toxicity for this group. The oral 24h LD₅₀s for *A. io*, *G. rhamni*, *P. machaon*, *P. c-album*, and *P. brassicae* were 16.7, 41.6, 53.0, 63.7, and 126.4 µg/individual, respectively. Our results reveal interspecific variation in LD₅₀s, with *A. io* being the most and *P. brassicae* the least sensitive when 24h LD₅₀s were compared, but *P. brassicae* being the most and *P. c-album* the least sensitive when 96h LD₅₀s were compared (3.0 and 41.8 µg/individual, respectively). However, when in the mortality analysis we assumed “dead” to be all individuals that either indeed died or were moribund (unable to walk/relocate, so in fact unable to carry out essential functions), the LD₅₀ values tend to be lower: the 24h LD₅₀ values for *A. io*, *G. rhamni*, *P. machaon*, *P. c-album* and *P. brassicae* were 15.9, 26.2, 8.9, 41.5 and 3.6 µg/individual, respectively, indicating *P. brassicae* being the most and *P. c-album* the least sensitive species (also in terms of their 96h LD₅₀). Whether the order of species sensitivity changes when the LD₅₀ is expressed per unit of mass (µg/g) rather than per individual (µg/individual) will also be discussed. So far, the honey bee appeared more sensitive (24h LD₅₀ of 1.2 µg/individual) than any of the butterfly species tested, suggesting that current risk assessment procedures sufficiently protect a wide range of pollinators. However, the large variability in sensitivity among pollinators indicates that the potential effects of pesticides on this group as a whole are poorly recognized.

2.03.P-We121 Screening of Pesticides in Pollen Collected by Honey Bees in the Northern Zone

Maj Rundlöf¹, Elin Eriksson², Julia Bergman², Sara Erling², Ove Jonsson³, Mariana Ledesma⁴, Laima Blažytė-Čereškienė⁵, Bjørn Arild Hatteland⁶, Glenn P Svensson⁷, Kajsa Weslien², Ola Olsson⁷ and Mikaela Gönczi³, (1)Department of Biology, Lund University, Sweden, (2)Swedish University of Agricultural Sciences (SLU), Sweden, (3)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (4)Swedish Chemicals Agency, Sweden, (5)Nature Research Centre, Lithuania, (6)Norwegian Institute of Bioeconomy Research, Norway, (7)Lund University, Sweden

Pesticides (plant protection products) are used to control pests and support agricultural production, but they can also have negative effects on pollinating insects and their ecosystem services. The primary objectives of this project were to increase knowledge about pesticide exposure of pollinating insects and to contribute to the establishment of a long-term monitoring program for pesticide residues and risks to non-target organisms in the terrestrial environment.

Pollen was collected from honey bee colonies at six locations in Lithuania, Norway and Sweden during May–June 2024. Selected sites represent agricultural areas expected to have high pesticide use. Weekly samples were taken with pollen traps for 3–4 weeks.

At the Swedish University of Agricultural Sciences, pollen samples were analyzed for 173 pesticides using liquid and gas chromatography coupled with mass spectrometry (LC-MS/MS and GC-MS), and 58 of these were detected in at least one sample. An index reflecting the direct pesticide risk to bees was calculated by weighting the measured concentrations of each pesticide with its acute toxicity to honey bees and then summarizing per sample. The insecticide indoxacarb posed the highest risk across all samples, despite it not being approved for use as a plant protection product in the region since 2022. Acetamiprid had the second highest risk and was detected in 96% of the samples. Acetamiprid is one of the few insecticides that is still approved for use in the Northern Zone, with an increase in detection frequency compared to previous studies of pollen in the same region in 2019-2021. The fungicides boscalid, captan, azoxystrobin and fluopyram had the highest maximum concentrations per sample.

At Lund University, the pollen samples were analysed for plant origin using image analysis and machine learning. The commonest pollen type was Brassicaceae, which include cultivated oilseed rape, followed by the Sorbus group, which includes apple. The risk index correlated positively to the proportion of crop pollen in the sample. Oilseed rape and apple were the main flowering crops at the sampled locations and previous studies have identified regions with apple orchards as high-risk areas. In this study, monitoring locations with high

expected pesticide use and potential direct risk to bees were selected, which could be a good strategy when resources are limited.

2.03.P-We122 Characterising Pollinator Exposure Pathways Through Multi-Matrix Pesticide Residue Analysis

Alina Koch¹, Harriet Arnberg², Agnieszka Bednarska³, Julia Bergman¹, Lisa Cabiddu⁴, Elin Eriksson¹, Lina Herbertsson², Ove Jonsson¹, Lars B. Pettersson², Francesco Lami⁴, Ryszard Laskowski⁵, Lucia Lenzi⁴, Mariana Paola Mazzei⁴, Alison O'Reilly⁶, Inés Prieto Ruiz², Fabio Sgolastra⁴, Dominika Twaróg⁷, Elżbieta Ziolkowska⁵ and Maj Rundlöf², (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Biology, Lund University, Sweden, (3)Polish Academy of Sciences (PAS), Poland, (4)Department of Agricultural and Food Sciences, University of Bologna, Italy, (5)Institute of Environmental Sciences, Faculty of Biology, Jagiellonian University, Kraków, Poland, (6)Centre for Environmental and Climate Science, Lund University, Sweden, (7)Institute of Nature Conservation, Polish Academy of Sciences, Kraków, Poland

Understanding co-occurrence of pesticide residues across relevant environmental matrices is essential for characterising pollinator exposure pathways, evaluating exposure modelling, and improving risk assessment. Within the EU Horizon project PollinERA, which aims to advance knowledge on pesticide–pollinator interactions to support European environmental risk assessment and policy, we conducted a coordinated, multi-country residue monitoring campaign to characterise key exposure routes and risks for pollinators. Pollen, nectar, soil, plant material, and surface water were collected in spring and summer 2024 from 18 agricultural sites with either apple orchards or oilseed rape fields in Sweden, Poland, and Italy. Samples were analysed using multi-residue LC-MS/MS and GC-MS methods covering 182 active substances and transformation products. Preliminary results for pollen, nectar, and soil show substantial variation in detections and concentration levels. Across all samples, individual pesticide concentrations ranged from 0.001 to 26,000 ng/g. Non-parametric pairwise tests showed fungicide concentrations were highest in pollen, intermediate in nectar, and lowest in soil (all comparisons significant). Herbicides were highest in pollen (significantly higher than nectar and soil), while insecticide levels did not differ among materials. The most complex mixture occurred in a soil sample collected in spring, containing 72 pesticides (36 fungicides, 18 herbicides, 15 insecticides and 3 metabolites). Twenty-one pesticides were detected in at least 40% of pollen samples, 43 in at least 40% of soil samples, and one compound (insecticide acetamiprid) reached this frequency also in nectar. Overall, soil exhibited the highest detection frequencies, indicating a substantial mixture burden. In contrast, pollen contained higher concentrations, suggesting it may be the more critical exposure route for foraging pollinators, acting both through contact and via feed intake.

These data provide a robust empirical basis for evaluating co-exposure scenarios, identifying realistic pesticide mixtures, and informing the development of PollinERA's pesticide and pollinator co-monitoring scheme. The dataset will support planned pollinator exposure tests, modelling activities within PollinERA, and the development of an integrated, one-system environmental risk assessment approach for pollinators.

2.04.A Ecological Effects of Chemical Mixtures and Multiple Stressors with Special Emphasis on Space and Time

2.04.A.T-01 Spatio-temporal characterization of pesticide mixtures and associated ecological risks at a landscape scale

Pablo Amador¹, Valerio Gherardi¹ and **Andreu Rico²**, (1)University of Valencia, Spain, (2)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain

The ecological risk assessment of pesticides is typically performed at the edge-of-field scale and on a substance-by-substance basis. This approach does not adequately capture the complexity of real-world exposure scenarios, where multiple pesticides are applied over one or several crop cycles within heterogeneous agroecological landscapes. In this study, we developed a large-scale modelling framework (ERAHUMED) capable of predicting the spatio-temporal dynamics of pesticide mixtures and associated risks in freshwater ecosystems. The ERAHUMED model was designed to calculate pesticide exposure and ecological risks in the Albufera Natural Park (Valencia, Spain), which is dominated by intensive rice cultivation, an extensive irrigation and drainage network, and the Albufera Lake. Pesticide exposure simulations were performed for eight pesticides currently used in three rice varieties within the park, while pesticide risks were assessed using the multi-substance Potentially Affected Fraction approach (msPAF) for acute and chronic exposure.

The study shows that acute msPAF reached 25% in rice paddies, 22% in ditches, and 7% in the Albufera Lake. The chronic msPAF indicated 55%, 45%, and 32% in rice paddies, ditches, and the lake, respectively. Acute risks were dominated by 1 or 2 compounds, while chronic risks were dominated by mixtures of 3-6 compounds. In early summer, mixtures posing chronic risks were dominated by a combination of herbicides (MCPA, penoxsulam, cyhalofop), while in late summer chronic risks were mainly driven by a combination of these herbicides, an insecticide (acetamiprid) and two fungicides (azoxystrobin, difenoconazole). The southern section of the lake and its adjacent ditches were identified as the areas with the highest acute and chronic exposure and risks.

The implementation of the ERAHUMED model to the ANP shows that aquatic organisms are exposed to both co-occurring and sequential mixtures of pesticides, and that the current substance-by-substance approach used in pesticide risk assessment significantly underestimates ecological risks. During the presentation, we will explain how the ERAHUMED model can support decision-making related to pesticide management, as well as its applicability for conducting landscape-level evaluations for threatened aquatic populations.

2.04.A.T-02 Toxicity mechanisms and climate govern the global effects of the insecticide imidacloprid on aquatic invertebrates

Paul van den Brink¹, Andreu Rico², Anna Huang¹, Annika Mangold-Döring³, Ivo Roessink¹, Markus Hermann⁴ and Lemessa Merga⁵, (1)Wageningen University and Research (WUR), Netherlands, (2)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain, (3)Environmental Risk Assessment team, Wageningen University and Research (WUR), Netherlands, (4)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (5)Ambo University, Ethiopia

The neonicotinoid insecticide imidacloprid is widely used worldwide in terrestrial environments. It is primarily used as a systemic insecticide when applied as a seed coating. After application, it also enters the aquatic environment through spray drift, surface runoff, and leaching. Imidacloprid has been banned for outdoor use in the EU since 2018, and for many uses in the US, but is still widely used elsewhere. This presentation aims to unravel the mechanisms underlying the long-lasting effects of imidacloprid on aquatic invertebrates and how these mechanisms are influenced by temperature, leading to differences in effects across climatic regions. In our studies, we found increased toxicity over time for some invertebrate species, which can be explained by the formation of a toxic metabolite, imidacloprid-olefin, which is poorly eliminated from the body, leading to the absence of an incipient toxicity value. This observation is supported by findings from a long-term population study (120 days) with an insensitive invertebrate species, which yielded extremely low toxicity values (< 0.003 µg/L).

We found, in both single-species and ecosystem-level studies, that increased temperature increases the toxicity of imidacloprid to aquatic invertebrates. This can be explained by an increased uptake of imidacloprid and an increased biotransformation to the toxic metabolite imidacloprid-olefin.

We reviewed 15 mesocosm studies performed with imidacloprid around the world. The reported ranges of nominal NOEC values for mesocosm studies are 0.5–7.5 µg/L, <1–1 µg/L, 0.03–0.3 µg/L, and <0.01–0.1 µg/L for temperate, Mediterranean, subtropical, and tropical regions, respectively. Our review showed that (sub-) tropical communities are more sensitive to imidacloprid than their Mediterranean-temperate counterparts. Temperature differences can partly explain these differences in sensitivity. This indicates the threat posed by pesticides to aquatic ecosystems globally, thereby contributing to global insect decline. It is clear that, besides Europe and the US, the use of imidacloprid should be restricted in other climate regions (especially the (sub-)tropics) as well.

2.04.A.T-03 Seasonality Matters: Opposing Winter and Summer Pathways of Ecological Response to Warming and Pesticides

Claire Duchet¹, **Helena Švecová²**, **Vojtech Kolar¹**, **Olga Lepšová¹**, **Kateřina Grabicová²** and **David Boukal¹**,
(1)Faculty of Science, University of South Bohemia, Czech Republic, (2)Faculty of Fisheries and Protection of Waters, University of South Bohemia, Czech Republic

Freshwater ecosystems are increasingly confronted with interacting stressors whose impacts can change substantially across seasons. Yet ecotoxicological studies rarely test whether the ecological pathways of stressor effects remain consistent over time. We conducted a full-factorial mesocosm experiment in winter and summer to assess how a mixture of herbicides and fungicides, commonly detected in surface waters, interacts with +4 °C warming to shape community and ecosystem responses.

Pesticides and warming produced complex, non-additive effects from phytoplankton to predatory insects and benthic detritivores, but the dominant pathways shifted seasonally. In winter, the pelagic food web was dominated by top-down control as warming reduced key predators, weakening regulation of grazers, while pesticides suppressed zooplankton. Nutrient stoichiometry (dissolved nitrogen (DN): soluble reactive phosphorus (SRP) ratio) further shaped predator–grazer–phytoplankton interactions, with higher DN:SRP ratios increasing filter-feeder biomass but reducing odonates, thereby altering the trophic cascade. In summer, community dynamics shifted to bottom-up control with warming and elevated DN:SRP ratios associated with increasing phytoplankton, and both warming and pesticides reducing filter feeders, leading to weaker grazing and top-down control.

Benthic detritivores were sensitive to the stressors in both seasons, but consequences differed. In winter, warming and pesticides reduced Asellus and chironomid larvae, yet leaf litter decomposition remained stable. In summer, both stressors reduced detritivore biomass, emergence, and leaf litter breakdown. Across compartments, DN:SRP ratios emerged as a key mediator, structuring grazer, predator, and detritivore responses, highlighting how stoichiometric context interacts with warming and pesticides to shape food-web outcomes

Our findings show that warming can restructure the ecological pathways of chemical mixtures, producing context-dependent, seasonally variable stressor interactions. The shift from top-down mediation in winter to bottom-up mediation in summer highlights the need to integrate seasonal dynamics into empirical assessment and predictive modelling. Ignoring seasonal variability would bias the estimated magnitude and direction of long-term ecological impacts, emphasizing the importance of seasonality for freshwater ecosystem risk assessment under climate change.

2.04.A.T-04 Pulsed Antibiotic Inputs into the Environment May Foster the Spread of Antimicrobial Resistance

Matthias Böckmann¹, **Katharina Axtmann²**, **Gabriele Bierbaum²** and **Christiane Zarfl¹**, (1)Eberhard Karls University of Tübingen, Department of Geosciences, Germany, (2)University Hospital Bonn, Germany

The World Health Organization (WHO) has identified rising antibiotic resistance as a “global threat” underscoring the need to understand resistance dynamics. A key concept is the minimum selective concentration (MSC), the threshold at which resistant bacteria outcompete susceptible ones. While MSC studies usually test single antibiotics, real environments contain fluctuating levels and mixtures from sources like wastewater. This study presents a process-based model of antibiotic accumulation in aquatic systems with and its influence on selection in microbial communities. It incorporates dynamic inputs of antibiotics, photolytic/biotic degradation, cellular uptake and microbial competition. Environmental accumulation from pulses depends on pulse frequency and half-life and can drive selection. Intracellular accumulation depends on intracellular pH, environmental pH, and antibiotic pKa. Antibiotic combinations alter competition depending on synergy, additivity, independence, or antagonism. Synergy can intensify selection even when individual concentrations are below their MSCs. Environmental factors such as nutrients, temperature, and pH modulate but rarely dominate these dynamics. However, intracellular accumulation can strongly affect resistance when conditions are met. These findings clarify how changing concentrations of multiple antibiotics and their chemical properties shape selection and inform mitigation.

2.04.A.T-05 Using Formal Causal Analysis to Differentiate among Chemical, Physical, and Biological Stressors Regarding Observed Environmental Harms

Charlie Menzie and **Ann Michelle Morrison**, *Exponent Inc., United States*

Causal analysis has a long history of development but in 2005 the U.S. EPA introduced CADDIS (Causal Analysis/Diagnosis Decision Information System) focused on diagnosing causes of stream impairments. We

worked with CADDIS and extended it to a tiered approach designed to diagnose causes of complex environmental harms often involving multiple stressors. The challenge is to identify the relevant stressors, to identify the manner in which they contribute to the observed harms, to ensure that adequate data and evidence are available or can be obtained. A conceptual model is used as a foundation for evaluating the weight of evidence for differentiating among the candidate causes of observed harms. An additional challenge is the consideration of the passage of time in that the original stressor events need to be unearthed through historical reviews. Another time-related challenge is the periodic oscillation in climatic conditions (e.g., cycles of dry and wet periods) that fall within the current longer-term trajectory in climate. This emerged as important in one of our case studies and was tracked using dendrochronology (i.e., tree ring analyses).

We illustrate application of the methodology using three cases which individually highlight evaluations of chemical, biological, and physical stressors. The first case involves differentiating among air pollution, saline groundwater, and plant diseases for determining the main causes of crop and plant damage in the Yemen desert; the second case focuses on biological and chemical stressors contributing to losses of honey bees in the United States; the third case evaluates the role that water management and other factors explain the loss of a highly valued oyster fishery and adverse impacts to wetlands impacts in a major river and estuarine system.

While the methodology serves to identify causes of harm, it also serves to guide solutions. The third case - loss of valued oyster beds - will be used to describe what has emerged as a solution. That solution weaves together educational, sociological, political, and scientific elements.

2.04.B Ecological Effects of Chemical Mixtures and Multiple Stressors with Special Emphasis on Space and Time

2.04.B.T-01 Applying Comprehensive Ecological Risk Assessment to Urban Tropical Rivers: Departures from Temperate River Paradigms

Emmanuel Ansah¹, Heiko L. Schoenfuss², Riley Hershberger³, Paul Edmiston³, Paige Novak⁴ and Christopher Gordon⁵, (1)University of Ghana, United States, (2)St. Cloud State University, United States, (3)College of Wooster, United States, (4)University of Minnesota, St. Paul, USA, United States, (5)University of Ghana, Ghana

Understanding contaminant dynamics and ecological effects in tropical urban rivers remains a major challenge, as most ecological risk assessment (ERA) frameworks are derived from temperate regions of the Global North. These frameworks often overlook the distinct climatic, hydrological, and socioeconomic conditions of tropical environments. This study aimed to generate empirical data on multiple pollutant stressors and evaluate their ecological risks across seasons within an urban tropical river basin in Ghana. Water samples were collected from 12 sites along the river continuum during both dry and wet seasons, including adjacent groundwater sources. Analyses covered physical-chemical parameters, historical pollutants (nutrients and heavy metals), and quantification by GC-MS/MS of contaminants of emerging concern (CECs), including pharmaceuticals, personal care products, hormones, and PFAS. Ammonia (range: 0.-21.5 mg/L; Risk Quotient [RQ]=976) and Nitrate (4.4-75.0 mg/L; RQ=66) posed the highest nutrient-related risk, exceeding aquatic life protection limits, while lead (<LOD-0.58 mg/L; RQ=2,065) and cadmium (<LOD-0.23 mg/L; RQ=4,966) and mercury (<LOD-0.042 mg/L; RQ=11,160) dominated metal toxicity. Among CECs, trimethoprim (<LOD-1,042 ng/L; RQ=3.9), diclofenac (<LOD-174 ng/L; RQ=16.2), estrone (10-2,000 ng/L; RQ=548), and PFOS (5.66 ng/L; RQ=20.6) were major ecological risk drivers. Antibiotic-resistant genes were numerous and spiked at downstream sites. RQs exhibited limited seasonal trends but increased along an upstream-to-downstream gradient, with an astonishing cumulative ΣRQ of 18,434 at a downstream site used for informal electronic waste recycling. Compared to temperate rivers, the ecological risk in this urban tropical river was driven by nutrients and heavy metals, primarily due to limited wastewater infrastructure and informal recycling practices, respectively. Although CEC contaminant classes mirrored those found in temperate rivers, concentrations and RQs were markedly greater. Sources of contaminants (untreated municipal wastewater, unregulated artisanal industries) also differed from those typically causative in temperate rivers. This study presents the first integrated ERA for a tropical urban river, providing a scientific foundation for regulatory interventions, improved wastewater treatment, and ecological restoration in developing regions.

2.04.B.T-02 Context-dependent Invertebrate Biomarker Responses to Micropollutant Mixtures Across Aquatic Agroecosystems: Insights from Lentic Small Water Bodies

Gaspard François Léopold Conseil¹, Olivier Cardoso², Vincent Felten³, Christophe Rosin⁴ and Damien Banas³, (1)University of Lorraine (UL), Nancy, France, (2)French Biodiversity Agency (OFB), France, (3)University of

Lorraine (UL), France, (4)French Agency for Food, Environmental and Occupational Health & Safety (ANSES), France

Lentic small water bodies (LSWBs) are highly sensitive to the combined influence of chemical mixtures and multiple environmental stressors, yet their spatiotemporal dynamics remain poorly characterised. In agricultural landscapes, LSWBs may concentrate complex contaminant mixtures composed of both pesticides and their transformation products (TPs), alongside natural stressors such as variable oxygen levels. These interacting pressures may generate context-dependent biological responses that may not be predicted from exposure to single contaminants alone.

This study investigates how spatial variation in pesticide mixtures and associated stressors shapes the ecological responses of a sentinel invertebrate (i.e., *Gammarus roeseli*). Active biomonitoring was conducted across LSWBs (specifically fishponds) differing in land-use influence, where caged freshwater amphipods were exposed for several days. Water quality was characterised through targeted chemical analysis of pesticides and their TPs, while biological responses were assessed using a multibiomarker approach integrating antioxidant defence, neurophysiology and energy metabolism.

Clear spatial contrasts emerged among ponds, both in chemical mixtures and in biological responses. TPs represented a substantial fraction of total pesticide occurrence, including compounds derived from herbicides intensively used in surrounding watersheds. The biomarker patterns observed enabled the discrimination of sites with elevated concentrations of these TPs and highlighted oxidative stress and metabolic disturbance in exposed organisms. In LSWBs subject to additional environmental pressures such as reduced dissolved oxygen levels, biological alterations were amplified despite comparable contaminant loads, revealing environmentally driven and potentially non-additive effects.

Our results show that integrating active biomonitoring with contaminant profiling provides a refined understanding of how spatially structured mixtures and co-occurring stressors interact to affect aquatic organisms. This approach improves ecological relevance in risk assessment by capturing real-world exposure scenarios and supports the identification of vulnerable understudied freshwater habitats within agricultural landscapes.

2.04.B.T-03 The Ecosystem Function of Microbial Leaf Decomposition in Streams Responds Stronger to Land Use than to Pesticides

Verena Christina Schreiner¹, Moritz Link², Anke Schneeweiss³, Matthias Liess⁴, Oliver Weisner³, Philipp Vormeier³, Liana Liebmann³ and Ralf Bernhard Schaefer⁵, (1)University Duisburg-Essen (Uni DUE), Germany, (2)RPTU University of Kaiserslautern-Landau, Germany, (3)German Environment Agency (UBA), Germany, (4)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (5)University Duisburg-Essen (Uni DUE), Duisburg, Germany

The decomposition of allochthonous organic matter is the base of the so-called brown food web, which dominates in headwater streams. Agricultural streams are subject to multiple stressors, including pesticide exposure, excessive nutrients and habitat degradation. Those stressors can positively (e.g., moderate nutrient exposure) or negatively (e.g., pesticide toxicity) impact organisms such as aquatic fungi which then has consequences on matter decomposition. To date, most field studies investigating multiple stressor impacts have exclusively focused on the ecosystem function of leaf decomposition, without considering associated proxies for the capacity of fungal communities to decompose leaves, such as the fungal biomass or the activity of exo-enzymes. In a German-wide small stream monitoring (KgM) with most stream sampling sites located adjacent to agricultural land use, we aimed to identify the environmental variables that exert the strongest association with microbial leaf decomposition, fungal biomass and exo-enzyme activities. We quantified water quality parameters spanning from a range of chemicals including fungicides, nutrients, trace elements, to several basic physicochemical properties and determined the ratio of agricultural land use in the catchment was determined per site. Between May and July of 2018 and 2019, we deployed fine mesh bags filled with black alder leaves to determine the microbial leaf decomposition, fungal biomass (as ergosterol concentration) as well as exo-enzyme

activity. In contrast to expectations and previous findings, neither the microbial decomposition nor the fungal biomass was related to the potential fungicide toxicity towards fungi, but to the agricultural land use. The land use can be considered a proxy variable integrating various anthropogenic environmental changes. The exo-enzyme activity was associated with variables, such as water temperature, oxygen, conductivity or pH, which directly influence the production and stability of enzymes. This study highlights that the ecosystem function of decomposition in streams is influenced by agricultural land use, but not as expected by potential fungicide toxicity. Additional endpoints provided further insight into the mechanisms of decomposition and showed the relevance of single variables in the process of decomposition. The fact that decomposition was maintained despite multiple stressor effects hints towards a substantial functional redundancy of fungal communities.

2.04.B.T-04 Beyond Additivity: Interactions Between Environmental Stressors and Pesticides

Naeem Shahid¹, Ayesha Siddique² and Matthias Liess², (1)System-Ecotoxicology, Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Global biodiversity is declining at an unprecedented rate in response to multiple stressors. Effective biodiversity management requires a deeper understanding of the relevant mechanisms behind such ecological impacts. A key challenge is understanding synergistic interactions between multiple stressors and predicting their combined effects. Here, we used *Daphnia magna* as a model and quantified responses to a single pesticide (esfenvalerate) and a field-realistic mixture of 13 pesticides under two climate-related stressors: food limitation and elevated temperature. The pesticide mixture followed Concentration Addition (CA), whereas the environmental stressors produced strong synergistic effects that were accurately predicted by the Stress Addition Model (SAM). Food limitation increased toxicity four-fold for esfenvalerate and ten-fold for the mixture (MDR = 4 and 10). Elevated temperature (+5 °C) further intensified these interactions, yielding MDRs of 19 and 42, with latent synergism strengthening through the 21-day test. Notably, the 19-fold synergism resulted almost entirely from the two non-chemical stressors; adding pesticide mixtures merely doubled the effect. Consequently, LC50 values declined sharply – from TU 3.46 to 0.18 for esfenvalerate and from TU 2.85 to 0.068 for the mixture – while LC10 values dropped by more than two orders of magnitude. Food limitation and warming were the dominant drivers of synergism, whereas pesticide mixtures contributed comparatively little. Our findings demonstrate that environmental stressors can drastically magnify pesticide toxicity. Thus, ecological risk assessments must explicitly incorporate both chemical mixtures and co-occurring environmental stressors to avoid underestimating ecological impacts.

2.04.B.T-05 Linking aquatic and terrestrial decomposition responses to hydrological extremes and pesticide exposure

Aida Viza¹, Carsten A. Brühl¹, Tom Dekker¹, Alexander Feckler¹, Tiare Huizar¹, Ralf Schulz², Ogechi Ugbor¹ and Mirco Bundschuh¹, (1)Rhineland-Palatinate Technical University Kaiserslautern-Landau, Germany, (2)iES Landau, Institute for Environmental Sciences, Rhineland-Palatinate Technical University Kaiserslautern-Landau, Germany

Rivers are characterised not only by longitudinal flow but also by vertical and lateral dimensions. The lateral dimension links aquatic and terrestrial ecosystems through reciprocal subsidies. Leaf litter decomposition plays a key role in carbon and nutrient cycling, yet it is often studied in isolation in aquatic and terrestrial systems, with limited research spanning the aquatic–terrestrial continuum. Both ecosystems are increasingly exposed to anthropogenic stressors and climate change, including chemical pollution and extreme hydrological events. We conducted a mesocosm experiment to investigate the effects of contrasting hydrological events (floods and droughts) and pesticide contamination originating from leaf litter collected in agricultural riparian areas on decomposition and associated communities (invertebrates and microorganisms) along the aquatic–terrestrial gradient. To reflect environmentally relevant conditions, leaf litter was collected from both forested and agricultural sites, the latter containing pesticide residues acquired in situ. The experiment lasted 25 days and comprised four phases: acclimation (10 days), drying (5 days), flooding (5 days) and recovery (5 days). Litter was exposed to drying and flooding, individually and in combination, at three distances perpendicular to flow: within the stream (0 m), on the shoreline (0.5 m) and in the riparian zone (5 m). We are quantifying decomposition rates and characterising microbial (fungal and bacterial) and invertebrate communities to evaluate how hydrological extremes and pesticide-laden litter interact to influence ecosystem processes. Pesticide content will also be analysed at the beginning and end of the experiment to assess potential changes over time. Outcomes are expected to provide new insights into how climate- and human-induced stressors alter cross-boundary ecosystem functioning, addressing key knowledge gaps related to global change in interface habitats.

2.04.P Ecological Effects of Chemical Mixtures and Multiple Stressors with Special Emphasis on Space and Time

2.04.P-Mo107 Aquatic invertebrates under pressure: The interplay of temperature and receptor binding in bioaccumulation

Johannes Raths¹, Markus Hermann¹, Clarissa von Au¹ and Juliane Hollender², (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Chemical pollution and climate change are major planetary boundaries exceeding the safe operating space the. Yet, the interaction between contaminant exposure and climate conditions remains poorly understood, as laboratory predictions often underestimate environmental risks. This study examines temperature-dependent toxicokinetics of the neonicotinoid thiacloprid in the aquatic invertebrate *Gammarus pulex* to improve predictions of bioaccumulation across laboratory and field conditions. Neonicotinoids show strong binding to nicotinic acetylcholine receptors (nAChRs), which may reduce elimination and enhance accumulation at higher temperatures.

Toxicokinetic experiments were conducted under constant temperatures (6–21°C) at 50 µg/L (one day uptake, three days elimination). Additional receptor binding assays quantified membrane-bound fractions. Chemical analyses were performed using online-SPE coupled with LC-HRMS/MS. A multicompartment toxicokinetic model was applied and combined with the Arrhenius equation to describe temperature-dependent rate constants. Model validation took place in stream mesocosms with thiacloprid spikes (10 µg/L) under ambient and heatwave (+8°C) conditions.

The two-compartment model fitted laboratory data well ($R^2 = 0.80\text{--}0.98$) accurately predicted thiacloprid concentrations. Temperature dependencies of toxicokinetic rate constants (Arrhenius temperature $TA = 7900 \pm 500 \text{ K}^{?1}$) matched physiological expectations and observations from previous experiments. Most residual thiacloprid remained bound to membrane proteins, explaining its persistence. In mesocosms, tissue concentrations were almost twice as high under heatwave conditions ($46 \pm 10 \text{ µg/kg}$) compared to ambient conditions ($25 \pm 6 \text{ µg/kg}$). After exposure, the concentration in the gammarids remained constant with no observed elimination. This indicates a higher body burden – lasting far longer than the event of exposure – if neonicotinoid exposure and heatwaves cooccur simultaneously, such as in typical pesticide application seasons such as late spring and summer.

Our results advance the mechanistic understanding of chemical exposure and fate under changing climatic conditions and highlight how heat events can intensify risks caused by neonicotinoids. These findings emphasize the need for regulatory strategies addressing long-term ecological impacts in a warming climate.

2.04.P-Mo108 Bugs on drugs: Short-term Exposure of Fluoxetine and Clobazam impacts the Activity and Foraging Behaviour of the Northern Damselfly under different Temperature Scenarios

Nicole Goede¹, Daniel Cervený², Daniel Cebrián Lacasa³, Lendert Gelens⁴, Tomas Brodin² and Eli Thoré⁵, (1)KU Leuven, University of Namur (UNamur), Belgium, (2)Swedish University of Agricultural Sciences (SLU), Belgium, (3)KU Leuven, University of Edinburgh, Belgium, (4)KU Leuven, Belgium, (5)Université de Namur (UNamur), Katholieke Universiteit Leuven (KULeuven), Belgium

Freshwater systems are increasingly contaminated with pharmaceuticals and personal care products and are simultaneously affected by rising global temperature, placing roughly a quarter of their fauna at risk of extinction. Psychoactive pharmaceuticals are of particular concern because they are biologically active at low concentrations, persist in the environment, and often co-occur as mixtures. But despite their widespread occurrence, we still lack a clear understanding how warming alters the behavioural effects of these pharmaceuticals—especially when organisms are exposed to multiple compounds simultaneously.

Therefore, we conducted a controlled laboratory experiment using northern damselfly nymphs—a widespread aquatic predator sensitive to environmental change—to test how a two-week exposure to two psychoactive pharmaceuticals (Fluoxetine and Clobazam), individually and in mixture, affect their activity and foraging behaviour under two temperature scenarios. Fluoxetine reduced attack success at low temperature, while Clobazam consistently decreased movement speed across temperatures. The mixture did not produce clear interactive effects.

Overall, our findings show that temperature modulates the behavioural impact of pharmaceuticals, with potential

implications for predator-prey interactions and ecosystems functioning. This underscores the need to consider interactive stressors—especially warming-pollutant interactions—in future ecological risk assessments.

2.04.P-Mo109 Multistress in *Chironomus riparius*: Response of Endocrine-Related Genes to Chemical Mixtures and Temperatures

Ahlam Mohamed-Benhammou and Jose-Luis Martinez-Guitarte, National University of Distance Education (UNED), Spain

Pollution and climate change are among the main concerns today. There is a lack of knowledge about the mechanisms underlying responses to chemical mixtures when temperatures change, a condition that will occur under current climate change. The gap is especially evident in aquatic invertebrates, which are essential in the food web of freshwater ecosystems. To gain insight into how invertebrates can manage pollution during climate change, the effects of single, double, and triple mixtures of bisphenol A, cadmium, and endosulfan at four temperatures (18, 21.5, 23, and 25 °C) have been studied. Five receptor genes related to the endocrine system (EcR, Met, InR, MAPR, and AllaR) were selected to examine the impact of the three selected chemicals on their endocrine-disrupting activity. Fourth instar larvae were exposed for 1, 2, and 4 days and frozen individually. The RNA was extracted and retrotranscribed to analyze the mRNA levels of the five genes selected by Real-Time PCR. As reference genes, actin and glyceraldehyde-3-phosphate dehydrogenase were used. The results show the differential impact of time, temperature, and chemical stressors, opening new perspectives for mimicking the wild conditions organisms encounter. In addition, the complexity of result interpretation is highlighted by the number of variables implicated and the potential events that can occur in the cell during short-, medium-, and long-term molecular responses.

2.04.P-Mo110 Multi-generational Sub-lethal Effects of Fungicide Tebuconazole Under Climate Change Scenarios in *Daphnia magna*

Marina Lochanin¹, Verena Christina Schreiner², Sonja Zimmermann³ and Thomas-Benjamin Seiler⁴, (1)University Duisburg-Essen, Ruhr District Institute of Hygiene, Germany, (2)University Duisburg-Essen, Research Center One Health Ruhr, Germany, (3)University Duisburg-Essen, Germany, (4)Ruhr District Institute of Hygiene, Germany

European freshwater streams are regularly exposed to multiple stressors including a multitude of chemicals designed for agricultural use. These chemicals, such as pesticides, are known to inhibit and cause a range of defects in the reproduction of freshwater organisms. Chronic pesticide exposure, which occurs due to the repeated application to crops across several seasons, in particular is of high interest due to the potential interaction with other stressors. Thus, seasonal and daily changes in variables such as temperature might cause altered effects of pesticides on freshwater organisms. Thermal fluctuations can have an effect on pesticides availability for uptake, its distribution and metabolism, as well as general organismal functions of different invertebrates. We assessed how changes in temperature can influence effects of pesticides on a macroinvertebrate. We performed a multi-generational study on *Daphnia magna* using the fungicide tebuconazole. Tebuconazoles is widely used as a systematic fungicide and was shown to cause oxidative stress generation and neurotoxic effects in macroinvertebrates. Therefore, it is likely to impact multiple trophic levels within an ecosystem. We extended the pre-established OECD 211- protocol to assess three generations of *Daphnia magna*, allowing us to study chronic propagation effects. For all generations, we collected data on multiple sub-lethal parameters, such as size, swimming behavior and oxidative stress markers in addition to mortality, produced sex ratios and juvenile production. To assess the possible temperature-dependent effect modulation, three different temperature conditions were evaluated with decreased (16°C), laboratory culture standard (20°C) and increased (24°C) temperatures representing a realistic fluctuation within a waterbody We hypothesize that both 16°C and 24°C-temperature conditions will lead to decreasing effect concentrations. During the conference, we present and discuss our findings in light of risk assessment in the context of multiple stressors.

2.04.P-Mo111 Seasonal Context Modulates Multiple-Stressor Effects on Aquatic Microbial Function

Aqeela Muheen, Alexander Feckler, Sadia Rahat, Katharina Wifling, Nwoye Chukwuma and Mirco Bundschuh, Institute for Environmental Sciences, RPTU University of Kaiserslautern-Landau, Germany

Microbially-driven leaf litter decomposition (LLD) is an important ecological function in streams that can be altered by multiple stressors originating from agricultural runoff, such as pesticides, nutrients and suspended solids. However, seasonal shifts in leaf-associated microbial communities, which is triggered by the seasonal context in terms of temperature, flow, and nutrient availability, may change the community's stress-tolerance. We expected fungicides and suspended solids to reduce and nutrients to enhance LLD, with effect sizes being dependent on the season during which the experiment is performed. Therefore, we conducted a 4×3×3 factorial experiment over 21 days over four seasons in 2024. The three factors included a fungicide mixture (4 levels), nutrients (3 levels), and suspended solids (3 levels), while microbial communities were sampled during winter, spring, summer and autumn from the same near-natural site. LLD was selected as the functional variable, while structural changes will be assessed using molecular techniques. We observed that higher levels of fungicides and suspended solids reduced LLD, while nutrients availability stimulated it, supporting our hypothesis, although the effects varied seasonally. The highest fungicide treatment (600 µg/L) reduced LLD in winter (?7%), summer (?2%), and autumn (?17%), but increased it in spring (+7%) compared to controls. At the same time, the high solids treatment (100 mg/L) reduced LLD in winter and spring (?7%), while no significant effect was observed in summer or autumn. Elevated nutrient concentrations (NO₃-N/PO₄-P: 18/1.8 mg/L) increased LLD significantly across all seasons. Seasonal differences in LLD in response to the applied stressors likely reflect temporal changes in microbial community structure and thus their successional dynamics, which influence their functional sensitivity over time. We will verify this by analysing the microbial community structure across seasons using quantitative real-time polymerase chain reaction (qPCR).

2.04.P-Mo112 Distance-decay Patterns of Riverine Microbial Communities and Their Biodegradation Potential

Sofia Miranda Rosete¹, Joeselle Serrana², Arild Gustafsson¹ and Malte Posselt³, (1)Stockholm University, Sweden, (2)Department of Environmental Science, Stockholm University, Stockholm, Sweden, (3)Department of Environmental Science, Stockholm University, Sweden

Microorganisms are fundamental to the biodegradation of micropollutants, a process that underlies the self-purification capacity of river systems. Understanding their dynamics and the factors influencing their functionality is critical, as alterations in microbial diversity and composition can directly affect purification efficiency. This study investigated changes in benthic and pelagic microbial communities along a 5?km stretch of the wastewater-impacted Örsunda River, focusing on spatial distance-decay patterns before and after a flood event. We hypothesized that distance-decay would occur in both environments and that flooding would attenuate these patterns. Microbial communities were profiled using 16S rRNA metabarcoding, while biodegradation potential was evaluated with the modified OECD 309 test. Analyses revealed distinct differences in diversity and composition between benthic and pelagic communities, both of which exhibited distance-decay relationships. Notably, flooding weakened these spatial patterns. Across the 5?km transect, communities degraded 57 compounds, of which 11 showed apparent spatial variation. Preliminary evidence further indicated that flooding altered the biodegradation of specific compounds. These findings highlight the need to consider spatial distance and disturbance regimes when assessing the ecological impacts of Wastewater Treatment Plants. They also suggest that biodegradation studies should ideally be conducted during periods of minimal disturbance to ensure ecologically meaningful interpretations.

2.04.P-Mo113 SPATIOTEMPORAL FACTORS RELEVANT IN THE POPULATION DYNAMICS OF SNAIL HOST IN RELATIONSHIP TO SCHISTOSOMIASIS TRANSMISSION

Akbar Ganatra¹, Eric Agola Lelo², Isaiah Omondi², Caroline Ndege², Isaac Cheruiyot Tanui³, Faith Kandie⁴, Werner Brack³, Ulrike Fillinger⁵, Matthias Liess⁶ and Naeem Shahid³, (1)Wageningen University and Research (WUR), Netherlands, (2)Kenya Medical Research Institute, Kenya, (3)Helmholtz Center for Environmental Research (UFZ), Germany, (4)Moi University, Kenya, (5)International Centre of Insect Physiology and Ecology, Kenya, (6)Department Ecotoxicology, Helmholtz Centre for Environmental Research (UFZ) & Institute for Environmental Research (Biology V), RWTH Aachen University, Germany

Schistosomiasis remains a public health problem in Kenya where ~4.3 million people require preventative chemotherapy. Recent research highlighted the role pesticide pollution can play in the transmission of the disease, by disrupting the ecosystem and favoring the host snails over their competitors. Here, we expand on that research by carrying out surveys along 5 rivers over the course of a year (2 wet and 2 dry seasons),

measuring snail incidence & abundance in comparison to predator & competitor dominance and pesticide pollution. We observed that host snail abundance increases with pesticide pollution ($R = 0.23$, $P = 0.009$) but decreases with competitor dominance ($R = 0.15$, $P = 0.006$) in the wet seasons. We also observed that both predator ($R = 0.34$, $P < 0.001$) and competitor dominance decreased with T_{Umax} in the same period ($R = 0.27$, $P = 0.004$). From these, we postulate that pesticide pollution contributes to increased *Schistosoma*-host snail abundance, primarily by reducing the dominance of their competitors. The study adds evidence to the hypothesis that pesticide pollution leads to more favorable conditions for the host snails, including for the first time, temporal evidence showing seasonal influence, increasing disease risk in areas where agriculture and the host snail habitat intersect.

2.04.P-Mo114 Balancing Risk and Vermiremediation: Temperature Effects on Heavy Metal Removal by *Eisenia fetida* in Sewage Sludge-Amended Soils

Inesa Kniūpytė¹, Diana Miškelytė², Marius Praspaliauskas¹ and Jurate Zaltauskaite², (1)Laboratory of Heat Equipment Research and Testing, Lithuanian Energy Institute, Lithuania, (2)Department of Environmental Sciences, Vytautas Magnus University, Universiteto 10, Akademija, Kaunas district, Lithuania, Lithuania

The increasing generation of sewage sludge (SS) poses growing challenges for its safe and sustainable management. While SS can be reused in agriculture for its nutrient-rich organic matter, these benefits are counterbalanced by contaminants such as heavy metals (HM) and other potentially harmful substances. Current regulations often fail to capture broader ecological risks to soil organisms and ecosystems. Vermiremediation, the use of earthworms, sustainably removes pollutants and enhances soil properties (e.g., pH, organic matter content). Climate change may alter HM mobility, availability, toxicity, affecting soil organisms and bioremediation potential. It is therefore crucial to understand how temperature influences earthworm activity, survival, and overall vermiremediation efficiency.

In this study, we examined the effect of temperature on vermiremediation in soils amended with SS from a municipal wastewater treatment plant serving 10,000–20,000 population equivalents (PE), containing Co, Mn, Cr, and Cu. Two temperature regimes (21 °C and 25 °C) were tested under optimal soil water content (45–50% of maximum WHC) using compost earthworms (*Eisenia fetida* L.). HM accumulation, survival, and weight gain were monitored to assess how temperature affects remediation performance.

The results showed that *E. fetida* tolerated low HM mixtures under both temperatures. SS dose, temperature, and their interaction significantly affected survival (Factorial ANOVA, $F = 66.66$ – 86.23 , $p < 0.05$). At 21 °C, low SS doses (12.5 and 25 t/ha) promoted growth (18–25% weight gain), while the highest dose (50 t/ha) caused the lowest survival. Elevated temperature (25 °C) intensified HM toxicity, reducing both survival and growth. One-way ANOVA showed that sludge dose significantly influenced HM removal: Co and Mn were removed efficiently (>80%), while Cr (20.8–35.2%) and Cu (17.9–40.3%) showed lower removal, particularly at higher SS doses and elevated temperature.

Careful management of environmental conditions and pollutant levels is essential to maintain soil organism health and ensure effective remediation. These findings provide valuable insights into how temperature modulates vermiremediation in SS-amended soils, emphasizing the need to consider climate-related factors when applying biological remediation. They have important implications for optimizing future bioremediation strategies and ensuring the safe agricultural reuse of SS.

2.04.P-Mo115 Mixture Effects of Metal-Organic Pesticides on a Freshwater Ecosystem: A Microcosm Study

Emma Yenney¹, Marius Schmitt², Apurva Deepak Bhatkhande³, Dirk de Leijer³, Karel De Schamphelaere², Ronny Blust³, Gudrun de Boeck³, Nina Cedergreen⁴ and Raewyn M. Town³, (1)University of Copenhagen, Denmark, (2)GhEnToxLab, Ghent University, Belgium, (3)University of Antwerp, Belgium, (4)Plant and Environmental Sciences, University of Copenhagen, Denmark

Chemical pollutants in the environment rarely occur as single compounds. Runoff from agricultural fields often introduces pesticide mixtures into freshwater systems, yet current regulatory guidelines typically evaluate toxicity of individual active substances only. This method neglects potential mixture effects, which can influence toxicity directly, as well as cause indirect ecological interactions across the food chain. These oversights of particularly the ecological interactions may lead to inaccurately predicted toxicity with the standard reference models Concentration Addition (CA) and Independent Action (IA).

To address these gaps, a three-month microcosm experiment was run to investigate the combined effects of an organic fungicide, azoxystrobin, and the metal, copper, on freshwater ecosystems. The study looked at both direct and indirect effects on algal population density, macrophyte growth, macroinvertebrate populations, and zooplankton populations and communities. Comparing observed outcomes with expectations from single

chemical laboratory assays, we assessed whether standard regulatory methods can capture mixture effects on an ecosystem level.

The results showed that when chemicals were applied in the microcosms at concentrations proven to have effects in the lab, no significant effects were detected. Instead, organism effects were more strongly influenced by environmental parameters such as heatwaves and nutrient limitations. This indicates that once dynamic ecological variables are introduced, current toxicity assays fail to predict ecosystem-level outcomes.

Furthermore, it shows the urge to take environmental stressors into account, besides chemical stress alone.

However, as the laboratory results showed the highest toxicity, and strongest mixture effects, using lab-data to set ecological limit values would still be a protective strategy.

2.04.P-Mo116 Developing a Monitoring Framework for UK Protected Waters: Integrating Chemical Surveillance and eDNA to Identify Emerging Risks to Sensitive Species

Gareth Le Page¹, Alice Tagliati¹ and Graeme Shaw², (1)*Enviresearch Ltd., United Kingdom*, (2)*Natural England, United Kingdom*

Freshwater ecosystems in the UK host a high proportion of nationally important and vulnerable habitats, yet the pressures from agricultural, veterinary, and wider land-use chemicals remain poorly characterised at catchment scale. Regulatory monitoring typically focuses on a suite of priority substances to inform on water quality but tends to lack parallel ecological parameters, leaving major uncertainties regarding the occurrence, mixture exposures, and ecological relevance of many pesticides and veterinary medicines with plausible pathways to protected sites. Furthermore, it is rare that monitoring programmes are designed to ensure a robust integration of both chemical surveillance and biomonitoring to identify the impact of chemical pressure to vulnerable species and communities. To address these gaps, we are developing a monitoring programme that integrates targeted chemical surveillance with biomonitoring metrics derived from environmental DNA (eDNA) to provide reliable and robust data for environmental risk assessment.

We first undertook a systematic process to identify and prioritise chemicals of interest, combining usage indicators, physicochemical properties (persistence, mobility, bioaccumulation potential), and ecotoxicological endpoints relevant to the specific aquatic habitats (e.g. the Pesticide Load Index). Both passive and spot-sampling methodologies were evaluated to determine feasible approaches for capturing low-level, intermittent, and mixture exposures in flowing waters. A parallel examination of traditional and an eDNA-based biomonitoring strategies was also conducted and brought together with the chemical monitoring approaches to design a monitoring programme designed for the assessment of community-level responses and the detection of sensitive or declining taxa potentially at risk from chemical pressures.

Here we present the development of a forthcoming UK monitoring project aiming to (i) establish practical sampling designs that reflect realistic chemical exposure profiles; (ii) develop approaches for linking chemical occurrence with biodiversity indicators to strengthen causal inference; and (iii) design a robust monitoring programme that will provide a transparent evidence base for spatiotemporal effects of chemical mixtures on aquatic communities and provide data for environmental risk assessment which can then in turn inform future UK monitoring and regulatory protection strategies for freshwater habitats.

2.04.P-Mo117 Exposure to Chemical Mixture Triggers Oxidative Stress Biomarkers under Environmental Stress

Imrana Mushtaq¹, Naeem Shahid², Ayesha Siddique³ and Matthias Liess³, (1)*RWTH Aachen University, Germany*, (2)*System-Ecotoxicology, Helmholtz Centre for Environmental Research GmbH (UFZ), Germany*, (3)*Helmholtz Centre for Environmental Research GmbH (UFZ), Germany*

Natural ecosystems include multifactorial stressor mixtures that can induce sublethal effects at concentrations far below lethal levels, yet their long-term physiological consequences remain poorly understood, thereby challenging the traditional risk assessment framework. In this study, we investigated the chronic effects of combined chemical and environmental stressors on the freshwater cladoceran *Daphnia magna*, focusing on how molecular stress biomarkers can be used as predictors for individual survival. Organisms were exposed continuously for 21 days to copper and food limitation, with an additional 24-hour pulse exposure to the pyrethroid insecticide esfenvalerate. Survival was modeled using CA, EA, and SAM approaches across different time points, with SAM providing the most accurate predictions of combined stressor effects. The addition of 0.1 µg/L esfenvalerate to the combination of copper and food stress accelerated the onset and increase of synergistic effects (MDR EA = 2.46) compared to copper and food stress alone (MDR EA = 1.61). At the molecular level, activities of the oxidative stress biomarkers catalase (CAT), superoxide dismutase (SOD), and glutathione S-transferase (GST) were quantified. Significant upregulation of CAT and GST activities was observed only under multiple-stressor exposure (two-way ANOVA, $p < 0.01$ and $p < 0.001$). Moreover, enzyme activity exhibited a significant negative correlation with survival in copper + food stress and copper + food stress + esfenvalerate treatments ($R^2 > 0.2$, $p < 0.001$), suggesting biomarker responses serve as early indicators of physiological stress preceding mortality only when food stress is present. These findings reveal how environmental stressors modulate oxidative defense systems under chemical stress, highlighting the importance of food restriction to reveal the response of stress biomarkers. Overall, the results enhance understanding of toxicity and defense mechanisms under continuous and pulse exposures of differently acting chemicals.

2.04.P-Mo118 Linking life-history shifts and gut microbiome restructuring in *Daphnia magna* under combined nanoplastic–antibiotic stress

Maria Wierzbicka¹, Bartosz Kiersztyn², Grzegorz Kowalczyk², Sebastiano Gozzo³, Javier Jimenez-Lamana³, Joanna Szpunar³, Joanna Pijanowska², Marcin Żebrowski², Ewa Babbiewicz⁴ and Piotr Maszczyk⁵,
 (1)Department of Hydrobiology, Institute of Ecology, Faculty of Biology, University of Warsaw, 00-927 Warsaw, Poland, Poland, (2)Department of Hydrobiology, Institute of Functional Biology and Ecology, Faculty of Biology, University of Warsaw, 00-927 Warsaw, Poland, Poland, (3)IPREM, UMR 5254, E2S UPPA, CNRS, Universite de Pau et des Pays de l'Adour, 64053 Pau, France, France, (4)Department of Hydrobiology, Institute of Functional Biology and Ecology, Faculty of Biology, University of Warsaw, 00-927 Warsaw, Poland; Biological and Chemical Research Centre, University of Warsaw, Warsaw, Poland, Poland, (5)Department of Hydrobiology, Institute of Functional Biology and Ecology, Faculty of Biology, University of Warsaw, 00-927 Warsaw, Poland, Poland

Nanoplastics (NPs) can modify the toxicity of co-occurring pollutants, including antibiotics, yet their combined impacts on freshwater keystone grazers and their associated microbiota remain poorly understood. We tested how spherical polystyrene NPs and the fluoroquinolone enrofloxacin jointly affect life-history traits of the planktonic crustacean *Daphnia magna* and the metabolic and taxonomic structure of its gut microbiota, aiming to link organismal performance to microbiome-level mechanisms relevant for eco-evolutionary responses. In a factorial experiment with multiple NP and ENR concentrations, we quantified (i) body size and reproductive traits (clutch size, egg volume, and total reproductive investment), (ii) gut microbial metabolic diversity (respiration rate and relative use of different carbon sources), and (iii) gut microbial taxonomic diversity. Both stressors alone significantly affected most life-history and microbiome parameters, and their effects were consistently interactive across all measured endpoints. Nanoplastics and enrofloxacin reduced *Daphnia* body size and reproductive investment, indicating fitness costs of exposure, while simultaneously reshaping gut microbiome metabolism and composition. NP exposure generally increased the metabolic rate of the gut microbiota whereas enrofloxacin decreased it, and co-exposure altered the relative use of carbon substrates and increased the contribution of Firmicutes in the gut community. These patterns support a “Trojan horse” and interaction-based view of nanoplastic–antibiotic effects, in which contaminant mixtures generate non-additive impacts on host fitness and microbiome structure. Overall, our study highlights mechanistic links between individual life-history responses and microbiome restructuring under combined chemical stress, providing a framework for integrating host–microbiome dynamics into predictive, evolution-aware ecotoxicology.

2.04.P-Mo119 From acute stress to community-level adaptation: eco-evolutionary responses of lake microbiota to nanoplastic–enrofloxacin co-exposure

Ewa Babbiewicz¹, Katarzyna Lysik², Marcin Żebrowski², Sebastiano Gozzo³, Jae-Seong Lee⁴, Maria Pyznar², Javier Jimenez-Lamana³, Joanna Szpunar³, Bartosz Kiersztyn² and Piotr Maszczyk²,
 (1)University of Warsaw, Poland, (2)Department of Hydrobiology, University of Warsaw, Poland, (3)Universite de Pau et des Pays de l'Adour, France, (4)Department of Biological Sciences, College of Science, Sungkyunkwan University, Korea, Republic of

Nanoplastics (NPs) and antibiotics co-occur in freshwaters, yet their time-resolved, joint impacts on microbial communities, and the scope for rapid community-level adaptation, remain poorly constrained. We exposed lake microbiota to polystyrene NPs (~420 nm; 10^3 – 10^7 particles L⁻¹) and enrofloxacin (ENR; 10 or 100 ng L⁻¹) for 14 days, tracking abundance, per-cell respiration, community-level physiological profiles (CLPP), and taxonomy. By day 7, both stressors reduced abundance, with stronger ENR effects; CLPP was depressed mainly by ENR, whereas per-cell respiration increased in several NP×ENR combinations, and substrate use shifted transiently from complex carbons toward simpler substrates (notably amines), consistent with an acute stress response. By day 14, population-level responses attenuated, but community structure diverged: α -diversity remained depressed only under high ENR with NPs, β -diversity resolved into three distinct assemblages (enriched Sporichthyaceae and Comamonadaceae; reduced Burkholderiaceae and Verrucomicrobiaceae), and Actinobacteriota remained dominant. A Mantel test indicated that taxonomic restructuring increasingly explained CLPP at day 14, pointing to community reassembly and selection for stress-tolerant lineages that partly restore function under continued exposure.

A complementary fate experiment showed that dissolved ENR declined strongly over days, more rapidly in bacteria-present (unfiltered) water and further in the presence of NPs, with several NP-amended, unfiltered treatments approaching the analytical LOD by days 7–14. A 4 h assay detected no treatment differences, indicating negligible immediate photolysis or rapid sorption and implicating biological sinks that strengthen over multi-day, multi-generation timescales. Together, these results show that NP–antibiotic interactions are time-dependent and sometimes antagonistic at the population level, yet drive lasting community reassembly and altered contaminant fate. Our time-resolved, multi-level assessment illustrates how eco-evolutionary dynamics of freshwater microbiomes can decouple early physiological stress from later partial functional recovery, with implications for predicting long-term ecological risk of contaminant mixtures under global change.

2.04.P-Mo120 Modelling Chemical Mixtures and Disentangling its Effects on River Ecology in a Multiple Stressors Context

Ariane Moulinec¹ and **Ralf Bernhard Schaefer²**, (1)University Duisburg-Essen (Uni DUE), Germany, (2)University Duisburg-Essen (Uni DUE), Duisburg, Germany

River ecosystems are shaped by a multitude of processes that operate across a hierarchy of spatial scales, from local to regional factors. In this context, identifying how chemical pollution shapes community composition is challenging, notably due to the diversity of chemicals released into the systems, the scarcity of large-scale monitoring programs that jointly assess chemical pollution and biota, and the interactions between pollutants and other environmental drivers.

In this study, we examined relationships between catchment land-use and water chemistry, which were subsequently used to evaluate large scale links between chemical and biological patterns in European rivers. In detail, we used *in silico* ecotoxicological predictions to evaluate potential toxicity of chemical exposure from European monitoring databases such as the NORMAN EMPODAT database and WISER. We established toxicity estimates independently for different chemical classes of hazardous substances such as pharmaceuticals, metals or biocides. The potential toxicity of each chemical class and the joint toxicity was then linked to detailed land-use descriptors to predict the toxicity at unmeasured locations. In the next step, we examined associations between the estimated potential toxicity and ecological communities. We considered the four biological quality elements defined by the Water Framework Directive, namely fish, macroinvertebrates, diatoms and macrophytes. Finally, we modelled functional and taxonomical community composition as a function of land-use, different variants of estimated potential toxicity, environmental parameters (e.g. nutrients, general physico-chemistry, discharge), and ecological processes such as competition. Thus, we integrated chemical, environmental, and biotic drivers into a single analytical framework. We tested the hypothesis that the explanatory power of estimated potential toxicity for community composition is negatively associated with the explanatory power of local environmental and ecological processes. In other words, land-use drive toxicity is hypothesised to mask local processes shaping communities. We discuss how land-use can be used to predict chemical mixture patterns and, ultimately, improve our understanding of the relevance of chemical emissions in a multiple stressors context.

2.04.P-Mo121 Chemical Mixtures in European River Basins: A Probabilistic Risk Model for Integrating Additive and Independent Effects

Jannicke Moe¹, **Anders L. Madsen²**, **Sophie Mentzel¹**, **Karel Viaene³**, **Karel Vlaeminck³**, **Merete Grung¹**, **Samantha Eslava Martins¹**, **Gašper Šubelj⁴**, **Sam Welch¹** and **Frederik Verdonck³**, (1)Norwegian Institute for Water Research, Norway, (2)HUGIN EXPERT, Denmark, (3)ARCHE Consulting, Belgium, (4)TC Vode, Slovenia

Chemical mixtures and potential cocktail effects in aquatic ecosystems are recognised as a threat for river basins across Europe. Risk assessment for chemical mixtures has been subject to much development and debate in the last decade, but many challenges remain. Probabilistic risk methodologies are becoming more common in both human and environmental risk assessment (ERA) and offer new opportunities for fundamental challenges in ERA, such as the characterisation of mixture risk. The Concentration Addition (CA) concept is commonly used in lower-tier risk assessment (e.g., sum of risk quotients). However, the Independent Action (IA) concept lends itself more easily to probabilistic risk calculation (e.g., joint probability of threshold exceedances).

We have developed a hierarchical probabilistic model for integrating these two concepts, formulated as an object-oriented Bayesian network (OOBN). First, probabilistic risk quotients (RQ) are calculated for individual chemicals, as probability distributions of environmental concentrations divided by a threshold environmental value. Next, the CA concept is applied within groups of substances (e.g., with similar mode of action) by summing the RQ distributions. Finally, the IA concept is applied across the different substance groups, to combine RQ distributions by joint probability calculation ("OR" expressions). This approach to mixture risk calculation was first developed for nature-based wastewater treatment systems in the EU project MULTISOURCE. In the ongoing project ENCORE (ENVIRONMENTAL CO-exposure and Risk Estimation) we will apply the same approach at larger spatial and temporal scales. We obtain predicted exposure concentrations data from the ENCORE fate model, a process-based model for simulation of environmental concentrations in river basins across Europe (to be presented in a different session).

Here we present a pilot study for a subset of the substances (15 pesticides) and river basins (in Belgium), as a proof-of-concept. The aims of this presentation are: (1) to demonstrate a novel probabilistic approach to mixture risk characterisation, which integrates the CA and IA concepts in a hierarchical probabilistic model; (2) to demonstrate the applicability of the model to the pilot study; and (3) to consider the potential for upscaling this approach to larger spatial and temporal scales.

Disclaimer/Disclosure:

The ENCORE project is sponsored by the European Chemical Industry Council (CEFIC) as part of the Long Range Initiative (LRI) under project ECO-66 "Next generation risk assessment methods supporting the identification of environmental co-exposures of potential concern".

2.05 Extreme Events in Remote Ecosystems: Environmental Chemistry and Ecotoxicological Responses

2.05.T-01 Effects of Hydrological Extreme Events on Organic Micropollutants in a Large River

Liza-Marie Beckers, Nina Hermes and Arne Wick, Federal Institute of Hydrology (BfG), Germany

Heavy rain events, floods and droughts will likely increase in the future due to climate change. These events can have a profound impact on freshwater quality including concentrations of organic micropollutants (OMPs). The data basis on event-based pollution with OMPs is particularly sparse for large rivers. Here, high time-resolved sampling and comprehensive screening approaches, such as suspect and nontarget screening (NTS), are required. In this study, we investigated pollution patterns of OMPs in the Moselle River during rain events, a flood and a low flow event. Daily composite water samples were collected at a monitoring station in Koblenz (Germany) in 2021 and 2022 and subjected to NTS and target analysis. During a heavy rain and flood event in July 2021, three pollution patterns were identified in NTS data reflecting i) wastewater and immediate surface runoff emissions, ii) groundwater emissions and iii) flood-related emissions from agricultural and forested areas. The event led to high concentrations of pesticides and their transformation products (TPs) and affected water quality for several weeks. In summer 2022, a 67-day period of low flow and an intensive cyanobacteria bloom occurred. Again, OMPs were sorted into three groups. i) Persistent wastewater-related OMPs increased and ii) rather degradable OMPs decreased during low flow. Opposing trends of some pharmaceuticals and their TPs were observed. This suggests enhanced transformation processes in wastewater treatment plants or in the environment. The third pattern summarised OMPs which decreased during the monitoring period, e.g., pesticides emitted via surface runoff and groundwater. The generally opposing behaviour of wastewater- and groundwater-related pollutants was observed in the drought and flood event and was transferable to smaller rain events and long-term monitoring data. Our studies showed that hydrological and meteorological (extreme) events can considerably affect the pollution with OMPs in large rivers – calling for adjustments in future monitoring, e.g., by implementing continuous and flow-proportional sampling and using pattern-representative OMPs and TPs as indicators for pathway-specific contributions and altered transformation processes. To gain a

deeper understanding on the impact of droughts and algae blooms, unannotated, drought-related features are currently investigated. Further, event-based exposure scenarios should be considered in ecotoxicological studies.

2.05.T-02 Sublethal Chemical Exposure Decreases Thermal Tolerance and Increases Variability Differentially in Freshwater Fish and Invertebrates

Helena Bayat¹, Verena Christina Schreiner¹ and Ralf Bernhard Schaefer², (1)University Duisburg-Essen (Uni DUE), Germany, (2)University Duisburg-Essen (Uni DUE), Duisburg, Germany

In environments increasingly afflicted by extreme climatic events, a considerable fraction of organisms are likely to experience temperatures approaching their physiological limits while simultaneously exposed to chemical pollution. Realistic contaminant exposure conditions for freshwater organisms often entail exposure well below lethal thresholds, yet such sublethal exposures may still prove harmful, especially in conjunction with extreme temperatures. The impacts of chemical contaminants on organism's upper thermal tolerance are understudied relative to the effects of temperature on pollutant toxicity. These have not yet been quantitatively analysed across different species, despite increasingly frequent extreme heat events. To fill this gap, we set out to determine whether sublethal chemical exposure changes the upper thermal tolerance of freshwater invertebrates and fish using a meta-analytic approach. We test the hypotheses that sublethal chemical exposure will change upper thermal tolerance and increase variance thereof, and that the magnitude and direction of these changes depends on stressor intensity and taxonomic group (fish or invertebrate) with a three-level random effects meta-analysis and meta-regression. Sublethal chemical exposure decreased upper thermal tolerance overall for fish and invertebrates, with an overall effect estimate of $-1.14\text{ }^{\circ}\text{C}$ (-1.66 to -0.62 95% CI, $p < 0.0001$). The meta-regression with log toxic units (logTU) displayed a significant negative relationship, with greater reductions in upper thermal tolerance with increasing logTU (estimate -0.85 , $p = 0.0008$). The effect of sublethal chemical exposure on the log coefficient of variation ratio differed significantly between fish (0.91) and invertebrates (0.46), indicating a greater increase in variability of upper thermal tolerance with sublethal chemical exposure in fish than in invertebrates. Therefore chemical pollution potentially impedes freshwater organisms' ability to cope with extreme temperature events, and the increased variability found in fish could complicate predictions of sublethal chemical effects. However, mechanisms governing these effects have not yet been elucidated, and studies conducted with a variety of additional species and chemicals are needed to confirm this pattern.

2.05.T-03 Spatial Patterns and Dynamics of Organic Contaminants in Urbanized Rivers Under Drought Conditions

Lukas Nerlich¹, Stephanie Spahr² and Christiane Zarfl¹, (1)Eberhard Karls University of Tübingen, Germany, (2)Ecohydrology and Biogeochemistry, Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Germany

One of the most pressing concerns for urban river systems is the pollution with organic contaminants. In addition, river water quality is affected by extreme weather events. Drought conditions are known to exacerbate the deterioration of water quality in terms of nutrient concentrations, but the effects of droughts on the concentration of organic contaminants such as pharmaceuticals and industrial chemicals in rivers have not yet been quantified. Conceptually, reduced river flows can decrease the dilution capacity of rivers, resulting in higher concentrations of pollutants, particularly those originating from continuous emissions through wastewater treatment plants (WWTPs). Simultaneously, low water levels and long retention times in combination with increased sunlight penetration during droughts might enhance the photochemical transformation of organic contaminants. Thus, the goal of this study was to determine and quantify how the organic contaminant concentrations and compositions in urban rivers shift during drought periods compared to conditions of mean river flow. To this end, we conducted five sampling campaigns along the Neckar River during drought periods and three under mean discharge conditions between May and November 2025. The sampling sites were located upstream as well as 500 and 2000 m downstream of municipal WWTPs where the ratio of effluent to river discharge is high. All samples were analyzed for 21 selected organic contaminants using liquid chromatography mass spectrometry. The set of organic contaminants covered compounds persistent to (a)biotic degradation, photolabile compounds as well as photo transformation products. Our results demonstrate

that concentrations of pharmaceuticals downstream of WWTPs were elevated during drought periods due to lower dilution in the river. In addition, photo transformation was enhanced during droughts, which lead to a faster decrease in contaminant concentrations down the waterline compared to mean flow conditions. Our data will flow into a model to elucidate the impact of droughts on the water quality of urban river systems under different climatic scenarios, which is important for urban water management.

2.05.T-04 Presence and Temporal Trends of Polycyclic Aromatic Hydrocarbons in Arctic Char from Remote High Arctic Lakes

Samuel García García¹, Ana Cabrerizo Pastor¹, Derek C.G. Muir², Jane Kirk³, Amila O. De Silva³ and Xiaowa Wang⁴, (1)University of Valladolid, Spain, (2)No Affiliation, Canada, (3)Environment and Climate Change Canada (ECCC), Canada, (4)Aquatic Contaminants Research Division, Environment and Climate Change Canada (ECCC), Canada

Polycyclic aromatic hydrocarbons are toxic and persistent organic contaminants that can bioaccumulate in organisms and the environment and biomagnify at the highest levels of food chain, posing ecological and human health concerns. Despite the perceived isolation of High Arctic ecosystems, recent environmental change driven by regional warming and permafrost degradation may mobilize contaminants stored in soils and sediments, increasing their availability to aquatic food webs. However, long-term trends of these compounds in Arctic biota remain poorly understood.

This study investigates temporal changes in concentrations and profiles of polycyclic aromatic hydrocarbons in Arctic char (*Salvelinus alpinus*), the only fish species present in isolated lakes of the Canadian High Arctic. We analyzed muscle samples (n=73) collected between 2008 and 2023 from two contrasting lakes on Melville Island, representing systems with different degrees of geomorphological disturbance. Concentrations were determined using gas chromatography coupled to tandem mass spectrometry, following validated extraction and clean-up procedures, and normalized to lipid content.

Results reveal clear differences between lakes. Total polycyclic aromatic hydrocarbons ranged from 12 to 900 ng g⁻¹ lipid weight, with a predominance of low and medium molecular weight compounds such as naphthalene, phenanthrene, fluorene and pyrene. The western lake showed a marked increasing trend over time, coinciding with documented active layer detachments, higher turbidity and enhanced delivery of terrestrial organic matter. In contrast, the eastern lake exhibited a progressive decrease in concentrations, suggesting a more stable system with limited remobilization from surrounding catchments.

These findings indicate that physical disturbances linked to permafrost thaw can remobilize historically deposited contaminants, increasing their bioavailability and incorporation into aquatic food webs. Understanding these processes is essential for predicting future contaminant exposure in Arctic ecosystems under continued warming.

This work advances knowledge on contaminant dynamics in changing polar environments and provides baseline information for assessing future ecological risks associated with permafrost degradation.

2.05.P Extreme Events in Remote Ecosystems: Environmental Chemistry and Ecotoxicological Responses

2.05.P-Mo122 High-Frequency Multivariate Multi-Tracer Analysis of Combined Sewer Overflow Contributions in Small Urban Streams: Prioritising Chemical Tracers for Quantitative Source Apportionment

Manu Dörrich¹, Lukas Althoff¹, Jonas Schaper² and Christiane Zarfl¹, (1)Eberhard Karls University of Tübingen, Germany, (2)German Environment Agency (UBA), Section II 3.3, Germany

Urban rivers can receive large amounts of untreated wastewater during storm events through combined sewer overflows (CSOs), causing rapid and transient spikes in chemical contaminant loads. Effects of these events are difficult to quantify with standard monitoring methods due to limiting insights into the dynamics of both pollutant concentrations and discharge volumes of CSOs and receiving rivers during storm events. The present study aims to develop a streamlined approach to track CSO contributions with high temporal resolution and identify the most effective indicators and model approaches for quantitative source apportionment in urban streams during storm events.

High-frequency monitoring was conducted at multiple locations along two small urban streams, capturing variations in water level, electrical conductivity, and turbidity. Water samples were collected at high temporal resolution both in the main channels and directly at overflow points. Samples were analysed for a selection of 32 trace organic compounds, major ions, and stable water isotopes. A multivariate mixing model was applied to jointly constrain the relative contribution of CSOs to the river water using multiple chemical tracers and discharge measurements.

Results indicate that a limited set of compounds, including commonly used artificial sweeteners and certain pharmaceuticals, provides a reliable signal to distinguish CSO water from river water. Overflow contributions were found to fluctuate substantially during storm events, with chemical tracers capturing local impacts more precisely than volumetric flow estimates.

The present study demonstrates that a focused, tracer-based monitoring strategy allows for robust and minimally invasive quantification of CSO contributions in urban streams. The approach improves understanding of short-term contaminant dynamics and offers practical guidance for managing urban water quality and prioritizing monitoring resources. Ongoing research focuses on the development of a joint multi-tracer, joint inversion approach that simultaneously integrates different chemical tracers, discharge measurements and their uncertainties.

2.05.P-Mo123 Impacts of a massive flash flood event on organic pollutant risks in a protected Mediterranean wetland (L'Albufera, Valencia, Spain)

Julian Campo¹, Jhesibel Chavez¹, Pere Colomer Vidal², Juan Muñoz-Arnanz², Begoña Jiménez², Cristiana Rizzi³, Lorenzo Federico³, Sara Villa³, Pablo Amador⁴ and Andreu Rico⁴, (1)Environmental and Food Safety Research Group (SAMA-UV). Desertification Research Centre - CIDE (CSIC, UV, GVA), Spain, (2)Department of Instrumental Analysis and Environmental Chemistry, Institute of Organic Chemistry (IQOG-CSIC), Juan de la Cierva 3, Madrid, 28006, Spain, Spain, (3)Department of Earth and Environmental Sciences (DISAT), University of Milano-Bicocca, Piazza Della Scienza 1, Milan, 20126, Italy, Italy, (4)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain

Flood events are becoming more frequent and severe due to climate change, with projections indicating further increases in the coming decades. On the 29th of October 2024, the Valencia region (Spain) experienced very intense rainstorms (200-700 L/m²), which resulted in a catastrophic flash flood. A significant proportion of the floodwaters and sediments generated were discharged into L'Albufera Natural Park (ANP) - a Ramsar-listed wetland. The flash flood carried a wide range of urban and industrial residues into the ANP, and produced the collapse of the sewage network, which could contribute to the release of various types of organic pollutants. This study aimed to characterize the pollutant footprint of the massive flash flood that impacted the ANP and to assess its ecological risks. To do so, a monitoring campaign was conducted after the flash flood, involving the collection of water and sediment samples from 15 locations, and the analysis of 241 organic pollutants, including pesticides (PEST), pharmaceuticals and personal care products (PPCPs), perfluoroalkyl substances (PFAS), organophosphorus flame retardants (OPFRs), polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), polychlorinated dibenzo-p-dioxins (PCDDs), and polychlorinated dibenzofurans (PCDFs). The study shows that the combined effect of the massive flooding and the sewage system collapse led to a surge in pollutants—mainly PPCPs and PAHs—and the widespread remobilization of other hydrophobic compounds. While acute lethal effects on aquatic life were unlikely, we identified 44 OPs that surpassed the long-term aquatic toxicity thresholds. The most significant exceedances in water included ibuprofen, PFOS, and fluoranthene, while sediments contained 13 high-risk compounds (PFOS, PESTs and PPCPs). Spatially, the highest ecotoxicological risks from water exposure were in the lake and the NW sector, and from sediment were uniformly distributed. This study presents one of the first detailed investigations of extreme flood impacts on aquatic ecosystems in Europe, highlighting pollutant mixtures that are likely emitted into the environment following such extreme events. The findings offer critical insights for guiding ecosystem management in the ANP by identifying vulnerable areas and environmental compartments at risk of contamination due to flooding.

2.05.P-Mo124 Local Sources vs Long-Range Transport: Cyclic Volatile Methylsiloxanes in Antarctica and the Arctic

Maja Nipen¹, Jeremy Durham², Debra Ann McNett², Oda Siebke Løge¹, Vladimir Nikiforov¹, Kathy Plotzke², William Hartz¹, Mark Irvine³, Isabel Sauermilch⁴, Rita M. Seston⁵, Robert Bialik⁶, Katarzyna Fudala⁶, Dragomir Mateev⁷, Evgen Dykyi⁸, Shihe Xu⁹ and Reinhard Gerhards¹⁰, (1)NILU, Norway, (2)Dow Chemical Company, United States, (3)ERM International Group Limited, United Kingdom, (4)ERM International Group Limited, Germany, (5)Hyla Environmental Consulting LLC, (6)Institute of Biochemistry and Biophysics Polish Academy of Sciences, Poland, (7)Bulgaria Antarctic Institute, Bulgaria, (8)State Institution National Antarctic Scientific Center, Ukraine, (9)Tridge Consulting, United States, (10)Gerconsult, Germany

Cyclic volatile methylsiloxanes (cVMS) are high-production-volume chemicals used globally in personal care products and industrial applications. Their occurrence in remote environments raises questions about long-range atmospheric transport and local emissions. We present results from two studies investigating the cVMS D4, D5, and D6 in polar regions: Antarctica (2023/24) and Arctic Svalbard (2023). Comparable sampling and analytical methods were applied for air, terrestrial, and aquatic matrices to enable comparison between sites and hemispheres.

Across all Antarctic stations, D4, D5, and D6 concentrations in outdoor air were generally very low, with detectable levels primarily restricted to research-station settlements and absent or near detection limits in more remote areas. Extended winter deployments at the Norwegian Troll station revealed extremely low background concentrations, confirming minimal long-range inputs. In contrast, targeted sampling near wastewater outlets at one Antarctic research station showed clear evidence of local contamination in sediments, demonstrating the relevance of point sources in remote regions. Terrestrial matrices (moss, lichen, soil) showed almost exclusively non-detects, while krill showed exclusively non-detects.

In Svalbard, D4, D5, and D6 concentrations were higher than Antarctica, reflecting a combination of long-range or regional transport and local human activity. Air concentrations at the settlement of Ny-Ålesund exceeded those at Antarctic stations by two to three orders of magnitude, while a remote Arctic location (Zeppelin Observatory) showed low but detectable background levels. No or extremely low levels of the studied cVMS were detected in Arctic terrestrial and aquatic media, aligning with the Antarctic findings and supporting negligible accumulation in these matrices.

Together, these polar datasets provide the most geographically extensive assessment of D4, D5, and D6 in remote environments to date. The results highlight (i) the dominance of local emissions in shaping near-field concentrations at research stations, (ii) very low to undetectable levels in terrestrial and aquatic compartments, and (iii) clear hemispheric differences in atmospheric burdens. These findings contribute to ongoing regulatory discussions by demonstrating the extremely low environmental presence of the studied cVMS in pristine regions and the importance of distinguishing true background levels from isolated point sources.

2.05.P-Mo125 Combined Effects of the Bio-pesticide Azadirachtin and Climate Change Warming Scenarios on Freshwater Communities

Pierina I. Rivas-Comerlati¹, Judith Epping², Camilla Calò¹, Miriam Krempien¹, Ivo Roessink¹ and Paul van den Brink¹, (1)Wageningen University and Research (WUR), Netherlands, (2)Wageningen University and Research (WUR), Wageningen, Netherlands

Due to Global Climate Change (GCC), we expect rising temperatures and more often reoccurring heatwaves in aquatic ecosystems every year. Previous studies have found that warming may influence the toxicity of chemicals (e.g., pesticides) in the environment by complex mechanisms not yet fully understood. However, in standard ecotoxicological testing warming conditions are not usually considered. Pesticides commonly pollute aquatic ecosystems through spray-drift, agricultural runoff, and chemical spills. That is also the case for bio-pesticides, even if considered a more chemically-friendly option, their effects on non-target aquatic species might still be significant and are not well investigated. One of the most successful commercial biopesticides is

Azadirachtin. This Neem extract with Azadirachtin A (AzA) as the lead component is known for its strong insecticidal properties and its low persistence. Thus, it is key to evaluate its toxicity under different temperature regimes that reflect natural conditions with future climate change scenarios. The aim of this study was to assess the single and combined effects of the bio-pesticide NeemAzal-T/S (Neem product) and GCC warming scenarios (fluctuating elevated temperatures and extreme heatwave events) on freshwater communities under a realistic set up (outdoor mesocosms). The experiment consisted of a full factorial design with 9 treatments, combining 3 temperature scenarios (ambient, elevated temperature (+4°C) and recurring heatwaves (+8°C for 1-week intervals)) with 3 AzA concentrations (0, 30 and 300 µg/l) over a period of 6-weeks during late summer 2025. Direct and indirect effects on different trophic levels including zooplankton, macroinvertebrates, insects and macrophytes communities were evaluated. The main endpoints assessed included: biweekly samples of zooplankton, macroinvertebrates feeding rate and insect emergence; in-situ identifications of macroinvertebrates community; and macrophytes coverage. Preliminary results show clear effects from both AzA concentrations on the macroinvertebrates community and insect emergence. Combined effects of the two stressors are expected to be found on the zooplankton community; however, further analysis need to be conducted. The results from this study allows us to better understand the mechanistic pathways of these stressors' interactions for a more accurate risk assessment in the future.

2.05.P-Mo126 Developmental Hindrance Effects of Five Antifouling Agents on the Sea Urchin *Hemicentrotus pulcherrimus*

Hoon Choi¹, **Un-Ki Hwang²** and **Moonjin Lee¹**, (1)Korea Institute of Ships & Ocean Engineering, Korea, Republic of, (2)National Institute of Fisheries Science(NIFS), Korea, Republic of

Organotin compounds (e.g., TBT) were previously used as antifouling agents to prevent biofouling on marine structures. However, due to their harmful effects on marine life, their use has been banned internationally. As a result, various organometallic and non-metallic antifouling paints have been developed as alternatives. Nevertheless, these substitutes remain under continuous safety evaluation due to concerns regarding their biological hazards.

The aim of this study was to investigate the toxic and developmental inhibitory effects of selected antifouling agents (Chlorothalonil, DCOIT, Diuron, Dichlofluanid, and Irgarol) on the normal embryogenesis rate of the sea urchin *Hemicentrotus pulcherrimus*, a representative primary consumer in the marine ecosystem. Additionally, we sought to identify the effects of these substances on each stage of early embryonic development. Embryos exposed to the antifouling agents showed accelerated development during the 2.5–6 hour period. However, exposure to Diuron and Irgarol at half the effective concentration began to delay progression to the early gastrula stage after 18 hours, with significant developmental delays observed after 24 hours. Continued retardation was evident in the developmental sequence from early gastrula to gastrula, early pluteus, and pluteus stages. The severity of developmental delay followed the order: DCOIT > Irgarol > Diuron > Dichlofluanid > Chlorothalonil (with greater delay indicating lower developmental progression).

These findings suggest that the toxic effects of the five antifouling agents on sea urchins are largely attributable to disruptions in early developmental processes. Given that antifouling agents are highly persistent in the environment and are known to exert toxic effects on various marine organisms, including invertebrates as demonstrated in this study, it is critical to conduct further research at the genomic level. Moreover, the urgent establishment of effective environmental protection strategies is essential to prevent marine pollution and safeguard marine ecosystems.

2.05.P-Mo127 Organic Pollutants Mobilization After the 2024 DANA Floods in Valencia (Spain): Implications for Environmental Risk

Maria Vittoria Barbieri¹, **Alex Balasch Garcia²**, **Julio Fernández-Arribas²** and **Ethel Eljarrat²**, (1)ONHEALTH, Institute of Environmental Assessment and Water, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (2)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain

Valencia province (Spain) suffered a catastrophic cut-off low (COL), known locally as DANA in October 2024, resulting in torrential rainfall and severe flooding. This extreme weather event generated approximately 2.24

million cubic meters of sludge, which, upon drying, formed a dense dust cloud containing particles potentially harmful to human health. Few studies have investigated the chemical fingerprint of sludge and dust residues left in the wake of COL events, especially for organic contaminants in Mediterranean regions. This study aimed to address this gap by characterizing the occurrence and distribution of both legacy and emerging pollutants in sludge and atmospheric dust following the DANA event. A total of 13 sludge and 16 dust samples were collected in November 2024 from the Valencia area, subject to mixed urban, industrial, and agricultural pressures. A broad spectrum of contaminants was analyzed, including pesticides, plastic additives (phthalates, non-phthalate plasticizers, and organophosphate esters), brominated flame retardants (BFRs), and short-chain chlorinated paraffins (SCCPs). Samples were analyzed using gas and liquid chromatography-tandem mass spectrometry. The obtained data were treated to perform an integrated environmental risk assessment (ERA). All major contaminant classes were detected, with total levels up to 9,000 ng/g wet weight (ww) in sludge and nearly 39,000 ng/g dry weight (dw) in dust. Sludge showed highlightable levels of legacy pesticides like endosulfan (max. 1,395 ng/g ww) and lindane (max. 363 ng/g ww). Dust contamination was dominated by plastic additives, specifically diisononyl phthalate (DINP) (max 13,117 ng/g dw) and di-2-ethylhexyl phthalate (DEHP) (max 10,286 ng/g dw). SCCPs were ubiquitous in dust (median of 620 ng/g dw). The ERA indicated a potential elevated risk (HQ>10) for 13 pesticides, 9 plastic additives, one BFR, and SCCPs in the worst-case scenario. The highest HQ (>10,000) corresponded to heptachlor epoxide, lindane, cypermethrin, and DEHP. The DANA flood acted as a significant mobilization mechanism for a wide spectrum of contaminants. The higher concentrations in dust suggest that dried sludge may act as a secondary pollution source and create a potential route for long-term human exposure. Characterizing this contamination profile is crucial for informing risk assessors and post-disaster remediation policies in vulnerable regions subject to increasing climate-related hydrometeorological events.

Disclaimer/Disclosure:

This work was financially supported by funds from PIE202460E236 (CSIC). We thank SEPRONA (Guardia Civil) for their assistance in collecting sediment and dust samples. This study also represents a contribution to the CSIC Scientific-Technical Advisory Group for Emergency Crises (GADE-CSIC, Spain). A special acknowledgment to Gloria Sánchez for her support in sample storage and distribution.

2.05.P-Mo128 Sediment Toxicity in Northern Patagonia: Multiple Biomarker Responses in Gammarus spp.

*Camila Agostina Solari¹, Romina Belén Baggio¹, Florencia Fernanda Liquin², Ksenia J Groh³, **Henner Hollert⁴**, Francisco Sylvester⁵ and Leandro Andrés Hünicken¹, (1)National University of Rio Negro, Argentina, (2)Goethe University Frankfurt, Germany, (3)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (4)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (5)Faculty of Biological Sciences, Goethe University Frankfurt, Germany*

The Valcheta Stream, located in an endorheic basin in Northern Patagonia, Argentina, is a remote system increasingly exposed to diverse anthropogenic pollutants. To evaluate sediment-associated toxicity, we collected composite samples (right bank, left bank, and mid-channel) from three sites with different contamination sources—an agricultural impact zone, an urban-influenced area, and a sewage-affected reach—along with an upstream reference site. Lyophilized sediments were transported under cooled conditions to Germany and Switzerland, where we applied an integrated suite of physiological, behavioral, and molecular biomarkers using amphipods of the genus *Gammarus*.

Amphipods were collected from the Main River and acclimated for 5–10 days before exposure. Experiments followed OECD/ISO guidelines employing four sediment treatments and a negative control consisting of six replicates, six organisms per 250-ml aerated beaker at 16 °C (total 30 beakers, 180 organisms). Behavioral responses were measured at 24, 48, and 96 h with the ToxmateLab system (ViewPoint, Lyon), using alternating light–dark cycles. Automated analyses identified distinct activity patterns. Preliminary assessments of hyperactivity and hypoactivity revealed clear deviations from baseline locomotion in organisms exposed to sediments from the more impacted sites. Urban sites produced the greatest deviations, potentially suggesting a combination of stressors. Additional parameters, including activity time and average and maximum speed at light and dark conditions, are currently being evaluated in an attempt to obtain a higher sensitivity to these effects.

Following behavioral tests, organisms were frozen at –70 °C for subsequent biochemical and proteomic analyses. Planned endpoints include oxidative stress markers (lipid peroxidation via TBARS, antioxidant and

metabolic enzyme activities) and mass-spectrometry-based proteomics with label-free quantification on a Thermo Astral instrument operated in DIA mode. By integrating behavioral and molecular biomarkers, this study aims to establish sensitive early-warning indicators of sediment toxicity in the Valcheta Stream and to improve understanding of contaminant-related stressors in Patagonian freshwater ecosystems.

Funding provided by the RobustNature Excellence Initiative and GREP Program of Goethe University Frankfurt and the Municipality of Valcheta.

2.05.P-Mo129 Beyond Single Stressors: A Review of Climate Modulation of Chemical Fate and Toxicity In Freshwater Ecosystems.

Toby Popple¹, Alistair Boxall¹, Frances Orton² and John Guy³, (1)University of York, United Kingdom, (2)Heriot Watt University, United Kingdom, (3)Reckitt Benckiser Group PLC, United Kingdom

Climate change is driving rapid and substantial changes in the frequency and intensity of extreme weather events. Global alterations to temperature, precipitation patterns, and acidification have the ability to dramatically disrupt the dynamic equilibrium of freshwater systems. These physicochemical changes are likely to influence chemical fate, behaviour, and effects so consideration of climate change should be integrated into the chemical risk assessment process. Previous reviews have explored how climate change can impact the fate, behaviour, and effects of chemical pollution, although recent advances necessitate an update to these reviews. This poster aims to synthesise these results on an endpoint-by-endpoint basis to best explore how climate change may impact species differently depending upon the study scale whilst simultaneously assessing how changes to chemical fate and behaviour may exacerbate this. Using a systematic review approach, a combination of 9 search strings and citation searching, 128 papers were identified. Over 68% of papers reviewed, suggested that climate driven changes are able to increase the toxicity of chemical pollutants; although, this result varied depending upon study design. Much of the literature was focused on temperature and pesticide pollution and considered survival and biochemical endpoints. Fewer than 10% of studies focus on climatic variables other than temperature (precipitation and acidification), many of which fail to be adequately assessed. This review has identified that these climatic variables can influence chemical fate, behaviour, and effects, impacting life-history, biochemical stress, and mortality. Whilst the evaluation of papers on effects on chemical fate is ongoing, preliminary results suggest that drought reduces dilution, flooding increases resuspension, whilst temperature and pH can significantly influence bioconcentration of pollutants. Further laboratory-based research is required to explore how extreme weather events influence an organism's physiology and energetics especially at the population and community level, whilst still accounting for biochemical and molecular endpoints. These results will be able to inform directions for further study, regarding multiple stressor studies in freshwater environments.

2.05.P-Mo130 Presence and distribution of microplastics in soils from the Arctic and Antarctic Peninsula

Ana Cabrerizo Pastor¹, **Samuel Garcia Garcia¹**, Silvia Pinardo Barco¹, Benjamin Barts², Gerald Tetreault³, Jane Kirk³ and Derek C.G. Muir⁴, (1)University of Valladolid, Spain, (2)University of Calgary, Canada, (3)Environment and Climate Change Canada (ECCC), Canada, (4)University of Guelph, Canada

In recent years, airborne microplastics have been identified in a range of remote environments including the Arctic and Antarctica. While most of the data available is focused in seawater and sediments, little is known about their present in Arctic and Antarctic soils. In this study, we have collected 20 surface soil samples from remote lakes in the Arctic and Antarctica during various sampling campaigns in 2024 and 2025.

Soil samples were homogenized and treated to isolate microplastic particles. Suspected microplastic particles were isolated and their composition confirmed using micro-Fourier transform infrared spectroscopy (μ FTIR). This study reports the identified microplastics in Antarctic and Arctic soils, being the highest in concentration, found in those soils collected close to research stations.

2.05.P-Mo131 Exploring the Fate of Tire-wear Particles and De-icing Salts in High Mountain Streams of Spanish Protected Areas

Gabriela Ágreda-López¹, Raúl Acosta², Ana de Santiago-Martín³, Virtudes Martínez-Hernández³, Marco J. Cabrerizo⁴, Laura Cherta-Cucala³, Miguel Canedo-Arguelles² and **Paula Redondo-Hasselerharm³**, (1)Imdea Water Institute, Spain, (2)Institute of Environmental Assessment and Water Research (IDAEA), Spain, (3)IMDEA Water Institute, Spain, (4)University of Granada, Spain

As a consequence of the use of roads, particles are continuously being released due to the mechanical abrasion of tires with the road surface, which can enter nearby aquatic ecosystems through runoff water in protected areas, such as Spanish National Parks. In addition to rubber, these particles contain additives that are potentially toxic to aquatic communities, such as metals or polycyclic aromatic hydrocarbons (PAHs). In parallel, the use of de-icing agents for winter viability on roads in High Mountain National Parks could be causing an increase in the salinity of adjacent ecosystems. The objective of this work was to determine whether tire-wear particles (TWPs) and de-icing salts can enter streams of High Mountain National Parks from nearby roads. For this purpose, we collected water and sediment samples in rivers and streams with and without road influence in three National Parks in the north, centre and south of Spain during spring and fall 2025. We measured water quality parameters (temperature, dissolved oxygen, electrical conductivity and pH), ions (Cl⁻, Na⁺, Ca²⁺, Mg²⁺), metals (Cd, Cu, Cr, Ni, Pb, Zn), styrene-butadiene and polyisoprene rubbers, and different tire-derived additives, including PAHs, benzothiazoles, N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD) and its ozonated derivate, 6PPD-quinone. To assess major source points of TWPs and de-icing salts, we sampled road runoff water and adjacent soil in one of the parks during early spring. Only in one out of three roads sampled, a concentration of 2.04 µg/L styrene-butadiene rubber was detected in the runoff water. In the soil adjacent to this road, the concentration of zinc, often used as an indirect proxy of TWPs, was 1216 mg/L. In road runoff water, chloride and EC levels were significantly correlated and differed between the locations sampled. Chloride concentrations ranged from 1.2 mg/L to 30.7 mg/L, and EC levels ranged from 19.5 to 158.8 µS/cm. Chloride levels were significantly higher in streams influenced by roads with de-icing salt application, often showing tenfold differences. In stream water, rubber particles were not detected, and metals were generally below the limit of quantification. Our preliminary results suggest that de-icing salts may enter nearby aquatic ecosystems through road runoff, while TWPs and their associated additives may not reach streams from nearby roads and be potentially retained in the adjacent soil

Disclaimer/Disclosure:

Project 3303/2024 is funded by the Autonomous National Parks Agency of the Ministry for Ecological Transition and Demographic Challenge.

2.05.P-Mo132 Bioconcentration of metals in *Gambusia holbrooki* exposed to forest fire ash: implications for freshwater ecosystem risk assessment

Isabel Campos¹, Patricia Pereira², Jan Jacob Keizer³, Vera Silva⁴, Fernando Gonçalves⁵ and Nelson Abrantes⁵, (1)CESAM, University of Aveiro (UA), Portugal, (2)University of Aveiro, Portugal, (3)GEOBIOTEC, Department of Environment and Planning, University of Aveiro (UA), Portugal, (4)Soil Physics & Land Management Group, Wageningen University and Research (WUR), Netherlands, (5)CESAM, University of Aveiro, Portugal

Rural fires can mobilise metals bound to ash, which may enter aquatic ecosystems through runoff, posing risks to freshwater organisms. These metals can persist in water bodies and accumulate in aquatic biota, potentially disrupting ecosystem health. This study investigated the bioconcentration of metals in the fish *Gambusia holbrooki* exposed to ash elutriates from a recent forest fire, under controlled laboratory conditions. Fish were exposed individually to 200 mL of elutriate, and ten replicates were running per sampling time. The test lasted 15 days, including 10 days of exposure and 5 days of depuration. The exposure medium was renewed every 48 hours. During exposure, water samples and ten fish were collected sequentially at 0, 12, 24, 48, 72, 96, 144, 192, and 240 hours, removing a set of ten containers at each time point. Following 240 hours of exposure, fish were transferred to uncontaminated medium for depuration, with sampling of ten fish at 12, 24, 48, 96, and 144 hours. Water parameters, including pH, conductivity, and metal concentrations, were monitored throughout. Metal accumulation in fish tissues was quantified using ICP-MS, and bioconcentration factors (BCFs) were calculated. Results showed rapid uptake of some metals, while depuration revealed partial elimination, with retention varying by metal. These findings demonstrate that wildfire ash can serve as a substantial source of metals to freshwater organisms, with bioaccumulation varying according to metal type, exposure duration, and depuration dynamics. As a pioneer, this study provides critical insights into post-fire metal behaviour in aquatic ecosystems, enhancing understanding of bioaccumulation under realistic exposure scenarios. These results can inform ecological risk assessments, guide monitoring strategies in fire-affected watersheds, and support management actions to mitigate metal contamination and safeguard freshwater biodiversity.

2.05.P-Mo133 Elevated Mercury Concentrations in Riparian Predators Unaccounted for by Trophic Magnification

Connor Olson¹, Gale B Beaubien², David Walters³ and Ryan R Otter⁴, (1)Harvard University & CU Boulder, United States, (2)U.S. Environmental Protection Agency, United States, (3)U.S. Geological Survey, United States, (4)Grand Valley State University (GVSU), United States

Riparian predators integrate both nutrients and contaminants from neighboring aquatic systems through their predation of emerging aquatic insects. The reliance of some riparian taxa on aquatic subsidies has led to them being utilized as biosentinels of aquatic contamination, often justified through stable isotope studies ($\delta^{13}\text{C}$, $\delta^{15}\text{N}$) and trophic magnification models. However, evidence suggests that both isotopic signatures and contaminant burdens can be altered during insect metamorphosis, which could propagate to riparian predators. Here, we measured total mercury and $\delta^{15}\text{N}$ in riparian and aquatic organisms in the headwater streams of the southern Appalachian Mountains (Tennessee, USA) to compare biomagnification in both systems. We found that biomagnification rates were similar, but that mercury concentrations in riparian organism were approximately 6x higher than neighboring aquatic organisms. We propose possible ecological mechanisms, occurring separately or simultaneously, that might explain these surprising observations: 1) metamorphosis bioamplifies mercury, 2) metamorphosis enriches $\delta^{15}\text{N}$ values, and/or 3) the fractionation of $\delta^{15}\text{N}$ that occurs during predation is less for the observed riparian predators than for the aquatic organisms. Further study is needed to elucidate the exact mechanism driving elevated mercury concentrations in riparian predators.

2.05.P-Mo134 Physically Based Pharmacokinetic (PBPK) model for the Arctic fish species Atlantic halibut (*Hippoglossus hippoglossus*)

Hanne Gladhaug Wøien Mo¹, Gregory Martin Langlois², Ian Edhlund³, Peter van den Hurk² and **Knut Erik Tollefsen⁴**, (1)Norwegian University of Life Sciences, Norway, (2)Clemson University, United States, (3)U.S. Food and Drug Administration (FDA), United States, (4)Norwegian Institute for Water Research, Norway

The reduction of sea ice in the Arctic has opened previously inaccessible areas to commercial activity, increasing anthropogenic pressure on this pristine environment. Climate change and rising emissions are introducing new substances into Arctic waters, threatening marine life and human consumers of fish. Due to the vast number of chemicals, it is not feasible to test all substances on all species, highlighting the need for predictive tools in environmental exposure, hazard and risk assessment. Physiologically based pharmacokinetic (PBPK) models are foreseen to play a key role in characterization of absorption, distribution, metabolism, and excretion (ADME) of pollutants and aid in vitro to in vivo extrapolation (IVIVE) in Next Generation Risk Assessment (NGRA).

This work aimed to support PBPK model development for a key Arctic species, the Atlantic halibut (*Hippoglossus hippoglossus*), by characterizing relevant physiological parameters. A multi-compartment PBPK model was established based on existing fish PBPK models. Each compartment was defined by volume, lipid and water content, and blood flow. Parameters were obtained through measurements in halibut and literature reviews. The data lays the foundation for Arctic-relevant PBPK models in general, a halibut PBPK in particular, and support future NGRA of chemical exposures to Arctic marine fish species.

2.05.P-Mo135 Analysis of Mercury and Cyanide Concentrations in River Waters of Areas Within the Yanomami Indigenous Territory Affected by Illegal Gold Mining

Marcos Yamada, **Natalino Lucena**, Cândida Paim and Vitor Domingues, Instituto Brasileiro do Meio Ambiente e dos Recursos Naturais Renováveis – IBAMA, Brazil

The rapid expansion of illegal gold mining in the Amazon and the associated use of mercury (Hg) and cyanide (CN⁻) have raised serious environmental and public health concerns for traditional communities within the Yanomami Indigenous Territory. In 2023, the Brazilian Institute of the Environment and Renewable Natural

Resources (IBAMA) and the Brazilian Center for Mineral Technology (CETEM) launched an Environmental Monitoring Network to assess contamination in multiple matrices within the Yanomami Territory and adjacent Conservation Units. Sampling points were chosen based on proximity to villages and mining sites, major rivers, and accessibility. Most areas are reachable only by small aircraft, imposing logistical challenges. This study presents results for total Hg and CN⁻ in surface waters. Over one year, 27 priority locations were monitored using standardized protocols for water, sediment, and fish sampling. Of 25 water samples analyzed for THg, 24 (96%) exceeded maximum permissible values. For CN⁻, 33 (63.5%) of 52 samples surpassed regulatory limits. Elevated CN⁻ near active mining suggests cyanidation processes, while high concentrations in Conservation Units with no mining history highlight the complexity of distinguishing natural sources from contamination. Reliable differentiation will require long-term monitoring, control sites, or advanced analytical methods. Historically, Hg dominated artisanal gold extraction due to amalgamation simplicity, but CN⁻ detection may indicate cyanidation, demanding stricter oversight. As sediment and biota data emerge and new campaigns proceed, understanding pollutant dynamics will improve—especially for cyanide, whose behavior in Amazonian systems remains poorly characterized. Despite limited baseline data, these findings represent a critical step toward establishing reference conditions and supporting policies to protect Indigenous and riverine communities from illegal mining impacts.

2.05.P-Mo136 Atmospheric deposition and long-range transport of micro- and nanoplastics

Antonia Praetorius¹, Marianne Seijo², Todd Gouin³ and Michael Whelan⁴, (1)IBED, University of Amsterdam (UVA), Netherlands, (2)University of Amsterdam (UVA), Netherlands, (3)TG Environmental Research, United Kingdom, (4)University of Leicester, United Kingdom

Atmospheric deposition plays an important role in the global distribution and long-range transport of environmental pollutants towards remote regions. While modelling frameworks for long-range atmospheric transport are well-established for organic contaminants, mechanistic models for micro- and nanoplastics (MNPs) are limited. This challenges the interpretation monitoring data of MNPs in remote areas and our ability to estimate environmental exposure to MNPs at the global scale.

We here present a model framework for atmospheric transport of MNPs, with a particular focus on physical descriptions of deposition, which exerts the key control on atmospheric residence times and apply the framework to selected scenarios representing a wide range of MNP properties and environmental conditions, to disentangle their respective influences on the potential for MNP transport to remote regions. We combine existing equations and theories for atmospheric particle transport (e.g. from aerosol and pollen research) with empirical data on MNP properties (e.g. effect of surface ageing on hydrophobicity). We include multiple mechanistic descriptions of wet and dry deposition processes, accounting for particle size, shape, density, surface hydrophobicity) and the impact of land surface properties, surface wind speed, atmospheric stratification and precipitation patterns.

Our model framework enables an in-depth analysis of the different deposition mechanisms contributing to the atmospheric removal of MNPs. We estimate that atmospheric half-lives for MNPs can range from a few seconds to weeks and find that the main drivers for these differences are particle size and shape, precipitation characteristics, atmospheric stratification, land surface features and surface wind velocities. In all scenarios, deposition rates are lowest for intermediately sized MNPs (around 1 µm) and even lower for fibres, resulting in longest atmospheric half-lives. Under dry conditions, these MNPs can exhibit atmospheric half-lives of up to two weeks, which is sufficient for long-range atmospheric transport from Europe to the Arctic during weather patterns where prevailing air flows trajectories favor transport to high latitude.

2.05.P-Mo137 Organofluorine in the Arctic and Northern European Atmosphere – a Current Overview

William Hartz, Helene Lunder Halvorsen, Maja Nipen, Ove Hermansen, Norbert Schmidbauer, Chris Lunder, Linda Hanssen, Vladimir Nikiforov and Pernilla Bohlin Nizzetto, NILU, Norway

The atmosphere is important for the global distribution of organofluorine contaminants (OFCs). Several are commonly known as per- and polyfluoroalkyl substances (PFAS), of which some pose a hazard for human and environmental health. Other OFCs, such as chlorofluorocarbons (CFCs), are ozone depleting substances (ODSs), and others, such as hydrofluorocarbons (HFCs), have high global warming potentials (GWPs) and

therefore contribute to ongoing climate change. OFCs are a vast group, and environmental persistence is a key common property for enabling their diverse range of hazards. Long-term atmospheric monitoring is important for understanding their sources and fate, as well as evaluating the effectiveness of international regulations such as the Montreal Protocol and Stockholm Convention. NILU monitors numerous OFCs in the atmosphere at three stations using four different measurement techniques. In this study, we measure 84 OFCs (containing at least one C–F bond) across three Norwegian sites: the Zeppelin Mountain (Arctic), Birkenes (rural Norway) and Oslo (urban) in 2023/24.

65 OFCs were detected at Zeppelin. This indicates the diversity of OFCs present in the background Arctic atmosphere. CFCs, HFCs, perfluorocarbons (PFCs) and halons were expectedly high (with mean concentrations 210 – 490,000 ppq). Several (semi-)volatile OFCs were lower – desflurane, perfluorotributylamine (PFTBA), perfluorotripentylamine (PFTPeA), tetrachlorohexafluorobutane (TCPFB) and perfluorophenanthrene (PFPHP), of which most were present at both Arctic and urban locations (0.50 – 360 ppq). Perfluoroalkyl acids (PFAAs) and their semivolatile precursors were lower still, with sum values often <1 ppq, but still notable given the bioaccumulative and toxic properties of some of these OFCs. Both PFAAs and their semivolatile precursors were higher at Birkenes and in Oslo than at Zeppelin, owing to closer proximity to polluted airmasses. Those compounds with the highest levels (CFCs, HFCs, PFCs and halons) are known to have long atmospheric lifetimes (often >10 years), and several are known ODSs and/or have high GWPs (often >1000).

The widespread detection of PFAAs and numerous other OFCs, including at a remote Arctic location, indicates the importance of the atmosphere for their global distribution. Long-term atmospheric monitoring is needed to understand their environmental processes and evaluate the effectiveness of their ever developing regional/international regulation.

2.05.P-Mo138 From the summit to the sea: Tracking biodiversity along interacting stressor gradients in a high-altitude tropical river

Milo Leon de Baat¹, Raul Loayza Muro² and Michiel Kraak³, (1)Chemical Water Quality & Health, University of Amsterdam (UVA), Netherlands, (2)Peruvian University Cayetano Heredia, Peru, (3)Sciencepark 904, University of Amsterdam (UVA), Amsterdam, Netherlands

Tropical high-altitude riverine systems, such as those found in the South American Andes, have a particularly high biodiversity potential, as they span a remarkable gradient of climatic and geological zones. As these rivers flow from their often-pristine headwaters through their middle reaches, ending up in lowland deltas and estuaries, their waters experience a highly diverse set of environmental variables. These variables can be natural or anthropogenic and can induce stress on riverine organisms. Naturally occurring stressors dictate niches and species composition along altitude gradients (Loayza-Muro et al., 2014). Alongside these natural stressors, human-impacted rivers often contain complex mixtures of micropollutants, which pose significant risks, including biodiversity loss, degradation of drinking water quality, and impairment of ecosystem services. However, little is known about the impacts of multiple interacting anthropogenic and naturally occurring stressors on river biodiversity, especially in tropical ecosystems.

Therefore, this project aimed to disentangle the effects of multiple interacting stressors on biodiversity in a tropical Andean river. The Rímac River is ±200 km long and flows from the highlands in the central Andes in Western Perú through the city of Lima to its mouth in the Pacific Ocean. The river flows from its source at approximately 4700 m down to sea level as it passes through increasingly anthropogenically impacted and urbanized landscapes, making it an excellent natural laboratory to study the impacts of multiple interacting stressors on river biodiversity.

The river was sampled at 15 locations along its course for physicochemical measurements, water, and sediment grab samples for nutrients, organic-, and inorganic pollutants. Macroinvertebrates and biofilm were collected for morphological and molecular biodiversity assessment.

The initial results show that macroinvertebrate biodiversity was lowest at both ends of the Rímac River, with very low numbers of individuals collected at the source in the urban zone of the river, and the highest diversity in the middle reach of the river. A sudden drop in biodiversity was observed starting at the city limit, coinciding with a strong influx of organic pollution. The results suggest that moderately anthropogenically impacted river sections can still host substantial biodiversity, while organic pollution in urban areas strongly impacts riverine biodiversity in the tropical Andes.

2.05.P-Mo139 Presence and distribution of legacy polychlorinated biphenyls (PCBs) and emerging Perfluoroalkyl substances (PFAS) in soil, freshwater and seawater from the Antarctic Peninsula

Silvia Pinardo Barco¹, Samuel Garcia Garcia¹, Ana Cabrerizo Pastor¹, Rebeca López¹, Javier Benayas² and

Derek C.G. Muir³, (1)University of Valladolid, Spain, (2)Universidad Autónoma de Madrid, Spain, (3)Environment and Climate Change Canada (ECCC), Canada

Antarctic ecosystems, despite their remoteness, act as long-range sinks for persistent organic pollutants (POPs) both emerging perfluoroalkyl substances (PFAS) and legacy polychlorinated biphenyl (PCBs). Understanding the presence and distribution of these contaminants is essential as climate-driven melting may enhance the remobilisation of historically accumulated POPs. This study investigates the occurrence of PFAS and PCBs in freshwater and soils from Byers Peninsula (ASPA 126), as well as in seawater and soils collected at tourism-influenced coastal sites across the South Shetland Islands. Surface freshwater, seawater and soils samples were collected and analysed using solid phase extraction (SPE) cartridges followed by LC-MS/MS for PFAS. PCBs analysis required large-volume water sampling using XAD2 resin columns and subsequent GC-MS/MS quantification. Preliminary results reveal detectable PFAS across all matrices. Seawater near tourist landing sites showed PFAS ranging from 3.6 to 7.4 pg/L, while much lower concentrations were found in Byers' freshwater lakes. Long-chain PFCAs (notably PFDA and PFDaDA) and PFOS were the dominant compounds, reaching up to 1.9 pg/L. In soils, PFBA, PFOA and PFNA represented up to 60% of PFCAs. PCBs were also detected in soils and lake water, with higher concentrations observed during melting periods suggesting cryosphere release. These results provide the first integrated assessment of PFAS and PCBs across multiple Antarctic environmental compartments, offering baseline information to understand contaminant partitioning, persistence and potential links with tourism and climate-driven remobilization.

2.06 Higher Tier Testing and Risk Assessment for Aquatic Organisms

2.06.T-01 A Deep Dive into Aquatic Mesocosms – Exploring Ecosystem Dynamics and Veterinary Drug Impacts

Lukas Kruckenfellner¹, Andre Patrick Heinrich², Louis Sollinger¹, Rolf-Alexander Düring² and Klaus Peter Ebke¹, (1)Institut für Gewässerschutz MESOCOSM GmbH, Germany, (2)Justus-Liebig-University Department of Soil Science and Soil Conservation, Germany

In chemical risk assessment, standardized methods such as those by OECD are commonly applied to gain an impression of potential environmental hazards. However, extrapolating effects from these standardized experiments to broader ecosystem impacts can be challenging. Aquatic mesocosms are a well-established and valuable tool to bridge the gap to realistic exposure. But how can we further improve the data output from higher tier experiments supporting e.g. modelling and statistic interpretation?

The aims of the MeMo project were: to examine the year-round dynamics in aquatic model ecosystems, establish new endpoints, and provide a solid base data set for mesocosm modelling. Two mesocosm studies – one conducted under Good Laboratory Practice (GLP) standards – were carried out at a test facility at the Research-Centre Neu-Ulrichstein in Hesse, Germany.

Study A was designed to detect threshold levels of endectocide treated mesocosms. Each four replicates were treated once with different concentrations of the veterinary drug eprinomectin. The fate and ecotoxicological impact of the stressor was assessed over a span of 100 days post-application. Residues of the substance were measured in water, sediment and macrophytes. Despite a DT90 of approximately 50 days in the water phase, the drug was still detectable in plants and sediment after more than 80 days after application. In addition to abundance counts of zooplankton and macroinvertebrates and chlorophyll-a measurement, other non-lethal endpoints were assessed as well. These included calculating the mean time to emergence and sex ratio of emerging insects, as well as measuring the community structure of macroinvertebrates post-application. Concentration-dependent effects of up to 100% without recovery were observed in some groups, while clear indirect (e.g., higher abundances) concentration-response relationships were seen in others.

Study B focused on seasonal dynamics, population structure, and data translation in enclosure mesocosm systems. A mesocosm was sampled holistically on a monthly basis for one year. Population data were derived by standard sampling procedures and by the total abundance of the animals. This two data sets allow to generate a relation factor to link standard sampling to absolute abundances of the whole mesocosm for all species. At the

same time, all animals in the standard samples were measured to determine the seasonal progression in the population structure of aquatic organisms.

2.06.T-02 Long-term Effects of Nicotine on Freshwater Communities using Outdoor Mesocosms

Paula Redondo-Hasselerharm¹, Daniel Franco-López¹, Melina Crettaz-Minaglia¹, Mónica Gámez¹, Isabel López-Heras¹ and Andreu Rico², (1)IMDEA Water Institute, Spain, (2)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain

Nicotine and its main metabolite, cotinine, are released into the environment during the production and disposal of cigarettes, after the application of neonicotinoid pesticides or via wastewater discharges. Although nicotine and cotinine are widespread over the world's freshwater bodies, with concentrations reaching 11.7 µg/L and 9.57 µg/L, respectively, very limited data is available on their toxicity to aquatic species. This study aimed to assess the dissipation rate of nicotine and the formation of cotinine under semi-natural freshwater conditions and to assess their toxic effects to aquatic phytoplankton and invertebrate communities. A twelve-weeks mesocosm experiment was conducted using outdoor 1 m³ circular tanks, which included 4 untreated controls and 5 exposure concentrations (0.1, 1, 10, 50 and 100 µg/L), in triplicate. On days 0, 28, 56 and 84, water samples were taken from all mesocosms for nicotine and cotinine analysis. Weekly water samples were collected in two treatments to assess nicotine degradation and cotinine formation. Water quality parameters were monitored weekly, and phytoplankton, zooplankton and macroinvertebrate samples were collected on days -7, 14, 28, 56, and 84. Emergence traps were installed to collect insect adults emerging from the mesocosms over time. Total average nicotine concentrations through the whole exposure period were 0.17, 0.69, 7.91, 32.5, and 84.3 µg/L for the nominal concentrations of 0.1-100 µg/L, respectively. A significant positive correlation between the degradation of nicotine and the air temperature was found. Principal Response Curve analysis showed no significant effects of nicotine on the different communities, except for zooplankton. The taxa that showed consistent treatment-related effects were *Daphnia pulex*, Ostracoda, *Keratella tropica*, *Echinogammarus* sp. and Lumbriculidae. The first three species had very low population abundances, making it difficult to establish robust conclusions. In contrast, *Echinogammarus* sp. and Lumbriculidae showed a consistent treatment-related population decline and had higher abundances, with the lowest population No Observed Effect Concentration (NOEC) being 10 µg/L. Our results indicate that nicotine does not pose consistent effects on the aquatic community structure at the tested concentrations. However, considering the lowest population NOEC identified in this study, risks could occur at hotspot locations for two of the macroinvertebrate populations studied.

2.06.T-03 Comparing Morphological and Molecular Diatom Identification in a Multi-Stressor Microcosm Experiment

Sarah Descloux¹, Ahmed Tlili², Soizic Morin³, Kristin Schirmer¹, Nele Schuwirth⁴ and Alexandra Kroll⁵, (1)Eawag - ETH Zurich, Switzerland, (2)DSM-Firmenich SA, Switzerland, (3)INRAE, National Research Institute for Agriculture, Food and the Environment, UR EABX, France, (4)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (5)Ecotox Centre, Switzerland

Protecting aquatic ecosystems from pesticide pollution is a critical regulatory task. Benthic diatoms, as part of aquatic biofilms, are commonly used to indicate nutrient pollution. To assess if they could also serve as bioindicators for pesticide pollution, we conducted a laboratory experiment using flow-through chambers for aquatic biofilm colonisation and exposure, integrating realistic gradients of pesticides, light, temperature, and nutrients to optimise transferability to the field.

Diatom community composition can be analysed using both morphological and molecular techniques. Currently, it is unknown how these two methods compare in their ability to detect pesticide-responsive taxa. This study therefore evaluates whether morphological and molecular identification diverge in their detection of diatom species that respond to realistic pesticide mixtures. For both identification techniques (morphological and molecular), no significant differences in community composition based on relative abundances were detected at the genus level. At the species level, a significant

difference in diatom community composition was observed between taxonomic experts' identification, driven primarily by morphologically similar groups where subjective interpretation affects species resolution. For the molecular data, species-level assignments were higher with the older curated database version than with the more recent one, suggesting that increased curation reveals taxonomic uncertainty previously masked.

Significant discrepancies between identification techniques were detected at both the genus and species levels, likely reflecting methodological differences such as size-related detection thresholds in microscopy and abundance biases inherent to amplicon sequencing. Despite these differences, beta-regression analyses indicated that most species exhibited convergent patterns across methods, suggesting that the overarching ecological signal remains robust even when taxonomic resolution varies.

With this study, we highlight how taxonomic assignment discrepancies propagate into ecological interpretation and demonstrate how methodological harmonisation and curated reference databases can strengthen comparability between approaches. These findings offer a systematic evaluation of the suitability of next-generation sequencing alongside traditional morphology-based approaches and contribute to advancing diatom monitoring frameworks for assessing pesticide impacts.

2.06.T-04 Bridging Lab Studies to Mesocosms: Case study for *Cloeon dipterum* to Understand Temperature Mediated Effects of Imidacloprid Exposure

Daniel Harrison Burkow, Eric Bruns, Jutta Agert and Thomas G. Preuss, Bayer Research & Development Services LLC, Germany

Temperature can play an important role in shaping the effects of chemical stress responses, leading to shifts in study outcomes. Evidence from non-GLP (good laboratory practice) mesocosm studies for neonicotinoids (e.g., imidacloprid) suggests that warmer environmental conditions can shift the sensitivity of organisms and the resulting ecological endpoints. Risk assessment endpoints derived from laboratory studies are typically conducted at standardized optimal food and temperature conditions to measure the effects of the test item with high precision. To bridge this gap, we apply a mechanistic population model with temperature-dependent TKTD (toxicokinetic-toxicodynamic) processes, including lethal and sublethal effects such as immobility and reduced feeding.

Individual life histories of *Cloeon dipterum* are simulated with a Dynamic Energy Budget (DEB) model calibrated using variable-temperature laboratory data and fed into a population model. The population model is evaluated against available mesocosm experiments conducted across tropical, subtropical, and Mediterranean climates. Across climates, observed effects in mesocosms aligned with model predictions derived from laboratory calibration. Differences in mesocosm endpoints were attributable to a combination of extended exposure duration, temperature, and poor food availability. No additional adverse mechanisms were required to fit the observations in mesocosms beyond those established in laboratory studies. Notably, recovery in mesocosms often exceeded model predictions.

Our findings demonstrate that mechanistic population models, when properly calibrated on variable-temperature laboratory data, can reliably predict mesocosm outcomes across diverse environments, supporting their use as tools in environmental risk assessment.

2.06.T-05 Predictability of higher-tier outcomes in the aquatic risk assessment of plant protection products: Evidence from EU regulatory data

Paul Nnamdi Ozoh¹, Hanh Nguyen¹ and Ralf Bernhard Schaefer², (1)University Duisburg-Essen (Uni DUE), Germany, (2)University Duisburg-Essen (Uni DUE), Duisburg, Germany

The environmental risk assessment of plant protection products (PPPs) in the European Union uses a tiered framework where conservative Tier 1 estimates can be refined through higher-tier modelling or field studies. However, it remains uncertain how well Tier 1 risk quotients (RQs) predict outcomes in subsequent tiers, and whether refinement systematically reduces risk. Gaining this understanding can support more effective regulatory decision-making and help identify cases where further refinement is either justified or unlikely to alter the final conclusion.

To address this, we analysed a regulatory dataset covering 676 aquatic Tier 1 assessments for EU-approved insecticides and acaricides. For each substance–use–organism combination, we recorded the Tier, FOCUS step, organism group, time scale, and RQs. We then identified the first tier or step achieving acceptable risk (RQ ≤ 1), quantified reduction factors between Tier 1 and the first acceptable refinement level, and applied ordinal logistic regression and decision tree models to evaluate whether Tier 1 exceedance magnitude predicts refinement outcomes.

Most Tier 1 assessments (781%) surpassed the acceptability threshold. Among these, about half achieved

acceptability within Tier 1 refinements, while approximately 40% remained unacceptable at all refinement levels. Reduction factors consistently increased with each refinement level, typically gaining one to two log-units per tier. Model results indicated that the magnitude of Tier 1 exceedance strongly predicted the extent of required refinement. The decision tree identified two thresholds in Tier 1 log₁₀ RQ—about 1.7 and 2.9—that distinguished cases usually resolved at Tier 1, those with mixed outcomes, and those that needed Tier 3 or remained unacceptable. Many “no acceptable” outcomes reflected a lack of submitted higher-tier studies rather than confirmed ecological risk.

Overall, the analysis shows clear quantitative links between Tier 1 exceedances and the success of refinement. These insights may help develop benchmarking tools and prioritisation schemes to make future PPP evaluations more efficient. Ongoing work will extend this analysis to herbicides, plant growth regulators, and fungicides to further test the broad applicability and regulatory significance of these findings.

2.06.P Higher Tier Testing and Risk Assessment for Aquatic Organisms

2.06.P-Th005 Challenges in aquatic higher tier risk assessment for pesticides

Seamus Taylor¹, Udo Hommen², Tido Strauss³ and Eric Bruns⁴, (1)ADAMA, United Kingdom, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)gaia Research Institute, Germany, (4)Bayer Research & Development Services LLC, Germany

Aquatic organisms can potentially be exposed to plant protection products, biocides and general chemicals via numerous exposure routes. Taking the example for plant protection products, there is a potential for exposure to edge of field water bodies, and thus a risk assessment is required under Regulation (EC) 1107/2009.

The current guidance document used for the aquatic risk assessment of Plant Protection Products (AGD) in the European Union (and GB) was adopted in 2013. Advancements in regulatory science since then have created an opportunity to revisit elements of the guidance that would support the adoption of a more efficient approach to aquatic risk assessment.

For example, mesocosm studies and higher tier studies in general, are a challenge due to their complexity (black box problem), their high amount of data and less well-defined evaluation criteria when compared to standardised laboratory studies, presenting issues around subjectivity. So, there are still some open issues and uncertainties how higher tier studies should be conducted, reported, evaluated and used.

In this poster, the authors will present some of their concerns around common higher tier approaches for aquatic risk assessment.

One example of open issues is the use of Minimum Detectable Difference for mesocosm studies. Reporting was required by EFSA PPR panel (2013) but due to the missing experience there was no clear guidance on how they should be used. Thus, industry and test facilities need to know better what regulators expect. On the other hand, it becomes more difficult for the notifiers to decide whether resources should be spent into such complex studies due to uncertainties on requirements in the coming years. In addition some member states are considering simplifying the tiered approach and to avoid higher tier studies in general. This in turn leads to the risk that effects at the population level and indirect effects at the community level are completely ignored.

The purpose of this poster is to stimulate a joined-up discussion on aquatic higher tier risk assessment with the goal of establishing a SETAC tripartite interest group to support the future development of updates to the aquatic guidance document.

2.06.P-Th006 Risk assessment of plant protection products (PPP) for aquatic organisms: relevance of exposure pattern in mesocosm studies compared to predicted exposure in surface waters

Jérémy Foldrin, Vanessa Mazerolles, Emilie Farama and Pierre-François Chaton, French Agency for Food, Environmental and Occupational Health & Safety (ANSES), France

For the authorization of plant protection products (PPP) in the context of the Regulation (EC) N°1107/2009, a higher tier risk assessment for aquatic organisms can rely on mesocosm studies. According to the “Guidance on

tiered risk assessment for plant protection products for aquatic organisms in edge-of-field surface waters” (EFSA Journal 2013;11(7):3290), the exposure pattern in a mesocosm study should be realistic to worst case compared to the relevant predicted exposure profiles in edge-of-field surface waters based on FOCUS methodology (FOCUS (2001). “FOCUS Surface Water Scenarios in the EU Evaluation Process under 91/414/EEC”. Report of the FOCUS Working Group on Surface Water Scenarios, EC Document Reference SANCO/4802/2001-rev.2. 245 pp). Such comparison is also called “concept of the envelope curve” in the Critical Appraisal Tools (CATs) (Proposal of critical appraisal tools for the evaluation of ecotoxicology studies, EFSA Supporting publication 2023:EN-7787) developed for mesocosm studies. For this purpose, “Regulatory Acceptable Concentration profiles” (“RAC profiles”) should be generated and plotted alongside the predicted exposure profile in edge-of-field surface waters. Some critical issues have been raised in recent years during peer review of active substances and PPP concerning the relevance of exposure pattern in mesocosm compared to predicted exposure profiles (e.g., acceptability of exposure pattern in mesocosm for the intended uses, method to be used to show the “concept of the envelope curve”, ecotoxicological dependence/independence of the peaks, etc.). The aim of this poster is to show the usefulness of graphical illustration to address these issues, through some recommendations and few illustrative examples. Overall, this approach facilitates the interpretation of results and supports their use in risk assessment of plant protection products.

2.06.P-Th007 The Role of Mesocosm Data in Ecotoxicological Legislation

Ellie Welch¹, **Hanna Samantha Schuster¹**, **Helena Crosland¹**, **Sarah Priestly²** and **Nadine S Taylor¹**,
(1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)RSK Adas Ltd., United Kingdom

Mesocosm studies serve as a regulatory accepted study, seen as bridging a gap between lower tier laboratory-based toxicity tests and dynamic natural ecosystems. They represent standardised experimental systems that aim to capture the interactions, variability, and recovery dynamics of aquatic communities and populations under realistic environmental conditions. Within the context of environmental risk assessment for plant protection products (PPPs), mesocosms provide higher-tier data that go beyond individual species response, generating ecologically relevant data into population, community, and functional-level effects.

In regulatory frameworks, mesocosm studies can be used to simulate real-world exposure scenarios while maintaining reproducibility and scientific consistency. This balance between control and environmental realism enables authorities, including the European Food Safety Authority (EFSA), to integrate mesocosms as refinement options for aquatic risk assessments. These studies can also help to define the environmental safety thresholds used in pesticide registration and management.

Multivariate statistical approaches, such as Principal Response Curves (PRCs), offer a multidimensional perspective on ecological integrity. They allow for an assessment on both immediate toxic effects, and on recovery following exposure. Understanding how these endpoints are interpreted within regulatory evaluations is key to determining how mesocosm data influence final legislative outcomes.

However, the complexity of mesocosm datasets also presents challenges for interpretation across studies and the integration of mesocosms into regulatory decision-making. Whilst there may be efforts toward standardisation in an aim to increase comparability and transparency across studies, differences in design that are required for chemical loading and behaviour, sediment characteristics, species composition, and environmental conditions can all affect study outcomes.

The aim of this poster is to show how mesocosm experimental data can inform the development, refinement, and implementation of environmental legislation related to PPPs. By linking practical experimental evidence to policy frameworks, mesocosm research has the potential to strengthen the scientific foundation of ecotoxicological regulation, giving confidence in environmental protection goals, and ensuring that legal standards are grounded in ecological realism.

2.06.P-Th008 Sediment: an undervalued compartment in mesocosm studies

Ellie Welch, **Charlotte Court** and **Nadine S Taylor**, Cambridge Environmental Assessments (CEA), United Kingdom

The sediment layer is a key part of any mesocosm test system, however, its influence on the test design is largely undervalued. Generally, the sediment compartment is only of interest if the test substance is known to have physio-chemical properties of concern, e.g. they would bind to the sediment, or degrade slowly, and is often only investigated for analytical residues. However, the sediment composition can influence the biological community and the interpretation of mesocosm studies. Variations in sediment type, from sandy and silty/clay substrates, to the amount of organic matter present, can alter chemical movement, nutrient cycling, biological interactions, and function of benthic habitats within test systems.

Physical characterisation of sediment is usually focused on the percentage of stones > 10 mm to interpret the

sediment structure. Whereby, variability in the coarseness of the sediment affects, macrophyte health, filtration, and groundwater exchange. In these aspects sandy based sediments, with little to no organic matter, are considered to represent a “worst-case” scenario for retention of water and ease of transport. Dipwell monitoring of groundwater simulations could be valuable data to interpret contaminant dynamics for transport and exposure persistence, thereby influencing test system stability and recovery. This could be carried out with a stone or mesh base with an overlaying membrane and a siphon tube.

Varying sediment types would also influence the biological impacts within the mesocosm, e.g. through activities of burrowing macroinvertebrates and macrophyte stability, highlighting how biological disturbance can alter sediment-water interactions and exposure profiles.

The aim is to highlight the need for sediment-type considerations in the design and interpretation of mesocosm studies. Moving forward, there is a potential to create an ‘ideal’ sediment that incorporates more sand or clay in their design according to what is most appropriate, incorporation of groundwater monitoring to understand transportation dynamics, and monitoring macrophyte health as a proxy for sediment structure and function. Knowing the influence of sediment structure on contaminant transport and exposure dynamics enhances ecological understanding and data interpretation of mesocosm studies. The influence of sediment characteristics on the chemical, physical and biological function of the test system should have greater consideration in mesocosm studies.

2.06.P-Th009 Considerations for Designing Emergent Insect Traps in Mesocosm studies

Ellie Welch, Robert Rivett, Cameron Swain and Nadine S Taylor, Cambridge Environmental Assessments (CEA), United Kingdom

The emergence of insects from aquatic habitats is a key indicator of ecological integrity and reflects how successfully aquatic insects complete their life cycle within a test system. As such, it provides an integrated signal of population dynamics, contamination effects, and overall ecosystem function. These taxa are known to be sensitive to chemical stressors and are considered a key biological compartment in mesocosm studies. Reliable, representative emergence data are essential for assessing impacts on community structure and function.

Trap design plays a major role in the accuracy and representativeness of these measurements. Different insect groups use different emergence routes; some emerge directly from the water surface, while others climb macrophytes, or use the pond edge. Deployment of a single trap, or even a single trap type, may, therefore, under-represent important taxa. Effective traps must consider emergence behavior, placement within the mesocosm, mesh characteristics, and accessibility for sampling activities.

This poster presents a theoretical comparison of potential trap designs suitable for regulatory mesocosm studies. The design challenge is to balance two goals; (1) allow natural ecosystem functioning, including recolonisation, free movement of insects and population recovery, and (2); capture a sufficiently representative proportion of emergent organisms to support reliable trend detection and statistical analysis.

The baseline design is a traditional cone-shaped emergence trap with a pitfall trap on top. This design is well established, but primarily only captures taxa emerging directly from the water surface. It offers limited support for species dependent on plant surfaces or solid substrates.

Alternative designs considered here include cone traps using artificial macrophytes to improve representation of vegetation-dependent emergers; plant basket traps enclosed with mesh and topped with a pitfall collector, targeting taxa emerging from submerged or emergent plants and full-coverage mesh “roof” systems with pitfall traps to catch both vertical and horizontal dispersers.

Each design is compared based on coverage of emergence pathways, capture efficiency, ease of deployment, consistency across replicates, and suitability for requirements. The objective is to identify trap configurations that improve representativeness without compromising mesocosm data integrity and ecosystem function.

2.06.P-Th010 Emerging Evidence: The fungicide pyraclostrobin reduces aquatic insect emergence

A. Daniëlle van der Burg, Martina G. Vijver, Sander van Heijningen and S. Henrik Barmantlo, Institute of Environmental Sciences, Leiden University, Einsteinweg 2, 2333CC, Leiden, the Netherlands, Netherlands

Pesticide emittance is seen as one of the leading causes of global declines in insect biomass, which has repeatedly been shown over the last few decades. A decline of, specifically, emerging aquatic insects may directly limit energy flow from aquatic to terrestrial systems, altering ecosystem structure, and impeding ecosystem functioning, and services. Although some research has examined how insecticides affect insect emergence in natural populations, very few studies have explored the effects of other pesticide classes – such as fungicides. In addition, ecotoxicity data for fungicides are scarce for many groups of emerging insects.

In this study, we investigate the impact of environmentally relevant concentrations of the strobilurin fungicide

pyraclostrobin on insect emergence, and their aquatic larvae, for the most common emergent insect orders (i.e. Diptera, Coleoptera, Ephemeroptera, Odonata, and Trichoptera). We applied a field-realistic concentration range (based on data analyses of the Dutch Pesticide Atlas) of pyraclostrobin (concentration range up to 29 µg/L) to 32 experimental ditches, representing a non-target small-bodied freshwater system closely linked to agricultural land. The ditches were naturally colonized prior to the start of the experiment by communities from the adjoining canal, leading to a robust and realistic insect community within our experimental set-up, allowing for the assessment of causal toxicity effects on emerging insects. We tracked insect emergence two months prior, and three months post treatment application. Additionally, we aim to determine toxicity data (i.e. effective concentration values) from the observed biomass and abundance per insect order. We observed a decline in emerged insect biomass and abundance with increasing pyraclostrobin concentration for four out of five common insect orders, with an effective concentration of 10% reduction in total insect biomass at 2 µg/L. This decline in emergence could not directly be related to a decline in aquatic insect larvae. The data are currently being analyzed and prepared for scientific publication, and will be presented at SETAC 2026 upon acceptance of this abstract.

2.06.P-Th011 The Right Species Matter: Advancing Macroinvertebrate and Zooplankton-Based Species Sensitivity Distribution Studies Through Targeted Selection and Cultivation

Rabea Christmann¹, Theresa Graf¹, Marcel Kahlke¹ and Guido Gonsior², (1)GG BioTech Design GmbH, Germany, (2)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany

Accurate Species Sensitivity Distribution (SSD) modelling relies heavily on the ecological relevance and experimental reliability of organisms selected for laboratory investigations. Freshwater macroinvertebrates and zooplankton as key indicators of ecosystem health, offer strong potential for linking field observations with controlled experimental data.

This project establishes a systematic framework for selecting suitable macroinvertebrate and zooplankton species for SSD development, integrating ecological traits, habitat specificity, tolerance characteristics, and the practical feasibility of laboratory cultivation.

The resulting shortlist of selected species, combined with an exemplary SSD analysis, demonstrates how careful test-species selection underpins realistic and ecologically meaningful risk assessments. This approach strengthens the protection of sensitive and conservation-relevant freshwater taxa and supports more robust regulatory decision-making in ecological risk assessment.

2.06.P-Th012 Systematic and objective profile analysis in support of use of an ERO-RAC (ecological recovery option-regulatory acceptable concentration) from a mesocosm study: a case study with lambda-cyhalothrin

Daniel Bruce Pickford¹, Onofrio Schifanella², Theo Reyman³, Claudia Janoske³, Cecilie Rendal⁴ and Roger Baetscher³, (1)Product Safety Global Strategic Science, Syngenta Ltd, United Kingdom, (2)Syngenta Ltd, Italy, (3)Syngenta Ltd, Germany, (4)Syngenta Ltd, Denmark

Experimental ecosystem (microcosm/mesocosm) studies are a valuable refinement tool in aquatic risk assessment for plant protection products (PPPs), accommodating environmental fate and behaviour of the active substance while addressing ecological processes such as community level effects and recovery. The latter is addressed by recommendations in the Aquatic Guidance Document (AGD, 2013) on derivation of regulatory acceptable concentrations (RACs). Both ecological threshold option (ETO) and ecological recovery option (ERO) RACs may be derived from a mesocosm if the recovery meets certain criteria and the exposure profile in the study is representative of those expected in edge of field surface waters. Additional guidance was released by EFSA as part of the Critical Appraisal Tool (CAT) for relevance of mesocosm studies (2023), which builds on the AGD in proposing the “concept of the envelope curve”: that a RAC profile be generated by dividing each measured concentration of the mesocosm exposure pattern at the relevant treatment level (the NOEAEC) by an assessment factor throughout the measured mesocosm profile. However, the practicality of checking that this RAC profile fully ‘covers’ the exposure profiles generated in FOCUS depends greatly on the complexity of the predicted profiles, in turn dependent on the physicochemical properties of the active substance, the intended uses and the local conditions. In response to a request from a Member State for analysis of many profiles according to the CAT for intended uses of a lambda-cyhalothrin product (KarateTM), we developed a methodology for systematic and objective analysis in accordance with the “concept of the envelope curve”. This comprised identification of toxicologically independent clusters of peaks, visual assessment of the clusters relative to the RAC profile, and where necessary detailed assessment of peaks using a “Profile Comparison Factor” (PCF). The PCF provides a numerical integration of key attributes of a cluster of peaks that exceed a threshold (ETO-RAC), and indicates the intensity of exposure to an active substance in a cluster of peaks in a

FOCUS profile, relative to the exposure profile in the mesocosm study, by reference to the following parameters: number of peaks, total duration of cluster (from start of first exceedance to end of last exceedance), maximum duration of a single exceedance in the cluster, total duration of intervals (exposure below ETO-RAC) within the cluster.

2.06.P-Th013 Evaluation of mesocosm studies conducted in support of higher-tier aquatic risk assessment – look what the CAT dragged in

Daniel Bruce Pickford¹ and Pria Mahabir², (1)Product Safety Global Strategic Science, Syngenta Ltd, United Kingdom, (2)Syngenta Ltd, Canada

Experimental ecosystem (mesocosm/microcosm) studies are a valuable refinement tool in aquatic risk assessment for PPPs, accommodating environmental fate and behaviour of the active substance while addressing ecological processes such as community level effects and recovery. These processes occur in real world edge of field surface waters, and mesocosms therefore act as the surrogate reference tier, supporting prediction of risks to aquatic flora and fauna arising from uses of PPPs. In spite of the obvious value of mesocosm studies in higher tier aquatic risk assessment, their acceptance by regulators is still subject to significant uncertainty. This relates both to technical conduct of the studies, in particular statistical power and taxonomic representation, but also to the ability to use a recovery endpoint. Use of an ecological recovery endpoints is increasingly contingent on the ability to demonstrate that the exposure profile generated in the mesocosm study is sufficiently worst-case. In 2023 EFSA published their “Proposal of critical appraisal tools (CATs) for the evaluation of ecotoxicology studies” and the CAT for evaluation of mesocosms provided additional guidance on profile analysis, namely the “concept of the envelope curve”. This appears to present a more conservative approach to assessing the representativeness of mesocosm exposure profiles. While a specific checklist directly addressing the characteristics of mesocosm studies is in many ways preferable to trying to use a generic approach, e.g. Klimish score, it seems worthwhile to compare this tool with the pre-existing guidance (Aquatic Guidance Document, 2013) and the checklist for assigning a Reliability Index therein, to see whether coverage of key aspects is comparable and the level of conservatism has been maintained. We found that the wording of the items in the CAT is rather brief and in places ambiguous, which potentially leads to uncertainty as to how it will be applied. Interestingly, there are more items in the CAT referring to the mode of action of the test substance than in the 2013 guidance while there is less attention to basic aspects of ensuring reliable exposure. Realism of exposure is given more prominence in the CAT but little practical detail is provided on how to adequately demonstrate representativeness of exposure profiles using the concept of the envelope curve, which appears to be a more conservative approach for anything other than the simplest expected profiles.

2.06.P-Th014 Revisiting Time-Weighted Average Approaches in Aquatic Risk Assessment: Scientific Basis, Regulatory Challenges, and Future Direction

Kristi Tatsi¹ and Anastasia Del Signore², (1)Corteva, United Kingdom, (2)Corteva Agriscience, Germany

The EFSA aquatic guidance (2013) introduced the use of Predicted Environmental Concentration Time-Weighted Average (PEC_{sw;twa}) in chronic risk assessment under specific conditions, primarily when PEC_{sw};max exceeds RAC_{sw};ch. This approach is based on the principle of reciprocity (Haber’s law), which assumes toxicity depends on both concentration and exposure duration, allowing similar effects from short-term high concentrations or long-term low concentrations. EFSA guidance requires evidence such as early treatment-related responses, minimal latency of effects, and overlap with sensitive life stages of short duration. A case where PEC_{sw;twa} was successfully applied has been documented (Belgers et al., 2011), demonstrating its potential scientific validity.

However, EFSA’s 2015 technical report highlighted ambiguities and stressed that linear reciprocity must be demonstrated experimentally before PEC_{sw;twa} can be used. It also clarified latency considerations: gradual effect progression may allow PEC_{sw;twa} use, whereas late-onset effects indicate latency and require additional testing. Higher-tier refinements using TWA approaches remain rare due to lack of standardized guidance, reluctance among evaluators, and uncertainty in practical implementation.

Given that EFSA aquatic guidance does not foresee revisions soon, this project aims to re-evaluate PEC_{sw;twa} applicability. Specifically, it will:

- Critically analyze objections raised in recent EU active substance renewals.
- Examine uncertainties and shortcomings in applicant data and argumentation.
- Address key issues from EFSA (2015), including defining time frames for reciprocity, reporting endpoints when reciprocity applies partially, and clarifying latency assessment.

Case studies on data-rich substances will illustrate common pitfalls and propose solutions. Scientific evidence supporting reciprocity will be explored, particularly for herbicides used in aquatic weed control, where this

concept is essential. Ultimately, the project seeks to provide recommendations for harmonizing guidance, improving transparency, and enabling scientifically robust higher tier refinements in aquatic risk assessment.

2.06.P-Th015 Be more realistic: Predicting the effects of short-term exposure events on Zebrafish Early Life Stages using the GUTS-model

Matthias Teigeler¹, Thorsten Behsen², Gottfried Eisner² and Udo Hommen³, (1)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)LKC Switzerland Ltd, Switzerland, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Toxicokinetic-toxicodynamic (TKTD) models are increasingly used to analyse and predict effects of time-variable exposure on survival and sublethal endpoints. Here we present an example on the use of the GUTS model to describe effects of an insecticide on survival of fish larvae. In a Fish Full Life Cycle Test with zebrafish under flow-through conditions to achieve constant exposure, survival of larvae of the parental and filial generation was the most sensitive endpoint. Since results for both generations did not differ significantly, the pooled data were used to calibrate the reduced GUTS model by means of the openGUTS software. Both, the stochastic death (SD) and the individual tolerance (IT) variants of the reduced GUTS model could be fitted well to this data set. To validate the model, a zebrafish Early Life Stage test over 35 d was designed to provide data on effects of short-term exposure as recommended by EFSA's Scientific Opinion on TKTD modelling (EFSA PPR Panel 2018). The exposure pattern was decided based on available FOCUS exposure estimations and practical considerations. Effects of three exposure concentrations, each resulted from two pulse exposure events of 24 h and an interval of 7 days in between, were tested. The pulses were on day 7 and 15 post fertilization. A second larger interval to test toxicologically independent peaks was not tested because independent peaks would require an interval exceeding the duration of the test. Animal welfare is a further strong argument to skip testing of a second interval. The reduced GUTS model was able to predict the survival over time observed in the pulse exposure experiment reasonable well. Since the model validation showed acceptable goodness of fit parameters, we conclude that the model can be used as a Tier 2C approach to assess effects of the diverse dynamic exposure pattern predicted by FOCUS modelling on the survival of zebrafish larvae.

2.06.P-Th016 Exploring Climate-Linked Shifts in Zooplankton Communities and Water Quality Parameters Using Historical Mesocosm Data

Zoe Leanne Parker-Crosse, Harry Pope and Nadine S Taylor, Cambridge Environmental Assessments (CEA), United Kingdom

Mesocosm studies can provide valuable insights into how aquatic ecosystems respond to environmental stressors under controlled, yet ecologically relevant, conditions. Mesocosm facilities typically have an abundance of historical data from these studies that has the potential to be utilised to investigate and interpret long-term trends and changes. In this poster, we analysed a unique archive of historical mesocosm data, spanning a decade, from Cambridge Environmental Assessments (CEA); a GLP-compliant facility in Cambridgeshire, UK, specialising in the aquatic testing of plant protection products (PPPs). The data was used to investigate potential climate-driven trends in water quality parameters and zooplankton dynamics, with a particular focus on changes in zooplankton communities.

Although designed for higher-tier regulatory assessments, the consistent experimental protocols, semi-natural conditions, and detailed monitoring at CEA provide a unique opportunity to explore long-term ecological patterns. We analysed trends in baseline water quality parameters (e.g., temperature, dissolved oxygen, pH, and conductivity), alongside zooplankton community structure, abundance, and diversity.

Preliminary findings indicate subtle, but consistent, shifts in zooplankton community structure and behaviour over time. These outcomes emphasise the value of long-term mesocosm data for detecting ecological signals of climate change and highlight the need for further research into how global change may influence intra- and interspecific community structure and function in aquatic systems.

These findings reveal that historical GLP mesocosm data, such as those from CEA, could provide valuable insights into the subtle ecological impacts of climate change. Beyond their regulatory function, such datasets may serve as important archives for understanding how global change influences freshwater ecosystems and species interactions over time.

2.06.P-Th017 Ecotoxicity of agricultural pesticide mixtures in freshwater microcosms: Insights into bioconcentration and trophic transfer

Isabel Campos¹, Ana Ré², Mariana Rodrigues³, Joana Luisa Pereira⁴, Fernando Gonçalves⁵, Hans Mo⁶, Rima Osman⁶, Maria Angeles Martínez⁷, Adrian De la Torre⁷, Irene Navarro⁷, Jakub Hofman⁸, Francisco Alcon⁹, Josefina Contreras⁹, Vera Silva¹⁰, Violette Geissen¹¹ and **Nelson Abrantes¹²**, (1)CESAM, University of Aveiro (UA), Portugal, (2)Department of Environment and Planning, University of Aveiro, Portugal, (3)Department of Biology & CESAM, University of Aveiro, Portugal, (4)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal, (5)University of Aveiro, Portugal, (6)Wageningen Food Safety Research (WFSR), Netherlands, (7)Unit of POPs and Emerging Pollutants in the Environment, Department of Environment, Spain, (8)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (9)Department of Agricultural Engineering, Universidad Politecnica de Cartagena, Spain, (10)Soil Physics & Land Management Group, Wageningen University and Research (WUR), Netherlands, (11)Wageningen University and Research (WUR), Netherlands, (12)Department of Biology, University of Aveiro, Portugal

Freshwater ecosystems near agricultural areas are highly vulnerable to complex pesticide mixtures that can affect aquatic organisms. Predicting organismal responses to simultaneous exposure to multiple pesticides remains a major challenge in ecotoxicological risk assessment. Within the H2020 SPRINT project, we addressed this challenge using a high-tier evaluation based on a two-trophic-level aquatic microcosm structured into three experimental stages. The microcosm included a producer (*Nasturtium officinale*), a primary consumer (*Atyaephyra desmarestii*), and a secondary consumer (*Procambarus clarkii*). Two pesticide mixtures, each containing five active substances detected in aquatic systems of Spain and Czechia, were tested under control conditions and at predicted environmental concentrations (PEC). Results showed that pesticide levels in producer tissues directly determined the amounts ingested by the primary consumer. The highest bioconcentration occurred when the primary consumer ingested contaminated producers while simultaneously being exposed to PEC, underscoring the combined influence of dietary and waterborne exposure. Bioconcentration factors varied regionally: acetamiprid showed the highest accumulation in Spain, whereas terbutylazine had the highest, though lower overall, accumulation in Czechia. Biomagnification factors were consistently low across both case studies, indicating limited trophic transfer from *A. desmarestii* to *P. clarkii*. Overall, the study indicates a low risk of bioaccumulation and biomagnification of the tested pesticide mixtures within this simplified aquatic food chain. These findings are ecologically encouraging yet highlight that pesticide behaviour varies across regions, warranting further investigation. The study advances ecotoxicological assessment by providing an experimentally validated approach for evaluating pesticide mixtures under realistic exposure scenarios and offers insights that support more accurate environmental risk assessments.

Disclaimer/Disclosure:

This work was also funded by national funds through FCT – Fundação para a Ciência e a Tecnologia I.P., under the project CESAM-Centre for Environmental and Marine Studies, references UID/50017/2025 (doi.org/10.54499/UID/50017/2025) and LA/P/0094/2020 (doi.org/10.54499/LA/P/0094/2020).

2.06.P-Th018 Ecological Risk Assessment of Growth and Reproductive Toxicity of Benzalkonium Chloride in Aquatic Environments

*Chi-Wei Huang and **Chin-Jou Wang**, National Kaohsiung University of Science and Technology, Taiwan (Greater China)*

Benzalkonium chloride (BAC), a quaternary ammonium cationic surfactant, is widely used as a disinfectant and biocidal agent in environmental and household applications. Following the surge in disinfection demand during the SARS-CoV-2 pandemic, BAC usage has increased substantially, with residues potentially entering aquatic environments through domestic sewage and hospital wastewater. Previous studies have detected BAC in environmental waters—for instance, 31.4 µg/L in municipal wastewater in the Netherlands and 256.6 µg/L in Poland—indicating potential ecological risks that require further investigation. In this study, the model organism *Caenorhabditis elegans* (*C. elegans*), commonly used in environmental toxicology research, was employed to evaluate the ecological toxicity of BAC, using the Love River in Kaohsiung City, Taiwan, as a representative urban river system. The maximum BAC concentration detected in the Love River was 35.2 µg/L. Toxicity assessment revealed that BAC inhibited the growth and reproduction of *C. elegans* and increased intracellular oxidative stress. The predicted no-effect concentration (PNEC), estimated using the Hill model, was approximately 0.033 µg/L. Furthermore, exposure experiments at the highest concentration (1000 µg/L) demonstrated that reproductive toxicity induced by BAC was positively correlated with total nitrogen and total phosphorus levels in river water samples. These findings suggest that BAC in urban river systems may pose

potential ecological risks, and the results of this study provide valuable reference information for the ecological safety assessment and environmental management of BAC and similar disinfectants.

2.06.P-Th019 Interactive Effects of Light Pollution and Co-occurring Stressors on an Aquatic Insect (*Chironomus riparius*)

Joana Carmo¹, Bruna Silva¹, Diana Campos¹, Ana L. Machado¹, Robby Stoks² and João L.T. Pestana¹,
(1)CESAM, University of Aveiro, Portugal, (2)Laboratory of Evolutionary Stress Ecology and Ecotoxicology, University of Leuven, Belgium

Light pollution or the excessive use of Artificial Light at Night (ALAN) negatively affects most urban aquatic ecosystems with potential negative ecological consequences for aquatic biota. The highest levels of ALAN occur in urban areas, where aquatic ecosystems are also exposed to other stressors such as warming, salinisation and pesticide exposure. These stressors can interact and act additively or even synergistically. However, combined stressor effects with ALAN are still unexplored.

In this work, we evaluate the effects of light pollution (1 and 10 lux) with increased temperature, salinity and pesticides (glyphosate) on the physiological and life-history responses of the non-target species *Chironomus riparius*. Our work demonstrates that exposure to low and relevant levels of ALAN increases the sensitivity of *C. riparius* to other urban stressors. Light pollution decreases heat tolerance (lower Critical Thermal Maximum, CT_{max}) and reduces lethal tolerance of larvae to chemical stressors (glyphosate and salinity). Interactive effects, including synergisms, were also observed under combined exposures to ALAN and these stressors for the development and emergence (Mean Emergence Time, EmT₅₀) of *C. riparius*, suggesting that light pollution can have detrimental impacts on aquatic insects living in urban aquatic ecosystems.

The data obtained in this work that used low ALAN levels and realistic exposure scenarios for urban areas show that light pollution should be an important consideration in ecological risk assessment of chemical stressors including plant protection products. Results can also contribute to future legislation on light pollution and to a more effective protection of biodiversity and the ecological integrity of urban ecosystems.

2.06.P-Th020 Effects and Fate of the Nitrification Inhibitor N-[3(5)-Methyl-1H-pyrazol-1-yl)methyl]acetamide and the Urease Inhibitor N-(2-Nitrophenyl)phosphoric Triamide in a Preliminary Freshwater Mesocosm Study

Björn Kusebauch¹, Ulrike Scholz², Steffen Schüler¹, Bonny Haueisen¹, Dagmar Schnee¹, Ina Janthur¹, Astrid Bethe¹, Ronny Schmiediche¹, Stefan Loth¹, Valeska Contardo-Jara¹, Silvia Mohr² and Erik Sperfeld¹, (1)German Environment Agency (UBA), Germany, (2)IV 2.5, German Environment Agency (UBA), Germany

Nitrification and urease inhibitors (NUIs) are applied as fertilizer additives in agriculture to reduce emissions of the greenhouse gases ammonia and nitrous oxide, as well as leaching of nitrate into groundwater. Their modes of action rely on the suppression of soil enzymes and bacteria that play a crucial role in the nitrogen cycle. Among the inhibitors approved in the EU, only Nitrapyrin was considered as hazardous to the environment during the approval process. Other NUIs, such as N-[3(5)-methyl-1H-pyrazol-1-yl)methyl]acetamide (MPA), 3-methylpyrazole (3-MP), and N-(2-nitro-phenyl)phosphoric triamide (2 NPT), are classified as carcinogenic, mutagenic, and reproductive toxic, respectively. 3-MP, which is both an active substance and a metabolite of MPA, is also under assessment for endocrine-disrupting properties. Previous research has primarily focused on terrestrial systems, whereas potential environmental risks in aquatic systems due to runoff events remain insufficiently studied.

Here, the fate of MPA and 2-NPT as well as their potential effects on aquatic organisms were investigated over 105 days using small pond mesocosms (2 m³) with sediment from June to September 2025. In an establishing period prior to NUI application, the mesocosms were inoculated with water, plankton, and periphyton from natural ponds. Subsequently, the mesocosms were spiked individually with 50 µg/L MPA and 2-NPT or as a mixture at 5 µg/L. For fate investigations, water samples were analyzed via LC-MS/MS at defined time points. At the end of the study, MPA was no longer detectable (< 0.005 µg/L) in the water phase, whereas 3-MP was still present at up to 65 % of the initial amount of MPA. 0.10 and 0.37 µg/L 2-NPT was detected after 105 days,

whereas the metabolite 2-NA disappeared after its formation during the course of the study. Nutrient analyses revealed changes in the dissolved nitrogen forms nitrate, nitrite, and ammonium depending on the applied NUI. Ex situ cultivation assays of bacteria showed, based on preliminary data, generally a declining trend of overall bacterial abundance and the abundance of different bacterial species over time. NUIs had distinct effects on phytoplankton, zooplankton, and periphyton. In-situ assays of duckweed and snails disclosed minor effects on growth and no effects on reproduction, respectively. Our study provides first insights into the fate of selected NUIs in freshwater ponds, as well as their differential effects on the organisms.

2.06.P-Th021 Transgenerational impacts of TBBPA on the freshwater snail *Lymnaea stagnalis*
Obianuju Oluchukwu Eze¹, Mechthild Schmitt-Jansen², Alexander Böhme³, Eberhard Kuester² and Stefan Lips³, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Department Ecotoxicology & Ludwig Maximilian University Munich, Department of Aquatic Ecology, Germany, (2)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (3)Helmholtz Centre for Environmental Research GmbH (UFZ), Department Ecotoxicology, Germany

TBBPA, a brominated flame retardant (BFR), is a widely used plastic additive that poses ecological risks due its endocrine-disrupting potential, bioaccumulation and toxicity in aquatic environments. While its acute toxicity has been documented in several aquatic species, far less is known about the long-term and transgenerational effects in the freshwater snail *L. stagnalis*, limiting our understanding on long-term ecological consequences and its potential implication for population dynamics. Freshwater snails are key players in the ecosystem that helps in nutrient cycling and ecosystem stability. In this study, we assessed whether parental exposure to TBBPA will impact the vitality and early development of an unexposed F1 generation of exposed *L. stagnalis*, thereby addressing the carry-over effects.

Adult snails (F0) were exposed for up to 28 days to nominal TBBPA concentrations between 75 and 1500 µg/L. Egg masses produced by exposed parents (F1 embryos) on day 14 and 28 were transferred to 24-well glass plates containing clean medium to isolate carry-over effects from direct exposure. Additionally, embryos from unexposed parents were placed in a 24-well glass plate and exposed to nominal TBBPA concentrations of 50–1000 µg/L. Development of embryos was monitored for 14 days.

Parental exposure resulted in impaired reproduction, with reduced number of clutches and embryo/ clutch production as early as day 3 of adult exposure. Their embryos (F1) showed different types of abnormalities, including small shell, delayed hatching, low pigmentation and other malformations, even at the lowest nominal concentration. The EC₅₀ value was ~350 µg/L, suggesting transgenerational effects even without direct exposure. The F1-embryos that were further monitored for chronic effects didn't not compensate their abnormalities (e.g. smaller shell size) by the end of the observation period of 3 month. Embryos of the non-exposed parents showed similar abnormalities with an EC₅₀ of 235 µg/L after 14 days and 100% mortality at 1000 µg/L.

This finding reveals that TBBPA can impair offspring vitality even in the absence of continued exposure, suggesting potential long-term consequences for population stability. These findings highlight the need to consider both exposure pathways and transgenerational effects when assessing the ecological risk of high-Kow, bioaccumulative and hydrophobic contaminants.

2.06.P-Th022 A Risk Evaluation of the Ubiquitous Ultraviolet (UV)-Filter Octocrylene
Breanne Holmes¹, M. Carmen Casado-Martinez¹ and Alexandra Kroll², (1)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Switzerland, (2)Ecotox Centre, Switzerland

Octocrylene is an ultraviolet (UV)-B filter and sunscreen stabilizer that is used in sunscreens and personal care products and is the most frequently used UV filter in cosmetics. Sources in the environment are diverse and include sunscreen, machine washing liquids/detergents, automotive care products, paints, coatings or adhesives and fragrances, as well as construction materials, furniture, and flooring which enter aquatic ecosystems through runoff and wastewater effluents. Subsequently, recent reporting shows it is commonly found in recreational freshwater (geometric mean: 30 ng/L, maximum: 4.66 µg/L) and marine (geometric mean: 37 ng/L, maximum: 10.6 µg/L) ecosystems, as well as in sediment, but its concentrations vary considerably temporally and spatially.

It has been identified as hazardous to the aquatic environment through long-term chronic studies and has been determined by ANSES to be a persistent and toxic compound but not bioaccumulative. Since octocrylene has low solubility in water, and a high log K_{ow} (6.1), its effects on sediment-dwelling organisms are also potentially important. Ecotoxicity studies have been done for several trophic levels of freshwater and marine species, particularly in literature studies, and the risks to marine organisms is a growing area of research interest. Additional studies on the endocrine activity of octocrylene and its major metabolite, benzophenone, have been conducted as there are indications of endocrine activity from both compounds. Due to its widespread detection in the environment and its potential for aquatic toxicity, an assessment on the risk to aquatic and sediment-dwelling organisms was undertaken. Using the existing regulatory submission study reports and literature search results, environmental quality standards for octocrylene in surface waters and sediments were derived. Literature studies were assessed using the CRED approach, which takes into account the reliability and relevance of the study even when non-standard species or non-guideline studies are done. While no mesocosm data was available and there were not enough datapoints for a species sensitivity distribution (SSD) derivation, there was enough relevant and reliable data for the derivation of EQS values for acute and chronic aquatic ecosystems and sediment ecosystems, and to assess the risk for secondary poisoning to higher tier organisms.

2.06.P-Th023 Synergistic Threats: How Temperature and 6PPD-Q Contamination Reshape Arctic Char Development in Alpine Lakes

Emilie Réalis-Doyelle¹, Nathalie Cottin², Valérie HAMELET³, Allan Raffard⁴, Jean Guillard⁴ and Emmanuel Naffrechoux⁵, (1)No Affiliation, France, (2)université Savoie Mont Blanc, France, (3)INRAE-CARRTEL, France, (4)INRAE CARRTEL, France, (5)université Savoie Mont Blanc, France

Freshwater biodiversity faces severe threats from anthropogenic stressors, notably climate warming and emerging contaminants such as 6PPD-quinone (6PPD-Q), a highly toxic byproduct of tire wear. While 6PPD-Q is recognized for its acute lethality in species like coho salmon (*Oncorhynchus kisutch*), its synergistic effects with rising temperatures on cold-water fish—particularly during critical early life stages—remain poorly understood. Arctic charr (*Salvelinus umbla*), a cold-stenothermal species endemic to alpine lakes, may be especially vulnerable due to its limited thermal tolerance and increasing exposure to urban runoff.

In this study, we investigated the combined impacts of temperature (5°C and 8.5°C) and 6PPD-Q contamination (0, 1.0 and 3.5 µg/L) on larvae from two Arctic charr populations: one native and cold-adapted (Lake Geneva) and one introduced and putatively more thermally tolerant (Lake Annecy).

We assessed a range of traits to elucidate potential synergistic effects on larval development: Physiological (survival, metabolism, and oxidative stress via GST and catalase activity); Morphological (malformation and growth rates); Behavioral (swimming behavior).

Our results revealed significant interactive effects between temperature and 6PPD-Q, demonstrating that warming exacerbated the toxic effects of the contaminant. The chorion provided partial protection during embryogenesis, but post-hatch larvae were highly sensitive to the combined stressors. Annecy charr broodstock are raised in aquaculture for 1 to 5 years in water with a relatively stable temperature of 7 to 10°C.

This acquired thermal tolerance is likely transmitted to their offspring, suggesting a form of transgenerational effect or epigenetic inheritance of thermal stress adaptation. Contamination induced significant behavioral alterations (e.g., reduced swimming activity) and elevated oxidative stress, likely linked to underlying metabolic and cardio-respiratory disruptions.

These findings underscore the significant ecological risks posed by combined thermal and chemical stressors and highlight the crucial role of population-specific adaptations in environmental risk assessments. Our work calls for integrated conservation strategies that explicitly account for local genetic backgrounds and synergistic stressor interactions to effectively protect vulnerable cold-water species in a rapidly changing climate.

2.06.P-Th024 Synthesis, characterization and acute toxicity evaluation of functionalized maghemite nanoparticles in the ostracod *Cypridopsis vidua*.

Sandra Tiscareño-Magallanes¹, Jesús Alvarado-Flores¹, Mario Arzate-Cardenas², Roberto Rico-Martínez² and Roberto Carlos Valerio-García², (1)Unidad de Ciencias del Agua, Mexico, (2)Universidad Autónoma de Aguascalientes, Mexico

The increasing use of nanomaterials in industry, biotechnology, medicine and human consumption requires a toxicological assessment of their impact on aquatic ecosystems. In this study, maghemite (γ-Fe₂O₃) nanoparticles were synthesized by coprecipitation and functionalized with sodium citrate dihydrate.

Subsequently, they were characterized by X-ray diffraction analysis to determine their elemental composition and particle size, and then the acute toxicity of the maghemite nanoparticles was evaluated in juvenile ostracods of *Cypridopsis vidua*. The ostracods used were isolated from a karst aquatic ecosystem of the Yucatán Peninsula

and cultured monoclonal under laboratory conditions at 25°C. A 48-hour exposure bioassay was performed in sterile 24-well polystyrene plates, exposing 100 organisms per treatment to concentrations of 20, 50, 100, 200, 400, 500, 600, 800, and 1000 mg/L (5 organisms per well in 2 mL of nanoparticle solution). The dose-response relationship was analyzed using a log-logistic model with R software. The results showed an upward-sigmoid trend; however, mortality did not exceed 20% even at the highest assay concentration (1000 mg/L). Due to this low toxicity, the Median Lethal Concentration (LC50) values were estimated by extrapolation, resulting in an LC50 > 1000 mg/L. These findings suggest that the synthesized functionalized maghemite nanoparticles have low acute toxicity for ostracods, as the concentration required to affect 50% of the population significantly exceeds standard experimental limits and the conditions expected in natural environments. The demonstrated low toxicity of maghemite nanoparticles to aquatic organisms like *Cypridopsis vidua* is a finding of paramount importance. Being a biocompatible and

2.06.P-Th025 The eyes are the window to the sea: Metals and Metalloids in the ocular tissues of a coastal shark from Southeastern Brazil

Isabel Quental Willmer¹, Tatiana Dillenburg Saint'Pierre², Marcelo Vianna³ and Rachel Ann Hauser-Davis¹, (1)Laboratório de Avaliação e Promoção da Saúde Ambiental, Instituto Oswaldo Cruz, Brazil, (2)Laboratório de Espectrometria Atômica (LABSPECTRO), Departamento de Química, Pontifícia Universidade Católica do Rio de Janeiro, Brazil, (3)Laboratório de Biologia e Tecnologia Pesqueira, Departamento de Biologia Marinha, Instituto de Biologia, Brazil

Elasmobranchs are among the most threatened vertebrates worldwide, yet they remain critically understudied in terms of ecotoxicological impacts. This group relies heavily on vision for navigation, foraging, and predator avoidance, yet almost nothing is known about how metals accumulate within their ocular tissues, an increasing issue in coastal environments. In this context, this study aimed, for the first time, to assess different accumulation profiles in the different eye structures (cornea, lens, sclera, and choroid) metal in *Rhizoprionodon lalandii*, a small coastal shark in southeastern Brazil. Individuals were sampled from artisanal fisheries, eyes were dissected into distinct tissues, and elemental concentrations were quantified by ICP-MS, and age classes (adults, juveniles, and neonates) and sampling locations were compared. A consistent distribution pattern emerged across groups, where the cornea was the primary accumulation site for most elements, including Fe, Mn, Sr, Ti, Zn and, in some cases, Co and Ni, while the lens generally exhibited the lowest concentrations. The sclera often paralleled the cornea with high Mn, Sr, Ti, and Zn levels, suggesting similar affinities for these elements. The choroid displayed more variable behavior, accumulating certain elements such as Se in adults and As in neonates. Despite these variations, some elements showed little tissue differentiation, while others, such as Rb, Hg, or As, displayed age-specific or structure-specific preferences. Overall, the observed metal distribution within shark eyes seems to be highly structured, with the cornea and sclera consistently acting as key accumulation tissues for multiple elements, the lens serving as a low-accumulation compartment, and the choroid reflecting more specialized or dynamic patterns. These findings advance our understanding of ocular physiology under environmental contamination and provide a basis for evaluating how metal exposure might affect sensory performance in coastal shark species, guiding future ecotoxicological assessments and conservation efforts for elasmobranchs living in polluted habitats.

2.07 Identifying Safe Operating Spaces for Biodiversity in Water and Sediment Systems

2.07.T-01 Trends and Thresholds of River Macroinvertebrate Biodiversity Responses to Anthropogenic Stress for Identifying Safe Operating Spaces

Elmar Becker¹, Milo Leon de Baat², Annemarie van Wezel¹, Jennifer Laurent³, Anna Sobek⁴, Katarina Cetinic⁵,

James S. Sinclair⁶, Daniela Cortés Guzmán⁶, Iris Pit⁷, Peter Haase⁶, Susanne Schneider⁵ and Jes Rasmussen⁸, (1)University of Amsterdam (UVA), Netherlands, (2)Chemical Water Quality & Health, University of Amsterdam (UVA), Netherlands, (3)Stockholm University, Sweden, (4)Environmental Science, Stockholm University, Sweden, (5)Norwegian Institute for Water Research, Norway, (6)Senckenberg Research Institute and Natural History Museum Frankfurt, Germany, (7)Deltares, Netherlands, (8)Aarhus University, Denmark

Freshwater ecosystems globally face multiple environmental pressures, including climate and land-use change, altered hydrology and chemical pollution. These pressures threaten biodiversity and challenge efforts to balance ecological protection with societal needs. This study evaluates how riverine macroinvertebrate biodiversity responds to chemical pollutants within a multi-stressor context, with the goals of identifying consistently responding biodiversity metrics and determining levels of toxic pressure at which ecological degradation accelerates.

To this end, European macroinvertebrate time-series data from river sites distributed across 23 countries, spanning multiple decades was analysed. Multiple community, taxonomic, trait-based biodiversity metrics were derived. Environmental parameters included land cover, climate indices and modelled toxic pressure. Variable selection was performed using elastic-net regularisation with cross-validation, and selected biodiversity–stressor relationships were quantified using generalized additive models with spatial and temporal structure and site-level random effects. Change-points were explored using modelled response curves.

Most taxonomic and trait-based indicators demonstrated clear declines with increasing toxic pressure, even after accounting for climate and land-use covariates. Sensitive groups, such as insect orders that have low tolerance to pollution or taxa characterised by low dispersal capacity, showed particularly strong negative responses. Several metrics displayed non-linear patterns, with steep declines beginning at low levels of toxic pressure. In contrast, community- and functional metrics generally exhibited weaker or inconsistent responses, suggesting greater ecological redundancy or slower turnover. Although distinct thresholds were not sharply defined, the results indicate that adverse biodiversity responses likely emerge at low levels of chemical impact, warranting further investigation of low impacted sites.

Overall, this work demonstrates that chemical pollution exerts a strong, independent constraint on aquatic biodiversity across Europe, compounding the influence of climate and land-use stressors. These findings highlight the need for integrated strategies that simultaneously address chemical, climatic and habitat pressures to maintain ecological integrity and define safe operating spaces for freshwater ecosystems.

2.07.T-02 Real-time, high-throughput biodiversity monitoring reveals impacts of chemical mixtures in freshwater ecosystems

Niamh Eastwood¹, Arron Watson¹, Piangfan Naksukpaiboon¹, William A. Stubbings Dr¹, Mohamed Abou-Elwafa Abdallah Dr¹, Jiarui Zhou² and Luisa Orsini², (1)University of Birmingham, United Kingdom, (2)School of Biosciences, University of Birmingham, United Kingdom

Understanding how chemical mixtures, compounded by other stressors, impact freshwater biodiversity across space and time is essential for protecting ecosystems. We developed a scalable, high-throughput framework that integrates biodiversity quantified through environmental DNA, untargeted chemical analysis, and multimodal machine learning to identify biodiversity shifts and their drivers in freshwater ecosystems. Applying this approach to 52 English lakes, we found that spatial biodiversity patterns were strongly shaped by plant protection products and metals, with insecticides and fungicides emerging as key contributors to biodiversity loss. Lake typology and land use also played significant roles.

To explore temporal dynamics, we applied the same framework to a 100-year sediment archive from a lake with a well-documented history of human impact. Despite improvements in water quality, community composition and ecosystem functions exhibited irreversible changes. Biocide mixtures and climate extremes together explained up to 90% of observed biodiversity shifts over time. These findings expose critical limitations in traditional monitoring approaches and demonstrate the value of holistic, data-driven methods to identify and prioritize threats to biodiversity.

To support real-world uptake, we developed an in-field DNA monitoring platform combining our multiplex

metabarcoding protocol, which enables screening of entire freshwater communities in a single reaction, with portable Oxford Nanopore sequencing. This system provides rapid, low-cost, real-time biodiversity data, empowering stakeholders to monitor ecological status and act quickly in response to emerging risks. Looking forward, we are expanding our temporal analysis to national scales by reconstructing pollution and biodiversity trajectories from lake sediment archives. By linking persistent and bioaccumulative chemical mixtures with historical biodiversity, ecosystem functions, climate, and land use data, we aim to identify and rank threats to biodiversity using AI-enabled analytics. Long-term records are pivotal for forecasting biodiversity loss under future scenarios, enabling regulators to intervene early and preserve critical freshwater resources.

Our integrated approach offers a forward-looking, scalable solution to monitor, understand, and mitigate the ecological impacts of chemical mixtures, advancing sustainable freshwater management and aligning with EU biodiversity and Net Zero goals.

2.07.T-03 The freshwater amphipod *Gammarus fossarum* as European model species for substance toxicity assessment using spiked-sediment

Anthony Gérard Edouard Mathiron¹, Yohann Kubler², Mélaine Claitte³, Vanessa Brosselin³, Pierre-Louis HOMBERT³, Pascal Pandard⁴, Océane Lafargue⁵, M. Carmen Casado-Martinez⁵, Delphine Leroy⁶, Yves Marneffe⁶, Nicolas Delorme⁷, Olivier Geffard Pr⁷ and Guillaume JUBEAUX¹, (1)Biomae, France, (2)université de Lorraine, France, (3)BIOMAE, France, (4)L'Oréal, France, (5)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Switzerland, (6)Scientific Institute of Public Service (ISSeP), Belgium, (7)National Research Institute for Agriculture, Food and Environment (INRAE), France

A new OECD test guideline (TG) on freshwater amphipods is currently under development (“Sediment-Water Amphipod Toxicity Test Using Spiked Sediment”, Project 2.68) and validation through interlaboratory assay. The protocol focusing on the North-American amphipod *Hyaella azteca* assesses toxicity of persistent chemicals in sediment and comprises a chronic toxicity test that measure the effect on adults’ reproduction. Here we aim at highlighting the interest for including in this new TG the European freshwater amphipod *Gammarus fossarum*. To do so, we first determined if the composition and the aging duration of five formulated sediment included the one used in OECD protocol affected gammarids’ life-history traits (i.e. survival and fecundity). We found no effect of sediment aging on females’ survival after 18 days but we highlighted a significant effect of composition, sand alone being the worst sediment. No significant effect of sediment composition, aging or interaction was found on the number of embryos per females as reproduction endpoint. In 2025, we initiated an interlaboratory assay with several European countries to determine the effect of two molecules (bifenthrin and pyrene) selected for *H. azteca* validation test on gammarids’ reproduction (i.e. juveniles production). The proposed protocol is a 29-day chronic toxicity test during which adults couples are exposed to sediment spiked with different concentrations of bifenthrin or pyrene for 18 days, then females with developing embryos are transferred in control media so that they can release juveniles during an observation period of 11 days. Regarding our first results on pyrene exposure, females’ survival in the control condition met the validity criteria established for the test (? 60%). No significant concentration-dependent effect of pyrene was observed on survival but we found a significant decrease in number of juveniles produced per females after female exposure to pyrene-spiked sediment at the highest concentration (640 mg/kg). Overall, we demonstrated that *G. fossarum* is a suitable alternative species for the evaluation of persistent chemicals through sediment-water toxicity test.

Key-words: ecotoxicology; laboratory exposure; reproduction; OECD; gammarids

2.07.T-04 Reflecting on 20 Years of OECD 225: Advancing Standardised Testing With *Lumbriculus Variegatus* With Ecotoxicological Insight

Jacqueline Hilgendorf¹, Jesper Givskov Sørensen², Diogo Filipe Nunes Cardoso³ and Susana Loureiro³, (1)CESAM - Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal, (2)Department of Biology, Aarhus University, Denmark, (3)University of Aveiro, Portugal

Sediments are key environmental compartments that both accumulate and release chemical contaminants, leading to chronic exposure of benthic communities. The freshwater oligochaete *Lumbriculus variegatus* is the only sediment-dwelling model species recommended for sediment risk assessment under OECD guidelines. Despite its ecological relevance and high sediment ingestion rate, *L. variegatus* is used considerably less often than *Chironomus* sp. in ecotoxicological sediment studies.

Here, we systematically reviewed 302 ecotoxicological studies on *L. variegatus* published between 2007 and 2025, identifying 91 studies that met predefined inclusion criteria (e.g., laboratory-based chemical exposures,

assessment of ecotoxicological effects) and methodological quality standards (chemical analysis, use of controls, number of replicates). Only 10% of the chronic sediment studies (?28 days) strictly followed OECD Guideline 225 without deviations (e.g., additional food supplement, lack of synchronisation), whereas 40% did not adhere to the guideline at all. Conventional endpoints (mortality, growth, reproduction) were measured in 92% of all studies; however, life-stage differentiation was rarely applied, and 24% of the chronic studies failed to meet the reproduction criterion.

In total, 41% of the studies extended OECD 225 by measuring non-conventional endpoints (i.e., endpoints not described by the guideline). Behavioural measures (feeding, locomotion, sediment avoidance, and bioturbation) were most frequently used (29%), and often proved more sensitive than conventional endpoints. Comparative studies with *Chironomus* sp. (26 studies) revealed no consistent pattern of relative sensitivity, with observed differences largely attributed to exposure route, feeding behaviour, species-specific biotransformation capacities, and endpoint selection.

Our review identifies major gaps in standardisation, endpoint selection, and experimental design for *L. variegatus* studies. We recommend revising OECD 225 to include non-conventional endpoints, redefining synchronisation periods prior to exposure, synchronising organisms 14 days prior to exposure, and differentiating life stages for growth and reproduction. Implementing these improvements will enhance the ecological relevance and regulatory applicability of *L. variegatus* in sediment ecotoxicology. This work synthesises nearly two decades of research and provides a clear roadmap for advancing sediment risk assessment.

2.07.T-05 Multigenerational Disruption of Reproduction and Behaviour in a Benthic Worm Exposed to Sediment-Associated Antidepressants.

Martina Santobuono¹, Matteo Schiavinato², Elettra D'Amico¹, Wing Sze Chan¹, Mette Albrektsen¹ and Henriette Selck¹, (1)Roskilde University, Denmark, (2)Wageningen University and Research (WUR), Netherlands

Pharmaceuticals are increasingly recognized as emerging environmental contaminants, with selective serotonin reuptake inhibitors (SSRIs) such as sertraline of particular concern due to their widespread use and persistence in aquatic systems. Owing to its lipophilic, ionizable properties, sertraline accumulates in sediments and may become bioavailable to benthic deposit feeders like *Capitella teleta*, a species central to nutrient cycling and food web dynamics. To address knowledge gaps on long-term impacts, we investigated the effects of environmentally relevant sediment-associated sertraline concentrations across three generations of *C. teleta*. Both conventional life-history endpoints and behavioural responses were assessed to capture subtle, multigenerational effects. Sediment-associated sertraline caused generation-dependent changes in reproduction and behaviour of *C. teleta*, revealing trade-offs between reproductive effort, offspring quality, and locomotor function. These findings stress the need for multigenerational approaches and behavioural endpoints to better capture long-term ecological risks of pharmaceuticals in benthic systems. Results highlight the importance of extended exposure designs for evaluating sublethal pharmaceutical impacts on benthic invertebrates and their ecological functions.

2.07.P Identifying Safe Operating Spaces for Biodiversity in Water and Sediment Systems

2.07.P-Th026 Assessing Toxicity of Emerging Semiconductor Pollutants Gallium and Indium in Contaminated Paddy Soils with A Soil–Water–Fish System

Pei-Jen Chen¹, Lu-Sheng Lan¹, Michael Edbert Suryanto¹ and Jehn-Yih Juang², (1)Department of Agricultural Chemistry, National Taiwan University, Taiwan (Greater China), (2)Department of Geography, National Taiwan University, Taiwan (Greater China)

Gallium (Ga) and indium (In) are critical metals widely used in semiconductor and optoelectronic industries, where their compounds are indispensable to modern electronic devices. However, improper disposal and industrial effluents have led to their emergence as environmental contaminants, particularly in agricultural systems such as paddy fields. The environmental fate, ecological toxicity, and potential risks of these types of pollutants in the agroecosystem remain poorly understood. In this study, a static soil–water–fish exposure system was developed using juvenile rice fish, medaka (*Oryzias latipes*), as a model organism to investigate the bioavailability and toxic effects of Ga and In in two contrasting paddy soils: acidic, aluminum (Al)-rich Pingzhen (Pc) soil and neutral, low-Al Sangkang (Su) soil. Sequential and KCl extractions revealed that exchangeable Al in Pc soil increased markedly with rising Ga or In concentrations. Soil pH and Al content strongly influenced metal mobility and bioavailability—Su soil released more soluble Ga, while Pc soil released more soluble In, with Ga notably enhancing Al mobilization from soil to water phases. Medaka exposed to highly contaminated Pc soils (>1 mmol/kg Ga or >4 mmol/kg In) exhibited significant mortality, likely due to Al displacement and release. In Su soils, no significant mortality was observed, but exposed fish accumulated Ga or In in a dose-dependent manner, resulting in sublethal effects such as growth inhibition and altered swimming behavior even at lower exposure levels. The soil–water–fish exposure system established provides an effective method for assessing the agroecological risks of emerging semiconductor-related metals for environmental monitoring and soil quality guidelines to ensure sustainable rice production and food safety.

2.07.P-Th027 Formulated sediment: a good control for bioassays to assess freshwater sediment toxicity on *Gammarus fossarum*?

Cécile LUC-REY¹, Anthony G.E. MATHIRON², Benoît J.D. FERRARI³, Hélène BUDZINSKI⁴, Pierre-Louis HOMBERT², Nicolas Delorme⁵, Olivier Geffard Pr⁵ and Guillaume JUBEAUX⁶, (1)BIOMAE & RiverLy, France, (2)BIOMAE, France, (3)Swiss Centre for Applied Ecotoxicology (Centre Ecotox), Switzerland, (4)Environnements et Paléoenvironnements Océaniques, Université de Bordeaux, France, (5)RiverLy, France, (6)Biomae, France

Freshwater sediments act as sinks for pollutants like metals, polycyclic aromatic hydrocarbons (PAHs), Polychlorinated biphenyls (PCBs), pharmaceuticals and personal care products (PPCPs), per- and polyfluoroalkyl substances (PFAS). While chemical analyses are the primary tool for studying sediment contamination, it is now useful to complete them with bioassays to provide effect-based sediment quality assessment¹. In order to perform those tests, standardized guidelines recommend the use of a formulated sediment as a laboratory control (eg. OECD 218). This formulated sediment is mainly composed of quartz sand, kaolin and peat and can be used for soil organisms (nematodes, ISO 10872), aquatic plants (watermilfoils, OECD 239), and benthic macroinvertebrates (amphipods, NF T 90-338-1).

In an effort to develop a new bioassay with a European amphipod, *Gammarus fossarum*, the relevance of the control sediment is questionable.

Two biomarkers, feeding rate and fertility, have been studied on gammarids exposed to 16 formulated sediments (with 3 replicates for each test) and 127 natural sediments (with 5 replicates for each condition) in order to assess their toxicity. Could this formulated sediment be good control to discriminate natural sediments depending on their toxicity?

First, the reproducibility of the formulated sediment was studied. Then, it was compared to uncontaminated natural sediments to see if the same amount of sediment is considered as toxic depending on the control used. While formulated sediment seems to be a good laboratory control for the reproduction test. It is not as efficient for the feeding rate test. Indeed, it does not allow the detection of as much toxic sediments as when using natural sediments considered to be uncontaminated.

Therefore, we propose to establish reference values, based on statistical method already used for those biomarkers^{4,5}, using the large dataset we have. At the end of this oral presentation, everybody will be able to do two bioassays to assess sediment quality using *Gammarus fossarum* and to interpret the results.

This work is aligned with the session 2.02 «Buried Risks and Hidden Insights: Advancing Sediment Quality Assessment for Ecosystem and Human Health».

2.07.P-Th028 Species Chemical Sensitivity Comparison Between Freshwater Amphipod *Hyaella azteca* and *Gammarus* spp.

Kyoshiro Hiki¹, Anthony Gérard Edouard Mathiron², Haruna Watanabe³, Guillaume JUBEUX², Pascal Pandard⁴, Olivier Geffard Pr⁵ and Hiroshi Yamamoto⁶, (1)University of Tokyo, Japan, (2)Biomae, France, (3)National Institute for Environmental Studies (NIES), Japan, (4)L'Oréal, France, (5)INRAE, France, (6)Health and Environmental Risk Division, National Institute for Environmental Studies (NIES), Japan

Toxicity tests with the North American amphipod *Hyaella azteca* are widely used for regulatory chemical risk assessment. However, *H. azteca* is not present in some regions, where native *Gammarus* spp. are more appropriate test organisms. To evaluate whether *Gammarus* spp. could serve as alternative species in a chronic sediment–water amphipod test method (that is under development at OECD as new test guideline (project 2.68)), we compared their sensitivity with that of *H. azteca* using the USEPA ECOTOX knowledgebase. We extracted 96-h LC50 values for water column exposure tests, because data on spiked sediment toxicity were limited for a robust comparison. Then we excluded censored values (< or >), and removed records exceeding 10 times aqueous solubility. When multiple LC50 values existed for the same chemical–species combination, we calculated geometric means. The final dataset comprised 780 LC50 records for 240 chemicals, including 203 records for *H. azteca* (64 chemicals) and 577 records for six *Gammarus* species (*G. fasciatus*, *G. fossarum*, *G. italicus*, *G. lacustris*, *G. pseudolimnaeus*, and *G. pulex*). For most chemicals (64%–90% chemicals that had data available for both taxa), the LC50 values for *H. azteca* and *Gammarus* spp. differed by less than 10-fold, indicating no clear interspecies differences. In addition to direct LC50 comparisons, we characterized the distribution of log-transformed LC50 values and examined the fifth percentile for all chemicals. As a result of 1,000 times bootstrap iterations, the 95% confidence intervals of fifth percentile values for *H. azteca* and *Gammarus* spp. strongly overlapped. Fifth percentile LC50 estimates and their confidence intervals were similar for both amphipod groups, even when chemicals were limited to specific classes (e.g., narcotics, acetylcholinesterase inhibitors). These results indicate that, on average across a broad range of organic chemicals, the acute toxicity towards *Gammarus* spp. is neither consistently more nor less than that of *H. azteca*. Our analysis supports the use of *Gammarus* spp. as appropriate alternative species for implementing an OECD chronic sediment–water amphipod test.

2.07.P-Th029 Interlaboratory Validation of Chronic Sediment–Water Amphipod Toxicity Test with *Hyaella Azteca*

Kyoshiro Hiki¹, Haruna Watanabe², Pascal Pandard³ and Hiroshi Yamamoto⁴, (1)University of Tokyo, Japan, (2)National Institute for Environmental Studies (NIES), Japan, (3)L'Oréal, France, (4)Health and Environmental Risk Division, National Institute for Environmental Studies (NIES), Japan

Chronic sediment–water toxicity tests with benthic organisms are crucial for the risk assessment of hydrophobic and sediment-associated chemicals. However, internationally harmonized long-term methods are still limited. Within an OECD-approved project, we conducted interlaboratory validation tests of a 42-day sediment–water toxicity test using the freshwater amphipod *Hyaella azteca* and spiked formulated sediment. The amphipods were exposed to the spiked sediment for 28 days and then transferred to clean water for 14 days to observe reproduction. A total of seven laboratories from Europe, North America, and Japan participated; five conducted tests with the pyrethroid insecticide bifenthrin and six with the polycyclic aromatic hydrocarbon pyrene. At all laboratories, the concentrations of test chemicals in sediment were measured.

For bifenthrin, all five laboratories met the predefined validity criteria (control survival ? 80%, dry weight per surviving amphipod ? 0.50 mg, number of young amphipods per adult female ? 6.0, and basic water quality parameters), whereas four of six laboratories met the criteria for pyrene. Both test chemicals remained mostly in sediment phase throughout exposure period at all laboratories. Across laboratories, differences in NOEC values for survival, biomass, and reproduction were within a factor of four for bifenthrin, but those for pyrene exceeded a factor of 10 for pyrene due to the outlier values from laboratories that did not meet the criteria. When data from these two laboratories were excluded, coefficients of variation (CVs) for NOEC and EC50 values based on measured sediment concentrations fell between 31% and 94%, comparable to a previous interlaboratory chronic validation test with *H. azteca* using field-contaminated sediments.

These results demonstrate that the proposed 42-day sediment–water test with *H. azteca* yields reproducible chronic toxicity evaluation across a broad range of laboratories and test designs. The validated protocol provides a robust basis for regulatory sediment risk assessment.

2.07.P-Th030 Sedimentary Co-exposure of Polystyrene Nanoplastics and Lithium Bis(trifluoromethanesulfonyl)imide Synergistically Exacerbates Ecotoxicity and Risk in *Caenorhabditis*

elegans

Bo-Wei Jhang and Vivian Hsiu-Chuan Liao, National Taiwan University, Taiwan (Greater China)

The increasing production of lithium-ion batteries and the pervasive presence of nanoplastics have raised concerns about their coexistence and combined impacts in sedimentary ecosystems. Yet, the interactive ecotoxicological effects of these emerging contaminants remain poorly understood. This study aimed to assess the joint toxicity of lithium bis(trifluoromethanesulfonyl)imide (LiTFSI), a lithium salt widely used in battery electrolytes, and polystyrene nanoplastics (PS-NPs) using *Caenorhabditis elegans* as a sediment-dwelling model organism. Worms were exposed for 96 hours to various concentrations of LiTFSI and environmentally relevant PS-NPs (0.015 µg/g), alone and in combination. Growth, reproduction, and molecular endpoints were evaluated, and toxicity interactions were analyzed using Hill modeling, Bliss independence analysis, and DEBtox modeling. Results showed that PS-NPs significantly amplified LiTFSI-induced developmental and reproductive toxicity. Bliss analysis confirmed a synergistic effect between the two contaminants, while DEBtox modeling indicated that PS-NPs shifted LiTFSI's physiological mode of action from reproduction impairment to increased maintenance costs. At the cellular level, PS-NPs enhanced LiTFSI-induced mitochondrial stress, fragmentation, and germline DNA damage. Risk quotient assessments based on sediment data from Belgium, the United States, and China further suggested that co-exposure of PS-NPs and LiTFSI substantially elevates ecological risks. In conclusion, this study demonstrates that environmentally relevant level of nanoplastics can exacerbate the toxicity and ecological risk of lithium battery-related contaminants, emphasizing the need to consider co-contaminant interactions in environmental risk assessment and sediment management.

2.07.P-Th031 The Effect of Elevated Temperature on Pesticide Terbutylazine and Antimicrobial Triclosan Toxicity to *Daphnia magna*

Jurate Zaltauskaite¹, Levonas Manusadzianas² and Diana Miškelytė³, (1)Vytautas Magnus University, Lithuania, (2)The State Scientific Research Institute Nature Research Centre, Lithuania, (3)Nature Research Centre, Lithuania

Anthropogenic chemical pollution poses one of the largest environmental threats to humanity, yet global understanding of the issue remains fragmented. Water pollution is alarming because anthropogenic activities contaminate water bodies with various pollutants, which in turn reduce ecosystem functioning and pose human health risks. Pesticides and pharmaceutical and personal care products (PPCPs) stand out for their widespread occurrence and highly diverse biological effects and are considered emerging contaminants (ECs). In addition to the direct stress caused by chemical contamination, there are certain environmental stressors (such as elevated temperature) that might cause additional stress. Thus, it is important to understand the effects of changing environmental factors on pollutants' ecotoxicity to aquatic organisms. To address the knowledge gap of the effects of emerging contaminants in a changing climate, we aimed to test the ecotoxicological effects of chronic exposures to the frequently detected pesticide Terbutylazine (TBA) and antimicrobial Triclosan (TCS) on *Daphnia magna*. *D. magna* was exposed to 5 different single TBA and TCS concentrations under different temperature regimes (22°C and 26°C) for 21 days. Mortality and reproduction rates as well as body size of *D. magna* were observed.

2.07.P-Th032 An Integrated Weight-of-Evidence Approach for Establishing Causality between Heavy Metal Contamination and Ecological Impacts in Aquatic Ecosystems

Jong-Hyeon Lee¹, Dong-Hyuk Yeom², Su-Hyun Kim¹, Jung-Hyun Park¹ and Jang-Yeon Park¹, (1)EH R&C Co., Korea, Republic of, (2)Korean Institute of Toxicology, Korea, Republic of

Establishing a robust causal link between heavy metal contamination and observed ecological impairments remains a critical challenge in environmental risk assessment. This study presents an integrated Weight-of-Evidence (WoE) framework that combines the empirical Sediment Quality Triad (SQT) approach with John Norton's philosophical causal justification framework to assess the ecological impact of metals in aquatic ecosystems. The assessment integrates three distinct lines of evidence (LOE): (1) chemical assessment using Hazard Quotients (HQ) for surface water and mean Probable Effect Level quotients (mPELq) for sediments; (2) toxicological evaluation through sediment and elutriate toxicity tests; and (3) biological assessment utilizing a stressor-specific ecological index (SPEAR_metal) alongside traditional community metrics. Applied to a case

study in the Nakdong River basin, South Korea, the integrated framework successfully linked exposure to ecological responses. The chemical LOE identified spatial hotspots of contamination, while the toxicological LOE confirmed adverse effects consistent with metal concentrations. Crucially, the biological LOE demonstrated that the SPEAR_metal index exhibited a stronger and more significant negative correlation with metal gradients compared to general diversity indices, effectively serving as evidence for "specific alteration." Through hierarchical integration of these evidences, Zinc (Zn) and Cadmium (Cd) were identified as the primary causative agents driving ecological degradation among the complex mixture of pollutants. This study validates the utility of SPEAR_metal as a key diagnostic tool and demonstrates that the proposed causal confidence-based WoE framework significantly enhances the transparency and defensibility of ecological assessments in complex aquatic environments.

2.07.P-Th033 Life of a sediment dweller in a mesocosm – Strategies to assess sediment communities in regulatory mesocosm studies for PPP risk assessment

Zoe Leanne Parker-Crosse¹, Hanna Samantha Schuster¹, Ellie Welch¹, Katie Smith², Akshaya Lekha¹, Harry Pope¹, Charlotte Court¹ and Nadine S Taylor¹, (1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)Cambridge Environmental Assessments (CEA), United States

Sediment-dwelling organisms play a critical role in the ecological functioning of waterbodies in agricultural areas and form part of the environmental risk assessment of plant protection products (PPPs), albeit only one representative species is included as a standard test species (Chironomids). While laboratory tests provide controlled conditions for evaluating chemical effects, they often lack the environmental realism needed to capture community-level responses. Mesocosm systems bridge this gap by integrating multiple biological compartments and their interactions, temporal dynamics, and environmentally relevant exposure pathways. However, the assessment of sediment organisms within mesocosm studies remains methodologically challenging due to the heterogeneous sediment structure, low organism densities, and practical constraints associated with sampling without disturbing the system's integrity.

At CEA, we utilise flat-bottomed aquatic mesocosm test systems, designed to simulate natural freshwater communities, including benthic invertebrate assemblages. Recently, we have been investigating ways to improve sampling strategies and analytical approaches for sediment-associated endpoints, with a particular focus on enhancing robustness and statistical power, as well as reducing intrinsic variability. Our method development work includes optimisation of sediment coring techniques, refinement of subsampling procedures, evaluation of organism recovery efficiency, and an assessment of spatial variability across replicates. We have also explored how sampling frequency and timing influence the detectability of PPP-related effects on benthic communities.

This poster presents our methodological advancements to date, compares multiple sampling approaches tested within our mesocosm system, and discusses implications for generating robust, ecologically relevant data to support regulatory ecotoxicology risk assessments. Our results are intended to contribute to ongoing efforts within the mesocosm research community to improve data quality and strengthen the reliability of sediment organism endpoints in higher-tier PPP assessments.

2.07.P-Th034 Sediment-Water Toxicity Testing Beyond Standard Guidelines: Insights from Using Non-Guideline Aquatic Invertebrates

Suzanne Zvalaren Schneider¹, Elizabeth Ostermann¹, Sean Gallagher¹, Alan Samel² and Henry O Krueger¹, (1)Eurofins Agroscience, United States, (2)Stone Environmental Inc., United States

Invertebrate toxicity testing is an important component in the registration process for today's modern chemicals. Although current tier 1 testing requirements primarily focus on standard laboratory-cultured aquatic invertebrates, there is an increasing interest in expanding the range of species evaluated to enhance environmental risk assessments. In recent years, the demand for testing a broader range of invertebrate species for higher tier risk assessment studies has steadily increased to support the development of species sensitivity distributions (SSD) for European risk assessments and for Endangered Species evaluations in the US. Current

OECD and OCSPP guidelines for invertebrate testing include daphnids, mysids, amphipods, oligochaetes and chironomids. To develop species sensitivity distribution, non-guideline aquatic insects such as the stonefly, caddisfly and mayfly were incorporated to provide additional toxicity data. SSD testing has commonly been utilized for acute testing in water only exposures based on OECD Guidelines 202 and 235. For chronic testing, SSD approaches have been implemented in sediment/water systems in accordance with OECD Guidelines 218 and 219. Sediment-water toxicity testing with non-standard and non-guideline freshwater aquatic invertebrates introduces unique challenges for Good Laboratory Practice (GLP) studies. In this work, we summarize our experience conducting GLP-compliant acute and chronic toxicity tests with additional aquatic invertebrate species and discuss critical factors influencing study success, including test design, organism availability and age, acclimation procedures, and dietary requirements. Key takeaways and practical considerations are presented to inform future testing strategies and support method development for expanding species coverage beyond standard guidelines.

2.07.P-Th035 Toxicity evaluations in coastal sediments using fish embryos and explorations of causative contaminants

Seiichi Uno¹, Kazuki Imamura² and Emiko Kokushi¹, (1)Kagoshima University, Japan, (2)The United Graduate School of Agricultural Sciences, Kagoshima University, Japan

Chemicals released through human activities are transported to coastal areas by rivers, rainfall, and other pathways, and ultimately settle in sediments. Some pollutants are poorly degradable and can remain buried for long periods due to ongoing sedimentation, potentially affecting benthic organisms individually or in combination. To assess these impacts, we have developed a method that uses fish embryos to evaluate field-collected sediment toxicity. Because embryos are placed directly on contaminated sediments with only a small amount of pore water and no overlying water, this approach isolates sediment-driven toxicities.

Using this method, earlier toxicity assessments revealed areas of severe biological impact risk in Osaka Bay near Osaka and Kobe, in Ise Bay near Nagoya (home to Japan's largest port), and in Hiuchi-nada of the Seto Inland Sea. To examine the persistence of these impacts, we resampled the same sites one to several years later and reassessed risks using embryos. Several sites continued to exhibit high biological impact risk, while at others the sediment-related biological effects were minimal or undetectable. Conversely, new biological impacts emerged at sites that had previously shown no sediment toxicity. Even in areas with consistently high risk, some sites displayed markedly different effect patterns in fish embryos, suggesting shifts in the causative agents over time.

We measured representative sediment pollutants, including polycyclic aromatic hydrocarbons (PAHs), but changes in PAH concentrations did not explain the observed shifts in biological impacts. These findings indicate that sediment-associated biological risk can fluctuate relatively rapidly and that the causative substances may change over time. Although sediments are generally thought to exhibit smaller temporal changes in chemical concentrations than the water column, chemical monitoring alone may be insufficient to infer biological impact risk.

To further pinpoint the causative agents, we prepared multiple extracts from collected sediments using solvents with differing physicochemical properties or column chromatography and inferred agent characteristics from the toxicity profiles of each extract. Comprehensive chemical analyses of compounds within each fraction are underway to aid identification of the responsible agents. An overview of these ongoing efforts will be presented.

2.08 Integrating Evolution and Mechanisms to Advance Ecotoxicology Under Global Change

2.08.T-01 Effects of Adaptation on Evolutionary Potential in Multi-stressor Environments: Insights from Sequential Laboratory Evolution Experiments.

Steven Declerck¹, Shuwen Han² and Paul van den Brink³, (1)Netherlands Institute of Ecology (NIOO-KNAW), Netherlands, (2)NIOO, Netherlands, (3)Wageningen University and Research (WUR), Netherlands

Populations are increasingly confronted with multiple, often novel, combinations of environmental stressors that threaten their persistence and adaptive potential. Using sequential evolution experiments with cyclic parthenogenetic rotifers, we examined how prior adaptation to heat stress shapes subsequent evolutionary responses to copper stress, and vice versa. Our results reveal asymmetric cross-tolerance: adaptation to heat increased tolerance to copper, whereas adaptation to copper provided no protection against heat stress. Furthermore, heat adaptation was weakened when it was either preceded or followed by multigenerational

exposure to copper. In contrast, copper adaptation remained robust regardless of whether populations experienced heat stress before or after selection. These findings highlight the complex ways in which stressors interact to influence microevolutionary trajectories. Understanding such dynamics is crucial for predicting population persistence in variable, multi-stressor environments and carries important implications for biodiversity management under climate change and anthropogenic pollution.

2.08.T-02 Epigenetic Plasticity Enables Copepods to Cope with Ocean Acidification

Jae-Seong Lee, *Sungkyunkwan University, Korea, Republic of*

Plasticity enhances species fitness and survival under climate change. Ocean acidification poses a potential threat to copepods, a major zooplankton group that serves as a key link between the lower and higher trophic levels in the marine environment, yet the mechanisms underlying different adaptive responses remain poorly understood. Here we show that although elevated CO₂ can exert negative effects on reproduction of *Paracyclops nana*, multigenerational plasticity can enable recovery after three generations. By integrating the methylome and transcriptome with the draft genome and undertaking DNA methylation treatments, we demonstrate the vital role of epigenetic modifications in ocean acidification responses and identify regions associated with reproductive resilience. Our results demonstrate that DNA methylation might play an important role in enhancing species fitness of copepods and that failing to consider phenotypic plasticity could lead to overestimation of species' vulnerabilities.

2.08.T-03 Springtails in Distress - How Are Soil Fauna Impacted by Pesticides in a Changing Climate?

Katrine Borga¹, *Silje Marie Kristiansen*¹, *Sagnik Sengupta*¹, *Heidi Sjursen Konestabo*², *Yngvild Vindenes*², *Tone Birkemoe*³, *Jan Thomas Rundeberger*⁴, *Cornelis A.M. van Gestel*⁵ and *Hans Petter Leinaas*², (1)*University of Oslo (UiO), Norway*, (2)*University of Oslo, Norway*, (3)*Norwegian University of Environmental Sciences, Norway*, (4)*Norwegian Institute for Water Research, Norway*, (5)*Vrije Universiteit, Netherlands*

Climate change, pollution and biodiversity loss rank among the most pressing environmental challenges. The 4-year project MULTICLIM -Effects of climate change in a multiple stress multispecies perspective- studied how climate change and pollution combined may affect soil fauna on individual, population, species and community levels. Effects included were somatic growth, maturation, age-specific reproduction, mortality and species abundance. We focused on how temperature and humidity conditions may alter responses in springtails and other soil fauna to the neonicotinoid imidacloprid, which is widely used in global crop production. We compared springtail species and population sensitivity to climatic conditions and pesticides exposure in two species adapted to different habitats; surface dwelling *Hypogastrura viatica* and soil dwelling *Folsomia quadriocculata* (Collembola), in populations adapted to Temperate and Arctic climatic regions of southern Norway and Svalbard, by combining laboratory experiments and population modelling. Effects on soil fauna diversity following a single dose of imidacloprid under different watering regimes were studied in a 3-month field experiment.

Both springtail species were more sensitive to imidacloprid than commonly used model springtails, and pesticide toxicity increased with climatic stress conditions in a population-dependent way: Temperate populations were most sensitive to elevated temperatures and pesticide exposure, and to elevated temperature and drought exposure following prior pesticide exposure, contrary to our hypothesis. Even low sublethal imidacloprid concentrations reduced recruitment, despite not always affecting all fecundity measures or causing mortality. Population models showed that even small individual-level negative effects strongly reduced population growth. The 3-month field experiment overall reduced biodiversity for springtails, whereas mite diversity declined the first 6 weeks, and then recover to week 12 for most imidacloprid treatments, except the highest exposure. Watering in addition to natural precipitation had no effect neither springtail nor mites' diversity.

Our findings show that field-realistic pesticide concentrations combined with simultaneous or subsequent warming (and drought) can reduce springtail populations, and that population and species adaptation shapes the climate change dependent toxicity response, of importance for future pesticide risk assessment.

2.08.T-04 Effects of Chronic Ionizing Radiation on *Arabidopsis thaliana* Populations: Evidence for Selection and Microevolution

Gustavo Turqueto Duarte¹ and **Polina Volkova²**, (1)Belgian Nuclear Research Center (SCK CEN), Belgium, (2)Independent Researcher, Belgium

Radiation disasters such as Chernobyl (1986) and Fukushima (2011) cause long-term environmental contamination, raising concerns for the radioprotection of biota. Despite growing attention to ecosystem conservation, radioprotection remains largely anthropocentric. Impact assessments have mainly evaluated ionising radiation (IR) effects in a narrow set of reference species and focused on evident endpoints (e.g. mortality, morbidity, fecundity), although recent molecular studies show that doses deemed safe in natural environments can already trigger stress responses at the molecular level. We previously proposed that maintaining DNA repair and protection mechanisms in a constantly active state is energetically costly. Accordingly, transcriptome profiles of chronically irradiated plants commonly show reprogramming of oxidative stress and epigenetic pathways, but limited modulation of DNA repair genes. This suggests that (1) protective mechanisms trade off against other metabolic processes, ultimately affecting growth, fitness and, over time, population structure and evolution; (2) under sustained reactive oxygen species (ROS) production (intrinsic and IR-induced), organisms may prioritise antioxidant and epigenetic defences over high DNA-repair activity; and (3) over generations, such pressures can drive evolutionary changes that enhance adaptive responses. Here, consistent with this view, genome resequencing of populations of *Arabidopsis thaliana*, a radioresistant species, chronically exposed to IR in the Chernobyl Exclusion Zone, revealed increased nucleotide diversity, signs of a selective sweep and higher fixation rates of exonic single-nucleotide polymorphisms (SNPs). These polymorphisms accumulated in genes involved in DNA repair, cell cycle, oxidative stress and Ca²⁺/ROS signalling, and epigenetic regulation. While such microevolutionary changes may improve genome stability and stress-signalling networks under chronic IR exposure, they appear to come at the cost of seed performance and plant growth.

2.08.T-05 Assessing Transgenerational Behavioral Responses to EE2 in *Kryptolebias marmoratus*: Implications for Neurotoxicity and Multistress Adaptation

Noémie Guirandy, Clémence Théron, Jérôme Lambert, Jean Baptiste Robert and Frédéric Silvestre, University of Namur, Belgium

Environmental stressors such as endocrine-disrupting chemicals and rising temperatures can interact to shape physiological and behavioural phenotypes across generations. Non-genetic mechanisms are increasingly recognised as potential drivers of rapid adaptation, especially when stressors persist across multiple generations. To study these processes, we used the self-fertilising mangrove killifish *Kryptolebias marmoratus*, a relevant model for studying inherited environmental effects with minimal genetic variability.

This study aimed to determine whether transgenerational exposure to 17 α -ethinylestradiol (EE2) induces behavioural effects in unexposed F2 individuals and whether ancestral EE2 exposure influences responses to a secondary thermal stressor. We examined delayed behavioural effects, potential involvement of neuronal regulatory pathways, and whether adaptive mechanisms established under EE2 exposure modulate behavioural responses when temperature is added.

Behaviour and body length were assessed at two stages in F2 generation (24 and 50 days post-hatching). The Vibrational Startle Response, in which a mechanical tap mimics sudden predation, was used to evaluate locomotor activity, startle sensitivity and resilience to fluctuating environmental cues. At 24 days, four F2 conditions were tested: control, EE2 (4 ng/L), elevated temperature (30 °C), and combined EE2+temperature. At 50 days, only control and EE2 groups were analysed. Targeted DNA methylation and mRNA expression analyses are underway to investigate regulatory mechanisms.

At 24 days, ancestral EE2 exposure did not alter behaviour, whereas temperature induced clear behavioural changes, indicating a thermal rather than EE2 effect at this stage. Body length was also affected, with distinct responses in EE2 and EE2+temperature groups, supporting both a transgenerational effect and altered responses under multi-stress conditions. At 50 days, length differences were no longer observed, but preliminary behavioural results revealed differences between EE2 and controls, suggesting delayed transgenerational effects. Ongoing molecular analyses will clarify whether epigenetic regulation contributes to these long-term outcomes.

Overall, this work provides new insight into how early exposure to an endocrine disruptor induce behavioural phenotypes across generations and influence responses to additional stressors, improving our understanding of rapid adaptive mechanisms.

2.08.P Integrating Evolution and Mechanisms to Advance Ecotoxicology Under Global Change

2.08.P-Tu082 Community-Wide Micro-Evolutionary Adaptation in Zooplankton and its Ecological Consequences

Vera van Santvoort¹, Paul van den Brink² and Steven Declerck¹, (1)*Netherlands Institute of Ecology (NIOO-KNAW), Netherlands*, (2)*Wageningen University and Research (WUR), Netherlands*

Freshwater ecosystems are facing numerous stressors arising from climate change and anthropogenic influences. One potential mechanism through which organisms can cope with (anthropogenic) stressors is micro-evolutionary adaptation – rapid evolution occurring on a short, ecologically relevant timescale. Such rapid evolutionary change can feed back to influence ecological processes, giving rise to eco-evolutionary dynamics: the reciprocal interactions between ecology and evolution. While most previous research in the field of eco-evolutionary dynamics has focused on single species, we adopt a community-level perspective.

In order to investigate whether Cladocera (water fleas) are able to rapidly adapt to salt stress and whether this is species-specific, we performed an evolutionary selection experiment in outdoor mesocosms and a follow-up laboratory common garden survival experiment. Three different species (*Daphnia pulex*, *D. galeata* and *Simocephalus vetulus*) were either exposed to a gradually increasing salt concentration (up to 3.2 g NaCl/L) or a control treatment in fresh water in the mesocosms, either in a single-species or a community context. At the end of the experiment, laboratory clonal lines were started by selecting individuals from each of the mesocosms. With those salt-exposed or salt-naïve clonal lines, we performed a common garden experiment in which the clonal lines were exposed to a daily increasing salt concentration over a period up to 6 days – until dying. Each day, survival was determined by counting the number of individuals still alive. Results showed that for each of the three species, salt-exposed clonal lines survived longer (i.e. to higher salt concentrations) than salt-naïve clonal lines, indicating micro-evolutionary adaptation. Besides, species-specific differences in salt tolerance and the extent of adaptation were shown. A follow-up mesocosm experiment aims to investigate the effect of micro-evolutionary adaptation to salt stress on community composition and ecosystem functioning. This is of great importance to understand and predict the long-term effects of human-induced stressors on ecosystems in a rapidly changing climate.

2.08.P-Tu083 Multiple stressor exposure in Arctic zooplankton during the polar night: Applications for ecological risk assessment

Khuong V. Dinh¹, Mathieu Lutier², Jildou Dijkstra³, Dania Albini⁴, Nele Thomsen⁵, Michelle C. Jackson⁴, Helena Reinardy⁵, Janne E. Søreide⁶ and Katrine Borga¹, (1)*University of Oslo (UiO), Norway*, (2)*University of Oslo (UiO), France*, (3)*Leiden University, Netherlands*, (4)*Department of Biology, University of Oxford, United Kingdom*, (5)*Scottish Association for Marine Science, United Kingdom*, (6)*Department of Arctic Marine Biology, The University Centre in Svalbard, Norway*

The Arctic Ocean is experiencing accelerated rates of warming and acidification, up to four times the global average, compounded by pollutant releases from expanding oil exploration activities. These anthropogenic stressors can elicit maladaptive physiological responses, elevating mortality risks for Arctic species, particularly during the vulnerable overwintering period in the Polar Night. In this presentation, we present empirical data on the individual and interactive effects of multiple stressors, including ocean warming (+4 to +5°C), acidification (ΔpH -0.1 to -1.5 units), and contaminants such as polycyclic aromatic hydrocarbons (PAHs; 100–200 nM) and microplastics, on key Arctic zooplankton species during overwintering. We will show preliminary data on critical role of exposure timing in modulating stressor interactions and reveal potential tipping points. We elucidate underlying physiological mechanisms (e.g., metabolic disruption and oxidative stress) and genetic responses (e.g., altered gene expression in stress-response pathways) driving these effects. To advance environmental toxicology and chemistry in polar ecosystems, we propose a conceptual framework for integrating Polar Night dynamics into future multi-stressor studies, with applications for refining ecological risk assessments of Arctic biodiversity under ongoing climate and pollution pressures.

2.08.P-Tu084 Integrating Biomarker and Mechanistic Evidence to Assess Antibiotic Toxicity under Global Change Scenarios

Bárbara Salazar Diogo¹, Sara Rodrigues² and Sara C. Antunes³, (1)ICBAS/CIIMAR/FCUP, Portugal, (2)CBMA/IB-S, Portugal, (3)FCUP/CIIMAR, Portugal

Aquatic ecosystems are increasingly exposed to multiple stressors, including rising temperatures, pH fluctuations, and antibiotic contamination [e.g., sulfamethoxazole (SMX) and trimethoprim (TRIM)]. These factors interact in complex ways, altering antibiotic toxicity and disrupting key biological processes in aquatic organisms. However, their combined effects remain poorly understood, particularly under climate change conditions. This study investigated the chronic effects of environmentally relevant concentrations of SMX (150 µg/L), TRIM (30 µg/L), and their mixture (MIX: 150 µg SMX/L + 30 µg TRIM/L) on *Danio rerio* juveniles under different abiotic scenarios: temperature (26, 28, and 32 °C), pH (6.5, 7.5, and 9.0), and a combined climate-change scenario (28 °C + pH 9.0). A multi-biomarker approach, encompassing oxidative stress, lipid peroxidation, cholinergic activity, energy metabolism, and DNA damage, was used to assess toxicity and *D. rerio* health impacts. SMX showed marginal temperature-dependent toxicity but was strongly influenced by pH, causing severe effects under acidic conditions and moderate/major alterations at neutral and alkaline pH. TRIM displayed low overall toxicity, decreasing under warming but increasing with pH, leading to oxidative stress, lipid peroxidation, and neurotoxicity. MIX was generally more harmful than individual antibiotics under standard conditions, with moderate toxicity under warming and pH-dependent responses. Acidic and alkaline pH induced oxidative stress and lipid peroxidation, while neutral pH caused pronounced DNA damage. Under the combined climate-change scenario, SMX and TRIM toxicity intensified, causing severe disruptions such as lipid peroxidation and DNA damage that compromised *D. rerio* health, whereas MIX toxicity was slightly lower, suggesting compensatory or adaptive interactions during co-exposure. Overall, temperature and pH significantly modulated antibiotic toxicity by altering chemical bioavailability and physiological responses. Combined stress conditions further intensified adverse effects, emphasizing the interactive influence of chemical pollution and climate-driven stressors. These findings highlight the importance of considering multiple, co-occurring environmental stressors in ecotoxicological research and advocate for integrative approaches that better reflect realistic environmental conditions, supporting accurate ecological risk assessments and effective protection of aquatic ecosystems.

Funding - The research conducted on this topic was funded by the Foundation for Science and Technology and by the Strategic Program UIDB/04423/2020 and UIDP/04423/2020. Bárbara S. Diogo was supported by a FCT Ph.D. grant (ref. 2022.10505.BD).

2.08.P-Tu085 Unraveling coral sensitivity to desalination antiscalants and elevated salinity: A physiological and biochemical assessment

Alice Facques¹, Imke Böök¹, Micaela Sofia dos Santos Justo², Ricardo Alves¹, Fern Lyne-Temple¹, Andreia Sofia Filipe Farinha¹ and Susana Carvalho¹, (1)King Abdullah University of Science and Technology, Saudi Arabia, (2)Red Sea Research Science, King Abdullah University of Science and Technology, Saudi Arabia

Desalination is a critical source of freshwater in the Red Sea region, which hosts the highest density of desalination plants globally, filtering approximately 3.4 million cubic meters of seawater per day. Seawater reverse osmosis (SWRO) is widely regarded as the most sustainable and efficient desalination technology. SWRO filters seawater through semi-permeable membranes to produce freshwater while generating a hypersaline concentrate; brine. To prevent scaling on these membranes, antiscalants typically composed of polymers and polyphosphates are added. Brine and antiscalants are often discharged untreated, yet their behaviour in seawater remains poorly understood, raising concerns about their persistence, toxicity and impact on benthic organisms. This study aims to evaluate the isolated and combined effects of a phosphonate-based antiscalant (DTPMP-Diethylenetriaminepenta(methylenephosphonic acid)) and elevated salinity on the physiology and gene expression of the Red Sea coral *Acropora arabiensis*. Coral fragments were exposed to five concentrations of DTPMP, five salinity levels or both stressors simultaneously in a 7-day controlled ex-situ experiment. Coral photophysiology was investigated through measurements of the maximum quantum yield of

Photosystem II (Fv/Fm) to assess photosynthetic efficiency, calculation of the Normalised Difference Vegetation Index (NDVI) from coral reflectance, and rapid light curves to estimate the maximum electron transport rate (ETR_{max}) as a proxy for photosynthetic capacity. Water quality parameters (nutrients, ammonium and total alkalinity) were monitored throughout the study, and coral tissues were collected at the end of the experiment for transcriptome-wide gene expression. Preliminary results showed that DTPMP alone had no significant effect on Fv/Fm, NDVI, or ETR_{max}. Elevated salinity caused a significant decline in Fv/Fm and NDVI, while no interactive effect between DTPMP and salinity was observed for any of the three parameters. Transcriptomic analyses are ongoing and will elucidate whether cellular stress pathways are activated prior to changes detectable through photophysiology. This work provides the first mechanistic assessment of coral responses to phosphonate antiscalants under realistic hypersaline scenarios and contributes to environmental risk evaluation of desalination activity in coral-dominated ecosystems.

2.08.P-Tu086 Animal Organ Size Database: A Resource for Toxicology Research

Félix Leiva, Luke Ockhuijsen, Jasmijn Polinder, Louise Schreyers, Jie Xiong and Jan A.J. Hendriks, Radboud University, Netherlands

After substances are released into the environment, they become available to organisms. The metabolism of these substances in animals, particularly vertebrates, is studied *in silico* using Physiologically Based Kinetic (PBK) models. These models simulate absorption, distribution, metabolism, and excretion through organ compartments. Currently, PBK models mainly focus on adult humans, rats, and a limited number of other species, and they require species- and substance-specific parameters that depend on how substances are distributed across different organs. A key parameter in this context is size, as many physiological functions, such as organ perfusion, may inevitably be influenced by organ size. However, comprehensive risk assessment requires broader coverage across taxa, species, and organs, which poses challenges for developing generalized PBK models. To address this gap, we developed a systematic map and compiled an extensive database from literature of paired organ and body size measurements. This database comprises over 10,000 records from 366 species spanning eight animal classes. It provides size estimates for 53 organ types organised into ten physiological systems, with most data derived from the digestive, circulatory, and excretory systems. In addition, extensive metadata are included to contextualise the original studies. This database enables (i) exploration of interspecific variation patterns and derivation of interspecific regressions linking organ metrics to body size, ecological traits, and habitat; ii) examination of intraspecific scaling relationships, incorporating variables such as sex to assess whether males and females differ. In vertebrates, sexual dimorphism can influence these scaling relationships, while shared evolutionary history (phylogeny) introduces non-independence among species that must be accounted for in comparative analyses; and iii) integration with other traits, such as organ-specific perfusion and metabolic rates. Finally, due to its flexible metadata structure, the database can be expanded to include the effects of chemical exposure on organ size itself. Altogether, this comprehensive and reproducible resource provides a robust foundation for improving the parameterisation and cross-species applicability of simulation models based on physiological and kinetic principles, thereby enhancing understanding of how substances accumulate in organisms and the underlying mechanisms, particularly those related to organ size.

2.09 Integrative and Mechanistic Approaches to Wildlife Ecotoxicology: Cross-Species Variability and One Health perspective

2.09.T-01 Sublethal Anticoagulant Rodenticide Exposure Drives Systemic Stress Signatures in the Eurasian Eagle-Owl (*Bubo bubo*): Insights from blood RNA-Seq

Camilo Escobar-Sierra¹, Clara Bravo-Jiménez², Livia Spadetto³, Pilar Gomez-Ramirez³, Antonio Juan Garcia-Fernandez³, María Santos-Galindo⁴, Jose María Navas⁵ and Azucena Bermejo-Nogales², (1)Institute for Environmental Research, RWTH Aachen University, Aachen, Germany, Germany, (2)Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA-CSIC), Madrid, Spain, Spain, (3)Faculty of Veterinary, University of Murcia, Spain, (4)Centro de Biología Molecular Severo Ochoa (CBM) CSIC-UAM, Madrid, Spain, Spain, (5)Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA-CSIC), Madrid, Spain., Spain

Anticoagulant rodenticides (ARs) inhibit VKORC1 and disrupt the vitamin K cycle, but sublethal exposure in predators can also provoke oxidative, metabolic and immune disturbances. Raptors are especially vulnerable due to their trophic position and repeated ingestion of contaminated prey. The Eurasian eagle-owl is a key sentinel species, yet the systemic molecular effects of environmentally relevant AR exposure remain poorly characterised. Here, we used whole-blood RNA-seq combined with EchoGO, a cross-species enrichment

framework, to resolve transcriptional pathways affected by AR exposure in wild nestlings.

Blood samples from chicks with high and low VKORC1 expression and detectable AR residues were analysed using DESeq2 (FDR < 0.05). Goseq was used for bias-aware enrichment, and EchoGO integrated Goseq with g:Profiler across eight avian reference species, generating strict and exploratory consensus terms. Semantic reduction (RRVGO) summarised pathway-level responses, and a mechanistic AR-toxicity panel (predefined from the literature) was used to test expected physiological axes, including coagulation, vascular integrity, xenobiotic metabolism, unfolded-protein response, immune activation and energy balance.

EchoGO revealed a multi-systemic stress architecture consistent with sublethal AR exposure. Key high-level terms included blood circulation, defence response to virus, antigen presentation via MHC I, positive regulation of type II interferon response, macromolecule biosynthesis, pyruvate metabolism and intracellular potassium homeostasis. These clusters collectively indicate vascular remodelling under VKORC1 blockade, ER-stress and proteostasis responses, metabolic and redox reprogramming, and strong innate immune activation dominated by interferon-stimulated genes (e.g., RSAD2, OAS2, STAT1, IRF3, STING).

The a priori mechanistic panel was fully validated: all predicted parent categories were significantly represented in EchoGO consensus outputs. Cross-species evidence (especially from *Aquila chrysaetos*, *Gallus gallus* and *Serinus canaria*) highlighted conserved immune-metabolic signatures across birds.

Overall, blood transcriptomics provided a non-lethal window into systemic AR impacts in a wild raptor. These results support the use of OMICs-based, cross-species frameworks for biomonitoring and for improving mechanistic understanding of chemical stress in wildlife under a One Health context.

2.09.T-02 Mechanistic Effect Models in Wildlife Risk Assessment: Insights from 15 years of Application *Oliver Jakob¹, Torben Wittwer¹, Lara Ibrahim¹, Martin Vallon¹, Finn Bastiansen¹, Felix von Blanckenhagen² and Jan-Dieter Ludwigs², (1)RIFCON GmbH, Germany, (2)Rifcon GmbH, Germany*

Mechanistic effect models (MEMs), including population models, are increasingly recognized as higher-tier tools in environmental risk assessment for wildlife because they link individual-level effects to population-level outcomes under realistic scenarios. Despite being mentioned in relevant guidelines for nearly two decades, their practical implementation has faced significant hurdles. Nevertheless, MEMs provide ecologically relevant insights beyond standard laboratory tests and support regulatory decision-making by providing weight-of-evidence data, guiding field study design, and evaluating mitigation measures. Overall, they are and will remain a valuable tool for reliable assessments in the approval process.

This presentation summarizes nearly 15 years of experience applying population models to wildlife in agricultural landscapes. We highlight three key applications using eVole, an individual-based, spatially explicit simulation model for common voles (*Microtus arvalis*): (i) informing risk assessments through simulations of long-term population responses under conservative environmental and exposure scenarios, (ii) supporting field studies design and interpretation by comparing habitat-specific population dynamics and (iii) evaluating mitigation strategies such as precision pesticide applications. We also share insights from stakeholder discussions and regulatory evaluations, concluding with key advantages and remaining challenges.

Our review shows that population modelling can (i) identify population-level risks posed by pesticides and quantify margins of safety, (ii) assess habitat-specific population dynamics to support conservative field study designs, and (iii) explore precision application patterns to better understand how exposure fragmentation interacts with average activity ranges of farmland species. These findings highlight the potential of MEM applications to complement empirical approaches and enhance ecological realism in pesticide risk assessments. Beyond current advances, future adoption in regulatory frameworks will benefit from standardized processes, transparent documentation, and active stakeholder engagement. MEMs offer cost-effective, powerful tools for advancing pesticide risk assessment and management by integrating ecological complexity and supporting informed decisions. With regulatory willingness, modelling – long referenced in wildlife guidelines and validated through practice – can readily evolve into a standard procedure.

2.09.T-03 Multi-Level Impacts of Fungicide Exposure on Red-Legged Partridge

Claudia Santamaria Cervantes¹, Paula Bolívar¹, Marta Herrero Villar¹, Ricardo Sanchez de la Nieta¹, Manuel Ortiz Santaliestra¹ and Rafael Mateo², (1)University of Castilla-La Mancha (UCLM), Spain, (2)Institute of Environmental Assessment and Water Research (IDAEA), Spain

Triazoles are a group of fungicides applied as seed coating treatments which pose a potential threat to granivorous birds. Experimental studies have shown that triazoles may impair avian reproduction by reducing fertilization rate and brood size even if exposure occurs months earlier, but the mechanism behind these effects remains unknown. Triazoles inhibit lanosterol-14 α -demethylase, a key enzyme in fungal cell wall synthesis which also plays an essential role in endogenous cholesterol synthesis in animals. Triazole exposure have been shown to reduce cholesterol levels and alter gene expression linked to its synthesis. Disturbances at this step can affect the biosynthesis and regulation of steroid hormones, derived from cholesterol, potentially causing structural and functional alterations in endocrine organs and compromising reproductive success. This study evaluates the reproductive effects of Raxil Plus on red-legged partridges and explores how triazoles may generate long-term reproductive impacts by through gonadal and molecular alterations. Partridges were fed with wheat seeds treated at 0%, 20% or 100% of the labelled application rate (n= 38 per treatment) for 21 days in late autumn, and reproductive parameters were monitored in spring. In addition, 6 partridges (3 males and 3 females) from each treatment were euthanized after exposure (December), and at the beginning (March), during (June) and the end (July) of the egg laying period to assess gonadal size, histopathology and expression of 13 steroidogenesis-related genes. Significant reductions in fertilization, hatching, and chick survival rates were observed in couples exposed more than 4 months before. In June, right testis length decreased in treated males, while females consistently showed larger gonads in the high-dose group across all samplings. Histological analysis showed increased atretic follicles in July, during the end of reproductive period, but highest-dose females had a significantly higher proportion of viable follicles in that sampling. In exposed males, reduced gonadal expression of PGR, ESR1, CYP19A1 and ABCA1 was detected in March. PGR showed the same pattern in females. In June, ABCA1 was overexpressed in high-dose females. Results indicate that Raxil Plus exposure induces long-term reproductive impairment through multiple physiological mechanisms, including gonadal size changes, altered follicular dynamic and molecular disruptions in steroidogenesis.

2.09.T-04 Predicting Acetaminophen Toxicity in Protected Bird Species Based on UDP-Glucuronosyltransferase Docking Site Analysis

Peter van den Hurk, Clemson University, United States

Previous work has demonstrated that snake species are extremely sensitive to acetaminophen, the active compound in paracetamol. The underlying mechanism for this toxicity was determined to be the lack of phenol-type UDP-glucuronosyltransferase, and N-aminotransferase. To investigate if bird species could also be sensitive to acetaminophen, which is used to manage the invasive brown treesnake on the island of Guam, a dosing experiment was conducted with chickens. PCR analysis showed that chickens do have 4 isoforms of the glucuronosyltransferase (UGT) enzymes that were upregulated in response to the acetaminophen exposure. To explore if other bird species have UGT isoforms that can metabolize acetaminophen, liver samples were collected from a wide variety of coastal Carolinian bird species, including crow, wading birds, pelican, vulture, hawks and owls. Liver samples of 15 different species were tested for phenol-type UGT enzymatic activity and demonstrated that some birds have very good activity towards acetaminophen-like compounds, while others had no significant activity. Surprisingly, there did not seem to be a connection between phylogenetic relationship, or food preference, and the enzyme activity, which complicates extrapolation to protected species, like native Pacific Island bird species.

PCR primers for the four UGT isoforms that were upregulated in chicken after acetaminophen exposure were tested in PCR and qPCR reactions on liver samples from all other collected bird species. While PCR analysis initially suggested that some of these primers would work in all 15 species, quantitative PCR showed only results for chicken and one of the owl species. Further work was pursued to evaluate UGT isoforms in published genomes for similarity between bird and mammalian isoforms that are active towards acetaminophen. Using 3D protein folding and AI-driven docking and homology models, conserved regions in the protein sequences were identified that are essential for substrate binding. Based on these sequences universal PCR primers for UGT isoforms that are predicted to have enzymatic activity towards acetaminophen were designed and tested for use

in a larger variety of bird species, thus providing a predictive tool for acetaminophen metabolism and toxicity in all birds.

2.09.T-05 Age-dependent variation in trophic ecology and mercury concentration in Whiskered tern (*Chlidonias hybrida*) chicks.

Izabela Wiśniowska¹, Łukasz Binkowski¹, Paco Bustamante², Mateusz Lewoń³, Adam Flis⁴, Bartłomiej Kusał³, Halszka Łożyńska³ and Paulina Smużyńska¹, (1)Institute of Biology and Earth Sciences, University of the National Education Commission, Poland, (2)Littoral ENvironnement et Sociétés (LIENSs), CNRS-La Rochelle Universite, France, (3)Institute of Systematics and Evolution of Animals, Polish Academy of Sciences, Poland, (4)Institute of Nature Conservation, Polish Academy of Sciences, Poland

Mercury (Hg) occurs naturally in the environment; however, anthropogenic activities have increased its turnover, making it more available to living organisms. In aquatic ecosystems, one of its forms, inorganic mercury (iHg), is converted to its organic form methylmercury (MeHg), which can be easily bioaccumulated in organisms and biomagnified along the food chain. In the early life of nestlings, maternal transfer is responsible for Hg exposure, whereas dietary uptake dominates as a main source of Hg in later development.

In that context, the study aimed to determine whether total Hg concentrations in blood were related to chick age. We also investigate whether foraging ecology, including trophic position (proxied by $\delta^{15}\text{N}$) and feeding habitat (proxied by $\delta^{13}\text{C}$), differs according to their age. The study was conducted in the northern part of the Upper Vistula Valley (southern Poland, Central Europe) on 224 Whiskered tern (*Chlidonias hybrida*) chicks (117 and 107 individuals in 2024 and 2025, respectively). Blood samples were collected from the same individuals every few days, from hatch until fledge or death. Total Hg concentration (Hg, hereafter) was measured in 625 samples using a cold vapour atomic absorption spectrometer (CV-AAS) with no prior mineralisation. The relative abundance of stable isotopes ($\delta^{15}\text{N}$ and $\delta^{13}\text{C}$) was measured in 174 samples using isotope ratio mass spectrometry (IR-MS). All procedures and data representation were carried out in R 3.5.2 (R Core Team, 2018).

We found that Hg was present at quantifiable concentrations in all specimens (ranging from 0.02 to 0.71 $\mu\text{g}\cdot\text{g}^{-1}$, wet weight). After hatching, Hg concentration decreases, which suggests the impact of body dilution and deposition into growing feathers. In the middle of the growth, Hg started to increase, suggesting the influence of dietary uptake. According to trophic ecology, the $\delta^{13}\text{C}$ values (ranging from -30.60‰ to -22.42‰) remain constant during the nestling period, in contrast to $\delta^{15}\text{N}$ values (ranging from 8.03‰ to 14.15‰), where a non-linear pattern was observed. Our results suggest that despite the similar foraging habitat, a dietary shift of prey is observed during the chick growth period. Overall, the study highlights the importance of biomonitoring Hg concentrations in adult birds, especially females, as a potential main source of mercury in hatchlings. Moreover, it is worth emphasising to consider age in the dietary interpretation of isotope signatures in wild nestlings.

2.09.P Integrative and Mechanistic Approaches to Wildlife Ecotoxicology: Cross-Species Variability and One Health perspective

2.09.P-Tu087 Dried Blood Spots as a Tool for Wildlife Ecotoxicology: Insights from Bat Omics

Natalia Sandoval Herrera¹, Yonas Meheretu¹, Frauke Ecke¹, Lea Marie Lovin¹ and Martin Hansen², (1)Department of Wildlife, Fish, and Environmental Studies, Swedish University of Agricultural Sciences, Umeå, Sweden, Sweden, (2)Technical University of Denmark (DTU), Denmark

Understanding the impact of environmental contaminants on wildlife health requires analytical approaches that are both sensitive and logistically feasible in field settings. In this study, we explore the potential of using dried blood spot (DBS) sampling as a minimally invasive, cost-effective, and scalable tool for wildlife ecotoxicology, with a focus on bats as bioindicators of environmental pollution. DBS sampling simplifies field collection, storage, and international transport of biological material, overcoming many of the challenges associated with conventional blood sampling in wildlife research. Using DBS from multiple bat species, we demonstrate how this approach can support exposomics analyses to profile chemical exposures and metabolomics analyses to assess physiological and biochemical effects of contaminant burdens. Our findings highlight the robustness of

DBS for both targeted and untargeted analyses, offering new opportunities for large-scale, integrative monitoring of wildlife health in the context of global environmental change.

2.09.P-Tu088 Multiple Stressors in Killer Whales: Using the COVID-19 Travel Restrictions to Explore the Effect of Whale Watching, Contaminants and Nutritional Status

Clare Andvik¹, Eve Jourdain², Daniela Dulgheriu³, Marie Noël⁴, Tanya Brown⁵, Peter Ross⁶, Bo Yuan⁷, Melissa A McKinney⁸, Gabrielle Haddad-Weiser³, Jan Ludvig Lyche⁹, Richard Karoliussen¹⁰, Anders Ruus¹¹ and **Katrine Borga**¹, (1)Department of Biosciences, University of Oslo, Norway, (2)Department of Biosciences, University of Oslo; Norwegian Orca Survey, Norway, (3)Department of Paraclinical Sciences, Norwegian University of Life Sciences, 1433 Ås, Norway, (4)Fisheries and Oceans Canada, Canada, (5)Department of Biological Sciences, Simon Fraser University, Canada, (6)Raincoast Conservation Foundation, Sidney, BC, Canada, (7)Department of Chemistry, Norwegian University of Science and Technology (NTNU), Norway, (8)Department of Natural Resource Sciences, McGill University, Sainte-Anne-de-Bellevue, QC, Canada, (9)Department of Paraclinical Sciences, Norwegian University of Life Sciences, 1433, Ås, Norway, (10)Norwegian Orca Survey, Andenes, Norway, (11)Norwegian Institute for Water Research, Norway

Marine mammals are continuously exposed to multiple stressors, however, risk assessments often address only single stressors and underestimate combined effects. Killer whales (*Orcinus orca*) from Norway have high concentrations of contaminants. In addition, they face frequent boat traffic, as winter whale watching has increased dramatically since 2012. Contaminants and boat traffic, as well as fluctuations in prey availability, can cause physiological and nutritional stress, possibly affecting health. This study assessed the effect of multiple stressors on Norwegian killer whales by steroid hormone analysis and transcriptomics. Blubber and skin biopsy samples were obtained from 88 photo-identified individuals of varying age and sex. Samples were taken in both seasons of low boat traffic (spring/summer months and winter 2020, with reduced boat traffic due to COVID-19 travel restrictions) and high boat traffic (winters 2019, 2021 and 2022). Five of the 88 individuals were sampled in both low and high boat traffic seasons. Cortisol, cortisone, progesterone, testosterone and androstenedione were quantified by liquid chromatography-tandem mass spectrometry, and 28 health-related mRNA transcripts were additionally evaluated. Legacy and emerging contaminants, fatty acids, stable isotopes, and mercury were also analysed from the same biopsy samples to provide information on contaminants, nutritional status, and diet. We found no effect of boat traffic on cortisol levels across all whales, however, all re-sampled whales had higher cortisol levels in the high boat season. This highlights that population-level averages may hide individual responses. We found a positive correlation between pollutants and cortisol, and a subtle but significant synergistic effect between contaminants and boat traffic. Furthermore, genes typically expressed in response to stress and the biotransformation of contaminants were more strongly associated with whales that had been sampled in high boat traffic seasons. Female killer whales appeared to have a stronger response to contaminants than males, and a higher rate of lipid catabolism in winter seasons, possibly due to reproduction. This is the first investigation of the interaction between contaminants, nutritional stress, and boat traffic, and can aid the establishment of protective conservation and management strategies.

2.09.P-Tu089 First report of anticoagulant rodenticides and their impact in birds of prey from Northern Patagonia, Argentina

Laura M. Casalins¹, **Rafael Mateo**², Mariana Langenheim³, Pablo R. Camarero⁴, Miguel Saggese⁵, Gala Ortiz⁶, Mauricio Failla⁷ and Valeria Ojeda³, (1)INIBIOMA, CONICET, Argentina, (2)IDAEA-CSIC, Spain, (3)INIBIOMA-CONICET, Argentina, (4)IREC-UCLM, Spain, (5)College of Veterinary Medicine, Western University of Health Sciences, United States, (6)Fundación Rewilding Argentina, Argentina, (7)Proyecto Patagonia Noreste, Argentina

Recent studies have shown that the second-generation AR (SGARs) can induce coagulopathy in terrestrial raptors at very low concentrations. The Andean region of northern Patagonia (Argentina) represents a critical scenario for this threat, as it is the epicentre of a deadly hantavirus transmitted by wild rodents, which in turn undergo cyclic population outbreaks due to masting of native bamboo. This has triggered the massive application of ARs in peridomestic and institutional settings. High mortality in American barn owls (*Tyto furcata*) has been associated with some of these episodic rodent outbreaks, but an association with ARs has not yet been tested. In the present study, birds of prey (n=44) from a total of 12 species were collected dead or

moribund in northern Patagonia between 2012 and 2025. The details of the collection site, the clinical signs, the necropsy findings, including the presence of haemorrhages and non-clotted blood, the body condition and the suspected cause of death were recorded. Liver samples were collected analysed using liquid chromatography combined with tandem mass spectrometry. Anticoagulant rodenticides were detected in the liver of avian scavengers and in diurnal and nocturnal birds of prey. In total, 6 out of the 12 studied species showed AR residues in liver, and this included individuals of 4 families of birds with an overall prevalence of 18.1%. The prevalence of SGARs was 33.3% in the avian scavengers, 18.2% in the diurnal raptors and 16.7% in the nocturnal raptors. The most frequently detected SGAR was brodifacoum (17.8%), followed by bromadiolone (8.9%) and difenacoum, flocoumafen and difethialone (2.2%). The prevalence of SGARs did not differ between urban, rural and natural areas nor between the three groups of birds (scavengers, diurnal and nocturnal raptors). The highest prevalence was observed in western Patagonia (but not significantly). The two individuals with the highest concentration of SGARs in liver were a Magellanic horned owl (*Bubo virginianus magellanicus*) with 1119.2 ng/g and a rufous-legged owl (*Strix rufipes*) with 267.3 ng/g. In both cases, field and necropsy findings and the reduced vitamin K1 levels indicated that these birds may have died by SGAR poisoning. This is the first report of the presence of SGARs in birds of prey from Argentina, which confirms the suspects of the potential impact that these biocides may have on the conservation of South American wildlife.

The authors thank the Williams Foundation and the Oscar Beingolea raptor research grant (Raptor Research Foundation) for the financial support of this study.

2.09.P-Tu090 New Approach Methods (NAMs) offer opportunities for hazard assessment in species at risk

Jessica Head¹ and **Ryan Chui²**, (1)*Faculty of Agricultural and Environmental Sciences, McGill University, Canada*, (2)*McGill University, Canada*

Species at risk (SAR) may be disproportionately affected by environmental contaminants, but demonstrating this impact can be difficult. One key challenge is that chemical hazard data are rarely available for ecologically vulnerable species. International efforts to develop New Approach Methods (NAMs) for toxicity testing - which aim to replace, refine, or reduce animal use - may offer solutions. NAMs are typically high-content and animal-free, making them well-suited for application to SAR. In this talk, I will review our recent experiences developing NAMs for fishes and birds, emphasizing our work on vulnerable species. In one study, we generated transcriptomic points of departure (tPODs) for the tire-wear transformation product, 6PPD-Quinone, in six different fishes including two listed species of the genus *Moxostoma*. These data helped us to identify outlier species that have poor conservation status and the potential for heightened sensitivity to this chemical. In another study, we used in vitro and in silico approaches to identify avian species that may exhibit heightened sensitivity to dioxin-like compounds. Our investigations focus on two avian orders: Psittaciformes (parrots) and Procellariiformes (petrels and albatrosses). Collectively, our experiences suggest that NAMs can facilitate hazard assessment for species at risk. However, selecting an ecologically vulnerable species over a standard laboratory model requires careful consideration of the trade-offs involved.

2.09.P-Tu091 Transcriptome analysis in free-ranging wood mice under a chronic exposure to a mixture of trace metal

Colette Gaillard¹, **Benoit Valot¹**, **Alejandro Garcia leon²**, **Cloé Roux¹**, **Clémentine Fritsch¹**, **Nadia Crini¹**, **Caroline Amiot¹**, **Nico van den Brink³** and **Renaud Scheiffler¹**, (1)*Laboratoire Chrono-Environnement, France*, (2)*Center for Experimental Pathogen Host Research, Ireland*, (3)*Wageningen University and Research (WUR), Netherlands*

Anthropization is known to negatively impact the environment, notably through the release of harmful contaminants such as trace metals (TMs). The impacts of some TMs such as Cd and Pb on the immune system and oxidative stress response are well known in laboratory based models. These models exhibit significant differences with wild animals as they do not face similar challenges and consequently poorly represent wild animals physiological response to TMs exposure. To address this gap, we investigated the effects of a chronic exposure to TMs on free ranging wood mice (*Apodemus sylvaticus*) on the immune system at the gene expression level. Wood mice were captured following a well characterized pollution gradient in the vicinity of a former smelter including three levels of contamination: contaminated, intermediate and control. The liver and kidneys were used to measure the levels of TMs in the individuals (ICP-MS and ICP-AES). Blood samples were used to evaluate the antioxidant response biomarkers using Randox® automated assays. RNA extracted from the

spleen was sequenced with Novogene in order to assess the status of the immune system across groups. Both Pb and Cd concentrations were significantly higher in the contaminated group than the control group. Glutathione peroxidase (GPx) concentration was also significantly increased in the contaminated individuals, indicating a rise in oxidative stress response consistent with previous studies on wild mammals. Differentially expressed genes we found to belong to five different categories including: B-cell mediated immunity, haematopoiesis, immunity and oxidative stress and Ca²⁺ dependent. Overall, most genes were found to be suppressed in the individuals from the contaminated area and activated in the control area, which could suggest the potential suppression of key immune mechanisms. Several Ca²⁺ genes were also found to be suppressed in the contaminated group which is consistent with known interference of Pb in calcium dependant functions. Our study shows that chronic exposure to a mixture of Cd and Pb increases the oxidative stress response and impacts the immune system in free-ranging wood mice. These results highlight the need for the development of techniques applicable to wild species for accurate protein quantification (e.g cytokines) to complement transcriptomic data thereby improving our understanding of how environmental contaminants can modify the physiology and affect the health of wild mammals.

2.09.P-Tu092 Linking Mercury and Reproductive Performance in Grey Seals (*Halichoerus grypus*)

Amy Bishop¹, Lorrie Rea², Benjamin D Barst³, Sean D. Twiss⁴, Patrick Pomeroy⁵ and Madison Haumschild¹, (1)University of Alaska Anchorage, United States, (2)University of Alaska Fairbanks, United States, (3)Earth, Energy, and Environment, University of Calgary, Canada, (4)Department of Biosciences, Durham University, Durham, United Kingdom, (5)University of St. Andrews, United Kingdom

Mercury is a heavy metal and global contaminant that previous studies have linked to deleterious effects on wildlife health, survival, and reproduction. Significant knowledge gaps remain in the research regarding how mercury toxicity in individuals may eventually compound, leading to population impacts in wildlife. It is unclear how maternal mercury load in individuals directly impacts maternal reproductive performance and offspring fitness. As a part of a larger project exploring relationships between total mercury concentrations ([THg]) in tissues and reproductive performance in female grey seals and their pups, here we present on (1) intra- and interannual variation in adult female [THg] and (2) connections between adult female [THg] and pup fitness characteristics, such as birth or weaning mass. Understanding intra- and interannual variation in adult female [THg] will aid in identifying dynamics underlying mercury transfer in marine food-webs, while links between adult female [THg] and pup fitness characteristics will help identify potential mechanisms linking mercury and population level dynamics. From 2010-2013, vibrissae samples (n = 211) from breeding adult female grey seals and their pups were collected in conjunction with a long-term monitoring project tracking individuals over time at two locations in Scotland (Isle of May and North Rona). Reproductive data were also collected including adult female and pup mass both near birth and at weaning. Whiskers were sequentially sectioned from the root to the tip and analyzed for [THg] (ppm). As whiskers represent approximately one year of growth, intra-annual patterns in [THg] were examined to characterize individual seasonal patterns in mercury and health risk. Interannual [THg] were found by utilizing whiskers repeatedly collected from the same individual across multiple breeding seasons. Preliminary data revealed considerable intra- and interannual variation in [THg] among individual adult females, with some individuals reaching levels of moderate risk. Future results will continue to shed light on how maternal mercury load may directly impact pup fitness characteristics or maternal reproductive efficiency, and how these impacts may contribute to population level effects in a wild system. These data become more meaningful as a rapidly changing climate impacts marine ecosystems, the species that occupy them, and the humans that rely on them for subsistence or traditional resources.

2.09.P-Tu093 Anticoagulant Rodenticides in Birds of Prey from Switzerland - A combined approach of chemical analysis and pathological examinations

Sibylle Xenia Maletz¹, Daniel Olbrich¹, Sarah Albini², Saskia Keller³, Michelle Imlau³, Petra Kunz⁴ and Etienne Vermeirssen¹, (1)Swiss Centre for Applied Ecotoxicology, Switzerland, (2)Institute for Food Safety and

Hygiene, University of Zurich, Switzerland, (3)Institute for Fish and Wildlife Health, University of Berne, Switzerland, (4)Federal Office for the Environment (FOEN), Switzerland

Anticoagulant rodenticides (ARs) enter the environment due to their widespread use for rodent control. These substances, particularly second-generation ARs (SGARs), possess persistent, bioaccumulative, and toxic (PBT) properties that can result in the secondary poisoning of non-target organisms. In this context, the exposure of birds of prey to ARs is well-documented internationally. Recently a total SGAR liver toxicity threshold of 10 ng/g has been proposed.

The current study aimed to expand the monitoring of AR exposure in Switzerland and combined it with postmortem examinations of birds of prey. A total of 21 common kestrels (*Falco tinnunculus*) and 82 common buzzards (*Buteo buteo*) were sampled from April 2024 to February 2025. Fresh carcasses were submitted from wildlife rehabilitation centers after birds died during rehabilitation or needed to be euthanized. The carcasses were examined macroscopically to determine the cause of death and categorized as follows: "common trauma", "AR toxicosis", or "other". A liver sample and, if possible, a blood sample were analyzed for residues of seven SGARs.

Only 4% of the birds were diagnosed with suspicion of "AR toxicosis", while 30% were categorized as "common trauma". The majority of the examined birds (66%) were categorized as "other". Histopathology was performed on ten birds with different death causes but no severe internal bleeding, as would be expected from AR toxicosis, was found. 84% of all examined liver samples showed SGAR residues above the sample-specific LOQ. Total residue concentrations ranged from 0.1 to 582 ng/g. 46% of the samples had concentrations above the proposed threshold of 10 ng/g. 15% of the concentrations exceeded 100 ng/g. 69% of the bird livers examined in this study contained two or more ARs, and nearly 10% contained up to five different ARs.

This study found no link between the diagnosis "AR toxicosis" based on postmortem examinations and AR-concentrations measured by chemical analysis. However, the study confirmed widespread and, in some cases, high background contamination of ARs in Swiss birds of prey. Since 86% of the animals studied were affected, the influence of sublethal effects should be considered. These can include reduced general fitness and impaired breeding success, both of which may negatively impact overall survival. Since ARs are PBT substances that are regularly found in wildlife, the overall focus should be on replacing them with less problematic substances.

2.09.P-Tu094 Mapping Anticoagulant Rodenticide Binding Across Chordata VKORC1 Via Molecular Docking: Revealing Taxonomic Patterns And Outliers

Noelia Marín-Prat, David Hernandez-Moreno, María Luisa Fernández-Cruz, Jose María Navas and Azucena Bermejo-Nogales, National Institute of Agricultural and Food Research and Technology - Spanish National Research Council (INIA-CSIC), Spain

Anticoagulant rodenticides (AR) control rodents through VKORC1 inhibition, but may harm non-target species. Regulatory in vivo tests use limited representative species, overlooking species sensitivities. Computational docking assesses AR-VKORC1 binding affinity (BA) and ligand position across species, offering mechanistic insight and reducing animal use. We hypothesized that docking with high taxonomic resolution could provide detailed in silico risk assessments by evaluating susceptibility across species and identifying outlier species. First, we searched for protein sequences homologous to brown rat VKORC1 (SeqAPASS v9) and found 2166 initial results. Many sequences were predicted, partial or inconsistently annotated, often corresponding to VKORC1-like1, and after an essential curation we kept 760 complete VKORC1 sequences. Then, we selected among the Chordata all those sequences from the least represented classes and those with >80% similarity among the most represented, resulting in 101 species belonging to six classes (4 Actinoterygii, 7 Amphibia, 2 Ascidiacea, 2 Aves, 65 Mammalia and 21 Reptilia). After sequence comparisons analysis among species, we obtained 76 unique VKORC1 sequences. Then, we performed blind docking of nine AR (AutoDock Vina v1.1.2) to analyze binding positions and taxonomic patterns in AR-VKORC1 interactions. Second generation AR showed the highest BA, ranked as flocoumafen, brodifacoum, difenacoum, difethialone and bromadiolone (-12.62±0.96 to -10.52±0.53 kcal/mol), over the first generation AR diphacinone, chlorophacinone, coumatetralyl and warfarin values (-10.31±0.63 to -8.86±1.27 kcal/mol). High-BA conformations occupied the central 3D region, with a gradient of decreasing affinity outwards. Clear taxonomic patterns emerged as mammals formed a compact cluster, and amphibians overlapped with reptiles and birds, the latter separating into Galliformes and Columbiformes. Also, Actinopterygii and Ascidiacea formed distinct groups, with Ascidiacea separating into two clusters consistent with Enterogona and Phlebobranchia. Several species-ligand combinations showed outlier behavior, including *Mus caroli*, *Suricata suricatta* and *Sigmodon hispidus* (Mammalia), *Xenopus laevis* (Amphibia) and *Gallus gallus* and *Caloenas nicobarica* (Aves). Outlier species may exhibit distinct interactions with key active-site residues, suggesting AR effects could differ from related species and highlighting the need for species-specific assessment.

2.09.P-Tu095 New Approach Methodologies to Assess Rodenticides Effects: Application of Transcriptomics in a Rat (*Rattus norvegicus*) Hepatoma Cell Line after Exposure to Difenacoum

Clara Bravo-Jiménez, Ana Valdehita, Jose María Navas and Azucena Bermejo-Nogales, National Institute of Agricultural and Food Research and Technology - Spanish National Research Council (INIA-CSIC), Spain

The brown rat (*Rattus norvegicus*) is a globally distributed species and one of the most significant urban pests, frequently associated with public health risks. Its remarkable metabolic adaptability has facilitated the development of resistance to anticoagulant rodenticides (ARs). This resistance can be provoked by mutations in the *vkorc1* gene, encoding the vitamin K epoxide reductase complex subunit 1. However, growing evidence suggests that additional molecular mechanisms, including detoxification and redox pathways, may contribute to tolerance and metabolic adaptation. Understanding these mechanisms is essential to improve toxicological assessments for cross-species extrapolation and to refine environmentally responsible pest management strategies under the One Health paradigm. In this context, the application of New Approach Methodologies (NAMs) allows generating extensive information with important savings of time, resources and experimental animals.

We hypothesized that exposure to ARs would activate metabolic and stress-related pathways beyond the classical vitamin K pathway. In order to explore these additional molecular responses, we analysed the transcriptomic profile of the rat hepatoma cell line (H4IIE) exposed to sub-lethal concentrations of the second-generation AR difenacoum. Control and treated cells were analysed by RNA sequencing and processed using an integrative online bioinformatics pipeline (RaNA-seq). Differential gene expression was assessed using DESeq2 (Wald test), identifying 252 differentially expressed genes (DEGs) between both conditions. Functional enrichment analysis of gene ontology (GO) terms and metabolic pathways indicated upregulation of genes related to drug response, transmembrane transport and ROS biosynthesis, indicating activation of detoxification and oxidative stress defence mechanisms. Conversely, mitochondrial functions such as oxidative phosphorylation and ATP synthesis were downregulated, suggesting impaired energy metabolism and mitochondrial dysfunction.

Overall, these in vitro approaches provide novel insights into the molecular response of *R. norvegicus* to AR exposure. The OMICs-based findings highlight candidate genes linked to metabolic resistance and enhance understanding interspecies variability, supporting more predictive, One Health-oriented risk assessments.

Keywords: anticoagulant rodenticides, *vkorc1*, transcriptomic, New Approach Methodologies, metabolic adaptation, One Health.

2.09.P-Tu096 Exposure to Anticoagulant Rodenticides Along the River Gradient: A Case of Study of the American Mink in Eastern Spain.

Isabel Navas¹, Toni Vicedo², Sonia Calatayud³, Pedro María-Mojica⁴ and Antonio Juan García-Fernandez¹, (1)Toxicology and Risk Assessment, IMIB-University of Murcia, Spain, (2)Biodiversity Research Institute (IMIB, UO- CSIC-PA), Spain, (3)Toxicology Area, University of Murcia, Spain, (4)Wildlife Rehabilitation Center "Santa Faz", Spain

The American mink (*Neovison vison*) is a semi-aquatic medium-sized carnivore of Mustelidae family that became an established alien species in Europe during the last decades.

This species is an opportunistic and generalist predator which typically preys on fish and amphibian species close to rivers, lakes, or dams, but also can feed on birds or small mammals such as rodents or lagomorphs. In this study, we evaluated the exposure to anticoagulant rodenticides in 48 American mink specimens captured along the Palancia river (Castellón, Valencia Autonomous Community, eastern Spain). We further evaluated urban and agricultural relationships of ARs exposure. The main objectives of this study were to: 1) quantify the levels of exposure in American mink individuals from eastern Spain, 2) evaluate variation of AR exposure along a riverine gradient, 3) evaluate the relationship between environmental variables and anticoagulant rodenticide

exposure, 4) assess how different spatial scales may influence the factors determining ARs exposure and, 5) estimate the intensity of exposure to these compounds in continental water masses in Spain. American mink specimens came from direct captures on trapping platforms located along the Palancia river. The individuals were necropsied after death, and liver samples were kept frozen until procedure. ARs were extracted using an adapted technique of QUECHERS, and quantified using a LC-MS-qTOF equipment.

The study demonstrated that anticoagulant rodenticides were present in the aquatic environment and that some of the captured American mink individuals may have suffered effects derived from acute intoxication to SGARs. Additionally, given the ongoing control and eradication programmes targeting American mink in Spain, we propose this species as an appropriate sentinel for monitoring AR exposure in continental freshwater systems.

The American mink is an invasive species in Spain but also is the main competitor of the European mink (*Mustela lutreola*), a native species recently classified as one of the most endangered mammal species in the world. The great niche overlap between both species has contributed to the severe decline of the latter. However, our findings provide valuable insights in the conservation of the European mink, as the threats currently affecting American mink populations may be impacting the remaining European mink populations.

2.09.P-Tu097 Biomonitoring of Heavy Metals in Non-Commercial Elasmobranchs for Human Consumption in Southeastern Spain

José Peñalver¹, Isabel Navas², Crisitina Jiménez³, Alessandro Costanzo³ and Antonio Juan García-Fernández², (1)Toxicology-University of Murcia, Spain, (2)Toxicology and Risk Assessment, IMIB-University of Murcia, Spain, (3)Toxicology Area, University of Murcia, Spain

Heavy metals are a threat to both marine and terrestrial ecosystems, including humans. In the case of elasmobranchs, their high trophic position and prolonged longevity make them particularly susceptible to bioaccumulation of these pollutants. In certain scenarios, the fishing exploitation of these species can pose a risk to public health. The objectives of this study were: 1) to evaluate the degree of exposure to heavy metals in non-commercial sharks caught in the Murcian coast, 2) to evaluate the possible consequences on the health of these species and 3) to estimate the potential risk to the human population if they were to be consumed. The concentrations of certain heavy metals (Hg, Cd, Pb, As and Se) were quantified in liver and muscle of individuals non-marketable of seven species shark and two species rays, caught off the coast of the Region of Murcia during the period 2010-2024. Correlations between tissue concentrations of metals were also examined, as well as the influence on exposure of variables such as gender, the taxonomic group and the area from which they come. All concentrations were expressed in wet weight (w.w.). The maximum concentrations of Hg in liver were detected in sharks (14.42 ± 16.44 mg/kg, w.w.), while in muscle they were found in rays (4 ± 7.99 mg/kg, w.w.). As for Cd, the highest concentrations in liver were found in sharks (1.25 ± 2.04 mg/kg, p.h.). In muscle samples, neither Cd nor Pb was detected. The latter metal was only residually found in one liver sample. As was found in higher concentration in shark liver (20.66 ± 17.63 mg/kg, p.h.) and in ray muscle (41.90 ± 30.87 mg/kg, p.h.). Finally, Se was found in higher concentrations in both liver (7.61 ± 7.3 mg/kg, p.h.) and muscle (1.38 ± 3.1 mg/kg, p.h.) of sharks. Significant differences in Cd and Se concentrations were observed between tissues, with higher concentrations found in liver tissue. Significant differences were also observed between groups, with higher Cd concentrations in sharks. The levels of metals in sharks did not differ according to area and sex. Regarding the risk to public health that these heavy metals may present, more than 75% of the specimens sampled showed muscle concentrations of Hg above the legal limits established for human consumption.

Disclaimer/Disclosure:

Thanks to Autonomous Community of Murcia Region for helping in collection of the samples.

2.09.P-Tu098 What's on the Menu? Deciphering Rodenticides' Trophic Transfer to the Aquatic Top Predator Eurasian otter (*Lutra lutra*)

Antonia Hennicke¹, Anton Friesen², Julia Regnery³ and Ursula Siebert¹, (1)Institute for Terrestrial and Aquatic Wildlife Research, Germany, (2)Sect. IV 1.2 Biocides, Federal Environment Agency, Germany, (3)Department of Biochemistry, Ecotoxicology, Federal Institute of Hydrology, Germany

Anticoagulant rodenticides (ARs) such as brodifacoum, difenacoum, and bromadiolone are widely applied to control commensal rodents. Their frequent use in sewer systems and along riverbanks creates direct pathways for emissions into water bodies, thereby increasing the risk of unintended AR exposure of aquatic wildlife. Correspondingly, hepatic AR residues have been detected in fish and at even higher concentrations in upper-trophic predators, indicating not only bioaccumulation but also potential biomagnification. However, exact exposure routes of biota in aquatic ecosystems, as well as specific trophic pathways involved, remain poorly understood. This study aims to assess the exposure of Eurasian otters (*Lutra lutra*) in Germany to approved first- and second-generation ARs by identifying trophic pathways that may mediate the transfer of these contaminants within aquatic food webs. We hypothesise that specific taxonomic prey groups may promote trophic transfer of ARs, and that otters specialising on prey of higher trophic levels may exhibit elevated AR burdens due to biomagnification. To address this research question, otter carcasses (n = 121) were collected across Germany between 2007- 2025, and liver tissues and intestinal contents were sampled. AR residues were quantified in liver samples by liquid chromatography - tandem mass spectrometry, while diet composition was reconstructed through metabarcoding of gut contents combined with hard-part analysis of stomach contents. This study contributes to understanding the behaviour and exposure pathways of ARs in aquatic environments, thereby providing important information concerning the risks for wildlife, as well as guidance for future monitoring and risk mitigation efforts.

This research is funded by the German Environment Agency through grant FKZ 3723 64 4040

2.09.P-Tu099 Environmental RNA metabarcoding enables community-level risk assessment based on response of benthic communities

Yasuaki Inoue, Kaede Miyata, Hiroshi Honda, Takahiro Suzuki and Masayuki Yamane, Kao Corporation, Japan

To achieve the biodiversity restoration, it is important to identify the impact of chemicals on ecosystems and strategically reduce their risks. The effects of chemicals on ecosystems in aquatic environments has generally been predicted using the assessment factor (AF) method, in which the toxicity data for test organisms is extrapolated to calculate the predicted no-effect concentration (PNEC). However, contaminated aquatic ecosystems are affected by both the direct toxic effects of chemicals on single organisms and indirect changes via ecological interactions; thus, the results of the hazard assessment methodologies that are based on extrapolation from toxicity tests reflecting only the direct effects of chemicals are likely associated with large uncertainties. The development of community-level assessments that consider complex ecological interactions may contribute to the accurate visualization of the effects of chemical contamination on ecosystems. Therefore, we focus on the environmental RNA (eRNA) and the environmental DNA (eDNA) released by macroorganisms in aquatic environments to directly capture the responses of biological communities.

In this study, eRNA/eDNA metabarcoding was performed in a mountain stream receiving linear alkylbenzene sulfonate (LAS) effluent from a chemical plant to assess the effects of LAS on ecosystems by comparing the biological communities at sites with different levels of LAS contamination. This approach revealed that eRNA can capture the response of benthic communities to LAS more sensitively than eDNA, and that the effects of LAS contamination on ecosystems can be visualized directly from the responses of biological communities in the real environment.

Our findings indicated that eRNA metabarcoding may be useful for community-level ecological risk assessment and provide important knowledge that complements the assessment results using the AF method. To properly manage chemical substances, it is important to actively incorporate the results of community-level hazard assessments as a priority and to discuss the validity of current risk assessment methods and environmental standards.

2.09.P-Tu100 Mercury Bioaccumulation in Pacific Bald Eagle Nestlings – Spatial and Dietary Differences and Influences

John Elliott¹, Kate Fremlin² and Myles Lamont³, (1)Environment and Climate Change Canada (ECCC), Canada, (2)Simon Fraser University, Canada, (3)Hancock Foundation, Canada

We investigated how spatial and dietary variation influenced the total mercury (THg) concentrations in bald eagles (*Haliaeetus leucocephalus*) across a marine-freshwater-terrestrial habitat gradient. Blood samples were

collected from 91 nestlings (n = 64 nests), 2021 – 2023, at sites in southwest British Columbia, Canada, including the Fraser Valley, Delta, Burrard/Howe Sound, North/South Salish Sea, Southeast Vancouver Island, Thompson River, and a reference site on the west coast of Vancouver Island. Nestling plasma was analyzed for THg, stable isotopes ($\delta^{13}\text{C}$, $\delta^{15}\text{N}$, and $\delta^{34}\text{S}$), and fatty acid methyl esters (FAME) to help distinguish among marine, aquatic and terrestrial diets. Isotope signatures and FAMES had a clear spatial gradient with marine focused diets more prevalent on the outer west coast with higher $\delta^{13}\text{C}$, $\delta^{15}\text{N}$, $\delta^{34}\text{S}$ and $\omega\text{-3}$ levels while transitioning to more terrestrial and freshwater diets inland with lower $\delta^{13}\text{C}$ and higher $\omega\text{-6}$ levels. When averaged across sex, THg concentrations in nestling plasma were generally higher in the Thompson River and South Salish Sea with geometric mean concentrations of 1.2 ug/g dry weight (dw) and 0.54 ug/g dw, respectively, and lower in Burrard/Howe Sound and Southeast Vancouver Island with geometric mean concentrations of 0.12 ug/g dw and 0.16 ug/g dw, respectively. Linear mixed effects modelling indicated that $\delta^{15}\text{N}$ and $\delta^{34}\text{S}$ in nestlings generally increased with increasing THg concentrations in plasma ($p < 0.05$), whereas $\delta^{13}\text{C}$ decreased with increasing THg concentrations ($p < 0.05$). We will further examine those relationships, and implications for identifying Hg sources. The lowest documented toxic effect concentrations in birds occurs at a blood-equivalent THg concentration of 0.2 ug/g wet weight; eight nestlings had THg concentrations in plasma above that threshold.

2.09.P-Tu101 Mercury Exposure and the Protective Effect of Selenium in a Wintering Population of Common Razorbill (*Alca torda*) in the Southwestern Mediterranean

Marta Mármol¹, Isabel Navas,² Pedro María-Mojica³, Pedro Jiménez¹ and Antonio Juan García-Fernández²,
(1)Toxicology Area, University of Murcia, Spain, (2)Toxicology and Risk Assessment, IMIB-University of Murcia, Spain, (3)Wildlife Rehabilitation Center "Santa Faz", Spain

Razorbills are marine birds that breed along the North Atlantic coasts, especially in Iceland, Norway, the British Isles, and the North Sea. After the breeding season, many individuals migrate southward to overwinter in more temperate regions, crossing the Strait of Gibraltar and dispersing across the western Mediterranean basin. In this study, 27 razorbills found dead along the eastern Spanish coast were collected between November 2022 and January 2024. Necropsies were performed and samples of liver, kidney, muscle, feather, and bone were collected for analysis of Hg and Se by ICP-MS. In addition, the molar ratio Se:Hg was calculated for each tissue. The influence of biological variables (sex, age, body mass, and body condition) on metal concentrations and molar balance was also assessed.

The liver had the highest mean concentration of Hg, followed by kidney and muscle. Feathers and bone showed lower concentrations. Selenium concentrations were highest in kidney tissue, followed by liver and muscle. The molar ratio Se:Hg was above 1 in most tissues, especially in kidney and bone, suggesting a potentially protective balance. However, in several individuals, the ratio was close to or below 1 in liver and muscle, indicating possible risk of Hg-induced toxicity due to low Se levels.

Statistical analysis revealed significant differences between sexes showing higher concentrations in females. Adult birds tended to have higher Se:Hg ratios in liver than juveniles.

In some individuals, Hg concentrations in liver and kidney exceeded levels associated with reproductive or physiological harm. While Se concentrations in isolation did not indicate toxicity, the Se:Hg ratio proved more informative in evaluating potential risk. The fact that several individuals had ratios < 1 in metabolically active tissues like liver supports the concern that Se reserves may not be sufficient to counterbalance Hg burden in all cases.

In conclusion, razorbills wintering in the southwestern Mediterranean show measurable exposure to mercury, with some individuals reaching toxic levels in internal organs. Selenium appears to play a protective role, but its effectiveness depends on the relative concentration of Hg. The Se:Hg molar ratio is confirmed as a useful biomarker of toxicological vulnerability. These findings support the use of *Alca torda* as a sentinel species for evaluating trace metal contamination in marine environments.

Thanks to "Santa Faz" Wildlife Rehabilitation Center (Generalitat Valenciana) for helping in collection of the carcasses.

2.09.P-Tu102 A Field Study Examining the Acute Effects of Copper Applied as a Spray Fungicide in Citrus Orchards to Fruit-Eating Birds and the Garden Dormouse

Apostolos Koutsafitis¹, Silke Laucht², Diana Nakunst³ and Daniele Ruccia⁴, (1)ERM Europe Ltd, Netherlands, (2)Rifcon GmbH, Germany, (3)Cosaco GmbH, Germany, (4)ERM Europe Ltd, France

The present study assessed whether copper applications in citrus orchards in Southern Europe, following Good Agricultural Practice (GAP), cause acute effects on fruit-eating birds and garden dormice. Conducted in Valencia (Spain) and Algarve (Portugal) across seven orchards (six orange orchards were selected in Spain and one in Portugal, representing the common size and basic structure of citrus orchards), treatments were applied twice at BBCH 73 (2.4 kg Cu/ha) (5-day interval in Spain, 7-day interval in Portugal) under suitable conditions in May 2024.

A total of 68 birds from seven species (blackbird, great tit, greenfinch, magpie, nightingale, Sardinian warbler, serin) were radio-tagged; 63 were successfully tracked. Telemetry checks occurred before, during, and after applications to confirm exposure and monitor health. After exposure confirmation, checks continued twice daily for at least seven days post-treatment. Additional monitoring included orchard walks, night vision, nest box inspections, and camera traps.

Results showed 84% of tracked birds remained active and healthy until seven days after the second application, and 76% until at least ten days after. Exposure was confirmed for 50 birds and likely for all others. Bird monitoring recorded 3,277 sightings of 45 species, with blackbird and Sardinian warbler most frequent. Foraging behaviour occurred in 37% of sightings, confirming exposure via food intake. No signs of intoxication, abnormal behaviour, or carcasses were observed.

Six garden dormice were radio-tagged in two orchards, with 17 additional captures untagged. Exposure was confirmed for all tagged individuals. Three dormice were tracked until DAT 12, two until DAT 15, and one recaptured on DAT 17; one signal was lost early due to tag malfunction. Two dormice died, but post-mortem excluded copper as cause, attributing deaths to collar issues. Visual observations (33 sightings), camera traps, and nest box checks confirmed normal behaviour and health, with no signs of sickness or copper-related effects.

Overall, based on the radio-tracking results as well as further monitoring methods, there was no evidence either of observable acute mortality or abnormal behaviour which could be directly related to the copper applications. In conclusion, there were no indications for acute effects for both birds and mammals, demonstrating acceptable risk following GAP-conform copper application in citrus orchards.

2.09.P-Tu103 Biomonitoring of Heavy Metals in Red-Billed Chough (*Pyrrhocorax Pyrrhocorax*) to Assess the Impact on Health Following the Eruption of the Tajogaite Volcano (La Palma) in 2021

Isabel Navas¹, Guillermo Blanco², Martina Carrete³, Vicente Revilla⁴, Pedro María-Mojica⁵, Félix M. Medina⁶, Óscar Frías⁷, José Luis González del Barrio² and Antonio Juan García-Fernández¹, (1)Toxicology and Risk Assessment, IMIB-University of Murcia, Spain, (2)Museo Nacional de Ciencias Naturales, CSIC, Spain, (3)Universidad Pablo Olavide, Sevilla, Spain, (4)Toxicology, University of Murcia, Spain, (5)Wildlife Rehabilitation Center "Santa Faz", Spain, (6)Cabildo de La Palma, Canary Islands, Spain, (7)GEO3BCN, CSIC, Spain

The eruption of the Tajogaite volcano on the island of La Palma in 2021 provided an opportunity to study the impact on wildlife health. A biomonitoring study was designed using an emblematic species exclusive of La Palma in the Canary Islands (Spain), the red-billed chough (*Pyrrhocorax pyrrhocorax*), as a sentinel species to assess environmental contamination and the potential risk to animal, and presumably human, health caused by the eruption. The main objective of this study was to quantify the concentration of various heavy metals in different tissues (brain, liver, muscle, bone, lung, and kidney) of choughs that died before and after the eruption, in order to estimate the potential health risks. Additionally, correlations between metals were evaluated. For the study, 18 chough carcasses were necropsied and internal tissues were collected. The samples were analyzed using ICP-MS to quantify concentrations of 14 metals. Statistical analyses were used to determine differences between pre- and post-eruption individuals. The results showed significant increases in the concentration of several metals in the studied tissues from carcasses collected after the eruption, particularly in the lungs, muscle, and liver. Metals such as Ni, Cr, Co, Cd, Fe and Al increased considerably in the tissues of the animals that died after the eruption, suggesting a rise in environmental exposure to these elements. Additionally, several significant correlations between metals were detected, indicating possible shared mechanisms of distribution and storage in the organism, or a potential common source of contamination. Overall, these findings support the hypothesis that the eruption caused an increase in environmental levels of heavy metals; however, when compared to other studies, no clearly toxic levels for birds were found in most individuals after the eruption (6). Nevertheless, this work should serve as a warning about potential ecotoxicological and health impacts on La Palma's ecosystem and its inhabitants, reinforcing the need for continued environmental monitoring of soil, water, and other sentinel species to keep animal and human health risks in the area under control.

Disclaimer/Disclosure:

Thanks to Cabildo Insular de La Palma for helping in collection of the carcasses.

2.09.P-Tu104 Assessment of the impact of metals and parasites on the cetaceans stranded along the Basque Coast (2012-2025)

Andrea Estarrona¹, Iruñe Valenciano², Xabier Lekube¹, Manuel Soto¹, Urtzi Izagirre¹ and Denis Benito¹, (1)University of the Basque Country, Spain, (2)Research Centre for Experimental Marine Biology and Biotechnology (PiE-EHU/UV), University of the Basque Country, Spain

Marine mammals have a relatively long-life span, and some species are in the upper level of the food web. Thus, they can bioaccumulate the environmental contaminants in their tissues, becoming effective sentinel species for assessing the pollution of marine food webs. The marine ecosystems are continuously subjected to anthropogenic sources of contamination which can compromise marine animals' health status. Among all the pollutants present in the marine environment, special attention should be given to metals, because these are persistent, and some have the capacity to bioaccumulate and biomagnify. In the present study, the content of metals in muscle was evaluated in 7 cetacean species stranded along the Basque Coast (2012-2025). In addition, subcutaneous fat, muscle, mesentery, lungs and stomach were analysed to determine the prevalence of different species of parasites and their parasitic load. Statistical analysis was carried out to evaluate differences in metal content and correlations with different variables (sex, developmental state, corporal condition, decomposition status...) and parasitic burden. Overall, cetaceans of this study presented comparable values of metal levels in muscle to those inhabiting other localities of the Atlantic Ocean. In contrast, Ni presented high values that could compromise the health status of the dolphins inhabiting the Bay of Biscay, as well as high levels of Pb in striped dolphin and harbour porpoises. *D. delphis* showed significantly lower values than *S. coeruleoalba* ($p < 0.01$) in Hg, and *T. truncatus* ($p < 0.05$) presented lower values than the other dolphins. Parasites from the Pseudaliidae family, *Anisakis* sp. and isolated cases of trematode eggs seemed to be the most relevant parasites impacting the health of these cetaceans. Correlations between metal levels and parasitic burdens were obtained, suggesting potential synergistic effects. No significant differences were found in metal levels relative to morphometric or biological traits, nor were any significant differences detected in parasite content across species. The present work is the first report determining the levels of metals in cetaceans stranded along the Basque Coast, and their possible relationships with parasitic loads. SAREUS project is funded by Fundación Biodiversidad (MITECO, PRTR, NextGenerationEU) & Basque Government. This work was supported by the CBET+ (IT1743-22) Consolidated Research Group (Basque Government).

2.09.P-Tu105 Toxicokinetics of the UV Absorbent, UV-328, in Japanese Quail Embryos

Ramela Koumrouyan¹, Doug Crump², Jessica Head¹ and Zhe Lu³, (1)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (2)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada (ECCC), Canada, (3)University of Quebec at Rimouski (UQAR), Canada

Ultraviolet absorbents (UVAs) are industrial chemicals used for their photoprotective properties. These emerging contaminants have become ubiquitous in various environmental media and adversely affect certain species. UVAs have been measured in colonial waterbirds and terrestrial birds from various environments. Egg injection studies from our lab demonstrated that select UVAs (UV-328, UV-329, UV-9, BP-3) were not acutely toxic to Japanese quail or Double-crested cormorant embryos. Avian livers were sampled at mid-incubation and pre-hatch. Chemical residue analysis revealed that a certain percentage of administered UVAs were found in avian embryo livers. UV-328 concentration was higher in pre-hatch quail livers compared to mid-incubation livers, suggesting accumulation. We do not have a clear picture of how UVAs are distributed across the rest of the embryo, nor do we know how much each UVA accumulates or is metabolized in the liver and/or other organs of interest. Therefore, the objective of the current study was to investigate the partitioning of UV-328 in various tissues and compartments (e.g. shell membrane, embryonic contents) in developing Japanese quail embryos. UV-328 is of international interest based on its accumulation potential, physicochemical properties and potential for hazard, warranting its addition to Annex A of the Stockholm Convention. Based on preliminary data and literature, I predict UV-328 will accumulate in the quail liver throughout incubation. An ongoing mass-balance experiment in quail embryos will allow us to determine UV-328 toxicokinetics in quail and subsequently improve our risk assessment for this relatively novel chemical.

2.09.P-Tu106 First determination of Persistent Organic Pollutants (PCBs, PAHs and BFRs) in tegument of six species of cetaceans stranded along the Basque Coast (NE Iberian Peninsula)

Andrea Estarrona¹, Irune Valenciano², Lucía Viñas³, Begoña Pérez³, Xabier Lekube¹, Urtzi Izagirre¹, Denis Benito¹ and **Manuel Soto¹**, (1)University of the Basque Country, Spain, (2)Research Centre for Experimental Marine Biology and Biotechnology (PiE-EHU/UV), University of the Basque Country, Spain, (3)Oceanographic Center of Vigo, Spanish Institute of Oceanography (IEO), Spain

Marine ecosystems are particularly vulnerable to toxic and persistent chemical compounds, as they are continuously subjected to anthropogenic sources of contamination. Furthermore, projections indicate that pollutant concentrations in marine environments will escalate in parallel with ongoing population growth and the intensification of global industrial production. Due to their position in the food web and large lipid deposits, marine mammals are exposed to the highest concentration of pollutants of all marine wildlife. Thus, they are vulnerable to the bioaccumulation, biomagnification, and lactational transfer of lipophilic and hydrophilic persistent organic pollutants (POPs). Elevated PCB concentrations are still a significant cause of European cetacean population's decline, and levels of this compound exceed all known protective thresholds in multiple dolphin species. Biomagnification and consumption of lipid-rich tissues enhance the risk of endocrine and metabolic disruption, which can result in alterations to reproduction, metabolic and immune function, and may influence populations' dynamics. In the present study, the content of POPs in tegument samples from 41 individuals belonging to six species of marine mammals stranded along the Basque Coast (2012-2023) was evaluated. The analyses focused on three main groups: polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs) and brominated flame-retardants, including polybrominated diphenyl ethers (PBDEs) and new flame-retardants (EHTBB, BTBPE, BEHTBP). The results showed wide variability in contaminant concentrations between species, sexes and maturity. PCBs had the highest concentrations, especially in adult males of *Stenella coeruleoalba* (SCO), with Σ7PCBs values above 70 mg/kg lipid weight. PAHs showed concentrations one or two orders of magnitude lower, with maximums in *Ziphius cavirostris* (ZCA) and *Tursiops truncatus* (TTR), while PBDEs reached higher levels in some individuals, notably in a TTR male with more than 1500 µg/kg lipid weight. Results were within the expected range for populations in the northwestern Atlantic. The present work presents the first record of POPs in cetaceans stranded along the Basque Coast. SAREUS project is funded by Fundación Biodiversidad (MITECO, PRTR, NextGenerationEU), and Basque Government. This work was supported by the CBET+ (IT1743-22) Consolidated Research Group (Basque Government).

2.09.P-Tu107 Skuas as Bioindicators of Emerging Pollutants in Antarctica

Nadia Soledad Haidr¹, **Pilar Gomez-Ramirez²**, William Mills³, Lara Mariel Morales⁴, Aylen Maria de Prinzi⁵, Diego Sebastian Torres⁴, Rocio Mariano-Jelicich⁵, Diego Montalti⁶, Yuste-Jiménez José Enrique⁷, Fernando Vallejo⁷, Veerle L. B. Jaspers⁸ and Andrés Esteban Ibáñez⁴, (1)División Zoología Vertebrados, Museo de La Plata, Facultad de Ciencias Naturales y Museo, Universidad Nacional de La Plata (Argentina), Argentina, (2)Toxicology Research Group, Faculty of Veterinary Medicine, University of Murcia, Spain, (3)Department of Geography and Environmental Science, University of Reading, Reading, UK, United Kingdom, (4)División Zoología Vertebrados, Museo de La Plata, Facultad de Ciencias Naturales y Museo, Universidad Nacional de La Plata (Argentina), Argentina, (5)Instituto de Investigaciones Marinas y Costeras (IIMyCCONICET), Universidad Nacional de Mar Del Plata (FCEyN, UNMdP), Mar del Plata, Argentina, Argentina, (6)División Zoología Vertebrados, Museo de la Plata, Facultad de Ciencias Naturales y Museo, Universidad Nacional de La Plata (Argentina), Argentina, (7)Metabolomics Platform, Spain, (8)Department of Biology, Norwegian University of Science and Technology, Norway

Poly- and perfluoroalkyl substances (PFASs) are highly stable fluorinated compounds widely used in industrial and consumer products. They reach aquatic ecosystems via atmospheric and oceanic transport; persist in the environment, and bioaccumulate through the diet, leading to elevated concentrations in top predators. In organisms, PFASs bind mainly to albumin and lipoproteins in blood, and to fatty acid transport proteins in the liver. Particularly in Antarctica, atmospheric transportation, research stations activities and plastic debris presence may act as a dispersion route for PFASs. Brown and South Polar skuas (*Stercorarius antarcticus* and *S. maccormicki*) breed in Antarctica and can nest in sympatry. Both species have generalist and scavenger feeding behaviors. However, Brown Skuas diet rely primarily on land-based resources, while South Polar skuas are forced to feed on marine prey when occur in sympatry. Previously, we demonstrated spatial and interspecific differences in exposure risk to other pollutants in skuas across the Southern ocean, and that skuas are adequate bioindicators of emerging pollutants in Antarctica. This study aims to i- examine serum PFASs concentration in Brown and South Polar skuas along a latitudinal gradient (Potter Cove-South Shetlands ? Hope-Northern Antarctic Peninsula ? Cierva Cove-West Antarctic Peninsula), ii- determine serum trophic markers ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$) and iii-assess trophic drivers of PFASs contamination. Serum was obtained from blood samples taken from adult skuas (n=100) from three Antarctic locations during incubation. PFASs were quantified in serum using an ultra-performance liquid chromatography system coupled to tandem mass spectrometry (UPLC-

MS/MS), while the serum isotopic composition was analysed with a continuous flow-isotope ratio mass spectrometer. Differences in feeding habits were observed between species and locations. Brown skuas at Hope Bay and Potter Cove display a high reliance on land-based resources (such as penguins), whereas, South Polar skuas feed mainly on marine resources (such as fish). Higher loads of PFASs are expected to be found in skuas that breed in northern latitudes. Furthermore, PFASs loads are expected to be associated to feeding traits of each species, being higher in skuas feeding on land based resources which are more exposed to anthropogenic activities. Understanding PFAS presence in polar food webs is crucial for assessing their sources, distribution, and long-term impact.

2.09.P-Tu108 First Assessment of PFAS Exposure in East African Lions Using Targeted Analysis and the Total Oxidizable Precursor Assay (TOPA)

Pablo Sanchez Virosta¹, *Veerle L. B. Jaspers¹, Stanslaus Mwampeta², Justin Shamanche³, Susana Villa Gonzalez¹, Liang Zhao¹ and Alexandros G. Asimakopoulos¹, (1)NTNU, Norway, (2)Grumeti Fund, Tanzania, United Republic of, (3)TAWIRI, Tanzania, United Republic of*

Lions (*Panthera leo*) are apex predators expected to integrate chemical exposure across soils, waters, vegetation and prey, making them powerful sentinels of ecosystem contamination in Africa. Despite this relevance, virtually nothing is known about their exposure to pollutants and, specifically, per- and polyfluoroalkyl substances (PFAS). These “forever chemicals” are globally distributed emerging contaminants whose persistence, bioaccumulation potential and toxic effects have raised increasing concern for wildlife health. Standard targeted PFAS analyses may underestimate total exposure because many PFAS occur as precursors that remain undetected unless oxidized, as demonstrated in several wildlife studies applying the Total Oxidizable Precursor Assay (TOPA) to reveal hidden PFAS burdens.

In this study, we assessed PFAS exposure in free-ranging lions inhabiting Serengeti National Park (Tanzania), generating the first PFAS dataset for an African terrestrial apex predator in the framework of the Marie Skłodowska Curie-funded project LEOTHREAT. Plasma samples collected through the project were analyzed by UPLC-MS/MS to quantify a broad suite of legacy and emerging PFAS. To evaluate the contribution of oxidizable precursors, paired aliquots of each plasma sample were subjected to TOPA, enabling direct comparison between native and oxidized PFAS profiles. This dual approach allowed us to characterize both directly measurable PFAS and those formed through precursor oxidation, providing a more complete representation of total PFAS exposure than targeted analyses alone.

The integration of targeted PFAS quantification with TOPA offered a robust framework to investigate PFAS pathways in lions and the ecosystems they inhabit. The study design also enabled the identification of potential precursor-rich sources that might contribute to PFAS accumulation through trophic transfer or environmental interfaces. By applying this two-tiered analytical strategy, this project establishes the methodological foundation necessary to explore PFAS behavior in African terrestrial food webs, a region and taxonomic group that have received minimal attention in contaminant research.

By generating the first PFAS dataset for East African lions and explicitly incorporating precursor assessment, this study provides essential baseline information for understanding PFAS dynamics in African ecosystems and supports future evaluations of contaminant exposure and wildlife health.

2.09.P-Tu109 COLLABORATING WITH AN INDIGENOUS COMMUNITY TO STUDY ARCTIC CONTAMINANTS: 25 YEARS OF RESEARCH WITH QIKIQTARJUAQ, NUNAVUT

Mark Mallory¹ and *Jennifer Provencher², (1)Department of Biology, Acadia University, Canada, (2)Environment and Climate Change Canada (ECCC), Canada*

In 2000, we initiated work with the Inuit (Indigenous) community of Qikiqtarjuaq, Nunavut in Arctic Canada, on eastern Baffin Island, to create two new National Wildlife Areas (NWAs) at large seabird colonies. These colonies are located close to former weather and radar stations established during the Cold War, and the community was concerned about contamination of wildlife near these sites, because Inuit still rely heavily on wildlife as primary food sources. To address their concerns, we undertook studies in the mid-2000s to determine trace element and legacy persistent organic pollutants in local animals, establishing that levels were consistent with regional background concentrations, as well as collaborating on an Indigenous Knowledge study on the region. Following the establishment of the NWAs in 2010, the community and government formed the Sululiit

Area Co-Management Committee, where the community plays the major role in driving management, research, and monitoring priorities for the sites. As we continued to work with the committee, starting in 2018 they sought information and advice to address a major Strategic Environmental Assessment for the Baffin Bay marine region for future oil development, and thus we collaboratively undertook new studies with the community to address their concerns over increased shipping, increased fisheries, increased tourism, oil-related contamination, and new contaminant threats. In particular, in nearby environmental matrices we have completed or ongoing studies examining: macro- and microplastics pollution, plastic-associated chemicals (organophosphate esters, ultraviolet stabilizers), polycyclic aromatic compounds (PAC), fisheries bycatch, toxic trace elements, and wildlife health metrics. We present some key products from this research including a toxicogenomics “toxchip” to assess PAC exposure in wild birds, wildlife biovectoring of plastics and identification of matrix-specific microplastics differences, and different fuzzy cognitive maps produced by local residents and southern scientists on threats to wildlife in this region. Importantly, we identify successful steps we took to support this ongoing, mutually beneficial research and monitoring program.

2.09.P-Tu110 Understanding Spatial Patterns of PFAS Exposure for two Terrestrial Species in the UK

Rosie J Lennon¹, Lee Walker², M. Gloria Pereira², Carmel Ramwell³ and Sheonaidh Charman³, (1)Natural England, United Kingdom, (2)United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Fera Science Ltd, United Kingdom

Per- and polyfluoroalkyl substances (PFAS) are now unequivocally recognised as a major environmental concern, necessitating urgent policy interventions to mitigate widespread contamination and exposure. The identification of exposure patterns can be an important step to prioritise necessary policy changes for effective regulation to better protect vulnerable species and ecosystems. However, PFAS present a challenge in this regard due to the large number of compounds, associated properties and variety of potential exposure sources. National, long-term monitoring data for PFAS in wildlife provides valuable information to address this evidence gap. As part of a UK government-led chemical monitoring programme, liver residue data for 40-55 PFAS have been collected from two sentinel species in England - the common buzzard (*Buteo buteo*; n=180) and the European red fox (*Vulpes vulpes*; n=230) - across the period 2014–2024. In this study, these wildlife exposure data are spatially integrated with the EU Forever Pollution Project PFAS dataset, alongside UK-specific datasets that capture other potential PFAS emission sources. Combined with species-specific ecological parameters, such as home range and habitat use, these data will be analysed to assess whether any particular sources of PFAS contamination are influencing observed exposure patterns in the focal species or localised areas. Results will be presented for both species, highlighting associations between PFAS residues and known contamination sources, and evaluating whether any UK protected sites may be disproportionately at risk from this contaminant group. By linking wildlife monitoring with spatially explicit pollution datasets, this work will strengthen the evidence base for national-level PFAS policy development as well as the provision of localised advice to managers of protected sites in England. Ultimately, these findings aim to increase awareness and our understanding of PFAS exposure in terrestrial wildlife, and contribute to broader efforts to maintain environmental quality in the face of persistent chemical pollutants.

2.09.P-Tu111 From Guidance to Practice: Implementation Challenges and Strategic Approaches for Applying fTWA in Wildlife Risk Assessment

Viktoriia Ovcharova and Eva Eschenbach, Exponent, Germany

Since the publication of the EFSA revised Guidance document on the risk assessment for birds and mammals in 2023 and its notification in October 2025, the concept of the time-weighted average factor (fTWA) has gained considerable attention. The fTWA accounts for pesticide residue decline over time and may be applied in long-term risk assessments for birds and mammals if relevant long-term toxicity effects (within a factor of 3 of the lowest effect value, i.e. “rule of three”) are driven by long-term exposure, not by short-term exposure during critical or sensitive life stages (e.g. primary effects on reproduction or development). Where application of the fTWA is deemed inappropriate, exposure estimates increase significantly, which is likely to require a higher-tier assessment, rendering substance-specific residue decline studies unusable and thus limiting the available options for risk refinement.

Despite the availability of the revised guidance and further recommendations from the Post Approval Issues Group, uncertainties remain regarding its practical implementation at the product (re-)authorisation stage. A primary challenge arises from the need to re-evaluate all relevant long-term avian and mammalian toxicity data to verify fTWA applicability, encompassing the EU-agreed endpoints and beyond, to comply with the “rule of three”. Such reassessment is not foreseen at the national level once EU-agreed endpoints have been established and may lead to divergent interpretations and compromise harmonisation across Member States. Furthermore,

detailed re-examination of study reports is often not feasible for applicants other than the original EU notifier, due to restricted access.

Against this background, we propose strategic approaches to navigate various likely scenarios while verifying the fTWA applicability. These approaches are intended to enable targeted data interpretation and facilitate the preparation of robust and compliant regulatory dossiers in support of the (re-)authorisation of plant protection products. Early adoption of a structured and harmonised strategy for evaluating fTWA applicability can provide distinct procedural and scientific advantages, including timely identification of data gaps and methodological uncertainties. It also promotes a more efficient alignment of data interpretation, endpoint justification and potential refinement options, thereby reducing the likelihood of additional information requests during the evaluation phase.

2.09.P-Tu112 EchoGO: A Cross-Species Consensus Framework for Functional Enrichment in Non-Model Organisms

Camilo Escobar-Sierra¹, Felix Langschied² and Pedro A. Inostroza¹, (1)Institute for Environmental Research, RWTH-Aachen University, Germany, Germany, (2)Applied Bioinformatics Group, Institute of Cell Biology and Neuroscience, Goethe University, Germany

Functional enrichment in non-model organisms is often limited by sparse annotations and the narrow perspective of single-species analyses. EchoGO, an open and reproducible R package, addresses these constraints by integrating GSeq enrichment from experiment-specific annotations with orthology-based enrichment across multiple reference species. The framework builds on a simple premise: many biological pathways originated before major evolutionary splits. When orthologs of differentially expressed genes yield the same enriched terms across several well-annotated species, the replicated signal is more likely to reflect a true biological pattern. EchoGO operationalises this by running enrichment independently in each species and identifying terms that consistently appear across GSeq, g:Profiler, and taxa.

EchoGO provides two complementary outputs. The True Consensus stream retains terms jointly supported by GSeq and background-corrected orthology-based enrichment, offering high interpretive confidence. The Exploratory stream includes all significant orthology-derived terms for broader hypothesis development. A transparent scoring system integrates multi-species support, fold enrichment, statistical strength, and provenance, while semantic similarity reduction and network analysis group redundant terms and reveal coherent functional modules.

EchoGO is particularly valuable for de novo or poorly annotated organisms, where GSeq alone provides limited certainty. Across multiple datasets, EchoGO increased enriched GO terms from 64 (GSeq) to 345 (EchoGO), a five-fold improvement in depth and coverage. In Biological Process networks, GSeq produced 25 terms and 108 edges, whereas EchoGO yielded 123 terms and 2,876 edges, revealing functional organisation that was otherwise invisible. Because EchoGO tests enrichment independently in each reference species and tracks term provenance, additional terms reflect replicated signals rather than annotation inflation. This yields clearer ontology structures, more robust similarity clusters, and denser network topologies. Compared with tools such as Fun2Seq, AllEnricher or PipeOne-NM, EchoGO uniquely combines bias-aware enrichment, independent multi-species validation, and transparent consensus scoring rather than simply aggregating ortholog annotations.

Altogether, EchoGO provides a reproducible and biologically grounded framework that strengthens functional interpretation in ecotoxicology and environmental omics.

2.09.P-Tu113 The Atlantic Blue Crab as a Cross-Ecosystem Outlier: A Framework for Wildlife Toxicology and One Health

Concepción Martínez-Gómez¹, Begoña Pérez¹, Lucía Viñas¹, Beatriz Fernández¹, Francisco Acosta-Cifuentes¹, Jessica Bargiela¹, Ignacio Franco¹, Antonio Zamora-López², Claritxa Neal¹, Antonio Andres Herrero-Reyes² and Pilar Gomez-Ramirez³, (1)Oceanographic Centre of Murcia, Instituto Español de Oceanografía, Spain, (2)Department of Zoology and Physical Anthropology, Faculty of Biology, University of Murcia, Spain, (3)University of Murcia, Spain

The invasive Atlantic blue crab *Callinectes sapidus*, now widely established in Mediterranean coastal ecosystems, represents an ecotoxicological outlier due to its distinctive physiological traits, ecological plasticity, and complex exposure pathways. These features likely modulate contaminant absorption, distribution, metabolism, and excretion in ways that differ markedly from standard ecotoxicological model taxa. Despite its

invasive status, the species is increasingly incorporated into Mediterranean fisheries, raising concerns about its role as a vector of contaminants across lagoon and coastal marine systems.

However, toxicological and ecotoxicological data for *C. sapidus* under variable environmental conditions remain scarce. Here, we present preliminary results on behavioural, physiological, and sub-organismal responses to neonicotinoid exposure, complemented by field sampling in two semi-enclosed coastal systems with contrasting physicochemical profiles and resource availability. Analyses include bioaccumulation of trace metals, polycyclic aromatic hydrocarbons, organochlorinated and organobrominated compounds, and neonicotinoids, as well as biomarker responses across multiple tissues (biotransformation enzymes, metallothioneins, acetylcholinesterase, antioxidant enzymes, and lipid peroxidation).

These results provide baseline information on contaminant loads and biomarker profiles under differing environmental regimes and reveal pronounced sensitivity to neurotoxicants targeting crustacean cholinergic pathways. Overall, the findings support the potential of *C. sapidus* as an outlier sentinel species within integrated environmental pollution assessments, highlighting its relevance at the interface of ecological and human health risk.

Disclaimer/Disclosure:

Funded by the Spanish Ministry of Science, Innovation and Universities and the Spanish State Research Agency (MICIU/AEI/10.13039/501100011033; CRABMEDPOL project (PID2022-138720OA-I00))

2.09.P-Tu114 Revised EFSA Wildlife GD: Field study scale matters for birds and mammals - representativeness reconsidered

Tina Grimm¹, Martin Vallon¹, Imme Katzschnher², Silke Laucht², Oliver Jacoby², Kaat Brulez² and Ines Hotopp², (1)RIFCON GmbH, Germany, (2)Rifcon GmbH, Germany

For environmental risk assessments of pesticides, e.g. movement or occurrence data of birds and mammals in the agricultural landscape can be considered. The EFSA Bird & Mammal 2023 Guidance suggests that selected landscapes used for crop-related higher tier field studies to investigate vertebrates within the landscape should preferably contain at least 33.3% of the respective crop type. This fixed proportional threshold is intended to ensure that study sites are considered representative and conservative regarding assumed crop-species relation. However, this value is actually difficult to be classified without reference to the size of the area, and even for widespread and commonly grown crops like cereals > 30% coverage is rarely achieved in wider agricultural landscapes across Europe. As a result, the threshold often proves to be unrealistic for practical site selection regarding areas needed to contain diverse structures, such as several fields of different crops alongside natural habitats, water bodies or anthropogenic structures.

Moreover, vertebrate species interact with their environment at multiple spatial scales — from very local activity to e.g. large-scale movement ranges. Using habitat models and multi-scale mapping, we illustrate how the perceived representativeness of a ‘study site’ strongly depends on the chosen spatial frame. Small changes in the defined boundary can substantially affect the calculated crop share, while the ecological situation for the species remains unchanged.

We argue that representativeness should be based on the species and its ecology rather than on a numerical threshold. That would provide a more meaningful basis for field study site selection, improving ecological relevance and revealing most realistic field data for reliable use in environmental risk assessments for pesticides.

2.09.P-Tu115 Northern fulmar and black guillemot as monitoring organisms for environmental pollutants

Katrin Hoydal¹, Bjarta O. Johansen², Halla Weihe Reinert² and Sjúrdur Hammer², (1)Environmental Protection, Faroese Environment Agency, Faroe Islands, (2)Faroese Environment Agency, Faroe Islands

Black guillemot has been used as a monitoring organism for environmental pollutants for several years as part of the AMAP environmental monitoring in the Faroe Islands. Northern fulmars have also been monitored during the same time period, however more irregularly. In recent years, it has not been possible to obtain sufficient samples of black guillemot, and the monitoring has thus focused more on the Northern fulmar. The two species have different ecology and behaviour which may influence their exposure to various environmental pollutants analysed in the monitoring programme. In addition, there is also a partial human exposure purpose of our monitoring. Although black guillemot is a protected species (since the 1950s) and have not been consumed to a great extent in the Faroe Islands in recent years, the fulmars on the other hand are a popular food, and are consumed both as eggs, fledglings and adults, so monitoring fulmars holds a special human exposure relevance in addition to their ecological role and as a sentinel species.

Contaminants such as mercury (Hg) and persistent organic pollutants (POPs) have been analysed in black guillemot eggs since 2000, and heavy metals have been analysed in black guillemot liver since 1999. Fulmar eggs have been analysed sporadically since 2000 and became the primary seabird egg matrix in the monitoring programme from 2016. Fulmar muscle, and in some cases also liver, have been analysed for metals and POPs in the late 1990s and again since 2008, with PFAS included from 2016. The contaminant levels in black guillemot and fulmar are not directly comparable: Hg concentrations are higher in black guillemot, whereas POP concentrations are substantially higher in fulmar eggs. These differences are most likely due to different foraging methods, different distribution ranges, and other biological factors such as age at sampling. Contaminant levels in black guillemot are considered more representative of the long-range pollution reaching the Faroe Islands, since the black guillemot is more sedentary, forages locally, and has a more selective diet. Fulmars, on the other hand, forage over a wide area and have an opportunistic feeding strategy, resulting in contaminant levels that reflect pollution across a much broader geographical region. However, monitoring pollution in fulmars remains relevant for assessing human exposure, since fulmars and their eggs are still used as a food source.

2.09.P-Tu116 Implications of the Updated EFSA Guidance on Birds and Mammals: Evaluating the Use of the fTWA Factor in Risk Assessment

Ricardo Petersen¹, Apostolos Koutsafitis², Ana Raquel Sales³ and Ana Pereira³, (1)ERM - Environmental Resource Management, Portugal, (2)ERM - Environmental Resource Management, United Kingdom, (3)Ascenza Agro, S.A., Portugal

Risk assessment for birds and mammals exposed to plant protection products (PPPs) in the European Union has undergone a significant methodological shift with the transition from EFSA's 2009 Guidance to the updated EFSA 2023 Guidance, implemented in October 2025. Under the 2009 framework, chronic dietary exposure assessments systematically incorporated the time-weighted average factor (fTWA) to account for residue decline in treated crops over time. This approach assumed that long-term exposure was best represented by averaged concentrations, irrespective of the toxicological endpoint or residue dissipation dynamics.

The 2023 Guidance introduces a more nuanced paradigm: the application of fTWA is no longer default but contingent upon scientific justification. Specifically, its use depends on the nature of the endpoint (e.g., reproductive vs. growth) and whether chronic effects are driven by sustained exposure or short-term critical windows. This change introduces a requirement for endpoint-driven justification, ensuring that exposure estimates reflect the biological interpretation of the study results.

In this poster, we evaluated the impact of this regulatory shift by comparing risk assessments for selected active substances using publicly available ecotoxicology data used to define the regulatory agreed endpoints. For each substance, an assessment was made to evaluate whether fTWA application is justified under the new criteria and quantified its influence on toxicity-exposure ratios (TERs) and risk characterization outcomes.

Conversely, justified application of fTWA reduces conservatism without compromising ecological safety, particularly for substances with rapid dissipation and endpoints linked to prolonged exposure. These findings highlight the importance of transparent justification for fTWA use and consistent interpretation of study endpoints under EFSA's 2023 Guidance.

2.09.P-Tu117 How Appropriate is it to use Mammalian Model Deviation Ratios (MDRs) to Predict Mixture Toxicity in Birds?

Sarah Priestly¹, Helena Crosland², Nadine S Taylor² and Sonja Wich³, (1)RSK Adas Ltd., United Kingdom, (2)Cambridge Environmental Assessments (CEA), United Kingdom, (3)BASF, Germany

The new bird and mammal risk assessment guidance for plant protection products (PPPs) (EFSA 2023) requires mixture toxicity risk assessment using dose addition. If experimental data are available, a model deviation ratio (MDR) is calculated to estimate how well experimental data fits predicted mixture toxicity. According to EFSA (2023), when $MDR > 3$, effects greater than additive are assumed, suggesting synergistic interaction. However, MDRs are usually only calculable for acute mammal endpoints because bird formulation studies are unlikely to have been conducted (vertebrate testing reductions where possible). Therefore, extrapolation from mammals to birds is currently proposed, which assume physiological similarities and comparable sensitivity between taxa. This analysis evaluated whether extrapolating mammalian MDRs to predict mixture toxicity in birds is scientifically justified, and investigated potential sources of differences in mixture toxicity between birds and mammals.

Acute toxicity data and MDRs for 84 formulated products were analysed, comparing bird and mammal datasets. MDRs were evaluated based on mode of action, pesticide type, and formulation type. Study methodologies and physiological differences between species were examined. Toxic units (TUs) were investigated to explore

differential sensitivity patterns using a representative formulation as a case study.

All bird formulation studies with MDR > 3 (7/7, 100%) were derived from unbound endpoints (no effects at highest dose tested). Similarly, most mammalian formulation studies with MDR > 3 (7/9, 78%) were from unbound endpoints. In addition, TU analysis from the case study revealed that, although the compound with highest TU was highly toxic to birds alone, mammals showed greater sensitivity to the complete formulation, indicating different toxicity profiles across taxonomic groups.

The prevalence of unbound endpoints driving high MDRs suggests these values reflect testing limitations rather than true synergistic toxicity. Extrapolating mammalian MDRs to birds appears overly conservative due to physiological differences and data limitations, potentially inflating mixture toxicity risk assessments for birds. These findings underscore the importance of testing both taxa, as active ingredients exhibit different toxicity profiles across taxonomic groups that cannot be predicted from single-species data. New approach methodologies (NAMs) might be supportive to avoid further vertebrate testing.

2.09.P-Tu118 Bridging the Gap Between First Tier and Higher Tier Risk Assessments for Seed Treatment Plant Protection Products: Refinement Options for Birds and Mammals

Melissa Reed¹, Michael Fryer², Sofia Sangiorgi¹ and Sally Ralls¹, (1)Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom, (2)Ecotoxicology, Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom

Seed treatment plant protection products (PPPs) provide protection to crops against pathogens, diseases and pests from germination. Authorisation of these PPPs is subject to demonstration that their use does not result in unacceptable effects on non-target organisms, including birds and mammals. Demonstrating that the actual protection goal has been met, by clearly establishing that there will be no visible mortality and no long-term repercussions for abundance and diversity, has often proved challenging. In the UK, this has resulted in a reliance on emergency applications or import of treated seeds to meet growers needs.

The first tier risk assessment scheme for seed treatments in the EFSA bird and mammal guidance (EFSA 2009 and 2023) uses generic focal species to assess exposure and risk based on worst case assumptions. The treated seed itself can be a food source for granivorous species and the emerged seedlings can be a food source for herbivorous species.

In order to move away from worst case assumptions, data are required to refine the risk assessment. Some of these data are substance specific, others are common across substances and relate to the ecology and behaviour of birds and mammals.

Since the introduction of EFSA (2009), data on focal species and their use of farmland have been collected by regulatory authorities and applicants for authorisation of PPPs. There is also published ecological data in the scientific literature.

The UK currently relies on applicants to bring together the information they have generated or have available to perform the risk assessment, which can require complex weight of evidence approaches. The aim of this work is to bring together existing information from a variety of sources to provide standardised refinement options. This simplifies the initial stages of a higher tier risk assessment, while ensuring the required protection goal is met.

The work has considered unprotected data available to HSE to identify suitable bird and mammal focal species for a range of seed treatments in the UK. Refinements of the proportion of diet obtained in the treated area (PT) and the composition of diet obtained within the treated area (PD) associated with those focal species have been derived, where sufficient data exists, thus providing robust refinement options accessible to all applicants.

The options presented do not prevent the use of other refinements considered in the EFSA guidance, when suitable data are available.

2.09.P-Tu119 The known unknowns – An approach how to assess adverse effects of Anticoagulant Rodenticides in wildlife

Susanne Schwonbeck¹, Torsten Hahn¹ and Vesna Cerkenik Flajs², (1)Fraunhofer Institute for Toxicology and Experimental Medicine (ITEM), Germany, (2)Institute of Pathology, Wild Animals, Fish and Bees, University of Ljubljana, Ljubljana, Slovenia

Anticoagulant rodenticides (ARs) are found in wildlife and pets in many European countries and elsewhere. Their occurrence is primarily linked to the use of ARs as biocidal products for pest management and also to their use as plant protection products. However, little is known about effect levels, toxic thresholds, and precise routes of uptake in non-target animals. Secondary poisoning of non-target animals has been demonstrated by monitoring data in mammals (e.g. foxes, cats, dogs, pigs, sheep, bats) and birds (e.g. owls, kestrels, geese). This is assessed in regulatory dossiers, but calculations are mostly based on effect data from target animals. Toxicological data are often scarce, and when available, they frequently originate from the 1970s and 1980s and provide very little detail on data collection methods. Furthermore, more than one AR is often found in the livers of free roaming cats, dogs, or wildlife. In contrast, mixture effects are not addressed in regulatory dossiers. Here we present a collection of reviewed toxicological data from publicly available sources. These data were used to assess risks to wildlife and pets in a harmonised manner. This may help to improve understanding of the overall impact of ARs on non-target animals.

2.10 Microbial Ecotoxicology: From Ecosystem Resilience to Environmental Health

2.10.T-01 Pollutant Biodegradation Profile Mediated by Multi-trophic Microbial Dynamics in Rivers

Joëlle Serrana¹, Run Tian², Francisco J. A. Nascimento³, Elias Broman³, Benoit Dessirier³ and Malte Posselt⁴, (1)Department of Environmental Science, Stockholm University, Stockholm, Sweden, (2)University of Queensland, Australia, (3)Stockholm University, Sweden, (4)Department of Environmental Science, Stockholm University, Sweden

Microbial communities and environmental conditions are closely linked to ecosystem functions and directly govern the biodegradation of pollutants in aquatic environments. However, the role of multi-trophic interactions and their spatiotemporal dynamics in these processes remains poorly understood. Here, we examined how seasonal and spatial variations, mediated by trophic interactions within benthic microbial communities, influence their composition, functional capacity, and collective potential to degrade a diverse array of organic pollutants in rivers. By characterizing both prokaryotic (i.e., archaea and bacteria) and eukaryotic taxa (i.e., algae, fungi, protists, and metazoans), and inferring metabolic pathways, we explored the connections between community composition and pollutant degradation in wastewater-receiving rivers across four seasons. Mediation analysis revealed that multi-trophic communities mediate the total effect of environmental factors on the biodegradation of 96 organic pollutants. Prokaryotic communities explained 60% of the total environmental influence on pollutant biodegradation. Additionally, eukaryotic groups had significant indirect mediation effects, with fungal, protistan, algal, and metazoan communities responsible for 56%, 53%, 26%, and 38%, respectively. Notably, fungal and protist communities also mediated approximately 83% and 73% of the environmental impacts on prokaryotic community composition. We also found that spatial variation at the river and reach scale had a greater influence than seasonality in shaping benthic microbial communities. Our findings improve understanding of ecosystem resilience and support the development of predictive models and sustainable water management strategies in dynamic aquatic environments.

2.10.T-02 Impacts of Chronic Sodium Fluoride Exposure Followed by a Viral Challenge on Juvenile Rainbow Trout and Their Microbiomes

Marine Suchet¹, Jérôme Cachot¹, Pauline Pannetier², Emilie Chancere³, Morgane Danion² and Laure Bellec¹, (1)UMR EPOC 5805, Université Bordeaux, France, (2)Agence Nationale de Sécurité Sanitaire de l'Alimentation, de l'Environnement et du Travail, Laboratoire de Ploufragan-Plouzané, France, (3)Plateforme Génome Transcriptome de Bordeaux (PGTB), France

In recent years, ecotoxicological research progressively adopts a holistic holobiont perspective integrating the host and its microbiomes. However, multi-stress interactions, e.g. how pollutants affect microbiomes and host disease resistance, remain largely unstudied. Sodium fluoride (NaF) is a contaminant of renewed interest found in surface waters. Its acute toxicity is described, but chronic and microbiome-mediated impacts remain largely unexplored. This study aimed to determine how NaF exposure impacts the rainbow trout (*Oncorhynchus mykiss*) holobiont, and its response to a viral challenge. Trout were chronically exposed to environmentally relevant NaF concentrations (0, 5, 17 mg/L) for 7 months, before being challenged with the Infectious Hematopoietic Necrosis Virus (IHNV). Trout tissues (gill, skin, gut) were sampled at 7 months or 96h, 1 and 6 weeks post-infection. DNA was extracted and the v3-v4 region of the 16S rRNA gene was amplified and sequenced for metabarcoding. Reads were processed using FROGS v5 and analysed for microbial diversity and composition. NaF exposure induced tissue-specific microbiome changes: while Alpha-diversity and microbial interconnexions decreased in gills, both increased in skin following NaF exposure. Beta diversity was significantly affected in the three tissues. Impacts on the microbiomes also differed depending on the exposure

concentration: Bêta diversity significantly differed between trout exposed to 5 or 17 mg/L in gills and microbial interconnexions alterations were more pronounced in 5 mg/L condition. This pattern was also observed for mortality: trout exposed to 17 mg/L exhibited higher mortality after the viral infection compared to unexposed fish, whereas this was not the case for trout exposed to 5 mg/L. An increase in the relative abundance of potential pathogenic taxa was also reported in gills and gut samples following NaF exposure. Microbiome analyses suggest a temporal evolution of microbiome diversity and composition after the infection (96 h, 7 days or 6 weeks). These analyses also enabled characterization of microbiomes from fish that survived the viral challenge. To conclude, NaF exposure significantly affected the trout microbiomes in a tissue-specific manner, and the two tested concentrations exhibited different impacts. Further analyses will explore how prior NaF exposure influences microbial communities and their relationship with host immunity after a viral challenge.

2.10.T-03 Cryogenically milled tire tread induces functional and structural changes in natural periphyton communities

Sara Isabel Bastos Gonçalves¹, Alexandra Kroll², Thibault Masser³, Anna Toso⁴, Alan J Bergmann⁵, Etienne Vermeirssen⁵, Florian Breider³, Benoît J.D. FERRARI² and Kristin Schirmer⁶, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Ecotox Centre, Switzerland, (3)Swiss Federal Institute of Technology Lausanne (EPFL), Switzerland, (4)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (5)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Switzerland, (6)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Tire and road wear particles (TRWP) are generated through abrasion and subsequently accumulated along the roadside, where they can be transported into nearby soils and surface waters. Environmental concentrations of TRWP are generally not expected to exceed 10 mg/L in streams although concentrations reaching the g/L range have been reported in extreme situations. While interest in TRWP and their related chemicals has grown, their interactions with periphytic biofilm communities remains poorly understood. Such communities are complex assemblages of microorganisms, including algae, bacteria and fungi, at the base of aquatic food webs. They have a key role in various processes, such as photosynthesis and biogeochemical cycles. Naturally growing and covering large surfaces of the freshwater streambeds, periphyton can also act as a sink for a diverse range of particles and chemicals, including TRWP. In this study, we used cryogenically milled tire tread (CMTT) as a TRWP surrogate to (Experiment 1) expose periphyton to three CMTT concentrations (50, 500, and 1000 mg/L) and a control for 14 days, and (Experiment 2) compare periphyton responses to CMTT particles (1000 mg/L) and their associated chemicals over 4 days. In both exposure scenarios, approximately 25–30% of CMTT became associated with the periphyton assemblage, highlighting its role as a sink for tire-derived particles. Photosynthetic efficiency showed slight declines at the highest concentration (1000 mg/L, Exp. 1 & 2) and in associated chemicals-only (Exp. 2) treatments, while algal biomass (chlorophyll a) decreased by ~30% after 14 days at 500–1000 mg/L. For Experiment 1, shifts in periphyton's structure and composition were observed at all CMTT concentrations tested. Above all, we observed the near disappearance of the bacterial phylum Firmicutes in presence of CMTT and substantial reductions in diatom abundance (45%, 85%, and 70% at 50, 500, and 1000 mg/L, respectively). These declines corresponded with increased relative abundances of cyanobacteria and green algae at 50-500 mg/L CMTT. In Experiment 2, exposures to CMTT-related chemicals alone produced effects comparable to those of CMTT particles, indicating that chemical leaching largely drove the observed responses. Overall, these findings suggest that periphyton communities can both influence fate, retention and effects of tire particles and associated chemicals in aquatic environments and undergo CMTT-induced ecological changes.

Disclaimer/Disclosure:

The work presented, including production, handling, distribution and information related to CMTT, was funded by the World Business Council for Sustainable Developments (WBCSD) Tire Industry Project (TIP). TIP is a global CEO-led initiative undertaken by leading tire-manufacturing companies. TIP drives research on potential human health and environmental impacts of tires throughout their lifecycle. Solely the authors conducted the study design, execution, interpretation, and abstract preparation.

2.10.T-04 Environmental concentrations of the fungicide tebuconazole alter microbial biodiversity and trigger biofilm-released transformation products

Natàlia Corcoll¹, Daniela Gomez-Martinez², Anders K Nilsson³, Erik Kristiansson⁴, Henrik R Nilsson⁵ and Eric Carmona Martinez⁶, (1)University of Gothenburg, Sweden, (2)Dept of Biological and Environmental Sciences, Center for Future Chemical Risk Assessment and Management Strategies (FRAM), University of Gothenburg, Sweden, (3)Section for Ophthalmology, Dept of Clinical Neuroscience, Institute of Neuroscience and

Physiology, Sahlgrenska Academy, University of Gothenburg, Sweden, (4)Dept of Mathematical Sciences, Chalmers University of Technology and University of Gothenburg, Sweden, (5)Dept of Biological and Environmental Sciences, University of Gothenburg, Sweden, (6)Department of Effect-Directed Analysis, Leibniz Institute for Tropospheric Research, Germany

Although aquatic microbes are relevant components of riverine biodiversity, they are largely neglected in current risk assessments frameworks. In this regard, ecotoxicological data on the effects of fungicides on aquatic microorganisms - including fungal communities - are essential for informed risk assessment and regulation. In the European context, azole fungicides have recently been added to the Watch List due to growing concern about their hazardous properties. In this study, we investigate the ecotoxicological effects of both chronic and acute exposure to the azole fungicide tebuconazole on the biomass and diversity of fungi, bacteria, and algae in stream biofilms using an RNA metabarcoding approach. In addition, the study uses LC-MS/MS to evaluate the capability of biofilms to metabolize tebuconazole. Natural biofilm communities from a Swedish stream were exposed chronically (24 days) and acutely (96 h) to environmental concentrations of tebuconazole (10 and 100 µg/L) in microcosms conditions. The diversity and community structure of fungi and bacteria were assessed by ITS2 and 16S cDNA metabarcoding, respectively. Biofilms chronically exposed to tebuconazole produced and released unidentified transformation products into the water column, suggesting a biotransformation capability following 24 days of uninterrupted exposure. The fungal biomass markedly decreased by a biomass loss of 40% when chronically exposed to 10 µg/L, and 60% when chronically exposed to 100 µg/L. Bacterial and algal biomass remained comparable with the controls in all tebuconazole treatments. Fungal and bacterial alpha diversity metrics were not significantly affected, although a decreasing trend in fungal richness was observed with the treatments. However, beta diversity was significantly affected in both fungal and bacterial compartments. Chronic exposures resulted in a shift in community composition, where taxa potentially more tolerant to tebuconazole (i.e. Lecanoromycetes) replaced more sensitive taxa (i.e. Malasseziomycetes). This study indicates that tebuconazole at environmental concentrations might pose a risk to freshwater systems, mainly due to its high toxicity to fungi.

2.10.P Microbial Ecotoxicology: From Ecosystem Resilience to Environmental Health

2.10.P-Tu120 Aquatic Biofilm as an Ecotoxicological Test System: A Systematic Review of Controlled Exposure Studies

Sonja Schaufelberger¹, Pedro A. Inostroza² and Thomas Backhaus¹, (1)RWTH Aachen University, Germany, (2)Biological and Environmental Sciences, RWTH Aachen University, Germany

The majority of aquatic microorganisms doesn't live planktonic but is organised in biofilms covering submerged surfaces such as rocks, sand or macrophyte leafs. These complex assemblages consisting of algae, bacteria, fungi, protozoa and viruses are vital for the functioning of aquatic ecosystems, contributing to primary production, nutrient cycling, and degradation of pollutants. As ecotoxicological test system, it poses additional challenges compared to single-species assays but can offer more realistic insights into environmental effects of pollutants and allows the investigation of community level effects. Fast growth, minimal space requirements and a multitude of different endpoints make it an ideal choice for researchers. This review provides an overview of current knowledge on the effects of contaminants on aquatic biofilms, compares methodologies and highlights research gaps as a foundation for future studies.

A systematic literature search was conducted using Scopus and Web of Science to identify studies exposing aquatic biofilm to chemical pollutants under controlled laboratory conditions. Data retrieved from the study reports include biofilm origin and age, substrate, test substances, exposure design (i.e., single/mixture, duration, recovery time), endpoint categories, and whether interactions with other stressors were assessed; and analysed statistically.

Herbicides, antibiotics, and metals are the most frequently tested chemical classes investigated in the various biofilm assays. Most experiments expose aquatic biofilm to single substances; mixtures of more than two compounds are rare. Mixtures are almost exclusively composed of chemicals from the same class (e.g., two pesticides), cross-class mixtures (e.g., pesticide + pharmaceutical) are underrepresented. About half the studies test only one or two concentrations. Only few determine effect concentrations such as EC50 values, hampering comparisons. While community composition remains a common endpoint, molecular methods such as metabarcoding increasingly replace microscopy. OMICs approaches like transcriptomics and metabolomics are also emerging. Current research focuses strongly on the phototrophic community using endpoints such as chlorophyll concentration or photosynthetic activity, and to a lesser extent, bacterial metabolism. In contrast, impacts on fungi, protozoa, and viruses remain underexplored, underlining the need for more inclusive and functionally diverse testing frameworks.

2.10.P-Tu121 Optimizing a Periphytic Biofilm-based Bioassay for Ecologically Relevant Effect-Directed Analysis

Asadulla Hil Galib¹, Adibia Umoroye Nathan², Lorenzo Proia³, Nicolas Creusot⁴, Sandra Perez Solsona⁵ and Victoria Osorio¹, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (2)University of the Basque Country (UPV/EHU), Spain, (3)University of Vic - Central University of Catalonia (UVic-UCC), Spain, (4)National Research Institute for Agriculture, Food and Environment (INRAE), France, (5)Environmental Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

In aquatic systems, chemical contaminants usually occur as complex mixtures that can impact ecosystems even at trace levels, while standard monitoring often overlooks their combined effects. Effect-Directed Analysis (EDA) links toxicity to causative compounds by combining bioassays, chemical analysis, and fractionation. But it lacks ecological relevance as typical EDA bioassays target narrow in vitro or cellular endpoints. This study addresses these gaps by advancing an ecologically relevant EDA framework that uses natural freshwater biofilms as model communities. Made up of autotrophic and heterotrophic organisms, biofilms are sensitive to stress and serve as indicators of ecosystem condition. By integrating early metabolic disruptions with functional and community-level responses, this approach aims to identify key toxicants in mixtures and enhance the ecological relevance of EDA outcomes.

Biofilm bioassays were run in 6-L microcosms mimicking oligotrophic streams, using nutrient-enriched water, recirculation, and sterilized glass tiles for 21 days of colonization. For dose-response tests, tiles were randomly moved to 6-well plates and exposed to a nine-compound sub-mix (Diuron, Bisphenol-A, Atrazine, Terbutryn, Acetaminophen, Clarithromycin, Carbamazepine, Diclofenac, Triclocarban) spanning diverse physicochemical properties. Short-term exposures (6–48 h) at six concentrations across 0–50 µg/L included a chemical-free control and a 0.5% methanol control. Phototrophic community composition and photosynthetic efficiency were assessed at 0, 6, 24, and 48 h.

Biofilm community composition remained stable throughout the 48-hour exposure, with no significant differences across replicates or treatments, highlighting the resilience of biofilms to short-term chemical stress. In contrast, Photosynthetic efficiency was highly responsive, showing a dose-dependent drop with significant declines at 10 and 50 µg/L from 6 h through 24 h. The results show that fluvial biofilms offer sensitive, ecologically relevant endpoints suitable for integrating into Effect-Directed Analysis to identify and prioritize toxic surface-water contaminants. Upcoming work will test additional biofilm endpoints, such as enzyme activity, cell viability, live/dead bacteria ratios, and metabolomics, and validate the most suitable ones using a complex mix of 80 diverse CECs. The final goal is to apply this refined EDA to surface waters to evaluate acute mixture impacts and pinpoint key stressors

2.10.P-Tu122 Effects of Different Types of Biochar on the Microbial Activity and Community Composition of PFAS- and PAH Contaminated Soils

Ingrid Rijk¹, Maria Florberger², Alf Ekblad³, Maria Larsson⁴, Anna Kärrman⁵, Dan Berggren Kleja⁶, Anja Enell⁶, Sigrun Dahlin⁷, Susanne Karlsson⁸, Matilda Wiberg⁹, Melody Vachon-Gregory¹⁰ and Philip Dennis¹⁰, (1)School of Science and Technology, Örebro University, Örebro, Sweden, (2)Geosyntec Consultants AB, Sweden, (3)School of Science and Technology, Örebro University, Sweden, (4)MTM Research Centre, Örebro University, Sweden, (5)Örebro University, Sweden, (6)Swedish Geotechnical Institute, Sweden, (7)Swedish University of Agricultural Sciences, Sweden, (8)Structor Miljö Öst, Sweden, (9)Structor Miljöteknik, Sweden, (10)SiREM, Canada

Biochar is a carbonous, porous material produced by pyrolysis of biomass, which can be potentially used as an amendment for soil remediation, whereby contaminants are stabilized and ecological restoration of soil is promoted. However, the profound effects that these sorbents can have on soil microorganisms remains an area requiring further research. Here, we investigated the effects of different biochar treatments in various contaminated soils.

Two per- and polyfluoroalkyl substances (PFAS) contaminated soils were treated with either 1% compost and

NPK fertilizer alone or combined with 2% (w/w) of either wood-based activated carbon or sewage sludge-based biochar. Two soils that were contaminated with polycyclic aromatic hydrocarbons (PAH) were treated with compost and fertilizer, alone or combined with two types of wood-based biochar, added to 3% (w/w). To analyze effects on soil microorganisms, we combined next generation sequencing providing information on microbial community structure, diversity and functional analysis, with the analysis of microbial respiration using a stable isotopic approach.

The treatments with biochar, compost and fertilizer increased the rate of microbial respiration of the soils, except for one soil that had a higher baseline soil quality compared to the other soils which were more nutrient-poor. The functional diversity of the soils decreased somewhat due to the addition of compost and fertilizer, which was also added to the treatments with biochar. However, there was an increase in the Shannon diversity index in samples treated with biochar, compared to compost and fertilizer only. The microbial community showed shifts in species composition between the treatments and some differences between the different types of biochar. A positive trend was seen in the increased presence of the bacteria *Sphingomonas* in PAH-contaminated soil, which is a known PAH degrader, potentially signaling a higher bacterial degradation capacity.

In summary, biochar and nutrient treatments have most profound effects on the microbial communities in nutrient-poor soils. The addition of biochar can be beneficial to maintain microbial diversity under nutrient addition and potentially promote contaminant degradation. A combined functional and structural approach provides better insights into the changes in microbial communities in biochar remediated contaminated soils, and can help us better assess performance and to optimize biochar remediation systems.

2.10.P-Tu123 Impacts of Perfluorobutanoic Acid (PFBA) on the Growth of Filamentous Cyanobacteria (*Microseira wollei*) and the microbial community at Environmentally Relevant Concentrations

Jacob Cram¹, Judy O'Neil¹, Joseph Pitula², Wayne Omagame² and Michella Paige Salvitti², (1)University of Maryland Center of Environmental Science - Horn Point Lab, United States, (2)University of Maryland Eastern Shore, United States

Per- and polyfluoroalkyl substances (PFAS) are increasingly detected in aquatic systems, yet their impacts on primary producers and associated microbial communities remain poorly understood. Perfluorobutanoic acid (PFBA), a short-chain PFAS widely found in surface waters, may pose distinct impacts on growth and community dynamics. This study investigates how PFBA exposure influences the growth of the filamentous cyanobacterium *Microseira wollei* and alters the surrounding microbial community. We conducted laboratory exposures in which cyanobacterial cultures were treated with environmentally relevant PFBA concentrations (1 ng/L, 10 ng/L, 100 mg/L, and 100 ug/L) for 21 days. Cyanobacteria were grown in all concentration with site water that was autoclaved and site water that was untouched. Cyanobacteria grown in site water that was not autoclaved at 100 ug/L grew significantly longer ($p = 0.012$) than the control group. Cyanobacteria that were grown in autoclaved site water showed no significant growth changes. Additionally, for all concentrations of cyanobacteria that were grown in unautoclaved site water, the cyanobacteria that survived for 21 days had symbiotic growth. At day 21 of the study, all the dead cyanobacteria had no symbiotic growth. Our results suggest that PFBA stimulates cyanobacteria growth and impacts the microbial community associated with this cyanobacteria species. These findings provide new insight into how short-chain PFAS may influence cyanobacterial dynamics and the structure of freshwater microbial communities.

2.10.P-Tu124 Microbial Infallibility to Degrade Per- and Polyfluoroalkyl Substances

clara van Meegen, samuel bickel and gabriele berg, Tugraz, Austria

The microbial infallibility hypothesis suggests that microorganisms can evolve to degrade any organic compound. Per- and polyfluoroalkyl substances (PFAS) challenge the microbial infallibility hypothesis due to their extreme persistence and the exceptional stability of the C-F bonds. Despite this, emerging evidence suggests that long-term microbial exposure can induce adaptive shifts in genomic, transcriptomic, and metabolic pathways with potential relevance to PFAS transformation. In this work, we investigate how PFAS influences the bacterial genomic potential and quantify how PFAS exposure reshapes bacterial communities.

We hypothesize that: (i) long term exposure accumulates PFAS degraders, in line with microbial infallibility, (ii) short-term exposure provides insight into the genetic machinery of responders, and (iii) isolates from sites with legacy exposure respond differently to acute PFAS exposure compared to isolates from non-contaminated sites.

We collected data from controlled studies analyzing the microbiome with PFAS exposure. We assessed the

effect of short-term and long-term PFAS exposure on bacterial community composition. The meta-analysis provides a general and robust overview of microbiome shifts under legacy PFAS exposure. *Delftia acidovorans*, a taxon described as PFAS-degrading in the literature, emerged in our analysis together with several additional candidate species. These taxa will be isolated and subjected to targeted degradation assays in follow-up laboratory work. Our findings reveal candidate species for PFAS degradation and pave the way to identify the genetic background for potential PFAS remediation.

2.10.P-Tu125 Inhibition and Metabolic Responses of Aquatic Hyphomycetes to the Fungicide Tebuconazole - an Easy to Apply Laboratory Approach

Silvia Mohr¹, Björn Kusebauch², Stefan Bader², Christiane Baschien³, Valeska Contardo Jara⁴ and Steffen Carl², (1)IV 2.5, German Environment Agency (UBA), Germany, (2)German Environment Agency (UBA), Germany, (3)Leibniz Institute DSMZ, German Collection of Microorganisms and Cell Cultures GmbH, Germany, (4)Zentrum für Wasser- und Chemikalienforschung, German Environment Agency (UBA), Germany

Aquatic hyphomycetes (AH) are key drivers in the decomposition of organic matter such as leaf litter in streams. Thus, AH provide an important bottom-up function for freshwater ecosystems. Although there are several studies about the effects of plant protection products on leaf associated AH communities, the sensitivities of single AH species towards fungicide stress remain understudied. In the present study, we tested the effects of different concentrations of the azole fungicide tebuconazole (TBZ) on the growth of nine aquatic hyphomycete species in 2% malt extract broth (endpoint: dry mass). Two species (*Neonectria lugdunensis* and *Flagellospora curvula*) showed significantly lower growth beginning with nominal concentrations of 50 µg/L TBZ, whereas three species (*Tetracladium marchalianum*, *Clavariopsis aquatica*, and *Anguillospora crassa*) showed no significant growth inhibition. These results confirm different tolerances of certain AH species towards fungicide stress that were reported in previous studies with leaf litter associated fungal communities. Interestingly, varying TBZ concentrations and metabolites in the malt extract broth were observed at the end of the experiments, indicating that the fungi are dealing differently with fungicide stress. This finding is supported by first results from the quantification of ergosterol (fungal cell wall molecule whose biosynthesis is inhibited by azole fungicides) as well as differing concentrations of selected TBZ metabolites in the culture medium. Further research should focus on the reasons for different sensitivities (e.g. fungicide resistance and metabolization) in order to facilitate the choice of responsive indicator organisms and the development of standard test systems for aquatic fungi.

2.10.P-Tu126 Microbial–Plant Biostimulants Enhance *Medicago sativa* Growth Under Metal and Drought Stress

Ana Rita R. Silva¹, José Nereu Pinto¹, Marija Prodana¹, Patricia Verissimo Silva¹, Diogo Filipe Nunes Cardoso¹, Susana Loureiro² and **Sara Peixoto¹**, (1)CESAM, University of Aveiro, Portugal, (2)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal

Organic agriculture has emerged as a crucial strategy for promoting sustainable and environmentally responsible food production. Microbial biostimulants (mPB) have become natural alternatives to fertilisers, stimulating plant growth by improving soil nutrient availability. Nonetheless, their performance under anthropogenic stress and water-deficient conditions remains insufficiently characterised, highlighting the need for further empirical investigation. Therefore, this study aimed to assess the performance of a commercial mPB containing *Pseudomonas fluorescens* and *Azospirillum brasilense* in a soil historically contaminated with metal(loid)s under drought stress. A plant pot experiment was conducted using two soils: metal-contaminated soil from Estarreja (Aveiro, Portugal) and uncontaminated natural standard soil (Lufa 2.2). Each soil underwent two moisture treatments: one simulating a standard condition (50% water-holding capacity, WHC) and the other simulating a drought condition (25% WHC), both with and without mPB application. The mPB was applied 5 days after seed addition to the soil using a recommended field concentration. After 21 days of growth under controlled light and temperature, soil and plant samples were analysed for germination, plant biomass, mercury concentration in dry shoot, soil enzymatic activities, pH, and electrical conductivity (EC). Results revealed that *M. sativa* germination and growth were significantly influenced by soil type, drought stress, and mPB application. Drought conditions significantly delayed germination (delay of 5 days) and reduced root length and biomass in Estarreja soil. Nonetheless, the mPB application partly mitigated these adverse effects, improving the germination index and stimulating root and shoot growth under metal stress and limited water availability. Mercury concentrations in shoots were primarily influenced by soil type, being up to ten times higher in Estarreja soil than in Lufa 2.2, regardless of mPB presence. Soil enzymatic activities (urease, β -glucosidase, and dehydrogenase) were generally reduced in Estarreja soil. Generally, drought reduced these activities, but the application of mPB enhanced dehydrogenase. Ultimately, these findings suggest that microbial inoculants can mitigate drought-induced stress and enhance plant and soil functioning in metal-polluted environments. The use

of mPB represents a promising strategy for improving crop performance under combined environmental stressors.

2.10.P-Tu127 Alginate-bead delivery of fungal inoculum improves plant physiological response under saline stress

Carlos Silva¹, Paulo Cardoso², Isabel Lopes² and Cátia Venâncio², (1)GEOBIOTEC, Geosciences Department & Center for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal, (2)CESAM, University of Aveiro, Portugal

Soil rot fungi can greatly impact soil structure and functionality, which may be particularly relevant for poorly structured and/or nutrient deficient soils. Fungal bioencapsulation, by providing more favorable conditions for early fungal development, may be an efficient way to introduce fungi into soil, especially in those under some type of stress, like salinity.

In the present work, lyophilized mycelium of *Pleurotus sajor-caju* was encapsulated in alginate beads produced with two different sizes (50 or 30 µL per droplet) and two viscosities (high and low, H and L, respectively). Aiming at assessing improvements after fungal beads addition, 14-days seedling emergence and growth tests were performed with *Zea mays* (maize) and *Brassica rapa* (turnip) following OECD Test No. 208 in OECD artificial soil, in the absence and presence of an abiotic stressor (salinity). The following treatments were tested: Control (no beads), 30 LV, 30 HV, 50 LV, 50 HV under no salinity (0 mS/cm) and under salinity (4 mS/cm). Plant response was evaluated through measurements of growth (length and weight), soluble sugar content, and chlorophyll content.

Results show that for *Z. mays*, salinity caused a significant increase in chlorophyll b content. Salinity also caused a decrease in the aerial dry weight in the 50 µL beads of both viscosities. There was a significant increase in sugars concentrations for the 50 LV beads compared to the control for both salinity levels. There was also a general tendency for increased production of photosynthetic pigments and weight in treatments with beads, indicating possible positive effects attributable to the beads.

For *Brassica rapa*, salinity led to a significant decline in dry weight in the controls. Salinity led to a significant decrease in chlorophyll a in control and the 50 HV beads. Results also show a tendency for higher weights in treatments with beads, which is indicative of seemingly positive effects of the bead's presence.

Overall, these results support the use of alginate beads as a vehicle to inoculate fungi into soil. Results also show a positive impact of the fungal-loaded beads in some plant growth parameters and notably, a positive impact on the ability of plants coping with salinity.

2.10.P-Tu128 Effects of the Antimicrobial Benzalkonium Chloride on the Host Microbiome of Aquatic Insects and Riparian Spiders

Sara Gharouni Saffar¹, Milena Esser¹, Jose Luis Rodriguez Gil², Lauren Timlick² and Karen A. Kidd¹, (1)McMaster University, Canada, (2)International Institute for Sustainable Development (IISD), Winnipeg, Canada

Benzalkonium chloride (BAC) is a potent antimicrobial commonly used in disinfectants and sanitizers. Its use has increased globally in industrial, clinical, and household settings and it has been detected in surface waters downstream of municipal wastewater treatment plants. A whole lake experiment is being done at the International Institute for Sustainable Development – Experimental Lakes Area (IISD-ELA) in northwestern Ontario, Canada, to assess the effects of BACs on a lake's food web. Baseline sampling was done in 2024 and BAC additions (target 2,000 ng/L) occurred weekly from June to October, 2025. As part of this larger study, we collected macroinvertebrate larvae and adults (dragonflies, damselflies, chironomids, mayflies) and their riparian spider predators (tetragnathids and araneids) before and during BAC additions from the experimental and reference lakes. Bacterial DNA was extracted from whole invertebrates (n=6-10/taxon), and the communities were characterized using 16S rRNA gene amplicon sequencing. Baseline data from 2024 indicates that larval insects had the highest diversity of ASVs whereas spiders had the lowest diversity across both lakes.

Multivariate analyses indicated that the bacterial communities of larval insects differed among taxa and lakes, and were mainly dominated by the phylum Pseudomonadota (except tetragnathids and chironomids). In contrast, tetragnathid spiders and chironomids were dominated by the phylum Bacillota. Endosymbionts such as *Spiroplasma*, *Wolbachia*, and *Tyzzzeria* were found in some larval insects and all spiders. Analyses of samples from 2025 are ongoing and will be used to assess whether BAC exposure shifts the composition of invertebrate microbiomes in this lake.

2.10.P-Tu129 Diversity of Microbial and Macroinvertebrate Communities Growing on Plastics and Bioplastics in a Pristine Mountain Stream

Selma Abdelhak¹, Yoann Menard¹, Mar Oliva-Albert², Daniel Boix², Jordi Sala², Jan Tomàs², Maria L Moraza³, Alba Bellostas-Carreras², José-Luis Guijosa-Ortega², Anna Domènech-Pascual², Judith Boadella², Joan Pere Casas-Ruiz², David Pineda⁴, Laura Ayuso⁴, Anna Lupon⁴, Eugènia Martí⁴, Helena Guasch⁴, Anna M. Romani² and Joan Artigas⁵, (1)University of Clermont Auvergne, France, (2)University of Girona, Spain, (3)University of Navarra, Spain, (4)CEAB-CSIC, Spain, (5)Agence Comptable Service Facturier, University of Clermont Auvergne, France

Activities such as hiking, climbing, skiing and camping put significant pressure on mountainous aquatic ecosystems. Although the ecological transition encourages the use of bioplastics, it is unclear whether these materials allow colonisation and degradation by microorganisms and macroinvertebrates similar to that of natural substrata. This study compares the colonisation of two bioplastics (polyhydroxyalkanoate (PHA) and polylactic acid (PLA)), two plastics (polyethylene (PE) and polypropylene (PP)) and wood by microorganisms and macroinvertebrates in the aquatic and terrestrial habitats of a mountain stream in the Pyrenees. Each material was placed in three evenly distributed transects in the stream and riparian forest for one year. Four samples were collected, one in each season, and the substrata were analysed for bacterial and fungal diversity using MiSeq 16S rRNA and ITS3-4 gene analyses, as well as for taxonomic identification of macroinvertebrates. The results showed that the type of substrata affected the richness of bacterial species, but not their Shannon index or the richness and indexes of fungal and/or macroinvertebrate communities. Specifically, bacterial species richness was significantly higher in wood than in the plastics deployed in the stream. Non-metric multidimensional scaling plots showed that the bacterial and fungal community compositions in wood differed significantly from those on plastics in the stream. Co-occurrence networks including bacterial, fungal and macroinvertebrate taxon abundances show a greater number of nodes establishing strong correlations (Spearman's rho >0.9) in bioplastics (PLA =121, PHA =101) than in plastics (PE =96, PP =94). In conclusion, both bioplastics and plastics are colonised by communities of microorganisms and macroinvertebrates that are similar in terms of alpha- and beta-diversity, but differ in terms of community interactions. Most of the colonisation differences observed between plastic and wood substrata in the aquatic habitat were no longer apparent in the terrestrial habitat. This is probably due to greater leaching of plastic additives into the water, which would exert greater selection pressure on colonising biological species.

2.10.P-Tu130 Tiny Tenants, Big Impact: Deciphering the Mechanisms Linking Gut Microbes to Invertebrate Physiology

Alexander Feckler¹, Hannah Siebert¹, Eric Bollinger¹, Sven Katzenmeier¹, Hans-Werner Breiner¹, Davide Degli Esposti², Ondrej Adamovsky³, Hana Vespalcova⁴, Eva Bundinská⁴, Thorsten Stoeckl¹ and Mirco Bundschuh¹, (1)RPTU University of Kaiserslautern-Landau, Germany, (2)National Research Institute for Agriculture, Food and Environment (INRAE), France, (3)Recetox, Masaryk University, Czech Republic, (4)Masaryk University, Czech Republic

Host-associated microbiomes play crucial roles in nutrient uptake and processing, yet disturbances can profoundly affect host health. While such effects are well known in humans and mammals, consequences for (aquatic) invertebrates remain poorly understood. Evidence suggests that chemical stress can alter the gut microbiomes of invertebrates, potentially influencing host physiology. To explore these interactions, we conducted experiments with the leaf-shredding amphipod *Gammarus fossarum*, exposing specimens to the antibiotic ciprofloxacin, the fungicide azoxystrobin, and their mixture via water, food, or both, to assess direct microbiome effects. A second experiment involved exposure to the insecticide thiacloprid via water to

investigate host-mediated, indirect microbiome responses.

Exposure to ciprofloxacin, azoxystrobin, and their mixture altered the relative abundance of several bacterial classes, including Verrucomicrobiae and multiple Proteobacteria, with effect directions depending on the antimicrobial. Phylogenetic Investigation of Communities by Reconstruction of Unobserved States (PICRUSt) analyses predicted enhanced lipid and energy metabolism, particularly under dietary and combined exposure, suggesting potential implications for host physiology. Previous studies on the same species reported up to 25% higher biomass gain under these exposure routes, while waterborne exposure showed negligible effects. Although microbiome and proteome analyses from the second experiment using thiacloprid as a stressor are ongoing, we observed a dose-dependent reduction in feeding rate and significant shifts in fatty acid content and composition. These findings indicate altered lipid and energy metabolism, potentially driven by gut microbiome changes.

Overall, our results highlight the gut microbiome as a promising driver explaining physiological responses in invertebrates under chemical stress, emphasizing its relevance for understanding contaminant effects on aquatic ecosystem health.

2.10.P-Tu131 Antiviral Effects on Methane Formation in Freshwater Sediments

Eric Bollinger¹, Alexander Feckler¹, Hajar Bourassi¹, Andreas Maccagnan², Christa McArdell² and Mirco Bundschuh¹, (1)Rhineland-Palatinate Technical University Kaiserslautern-Landau, Germany, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Antiviral substances are used in large quantities to combat viral diseases but inadvertently enter aquatic ecosystems. Yet their impacts on sedimentary microbiomes and key biogeochemical processes remain poorly understood. Methane formation (i.e., methanogenesis) is a central anaerobic pathway in freshwater sediments fueling both organic matter processing and the release of this greenhouse gas. Considering recent evidence for other pharmaceuticals, such as antibiotics, influencing this process through alterations in the sediment-associated microbial community, we hypothesize that antiviral substances may cause a similar outcome by modulating viral-bacterial interactions.

To address this question, we conducted controlled sediment microcosm incubations and quantified methane production at six levels of the antiviral agent Oseltamivir carboxylate (0.01-1000 µg/L). In parallel, sequencing of the 16S rRNA gene was used to resolve changes in bacterial and archaeal taxa. This approach allowed us to link functional responses in methane production with community-level shifts.

Oseltamivir exposure consistently suppressed methane formation during the initial phase of the incubation. While this pattern continued throughout the study at the highest treatment, effects diminished at lower concentrations as incubation progressed. Metabarcoding revealed rather minor effects on community composition compared to earlier studies with antibiotics, which suggests a latent but ecologically meaningful disturbance.

Our findings show that antiviral agents can disrupt the activity of methanogenic communities in freshwater sediments, while structural changes are comparatively minor. This highlights a new and distinct pathway of toxic action that is rather driven by viral-bacterial interactions and their effects on bacterial performance instead of direct bactericidal effects shifting the community. This work advances understanding of how emerging contaminants influence carbon-cycling and underscores the importance of the understudied group of antiviral agents.

2.10.P-Tu132 Urban Infrastructure Impacts on Freshwater Periphyton Microbiomes: The Aachen Case Study

Valeria Ascani¹ and Pedro A. Inostroza², (1)Institute for Environmental Research (IFER), RWTH Aachen University, Germany, Germany, (2)Institute for Environmental Research (IFER), RWTH Aachen University, Germany; Department of Biological and Environmental Sciences; University of Gothenburg, Gothenburg, Sweden, Germany

Urban freshwater systems are increasingly affected by anthropogenic pressures, including wastewater treatment plant (WWTP) discharges, eutrophication, and hydromorphological modifications such as canalisation. These pressures can alter the composition of aquatic microbiota, which plays a central role in biogeochemical cycling by mediating nutrient turnover, organic matter degradation, and pollutants transformation or removal.

Periphyton, a complex biofilm assemblage colonizing submerged surfaces, is a key component of stream ecosystems, acting as a “solar-powered biochemical reactor.” Its high ecological relevance and sensitivity make periphyton a suitable bioindicator for assessing water quality and ecosystem integrity in human-impacted rivers. This study aimed to evaluate how bacterial periphyton diversity responds to urbanization and WWTP inputs along a pollution gradient in small- to medium-sized urban areas. Genomic DNA was extracted from periphyton

biofilms collected at 7 sites (i.e., reference, urban, upstream-WWTP, and downstream-WWTP). The 16S rRNA gene (V3–V4) was amplified and sequenced using high-throughput Illumina technology. Bioinformatic analyses (QIIME2, DADA2) were applied to characterize α - and β -diversity patterns and taxonomic restructuring. The river microbiome displayed a clear spatial pattern primarily shaped by urban pressure. Urban sites exhibited high diversity metrics and a markedly distinct community structure in comparison to reference conditions. Compositionally, the reference site hosted an even Proteobacteria-dominated community with Moraxellaceae prevailing in this habitat. Conversely, sites located downstream of WWTPs and/or highly impacted by urbanization were characterized by a pronounced decline of Moraxellaceae in favour of tolerant families such as Sphingomonadaceae and Comamonadaceae. Strong spatial differentiation was observed in highly impacted sites, with urban areas forming the most distinct cluster. WWTP-related locations showed moderate shifts in community composition relative to the reference site, indicating a progressive alteration consistent with the upstream-downstream gradient.

These findings highlight the strong influence of urbanization on freshwater periphyton structure and support the use of microbial indicators for assessing ecological status and monitoring human-driven impacts in freshwater ecosystems.

2.10.P-Tu133 Urban Contaminants Affect Microbe Functioning in Freshwater Streams

Hajar Bourassi¹, Alexander Feckler¹, Eric Bollinger¹, Elizaveta Repich¹, Kevin Doheny², Timo Fuchs¹, Peya Basak¹, Christiane Baschien³, Felix Kögler⁴, Gwenaél Imfeld⁴, Immanuel Frenzel⁵, Jens Lange⁶ and Mirco Bundschuh¹, (1)Rhineland-Palatinate Technical University Kaiserslautern-Landau, Germany, (2)Rhineland-Palatinate Technical University Kaiserslautern-Landau, United States, (3)Leibniz Institute DSMZ, German Collection of Microorganisms and Cell Cultures GmbH, Germany, (4)French National Centre for Scientific Research (CNRS), France, (5)University of Freiburg, Germany, (6)Chair of Hydrology, Faculty of Environment and Natural Resources, University of Freiburg, Germany

In urban landscapes, wastewater containing chemicals such as pharmaceuticals and biocides is a major source of freshwater contamination. Although treated by wastewater treatment plants (WWTPs), some contaminants persist during conventional treatment steps, jeopardizing freshwater organisms and the ecosystem processes they perform. One vital process threatened by urban contaminants is leaf litter decomposition, a microorganism-mediated function essential for nutrient cycling, energy flow, and ecosystem productivity. The present study aims to quantify the impact of urban wastewater on leaf litter decomposition and to identify the structural changes in the involved microbial communities. Therefore, nine streams within the upper Rhine valley receiving WWTP effluents were studied in January 2025. To quantify the microbial decomposition rate of leaf litter, fine-mesh bags filled with leaves of black alder or beech were deployed upstream and downstream of WWTPs (n=9) for three weeks. We used different plant species as these differ in terms of chemical composition, leading to variation in microbial colonization and degradation patterns. In addition, physico-chemical properties and the pollution load of the streams were quantified. To assess the changes in microbial communities, metabarcoding analyses were performed targeting the fungal ITS2 rDNA region. We observed that alder leaf litter decomposes at faster rates than beech regardless of the position in the stream. This may be linked to the quality of alder leaf litter, which provides more nutrition for microorganisms involved in the decomposition. Additionally, decomposition rates were negatively affected by the effluents of the WWTPs. The decomposition of leaf litter was up to 20% slower downstream of the WWTPs. The chemical analysis revealed the presence of more contaminants in the downstream sites compared to the upstream site explaining the inhibition of the decomposition. The portfolio of contaminants found included Pharmaceuticals and personal care products, detergents and pesticides which might present antimicrobial effects that could lead to the reduction of decomposition. As the ecosystem function was affected by the wastewater effluents, we hypothesize that the microbial community composition also shifted to adapt to more contaminated conditions reigning downstream of the WWTPs. The metabarcoding data is currently being processed to prove this hypothesis, and should be available for presentation.

2.10.P-Tu134 Aquatic Bacterial-Fungal Interactions Modulate the Effects of the Biopesticide Kasugamycin on Leaf-Associated Microorganisms

Thibaut Ponchon¹, Isabelle Batisson¹, Hermine Billard¹, Corinne Bardot¹, Sebastien Carrier¹, Fanny CHARRIER², Chloe Bonnineau², Melissa Eon², Nicolas Creusot² and Joan Artigas¹, (1)University of Clermont Auvergne, France, (2)National Research Institute for Agriculture, Food and Environment (INRAE), France

Pesticides sprayed on crops can reach adjacent aquatic ecosystems where they can affect various non-target organisms even at low concentrations. In response, biopesticides appear to be a more sustainable alternative because they are supposed to be more specific and more biodegradable in the environment than synthetic

pesticides. However, their effects on non-target microorganisms remain poorly documented. This study evaluates the effects of kasugamycin, a biopesticide with dual antifungal and antibacterial action, on a simplified synthetic consortium consisting of the fungus *Paraconiothyrium variabile* and the bacterium *Shewanella putrefaciens*, both of which were isolated from alder leaf litter submerged in a pond ecosystem. Microorganisms were exposed for 28 days to two concentrations of kasugamycin (1 and 100 mg L⁻¹), under mono- and co-culture conditions. Our study is particularly innovative because it integrates microbial interactions into the assessment of biopesticide effects. Bacterial and fungal biomass, a range of functional measurements (i.e., extracellular enzyme activities, respiration, litter mass loss) and kasugamycin tolerance acquisition were measured. Our results show that high kasugamycin concentration (100 mg L⁻¹) has an inhibitory effect on fungal biomass but not on bacterial biomass in monocultures. In co-culture, competition between the fungus and the bacterium accentuates the inhibitory effect of kasugamycin on fungal biomass (day 14) in parallel with a decrease in respiration rate (day 21). A greater resistance to kasugamycin, proportional to the concentration of biopesticide prior to exposure, was observed in the bacterium-fungus consortium, as attested by the higher EC₅₀ value. Kasugamycin, being highly soluble and weakly adsorbed onto organic matter, can easily reach aquatic ecosystems and impact leaf-associated microorganisms. Ecotoxicological responses differ between monoculture and co-culture exposures, with competition between bacteria and fungi exacerbating the fungicidal effect of the molecule. These results highlight the importance of integrating biotic interactions when assessing the ecotoxicological impacts of biopesticides in aquatic environments.

2.10.P-Tu135 Microbial metamorphosis under environmental stress: restructuring of insect-associated microbiomes across life stages in a wastewater-impacted system

Milena Esser¹, Brittany Grace Perrotta² and Karen A. Kidd¹, (1)McMaster University, Canada, (2)U.S. Geological Survey, United States

Aquatic insects host microbiomes essential for digestion, immunity, and ecosystem interactions, which are strongly reshaped during metamorphosis, the developmental transition from aquatic larvae to terrestrial adults. Wastewater effluent introduces microbes, nutrients, and contaminants that may alter these microbial communities, but it is unclear whether such changes persist across development or transfer to terrestrial predators. We addressed this question by examining microbiomes of larval and adult aquatic insects (Hydropsychidae, Chironomidae, Heptageniidae), and riparian spiders (Araneidae, Tetragnathidae) collected up- and downstream of four wastewater treatment plants along the Grand River, Ontario, Canada. Whole-body bacterial communities were characterized using 16S rRNA gene amplicon sequencing, and community differences were assessed with PERMANOVA, beta dispersion, and differential abundance analyses.

Microbial composition differed strongly between life stages. Larvae harbored microbiomes dominated by anaerobic and gut-associated taxa, whereas adults and riparian spiders were dominated by more aerobic taxa. These differences may reflect the presence of an active gut in larvae, which supports gut-specialized microorganisms, in contrast to adults, which have a reduced or inactive gut, and spiders, which feed externally. Wastewater exposure influenced aquatic insect microbiomes, including enrichment of environmental and wastewater-associated taxa and reductions in core endosymbionts such as *Wolbachia* and *Rickettsiella*. Notably, reductions in endosymbionts were also observed in adults, suggesting that wastewater exposure can disrupt microbial persistence across metamorphosis and potentially impair symbiont transfer between life stages. In contrast, spider microbiomes showed no significant upstream-downstream differences, indicating limited propagation of wastewater-induced microbial changes into terrestrial predators.

Overall, metamorphosis was the dominant driver of microbiome restructuring, while wastewater effluent introduced additional, taxon and life stage specific shifts. These findings highlight how development and anthropogenic contamination jointly shape host-associated microbial communities, emphasizing the potential for wastewater to alter microbial stability, host-symbiont interactions, and cross-ecosystem microbial transfer, with implications for both ecological function and the health of aquatic-terrestrial food webs.

2.10.P-Tu136 Microbial Response Patterns as Predictors of Sediment Contamination Levels in a Korean Coastal (Gyeonggi) Bay

Gyunmin Yi¹, Junghyun Lee², Taewoo Kim¹ and Jong Seong Khim¹, (1)Seoul National University, Korea, Republic of, (2)Kongju National University, Korea, Republic of

Marine sediments record both natural ecosystem dynamics and human-derived contaminants. Microbial communities inhabiting these sediments react quickly to environmental pressures, and shifts in their composition can serve as sensitive indicators of sediment condition. Although associations between pollutants and microbial assemblages have been widely documented, relatively few studies have integrated these biological signals with chemical and ecological assessment frameworks to identify robust indicator taxa. In this study, we examined whether selected microbial taxa could function as consistent indicators of sediment contamination in Gyeonggi Bay, including sites designated as Special Management Zones. High-throughput sequencing revealed microbial groups that showed consistent patterns along contamination gradients. Several taxa exhibited strong concordance with both chemical (SQG-Q) and ecological (microgAMBI) indices, supporting their potential roles as tolerance- or sensitivity-based indicators. Notably, *Romboutsia* dominated at heavily impacted sites, whereas *Woeseia* was more characteristic of less disturbed sediments. Overall, these findings highlight the utility of microbial indicators as rapid, cost-effective, and ecologically meaningful tools that complement traditional chemical analyses and enhance sediment monitoring and management strategies in coastal environments.

Disclaimer/Disclosure:

2.10.P-Tu137 Microplastics alters the functional response of the Protozoa *Tetrahymena pyriformis* Ekoja-Smah Faith¹, Julia Reiss², Daniel Perkins² and Anne Robertson³, (1)University of Roehampton, London, United Kingdom, (2)Centre for Pollution Research and Policy, Brunel University of London, United Kingdom, (3)Roehampton University, United Kingdom

Microplastics (MPs) are ubiquitous in the environment and contaminate aquatic systems, posing a threat to aquatic organisms at different trophic levels. The impacts of MP contamination on microzoans (microscopic animals like Protozoa), which are major drivers of the microbial ecosystems, are not fully understood. To understand the effects of MPs on microzoans, we conducted an MP exposure experiment using the protozoan *Tetrahymena pyriformis*, a model bacteria grazer in freshwater microbial systems. Six different combinations of bacteria and MP concentrations were used to determine how MP exposure alters *T. pyriformis* feeding over the course of three hours of exposure. We expected that exposure to MP would reduce *T. pyriformis* consumption of their natural prey, with increasingly higher concentrations of MP resulting in a substantial decline in ingestion rate. This will alter the functional response pattern of the consumer.

Our findings show that MP exposure can disrupt the trophic interaction of microbial communities even at low concentrations. This highlights an ecotoxicological disruption introduced by the physical presence of MP particles rather than chemical toxicity, a disruption that is not currently incorporated into the framework of environmental risk assessment. Since microzoans regulate the abundance of bacteria, nutrients, and the transfer of energy in aquatic systems, alteration in the grazing efficiency by the presence of MPs may result in a shift in community structure and obstruct normal ecosystem functioning. This study highlights the need to include microbial predators in hazard evaluation for MP and advances the mechanistic knowledge of how particulate pollutants change ecological processes at the base of the aquatic food webs.

2.10.P-Tu138 Single-cell Analysis of Silver Nanoparticles Effects on Natural Phytoplankton Assemblages in Two Pre-alpine Lakes with Contrasting Trophic Status

Rémy Millet, Inés Segovia-Campos, César Ordóñez and Vera Slaveykova, University of Geneva, Switzerland

Silver nanoparticles (AgNPs) have found wide application in various commercial, medical and industrial products due to their unique properties. Their broad use has led to an increased release into aquatic environments, posing a threat to primary producers. Despite extensive research on nanoparticle toxicity, most studies have focused on laboratory cultures, leaving a critical gap in understanding their impacts under environmentally relevant conditions. To accurately assess the ecological risks of AgNPs and predict their long-term environmental impacts, it is crucial to understand how these nanoparticles interact with natural

phytoplankton communities across diverse trophic and physicochemical conditions. By integrating flow cytometry, pulse-amplitude-modulated fluorescence, optical microscopy, and AgNPs characterisation, our work links AgNPs behaviour in natural waters to taxon-specific and size-dependent physiological responses within complex phytoplankton assemblages. Our findings demonstrate that lake trophic status and community composition jointly shape AgNPs toxicity, with assemblages from the eutrophic lake being more sensitive than those from the mesotrophic one. At the single-cell level, cyanobacteria and smaller phytoplankton species emerged as the most vulnerable groups, highlighting fundamental ecological traits driving nanoparticle effects in situ. This study provides novel insights into the impacts of AgNPs on freshwater ecosystems by demonstrating that differences in water chemistry and phytoplankton community composition between eutrophic and mesotrophic lakes play a determinant role in shaping AgNPs effects. Furthermore, this study emphasises the value of high-resolution single cell techniques for evaluating the impact of anthropogenic pollutants on natural phytoplankton assemblages.

2.10.P-Tu139 Fitness Cost and Community Stability Shape Multidrug-Resistant Bacterial invasion in Freshwater Sediment

Ana Luisa Mejía Camacho¹, Oliver Jyrmark¹, Victoria Osorio², Asadulla Hil Galib², Fabrice Martin Laurent³, Alexandra Meziti⁴, Åsa Sjöling⁵ and Natàlia Corcoll⁶, (1)Dept. of Biological and Environmental Sciences, University of Gothenburg, Sweden, (2)ONHEALTH, IDAEA-CSIC, Spain, (3)University Bourgogne Europe; Institut Agro Dijon, INRAE, Agroécologie, France, (4)Dept. of Marine Sciences, University of the Aegean, Greece, (5)Dept. of Chemistry & Molecular Biology, University of Gothenburg, Sweden, (6)Dept. of Biological and Environmental Sciences, Center for Future Chemical Risk Assessment and Management Strategies (FRAM), University of Gothenburg, Sweden

The spread of antibiotic resistance is a worldwide health, economic, and environmental concern, particularly in hotspots like wastewater treatment plants (WWTPs), which release antibiotic residues and antibiotic-resistant bacteria (ARB) into freshwater environments, possibly contributing to the spread of antibiotic-resistant genes (ARGs). However, the success of ARB in natural communities depends on the fitness of the invader and on the biotic resistance of the receiving community. This study examines the fitness cost of bacteria carrying MDR plasmids and their invasion capacity in freshwater sediment. Moreover, we tested whether low antibiotic levels can disrupt sediment microbial community structure, increasing ARB invasion potential and ARGs spread. We assessed plasmid-associated fitness costs through growth assays in freshwater, comparing a plasmid-free *Escherichia coli* CV601 strain with an MDR transconjugant. To determine whether low antibiotic concentrations could alter sediment microbial community structure and promote ARB invasion and/or ARG dissemination, we conducted a 10-day static microcosm experiment with five treatments: (i) control, (ii) antibiotic mixture (trimethoprim 10 µg/L, cefotaxime 4 µg/L, ciprofloxacin 1 µg/L), (iii) *E. coli*, (iv) MDR *E. coli*, and (v) MDR *E. coli* with antibiotics. MDR *E. coli* exhibited significantly reduced growth in freshwater, indicating a fitness cost of plasmid carriage. In sediment, the MDR strain showed limited capability to invade sediments compared to a plasmid-free strain, and ARGs associated with the plasmid were detected only one day before their decline. Sediment bacterial diversity and community composition remained stable across treatments, suggesting that low antibiotic concentrations in water did not disrupt sediment community structure. Together, the community's stability and the fitness burden of the plasmid likely constrained the establishment of MDR *E. coli* and the spread of ARGs. Overall, our findings indicate that MDR plasmid carriage restricts bacterial invasion in freshwater sediments, and that sub-inhibitory antibiotic levels in water do not necessarily facilitate invasion in freshwater sediments. Nevertheless, the transient detection of ARGs despite low invader establishment suggests that continuous WWTP inputs may still contribute to the persistence of resistance genes in freshwater ecosystems.

2.11 Non-Target Arthropod Risk Assessment: A Simple Matter of Protection Goals or a Complex Web of Interactions?

2.11.T-01 Protocol for the revision of the risk assessment of terrestrial non-target organisms

Rachel Sharp¹, Fernando Alvarez¹, Maria Arena¹, Alessio Ippolito¹, Alberto Linguadoca¹, Csaba Szentes², Laura Padovani¹ and Gabriella Fait¹, (1)European Food Safety Authority (EFSA), Italy, (2)No Affiliation, Italy

The protocol for the revision of the EU terrestrial guidance document for the risk assessment of pesticides, covering non-target arthropods (NTAs), in-soil organisms, and non-target terrestrial plants (NTTPs), falls within the remit of the EFSA mandate M-2024-00086. It describes the problem formulation, evidence needs, and approach for Tier 1 RA developed by the Environmental Risk Assessment Working Group (ERA Working Group) and the EFSA Panel on Plant Protection Products and their Residues (PPR Panel). The protocol follows the principles outlined in the EFSA Guidance on protocol development for EFSA generic scientific assessments. It was considered beneficial for the Tier 1 risk assessment of the three GD since it allows for a transparent and balanced approach for the revision of the guidance document. From a biological standpoint, the compartmentalisation of the terrestrial ecosystem for regulatory risk assessment is recognised as arbitrary. However, the regulatory framework simplifies the inherent complexity of natural systems through this separation, since addressing the risk of PPPs to all organism groups within a single guidance document would be extremely complex. Nevertheless, the combined protocol allows for efficiency and harmonisation of cross-cutting parameters and approaches.

The protocol defines the evidence needs and approaches for addressing data gaps, thereby establishing the basis for the forthcoming revision of the three Guidance Documents. The protocol is composed of an introductory part followed by a section specific to NTAs, in-soil organisms and NTTPs. To ensure a harmonised approach across the three protocols, the concepts of source of emission, exposure pathway, exposure-relevant environmental matrix, and exposure route were introduced in a common introductory section.

Gaps in the current risk assessment of NTAs, in-soil organisms, and NTTPs were identified initially based on the EFSA PPR Panel Opinions [3,4,5] and other available documents, such as the report from the 2025 workshop co-organised by EFSA and the European Commission [6] and were further complemented with expert judgement. Each identified gap was assigned a relative priority score using expert judgment and the appropriate method for collecting additional evidence was selected.

The presentation will focus on the main highlights of the protocol and the comments received during the public consultation that should run from December 2025 until end of January 2026.

2.11.T-02 Moving forward on Non-Target Arthropods Environmental Risk Assessment - Are Current Tier 1 Species Protective Enough?

Artur Miguel Paiva Sarmiento¹, Steven Droge², Mykola Rasko¹, Antonio Cubells¹, Dick Belgers³, Nina Jansen³, Maria Mendes¹, Kas Swinkels³, Daniel Paredes Llanes⁴, Ángel Plata¹, Grzegorz Sowa⁵, Lorraine Maltby⁶, Louise Wipfler⁷ and Jose Paulo Sousa¹, (1)University of Coimbra, Portugal, (2)Environmental Risk Assessment, Wageningen University and Research (WUR), Netherlands, (3)Wageningen University and Research (WUR), Netherlands, (4)University of Extremadura, Spain, (5)University of Sheffield, Poland, (6)School of Biosciences, University of Sheffield, United Kingdom, (7)Environmental Risk Assessment, Wageningen University and Research (WUR), Wageningen, Netherlands

European environmental risk assessment of plant protection products includes an assessment of risks to terrestrial non-target arthropods (NTAs). As a data requirement in the first Tier, effect studies with two NTA species - the parasitic wasp *Aphidius rhopalosiphii* and the predatory mite *Typhlodromus pyri* - must be performed. Nonetheless, there has been a growing discussion if the current first tier effect assessment is sufficiently protective of vulnerable key driver NTA species in the field. By generating comparable sensitivity data across a broader range of functionally relevant species, this work provides a valuable evidence base for evaluating how protective the current “surrogate” species are. For that purpose, cultured NTA species from 16 representative arthropod families were exposed in dose-effect series to three formulations of insecticides with different modes of action - lambda-cyhalothrin, flupyradifurone and cyantraniliprole - via overspray application. Effects were assessed 4h, 24h and, at least, 48h after exposure. Medium Lethal Doses (LD50) were derived and grouped per insecticide in Species Sensitivity Distribution (SSD) curves. Across insecticides, the most sensitive species overall were parasitoids such as *Encarsia formosa*, *Trichogramma achaea* and *A. rhopalosiphii*, while the least sensitive included bees, such as *Bombus terrestris* and *Apis mellifera*, as well as the ground beetle *Poecilus cupreus*. At the trophic group level, comparisons of the “surrogate” species with other taxa showed that *T. pyri* provided a consistently protective representation for predators, whereas *A. mellifera* and *A. rhopalosiphii* did not always secure the full spectrum of sensitivity for pollinators and parasitoids, respectively. Notably, at least one

Tier 1 standard species (*T. pyri* or *A. rhopalosiphii*) consistently ranked among the most sensitive organisms for the tested compounds, supporting their continued relevance in testing schemes. Nonetheless, reliance on a single species may still underestimate effects within the broader trophic group, as observed for pollinators and parasitoids. Interestingly, ladybug larvae were consistently among the most sensitive organisms, in contrast to adults. Taken together, while current Tier 1 test species provide a practical foundation, expanding taxonomic coverage, accounting for life-stage differences, and refining surrogate species selection will be key to achieving more a realistic and protective pesticide risk assessment.

Disclaimer/Disclosure:

The authors thank the European Food Safety Authority (EFSA) for funding and guiding the project (AENEAS - OC/EFSA/ED/2021/02) under which the study was performed.

2.11.T-03 Do Age and Exposure Route Make the Poison? Insights from a Multi-Route Pesticide Uptake Study with Ladybugs

Steven Droge¹, Dick Belgers², Kas Swinkels², Marie-Claire Boerwinkel², Nina Jansen², Louise Wipfler³, Andreas Focks⁴, Artur Miguel Paiva Sarmiento⁵, Antonio Cubells⁵, Mykola Rasko⁵ and Jose Paulo Sousa⁵, (1)Environmental Risk Assessment, Wageningen University and Research (WUR), Netherlands, (2)WENR, Netherlands, (3)Environmental Risk Assessment, Wageningen University and Research (WUR), Wageningen, Netherlands, (4)FB06/Institute of Mathematics, University of Osnabrueck, Germany, (5)University of Coimbra, Portugal

The first Tier of the pesticide environmental risk assessment for non-target terrestrial arthropods (NTAs) has a data requirement on effect studies with two standard test species involved in pest control, using contact exposure to dried spray residues on glass plates. The glass plate residue is considered a worst-case exposure scenario compared to the exposure that NTA experience after a downward spray event in the field via contact with residues on (3D-structured) natural substrates, such as plant leaves and soil. This exposure scenario may still underestimate the dietary intake from food residues (e.g., prey material for predaceous NTA), as well as direct exposure to the spray droplets during PPP-application (and spray drift), as discussed in the EFSA PPR Scientific Opinion on NTA risk assessment. The EFSA funded 2021-2025 project AENEAS set out to study the pesticide accumulation in NTA over a 1 week period using different exposure routes. A single (non-toxic) spray dose was applied using a Potter tower spray system to expose ladybugs via (i) topical overspray, (ii) a dried residue on natural substrate surface (leaf or soil), (iii) dietary intake of oversprayed food items. Two binary mixtures of two active substances were tested on larvae and adult ladybugs (*Coccinella septempunctata*). After topical overspray, all four chemicals decreased from the exterior residues of larvae and adults to <20% within one day, and the volatile chemicals showed faster disappearance from the exterior residue. Internal residues were highest at the first sampling point of 2 h, and after that more slowly decreased from tissue. For ladybird larvae intake via contaminated food items was the dominant exposure route in the next five days studied, for ladybird adults the leaf residue contact and soil residue contact was the long term dominant exposure route. For both tested species residues for several exposure routes were above the 90-percentile Residue Unit Dose values measured in field studies. Topical overspray exposure results in a short term peak, and other exposure routes dominate the exposure profile depending on NTA species/lifestage/chemical. Based on these findings we suggest to take additional exposure routes into account in NTA risk assessment, while differentiating between organism groups.

2.11.T-04 Integrating GUTs Modeling into Ecotoxicological Assessments of Non-Target Arthropods in European Regulation

Daniela Jans¹, Charlotte Elston², Edward Pilling³, Thomas G. Preuss⁴, David Schneider⁵ and Heike Fremdt¹, (1)Bayer AG, Germany, (2)Syngenta Ltd, United Kingdom, (3)Corteva Agriscience, United Kingdom, (4)Bayer Research & Development Services LLC, Germany, (5)Bayer AG CropScience, Germany

The regulation of plant protection products in Europe mandates comprehensive environmental risk assessments for non-target arthropods (NTAs), which are essential for ecological safety evaluations. Over the past decade, effects modeling has gained recognition and has been incorporated into regulatory frameworks, for example in the recent European Food Safety Authority (EFSA) guidance on birds and mammals. However, current NTA test protocols are based on the International Organization for Biological Control (IOBC) guidance published in 2000, predating the development of effects models. Thus, these protocols are not specifically optimized to generate time-resolved data required for a robust parametrization of toxicokinetic-toxicodynamic (TKTD) models.

The General Unified Threshold model for Survival (GUTs) offers a framework for assessing survival under

chemical stress, incorporating temporal dynamics that traditional endpoints—typically measuring toxicant rates causing 50% mortality at a fixed time point—fail to address. We present a GUTs model specifically for *Coccinella septempunctata*, utilizing a data set that was originally produced for the registration of a plant protection product as a case study.

This presentation evaluates the compatibility of existing NTA testing methodologies with the GUTs framework, emphasizing implications for test design and data interpretation. We provide recommendations for enhancing the assessment and reporting processes in NTA ecotoxicological studies, advocating for adjustments that align with the GUTs approach. By bridging the gap between experimental ecotoxicology and effects modeling, this work aims to modernize the ecological relevance of risk assessments for NTAs in the context of plant protection product regulation.

Ultimately, this integration will contribute to more effective ecological risk management and regulatory decisions, ensuring the protection of non-target species as key components of agricultural biodiversity.

2.11.T-05 Risk Assessment for Off-Crop Habitats: Interactions Between Plant Protection Products and Non-Target Arthropods

Michael Peter Meissle, Marco Fioratti, Jörg Romeis and Vera Zina, Agroscope, Switzerland

Concerns about the impact of plant protection products (PPPs) on biodiversity persist, despite established tiered risk assessment frameworks for non-target arthropods (NTAs). Current approaches mainly address single active ingredient–NTA relationships within crops, leaving major knowledge gaps for NTAs inhabiting off-crop habitats. Semi-natural elements, such as hedgerows, flower strips, and field margins, are promoted to enhance biodiversity and ecosystem services, yet may also be exposed to PPP drift, potentially creating ecological traps. We present three complementary approaches to improve landscape-scale NTA risk assessment:

1. EU-wide biodiversity data compilation: We assembled a database of 130'000 NTA occurrence records linked to agricultural habitats either through systematic literature searches or by combining open-source biodiversity data with CORINE landcover information. This resource enables filtering by landcover type, environmental zone, taxonomy, and time to characterize species assemblages across agroecological contexts.

2. Systematic review of PPP–habitat interactions: A literature review on linear managed off-crop habitats examines biodiversity functions and PPP interactions (drift, residue dynamics, toxicity). Preliminary results highlight limited but increasing evidence on how these habitats mitigate or amplify PPP effects.

3. Field study on insecticide drift: A two-year experiment in Switzerland exposed flower strips to realistic acetamiprid drift doses. Short-term knockdown effects were observed within the first meter, especially for parasitic Hymenoptera, but no persistent population-level changes occurred across the 6-m-wide strips. Wider strips thus help buffer drift impacts, though minimizing drift remains essential.

These efforts provide critical building blocks for next-generation, holistic risk assessments that integrate spatial and temporal dynamics. Combining biodiversity databases, systematic reviews, and targeted field studies will reduce uncertainty and support more sustainable PPP use across diverse European landscapes.

Disclaimer/Disclosure:

The presented projects were supported by the European Food Safety Authority (EFSA), the EU Horizon Project PARC, and the Swiss Federal Office for the Environment (FOEN).

2.11.P Non-Target Arthropod Risk Assessment: A Simple Matter of Protection Goals or a Complex Web of Interactions?

2.11.P-We123 Risk assessment in an agronomic context – direct and indirect impacts of non-chemical management practices

Sarah Wynn¹, Lucy Noon¹, Jack Scotney¹, James Masvongo¹, Jim Dimmock¹, Nadine S Taylor², Pernille Thorbek³, Joanna Davies⁴ and Christian Bogen⁵, (1)RSK ADAS Ltd, United Kingdom, (2)Cambridge Environmental Assessments (CEA), United Kingdom, (3)BASF, United Kingdom, (4)Product Safety, Syngenta Ltd, United Kingdom, (5)Bayer CropScience AG, Germany

The risk to non-target terrestrial organisms (NTTO) from chemical plant protection products (PPPs) is well researched and the risks are evaluated during the registration process. However, chemical PPPs are only one set

of tools among a many other agronomic practices, supporting a range of agricultural activities that take place on-farm with the objective of optimising food production. These activities have the potential to either benefit or harm NTOs. Moreover, if PPPs are not available, the growers will take other actions to protect crops from pest and diseases. Consequently, changing one practice to manage one environmental risk or hazard can inadvertently impact other risks and even result in more harmful environmental outcomes. It is therefore important when considering the potential risk posed by PPPs to be able to put those into the context of the impacts presented by wider agricultural activities. Specifically, a solid knowledge of typical agronomic practices and the impact thereof on NTOs is essential 1) to take into consideration the agronomic reality when setting Specific Protection Goals for NTO for environmental risk assessments of PPP, and 2) to integrate a realistic agronomic baseline in future landscape models to address potential environmental risk by PPP.

In this poster we will present crop management calendars for two key European crops – wheat, representing annual arable production, and apples, representing perennial orchard production. We also examine differences in crop management between three different geographies from Northern Europe to the Mediterranean. The typical timing and frequency of key management practices and the proportion of the crop managed using them is evaluated, e.g. the proportion of the crop area subjected to inversion tillage vs. non-inversion tillage vs. direct drilling.

Via literature review, four regularly used non-chemical management practices (cultivation, mowing, harvesting and fertiliser use) are investigated in more depth to determine their impact on seven groups of non-target terrestrial organisms (earthworms, collembola, staphylinids, carabids, arachnids, lepidopteran larvae and soil mites).

The literature review covers direct impacts on abundance, diversity and biomass and longer term or indirect impacts such as recovery time and habitat changes.

2.11.P-We124 CropLife Europe Proposal for Specific Protection Goals for NTA Risk Assessment

Sonja Braaker¹, Heike Fremdt², Stefan Kroder³, Charlotte Elston⁴, Stephanie Tokar⁵ and Thomas G. Preuss²,
(1)BASF, France, (2)Bayer Research & Development Services LLC, Germany, (3)ADAMA, Germany,
(4)Syngenta Ltd, United Kingdom, (5)UPL Limited, Canada

To approve Plant Protection Products (PPPs) under Regulation (EC) No 1107/2009, the absence of unacceptable environmental effects must be demonstrated. Specific Protection Goals (SPGs) translate this General Protection Goal into practical guidance for Non-Target Organisms risk assessment, including Non-Target Arthropods (NTAs). EFSA was mandated in 2024 to develop a NTA Guidance Document. To support this work, CropLife Europe experts have developed a proposal for SPGs for NTAs.

The first step in setting SPGs is identifying key Ecosystem Services relevant for agriculture provided by NTAs. Relevant regulating services provided by NTAs are pest regulation and pollination, which enhance agricultural production. Further supporting services such as habitat provision and nutrient cycling also play a role outside the production area. According to the EC mandate, SPGs are to be defined for the target application area managed by farmers (in-field) and areas outside the production area. In addition, the possibility of recovery as a normal ecological process, especially in disturbed habitats, which are typical for the agricultural landscape, should be considered when setting SPGs.

Further, when establishing SPGs it is essential to consider the agricultural context and to acknowledge that farming must be productive. The primary ecosystem service of the agricultural field is food production and consequently potential trade-offs with the protection of NTAs may arise and need consideration. In addition, the agricultural landscape is not a pristine environment and non-target organisms are constantly exposed to typical agronomic practices beyond PPPs (e.g. ploughing, harvesting, fertilization). These regular disturbances determine the spatio-temporal composition of NTA communities in agricultural landscapes. It is essential to take this agronomic context into account when setting SPGs to enable a translation of the SPGs into a fit for purpose, feasible, flexible and proportionate risk assessment framework.

SPGs for non-target terrestrial plants and soil organisms are also proposed and will be presented in separate posters at this conference.

2.11.P-We125 Developing an Impact Assessment Framework for Specific Protection Goals for Non-Target Arthropods

Sonja Braaker¹, Helena Crosland², Pernille Thorbek³, Joanna Davies⁴, Sarah Wynn⁵, Christian Bogen⁶ and Nadine S Taylor²,
(1)BASF, France, (2)Cambridge Environmental Assessments (CEA), United Kingdom,
(3)BASF, United Kingdom, (4)Product Safety, Syngenta Ltd, United Kingdom, (5)RSK ADAS Ltd, United Kingdom, (6)Bayer CropScience AG, Germany

In 2024, the EU Commission mandated EFSA to update the risk assessment methodology for the assessment of active substances and plant protection products (PPPs) with respect to their potential effects on non-target arthropods (NTAs) other than bees, soil organisms and non-target terrestrial plants (NTTPs). This process will require revision of the Specific Protection Goals (SPGs) and the associated Terrestrial Guidance Document that currently defines the risk assessment scheme for each organism class. The revision of the Terrestrial Guidance documents could lead to major changes in the agricultural practices and thus in important unintended socio-economic and environmental consequences. It is therefore relevant to evaluate the impact of these consequences and alternative options during the Guidance revision, as recommended according to the Better Regulation Guideline (2021).

In this poster, we present an impact assessment framework in which both environmental and socio-economic impacts are simultaneously addressed. The framework uses an ecosystem service (ES) approach to assess the impact of changes to Protection Goals and risk assessment scheme for NTAs (both in-field and off-field) on the availability of PPPs to growers, the alternative pest / disease control methods likely to be adopted by growers and wider socio-economic and environmental factors. This approach enables a holistic identification of trade-offs between changes in ES, the resulting adjustments to pest control methods used by growers and the broader consequences for food production, in terms of socio-economic and environmental costs and benefits (e.g. on sustainable productivity for EU farmers including the ability to handle pest outbreaks). In addition, a more targeted investigation, gaining insight from EU agronomists resulting in a series of crop and country-specific case studies, collates the predicted effects and changes to agronomic management practices that would result from changes to SPGs. The proposed framework allows evaluation of the impact of different SPGs and risk assessment options on ES provided by NTAs and agricultural land in terms of socio-economic and environmental costs and benefits. The outcome can contribute to the necessary trade-off decisions while evaluating alternative SPG options.

2.11.P-We126 Non-Target Arthropods (NTA): Specific Protection Goals, Indirect Effects and Ecosystem Services

Melanie Hagen-Kissling¹, Livia De Felici¹, Julia Friman¹, Josep Roig Garriga² and Bogdan Dehelean¹,
(1)Eurofins MITOX, Netherlands, (2)Eurofins MITOX FOPSE, France

Higher-tier NTA studies assess how local communities respond to test item exposure within highly complex natural systems. Evaluating species abundances in isolation is considered insufficient for predicting the strength of an ecosystem as emergent or counterintuitive effects often arise from interactions within community networks. Within an ecosystem, organisms fulfil specific functions—such as pest control or pollination—through their interactions with other organisms and with the environment; these functions reflect their ecological roles. Such ecosystem services relate directly to the specific protection goals defined by EFSA.

Here, we do not focus on the direct effects of PPP applications on single species. Instead, we shift attention to species interactions and to the indirect effects of PPP applications through interactions within an NTA community.

In the first step, we analyse community composition and the proportions of different ecological roles in NTA communities across several habitat types (off-crop, in-crop, apple orchard). We then examine if and how these proportions change over time, both with and without PPP application.

In the second step, we concentrate on selected pest species and their principal predators. We investigate their population dynamics over time, with particular emphasis on indirect effects of PPP applications on predatory species that are not the intended targets of an intervention.

Overall, shifting the perspective from single-species assessments to a community-level approach—including explicit consideration of species interactions—is essential for achieving sustainable pest management and maintaining key ecosystem processes.

2.11.P-We127 Classification and Risk Assessment of Terrestrial Arthropods in European Agriculture: Integrating Ecological Diversity within the Revised NTTO Guidelines

Heike Fremdt¹, Gregor Ernst², David Schneider³ and Thomas G. Preuss⁴, (1)Bayer AG, Germany, (2)Bayer CropScience AG, Germany, (3)Bayer AG CropScience, Germany, (4)Bayer Research & Development Services LLC, Germany

Regulatory frameworks for plant protection products (PPPs) mandate thorough assessments of their safety to non-target arthropods. These assessments ensure that agrochemicals do not adversely affect beneficial insects, crucial for ecosystem functions like pollination and pest control. We present a trait-informed framework for classifying terrestrial arthropods into ecologically meaningful groups to support ecological risk assessment (ERA) and inform trait-based modeling approaches, thereby enabling future population-level risk assessments.

Classification of terrestrial arthropods in European agricultural landscapes is based on taxonomy, habitat, movement behavior, diet, life cycle, and overwintering strategies complemented by representative species. Using the Pop-GUIDE approach, we developed matrices for major groups (e.g., ground-active predators, pollinators, foliage herbivores) detailing model objectives (persistence, connectivity, acute risk), trait precision levels (General, Realistic, Precise), exposure pathways, spatial/temporal resolution needs, and uncertainty drivers. Each profile also includes key life-history traits and ecological interactions relevant for ERA endpoints such as dose-response, TKTD, and indirect effects. Among these ecological groups, ground-active predators and omnivores (Carabidae, Araneae) play significant roles in prey dynamics, while foliage-dwelling herbivores (Lepidoptera, Hemiptera) highlight the risks posed by agricultural inputs. Pollinators (Apidae, Syrphidae) illustrate the connectivity vital for ecological functioning, and parasitoids (Hymenoptera) are essential biocontrol agents.

This structured approach enables prioritization of surrogate species and supports the development of group-specific population models under the revised EFSA NTTTO guidance mandated by the European Commission to the European Food Safety Authority (EFSA) in 2024. By linking ecological traits to modeling requirements, it improves realism in risk assessments and promotes sustainable management strategies. The framework addresses regulatory demands for representative surrogate species across NTA taxa, ensuring sufficient conservatism and integration of ecological data into agricultural risk management.

By providing a comprehensive classification of non-target arthropods, this research supports informed decision-making for biodiversity conservation and the protection of ecosystem services in agricultural landscapes.

2.11.P-We128 NTA Field Studies: Effect of Sampling Effort on Non-Target Arthropods (NTA) Field Data

Melanie Hagen-Kissling¹, Bogdan Dehelean¹ and Josep Roig Garriga², (1)Eurofins MITOX, Netherlands, (2)Eurofins MITOX FOPSE, France

In higher tier field studies conducted to assess the effect of plant protection products (PPP) on non-target arthropods (NTA), the composition of the arthropod's community is influenced by several biotic and abiotic factors (e.g. food availability, predator-prey interactions, etc.) on different spatial and temporal scales. To ensure a robust risk assessment, it is essential to sample a representative portion of the NTA community with respect to both diversity and abundance. Arthropod abundance is particularly important because it determines the strength and reliability of statistical analyses. However, sampling effort is constrained by practical considerations: although increasing the number of replicates generally improves data quality, there is a threshold in terms of feasibility due to limitations in e.g. field size, labour, and cost.

Here, we evaluate how sampling effort influences (1) NTA community composition (diversity and abundance) and (2) the number of taxa available for population-level statistical analyses. Specifically, we examine how sampling between 3 and 12 replicates in apple orchards and between 3 and 28 replicates in meadow systems affects the taxonomic richness (diversity and abundance) captured. As replication increases, the number of taxa reaching sufficient abundance for statistical evaluation is expected to rise until reaching a saturation point. Our goal is to determine where this saturation occurs and whether such replication levels are practically achievable in routine field studies.

Additionally, we (3) compare the taxa that achieve adequate abundance for analysis with the list of focal taxa recommended for inclusion in NTA studies by De Jong et al. (2010). Special attention is given to how replicate number influences variability—and therefore the robustness—of the dataset. Using this approach, we evaluate how good the commonly used four-replicate design is for detecting less abundant taxa, how many additional taxa can become available for population analysis with increased replication, and whether such increased sampling intensity provides an advantage for the risk assessment while keeping a cost-effective approach.

Reference: De Jong, F.M.W. et al 2010. Guidance for summarising and evaluating field studies with non-target arthropods. RIVM report 601712006/2010. 76 pp.

2.11.P-We129 Developing a Framework For Identifying Sentinel Taxa for the Non-Target Arthropod Risk Assessment in Europe Using Field Effect Studies – A Case Study with Bembidion

Charlotte Elston¹, Ed Pilling², **Saskia Aldershof³** and Frank Bakker⁴, (1)Syngenta, United Kingdom, (2)Corteva, United Kingdom, (3)Bioresearch & Evaluation, Netherlands, (4)Bakker Onderzoeks Beheer, Netherlands

Non-target arthropod (NTA) field studies represent the highest tier of study available in the tiered regulatory process. Field studies have the highest degree of realism, but also a high degree of variability and unlike higher tier bee studies, NTA field studies are conducted with naturally occurring populations of multiple species. This results in large, complex datasets involving hundreds of different taxa with differing compositions, abundances

and phenologies, as a result these studies can be difficult to interpret and ascertain what is a potential effect of a plant protection product (PPP) on populations and communities versus natural background and seasonal variability.

In addition, the current NTA risk assessment in Europe (ESCORT 2) and Terrestrial Guidance Document (SANCO/10329/2002 rev 2 final) are currently undergoing revision meaning there are discussions ongoing in terms of what to protect, where to protect it, over what time period and with what degree of certainty (Specific Protection Goals SPGs).

The compiled NTA field effect database and its analysis represent a powerful resource for the development of the future risk assessment scheme for NTAs. In the first instance, it allows to derive recommendations for future field trial design and for its data analysis and interpretation. Further, the identification of sentinel taxa is not only relevant for the evaluation of field effect studies but also for the development of ecological models. Considering the spatial and temporal scale of NTA field studies and the number of taxa that are observed, ecological models are expected to gain in importance in the future NTA higher tier risk assessment in Europe. As it will not be feasible to develop models for all taxa potentially present in an area, a framework to understand the key representative taxa is therefore essential for model development. In addition, the database is valuable for analysing the spatial and temporal variability of taxa or ecological traits, thus making it a valuable resource for establishment of Normal Operating Ranges or/and Specific Protection Goals. We present a case study using *Bembidion* ground beetles, highlighting both the challenges of identifying sentinel taxa but also possible solutions including pooling of species based on analysis of traits and chemical sensitivity.

2.11.P-We130 From Field Variability to Regulatory Reliability: Rethinking Spider Testing in PPP Assessment

Renan Toscano and Dominic Sacker, Labcorp, United Kingdom

Spiders of the genus *Pardosa* (wolf spiders) are ecologically significant non-target arthropods widely present in European agroecosystems. As generalist predators, they contribute to pest regulation and biodiversity, making them valuable indicators in environmental risk assessments for plant protection products (PPPs). To address this, the International Organisation for Biological and Integrated Control (IOBC/WPRS) developed an acute contact toxicity test for *Pardosa* spp., which is commonly used in tiered terrestrial ecotoxicity assessments under EU Regulation (EC) No 1107/2009. However, concerns have emerged regarding the reproducibility and regulatory robustness of this guideline compared to Organisation for Economic Co-operation and Development (OECD) terrestrial protocols, such as Test No. 207 for earthworms.

This study critically evaluates the *Pardosa* guideline, highlighting methodological inconsistencies and proposing harmonization with OECD standards. A comparative analysis shows that while spider and earthworm tests share core elements—such as mortality and body weight endpoints—the spider test suffers from overly stringent and arbitrary validity criteria, particularly for control mortality thresholds. These criteria often invalidate tests due to natural variability in field-collected populations, exacerbated by sex-related differences and seasonal effects. A case study of three control tests demonstrated male mortality rates far exceeding guideline limits (up to 59%), while females consistently showed 0% mortality, indicating that mixed-sex controls introduce unnecessary variability.

Statistical modeling using binomial probability supports replacing fixed percentage thresholds with confidence-based criteria, advocating a 10% mortality limit as statistically defensible. Additional refinements include sex-specific testing, standardized acclimation and feeding protocols, and the use of artificial soil to improve ecological relevance. Aligning the spider test with OECD principles would enhance methodological consistency, reduce invalidations, and ensure data comparability across studies.

This work underscores the need for guideline revision to strengthen reliability and regulatory acceptance. Implementing these changes will facilitate robust datasets for ecological modeling and PPP risk assessment, ensuring that testing protocols reflect both ecological importance and regulatory rigor.

2.11.P-We131 In-field exposure of non-target arthropods in the litter layer of treated crops

Dinand Scholten, Dick Belgers, Marie-Claire Boerwinkel, Nina Jansen, Steven Droge, Kas Swinkels and Ivo Roessink, Wageningen Environmental Research, Netherlands

In agricultural fields, pesticides are typically applied spraying downward onto standing crops, where they adhere to plant surfaces and the soil before reaching NTAs in the litter layer. Ground-dwelling NTAs may be exposed directly through overspray or subsequently through contact with wet formulations, dried residues on vegetation or soil, or by ingesting contaminated plant material, prey, or other surface substrates. Since plant structures intercept much of the spray, deposition typically decreases from the crop canopy toward the soil, leaving soil-dwelling NTAs less exposed than organisms higher in the canopy. However, it remains unknown what proportion of the pesticide that reaches the soil ultimately adheres to soil-dwelling NTAs. To address this gap, we conducted an experiment in a rapeseed field to measure how pesticide deposition declines along the plant's vertical profile before reaching the soil and sampled soil-dwelling NTAs using pitfall traps. The field was sprayed with a non-toxic fluorescent dye (Acid Yellow), using standard agricultural application techniques. The vertical distribution of the chemical in the crop was measured by placing four glass-fiber filter discs at different plant heights (100, 60, 30, and 0 cm above the soil). Pitfall-traps were emptied on two consecutive sampling days at 4- and 16-hours post-spray. Exposure decreases by more than fivefold from the top of the canopy down to the soil layer, with the decline being gradual near the upper canopy and much steeper in the lower canopy. NTAs captured 4 hours after spraying were on average 2.5 times less exposed than measurements of soil-level filters would suggest, while individuals captured 16 hours after spraying were 4 times less exposed than soil-level values from the initial application on the previous day. These results show that actual exposure of ground-dwelling NTAs is much lower than expected from the initial amount of chemical sprayed per hectare (kg/ha) and even lower than actual measured levels on ground level (taking crop inference into account).

2.11.P-We132 Clarifying Terminology for Off-Field Risk Assessment: Definitions of Edge-of-Field and Field Margin

Sonja Braaker¹, Joanna Davies², Monika Maler³, Carola Schriever¹ and Thomas G. Preuss⁴, (1)BASF, Germany, (2)Syngenta Ltd., United Kingdom, (3)Corteva Agriscience, Germany, (4)Bayer AG, Germany

Under Regulation (EC) No 1107/2009, the approval of Plant Protection Products (PPPs) requires demonstrating the absence of unacceptable environmental effects. This overarching General Protection Goal is operationalized through Specific Protection Goals (SPGs), which provide practical guidance for risk assessment of Non-Target Organisms (NTOs). In 2024, EFSA was mandated to revise and update its existing Guidance Document to ensure SPGs remain scientifically robust and aligned with current regulatory needs.

SPGs are inherently linked to spatial scale and location. Nevertheless, clarity regarding the extent and positioning of the spatial scale and location of an SPG is lacking, which is mostly due to the fact that used terms are not clearly defined. This ambiguity complicates exposure modeling and mitigation strategies. One critical aspect is the delineation of edge-of-field and field margin, which plays a pivotal role in environmental risk assessment.

Clarifying these spatial concepts is essential because it underpins SPG discussions and supports the development of spatiotemporally explicit models (e.g., xOffFieldSoil) and tiered risk assessments that integrate realistic exposure patterns and mitigation measures.

To address this, experts from CropLife Europe (CLE) have developed a proposal to harmonize definitions. The adoption of standardized definitions for terms such as “field”, “edge-of-field” and “field margin” will:

- Enhance regulatory consistency across Member States.
- Improve comparability of risk assessments.
- Strengthen the scientific basis for protecting off-field habitats and biodiversity within agricultural landscapes.

2.11.P-We133 Simulated Drift in Flower Strips – Effects on Non-target Arthropods

Vera Zina¹, Thomas Poiger², Judith F. Blom³, Jörg Romeis¹ and **Michael Peter Meissle¹**, (1)Agroscope, Switzerland, (2)Plant Protection Products – Impact and Assessment, Agroscope, Switzerland, (3)Plant Protection Products - Impact and Assessment, Agroscope, Switzerland

Plant protection products (PPP) can reach off-crop habitats through spray drift and potentially affect non-target arthropods (NTAs). Flower strips are increasingly established to support biodiversity and ecosystem services in agricultural landscapes, yet their placement along cropped fields exposes them to PPP drift. Despite their relevance, empirical data linking realistic drift exposure to population- and community-level responses in these habitats remain limited. This study addresses two related questions: how much insecticide reaches flower strips and how do these drift levels affect resident NTA communities?

In 2022, tracer-based drift measurements quantified insecticide deposition on 6-m flower strips in Tänikon, Switzerland. While deposition reached up to 28% of the field rate in the first meter, it declined sharply with distance. These field-derived values were then used to design a two-year drift simulation experiment at the same location (2023-2024). Annual flower strip plots in a randomized block design were exposed to simulated Drift-rates of the broad-spectrum insecticide acetamiprid (High: 28%, Medium: 1.2%, Low: 0.4%), alongside with untreated controls and Full-rate positive controls. The NTA community was monitored before and after applications from June to August. Short-term effects were assessed using dry pan traps (knockdown) and sticky traps (escape and movement). Suction sampling and pitfall traps were used to quantify longer-term population responses and recovery.

Drift-rate exposure caused short-term knockdown effects mainly within the first meter of the flower strip, affecting several taxa including parasitic Hymenoptera. No persistent changes at the population or community-level were detected across the 6-m flower strips over the season. In contrast, Full-rate treatments caused strong and sustained reductions in multiple taxa, confirming the sensitivity of the monitoring design. NTAs exposed to simulated Drift-rates of acetamiprid recovered rapidly during the season, with no indication of cascading or sustained impacts.

By integrating measured deposition patterns with controlled drift simulations, this study provides a field-validated basis for evaluating realistic off-crop exposure scenarios. The findings suggest that wide flower strips (? 6-m) can buffer local drift impacts, while highlighting the first meter as a critical zone where drift reduction measures remain essential.

2.11.P-We134 Reviewing Toxicokinetic Determinants of Pesticide Sensitivity in Invertebrates: a Bridge between Target and Non-Target Species

Giulia Cafiero¹, Sanne van den Berg¹, Tobias Pamminer², Ivo Roessink¹ and Paul van den Brink¹,
(1)Wageningen University and Research (WUR), Netherlands, (2)Early Environmental Safety, Bayer AG, Monheim am Rhein, Germany

Species sensitivity to chemicals is determined by a complex combination of factors that influence the chemical exposure and its biological effects. Pesticide properties and species-specific traits may affect toxicokinetic processes, as well as toxicodynamics. Sub-organismal features in invertebrates can influence pesticide toxicokinetics and may contribute to interspecies sensitivity differences. Adaptation to repeated pesticide exposure can lead to resistance as the organism (usually the target pest) produces more or effective systems to tolerate the pesticide. While the molecular determinants of resistance and sensitivity in target arthropods are well studied, those in non-target invertebrates remain poorly understood, often due to experimental challenges and limited availability of suitable methods. Mechanistic approaches in ecotoxicology are limited to a few model species due to their relevance in environmental risk assessment, but their extrapolation power to other invertebrate species is still low. In this review, we summarize current research on sub-organismal, toxicokinetic-related mechanisms in target and non target species and identify molecular endpoints that can be translated between resistance and sensitivity research.

We conducted a Web of Science search to identify (eco)toxicology studies on invertebrates, pesticides, and toxicokinetic-related molecular endpoints. The literature was categorized based on the investigated process (Uptake, Distribution, Detoxification, Elimination). The uptake and distribution categories yielded few results in terms of sub-organismal methods. In elimination and detoxification research, a broad range of molecular methods was applied to study resistant pest, with methods often performed in combination. Network analysis showed that sensitivity studies most often pair gene expression with enzyme activity measurements, while resistance studies combine multiple molecular approaches.

The methodological divide found in our search reflects a broader disconnect between research communities studying target and non-target organisms. Contributing factors include different vocabulary, geographical biases, and weak academia-industry partnerships.

Despite shared processes underlying pesticide toxicity, molecular tools routinely applied in pest research are

rarely applied to non-target invertebrates. Filling these gaps requires access to annotated genomes, standardized methods, and taxonomically broad data generation.

2.11.P-We135 Triazole Fungicides: New Disruptors of Hormonal Signaling in Coleopterans

Paula Bolívar¹, Claudia Santamaria Cervantes¹, Rafael Mateo², Manuel Ortiz Santaliestra¹ and Ricardo Sanchez de la Nieta¹, (1)University of Castilla-La Mancha (UCLM), Spain, (2)Instituto de Diagnostico Ambiental y Estudios del Agua (IDAEA, CSIC), Spain

The application of pesticides, especially triazole fungicides, contributes significantly to biodiversity loss in agroecosystems. Although their mode of action targets the inhibition of ergosterol synthesis in fungi, in arthropods they may interfere with the production of ecdysteroids, hormones essential for molting and reproduction. Given the key role of invertebrates in maintaining plant biodiversity and in trophic networks, it is crucial to understand how these compounds affect their physiology. In this study, the effects of prothioconazole and tebuconazole were evaluated in the beetle *Tenebrio molitor*, reproducing a field-like exposure through the ingestion of treated cereal seeds.

Three treatments were used: untreated seeds, treated seeds, and a 50:50 mixture. For ten days, larvae consumed only these food sources, and their weight, consumption, development, mortality and potential malformations were recorded. In addition, the expression of 13 genes related to the ecdysteroid pathway was analyzed using RT-qPCR, and levels of 20-hydroxyecdysone and cholesterol were quantified. Models of the ligand-binding domain of the ecdysone receptor (EcR) were also generated to perform molecular docking studies with triazoles and known EcR-binding molecules.

The results showed a drastic reduction in food consumption in larvae exposed to Raxil® Plus and a significant decrease in larval weight, although no subsequent effects were detected in pupae or adults. No alterations in development, mortality or morphology were observed. However, exposure caused a strong decrease in the expression of key ecdysteroidogenesis genes in larvae, as well as a marked downregulation of HR3 and overexpression of E75. Larval ecdysone levels were also significantly reduced, while cholesterol levels showed no variation. Molecular docking analyses indicated that triazoles displayed binding similar to compounds with known affinity for EcR in the non-steroidal conformation.

Overall, the data demonstrate that triazoles, even at environmentally realistic levels, alter growth, hormonal regulation and ecdysone receptor function in *T. molitor*, suggesting potential impacts on beetle populations and other arthropods in agricultural environments.

2.11.P-We136 A First Modelling Approach to Predict Behavioural Alterations in *Porcellionides pruinosus*

Lorenzo Federico, Roman Parzer, Gianna Serafino Monti and Sara Villa, University of Milano Bicocca, Italy

Behavioural alterations in terrestrial isopods emerged as early warning signals of soil pollution, but their link to specific physicochemical properties of contaminants remains unexplored. Clarifying which chemical properties predict behavioural disruption is essential for advancing ecotoxicological assessment. This study aims to examine the correlation between a selection of physicochemical properties of chemicals and the onset of behavioural changes in *Porcellionides pruinosus* population. Behavioural effects were assessed performing the avoidance bioassay, which reflects active migration away from contaminated soil, in combination with the disaggregation effects, which reflects the alteration of social behaviour of woodlice. Twenty-five synthetic organic chemicals, with different modes of action, and representing three use categories (plant protection products, pharmaceuticals and personal care products, and perfluorocarboxylic acid) were tested. Several nominal concentrations expressed in mg/kg dry soil (d.w.) were selected based on the respective maximum solubilities (g/L) of each compound, in order to avoid the use of organic solvents that could have masked or affected the behavioural responses and the related study of physicochemical descriptors. The behavioral bioassays were carried out in thermostatic chambers at 20 ± 1 °C, with a 16:8 h (light:dark) photoperiod, for 48 h. Based on the outcomes, chemicals were classified into three categories: those inducing both avoidance and disaggregation, those eliciting only one response, and inactive substances within the selected concentrations. Regression models revealed a significant positive association between disaggregation and Henry's law constant, with a threshold of 1×10^{23} Pa·m³·mol⁻¹, with 95% confidence interval estimated using the Delta method, above which aggregation breaks down. This finding suggests that Henry's law constant may serve as a potential, though yet to be validated, predictor in regulatory contexts for assessing the impact of chemicals on gregarious populations. No predictive descriptors were identified for avoidance, indicating that further research is required to elucidate the factors driving migration. Furthermore, in view of the heterogeneity of behavioural responses,

the combined use of avoidance and disaggregation endpoints is recommended for a more comprehensive investigation.

2.11.P-We137 Developing a Generic Exposure Model for Leaf-Feeding Lepidopteran Larvae To Support Non-Target Arthropod (NTA) Risk Assessment (RA)

Klaus Swarowsky, Thomas Gräff, Mareike Güth, Dirk Süßenbach and Jörn Wogram, German Environment Agency (UBA), Germany

Non-target Lepidopteran larvae are increasingly recognized as vulnerable recipients of plant protection product (PPP) exposure on treated foliage. The EFSA scientific opinion on NTA RA recommends including oral toxicity studies for Lepidopteran larvae as representatives of herbivorous NTAs in PPP RA for the upcoming revision of the terrestrial Guidance document. In order to use existing and future oral toxicity data for Lepidopteran larvae in risk assessment, a transparent exposure model to derive daily food intake and corresponding PPP dose is required. We present the conceptual design of such a model, which is currently under development for leaf-feeding Lepidopteran larvae. The model builds on work by the German Environment Agency (UBA) on the threatened butterfly *Parnassius apollo vinningensis* (Stichel 1899), the Mosel Apollo, an endemic subspecies of the Apollo butterfly restricted to steep vineyard slopes in the Mosel river region. In this case study, the key question was whether PPP deposition on larval host plants may pose an unacceptable risk, thereby potentially contributing to the imminent extinction of this subspecies. Motivated by this example, we develop a more generic exposure model for leaf-feeding Lepidopteran larvae. Larval development is represented on a relative time axis and combined with literature-based growth curves and simple allometric relationships between body mass and food intake, with explicitly increased feeding in late instars. By coupling predicted daily food intake with residue levels on host plants, the model provides estimates of daily PPP dose to caterpillars for different larval groups (for example small/medium/large species, four to six larval instars). We will present the model framework, key parameter choices and parameterization using published data for several Lepidopteran species taking into account uncertainties. Planned applications include (i) screening-level risk characterisation for caterpillars based on existing oral toxicity data for Lepidoptera or other insects, and (ii) sensitivity analyses exploring how assumptions on growth and feeding behaviour affect exposure estimates. The model is intended as a pragmatic, transparent tool to help address current gaps in non-target arthropod risk assessment for Lepidopteran larvae and to support future refinement of guidance for non-target Lepidoptera.

2.11.P-We138 Application of the BufferGUTS model to determine toxicity thresholds for a set of 16 NTA species as key drivers for ecosystem services

Andreas Focks¹, Artur Miguel Paiva Sarmento², Steven Droge³, Mykola Rasko², Antonio Cubells⁴, Dick Belgers⁵, Nina Jansen⁵, Maria Mendez⁴, Daniel Paredes Llanes⁶, Kas Winkels⁵, Louise Wipfler⁷, Grzegorz Sowa⁸, Lorraine Maltby⁹ and Florian Schunck¹⁰, (1)FB06/Institute of Mathematics, University of Osnabrueck, Germany, (2)University of Coimbra, Portugal, (3)Environmental Risk Assessment, Wageningen University and Research (WUR), Netherlands, (4)Centre for Functional Ecology, Associate Laboratory TERRA, Department of Life Sciences, University of Coimbra, Portugal, (5)Team Environmental Risk Assessment, Wageningen Environmental Research, Wageningen University, Netherlands, (6)University of Extremadura, Spain, (7)Environmental Risk Assessment, Wageningen University and Research (WUR), Wageningen, Netherlands, (8)University of Sheffield, United Kingdom, (9)School of Biosciences, University of Sheffield, United Kingdom, (10)University of Osnabrueck, Germany

For a set of 16 NTAs species, representing the trophic groups of predators, pollinators and parasitoids, laboratory toxicity tests using three pesticide commercial formulations with different modes of action were performed: Karate Garden (a.i., lambda-cyhalothin), Sanium (a.i., flupyradifurone), and Mainspring (a.i., cyantraniliprole). Test organisms were exposed to the products by a single direct overspray application using a Potter spray tower. After exposure, the oversprayed organisms were transferred to incubation cages, supplied with food ad libitum, and effects were assessed 4, 20, 24, 28, 44 and 48h after exposure and then every 24h until the end of the test. For the interpretation of acute test dose-response data, we used the recently published BufferGUTS model. Nominal application rates application rates (ng a.i. cm⁻²) and raw observations of survival over time were used to calibrate the BufferGUTS model using the implementation in the MemPyGUTS Python package hosted by Osnabrück University. The results of the model calibration to raw observations of survival over time resulted in a set of BufferGUTS parameter values including uncertainties. Using the calibrated model, lethal rate (LR50) values after 48 and 96 hours were calculated.

Comparison to experimentally derived LR50 values shows that lethal doses after 48 hours tend to be very similar using the BufferGUTS model but show smaller uncertainties. The matching of model-derived with data-derived LR50 values confirms the realism of the BufferGUTS model, while the smaller uncertainties of the

model-derived values indicate that the model is using more data points. The extrapolation of LR50 values to 96 hours observation time indicates that the toxicity thresholds are expected to generally decrease for a prolonged observation time. A more detailed analysis reveals that a simulated prolonged exposure time has different consequences for the LR50 values for three tested PPPs and the tested species. For Mainspring, for 11 species the LR50 values were reduced by about 50% of the values after 48 hours, while for Sanium and Karate this was the case for 5 species.

These calculations show the potential of using GUTS modelling for the analysis of results from toxicity testing. Once calibrated, these models can be used to predict toxicity thresholds for inter- or extrapolated exposure times.

2.11.P-We139 Identification of Biomarkers for Immunosuppression in PAMP-challenged *Tribolium castaneum* larvae using Transcriptome Analyses

Kirsten Germing¹, Elke Eilebrecht¹, Sebastian Eilebrecht², Martina Roß-Nickoll³, Joachim Kurtz⁴ and Christoph Schaefers¹, (1)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)RWTH Aachen University, Germany, (4)University of Munster, Germany

It is assumed that in stressed ecosystems, pathogens exert strong pressure on populations. In addition, the organisms in the environment are exposed to a large number of environmental pollutants such as pesticides or drugs. The ecotoxicological hazard and risk assessment of chemicals currently do not include the identification of effects regarding the immunocompetence of organisms. However, studies indicate that chemicals can induce various effects on immune related parameters of organisms. In relation to the increasing pressure from pathogens, immunotoxic effects of chemicals that impair the immunocompetence of organisms could influence host-pathogen-interactions and could pose a significant threat to the stability of ecosystems. Thus, the regulatory authorities claim that methods must be developed to identify immunotoxic modes of action (MoA) of chemicals. The project aims at the identification of reliable markers for the MoA of immunomodulatory chemicals in Red Flour Beetle larvae (*Tribolium castaneum*). For this, exposure by a chemical with a known mode of action (MoA; immunosuppressive or non-immunomodulative) will be followed by an immune challenge. This setting enables the investigation of chemical effects in the activated immune system of the beetle larvae. The exposure chemical will be mixed with the food of the larvae, a flour-yeast-mixture, and the larvae are exposed for five days ad libitum. After the exposure, the larvae are challenged via injection of a Pathogen-associated-molecular-pattern (PAMP) that induces an immune system activation. 6 h later the RNA of the larvae is extracted and the transcriptome is analyzed. The analysis of the total RNA enables a clear differentiation of chemical MoA in the resting as well as the activated immune system. With this approach, we will be able to gain insight into the immune system of the invertebrate species *Tribolium castaneum* and to define marker genes for the discrimination between immune-modulating chemicals and other MoA.

2.11.P-We140 Determination of Immuno-Ecotoxicological Effects on the Ground Beetle Species *Poecilus cupreus* under Lab- and Landscape Conditions

Erik Melchior¹, Kirsten Germing², Elke Eilebrecht², Sebastian Eilebrecht³, Joachim Kurtz⁴, Christoph Schaefers² and Martina Roß-Nickoll¹, (1)Institute for Environmental Research (IFER), RWTH Aachen University, Germany, (2)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Research Group Animal Evolutionary Ecology, University of Münster, Germany

Climate change, habitat fragmentation, and invasive species represent major challenges for ecosystems and their stability, exerting significant pressure on the organisms living within them. This increased pressure makes it easier for additional factors, such as pathogens or the growing contamination by various chemicals and fertilizers, to cause harmful effects and add further stress to these organisms. Currently, multiple stressors and their effects on the immune system are either not considered or only insufficiently addressed in the approval process of substances. However, it is well known that chemicals, such as pesticides, can have numerous effects on immune-specific factors and, in combination with pathogen pressure, may destabilize ecosystems. Therefore, it is essential for the approval and restriction of substances used by humans and released into the environment to identify immuno-ecotoxicological modes of action (MoA) and determine their current impact on ecosystems. The aim of this project is to compare the immune status of free-living ground beetles with that of laboratory-reared individuals of the same species, and the model organism *Tribolium castaneum* (red flour beetle). The study focuses on the ground beetle species *Poecilus cupreus* (copper greenclock beetle), which is of high ecological relevance due to its presence in a wide range of habitats, its extensive research history, and its suitability for laboratory maintenance and breeding. Laboratory beetles and larvae are treated with

immunosuppressive and immunostimulatory chemicals with known MoA and subsequently injected with pathogen-associated molecular patterns (PAMPs) to activate the immune system from its resting state. This process, also called "challenge", and the immune system's response to the treatments are detected and identified through transcriptomic and proteomic analyses. Special attention is given to parameters and molecular reactions that affect the immune system and lead to changes within the organism. These reactions in laboratory-bred beetles will then be compared to the molecular immune responses of free-living beetles, ultimately enabling an assessment of the immuno-ecotoxicological status of individual habitats and facilitating the transferability of findings to other locations.

2.12.A Terrestrial Biodiversity and Chemical Pollution: Understanding Exposure and Impacts Towards Improving Risk Prevention and Management

2.12.A.T-01 Occurrence and Distribution of Organic Micropollutants in the Barn Owl Food Chain: A Pan-European case study

Antigoni Konomi¹, Nikolaos Boinis², Georgios Gkotsis¹, Anthi Karageorgoudi¹, Eleni Panagopoulou¹, Reza Aalizadeh¹, Nikiforos Alygizakis¹, Guy Duke³, Ali Akbar Eftekhari⁴, Oliver Machate⁵, Susan Oginah⁴, Dörte Themann⁶, Nikolaos S. Thomaidis¹, Panagiota Kontogianni¹, Dafni Preza Mayo Katak¹, Nikolaos Dragazis¹, S. Henrik Barmenlo⁷, Koos Biesmeijer⁷, Paola Movalli⁸, Dominik Thomas Nerlich⁵, Peter Oswald³, Gabriele Treu⁵, Martina G. Vijver⁷ and Jaroslav Slobodnik³, (1)National and Kapodistrian University of Athens, Greece, (2)Chemistry, National and Kapodistrian University of Athens, Greece, (3)Environmental Institute s.r.o., Slovakia, (4)Technical University of Denmark (DTU), Denmark, (5)German Environment Agency (UBA), Germany, (6)Free University Berlin, Germany, (7)Institute of Environmental Sciences (CML), Netherlands, (8)Environmental Institute s.r.o, Italy

Organic micropollutants pose significant threats to terrestrial ecosystems by disrupting biodiversity, ecosystem structure, and function. Understanding the extent and pathways of chemical pollution in these systems is critical for effective environmental management. The EU-funded TerraChem project addresses this challenge through an integrated systems approach, combining advanced monitoring, modeling, and analytical technologies to map chemical exposure across multiple trophic levels in European terrestrial habitats. This study contributes to TerraChem by investigating organic micropollutant occurrence and biomagnification within the barn owl (*Tyto alba*) trophic chain across six European countries (Netherlands, Germany, Spain, Portugal, Greece, Romania). Samples of barn owl livers, rodents, invertebrates, plants, and soils were collected and analyzed using optimized multi-matrix extraction protocols including Accelerated Solvent Extraction and ultrasonic-assisted extraction, followed by high-resolution and low-resolution mass spectrometry techniques (LC-TIMS-HRMS, GC-HRMS, GC-MS/MS). Results reveal widespread detection of per- and polyfluoroalkyl substances (PFAS), with perfluorooctanesulfonic acid (PFOS) ubiquitously present in all barn owl livers, demonstrating bioaccumulation and biomagnification along the food chain. Additionally, second-generation anticoagulant rodenticides such as brodifacoum showed high concentrations particularly in owls and rodents, reflecting trophic transfer from prey to predator. A suite of plant protection products (including insecticides, fungicides, and herbicides) were also identified, with the lowest contamination in plants, indicating differential exposure across trophic levels. This evidence underscores the barn owl's value as a biomonitor for assessing environmental organic contaminants and highlights complex exposure pathways. The findings emphasize the need for sustained surveillance and comprehensive chemical risk management to protect terrestrial biodiversity and ecosystem services, supporting the EU's zero pollution ambitions through data-informed regulatory frameworks.

2.12.A.T-02 A new systems approach addressing chemical risks to terrestrial biodiversity in Europe

Guy Duke¹, Nikiforos Alygizakis², Paola Movalli³, Susan Oginah⁴, Gabriele Treu⁵, Nikolaos S. Thomaidis², Marissa B Kosnik⁶, Martina G. Vijver⁷, S. Henrik Barmenlo⁷, Koos Biesmeijer⁸, Peter Fantke⁹, Georgios Gkotsis², Romana Hornek-Gausterer¹⁰, Olivier Jolliet¹¹, Oliver Machate⁵, Peter Oswald¹², Laura Scherer⁷ and Jaroslav Slobodnik¹², (1)Environmental Institute s.r.o., Slovakia, (2)National and Kapodistrian University of Athens, Greece, (3)Naturalis Biodiversity Center, Slovakia, (4)Technical University of Denmark (DTU), Denmark, (5)German Environment Agency (UBA), Germany, (6)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (7)Leiden University, Netherlands, (8)Naturalis Biodiversity Center, Netherlands, (9)Environmental Institute s.r.o., Denmark, (10)University of Applied Sciences Vienna (UAS Technikum), Austria, (11)Danish Technical University, Denmark, (12)Slovakia, Slovakia

Anthropogenic chemicals (with other novel entities) have passed the safe operating space of the planetary boundary, since annual production and releases outstrip global capacity for risk assessment and environmental monitoring. In Europe, the number of chemicals in use far exceeds capacities of conventional risk assessment

and monitoring, chemical registration data is often inadequate and risk assessment does not sufficiently consider damages to biodiversity and ecosystem services, in particular in the terrestrial compartment. To address these challenges, we propose a new systems approach, which can support regulators in accelerating delivery of the European Union's zero pollution ambition in the terrestrial compartment. This approach is being developed and tested by the Horizon Europe project TerraChem. The systems approach integrates four key elements: (1) periodic pan-European monitoring of chemicals exposure and mixture effects in selected apex species food chains across representative terrestrial biomes; (2) modelling of chemical source-to-damage pathways in terrestrial ecosystems; (3) novel tools to prioritise substances for further risk assessment and novel approaches to better address terrestrial biodiversity and ecosystem services in environmental risk assessment and risk management of chemicals; (4) a European data management and early warning system for chemicals in terrestrial biota and soils that integrates the monitoring data, modelling output and prioritisation tools. This 'TerraChem approach' would provide a near real-time picture of which substances – among the entire universe of ERACs – are turning up in terrestrial biota and soils across Europe, provide early warning of emerging contaminants, prioritise substances for further risk assessment and risk management measures, and enable risk assessment and management to better take account of damages to terrestrial biodiversity and ecosystem services. TerraChem will test this systems approach, deliver a blueprint for a robust, coherent, pan-European monitoring-modelling-prioritisation-risk assessment and management scheme for chemicals in the terrestrial compartment, and identify next steps to put such a scheme in place. This platform presentation will present interim findings at the project's midway point.

2.12.A.T-03 A Historical Perspective on Bioaccumulation Research and Regulations

Kate Fremlin¹ and **Frank A Gobas²**, (1)*Amaroq Wildlife Services, Canada*, (2)*Simon Fraser University, Canada*

At present, most government jurisdictions around the world use bioaccumulation screening criteria that represent chemical exposure to aquatic water-breathing organisms, which includes the bioconcentration factor (BCF) and bioaccumulation factor (BAF) in fish and the octanol-water partition coefficient (KOW). These metrics are limited in their ability to assess bioaccumulation in organisms because they only assess bioaccumulation in aquatic water-breathing organisms and are not representative of bioaccumulation in many wildlife species or classes of species such as birds and mammals that are air-breathing organisms (Kelly et al., 2007). The continued use of BCFs to assess bioaccumulation potential is astounding from an historical perspective since birds and marine mammals were found to be the most impacted by the dirty dozen of organochlorines that gave rise to environmental regulations of substances and from a current modern perspective where substances of current interest like many perfluoroalkyl substances (PFAS) have low BCFs in fish, low or no KOW, but are highly bioaccumulative in birds and mammals. BCFs and BAFs also do not represent or assess biomagnification in organisms. Hence, field-based biomagnification and trophic magnification factors (BMFs and TMFs) are regarded by many experts as more appropriate metrics for assessing biomagnification potential than the BCF and BAF (Gobas et al., 2009; Borgå et al., 2012; Burkhard et al., 2012). This expert advice has now been incorporated into the recent Guidelines on Information Requirements and Chemical Safety Assessment (European Chemicals Agency, 2023), which has made BMFs and TMFs more prominent tools for bioaccumulation assessments. This opens the door to the use of wildlife data for regulatory purposes. However, the use of wildlife data has been viewed with considerable wariness because of the inherent variability and uncertainty of real-world bioaccumulation data and the challenging conditions for replication. The purpose of this presentation is to discuss the historical context of the bioaccumulation regulations and to highlight a path forward for the use of wildlife data for regulatory bioaccumulation assessment.

2.12.A.T-04 Linking Pesticide Mixture Toxic Pressure to Species Loss in European Agricultural Soils

Susan Oginah, **Farshad Soheilifard** and **Olivier Jolliet**, *Quantitative Sustainability Assessment, Technical Univ. of Denmark, Denmark*

Predicting the damage caused by chemical mixtures to structural biodiversity is relevant for conducting integrated chemical risk assessments and protecting biodiversity. A robust relationship has been established between the effects of toxic pressure mixtures and species loss in aquatic ecosystems. However, we still lack such refinement in terrestrial ecosystems due to data gaps. To address this gap, we began by combining modelled pesticide exposure data from the Pangea model with approximately three million species occurrence records from the Global Biodiversity Information Facility (GBIF), which were harmonized at a 10×10 km grid. A partial mixture toxic pressure was derived from 133 of 900 substances, expressed as summed hazard units (like PAF, the potentially affected fraction of species), based on chronic EC10 endpoints and aggregated across substances per site. To explore the relationship between toxic pressure and biodiversity loss, we applied Generalized Additive Models (GAMs) to predict the potentially disappeared fraction (PDF) of species as a function of increasing toxic pressure. Our preliminary results indicate that species richness declines with increasing toxic pressure, with no observations of high richness at high exposure levels. The GAM model shows that a 20% change in mixture toxic pressure results in 25% of the present species disappearing. Thus, we determined an extrapolation factor of a near 1:1 relationship between predicted effects and actual damage required for different decision-support tools, such as Life Cycle Assessment. The current results represent only partial estimates and are based on agricultural soils with frequent chemical inputs; they may overestimate the biodiversity impact compared to that in natural or semi-natural soils. We will incorporate biomonitoring data from WP1 in the TerraChem project and expand the scope to include other substances beyond pesticides. This will enable the development of a robust PAF-to-PDF relationship for the terrestrial ecosystems, supporting the implementation of improved chemical risk prevention and management strategies.

2.12.B Terrestrial Biodiversity and Chemical Pollution: Understanding Exposure and Impacts Towards Improving Risk Prevention and Management

2.12.B.T-01 Relating Chemical Effects to Ecosystem Functioning: Introducing the Functional Sensitivity Distribution

Annetrude Boeije¹, S. Henrik Barmentlo², Martina G. Vijver¹ and Laura Scherer², (1)Leiden University, Netherlands, (2)No Affiliation, Netherlands

1. Introduction

Current approaches for estimating the effects of chemical exposure commonly rely on species sensitivity distributions, which focus on species richness. However, the concept of biodiversity is much broader, and the species sensitivity distribution does not consider the functional role species have within ecosystems. Functional richness, based on species traits, provides a more direct relation to ecosystem functioning. In this study, we developed the “functional sensitivity distribution” to examine chemical effects on functional richness and compared it with the species sensitivity distribution.

2. Materials and Methods

To assess the effect of chemicals related to ecosystem functioning, we adapted the species sensitivity distribution by replacing species richness with functional richness. Both trait data and ecotoxicity data served as inputs. Functional richness was calculated by mapping traits in a multidimensional space and determining the volume within. Firstly, we calculated the base functional richness at the absence of a toxicant, thus with all species. Next, we used the ecotoxicity data to determine at which concentration a species was affected. Once affected, we excluded this species from the calculation and recalculated functional richness without that species. This process was continued until all species were affected. We then determined the potentially affected fraction of functional richness. Lastly, we constructed the functional sensitivity distribution by fitting a logistic curve through all data points.

3. Results and Discussion

Both species richness and functional richness declined with increasing chemical concentration. While the species sensitivity distribution showed a uniform decline, the functional sensitivity distribution revealed a stepwise decline. Functional groups showed redundancy, and notable changes occurred only when the last species within a group was affected. Therefore, both methods together enhance understanding by providing information on the effects on biodiversity and its implications for ecosystem functioning.

4. Conclusions

The functional sensitivity distribution revealed patterns like the species sensitivity distribution but added insight into how effects on species relate to functional change. Together, these methods provide a more robust basis for chemical risk assessment and can support policymakers in setting safe background concentrations.

2.12.B.T-02 Are pesticides a relevant driver of terrestrial biodiversity loss?

Ralf Bernhard Schaefer, University Duisburg-Essen (Uni DUE), Duisburg, Germany

Agricultural intensification is a major driver of biodiversity decline in Europe, and pesticides are increasingly discussed as an important contributing factor. However, it remains unclear whether current environmental risk assessment (ERA) sufficiently captures their effects on non-target organisms at population and higher levels. This study synthesises quantitative evidence on the effects of currently used pesticides in Europe on terrestrial biodiversity.

We conducted a literature search for the period 1.1.2015–1.5.2025 and restricted inclusion to syntheses, systematic reviews and meta-analyses addressing synthetic organic pesticides currently authorised in at least one EU Member State, with effects on non-target organisms relevant for Europe and reported at population level or above. Narrative reviews, studies focusing only on sublethal endpoints, and clearly non-authorised legacy substances were excluded. Titles and abstracts (10,798 unique records) were screened using a machine-learning assisted tool (ASReview 2.1.1), applying stopping rules (?7.5% screened and ?100 consecutively predicted non-relevant records). Deep screening further required environmentally realistic exposure, clear attribution to agricultural pesticide use in field studies, systematic literature coverage, and at least five observations from ?3 primary studies.

This process yielded 10 publications comprising 51 effect-size cases. Of these, 39 effect sizes were negative, seven indicated no effect and five were positive. Restricting to statistically significant cases (95% confidence intervals not overlapping zero) resulted in 17 effect sizes, all negative. For studies that exclusively considered current-use pesticides, the seven effect sizes were negative. Mean log response ratios were generally negative. Insecticides showed the strongest negative effects on animals and soil invertebrates, whereas herbicides most strongly affected microorganisms and plants. The results demonstrate consistent negative effects of pesticides, including currently authorised substances, on terrestrial biodiversity. These findings challenge the assumption that current ERA approaches are broadly protective at ecosystem level and highlight the need to better align regulatory thresholds with empirically observed biodiversity impacts.

2.12.B.T-03 Protecting Terrestrial Biodiversity Through Chemical Regulation: A Critical Review of European Environmental Risk Assessment Frameworks

Romana Hornek-Gausterer¹, Dörte Themann², Oliver Machate², Dominik Thomas Nerlich², Johan Axelman³ and Gabriele Treu², (1)University of Applied Sciences Vienna (UAS Technikum), Austria, (2)German Environment Agency (UBA), Germany, (3)Swedish Chemicals Agency, Sweden

Chemical pollution is one of the five main drivers of biodiversity loss, yet European chemical regulatory frameworks provide fragmented and inadequate protection. This systematic review examines how REACH, CLP, Biocidal Products Regulation, Plant Protection Products Regulation (PPPR), and pharmaceutical regulations integrate biodiversity into Environmental Risk Assessment (ERA) through comprehensive analysis of legal texts and technical guidance documents.

Findings reveal critical gaps: only PPPR and Biocidal Products Regulation explicitly designate biodiversity as a protection goal. Terrestrial species assessment is severely limited—birds and mammals receive only in some frameworks routine evaluation while amphibians and reptiles remain largely unassessed. Risk assessment relies predominantly on single-species toxicity endpoints, with population-, community-, and ecosystem-level effects absent. No regulation systematically applies Essential Biodiversity Variables across genetic, species, and ecosystem levels. Additional deficiencies include inadequate assessment of transformation products, insufficient mixture toxicity evaluation and integration, and systematic failure to integrate environmental monitoring data into risk management.

We conclude that current ERA schemes inadequately protect terrestrial biodiversity due to: (1) missing operational interpretation of biodiversity protection goals across regulations, (2) limited species representation failing to predict population and ecosystem effects, (3) fragmented assessment approaches, and (4) absent systematic monitoring data integration. Recommendations include revising legal frameworks to enshrine biodiversity as explicit protection goal across all chemical regulations, establishing EU-wide early warning systems linking chemical and biodiversity monitoring data, and integrating biodiversity expertise into regulatory decision-making processes.

Disclaimer/Disclosure:

This work was supported by the TerraCHEM project, funded by the European Union under Grant Agreement No. 101135483. Further information about the project can be found at <https://terrachem.eu/>. Views and opinions expressed are however those of the author(s) only.

2.12.B.T-04 Occurrence and concentration of organic pesticides in Europe's wildlife

Philipp Kropff¹, Martina G. Vijver¹, Laura Scherer¹, Jaroslav Slobodnik² and S. Henrik Barmantlo¹, (1)Leiden University, Netherlands, (2)Environmental Institute s.r.o., Slovakia

1. Introduction

Pesticides unintentionally can end up in non-target species and ecosystems where they exert toxic pressure. The environmental fate of pesticides is predicted based on their chemical properties, but this is not systematically monitored after legislation. Therefore it remains unclear if and in what quantities pesticides find their way into terrestrial biota. To shed light on this we systematically collated field data reporting concentrations of pesticides in European wildlife (i.e. vertebrates, invertebrates and plants). We harmonized all data, establish research and monitoring gaps, and analysed the concentration levels of the most common pesticides over time.

2. Materials and Methods

We performed a literature search with which identified data from 190 published publications, yielding 176,257 rows of data of pesticide concentrations in wildlife together with up to 49 columns of metadata. The collected data was curated and integrated into the NORMAN database system. To understand patterns inside the data we calculated the frequency of appearance of chemicals and their respective groupings and analysed the proportional coverage of 257 species and species groups had in monitoring.

3. Results and discussion.

For most chemicals only few data exist with over 300 of 800 pesticides were tested for only once. While over half of chemicals were not studied more than twice. Organochlorines are still the most frequently detected pesticides with an average FoA of 66 % and are the most tested pesticides overall. Other banned pesticides like Carbofuran are also still found decades after ban. The most common compounds that are still legal to use are rodenticides, which also increase in frequency of appearance when compared to data from before 2010. We also identified that most monitoring is performed on key species groups (mammals, birds, crops) with few studies outside that scope. Mammals and birds make up of 50 % of data in almost every pesticide class. Rodenticides for example, report studies exclusively on mammals and birds, except one.

4. Conclusions

We show that regardless of legal status pesticides occur in most wildlife around Europe even after decades of bans. The pollution seems to be persistent, while newer compounds are now also found in wildlife. However, we also show that the breadth of testing is increasing doing the amount of used pesticides justice and allowing a more encompassing look at pesticides in nature.

2.12.P Terrestrial Biodiversity and Chemical Pollution: Understanding Exposure and Impacts Towards Improving Risk Prevention and Management

2.12.P-Tu140 The Invisible Threat: Tracing Organic Micropollutants Across Diverse European Terrestrial Food Chains Using Cutting-Edge Mass Spectrometry

Nikolaos Boinis¹, Antigoni Konomi¹, Anthi Karageorgoudi¹, Dafni Preza Mayo Katak¹, Panagiota Kontogianni¹, Nikolaos Dragazis¹, Faidra-Angeliki Mourtzoukou¹, Nikolaos Floros¹, Eleni Panagopoulou¹, Reza Aalizadeh¹, Nikiforos Alygizakis¹, S. Henrik Barmentlo², Koos Biesmeijer², Guy Duke³, Ali Akbar Eftekhari⁴, Romana Hornek-Gausterer⁵, Philipp Kropf⁶, Oliver Machate⁶, Paola Movalli⁷, Dominik Thomas Nerlich⁶, Peter Oswald³, Susan Oginah⁴, Dörte Themann⁶, Gabriele Treu⁶, Martina G. Vijver², Georgios Gkotsis¹, Jaroslav Slobodnik³ and Nikolaos S. Thomaidis¹, (1)National and Kapodistrian University of Athens, Greece, (2)Institute of Environmental Sciences (CML), Leiden University, P.O.Box 9518, 2300 RA Leiden, The Netherlands, Netherlands, (3)Environmental Institute s.r.o., Slovakia, (4)Technical University of Denmark (DTU), Denmark, (5)University of Applied Sciences Vienna (UAS Technikum), Austria, (6)German Environment Agency (UBA), Germany, (7)Environmental Institute s.r.o., Netherlands

Organic micropollutants (OPs) threaten terrestrial ecosystems and biodiversity by causing physiological, reproductive, and immune harm to wildlife, disrupting food webs and ecosystem stability. They biomagnify in food chains, impacting apex predators and causing epigenetic effects that threaten populations over generations. Addressing biodiversity loss from OPs requires integrated policies combining pollution reduction, ecosystem restoration, and strong regulations. Although OPs' impact on aquatic systems is well-studied, terrestrial effects remain under-researched. The EU-funded TerraChem project (2023-2026) fills this gap by monitoring chemical exposure across trophic levels in six European countries using innovative methods. TerraChem's 2024–2025 sampling in the Netherlands, Germany, Romania, Portugal, Spain, and Greece targeted apex predators—beech martens, grey wolves, red foxes, Egyptian mongooses, European badgers, and northern white-breasted hedgehogs—at six sites per country, plus soil, plants, invertebrates, rodents, and prey species. Sample preparation employed optimized methods, including modified QuEChERS for soil/plants and solvent-SPE protocols for tissues, enabling liquid and gas chromatography analyses. Advanced analytical techniques included high-resolution mass spectrometry (HRMS) coupled with liquid chromatography-ion mobility spectrometry (LC-IMS-HRMS), gas chromatography-HRMS (GC-HRMS), and tandem mass spectrometry (GC-MS/MS). GC-MS/MS quantitatively targeted trace levels of priority OPs, while LC and GC HRMS enabled comprehensive targeted and non-targeted screening using a large, curated database maintained by the National and Kapodistrian University of Athens, containing over 3,000 environmentally relevant compounds. Hundreds of OPs were detected, including 18 per- and polyfluoroalkyl substances (PFAS) such as PFOS, PFOA, and 6:2 FTS, concentrated especially in apex predator livers, showing biomagnification. Legacy pesticides like DDT and metabolites persisted despite decades-long bans. Anticoagulant rodenticides (Brodifacoum, Bromadiolone) appeared mainly in livers from Spain, Greece, and Romania. These emerging contaminants and persistent organic pollutants, combined in complex mixtures, act as stressors for wildlife and possibly humans. TerraChem's multi-trophic, state-of-the-art HRMS approach advances knowledge of OP distribution, exposure routes, trophic transfer, and ecological impacts across Europe's terrestrial ecosystems.

2.12.P-Tu142 Automating Reliable Input Data: The PROVES Python Packages for Chemical Structure and Property Verification in Environmental Modeling

Ali Akbar Eftekhari¹, Kerstin von Borries¹, Peter Fantke² and Olivier Jolliet¹, (1)Technical University of Denmark (DTU), Denmark, (2)substitute ApS, Denmark

Characterizing the impact of chemicals on humans and the environment requires several substance-specific thermodynamic, transport, and fate parameters. We implement systematic workflow and computational tools for a transparent and comprehensive evaluation of the most used QSAR models for the prediction of physicochemical and environmental properties of chemical substances required for the USEtox model. The workflow aims to reduce uncertainty and clarify the provenance of parameters, consequently helping to transparently quantify the impact of the input parameters on the USEtox results.

To fully automate this complex workflow, we have developed a family of open-source Python packages collectively known as PROVES (Preprocessing and Verification of Substance Properties). The cornerstone of this suite is PROVESID, a unified library designed for finding chemical identifiers and structures, performing structure verification, and handling conversion between various formats using major public sources, e.g. PubChem, CAS Common Chemistry, and tools e.g. IUPAC OPSIN. It also includes functions for downloading available experimental data. Complementing this, we introduce PyCompTox and PyEPISuite. PyCompTox offers the capability to efficiently search and retrieve properties and data from the CompTox Chemicals Dashboard, while PyEPISuite provides well-structured data access from the EPI Suite web application. Finally, PyQSARToolbox provides an interface to the QSAR Toolbox and its key addons, including OPERA and VEGA, allowing users to programmatically run prediction models and access experimental reference data, making the entire prediction process fully automatable. Finally, EXPROVES provides a collection of literature data for physicochemical and fate properties of chemicals with a Python interface for the verification of the predictions.

Collectively, these PROVES packages streamline the entire process from initial chemical identification and verification to multi-model prediction and systematic quality control. The entire suite of packages will be an integral part of the new USEtox web application and will be released open-source on GitHub under the USEtox organization, providing the environmental modeling community with transparent, traceable, and validated chemical property and environmental data.

This research is part of the project “TerraChem” funded under EU project number 101135483.

2.12.P-Tu143 A Systematic Workflow for Generating Accurate and Transparent Chemical Input Data for Environmental Modelling

Ali Akbar Eftekhari¹, Kerstin von Borries¹, yuyue zhang¹, Peter Fantke² and Olivier Jolliet¹, (1)Technical University of Denmark (DTU), Denmark, (2)substitute ApS, Denmark

Environmental models that deal with the transport, fate, and effect of chemicals in a multimedia environment, e.g. USEtox, require reliable data on the physicochemical properties and reactivity of chemical substances. However, due to lack of experimental data, environmental models must rely heavily on predictive methods, often based on Quantitative Structure-Activity/Property Relationships (QSAR/QSPR). Reliance on unverified predictive models can introduce significant uncertainty into environmental risk assessments, potentially leading to inaccurate estimations of chemical impact on human health and ecotoxicity. We address these problems by proposing a new, systematic workflow to improve the transparency and accuracy of USEtox input parameters by systematically verifying predictive performance. We first obtained chemical structures for chemical identifiers. The verified structures are then used in OPERA, VEGA, EPI Suite, and QSAR Toolbox, and IFSQSAR. For each required parameter, we calculate the Root Mean Square Error (RMSE) of the deviations of predicted values from experimental data. We ranked the models by the reducing order of the calculated RMSE and selected the two highest-performing models for each parameter, unless one model significantly outperforms the second best. The systematic evaluation successfully identified the most reliable models: OPERA showed reasonable performance for most physicochemical parameters, although there is still room for improvement for the Henry’s law constant estimation, and almost all models failed to satisfactorily predict acid and base dissociation constants. Notably, EPI Suite showed the best performance for the prediction of degradation rates. This work culminates in the generation of a new transparent database of USEtox input parameters for over 10,000 substances, prioritizing experimental data, the geometric average of the predictions of the two best models, and, lastly, lower-performance model predictions. Each reported value is labeled with full metadata, indicating the source and whether the prediction is within the applicability domain of the utilized model. This open-source workflow and database, which will be available on GitHub, advances environmental modeling by providing a verified and transparent set of input parameters, substantially reducing uncertainty and improving the reliability of chemical impact assessments.

TerraChem establishes an integrated framework for identifying contaminants of emerging concern (CECs) in terrestrial ecosystems by combining novel sampling approaches, advanced high-resolution mass spectrometric (HRMS) analysis, FAIR data management, harmonized data processing, and predictive modelling. The TerraChem Data Management System (TDMS) structures and disseminates all project information. It includes a comprehensive sample catalogue containing rich metadata on collected specimens; a chemical occurrence database storing targeted monitoring results; a literature-derived occurrence database mined from scientific publications; and the Digital Sample Freezing Platform (DSFP), which stores and processes untargeted HRMS data and performs wide-scope suspect screening across ~95,000 contaminants included in the Substance Database. All modules expose data through open APIs. A new module, the TerraChem Early Warning System (TEWS) processes DSFP outputs filtered for terrestrial biota, grouping HRMS features and modelling their spatial distributions, temporal behaviours, and biomagnification potential using generalized additive models. A Priority Index is derived to highlight unknown or insufficiently characterized compounds that display hotspots, historical trends, or complex bioaccumulation patterns. Once identities are elucidated, these early signals feed into the broader PARC Early Warning System, which applies hazard, exposure, and ecotoxicological modelling to classify chemicals as NERCs or non-NERCs.

2.12.P-Tu145 Spatially-explicit Impact Assessment of Pesticide-induced Terrestrial Biodiversity Loss yuyue zhang¹, Susan Oginah¹, Farshad Soheilifard¹, Peter Fantke² and **Olivier Jolliet¹**, (1)Technical University of Denmark (DTU), Denmark, (2)substitute ApS, Denmark

Chemical pesticides exert pressure on terrestrial ecosystems through ecotoxicity effects on organisms. Global reduction targets, including the UN Sustainable Development Goals, call for decreased pesticide use, yet a spatially-explicit global overview of impacts on terrestrial biodiversity is lacking. Existing studies focus on specific regions or extrapolate from limited data, leaving no overview that accounts for regional differences in species vulnerability. Biodiversity hotspots with endemic species face disproportionately higher extinction risks, yet current Life Cycle Impact Assessment methods lack the spatial resolution to capture this variation.

To address this gap, we integrate the full impact pathway from pesticide use through emissions and environmental fate to damage on terrestrial species. Three objectives are addressed: (1) Linking pesticide application to Predicted Environmental Concentrations (PEC) in soils using the multimedia Pangea fate model. (2) Combining PEC with Global Extinction Probability (GEP) data for terrestrial taxonomic groups to calculate area-normalized impact scores. (3) Identifying terrestrial biodiversity impact hotspots to inform prioritization for pesticide reduction.

Spatially-resolved emissions were modeled based on application method, crop type, and growth stage. Pangea estimated PEC for glyphosate across 87,063 global catchments. Biodiversity impact was calculated as: $\text{Damage} = \text{PEC} \times \text{EF} \times \text{XF} \times \text{GEP}$, expressed as Potentially Disappeared Fraction (PDF) per year per km².

Results show highest impact intensities where intensive agricultural use overlaps with high-GEP regions, particularly in Brazil, Argentina, Central Europe, India, and China. Some high-GEP regions (e.g., Congo Basin) show lower damage due to limited pesticide application, while moderate-GEP regions (e.g., US Midwest) show elevated damage due to intensive use. This framework enables identification of impact hotspots and supports prioritization of interventions in biodiversity-sensitive areas.

2.12.P-Tu146 Assessing the Temporal and Spatial Distribution of Chemical Exposure via Heavy Metal and Other Element Concentrations in Peregrine Falcon Down Feathers in the Netherlands Using INAA **Cristina Ruiz González¹**, Paola Movalli², Lambert van Eijck³, Peter Bode³, Mehmet Sarilar³ and Delia van Rij³,

(1)Faculty of Applied Sciences, TU Delft, Netherlands, (2)Naturalis Biodiversity Center, Netherlands, (3)Reactor Institute Delft, Delft University of Technology, Netherlands

Understanding chemical exposure in terrestrial wildlife is essential for detecting environmental and human health risks, providing early warnings of emerging contaminants and improving our knowledge of how pollutants affect European biodiversity. As part of this broader effort, this study assesses the temporal and spatial distribution of heavy metals and other elements in peregrine falcon (*Falco peregrinus*) feathers in the Netherlands, contributing both to EU priorities on addressing chemical risks and to TerraChem's objective of improving understanding of chemical stressors in terrestrial biota. A statistically valid number of chick down feathers from the Naturalis Biodiversity Center, collected in five different years between 2017 and 2024, were analysed to establish historical reference values for elements of societal concern. These baselines support interpretation of current concentrations and spatial patterns derived from recent (2024) samples collected across more than 50 nest locations, including Eindhoven, Veldhoven, Duiven, 's-Hertogenbosch, Budel, Apeldoorn, Maastricht, Zwolle, Arnhem and Meppel, among others. The sampled sites represent urban, industrial and rural areas, allowing exploration of spatial patterns linked to potential pollutant sources. All feather samples were analysed using instrumental neutron activation analysis (INAA), a non-destructive technique that provides consistent quantitative data across years and sites and allows examination of concentration values to compare historical and more recent exposure patterns. The resulting dataset will offer reference values for selected contaminants in peregrine feathers, supporting more accurate interpretation of current exposure levels and revealing trends in elements that may pose risks to peregrines, wider terrestrial ecosystems or human health. The final results and conclusions will be presented in the poster.

2.12.P-Tu147 Do Gammarids Play a Role in the Transmission of Anticoagulant Rodenticides?

Julia Regnery¹, Valeska Contardo Jara², Ronny Schmiediche², Julia Bachtin³, Christel Möhlenkamp³, Kai Sören Lehmann⁴ and Anton Friesen², (1)German Federal Institute of Hydrology (BfG), Germany, (2)German Environment Agency (UBA), Germany, (3)German Federal Institute of Hydrology (BfG), Germany, (4)University of Veterinary Medicine Hannover, Foundation, Germany

Tracking the environmental fate of anticoagulant rodenticides (AR) across food webs can be challenging. Aquatic exposure pathways of these problematic substances appear to be more diffuse than terrestrial, suggesting multiple sources of contamination at trace level. One understudied group of organisms in terms of rodenticide exposure and transmission are invertebrates, which serve as a nutrition base for a variety of higher tier species. In the present study, the abundant amphipod crustacean *Gammarus* sp. was chosen as a model organism for freshwater ecosystems to investigate two hypothetical exposure pathways. Although known as shredders, gammarids are opportunistic omnivores, and thus potentially attracted to baits or poisoned carcasses flushed into surface waters during rodent baiting campaigns. Here, we studied the behavior of freshwater gammarids (*Gammarus pulex* and *G. roeselii*) feeding on commercial rodenticide bait blocks under controlled laboratory conditions. In a second laboratory experiment, gammarids were offered poisoned rodent liver tissue as a food source. Rodenticides comprised the second-generation active ingredients brodifacoum and bromadiolone. In each experiment, we measured the AR body burden of gammarids after 36 hours of exposure using LC-MS/MS. In addition, a field monitoring was conducted, and native freshwater gammarids collected from 25 German surface water locations were screened for AR residues.

Overall, our results show that gammarids consumed offered bait as well as rodent liver tissue in the laboratory experiments. The AR body burdens of gammarids exposed to bait were in the range of 0.72 µg/g dry weight (bromadiolone) and 1.65 µg/g dry weight (brodifacoum), respectively. Residue levels were below the method quantification limit of 0.015 µg/g dry weight in controls feeding on alder leaves. Dietary uptake of fluorescent bait by gammarids was visually confirmed using a stereomicroscope. No mortality associated with rodenticide bait or poisoned tissue consumption was observed over a 36 hours exposure period. Unlike vertebrates, invertebrates are not susceptible to the specific mode of action of AR. All of the randomly collected 25 field monitoring samples revealed no quantifiable AR residues. Yet, our straightforward laboratory experiments demonstrate that gammarids may contribute to the transmission of AR in the aquatic food web after their opportunistic feeding on bait or poisoned carcasses.

SETAC Europe 36th Annual Meeting

soil water contaminations for plants, and to aerial transport of pesticides for aphids. This study thus showed that pesticide exposures within non-target ecosystems adjacent to crops drive, at least to short-term, organisms' responses to later exposure to sublethal doses of pesticides, with different outcomes depending on the considered organism.

2.12.P-Tu150 Chemicals in Agricultural Soils in Germany

Judith Klein¹, Karlheinz Weinfurter¹, Cecilia Diaz¹, Fabian Essfeld², Bernd Gockener¹, Udo Hommen¹, Michael Hüben³, Benedikt Ringbeck⁴, Dimitrios Alexander Skodras¹, Marie Winter⁵, Daniela Gildemeister⁶, Lisa Noll⁷, Ricardo Schöps⁸ and Pia Kotschik⁸, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (5)University of Osnabrueck, Germany, (6)Pharmaceuticals, German Environment Agency (UBA), Germany, (7)Pesticides Unit, German Environment Agency (UBA), Germany, (8)German Environment Agency (UBA), Germany

The aim of the project 'Chemicals in Agricultural Soils in Germany' is to provide a first overview on the contamination of agricultural sites with different types of chemical pollutants. Soil samples were collected in the years 2022 – 2024 from 110 sites across Germany, covering arable land (62), grassland (30), orchards (9) and vineyards (9). The chemical monitoring focused in a first step on a comprehensive screening of pesticides, i.e. active substances and metabolites of plant protection products and biocides, pharmaceuticals and a small number of selected industrial chemicals in two soil layers (0–5 cm and 5–20 cm). Within a second step, a subset of substances was analysed with lower detection limits. In addition, neonicotinoids were analysed separately with significantly lower detection limits. Concentrations of the analytes were on average lower in the deeper soil layer. Insecticides, particularly imidacloprid and clothianidin, were the most frequently detected compounds across all sites. The diversity and total number of detected substances varied considerably between locations, but no clear geographical pattern was observed. Arable soils showed the highest prevalence of fungicides, herbicides and insecticides. Pharmaceuticals and industrial chemicals were only rarely detected.

Disclaimer/Disclosure:

Project was funded by the Federal Ministry for the Environment, Climate Action, Nature Conservation and Nuclear Safety and supervised by the German Environment Agency (UBA).

2.12.P-Tu151 Cumulative Risk in Soil

Judith Klein¹, Karlheinz Weinfurter¹, Cecilia Diaz¹, Fabian Essfeld², Bernd Gockener¹, Udo Hommen¹, Michael Hüben³, Benedikt Ringbeck⁴, Dimitrios Alexander Skodras¹, Marie Winter⁵, Daniela Gildemeister⁶, Lisa Noll⁷, Ricardo Schöps⁸ and Pia Kotschik⁸, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (5)University of Osnabrueck, Germany, (6)Pharmaceuticals, German Environment Agency (UBA), Germany, (7)Pesticides Unit, German Environment Agency (UBA), Germany, (8)German Environment Agency (UBA), Germany

This study provides an overview of pesticide (plant protection products, biocides and metabolites) contamination in agricultural soils in Germany, measured at 110 sites sampled between 2022 and 2024 across arable land, grassland, orchards, and vineyards. Measured concentrations of active substances were evaluated using ecotoxicological threshold values to characterize potential risks for soil organisms. Toxic Units (TUs) were calculated for each detected compound, using Regulatory Acceptable Concentrations (RACs) for plant

protection products (PPPs) derived from data for soil invertebrates and Predicted No-Effect Concentrations for soil (PNECsoil) for biocides. Cumulative Risk Indicators (RIs) were determined by summing all substance-specific TUs per site, applying the principle of concentration addition to capturing mixture effects. PPP-related TUs showed that a few soils exhibited exposure levels of ecological concern. Six arable fields exceeded RI values above 1, indicating that acceptable thresholds were surpassed. Vineyards and orchards also showed RIs > 1, though generally at fewer sites. In contrast, grassland displayed consistently low risk index values. Key risk drivers included Dimoxystrobin, Boscalid and Clothianidin, as well as isolated exceedances from Hydroxysimazine. Mixture risks in high-impact sites were typically dominated by one or two substances. Biocide contamination contributed less overall but still produced notable risk at individual sites. PNEC-based TUs revealed exceedances for Clothianidin, Fludioxonil, and Azoxystrobin, with highest cumulative biocide RIs observed in arable soils. However, these substances could have been used as plant protection products on arable fields. The only biocides found which are not also authorized as plant protection products, the quaternary ammonium compounds (BAC12, BAC14), both generally played a minor role within the overall RI. Overall, the results show that cumulative chemical exposure in agricultural soils may adversely affect soil invertebrates, and that combined PPP and biocide mixtures could exert additive effects not captured through single-substance evaluation. The study underscores the need for continued chemical and biological soil monitoring, inclusion of monitoring results in the risk assessment, improved mixture-risk assessment approaches, and consideration of cumulative chemical pressure in regulatory frameworks.

2.12.P-Tu152 Earthworm Communities in German Agricultural Soils: Patterns, Drivers and Chemical Risk

Fabian Essfeld¹, Udo Hommen², Dimitrios Alexander Skodras², Marie Winter³, Karlheinz Weinfurter², Cecilia Diaz², Bernd Göckener², Michael Hüben⁴, Benedikt Ringbeck⁵, Lisa Noll⁶, Ricardo Schöps⁷, Pia Kotschik⁷ and Judith Klein², (1)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)University of Osnabrueck, Germany, (4)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (6)Pesticides Unit, German Environment Agency (UBA), Germany, (7)German Environment Agency (UBA), Germany

The aim of the project ‘Chemicals in Agricultural Soils in Germany’ is to provide a first overview on the contamination of 110 agricultural sites with different types of chemical pollutants. In addition to the chemical monitoring, the earthworm communities were analysed at 51 sites representing arable land, grassland, orchards, and vineyards. On average, total earthworm abundance and biomass were highest in grassland and lowest in arable land and vineyards reflecting the influence of land use and management intensity. However, variability within the arable soils was high - the highest abundance and biomass values were found here. Multivariate analyses revealed that soil properties (e.g., pH, organic carbon, texture) were the primary drivers of earthworm abundance and biomass, while cumulative chemical risk indicators also negatively influenced earthworm abundance and biomass. These findings highlight the complexity of soil ecosystems and the need for integrated monitoring approaches that consider both chemical mixtures and ecological context.

Project was funded by the Federal Ministry for the Environment, Climate Action, Nature Conservation and Nuclear Safety and supervised by the German Environment Agency (UBA).

2.12.P-Tu153 Tropical Mesocarnivores as Heavy Metal Sentinels in Proximity to Oil Palm Plantations

Tyler Cuddy¹, Mohamed Reza Mohamed Tarmizi², Amanda Wilson³, Rakhee Dhorajiwala¹, Nur Alwanie Maruji⁴, Jason Weeks⁵, Susan Zappala⁵, Claus Svendsen⁶, Benoit Goossens³ and Pablo Orozco-terWengel¹, (1)Cardiff University, United Kingdom, (2)Danau Girang Field Centre, Malaysia, (3)Cardiff University, Danau Girang Field Centre (DGFC), Malaysia, (4)Sabah Wildlife Department, Malaysia, (5)JNCC, United Kingdom, (6)UKCEH, United Kingdom

The Bornean state of Sabah has lost ~40% of its forests to oil palm. Despite this, generalist mesocarnivores such as civets and leopard cats persist in plantations, potentially increasing exposure to inorganic pollutants, including heavy metals from agrochemicals and regular chemical fertiliser use. We assessed acute and chronic non-essential heavy metal burdens in wild mesocarnivores from the Lower Kinabatangan Wildlife Sanctuary, where remnant forest lots are surrounded by plantations, using inductively coupled plasma optical emissions spectroscopy (ICP-OES) of blood and hair samples. Blood samples were used to provide acute estimates of exposure, and hair samples were used to estimate chronic exposure.

Sunda leopard cats, as a model species for a persistent plantation predator, show elevated arsenic (As) (acute: 9.86 ± 1.56 ; chronic: 2.86 ± 2.65 mg/kg) and lead (Pb) (0.32 ± 0.31 ; 1.93 ± 3.15 mg/kg). Common palm civets, as generalists with a preference towards frugivory, exhibit elevated As (0.95 ± 0.70 ; 1.11 ± 0.60 mg/kg), Pb (0.74 ± 0.33 ; 0.80 ± 0.53 mg/kg), and aluminium (Al) (43.43 ± 23.92 ; 24.56 ± 13.43 mg/kg). Malay civets as generalists show high Al (38.94 ± 25.02 ; 53.16 ± 46.83 mg/kg), As (0.95 ± 0.33 ; 1.10 ± 0.19 mg/kg), cadmium (Cd) (0.41 ± 0.79 ; 0.12 ± 0.07 mg/kg), mercury (Hg) (2.69 ± 5.64 ; 7.88 ± 12.82 mg/kg) and Pb (0.98 ± 0.63 ; 0.55 ± 0.29 mg/kg).

Results suggest that metal bioaccumulation is a constant pressure, with As and Pb particularly elevated in plantation-persistent mesocarnivores and those living in proximity to plantations. All elevated non-essential metals exceeded thresholds of concern for each study species, raising urgent questions about the future for mesocarnivore persistence in oil palm systems and the invisible impacts of extensive agriculture on tropical communities.

This work is currently published as part of my PhD with the ECORISC CDT. Funding is from the ECORISC CDT, and Joint Nature Conservation Committee (JNCC), with additional grants acquired from the Society of Tropical Ecology, and Taith. All fieldwork undertaken was under an approved access license from the Sabah Biodiversity Centre, with support from Sabah Wildlife Department. All work directly with wildlife was conducted with an experienced wildlife vet.

2.12.P-Tu154 Nano-Enhanced Phytoremediation of Cd-Contaminated Soil: ZnO NPs Stimulate Brassica juncea Growth and Stress Tolerance

Inesa Kniūpiūtė¹, Inesa Sinkevičiūtė¹, Aušra Sinkevičienė², Rasa Kimbirauskienė² and Marius Praspaliauskas¹, (1)Laboratory of Heat Equipment Research and Testing, Lithuanian Energy Institute, Lithuania, (2)Department of Agroecosystems and Soil Sciences, Agriculture Academy, Vytautas Magnus University, Lithuania

Heavy metal (HM) contamination remains a persistent environmental challenge, as these elements do not degrade and accumulate in soils, plants, and food webs. Phytoremediation provides a sustainable approach for HM removal, but its efficiency is often limited by slow plant growth and metal-induced stress. In parallel, engineered nanomaterials—particularly zinc-based formulations—are increasingly used in agriculture to enhance nutrient availability, strengthen stress tolerance, and stimulate biomass production. Their reactivity has recently prompted interest in applying them as soil amendments to support remediation, yet nano-assisted phytoremediation remains at an early stage, with major gaps concerning nanoparticle–metal interactions, mixture effects, and safe but effective dose ranges.

To address these questions, we evaluated how different concentrations of ZnO nanomaterial (0, 100, 200, 300 mg kg⁻¹) influence Indian mustard (*Brassica juncea*) grown in Cd-contaminated soils (0–100 mg kg⁻¹) under controlled ambient conditions (21/14°C day/night; 400 ppm CO₂; 55–70% RH). Plant responses were assessed via chlorophyll content, shoot height, root length, and shoot and root dry biomass, representing key indicators of physiological stress and phytoremediation performance.

Cadmium reduced all growth traits in a concentration-dependent manner. In contrast, low-dose Zn NPs amendments partially alleviated Cd stress, increasing chlorophyll retention, promoting root elongation, and enhancing shoot and root biomass by ~10–30% relative to Cd-only controls. The strongest improvements occurred at 1–10 mg kg⁻¹ Cd, likely reflecting micronutrient supplementation and reduced Cd adverse effects. At 50 mg kg⁻¹ Cd, mitigation effects remained but were insufficient to fully counteract toxicity, whereas the highest nanomaterial dose (300 mg kg⁻¹) occasionally intensified HM stress, indicating a potential shift from beneficial to inhibitory effects.

Overall, the findings show that small additions of ZnO NPs amendments can modulate plant stress responses, enhance growth, and increase Cd accumulation, thereby improving the overall phytoremediation efficiency of

contaminated soils. These results provide new insight into mixed nanoparticle–HM interactions and underscore the promise—and the need for careful dose optimisation—of nano-assisted phytoremediation in environmental risk management.

2.12.P-Tu155 Unraveling Soil Interactions and Ecological Risks of Zinc Oxide Nanoparticles and Cadmium

Inesa Sinkevičiūtė¹, Aušra Sinkevičienė², Rasa Kimbirauskienė², Inesa Kniūpytė¹ and Marius Praspaliauskas¹, (1)Laboratory of Heat Equipment Research and Testing, Lithuanian Energy Institute, Lithuania, (2)Department of Agroecosystems and Soil Sciences, Agriculture Academy, Vytautas Magnus University, Lithuania

Global population growth is expected to reach 9.6 billion by 2050, intensifying pressure on agricultural soils and increasing the need to manage contamination while sustaining productivity. Nanotechnology has emerged as a promising tool to enhance crop performance and support heavy metal (HM) remediation. Due to their high surface area and reactivity, nanoparticles (NPs) can reduce metal toxicity or stimulate plant growth at low doses, yet excessive inputs may create new risks, as unabsorbed particles can persist in soil, alter physicochemical properties, and affect soil biota. When applied to contaminated soils, NPs may also modify soil functioning in ways that influence both plant performance and ecological safety, underscoring the importance of evaluating combined HM–NPs effects.

To investigate these interactions, we conducted a phytoremediation experiment with *Brassica juncea* grown at 21°C in soils amended with cadmium (0, 1, 10, 50 mg/kg) and ZnO nanoparticles (0, 0.1, 0.2, 0.3 g/kg). Soil CO₂ and O₂ concentrations, electrical conductivity (EC), soil water content (SWC), pH, temperature, and organic matter were monitored to assess soil–plant–microbe responses. Moderate ZnO additions (0.1–0.2 g/kg) enhanced soil respiration, increasing CO₂ from 10% to 2.8-fold above untreated soil, suggesting stimulated microbial and root activity. O₂ decreased slightly (~1–8.2%), consistent with elevated respiration, with stronger declines as Cd increased from 0 to 10 mg kg⁻¹. EC and SWC remained stable at moderate NP doses but declined at 0.3 g kg⁻¹, indicating potential stress on soil structure or biota. Soil pH varied only ±0.3 units around neutrality. Organic matter increased markedly across all Cd–ZnO treatments, rising by 4.4–70.4% relative to the control without ZnO NPs.

Overall, the study shows that ZnO nanomaterials have a dual role in Cd-contaminated soils: low to moderate doses enhance biological activity, support Cd stabilization, and improve conditions relevant to phytoremediation, whereas excessive NP inputs or elevated Cd levels reduce soil respiration and disrupt moisture dynamics. These findings advance the ecological risk assessment of HM–NP mixtures and highlight the need for careful dose optimisation to enable sustainable nano-assisted bioremediation strategies that balance remediation efficiency with ecological safety and agricultural productivity.

2.12.P-Tu156 Removal of emerging contaminants in wastewater treatment: comparison of photosynthetic systems and activated sludge

Félix Gaspar Gonzalo Ibrahim, Samuel Garcia Garcia and Ignacio de Godos Crespo, University of Valladolid, Spain

Contaminants of emerging concern (CECs) are chemical substances that are commonly detected in the environment and can cause ecological or human health effects. In this scenario, algal-bacterial processes have recently emerged as an economically viable and environmentally friendly option for eliminating chemical and biological contamination from different types of wastewaters: domestic, industrial and agricultural. Utilizing solar energy, wastewater treatment with microalgae converts carbon and nutrients into algal and bacterial biomass and showed similar high removal efficiencies with membrane bioreactor of activated sludge systems.

2.12.P-Tu157 Ecotoxicological Dynamics of Insecticide Resistance in Cotton-Feeding *Spodoptera littoralis*

Melis Yalcin and Refik Efe Ege, Aydın Adnan Menderes University, Turkey

The cotton leafworm (*Spodoptera littoralis*) (Boisduval) (Lepidoptera: Noctuidae), is one of the primary pests in cotton production, causing significant yield losses due to its high population densities. This situation has led to increased pesticide applications, resulting in the development of insecticide resistance in the pest. Effective pest management today requires determining the resistance status to insecticides and investigating the effects of synergistic substances on resistance mechanisms. In this study, the resistance of *S. littoralis* populations collected from the Aydın region of Turkey to active ingredient indoxacarb was examined. Additionally, the effects of commonly used synergists diethyl maleate, piperonyl butoxide, and triphenyl phosphate on the resistance mechanisms of the pest to insecticides were evaluated.

Experiments were conducted following the methodology recommended by the Insecticide Resistance Action

Committee (IRAC). Second instar larvae were exposed to six different doses with three replicates placed in petri dishes, each containing 10 larvae. Mortality was recorded at 24 and 48 hours, and LC50 values were calculated using the Polo Plus program to assess resistance levels. To evaluate the effects of synergistic substances, 1 µl of each synergist was applied to third instar larvae using a Hamilton syringe, and mortality rates were recorded after 24 and 48 hours.

The results indicated that the pest population has developed insecticide resistance, while synergistic substances played a significant role in overcoming resistance mechanisms. These findings allow for the optimization of pesticide applications by selecting effective insecticides and utilizing synergists in resistance management. Consequently, unnecessary pesticide use can be reduced, promoting sustainable pest control. Future studies are planned to investigate resistance mechanisms at the molecular level and explore new synergistic combinations.

2.13.A Unpacking Plastic Complexity: Investigating the Biological Impacts of Micro- and Nanoplastics, and Plastic Associated Chemicals

2.13.A.T-01 A New Methodology for the Quality Assessment of Recycled Plastics

Richard Becker, Marcus Lukas and Ulrike Braun, German Environment Agency (UBA), Germany

To establish wide spread recycling of plastic in the packaging and other short-life segments it is necessary to monitor the quality of the materials with methods that appropriately address their complexity while being practical in day-to-day operations. A recyclates quality is determined based on the release of potentially harmful substances in the context of this study. The challenge lies in the large variety of possible substances ranging from additives, degradation products, non-intentionally added substances to all kinds of contaminants and the realistic description of their behaviour. While this situation calls for comprehensive analysis, the volume based low-cost business model of plastic packaging and by extension also its recycling call for fast decisions based on practical parameters.

As basis for the method development a migration scenario at room temperature and 70°C utilizing water as eluent was devised and implemented with recycled polypropylene pellets from different input streams. The produced eluate was assessed in terms of released dissolved organic carbon (DOC) and estrogenic potential. First results show the influence of an increased temperature during elution on the DOC value which appears to be connected to the release of compounds with estrogenic potential for one sample only. To complement these tests with data about the release of individual substances passive sampler mediated thermal desorption gas chromatography mass spectrometry (TD-GCMS) is used in the eluates. On the level of single substances, the differences between samples become less obvious but an evaluation scheme based around congruent and unique signals opens a new angle at the problem. By dividing signals from the TD-GCMS analysis in this manner two goals can be achieved. Firstly, insights about the commonly found substances in these recyclates are generated and secondly it acts as a filter to focus on relevant signals likely associated with effects observed in individual samples. Finally, a database storing all signals from past measurements attributed to their respective samples is continuously maintained. With this approach each additional processed sample will improve the clarity of correlations between signals, observed effects and input materials used for recycling.

2.13.A.T-02 Intestinal Toxicity of Polyethylene Terephthalate Micro- and Nanoplastics and Their Degradation Products: A Multi-Endpoint Cellular Analysis

Catarina Filipa Eira Velha Cunha¹, Alberto García Martín², Fernanda De Oliveira Esteves Rosário¹, Verónica Bastos¹, Teresa Rocha-Santos¹, Juan M. Bolívar² and Helena Oliveira¹, (1)CESAM, University of Aveiro, Portugal, (2)Faculty of Chemical Sciences, Complutense University of Madrid, Spain

The increase in plastic production has generated large amounts of waste, much of which enters in the environment and degrades into small particles, classified as microplastics (<5 mm) and nanoplastics (<100 nm) (MNPs). The widespread of MNPs in the environmental resulted in their recognition as emerging pollutants, raising the risk of human exposure to both the particles and their degradation products (DPs). Ingestion is considered the primary exposure route, allowing both MNPs and DP to interact with gut epithelium. However, their cellular and molecular effects remain largely unknown. Understanding the cytotoxic and mechanistic

effects of MNPs and their degradation products is essential to assess their potential risks to human health. Polyethylene terephthalate (PET), a plastic widely used in food and beverage packaging, can be degraded into bis(2-hydroxyethyl) terephthalate (BHET), mono(2-hydroxyethyl) terephthalate (MHET), terephthalic acid (TPA) and ethylene glycol (EG). Here, the intestinal cell line Caco-2 was used to evaluate the effects of PET particles at micro and nanosize (12µm;80nm) and PET-degradation products (BHET; MHET; TPA; EG) on cell viability, ROS production, cell-cycle dynamics and apoptosis. PET particles induced a slight decrease in cell viability and no detectable effects on cell-cycle dynamics or apoptosis. In contrast, PET-DP showed a more pronounced biological activity. MHET showed a dose-dependent cytotoxic effect and increased the ROS production, indicating oxidative stress despite the absence of cell-cycle or apoptotic alterations. Similarly, BHET reduced the cell viability, and induced the cell cycle arrest at G2 phase and early apoptosis. TPA did not cause changes in none of the endpoints tested, whereas EG produced no cytotoxic or oxidative effects but decreased the percentage of cells at G2 phase and increased the percentage of cells undergoing late apoptosis, suggesting more subtle modulatory actions. Together, these findings demonstrate that PET particles have relatively low adverse effects in intestinal cells, while PET-DP, particularly MHET and BHET, showed a more intense cytotoxic and mechanistically effects. These results highlight the importance of hazard assessments for both MNPs and its by-products to a more accurate evaluation of the potential health risks associated with human exposure.

2.13.A.T-03 Breaking Ground: The Effect of Leachates from Conventional and Biodegradable Mulching Films on Plants

Laura Zantis¹, Sophie Straetemans², Sylwia Adamczyk³, Bartosz Adamczyk³, Sannakajsa Velmala³, Sicco Brandsma⁴, Maria Margalef⁵ and Thijs Bosker⁶, (1)Rhineland-Palatinate Technical University Kaiserslautern-Landau, Germany, (2)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (3)Natural Resources Institute Finland (Luke), Finland, (4)VU University Amsterdam (VU), Netherlands, (5)A-LIFE (Environment & Health), VU University Amsterdam (VU), Netherlands, (6)Leiden University, Netherlands

The growing use of plastics in agriculture, such as mulching films, has led to the accumulation of plastic residues in soils. Biodegradable plastics are often proposed as an alternative to conventional plastics because of their presumed faster degradation rates. However, both types are subject to weathering processes and can release degradation products into the environment. Despite this, the effects on plant development of these leached chemicals and residues remain poorly understood. This study investigates the impact of artificially weathered plastic leachates on four widely cultivated crops: two monocots, barley (*Hordeum vulgare*) and wheat (*Triticum aestivum*), and two dicots, carrot (*Daucus carota*) and lettuce (*Lactuca sativa*). We compared conventional low linear density polyethylene with a biodegradable starch-polybutylene adipate-terephthalate blend. Effects on plant growth were assessed during germination and early development, as well as in a chronic pot experiment (lettuce and barley only), using concentrations of 0.01%, 0.1%, and 1% w/w. The acute exposure showed limited effects overall, with root length being the most sensitive endpoint for both monocots and dicots. Interestingly, an increase in root length was observed for both barley and lettuce. During chronic exposure, the increase in root length persisted for these species. In addition, lettuce seedlings showed a decrease in shoot fresh weight. Importantly, the plant defence mechanisms were upregulated in both species for both plastic types, indicating that the exposure to leachates causes stress to plants. Our work is among the first to directly compare the effects of leachates from conventional and biodegradable plastics on plants. The study demonstrates that the impact of mulching film residues is not solely a physical issue (i.e., fragment presence) but also a chemical one, via leached compounds. Although the immediate impact of conventional and biodegradable plastic leachates appeared limited, they nonetheless produced measurable adverse effects that could be amplified under natural and multi-stressor conditions.

2.13.A.T-04 Multi-Species Toxicity of Leachates Containing Microplastics, Nanoplastics and Additives from Artificially Aged Oil-Based and Partially Biobased and Biodegradable Fishing Nets

Edgar Dusacre¹, Coralie Julia Le Picard², Valérian Hausard³, Yann Combes³, Christelle Clérandeau³, Sandrine Villette³, Sophie Lecomte³, Jérôme Cachot³ and Miren P. Cajaraville⁴, (1)University of Bordeaux & University of the Basque Country, France, (2)University of La Rochelle, France, (3)University of Bordeaux, France, (4)University of the Basque Country, Spain

Plastic gillnets represent one of the most extensively used and lost fishing gear worldwide. However, their contribution to the microplastic (MP), nanoplastic (NP) and chemical pollution of the ocean is still insufficiently understood. To fill this knowledge gap, one partially biobased and biodegradable gillnet made of polybutylene succinate-polybutylene adipate terephthalate (PBS-PBAT) and three gillnets made of polyamide (PA) were artificially aged (25 days at 23°C) using UV irradiation (UV-A and UV-B) and then agitation (24h at 190 rpm) with abrasion (glass microbeads) in water. Leachates of non-aged gillnets were also produced using the same protocol. The toxicity of the leachates produced was evaluated in four aquatic organisms (*Aliivibrio fischeri*, *Tisochrysis lutea*, adult *Acartia tonsa*, fish *Oryzias latipes* larvae). All the studied gillnets produced MPs (median size 23.6 µm, with a shape of fragment) and NPs. On average, the non-aged and aged PA gillnets produced 4.1x10⁴ MP per gram of FN (95% CI: 3.5x10³-6.6x10⁴) and 3.1x10⁵ MP per gram of FN (95% CI: 8.4x10³-6.6x10⁵), respectively. In comparison, the PBS-PBAT gillnet produced less MPs with 2.7x10⁴ MP per gram of FN (95% CI: 1.5x10³-6.8x10⁴) and 9.7x10³ MP per gram of FN (95% CI: 2.2x10⁻⁴-2.8x10⁴), respectively. Four trace metals were quantified in the leachates (Cu, Fe, Pb, Zn). Moreover, 7 organic plastic chemicals were quantified in the leachates, some of which are known to be hazardous to aquatic species. Three leachates of non-aged FNs (2 PA and the PBS-PBAT) and leachates of one aged FN (PBS-PBAT) caused significant *A. fischeri*'s bioluminescence inhibition (16% to 23%). None of the leachates caused a significant growth inhibition of *T. lutea*. Leachates of two FNs (one aged PA and the aged and non-aged PBS-PBAT) caused significant mortality in *A. tonsa* (37.8±13.3% to 41.1±11.3%). The three PA FNs significantly disrupted the heartbeat (± 13% to 18%) and behavior (behavior stress index (BSI): 0.5 to 7) of *O. latipes*' larvae. The PBS-PBAT FN only affected the behavior of the fish larvae (BSI: 1 to 1.5). Based on PCA results, the observed toxicity was predominantly attributed to the plastic chemicals released. Taking into account the 4 species tested, the PBS-PBAT FN displayed a similar toxicity than the oil-based PA gillnets. The findings presented herein indicate that rigorous toxicity assessments are imperative prior to the introduction of novel biobased and biodegradable nets into the market.

2.13.B Unpacking Plastic Complexity: Investigating the Biological Impacts of Micro- and Nanoplastics, and Plastic Associated Chemicals

2.13.B.T-01 Plastic Litter in the Arctic as a Research Asset: Investigating the Impacts of environmental Nanoplastics and Associated Contaminants on Human Digestive Health

Melanie Mobley¹, Mathilde LEVEQUE¹, Charlotte B.A. STOFFELS², Elise LEPY³, Thora HERRMANN³, Florent BLANCHON⁴, Jean-Nicolas AUDINOT², Hervé Robert¹ and Muriel Mercier-Bonin¹, (1)Toxalim, Université de Toulouse, INRAE, ENVT, El-Purpan, Toulouse, France, France, (2)Luxembourg Institute of Science and Technology, Luxembourg, (3)Faculty of Humanities, University of Oulu, Finland, (4)IFREMER, Laboratoire Environnement Ressources Provence-Azur-Corse, PDG-DGDS-ODE-COAST-LERPAC, 83500 La Seyne sur Mer, France, France

Plastic pollution has reached the most remote regions on Earth, including the Arctic. Particulate plastics have been detected in various media of this fragile ecosystem, making exposure for Arctic biota unavoidable. Given that coastal Arctic communities rely heavily on a traditional marine-based diet, the presence of micro- and more

recently nanoplastics (NPLs) raises concerns about potential health risks for both wildlife and humans even in these supposedly “pristine” regions. However, the impacts of environmental NPLs on the first biological barrier they encounter after oral exposure, the human digestive tract, remain largely unknown. To address this knowledge gap, we use an innovative NPL model produced through mechanical extraction of weathered plastic surfaces collected directly from Arctic shorelines [1]. First batches generated from polystyrene debris collected in partnership with local communities from Northern Iceland, demonstrate the feasibility of generating environmentally relevant random-shaped NPLs within the desired size range (<300 nm), suitable for biological toxicity assessments. Plastic debris should not be viewed as inert materials; they can carry a complex mixture of chemicals, including environmental contaminants, notably persistent organic pollutants. Among these, PFAS, and in particular PFOA, have been detected in various Arctic media, and are known to adsorb onto plastic debris [2]. Using human intestinal in vitro models, we assess the toxicity of these emerging contaminants, alone and potentially adsorbed onto NPLs (the “Trojan horse” effect). Experiments using Caco-2 monolayers revealed a dose-dependent reduction in transepithelial electrical resistance following repeated PFOA exposure, suggesting impaired barrier integrity, which was attributed to cell death. The subcellular distribution of PFOA was visualised using high-resolution FIB-SIMS imaging in cell cytosol. By coupling environmentally derived nanoplastics with Arctic-relevant contaminant profiles, this study advances current models of ingestion-based plastic toxicity and provides evidence crucial for public health guidance and policy planning in Northern communities.

2.13.B.T-02 Organelle crosstalk as a central regulator of micro- and nanoplastics-induced stress responses: an in vitro approach

Nelly Saenen¹, Anke Huysmans¹, Inés Tejeda¹, Margo Witters¹, Annelies Bronkaers¹, Alexander Remels², Frank G.A.J. Van Belleghem¹, Eveline Verleysen³, Jan Mast³ and Karen Smeets¹, (1)UHasselt, Belgium, (2)Department of Pharmacology and Toxicology, Institute of Nutrition and Translational Research in Metabolism (NUTRIM), Maastricht University, the Netherlands, Netherlands, (3)Trace elements and Nanomaterials service, Sciensano, Brussels, Belgium, Belgium

Human exposure to micro- and nanoplastics (MNPs) is increasing, yet their complex composition complicates the prediction of biological effects. To identify mechanistic patterns that may recur across particles and biological systems, we examined how selected engineered nanoparticles, PS beads, digestion-relevant LDPE microplastics, and virgin or UV-aged MNPs influence cellular stress responses in developmental (hDPSCs) and intestinal (co- and tricultures) in vitro models. Analyses included cytotoxicity, redox homeostasis, mitochondrial morphology, cell cycle dynamics, and gene expression of ER stress, mitochondrial dynamics, autophagy, and ferroptosis markers. Not all particles were tested in all models; therefore, the observations reflect mechanistic tendencies rather than direct comparison between models/particles.

In hDPSCs, Ag, TiO₂, and PS nanoparticles activated distinct stress pathways linked to their chemical reactivity and surface properties. Ag nanoparticles induced pronounced lipid peroxidation, ferroptotic signaling, and disruption of mitochondrial dynamics, driving dose- and time-dependent cytotoxicity and altered cell cycle progression. PS nanoparticles induced limited cytotoxicity but exhibited signatures of ER- and lysosomal-associated stress, consistent with altered autophagy and ion imbalance effects. TiO₂ nanoparticles were non-cytotoxic and elicited only mild ER stress and subtle mitochondrial remodeling while supporting osteogenic differentiation. All nanoparticles are localized primarily within endosomal compartments.

In intestinal epithelial systems, virgin and UV-aged PA, PET, PVC, and PS microplastics caused minimal barrier disruption but produced early transcriptional suppression of genes related to ER stress, antioxidative defense, autophagy, and ferroptosis, followed by later compensatory activation. In a separate context, stomach-acid-weathered LDPE generated enhanced extracellular ROS due to surface and compositional changes, initiating marked mitochondrial fusion and branching in Caco-2 cells even without measurable particle uptake. These findings across distinct experimental settings indicate that diverse particles can engage stress pathways centered on mitochondria-ER cross-talk, involving ER stress, redox imbalance, autophagy, and mitochondrial remodeling. These shared mechanistic themes may help guide future work aimed at resolving the sequence and hierarchy of signaling events underlying particle-induced cellular stress.

2.13.B.T-03 Microplastic Fiber-Induced Transgenerational Epigenetic Disruption Impairs Fitness in *Daphnia magna*

Buom sup Shim and Young Hwan Lee, Gangneung-Wonju National University, Korea, Republic of

Microplastic fibers (MPFs) are the most prevalent type of microplastics in freshwater environments. However, although the effects of plastic pollution on various aquatic species have been extensively studied, its intergenerational impact on aquatic organisms remains largely unknown. Here, we investigated the multi and transgenerational toxicity of MPFs in *Daphnia magna* over three generations. Our findings revealed that MPF exposure negatively affects reproduction and molting frequency across generations. Notably, the transgenerational groups exhibited reproductive impairments and reduced molting frequency in the F1 and F2 generations (F1T and F2T), despite never being directly exposed to MPFs. Furthermore, whole-genome bisulfite sequencing revealed that these transgenerational adverse effects are associated with differential DNA methylation patterns in specific genes, suggesting that MPFs may threaten *Daphnia* populations through epigenetic modifications. Collectively, our findings provide valuable insights into the intergenerational toxicity of MPFs and the underlying molecular mechanisms driving these responses.

2.13.B.T-04 Behavioural and Sub-lethal Effects of Microplastic Exposure in Key Coastal

Macroinvertebrates

Zaib Ullah¹, Kay Critchell², Ty Matthews¹, Aaron Schultz¹ and Chi Le³, (1)School of Life and Environmental Sciences, Faculty of Science, Engineering and Built Environment, Deakin University, VIC, Australia, (2)School of Life and Environmental Sciences, Faculty of Science, Engineering and Built Environment, Deakin University, VIC, Australia, (3)School of Science, Edith Cowan University, Australia

Microplastics pose a serious threat to marine and coastal ecosystems, yet their behavioural and physiological effects on macroinvertebrates remain poorly understood. This study investigated the sub-lethal effects of polypropylene and polystyrene microplastics on two ecologically significant coastal species: sandhoppers (Talitridae) and brown kelp beetles (Tenebrionidae). Specimens were exposed to three environmentally relevant microplastic concentrations (0.25, 0.50, and 1.00 mg g⁻¹ of sediment) and a control across four exposure durations (1, 7, 14, and 21 days) under controlled laboratory conditions. Behavioural endpoints, including flipping time, latency to first jump, jump frequency, jump height, burrowing time, distance moved, and velocity, were quantified using live filming and EthoVision XT software. Ingested microplastics were recovered from macroinvertebrates using a soft digestion protocol, enabling precise quantification and characterisation of internalised particles. This study provides robust evidence of sublethal behavioural alterations, emphasising the vulnerability of beach fauna to plastic contamination. These results highlight the ecological risks posed by pervasive plastic pollution in coastal environments.

2.13.P Unpacking Plastic Complexity: Investigating the Biological Impacts of Micro- and Nanoplastics, and Plastic Associated Chemicals

2.13.P-We141 Effects of Leachate Prepared from Plastic Bag Microplastics on Aquatic and Terrestrial Organisms

Anita Jemec Kokalj¹, Taja Korpar¹, Tina Skalar¹, Jure Mravlje¹, Valentina Perc², Sara Novak¹, Damjana Drobne¹, Katarina Vogel-Mikuš¹, Aristeidis S. Tsagkaris³, Darina Dvorakova³, Ula Putar¹, Gabriela Kalcikova¹ and Barbara Klun⁴, (1)University of Ljubljana, Slovenia, (2)Biotechnical faculty, University of Ljubljana, Slovenia, (3)Department of Food Analysis and Nutrition, Faculty of Food and Biochemical Technology, University of Chemistry and Technology Prague, Prague, Czech Republic, Czech Republic, (4)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia

Plastic pollution is a major global concern, with plastic bags contributing significantly to environmental waste. To mitigate this the use of biodegradable alternatives such as polybutylene adipate terephthalate (PBAT) and polylactic acid (PLA) is promoted. However, recent studies indicate that these materials can fragment under environmental conditions, releasing microplastics (MP) and potentially harmful chemical additives. Data on additive composition, leaching behavior, and ecological effects of biodegradable plastics remain scarce. This study assessed leachates from three bag types: conventional polyethylene (M1) and two certified biodegradable starch-PBAT blends: home-compostable (M2) and industrially compostable (M3) bags. MPs were prepared by cryomilling the bags and characterized via imaging techniques. Leaching was performed under high-exposure conditions (5 g MPs/L) in OECD TG 202 medium for 14 days at 37°C with continuous stirring. Filtrates were analyzed for particle presence (SEM) and additive content. Ecotoxicity of leachates (1% v/v) was evaluated on aquatic species (waterflea *Daphnia magna*, duckweed *Lemna minor*, protozoan *Tetrahymena thermophila*) and terrestrial plants (buckwheat *Fagopyrum esculentum*, *F. tataricum*) using established protocols. Endpoints included growth, chlorophyll content, photochemical efficiency, transpiration, and viability. Microplastic size varied significantly among materials (mean $\pm$ SD: M1 = 629.5 $\pm$ 537.4 μ m; M2 = 872.5 $\pm$ 613.4 μ m; M3 = 990.7 $\pm$ 635.9 μ m; $p < 0.001$). No particles were detected in filtrates. Additive analysis revealed irgafos 168 (394 μ g/g) in M1, while M3 contained triethyl acetyl citrate (14 μ g/g) and irganox 1010 (13 μ g/g); M2 showed no detectable additives. Toxicity tests indicated no significant effects on *D. magna*, *T. thermophila*, or buckwheat growth. *L. minor* exhibited a non-significant trend of chlorophyll b reduction (~22–27%). No ingestion of MPs by *T. thermophila* was observed. Overall, MPs from plastic bags contain additives that may leach into aquatic media, but under tested conditions, acute toxicity was absent. Slight effects on aquatic plants suggest potential relevance for chronic exposure. The presented leaching approach simulates high-concentration scenarios under environmentally relevant conditions, providing a basis for future risk assessments of biodegradable plastics.

2.13.P-We142 A Western-style diet shapes the gut and liver responses to low-dose, fit-for-purpose polystyrene nanoplastics in mice

Chloé LIEBGOTT¹, Melanie Mobley¹, Sophie Miguel², Valérie Bézirard¹, Catherine Beaufrand¹, Javier Jimenez-Lamana², Rémi Dages¹, Marie Tremblay-Franco¹, Roselyne Gautier¹, Jordan Denis³, Renaud Léonard³, Grégory Da Costa⁴, Cathrine Robbe-Masselot³, Mathias Richard⁴, Cécile Canlet¹, Bruno Grassl², Stéphanie Reynaud², Hervé Robert¹, Hélène Eutamène¹ and **Muriel Mercier-Bonin¹**, (1)Toxalim, Université de Toulouse, INRAE, ENVT, EI-Purpan, Toulouse, France, France, (2)Université de Pau et des Pays de l'Adour, E2S UPPA, CNRS, IPREM UMR 5254, Pau, France, France, (3)Univ. Lille, CNRS, UMR 8576 – UGSF – Unité de Glycobiologie Structurale et Fonctionnelle, Lille, France, France, (4)Université Paris-Saclay, INRAE, AgroParisTech, Micalis Institute, Jouy-en-Josas, France, France

The potential hazards of nanoplastics to human health are not well understood, and multidisciplinary studies are crucial to addressing such complex issue. The likely presence of nanoplastics in our diet indicates that ingestion is a major exposure route, with the intestine being the primary organ affected. However, research in this area remains limited and assessing human health risks from oral exposure to nanoplastics is a pressing public health concern. Additionally, existing studies mainly rely on commercial nanoplastic models, whose synthesis processes are poorly described, complicating the assessment of their actual toxicity.

In this context, we used fit-for-purpose gold-labelled polystyrene nanoplastic models, synthesised without chemical additives. We investigated the impact of nanoplastic exposure on the digestive environment in a preclinical in vivo model under two dietary conditions: a control diet and a Western diet, to mimic the conditions experienced by at-risk overweight populations. Based on existing literature, adult male mice were exposed to different doses of nanoplastics (0.1, 1 and 10 mg/kg body weight per day) in drinking water for 90 days.

Low-dose exposure to additive-free polystyrene nanoplastics induced alterations along the gut-liver axis, whereas higher doses had little effect. In the intestine, low doses modulated tight junction gene expression and altered mucus quality through mucin O-glycosylation (i.e. increased mucin sialylation), without inducing measurable changes in mucus quantity. Low-dose exposure also shifted the gut microbiota composition in a diet-dependent manner, with an enrichment in taxa known to feed on sialylated substrates, consistent with mucin O-glycan profiles. Metabolomic changes were only detectable under the control diet, indicating disrupted microbial metabolism.

Overall, low-dose exposure to nanoplastics in their particulate form, in the absence of chemical additives, induces effects on the intestinal barrier, including the gut microbiota, as well as on liver function, particularly with regard to glucose and lipid metabolism. Interestingly, these changes are not observed at higher doses and depend on the nutritional status. This contributes to addressing the critical need to assess nanoplastic-related health risks to healthy but also at-risk populations. Given the prevalence of Western dietary habits, the interplay between diet, nanoplastics and digestive health is a significant public health concern.

2.13.P-We143 A Risk Prioritisation Approach for Intentionally Added MPs for a UK Regulatory Context

Sarah Roberts¹, David Spurgeon¹, Cansu Uluseker¹, Hongyan Chen¹, Oliver Pilkington², Thea Marcelia Sletten³, Sam Harrison¹ and Richard Cross¹, (1)United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)Economics for the Environment Consultancy (EFTEC), United Kingdom, (3)Economics for the Environment Consultancy (EFTEC), London, United Kingdom

Due to wide use of intentionally added microplastics (IAMPs) in products across broad use categories (e.g., cosmetic products, detergents, paints and sports infill materials) there is a growing need to understand their environmental risks. This work aims to develop a risk prioritisation approach for IAMPs, to generate risk indicators for UK regulatory purposes.

A national scale risk prioritisation approach for IAMPs has been developed using a new Environmental Risks and Impacts of Chemicals “ENRICH” framework (developed by UKCEH). This combines eco-potency and exposure groupings derived from hazard and exposure assessments of IAMPs from different broad use categories. The risk indicators can be used to explore the relative eco-potency and exposure of different broad use categories of IAMPs, as compared to one another, but also as compared to other known chemical exposures in the UK.

There is an absence of specific ecotoxicity data for IAMPs. To establish eco-potency groups in the risk indicator, results from an assessment of two alternative approaches will be presented. Ultimately, a data re-alignment approach was used to estimate provisional effect thresholds (HC50) from species sensitivity distributions (SSDs), specifically for MP particle driven effects. An eco-potency grouping was assigned to particle driven effects of IAMPs as a class, using an existing SSD database, comparing MP HC50 to other chemicals.

For exposure assessment, the UTOPIA model was used to predict environmental concentrations of IAMPs released from different product uses (presented elsewhere). These were compared to concentrations of other chemicals in soils and waters, to assign an exposure grouping for each broad use category of IAMPs. Both eco-potency and exposure groups are combined to create a relative risk matrix, supporting decisions whether IAMPs should be prioritised for regulatory or policy actions over other pollutants in the same environment. Results show that sports infill materials have the highest relative risk indicator in UK freshwaters, in comparison to other IAMPs, such as cosmetics and detergents. This is driven by higher emissions and exposure in freshwaters of this broad use of IAMPs.

2.13.P-We144 Size Matters: Challenges and Recommendations for Reliable Microplastic Size measurement

Tina Skalar¹, Mark Starin¹, Ula Putar¹, Barbara Klun¹, Stefania Federici², Martin G.J. Löder³, Anja F.R.M. Ramsperger³, Daniel Wagner⁴, Seema Agarwal⁴, Julian Brehm³, Christian Laforsch³ and Gabriela Kalcikova⁵, (1)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia, (2)Department of Mechanical and Industrial Engineering, University of Brescia and INSTM, Italy, (3)University of Bayreuth, Germany, (4)Macromolecular Chemistry II, University of Bayreuth, Germany, (5)Faculty of chemistry and chemical technology, University of Ljubljana, Slovenia

Reliable size determination of microplastics is essential for interpreting their environmental behaviour, fate, and ecotoxicological effects. However, there are currently no harmonised recommendations on how microplastic size should be measured or presented. To address this gap, we conducted a systematic literature search that included 400 laboratory studies, examining both the techniques used for microplastic size determination and the ways in which size data are reported and treated. The review revealed a wide variety of analytical approaches, with optical microscopy being the most commonly used technique, followed by laser diffraction and other image-based methods. Despite this diversity, the most significant challenges arise from incomplete or inconsistent reporting. In many studies, key information on particle size or data processing was missing. As a result, it is often difficult to interpret experimental outcomes or compare findings across studies when the actual

size characteristics of the microplastics are not reliably documented. To support improved practice, we provide practical examples illustrating common issues in size determination, especially for polydisperse samples and fibrous microplastics, where measurement and data interpretation are particularly challenging. Based on the identified gaps, we propose recommendations for future laboratory research, including considerations of sample size, detection limits, appropriate size metrics, quality control, and consistent reporting standards. Adopting these recommendations will enhance the transparency, reproducibility, and comparability of microplastic size data, ultimately strengthening exposure assessments and the interpretation of microplastic effects in environmental and ecotoxicological studies.

2.13.P-We145 Tire Rubber Particles Leachate Toxicity in Freshwater Ecosystems: Behavioral, Predator-Cue Responsiveness and Developmental Impairments in *Physa acuta*

Ahlam Mohamed-Benhammou¹, Jussi V.K. Kukkonen², Jose-Luis Martinez-Guitarte¹ and Victor Carrasco Navarro², (1)National University of Distance Education (UNED), Spain, (2)University of Eastern Finland, Finland

Tire rubber particles (TRPs), generated through tire wear, represent a significant yet understudied source of anthropogenic pollution in freshwater ecosystems. Beyond their physical presence, TRPs release complex mixtures of organic compounds, metals and additives into the water, raising concerns about potential ecotoxicological impacts. Increasing attention has been given to behavioural alterations as sensitive endpoints for environmental risk assessment. This study investigated the sublethal and developmental effects of TRP leachates on the freshwater gastropod *Physa acuta*.

Adult snails were exposed to leachates at 0, 1, 5, 15 and 25% for 24 hours (acute) and 7 days (chronic). After exposure, behavioural endpoints, including speed, distance moved and exploration, were quantified before and after the addition of a crayfish (*Astacus astacus*) extract used as a predator cue. In parallel, egg masses were exposed for two weeks to 0, 5, 10, 20, 25, 50 and 100% leachates to assess embryonic development, hatching success and morphological abnormalities.

Adult snails showed clear behavioural impairment at the highest concentration (25%), with marked reductions in locomotion and slower responses to the predator cue, suggesting neurotoxicity or physiological stress. In contrast, low concentrations (1 and 5%) increased activity, potentially indicating nervous system excitation. Predator cue tests revealed that individuals at 25% exhibited diminished antipredator responses, which could increase predation risk in natural conditions. Embryonic exposure resulted in delayed development, reduced hatching rates and increased malformations—such as shell and radula deformities, at moderate concentrations (5 and 10%). At higher concentrations, no development occurred. The LC50 for hatching was 7.9%, equivalent to 0.79 g/L under the experimental conditions, confirming high embryonic sensitivity to TRP leachates.

Overall, these findings demonstrate that TRP leachates cause both acute and chronic toxicity, affecting essential behavioural traits and early developmental stages. Such impacts may compromise population viability and highlight *P. acuta* as a sensitive bioindicator of tire-derived pollution. This study contributes to the growing evidence of ecological risks posed by TRPs and underscores the need to better assess and mitigate their presence in freshwater environments.

2.13.P-We146 Evaluation of Plastic-Water Partitioning Coefficients of Polycyclic Aromatic Hydrocarbons in Seawater and Marine Plastic Wastes in Japan

Hinata Mikuni¹, Tetsuya Takikawa¹, Satoshi Akiyama², Yuki Tsujimura², Kazushi Noro¹ and Takashi Amagai¹, (1)University of Shizuoka, Japan, (2)Research Institute of Environment, Agriculture and Fisheries, Osaka Prefecture, Japan

Marine plastic waste acts as a vector for environmental pollution, carrying adsorbed hydrophobic contaminants, such as polycyclic aromatic hydrocarbons (PAHs). These pollutants pose significant risks to aquatic organisms through potential transfer via the digestive process. While listed PAHs by the United States Environmental Protection Agency are frequently monitored, investigations into non-listed PAHs are limited. This study addresses this gap by investigating the concentrations and fate of 26 PAHs in both seawater and marine plastic wastes. The total concentrations of PAHs adsorbed on plastic wastes ranged from 8.43 to 5.06×10³ ng g⁻¹ for polyethylene (PE), 4.47 to 1.67×10³ ng g⁻¹ for polypropylene (PP), 27.4 to 1.55×10³ ng g⁻¹ for polystyrene (PS), and 0.63 to 102 ng g⁻¹ for polyethylene terephthalate (PET) collected from Suruga Bay and Osaka Bay, Japan between April 2023 and March 2025. The adsorption trends observed—PE adsorbing higher concentrations than PP, and PP higher than PET—were consistent with previous studies. In the partially burned, pyroplastic-like PE sample, showed that the total PAH concentrations were 2.1 times higher in the burned part than in the unburned part. In seawater samples, the total PAH concentrations ranged from 1.20 to 14.9 ng L⁻¹. These concentrations were

comparable to those reported in the northwestern part of the Japan Sea, but lower than those reported in highly polluted areas such as Liaodong Bay in China or the Elefsina Gulf in Greece. For PE, apparent plastic-water partitioning coefficients (logK_{pw}) values of low molecular weight PAHs were consistent with those in laboratory tests in the previous studies, whereas those of high molecular weight PAHs were lower than the previous studies. This suggests that high molecular weight PAHs may not be in equilibrium or may have undergone degradation, such as photolysis. Conversely, apparent the logK_{pw} values for PS were notably higher than those reported in the previous studies, potentially due to the relatively large specific surface area of the environmental samples. Our investigation demonstrated that PAH adsorption behavior is influenced not only by the material type but also by the specific surface area of plastic wastes. These insights serve as a foundation for understanding the PAH-induced acceleration of microplastic degradation and contribute to more precise ecotoxicological risk assessments of microplastics, considering adsorbed contaminants.

2.13.P-We147 Toxicity of Tire Rubber Additives 1,3-Diphenylguanidine and 4-Hydroxydiphenylamine to the Water Flea *Daphnia magna*

Onni Sirkiä, Sari Lehtosaari, Jussi V.K. Kukkonen and Victor Carrasco Navarro, University of Eastern Finland, Finland

Tire rubber (TR) is a semisynthetic polymer with varying chemical properties. It consists of polymer chains and different additives that are used to modify the properties of rubber mass depending on the intended use. These additives are not chemically bonded to the TR and can leach out over time, potentially causing harm in the surrounding environment. Still, the majority of TR-related research focuses on particles rather than the released additives.

In our study, we wanted to assess the ecotoxicity of 1,3-diphenylguanidine (DPG), a commonly used TR vulcanization agent, and 4-hydroxydiphenylamine (HDP), a hydrolysis product of TR antiozonant 6PPD. Our previous work has highlighted these chemicals as possible effectors of the *Daphnia magna* immobilization caused by tire rubber leachate. *D. magna* is a common freshwater crustacean and a vital part of the aquatic food web. We also wanted to compare the toxicity of DPG and HDP to that of tire rubber leachate.

TR leachate was prepared in 10 g/L concentration over a 20-day period (room temperature, darkness, 160 rpm). After leaching, TR particles were removed via filtration (0.22 µm), and concentrations of DPG and HDP were determined with LC–MS/MS. The toxicity of leachate was tested on *D. magna* neonates (< 24h old) in different dilutions (1, 2.5, 5, 10 and 20%) by monitoring their mobility at 24 h and 48 h according to the OECD guidelines. The test concentrations of DPG and HDP were selected to match the TR leachate dilutions both with and without added ZnSO₄ to account for the possible effects of Zn present in the leachate.

Our previous results have shown that 10 g/L TR leachate can induce acute immobilization of *D. magna* already at 5% concentration. Results of this study support that as the lowest observed effect concentration was shown to be 5% with complete immobilization occurring at 10% and 20% dilutions. Of the individual additives, HDP showed clear immobilization at the highest test concentration, especially with the added ZnSO₄. DPG, in turn, had no effect on *D. magna*. We are currently performing a chronic 21-day reproduction test to assess whether the effects of TR leachate and HDP are limited to acute toxicity or if they also have long-term effects. Overall, our study demonstrates the important role of TR-derived chemicals in ecotoxicology and the hazards they may pose to the environment already at low concentrations.

2.13.P-We148 Transcriptomic Signatures of Phthalates Exposure Reveal Potential Dysregulation of DNA Replication in Free-Ranging Mediterranean Fin Whales

Giacomo Limonta¹, Matteo Baini¹, Matteo Galli², Cristina Panti¹ and Maria Cristina Fossi¹, (1)Department of Physical Sciences, Earth and Environment, University of Siena, Italy, (2)University of Siena, Italy

The fin whale (*Balaenoptera physalus*) is the second-largest whale species and one of the most iconic marine mammal in the Mediterranean Sea, one of the most anthropogenically impacted marine basins. Consequently, this population is chronically exposed to both legacy and emerging contaminants, including plastic-derived endocrine-disrupting chemicals such as phthalates. To investigate whether phthalates produce detectable biological effects in free-ranging whales, we analysed the skin whole transcriptome of 20 individuals (13 females, 7 males) and examined gene expression patterns in relation to the concentrations of 11 phthalate

compounds measured in the corresponding blubber samples. Phthalates were quantified via ultrasound-assisted extraction, d-SPE purification, and GC-MS, while RNA-seq libraries were generated following ribodepletion and sequenced on an Illumina NovaSeq X Plus platform. Processed reads were aligned to the *Balaenoptera acutorostrata* genome, quantified with RSEM, and analysed using DESeq2 and correlation approaches, followed by STRING functional analyses.

Mean total phthalate concentration in blubber was 2401.1 ± 1361.5 ng/g l.b., with DBP and DEPH as most abundant compounds. Correlation analysis between transcriptomic data (15,144 genes) and phthalate concentration revealed 115 significant genes (p -value < 0.05), including 46 upregulated and 69 downregulated. Notably, a functionally cohesive subset of upregulated genes enriched for DNA helicase activity and DNA replication pathways was detected. Key components of the MCM helicase complex, replication protein A, PCNA, and RFC subunits showed positive correlations with phthalate levels, suggesting activation of replication-associated stress responses. These transcriptional signatures are compatible with increased cellular proliferation, DNA damage, and potential genome instability.

Overall, our findings indicate that phthalate exposure in free ranging fin whales is associated with significant transcriptional changes in DNA replication that could compromise genome stability and promote neoplastic transformation. The observed transcriptional alteration rise a warning sign regarding potential health implication, highlighting the need for further multidisciplinary studies on this matter.

2.13.P-We149 Investigation of the Adsorption of Dodine on Virgin and Artificially Aged Microplastics Using Ecotoxicological Methods

Balázs Göbölös, István Szabó, Cintia Bartucz, Zsolt Csenki-Bakos, Sándor Szoboszlay, Edit Kaszab, Gergő Tóth, Péter Harkai, Balázs Kriszt and Judit Háhn, Hungarian University of Agricultural and Life Sciences (MATE), Hungary

Microplastics (MP) are persistent environmental pollutants mainly formed through the aging and fragmentation of plastics. During the aging process, the specific surface area of plastics increases and their surface properties undergo significant changes. MPs also enter the food chain. Their surfaces may be colonized by pathogenic microorganisms, absorb various pollutants them, and various plastic additives originally used in manufacturing could also be released. Our current knowledge of the toxicology of the additives released from them and the pollutants adsorbed on their surface, as well as their transport processes between trophic levels, remains incomplete.

Our research focused on the fungicide dodine and three MPs: polyester (PES 16-20x3000 μ m fiber), polypropylene (PP 20-22x3000 μ m fiber), polyethylene (350 μ m sphere), and their counterparts artificially aged in an aging chamber.

Dodine was incubated in a 2 m/m% NaCl solution at a concentration of 20 mg/L, either alone or in combination with an untreated (virgin) polymer or its aged counterpart (at a concentration of 10 g/L), in the dark for 168 hours with shaking at 160 rpm, and then the solutions were separated from the MPs using a filter cartridge with a pore diameter of 0.7 μ m. The cytotoxicity of the filtrates were tested using a standard acute 30-minute test (ISO 11348), and a chronic test (at 10 and 15 hours of exposure) based on the bioluminescence inhibition in *Aliivibrio fischeri* test organism, and a BLYR bioreporter based on *Saccharomyces cerevisiae*. Virgin and aged PES fibers were examined in a chronic solid phase *Aliivibrio fischeri* test.

In the acute tests among the tested polymers, PES showed the highest toxicity. PE+dodine displayed toxicity comparable to the fungicide control, while PP+dodine and PES+dodine were less toxic thus showing the higher adsorption capacity. In the chronic tests aged PES filtrate induced stronger bioluminescence inhibition than virgin PES filtrate. In the BLYR system, luminescence inhibition decreased by 41% for PES+dodine solution and 77% for aged PES+dodine compared to the MP-free dodine control. Chronic solid phase *A. fischeri* tests confirmed enhanced toxicity of aged PES+dodine ($EC_{50} = 1.13$ mg/L) compared to virgin PES+dodine ($EC_{50} = 7$ mg/L), demonstrating increased adsorption and possible release of toxic substances after aging. We detected the adsorption of dodine fungicide using indirect and direct ecotoxicological methods.

2.13.P-We150 Synthetic microfiber-active pharmaceutical ingredients interactions: Toxicity in cells of a model oyster species

Leticia Fernanda da Silva¹, Caio Rodrigues Nobre², Renata de Britto Mari¹, Ika Paul-Pont³ and Rafael Trevisan³, (1)Instituto de Biociências, Campus do Litoral Paulista, Universidade Estadual Paulista (Unesp), Praça Infante Dom Henrique, s/n, Parque Bitaru, São Vicente, São Paulo, Brazil, (2)Departamento de Ciências do Mar, Universidade Federal de São Paulo, Campus Santos (Unifesp), Rua Carvalho de Mendonça, 144, 11070-102, Santos, São Paulo, Brazil, (3)Univ Brest, Ifremer, CNRS, IRD, LEMAR, IUEM, France

Synthetic fibers constitutes a significant fraction of microplastics polluting the oceans, threatening marine life. Considerable loads in urban wastewater endanger species and ecosystems, but also indicate that they can interact with other harmful contaminants amplifying the risk to marine organisms. Therefore, the present study aims to investigate the toxicity mechanisms and modes of action of polyester microfibers contaminated with active pharmaceutical ingredients (APIs) in hemocytes of the oyster *Crassostrea gigas*. Polyester fabrics were washed in a commercial washing machine then the first washing effluent was filtered and microfibers recovered. Fibers were fortified in vitro with amoxicillin (AMX), caffeine (CAF), carbamazepine (CBZ), citalopram (CIT) and orphenadrine (ORPH) to simulate textile fibers and urban contaminants interactions. Selected experimental groups were: control, polyester fibers and polyester fibers fortified with AMX, CAF, CIT, ORPH or CBZ. Primary hemocyte cultures of *C. gigas* were exposed to concentrations ranging from 15 and 250 MFs/ml over 1 day at 17° or 20°C for cellular metabolic activity analyses through the resazurin assay and at 20°C for lysosomal membrane stability evaluation by the neutral red retention time assay. Results demonstrated that polyester fibers did not affect global metabolic activity in both temperatures, however the interaction with CAF increased cells' metabolic activity at 20°C, at lower concentrations (31 and 62 MFs/ml) while for CBZ and CIT the increase was at higher concentrations (62-250 MFs/ml and 125 MFs/ml respectively), these results might be related to the need of maintenance of cell requirements in response to increased pharmaceutical and microfibers concentration, with microfibers acting as a carrier increasing pharmaceuticals internal dose. The opposite occurred for lysosomal membrane stability, where lower concentrations reduced neutral red retention time for polyester microfibers (15-62 MFs/ml), and polyester fibers fortified with CIT (15 and 31 MFs/ml), ORPH (15 and 62 MFs/ml) and CBZ (15 and 62 MFs/ml). These effects might be due to the fact that lysosomes seems to be target for these contaminants and hormesis phenomena. Overall, microfibers interaction with APIs could enhance cellular toxicity increasing the risk of synthetic microfibers pollution. Therefore, to better understand these results, cell morphology and hemocyte-microfiber interactions analyses are intended to be performed.

2.13.P-We151 Interactive Effects of Surface-Modified Polystyrene Microplastics and P25 TiO₂ Nanoparticles Under UV-A Irradiation: Experiments with a Marine Crustacean *Artemia salina* **Camil Rex M and Amitava Mukherjee, Vellore Institute of Technology, Vellore, India**

Microplastics (MPs) and titanium dioxide nanoparticles (TiO₂ NPs) are increasingly reported in marine environments due to their extensive use and improper waste management. Although natural sunlight contains a substantial ultraviolet-A (UV-A) component that can influence contaminant behaviour, many laboratory toxicity studies rely on visible light conditions, potentially misrepresenting environmental risks. Hence, this study investigated how UV-A exposure modifies the P25 TiO₂ NPs toxicity both in the presence and absence of surface-modified amine (AMPs) and carboxyl (CMPs) polystyrene MPs towards the marine crustacean *Artemia salina*. MPs and TiO₂ NPs were characterised using field emission scanning electron microscopy, dynamic light scattering, and zeta potential analysis. Multiple biological endpoints were assessed, including mortality, oxidative stress responses, lipid peroxidation, antioxidant activity, acetylcholinesterase activity, titanium uptake, and bioconcentration factor. TiO₂ NPs exhibited significantly higher toxic responses than in the presence of MPs. AMPs combined with TiO₂ NPs induced higher mortality than CMPs with TiO₂ NPs, indicating the importance of surface charges in mediating toxicity. In the presence of MPs, titanium uptake and

bioconcentration factor for titanium were decreased, suggesting lower bioavailability of titanium in the presence of MPs. Mixture modelling indicated antagonistic interactions between TiO₂ NPs and functionalised MPs. All these effects were more pronounced under UV-A than under visible light exposure. These results highlight the need to consider realistic light conditions when assessing the ecological risks of photoactive contaminants in marine environments. Overall, the findings revealed that MPs can modify the toxicity of TiO₂ NPs and that UV-A irradiation plays a critical role in influencing their combined effects.

2.13.P-We152 Effect of Dissolved Organic Matter on the Chronic Toxicity of Ultraviolet-weathered Polylactic Acid Microplastics to *Daphnia magna*

HyeonYeong Kim, Hanseong Kim, Nehala Sona Payanthoth, Gersan An and Jinho Jung, Korea University, Korea, Republic of

Although biodegradable plastics have been increasingly used as alternatives to conventional plastics, their ability to produce biodegradable microplastics (BMPs) has been reported, and BMPs are known to have similar or even greater toxicity than conventional microplastics (MPs). Numerous studies have also investigated how MP properties change due to various physicochemical and biological factors, as MPs undergo multiple weathering processes in the natural environment, and their toxicity is consequently affected. In this study, we aimed to examine how ultraviolet (UV) exposure affects the toxicity of polylactic acid (PLA) MPs to *Daphnia magna* in freshwater, especially in the presence of natural organic matter (NOM), given that MPs inevitably coexist with NOM in aquatic environments and their interaction alters MP properties. While several studies have shown that NOM can either mitigate or enhance the toxicity of MPs to *Daphnia magna*, the results vary depending on the experimental conditions, and the underlying mechanisms remain uncertain. In addition, the long-term effects of NOM on MPs toxicity have not been extensively studied. To address this knowledge gap, a chronic toxicity experiment was conducted after a UV weathering process, exposing *D. magna* to pristine and UV-weathered PLA MPs with and without dissolved organic matter (DOM). It was hypothesized that UV-weathered PLA MPs would interact differently with DOM owing to UV-induced changes in MP surface properties, therefore altering their chronic toxicity compared to pristine PLA MPs. This study will provide fundamental information for understanding natural factors that influence BMPs toxicity under environmentally realistic weathering scenarios.

2.13.P-We153 Sub-Lethal Effects of Antibiotics and Microplastics on *Daphnia magna*: Reproduction and Microbiome Disruption

Qiyun Zhang, Ph.D. candidate¹, Vanessa de Almeida Moreira¹, Apolline Lucic¹, Jana Asselman² and Karel De Schampheleere¹, (1)Laboratory of Environmental Toxicology and Aquatic Ecology (GhEnToxLab), Department of Animal Sciences and Aquatic Ecology, Belgium, (2)Blue Growth Research Lab (BGRL), Ghent University, Belgium

Antibiotic pollution in aquatic environments is a global concern due to its potential harmful effects on non-target organisms and its contribution to the emergence and spread of antimicrobial resistance (AMR). Equally alarming is the pervasive presence of plastic pollution, including micro- and nanoplastics (MNPs). MNPs can act not only as physical stressors but also as vectors for chemical pollutants, which might potentially alter the bioavailability and ecotoxicity of those other chemical pollutants, including antibiotics. In particular, the absorption of chemicals to these plastics, particularly as the sizes decreases increasing the surface to volume ratio, may lead to increased exposure and bioavailability of specific adsorbed chemical pollutants to aquatic organisms

In this study, we assessed the individual and combined effects of antibiotics and MNPs on the freshwater crustacean *Daphnia magna* assessing both traditional (*daphnia* reproduction) and novel (*daphnia* microbiome composition) endpoints. We examined the individual effects of three antibiotics commonly detected in European surface waters: sulfamethoxazole (SMX), ciprofloxacin (CIP), and azithromycin (AZI), at both predicted no-effect concentrations (PNECs) and elevated levels (10× PNEC), using a 21-day chronic exposure. Given the widespread occurrence of antibiotics and MPs, we also investigated the influence of polyethylene (PE) microplastics (MPs, 10-45 µm, 7 MPs mL⁻¹) alone and in combination with antibiotics to evaluate potential effects of MP-antibiotic mixtures (SMX = 16 and 160 µg L⁻¹; CIP = 60 and 600 ng L⁻¹; AZI = 0.25 and 2.5 µg L⁻¹; 21-day exposure). By integrating ecological toxicity testing with molecular tools, this work aimed to

uncover subtle sub-lethal effects of low-dose antibiotic exposure and their implications for AMR dynamics in freshwater ecosystems.

2.13.P-We154 Influence of Environmental Weathering on Microplastic Toxicity and Cadmium Vector Potential in Mussels *Mytilus galloprovincialis*: Histological, Histochemical and Biochemical Biomarker Assessment

NAGORE BLASCO¹, ESTIBALIZ BAZAN¹, IRUNE SANTAMARIA¹, Denis Benito¹, Erik Urionabarrenetxea¹, JOSE ANTONIO CARRERO², JULENE ARAMENDIA², Urtzi Izagirre¹, Nerea Garcia-Velasco¹ and Manuel Soto³, (1)CBET+ Research Group, Dept. Zoology and Animal Cell Biology, Research Centre for Experimental Marine Biology and Biotechnology (PiE-UPV/EHU), Spain, (2)IBeA Research Group, Dept. Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (3)Plentzia Marine Station, University of the Basque Country (UPV/EHU), Spain

Plastic pollution is an increasing threat to marine ecosystems, with microplastics (MPs) frequently co-occurring with other pollutants such as trace metals. Weathering alters MP physicochemical properties, potentially modifying their adsorption capacity and toxicity, thereby influencing their role as pollution vectors. This study evaluates the influence of weathering on polystyrene MP adsorption and toxicity, determining the role of weathered and non-weathered MPs as vectors of metal pollution, using Cd as a model pollutant. MPs were obtained by the cryo-fragmentation of both, non-weathered macroplastics (NW), and macroplastics weathered for 10 months in an outdoor seawater mesocosm (W). Prior to the experiment, a Cd exposure was performed to obtain MPs with adsorbed Cd and to determine the maximum metal load adsorbed onto each MP type. Mussels *Mytilus galloprovincialis* were then exposed for 3 d to six different experimental conditions: NW and W MPs (5·10³ particles/mL), MPs with adsorbed Cd (same concentration), and Cd at concentrations corresponding to each MP adsorption capacities (232 µg/L & 60 µg/L). Histochemical (lysosomal membrane destabilization, as labilization period, LP), biochemical (CAT, GST and AChE) and histological biomarkers were assessed. Both types of MPs were characterized by SEM-EDS and ICP-MS. Results showed an unexpectedly reduced adsorption capacity of Cd in W MPs compared to NW MPs, probably related to the competitive behaviour of seawater salts for surface binding sites. In addition, weathering did not show an enhancement in polymer toxicity, which was attributed to the similarity in both particle type properties. Overall, no significant differences in oxidative stress markers or neurotoxic responses were observed in any of the treatments. However, LP and tissue-level alterations (increased number of hypertrophic mucocytes and haemocytic infiltration), were notable responses to the tested pollutants, particularly under Cd exposure, which caused the highest toxic effects. Nevertheless, Cd toxicity decreased when it was adsorbed to MPs, indicating a neutralizing effect in the presence of the polymer. MP alone treatments caused limited or no significant biological response. This work sheds light on the influence of weathering of MPs and their debated role as pollution vectors, providing an integrated view of MP-mediated metal toxicity. Funded: Basque Government (IT1743-22, IT-1446-22) and MICINN (PID2020-118685RB-I00).

2.13.P-We155 Chasing microplastics: Experimental data for modelling their fate in sediments

Barbara Klun¹ and Gabriela Kalcikova², (1)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia, (2)Faculty of chemistry and chemical technology, University of Ljubljana, Slovenia

Although microplastics are widely recognized and investigated in water bodies, their story continues by entering sediments and by interacting with complex pore structures and slow-moving flows. How far they travel, how quickly they spread and where they become trapped are questions still lacking robust datasets. This work aims to fill that gap by generating experimental data that will support a predictive model describing microplastic transport, dispersion and retention in sediments.

Three sediment types with distinct grain sizes and two microplastics with contrasting densities—polyethylene (density 0.917 ± 0.052 g/mL) and polylactic acid (density 1.459 ± 0.037 g/mL)—were examined. Prior to transport experiments, sediment porosity, dispersivity, permeability and grain size distribution were measured. Experiments were conducted in a horizontal glass column (5.5 cm diameter; 60 cm sediment bed length) with flow driven by a controlled head difference between inlet and outlet tanks, resulting in flow rates of 0.25–1 mL/s, comparable to riverbed sediment conditions. Microplastics were introduced at the inlet of the column, and each experiment continued for four pore volumes to track their migration through the sediment. After each experiment, the column was sectioned to recover microplastics using water for polyethylene and saturated calcium nitrate solution for polylactic acid. Extracted particles were then stained with Nile red to differentiate microplastics from sediment grains, observed under a fluorescence microscope and enumerated to determine their spatial distribution.

Results indicate distinct transport behaviour between low-density and high-density microplastics and highlight

the strong influence of sediment grain size on retention. These data provide key empirical parameters for developing predictive fate models of microplastics in sediments. Such models, together with standardized experimental protocols, can support efforts to forecast contaminant behaviour in aquatic environments and help prioritize sites for monitoring and remediation.

2.13.P-We156 Nitrogen–microplastic interactions shaped by biofilm development on conventional and biodegradable microplastics

Ula Putar¹, Mark Starin¹ and Gabriela Kalcikova², (1)University of Ljubljana, Slovenia, (2)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia

Microplastics are now recognized as ubiquitous components of aquatic ecosystems, where they interact with organisms and influence water quality, sediment properties, and nutrient dynamics. Although biological and chemical interactions involving microplastics have been widely investigated, their interactions with nutrients remain understudied. Here, we examined how three nitrogen species, namely ammonium nitrogen, nitrite, and nitrate, interact with two microplastic types: conventional polyethylene (PE) and biodegradable polybutylene adipate terephthalate blended with starch (PBAT). To assess the influence of biological conditioning, both pristine and biotically aged particles were tested. Our results show that biofilm presence and viability strongly modulate these interactions. Ammonium nitrogen associated with aged PBAT in substantially lower quantities compared with pristine PBAT, whereas PE showed no notable biofilm-related changes. In contrast, viable biofilm enhanced nitrite association with both polymers, suggesting microbial uptake rather than simple surface adsorption. Nitrate adsorption was highest on pristine PBAT, while PE with non-viable biofilm exhibited the strongest nitrate adsorption, indicating a shift toward physical rather than biological adsorption mechanisms. Overall, these findings demonstrate that microplastics can interact with nitrogen species in ways that depend strongly on polymer type, aging, and biofilm activity. Consequently, the potential role of microplastics in altering nitrogen cycling and associated processes, such as greenhouse gas emissions, should be further investigated.

2.13.P-We157 Biofilm Formation and Gene Expression in Bacteria Exposed to Microplastics and Plastic-Derived Chemicals

Marcus Lukas, Natalie Marquar and Ulrike Braun, German Environment Agency (UBA), Germany

Micro- and nanoplastics (MNPs) are ubiquitous environmental contaminants that provide habitats for microbial colonization and act as vectors for plastic-associated chemicals. Their surfaces support biofilm formation, which can influence microbial ecology and facilitate horizontal gene transfer. Moreover, plastic additives and degradation products may exhibit toxicities distinct from their parent polymers, increasing the complexity of environmental risk assessment.

This study investigates microbial responses to microplastics and plastic-derived compounds by combining microbiological assays with molecular analyses. The model organisms *Escherichia coli* K12 MG1655 and *Pseudomonas aeruginosa* PAO1 were exposed to polyethylene terephthalate (PET) microplastic particles and carbon black (CB) as a non-plastic reference material. Biofilm formation was quantified using the crystal violet assay, and bacterial growth was monitored photometrically. Total RNA was extracted from planktonic and biofilm-associated cells, transcribed into cDNA, and analyzed for biofilm-related genes (e.g. *rpoS*, *csgD*) using polymerase chain reaction (PCR) and agarose gel electrophoresis.

PET exposure did not inhibit bacterial growth and resulted in neutral or slightly reduced biofilm formation, whereas CB occasionally enhanced biofilm accumulation but interfered with optical measurements due to its pigmentation. PCR analyses indicated differences in gene expression between planktonic and biofilm-associated states, with a weaker *rpoS* signal observed in *P. aeruginosa* biofilms. In addition, benzoic acid, a potential degradation product of PET, significantly reduced bacterial growth and biofilm development, demonstrating that leachates can exert biologically active, potentially anti-biofilm effects independent of particle interactions. These findings highlight material-specific microbial responses and underscore the importance of considering both physical and chemical aspects of plastics in environmental hazard assessments. The combined methodological approach provides a basis for improved mechanistic understanding and supports the development of predictive tools for evaluating complex plastic exposure scenarios.

2.13.P-We158 Exploring the Role of Biofilms on the Co-Occurrence of Material and Chemical Pollution in a Changing World

Louise Thurston¹, Thomas Stanton¹, Helen Glanville¹, Jim Reynolds¹, Marco Mazza¹, Charlotte E M Lloyd² and Patricia Sanchez-Baracaldo², (1)Loughborough University, United Kingdom, (2)University of Bristol, United Kingdom

Macroplastic pollution is a prominent concern in freshwater systems. Plastic polymers are known sources and vectors of chemical pollutants, concentrating them at levels exceeding their surrounding environment. Treated wastewater emits both plastics and chemical pollutants, with their loading forecast to increase as populations grow and extreme weather events periodically overwhelm wastewater treatment infrastructure. Their co-occurrence is a prominent concern for freshwater ecology.

This study investigates interactions between anthropogenic substrates, microbial biofilms, and pharmaceutical pollution in a treated effluent stream. Anthropogenic material tiles (7cm²) made of three plastic polymers (High density polyethylene, Polypropylene, Polystyrene), aluminium, and glass are deployed to examine variations in biofilm composition across materials. The influence of material type and microbial profile on pharmaceutical assimilation will be assessed. Therefore, this study aims to answer the following research question ‘Are biofilms assimilating pharmaceuticals based upon microbial community and does this change with material?’, with the primary hypothesis being ‘Biofilm pharmaceutical assimilation changes with anthropogenic material’.

These findings will provide novel insights into implications of plastic–pharmaceutical interactions, enhancing understanding of their combined impacts under different hydrological scenarios, informing future wastewater management and ecological risk assessments.

2.13.P-We159 Assessing Microplastic Impact on Soil Microbial Communities: Integrating Metabarcoding Data into Regulatory-Relevant Endpoints

Cecilia Diaz¹, Fabian Essfeld², Udo Hommen¹, Sebastian Eilebrecht² and Karsten Schlich³, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Microplastics (MP) are emerging environmental contaminants that may affect soil ecosystems, yet their impacts on soil microbial communities remain poorly understood. There is growing interest in developing regulatory endpoints that better reflect actual ecological effects and in incorporating molecular data, such as metabarcoding. This study investigates how exposure to MPs may alter soil microbial structure and diversity using 16S metabarcoding data and explores how these shifts can be translated into regulatory-relevant metrics. The effects of three MPs on the structure and function of the natural soil microbial community were assessed using five nominal concentrations of 0.1, 1, 10, 100 and 1000 mg/kg dry weight (dw) soil applied to a reference soil and a control treatment without particles. The polymer type of all MPs was low density polyethylene (LDPE) and the MPs were fragmented. The particle size ranged from (i) 4.6 µm to (ii) ~500 µm and the larger LDPE particle (ii) was treated with UV irradiation to simulate aging (iii). After 56 days of exposure, we analyzed changes in the microbial composition by high-throughput 16S RNA amplicon sequencing, and the effect on nitrogen transformation by measurements of nitrate in soil extracts following the recommendations of the OECD Test Guideline (TG) 216.

No effect of the small fragmented LDPE particle (i) and the larger fragmented LDPE particle (ii) on the Nitrogen Transformation (OECD TG 216) was observed after 56 days exposure. The lowest observed effect concentration was above the highest test concentration of 1000 mg/kg dw soil. However, after aging of the larger particle with UV irradiation, after 56 days an EC₅₀ of 156 mg/kg dw soil was observed, indicating that the aging of the particle lead to an effect on the soil microbial function. Preliminary differential abundance analysis of metabarcoding data revealed shifts in various taxa in response to microplastic particles, although not all changes followed a clear dose-dependent pattern.

This study found minimal effects of LDPE on soil microbial structure and only modest impacts on specific functional groups, consistent with the functional test observations. These preliminary results provide a foundation for incorporating molecular data into ecologically meaningful thresholds for risk assessment, but further research and method validation are needed.

2.13.P-We160 Bioplastics in Simulated River Systems: Additive Release and Dissolved Organic Matter (DOM) Characterization

David Alcaide Benavides¹, Julio Lopez-Dova², Marinella Farre³ and Marta Llorca-Casamayor³, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC),

Barcelona, Spain, (2)University of Vic - Central University of Catalonia (UVic-UCC), Spain, (3)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain

Bioplastics have emerged as promising alternatives to fossil-based plastics products due to their higher biodegradability and renewable origin. However, a key challenge is that bioplastics often require larger amounts of plastic additives to achieve mechanical and functional properties comparable to those of conventional plastics, raising concerns about their potential environmental impact.

Among the different environments where biodegradation have been investigated, riverine systems are particularly relevant due to their dynamic physical and chemical conditions. Ultraviolet (UV) radiation promotes photooxidative degradation, leading to polymer chain scission, while hydrodynamic forces and interactions with sediments enhance mechanical fragmentation. Together with microbial biodegradation and hydrolysis, these processes play a crucial role in the degradation of plastics and the release of associated additives.

In this study, we simulated riverine biodegradation conditions using continuous water recirculation channels to investigate the leaching behaviour of plastic additives from four different materials: a polyethylene (PE) trash bag and three commercial bio-based materials used for single use applications: trash bags, single use glasses and plates. Released additives were analysed using liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS) via suspect screening analysis. Additionally, dissolved organic matter (DOM) was characterized through high resolution mass spectrometry (HRMS) to assess the extent and nature of the biodegradation processes occurring during the experiment. Among all the materials, the bio-based glass showed the highest number of leached additives (162 over the month-long experiment), while the bio-based plate exhibited the lowest (129). The most leached compound families were plasticizers and polymer-production-related compounds. In terms of biodegradation and in every material, lignin-type compounds increased over the course of the experiment due to their lower biodegradability compared to the other compounds studied.

2.13.P-We161 Differences for effects between crustaceans and fish exposed to tire war particles

Seiichi Uno¹, Tatsuhiko Bito¹, Masatoshi Yamasaki¹, Emiko Kokushi¹, Go Suzuki² and Kei Nakayama³, (1)Kagoshima University, Japan, (2)Material Cycles Division, National Institute for Environmental Studies (NIES), Japan, (3)Ehime University, Japan

Since the impact of 6-PPD quinone, derived from a tire constituent, on coho salmon was clarified in 2021, research on the biological effects of tire particulates has become active. Subsequently, it has been revealed that the biological impacts of tire particulates are induced not only by 6PPD quinone but also by its isomers and related compounds, and even by the parent compound 6PPD. Tires themselves are manufactured from more than one hundred chemicals. Moreover, there are countless types of tires tailored to various applications, and the substances they contain vary widely. Therefore, many researchers suspect that, in addition to 6PPD quinone, other substances capable of inducing biological effects are also present.

In this study, we introduce the effects of tire ware particulates (TWPs) on aquatic organisms using Cryo-Milled Tire Tread (CMTT) obtained from the U.S. Tire Manufacturers Association. We investigated the impacts on the marine amphipod *Ptilohyale barbicornis* and the freshwater amphipod *Hyalella azteca* when exposed to water suspending TWPs, or to water containing components leached from TWPs. As a result, exposure to suspensions of TWPs produced much stronger mortality effects than exposure to the leachate. The amphipods were found to ingest the particulates, and because the mode of toxicity expression differed between the suspension and the leachate, we considered the possibility that substances retained in the particulates and poorly soluble in water were absorbed in the body after the particulates were taken up, thereby exerting strong effects.

Furthermore, we conducted the same exposures with suspensions and leachates on 2-week-old medaka (*Oryzias latipes*), as we did for the amphipods. At least for the suspensions, medaka exhibited far lower toxicity than amphipods, and almost no effects on growth were observed. These results confirmed a large difference in sensitivity to tire-derived substances between amphipods and medaka.

We also consider the impacts of tire particulates after being released onto roads and degraded, and present changes in effects observed when organisms are exposed to tire particulates that have been irradiated with ultraviolet light for a defined period.

2.13.P-We162 From Algae to Daphnia: Diet-Borne Nanoplastic effects on Transgenerational Transfer and Life-History Analysis

Rega Permana¹, Miguel Gomez-Gonzalez², Christian Pfrang¹ and Eugenia Valsami-Jones¹, (1)University of Birmingham, United Kingdom, (2)Diamond Light Source, United Kingdom

Nanoplastics (NPs) are known to have the potential to be transferred along the food chain through a feeding-predatory pathway. However, it is unclear how this dietary exposure influences their life-history and its transgenerational toxicity. In this study, a simple model of aquatic food chain was developed using microalgae *Chlorella vulgaris* as primary producer and *Daphnia magna* as first consumer. Microalgae were initially pre-exposed to NPs doped with europium (Eu) at 10 mg L⁻¹ for 5 days. *Daphnia magna* were then fed with a daily dose of 0.1 mg C microalgae per individual daphnia for 21 days. The results showed that *Daphnia magna* accumulated low amount of NPs during the chronic test but exhibited significant developmental damage and reproductive toxicity. A logistic growth model estimated both lower carrying capacity for the exposed group compared to the control group ($p < 0.05$) and non-significant trend of lower intrinsic growth rate. *Daphnia magna* fed with contaminated microalgae showed a significant delay in brood production and average number of neonates per parent ($p < 0.05$). Additionally, NPs were detected in the newly born neonates from exposed *Daphnia magna*, implying a transgenerational transfer of the NPs. Synchrotron-based nanoprobe X-Ray Fluorescence (XRF) further revealed NPs localization in the eggs of exposed *Daphnia magna* which may indicate the migration of ingested NPs from the gut environment to the brood chamber. Together, these findings show that trophic transfer of NPs elicits transgenerational transfer of NPs in *Daphnia magna* and significantly affected their life history, underscoring the need to include dietary routes and generational windows in ecological risk assessments.

2.13.P-We163 Effects Of Micro- and Nanoplastic Exposure on Biological Endpoints as a Function of Particle Characteristics and Species Sensitivity

Maaïke Vercauteren¹, Dries Knapen² and Andreja Rajkovic³, (1)Blue Growth Research lab, Ghent University, Belgium, (2)University of Antwerp, Belgium, (3)Ghent University, Belgium

Micro- and nanoplastic (MNP) pollution has emerged as a pervasive environmental and food safety issue with documented toxicological effects spanning all levels of biological organization and raising significant concerns for human health. Despite the numerous papers that are published - ±3000 publications in 2024 - the full extent of MNP effects on environmental and human health remain unclear due to the fragmented nature of existing studies. The inherent heterogeneity of MNPs, combined with the high diversity of species, model systems and exposure scenario's used in MNP research, complicates extrapolation of results, hampers cross-study comparisons and comprehensive risk assessment.

To provide an detailed overview of reported toxicological outcomes, relevant publications on MNP effects on different levels of biological organization were retrieved from eight databases, using pre-defined Boolean search strings. The publications were screened for eligibility and quality based on pre-determined criteria. Following a risk-of-bias assessment and selection of publications, critical data elements were extracted in a systematic manner. These elements encompassed bibliographic information, experimental model characteristics, target organ information, detailed specifications of the intervention (treatment and control groups), and the quantitative assessment of biological endpoints (outcomes). A quantitative synthesis was performed to summarize experimental findings and establish the interconnectedness of observed effects. The initial step involved determining the frequency distribution of toxicity endpoints (e.g., oxidative stress, inflammatory responses, membrane integrity disruption, and bioenergetic alterations), correlating them with upstream molecular mechanisms and functionally mapping them onto cellular pathways, such as apoptosis, autophagy, or immune system activation. These findings provide insights into MNP toxicity and facilitate identification of the most common molecular and cellular "hotspots" as a function of particle characteristics and species specificity.

The resulting integrated dataset, linking outcomes to defined Key Events or as modulators of Key Event Relationships, will serve as a foundation for future predictive hazard characterization and quantitative risk assessment. The generated dataset will demonstrate its value through incorporation into existing and novel evidence-based Adverse Outcome Pathway (AOP) networks.

2.13.P-We164 Mitochondrial Dysfunction Induced by 6PPD-Q and Its Metabolites in Salmonid Fish

Kyoshiro Hiki¹, Kenji Inoue¹, Chenyang Rao², Tomohiro Tobino¹ and Fumiyuki Nakajima¹, (1)University of Tokyo, Japan, (2)National Institute for Environmental Studies (NIES), Japan

Tire wear particles (TWPs) have been recognized as a significant source of microplastics in urban aquatic environments. After being transported by rainfall, TWPs have been demonstrated to cause adverse effects on

aquatic organisms. Recently, 6PPD-Q, an oxidation product of the widely used tire additive 6PPD, was identified as a toxic chemical causing acute mortality in coho salmon exposed to road runoff. Subsequent studies found that significant acute mortality was found only for salmonid species and there were large differences in sensitivity to 6PPD-Q (>100-fold) even among salmonid species. For example, 24-hours LC50 values of 6PPD-Q were 0.095 µg/L for coho salmon and 0.51 µg/L for white-spotted char, whereas significant mortalities were not observed for chum salmon at environmentally relevant levels of 6PPD-Q. Despite the recent intensive research efforts, the mechanism of 6PPD-Q lethality to sensitive salmonid species remains unclear, although a few molecular and cellular effects, such as mitochondrial uncoupling, disruption of blood-brain barrier, and enhanced vascular permeability, have been reported. In addition, it is still unclear whether 6PPD-Q itself or its metabolites is the key driver for the observed lethality.

In this study, to clarify the molecular and cellular toxicity of 6PPD-Q in sensitive salmonid species, we evaluated the effects of 6PPD-Q and its two major metabolites, 6PPD-Q-1-OH and p-hydroxy 6PPD-Q, on RTgill-W1 cells, a rainbow trout gill cell line. Cytotoxicity for 24 hours was first assessed across concentrations ranging from 62.5 to 2000 µg/L. Subsequently, mitochondrial function was examined at three exposure levels (2, 20, and 200 µg/L), for mitochondrial membrane potential (MMP), intracellular ATP, intracellular calcium, and oxygen consumption rate (OCR). All three compounds reduced cell viability, MMP, and ATP levels, while increased intracellular calcium. OCR did not show significant changes across treatments. Among the tested compounds, p-hydroxy 6PPD-Q exhibited the greatest overall toxicity. These results provide new insights into the subcellular impacts of 6PPD-Q and its metabolites, highlighting mitochondrial dysfunction as a key pathway involved in their toxicological effects. In addition to these experiments, we will present results using crude mitochondria isolated from another sensitive salmonid species, white-spotted char.

2.13.P-We165 Impact of Polystyrene and Polyamide Micro and Nano Plastics on Zebrafish Development

Jiayi Yang¹, Nikita Korpel¹, Roeland Jackson¹, Laurens Dirk Bernardus Mandemaker², Juliette Legler¹, **Jorke Kamstra¹** and Hanna Dusza¹, (1)Institute for Risk Assessment Sciences, Department of Population Health Sciences, Faculty of Veterinary Medicine, Utrecht University, Netherlands, (2)Institute for Sustainable and Circular Chemistry, Department of Chemistry, Faculty of Science, Utrecht University, Netherlands

Micro- and nanoplastics (MNPs) are increasingly detected in the environment, and recent studies indicate the presence of MNPs in different organs, including the reproductive tract. Despite this, the potential impact of MNPs on early-life development remains poorly understood. This study aims to address this gap by assessing the uptake, distribution, and toxicity of different MNPs (commercial polystyrene beads (PS) and custom-made nanoprecipitated polyamide particles (PA)) in zebrafish (*Danio rerio*) embryos. As MNPs are often recognized as foreign particles, our hypothesis is that exposure might trigger innate immune responses.

To test this, we used both wild-type AB and macrophage-specific transgenic zebrafish (Tg(mpeg1.1:EGFP)). For uptake and distribution, embryos (<8-cell stage) were microinjected with 0.5 nL of 5 mg/mL or 10 mg/mL solutions containing either 50 nm or 200 nm fluorescent PS particles, or non-fluorescent PA particles (average size distribution 620 nm), directly into the yolk sac. Uptake and distribution were assessed through automated fluorescence microscopy. Developmental toxicity was assessed in both strains, and transcriptomics was performed in the wild-type strain at non-toxic concentrations to assess early molecular responses. Macrophage recruitment was evaluated in the transgenic line.

Preliminary data show clear distribution of all fluorescent PS particles across tissues in zebrafish embryos, whereas no developmental toxicity was observed with either polymer type. Ongoing analyses will determine whether immune-related pathways are activated at the molecular or cellular level.

2.13.P-We166 How Tire Particles Affect Fish: Integrating Cellular Stress Responses and Zn Accumulation

Agnė Bučaitė¹, Vaidotas Danila² and Milda Stankevičiūtė¹, (1)Laboratory of Ecotoxicology, State Scientific Research Institute Nature Research Centre, Lithuania, (2)Research Institute of Environmental Protection, Vilnius Gediminas Technical University, Lithuania

Tire particles have received increasing attention as a considerable source of microplastic pollution in aquatic environments. Tire rubber is a complex chemical mixture of elastomers, metals, fillers and additives, many of which are known to be toxic, although Zn is considered as the key toxicant. Due to the process of vulcanization, which cross-links elastomers through polysulfide bonds into a three dimensional network, tire rubber is practically impossible to recycle using conventional means. For this reason, different methods for rubber devulcanization have been proposed.

Although the ecotoxicology of tire particles have become a major subject of microplastic research, studies in aquatic toxicology mostly focus on acute exposure and only recently the role of particle itself was taken into consideration. Likewise, the biological effects of devulcanized rubber compared to conventional rubber in aquatic organisms are unknown.

For this reason, a 3.6 month long-term feeding experiment was conducted in which rainbow trout (*Oncorhynchus mykiss*) were exposed to two types of tire particles. The cellular responses were assessed by evaluating cytogenetic endpoints, including micronucleus formation, as well as DNA fragmentation via the comet assay. Additionally, metallothionein levels and Zn concentrations were measured in liver tissue. Although genotoxicity increased, hepatic Zn concentrations did not change significantly, indicating that the genotoxic effects of tire particle exposure are not directly related to Zn accumulation.

It is estimated that by 2030, waste will increase to 1.2 billion tires annually, yet some argue that this estimate is far too optimistic, suggesting that the actual number could be more than 4 times higher within the same time frame. While the introduction of Euro 7 regulation will limit the emissions from tire wear within EU, toxicological research should go hand in hand with the development of new recycling methods to ensure safe disposal of anthropogenic waste.

2.13.P-We167 Medium-Driven Charge Shifts and Functionalized Nanoplastics Alter Developmental and Molecular Pathways in an Amphibian Model

Mohamed Helal¹, Jakub Sedzinski², Xiaoyu Duan³, Shan Wang⁴, Changzhu Wu⁴, Henrik Holbech⁵ and Elvis Genbo Xu⁵, (1)Biology, University of Southern Denmark (SDU), Denmark, (2)The Novo Nordisk Foundation Center for Stem Cell Medicine (reNEW), University of Copenhagen, Copenhagen, Denmark, (3)Department of Biology, University of Southern Denmark (SDU), Denmark, (4)Department of Physics, Chemistry and Pharmacy, University of Southern Denmark, Denmark, (5)Department of Biology, University of Southern Denmark, Denmark

Nanoplastics become emerging pollutants of concern, yet their effects on early amphibian development, despite amphibians' ecological importance and vulnerability, are understudied. We investigated the morphological, behavioral, and transcriptomic responses of *Xenopus laevis* larvae (up to NF45) exposed to clean, dialyzed 200 nm polystyrene nanoplastics functionalized with either carboxyl (PS-COOH) or amine (PS-NH₂) surface groups, alone or in combination, across environmentally relevant concentrations (0.1–10 ppm). Dynamic light scattering confirmed negligible nanoplastics aggregation in the exposure medium, while zeta potential measurements revealed an unexpected medium-induced negative surface charge in PS-NH₂, indicating previously unrecognized charge shifts in specific aqueous exposure conditions. Both nanoplastic types caused low mortality but measurable, charge-dependent morphological disruptions, including reduced body length, head height, and eye area, with PS-NH₂ exerting stronger structural effects in general. Larval behavior remained largely unchanged across different treatments. Transcriptomic profiling provided a comprehensive view of the molecular response of *X. laevis* to nanoplastics, revealing widespread transcriptional downregulation affecting both coding genes and long non-coding RNAs. Distinct pathway signatures were also identified. PS-COOH altered oxidative phosphorylation and ribosomal function; PS-NH₂ induced dose-dependent enrichment in peptide metabolism, cytoskeletal organization, and cell adhesion pathways; and the mixture affected extracellular-matrix-associated processes. Together, these results demonstrate that even clean, dialyzed nanoplastics can perturb amphibian development through charge-specific and mixture-specific molecular pathways. The discovery of medium-driven charge inversion in PS-NH₂ and the identification of global transcriptome repression provide new mechanistic insights into how nanoplastic surface chemistry and text medium shape toxicity, with implications for environmental risk assessment in freshwater ecosystems.

2.13.P-We168 Amniote Embryos Uncover Interactive Early Developmental Responses to Oppositely Charged Nanoplastics

Xiaoyu Duan¹, Xin Wang¹, Mohamed Helal², Ayoub Laghrissi³, Knut Erik Tollefsen⁴, Warren Burggren⁵, Honghong Chen⁶, Shan Wang⁷, Ren Wei⁸, Changzhu Wu⁷, Jacek Fiutowski⁹, WenHui Qiu⁶, Henrik Holbech¹⁰ and **Elvis Genbo Xu¹⁰**, (1)University of Southern Denmark, Denmark, (2)Biology, University of Southern Denmark, Denmark, (3)NanoSyd, NanoSyd, University of Southern Denmark, Denmark, (4)Norwegian Institute for Water Research, Norway, (5)Developmental Integrative Biology Group, The University of North Texas, United States, (6)School of Environmental Science and Engineering, Southern University of Science and Technology, China (Mainland), (7)Department of Physics, Chemistry and Pharmacy, University of Southern Denmark, Denmark, (8)Department of Microbiology and Bioprocess Technology, Institute of Biochemistry, Leipzig University, Germany, (9)NanoSyd, University of Southern Denmark, Denmark, (10)Department of Biology, University of Southern Denmark, Denmark

Micro- and nanoplastics are increasingly recognized as emerging contaminants, but their molecular effects on developing amniotes remain unclear. Using the chicken embryo as an amniote model, we examined how oppositely charged polystyrene nanoplastics, carboxylated (PS-COOH) and aminated (PS-NH₂) of the same particle size (50 nm), and their mixture influence early development. Both particle types, at sublethal concentrations, impaired embryonic progression and produced abnormal phenotypes, demonstrating charge-dependent developmental sensitivity. Exposure to a mixture of PS-COOH and PS-NH₂ reduced the incidence of deformities relative to single-particle treatments but produced a more pronounced developmental delay. RNAseq analysis revealed that the mixture elicited broader gene expression changes than either particle alone, and produced interaction effects consistent with antagonistic molecular responses. Across treatments, extracellular matrix (ECM) remodeling emerged as a shared pathway, whereas pathway analysis indicated that the mixture produced the strongest activation of canonical signaling pathways and upstream regulators in the embryonic brain. Proteomic analyses further supported charge-specific and mixture-specific effects. PS-COOH altered ECM-associated proteins, such as LARGE1 and LOX, whereas PS-NH₂ affected proteins linked to immune and tumor-related functions, such as IL1B, ATP6V0A2, and SEMA3A. The mixture exposure produced the broadest protein changes, including HIC1, MMS19, and PDE1B, which are involved in processes such as DNA repair and neuronal signaling. Together, these results uncovered that charged nanoplastics and their mixture disrupt embryonic development and molecular pathways in an amniote vertebrate. By integrating developmental, transcriptomic, and proteomic data, our findings highlight charge polarity and mixture interactions as key determinants of nanoplastic effects.

2.13.P-We169 Toxicological Profiling of Polyethylene Terephthalate Micro- and Nanoplastics and Degradation Compounds in Human Liver Cells

Helena Oliveira¹, Mariana Monteiro², Catarina Filipa Eira Velha Cunha², Alberto García Martín³, Verónica Bastos², Juan M. Bolívar³ and Fernanda De Oliveira Esteves Rosário⁴, (1)No Affiliation, Portugal, (2)CESAM, University of Aveiro, Portugal, (3)Faculty of Chemical Sciences, Complutense University of Madrid, Spain, (4)University of Aveiro, Portugal

The growing production and persistence of plastics have led to the widespread presence of micro- and nanoplastics (MNPs) in the environment, raising concerns about their effects on human health. These particles, ranging from 1 nm to 5 mm, possess physicochemical properties that influence their behavior in biological systems. Polyethylene terephthalate (PET), widely used in single-use packaging, degrades into smaller particles and compounds such as bis-2-(hydroxyethyl) terephthalate (BHET), mono-2-(hydroxyethyl) terephthalate (MHET), terephthalic acid (TPA) and ethylene glycol (EG). However, the toxicological impact of these degradation products remains poorly defined. Ingestion is a major human exposure route to MNPs, enabling their accumulation in metabolic organs such as the liver. To clarify their hepatotoxic potential, we evaluated the effects of PET MNPs and PET degradation products on human liver cells (HepG2). Cells were exposed to 12.5-400 µg/mL of PET MNPs and respective degradation products for 24, 48 and 72 h and the effects on cell viability, cell cycle dynamics and production of reactive oxygen species (ROS) were assessed. Results showed that PET MNPs reduced cell viability in a concentration-dependent manner. Degradation products showed marked toxicity at concentrations ≥12.5 µg/mL, with BHET and TPA being the most cytotoxic. BHET, MHET

and TPA altered cell cycle dynamics, increasing the S-phase population and reducing the percentage of cells at G0/G1, whereas PET<12 µm did not significantly affect the cell cycle. All degradation products induced ROS production, indicating oxidative stress associated with decreased viability and cell cycle disturbances. These findings show that PET-derived MNPs and, notably, their degradation chemicals exert cytotoxic and oxidative effects in human hepatocytes. Incorporating both particles and associated chemicals into human health risk assessments is therefore essential.

2.13.P-We170 Combined Effects of Mercury and Polyester Nanoplastics on Human Lung and Liver Cells

*Fernanda De Oliveira Esteves Rosário¹, Ana Teresa Reis², **Helena Oliveira¹** and Teresa Rocha-Santos¹, (1)CESAM, University of Aveiro, Portugal, (2)Department of Environmental Health, Portuguese National Institute of Health, Rua Alexandre Herculano, 321, 4000-055 Porto, Portugal, Portugal*

The environmental persistence of plastic waste leads to the formation of microplastics (MPs <5 mm) and nanoplastics (NPLs <1 µm), increasingly detected in drinking water and food products. Due to their small size and high surface reactivity, NPLs can interact with coexisting pollutants, potentially altering their mobility and toxicity. Mercury is of particular concern because of its persistence and potent toxicity, making the evaluation of combined exposure with NPLs essential for realistic human health risk assessment.

This study investigated the toxicological interactions between Polyester NPLs (PENPLs) and mercury in human lung (A549) and liver (HepG2) cells. Our findings show that binary mixtures produce biological effects distinct from those induced by each contaminant alone. Co-exposure modified the surface properties of the plastic particles, indicating physicochemical interactions capable of altering their cellular behaviour. The mixtures also demonstrated a substantial enhancement of mercury toxicity. Co-exposure to 10 mg/L Hg with PENPLs (both concentrations) led to a marked reduction in mitochondrial activity in A549 and HepG2 cells, decreasing from approximately 83% under single exposure to around 42% in mixtures. Additionally, prolonged co-exposure altered the individual toxicity of each substance even at lower concentrations, revealing interactions that modify expected dose-response patterns. The migratory capacity of both cell lines was also affected differently under mixture conditions, reflecting cell-specific sensitivities not observed during isolated exposures. Finally, oxidative stress occurred only in the mixtures, and increased with mercury concentration, suggesting that NPLs enhance the reactivity of mercury at the cellular level.

Overall, these results show that NPL-mercury mixtures possess unique toxic profiles, including particle surface modification, oxidative stress exclusive to combined exposure and amplified mercury-induced cytotoxicity. These findings underline the need to incorporate mixture toxicity into human health risk assessment frameworks.

2.13.P-We171 Micro- and Nano-plastic Exposure and Placental Health Risks: Evidence Integration within the TRAEC Strategy

***Yujie Liu¹**, Quanquan Guan¹, Xuan Ma² and Yankai Xia¹, (1)State Key Laboratory of Reproductive Medicine, Center for Global Health, School of Public Health, Nanjing Medical University, Nanjing, China; Key Laboratory of Modern Toxicology of Ministry of Education, School of Public Health, Nanjing Medical University, China (Mainland), (2)The Affiliated Wuxi Center for Disease Control and Prevention of Nanjing Medical University, Wuxi Center for Disease Control and Prevention, Wuxi Medical Center, Nanjing Medical University, Nanjing, China, China (Mainland)*

Micro- and nanoplastics (MNPs) have been widely detected in the human body, and accumulating evidence indicates their potential reproductive toxicity. However, their placental health risks and the mechanisms underlying size-dependent responses remain insufficiently characterized. To provide a systematic and quantitative evaluation of their potential risks to placental health, this study adopted the Targeted Risk Assessment of Environmental Chemicals (TRAEC) strategy, constructing an integrated scoring system based on four dimensions: evidence reliability, exposure-level weighting, risk intensity, and direction of association, incorporating both published literature and our experimental findings. Initially, we detected plastic particles in human placental villi using Raman spectroscopy and obtained in situ nanoscale images and complementary

chemical information for individual MNPs through atomic force microscopy-infrared spectroscopy and scanning transmission electron microscope. In parallel, our in vitro experiments demonstrated that exposure to high concentrations (100 µg/mL and 200 µg/mL) of 50 nm and 200 nm polystyrene nanoplastics (PS-NPs) induced cell-cycle arrest and apoptosis in human trophoblast HTR-8/SVneo cells, mediating placental reproductive toxicity through mitochondrial dysfunction. Under the same experimental conditions, exposure to 2 µm microplastic particles did not cause significant functional impairment, supporting a particle size-dependent toxicity pattern. By integrating literature-based evidence with our own experimental findings, the final TRAEC scores indicated an overall moderate level of reproductive toxicity risk, with higher risk estimates for nanoplastics than for microplastics. This study demonstrates the practical applicability of the TRAEC strategy in reproductive health risk assessment of MNPs and provides a methodological framework for understanding the health implications of ubiquitous micro- and nanoplastic exposure in the environment.

2.13.P-We172 Beyond the Polymer: Investigating How Plastic-Associated Chemicals Impact Algal Growth and Crustacean Behaviour

Megan Olley¹, Enda Gibney¹, Roisin Nash¹ and Darragh Doyle², (1)Marine and Freshwater Research Centre, Atlantic Technological University Galway, Ireland, (2)Department of Biological and Environmental Sciences, University of Gothenburg, Sweden

Plastic pollution poses a critical threat to aquatic ecosystems, with 4-12 million tonnes entering waters annually. While bioplastics offer potential alternatives that degrade up to 20 times faster than conventional plastics, critical gaps remain regarding their leachate toxicity. This study evaluates the ecotoxicological impacts of polylactic acid (PLA), polypropylene (PP), and paper (PAP) leachates using a multispecies approach spanning freshwater and marine environments.

Leachates were generated through passive water migration (10g polymer in 200mL water at 40°C for 10 days) for algal studies and ultrasonic methanol extraction for behavioural assessments. Growth inhibition assays with *Raphidocelis subcapitata* revealed distinct material-specific toxicity profiles: PP caused severe inhibition (62% at full concentration), PLA showed minimal toxicity (4.2% inhibition), while PAP unexpectedly stimulated algal growth (-17%), raising eutrophication concerns. Ongoing behavioral studies with hermit crabs (*Pagurus bernhardus*) assess sublethal effects through startle response experiments (cognitive function) and affiliation/avoidance trials. Preliminary results with oleamide, a plastic additive, showed strong crab attraction, suggesting plastic-associated chemicals may create "ecological traps."

These findings demonstrate that "bioplastic" does not guarantee environmental safety and that material-specific responses require individual evaluation beyond biodegradability metrics. This research establishes a holistic assessment framework combining chemical analysis, toxicity assays, and behavioural endpoints to inform evidence-based policy on sustainable plastic alternatives, ensuring material choices genuinely reduce environmental harm across aquatic ecosystems.

2.13.P-We173 Does the Size of Incubated Biodegradable Mulch Microplastics Alter Lettuce In Vitro Growth?

Mathilde Henrion¹, Lluís Martín-Closas¹, Iseult Lynch² and Ana M. Pelacho³, (1)Dpt. Agricultural and Forest Science and Engineering, University of Lleida, Spain, (2)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom, (3)University of Lleida, Spain

The use of biodegradable mulches in agriculture is expanding because its biodegradability offers an advantage over conventional plastics used for mulching, which end up accumulating microplastics in the soil. As they degrade within soil into microplastics, they can release compounds and modify soil properties that may harm plants and soil life. In vitro systems allow studying the effects of the microplastics and of the compounds they release on plants, without the complexity of the soil environment. This work aims to assess how microplastics of different sizes from biodegradable mulches, after an incubation period, affect the in vitro development of lettuce plants.

For this purpose, microplastics were produced from a commercial virgin biodegradable mulch made from PBAT-corn starch and vegetable oils, and classified into 4 size fractions: 5-2; 2-0.5; 0.5-0.2 and <0.2 mm. After

UV-sterilisation, microplastics were incorporated into a plant tissue culture MS medium at 0.1% (w/w) and incubated for 8 weeks in a growing room, with a control set without microplastics. Sterilized lettuce seeds were sown and allowed to grow for 4 weeks. Germination was regularly monitored for the first 10 days, the plantlets growth was visually assessed weekly, and the shoot and root weight, length and the photosynthetic pigments were analyzed at the end of the experiment.

Germination proceeded faster in the microplastics treatments while it was very similar to the control treatment at full germination. The microplastics also resulted in longer roots developing at the end of the 4 weeks of culture, the smaller the microplastics, the strongest the effects, despite there being no changes in the pigments' concentration. Microplastics smaller than 0,2 mm also significantly increased root weight. These observations are likely linked to the releasing of di- and tri- glycerols from the biodegradable mulches, which is to be higher for the smallest size microplastics, with larger contact surface with the medium. These compounds may interact in metabolic pathways and in cell elongation, finally enhancing root development.

This work is the first report on the size-dependent after-effects of incubated biodegradable mulches microplastics on plant growth. The results highlight the potential effects the biodegradable mulches microplastics may have on plants, especially the smallest ones, while not exhibiting toxicity.

2.13.P-We174 Strategic approach to increase environmental realism in leachate testing

Dana Kühnel¹, Annegret Benke², Annegret Potthoff², Annika Jahnke¹, Mbuyiselwa Shadrack Moloi¹, Rudolf Reuther³ and Anita Jemec Kokalj⁴, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Fraunhofer Institute for Ceramic Technologies and Systems - IKTS, Germany, (3)ENAS Environmental Assessments, Germany, (4)University of Ljubljana, Biotechnical Faculty, Slovenia

The growing recognition that plastic-associated chemicals, not just the polymer particles themselves, can harm biota has prompted a surge of leachate studies. Reported methods span a wide spectrum of leaching protocols, from environmentally realistic to highly accelerated conditions. Consequently, leachates produce variable biological effects that depend on polymer type, product shape and unknown mixtures of chemicals released. Hence, specific toxicants often remain unidentified.

This review systematically compiles existing leachate-generation, analysis, and testing protocols. It proposes a flexible yet structured workflow for producing environmentally relevant leachates. The workflow is organized around five key elements:

1. Plastic material, e.g. pristine, consumer-grade, recycled or post-consumer items.
2. Pre-leaching steps, e.g. removal of background contaminants.
3. Leaching conditions, e.g. choice of medium, solid-to-liquid ratio, temperature, UV irradiation, duration and mechanical energy.
4. Chemical analysis, e.g. targeted and non-targeted screening, prioritisation of detected compounds.
5. Toxicity testing, e.g. dosing strategy, exposure metrics and endpoints.

Our analysis shows that leaching conditions are tailored to the research question: mild protocols mimic natural exposure, whereas accelerated, harsher conditions enhance detection of low-level chemicals and mimic extended leaching over time. The presented workflow assists researchers to select the most appropriate protocol while maintaining comparability across studies, a step toward harmonised leachate testing.

Nevertheless, several challenges remain. First, the diversity of potential leachates demands comprehensive analytical strategies and prioritisation schemes, yet hazard data are missing for many plastic-associated chemicals. Second, linking toxicity outcomes to specific compounds is complicated by the formation of unknown transformation products during leaching. Third, for end-of-life and recycled plastics, distinguishing intentionally added additives from contaminants adsorbed during the product's life cycle is difficult.

Addressing these challenges requires coordinated efforts in advanced chemical characterisation, toxicological modelling and the development of databases that integrate chemical composition with hazard information. The systematic approach aims to guide future studies toward a clearer understanding of the ecological risks posed by plastic-associated chemicals.

2.13.P-We175 Microbial, Crustacean and Algal Responses to Leachates of Consumer Plastics: Assessing Toxicity and Biodegradation Potential

Olga Novillo-Sanjuan¹, Anna Luna Holm Elvekjær¹, Sevil Vafadar Afshar¹, Eva C. Sonnenschein² and Nanna B. Hartmann³, (1)Technical University of Denmark (DTU), Denmark, (2)Swansea University, United Kingdom, (3)DTU Sustain, Technical University of Denmark (DTU), Denmark

Leaching chemicals from environmental plastic litter is a well-established concern, with the potential to cause negative impacts across all levels of biological organization. The composition and magnitude of chemical release vary widely with polymer type and product-use category, underscoring the need for comparative assessments across plastic types and sources, including new biobased plastics. Here, two environmental bacterial isolates, *Paraburkholderia dioscureae* and *Pseudomonas putida*, a copepod species (*Acartia tonsa*) and a microalgae species (*Rhodomonas marina*) were exposed to leachates derived from five widely used consumer plastic types: polyethylene terephthalate (PET), polypropylene (PP), polystyrene (PS), polylactic acid (PLA), and a biobased starch blend. With this experiment, we analyze whether exposure to these leachates is toxic to the aforementioned species by measuring growth and survival rate, among other endpoints.

The leachates were produced by submerging the plastics in ultrapure water and were subsequently exposed to 20°C, UV light and constant shaking for 38 days to simulate environmentally relevant degradation. Additionally, each leachate was diluted to 50 and 25 % to account for effect differences depending on leachate concentration. Bacterial growth was measured over the course of 72h by optical density (OD). Additionally, bacteria were plated to count the number of Colony Forming Units (CFUs) and control potential contamination by other microorganisms. *A. tonsa* and *R. marina* will be exposed to these but also to ten more additional materials, composed of a mixed of commonly used items and marine relevant materials, such as fishing nets and car tires.

Across all plastic leachates, the growth of *P. dioscureae* was significantly reduced when compared to the negative control after 72 hours (t-test, p-values < 0.05, figure 2), indicating an overall inhibitory effect. For most plastic leachates, growth is already reduced after 24 hours, only the PLA leachate, showed a delayed inhibitory effect with growth being suppressed after the 24 hours. Preliminary findings on bacterial growth reveal differences in leachate effects between product types. These results will demonstrate whether plastic leachates cause ecotoxicological effects. These findings will underscore the complexity of plastic-associated chemical risks and the value of integrating diverse biological models in environmental impact assessments and nature-based solutions.

2.13.P-We176 Microplastics in Regurgitated Pellets of Predatory Birds in Southern England: Have We Been Underestimating Exposure?

Rana Ozturk¹, Gbotemi Adediran², William Mills³, Dominic Brass⁴, Matt Stevens⁵, Alex Robinson⁶ and Stuart Black³, (1)University of Reading/UK Centre for Ecology & Hydrology, United Kingdom, (2)University of Leeds, United Kingdom, (3)University of Reading, United Kingdom, (4)UK Centre for Ecology & Hydrology, United Kingdom, (5)Hawk Conservancy Trust, United Kingdom, (6)United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom

In recent years, microplastics have emerged as pervasive environmental contaminants, raising concerns about exposure levels of wildlife. Predatory birds occupy high trophic positions, and hence are susceptible to the biomagnification of pollutants. There is a rising body of evidence pointing towards birds of prey ingesting microplastics; however, the drivers of exposure are poorly understood. This study is the first to quantify microplastic ingestion by UK raptors. We quantify microplastic ingestion by two raptor species in southern England, barn owls (*Tyto alba*) and kestrels (*Falco tinnunculus*), which share overlapping habitats and diets.

Sampled nests were separated into eight pairs with one nest for each species in the pair (n=16). These paired nests were >10km apart from other pairs, to avoid pseudo replication. Three regurgitated pellets were collected from each nest, totalling 48 pellets. Each pellet was digested with 10% KOH, followed by a Fenton's reaction

and density separation with ZnCl₂. Microplastic presence, size, and polymer composition were analysed using Fourier-transform infrared (FT-IR) spectroscopy.

Out of a potential 21 polymers, 14 were detected with dominant polymers being polypropylene, polyurethane, ethylene vinyl acetate, ethylene vinyl alcohol and polyethylene terephthalate. Microplastic presence was detected in 83% of barn owl and 92% of kestrel pellets. Kestrel pellets contained significantly higher numbers of microplastic particles per gram (20.8 particles/g) compared to barn owl pellets (0.78 particles/g). For both species the number of particles detected increased as particle size decreased, with the highest number of particles found between 25-50 µm.

Our findings demonstrate interspecific differences in microplastic ingestion between barn owls and kestrels. The significant differences in microplastic ingestion between two species that have such closely overlapping foraging ecologies raises important ecological questions, such as whether minute differences in prey ingested can cause significant differences in exposure. Such investigations may allow us to assess which species are at higher risk of exposure based on prey choice. These findings also evidence the value of analytical techniques such as FT-IR spectroscopy, revealing higher ingestion rates than previously recorded using visual identification and demonstrating the prevalence of smaller microplastic particles missed when relying solely on visual identification.

Track 3: Environmental Chemistry and Exposure Assessment: Analysis, Monitoring, Fate and Modelling

3.01 Advances in Bioaccumulation Science and Assessment

3.01.T-01 Development and Evaluation of Data, Models and Tools to Support Bioaccumulation Assessment

Jon A. Arnot¹, Alessandro Sangion¹, Liisa Toose, M.Sc.¹, Trevor N Brown¹, Pippa Kate Curtis-Jackson², Steph Jones², Leslie J Saunders³, Heike Laue⁴ and Michelle Rau Embry⁵, (1)Arnot Research & Consulting (ARC), Canada, (2)Environment Agency United Kingdom, United Kingdom, (3)Department of Physical and Environmental Sciences, European Fuel Manufacturers Association Division Concawe, Brussel, Belgium, (4)Givaudan, Switzerland, (5)HESI Global

Bioaccumulation (B) assessment is challenging because of measurement data gaps and all B assessment metrics and methods have merits and limitations; uncertainty is inherent. B screening criteria use the octanol-water [KOW] and octanol-air [KOA] partition ratios as surrogates for partitioning to biological phases. Octanol is a reasonable biopartitioning surrogate for many hydrophobic neutral organic chemicals; however, its application for ionisable organic chemicals (IOCs), such as perfluorinated alkyl acids (PFAAs), is limited. Requirements to reduce or eliminate animal testing have prioritized the development of new approach methods (NAMs) employing in vitro and in silico methods, which require evaluation and data generation. In vitro methods include Organization for Economic Coordination and Development (OECD) fish S9 and hepatocyte assays for estimating biotransformation rates (TG 319A/B), which subsequently require in vitro-in vivo extrapolation (IVIVE) and mass balance one-compartment physiologically-based biokinetic (1Co-PBK) models to calculate B metrics. In silico methods also include Quantitative Structure Activity Relationships (QSARs) for B metrics and toxicokinetic parameters, e.g., whole body biotransformation [HLB] half-lives. This presentation provides an overview of recently developed and evaluated databases, methods and tools to support B assessment decision-making including (i) a weight of evidence (WoE) approach to aid B assessment decision-making following OECD (WoE) guidelines and its implementation in the Bioaccumulation Assessment Tool (BAT), (ii) the Bioaccumulation Evaluation Tool (BET) to calculate B metrics in representative aquatic and air-breathing organisms under laboratory and field conditions using in vivo, in vitro and in silico data, (iii) an OECD B Integrated Approach to Testing and Assessment (IATA), (iv) new models for predicting KOW and KOA, (v) new biopartitioning databases and new polyparameter linear free energy relationships (PPLFERs) for predicting

chemical partitioning to storage lipids, membrane lipids, structural proteins and serum albumin, and (vi) updated IVIVE models for using S9 and hepatocyte data to parameterize 1Co-PBK models. The presented case studies outline possible future IATAs for biopartitioning and biotransformation rates which are Key Areas of Regulatory Challenge identified in the scientific community and by the European Chemicals Agency (ECHA).

3.01.T-02 Application of EAS-E Suite to Inform In Silico-Based Assessments of Bioaccumulation in Air Breathing Organisms: Case Study with Hydrocarbons in Laboratory Rat

Leslie J Saunders¹, Alessandro Sangion² and Jon A. Arnot², (1)Concawe, Belgium, (2)Arnot Research & Consulting (ARC), Canada

Bioaccumulation (B) assessments have traditionally focused on aquatic organisms, but regulatory agencies are increasingly considering air-breathing species. The European Chemicals Agency (ECHA) outlines a framework for assessing B in air-breathers (mammals): initial screening by physicochemical properties (i.e., octanol-water [KOW] and octanol-air [KOA] partition ratios); refined screening using quantitative structure-activity relationships (QSAR) or in vitro toxicokinetic (TK) data (e.g., biotransformation [HLB] or elimination [HLT] half-lives); and definitive in vivo testing. Because empirical data and standardized in vivo methods for assessing B in air-breathers are limited (and animal testing conflicts with 3Rs principles), assessments are expected to rely on in silico and in vitro new approach methods (NAMs). We applied the Exposure And Safety Estimation (EAS-E) Suite to evaluate the B potential of 1981 unique hydrocarbons (HC) in a representative air-breathing organism (laboratory rat). Key data (i.e., KOW, KOA, HLB, HLT) were compiled from available measurements or predicted using multiple QSAR models. Central-tendency estimates (e.g., mean, median, SD) for each parameter were incorporated into a one-compartment physiologically based TK model to estimate biomagnification factors (BMF) with propagated uncertainty. When biotransformation was excluded, 60% of HCs exceeded the regulatory BMF threshold of 1, while the rest had reduced dietary uptake efficiency due to their high hydrophobicity ($\log KOW > 12$). As most hydrocarbons are expected to undergo biotransformation, incorporating HLB predictions substantially reduced median BMFs for all HCs to below 1. When 95% confidence intervals were included, 88% of HCs had upper-bound BMFs below 1, suggesting they may be deprioritized for further B assessment. 90% of the variation in BMF estimates was driven by HLB, underscoring the critical influence of biotransformation in determining B potential. For HCs with upper-bound BMFs above 1, the uncertainty may reflect compounds falling outside the applicability domain of HLB QSARs, particularly aliphatic HCs, and underscores the need for additional data to improve QSAR-based assessments of these substances. This work illustrates how in silico NAMs can be effectively integrated into a tiered framework for assessing B in air-breathing organisms.

3.01.T-03 fishFingers: Bioconcentration factor (BCF) and fish species bioaccumulation distribution prediction for chemicals detected by HRMS using recommender system machine learning

Drew Szabo¹, Katie Plaisted², Alistair Boxall¹ and Jackie Mosely¹, (1)University of York, United Kingdom, (2)University of York, Sweden

Exposure to novel entities in the environment now exceeds our capacity to evaluate the risk of each chemical under traditional frameworks. Detecting, prioritising and identifying thousands of anthropogenically-derived chemicals already present in the environment is a key challenge to understand this planetary boundary. The application of machine learning to chemical risk management has already demonstrated quick and accurate ecotoxicological characteristics of chemicals with low confidence structural annotation inferred from high-resolution mass spectrometry (HRMS). The rate at which a chemical is absorbed into an organism compared to the rate it is excreted, known as the bioconcentration factor (BCF), is also an important factor for evaluating chemical risk. Since toxicity and bioaccumulation are often used to regulate chemicals, accurate and precise in silico techniques can greatly enhance our capacity for chemical risk assessment. Unfortunately, all known methods of reliable BCF prediction require a confident chemical structure. The prediction of BCF from HRMS features without a priori structural annotation will be demonstrated, using high-quality tandem mass spectrometry (MS2) to elucidate key structural fingerprints. This offline prioritisation method for non-targeted screening can quickly rank features in order of decreasing risk of bioaccumulation. A dataset containing measured BCF values for more than 1000 chemicals was obtained and curated for training and testing. For each chemical, a matrix of 2691 structural fingerprints were calculated using the redk package, incorporating MACCS, PubChem, Klekota-Roth, and a number of custom SMARTS. A recommender system approach was applied to model BCF with inputs from structural fingerprints from over 100 species of fish. The performance of linear regression, decision tree and dropout tree algorithms were compared, and the best performing model was optimised and tested to achieve the highest balanced accuracy, calculated as $(TPR+TNR)/2$. Chemicals with high-quality MS2 in the MassBank spectral library were then used to simulate HRMS results and validate the

model using SIRIUS CSI:FingerID v5.8 to generate the structural fingerprints using the averaged peak lists. The performance of the model was compared with methods described in the literature, including hydrophobicity-based models (log Kow) and other popular QSAR models that use known structural annotations.

3.01.T-04 Gammarus fossarum as European freshwater amphipod species for bioconcentration application

Anthony Gérard Edouard Mathiron¹, Vanessa Brosselin¹, Méline Claitte¹, Pierre-Louis HOMBERT¹, Nicolas Delorme², Mathilde Duny³, Mickaël Nicolas³, Vivien Lecomte⁴, Delphine Leroy⁵, Yves Marneffe⁵, Pascal Pandard⁶, Guillaume Cottin⁶, Alaa Bensetra⁶, Céline Le Cocq⁶, Cyril Sweetlove⁶, Olivier Geffard Pr² and Guillaume JUBEAUX¹, (1)BIOMAE-CARSO group, France, (2)National Research Institute for Agriculture, Food and Environment (INRAE), France, (3)CARSO-LSEHL, France, (4)INRAE, France, (5)Scientific Institute of Public Service (ISSEP), Belgium, (6)L'Oréal, France

Bioconcentration factor (BCF) is the ultimate decisive bioaccumulation criterion as part of the regulatory chemical safety assessment of pollutants in aquatic ecosystem (REACH regulation). The Hyalella azteca Bioconcentration Test (HYBIT) - that aims to determine BCF in the North-American amphipod H. azteca for regulatory purposes - provides a non-vertebrate alternative to fish bioconcentration studies. Here, we aim to highlight the interest of the European amphipod Gammarus fossarum as model in HYBIT test guideline (TG) 321 that has been recently adopted at OECD. To do so, we initiated in 2025 an interlaboratory assay (Ring-test) with three European countries to determine the kinetics of bioaccumulation and depuration of terbutryn (herbicide of the triazine family) and prochloraz (fungicide of the imidazole family), two molecules that were previously selected for H. azteca validation test. During experiments, amphipods are exposed to chemicals dissolved in water for 4 days (uptake phase; nominal concentration: 50 µg.L⁻¹), then transferred to controlled conditions for 4 days (depuration phase). Pools of individuals and water samples are collected and analysed at different intervals. Results from three laboratories showed that the mortality rate remained below 20% regardless of the treatment (mean ± SE: 9.2 ± 1.6%, 11.1 ± 3.7% and 12.8 ± 2.1%, respectively for control, terbutryn and prochloraz), which meets the corresponding validity criterion of the HYBIT protocol. Test solutions and gammarid tissue analyses from one laboratory allowed us to calculate BCFs values (BCF = 0.8 and 20 respectively for terbutryn and prochloraz) which indicated that prochloraz bioconcentrated more than terbutryn in G. fossarum, as previously shown for H. azteca. First conclusions of the Ring-test will be presented during SETAC 2026 conference.

Key-words: ecotoxicology; laboratory exposure; bioconcentration factor; HYBIT; OECD; gammarids

3.01.T-05 Trophic Transfer and Interactions of TiO₂ Nanoparticles in a Simplified Aquatic Trophic Chain

Maria Inés Rivadeneira¹, Isabel Benta Oliveira¹, Antonio Cascajosa Lira², Teresa Neuparth¹, Rodrigo Ozório¹, Helena Peres¹, Antonio Moreda³, Begoña Espiña⁴, Alexandre Campos¹ and Mário Araújo¹, (1)Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portugal, (2)University of Sevilla, Portugal, (3)GETEE – Trace Elements, Spectroscopy and Speciation Group, Materials Institute (iMATUS), University of Santiago de Compostela, Spain, (4)INL - International Iberian Nanotechnology Laboratory, Portugal

Titanium dioxide nanoparticles (TiO₂ NPs) are widely used in several domains and can enter aquatic systems, where natural organic matter modifies their stability, aggregation and biological uptake. While waterborne toxicity of TiO₂ NPs is well studied, less is known about dietary transfer across trophic levels. Therefore, in this study, we aimed to examine the trophic transfer of Humic Acids-coated TiO₂ NPs (21 nm) along a three-level chain comprising the microalgae "Tetraselmis suecica", the brine shrimp "Artemia" sp. and the zebrafish (Danio rerio). In addition to bioaccumulation/quantification of total titanium and NPs in tissues of three trophic levels (studied by ICP-MS/sp-ICP-MS), biochemical markers (LPO, GST, CAT), energy content, and C:N ratio were assessed.

Microalgae exposed to TiO₂ NPs accumulated notable Ti concentrations (~14 µg g⁻¹), though <2% was detected as discrete particles, reflecting strong aggregation in saline media and surface attachment to cells. Artemia accumulated low and variable Ti (<1 µg g⁻¹), suggesting rapid clearance, yet zebrafish still showed clear

evidence of dietary uptake. Ti levels in the zebrafish gastrointestinal tract were about twice those of controls, confirming trophic transfer to the highest consumer despite the aggregated state of the particles. Single-particle ICP-MS signals were often below detection, indicating that Ti reached fish mainly as non-particulate or aggregated forms rather than as individualized NPs. Lower-trophic-level nutritional markers showed minor changes (e.g., non-significant C:N increase in *Artemia*) and require additional attention. In zebrafish, no statistically significant alterations were detected in muscle energy reserves or liver oxidative stress markers ($p > 0.05$); however, subtle tendencies (e.g.: marginally higher lipid peroxidation and reduced catalase activity) suggest antioxidant responses that could intensify under longer exposures or higher dietary loads. Ongoing analyses are assessing cellular alterations in zebrafish gonads (histology) as well as lipid and FAME profile changes resulting from dietary exposure to TiO_2 NPs.

Overall, TiO_2 NPs rapidly aggregated but still adhered to microalgae and were transferred through the diet up to zebrafish. Although biological impacts were not fully clear, the demonstrated bioaccumulation at the top trophic level highlights the ecological relevance of dietary exposure pathways and the need for longer-term, tissue-specific assessments.

3.01.P Advances in Bioaccumulation Science and Assessment

3.01.P-Mo140 Proposal for an Integrated Assessment Strategy for Aquatic and Terrestrial Bioaccumulation

Caren Rauert¹, Daniel Frein¹, Verena Kosfeld², Monika Nendza³ and Christian Schlechtriem²,
(1)Umweltbundesamt, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)AL Luhnstedt, Germany

An assessment strategy for evaluating bioaccumulation in aquatic and terrestrial organisms is introduced. Building on existing regulatory guidance, the strategy combines *in silico*, *in vitro*, and invertebrate approaches with existing *in vivo* knowledge to minimise vertebrate testing while ensuring the quality of regulatory decisions. It covers neutral lipophilic, ionisable, superhydrophobic, and amphiphilic substances, providing both a stepwise pathway for new chemicals and a weight-of-evidence approach for existing substances. The strategy consists of a tiered aquatic system and a parallel system for air-breathing organisms. In the aquatic scheme, tier 1 relies on hydrophobicity indicators (log K_{ow} or log D for ionisable substances). Tier 2 uses QSAR-based BCF estimates, with consolidation of multiple models to account for variability. Tier 3 introduces mechanistic non-vertebrate and *in vitro* tests, and tier 4 requires fish testing (OECD 305) only in cases where the available information from earlier tiers remains inconclusive. The scheme also addresses non-lipid-driven accumulation relevant to PFAS, ionisable substances, and surfactants. The terrestrial scheme incorporates log K_{oa} and metabolic capacity metrics to assess accumulation potential in mammals and birds. The integrated strategy was evaluated using 26 case study substances by comparing results from QSARs, OECD 319A/B, OECD 321, and OECD 305 tests. For moderately to highly hydrophobic chemicals, discrepancies between *in vitro*, invertebrate, and *in vivo* results highlighted the need for expert interpretation, and for superhydrophobic substances, methodological limitations reduced the applicability of current NAMs. Ionisable substances, PFAS, and surfactants also required specific considerations. For air-breathing organisms, rat hepatocyte and S9 assays showed promise, and a preliminary tier 2 screening threshold was identified, though further refinement is needed. In summary, the integrated testing and assessment strategy proved effective for identifying substances of bioaccumulation concern and for guiding efficient testing sequences that can be used across EU substance regulations. It confirmed the complementary roles of *in silico*, *in vitro*, and invertebrate methods and highlighted the importance of expert judgement for complex cases. NAMs can substantially reduce vertebrate testing while maintaining regulatory protection levels.

3.01.P-Mo141 Refining the Bioconcentration Testing Trigger: A Weight of Evidence Approach

Alison Nimrod Perkins, Laura Garcia Barcia and **Michael Lee**, Eli Lilly and Company, United States

Environmental risk assessments for human medicines require fish bioconcentration testing (OECD 305) when $\log K_{ow} \geq 3$. If bioconcentration factor (BCF) >100 L/kg, the risk for secondary poisoning is assessed. Industry data show ~60% of triggered OECD 305 studies for human medicines yield $BCF_{KgL} <100$ L/kg, the regulatory threshold for secondary poisoning assessment. K_{ow} poorly predicts bioconcentration of human medicines due to factors beyond hydrophobicity (e.g., metabolism, active transport, molecular properties). Since most human medicines trigger unnecessary testing, significant opportunity exists to apply 3R principles. Using a small dataset of pharmaceuticals with measured BCF, we evaluated potential screening tools that could be used in a weight-of-evidence (WoE) approach to determine when to conduct an OECD 305.

One tool is tissue analysis of fish from a required early-life stage study (OECD 210). Tissue samples collected from 14-day post-hatch fathead minnows at the conclusion of the OECD 210 range-finding study, utilizing fish typically discarded after growth measurements. Another tool is a toxicokinetics study, that facilitates read-across between fish and preclinical species, where plasma and tissue concentrations are measured over a 14-day exposure and a 5-day clearance. For 5 pharmaceuticals evaluated, the toxicokinetic and/or OECD 210 body burden measurements accurately predict BCF. For molecules with OECD 305 $BCF_{KgL} <100$ L/kg ($n=4$), body burden show BCF below the regulatory threshold (range: 0.2-24 L/kg). For compounds >100 L/kg ($n=1$), the approach correctly identified a secondary poisoning potential (range: 188 to 241 L/kg). When used in combination, no false negatives occurred.

We also evaluate the use of intrinsic clearance by fish hepatocytes (OECD 319A) as a screening tool. When $\log K_{ow}$, hepatocyte clearance and body burden data indicate BCF >100 L/kg, an OECD 305 is conducted to evaluate secondary poisoning risks.

This proof-of-concept WoE approach demonstrates that pharmaceutical bioconcentration can be reliably predicted using tissue from fish already sacrificed for required testing. The approach eliminates redundant vertebrate use, saves ~10 mCi radiolabel, and maintains regulatory confidence through validated methods. With regulatory openness to 3R solutions backed by data, implementation could reduce unnecessary vertebrate use without increasing the risk of secondary poisoning.

3.01.P-Mo142 Small aquatic invertebrates in bioaccumulation assessment

Marta Markiewicz¹, Ekinadose Orose¹, Rana Erkin² and Stefan Stolte³, (1)*Dresden University of Technology, Germany,* (2)*Boğaziçi University, Germany,* (3)*Institute of Water Chemistry, Dresden University of Technology, Germany*

Current bioaccumulation assessments primarily depend on fish data, which are limited by kinetic constraints, as steady-state bioaccumulation factors are often calculated without confirming that steady-state conditions have been achieved. These experimental shortcomings compromise the reliability of QSAR models developed for *in silico* bioaccumulation predictions. Testing is particularly challenging for highly hydrophobic compounds due to difficulties maintaining stable exposure and long time needed to approach steady-state. The Environmental Chemicals Agency has recently identified improved bioaccumulation testing methods as one of the key regulatory challenges. However, ethical constraints and low throughput make fish tests ill-suited to addressing this challenge.

Smaller organisms achieve steady-state more rapidly than fish. *Daphnia magna*, well-established in laboratory and regulatory practice, exhibits depuration rates approximately 100-fold faster than fish, enabling substantially shorter test durations. We recently developed a testing method maintaining constant exposure at very low concentrations (ng/L range) while simultaneously assessing chronic toxicity and bioaccumulation.

The data requirements for advancing this approach toward standardized test procedures were systematically evaluated and the key advantages include: rapid uptake/depuration kinetics, small organism and housing container size, potential integration with chronic toxicity assessments, lower ethical constraints, and potential for dense sampling to obtain detailed kinetic profiles. Identified limitations include: limited tissue mass for chemical analysis, insufficient physiological data for mechanistic modeling, and periodically occurring moulting and offspring release.

To address critical data gaps, we characterized key *D. magna* physiological traits including: wet/dry weight dynamics during growth (yielding growth rate parameters), body composition, and feeding rates. These data enable assessment of different uptake and depuration routes using physiologically-based toxicokinetic (PBTK) models.

Our physiological characterization provides essential parameters for PBTK modeling, advancing the scientific foundation for standardized *Daphnia*-based bioaccumulation assessment methods. *Daphnia magna* represents a promising alternative platform for bioaccumulation testing, offering significant practical and ethical advantages over traditional fish tests.

3.01.P-Mo143 Implications of Variable Octanol-Water Partition Coefficient (KOW) Values in Bioaccumulation Assessment

Monika Nendza¹, Verena Kosfeld² and Christian Schlechtriem³, (1)*Computational Toxicology, Analytical*

Laboratory AL-Luhnstedt, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Bioaccumulation & Animal Metabolism, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

The octanol–water partition coefficient (log KOW) is both an intrinsic substance property and an input parameter for modelling, e.g. for quantitative structure-activity relationships (QSARs) and in vitro-in vivo extrapolations (IVIVE). These methods are increasingly used to reduce animal testing (following the 3R principles). Errors in log KOW values can therefore be critical if propagated in bioaccumulation assessments. When evaluating substances against regulatory thresholds, such as a log KOW value of 4.5, high-quality data is often not required. Where two log KOW estimates for a substance are clearly below this value, e.g. 1 and 3, or above it, e.g. 6 and 8, no further refinement is needed for a robust conclusion. Less variability is essential if the log KOW is within one log unit below or above the screening value of log KOW = 4.5. Then, consolidation of the log KOW value by consensus modelling can reduce uncertainties and is superior to the traditional preference for a single measured log KOW.

QSARs aim to describe and predict the bioaccumulation of substances from their chemical structures.

Considering bioconcentration as a distribution between aqueous and organic phases has produced many direct relationships with log KOW as a worst-case approach. There, log KOW error ranges of ± 0.3 or ± 0.5 may make the difference in the predictions of log BCF of substances being either non-bioaccumulative (BCF < 2000) or (very) bioaccumulative (BCF > 2000/5000).

One of the new approach methods (NAMs) is based on in vitro substrate depletion assays (OECD 319 A/B). It determines biotransformation rates in fish liver S9 fractions or hepatocytes. These are used to predict BCF values with IVIVE. Their input variables include the experimental specifications and measured biotransformation rates as well as log KOW values, which are intended to represent the distribution behaviour. Using case study chemicals, we will illustrate the consequences of variability in log KOW values for IVIVE-based BCF values. These will be compared with the predictivity of an empirical regression model based on the in vitro intrinsic clearance and log KOW.

Recommendations will be presented on appropriate methods to consolidate log KOW (fit-for-purpose).

Integrating multiple lines of evidence from refined physicochemical parameters, QSARs and NAMs can jointly provide reliable information for bioaccumulation assessments.

3.01.P-Mo144 Predictivity of Physicochemical Properties and Quantitative Structure-Activity Relationships (QSARs) in Tiered Bioaccumulation Assessments

Monika Nendza¹, Verena Kosfeld² and Christian Schlechtriem³, (1)Computational Toxicology, Analytical Laboratory AL-Luhnstedt, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Bioaccumulation & Animal Metabolism, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

The evaluation of bioaccumulation potential is one of the fundamental elements of environmental risk assessment for chemical regulation. Integrated Approaches to Testing and Assessment (IATA) have multiple tiers that combine in silico, in vitro, and invertebrate testing with established in vivo data, and aim at reducing the need for animal testing and improve regulatory efficiency.

At Tier 1, hydrophobicity is generally assessed using the octanol–water partition coefficient (log KOW) as the primary indicator for aquatic bioaccumulation potential. Comparative analyses revealed substantial variability in log KOW values determined with different experimental and computational methods. Iterative consensus modelling was found to reduce uncertainty and to provide more stable input values for bioaccumulation assessment. Furthermore, log KOW in combination with the octanol–air partition coefficient (log KOA) and biotransformation half-life, relate to the terrestrial accumulation potential. For low log KOA, the limited variability (within one order of magnitude) supports a reduced approach to assess substances against the threshold of 5 for unlikely bioaccumulation in air-breathing organisms.

At Tier 2, bioconcentration factors (BCFs) are usually estimated using QSAR models available, e.g., in EpiSuite, VEGA, OCHEM, etc. Variability among model outputs is notable, with differences of more than one log unit observed for some substances. Consolidation of QSAR results across datasets allowed estimation of uncertainty ranges and improved prediction reliability. However, further validation of relevant QSARs for regulatory purposes is necessary.

Using case study chemicals, we will illustrate the consequences of variability in input data on physicochemical properties and the benefits of QSAR-based classifications of substances as either not-bioaccumulative (nonB) or (very) bioaccumulative (B/vB). The focus is on REACH chemicals, including examples of superhydrophobics and a volatile substance that is likely to biomagnify in terrestrial food webs.

3.01.P-Mo145 Optimization of the Slow-Stirring Method for Measuring 1-Octanol/Water Partition Coefficients of Surfactants and Application to Bioaccumulation Assessment

Keiko Kondo, Kaku Oguro, Hiroya Shinozaki, Kikuo Yoshida and Yuki Sakuratani, Chemicals Management Center, National Institute of Technology and Evaluation, Japan

The 1-octanol/water partition coefficient (log Pow) reflects the hydrophobicity of organic chemicals and is used to predict their environmental behavior and toxicity. In particular, log Pow is a key parameter for estimating the bioconcentration factor (BCF), a critical indicator of bioaccumulation potential.

However, a reliable method for log Pow measurement has yet to be established for surfactants, due to their unique properties such as micelle formation, emulsification, and adsorption. Thus, log Pow is considered unreliable for estimating BCFs of surfactants.

Due to their amphiphilic nature, surfactants interact with biological membranes, affecting their distribution and accumulation. Therefore, measuring phospholipid membrane-water partition coefficients (log Km_w) may help estimate surfactant bioaccumulation, though derivation can be complicated by strong sorption, structural diversity, and membrane interactions.

In this study, we optimized the measurement conditions of the slow-stirring method for determining log Pow of surfactants. Previous studies have reported that this method can be applied to surfactants when the aqueous concentration during equilibration remains below the critical micelle concentration.

Furthermore, to evaluate the utility of log Pow measured by the slow-stirring method, we conducted regression analyses examining relationships between log Pow by the method and experimentally determined BCFs for anionic and cationic surfactants.

As a result, optimizing the initial concentration and stirring conditions enabled stable and reproducible measurement of log Pow by the slow-stirring method. For anionic surfactants, BCFs could be estimated using a simple linear regression equation based on log Pow measured in this way. In contrast, accurate BCF estimation for cationic surfactants required molecular weight as a descriptor in addition to log Pow obtained by the slow-stirring method.

Moreover, a good correlation was observed between log Pow measured by this method and log Km_w, suggesting that log Pow determined by this approach may be a useful indicator for quantitatively assessing the bioaccumulation potential of surfactants.

In conclusion, the optimized slow-stirring method established in this study enables appropriate measurement of log Pow for surfactants and offers an effective approach for assessing bioaccumulation potential. This method is expected to contribute to chemical regulation and environmental risk assessment frameworks.

3.01.P-Mo146 The Influence of Biological Traits on Bioconcentration of Organic Chemicals in Freshwater Invertebrates

Katie Plaisted¹, Claudia Rivetti², Lorraine Maltby³ and Alistair Boxall⁴, (1)University of York, Sweden, (2)Safety, Environmental and Regulatory Sciences (SERS), Unilever, United Kingdom, (3)School of Biosciences, University of Sheffield, United Kingdom, (4)University of York, United Kingdom

Organic chemicals released into aquatic environments, including pesticides, pharmaceuticals and personal care products, may pose ecological and human health risks. Uptake of organic chemicals can vary widely across aquatic species, yet the biological traits driving these differences remain poorly understood. Traits such as size, lipid content, body structure and respiration likely play a key role in chemical accumulation, but they are rarely incorporated into current risk assessment frameworks. Improving the understanding of how traits influence bioconcentration would strengthen cross-species extrapolation and enhance the ecological relevance of chemical hazard evaluations.

This work aims to develop a trait-based framework for predicting bioconcentration across aquatic invertebrates. Such an approach has the potential to improve ecological relevance, enhance cross-species extrapolation, and support reduced reliance on vertebrate testing in chemical hazard assessment.

This study investigates how biological traits affect toxicokinetics in freshwater invertebrates, using carbamazepine as a model compound. A minimised bioconcentration test design (48 h uptake, 48 h depuration) was applied to several taxa spanning multiple phyla and a broad size range under controlled laboratory conditions. Concentrations of carbamazepine were determined in the water phase and animal tissue at the end of the uptake and depuration phases. Toxicokinetic parameters (K_{in} and K_{out}) were estimated using a one-compartment first-order model and used to estimate bioconcentration factors. Uptake and depuration rates and BCFs were compared with trait data, compiled from direct morphometric measurements and established ecological trait databases, to identify potential drivers of uptake.

Preliminary analyses indicate that variation in toxicokinetic parameters aligns with key biological traits, such as the surface area-to-volume ratio and lipid content, suggesting that both structural and functional characteristics

influence chemical uptake and elimination. These patterns form the basis for expanding the approach to a broader set of organic chemicals spanning a range of Kow values and including ionisable compounds.

3.01.P-Mo147 In Silico Modelling of Bioaccumulation of Per- and Polyfluoroalkyl Substances

Darina Yordanova, Irina Dermen, Nadezhda Dimitrova and Ovanes Mekenyan, Laboratory of Mathematical Chemistry (LMC) Prof. Assen Zlatarov Burgas State University, Bulgaria

Per- and polyfluoroalkyl substances (PFAS) are a large family of fluorinated chemicals that vary widely in their chemical and physical properties. The persistence and mobility of certain PFAS, combined with their extensive use over decades in industrial applications and consumer products, have led to their global environmental presence. Toxicological studies have raised concerns about the bioaccumulative nature and potential health risks associated with some PFAS. However, risk assessment remains challenging due to their unique physicochemical properties, which result in complex and poorly understood biological and chemical transformation pathways. To address these challenges, developing non-animal testing approaches to evaluate the environmental fate and health-related properties of PFAS is essential. In this study, a new quantitative structure-activity relationship (QSAR) model has been developed for predicting the bioconcentration factor (BCF) of PFAS. Two datasets were built to investigate bioconcentration processes of PFAS. The first includes experimentally derived BCF values obtained from various open sources, curated to include only fish BCF data generated under the OECD 305 test guideline. The second dataset comprises documented *in vivo* and *in vitro* metabolism extracted from publicly available databases. This metabolism dataset was used to identify key molecular transformations and to train the system to simulate fish liver metabolism. A review of the literature indicates that PFAS bioaccumulation occurs through both passive diffusion (driven by lipophilicity) and active transport (mediated by protein interactions). These two mechanisms were used to derive the maximum bioconcentration potential (BCFMAX) of PFAS. Subsequently, several mitigating factors, such as molecular size, metabolic transformation of the parent compound, water solubility, and ionization, were incorporated to reduce the BCFMAX values. The resulting model demonstrates strong predictive performance for both endpoint estimation and simulated metabolism. It correctly predicts 91% of the chemicals in the training set within the experimental error and exhibits an average sensitivity of over 95% with respect to metabolism simulation.

3.01.P-Mo148 Practical Challenges, Methodological Insights and Key Takeaways from Conducting a *Hyalella azteca* Bioconcentration Pilot Study According to the OECD Test Guideline 321

Elizabeth Ostermann and Suzanne Zvalaren Schneider, Eurofins Agroscience, United States

Bioaccumulation testing is an important component in assessing a chemical's impact on the environment and human health as well as a conditional requirement in the registration process of modern chemicals. OECD Test Guideline 305 "Bioaccumulation in Fish" has undergone multiple revisions; however, new bioaccumulation test guidelines were not approved until 2024 when the OECD 321 guideline for the "*Hyalella azteca* Bioconcentration Test" (HYBIT) was adopted. This new guideline and test design provides the option for an invertebrate bioaccumulation test in an aqueous exposure system, which is the preferred test for bioaccumulation under REACH. To evaluate feasibility and refine laboratory procedures, a pilot bioconcentration study was conducted in our contract research organization (CRO) laboratory in accordance with the newly adopted OECD 321 guideline. This poster summarizes the challenges, insights gained and key lessons learned from the CRO perspective providing practical considerations for future studies used for regulatory submissions.

3.01.P-Mo149 OECD Ring Trial involving the NanoHYBIT: A Novel Method for Non-Vertebrate Regulatory Bioaccumulation Testing of Nanomaterials

Sebastian Kuehr¹, Doris Völker², Kathrin Schwirn², Susanne Walter-Rohde², Ina Ebersbach¹ and Christian Schlechtriem³, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)German Environment Agency (UBA), Germany, (3)Bioaccumulation & Animal Metabolism, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Validated non-animal methods for the regulatory bioaccumulation assessment, adapted to the specific needs for investigating engineered nanomaterials (ENMs) are still lacking in current guidelines. The freshwater amphipod

Hyaella azteca has proven suitable for determining bioconcentration (BCF) and biomagnification (BMF) factors for ENMs, and initial protocols have been established. These were further refined and standardized within the BMFTR-funded projects NanoHYBIT (FKZ 16LW0289) and NanoHYBIT 2.0 (FKZ 03LW0729), expanding the dataset for various ENMs. In conclusion, the resulting *Hyaella azteca* Nanomaterial Bioaccumulation Test (NanoHYBIT) shows strong potential as a non-vertebrate alternative for bioconcentration and biomagnification studies.

Before regulatory acceptance, however, validation is required to assess protocol transferability across laboratories, evaluation of the assay performance and confirm the reliability and reproducibility of NanoHYBIT-based BCF and BMF estimates for ENMs. Consequently, the OECD Working Party on Manufactured Nanomaterials has recommended validating a protocol aligned with OECD TG 321 through an international OECD ring trial.

Within this ring test, selected ENMs will be assessed for bioavailability and bioaccumulation (BCF and BMF), covering key properties influencing uptake and bioaccumulation. These include dispersibility versus agglomeration behavior, ion release, regulated uptake mechanisms, and the physiological relevance of the metal, chemical stability of metal or metal-oxide or polymer-based ENMs to define the applicability domain of the method.

The multi-laboratory ring trial aims to: i) compare BCF and BMF values generated across participating laboratories, and ii) provide the evidence base required to develop a new OECD Test Guideline for nanomaterial bioconcentration and biomagnification testing using *H. azteca*.

The ultimate goal is to establish a new OECD TG, based on the framework of OECD TG 321, that incorporates both aqueous bioconcentration testing and dietary biomagnification testing with *H. azteca*. This would provide a validated, non-vertebrate method tailored specifically to nanomaterials and ready for regulatory use.

3.01.P-Mo150 Assessing the OECD 321 *Hyaella azteca* Bioconcentration Test (HYBIT) for Polymer-Based Nanomaterials Using 14C-Labeled Polystyrene Nanoparticles

Leonard Plochocki¹, Boris Meisterjahn¹, Nicola Schroeder¹, Joana Bräutigam¹, Ina Ebersbach¹, Ralf Kaegi², Christian Schlechtriem³ and Sebastian Kuehr¹, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Process Engineering, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Bioaccumulation & Animal Metabolism, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

The identification and scientific evaluation of compounds that bioaccumulate in organisms and biomagnify in food webs is a key element of PBT assessment. Bioaccumulation potential is commonly expressed as bioconcentration factors (BCFs), derived from flow-through fish studies following OECD TG 305. For substances that cannot be maintained under constant aqueous exposure, TG 305 also allows dietary exposure to determine biomagnification factors (BMFs).

Recently, OECD TG 321 introduced a new non-vertebrate test (HYBIT) using the freshwater amphipod *Hyaella azteca* to determine BCF values of soluble, non-particulate substances. Although the OECD GD 406 for assessing the apparent accumulation potential of nanomaterials via dietary exposure in fish tests according OECD TG 305 provides guidance on testing engineered nanomaterials (ENMs), a non-vertebrate approach is desirable in light of the 3Rs principles.

Several studies have shown that *H. azteca* is capable to ingest metal- or metal-oxide-based ENMs present in water, sediment, or diet.

In this study, we evaluated the suitability of the HYBIT for polymer-based ENMs using self-synthesized 14C-labeled polystyrene nanoparticles (14C-nPS).

Besides aqueous exposures, we conducted a dietary exposure test using ENM-enriched artificial food to derive BMF data. Additional experiments assessed potential concentration-dependent uptake and the influence of amphipod sex on ENM accumulation.

Samples collected over 7–21 days were analyzed via liquid scintillation counting to quantify body burden and corresponding water or food concentrations. Using 14C-labeled nanoparticles enables straightforward detection and quantification of the ENMs based on their radioactivity, with minimal to no interference from the sample matrix.

Our results demonstrate that the applied methods are suitable for assessing the bioaccumulation potential of polymer-based ENMs following aqueous and dietary exposure. The resulting BCF and BMF values suggest an overall low bioaccumulation potential of the tested polystyrene ENMs.

3.01.P-Mo151 The Influence of Metal–Organic Mixtures on Chemical Speciation and Bioaccumulation in a Microcosm Study.

Apurva Deepak Bhatkhande¹, Dirk de Leijer¹, Emma Yenney², Marius Schmitt³, Ronny Blust¹, Nina Cedergreen⁴, Karel De Schampelaere⁵ and Raewyn M. Town¹, (1)University of Antwerp, Belgium,

(2)University of Copenhagen, Denmark, (3)GhEnToxLab, Ghent University, Belgium, (4)No Affiliation, Denmark, (5)Society for Environmental Toxicology and Chemistry (SETAC), Belgium

Freshwater ecosystems face growing pressure from complex mixtures of contaminants driven by agricultural practices, urbanization, and shifting climatic regimes. Copper-based products and strobilurin fungicides, such as azoxystrobin, are among the most frequently detected substances in surface waters, often occurring together. Yet, their combined influence on aquatic communities remains poorly understood, as most toxicological information derives from single-stressor laboratory studies on single biological species. This limits understanding of key drivers of ecological change in environments where multiple contaminants interact. The challenge is heightened by the dynamic behavior of copper, whose speciation depends on dissolved organic carbon concentration, pH, ionic strength and other organic compounds in the system. These fluctuations alter bioavailable fractions. Diffusive Gradients in Thin Films (DGT) devices, which provide time-integrated estimates of the chemical species which are (partially) labile on the DGT timescale, offer valuable insight into potential metal bioavailability under variable chemical conditions.

To address these complexities, a three-month microcosm experiment was conducted to explore the combined effects of copper and azoxystrobin on a simplified freshwater ecosystem. Throughout the exposure period, temperature, pH, conductivity, dissolved oxygen, and dissolved organic carbon were monitored alongside repeated DGT deployments to characterize DGT-labile copper in parallel with conventional water sampling. A variety of organisms were collected at multiple intervals during exposure and at the final exposure stage to quantify internal copper concentrations. These samples are currently undergoing processing, and the resulting data will clarify how chemical speciation and DGT-labile metal fractions relate to internal accumulation. This study aims to generate an integrated understanding of how metal-organic mixtures behave under ecologically relevant conditions by linking water chemistry dynamics, chemical speciation processes, and organismal accumulation. The resulting dataset is expected to provide insights into the factors governing the bioavailability and biouptake of contaminants in a mixed exposure scenario in freshwater systems, and to support future toxicokinetic evaluations and ecological risk assessments under increasingly complex pollution scenarios.

3.01.P-Mo153 Ecological Determinants of Mercury Accumulation in South Atlantic Marine Tetrapods

Guilherme Lima¹, Jorge Perez², Vladimir Costa², Marta Turull³, Sergi Diez⁴ and Amauri Menegario²,
(1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Brazil, (2)São Paulo State University, Brazil, (3)Institute of Environmental Assessment and Water Research, IDAEA-CSIC, Barcelona, Spain, Spain, (4)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain

Mercury is a persistent toxic metal that biomagnifies in marine food webs, creating risks for wildlife. Understanding how ecological traits of organisms shape mercury bioaccumulation patterns across different groups of marine tetrapods is essential for improving species risk assessment and management planning of their habitats. Here, we investigate the patterns of mercury bioaccumulation in sea turtles, seabirds and cetaceans and their association with organisms' trophic position in the South Atlantic Brazil.

We analyzed mercury concentration in the liver tissue of 151 stranded individuals from 18 species along the Brazilian coast and assessed $\delta^{15}\text{N}$, as a proxy for trophic position, in 93 of those individuals. We evaluated whether mercury concentration increases with trophic level and whether species with similar feeding strategies show comparable bioaccumulation patterns despite taxonomic differences.

Mercury levels varied widely across species and reflected their ecological habits. Sea turtles showed the lowest concentrations, consistent with their low trophic positions. Seabirds displayed a strong ecological variation, with pelagic predators presenting the highest values. Cetaceans showed the broadest variation, from low levels in coastal dolphins to extremely elevated concentrations in deep-diving oceanic species.

Grouping species by similar biological characteristics revealed a clear bioaccumulation pattern: oceanic cetaceans presented the highest values, followed by pelagic seabirds, non-flying seabirds, coastal cetaceans, estuarine birds, turtles and migratory cetaceans. This pattern highlights

intensified biomagnification in oceanic food webs and more homogeneous exposure among coastal species feeding on similar prey. Mercury was positively correlated with $\delta^{15}\text{N}$, confirming trophic-driven accumulation across taxa. Isotopic niches showed clear segregation among groups and broad trophic diversity in cetaceans.

Overall, mercury exposure in marine tetrapods is primarily determined by trophic position, foraging strategy and habitat use. Ecologically similar species accumulated comparable mercury levels regardless of taxonomy, underscoring the importance of multispecies ecological approaches for improving contaminant monitoring in marine ecosystems.

3.01.P-Mo154 Use of Fish In Vitro Clearance Assays for Bioaccumulation Assessment

Jane Caley¹, Romanas Cesnaitis², Maike Habekost³, Doris Hirmann¹, Anu Maarit Kapanen¹, Verena Kosfeld⁴, Heike Laue⁵, Leslie J Saunders⁶, Kristin Schirmer⁷, Gabriele Treu⁸, Waqar Ashraf¹ and Eric Verbruggen⁹, (1)European Chemicals Agency (ECHA), Finland, (2)Telakkakatu 6, European Chemicals Agency (ECHA), Finland, (3)BASF, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Givaudan, Switzerland, (6)Department of Physical and Environmental Sciences, European Fuel Manufacturers Association Division Concawe, Brussel, Belgium, (7)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (8)German Environment Agency (UBA), Germany, (9)RIVM, Netherlands

ECHA aims to reduce both the use of vertebrate animals and the number of animals required for chemical testing. For bioaccumulation assessments, this could be supported by using fish in vitro intrinsic clearance assays (OECD Test Guideline 319A/B) as an alternative to in vivo bioaccumulation studies (OECD Test Guideline 305). To evaluate this approach for regulatory use, ECHA established an ad hoc expert working group to provide scientific advice on the use of in vitro rainbow trout clearance assays, in vitro-in vivo extrapolation (IVIVE) and bioconcentration factor (BCF) models in bioaccumulation assessment. This advice will be based on an extensive comparison of empirical data and will consider several IVIVE/BCF prediction methods.

As a first step, good quality fish BCF and in vitro clearance assay data were collected for ~100 chemicals spanning a broad chemical space (neutral and ionizable organic chemicals; log KOW < 3 - 8). The data were evaluated against relevant OECD test guideline validity criteria to ensure that they are sufficiently reliable for further analysis.

The latest IVIVE/BCF models from the scientific literature were reviewed, their key input parameters summarized, and similarities/differences between the models assessed. A sensitivity analysis was conducted to assess model performance under different biotransformation scenarios (slow, moderate, fast) at log KOW values between 2 and 10. A subset of the reviewed IVIVE/BCF models will be used to predict BCFs from the fish in vitro clearance rate for the collected chemicals.

Finally, for each chemical, predicted BCFs will be compared with the corresponding experimental in vivo fish BCFs to examine data trends and identify any outliers. This comparison will help clarify the relationship between IVIVE-based predictions and measured in vivo outcomes. Based on this evaluation, we will recommend how the reporting of fish in vitro assay results can be improved and how these data can be integrated into regulatory bioaccumulation assessments.

3.01.P-Mo155 Applicability of fish cell lines for the bioaccumulation and toxicity assessment of structurally diverse zwitterionic surfactants

Marco Enrique Franco¹, Aureline Colin-Madan², Juliane Hollender³ and Kristin Schirmer¹, (1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Zwitterionic surfactants, widely used in consumer products and frequently detected in aquatic environments, exemplify the difficulties to conduct environmental risk assessment of chemicals with complex physicochemical properties (e.g. ionization, low solubility, and high hydrophobicity). To address the lack of available data regarding their environmental risks and improve the mechanistic understanding of surfactant-organism interactions, we evaluated the applicability of animal-free testing methods, namely the rainbow trout (*Oncorhynchus mykiss*) cell lines RTgill-W1 and RTL-W1, to characterize the acute toxicity and/or bioaccumulation of structurally diverse zwitterionic surfactants differing in carbon-chain length and functional groups. Cell viability assays, following the OECD 249 test guideline, revealed that amine oxide (AO) congeners

with 10-, 12-, and 14-carbon chains exhibited increasing toxicity with chain length (EC50 values: 134, 7, and 2 mg L⁻¹, respectively), though notable bioaccumulation was only observed for the AO-C12 compound (BCF_RTgill-W1: 52, BCF_RTL-W1: 41). In contrast, AO-C16 and AO-C18 congeners showed no further increase in toxicity nor bioaccumulation, suggesting limited bioavailability, likely due to their complex behavior. Furthermore, surfactants containing additional amide and carboxylate functionalities, including cocamidopropyl betaine and (Lauryldimethylammonio)acetate, displayed the highest cell-based bioaccumulation among all tested compounds: BCF_RTgill-W1: 303, BCF_RTL-W1: 254 and BCF_RTgill-W1: 77, BCF_RTL-W1: 133, respectively. Despite these findings, all tested surfactants remained below regulatory bioaccumulation thresholds under REACH. Collectively, these results reinforce the relevance of fish cell line-based assays as robust, animal-free tools to support the environmental risk assessment of structurally diverse zwitterionic surfactants.

Disclaimer/Disclosure:

This research is partly funded by the Swiss Federal Office for the Environment (FOEN), project 17.0101.PJ / 29BCFB472.

3.01.P-Mo156 Microcystin Accumulation and Progressive Liver Damage in Fish Under Repeated Exposure Conditions

Natalia Badagian¹, Maite Letamendia², Alejandro Peretta² and Beatriz Brena¹, (1)Biochemistry, DEPBIO, University of the Republic, Uruguay, (2)Pathology of Aquatic Organisms, Faculty of Veterinary, University of the Republic, Uruguay

Fish from eutrophic environments are exposed to recurrent cyanobacterial blooms, yet the biological processes underlying microcystins (MCs) accumulation under repeated exposures remain poorly characterized. The understanding of these processes is essential for improving toxicokinetic–toxicodynamic and ecological models to predict toxin burdens in natural environments. To address this gap, three experiments were conducted using *Microcystis* blooms containing MC-LR as a dominant congener, in triplicate, using 15 individuals (*Australoheros facetus*) per 20 L aquarium. A first experiment examined the kinetics of accumulation and clearance after a single 24-h exposure to a high MCs concentration (600 µg/L), followed by a 7-day depuration period. Two additional experiments simulated recurrent bloom events through repeated exposures at medium (60 µg/L) and high (600 µg/L) MCs concentrations. Blooms were added on day 1 and reintroduced on day 10 after MC levels in water declined to <1–5%. Fish were sampled on day 10 for histopathology and on day 18 for histopathology and MCs content. Analysis of MCs and its detoxification conjugates (n=6 per condition) was performed using our previously developed quantitative MALDI-ToF method with nanobody-based pre-concentration. After the single exposure, fish reached their highest MC accumulation at the end of intoxication, and ~95% of the toxin was cleared by day 7, coinciding with partial recovery of early liver damage. In contrast, repeated exposures produced progressive MC-typical hepatic lesions, more pronounced at 600 µg/L. By day 18, median MC concentrations were 15.8 ± 5.5 ng/g at 60 µg/L and 19.2 ± 21.0 ng/g at 600 µg/L, both exceeding the peak value observed after the single 1-day exposure (5.2 ± 6.5 ng/g). Because small group sizes and high variability limit formal comparisons, only descriptive statistics are presented in this preliminary report. Overall, these results suggest that factors associated with repeated exposure—including incomplete hepatic recovery—may reduce detoxification efficiency and influence toxin retention more strongly than exposure concentration alone. While this mechanism is provisional, it offers a biologically plausible interpretation that may guide more targeted experimental designs and improve ecological models of toxin dynamics in eutrophic fish populations.

3.01.P-Mo157 Feasibility Assay for OECD 305 Aqueous Exposure Test

Emma Dodd and Robert Unsworth, Labcorp, United Kingdom

The purpose of the OECD 305 guideline test is to assess the bioaccumulation potential of a test item via aqueous exposure or through a dietary route in fish. The tests are usually conducted with radiolabeled test items and optimum test concentrations are determined from preliminary testing. The use of radiolabeled test item allows assessment of water or feed concentrations to be monitored, accumulation and elimination of the test item to be followed and assess if metabolism of the test item has occurred which may require identification and quantification.

The preferred testing method is an aqueous exposure route and the choice of test is based on many factors including: solubility in water, n-octanol water partition coefficient (KOW), stability in water which is considered along with the regulatory requirements. The aqueous exposure route is most suited to stable organic test items with log KOW values generally between 1.5 and 6.0. Specific guidance cannot be provided on the method to choose for a test item due to other factors that may influence the method applicability. Although it is considered for substances with a log KOW above 5 and a water solubility below ~0.01 – 0.1 mg/L, an aqueous exposure route may be difficult to conduct.

To aid in the reasoning to conduct a dietary study where the test item characteristics may indicate an aqueous study should be conducted and has been requested by a regulatory authority, a feasibility assay has been developed. The test has been established to provide evidence that a stable, measurable dissolved concentration of the test item in water cannot be achieved.

The experiments designed for the feasibility assay use small tests which are devised to establish the solubility and stability of the test item in a dose solution and a small portion of test water at a nominal exposure concentration. The outcome of these tests supports whether a stable, measurable dissolved concentration of the test item in water can or cannot be achieved and helps define which testing method should be used for the OECD 305 study.

The conduct of the feasibility assay has shown to aid in the submission process of the test item for the client as weight of scientific evidence for justification to perform a dietary exposure test.

The poster will present an experimental design with the two different possible outcomes that can be obtained: aqueous exposure route being viable or a dietary exposure route.

3.01.P-Mo158 Do polycyclic aromatic hydrocarbons exhibit oral bioaccumulation in aquatic organisms? – Evaluations using fish and shellfish

Seiichi Uno, Ryo Takeshita, Tomohiro Fukamachi, Masatoshi Yamasaki and Emiko Kokushi, Kagoshima University, Japan

Aquatic organisms can absorb chemicals from the various tissues, with the primary routes are considered to be the uptake of waterborne chemicals through the respiration via the gill, and ingestion of ones contained in the diet during feeding. In the previous studies, there has been much information for accumulations of chemicals absorbed through the respiration and, as a result, bioconcentration factors (BCFs) estimated from the exposure examinations are frequently shown.

We previously conducted oral exposure to several polycyclic aromatic hydrocarbons (PAHs) in a few marine fish species. While the internal transfer of PAHs was confirmed, accumulation relative to the concentrations in the feed was not observed. Since then, we have examined multiple times whether PAHs could undergo oral bioaccumulation in fish, but we have not been able to confirm it.

In the present study, we used common carp (*Cyprinus carpio*), which is widely employed in chemical substance assessments in Japan, to newly perform oral bioaccumulation tests on several PAHs and verify whether accumulation can be detected. In parallel, we also conducted water-exposure/gill-uptake tests and compared the results.

The target PAHs, with logKow values ranging from 4.5 to 7.1, were dibenzothiophene, phenanthrene, methylphenanthrene, anthracene, pyrene, benz(a)anthracene, chrysene, benzo(a)pyrene, benzo(k)fluoranthene, and dibenz(a,h)anthracene. Each compound was added to the feed to achieve concentrations of 1 mg/g and 10 mg/g, and exposure was continued for 28 days. As a result, transfer from feed to tissues was observed for some PAHs, such as phenanthrene and pyrene; however, no accumulation with biomagnification factors exceeding 1 was observed. In contrast, when water exposure was conducted, a certain degree of bioconcentration was observed, with bioconcentration factors reaching several tens to several hundred. These results suggest that PAH accumulation in fish depends predominantly on gill-mediated bioconcentration, and the contribution of oral bioaccumulation is considered to be extremely low.

In this study, in addition to the results of the verification using carp, we conducted oral bioaccumulation tests of PAHs in the gastropod *Batillaria multiformis* (the estuarine snail) and report the findings on their accumulation levels as well.

3.01.P-Mo159 Bioaccumulation and Depuration of Lithium in Juvenile Trout (*Oncorhynchus mykiss*): A Comparative Study of Waterborne and Dietary Exposure Pathways

Shuting Tang¹, Marc Metian¹, Nathalie VIGER², Francois OBERHAENSLI¹, Khalil SDIRI¹, Sabine AZEMARD¹, Vanessa HATJE¹, Laurine PAYANT³ and Arbia JOUINI³, (1)IAEA Marine Environment Laboratories, Department of Nuclear Sciences and Applications, International Atomic Energy Agency, Monaco, (2)Laboratoire d'Océanographie de Villefranche (LOV), Monaco, (3)Laboratoire d'Océanographie de Villefranche (LOV), France

Lithium (Li), an emerging contaminant, has attracted increasing attention due to its high application in battery production, pharmaceuticals, among others, combined its potential toxicity in aquatic systems. To simulate environmentally relevant exposure routes, we conducted three experiments using juvenile trout (*Oncorhynchus mykiss*) as a model organism: (1) waterborne exposure, (2) dietary exposure, and (3) depuration following waterborne exposure. Time-resolved tissue sampling and tissue Li was used to evaluate Li bioaccumulation and depuration dynamics, and Li isotope ratios will also be investigated.

In the waterborne exposure experiment, four Li concentrations (control, 0.1, 1.0, and 10 mg/L) were tested, with three replicates per treatment. Fish were exposed for 4 days and samples were collected at 0.25, 1, 2, and 4 days. At 10 mg/L acute toxic effects were observed within 24 hours, with 27% mortality recorded by 48 hours, leading to early termination of this experiment. In the remaining treatments, Li accumulation was time dependent. By day 4, tissue Li concentrations reached 1.74 ± 0.50 and $42.1 \pm 12.2 \mu\text{g/g}_{\text{dw}}$ in the 0.1 and 1.0 mg/L treatments, respectively. Higher exposure concentrations resulted in faster accumulation rates and increased concentration factors, indicating nonlinear uptake behavior.

In the dietary exposure experiment, fish were fed a single dose (3% of body weight) of food pellets containing 5.8 $\mu\text{g/kg}$ Li, with sampling at 0, 3, 6, 24, and 48 hours ($n = 3$). Li was detectable in fish between 3–6 hours post-feeding but returned to control concentration levels after 24 hours, indicating limited Li body retention and rapid elimination.

In the depuration experiment, fish pre-exposed to 0.1 $\mu\text{g/kg}$ Li for 48 hours were transferred to an open clean-water system and sampled at 0, 3, 6, 24, and 48 hours ($n = 3$). Li concentrations in tissues declined rapidly and returned to control levels within 24 hours, mirroring the rapid elimination observed in the dietary exposure experiment.

This study highlights the route-dependent bioaccumulation and elimination dynamics of lithium in juvenile trout (*Oncorhynchus mykiss*) and provides experimental evidence to inform mechanistic insights and risk assessment related to Li contamination in aquatic environment.

3.01.P-Mo160 Species-specific Accumulation and Body Distribution of Organophosphate Esters and Their Metabolites in Marine Mammals along the Korean Coast

Hyo-Bang Moon and **Ji-Hyeon Lee**, Department of Marine Science and Convergence Technology, College of Engineering, Hanyang University, Ansan 15588, Republic of Korea, Korea, Republic of

Organophosphate esters (OPEs) are widely used as flame retardants and plasticizers following restrictions on brominated flame retardants. OPEs can be transformed into organophosphate diesters (di-OPEs) and hydroxylated OPEs (OH-OPEs), some of which exhibit higher toxicity or bioaccumulation potential than their parent compounds. Information on environmental and biological occurrences of OPE metabolites (mOPEs), particularly OH-OPEs, remains limited.

Marine mammals serve as sentinel species for evaluating marine ecosystem health, yet only a few studies have investigated OPEs and mOPEs in their tissues, and tissue-specific accumulation and metabolic patterns remain poorly understood.

In this study, muscle, liver, kidney, heart, lung, intestine, stomach, blubber, melon, and brain were collected from eight cetaceans and two pinnipeds incidentally captured or stranded along the Korean coast between 2008 and 2019. Eighteen OPEs, ten di-OPEs, and six OH-OPEs were quantified using ultrahigh-performance liquid chromatography coupled with triple quadrupole mass spectrometry.

Among parent OPEs, alkyl-OPEs such as tris(2-butoxyethyl) phosphate (TBOEP), tri-n-butyl phosphate (TnBP), and triethyl phosphate (TEP) dominated across tissues. For mOPEs, OH-OPEs, including hydroxyphenyl phenyl hydrogen phosphate (OH-TPHP) and hydroxyethyl bis(2-butoxyethyl) phosphate

(BBOEHEP) were frequently detected at higher levels than di-OPEs, underscoring the need to examine OH-OPEs in environmental and biological monitoring. Both OPEs and mOPEs, such as TBOEP, TnBP, TEP, diethyl phosphate (DEP), and OH-TPHP, were detected in brain tissues, suggesting that not only OPEs but also metabolites may cross the blood–brain barrier.

Across tissues, metabolites of TBOEP, TnBP, triphenyl phosphate (TPHP), and tris(2-ethylhexyl) phosphate (TEHP) showed higher proportions than their parent compounds in long-term storage tissues such as muscle and blubber, indicating bioaccumulation potential of mOPEs. Some species, particularly fin whales, exhibited higher proportions of parent OPEs relative to metabolites, implying possible interspecies differences in metabolic capacity.

The widespread detection of mOPEs, especially OH-OPEs, in diverse organs highlights their systemic transport and bioaccumulation potential in marine mammals. These findings emphasize the necessity of incorporating mOPEs into future monitoring frameworks and ecological risk assessments.

3.01.P-Mo161 Dioxins in Czech Rivers: Long-Term Monitoring of Fish and Sediments

Hedvika Roztočilová and Markéta Ackermanová, Czech Hydrometeorological Institute, Czech Republic

Dioxins are persistent organic pollutants characterized by high toxicity, hydrophobicity and a tendency to accumulate in biotic and abiotic environmental compartments. To evaluate the occurrence of polychlorinated dibenzo-p-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs) and dioxin-like polychlorinated biphenyls (DL-PCBs), we analyzed their levels and distribution in fish and sediments. In total, more than 250 samples of common chub and sediment were collected from major river sampling sites across the Czech Republic during 2014–2025. Results indicated different distribution patterns between the matrices. Throughout the monitoring period, DL-PCBs in fish were above the limit of quantification (LOQ) in 100% of the samples, whereas their occurrence in sediments was generally lower. Conversely, PCDDs and PCDFs were more frequently detected in sediment samples than in fish. On average, PCB 126 was the predominant congener in fish samples (80% of total TEQ), while the concentrations of individual compounds in sediments were more site-dependent. Based on these findings, monitoring of various matrices is needed to comprehensively understand contaminant fate and to appropriately assess aquatic ecosystem contamination.

3.01.P-Mo162 Bioaccumulation, Depletion and Maternal Transfer of Antibiotics in *Eisenia andrei*

Patricia Alexandre Evangelista¹, Felipe Machado de Oliveira Lourenço², Ítallo Cristian da Silva de Oliveira², Rodrigo Floriano Pimpinato² and Valdemar Luiz Tornisielo², (1)University of São Paulo, Brazil, (2)University of São Paulo, Brazil

The continuous use of antibiotics in agriculture can affect organisms that are fundamental to maintaining soil health. This study assessed the bioaccumulation, depletion, and reproductive effects of tetracycline (TTC) and sulfamethazine (SMZ) in *Eisenia andrei*, comparing their kinetic behaviour and reproductive toxicity potential under environmentally realistic conditions (TTC; 6.4 ng g⁻¹ e SMZ; 20.4 ng g⁻¹). The assays followed OECD Guideline No. 317, with 21 days of exposure and 21 days of depletion in clean soil, using radiolabelled compounds with quantification performed by liquid scintillation counting.

Both antibiotics exhibited low bioaccumulation (<1% of the applied dose). TTC showed faster elimination ($K_e = 1.3 \times 10^{-1} \text{ day}^{-1}$; $t_{1/2} = 5.3$ days), whereas SMZ exhibited slower elimination ($K_e = 8.2 \times 10^{-2} \text{ day}^{-1}$; $t_{1/2} = 8.5$ days). Regarding reproductive effects, TTC did not differ from the control ($p > 0.97$), while SMZ significantly reduced cocoon production during exposure (ANOVA: $F_{2,9} = 11.59$; $p = 0.0032$; estimate = -11.0; $p = 0.004$) and depletion (ANOVA: $F_{2,9} = 17.14$; $p = 0.00085$; estimate = -13.75; $p = 0.001$). Mean values decreased from 58.8 ± 2.6 (control) to 47.8 ± 2.5 and subsequently to 43.2 ± 1.3 cocoons in the SMZ group.

During bioaccumulation, both antibiotics were transferred to the cocoons (ANOVA: $F_{2,9} = 232.2$; $p < 0.0001$). After depletion, only SMZ retained detectable radioactivity (102 ± 2.4 DPM). This value is close to the method's background level (~100 DPM), yet still above what would be expected for complete elimination, indicating persistence in maternal tissue or delayed release. The control and TTC returned exactly to baseline (all values = 0). The differences remained highly significant (ANOVA: $F_{2,9} = 6936$; $p < 0.0001$), with an effect observed only for SMZ (Dunnett $p < 1 \times 10^{-10}$).

The results show that SMZ exerts substantial and persistent reproductive effects, with a tendency for transfer to cocoons and a potential transgenerational risk, even after the depletion phase. TTC showed rapid clearance and no reproductive effects. These findings reinforce that antibiotics from different classes pose distinct ecological

risks and highlight the need to integrate reproductive endpoints and internal kinetic parameters into environmental risk assessments for agricultural soils.

3.01.P-Mo163 Evaluation of a Non-Vertebrate Approach for the Assessment of Terrestrial Bioaccumulation of 14C-labeled Nanoparticles using Porcellio scaber

Lina Meinerzhagen¹, Boris Meisterjahn¹, Nicola Schroeder¹, Joana Bräutigam¹, Ralf Kaegi², Christian Schlechtriem³ and Sebastian Kuehr¹, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Process Engineering, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Bioaccumulation & Animal Metabolism, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Identifying compounds that bioaccumulate in organisms and biomagnify in food webs is a central aspect of PBT assessment. Bioaccumulation potential is usually expressed as a bioconcentration factor (BCF), determined in flow-through fish studies following OECD TG 305.

For substances that cannot be maintained under stable aqueous exposure conditions, TG 305 also provides a dietary exposure approach to determine biomagnification factors (BMFs). However, this fish test was originally developed for soluble, non-particulate substances. Since 2025, an OECD Guidance Document (No. 406) has been available offering recommendations on how to conduct biomagnification tests with engineered nanomaterials (ENMs). Nevertheless, appropriate non-vertebrate approaches are still missing.

While the *Hyalella azteca* bioconcentration test is currently being evaluated for its suitability as a non-vertebrate alternative for aquatic bioconcentration and biomagnification testing of ENMs, there is still a notable lack of terrestrial test systems that can generate regulatory-relevant endpoints - such as BMFs - with clearly defined uptake routes. For polymer-based nanomaterials (P-NMs) further challenges arise. For instance, conventional analytical approaches often risk artefacts or limitations, such as fluorescence dye leakage from the polymer matrix or altered material properties caused by metal doping for detection and quantification, which may change the physical behavior and environmental fate of P-NMs.

As an initial attempt to evaluate a terrestrial biomagnification test (in soil-free systems) with the isopod *Porcellio scaber* we conducted a feeding experiment with uptake and subsequent depuration phase, to derive kinetic data on P-NM uptake and potential biomagnification.

Radioanalytical methods using synthesized 14C-labeled P-NMs which were embedded in the experimental diet were applied. This allowed a straightforward, sensitive, and artefact-free quantification of dietary exposure, body and feces burdens, and compartment-specific distribution in the isopods.

3.01.P-Mo164 Pesticide Analysis of Water Sources via Solid Phase Microextraction and Ambient Mass Spectrometry

Dara Lorianne Pierre¹, David Douce², Monica Felipe-Sotelo¹ and Patrick Sears¹, (1)University of Surrey, United Kingdom, (2)Waters Corporation, United Kingdom

The widespread use of synthetic pesticides has resulted in environmental accumulation with residues and transformation products being frequently detected in surface and seawater. These contaminants pose a severe risk to the ecosystem and human health; yet current monitoring approaches rely on labour-intensive sampling, followed by off-site laboratory sample preparation and analysis, which limits throughput.

This investigation aims to develop a sensitive, quick, and sustainable method for detecting pesticide contaminants in various water sources using solid-phase microextraction (SPME) coupled with atmospheric solids analysis probe-mass spectrometry (ASAP-MS). To manage the challenges of low-level detection limits and potential matrix contamination, SPME utilises a pre-concentration and clean-up step, enabling efficient analyte transfer from the SPME fibre to the MS inlet while minimising solvent use.

The SPME method involves fibre conditioning, analyte extraction from water samples, and fibre washing using minute reagent volumes. This is followed by direct desorption into the ASAP-MS sample inlet. Mass Spectrometric analysis was carried out in scan and single ion monitoring (SIM) modes under optimised instrument conditions.

The method achieved limits of detection (LoD) in the parts-per-billion (ppb) range, with 11 of the 14 pesticides being successfully detected in either positive mode, negative mode or both. The results suggest that SPME-ASAP-MS provides a fast, sensitive and sustainable technique for pesticide screening in water, particularly seawater, which contains a wide variety of salts, with reduced sample preparation time and reagent consumption compared to conventional workflows. This methodology offers an updated, sustainable approach to environmental monitoring and proposes a field-deployable option for pesticide contamination monitoring in rivers and coastal systems.

3.01.P-Mo165 METABOLIC ALTERATIONS IN FISH EXPOSED TO ACID RESIN CHARACTERIZED BY METABOLOMIC ANALYSIS AND BIOCHEMICAL ANALYSES

Carlos H.L. Soares and Ivana Eunice Baptista, Federal University of Santa Catarina, CCB, Florianopolis, Brazil

Acid resins are diterpenoids produced by conifers, such as Pinus. These resins are widely released into soil in areas used for Pinus plantations. Pulp and paper industries, when producing cellulosic pulps, generate large quantities of effluents as byproducts, which may contain, on average, 50 to 250 µg/L of resins. Both resins released into soils and those produced in effluents can be carried to water bodies, contaminating them. In this study, the possible deleterious effects of abietic acid, one of the acid resins, were evaluated in fish (*Oreochromis niloticus*), under laboratory conditions, exposed to concentrations in the range of 100 to 150 µg/L. Fish were kept in groups of 10 individuals in 200L tanks and fed with commercial feed. Blood, liver, gonad, and gill samples were collected after a 7-day exposure period, with daily water renewal in the tanks. The obtained blood plasma was analyzed regarding AST, ALT, alkaline phosphatase, total cholesterol, glucose, albumin, and total proteins. Gonads, liver, and gills were homogenized, extracted with solvent (MTBE), and analyzed by GC/MS-TOF, in addition to the analysis of total carbohydrates and lipids. The obtained results indicated significant alterations in the total concentrations of lipids and carbohydrates in the gonads and liver, as well as alterations in the lipid (fatty acids and cholesterol) and carbohydrate profiles analyzed by GC/MS. The level of plasma enzymes was considerably altered, with a significant increase in the activities of the enzymes ALT, AST, and alkaline phosphatase. A significant reduction in plasma glucose and an increase in cholesterol was observed. Total proteins and albumin showed no modifications. Abietic acid proved to be toxic to the analyzed fish, promoting significant metabolic alterations.

3.02.A Advances in Exposure Modelling: Closing the Gap between Scientific Innovation and Regulatory Relevance

3.02.A.T-01 Predicting Chemical Co-Exposure in Europe: Development of a Continental Fate Model

Karel Vlaeminck¹, Frederik Verdonck¹, Jos van Gils², Devanshi Pathak², Jannicke Moe³, Sophie Mentzel³, Samantha Eslava Martins³ and Karel Viaene¹, (1)ARCHE Consulting, Belgium, (2)Deltares, Netherlands, (3)Norwegian Institute for Water Research, Norway

The ENCORE project develops a probabilistic modelling framework to identify priority chemicals contributing to co-exposure risk across Europe. Central to this effort is the ENCORE fate model, a continental-scale system that estimates environmental concentrations for a broad range of substances, including pesticides, pharmaceuticals, REACH chemicals, and legacy pollutants. The model integrates harmonised input data, advanced emission modelling, hydrological connectivity, and Monte Carlo simulation to account for uncertainty.

The European landscape is discretised into ~23 000 hydrologically connected sub-catchments. Chemical concentrations in surface waters are predicted in two steps. First, emissions are simulated based on substance-specific sources and pathways. Pesticides are modelled via agricultural applications on crops, pharmaceuticals through household consumption and wastewater release, and industrial chemicals via manufacturing and downstream uses. These pathways define the mass of each substance entering the aquatic environment per sub-catchment. Second, the water quality module propagates emissions through the river network while accounting for dilution, partitioning, degradation, and downstream transport.

Input data include application rates, sales and consumption records, and tonnage information for European countries, as well as physicochemical parameters required to simulate environmental fate. Uncertainty in emissions and fate parameters is addressed through Monte Carlo simulations. Preliminary findings show that emissions and source contributions dominate the variability in predicted environmental concentrations, whereas fate parameters exert comparatively less influence.

Model outputs reproduce realistic spatial trends across Europe. For example, predicted diuron concentrations are elevated along major river systems such as the Rhine, Danube and Po, reflecting agricultural use and downstream transport. In contrast, concentrations remain low in Scandinavia and high-altitude Alpine and Balkan regions due to limited agricultural inputs and strong dilution effects.

The ENCORE fate model provides a robust framework for predicting chemical concentration distributions and co-exposure patterns across European freshwater systems. Ongoing work focuses on refining uncertainty analyses and extending the framework to probabilistic mixture risk assessment, including the influence of legacy chemicals and variability in hazard data.

Disclaimer/Disclosure:

The ENCORE project is sponsored by the European Chemical Industry Council (CEFIC) as part of the Long Range Initiative (LRI) under project ECO-66 “Next generation risk assessment methods supporting the identification of environmental co-exposures of potential concern”.

3.02.A.T-02 Spatially Referenced Environmental Exposure Model for Down-the-drain Substance Emissions Across European Rivers

Susan A Csizsar¹, Chiara Maria Vitale², Raghu Vamshi³, Kyle Roush⁴, Brenna Kent⁵, Ryan Heisler⁶, Heather Summers⁷, Emily EA Burns⁸, Iain Davies⁹ and Darius Stanton¹⁰, (1)Procter & Gamble, Mason, United States, (2)Procter & Gamble, Belgium, (3)Corteva Agriscience, (4)Procter & Gamble, United States, (5)Waterborne Environmental Inc., (6)International Collaboration on Cosmetics Safety (ICCS), United States, (7)Integral Consulting Inc., United States, (8)Personal Care Products Council (PCPC), United States, (9)Science, Personal Care Products Council (PCPC), United States, (10)American Cleaning Institute (ACI), United States

A key aspect of chemical environmental safety assessment is understanding the environmental fate, transport, and exposure of a chemical. For ingredients used in household products that go down-the-drain, exposure assessment focuses on receiving waters from municipal waste water treatment plants. Traditionally, exposure assessment frameworks represent the environment as a single area using a deterministic approach and does not account for the spatial variability across a given country or region. To address this gap, we have developed a global framework based on the iSTREEM spatial modeling framework, to incorporate spatial variability in key determinants of down-the-drain substance environmental exposures. In this presentation, we focus on the expansion of the model to European rivers including the 27 EU member states, Norway, Switzerland, and the United Kingdom. Model inputs combine European Union data on wastewater-treatment plants, their locations and infrastructure, with global spatial datasets on population, river discharge, and routing. The model outputs concentration distributions that reflect geographic variation in these parameters while incorporating river connectivity, chemical movement between rivers, and in-stream decay. Chemical-specific inputs comprise wastewater treatment removals, in-stream decay rates, and emission estimates.

Four case-study chemicals that are commonly used in consumer products with down-the-drain exposure pathways were used to demonstrate the approach and evaluate model predictions: linear alkylbenzene sulfonates (LAS) and alkyl sulfates (AS) as surfactants used in products such as laundry detergents, and oxybenzone and octinoxate as UV-filter ingredients used in personal care products. Monitoring data were collected from several sources including European monitoring databases and the literature and compared to modelled concentrations. The results show that modelled concentrations are both predictive and conservative, with the 90th percentile of modelled values aligning with observed concentrations within a factor of two to eight across the four substances. The study demonstrates how the model can be used in prospective safety assessments by providing a tool to aid in understanding of chemical concentrations accounting for spatial variability in key aquatic exposure parameters.

3.02.A.T-03 Bridging Innovation and Regulation: High-Resolution Spatial Mapping of Sewage Connectivity for Refined Exposure Modelling

Juliet Hodges¹, Baile Xu², Jin Li², Simran Sandhu², Bing Zhang³ and Lei Wang³, (1)Safety & Environmental Assurance Centre, Unilever, United Kingdom, (2)Unilever, United Kingdom, (3)NIES, China (Mainland)

Chemicals from home and personal care products often enter aquatic environments via wastewater. Sewage treatment plants (STPs) play a critical role in removing these down-the-drain chemicals before their release into the aquatic environment. The connectivity rate, which defines the proportion of sewage safely treated, is key for environmental exposure modeling and risk assessment. However, existing estimates of connectivity rely

primarily on large-scale national surveys and coarse regional statistics, resulting in a lack of spatial resolution. In this case study for China, we developed a mathematical model to estimate STP connectivity, including a sewershed-based approach followed by a moving-window method. Based on these methods, we allocated gridded population cells to each STP and summarized connectivity at multiple spatial levels. We optimized the parameters using diverse data sources and subsequently generated a high-resolution (1-km) connectivity dataset. Under the most realistic scenario, the calculated Chinese national average sewage treatment connectivity was 46%, consistent with their regulatory default value (50%). Significant regional differences emerged with STP connectivity ranging from 0.4% to 99.9%. By using the moving window method to smooth the influence of extreme values and highly populated areas, we obtained a more representative and homogeneous national average of 34%. A comprehensive sensitivity uncertainty analysis was conducted ensuring the robustness of the estimates. Our methodology achieved higher-resolution estimates and improved spatial correspondence through its flexible parameter settings and strong correlation with population distribution, enabling more precise spatial analysis. The refined connectivity methodology can be applied across other countries and regions with results enabling higher-tier down-the-drain emission and exposure modeling, offering a robust scientific basis for regulatory policy-making.

3.02.A.T-04 From Pharmaceutical Emission Modelling Approach Toward an Applicable Risk Assessment Plugin in QGIS

Cristiano Guidi¹, Alena Seidenfaden¹, Lauri Äystö², Philip Marzahn¹ and Jens Tränckner¹, (1)University of Rostock, Germany, (2)Finnish Environment Institute (SYKE), Finland

Pharmaceuticals enter the environment primarily via wastewater treatment plants (WWTPs). Assessing environmental risks from pharmaceuticals is challenging due to the limited availability of monitoring data, particularly in rural areas and at small to mid-sized WWTPs. While awareness is increasing and introduced into EU legislation by the European Urban Wastewater Treatment Directive (UWWTD) in January 2025, data gaps persist.

Currently there is no unified risk assessment methodology to be used under the UWWTD. Such a methodology is needed to ensure the comparability of risk assessment results between river basins and countries. Based on established scientific approaches in exposure modelling, a deterministic steady-state-model was developed in an open-source QGIS plugin.

The approach integrates yearly pharmaceutical sales statistics and WWTP monitoring data to estimate active pharmaceutical ingredient (API) loads. Transferred to the river network, predicted environmental concentrations (PECs) were calculated and compared to available monitoring data. Flow was implemented as spatially distributed yearly averages in subcatchments. Dividing PECs by predicted no-effect concentration (PNECs) resulted in risk quotients (RQs) that were then mapped for river sections in catchments. These result maps directly support national and regional authorities in charge of risk assessment. Using this model, decision-makers can directly prioritize WWTPs between 10,000 and 150,000 population equivalents (PE) for quaternary treatment according to UWWTD in their daily-work practice in QGIS. In addition, other feasible mitigation options for smaller WWTPs can be tested *a priori*.

In this study, we tested the plugin in the German Warnow catchment as well as in the Finnish Kyrönjoki catchment. Modelled and monitored API loads were compared for selected APIs, such as Diclofenac. Results showed that PECs aligned well with averages from campaigns conducted in the catchments. To improve model accuracy, estimations of WWTP discharge loads were corrected by monitored data. Finally, the model showed that upgrading the mid-sized WWTPs will have only a limited effect in the rural areas with scattered treatment, especially upstream.

With its high relevance and applicability for regulation, the developed plugin is a user-friendly tool for authorities to close the gap towards regulatory practices: users can identify potential risk areas by integrating available expertise and new monitoring data.

Disclaimer/Disclosure:

The APRIORA project (#C038, index No. PIFC2_041) is funded by the Interreg Baltic Sea Region Programme. Co-founded by the European Union (ERDF), this #MadeWithInterreg project helps to remove pollutants from our waters.

3.02.A.T-05 An LLM-based Toolbox for Automated Text Mining on the Uses of Chemicals

Huadong Xing¹, Anna Shalin², Bianca Stadelmann³, Bernd Nowack¹, Antonia Praetorius⁴ and Zhanyun Wang⁵, (1)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (2)University of

Toronto, Canada, (3)University of Amsterdam (UVA), Netherlands, (4)IBED, University of Amsterdam (UVA), Netherlands, (5)ETH Zurich, Switzerland

The large number of chemicals used globally and the limited availability of structured information on their applications create challenges for exposure estimation, in silico modeling, and chemical safety assessment. Information on how chemicals are used is distributed across scientific literature, regulatory submissions, and technical reports, which makes it difficult to assemble coherent datasets for environmental and human health evaluations.

To address this challenge, we developed an open-access and fully automated toolbox that curates, standardizes, and integrates chemical use information at scale. The workflow applies a two-stage natural language processing framework based on large language models to extract chemical use pairs from unstructured text. The first stage is fine-tuned using low-rank adaptation, which allows the model to identify text segments that contain potential chemical information. The second stage uses a fine-tuned large language model trained with direct preference optimization to improve extraction accuracy for environmentally relevant chemical terminology. The toolbox includes components for named entity recognition, text classification, and relationship extraction. These components identify chemical entities, assign functional use categories, and organize results into structured formats that can be linked with existing datasets.

By applying this toolbox, we aim to develop an open access resource that compiles and standardizes chemical and material use data. The resulting dataset is intended to support chemical assessment, increase transparency, and provide a foundational resource for regulatory and research activities. Future work will focus on improving model performance, expanding data sources, and refining ontological alignment. These developments aim to increase the reliability and applicability of extracted information and to facilitate broader use of the toolbox within chemical safety and data harmonisation initiatives.

3.02.B Advances in Exposure Modelling: Closing the Gap between Scientific Innovation and Regulatory Relevance

3.02.B.T-01 Modeling Environmental Plastic Emissions: A Particle-based Approach to Dynamic Probabilistic Material Flow Analysis

Yvette Agnes Maria Mellink¹, Joris T.K. Quik², Merel Kooi¹ and Albert Koelmans¹, (1)Wageningen University and Research (WUR), Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands

Macro- and microplastic emission, transport, and fate models require that material characteristics such as size and shape are addressed, rather than focusing solely on mass flows. Existing dynamic probabilistic material flow analysis (DPMFA) models provide mass-based estimates but do not resolve particle size or shape, limiting realism in environmental fate and exposure assessments based on these models. Here, we introduce the use of size-dependent transfer coefficients in MFA modeling, enabling the partitioning of plastic flows while accounting for particle size distributions and cutoff sizes, thereby producing distinct, realistic emission pathways. Our novel DPMFA plastic emission model distinguishes between in-use and end-of-life emissions, capturing the temporal dynamics and differing emission potentials of (micro)plastics generated during use and (macro)plastics entering waste streams. We applied the model to the Netherlands and simulated plastic flows and emissions from 1950 to 2050. We show that using size-dependent transfer coefficients (SDTCs) not only leads to lower plastic emissions to some environmental compartments but also results in different allocations of plastics across compartments compared to traditional mass-based DPMFA models. Finally, we generated the size, shape, and density distributions of the polydisperse plastic particle mixtures emitted into the Dutch environment. Our DPMFA plastic emission model provides a robust tool to assess how policy measures targeting plastic production and use influence environmental emissions and associated risks.

3.02.B.T-02 Quantifying and Mitigating Environmental Emissions and Exposure of Intentionally Added Microplastics in the UK

Cansu Uluseker¹, Hongyan Chen¹, Thea Marcelia Sletten², Oliver Pilkington³, Sarah Roberts¹, David Spurgeon¹, Richard Cross¹ and Sam Harrison¹, (1)United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)Economics for the Environment Consultancy (EFTEC), London, United Kingdom, (3)Economics for the Environment Consultancy (EFTEC), United Kingdom

Microplastics are recognised as a widespread and persistent pollutant with potentially serious environmental and health impacts. They originate either as “intentionally added” microplastics (IAMP), added to products like cosmetics, detergents and paints, or as secondary microplastics formed through the breakdown of larger plastic items. While emissions from secondary microplastics are hard to regulate, IAMPs offer clearer opportunities for targeted regulatory intervention.

This study provides the first unified UK assessment of IAMP emissions and exposure across environmental compartments, with consideration of future risk management options. A framework was developed that reconstructed historical emissions (pre 2024) using sector-specific starting years and diffusion-based interpolation, and predicted future projections (2024–2043) based on UK market data, PRODCOM datasets, expert judgment, and scaled EU values. Material flow analysis mapped emission pathways and environmental exposure was simulated using a dynamic version of the UTOPIA microplastic unit-world exposure model, covering 17 compartments and accounting for particle size, transformations, and multimedia transport.

Results for the baseline “business-as-usual” scenario show soils as the dominant receiving environment, particularly agricultural soils via biosolid application, since wastewater treatment partitions ~99% of microplastics to biosolids, and almost all biosolids are applied to agricultural land in the UK. Urban soils are the second-largest sink, driven by runoff of infill from synthetic sports surfaces. Among sectors, synthetic sports infill contributes the highest emissions and exposure, followed by detergents.

Risk management scenarios highlight that broad restrictions with few derogations achieve the largest reductions in exposure. Targeted measures, such as improved controls for synthetic sports pitches or limits on biosolid application, are effective in specific compartments but less effective overall.

This work demonstrates the importance of considering both emission and exposure dynamics when prioritising regulatory interventions, showing how such work can feed into evidence-based regulatory decision-making.

3.02.B.T-03 A Modular Fate and Transport Model for Biological Treatment of Micropollutants During Wastewater Treatment

Imma Bortone¹, Pablo Campo², Tao Lyu³ and Pinelopi Savvidou⁴, (1)Senior Lecturer in Environmental Systems Modelling and Engineering, United Kingdom, (2)Senior Lecturer in Applied Chemistry, United Kingdom, (3)Senior Lecturer in Green Technologies, United Kingdom, (4)Researcher in Water Sciences, United Kingdom

Sewage treatment plants (STPs) play a critical role in reducing micropollutant emissions and discharges to the environment, yet comprehensive monitoring remains costly and difficult. We introduce a modular fate and transport model, developed in Python, to simulate the behaviour and treatment of organic micropollutants across various STP configurations. The model uses a multimedia box approach for STP compartments and combines mass-balance equations for the activated sludge process, the trickling filter, and the membrane bioreactor and an optional quaternary treatment using granular activated carbon. The framework requires only a small set of physico-chemical properties and key operating parameters to estimate emissions to air, water, and solids. Validation and calibration were performed using influent and effluent data for 40 emerging contaminants from 71 UK STPs (UK Chemical Investigations Programme; over 40000 data points), with performance assessed by MAE, MSE, and RMSE. The modular model's outputs are compared with results from SimpleTreat and TOXCHEM, which used the same dataset for validation. Previous comparisons between SimpleTreat and TOXCHEM showed that predicted removal efficiencies are more affected by chemical properties than plant operating conditions, and both tend to overestimate sorption and volatilisation, especially for per- and polyfluoroalkyl substances (PFAS). This new framework offers a transparent, reusable, and easily extendable environment to support regulators in scenario analysis, process selection, and future integration of data-driven models for recalcitrant and emerging contaminants. Its modular design enables replacement of treatment processes, multiple scenario analyses, and expansion as regulatory standards evolve (e.g., EU Urban Wastewater Directive).

3.02.B.T-04 Modelling Chemical Mixtures for Assessing the Impact on Freshwater Biodiversity in Yorkshire, UK

Martha Villamizar¹, Amy Rose Ockenden², Lorraine Maltby², Ivo Pink³, Sim Reaney³, Colin Brown¹, Jos van Gils⁴ and Alistair Boxall¹, (1)University of York, United Kingdom, (2)School of Biosciences, University of Sheffield, United Kingdom, (3)Durham University, United Kingdom, (4)Deltares, Netherlands

Water quality and freshwater biodiversity are declining due to human-made stressors resulting from a mixture of chemicals from a wide range of sources. Nevertheless, studies often focus on a small number of chemicals from single source types, ignoring the fact that freshwaters are exposed to complex mixtures of hundreds of chemicals originating from multiple sources that interact together to exacerbate impacts. To move forwards, a more integrated approach is required that considers all significant sources of chemicals, focuses on those chemicals that pose the greatest risk, and delivers a spatial and temporal understanding of how mixture profiles vary in the catchment. The ECOMIX project aims to develop innovative approaches for chemical mixture exposure and effects monitoring and modelling using nine catchments in Yorkshire, England as its test system. A stakeholder workshop prioritised 40 chemicals, including pharmaceuticals, pesticides, metals, personal care products, PAHs, and livestock and pet medicines. Source density maps were developed based on spatial data for population, combined sewer overflows, crops, livestock, pet ownership, mines and road emissions, and these were combined with an analysis of dilution potential within the catchment. Density maps of the sources of chemicals were calculated for 50 sub-catchments within the study area. Subbasins with high source density areas are widespread within the catchment. A catchment-scale model was developed to consider inputs from multiple sources, land uses, and pathways. The model was used to generate current (2002-2022) profiles for flow and chemical exposure. Spatially distributed stream flow and nutrients were generated using the terrestrial hydrological and biogeochemical model HYPE for 16,000 separate river reaches. The model runs on a daily time step to capture individual storms. Modelled WWTP-treated effluent concentrations of down-the-drain chemicals were simulated within the same order of magnitude to observed concentrations. Work is ongoing to model exposure concentrations that will provide data for ecological modelling. This presentation provides an overview of the modelling approach, including results of chemical emissions and river concentration of chemical mixtures in the catchment.

3.02.B.T-05 Screening-level exposure Models to Evaluate the direct Release of Cosmetic Ingredients (MERCi): Development and application to UV filters used in suncare products

Todd Gouin¹, Maura Roberts², W. Martin Williams², Eva Klingelmann³, Sascha Pawlowski⁴, Arnaud Franck BOIVIN⁵, Ryan Heisler⁶ and Amelie Ott⁶, (1)TG Environmental Research, United Kingdom, (2)Waterborne Environmental Inc., (3)Symrise AG, Germany, (4)GBP/RA, BASF, Germany, (5)L'Oréal, France, (6)International Collaboration on Cosmetics Safety (ICCS), United States

Concerns regarding the environmental risks of UV-filters used in suncare products have grown in recent years. Much of this concern has been driven by their use in products by consumers engaged in outdoor recreational activities, such as swimming, which can facilitate their direct emissions into aquatic systems. Uncertainties in estimating the amount of a UV-filter that might be directly emitted to water, however, represent a continuing challenge, and include the need to quantify the number of users of suncare products, the skin area covered, the concentration of the UV-filter in the product and the extent to which the UV-filter is 'washed-off'. This study aims to address this gap, which includes the development and application of screening-level exposure Models to Evaluate the direct Release of Cosmetic Ingredients (MERCi). The tier 1 and 2 MERCi models – SUNscreen and multi-SUNscreen – are described, with application to octocrylene, a well-studied UV-filter used in suncare products. Model results suggest that both tools provide reasonable estimates of environmental exposure. Specifically, the tier 1 SUNscreen model, estimates an environmental concentration of 1690 ng·L⁻¹ in freshwater and range from 765 – 1710 ng·L⁻¹ in marine water capturing differences between low – moderate tidal dilution rates, whereas sediment concentrations are estimated to be 825 ng·g⁻¹ dw (freshwater) and 374 – 838 ng·g⁻¹ dw (marine). The tier 2 multi-SUNscreen model, on the other hand, estimates freshwater concentrations of 324 ng·L⁻¹ in water and 2.04 ng·g⁻¹ dw in sediment, results that are observed to be in good agreement with monitoring data. Overall, both models support a conservative, screening-level approach for estimating environmental exposure to UV-filters, and thus represent tools that can be readily utilized to support both risk assessment and research prioritization.

3.02.P Advances in Exposure Modelling: Closing the Gap between Scientific Innovation and Regulatory Relevance

3.02.P-We177 Validation of SVOC Transfer Modeling from Flooring to Indoor Dust: A Comparative Study of Parameter Determination Scenarios using Test-bed Data

Jong-Hyeon Lee and Jung-Hyun Park, EH R&C Co., Korea, Republic of

Assessing the risk of Semi-Volatile Organic Compounds (SVOCs), particularly phthalates, is crucial for indoor air quality management. Emitted from building materials, SVOCs adsorb onto suspended particles and accumulate in dust due to their low vapor pressure. Consequently, accurately predicting dust concentrations is

essential for exposure assessment. This study evaluates the predictive performance of an existing mechanistic SVOC behavior model using empirical data from a residential test-bed, rather than developing a new model. We utilized a mechanistic model accounting for source emission, diffusion, and dust partitioning. To validate the model, a test-bed was established in an LH experimental housing unit (59?) in Sejong City. Rooms were installed with differing source strengths: PVC flooring (2.65% DEHP) and Deco-tiles (5.39% DEHP). Floor dust samples were collected monthly from July to November 2022. We compared three parameter determination scenarios for calculating the air-dust partition coefficient (K_{dust}) and other variables: 1) site-specific measured variables, 2) literature-based empirical estimates, and 3) theoretical estimates. Field measurements showed dust DEHP concentrations ranged from 96.2 to 997.3 ppm (average 425.6 ppm). The room with higher-content Deco-tiles exhibited the highest concentration (551.6 ppm), confirming a correlation between material content and dust contamination. Simulations revealed significant discrepancies; scenarios using literature estimates yielded highly overestimated concentrations (15,000–23,000 ppm), tens to hundreds of times higher than actual measurements. Conversely, using measured parameters predicted concentrations between 725 and 760 ppm, showing much closer agreement with observed data. This study confirms that model reliability depends critically on parameter accuracy, particularly K_{dust} . Generic literature values led to substantial overestimation of risk. Therefore, applying site-specific measured variables is essential for ensuring the predictive accuracy of exposure assessment models for flooring-derived SVOCs.

3.02.P-We178 Application of an Individual-Based Integrated Exposure Assessment for Predicting Blood Lead Concentrations and Validation Using Biomonitoring Data

Jung-Hyun Park and Jong-Hyeon Lee, EH R&C Co., Korea, Republic of

An individual-based risk assessment for lead exposure was conducted by reflecting children's physiological and behavioral characteristics. Exposure factors such as body weight, inhalation rate, and time spent in various microenvironments were set as fixed values, while the concentrations of lead in indoor and outdoor air, indoor dust and soil, food, drinking water, and children's products were represented by probabilistic distributions. Individual total exposure levels were then estimated using a probabilistic integrated exposure assessment. Food and indoor dust/soil were identified as the dominant exposure pathways for lead, with markedly higher exposure per unit body weight among children under six years of age, indicating greater vulnerability. The integrated exposure estimates were applied to the IEUBK model to predict blood lead concentrations, which were compared with national biomonitoring data. The observed blood lead concentrations were generally higher than those predicted under the average exposure scenario but lower than those under the maximum exposure scenario. The relative contributions of different exposure media varied by exposure level, and analysis of the high-exposure group highlighted the need for targeted and effective exposure-reduction strategies. These results indicate that managing indoor environmental contamination—particularly the control of surface materials and dust in children's activity areas—should be prioritized as a key exposure mitigation strategy. Overall, the findings emphasize the importance of shifting from population-average exposure assessments to individual-based integrated evaluations and developing risk management strategies focused on high-exposure subpopulations for more effective public health protection.

3.02.P-We179 Improved Chemical Product Evaporation Model (CPEM) using a Top-down Approach: Validation with Liquid Air Fresheners

Jong-Hyeon Lee and Jung-Hyun Park, EH R&C Co., Korea, Republic of

This study improves the Chemical Product Evaporation Model (CPEM) by integrating a "top-down" approach, utilizing measured product consumption rates to overcome the complexity and high uncertainty associated with mass transfer coefficients in traditional "bottom-up" models. We conducted small-scale chamber experiments over a 600-hour period to measure the time-resolved airborne concentrations of D-Limonene and Propylene Glycol emitted from liquid air fresheners. The proposed framework, which employs product weight loss as a primary input constraint, was rigorously compared with four existing mechanistic models—Weschler, Thibodeaux, Langmuir, and AMEM—under various parameter tuning scenarios ranging from complex substance-specific adjustments to a single product-level coefficient. The experimental results confirmed that product mass decreased linearly over time, thereby validating the fundamental assumption of a constant consumption rate (μ) inherent to the top-down approach. While D-Limonene exhibited a rapid initial peak typical of volatile organic compounds, Propylene Glycol showed a gradual concentration increase characteristic of semi-volatile compounds; the improved model successfully captured these distinct behaviors by integrating the total flux constraint with component-specific activity corrections. Notably, while complex tuning scenarios provided high precision, simplifying the model to use a single tuning parameter for the entire product yielded a robust fit to the experimental data, effectively balancing predictive accuracy with model parsimony and avoiding the risk of overfitting observed in multi-parameter cases. By substituting difficult-to-estimate theoretical parameters with easily measurable mass loss data, the improved CPEM significantly reduces predictive uncertainty. Consequently, this hybrid approach offers a practical, scientifically grounded tool for indoor chemical exposure assessment, effectively bridging the gap between theoretical mass transfer principles and real-world consumer product usage patterns.

Disclaimer/Disclosure:

3.02.P-We180 Modelled human exposure to trifluoroacetic acid (TFA) from atmospheric degradation of HFO-1234ze(E) emissions from prospective pMDI usage

Shivendra Tewari¹, Kun Zhao², Krish Vijayaraghavan², Irene Bramke³, Paul Giffen⁴ and Holly Kimko¹, (1)AstraZeneca, United States, (2)Ramboll Americas Engineering Solutions, Inc., United States, (3)AstraZeneca, Netherlands, (4)AstraZeneca, United Kingdom

HFO-1234ze(E) is a near-zero global warming potential, next generation medical propellant, being used in pressurised metered-dose inhalers (pMDIs). The chemical structure of HFO-1234ze(E) has the $-\text{CF}_3$ moiety, which is associated with formation of TFA after atmospheric degradation. In an earlier study, we coupled atmospheric GEOS-Chem modelling with fate-and-transport modelling to estimate TFA levels due to HFO-1234ze(E) emissions from prospective pMDI usage in the Rhine region, estimating TFA deposition fluxes between 0.9 and 3 $\mu\text{g}/\text{m}^2/\text{yr}$ [1]. Building on those deposition fluxes, we applied the methodology recommended in the US-EPA Human Health Risk Assessment Protocol (HHRAP) [2] to simulate chemical transport in the food chain using TFA-specific physicochemical inputs to predict TFA concentrations in edible plants and meats across Rhine sub-basins. Consistent with TFA's low hydrophobicity and limited sorption, modelled concentrations equilibrated rapidly (within months in all modelled environmental matrices). Steady-state concentrations were 85–150 ng/kg in total of above-ground and below-ground produce, 29–52 ng/kg in crop (wheat), and less than 0.34 ng/kg in meat (beef, pork, and chicken). These negligible TFA concentrations in foods provide the dietary inputs for subsequent Stochastic Human Exposure and Dose Simulation (SHEDS) modelling alongside inhalation, drinking water, and soil pathways. Our SHEDS modelling predicts that cumulative TFA intake rates for humans due to pMDI-based HFO-1234ze(E)-derived TFA in the environment are more than 150,000-fold below the existing threshold (30,000 ng/kg/day) of acceptable daily intake (ADI) for TFA established by European Food Safety Authority (EFSA).

3.02.P-We181 Numerical modelling of water discharge dispersion from offshore hydrogen production : The Gulf of Lion case study

Nicolas Michelet, Matthieu Dussauze, Marie Robert and Lénaïg Mellaza, France Energies Marines, France

As part of its carbon neutrality strategy, the European Union has set ambitious targets for offshore wind energy deployment. However, this expansion alone will not be sufficient to meet the growing demand for clean and sustainable fuels required to reduce reliance on fossil resources. In this context, hydrogen (H₂) offers a promising alternative to conventional power export, and stakeholders in Offshore Wind Farms (OWFs) are increasingly considering the integration of H₂ production within OWF facilities. In offshore settings, H₂ production generates significant volumes of Produced Water (PW), defined as a mixture of brine from desalination systems used to supply freshwater for electrolysis and cooling water from electrolysis units. These waters exhibit elevated temperature and salinity compared to ambient conditions and contain chemical additives used during water treatment. Since it is generally accepted that those waters will be discharged directly into the marine environment, its management has become a growing concern. To assess the potential environmental impact of such discharges, a 990 MW wind farm was simulated in a microtidal marine environment using two numerical models: PLUME2.0 for local-scale dispersion and CROCO for regional-scale transport. At the local scale, near a wind turbine or substation, PW dispersion showed rapid dilution within a short distance, with temperature and salinity gradients falling below natural daily variability after only dozen meters. At the regional scale, in the Gulf of Lion, the distribution of maximum chemical concentrations was primarily driven by dominant hydrodynamic processes. Furthermore, in such environments, the use of worst-case scenarios based on maximized production appears unsuitable for environmental impact assessment and highlights the need for more realistic operational scenarios.

Disclaimer/Disclosure:

This work is part of the OPHARM2 project which receives funding from France Energies Marines and its members and partners, as well as French State funding managed by the French National Research Agency under the France 2030 Investment Plan (ANR-10-IEED-0006-34). It also benefits from the financial support of Bretagne, Pays de la Loire, Occitanie and SUD Provence-Alpes-Côte d'Azur regions.

3.02.P-We182 Numerical modelling of chemical dispersion from offshore hydrogen production

Nicolas Michelet, Matthieu Dussauze, Marie Robert and Lénaïg Mellaza, France Energies Marines, France

As part of its carbon neutrality strategy, the European Union has set ambitious targets for offshore wind energy deployment. However, this expansion alone will not be sufficient to meet the growing demand for clean and sustainable fuels required to reduce reliance on fossil resources. In this context, hydrogen (H₂) offers a promising alternative to conventional power export, and stakeholders in Offshore Wind Farms (OWFs) are increasingly considering the integration of H₂ production within OWF facilities. In offshore settings, H₂ production generates significant volumes of Produced Water (PW), defined as a mixture of brine from desalination systems used to supply freshwater for electrolysis and cooling water from electrolysis units. These waters contain chemical additives introduced during treatment, such as chlorine, which is widely employed as a biocide in desalination and cooling processes. It is commonly admitted that those waters will be discharged directly into the marine environment, making their management an issue of growing importance. To assess the risks associated with such discharges, a 990 MW wind farm was simulated over the future 'Centre Manche 1' site using the CROCO model to estimate chemical dispersion and the corresponding Predicted Environmental Concentration (PEC). In this tidal environment, the distribution of maximum concentrations was primarily driven by tidal currents. Additionally, due to the highly dynamic conditions that promote dilution, PEC values estimated under both maximized and realistic scenarios were comparable. This indicates that a simplified maximized scenario is sufficient to provide a consistent PEC estimation and support subsequent risk assessment.

3.02.P-We183 Environmental Risk Assessment of Product Type 18 Biocidal Products: A Comparative Analysis of Emission Scenario Document 2008 and 2024 Using Real-World Applications

Kishor Acharya, Eva Tallentire, Martin Hilton, James Pemberton and Alison McGuire, Exponent International Ltd., United Kingdom

Environmental Risk Assessment (ERA) for biocidal products relies on Emission Scenario Documents (ESDs) to estimate exposure. Product Type 18 (PT18), covering insecticides and acaricides and products to control other arthropods, has undergone a major update: the 2024 ESD for household and professional uses replaces the 2008 version and applies to active substance approvals from June 2025, with product authorisation requirements

effective December 2026.

The new ESD introduces refined emission scenarios for residential and non-residential buildings based on a new scale concept and treatment patterns with new default parameters. This includes a revised approach for the derivation of the simultaneity factor and the wet cleaning efficiency. New emission scenarios are introduced for example, for bed-bug treatments, aircraft disinfection and large-scale outdoor spraying and new chapters on risk mitigation measures (RMM) and seasonal control. The guidance also presents a newly developed quantitative primary poisoning assessment and a revised secondary poisoning assessment.

The full extent of these changes on the ERA outcomes remains unclear. The 2024 ESD introduces a fundamentally different framework from the 2008 version, so exposure estimates and risk characterisation may vary significantly. This could affect active substance and product renewals, requiring additional data or refined risk assessments. Until experience with the new approach accrues, the impact of the new guidance creates regulatory unpredictability for future submissions.

To help address this, a comparison of common indoor and outdoor PT18 uses has been performed, applying both the 2008 and 2024 ESD frameworks. Its findings will help inform compliance strategies and support stakeholders in adapting to the new requirements.

3.02.P-We184 Optimal Ecological-Economic Harvesting of Bioaccumulators for Aquatic Bioremediation
Sebastian Verslycke¹ and Michael Neubert², (1)United World College, United States, (2)Woods Hole Oceanographic Institution, United States

Aquatic ecosystems worldwide face persistent contamination from bioaccumulative pollutants, increasing the need for cost-effective and ecologically grounded bioremediation strategies. Fish populations capable of bioaccumulating environmental pollutants provide a potential pathway for pollutant removal through targeted harvesting. We developed a dynamical model that integrates fish population growth and contaminant uptake within an explicit economic framework capturing harvesting costs, environmental externalities, and revenue associated with biomass extraction. While both bioremediation and optimal harvesting have been examined in prior studies, their explicit integration within a single eco-toxicological and economic model remains uncommon. We used our model to evaluate potential management strategies by formulating an optimal control problem that maximizes net societal benefit by balancing economic returns from biomass removal against the costs of harvesting effort and environmental contamination. The estimated model conditions provide a set of economically and ecologically feasible harvesting trajectories that maintain long-term population viability while enhancing pollutant removal efficiency. These findings highlight parameter regimes under which targeted harvesting can substantially improve remediation outcomes relative to unmanaged or conventional strategies. Overall, our modeling approach offers a quantitative basis for evaluating how coupled ecological and economic processes can be leveraged to support cost-effective bioremediation programs in contaminated aquatic systems.

3.02.P-We185 Chemical Risk Assessment Using Control Banding in the Safe and Sustainable by Design Framework: Application to Fuel Cell and Electrolyser Manufacturing
Manon Lisiecki and Joséphine STECK, Univ. Grenoble Alpes, CEA LITEN DTNM, France

Control banding provides a practical and accessible approach to chemical risk assessment, especially when traditional predictive methods are overly complex, costly, or require detailed data that may not be available in early stages. The proposed methodology is aligned with the Safe and Sustainable by Design (SSbD) framework proposed by the European Commission, by addressing safety throughout the product lifecycle. It integrates hazard identification with exposure scenarios and prioritize safety measures via the STOP principle (Substitution, Technical, Organizational, Personal). Two crucial products toward safer and more sustainable hydrogen production with the same functional unit as previous sustainability assessment are evaluated: the manufacturing of a fuel cell (PEMFC) and an electrolyzer cell (SOEC). First, the chemicals involved are inventoried and their hazards assessed with a score based on the Material Safety Data Sheet recalculating mixture hazards via regulation thresholds using Quarks Safety® software. Then, the exposure scenarios combine fixed (quantity, frequency) and adaptable (process type, protection equipment) parameters. The Gross Risk is defined under worst-fixed exposure parameters (no ventilation, fully exposed) for each chemical. Then, residual risks are calculated for the multiple exposure scenarios thanks to adaptable parameters (worker protection, closed-process, source of ignition) and control levels. Due to the high number of chemicals involved, a categorization of gross risk (low to high) is proposed. For highest-risk chemicals (e.g., solvent, ceramic slurries), substitution with less hazardous alternatives is recommended. Medium-risk require combined technical

and organizational controls, while low-risk solely require personal measures. This approach enables comprehensive risk reduction, identifying hazardous chemicals, addressing data gaps in product development while ensuring compliance with EU safety regulations. All the results are summarized into a self-assessment guide for rapid, time-efficient chemical risk evaluation in hydrogen product manufacturing. Unlike current SSbD safety approaches, it stands out by rapidly delivering semi-quantitative results using available data. By identifying inherently safer alternatives, and by optimizing processes that simultaneously improve worker protection and resource efficiency, it demonstrates that safety and sustainability can be complementary rather than competing priorities.

3.02.P-We186 Evaluating Metabolism and Accumulation of Polycyclic Aromatic Hydrocarbons in Juvenile Hybrid Striped Bass in Support of PBTK Modeling Efforts

Gregory Martin Langlois and Peter van den Hurk, Clemson University, United States

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous in marine/aquatic waters and sediments, and can have a range of toxic effects on aquatic organisms. This project aims to develop a physiologically based toxicokinetic (PBTK) model for the uptake of aqueous pyrene in juvenile hybrid striped bass, to model the absorption, distribution, metabolism and excretion of this compound. At this moment there are no established PBTK models for hybrid striped bass, despite the growing popularity of this animal as a sport fish and food source in North American waters. In the pursuit of developing this physiologically based toxicokinetic model, it is essential to define and parameterize both the physiological components of the model organism as well as the physiochemical properties of the compound selected for modeling.

One of the key components in PBTK models is biotransformation. In an effort to generate metabolic elimination parameters for a juvenile hybrid striped bass PBTK model, S9 liver fractions are used to perform overall elimination assays for a range of PAHs, including pyrene, which is the primary focus of this work, as well as a panel of other applicable PAHs to provide elimination rate constants for use in modeling efforts. Additionally, a characterization of the metabolic activity of juvenile hybrid striped bass for specific enzymes involved in PAH metabolism, such as CYP1A1 using the EROD assay, as well as UDP-glucuronosyltransferase activities, were performed to better understand the elimination pathways of PAHs in this poorly characterized species.

Additionally, to calibrate the PBTK model, free swimming exposures to aqueous pyrene were performed to calibrate model predictions to real time chemical exposures to evaluate the predictive capabilities of the developed PBTK model.

Keywords: Physiologically Based Toxicokinetic Modelling, ADME, Metabolism

3.02.P-We187 Advancing Geo-Environmental Risk Assessment for Residual Mercury in Soil: Modeling Mercury transformations and Exposure Dynamics

Monami Kondo, Yasuhide Sakamoto and Junko Hara, National Institute of Advanced Industrial Science and Technology, Japan

Mercury (Hg) is a globally circulating substance that moves between atmospheric, terrestrial and aquatic reservoirs through complex biogeochemical processes. While exposure and risk management through various Hg regulations have advanced, substantial quantities of Hg continue to enter the environment from localized emissions originating in industrial zones and mining areas. Particularly at artisanal and small-scale gold mining (ASGM) sites, Hg exposure may occur without awareness of its hazards, necessitating the promotion of worker safety education and transition to alternative methods. Therefore, it is essential to visualize Hg exposure risks and encourage restrictions on access to hazardous sites and groundwater use. To address this necessity, we aim to develop a model for assessing the short- and long-term exposure risks of residual Hg discharged at ASGM sites. We have already developed a geo-environmental risk assessment system (GERAS-3) and also enhanced it to enable the representation of time-variant atmospheric transport of volatile compounds such as Hg and volatile organic substances (VOCs) in unsaturated soil. Furthermore, this model can reproduce changes in mass transfer behaviour in response to meteorological conditions such as rainfall and air pressure changes at the soil-atmosphere boundary. We are further refining this model to incorporate form changes and chemical species in

both anaerobic and aerobic soil environments, enabling it to account for various Hg forms. This would enable the model to provide a more detailed analysis of Hg immobilisation within the soil and its release into the atmosphere and groundwater. In the presentation, we will discuss the advantages of understanding environmental behaviour and spatial distribution of Hg, including its morphological changes, for establishing a methodology to assess Hg inhalation exposure under specific scenarios.

This research was performed by the Environment Research and Technology Development Fund (JPMEERF20255M06) of the Environmental Restoration and Conservation Agency provided by Ministry of the Environment of Japan.

3.02.P-We188 Inverse TOXSWA Modelling for Level P-II Water-Sediment Kinetics: A Robust Approach *Gerald Reinken¹, Klaus Hammel¹, Kristina Hoffmann² and Ruth Porschewski², (1)Bayer AG, Research & Development, Crop Science, Germany, (2)knoell Germany GmbH, Germany*

Water-sediment degradation studies are currently evaluated according to FOCUS kinetics guidance at Tier-1 (P-I) and Tier-2 (P-II) levels. While Tier P-I relies on total-system half-lives, Tier P-II requires separate kinetic fits for water and sediment compartments including exchange processes. Due to strong parameter correlations and identifiable issues, these kinetic evaluations can give inconclusive results and force the use of regulatory default worst-case values (e.g. $DT_{50} = 1000$ d) in subsequent exposure modelling. In such cases, higher-tier kinetic evaluations by inverse TOXSWA are a regulatory recognised option as described in the FOCUS kinetics guidance from 2014.

This work demonstrates the successful application of inverse modelling with TOXSWA version 1.2 at Tier P-II for one parent substance across four laboratory water-sediment systems. The approach provided well-identified and robust kinetic endpoints: $DT_{50, \text{water}} = 98\text{--}117$ d, $DT_{50, \text{sed}} = 88\text{--}336$ d, and mass-transfer coefficients $k_{\text{ex}} = 0.14\text{--}0.22$ m³/kg. All three key parameters (DT_{50} water, DT_{50} sediment, and k_{ex}) were reliably and simultaneously fitted for every system with narrow confidence intervals.

These results demonstrate that inverse modelling with TOXSWA is a powerful, scientifically robust, and defensible higher-tier refinement tool at Tier P-II. It is therefore recommended that this approach be explicitly recognised and retained as an acceptable option in future revisions of the EFSA/FOCUS kinetics guidance.

3.02.P-We189 Revisiting MACRO 5.2 Parameterization for FOCUS Surface Water Scenarios *Gerald Reinken, Bayer AG, Research & Development, Crop Science, Germany*

The MACRO model is a cornerstone of pesticide fate assessment within the FOCUS Surface Water (SW) framework, providing a physically based simulation of macropore flow and solute transport in structured soils. The original FOCUS SW drainflow scenarios were parameterized using MACRO 4.3b, calibrated and validated against field data to ensure realistic hydrological behaviour.

With the release of MACRO 5.2, several technical updates were implemented, including changes in numerical routines, parameter management, and batch-execution functionality. While these updates improve model flexibility and performance, early comparisons indicated that outputs for standard FOCUS SW scenarios may deviate from those generated with the earlier version, potentially affecting regulatory consistency.

This work outlines a systematic approach to evaluate and better harmonize MACRO 5.2 with well established FOCUS drainflow benchmarks. A detailed comparison of process implementation and parameterization between MACRO versions 4.3b and 5.2 identified three categories of changes:

- 1) Modified parameter input values (e.g. numerical layers increased from 15 to 60; scenario-specific FRACMAC and replacement pre-defined PET values)
- 2) Newly introduced parameter and processes (e.g. internal EVAPORATE calculation; full dual-permeability formulation requiring explicit domain-exchange coefficients and aggregate half-width; optional scaling for OC partitioning in macropores)
- 3) Adjusted numerical solver technique (still using an implicit finite-difference method, but with a more precise numerical approximation for episodic macropore flow)

A structured global sensitivity analysis has been initiated using MACRO 5.2's Monte Carlo and batch-run

modules across all official FOCUS SW drainflow scenarios (D1–D6). Key parameters governing macropore flow are identified, and adjustment ranges are tested to restore better agreement with 4.3b reference loads while maintaining physical plausibility. The results are intended to serve as a basis for updated guidance on the regulatory use of MACRO 5.2 in European pesticide risk assessment.

3.02.P-We190 Spatial Representativeness and Temporal Variability in the FOCUS Surface Water Framework: Implications for Future Endpoint Selection

David Patterson¹, Beate Erzgraeber², Neil Mackay³, Monika Maleri⁴, Peter Rainbird⁵, Gerald Reinken⁶, Dieter Schaefer⁶ and Gregor Spickermann⁷, (1)Syngenta Ltd, United Kingdom, (2)BASF, Germany, (3)FMC Corporation, United Kingdom, (4)Corteva Agriscience, Germany, (5)Syngenta Ltd, Switzerland, (6)Bayer Research & Development Services LLC, Germany, (7)ADAMA, Germany

The FOCUS Surface Water (SW) framework remains the central EU approach for evaluating aquatic exposure to plant protection products. The 2020 FOCUS SW “repair action” advanced temporal representativeness by extending all scenarios to a 20-year assessment period. However, current discussions regarding the regulatory interpretation of aquatic exposure predictions resulting from FOCUS SW Repair risk overlooking the equally foundational spatial basis of protectiveness embedded in the original scenario design. The FOCUS scenarios were explicitly constructed from agro-environmental combinations of climate, soil texture, slope, drainage prevalence, land use and cropping, parent material and hydrological connectivity in a catchment to represent realistic “worst-case” conditions for drift, runoff and drainage. Their representativeness is a function of both spatial and temporal components.

We re-evaluate the spatial coverage and consider the percentile “worst-caseness” of the FOCUS scenarios using a 2007 extended spatial analysis for the EU25, which quantified the national extent of each scenario’s agro-environmental envelope. This analysis confirms that not all scenarios represent the same spatial percentile: some encompass extensive fractions of EU agricultural land, while others represent high-end, spatially scarce combinations of slope, drainage density or soil erodibility. This heterogeneity of spatial coverage and “worst-caseness” needs to be considered in conjunction with temporal variability. Certainly there may be lessons to be taken from the FOCUS groundwater approach in which an overall 80th percentile is achieved through the combination of spatial and temporal 90th percentiles. The additional complexity for surface water assessments concerning rules regarding application timing and drift loading percentiles should also be considered.

By combining the 2007 EU25 spatial quantification with the 20-year temporal outputs introduced in the repair action, we highlight how spatial and temporal considerations interact to yield the current protective benchmark. We argue that selection of regulatory endpoints from the 20-year simulation period must continue to reflect this dual foundation. Ignoring the spatial percentile risks shifting the balance between representativeness and conservatism that underpinned the original FOCUS surface water guidance.

3.02.P-We191 Field-Scale Run-off Vulnerability Mapping Using GIS Modelling to Support Precision Agriculture

Olha Khomenko¹ and Mercedes Franey-Gardiner², (1)Cambridge Environmental Assessments (CEA), Helsby, United Kingdom, (2)Cambridge Environmental Assessments (CEA), United Kingdom

Diffuse agricultural pollution from field run-off contributes significantly to water quality degradation, yet conventional farm management typically applies uniform practices across fields despite substantial spatial variability in run-off risk. This study aims to demonstrate how a GIS-based modelling can allow a field-specific run-off vulnerability mapping to enable targeted precision agriculture interventions. The methodology integrates multiple field-specific spatial data layers, including high-resolution digital elevation models for slope analysis, local hydrology networks, soil properties, and proximity to water courses.

Using weighted overlay analysis and hydrological modelling tools, we identify areas within individual fields where run-off of nutrients, pesticides, and sediments is most likely to occur. To enhance interpretability and support decision-making, we are developing a complementary machine learning component using random forests to classify field zones as high, moderate, or low run-off risk based on the GIS-derived variables. While the localised geology means models trained on one catchment may not transfer directly to others, the methodology itself is broadly applicable and can be calibrated for new regions with locally available data. Combining classical machine learning techniques with GIS approaches provides a deterministic, process-informed index of run-off susceptibility, evaluates and optimises variable importance, and classifies risk zones, improving predictive accuracy and interpretability. Although demonstrated in a single catchment, the modelling framework is designed for calibration and deployment in diverse agricultural landscapes.

While the existing run-off risk tools typically operate at field or catchment scale, our model aims to resolve risk at sub-field resolution, enabling targeted interventions. This precision approach has the potential to reduce agricultural chemical loading to water bodies while maintaining crop productivity, offering economic benefits to farmers through reduced input costs and environmental benefits.

3.02.P-We192 Outdated Forecasts: Climate Drift and the Future of Pesticide Risk Models

Olha Khomenko¹ and Mercedes Franey-Gardiner², (1)Cambridge Environmental Assessments (CEA), Helsby, United Kingdom, (2)Cambridge Environmental Assessments (CEA), United Kingdom

Regulatory risk assessments for Plant Protection Products (PPPs) in Europe rely on FOCUS scenarios, which use historical weather data. However, the climate has shifted since this baseline period, bringing changes to the crop calendars, precipitation patterns and average temperatures, raising questions about whether the current models' parameterisation is fit for purpose in 2025 and beyond.

The frequency and intensity of heavy rainfall events have increased significantly over the past decade, with more frequent extreme events. Temperatures across the UK have increased since the 1961-1990 baseline period, with recent years (2022-2024) averaging 9.8-10.0°C compared to the historical baseline of 8.3°C. While these changes may appear moderate, it remains unclear what level of change they bring to the model results. Using outdated values can potentially alter pesticide fate predictions as the higher temperatures increase degradation and volatilisation rates, while more frequent intense rainfall can lead to a higher surface run-off and leaching to groundwater, with seasonal shifts toward wetter winters and drier summers changing peak exposure timing. This study aims to investigate how rapidly climate change is rendering FOCUS weather files obsolete and aims to determine the frequency at which parameterisation datasets require updating to maintain regulatory relevance. We analyse how temperature and precipitation change in the Okehampton FOCUS groundwater scenario, comparing historical baseline conditions with observed climate data from 2000-2024. Using pesticide fate models, we quantify how these climatic shifts affect predictions of pesticide leaching and run-off. Key deliverables will include precipitation and temperature shift thresholds at which climate drift compromises model reliability, evidence-based recommendations for update frequency. This research will provide regulators with the evidence base needed to modernise pesticide risk assessment approaches and ensure protective standards remain robust in an era of accelerating climate change.

3.02.P-We193 Screening of PFAS Dynamics in the Rhine and Meuse Catchment: Future Scenarios in SimpleBox

Tjebbe Janson, Julia Hartmann and Joris T.K. Quik, National Institute for Public Health and the Environment (RIVM), Netherlands

Minimizing exposure to per- and polyfluoroalkyl substances (PFAS), for example via food and drinking water, is crucial to protect human health. In the Netherlands, approximately 40% of drinking water is sourced from surface water, mainly from the Rhine and Meuse rivers. The presence of PFAS in these rivers is therefore a concern, especially given the limited possibilities to effectively remove these substances during water treatment. This study aims to assess the future PFAS burden in surface water as Dutch drinking water source. The central research question is: How long will PFAS remain in the Rhine and Meuse after the implementation of emission-reducing measures? This was analyzed using a screening level multimedia fate model (SimpleBox) for conducting a semi-dynamic analysis of PFAS fate and transport in time. The landscape scenario was adapted to reflect the specific characteristics of the Rhine and Meuse River basins, including precipitation variability. Seven PFAS were selected based on their high prevalence in Dutch drinking water samples derived from surface water: PFBS, PFBA, PFPeA, PFHxA, PFHpA, PFOA, and TFA. For each of these substances, physicochemical properties and degradation rates were obtained. Several time-explicit emission scenarios were analyzed. Preliminary scenarios include a stringent scenario, involving complete emission reduction within a 10 to 15-year timeframe, and less stringent scenarios, such as a 5% derogation and the implementation of additional transition periods.

The preliminary results show that for the most stringent scenario a 99.9% reduction in PFAS in Rhine and Meuse water would be reached within 15 to 25 years. This is without consideration of groundwater as additional source. In less stringent scenario's the maximum level of reduction varies together with the time span to reach them. Differences between the PFAS compounds are relatively small, except for TFA and PFOA. The reduction level relevant for drinking water production depends on both the current concentrations of PFAS and the relative potency of the individual PFAS compounds. This was further analyzed using the Relative Potency Factor (RPF) approach in combination with recent measurements of PFAS in Rhine and Meuse.

This study offers insights into the purification measures that may be required for the Rhine and Meuse rivers in the future, and identifies key areas for further research.

3.02.P-We194 Climate-Driven PFAS Risk Prediction: Incorporating Rainfall Dynamics into Contamination Forecasting

Olha Khomenko, Cambridge Environmental Assessments (CEA), Helsby, United Kingdom

Per- and polyfluoroalkyl substances (PFAS) contamination of water sources used for drinking water is a growing public health concern. However, the influence of extreme weather events on PFAS transport and concentration dynamics remains poorly understood.

This study develops a predictive framework for PFAS contamination that moves beyond conventional spatial-only models. Specifically, we model PFAS mobilisation triggered by extreme rainfall events, integrating precipitation intensity as a dynamic driver of contamination risk. The framework links climate extremes directly to risk forecasting, offering a climate-informed tool for safeguarding drinking water supplies under intensifying weather variability.

We use public monitoring data to link the measured PFAS concentrations in UK drinking water sources with spatial and environmental predictor variables, including land use patterns, soil characteristics and precipitation intensity. Multiple classical ML algorithms, including random forests, gradient boosting machines, and support vector machines, will be trained to identify conditions under which PFAS concentrations spike in source waters. The impact of increased precipitation specifically examines whether extreme events have the potential to trigger a significant increase in PFAS concentrations, and whether these mobilisation events can be predicted sufficiently in advance to enable drinking water providers to implement mitigating strategies or alternative source water strategies.

This approach will enable utility providers to proactively respond to PFAS contamination threats during extreme weather, thereby improving protection of drinking water supplies and public health outcomes in an era of intensifying climate extremes. The novelty of this work lies in its explicit treatment of rainfall-driven contamination spikes, which are largely overlooked in existing PFAS machine learning models that focus primarily on spatial distribution patterns.

3.02.P-We195 Stay updated: use of Bayesian learning algorithms for updating a probabilistic exposure model with chemical monitoring data

Jannicke Moe¹, Anders L. Madsen², Sophie Mentzel¹, Karel Viaene³, Karel Vlaeminck³, Gašper Šubelj⁴ and Frederik Verdonck³, (1)Norwegian Institute for Water Research, Norway, (2)HUGIN EXPERT, Denmark, (3)ARCHE Consulting, Belgium, (4)TC Vode, Slovenia

A suite of process-based models are available for predicting the environmental release, transport, fate and exposure of chemical substances and mixtures in the aquatic environment. However, even advanced models do not always make optimal use of the latest scientific techniques or relevant available datasets. Precautionary principles are often incorporated in models to account for lack of information or other forms of uncertainty. Here, we present a large-scale study where Bayesian techniques are being explored for efficient integration of process-based model predictions with observations from river monitoring sites. Our starting point is the European-scale process-based fate model from the former EU project SOLUTIONS. Within the project ENCORE (ENVIRONMENTAL CO-exposure and Risk Estimation), this model has been revised and expanded with stochastic simulations (hereafter referred to as the ENCORE fate model). To further leverage the ENCORE fate model simulations, we will make use of river monitoring data from the European Environment Agency's Water Information System for Europe (Waterbase - Water quality), which contains observations of hazardous substances from more than 50 million samples across Europe. To this end, we have developed an object-oriented Bayesian network (BN) model representing the main properties and outputs of the ENCORE fate model, expressed as discrete probability distributions. This OOBN allows us to explore the use of Bayesian updating techniques at different levels of spatial aggregation, for different purposes such as the following:

- (1) River Basin District level - BN model exploration: evaluation of approach.
- (2) Water body level - refined BN model predictions: Bayesian inference for improved accuracy of exposure characterisation at higher spatial resolution.
- (3) Monitoring site level - parameter learning: Bayesian parameter learning for refined BN model settings (conditional probability tables).

This poster will present results from a pilot study with selected pesticides in Belgium. Other aspects of the ENCORE project will be covered by other presentation planned for this meeting: Work flow, information sources, data processing; the ENCORE fate model; and probabilistic approaches to mixture risk calculation.

Disclaimer/Disclosure:

The ENCORE project is sponsored by the European Chemical Industry Council (CEFIC) as part of the Long Range Initiative (LRI) under project ECO-66 “Next generation risk assessment methods supporting the identification of environmental co-exposures of potential concern”.

3.02.P-We196 Modelling the Fate of Chemicals from Untreated Wastewater Discharges: A Routed and Spatially refined Model

Simran Sandhu¹, Juliet Hodges², Hugh Barlow¹ and Stephen Glavin¹, (1)Unilever, United Kingdom, (2)Safety & Environmental Assurance Centre, Unilever, United Kingdom

Untreated Wastewater Discharge (UTWWD) poses a significant risk to river ecosystems globally, particularly where populations lack connection to Sewage Treatment Plants (STPs). Such discharges introduce high loading of sanitary determinands (notably unionised ammonia), as well as suspended solids, and down-the-drain chemicals directly into freshwater systems. Elevated ammonia and chemical concentrations can lead to oxygen depletion, toxicity, and disruption of aquatic communities, threatening biodiversity and ecosystem function. We present a routed and highly spatially refined model that determines both chemical loads and ammonia concentrations across entire river networks. The model integrates high-resolution population connectivity data, geospatial STP and other disposal mechanism infrastructure, and the HydroATLAS hydrological database to allocate unconnected populations to their nearest river segments. For each segment, chemical and ammonia loads are estimated based on population discharge, water use, and chemical-specific parameters (e.g., half-life). The model simulates routed transport and decay, identifying “impact zones” where ammonia concentrations exceed ecological thresholds and differentiates chemical decay based on the different water conditions. Outside these impact zones we map the concentrations, distribution and potential risks of down-the-drain chemicals. Importantly, outside the impact zone, concentrations of down-the-drain chemicals are predicted to be lower than within the impact zone. In the poster we will present a case study with preliminary results from Beijing’s river network, showing distributions of rivers within the impact zone and mapping concentrations of down-the-drain chemicals throughout rivers along with their potential impacts. Future development will focus on integrating STP effluent to assess the combined impacts of treated and untreated wastewater and validating predictions with monitoring data. This spatially refined and routed approach provides a robust foundation to scale to global river networks and provides a higher-tier model to supporting next generation risk assessment (NGRA). These advances enable science-based decision-making for regulators, industry, and water managers.

3.02.P-We197 Generating a Robust Global Dilution Factor Estimation from River Flow and Wastewater Effluent

Jillian La Roe¹, Christopher M Holmes¹, Andre Roberts² and Juliet Hodges³, (1)Applied Analysis Solutions LLC, United States, (2)Unilever, United Kingdom, (3)Safety & Environmental Assurance Centre, Unilever, United Kingdom

We present a global, high-resolution dataset of dilution factors (DFs) for chemical risk assessment in rivers, improving spatial and temporal resolution compared to existing datasets. DFs are critical for estimating environmental concentrations of contaminants discharged from wastewater treatment plants (WWTPs) into river systems. Currently, DFs used in chemical risk assessments are limited by spatial resolution, temporal depth, and methodology transparency. DFs individual river segments tend to vary according to natural variability in stream flow over time, and spatially across a landscape underscoring how the utility of a single default screening level DF is limited for refined environmental risk assessments. This work addresses these gaps by developing an up-to-date global DF dataset using high-temporal resolution hydro-environmental data and robust geospatial processing.

The dataset integrates HydroSHEDS river networks, HydroWASTE WWTP locations, and FLO1K flow grids representing annual mean and lowest monthly flows for 56 years. All FLO1K grid cells overlapping each river segment were analysed and a representative flow point (i.e., grid cell) selected.

DFs were computed as the ratio of river flow to WWTP discharge and summarised at multiple spatial scales (country, basin, administrative units) and temporal dimensions (annual, 30-year averages, and percentiles):

- 1: Raw STP-linked flow and discharge data annually.
- 2: Processed STP-level DFs with temporal percentiles (5th–95th).
- 3: Aggregated summaries by country and basin, including filtered datasets for rivers >0.1 cubic meters per second flow (best practice).

Global results reveal extreme variability in dilution potential: median DFs range from <10 in arid regions to >10⁷ in high-flow systems (for rivers exceeding 0.1 cms flow). Results also revealed considerable temporal variability over a 56-year window for individual rivers, highlighting the value of utilizing a range of flow values for DF generation. This work emphasizes the importance of spatially and temporally explicit DF estimates for

chemical risk modelling. The dataset supports probabilistic exposure assessments informing regulatory frameworks by providing transparent, reproducible metrics. By presenting both methodology and data, this novel work establishes a benchmark resource for environmental safety evaluations, enabling integration into contaminant fate models and supporting global initiatives on water quality and chemical risk.

3.02.P-We198 Monitoring and Modelling Exposure to 6-PPD Quinone in UK Rivers

Alistair Boxall¹, Martha Villamizar¹, Jun Li², Angelica Pardo Islas¹, Ivo Pink³ and Sim Reaney³, (1)University of York, United Kingdom, (2)University of York, United States, (3)Durham University, United Kingdom

6-PPD is a chemical antioxidant used in tyres to prevent degradation and extend the tyre's lifespan. Following release, it reacts with ozone to form 6-PPD quinone (6-PPDq) which can then be transported to surface water. The presence of 6-PPDq in highway runoff in the North-West of the United States has been linked to impacts on Coho salmon. While the UK, is a heavily populated country with areas of high traffic density, the occurrence and risks of 6-PPDq in the country have yet to be established. The aim of this study was to develop and evaluate a high temporal and spatial exposure assessment model for 6-PPDq and other highway-derived pollutants in UK surface waters. The model, which was developed for the Yorkshire region in England, utilised information on traffic densities, 6-PPD release rates, rainfall alongside a hydrological model and a river model to estimate concentrations of 6-PPDq in 16,000 sub-basins across Yorkshire. Alongside the modelling, continuous monitoring of surface water was performed at 19 locations across the region to generate weekly data on the occurrence of 6-PPDq to provide a dataset to evaluate the model. In the monitoring study, 6-PPDq was detected in 27% of the samples obtained and in between 70-80% of samples from the more urbanised monitoring locations. Maximum measured concentrations were seen in the more urbanised areas and were in the low ng/l range. Comparison of model predictions with the monitoring results showed model predictions to be fair and ranging from 1.3 to 6.6 times higher than the observed concentrations. Use of the model for the 16,000 sub-basins showed that more than 95% of sub-basins had concentrations lower than 5 ng/l but there were some situations where levels were high. The sub-basin with the highest exposure concentration had an annual average concentration of 72 ng/l and a peak concentration of 3500 ng/l. Our modelling approach provides a useful approach for characterising exposure and risks of 6-PPDq and other highway-derived contaminants and for identifying hotspots of exposure.

3.02.P-We199 Now You See It, Now You Don't: Describing Patterns in Environmental Chemicals at the Edge of Detection

Michael John Dunbar, Environment Agency, England, United Kingdom

Since the 19th century, analytical chemists have known about the concepts of limits of detection (LoD) and minimum recorded value (MRV). To summarise environmental chemistry data containing 'less-thans', we can use statistical techniques that inherit from epidemiological and actuarial science. Yet we want to move beyond data summaries to get the most from messy real-world monitoring data that vary in frequency across multiple sites: patchy datasets with a potentially high proportion of observed 'less-than' concentrations. We want to derive trends in chemical exposure for comparison with environmental standards. And at broad scales we want to gauge the success of policy and warn of emerging risks. We must avoid artifacts arising from changes in LoD/MRV as analytical methods have improved and would prefer to calculate confidence intervals for our estimates. Fortunately all this can be achieved within the broad statistical framework of generalised additive mixed modelling.

We present an approach for the analysis of trends in left-censored (containing less-than) chemical concentration time series from multiple river water monitoring sites with data gaps and varying sampling frequencies. We:

1. Incorporate spatial structure;
2. Describe observed concentration data not by a single number but as two columns indicating upper and lower boundaries. Behind the scenes, less-than values are treated as cumulative rather than point density estimates of probability.
3. Let the data describe potential non-linearities in an efficient manner;
4. Decompose the trend into annual and seasonal components;

5. Manage temporal correlation, but with monthly (or less) frequencies this is often not an issue;
6. Produce trends across multiple spatial scales from national down;
7. Derive optimal site-level predictions, even for sites with minimal data;
8. Optionally attempt to explain spatial and temporal patterns using sample and site-level covariates.

Using data for dissolved metals and trace organic chemicals, we illustrate how trends can emerge incrementally from the 'mess' of the raw data. We illustrate how, when analysed incorrectly, such trends can be biased, overly-certain or just missed. Implementing such approaches programmatically allows us to automate, reproduce and re-use the data extraction, analysis and graphical presentation. In England, while trends in metals and some organic chemicals are clearly downwards, this is not universally the case.

3.02.P-We200 Assessing the Significance of Heteroaggregation in Environmental Fate as a Tool for Nanoparticle Grouping

Szymon Swiatek Brzezinski, Michał Kalapus and Tomasz Puzyn, Laboratory of Environmental Chemoinformatics, Faculty of Chemistry, University of Gdańsk, Poland

Engineered nanoparticles (ENPs) introduced into aquatic environments are simultaneously subject to multiple removal processes, such as dissolution, sedimentation, advection, and aggregation. One of the main challenges in assessing the environmental fate of nanomaterials is accounting for aggregation processes.

In this study, we examined for which nanoforms heteroaggregation constitutes a sufficiently dominant process to shape their environmental behaviour. The analysis covered the aggregation propensity of 36 inorganic types of ENPs, each considered across multiple combinations of particle size and zeta potential. Using DLVO theory, attachment efficiencies (α) were estimated over a wide range of environmental conditions and subsequently incorporated into an environmental fate model. This enabled a direct comparison of aggregation rates with the kinetics of competing processes.

The results show that the likelihood of aggregation dominance varies widely — from a few to 100% — and depends on material composition, particle size, and zeta potential. Aggregation is nearly certain for metals and for small nanoparticles with near-neutral zeta potential, while its significance decreases with increasingly negative surface charge and varies depending on the bonding between atoms.

The analyses led to the development of a five-tier classification scheme that groups nanoparticles according to their expected environmental behaviour. The scheme enables rapid distinction between colloidally stable materials and those prone to aggregation. This tool aligns with current regulatory needs by providing criteria that support grouping and prioritisation of nanomaterials in environmental risk assessment.

3.02.P-We201 Comparative Assessments of Environmental Plastics by Exposure Metrics in UTOPIA Modeling Scenarios

Xiaoyu Zhang¹, Maria del Prado Domercq² and Matthew MacLeod¹, (1)Stockholm University, Sweden, (2)Environmental Science, Stockholm University, Sweden

Plastics are persistent environmental pollutants of increasing concern due to their extensive use and inadequate waste management. Once released into the environment, weathering processes promote their fragmentation into macro-, micro-, and nano-scale particles, which can interact with organic matter and microorganisms to form aggregates. Plastic fragments smaller than 100 μm might also biomagnify in coastal marine food webs, posing potential health risks to organisms. The environmental fate and transport of these plastics vary widely due to differences in particle shape, size, and density, and a wide variety of processes determine the environmental fate and lifetimes of plastic. Sustainability indicators have been proposed to guide plastic eco-design in terms of product lifetime or resource costs, however, metrics are also needed to assess environmental exposure to plastics. To address this gap, this study evaluates several possible exposure metrics for plastic pollution, including persistence and residence time, emission fractions, and committed dose to evaluate aspects of environmental exposure including reversibility and long-range transport potential. These metrics have been integrated into the UTOPIA unit-world model, which simulates the fate and transport of plastics with diverse physical properties, and can be used to comparatively assess environmental exposure to different plastics. Global sensitivity analysis with Monte Carlo simulations is applied to identify which particle characteristics most strongly influence exposure potential according to each metric. The results provide a quantitative modeling

perspective for the eco-design of next-generation plastics, offering insights into how physical properties can be optimized to reduce environmental persistence and exposure.

3.02.P-We202 The Emission and Spread of Tyre Wear Particles

Lout Kuiper¹, Shaya Algoe² and Clara van der Heijden¹, (1)Sweco, Netherlands, (2)No Affiliation, Netherlands

Tire wear is the main source of microplastics in the Netherlands; most is released directly into the environment from traffic. Tire wear particles (TWP) consist of natural and synthetic rubbers and additives that may be harmful. When TWP reach vulnerable sites such as agricultural land or playgrounds, they can pose health risks. Sweco developed a spatial model using a Multi-Criteria Analysis (MCA) to map risks and identify hotspots. This study refines that model by estimating concentrations instead of distance-based risk factors and by applying transport equations to make dispersion visible. This allows exposures at vulnerable sites to be determined more precisely and helps policymakers set priorities.

Methods

Emissions per m² of road were calculated with an FME workflow that links BGT road segments to speed limits and vehicle?kilometers by road and vehicle type. Additionally, emissions per vehicle?kilometer were based on three road categories: motorway, non?urban, and urban. This resulted in a map of different emissions per road type. The emission map was combined with layers of vulnerable sites.

For transport simulation we are developing an FME/Python model that couples the Shallow Water Equations (SWE) to mass?transport equations, discretized with the Finite Difference Method (FDM). This approach has been applied to microplastics and other contaminants, but not previously specifically to in situ TWP. Roads and their immediate surroundings were classified by land cover. Because TWP dispersal typically remains within about 30 m, the computational domain is limited to reduce runtime.

Results and discussion

Motorways emit far more TWP: roughly 20× more than urban roads and 6× more than non?urban roads. However, high road density in built-up urban areas can cause accumulation, producing locally high concentrations and exposing vulnerable locations such as schools. The next step is time?dependent transport modelling; initial results are expected by the end of December.

Conclusion

Shifting to concentration estimates and transport modelling makes exposures more concrete. Accumulation in densely built urban areas with high road density can lead to unexpectedly high TWP concentrations, which supports targeted mitigation and prevention.

3.02.P-We203 Comparison of exposure modelling tools used in different regulatory areas

Heike Schimmelpfennig¹, Andrea Brunswik-Titze² and Elena Perabo², (1) Brill Regulatory Services, Finland, (2)Hydrotox GmbH, Germany

In the frame of different regulatory areas of chemical substances (e.g. REACH, plant protection products, biocides) modelling tools are used for performing environmental risk assessment of these substances, requested under the respective regulation. The modelling tools predict in a first step the release of chemical substances into different environmental compartments after their use or during their service life. In a second step the modelling tools take into account the fate and distribution of chemical substances after release to different environmental compartments and predict an environmental concentration in different compartments. Depending on the regulatory area, the focus is on different environmental compartments and different release pathways.

We will give an overview on currently available standard tools and their use, also for the assessment of specific environmental compartments (e.g. FOCUS tools to simulate the release to groundwater or SimpleTreat to model a sewage treatment plant).

We further will show the limitations of such models for specific substances groups and will show recent and current developments of new IT tools. This includes also tools which attempt to cover different regulatory areas (e.g. Chesar platform for REACH and biocides). We will compare the models as far as possible in regard to

their input parameters, background distribution models and their output. One additional aspect is the flexibility of such models to replace default values with monitoring data in order to increase the realism of these tools and their predictions.

3.03 Advancing Environmental Monitoring through Ion Mobility Spectrometry coupled to HRMS: Innovative Strategies and Applications

3.03.T-01 Ion-mobility derived CCS-m/z trendlines for environmental contaminant screening – where are we and where can we go?

Lidia Belova, Maosen Zhao, Maarten Roggeman, Giulia Poma, Celine Gys, Paulien Cleys, Fatima den Ouden, Adrian Covaci and Alexander van Nuijs, University of Antwerp, Belgium

Ion mobility high-resolution mass spectrometry (IM-HRMS) derived collision cross section (CCS) values are a valuable additional identification parameter in suspect and non-target screening analysis (SSA/NTS) of legacy and emerging environmental contaminants. The utilization of CCS data is of special interest for contaminant classes occurring in homologue series as these show class-specific CCS-m/z trendlines. While the use of these trendlines for compound annotation has been documented in the context of per- and polyfluoroalkyl substances (PFAS), their applicability for the annotation of other classes of environmental contaminants remains largely unexplored.

The presented study focused on an extensive SSA study of >80 indoor dust samples collected at different locations (private housing, kindergartens, public buildings) in Belgium. After extraction and analysis by liquid chromatography drift-tube IM-HRMS, the obtained data were matched with a suspect list containing > 4000 compounds, covering various classes of indoor contaminants. Phthalates remained one of the major annotated classes showing the highest detection frequencies and semi-quantified concentrations. Alongside legacy phthalates identified at confidence level (CL) 1, annotated suspect phthalates covered homologue series with side chains ranging between C1 (dimethyl phthalate) and C12 (didodecyl phthalate). Additionally, homologue series of benzyl alkyl phthalates with varying side chains were annotated. Nevertheless, annotations were hampered by the occurrence of several isomeric structures for each homologue, resulting from differently branched side chains, allowing only an CL 3 annotation. Therefore, DTCCSN2 values were obtained for all analytes and were used to describe the corresponding CCS-m/z trendlines. For all suspect CECs, the experimental CCS values fell within the 95th percent confidence interval calculated for the CCS-m/z trendline deriving from available reference standards, contributing significantly to the confidence of the compound annotation. The reproducibility of observed trendlines was assessed between sample batches collected at different locations. The data is currently being evaluated aiming to characterize CCS-m/z trendline of additional emerging contaminant classes. On the basis of these examples, a discussion on an appropriate communication of the added identification confidence is conducted.

3.03.T-02 Holistic analysis of emerging contaminants in northern Antarctic Peninsula region waters through Liquid Chromatography–Ion Mobility Spectrometry–High-Resolution Mass Spectrometry

Dana Orlando-Véliz¹, Georgios Gkotsis², Cristina Postigo³, Jerónimo López-Martínez⁴, Thomas Schmid⁵, Luis Moreno-Merino⁶, Nikolaos S. Thomaidis⁷ and Miren López de Alda¹, (1)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (2)National and Kapodistrian University of Athens, Greece, (3)University of Granada, Spain, (4)Universidad Autónoma de Madrid, Spain, (5)Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas -CIEMAT, Spain, (6)Spanish Geological Survey CN IGME (CSIC), Spain, (7)National and Kapodistrian University of Athens, Spain

The Antarctic Peninsula region is among the most remote and least populated regions on Earth. Despite the protective measures to safeguard its fragile ecosystem and geographic isolation, anthropogenic pressures are increasing. Early research provided evidence on the presence of persistent organic pollutants, capable of long-range environmental transport in such a remote area. In recent years, the occurrence of contaminants of emerging concern (CECs) has also been flagged and linked to human activity taking place in the region. These findings are based on targeted studies examining a limited range of compounds, leaving a significant gap in the comprehensive characterization of water chemistry pollution. To address this issue, advanced analytical techniques based on wide-scope target screening and non-target analysis (NTA) by means of liquid chromatography coupled with hybrid ion mobility spectrometry - high resolution mass spectrometry were applied to the analysis of 19 water samples collected from ice-free areas of Deception, King George, and Livingston Islands (South Shetlands archipelago). These methods support retrospective analysis, providing a broad-spectrum detection of compounds not previously identified or anticipated. Incorporating ion mobility adds a complementary dimension to compound identification, enhancing confidence in NTA results. A semi-

quantitative approach has also been employed to assess environmental risk. In total, 88 compounds were detected in at least one sample with different identification confidence levels: 53 of them were confirmed with reference standards (Level 1), 28 matched with spectral libraries (Level 2A), and 7 were annotated with Level 3, following the Celma et al. (2020) criteria. Ion mobility data enabled the identification of conformational isomers, such as adenosine, and differentiation of isobaric compounds like paraxanthine and theobromine. Most compounds presented concentrations in the ng/L range (91.8%), although a few of them reached the µg/L level. Industrial chemicals, personal care products, and naturally occurring substances showed the highest levels. Diethyl phthalate, currently listed for endocrine disruptor assessment, was the most abundant and widespread compound. Regarding aquatic environmental risk, only 15 of the identified compounds showed some occasional (usually in only 1 or 2 samples) high risk (RQ > 1).

3.03.T-03 Advancing GC-APCI-TIMS-HRMS for Dioxins and POPs: A Comparative Evaluation of timsTOF Pro 2 and timsMetabo as Alternatives to Magnetic-Sector Instruments

Gauthier Eppel¹, Hugo Muller², Georges Scholl³, Carsten Baessmann⁴, Birgit Schneider⁴, Dimitrios E. Damalas⁵ and Nikolaos S. Thomaidis⁵, (1)CART-National Reference Laboratory for Halogenated POPs and Food Process Contaminants, MolSys Research Unit, Liège University, Belgium, (2)University of Liège, Belgium, (3)MolSys Research Unit, Liège University, Belgium, (4)Bruker, Germany, (5)National and Kapodistrian University of Athens, Greece

Magnetic-sector GC-HRMS remains the regulatory reference for dioxin quantification due to its high selectivity and sensitivity. However, its high cost and limited accessibility restrict global monitoring capacity. Recent advances in high-resolution GC-APCI-TIMS-HRMS provide a promising alternative. In previous work, we demonstrated that GC-APCI coupled to the timsTOF Pro 2 platform enables sensitive and confident determination of dioxins, and PCBs within a single analytical run. Building upon these validated results, the present study extends and enhances this framework by incorporating the next-generation timsMetabo platform, a small-molecule-optimized TIMS-QTOF system offering improved ion transmission and expanded mass/mobility range coverage.

A standardized GC-APCI workflow (35 min, 60 m × 0.25 µm column) was applied to both instruments to evaluate quantitation and identification performance for the 29 toxic dioxin, and PCB congeners, alongside additional POP classes. served as the reference platform, reflecting previously validated capabilities aligned with regulatory expectations for HRMS mass accuracy, retention-time stability, isotope-ratio agreement, MS/MS qualifier ion confirmation, CCS-based filtering, and Kendrick mass defect analysis. For the timsMetabo, data acquisition using the Mobility Range Enhancement (MoRE) mode, provided improved sensitivity and broader ion coverage. These enhancements particularly benefited congeners at the extremes of the mass range and species typically affected by transmission limitations, while also offering refined mobility separation and increased CCS precision.

Across both platforms, the workflow enabled robust quantitation of POPs in accordance with EPA 1613B and EN 1948 requirements. Detection limits for PCBs remained in the 10–20 ppt range, while timsMetabo allowed further improvements for several dioxin congeners. Real-sample applications (food and environmental matrices) confirmed the analytical reliability and showed the additional value of timsMetabo for challenging low-abundance analytes.

Overall, this evaluation demonstrates that GC-APCI-TIMS-HRMS is a viable and flexible alternative to magnetic-sector MS, with timsTOF Pro 2 providing a validated baseline and timsMetabo offering improved sensitivity and extended mass coverage for comprehensive multi-class POP analysis.

3.03.T-04 LC-IM-HRMS and Computational Methods for Characterization of Metal-Phytosiderophore Complexes in the Gas Phase

Stephan Hann¹, Laura Zellner², Christian Klampff², Younes Valadbeigi³ and Tim Causon¹, (1)BOKU University, Austria, (2)Johannes Kepler University Linz, Austria, (3)Imam Khomeini International University, Iran, Islamic Republic Of

Phytosiderophores (PS) released by graminaceous plants are root exudates that play a crucial role in the acquisition of micronutrients, particularly iron. Upon release into the rhizosphere, PS can also complex other metals present in the soil environment, potentially influencing their mobility and uptake, which may also lead to implications regarding safety of food and plant derived food additives.

Characterizing intact metal-PS complexes remains analytically challenging and so far, only a limited number of selected PS complexes have been investigated, primarily through targeted spectroscopy, mass spectrometry or electrochemical approaches. We will present a workflow using a mixed-mode stationary phase to separate 2'-deoxymugineic acid (DMA), mugineic acid (MA) and 3''-epi-hydroxymugineic acid (epi-HMA) and their complexes with Fe(III), Cu(II) and Ni(II). DTCCSN2 values were determined on two drift tube ion mobility systems in different labs using LC separation or direct infusion.

The DTCCSN2 values of the complexes were determined with excellent reproducibility (RSD $\leq$ 0.15%) across laboratories. These values were in linear relationship with the m/z of the investigated ligands and increased with the number of additional hydroxyl groups. Moreover, an inverse correlation of the ionic radii of the central atoms with the DTCCSN2 of the complexes was observed.

For better understanding correlations of metal-PS complex DTCCSN2 with other physical-chemical properties, such as the ionic radii of the central atom or the chemical structure of the organic ligands, DFT calculations were performed yielding optimized ion geometries and DTCCSN2 values predicted for all metal-PS compounds with excellent agreement to experimental values.

Disclaimer/Disclosure:

Eva Oburger (BOKU University, Institute of Soil Research) is acknowledged for providing phytosiderophore compounds.

3.03.P Advancing Environmental Monitoring through Ion Mobility Spectrometry coupled to HRMS: Innovative Strategies and Applications

3.03.P-Th036 Optimisation of a Liquid Chromatography-Trapped Ion Mobility-Time of Flight Mass Spectrometry Method for Suspect and Non-Targeted Analysis of Per- and Polyfluoroalkyl Substances in Fish

Stelios Papazoglou, Bruno Le Bizec and Gaud Dervilly, LABERCA, Oniris, INRAE, France

Per- and polyfluoroalkyl substances (PFAS) are a large and chemically diverse group of persistent contaminants that accumulate in biota and remain analytically challenging, particularly when linear and branched isomers co-elute with other halogenated species in complex matrices such as fish. This study aimed to develop and optimise a liquid chromatography-trapped ion mobility-time of flight mass spectrometry method using parallel accumulation serial fragmentation (LC-TIMS-QTOF PASEF) in negative electrospray mode for PFAS suspect screening and collision cross section (CCS) determination, and to assess the transferability of CCS values across different ion mobility platforms. From an initial panel of 105 PFAS standards, 36 compounds spanning a wide range of polarity, mass, CCS and functional classes were selected as an optimisation set. Key TIMS parameters, including accumulation time, mobility ramp, ion transfer settings and number of PASEF scans per cycle, were systematically adjusted to balance sensitivity, ion mobility resolving power and CCS precision. Application of the final method to the full PFAS panel provided reproducible CCS values and enabled partial separation of branched and linear isomers in the mobility dimension. Two complementary travelling-wave ion mobility spectrometry (TWIMS) methods were then implemented on a Synapt G2-Si to cover the full structural diversity of the PFAS panel, enabling subsequent assessment of CCS transferability across platforms. CCS values obtained by TIMS and TWIMS agreed within approximately 2%, consistent with well-calibrated ion mobility platforms. The resulting PFAS CCS database, combined with curated suspect lists, a fully vendor independent data processing workflow and an ion-mobility-based confidence framework, was applied to support non-targeted PFAS annotation in fish extracts. In this context, CCS values and mobility trends helped refine candidate lists and uncover PFAS beyond routine monitoring panels, including emerging and under-characterised compounds relevant for exposure assessment and future environmental biomonitoring.

3.03.P-Th037 Closing Sensitivity Gaps Across the Mass Range: Evaluation of a new Trapped-Ion-Mobility- QTOF MS for Emerging Contaminants Screening

Dimitrios E. Damalas¹, Georgios Gkotsis¹, Konstantina Diamanti², Birgit Schneider³, Carsten Baessmann³ and Nikolaos S. Thomaidis¹, (1)National and Kapodistrian University of Athens, Greece, (2)Chemistry, National and Kapodistrian University of Athens, Greece, (3)Bruker, Germany

The accurate characterization of emerging contaminants (ECs) in complex environmental and biological matrices is often limited by their vast number, trace concentrations and severe matrix interferences. Highly sensitive, multidimensional LC-HRMS workflows are required to reduce false negatives and enable comprehensive identification, particularly for analytes in the low (<200 Da) and high (>750 Da) m/z ranges, where conventional LC-HRMS platforms often suffer from reduced ion transmission and coverage. In this study, we evaluate a new small-molecule-oriented LC-TIMS-QTOF platform (timsMetabo) for targeted and untargeted screening of ECs and PFAS in wastewater, surface water and biota. A complex standard mixture containing >400 contaminants and a set of real samples were analyzed on both a timsTOF Pro 2 and timsMetabo. We specifically investigated the impact of key hardware and acquisition innovations of timsMetabo, like the Mobility Range Enhancement (MoRE) mode, an improved high-precision quadrupole and the Athena Ion Processor (AIP) system, on ion sensitivity and mass/mobility range coverage. MoRE exploits the full length of the dual TIMS tunnel by performing ion accumulation and mobility separation in successive stages, extending the effective mobility range per scan and increasing ion throughput, particularly in the low-m/z region. The AIP, an additional RF/DC ion-optical stage downstream of the collision cell, dynamically optimizes ion transfer to the TOF analyzer across the full mass range, while the redesigned TIMS funnel increases ion capacity and transmission. For 315 ECs monitored across both platforms, timsMetabo delivered systematically higher signal intensities, with gains up to eightfold below m/z 300, an m/z region containing 60% of the investigated analytes. In complex wastewater and biota extracts, these improvements translated into higher feature counts, improved signal-to-noise ratios and richer MS/MS spectra, resulting in an increased number of confidently identified compounds and a reduced likelihood of false negatives across the mass range. Overall, timsMetabo operated with MoRE provides improved sensitivity and extended low-mass coverage compared to the previous generation platform. The resulting enhancement in data quality and depth strengthens LC-TIMS-HRMS workflows for environmental monitoring, supporting more comprehensive and reliable identification and prioritization of contaminants of environmental and toxicological concern.

3.03.P-Th038 Spatial mapping of PFOS and PFOA reveals differential bioaccumulation patterns in zebrafish via DESI-MSI with single- and multi-pass ion mobility separation

Emmanuelle Claude¹, Matthew Smith², Angélica Diaz Basabe², Joanne Ballantyne¹, Craig Wheelock² and **Aron Dekkers¹**, (1)Waters Corporation, United Kingdom, (2)Karolinska Institute, Sweden

Introduction:

A toxicological concern of PFAS chemicals is their ability to bioaccumulate, leading to chronic exposure even at low environmental concentrations. Mass spectrometry imaging (MSI) enables the mapping of molecules directly in tissues. Here we use desorption electrospray ionization (DESI) combined with a Q-ToF mass spectrometer combined with ion mobility to evaluate the distribution of PFOS and PFOA in zebrafish exposed in PFAS-spiked water.

Methods:

Zebrafish were divided into 3 groups, 1 male and 1 female per group. They were placed in 2L plastic tanks filled with 1L of water. The groups were: 1) Control, 0.1% DMSO; 2) PFOA 10 µM; 3) PFOS 10 µM. Water was changed daily for seven days. Fish were sacrificed by thermal shock and embedded in 3% CMC for spatial analysis.

Results and Discussion:

Zebrafish were cryo-sectioned onto standard glass slides at a thickness of 18 µm and stored at -80°C until analysis using a DESI XS source mounted on a SELECT SERIES Cyclic IMS mass spectrometer. The DESI MSI analyses were performed in single pass IMS untargeted full scan MS mode to enable detection of PFAS. In negative mode, the ion mobility of PFAS species can be easily distinguished from singly charged tissue endogenous molecules, which have a longer drift time compared to PFAS ions that increase the peak capacity

for PFAS detection. PFOS was detected as its intact [M-H]⁻ ion, whereas PFOA fragmented with the loss of CO₂, giving [PFOA-CO₂-H]⁻ as the most abundant peak. PFOS was distributed throughout the zebrafish, but it was primarily accumulated in the gills, digestive system and surrounding the eye, whereas PFOA was mainly localised in the gills and less into the digest organs. Using a TWIMS cyclic device, following several passes of ion mobility separation, it was possible to optimise the number of passes to differentiate the linear and branched PFOS chemical standard that was used in the water spike. The IMS sequence was then used for the DESI MSI on the zebrafish enabling visualisation of the different isomers.

Conclusion

Using the IMS single pass, untargeted MSI experiments were performed to be able to localize PFOS and PFOA-CO₂ in zebrafish and evaluate their bioaccumulation. It was possible to visualize the distribution of metabolites and lipids within the same experiment. Furthermore, using the IMS multi-passes functionality within the cyclic IMS, linear and branched PFOS isomers were separated and localized in the contaminated zebrafish.

3.03.P-Th039 Illustrating the Use of Cyclic Ion Mobility to Enhance Specificity for branched-PFAS

Isomer Analysis

Michael Andrew McCullagh¹, Stuart Adams¹, Emma Marsden-Edwards², Isabel Riba Dr² and Hania Hollins², (1)Waters Corporation, Germany, (2)Waters Corporation, United Kingdom

Per- and polyfluoroalkyl substances (PFAS) are widely used chemicals with significant environmental and health concerns, particularly due to the complexity introduced by branched isomers such as those of perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS). This study demonstrates the application of LC-cIM-MS using the SELECT SERIES™ Cyclic™ Ion Mobility Mass Spectrometer to resolve and characterize PFAS isomers with enhanced specificity.

Travelling wave ion mobility (TWIM) collision cross section (CCS) values were measured for PFAS standards and showed excellent agreement (Δ CCS <0.7%) with drift tube and trapped ion measurements, confirming CCS reliability for transferable PFAS analysis. Chromatographically coeluting branched isomers were successfully separated using ion mobility-enhanced peak capacity, and multipass cyclic IMS improved resolution from R~65 to R~145, delivering an eight-fold increase in peak-to-peak resolution (RsP-P). Single-component fragmentation spectra enabled structural elucidation of branched PFOS byproducts, while PFOA isomer dimers provided additional specificity.

These findings highlight LC-cIM-MS as a robust, non-targeted screening approach for confidently identifying known and unknown PFAS isomers, supporting environmental monitoring and exposomics studies where differentiation of isobaric and isomeric species is critical.

3.03.P-Th040 Conformational Effects of Monovalent Cations on PFCA Homodimers Investigated by IMS-MS/MS and Theoretical Calculations

Aurore Schneiders¹, Johann Far², Edwin De Pauw², Lidia Belova³, Adrian Covaci³ and Gauthier Eppe², (1)University of Liège, Belgium, (2)Mass Spectrometry Laboratory, University of Liège, Belgium, (3)University of Antwerp, Belgium

Per- and polyfluoroalkyl substances (PFAS) are contaminants of emerging concern requiring non-targeted screening to identify novel species. When analyzed by liquid chromatography coupled to ion mobility-mass spectrometry (LC-IMS-MS), some PFAS, such as perfluorocarboxylic acids (PFCAs), form noncovalent proton-bound homodimers, raising questions about the conditions under which such aggregates form, their structures, and how cation binding influences their conformation. While proton-bound dimers have been previously characterized, the structural implications of replacing the proton with larger monovalent cations remain unclear. To address this, PFCA homodimers bound to Li⁺, Na⁺, K⁺, and Cs⁺ were analyzed using three IMS platforms: drift-tube IMS, trapped IMS, and traveling wave IMS (DTIMS, TIMS, TWIMS). Experimental collision cross-section (CCS) values were compared across instruments, and relative binding strengths were assessed through energy-resolved collision-induced dissociation (CID, also known as breakdown curve experiments). Three-dimensional structures were generated and evaluated by predicting CCS values via the trajectory method in nitrogen. Fragmentation pathways were examined to further support structural hypotheses.

CCS measurements for all cation-bound dimers were consistent across instruments (within 2% deviation) and increased with cation size, though the magnitude of this increase depended on chain length. This behavior suggests that CCS differences cannot be explained solely by mass increase and instead suggests structural rearrangements of the monomeric chain after cation binding. Quantum-chemistry results indicate that

fluorinated chains tend to fold toward the cation coordination site, similar to proton-bound dimers, at least in the case of sodium (the structures with the other cations still need to be computed). Breakdown curves and identified fragmentation channel support the proximity of a fluorine atom in agreement with theoretical modeling.

Overall, these results suggest that PFCA chains remain in close contact upon cation binding and that ion identity influences aggregate structure and stability. Final V_{50} values (acceleration voltage used during CID, which induces 50% fragmentation of the initial intensity of the precursor ion) and additional theoretical structural determination will further clarify the relationship between cation size, binding energetics, and dimer conformation.

3.03.P-Th041 Atmospheric PFAS Partitioning and Source Attribution Using a Trajectory-Informed Non-Targeted Approach: Insights from Seoul

Mina Do¹, Syed Wasim Sardar² and Jun-Tae Kim², (1)University of Science & Technology, Korea, Republic of, (2)Korea Institute of Science and Technology (KIST), Korea, Republic of

Poly- and perfluoroalkyl substances (PFASs) are synthetic chemicals widely used in industrial and consumer products. Their persistence, resistance to degradation, and potential toxicity raise concerns regarding their environmental fate and transport. This study investigates atmospheric PFAS concentrations in Seoul, Korea, focusing on their gas/particle partitioning behavior. A total of 21 atmospheric samples were collected from February 10 to June 20, 2024, using a High-Volume Air Sampler. Particulate matter was captured on Quartz Fiber Filters (QFF), while gas-phase compounds were collected using polyurethane foam (PUF)/activated carbon felt (ACF)/PUF blocks. The samples were analyzed by HPLC-MS/MS. Total PFAS concentrations ranged from 8.891 to 168.0 pg/m³ (mean: 51.68 pg/m³, median: 30.13 pg/m³). Overall, short-chain PFASs (C₇) exhibited higher concentrations than long-chain PFASs (C₂₈). For example, the concentrations of PFPeA (0.9160 pg/m³) and PFHxA (0.3095 pg/m³) were higher compared to PFDA (0.0767 pg/m³) and PFUnDA (0.0650 pg/m³). Phase-distribution analysis showed that PFBA (74%) and PFBS (99%) were predominantly in the gas phase, whereas PFOA (53%) and PFOS (80%) were more commonly found in the particle phase. The gas/particle partitioning indicated that short-chain PFASs are more volatile and likely to undergo long-range transport, whereas long-chain PFASs exhibit a stronger tendency to adhere to particulate matter and deposit locally.

In addition to target analysis, non-target screening (NTS) was conducted using high-resolution mass spectrometry to explore unknown PFASs in the atmosphere. Orbitrap-MS data were processed through the FluoroMatch Modular workflow, and 43 features with confidence level C or higher were identified. These features include many compounds that are not reported in existing databases, suggesting the presence of novel or transformation-derived PFASs. Multivariate analysis using Partial Least Squares Discriminant Analysis (PLS-DA) enabled differentiation of chemical profiles by air mass origin and revealed source-specific PFAS candidates. This integrated approach combining targeted quantification and NTS-based discovery highlights the complexity of airborne PFAS mixtures and underscores the necessity for comprehensive monitoring strategies.

3.03.P-Th042 Enabling In Vitro Studies of Difficult to Test Petroleum-Derived Unknown or Variable Composition, Complex Reaction Products, or Biological Materials with Nanoemulsion-Based Delivery

Devin J Teri, Ibrahim Alshammari, Shounak Roy, Akhilesh Gaharwar and Ivan Rusyn, Texas A&M University, United States

Refined petroleum products (RPPs) are classified as UVCBs (Unknown or Variable composition, Complex reaction products, or Biological materials) and contain diverse polycyclic aromatic compounds with varying hazardous properties. Although these UVCBs are regulated under EU REACH, most have limited compositional and toxicological data for registration. Efforts to use read-across to meet data requirements have been hampered by challenges in establishing chemical similarity and characterizing their compositional variability. To address these gaps, we developed a novel nanoemulsion-based delivery system, adapted from pharmaceutical formulations, to enable cell-based testing of hydrophobic petroleum substances without solvent extraction. Our objective was to compare toxicological responses of light versus heavy petroleum products and to evaluate

delivery performance in vitro. Stable nanoemulsions of light and heavy RPPs, crude oil, and vegetable oil were prepared using 2% Pluronic F-127 as surfactant under controlled shear conditions. EA.hy926 human endothelial-like cells were exposed to 1-50% (v/v) nanoemulsions for 120 hours, and cytotoxicity and metabolic activity were quantified via luminescent viability assays. Post-exposure media and lysates were analyzed by ion mobility spectrometry–mass spectrometry (IMS–MS) to characterize hydrocarbon profiles and cellular uptake. The Pluronic-stabilized nanoemulsions remained stable and reproducibly delivered both light and heavy RPPs to cells. Light aromatic RPPs (C9-C16 hydrocarbons) caused concentration-dependent decreases in viability, indicating higher cytotoxic potential. In contrast, heavy hydrogen-treated RPPs (C20-C50 saturated hydrocarbons) elicited no cytotoxicity across comparable exposures. These divergent cellular responses align with expected in vivo hazard profiles. IMS–MS analysis confirmed differential composition and bioavailability between products. This work establishes a feasible and reproducible nanoemulsion-based system for in vitro assessment of complex petroleum UVCBs, overcoming solubility and delivery barriers typical of hydrophobic substances. The approach enables mechanistic evaluation of toxicity, supports read-across justification, and advances hazard characterization of petroleum-derived mixtures under REACH and related regulatory frameworks.

3.03.P-Th043 Nontarget Identification of Contaminants of Emerging Concern in Campus Indoor Dust Using Ion Mobility High-Resolution Mass Spectrometry

Maosen Zhao¹, Lidia Belova¹, Yiming Yao², Giulia Poma¹, Alexander van Nuijs¹ and Adrian Covaci¹, (1)Toxicological Centre, University of Antwerp, Belgium, (2)MOE Key Laboratory of Pollution Processes and Environmental Criteria, Nankai University, China (Mainland)

Contaminants of emerging concern (CEC) are increasingly reported in indoor environment, where people spend most of their time, serves as a major reservoir for contaminants through the accumulation of indoor dust. Industrial additives such as organophosphate flame retardants, alternative plasticizers, and fluorescent brighteners are of particular interest due to their potential human toxicity and structural diversity. However, their identification in complex matrices is hindered by limited availability of reference standards. Ion mobility high-resolution mass spectrometry provides an additional dimension of confidence by incorporating collision cross section (CCS) values.

In this study, indoor dust was collected from multiple functional zones across a university campus in North China. A hybrid screening workflow combining diagnostic fragment filtering with suspect and nontarget screening was implemented to maximize analytical coverage. Automated processing integrated peak detection and alignment, reference databases matching, and in silico fragmentation matching, while ion mobility data enabled calculation of experimental CCS values.

A total of 81 CECs were identified, including 41 confirmed with reference standards and semi-quantified. An additional 40 CECs were identified and assigned at Level 3 or above with supporting evidence. These CECs showed high detection frequencies across all samples, with potential co-occurrence patterns among chemicals sharing similar industrial applications such as antioxidants, food-packaging additives, and polyvinyl-chloride-related additives. Correlations between parent compounds and their corresponding transformation products possibly suggesting common emission sources or in situ degradation. CCS versus m/z trendlines were established for all chemical classes (187 ions across adducts). Distinct class-dependent behaviors were observed, including a pronounced power regression trend for plasticizers and more dispersed distributions for bulkier fluorescent brighteners, reflecting differences in gas-phase structure. Overall, integrating collision cross section trendlines enhanced identification confidence and provided an effective filter for excluding false positives, supporting rapid discovery of unknown indoor dust contaminants.

3.03.P-Th044 Uncovering Chemical Signatures in PM10 Aerosols: Insights from Six Northern Italian Cities Across Two Seasons

Greta Palombella¹, Frederic Béen², Elisa Scalabrin³ and Andrea Gambaro¹, (1)Ca' Foscari University of Venice, Italy, (2)VU University Amsterdam (VU), Netherlands, (3)Polar Sciences Institute, National Research Council, Italy

Atmospheric aerosols, especially the PM10 fraction, are complex matrices composed of inorganic particles, biological material, and thousands of organic compounds originating from both natural and anthropogenic sources. In recent years, mass-spectrometry-based approaches have revealed the presence of numerous emerging contaminants within airborne particulate matter, including transformation products, industrial chemicals, and previously unreported molecular features. Understanding how these chemical signatures vary across locations and seasons is essential for characterizing air quality and identifying potential exposure-relevant compounds. In this study, we investigated whether reproducible chemical patterns can be observed in PM10 aerosols

collected in six cities in Northern Italy, representing three types of environments: two alpine, two urban, and two port areas. For each city, winter (December) and summer (July) samples were collected to assess both spatial and seasonal variability.

After extraction, samples were analyzed using a HPLC-TIMS-TOF system (timsTOF Pro 2, Bruker), leveraging trapped ion mobility separation to improve resolution of isomeric species. Data alignment and feature annotation were performed in MetaboScape (Bruker) using MassBank and NIST databases, followed by blank removal, normalization, and additional processing in R.

Multivariate and unsupervised analyses (including UMAP, hierarchical clustering, and heatmaps) revealed clear grouping patterns. Samples clustered strongly by city and by season, indicating consistent local chemical signatures and pronounced intra-city seasonal shifts. UMAP projections highlighted well-defined separations among the cities as well as between winter and summer aerosols. Ongoing work focuses on identifying the molecular features that drive these differences, with the aim of pinpointing compounds that are characteristic, shared, or unique across environments.

Overall, this study provides an initial framework for characterizing spatial and seasonal variability in PM10 composition and supports the use of ion-mobility high-resolution mass spectrometry to explore emerging contaminants in atmospheric aerosols.

3.03.P-Th045 Assessing & Predicting the Fate of Veterinary Pharmaceuticals & their Transformation Products in Soils and Towards the Aquatic Systems.

Venetios Michelioudakis¹, Leilei Zhang², Christelle Margoum³, Pierre Benoit⁴, Laure Mamy⁴, Luigi Lucini² and Federico Ferarri¹, (1)AEIFORIA SRL, Italy, (2)Università Cattolica del Sacro Cuore, Italy, (3)INRAE, UR RiverLy, France, (4)UMR EcoSys - INRAE, France

Pharmaceutical pollution in soil and aquatic ecosystems poses an increasing threat to environmental integrity, microbial diversity, and ultimately to human and animal health. Veterinary pharmaceuticals and their transformation products are of particular concern, as they enter soils through manure application and agricultural practices, subsequently migrating toward water bodies where they exert toxicity and selection pressure on microbial communities. Despite their importance, the environmental fate of many transformation products (TPs) remains poorly understood, limiting effective risk assessment and mitigation strategies.

This PhD project investigates the migration of Toltrazuril, a veterinary antiparasitic pharmaceutical, by assessing its fate across different environmental matrices (manure, soil, plants, and leachate). Additionally, it explores the plant metabolic response to Toltrazuril exposure. The project also integrates the use of TyPol, a compound classification tool, to enable a priori prediction of transformation products, their behaviour in soil, and their potential transfer to aquatic environments.

These objectives are addressed by (i) combining controlled semi-field degradation and plant uptake experiments, and (ii) conducting mesocosm dissipation studies. The samples are analysed using advanced LC-HRMS targeted methods alongside untargeted metabolomics.

Ultimately, this project aims to strengthen environmental risk assessment frameworks. While abundant information exists on pesticides in soil contamination, the data generated here will help fill the current knowledge gap regarding pharmaceuticals, thereby supporting both regulatory processes and agricultural decision-making.

3.04.A Advancing Understanding of Environmental Persistence of Chemicals

3.04.A.T-01 Biodegradation Testing Beyond Standardized OECD 301 Screening Methods

Glauco Battagliarin¹, Soumya Daturpalli² and Jervis Vermal Thevathasan³, (1)Research Biopolymers, BASF, Germany, (2)BASF, Germany, (3)KIT, Germany

Today persistence assessment relies on OECD testing guidelines that can be subdivided into two categories: stringent, but easy and rapid to perform (ready or inherent) screening biodegradability testing or complex and challenging higher tier simulation tests. In 2025 ECHA published the “Key areas of regulatory challenge” highlighting the existence of a methodological gap between biodegradation screening tests and higher-tier simulation tests.

This work introduces methodological advancements aimed at enhancing the reproducibility and understanding of screening biodegradation tests and addressing gaps between screening and simulation studies. Experimental efforts focused on three different aspects: firstly, optimization of the inoculum treatment to achieve more

reproducible results in OECD 301F or B methods. Secondly, the exploration of different inoculum to test ratios utilizing existing commercially available respirometric test set-ups. The conditions explored span from OECD 301 F/B conditions beyond those utilized for OECD 302 B protocol. Lastly, we investigated the use of microbial adaptation and enrichment experiments in combination with DNA sequencing to understand the role of microbial population in biodegradation tests. The experiments presented have been focusing mostly on water-soluble polymers, to assess the applicability of existing and optimized methodologies to this class of materials. For all tests protocols, testing times have been extended to reach biodegradation plateau.

Our findings highlight strengths and limitations of existing OECD 301 test methods and provide experimental insights on how to further develop biodegradation testing using respirometric methods and microbial cultivation to achieve affordable and reliable biodegradation results for chemicals and water-soluble polymers.

3.04.A.T-02 Regulatory degradation testing of difficult-to-test substances

Prasit Shrestha¹, Anu Maarit Kapanen², Romanas Cesnaitis², Vincent Bonnomet², Stefan Hahn³, Heidi Birch⁴, Philipp Mayer⁵, Susanne Schwonbeck⁶ and Dieter Hennecke⁷, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)European Chemicals Agency (ECHA), Finland, (3)Lower-Saxony, Fraunhofer Institute for Toxicology and Experimental Medicine (ITEM), Germany, (4)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark, (5)Technical University of Denmark (DTU), Denmark, (6)Fraunhofer Institute for Toxicology and Experimental Medicine (ITEM), Germany, (7)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Persistence assessment has a vital role in evaluating long-term risks of chemicals in the environment and human health. It is acknowledged that the testing and the identification of persistent chemical substances, is often challenging and time consuming which hampers efficient identification and management of hazardous substances. These challenges may result from specific physico-chemical properties of the substance leading to difficulties in conducting standard, screening and/or simulation tests relevant for the regulatory assessment or from the complexity of the substance composition causing specific challenges in analytics and interpretation of the results. Biodegradation testing of such substances may require specific precautions or even modifications or adaptation of the standard test guideline methodologies to obtain data adequate for regulatory purposes.

Available guidance to support regulatory degradation testing and persistence assessment of chemicals with difficult-to-test properties and/or of complex composition needs updating. In this presentation, the outcome of the literature review for available modifications in the standardised biodegradation test methods identified for potential regulatory use will be presented.

Four benchmark publications and reports were reviewed and used to list the properties of difficult-to-test substances discussed in each of these publications. The challenges associated with testing, sample processing, chemical analysis, and data treatment in standard biodegradation studies with difficult-to-test substances were reviewed and extracted from the literature. Then detailed targeted literature search was conducted in three databases for scientific literature to identify, as much as possible, all the available relevant publications which propose adapted methodologies or recommendations (e.g. for test procedures or data treatment) for testing the biodegradability of difficult-to-test substances.

The methodological modifications proposed in those publications, together with the challenges they are meant to address are being compiled. The regulatory relevance of those modifications as well as the practical applicability of proposed changes in routine laboratory work will then be assessed. The results of this literature search including modifications identified for potential regulatory use will be collected and presented at SETAC.

3.04.A.T-03 High-Throughput Miniaturized Biotransformation Screening: Method Validation and Robustness Testing

Kathrin Fenner¹, Sarah Partanen² and Chiel Kaal², (1)Environmental Chemistry, University of Zürich, Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag) & University of Zurich, Switzerland

The 2022 European Commission framework entitled “Safe and Sustainable by Design chemicals and materials” emphasizes the need for early assessment of the hazardous properties of chemicals during their design. One such property is environmental persistence, which is commonly evaluated using outdated, time-intensive, and resource-heavy methods. The European Chemicals Agency recently addressed this issue by describing a gap between generic screening methods and complex higher-tier simulation tests, and advocates for high-throughput methods for the assessment of degradation potential of substances under stringent and/or relevant conditions.

To address this, we developed a miniaturized high-throughput method for evaluating chemical persistence using

activated sludge as a microbial inoculum source. Performing the assay in activated sludge allows for a rapid (48 hour) assessment of pollutant primary biotransformation, while avoiding the “microbial lottery”. Our approach combines a 24-well plate format with an eight-minute reverse-phase liquid chromatography runtime and high-resolution mass spectrometry for the high-throughput detection of micropollutants.

Previous experiments validated biotransformation behaviour between the 24 well-plate format and 50mL glass control vessels by applying a library of 33 pesticides and pharmaceuticals. We aimed to expand this validation by analysing a mix that covered a larger chemical space and containing 189 chemicals, consisting of pharmaceuticals, household and personal care products, and pesticides. Good correlation between the scales confirmed the similarity in biotransformation behaviour.

To assess the influence of different activated sludges sources on biotransformation rates, we conducted experiments using sludges from multiple wastewater treatment plants. Approaches to minimize variance or increase robustness included normalization by total suspended solids, universal benchmarking, and categorization using benchmark compounds. On average, normalization using total suspended solids reduced multiplicative variability between sludges.

These results validate the use of the method for a larger chemical space than previously tested. In addition, method robustness was increased by reducing the variance between biotransformation rates. Using the method, a high-throughput assessment of degradation potential of substances in activated sludge can be obtained.

3.04.A.T-04 Linking Assimilable DOC Levels to Microbial Metabolic Strategies and OMP Persistence in Groundwater

Silvana Ines Quiton Tapia¹, Marina Ruiz Vidal¹ and Nora B Sutton², (1)Wageningen University and Research (WUR), Netherlands, (2)Environmental Technology, Wageningen University and Research (WUR), Netherlands

Groundwater microbial communities rely on dissolved organic carbon (DOC) as their primary energy source, yet the role of assimilable DOC (aDOC) in shaping biodegradation processes remains unclear. In oligotrophic conditions, where aDOC typically ranges between 0.01 to 0.1 mg/L, carbon scarcity may constrain metabolic activity and thereby limit the biotransformation of organic micropollutants (OMPs). Previous DOC-amendment studies have reported conflicting outcomes, highlighting the need to clarify how aDOC levels influence microbial metabolism and OMP biotransformation capacity in oligotrophic conditions. This research provides a mechanistic assessment of how the amount of aDOC affects microbial carbon utilisation strategies and OMP biodegradation kinetics in groundwater.

To investigate this, aerobic groundwater microcosms were amended with different aDOC concentrations spanning four orders of magnitude (0.001-10 mg/L). Biotic and abiotic microcosms were spiked with a 22-compound OMP mixture (~800 ng/L per compound). Microbial respiration, biomass production, and OMP concentrations were monitored over 100 days, and first-order biodegradation kinetics were derived after correcting for abiotic losses.

Results show that carbon availability strongly influences microbial metabolic strategies: low aDOC concentrations enhanced bacterial growth efficiency, while high concentrations promoted respiration at the expense of biomass synthesis. OMP biodegradation peaked at moderate aDOC levels (0.01–0.1 mg/L), with the greatest number of compounds exhibiting significant biotransformation. In contrast, both carbon scarcity and carbon saturation suppressed biotransformation—either by limiting microbial energy or by inducing substrate competition and potential functional shifts.

These results demonstrate that aDOC levels influence microbial metabolic strategies and, consequently, OMP biotransformation kinetics in groundwater. This mechanistic link between substrate availability, microbial metabolism, and biotransformation rates helps explain variability in groundwater persistence outcomes and provides insights relevant for refining biodegradation test conditions in groundwater-relevant systems.

3.04.B Advancing Understanding of Environmental Persistence of Chemicals

3.04.B.T-01 Effect of Inoculum Location on Marine Biodegradation Kinetics

Mette Møller¹, Tina K. Drist-Jensen¹, **Heidi Birch²** and Philipp Mayer¹, (1)Technical University of Denmark (DTU), Denmark, (2)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark

Marine pollution is of growing concern and produced water from offshore oil platforms is an example of a high-volume complex mixture being discharged to the sea. Biodegradation testing of chemicals for persistence

assessment is a crucial part of chemical regulation, however studies on differences and variation in biodegradation kinetics in marine environments are lacking. This study aims to 1) quantify the difference in marine biodegradation kinetics between harbors and open water (expected high preexposure compared to low preexposure), 2) quantify the variation in marine biodegradation kinetics between different open water sampling locations at expected low pre-exposure and across a salinity gradient) and 3) investigate if the microbial composition of the inoculum samples and composition during incubation can explain differences or similarities in biodegradation kinetics for different sampling locations. Seawater samples were collected in harbors and open water (6-8 km from shore) at three sites across Denmark. Test systems contained produced water diluted 1:200 in seawater (biotic test systems) and were incubated 1-60 days at 10°C. Solid Phase Microextraction coupled to GC-MS was used to determine primary biodegradation kinetics of 27 petrochemicals in the produced water based on the chromatographic peak area ratios (biotic test systems/abiotic controls). The biodegradation half-times of the 27 petrochemicals were on average 2.9-3.6 times shorter in harbor samples compared to open water samples, in agreement with higher initial microbial abundance in the harbor samples and higher expected pre-exposure. The variation in half-times of 27 petrochemicals between the three open water samples was on average a factor 1.2-1.9. Similarity in inoculum sample location and salinity were reflected in microbial composition for two sites, however, biodegradation kinetics correlated better with expected pre-exposure than similarity in geographic sampling location and salinity. Alignment of microbial composition development during incubation with biodegradation kinetics will be presented at the conference. In conclusion, biodegradation half-times were markedly shorter when using inoculum water from harbors compared to open sea. For conservative persistence assessment, these results support that inoculum generally should be sampled from less exposed locations. However, the optimal sample location ultimately depends on the specific purpose of the biodegradation test.

Disclaimer/Disclosure:

This research has received funding from DTU Offshore under the Produced Water Management programme.

3.04.B.T-02 Higher Microbial Diversity Enhances the Extent and Rate of Organic Micropollutant Biodegradation Under Aerobic and Nitrate-reducing Conditions

Alessia Ore¹, Emma Helena Palm², Annemarie van Wezel³ and Nora B Sutton⁴, (1)Wageningen University and Research (WUR), Wageningen, Netherlands, (2)University of Luxembourg, Luxembourg, (3)University of Amsterdam (UVA) and Utrecht University (UU), Netherlands, (4)Environmental Technology, Wageningen University and Research (WUR), Netherlands

Organic micropollutants (OMPs) are constantly released in the environment, where their fate depends on both molecular properties and biogeochemical conditions. Depending on site-specific environmental and microbial conditions, OMPs might persist or transform into transformation products (TPs), with distinct properties and potential risks. In our study, we investigated how microbial diversity and redox conditions influence the biodegradation and transformation of 20 spiked OMPs. Microbial communities with three different levels of diversity were created using a solid-phase dilution-to-extinction approach, and after regrowth, were incubated under aerobic and nitrate-reducing conditions. During incubation, biodegradation of the spiked OMPs and TP formation were monitored through target and non-target analyses. Our results show that higher-diversity communities achieved greater biodegradation performance, with significant biodegradation of 15 OMPs under aerobic and 5 OMPs under nitrate-reducing conditions. Higher diversity communities also showed higher OMP degradation rates and greater numbers of total and later-generation TPs. Low-diversity communities showed limited biodegradation, revealing a threshold in microbial diversity below which the biodegradation potential is affected. Redox conditions strongly influenced the fate of OMPs. Aerobic conditions were superior, while several OMPs were persistent only under nitrate-reducing conditions. Redox-specific TPs and TPs with potential endocrine-disruptive effects were identified through in-silico methods. These results demonstrate that both microbial diversity and redox conditions significantly influence environmental persistence and transformation of OMPs. However, standardized tests for persistence assessment, like OECD 308 and 309, overlook these factors, potentially leading to erroneous conclusions. Incorporating microbial diversity and redox conditions into regulatory biodegradation testing could improve the reliability and accuracy of persistence assessments and chemical risk evaluations.

3.04.B.T-03 Explaining the Variability in Micropollutant Biodegradation Across Aquatic Ecosystems Through Microbial Respiration

Arild Gustafsson¹, Joeselle Serrana², Mar Fauria Solé¹ and Malte Posselt³, (1)Stockholm University, Sweden, (2)Department of Environmental Science, Stockholm University, Stockholm, Sweden, (3)Department of Environmental Science, Stockholm University, Sweden

The significant variability observed in biodegradation rates across aquatic environments is a major source of uncertainty in assessing the persistence of micropollutants. While some parameters such as total organic carbon have been identified as influences on biodegradation rates, most of its variability remains unexplained. In a previous study, we observed significant positive relationships between biodegradation rates and water-sediment BOD for 23 of 34 tested compounds across 10 sites in a river system. This relationship can be mechanistically explained by higher BOD indicating increased microbial respiration and metabolic activity, which provides more opportunities for co-metabolic degradation. Here, we assess this potential relationship between biodegradation and respiration rates across 7 rivers using a modified OECD 309 incubation test alongside respiration tests on the same samples. Of the 50 assessed micropollutants, 24 showed a significant ($p < 0.05$) positive relationship, 2 showed a significant negative relationship, and 24 showed no significant relationship between biodegradation and respiration rates. Normalizing the biodegradation rate constants, k , by the highest k value for each compound to produce values between 1 and 0 enabled comparisons of overall biodegradation rates across sites. Among the 7 sites, three exhibited substantially higher respiration rates, and all three had generally higher normalized k than the four sites with lower respiration rates. This difference was significant for all pairs except one. After normalizing respiration rates in the same way as k , correlation analysis of normalized k against normalized respiration rates across the entire dataset showed a highly significant positive relationship ($p = 2.2 \times 10^{-16}$). The ρ value was 0.48, indicating that microbial respiration explains a modest but meaningful portion of biodegradation variability among rivers. Additionally, biphasic kinetics with rapid initial degradation that slowed considerably after approximately 50 hours were observed for certain compounds at low respiration sites, possibly indicating that biodegradation rates depend on compound or natural substrate concentrations. Overall, these findings demonstrate a significant positive relationship between microbial biodegradation and respiration rates for about half of the tested compounds and explain a considerable portion of the variability in biodegradation across the studied sites environments.

3.04.B.T-04 Tracing Organotin Degradation Using Multi-Isotope Labelling in Marine Sediments: The Role of Microbial Communities and Sediment Properties

Andela Bačinić¹, Ivna Vrana¹, Ines Sviličić Petrić¹, Goran Palijan², Maja Ivanić¹, Chrystelle Montigny³, Mavro Lučić¹ and Martina Furdek Turk¹, (1)Ruder Boskovic Institute, Croatia, (2)Josip Juraj Strossmayer University of Osijek, Croatia, (3)University of Montpellier, CNRS (Centre National de la Recherche Scientifique), France

Tributyltin (TBT), formerly one of the most widely used biocides in antifouling paints, has been globally banned for almost two decades due to its extreme toxicity to non-target organisms. Despite the ban, TBT is still detected in many coastal environments, raising concerns about whether recent contamination originates from the illegal use of antifouling coatings or from the remobilisation of “legacy” TBT stored in historically polluted sediments. Understanding the processes that control the fate, persistence and transformation of TBT in sediments is therefore essential. Although degradation rates clearly differ among sediments, the reasons for this variability remain poorly understood. In particular, the relative importance of abiotic processes such as sorption or mineral-mediated reactions versus biotic degradation driven by benthic microbial communities is still insufficiently resolved.

In this study, we investigated the mechanisms and kinetics of TBT degradation and its stepwise transformation through DBT and MBT to inorganic Sn in a range of marine sediments subjected to oxic and anoxic conditions. Sediments were spiked with isotopically labelled organotin species (^{119}Sn -TBT, ^{119}Sn -DBT and ^{119}Sn -MBT) to enable precise tracking of each individual degradation step over a 180-day incubation. Concentration changes were monitored to determine degradation pathways. The structure of benthic microbial communities was characterised by 16S rRNA amplicon sequencing at multiple taxonomic levels (phylum to family), performed on oxic and anoxic sediment samples at the start and after 50 days of incubation to assess community shifts. Functional genes associated with TBT degradation were quantified by qPCR, while sediment properties, including particle size distribution, mineralogical composition, carbonate content, multielement composition and total organic carbon, were measured to evaluate their role in transformation processes. Based on the obtained

results, kinetic rate constants were calculated for each degradation step and the overall mechanism of TBT transformation was established. Statistical analyses revealed how the composition of the benthic microbial community and key sediment characteristics influence degradation kinetics, thereby determining the environmental persistence of TBT in contaminated marine sediments.

3.04.P Advancing Understanding of Environmental Persistence of Chemicals

3.04.P-Tu158 Persistence Directed Testing of Chemicals in Mixtures

Heidi Birch¹, Rune Hjorth², Ivo Schliebner³, Michael Neumann³ and Philipp Mayer⁴, (1)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark, (2)Technical University of Denmark, Denmark, (3)German Environment Agency (UBA), Denmark, (4)Technical University of Denmark (DTU), Denmark

Test data for persistence assessments are lacking for many of the chemicals that are produced, imported, or used in the European Union. Typically, standardized tests are conducted as single substance tests aimed at demonstrating biodegradability, which directs a disproportionate fraction of an extensive testing effort on a large number of degradable chemicals. It is much more crucial to identify persistent chemicals since they can cause severe and long-lasting pollution.

In this project we develop and apply a persistence directed testing strategy to identify persistent chemical structures in an efficient way rather than confirming the biodegradability of chemicals. The strategy consists of persistence testing of chemicals in mixtures in aqueous simulation type tests. The absence of primary biodegradation is used as evidence of persistence.

Three rounds of testing will be conducted in the project. The first round was conducted with two mixtures containing 15 and 46 chemicals at constituent concentration levels of 1 and 5 µg/L. The mixtures showed no inhibition in a biotox test up to constituent concentrations of 10 µg/L. The tests were conducted with surface water from a Swedish stream draining forest and marsh areas with a high organic and low nutrient content (TOC: 24 mg/L and NOx: 52 µg N/L). Triplicate biotic and abiotic test systems were prepared in 1 L bottles for each mixture and concentration level, incubated at 12°C, and sub-sampled on day 7, 14, 21, 28, 40, 50 and 60. Samples were analyzed with LC-MS/MS. This first test round provides primary biodegradation kinetics for some chemicals and a list of chemicals that were not degraded. The non-degraded chemicals will be included in the second and third test round to confirm their persistence.

3.04.P-Tu159 Assessing fungal derived enzymes for screening biodegradability of plant protection products

Reiner Amir Yah¹, Gabriel Sigmund², Steven Droge³, Marc-Sven Roell⁴, Sebastian Schmidt⁴, Ivo Roessink¹ and Nora B Sutton⁵, (1)Wageningen University and Research (WUR), Netherlands, (2)EDGE, Wageningen University and Research (WUR), Wageningen, Netherlands, (3)Environmental Risk Assessment, Wageningen University and Research (WUR), Netherlands, (4)Bayer Research & Development Services LLC, Germany, (5)Environmental Technology, Wageningen University and Research (WUR), Netherlands

Plant protection products are widely used to manage weeds, pests and diseases threatening stable food crops. To avoid the accumulation of plant protection products in the environment, the persistence of the respective active ingredients (AI) is evaluated under standardised OECD tests. The OECD301 is used to identify degradable AIs by microbial breakdown under aerobic conditions. This approach allows screening multiple AIs and ensures compliance with AI persistence requirements in the EU. The OECD 301 test is resource-intensive and requires high active ingredient concentrations. A simpler, faster test would be useful for earlier screening of pesticide degradability during AI development.

This study aims to develop a fungal derived crude enzyme extracts (CEEs) based degradability screening assay as a simple and faster complementation to OECD301. CEEs, rich in laccase and lignin peroxidase, catalyse the oxidative transformations of phenolic compounds and are known for their broad substrate specificity, stability and capacity for breaking down of active ingredients of plant protection products.

CEEs were produced through a 14-day submerged fermentation of the fungal strain *Phlebia radiata* in a kraft lignin-based medium. The efficacy of these CEEs in degrading pesticides was evaluated over 9 days at 20 °C

and 120 RPM. Samples were analyzed for pesticide concentration and specific enzyme activities of laccases and lignin peroxidase. The tested pesticides and transformation products are: 2,4-D, 2,6-dichlorobenzamide, aminomethylphosphonic acid, atrazine, bromoxynil, chloridazon, mecoprop, imidacloprid, metolachlor ESA, and metolachlor OA.

Laccase activity was stable, ranging from 1.4 to 2.0 U/mg protein, and lignin peroxidase activity varied between 1.7 to 2.5 U/mg protein. Notably, a reduction of over 30% in concentration was observed for AMPA, atrazine, bromoxynil, and imidacloprid, while other compounds exhibited decreases of approximately 15-20%. These findings demonstrate the potential of CEEs to facilitate the oxidative degradation of pesticides. Future validation with a wider range of compounds will enhance the robustness of this rapid fungal exoenzyme assay, positioning it as a valuable tool for preliminary screening of pesticide biodegradability and prioritization for further testing.

3.04.P-Tu160 Exploring the Relationship between Microbial Biodiversity and Pollutant Biodegradation in Rivers

Joelle Serrana¹, Run Tian², Francisco J. A. Nascimento³, Elias Broman⁴, Benoit Dessirier⁵ and Malte Posselt⁶, (1)Department of Environmental Science, Stockholm University, Stockholm, Sweden, (2)The University of Queensland, Australia, (3)Stockholm University, Sweden, (4)Department of Ecology, Environment, and Plant Sciences, Stockholm University, Sweden, (5)Baltic Sea Centre, Stockholm University, Sweden, (6)Department of Environmental Science, Stockholm University, Sweden

Rivers are critical ecosystems that provide drinking water, support biodiversity, and regulate biogeochemical cycles, yet they are increasingly burdened by complex mixtures of micropollutants from urban, agricultural, and industrial sources. Microbial communities mediate the natural attenuation of these contaminants, but the extent to which biodiversity underpins biodegradation capacity across diverse environmental settings remains unresolved. We designed a comparative study of 18 river segments spanning five European countries to explore the relationship between microbial biodiversity and pollutant biodegradation. Biodegradation assays were conducted for 97 micropollutants, including pharmaceuticals, pesticides, and industrial chemicals, while microbial community profiles were generated using metagenomic sequencing. Central to our framework is the functional redundancy hypothesis, which posits that diverse microbial assemblages can sustain pollutant attenuation despite taxonomic turnover. By integrating taxonomic and functional diversity metrics with compound-specific biodegradation rates, this study aims to disentangle whether redundancy provides resilience across chemical classes or whether unique taxa and gene repertoires are required for specific degradation pathways. Situated within the context of escalating chemical pressures on European freshwater systems, anticipated outcomes will advance ecological theory on biodiversity–function relationships and inform strategies for incorporating microbial metrics into environmental risk assessment, river basin management, and water quality policy.

3.04.P-Tu161 What Drives Variability in OECD TG 309 Studies? A Data-Driven Evaluation of 176 Surface Water Simulation Tests

Louise Camenzuli¹, Mike Earl², Katie Endersby³, Richard Gibson⁴, Patricia Anna Golombek⁵, Jasmin Hafner⁶, Damian Helbling⁷, Christopher B Hughes⁸, Aurelia Lapczynski⁹, Sven Peter¹⁰, David MV Saunders¹¹, Balint Tamasi¹², Chiara Maria Vitale¹³, Neil Wang¹⁴, Philippe Lemaire¹⁵, Miriam Leon Paumen¹, Johannes Tolls Dir¹⁶, Lucy Wilmot¹⁷ and Marie Collard¹², (1)ExxonMobil Petroleum & Chemical BV, Belgium, (2)Syngenta Ltd., United Kingdom, (3)Unilever, United Kingdom, (4)Environment Agency United Kingdom, United Kingdom, (5)RG/TC, BASF, Germany, (6)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (7)Cornell University, United States, (8)Embark Chemical Consulting, United Kingdom, (9)Research Institute for Fragrance Materials, United States, (10)GBP/RA, BASF, Germany, (11)Shell Global Solutions International BV, Netherlands, (12)DSM-Firmenich SA, Belgium, (13)Procter & Gamble, Belgium, (14)Syensqo, France, (15)TotalEnergies, France, (16)Corporate Scientific Services, Henkel AG & Co. KGaA, Germany, (17)ECETOC, Belgium

The OECD Test Guideline (TG) 309 ‘Aerobic Mineralisation in Surface Water – Simulation Biodegradation Test’ is a cornerstone method for assessing the degradation of chemicals under environmentally relevant conditions. Despite its critical role in regulatory aquatic hazard and risk assessments, including PBT assessment, TG 309 studies are complex, technically demanding, and can exhibit substantial variability in outcomes (e.g.

half-lives).

High variability in reported half-lives has been attributed to multiple factors in the scientific literature, including inoculum properties, surface water characteristics, and differences in experimental design (e.g., test concentration and system configuration). While individual sources of variability have been explored in isolation, their relative influence and combined impact remain poorly understood, particularly in studies conducted for regulatory purposes.

This work aimed to identify and rank the key factors - both substance-specific and system-related - that influence outcomes in OECD TG 309 studies. A comprehensive database of 176 independent TG 309 studies was compiled, including data sourced from the European Chemicals Agency (ECHA) dissemination dossiers and European Food Safety Authority (EFSA) Risk Assessment Reports. Statistical analyses have been performed to examine relationships between test system parameters, chemical properties, and observed degradation half-lives, with the goal of quantifying which factors contribute most to observed variability. Initial results were presented at the SETAC Europe 35th Annual Meeting, and this presentation will report the final outcomes and interpretations from the completed analysis.

The insights gained from this work are expected to clarify the primary drivers of variability in TG 309 outcomes. This improved understanding could support the optimisation of the TG 309 protocol, enhance its reliability and reproducibility, and ultimately strengthen its application in regulatory hazard and risk assessments.

3.04.P-Tu162 Round Robin Test to prepare for consolidation of tests for ready biodegradability according to OECD 301/310

Ulrich Heinz Jöhncke¹, Andrea Brunswik-Titze², Stefan Gartiser², Daniel Sättler¹, Monika Ratte³ and Benjamin Daniels³, (1)German Environment Agency (UBA), Section IV 2.3 Chemicals, Germany, (2)Hydrotox GmbH, Germany, (3)ToxRat Solutions GmbH & Co. KG, Alsdorf, Germany

Persistence is a key component of the regulatory assessment, including the identification of substances of very high concern (SVHC) under European Chemicals Regulation (REACH; regulation (EC) Nr. 1907/2006). As a first step, Ready Biodegradability Tests (RBTs) are used to determine whether a substance can be exonerated from the concern of persistency, or if higher Tier simulation degradation tests are required for decision making on persistency. Although the RBTs are generally considered equivalent for verification purposes, they differ in some respects of the individual testing protocols.

The intention of this R&D project is therefore to prepare the first steps towards consolidation of the OECD guidelines for RBTs, i.e. to harmonise the test conditions as far as possible, taking into account the technical progress since the last major guideline revision in 1992.

In this context, a round robin test is being conducted with 12 GLP laboratories from across the OECD region. The test design involves performing a slightly modified OECD 301F test with additional DOC-measurement at the end and the beginning of the test (similar to OECD 301C). Three test substances, potassium hydrogenphthalate, diisobutyl hexahydrophthalate and acesulfame are tested, which cover the range of assessment criteria from “not readily biodegradable” to “readily biodegradable”. Aniline was chosen as a reference substance, with the aim of putting a very well-established reference substance to the test, for which historical data sometimes show differences.

The statistical analysis of the tests is to have a special significance. Therefore, two independent repetitions are conducted with different batches of inoculum. This enables to calculate intra- and interlaboratory variability according to ISO 5725-2. In combination with an extended inoculum analysis, which is intended to complement the determination of the CFU, this offers the possibility of illuminating the reproducibility of the results across geographical boundaries and different technical capabilities.

3.04.P-Tu163 Positive Controls for OECD Biodegradability Guidelines: Rethinking Robustness

Guillaume Cottin, Cyril Sweetlove, Nada Kerrich, Pascal Pandard and Elsa PAIVA, L'Oréal, France

Biodegradability is crucial for environmental assessment. OECD guidelines (301 A-F, 302 A-C) define standard tests requiring positive reference substances to validate analytical system performance and bacterial consortium activity. However, historical controls have limitations: toxicological concerns (aniline, classified CMR), abiotic degradation biasing interpretation, or overly restrictive physicochemical profiles for diverse chemical substances.

Addressing these challenges, this study aimed to select and validate new positive controls meeting strict criteria: toxicological safety, solubility, low volatility, absence of abiotic degradation, and chemical relevance for OECD tests. Three substances were chosen from distinct chemical families to broaden representativeness: caffeine, adipic acid, and 1,5-pentanediol.

These substances were tested according to OECD protocols 301B/301F (ready biodegradability) and 302B (inherent biodegradability). Activated sludge from French wastewater treatment plants was standardized to reflect biological variability. Additional tests confirmed no abiotic degradation or inhibitory effects on bacterial activity.

Results show rapid, complete, and reproducible degradation for all three substances, systematically meeting OECD criteria (?60% in 14 days for 301 tests; ?70% in 14 days for 302 test). The absence of abiotic degradation independent of microbial activity and lack of toxic effects on the inoculum were confirmed, validating profile relevance.

These findings establish caffeine, adipic acid, and 1,5-pentanediol as reliable, safe, and robust positive references, offering a relevant alternative to historical controls. Their integration into biodegradability test guidelines would improve methodological robustness, inter-laboratory comparability, and environmental assessment quality in demanding regulatory contexts.

Furthermore, ongoing work aims to consolidate these results by confirming performance under OECD 301A conditions, strengthening cross-method reliability. Concurrently, this approach will extend to polymeric materials to assess its relevance for complex matrices and support future polymer environmental evaluation developments.

3.04.P-Tu164 Illuminating Persistence Assessment: Environmental Relevance of Light in OECD 309 Testing

Carolin Ewers¹ and Phil Lamond², (1)CFCS-Consult GmbH, Germany, (2)Fera Science Ltd, United Kingdom

Standardized testing protocols for assessing aerobic degradation of chemical substances in surface waters typically involve incubation in continuous darkness for extended periods of time (60–90 days, OECD 309). While this approach is intended to prevent direct photolysis, it inadvertently suppresses key biological processes driven by light, particularly those involving photosynthetic microorganisms. Phototrophs possess diverse metabolisms and contribute substantially to biogeochemical cycling. Light exclusion likely reduces microbial consortia proliferation and may lead to significantly lower degradation rates. Furthermore, current test requests by ECHA allow only a minimal amount of suspended solids, limiting microbial diversity and activity, which potentially underestimates the true environmental degradation potential of substances.

This study investigates the role of non-UV photosynthetically active radiation (PAR, 400–700 nm)—with an intensity selected to represent light conditions typical of European surface waters—in supporting microbial biodegradation processes. Experimental results and literature analysis confirm that light exclusion reduces microbial growth and can lead to significantly lower degradation rates. In contrast, illumination with environmentally relevant non-UV PAR enhances microbial community function and can result in different degradation outcomes. In addition, oxygen released by phototrophs may help to maintain aerobic conditions in closed test vessels—an important approach in degradation testing of volatile substances.

Cyanobacteria and microalgae are integral to aquatic ecosystems and are among the most abundant organisms on Earth; recognizing their metabolic versatility and ecological significance is essential for advancing the robustness and environmental relevance of chemical persistence assessments. Consequently, test protocols that disregard the role of photosynthetically driven microbial interactions may not adequately reflect degradation under realistic environmental conditions.

We propose integrating controlled non-UV PAR into standardized test methods, especially pelagic tests, to better represent the ecological dynamics of surface waters. However, even with PAR light, the pelagic OECD 309 test may still fail to determine substance persistence reliably and reproducibly, underscoring the need for guideline revision.

3.04.P-Tu165 Investigating Closed Test Setups and Application Approaches for Biodegradation Testing of a Volatile and Hydrophobic Substance in Surface Water (OECD 309)

Prasit Shrestha¹, Louise Camenzuli², Christopher B Hughes³ and Marco Kraas⁴, (1)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Exxon Mobil, Belgium, (3)Embark Chemical Consulting, United Kingdom, (4)Evonik Operations GmbH, Germany

Understanding the biodegradation of chemicals in the environment is an important element of hazard classification, exposure assessment, and persistence assessment. Standardised biodegradation simulation tests are available to assess degradation rates in different environmental settings. However, it is recognised that certain substances can be difficult to test due to their physico-chemical properties. Substances that are volatile and hydrophobic are recognised as especially problematic. The OECD 309 test (Aerobic Mineralisation in Surface Water) faces particular challenges due to the requirement to apply and maintain the test substance within an aqueous medium. Abiotic losses of the test substance can occur at various stages of testing, including test substance application, testing phase, sampling and analysis. Such losses affect the recovery of the test substance, impacting the mass balance and the reliability of results. Further, the partitioning of the substance out of the aqueous phase reduces the bioavailability of the substance and artificially lowers the observed degradation rate. Various efforts have been made to try to address these challenges, but the issues are not yet solved for OECD 309 guideline compliant testing.

In this study, various experimental approaches were investigated for testing the volatile and hydrophobic substance decalin (decahydronaphthalene) under OECD 309 test conditions. These approaches centred around testing decalin in a closed system, and investigating some of the approaches used in a previous OECD 309 test where silicone oil was used as an application solvent for dosing the test substance. Further, efforts have been made to develop more appropriate volatile traps, and alternative dosing methods based on passive dosing or water-miscible solvents. The results of these investigations will be presented, demonstrating the significant challenges with dosing, testing and recovery of the test substance. Experiments with silicone oil showed a high tendency for decalin to remain partitioned within the silicone oil, which carries implications for the bioavailability, degradation and volatilisation of the test item. Based on the results obtained under this study, decalin proves to be an extremely challenging substance to test under OECD 309.

3.04.P-Tu166 Comparison of OECD 301 & 310 Guideline Studies Regarding Their Capability to Degrade Substances with Limited Bioavailability

Michael Essers¹ and Ulrich Heinz Jöhncke², (1)LANXESS Deutschland GmbH, Germany, (2)German Environment Agency (UBA), Section IV 2.3 Chemicals, Germany

This work is based on the hypothesis that results obtained from biodegradability screening studies correlate with the intrinsic physical substance properties, predominantly water solubility and octanol-water partition coefficient (log K_{ow}). The statistical evaluation of respective publicly available data sets retrieved from the OECD eChemPortal demonstrated a significant correlation, implying that substances exhibiting poor bioavailability fail ready biodegradability tests with higher probability. A substance failing such a test is considered potentially persistent and may require the next level of testing, e.g. simulation testing, although the root cause for not reaching the pass level may be a test system that impairs bioavailability.

The data evaluation additionally revealed that studies according to test guidelines (TGs) OECD 301 & 310 differ significantly in their capability to degrade substances with limited bioavailability. Among other things, this suggests that TG OECD 301C causes less degradation of such substances than the other respirometric test systems. One explanation could be that the standard treatment of inoculum specific to the test system impairs its degradation potential.

Poorly soluble substances (water solubility <1 mg/L): only a (very) small share of the test substance is dissolved in the test medium and thus bioavailable for degradation. Studies following TGs OECD 301D, 301B and potentially OECD 310 (small sample size) appear best suited for degrading poorly soluble substances.

Partially soluble substances (water solubility 1-100 mg/L): test substances in this class are considered to be partially dissolved, the share depending on the guideline used. When neglecting the small sample size with TG OECD 310 data, the TGs OECD 301B, 301D and 301F exhibit comparable performance in demonstrating ready biodegradability.

Soluble substances (water solubility >100 mg/L): the test substance can be assumed to be completely dissolved. In this class, similar performance of all different guidelines studies is observed, which underpins the relevant role of bioavailability (substance completely dissolved) for good performance in biodegradation tests.

The results of this work suggest that it is worthwhile to aim for a well-devised study design to avoid over-conservative or false-negative results from biodegradability screening tests, including choice of the test guideline offering the best conditions for poorly bioavailable substances in practice.

3.04.P-Tu167 In-depth Understanding of Bacterial Communities in OECD 301 Biodegradability Tests : Towards Identifying Key Polymer Degradators

Mahily CERÉYON¹, Elsa PAIVA¹, Guillaume Cottin¹, Anthony WOO¹, Jérôme LORIOT¹, Xavier Schultze¹, David LEJON², Cyril Sweetlove¹ and Pascal Pandard¹, (1)L'Oréal, France, (2)EquiTox, France

Biodegradability tests, conducted according to Organisation for Economic Co-operation and Development guidelines (OECD), are essential for assessing the fate of chemicals on ecosystems. As biodegradability is primarily a biological process carried out by specific microbial communities, the in-depth characterization of bacterial populations in the inocula used in these tests has become fundamental. This is particularly relevant for polymer biodegradation, which relies on complex enzymatic pathways and specialized bacterial functions. To address this gap and better capture the biological mechanisms underlying polymer degradation, this study aims to i) identify the major bacterial degraders and their potential enzymatic pathways involved during biodegradability processes and ii) to deepen our understanding of polymer-degrading bacteria, in order to contribute to the development of more effective and predictive screening tests.

OECD 301F tests were performed using Poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) micronized and non-micronized as well as Polyvinyl alcohol 8-88 (PVOH8-88).

Samples were taken at key time points: Day 0, D10, and D28 for controls (without polymer), and at D10 and D28 for test suspensions (inoculum + polymer). DNA was extracted and analyzed by high-throughput sequencing of the 16S rRNA gene, an environmental DNA technique allowing the identification of bacterial communities and their evolution during the biodegradability kinetics.

Preliminary results indicate that certain bacterial families show significant overexpression under polymer biodegradation conditions compared to controls. Taxonomic analysis, achieved with resolution down to the family level and in some cases to the genus and species levels, combined with biodegradation kinetics, reveals a clear association between polymer degradation and the selective activation of specific bacterial groups. Future work will extend this approach to additional polymers with varied chemical structures to identify a wider range of potential degraders and to refine the bacterial markers associated with biodegradation. In line with recent regulatory perspectives of European Chemicals Agency (ECHA, 2025), this work could ultimately support the development of faster and more relevant biodegradability screening tools, particularly for the assessment of polymers.

3.04.P-Tu168 Navigating the Unknown: The Critical Need for "Middle-Tier" Persistence Testing

Guillaume Cottin¹, Elsa PAIVA¹, Alaa Bensetra², Arnaud Franck BOIVIN¹, Pamela Abdallah¹, Cyril Sweetlove¹ and Pascal Pandard¹, (1)L'Oréal, France, (2)Analytical chemistry, L'Oréal, France

Persistence assessment has a vital role in evaluating long-term risks of chemicals in the environment and human health. Within different Regulations (i.e., REACH, BPR, CLP) persistence assessment and related information on degradation is needed for 1) PBT assessment, 2) hazard classification under CLP (PBT and vPvB, PMT and/or vPvM and aquatic environment) and 3) chemical safety assessment (e.g. exposure assessment).

The commonly accepted evaluation in a Tier 1 strategy is to initially use the results obtained from in silico tools and screening tests.

In silico screening tools, e.g. QSARs, can be used as part of a Weight-of-Evidence approach for the PBT/vPvB assessment, for instance predictions that the substance is not rapidly/readily degradable would support the conclusion that the substance is potentially P/vP.

There is a methodological gap between generic screening methods and complex higher-tier simulation tests.

Persistence assessment is based on either screening (relatively 'fast and easy') level ready/inherent biodegradability testing or 'complex and lengthy' higher-tier simulation type of testing. Current screening methods are stringent and often lead to a need of higher-tier testing when not conclusive. However, a negative result in a screening test does not necessarily mean that the substance will not be degraded under relevant conditions. Thus, 'middle' level testing methods which would address limitations of screening and higher-tier test methods are lacking.

The aim of this work is to demonstrate, through several relevant examples of biodegradability and persistence assessments, that the current testing strategy (in silico and screening) can lead to overly conservative conclusions regarding presumed persistence, whereas simulation test results demonstrate non-persistence. In this context, the conclusions of first-level tests can lead, in the context of industrial R&D, to a halt in development and may prove to be a barrier to innovation.

As part of the key areas of regulatory challenges addressed by ECHA in 2025, particularly regarding chemical pollution in the environment, it is necessary to develop and validate Middle-tier test that enable a more robust assessment of the persistence of chemical substances.

3.04.P-Tu169 Pre-Screening Biodegradability Potential of Chemicals Using an Artificial Bacterial Inoculum

Mickael Cregut¹, Cyril Sweetlove², Marie-Josée Durand³, Jean-Charles Cheneble², A. Taze², Olivia Dufour², Guillaume Cottin², Marc Leonard², Jacques L'Haridon² and Gerald Thouand³, (1)syensqo, France, (2)L'Oréal, France, (3)University of Nantes, France

Biodegradability assessment is essential for evaluating the environmental fate of chemicals, but regulatory ready biodegradability tests are long, costly, and highly sensitive to the variability of natural microbial inocula. As a result, industries increasingly require robust pre-screening tools to identify chemicals with a high likelihood of success before initiating standard assays.

To support early decision-making, we developed a pre-screening approach based on a defined artificial inoculum composed of 44 bacterial strains representative of key functional groups in activated sludge. This controlled microbial system provides consistent activity suitable for early assessment of biodegradation potential.

Each strain was individually exposed to 30 chemicals with known biodegradability profiles, yielding 3,960 oxygen consumption assays over 28 days. A 5 % respiration threshold was applied to determine whether a strain responded to a given substance, and the proportion of active strains was used to classify chemicals into three biodegradability categories (BIN 1, BIN 2, BIN 3). Substances activating more than 27.9 % of strains were consistently associated with BIN 1, whereas those with fewer than 4.5 % active strains were assigned to BIN 3. Intermediate proportions reflected inherently biodegradable substances, although discrimination between BIN 2 and BIN 3 remained limited.

The artificial inoculum correctly identified 75 % of readily biodegradable chemicals reported in the literature and showed strong reproducibility. Importantly, no known non-biodegradable substance was misclassified as readily biodegradable. These results demonstrate that the method can rapidly flag chemicals with high biodegradation potential, reducing false negatives and guiding the need for further testing.

This approach is not intended to replace regulatory tests but to serve as a practical and reproducible pre-screening tool supporting industrial prioritization and early-stage environmental assessment.

3.04.P-Tu170 How to prioritise - interannual and interlake variability makes UV Filter risk assessment challenging

Alex Kroll¹, Benjamin Gyga², Simone Tinguely² and Armin K. Zenker³, (1)Oekotoxzentrum, Switzerland, (2)FHNW, Switzerland, (3)School of Life Sciences, University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Switzerland

As of November 2024, 47 UV filters are authorised for use in cosmetics within the EU, with common sunscreen formulations containing several in combination. These compounds can enter aquatic systems directly during bathing or indirectly via wastewater effluents. Current cosmetic authorisation does not require environmental risk assessment, and many UV filters have additional applications that may increase environmental inputs. UV filters have been detected globally in surface waters; however, Swiss data on lake exposure is scarce.

In 2024–2025, five Swiss lakes were monitored at multiple points in the bathing season, with one influenced by wastewater treatment plant (WWTP) discharges. Sampling covered surface layers, the water column, and sediments. Concentrations of 11 organic UV filters were determined using HPLC–MS/MS. Parallel controlled experiments in artificial ponds assessed the fate of UV filters from sunscreen use, with two ponds receiving sunscreen under WHO recommended application rates and two as controls.

Results showed variable distribution patterns across lakes and years, with octocrylene (OC) detected in almost all lakes at high concentrations, especially in surface waters. Other prevalent filters included 2-ethylhexyl salicylate (EHS) and homosalate (HMS). Some filters, such as 4-methylbenzylidene camphor (4-MBC), persisted in sediments despite being phased out years ago.

In artificial ponds, UV filters remained longer in surface waters than expected; OC showed extreme partitioning to the surface, while hydrophilic PMDSA was more evenly distributed. OC and EHS accumulated rapidly and persistently in sediments and biofilms, whereas PMDSA dissipated quickly. Six months after application, measurable OC and EHS persisted in water and sediment.

Overall, lipophilic UV filters are retained strongly in surface and benthic compartments, creating potential long-term exposure for aquatic life. Further work aims to establish sediment Environmental Quality Standards based on ecotoxicological testing to better protect aquatic ecosystems.

3.04.P-Tu171 What Are the True Surface Water Half-Lives of Readily Biodegradable Substances? A Case Study on Surfactants

Takahiro Suzuki¹, Tohru Nishioka², Tomoaki Sasa³, Yasuaki Inoue¹, Ayame Maihara¹, Kiyoko Naruse¹, Takashi Ieki¹, Akiyo Kameyama¹ and Masayuki Yamane¹, (1)Safety Science Research, Kao Corporation, Japan, (2)Safety Science Research, Safety Science Research, Kao Corporation, Japan, (3)Kao Corporation, Japan

The half-lives of chemical substances in river water are important for assessing environmental persistence and estimating chemical concentrations through exposure modeling. Reports on the half-lives of readily biodegradable substances are limited, and regulatory guidelines provide default values for these substances in the absence of actual data. However, few studies have assessed the effect of experimentally derived half-lives on exposure estimates compared to default values. In this study, we investigated the half-lives of 12 readily biodegradable substances, including surfactants and tertiary amines, and evaluated the impact of the experimentally derived values on the accuracy of model estimation.

Most experimentally derived half-lives were less than 24 h, which is considerably shorter than the default values of 360 h (15 d) commonly used in regulatory assessment. When half-lives exceeded 60 h, biodegradability in surface water had a limited effect on concentration estimates in The National Institute of Advanced Industrial Science and Technology - Standardized Hydrology-based Assessment tool for chemical Exposure Load model, whereas half-lives below 24 h led to decreased concentration estimates. When concentration estimates using experimentally derived and default values were compared with environmental monitoring data, the experimentally derived half-lives improved the accuracy of the model estimations. These findings suggest that the experimentally derived half-lives of readily biodegradable substances considerably affect exposure estimates.

Our study suggests that readily biodegradable substances that show high exposure concentrations based on default values should be investigated further in higher-tier assessments with experimentally derived values, especially for surface water half-lives. In this presentation, the importance of experimentally derived half-lives and possible reconsideration of the default value will be discussed.

3.04.P-Tu172 Chemical Biodegradability and Persistence Assessment

Kirit Wadhia, National Oilwell Varco (NOV), United Kingdom

In consideration of ecotoxicological perspective regarding the impact of chemicals in the environment, indubitably it is important to ascertain the chemicals' persistence. Thus, a significant criterion is the rate of degradation in the environment and of particular value tests that can expeditiously screen out chemicals which are prone to degradation in diverse environments.

Biodegradation determination of chemicals is critical as it provides valuable insight of exposure and subsequently the long-term adverse effects on biota and implications for mankind [1].

Biodegradation screening tests (BSTs) have been developed and approved by the Organisation for Economic Co-operation and Development (OECD). BSTs are often a vital integral component of regulatory frameworks; OSPAR Agreement dealing with Harmonised Chemical Notification Format (HOCNF) is a casing point [2]. Its remit is the management of offshore exploration and production activities in the OSPAR maritime area. Their prominence in this context has been due to the associated relative low cost and presumed ease of implementation and interpretation.

However, biodegradation evaluation intrinsically is complex and unpredictable. Whereas the intended initial purpose of the BSTs was to screen out chemicals which are easily degraded, they have not evolved at the same rate as regulatory concerns, which now place an increased emphasis on environmental persistence.

Since the suitability of BSTs, for example OECD 306, is not deemed to be robust to identify persistent chemicals, projects to modify protocol have been instigated and proposal submitted to OECD for a new test guideline for a Marine biodegradation screening test for chemical Persistence assessment (MaP test). [3, 4, 5]. The MaP test incorporates increased bacterial cell numbers and uses manometric respirometers to run for 60 days or more. It has undergone ring-testing with the participation of 13 laboratories in 7 countries. [6] Does it have application in marine regulatory frameworks and conventions?

3.04.P-Tu173 Weight of Evidence Evaluation of Persistence for a typical UVCB Substance Using Persistence Assessment Tool (PAT)

Fola Ogungbemi¹, Jan Wolff² and Thomas Sadler², (1)Product Compliance, Currenta GmbH & Co. OHG, Leverkusen, Germany, (2)Product Compliance, Currenta, Germany

Assessing the environmental persistence of complex substances is critical for regulatory decision-making and risk assessment. A UVCB substance (unknown or variable composition, complex reaction products or biological materials) was evaluated for persistence using a weight of evidence (WoE) approach integrating several studies including: 1) ready and inherent biodegradation screening tests (OECD TG 301F, 302C) on the UVCB whole substance; 2) aerobic mineralisation in surface water simulation test (OECD TG 309) for the major constituent of the UVCB; 3) Quantitative structure–activity relationship (QSAR) modeling for 5 known constituents

covering approx. 90 % of the UVCB content; and lastly, QSAR modeling for 4 transformation products identified in the OECD 309 test.

Based on the available data, the result of the above studies was as follows: Screening tests for the UVCB indicated inherent biodegradability (73% in 28 days) but did not meet the criteria for ready biodegradability (50% in 28 days). Surface water simulation studies showed concentration-dependent degradation kinetics: at higher concentration (100 µg/L), the substance degraded rapidly ($DT_{50} = 37.5$ days), remaining below the regulatory persistence threshold, whereas at low concentration (10 µg/L) degradation was slower ($DT_{50} = 87.4$ days). This inconsistency could be due to variability in microbial community development across concentration treatments. QSAR predictions consistently indicated rapid biodegradability for all major constituents and transformation products. Due to the multitude of possible persistency interpretations for this complex substance, a solution was needed to enable a conclusive evaluation of all this data.

The Persistence Assessment Tool (PAT) was employed to quantitatively weigh all lines of evidence (LoE) and to enable transparent integration of these diverse data and LoEs, accounting for dataset quality, consistency, and strength of evidence. Despite some uncertainty from borderline results and concentration effects, the overall WoE based on expert judgement and PAT supports a conclusion of non-persistence for the UVCB substance. This case study highlights the value of quantitative WoE tools in environmental risk assessment, providing robust, reproducible conclusions for complex substances.

3.04.P-Tu174 The evaluation of the persistence of UVCBs in regulatory testing

Emma Danby and William Caseley, Scymaris Ltd., United Kingdom

Evaluating the environmental fate UVCBs presents unique scientific and technical challenges in standardized biodegradation studies. CROs frequently rely on OECD Test Guidelines 307, 308 and 309 to generate regulatory-ready data. However, these guidelines were originally designed for single, well-defined chemical entities and therefore present inherent limitations when applied to multi-constituent and compositionally variable materials.

A primary challenge is characterizing test item composition and selecting appropriate analytes. UVCBs often contain multiple constituents, many without definitive structural identification, complicating the choice of marker components for monitoring transformation. This difficulty is compounded by limited analytical standards, variable ionization efficiencies, and co-eluting constituents, which collectively hinder quantification and the interpretation of mass balance.

Another major issue is representative dosing. Achieving environmentally relevant, homogeneous, and analytically tractable dosing is particularly difficult for hydrophobic, viscous, or surface-active UVCBs. Poor dispersion can lead to non-ideal exposure conditions, test system artifacts, and increased variability.

Additionally, sorption to soil, sediment, and test vessels often masks true transformation kinetics, complicating the calculability of DT_{50}/DT_{90} values and sometimes preventing kinetic modelling entirely.

Maintaining test system stability is further complicated by the fact that UVCB constituents may partition differently across phases challenging the assumption of a single, well-mixed compartment. These dynamics can blur the line between dissipation driven by transformation and dissipation driven by physical processes.

Radiolabelling, while a powerful tool for tracing parent and metabolites, is frequently infeasible because UVCBs lack a single representative structure amenable to labelling.

Together, these issues create significant uncertainty in regulatory fate assessments. This poster highlights typical CRO experiences, method adaptations, and emerging strategies—including targeted analytical profiling, fraction-based approaches, improved dosing techniques, and collaborative discussions with regulators—to improve study robustness while maintaining adherence to OECD requirements. Continued dialogue is needed to ensure that environmental fate testing frameworks evolve to accommodate the inherent complexity of UVCB substances.

3.04.P-Tu175 Assessing the Biodegradability of Water-Soluble Polymers: Scientific and Regulatory Perspectives for Safe and Sustainable by Design Innovation

Chris Finnegan¹, Katie Endersby² and Jayne Roberts³, (1)Safety and Environmental Assurance Centre (SEAC), Unilever, United Kingdom, (2)School of Life Sciences, Unilever, United Kingdom, (3)Unilever, United Kingdom

Water-soluble polymers (WSPs) are essential in home and personal care products. However, the complexity of these materials is not adequately addressed by current regulatory biodegradability tests, which were designed for simpler substances. This disconnect complicates the assessment of environmental persistence and the development of safe and sustainable polymer innovations. Current OECD and ISO biodegradability tests,
