designed for low molecular weight chemicals, often underestimate WSP degradability due to high molecular weight, charge density, and limited bioavailability. This review identifies key limitations of existing test methods and proposes a mechanistically informed, tiered testing framework that aligns test selection with degradation pathways and environmental context.

The framework integrates polymer-specific adaptations to OECD/ISO methods, microbial profiling, and advanced analytical tools to improve realism and reproducibility. It also highlights the role of high-throughput screening for early-stage prioritisation and the potential of in silico modelling to accelerate biodegradable-by-design innovation. By combining empirical, mechanistic, and predictive approaches, the proposed strategy supports proportionate persistence assessments, enabling regulatory confidence and innovation aligned with Safe and Sustainable by Design principles.

Targeted actions for regulators, researchers, and industry are outlined to advance polymer-specific methods, data infrastructure, and predictive capabilities. The approach aims to enable more realistic, robust, and proportionate assessments of WSPs, supporting regulatory decision-making and sustainable innovation. Ultimately, this strategy will help ensure that future polymer development delivers both environmental responsibility and technological performance, in line with the latest scientific and regulatory expectations.

3.04.P-Tu176 Advancing Fate Assessment: Integrating Biodegradation and Microbial Toxicity Testing

Katie Endersby¹, Jayne Roberts², Chris Finnegan³ and Emily McGrory², (1)School of Life Sciences, Unilever, United Kingdom, (2)Unilever, United Kingdom, (3)Safety and Environmental Assurance Centre (SEAC), Unilever, United Kingdom

Understanding the fate of chemicals in the environment is essential for assessing exposure and risk. Current biodegradation screening tests, even when applied with modification, aim to demonstrate rapid and complete degradation, but some substances may not achieve these criteria. For such chemicals, particularly complex materials that may degrade slowly and form diverse intermediate metabolites, current frameworks only offer limited insight into transformation pathways or metabolite toxicity. When metabolites form, they may exhibit properties distinct from the parent chemical, creating uncertainty for persistence and risk assessment.

To improve understanding where standard tests and their modifications do not provide sufficient insight, we outline an alternative approach that combines established methods to address complex cases, within a tiered strategy including both in silico and laboratory-based experimental approaches. This approach integrates biodegradation screening, metabolite characterization, and microbial toxicity assays to provide a more complete picture of environmental fate.

The approach integrates four steps:

1. Extended biodegradation testing (OECD 301F) to determine degradation kinetics.
2. Identifying metabolites at multiple time points to characterize transformation pathways.
3. Assessing microbial toxicity of the test liquor using respiration (OECD 209) and nitrification inhibition (ISO 9509) tests, allowing comparison of metabolite toxicity with the parent chemical.
4. Evaluating the applicability and relevance of biodegradation data across environmental compartments, by testing in multiple matrices, including freshwater and activated sludge.

This combined strategy links chemical and microbiological perspectives, working alongside current frameworks toward a more comprehensive understanding of biodegradability in specific cases where regulatory or scientific needs require more detailed information than standard tests provide. Anticipated outcomes include improved understanding of degradation dynamics, metabolite formation, and associated toxicity risks. While broadly applicable to difficult-to-assess substances, its potential relevance for polymers and similarly complex materials is still being assessed. By integrating chemical and biological endpoints, this approach strengthens biodegradation assessment and offers insight under conditions more representative of environmental variability.

3.04.P-Tu177 Flow-Cytometric Quantification of Live and Dead Bacterial Cells in Environmental Inocula for Biodegradation Screening Tests

Kelly Jobling, Mathew Brown and Russell Davenport, Newcastle University, United Kingdom

Biodegradation screening tests (BSTs) such as ready biodegradability tests (RBTs) are key tools to evaluate and inform chemical persistence, environmental fate, and risk assessments. Standard protocols rely on low-density microbial inocula, often 100 – 10000 times lower than found in environmental matrices, and provide limited

characterisation of viable microbial cells – the primary drivers of biodegradation. The use of environmentally relevant increased microbial cell concentrations (ICCs) has been shown to reduce inocula variability and enhance test consistency, but the effect of their preparation on cell viability is unknown. Consequently, robust methods to quantify live microbial cells, in addition to total cells, are important in understanding their effect on biodegradation tests.

We have developed a flow-cytometric approach to enumerate live and dead bacterial cells in BST relevant inocula. Membrane integrity staining with SYTO 9 and Ethidium homodimer-2 was optimised for activated sludge and successfully applied to freshwater and marine samples, supporting cross-environment comparisons. Live/dead flow cytometry analysis is typically performed on fresh samples, but real-world BST workflows may limit immediate quantification. Therefore, we evaluated storage methods to determine whether samples could be preserved for accurate downstream analysis.

Activated sludge samples were stored at -80°C after preservation by two methods 1) glycerol and 2) glutaraldehyde fixation, and analysed by flow cytometry at 0, 7, 28 and 90 days. Glycerol preserved samples had significantly lower percentages of dead cells ($p < 0.001$) compared to fixed samples and did not show a significant increase dead cell percentage relative to untreated controls, indicating preservation of viability. In contrast, glutaraldehyde fixation showed elevated dead cell percentages compared to the untreated controls at later time points.

This flow-cytometry method provides a framework for live cell quantification in BST inocula and outlines evidence-based storage guidelines when immediate sample analysis is not feasible. Future work will compare this approach with complementary techniques such as 16S qPCR to further evaluate cell quantification methods. By improving microbial characterisation, this method supports reproducible and robust biodegradation testing, enabling correlations between microbial viability and test outcomes for environmental persistence and risk assessments.

3.04.P-Tu178 Colony Forming Units in Screening Tests: A Useful Predictor or Non-Informative Parameter?

Kristina Miller, Sarah Sertl and Christian Maeß, Noack Laboratorien, Germany

Colony Forming Units (CFU) are becoming increasingly important for characterizing inocula in OECD biodegradation tests, yet their predictive relevance remains uncertain. Furthermore a major limitation of CFU determinations in biodegradation testing is the lack of clear regulatory guidance on how the procedure should be performed. As CFU determinations are carried out after the start of the test, they cannot be used for pre test prediction. Since the result is only available during the test, the question arises as to whether the parameter offers any added value at all if the test meets the validity criteria. We compiled data from standard dilution plate counts from recent years and investigated whether there is a correlation between the performance of the inoculum and its CFU. We also examined whether it is possible to draw conclusions about the CFU based on dry matter of the inoculum, given that this is an important adjustable parameter within the framework of OECD 301. Although the CFU values depend on seasonal fluctuations as well as the operating conditions of the wastewater treatment plant, no relationship with degradation rates or test robustness was found. CFU results are highly method dependend and difficult to compare between laboratories or seasons. Furthermore, aerobic total variable cell count only detect microorganisms that are able to grow under the selected culture conditions, while many relevant organisms within the microbial community of the activated sludge remain uncultured. Overall CFU values represent a cultivation biased fraction of the microbial community present in the inoculum and therefore only provide contextual information but do not predict biodegradation outcomes.

3.04.P-Tu179 Validating Read-across Analogues Accounting for Metabolic Similarity. Application to Environmental Fate Endpoints

Hristiana Stoyanova (Ivanova), Darina Yordanova, Irina Dermen, Nadezhda Dimitrova and Ovanes Mekenyan, Laboratory of Mathematical Chemistry (LMC) Prof. Assen Zlatarov Burgas State University, Bulgaria

Read-across is one of the most frequently used non-animal approaches for filling toxicological data gaps. Traditionally, analogues selection for read-across has been based on physicochemical, structural, and mechanistic similarity, while metabolic similarity has been largely overlooked. This could lead to inconsistencies, as structurally similar substances may exhibit conflicting properties due to differences in their metabolic fate. There is a universal realization that considerations of the metabolic fates of the target substance and proposed source analogue(s) are important in accepting or rejecting a read-across hypothesis. Assessing metabolic similarity is challenging because metabolic pathways are complex and influenced by both biotic and

abiotic factors. Comparisons of target and source metabolic information most often suffers from the lack of experimental data. These data voids have prompted the development and use of alternative methods. In silico tools that simulate (a)biotic transformations provide efficient instruments of assessing metabolic consistency when experimental toxicokinetic data are limited. Integrating these assessments into analogue selection can help explain differences in endpoint values among analogue chemicals and support the identification of more suitable source substances for read-across purposes. This will aid in establishing metabolic consistency between the chemicals used in a read-across argument (i.e., establish similarity in their (a)biotic transformations). Of particular importance are found to be the identification of common metabolic pathway(s), common metabolite(s), and similarity concerning the formation of reactive metabolites. Illustrative examples will be used to demonstrate the advantages of considering the metabolic information, provided by the OASIS software, showing that even closely related chemicals can differ in microbial metabolism, underscoring the need to include metabolic similarity assessment as a key criterion in regulatory decision-making. This work highlights the importance of incorporating metabolism information into read-across justifications to improve scientific confidence and transparency. The absence of such considerations remains a major source of uncertainty in many read-across arguments.

3.04.P-Tu180 New perspectives for AI-assisted prediction of biodegradability - a status report

Markus Seyfried and Maximilian Beckers, DSM-Firmenich SA, Switzerland

Models predicting biodegradability are useful tools to provide early-stage assessments that can serve different purposes:

- 1- For Regulatory professionals to prioritize chemicals in the absence of experimental data, mitigate concerns or flag up potentially persistent molecules with otherwise harmful properties such as toxicity
- 2- For Researchers to design environmentally friendly chemicals, i.e., help identify and prioritize candidates with expected favorable properties and provide alternatives of improved biodegradability, thus contributing to efforts to make chemicals safer for the environment and more sustainable.

As presented recently, both public and commercially available prediction models are currently unfit for purpose for design of biodegradable molecules. In addition, both from a scientific and regulatory point of view, they are in need of updates, given the fact that historic biodegradation data sets are characterized by a high occurrence of false negatives and that models using the same sets have been in widespread use for decades.

This study sums up developments with a focus on experimental data and model training sets, provides a critical assessment of the current situation and shows how significant improvements in prediction output can be reached.

Repercussions will be discussed for future developments of fit-for-purpose models targeted to regulatory or scientific audiences.

3.04.P-Tu181 Persistence Assessment of Azo-Dyes Based on Metabolomics Approach

Ilaria Bruno¹, Chiara Volpe¹, Monica Locatelli² and Christian Espinoza³, (1)KAHLBERG Consulting S.r.l, Italy, (2)KAHLBERG Consulting S.r.l., Italy, (3)AkiNaO, France

According to the REACH Regulation (EC) No 1907/2006, further information on degradation behaviour is required when screening-level biodegradation tests indicate potential persistence.

The persistence assessment must be conducted based on simulation biodegradation studies, such as OECD TG 309, which require radiolabelling or analytical techniques capable of monitoring the parent substance and its potential transformation products.

The structural complexity of azo dyes, together with their variable composition, makes radiolabelling technically unfeasible or economically prohibitive. It also limits classical analytical methodologies that, being targeted approaches, are unable to identify transformation products with unknown structure.

The goal of this project is the application of the E-fate Metabolomic Footprint (EMF) approach adapted to the traditional OECD TG 309, to investigate the biodegradation pathway of parent compound and its potential biotransformation products, with the proposal of their chemical structures.

Two kinetic studies, based on both OECD TG 309 and EMF, were conducted in parallel on the reference azo dye in natural surface water.

These complementary studies led to comparable kinetic values of the parent compound, confirming the

suitability of the metabolomics approach as an alternative strategy to assess the persistence properties of the reference dye.

In addition, the EMF study showed the kinetic pattern of by-products, confirming their complete degradation during the study and enabling the identification of a number of transformation products, with the proposal of the most relevant chemical structures.

In conclusion, the alternative metabolomics approach allowed the monitoring of the biodegradation behaviour of both parent compound and its transformation products, also enabling the proposal of chemical structures for the most relevant by-products. Overall, the EMF study can be considered a robust alternative approach for assessing the potential persistence of organic dyes, for which classical methodologies represent obstacles for the application of the standard OECD TG guideline.

3.04.P-Tu182 Determining Degradation Rates Using OECD 302B Methodology with Concurrent Size Exclusion Chromatography Analysis: Case Study with Modified Celluloses

Yu Xue¹, Aschwin van der Horst¹, Thomas Ravensbergen¹, Imane Garcia² and Sang-Tae Kim³, (1)Ashland Central R&D Team, Netherlands, (2)Ashland Regulatory Affairs and Toxicology, France, (3)Ashland Regulatory Affairs and Toxicology, United States

In previous studies, a method for analyzing molecular weight changes for various types of modified cellulose polymers over the course of a 302B using size exclusion chromatography (SEC) assessment was presented. Through this assessment, molecular weight and chemical alterations could be observed that would not be identified with the traditional OECD 302B measurements alone. This study aims to focus on a single cellulose type, hydroxyethyl cellulose (HEC) with varying molar substitution (MS) to determine the effect MS has on the percent degradation result, the molecular weight distribution, and degradation rate constant over the course of a 60-day OECD 302B assay. Six grades of HEC, with MS ranging from 0.5 – 1.7 MS, were tested in an OECD 302B. All samples tested were found to be classified as “primary, inherently biodegradable” following OECD classification guidelines. The three HEC grades with “low” MS were found to have a different pattern of molecular weight changes compared to those at “high” MS, such as a further decrease in molecular weight (MW) and narrower MW distribution. The lower MS materials were calculated to have a two-phase degradation rate constant of 0.5-1.66/day in phase 1, and 0/day in phase 2. The higher MS materials were calculated to have a two-phase or three-phase degradation rate constant of 0.36-0.42/day in phase 1, 0.02-0.03/day in phase 2, and 0.01/day in phase 3. This acts as a case study to assess the: (1) usage of concurrent SEC monitoring during an OECD biodegradation screening assay to be able to determine the differences small changes in physio-chemical properties (i.e., MS) have on the biodegradation profile, (2) ability to calculate degradation rate constants without using higher tier testing methods, and (3) identify potential transformation products for further toxicity/biodegradation evaluation.

3.04.P-Tu183 Environmental Emissions and Human Exposure to PBDEs in South Korea using Material Flow Analysis and Multimedia modeling

Shi-Jin Kim and Hee Seok Kim, Seokyeong University, Korea, Republic of

Polybrominated diphenyl ethers (PBDEs), which are listed among persistent organic pollutants, have become ubiquitous in the environment and in human bodies due to their widespread industrial use as flame retardants. Human body burdens of PBDEs have increased exponentially, by approximately a factor of 100 from the 1970s to the 2000s. These lipophilic substances are known to enter the human body through various exposure routes, including environmental contact and fish consumption, and it is therefore necessary to quantitatively assess human exposure to evaluate their safety. In the present work, environmental emissions of four PBDE congeners (BDE-47, BDE-99, BDE-153, BDE-209) to air and water through their life cycles in South Korea were estimated using Material Flow Analysis (MFA). In addition, human daily intakes of PBDEs were simulated using environmental multimedia fate model K-SimpleBox and the European Union System for Evaluation of Substances (EUSES) exposure model. The estimated emissions of four congeners in South Korea indicated that atmospheric emissions were largely attributed to the production or product-use phase, depending on the substance. In contrast, emissions to water were predominantly driven by waste-treatment processes such as landfilling for all congeners. Annual human exposure through environmental and dietary intake showed distinct patterns by substance: low-brominated congeners were strongly influenced by water emissions, whereas highly brominated congeners such as BDE-209 were mainly driven by atmospheric emissions. The predicted human exposure levels were further compared with reference values to identify substances and life-cycle stages requiring improved exposure management. This study confirms that environmental emissions and human exposure to certain PBDE congeners may persist due to the waste-disposal phase of products, despite reductions in PBDE production and use following strengthened regulations in South Korea. However, as the modeling

results rely on several assumptions and involve considerable uncertainties, more refined follow-up studies will be required.

3.04.P-Tu184 BiSX and BiSX/g-C₃N₄ (X = Cl, Br, I): Synthesis, Characterization, Photocatalysis of Crystal Violet Dye and Carbon Dioxide

YU YUN LIN, Chin-Hsuan Tseng, Shiuh-Tsuen Huang and Chiing-Chang Chen, Department of Science Education and Application, National Taichung University of Education, Taiwan (Greater China)

Global climate change and water pollution are two major environmental concerns intensified by rapid industrialization and the discharge of organic dyes, which are difficult to degrade by conventional methods. Photocatalysis offers an efficient and sustainable solution, converting light energy into chemical energy for pollutant removal and CO₂ reduction. In this study, BiSX (X = Cl, Br, I) photocatalysts and their composites with graphitic carbon nitride (g-C₃N₄) were successfully synthesized via a high-pressure hydrothermal method to enhance visible-light-driven photocatalytic performance. The BiSX/g-C₃N₄ heterojunctions were designed to facilitate charge separation and suppress electron-hole recombination.

The photocatalytic degradation of crystal violet (CV) dye and CO₂ photoreduction were systematically investigated under visible-light irradiation. Kinetic analysis based on the pseudo-first-order model revealed that the BiSbI/5 wt% g-C₃N₄ composite achieved the highest degradation rate constant ($k = 0.066 \text{ h}^{-1}$), which is 3.35 times that of pure BiSbI. Enhanced activity was attributed to improved band alignment, larger surface area, and efficient charge transfer between BiSX and g-C₃N₄. For CO₂ photoreduction, all BiSX/g-C₃N₄ composites exhibited superior CH₄ generation compared with pure BiSX and g-C₃N₄, confirming the beneficial effect of heterostructure formation. Among them, the BiSbI/75 wt% g-C₃N₄ composite demonstrated the highest methane yield ($0.5993 \mu\text{mol g}^{-1} \text{ h}^{-1}$) and selectivity (92.60%), indicating excellent visible-light response and CO₂ conversion capability.

Overall, the incorporation of g-C₃N₄ significantly enhanced the photocatalytic efficiency of BiSX by promoting charge separation, light absorption, and CO₂ adsorption. This work provides insight into the rational design of Bi-based heterojunction photocatalysts for dual applications in environmental purification and solar-driven carbon conversion, demonstrating the potential of BiSX/g-C₃N₄ composites as efficient and sustainable materials for photocatalytic systems.

3.04.P-Tu185 Optimising the Adsorption System for Complex “Produced Water” Treatment: Exploring Mixtures of Sorbents with Variable Properties

Lucia Rodriguez-Freire, Kasim Sani Musa and David Werner, Newcastle University, United Kingdom

Crude oil extraction generates large volumes of wastewater known as Produced Water (PW), with quantities increasing significantly as wells mature. This PW contains hydrocarbons, heavy metals and dissolved salts, posing substantial environmental risks. Although physical, chemical and biological treatment processes exist, many advanced technologies are constrained by high energy consumption and operational costs. Adsorption remains a promising solution due to its simplicity, low cost, scalability and potential for regeneration. However, the use of single adsorbents limits treatment efficiency across diverse pollutant classes. This research addresses this gap by evaluating individual and composite adsorbent systems to enhance PW treatment performance.

Synthetic PW samples were prepared to enable controlled assessment of phenolic compounds and heavy metals in batch and column studies. Batch tests quantified pollutant removal and adsorption parameters for multiple adsorbents, including F400, RH550, RH700, softwood biochar and coconut shell, across defined particle size ranges. Initial experiments using 5 mg adsorbent per 50 mL sample showed that F400 (150–250 μm) effectively removed phenolic compounds, with preferential uptake following the order 2,4-dimethylphenol > m-cresol > phenol. Heavy metal adsorption followed the trend lead > zinc > manganese. Time-dependent distribution coefficients confirmed strong sorption of zinc, lead, m-cresol and 2,4-dimethylphenol, whereas phenol and

manganese exhibited weak affinity. Comparative assessments also highlighted differential interactions between pollutant classes and container materials.

A subsequent experiment using 10 mg of F400, RH550 and RH700 over four weeks reinforced these trends, particularly for heavy metals. An intraparticle diffusion model developed in MATLAB elucidated transport mechanisms within adsorbent pores, distinguishing internal diffusion control from film-based limitations. The combined experimental and modelling outcomes support the design of layered or mixed adsorbent configurations and contribute to a predictive column performance model. Overall, this work advances the development of efficient, low-cost adsorption-based filtration systems for sustainable PW treatment.

3.04.P-Tu186 The Importance of Being Extracted – How the Choice of Extraction Methods impacts Persistence Assessment

Daniela Classen, Anna Böhnhardt, Ulrich Joehncke and Daniel Sättler, German Environment Agency (UBA), Germany

In simulation tests using soil (OECD 307) and sediment (OECD 308), the fate and behavior of chemicals belonging to different classes were assessed for regulatory purposes. Frequently, [14C]-labelled substances were used in these tests which allow to quantify non-extractable residues (NER). Total NER, i.e. the NER remaining in the matrix after exhaustive extraction, can be categorised in three NER types depending on their release potential or environmental relevance. Type I NER are defined as sequestered and strongly sorbed parent compound or its transformations products and have the highest potential for remobilization. Two methods, Silylation and EDTA extraction, make it possible to extract the type I NERs from the total NERs and to quantify their proportion.

According to ECHA guidance R.11 the choice of extraction procedure depends on its applicability and efficiency and should be evaluated & justified in a pre-study. One of the two recommended extraction procedures is an exhaustive Pressurized Liquid Extraction (PLE) with a standard solvent. Alternatively, the sample can also undergo a stepwise solvent extraction first, followed by PLE, both with a substance specific solvent. Compared to the stepwise solvent extraction, exhaustive extractions are conducted under harsher conditions (e.g. elevated temperature and/or elevated pressure) and thus release part of the molecules strongly sorbed to the matrix. Key endpoint in persistency assessment are degradation half-lives (DegT50). Since the update of ECHA R.11 and CLP guidance, total NER have to be considered for DegT50 calculation. Thus occurrence of NER effects persistence assessment of chemicals registered under REACH as well as biocides and affecting also pharmaceuticals and pesticides. As type I NER are of regulatory importance, identified amounts of type I NER after Silylation or EDTA extraction have to be considered in DegT50 calculations. In case neither Silylation nor EDTA extraction are feasible or were not performed, the total NER should be regarded as non-degraded parent substance and considered as such for DegT50 derivation. In this study we want to illustrate the importance of extraction methods applied to soil and sediment for determination of total NER from a regulatory point of view. Based on substance cases we discuss how the efficiency of the extraction procedures in pre-tests could be assessed and show their impact on the persistence assessment of industrial chemicals under REACH and CLP.

3.04.P-Tu187 Speciation of Non-extractable residues of pesticides in soil and sediment by 4-pool kinetic analysis

Xiao (Michael) Huang¹, Dave Barnekow² and Mark Krieger², (1)Environaisoft, LLC & Corteva Agriscience, United States, (2)Corteva Agriscience

This study explores the feasibility of speciation of non-extractable residues (NERs) of pesticides in soil and sediments by 4-pool kinetic analysis. The 4-pool refers to parent compound, metabolites, NERs, and CO₂. We developed the parent->NER, one-metabolite->NER, and two-metabolites->NER 4-pool models to capture the following characteristic kinetic behaviors of formation of NERs in soil and sediment respectively: (1) If a parent compound is bound as NERs, the metabolites (in the unit of % applied radioactivity) kinetically drive the evolution of CO₂ only; (2) if a metabolite (x) in a sequential (as opposed to branched) pathway is bound as NERs, the metabolites are split into two terms (i.e., m1(t) and m2(t)) which kinetically drive the formation of NERs and evolution of CO₂ respectively; (3) if two metabolites (x) and (y) are bound as NERs, the metabolites are also split into m1(t) and m2(t) but m1(t) kinetically drives the formation of NERs in a biphasic manner. By these three 4-pool models, we could identify the bound metabolites in soil and sediment for the seven pesticides

respectively. We find that a metabolite, even bound as NERs in soil, is not necessarily bound in sediment if it degrades faster in water than it diffuses/adsorbs onto the sediment or the binding is hindered under anaerobic conditions. However, if metabolites are bound in soil or sediment, we could identify bound compounds by 4-pool kinetic analysis. By including NERs as bound compounds, we can also improve kinetic modeling of pesticide degradation in soil and water/sediment systems respectively. This approach allows for assessment of environmental risk of NERs and evaluation of the persistence of a pesticide with NERs from a molecular level.

3.04.P-Tu188 Spatial Distribution of PCB 28 and PCB 153 in Deep Oceans Using a Global Multimedia Model

Vikas Kumar Meena and Asif Qureshi, Indian Institute of Technology Hyderabad, India

Polychlorinated biphenyls (PCBs) are an important class of persistent organic pollutants, that are still widely detected in the environment despite a global ban. This persistence thus continues to be a threat to ocean health, human and environmental health by extension. While the behavior of PCBs in the atmosphere and surface ocean waters has been well studied, their fate and transport in the deep ocean is poorly known. Understanding the spatial distribution and transport of these pollutants in deep oceans is crucial for quantifying the role of oceans as the long-term reservoirs of PCBs. Additionally, it enables a better estimation of PCBs global residence times and their ability to be reintroduced into surface oceans, be exchanged with atmosphere, undergo long-range transport and bioaccumulate in marine food-chains. In this study, we expanded a widely used global multimedia fate and transport model, BETR-Global, to oceanic depths of up to 6000 m. Model simulations were run from 1930 to 2024 for two representative congeners PCB-28 and PCB-153. Modeled concentrations compared favorably with PCBs concentration in both surface and deep oceans. Our results showed that 82.5% of total oceanic PCB-28 exists in surface ocean, 13.1% between 200 to 1000 m and approximately 4.4% below 1000 m. In contrast, 13.9% of total oceanic PCB-153 exists in surface ocean, 15.0% between 200 to 1000 m and approximately 71.1% below 1000 m. Results thus showed a contrasting fate of PCB congeners, and that deep oceans will indeed form an important part of global PCBs cycle. Further detailed results will be presented during the conference.

3.04.P-Tu189 UV Filter Contamination in Indoor Dust across Residential and Educational Settings

Pablo Esteban, Irene Navarro, Covadonga Alonso, Silvia Royano, Juan Escobar Arnanz, Adrian De la Torre and Maria Angeles Martinez, Center for Energy, Environmental and Technological Research (CIEMAT), Spain

Organic ultraviolet (UV) filters are widely employed in industry as chemical additives in the manufacture of plastics, polymers, and pigments to prevent UV-induced photodegradation, thereby maintaining their original appearance, long-term stability, and physical integrity. Beyond their industrial use, UV filters are also extensively used in cosmetic and personal care products to protect the skin from ultraviolet radiation. Consequently, during the manufacture, use, and disposal of these materials and products, UV filters can be released and mobilized into different environmental compartments, where their presence can jeopardize the health of ecosystems. For this reason, this study conducted a quantitative assessment of 20 UV filters (industrial and cosmetic derivatives) present in dust from domestic and public indoor environments.

During 2022, a total of 84 indoor dust samples were collected from various locations across the Madrid metropolitan area, including urban residential settings and public spaces such as offices and primary and secondary schools. In the latter sites, both settled and airborne dust were sampled. Samples were processed using a QuEChERS procedure and analyzed by gas chromatography coupled with tandem mass spectrometry.

UV filters were quantified in all dust samples, with quantification frequencies (Qf) ranging from 57% to 100%. The pollution profile was dominated by octocrylene and 2-ethylhexyl p-methoxycinnamate (EHMC) (Qf = 100%) and two phenolic benzotriazoles, UV-328 and drometrizole (UV-P) (Qf = 99%). Interestingly, some compounds exhibited a wide concentration range, such as octocrylene (41,600 ng/g) and homosalate (HMS, 17613 ng/g), whereas others showed much narrower variability, with levels between N.D. 2 ng/g for UV-234 and N.D. 4 ng/g for UV-928.

The ubiquitous presence of UV filters in indoor residential and public dust samples highlights their continuous release from consumer products and persistence. As people spend most of their time indoors, the results underscore the importance of considering these settings as critical compartments for assessing human exposure to emerging contaminants and their potential environmental impact.

Disclaimer/Disclosure:

The present study is part of the project PID2019-105990RB-I00 funded by MICIU/AEI/10.13039/501100011033. Pablo Esteban's work is supported by Ministerio de Ciencia, Innovación y Universidades, Comunidad de Madrid and Fondo Social Europeo Plus through the contract PEJ-2024-AI/ECO-31738.

3.04.P-Tu190 Occurrence of Tire Rubber-Derived Compounds in Sewage Sludge from Spanish Wastewater Treatment Plants

Melanie Rojas, Irene Navarro, Silvia Royano, Juan Escobar Arnanz, Adrian De la Torre and Maria Angeles Martínez, Center for Energy, Environmental and Technological Research (CIEMAT), Spain

Tire wear particles (TWPs) are continuously generated from road traffic involving the release of tire rubber-derived compounds (TRDCs) such as N,N'-substituted p-phenylenediamines benzothiazoles and benzotriazoles, among others. Wastewater treatment plants (WWTPs) can contribute to the diffusion of these pollutants into the environment. During wastewater treatment, many of these substances can be retained in sewage sludge, which is often applied to agricultural soils as fertilizer. This practice can facilitate their transfer to terrestrial ecosystems, where they may persist, bioaccumulate, and potentially enter food chains, therefore posing an emerging environmental concern.

This study investigates the presence of 25 selected TRDCs in 16 sewage sludge samples collected before and after the anaerobic digestion process from two WWTPs located in the Tagus River basin (Spain). Samples (1 g) were extracted using an optimized procedure based on sequential sonication (2x15 min) with acetonitrile and acetone/hexane (1:1), followed by centrifugation (3000 rpm, 5 min). Extracts were analyzed by UHPLC–MS/MS and the identification and quantification were carried out using isotopic dilution method. The methodology was validated (SANTE/2020/12830; SANTE/11312/2021), achieving good recoveries (71–117%) and repeatability (RSDr <20%) for all analytes.

TRDCs were present in all samples with total concentrations in the range of 183.9 and 2257.4 ng/g. High detection frequencies (Df >85%) were observed for 72% of the target compounds, confirming their widespread occurrence in sludge. The most abundant compounds were MBTH (179.3 ng/g, median), 2-OH-BTH (34.8 ng/g) and DBZA (19.1 ng/g). Interestingly, 6PPD-Q was frequently (100%, Df) found at variable levels (0.3–25.8 ng/g, min-max).

The monitoring of TRDCs in WWTPs contributes to broaden the knowledge of their environmental impact and associated risks in the ecosystems. These findings highlight the persistence of TRDCs in sludge even after treatment and suggest their potential release into amended agricultural soils, with implications for soil quality and trophic transfer.

Disclaimer/Disclosure:

This study is part of the project PID2019-105990RB-I00 funded by the MCIN/AEI/10.13039/501100011033. Melanie Alejandra Rojas' work is supported by Ministerio de Ciencia, Innovación y Universidades, Comunidad de Madrid and Fondo Social Europeo Plus through the contract PEJ-2023-AI/ECO-26779.

3.04.P-Tu191 Biodegradation of Tire Additives by Sludge and River Microbiomes: Impacts of Pretreatment, Seasonality, Co-Substrates, and Microbial Community Shifts

Göksu Celik¹, Claire Lamb², Verena Reichart³, Camille von Den Langenberg², Alexander Loy² and Thilo Hofmann², (1)Institute of Water Chemistry, University of Vienna, Austria, (2)University of Vienna, Austria, (3)University of Applied Sciences Vienna (UAS Technikum), Austria

Tire-wear particles (TWPs) contribute an estimated 3.4–5.9 million tonnes of particulate pollution to aquatic environments annually. These particles, beside the road matrix, are complex mixtures of rubber polymers, fillers, metals, and various tire additives (TAs), including antioxidants, vulcanization agents, and corrosion inhibitors. While many additives and their transformation products exhibit toxicity and/or persistence, quantitative data on their biodegradation remain limited. This study investigated the effects of (i) microbiome sources (activated sludge vs. river), (ii) inoculum pretreatment (washed/aerated vs. fresh), (iii) seasonality (winter vs. spring), and (iv) co-substrate (glucose) availability on the biodegradation of eleven representative TAs (6PPD, IPPD, diphenylguanidine, benzothiazoles, benzotriazoles, and HMMM) using the OECD 301F respirometry test. Microbial community composition and genetic material abundance were monitored through 16S rRNA gene sequencing and qPCR. Biodegradation was highest with fresh activated sludge, followed by

river microbiomes, and washed sludge. The effect of seasonal variation on biodegradation rates was more pronounced in river microbiomes, with compounds like hydroxybenzothiazole and diphenylguanidine degrading by over 70% in spring but less than 20% in winter. The addition of glucose as a co-substrate enhanced degradation of most TAs in sludge microbiomes but reduced it in river microbiomes. Chemical treatments induced shifts in microbial community composition over 28-days test period, with *Rhodococcus* dominating benzothiazole treatments, while Gammaproteobacteria, including *Pseudomonas* and *Pseudoxanthomonas*, enriching on IPPD and 6PPD. Among the tested additives, only hydroxybenzothiazole was readily biodegradable, while the others appeared more persistent, warranting further investigation to determine their half-lives. These findings indicate that microbiome profiling provides valuable mechanistic insight for biodegradation studies, revealing treatment-specific community shifts and identifying taxa potentially responsible for degradation, information not captured by chemical analysis alone. Given the large-scale global emissions of TWPs, these findings also have implications for persistence assessments under frameworks such as REACH, as well as for policy decisions regarding additive regulation.

3.04.P-Tu192 Photooxidation of Polluting Oil Slicks: Linking Physical Changes and Chemical Transformations under Simulated Conditions

Manee Patanapongpibul, Anouk Volker, Wesley Browne and Nathalie Katsonis, University of Groningen, Netherlands

Catastrophic events such as tanker collisions and oil well blowouts, together with routine operational leaks from ships, ports, and industrial facilities, release oil that spreads across the ocean surface. These slicks now span an area twice the size of France. This pollution of seawater by oil slicks represents a significant environmental risk, affecting not only ecosystems but also economies and human health.

When exposed to sunlight, the oil slicks oxidize into persistent and potentially harmful products. The kinetics of this oil transformation under sunlight illumination remain incompletely understood. Our aim is to understand and predict the chemical transformation of polluting oil slicks, under solar illumination, in order to inform the development of safer and more effective oil spill response strategies, including optimized dispersant selection, dosage, and timing.

Our strategy involves an automated platform that simulates oil spill conditions to study photooxidation-driven degradation of light and heavy oils, linking physical and chemical changes. Oil film spreading is quantified over time, and associated changes in surface tension are measured to assess potential effects of photoproducts on oil-water interfacial properties. To explore environmental relevance, aqueous composition is varied in salinity and ion content to resemble marine and freshwater systems. Our early results show that both oil type and water chemistry strongly influence film thinning and photoproduct formation, allowing assessment of how water chemistry modulates degradation kinetics. This integrated approach connects physical behavior with chemical transformations under simulated spill conditions and lays the foundation for building a robust data set to support the predictive modeling of oil spill fate.

3.04.P-Tu193 Benzo[a]anthracene Triggers Metabolic Activation and Inflammatory Injury in Human Lung Cells via CYP450 Pathways

JIA-JIA TU¹, Li-Ling Ho¹, Chia-Wen Tsai² and Hui-Tsung Hsu¹, (1)Department of Public Health, China Medical University, Taiwan, Taiwan (Greater China), (2)Department of Nutrition, China Medical University, Taiwan, Taiwan (Greater China)

Polycyclic aromatic hydrocarbons (PAHs) are pervasive air pollutants that enter the respiratory system through inhalation and undergo metabolic activation to elicit toxic effects. Although benzo[a]pyrene (BaP) is well characterized as a known human carcinogen, its structural analogue benzo[a]anthracene (BaA) remains comparatively understudied, particularly regarding respiratory toxicity. This study systematically compared the cytotoxic, inflammatory, and metabolic effects of BaA and BaP to address this gap. Two human lung cell models—BEAS-2B and A549—were used to assess differences in susceptibility and biological responses. Cells were exposed to BaA or BaP at concentrations ranging from 0.5 to 20 μ M for 12, 24, and 48 hours. Cell viability was assessed using the MTT assay, and interleukin-6 (IL-6) secretion was quantified via enzyme-linked immunosorbent assay. Furthermore, the activation of the aryl hydrocarbon receptor (AhR) signaling pathway and the expression of downstream enzymes (CYP1A1, CYP1A2, and CYP1B1) were analyzed by Western

blotting.

Both PAHs decreased cell viability in a clear dose- and time-dependent manner, with BaA consistently exerting stronger cytotoxicity than BaP and BEAS-2B cells showing greater sensitivity than A549 cells. Inflammatory responses differed markedly: BaP induced a rapid six-fold increase in IL-6 secretion in A549 cells, whereas BaA triggered only a moderate three-fold rise. Mechanistically, both compounds activated the AhR–CYP1 pathway but with cell-type specificity. A549 cells showed ligand-dependent AhR degradation, while BEAS-2B cells maintained stable AhR levels. CYP1A1 and CYP1A2 were strongly induced, whereas CYP1B1 showed weaker activation.

In conclusion, although BaA and BaP share similar metabolic activation pathways, they manifest distinct toxicological profiles: BaA acts as a more potent cytotoxic agent, whereas BaP serves as a stronger pro-inflammatory stimulus. These findings highlight BaA as a PAH of emerging concern and suggest that risk assessments relying solely on BaP equivalence may underestimate the specific cytotoxic hazards posed by other abundant PAHs in the atmosphere.

3.04.P-Tu194 ANALYSIS OF BILE AS A BIOMARKER OF ABIETIC ACID TOXICITY IN FISH

Carlos H.L. Soares¹ and **Ivana Eunice Baptista²**, (1)*Federal University of Santa Catarina, CCB, Florianópolis, SC, Brazil*, (2)*Federal University of Santa Catarina, CCB, Florianópolis, SC, Brazil*

Abietic acid is one of the acid resins produced by conifers such as *Pinus*. Considerable amounts of acid resins are produced and released in pulp and paper mill effluents and discharged into rivers and water bodies. In this study, through bile analysis, the possible deleterious effects of abietic acid were evaluated in fish (*Oreochromis niloticus*), under laboratory conditions, exposed to concentrations in the range of 150 to 180 µg/L. Fish were kept in groups of 10 individuals in 300L water tanks and fed with commercial feed. Bile samples were collected after a 10-day exposure period. The bile samples were extracted with different solvents and prepared for analysis by GC/MS-TOF, after derivatization with BSA or by methylation in a basic medium. Samples were also analyzed by fluorescence, monitoring emissions at 250 and 280 nm, with excitation at 356 and 458 nm. The obtained results demonstrated alterations in the bile acid profile, especially cholic and deoxycholic acids. Fluorescence analysis demonstrated significant alterations in the emission spectrum of the bile samples, indicating alterations in their composition.

Keywords: Resin acids, toxicity, bile, bile acids.

3.05 Bridging Science, Regulation, and Remediation on PFAS: Addressing Unknowns and Emerging Challenges

3.05.T-01 Exploring the Unknown PFAS Space in Time Series From the Rhine and Danube: A Multi-Laboratory Study

Hanna Joerss¹, **André Macherius²**, **Bernd Göckener³**, **Boris Bugsel⁴**, **Pradeep Dewapriya⁵**, **Qiuguo Fu⁶**, **Christoph Kornpointner⁷**, **René Lämmer³**, **Jonathan Zweigle⁸**, **Christian Zwiener, Diploma⁹** and **Jan Koschorreck¹⁰**, (1)*Helmholtz Center Hereon, Germany*, (2)*Bavarian Environment Agency (LfU), Germany*, (3)*Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*, (4)*TZW: DVGW-Technologiezentrum Wasser (German Water Centre), Germany*, (5)*University of Queensland, Australia*, (6)*Helmholtz Centre for Environmental Research GmbH (UFZ), Germany*, (7)*Environment Agency Austria (EAA), Austria*, (8)*University of Copenhagen, Denmark*, (9)*Eberhard Karls University of Tübingen, Germany*, (10)*German Environment Agency (UBA), Germany*

Using sum parameters and screening approaches, recent studies have revealed that target analysis can considerably underestimate the environmental burden of per- and polyfluoroalkyl substances (PFAS). For suspended particulate matter (SPM) from the German Environmental Specimen Bank, the sum of PFAS concentrations determined by the direct total oxidizable precursor (dTOP) assay was up to 145 times higher as compared to target analysis for 41 PFAS. The ratio of the extractable organically bound fluorine (EOF) to the dTOP mass fraction increased after 2010, implying a higher proportion of organofluorine compounds not oxidizable to targeted perfluoroalkyl acids. To explore the delta, i.e. unknown precursors and other untargeted PFAS, and discuss time trends, seven laboratories investigated SPM extracts from the rivers Rhine (Koblenz, 2005-2021) and Danube (Jochenstein, 2009-2021). The covered chemical space was expanded by using both reversed-phase liquid chromatography and supercritical fluid chromatography coupled to high-resolution mass spectrometry. To evaluate the data, PFAS-specific suspect and non-target screening (NTS) approaches were applied.

Based on the in-house workflows of the participating laboratories, 617 prioritized features were reported, 24 by three or more laboratories. Relative peak areas and time trends agreed well with target analysis. As members of

a previously untargeted PFAS class, three keto-substituted fluorotelomer sulfonic acids (FTSA-ketones) were tentatively identified (6:2, 8:2 and 10:2), with the 6:2 homologue increasing over time. In addition, pentafluorosulfanyl (SF) PFOS was tentatively identified, potentially originating from aqueous film-forming foams. Similar to PFOS, SF5-PFOS showed a pronounced decline after 2009. FTSA-ketones may degrade to PFCAs in dTOP, adding to unknown precursors, while SF₅-PFOS has been shown to remain stable in dTOP but would still be captured in the EOF sum.

The results of this study demonstrate that a combination of targeted analysis, sum parameters, and suspect/non-target screening is essential to obtain a comprehensive understanding of environmental PFAS exposure.

Semiquantification will be conducted to assess how much of the delta can be explained and how much remains unresolved. In addition, selected raw datasets will be reprocessed to identify the major factors contributing to differences in reported features among laboratories and to compare the various platforms.

3.05.T-02 Defining the Use of Per- And Polyfluorinated Substances (PFAS) In Green Energy Technologies and Providing Information on Their Functions: The Case of Wind Turbines and Batteries

Amanda Rensmo¹, Anna J. Miller², Rainer Lohmann³, Carla A. Ng⁴, Xenia Trier⁵, Martin Scheringer² and Ian Cousins¹, (1)Stockholm University, Sweden, (2)ETH Zurich, Switzerland, (3)University of Rhode Island, United States, (4)University of Pittsburgh, United States, (5)University of Copenhagen, Denmark

PFASs are currently proposed for restriction under the EU's chemical legislation REACH (the universal PFAS restriction or uPFAS proposal). The aim is to address the risks these highly persistent chemicals pose to the environment and human health. Under the proposal, all uses, except those explicitly exempted, would be banned for manufacture, use or placing on the market as substances on their own. Detailed information on PFAS uses and functionalities is therefore crucial in making these decisions, as well as for other contexts including academia (e.g., alternatives assessments) and industry (e.g., development of new materials).

Prior work has catalogued PFAS uses across many sectors, but information on chemical function is often lacking. Here, we define both uses and functionalities in greater detail for the case of green energy technologies, specifically for wind turbines and batteries. To do so, we draw on the unique dataset of 5 600 comments from the uPFAS public consultation. We list candidate PFAS uses with various levels of information, starting from the chemical function, then the specific product or article component, and finally the broader area of use. By adopting the Functional Substitution framework we link the chemical, end-use, and service function of each listed candidate use. To verify a selection of these candidate uses, we assess the academic literature and engage directly with actors along the value chain for consultation and feedback.

In one prominent example, for wind turbines, we find that although some stakeholders indicated that wind turbine blades were coated with fluoropolymers, the verification step showed that other, more suitable, materials are actually used. Batteries, by contrast, are found across many areas of use, each with distinct technical requirements. Accordingly, the wide range of batteries on the market is included in our candidate list, incorporating available information on their specific functions. Drawing on additional sources, we identify which battery types typically require PFAS in certain components, and which components do not.

As a result, this work provides input for alternatives assessments and, in extension, for evaluation under the essential use concept. It also informs the universal PFAS restriction proposal and helps address the current data gaps noted for the energy sector.

3.05.T-03 Estimated Costs and Impacts of Widespread PFAS Remediation Across Europe

Alison Ling¹, Raphaëlle Aubert², Eurydice Bersi³, Stéphane Horel² and Hans Peter H. Arp⁴, (1)University of St Thomas, United States, (2)Le Monde, France, (3)Reporters United, Greece, (4)Norwegian Geotechnical Institute (NGI), Norway

Regulations and public concern related to PFAS in drinking water, wastewater, and soils continues to evolve. However, PFAS remediation and treatment space to date lacks context about how much it would cost to remediate PFAS across a wide geographical extent and targeting multiple media. This study aims to estimate PFAS remediation costs and mass removal impacts for targeted environmental media across the 27 EU member states for two different use restriction scenarios based on publicly available data. Identified media with available data, high potential PFAS impacts, and perceived likelihood of future regulation included heavily contaminated soil sites, drinking water, landfill leachate, and wastewater effluent and sludges. While direct industrial

discharges to water and air are likely a major source of PFAS, those were not included here due to limited data availability.

Two scenarios were developed: a "legacy" scenario to reflect remediation of previously emitted long-chain PFAS and an "emerging" scenario to reflect remediation of ongoing emissions of PFAS, including short-chain and ultra-short chain PFAS like TFA, many of which are still used with increasing emission rates. Site data was sourced from publicly available datasets and verified through industry sources, journalists, and academic partners. Costs and PFAS removed were estimated based on commercially available treatment trains using either published cost curves with associated uncertainty metrics or Monte Carlo simulations based on available data. Achievable removal of PFAAs and precursors through remediation was estimated by multiplying mass or volume treated for each media by estimated concentrations for those PFAS from the literature.

Legacy estimates total about €1.1 to €6.0 billion/yr, while emerging costs (adding wastewater effluent/sludges and more intensive treatment to address ultrashort-chain PFAS) are €52 to €200 billion/ yr. Estimated achievable removal and destruction of PFAAs and precursors under the emerging scenario totals 1 ton/year to 20 tons/year. Compared to the estimated total EU annual use rates for PFAAs and precursors of 15,000 to 50,000 tons/year, the emerging scenario could address less than 0.5% of annual EU PFAAs uses. This reflects limited impact of remediating the targeted media for PFAS. Results demonstrate that environmental remediation of PFAS is not a sufficient, affordable, or plausible approach to managing environmental PFAS stocks.

3.05.T-04 Advancing Our Understanding Point Sources of PFAS Emissions to Air

Jane Thrasher¹, Christopher Lutes², Sam Pollard¹ and Yolande Macklin¹, (1)Jacobs, United Kingdom, (2)No Affiliation, United States

Much effort has been focussed on understanding potential sources of per and polyfluorinated alkyl substances (PFAS) emissions directly to the ground and water environments. However there is increasing recognition that PFAS emissions to air are an ongoing and important source of environmental PFAS with potential for both local and global impacts.

In this presentation we consider some of the mechanisms by which PFAS can be emitted to air. We also discuss the activities, land uses and industries which may be resulting in point sources emissions of PFAS to air, and the gaps in our knowledge.

Research into aerial emissions from fluorochemical manufacturing sites illustrates the magnitude and wide area impact they have. However while industries such as semiconductor and textile manufacturing are recognised as being among the biggest global users of PFAS, there appears to be very little research into the magnitude of emissions from these activities.

It is well recognised that landfills have for many years been receivers of PFAS-containing waste, and household waste including PFAS will continue to be deposited to landfill even as regulations restricting new use of PFAS come into force. Concern is growing over the appropriate management of PFAS in leachate emissions from these sites, however the potential for aerial emission of PFAS should also be considered.

Pathways for emission include fugitive emissions and stack emissions. Stack emissions from many processes will be subject to abatement to control the emissions of other 'conventional' contaminants. There appears to be limited study of the effectiveness of these abatements for controlling the discharge of PFAS. Thermal treatments may alter and transform PFAS, but studies of incineration show that very high temperatures are required for complete PFAS mineralisation. It has been shown that products of incomplete combustion of commonly used PFAS (including those present in firefighting foams and fluoropolymers) can include Trifluoroacetic Acid (TFA) and other PFAS of concern within the atmosphere.

Further global effort is required to better understand these potential sources and their significance to future global management of PFAS. The authors will give recommendations on prioritisation of further work.

3.05.P Bridging Science, Regulation, and Remediation on PFAS: Addressing Unknowns and Emerging Challenges

3.05.P-Tu195 A curated PFAS polymer database: data extraction and chemical space mapping

Patrik Andersson¹, Anna Kärrman², Lili Jiang¹ and Lena Manzhynski¹, (1)Umeå University, Sweden, (2)Orebro University, Sweden

Per- and polyfluoroalkyl substances (PFAS) are widely used and highly persistent, yet most attention has focused on low-molecular-weight PFAS. Much less is known about PFAS polymers, even though they are used on a large scale and may act as both direct and indirect sources of non-polymeric PFAS. Their fuzzy naming, stochastic composition, and lack of standard structural identifiers mean they are poorly represented in public inventories and are rarely included in data analyses or modelling studies.

This work aims to systematically identify, curate and chemically characterise PFAS polymers from major public resources to support improved assessment of their chemical diversity and potential environmental fate. We developed a rule-based information extraction workflow using regular expressions for PFAS polymer extraction. Potential PFAS polymers were sampled and evaluated by experts, and overlapping entries between sources were removed. Polymer names were cleaned and deduplicated, and the resulting dataset was normalised for multivariate analysis.

The curated database contains more than 1,800 PFAS polymer entries with diverse naming conventions and structural descriptions, including relatively well-defined polymers and substances of Unknown or Variable composition, Complex reaction products or Biological materials (UVCB). A grey area was identified for polymers that meet the PFAS definition via perfluorinated end groups rather than backbone units, which are not clearly captured by current side-chain fluorinated polymer, perfluoropolyether and fluoropolymer classes. Ongoing work applies multivariate statistical methods to map chemical variation and explore classification schemes for PFAS polymers. The database and resulting analyses provide a new foundation for integrating PFAS polymers into chemical assessment, fate modelling, and regulatory discussions.

3.05.P-Tu196 If Fluoropolymer Production is of Concern, What is its Future?

Rainer Lohmann¹, Ian Cousins², Jamie DeWitt³, Gretta Goldenman⁴, Dorte Herzke⁵, Mark Miller⁶, Carla A. Ng⁷, Sharyle Patton⁶, Martin Scheringer⁸, Xenia Trier⁹ and Zhanyun Wang⁸, (1)University of Rhode Island, United States, (2)Stockholm University, Sweden, (3)Oregon State University, United States, (4)Milieu Consulting, Belgium, (5)Norwegian Institute for Air Research, Norway, (6)No Affiliation, United States, (7)University of Pittsburgh, United States, (8)ETH Zurich, Switzerland, (9)University of Copenhagen, Denmark

As concerns over the ubiquitous global contamination by per- and polyfluoroalkyl substances (PFAS) and impacts on environmental and human health have risen, the regulatory response has initially mainly focused on non-polymeric PFAS. Production and use of fluoropolymers (FPs) has received more attention recently, with respect to their essentiality to modern societies and considerations of their life-cycle impacts. The European Union is grappling with this in their PFAS restriction process, which might restrict the use of PFAS in many consumer products, while allowing the production and use of FPs in industrial applications.

Here we review available evidence on life-cycle impacts of FP production, use and end-of life. Fluoropolymer production sites remain contaminated from PFAS used as polymer processing aids, also often called 'dispersion aids', which typically have been perfluoroalkylcarboxylic acids (PFCAs) such as PFOA and PFNA that have well-documented toxicities. In recent years, substitute fluoropolymer processing aids (such as hexafluoropropylene oxide-dimer acid, HFPO-DA) have raised similar persistence and toxicity concerns to legacy PFCAs used initially. In addition to processing aids, there is further evidence of major emissions of a wider range of PFAS, including monomers, oligomers, other reagents, and synthesis by-products during fluoropolymer production. The toxicity of many FP processing aids is well-documented, while the toxicity of many other PFAS emitted during production and fluoropolymers themselves is less established. Concerns remain over the persistence and disposal of fluoropolymers. The persistence of FPs coupled with their associated emissions during production makes it inherently difficult for regulatory authorities to protect the environment and human health from PFAS, while keeping FPs being produced for applications deemed essential.

3.05.P-Tu197 Understanding Fluoropolymers and Their Life Cycle

Zhanyun Wang¹, Eeva Leinala² and Naoko Moritani², (1)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (2)Organization for Economic Co-operation and Development (OECD), France

Per- and polyfluoroalkyl substances (PFASs) are a diverse class of synthetic chemicals that have attracted significant attention since the early 2000s. While extensive research and regulatory efforts have focused on non-polymeric PFASs, their polymeric counterparts remain comparatively understudied. This report, developed by the OECD Global PFAS Group, synthesizes scientific and technical information on the life cycle of fluoropolymers—a key subclass of polymeric PFASs characterized by perfluorinated methylene moieties (e.g., $-\text{CF}_2\text{CF}_2-$, $-\text{CF}_2\text{CH}_2-$) within the polymer backbone. The study begins with a comprehensive review of the chemical identities of fluoropolymers in the global market, including a non-exhaustive inventory of over 130 unique active Chemical Abstract Service (CAS) Registry Numbers. It then examines the full life cycle of these materials, covering production and use, the presence of other PFASs in commercial formulations, degradation during use and end-of-life processing, and environmental releases. Despite their widespread industrial and consumer applications, significant knowledge gaps persist—particularly regarding the presence of other PFASs in formulations, degradation pathways, and environmental emissions. Nevertheless, existing evidence shows that PFAS contaminants can originate from unreacted materials, intermediates, processing aids, byproducts, and degradation products throughout the fluoropolymer life cycle. Many of these substances are highly persistent and may remain in products or be released at various stages. This work underscores the need for comprehensive investigation into the structural diversity and life-cycle behavior of fluoropolymers while providing information to regulators and other stakeholders to improve risk management of fluoropolymers. The findings provide a foundation for global stakeholders to develop coordinated and effective strategies, while highlighting critical areas for future research and policy development. This report completes a series of three reports from the Global PFAS Group on polymeric PFAS.

Disclaimer/Disclosure:

The report was prepared under the framework of the Global PFAS Group and developed with financial support of Denmark, Japan and the United Kingdom. The report was also reviewed and endorsed by the Working Party on Risk Management and is published under the responsibility of the OECD Chemicals and Biotechnology Committee.

3.05.P-Tu198 Global Inventory of Fluoropolymer Production Plants and Their Associated Environmental Contamination of Per- And Polyfluoroalkyl Substances (PFASs)

Anna J. Miller¹, Kevin Kleemann¹, Juliane Glüge², Ian Cousins³, Dorte Herzke⁴, Rainer Lohmann⁵, Mark F. Miller⁶, Amanda Rensmo³, Xenia Trier⁷, Zhanyun Wang⁸ and Martin Scheringer¹, (1)ETH Zurich, Switzerland, (2)Swiss Federal Office for the Environment, Switzerland, (3)Stockholm University, Sweden, (4)Norwegian Institute for Air Research, Norway, (5)University of Rhode Island, United States, (6)National Center for Advancing Translational Sciences, United States, (7)University of Copenhagen, Denmark, (8)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Fluoropolymers (FPs) are widely used across many sectors of industry and consumer products, due to their special properties including chemical, oxidative, and thermal resistance, and extreme durability. However, the life cycle of FPs, and especially their production, is associated with high emissions of a wide range of organofluorine substances including monomers, oligomers, reagents (such as processing aids), and reaction byproducts into the environment. Many of these are non-polymeric per- and polyfluoroalkyl substances (PFASs) that are highly mobile, persistent, and toxic. To begin to evaluate the worldwide environmental and health implications of FP production, a global overview of fluoropolymer production plants (FPPs) and their associated contamination is needed. In this study, we first identified, located, and documented FPPs worldwide, and then compiled previously published PFAS measurements in the environmental media surrounding them, including surface water, groundwater, air, dust, soil, sediment, plant material, human and animal blood serum and tissues.

We found 55 current and historical FPPs located across the United States, Europe, and Asia, in 44 different cities. Of these 45 locations, only 15 have associated PFAS measurements in environmental media reported in the peer-reviewed literature. PFAS concentrations were highest at or close to the FPPs (distance <1km) with concentrations in surface water reaching up to 100 000 µg/L and in soil or sediment up to 280 000 µg/kg dry weight. The measurements also show high concentrations in media at distances up to 150 km away from the FPP sites. Perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkyl ether carboxylic acids (PFECAs) were most often reported with very high concentrations, but many more PFASs (>230) were detected across all sites, highlighting the diversity of PFAS contamination. Finally, based on these data, we estimate that approximately 19 million people live within 10 km of an FPP (164 million in a 50-km radius, around 2% of the world population) and are therefore likely affected by associated PFAS contamination. This study shows the large global problem of FP production while also revealing gaps in measurement data, underscoring the need for increased monitoring, risk management, innovation in safe-and-sustainable-by-design FP alternatives, preventing non-essential FP uses, and comprehensive regulation covering all life-cycle stages of FPs.

3.05.P-Tu200 PFAS Emissions and Fragmentation Pathways During Fluorine-Based DRIE of GeSn Microstructures

Ira Villinger¹, Lea Ghisalberti¹, Stephan Pfister¹, Kirsten Moselund² and Rutuja Rajendra Mandavkar², (1)ETH Zurich, Switzerland, (2)Paul Scherrer Institute, Switzerland

The semiconductor industry's shift towards sustainable manufacturing demands a better understanding of scope 1 process emissions, which arise primarily from plasma etching and other vacuum-based processes. Plasma etching is a critical step in device fabrication. This step enables high-precision patterns and surface cleaning through the use of reactive gas chemistries. However, these same processes can generate and release potent greenhouse gases (SF₆, SF_x⁺, CF₄, C₄F₈ and more), contributing to the industry's carbon footprint and limiting advances in sustainable process design and posing a significant challenge to the sector's overall sustainability efforts, which lower-emission become more important with increased demand for semiconductors. In this work, we investigate emissions produced during deep reactive ion etching (DRIE) of germanium–tin (GeSn) microstructures, a promising material platform for next-generation Group IV photonics. Etching experiments were conducted on an SPTS Rapier system using fluorine-based chemistries, including sulfur hexafluoride (SF₆), a persistent perfluoroalkyl substance (PFAS) with a global warming potential of approximately 23,500–24,300 times higher than CO₂. Gas-phase analysis was performed using a ToFwerk Process Analyzer equipped with an electron-impact (EI) ion source and a compact time-of-flight (CTOF) mass analyzer. Time-resolved mass spectra were correlated with process flow data to identify characteristic isotopic and fragmentation signatures of SF₆, including SF_x⁺ (x = 1–5) ions and other fluorinated species formed during plasma-induced decomposition and additional EI-induced fragmentation. In addition, fragment analysis revealed the presence of sputtered Ge and Sn species in the exhaust, indicating that the energetic fluorine plasma promotes both chemical etching and physical sputtering of the GeSn surface. These measurements provide detailed insight into PFAS fragmentation pathways, plasma–surface interactions, and the formation of secondary fluorinated by-products, contributing to provide primary data for the life cycle inventory of products manufactured through fluorine-based DRIE.

3.05.P-Tu201 Removal of Per- and Polyfluoroalkyl Substances (PFAS) From Water Using Superfine Powdered Activated Carbon in Laboratory Batch Tests

Mélanie Z. Lauria¹, Florence Bonvin², Christophe Bonvin², Steven J. Chow¹ and Christa McArdell¹, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Membrtec S.A., Switzerland

Per- and polyfluoroalkyl substances (PFAS) present a major challenge for water treatment facilities and contaminated sites, where ensuring low concentrations in drinking water and preventing their release into the environment is critical. Increasingly stringent water quality regulations and rising treatment costs call for more efficient and sustainable remediation strategies. While granular activated carbon (GAC; typically, 0.4–2.4 mm) is widely used for PFAS adsorption, superfine powdered activated carbon (sPAC; ~0.001–0.003 mm), which is produced by wet-milling conventional powdered activated carbon (PAC; ~0.01–0.05 mm), offers substantially greater external surface area and reduced diffusion limitations, enabling faster adsorption kinetics and potentially more compact and cost-effective treatment. Although sPAC has shown superior performance for other micropollutants, its effectiveness for PFAS removal has not yet been systematically evaluated. In this study, several PAC materials were screened, and two were selected for detailed investigation using laboratory batch tests. Adsorption isotherms and kinetics were determined for both PAC and sPAC in groundwater, followed by evaluation of PFAS sorption behavior in different water matrices with varying dissolved organic carbon levels to assess competitive sorption effects. The influence of PFAS properties (e.g.

different head group, chain length) was examined to elucidate inter- and intra-class sorption trends. PFAS classes analyzed include e.g. perfluoroalkyl carboxylic and sulfonic acids, fluorinated ethers and zwitterionic PFAS. All PFAS analyses were carried out using liquid chromatography-high resolution mass spectrometry. These findings provide a basis for assessing the applicability of sPAC for PFAS remediation. A pilot-scale study is planned to validate laboratory results under realistic conditions. This work supports treatment strategies for PFAS-contaminated drinking water resources and discharge waters, contributing to the development of more efficient and sustainable mitigation approaches.

3.05.P-Tu202 PFAS sorption by sewage sludge biochar – influence of wastewater treatment line and pyrolysis residence time on sorbent performance

*Nicolas Estoppey¹, Katinka Muri Krahn², Junjie Zhang³, Aleksandar Ivaylov Goranov⁴, Andrew R. Zimmerman⁵, Pål Jahre Nilsen⁶, Michel Hubert¹, Karen Ane Skjennum², Alexandros G. Asimakopoulos³, **Hans Peter H. Arp¹**, Erlend Sørmo⁷ and Gerard Cornelissen¹, (1)Norwegian Geotechnical Institute (NGI), Norway, (2)Lindum, Norway, (3)Norwegian University of Science & Technology, Norway, (4)Old Dominion University (ODU), Norway, (5)University of Florida, United States, (6)VOW ASA, Norway, (7)Norwegian University of Life Sciences, Norway*

Sewage sludge (SS) pyrolysis is a promising strategy to eliminate persistent contaminants such as PFAS while sequestering carbon and producing biochar (BC), a sorbent that improves soil fertility, water retention, and pollutant immobilisation. However, the influence of wastewater treatment processes (e.g., use of coagulants) and pyrolysis conditions (e.g., residence time) on sorption properties remains poorly understood, limiting scalable production and product quality.

This study compares porosity and PFOA sorption efficiency of sewage sludge biochars (SSBC) from two wastewater treatment lines: one conventional using metal-based coagulants and anaerobic digestion (ChemDigSSBC) and the other producing biologically treated, non-digested sludges (BioRawSSBC). SSBC from both lines were produced at residence times of 20, 40, and 50 minutes in a full-scale pyrolyzer.

ChemDigSSBC exhibited a surface area (115 m² g⁻¹) 13 times higher than BioRawSSBC (8.9 m² g⁻¹) in the pore size range accommodating PFOA molecules (> 1.5 nm). This difference was mainly attributed to the higher iron content in chemically treated sludges used for ChemDigSSBC (12 g kg⁻¹) compared to biologically treated sludges used for BioRawSSBC (2.8 g kg⁻¹). Residence time had minimal impact. Consequently, PFOA-sorption to ChemDigSSBC showed values for Freundlich adsorption coefficients (log K_F 5.00-5.07) two orders of magnitude higher than those for BioRawSSBC (log K_F 2.84-3.25). The difference in iron content in the final biochars (24 vs. 7.3 g kg⁻¹) likely also contributed to this effect, since iron oxides provide positively charged surfaces that bind PFAS head groups. Carbon content was not a key factor since ChemDigSSBC (35.3% C) outperformed BioRawSSBC (45.7% C).

Using literature data, we showed that biochars with iron content > 20 g kg⁻¹ exhibited high porosity (> 60% of pores > 1.5 nm), and strong sorption (log K_F values > 4.3) when pyrolyzed at > 700°C.

This study indicates that wastewater treatment processes can substantially influence PFAS sorption performance of biochar from pyrolyzed sludge, which is key if facilities aim to produce high-value sorbents.

3.05.P-Tu203 Exposure-Led and Preventive PFAS Regulation: Diverging Policy Models and Global Implications

Adel Malek¹, Jude Arokianathar² and Joanna Matthew², (1)Yordas Group, Canada, (2)Yordas Group, United Kingdom

Global regulation of per- and polyfluoroalkyl substances (PFAS) is developing rapidly, but through different policy models across jurisdictions. While the European Union has moved toward preventive, class-based regulation, the United States and many other regions continue to rely primarily on exposure-led and substance-specific controls.

This work examines the regulatory design of exposure-led PFAS governance outside the EU, as well as the factors that shape these approaches, including political structure, jurisdictional authority, and regulatory risk tolerance. The objective is to explain how evolving scientific information is translated into enforceable regulatory controls across fragmented systems, and how this contrasts with the more centralised European model.

The analysis applies regulatory intelligence methods, including longitudinal horizon scanning, comparative policy assessment, and review of federal, state, and selected international regulatory initiatives. Emphasis is placed on drinking water regulation, hazardous substance designation, discharge permitting, product-level restrictions, and reporting requirements, with attention to how these instruments distribute compliance and remediation responsibility.

Preliminary observations indicate that exposure-led systems are increasingly concentrating PFAS management and remediation obligations on site owners, utilities, and waste operators. At the same time, upstream production and use controls remain more limited. This structure can create periods of regulatory uncertainty for several sectors as standards evolve.

The findings highlight how differing regulatory models create uneven planning horizons, compliance burdens, and remediation responsibilities across the global PFAS value chain. These insights are relevant to researchers, consultants, industry stakeholders, and regulators seeking to manage PFAS risk under evolving and decentralised regulatory frameworks.

3.05.P-Tu204 From Substance-Specific Controls to Class-Based Regulation: The EU Policy Shift on PFAS
Adel Malek¹, Jude Arokianathar² and Joanna Matthew², (1)Yordas Group, Canada, (2)Yordas Group, United Kingdom

Per- and polyfluoroalkyl substances (PFAS) have historically been regulated in the European Union through substance-specific controls. More recently, this approach has evolved toward class-based regulation, reflecting concerns related to persistence, widespread occurrence, and long-term environmental management. This shift is now reflected in the proposed EU-wide PFAS restriction.

This work examines the policy and regulatory drivers behind the EU transition from targeted substance controls to a group-based risk management framework. The purpose is to explain how environmental considerations, substitution feasibility, and regulatory practicality collectively shaped the current direction of PFAS regulation, and how this differs from exposure-led approaches used in other jurisdictions.

The analysis is based on regulatory pathway mapping, horizon scanning of ongoing EU consultations, and sector-level use profiling across industrial, medical, and professional applications. Particular attention is given to fluoropolymers, semiconductor manufacturing, medical devices, and personal protective equipment, where essential-use considerations intersect with regulatory transition planning.

Preliminary observations indicate that the EU approach places strong emphasis on prevention, upstream control, and transition to alternatives, while many non-EU systems continue to focus primarily on downstream exposure management, such as drinking water standards and site remediation. At the same time, the pace of regulatory development has moved faster than the availability of harmonised technical guidance in several implementation areas, creating short-term uncertainty for regulated sectors.

This work shows how policy design itself is now being used as a primary risk management tool for PFAS in Europe, and how this approach is increasingly diverging from exposure-led control strategies elsewhere. The findings are directly relevant to regulators, remediation professionals, and industry stakeholders planning compliance, substitution, and long-term regulatory obligations under class-based PFAS controls.

3.05.P-Tu205 Watch your blindspot: How chemical regulations drive regrettable substitutions
Ola Dosunmu¹, Rob Whiting², Avtar Mathar³, Nigel Watson⁴ and Andrew Sweetman⁵, (1)Lancaster University, United Kingdom, (2)WSP, United Kingdom, (3)University of York, United Kingdom, (4)Lancaster Environment Centre, Lancaster University, United Kingdom, (5)Lancaster University, United States

The need for an effective and dynamic chemical regulatory framework is increasingly evident. While chemicals contribute significantly to societal development and economic growth, hazardous chemicals pose major risks to human health and the environment. As chemical use increases, so does potential exposure, creating complex management challenges. Regulation is a key approach to mitigate these risks. For example, the EU's REACH Regulation seeks to protect health and the environment and promote substitution of the most harmful chemicals, while the Stockholm Convention targets persistent organic pollutants (POPs). In response, manufacturers have substituted chemicals such as PFAS, bisphenols, and flame retardants (e.g., PBDEs) with alternatives. However,

instances of regrettable substitutions where replacements are equally or more harmful are reported. This study examines how regulations like REACH and SC may unintentionally exacerbate regrettable substitutions, increasing risks to humans and ecosystems. We employed a mixed-method approach, combining survey (Likert-scale, multiple choice, free text), semi-structured interviews, and document analysis. Survey responses were analysed using descriptive statistics and qualitative data analysed using reflexive thematic analysis. 52 Participants completed the survey (Government: 13; Industry: 15; Academia: 7; Associations: 4; Consultancy: 10; NGOs: 2). We analysed 17 documents and conducted 31 interviews. When asked whether regulations exacerbate regrettable substitutions, 70% of government respondents, 50% from industry, and 13% from consultancy agreed (i.e., somewhat or strongly). Across all participants (N=43), about 50% agreed and 30% were neutral. Conversely, over three-quarters 95% (N=41) agreed that data availability strongly influences substitution outcomes, and 85% (N=34) viewed regulation as a major driver of substitution. Qualitative findings indicate that current frameworks may unintentionally promote regrettable substitutions due to prioritisation of market access for chemicals, fragmented regulatory approaches, exemptions (including data requirements), time-driven decisions, barriers to transparency and information exchange and the need to balance internal market functioning with chemical risk management. These findings highlight the importance of developing regulatory frameworks in a way that will ensure informed substitutions of hazardous chemicals such as PFAS.

3.05.P-Tu206 Ensuring Safety in PFAS Replacement: Chemical Stability and New Product Formation in Plasma-Processed Bio-Based Coatings for Textiles

Xiaoyu Zhang¹, Eduardo Santamaría Aranda², Panagiotis D. Kolokathis³, Lander Verlinden⁴, Jan Jordens⁴, Stefan Voorspoels⁴, Adrian Covaci⁵ and Milica Velimirovic⁴, (1)Flemish Institute for Technological Research (VITO) & University of Antwerp (UA), Belgium, (2)Department of Sustainability and Advanced Materials, NOVEX, Raposal 65, 26580 Arnedo, La Rioja, Spain., Spain, (3)NovaMechanics MIKE, Cyprus, (4)Flemish Institute for Technological Research (VITO), Belgium, (5)Toxicological Center, University of Antwerp (UA), Universiteitsplein 1, 2610 Wilrijk, Belgium, Belgium

Per- and polyfluoroalkyl substances (PFAS) are widely used for surface coating in textiles due to their low surface energy, which endows liquid repellent ability. However, growing evidence indicates that specific PFAS, such as perfluorooctanoic acid (PFOA), may be linked to human health adverse outcomes. In response, the European Union has implemented progressively stricter regulations on PFAS applications. Therefore, there is an increasing amount of studies on PFAS-free alternatives, e.g. cellulose, starch and chitosan. However, the safety of applying these PFAS-free alternative materials remains insufficiently understood.

This research, within the SSbD4CheM project, investigates the chemical changes occurring in bio-based coating materials for textiles during atmospheric plasma processing, a treatment that can potentially introduce oxidation and other chemical modifications to coating precursors. The tested bio-based formulations have already shown strong water-repellency on polyethylene terephthalate (PET) fabrics, with high water contact angles (>140°) and self-cleaning behavior against common liquids, such as coffee, milk, and red wine. To characterize the chemical changes and identify the transformation products, Liquid Chromatography–Mass Spectrometry (LC-MS) with different ionization sources, including Atmospheric Pressure Photoionization (APPI) and Electrospray Ionization (ESI) were applied, and reactions such as epoxidation have been observed. The toxicity of newly generated transformation products will be assessed through the SbD4Skin tool that incorporates quantitative structure-property relationship models for skin toxicity endpoints prediction. By integrating chemical characterization with toxicity prediction, this work will provide an evaluation of the overall safety of applying PFAS-free materials in textile coating applications.

3.05.P-Tu207 Closing the PFAS Mass Balance - Multi-Approach Data Processing for Enhanced Workflows.

Om Shrestha¹, Jeffrey Dahl¹, Toshiya Matsubara² and Ruth Marfil-Vega³, (1)Shimadzu Corporation, Japan,

(2)Shimadzu Scientific Instruments, Inc., (3)Marketing, Shimadzu Scientific Instruments

Comprehensive non-targeted screening of PFAS is essential to help scientists with closing the mass balance of PFAS in the environment. An untargeted LC-MS method employing a sensitive, high-mass-accuracy quadrupole time-of-flight (QToF) instrument coupled with a novel data-processing approach was used to participate in the PFAS NTA Interlaboratory Study organized by the National Institute of Standards and Technology (NIST) in 2024.

Three unknown samples (A, B, and C) obtained from NIST were analyzed to identify PFAS following the guidelines for the 2024 NTA ILS. To ensure maximum coverage of the PFAS chemical space analyzed a data-dependent acquisition (DDA) method in both positive and negative ionization modes was implemented using QToF mass spectrometry. The DDA method m/z trigger settings were validated using a standard mix with targets from method EPA 1633.

Multi-approach data processing included identifying PFAS compounds using NIST Library Match, the NIST suspect list, FluoroMatch and LabSolutions. This systematic and complimentary approach allowed for accurate analysis and identification of PFAS in the unknown samples. The NIST MS2 library was converted into a software-compatible format to facilitate accurate spectrum matching. Identification through NIST Suspect Match relied on common product ions, neutral losses, and isotope Score, with a mass error threshold of less than 5 ppm. FluoroMatch analysis incorporated its built-in PFAS library and algorithms, utilizing Kendrick Mass Defect plots to identify PFAS and related families. Results were dereplicated, and PFAS were identified and scored according to NIST-defined criteria. For samples A, B, and C, there were 40, 57, and 105 negative PFAS matches, respectively, and 9, 44, and 29 positive matches.

In this presentation we will demonstrate the workflow and how the comprehensive multi-data approach benefits the PFAS identification.

3.05.P-Tu208 Transcriptomic Benchmark Dose–Derived Human Equivalent Doses Following Subacute and Subchronic PFOA Exposure in Mouse Liver

Ivana Ivelja¹, Jelena Marković Filipović¹, Nemanja Todorović¹, Mladena Lalić Popović¹ and Nebojsa Andrić², (1)University of Novi Sad, Serbia, (2)University of Novi Sad, Faculty of Sciences, Department of Biology and Ecology, Serbia, Serbia

Perfluorooctanoic acid (PFOA) is a persistent per- and polyfluoroalkyl substance (PFAS) widely detected in environmental and biological samples, raising concerns about potential health effects. The liver, a major site for xenobiotic metabolism and accumulation, remains insufficiently characterized regarding molecular responses to subacute and subchronic PFOA exposure prior to overt toxicity. In this study, benchmark dose modeling was applied to derive human equivalent doses (HEDs) for transcriptomic changes in mouse liver following 14-day (subacute) and 90-day (subchronic) exposure to PFOA via drinking water at doses 0.06, 1.5, and 22 mg/kg B.W./day, and 0.006, 0.06, and 0.6 mg/kg B.W./day, respectively. mRNA sequencing revealed a dose-dependent increase in differentially expressed genes (DEGs), with the highest dose yielding 3,470 DEGs in subacute study, and 1,898 DEGs in subchronic study. Analysis of transcriptomic HEDs yielded median and 5th percentile values of 572.4 and 31.7 µg/kg B.W./day in the subacute study, and 22.6 and 0.0036 µg/kg B.W./day in the subchronic study. Functional enrichment analysis identified fatty acid metabolism and xenobiotic metabolism as the most sensitive biological processes. Process-level HEDs indicated greater sensitivity of fatty acid metabolism compared to xenobiotic metabolism, with median HEDs of 96.8 and 167.5 µg/kg B.W./day in the subacute study, decreasing to 11.3 and 20.1 µg/kg B.W./day following subchronic exposure. The 5th percentile transcriptomic HED from the subchronic study fell below the estimated population exposure level of 0.45 µg/kg B.W./day, while process-level HEDs for fatty acid metabolism were within one order of magnitude of this exposure estimate. These findings suggest that current population exposure may be sufficient to change hepatic gene expression, including pathways involved in fatty acid and xenobiotic metabolism.

3.06.P Chemical Additives in Consumer Products – Analytical Methods, Challenges, and Regulatory Needs

3.06.P-We204 Next Generation Chemical Risk Assessment of Plastic Additives in Consumer Products Using LC- and DART-timsTOF-MS

Lisa Marina Reinhardt¹, Kas Houthuijs¹, Federica Nardella¹, Maria Margalef² and Sicco Brandsma¹, (1)VU University Amsterdam (VU), Netherlands, (2)A-LIFE (Environment & Health), VU University Amsterdam (VU), Netherlands

Additives in plastic products, including flame retardants, plasticizers, and other substances, are intentionally added to improve product performance. Despite EU regulations on chemicals such as PBDEs, phthalates, and BPA, these chemicals still enter the market due to poor recycling practices or a lack of regulation in manufacturing countries. To ensure consumer safety by enforcing EU regulations, robust analytical high-throughput methods that determine the chemical composition of consumer products are needed.

This study assessed the extraction efficiencies of plastic additives, with a subsequent comparison of liquid chromatography-trapped ion mobility-mass spectrometry (LC-timsTOF-MS) analysis and high-throughput direct analysis in real time (DART)-timsTOF-MS workflow. The suspect screening lists used were based on relevant EU regulations the PlastChem database, and validated spectral libraries. Different approaches for extracting plastic additives were evaluated based on solvent extraction efficiency, compound coverage, and suitability for high-throughput workflows.

The best performing method was a two-step extraction using dichloromethane (DCM) and toluene. Re-extraction of the samples with methanol resulted in numerous features at RTs below 6 minutes, highlighting a gap of more polar compounds not extracted by DCM-toluene.

For the chemical analysis, TIMS was used to provide an additional separation dimension, which can enable the distinction of isomeric substances, such as certain phthalates. LC-timsTOF-MS analysis showed a variety of plastic additives, including antioxidants, biocides, and flame retardants. Initial experiments using DART-timsTOF-MS analysis with 12-QuickStrip sample cards have shown successful detection of plastic additives such as regulated phthalates, bisphenols and BFRs. The calibration curves for these compound groups showed good linearity, enabling quantification by DART-timsTOF-MS. Beyond this, DART offers several advantages: direct analysis without time-consuming dilution steps, the ability to analyse up to 12 samples within 2 minutes, and the elimination of large volumes of LC solvents. Full comparability assessment of LC vs. DART application is currently under assessment.

Altogether, these results highlight the potential of DART for high-throughput applications, making it particularly suitable for enforcement, where time-consuming and costly targeted methods need to be complemented by efficient suspect-screening approaches.

3.06.P-We205 Safe and environmentally sustainable textile revalorization via chemical oxidation

Tim Åström¹, Aji Mathew¹, Abhirami Manoj¹, Ulrika Nilsson¹ and Jutta Hildenbrand², (1)Stockholm University, Sweden, (2)Research Institutes of Sweden, Sweden

Accounting for more than 60% of all textiles manufactured, clothing is the most extensive application.

Europeans are estimated to consume approximately 19 kilograms per person annually. However, still, less than 1% of worn-out apparel is recycled into new garments, thereby contributing to an increased environmental load via incineration or landfill disposal. A majority of all household textiles, approximately 7 million tonnes within the EU-27 countries, corresponding to 75%, were either incinerated or deposited in landfills in 2022. However, a new EU amendment concerning textile waste was introduced in 2025 to promote a circular economy for worn-out textiles, with collection systems to facilitate an appropriate recycling of textile waste. Here, we present a novel methodology for the revalorization of worn-out textiles as an alternative to incineration and landfilling, achieved through the oxidation of cellulose in cotton-based garments using 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO).

The analytical non-target screening, based on the pre-concentration of aqueous waste effluents and solvent extraction of cotton-based textiles, was achieved using liquid chromatography coupled to a high-resolution mass spectrometer with data-dependent acquisition. Data mining was performed using Compound Discoverer 3.3 for feature extraction, peak alignment and identification with a mass spectral library, mzCloud. Only candidates with an associated fragmentation spectra, within 1.5 to 27 minutes and a fold change criterion of at least ten times the blank signal were kept during data processing.

The screening resulted in approximately 1,900 statistically significant features, where 75% were found to be more significant in the cotton-based starting material, and 25% were more pronounced in the crude cellulose nanofiber (CNF) product, indicating a small degree of chemical transfer during the valorisation of cotton. Additionally, the oxidation process resulted in several molecular features that were more pronounced in the aqueous waste effluent compared to the starting material, indicating the release of transformation products. To evaluate the sustainability of the entire valorisation process, a toxicological risk prioritisation will be conducted based on the screening results. A thorough quantification of the chemicals present in the starting material, CNF, and aqueous waste effluents will be performed to determine their distribution and levels within the process.

3.06.P-We206 Plastic Additives in Menstrual Products: from Analysis to Dermal Migration Experiments for Improved Exposure Estimates

Lara Cioni, Núria Tabla-Ruiz, Júlia Calvo and Ethel Eljarrat, *Institute of Environmental Assessment and Water Research (IDAEA)-CSIC, Spain*

Menstrual products are fundamental to ensure menstrual health, which is recognized as a fundamental human right by the World Health Organization (WHO). However, some of these products have been shown to contain chemicals of concern for human health, including phthalates (PAEs). Menstrual products are used in direct contact with vulvar or vaginal tissues, which have a high chemical absorption capacity. Therefore dermal contact with menstrual products might be a relevant exposure pathway for plastic additives. However, information about the presence of plastic additives other than PAEs in menstrual products is still poorly investigated and it is still unclear if plastic additives can be released from these products to the skin. To fill this gap, we analyzed PAEs, organophosphate esters (OPEs) and alternative plasticizers (APs) in various types of menstrual products and performed dermal migration experiments using sweat, sebum and vaginal/menstrual fluid to estimate the amount of plastic additives that is transferred from these products to the skin. All types of menstrual products analyzed (sanitary pads, panty liners, tampons, reusable sanitary pads, menstrual underwear and menstrual cups) had detectable concentrations of PAEs, OPEs and APs. Across all types of menstrual products 7 PAEs, 15 OPEs, 8 APs were detected. Differences in detection frequencies and concentrations were observed across different products potentially due to differences in product design. Reusable sanitary pads showed the highest concentrations of PAEs (median: 28856 ng/g; range: 5019–42193 ng/g) and OPEs (median: 1906 ng/g; range: 158–4068 ng/g), while the highest APs concentrations were observed in single-use sanitary pads (median: 8873 ng/g; range: 2830–11455 ng/g). Preliminary results from dermal migration experiments performed on single-use sanitary pads and panty liners showed that plastic additives can migrate from menstrual products and become available for dermal absorption. Measured easily releasable fractions (ERFs, i.e. the fraction of chemical that is released from a product and reaches the skin) ranged from 0 (<LOD) to 39% for OPEs, from 0 (<LOD) to 18% for PAEs and from 0 (<LOD) to 20% for APs. Experimentally derived ERFs constitute a step forward towards an accurate estimation of the contribution of the use of menstrual products to the overall exposure to plastic additives.

3.06.P-We207 Virtual effect-directed analysis of granulated rubber: identification of bioactive chemicals

Maria Larsson¹, Fredric Södergren Seilitz², Ayan Au Musse³, Nathalie Struwe⁴, Andi Alijagic⁴, Anna Kärrman², Thanh Wang⁵ and Magnus Engwall⁶, (1)MTM Research Centre, Örebro University, Sweden, (2)Örebro University, Sweden, (3)MTM Research Centre, Örebro University, Sweden, (4)Örebro University, Sweden, (5)Linköping University, Sweden, (6)School of Science and Technology, Örebro University, Sweden

Rubber is a ubiquitous material used in society. Chemicals are added to the rubber as processing aids, e.g. accelerators during vulcanization and to achieve desired properties, for example UV and ozone protection, leading to a complex chemical mixture in the final rubber product. Additionally, end-of-life rubber is frequently recycled into granulates used in playgrounds and artificial turf. This raises concern both for human exposure and leaching of poorly characterized chemicals, emphasizing the need for improved hazard evaluation and early-warning strategies.

In this study, we applied a virtual effect-directed analysis (vEDA) workflow integrating chemical profiling with bioreporter-based toxicological testing to characterize 21 rubber, rubber-like and alternative infill materials. Assays targeted key toxicological pathways relevant to endocrine disruption, genotoxicity and developmental toxicity.

Of the 21 samples, all but one activated the aryl-hydrocarbon receptor (AhR; 14–31,400 ng benzo[a]pyrene EQ/g), four activated the p53 pathway (0.04–0.53 µg actinomycin D EQ/g) and two activated the estrogen receptor α (ER α ; 530 and 1020 pg estradiol EQ/g). Targeted analysis of 87 polycyclic aromatic compounds (PAC) and GC-HRMS-based suspect screening were conducted.

Tentatively identified compounds were subset with bioreporter assay activity from databases and models, resulting in the tentative identification of 20 AhR- and 24 ER α - agonists and 13 potentially genotoxic compounds. Univariate analysis prioritized chemical features for quantification and toxicological confirmation. One P53-active compound, N-Isopropyl-N'-phenyl-p-phenylenediamine (IPPD) was confirmed and contributed approx. 50 % to the observed genotoxicity in the most p53 active sample. Phenylamine additives, while AhR active and detected in concentrations up to hundreds of $\mu\text{g/g}$, showed low potency, contributing little (<1 %) to the observed AhR activity. Methylated chrysene isomers conversely contributed substantially to the AhR activity. Notable differences in chemical hazards were observed between materials, with SBR showing the highest AhR and p53 activity as well as higher concentrations of quantified compounds compared to alternative materials.

Overall, this work demonstrates the capability of vEDA as an early-warning tool for detecting emerging hazards in rubber-based materials and highlights the need for continued assessment of recycled and alternative infill products.

We gratefully acknowledge the Environment and Health Department, City of Stockholm, for providing both financial support and the materials used in this study. This work was part of the European Partnership for the Assessment of Risks from Chemicals (PARC) and has received co-funding from the European Union's Horizon Europe research and innovation programme under Grant Agreement No 101057014.

3.06.P-We208 Impact of Sample Pre-processing and Extraction method on Quantification of Chemicals of Interest in Plastics

Stepan Soupal¹, Rozarka Jilkova², Jakub Martinik¹, Lisa Melymuk¹ and Katarina Rusinakova³, (1)Masaryk University, Czech Republic, (2)Faculty of Science, Masaryk University, Czech Republic, (3)No Affiliation, Czech Republic

Plastic materials are complex mixtures containing numerous additives, non-intentionally added substances and impurities, yet information on the chemical composition of plastic products remains limited. This lack of transparency, combined with concern regarding impurities, underscores the need to characterize chemical levels in plastic products to ensure regulatory compliance and improve chemical safety.

Instrumental techniques for plastic chemical analysis, whether targeted or non-targeted, require sample processing and isolation of analytes. Most reported approaches rely on solvent-based extraction. However, sample preparation methods are not standardized, and no widely accepted protocols exist. This lack of harmonization limits comparability across studies and introduces bias due to large uncertainties in chemical extraction efficiency.

In this project we evaluated existing analytical methods for the determination of chemicals in plastics. Sample preparation approaches differ widely across studies. Solvent extraction can be applied to whole pieces or powders obtained after fine homogenization, often using cryogenic milling to prevent thermolabile compounds from degradation. The most commonly used technique is ultrasound-assisted extraction, often combined with additional agitation (vortex). The primary extract may require purification before instrumental analysis, typically employing filtration in syringe, sorbent clean-up, or precipitation of polymer with methanol when the polymer dissolves in the extraction solvent.

We investigated how polymer type, sample pre-processing, solvent choice, and purification technique of primary extract influence extraction efficiency. Nine polymers were studied, including polypropylene, polyethylene, polyethylene terephthalate, polyvinyl chloride, polycarbonate, acrylonitrile butadiene styrene, high-impact polystyrene, silicone, and latex. These factors were evaluated based on extraction efficiencies of plasticizers in each polymer type.

By integrating method practicality with extraction performance, this work aims to provide recommendations for plastic extraction protocols and emphasizes the need for harmonization to improve data comparability and transparency of chemical composition of plastic consumer products, ensuring better protection of human health and the environment.

3.06.P-We209 Analysis of PFAS and Plastic Additives using DART-MS

Mariana Soares de Freitas¹, Lisa Marina Reinhardt², Jessica Schmidt³, Erik van Balderen³, Noud van der Borg⁴, Pim Leonards², Sicco Brandsma² and Maria Margalef⁵, (1)Vrije Universiteit, Netherlands, (2)VU

University Amsterdam (VU), Netherlands, (3)Bruker, Germany, (4)Bruker, Netherlands, (5)A-LIFE (Environment & Health), VU University Amsterdam (VU), Netherlands

Currently, the widespread presence of contaminants such as per- and polyfluoroalkyl substances (PFAS), legacy contaminants and other persistent organic pollutants in consumer products has raised growing concerns due to their persistence, mobility, bioaccumulative nature, and potential health and environmental risks. The large number of different PFAS and their varied structures are a great obstacle for monitoring purposes. Nowadays, liquid chromatography tandem mass spectrometry (LC-MS/MS) remains the standard technique for the detection and quantification of PFAS. However, this requires extensive sample preparation, solvent use, and long run times, factors that hinder high-throughput screening in these diverse sample sets.

To tackle these challenges, Direct Analysis in Real Time mass spectrometry (DART-MS) presents a promising alternative. DART allows the ionisation of analytes from solid, liquid or gaseous samples under ambient conditions. In addition, the analysis of one sample can be achieved within seconds. However, the quantification of analytes in samples with more complex matrices can be inaccurate due to matrix effects and would require more tedious preparations. This study focuses on the optimisation of protocols for the analysis of PFAS and plastic additives in environmental samples and consumer products. The results of newly developed DART-MS protocols will be compared to traditional PFAS quantification methods, such as LC-MS/MS. Standard mixes of diverse PFAS and plastic additives (standard mix) are used for the optimisation of instrumental parameters and refinement of analytical settings. After the method is validated for performance and robustness, complex real-life samples will be analysed using the two techniques: DART-MS and an in-house routine LC-MS/MS method. We hypothesise that DART-MS can achieve comparable identification as LC-MS/MS with less analysis time. In conclusion, this study develops DART-MS protocols for reliable contaminant detection, ultimately supporting scalable environmental monitoring and public safety initiatives.

3.06.P-We210 Hazardous chemicals in common infant garments – occurrence, migration into sweat and washout effect from laundry

Awat Dostberg, Tim Åström, Ioannis Sadiktsis, Conny Östman and Ulrika Nilsson, Stockholm University, Sweden

Skin-close infant garments from the Swedish open market were investigated for hazardous chemicals. These are compounds that may migrate from the textile fibres, be absorbed by the skin, and cause skin sensitization or other health effects. Infants are considered especially susceptible due to their thin, not fully developed skin. In this study, we screened 60 garments for 50 target compounds known from our previous surveys to occur in clothing textiles using Automated thermal desorption combined with gas chromatography-mass spectrometry (ATD-GC/MS). The aim was to determine the occurrence frequencies and the concentration levels of these compounds, as well as to investigate the washout effect from laundry of selected garments. To evaluate the wash-out effect, 10 of the 60 garments containing the highest levels of chemicals were washed separately for one, five, and ten laundry cycles, and compared with the corresponding non-washed garments. Thirty compounds, including arylamines, quinolines, phthalates, benzothiazole, and nitrobenzenes, were detected in the 60 garment samples with detection frequencies up to 80% and concentrations as high as 1.4 mg/g. The laundry experiments showed that a substantial amount of most of the target chemicals remain in the polyester garments even after ten laundry cycles. The 100% cotton garments on the other hand were found to exhibit higher washout rates, probably due to interruption of hydrogen bonds between the chemicals and the cellulose fibre. This implies that chemicals in cotton may be more readily desorbed into sweat and lead to higher migration rates than chemicals present in polyester materials. When performing artificial sweat migration experiments, we found that chemicals in cotton showed a migration rate up to three times higher compared to polyester garments. The results indicate that light coloured cotton garments are more suitable for infants due to both lower occurrence frequencies and lower concentration levels, as well as a higher chemical washout effect of the investigated chemicals. It also indicates that washing new garments, especially cotton, may reduce the risk of both migration of and exposure to these hazardous chemicals.

3.06.P-We211 Presence of Phthalate Impurities in Sunscreens and Implications for Exposure

Anezka Hudecova, Rozarka Jilkova, Jakub Martinik and Lisa Melymuk, Masaryk University, Czech Republic

The lack of compositional data for consumer products remains a widespread challenge for exposure assessment and pollutant source identification. Personal care products (PCPs) are one area where this information need is supported by regulatory requirements, with product ingredient lists identifying chemical components in a formulation. For many purposes, this provides sufficient information; however, it does not cover non-

intentionally added substances.

Based on recent concerns about the presence of di-n-hexyl phthalate (DnHexP) as an impurity from the production of the UV filter diethylamino hydroxybenzoyl hexyl benzoate (DHHB), we evaluated a range of sunscreen products on the Czech market for the presence of phthalate impurities. Products were selected based on ingredient lists, with a set of 27 products identified listing DHHB as an ingredient, and four sunscreens selected as controls that contained alternative UV filters. DnHexP was detected in 12 of 27 (44%) of the PCPs containing DHHB, and in none of the non-DHHB controls. The products containing DnHexP were diverse, including general and children's sunscreens, makeup, and lip balm. In products with detected presence of DnHexP, the concentrations ranged from 0.28 to 3.4 µg/g. Other phthalate esters, particularly shorter-chain phthalates that can be intentional additives in PCPs, were detected in five of 31 products (16%). Based on concentrations, prevalence and typical product use rates, we estimated exposure potential to European adults and children.

DnHexP is associated with reproductive toxicity and is restricted in the EU. The clear presence at levels exceeding 1 ppm in sunscreens and other cosmetics indicates a gap in information transfer requirements, as information on impurities in formulations is not systematically indexed.

3.06.P-We212 Elevated Rubber-derived Compound Concentrations in Indoor Climbing Halls Cannot be Mitigated by Climbing Hall Design or Operational Practices, Emphasizing the Need for Material-Level Solutions

Anya Sherman¹, Laura Lotteraner², Leah K. Maruschka² and Thilo Hofmann³, (1)IDAEA-CSIC, Spain, (2)University of Vienna, Austria, (3)University of Vienna, Spain

Rock climbing shoe soles are a consumer product containing elevated concentrations of many rubber-derived compounds (RDCs), including those of toxicologic concern such as 6PPD and 6PPD-quinone. Friction between climbing shoes and rock climbing holds leads to continuous generation of fine rubber particles which become airborne and are inhaled by climbers and climbing hall employees. Hence, indoor climbing halls are a hotspot for rubber-derived compound exposure. The goal of this study was to broadly assess RDC contamination levels in climbing halls globally, and to relate variations in RDC levels to climbing hall design or operational practices (e.g., ventilation), in order to identify mitigation strategies. Volunteers collected samples from forty-one climbing halls across Europe and North America utilizing a dual-sampling strategy: 119 samples of foothold powder, representing the source of rubber particle generation, and 120 samples of settled dust, representing a composite sample of airborne particulate matter, were analyzed from all halls for fourteen RDCs. RDCs were detected in every sample analyzed, with concentrations ranging from several ng/g to several hundred µg/g. Unsupervised analyses (hierarchical clustering and principal component analysis) revealed distinct groupings of samples with similar RDC levels. These groupings were relevant on a climbing hall level, as most samples within a given hall clustered together. However, supervised analyses (redundancy analysis, partial least squares regression, and univariate correlations) revealed only very weak relationships between RDC levels and climbing hall characteristics. These results demonstrate that hall design and operation cannot effectively mitigate the problem of RDC exposure in climbing halls: mitigation will require material-level solutions, specifically safe and sustainable-by-design (SSbD) innovations in the rubber used in climbing shoe soles.

3.07 Coastal Environments: At the Intersection of Human Activities and the Open Ocean

3.07.T-01 Standardization of an Acute Toxicity Test Method for Corals: A Multi-Laboratory Prevalidation Study

Kellermann³, Mareen Moeller¹, Samuel Nietzer¹, Camille Vizon¹, Tim Freitag⁴, Laura Lütjens⁵, Sascha Pawlowski⁵, Mechtilde Petersen-Thiery⁶, Nathalie Schwalbach⁷, Alice Rougier⁸, Guido Gonsior⁹, Pablo Canamas¹⁰, Olivier Detournay¹¹, Kristina Stemmer-Rau¹², Christian Lott¹², Catherine Lacherez¹³, Ana Catarina Almeida¹⁴, Christian Maeß¹⁵, Vincent Bourgetau¹⁶, Daniel Hill¹⁷, Marijn van der Laan¹⁸ and Peter J. Schupp¹, (1)Environmental Biochemistry Group, Institute for Chemistry and Biology of the Marine Environment (ICBM), Carl von Ossietzky University of Oldenburg, Germany, (2)Regulatory Services, BASF Service Europe GmbH, Germany, (3)Planeteers GmbH, Germany, (4)Experimental Ecology – Ecotoxicology, BASF SE, Germany, (5)Department of Product Safety, Regulatory Ecotoxicology, BASF SE, Germany, (6)Product Stewardship and EHS Data Management, BASF Personal Care and Nutrition GmbH, Germany, (7)Aquatic Biology, Eurofins Aquatic Ecotoxicology GmbH, Germany, (8)Eurofins Ecotoxicologie, France, (9)GG BioTech Design GmbH, Germany, (10)Helioscience, Cité de la

Cosmétique, France, (11)Planktovie, France, (12)HYDRA Marine Sciences GmbH, Germany, (13)L'Oréal, France, (14)Ecotoxicology and Risk assessment, Norwegian Institute for Water Research (NIVA), Norway, (15)Noack Laboratorien, Germany, (16)ECOSEASTEMS, France, (17)Department of Ecotoxicology, Scymaris, Brixham Laboratory, Freshwater Quarry, Brixham, Devon, TQ5 9JE, UK, United Kingdom, (18)Dept. Of Freshwater and Marine Ecology, University of Amsterdam, The Netherlands, Netherlands

Coral reefs support immense biodiversity and provide critical ecosystem services, yet face unprecedented threats from anthropogenic stressors including chemical contamination. A fundamental challenge in coral ecotoxicology is the absence of standardized testing methods. No internationally recognized test guidelines exist for assessing toxicity in corals, leading to variable and sometimes contradictory results across different laboratories and study designs. This fragmentation undermines reliable environmental risk assessments. Standardized test methods—such as those established by OECD and ISO—have proven effective for other aquatic toxicology test methods by ensuring reproducibility and comparability across different laboratories and geographic locations.

To address this critical gap, we developed a 96-hour semi-static acute toxicity test method specifically designed for the coral species *M. digitata*, evaluating both sublethal (bleaching; EC50) and lethal (mortality; LC50) endpoints. To evaluate whether this method produces reproducible and comparable results across different laboratory settings, multi-laboratory prevalidation trials were conducted involving thirteen independent laboratories across six European countries (six in Germany, four in France, one in the Netherlands, one in Norway, and one in the UK), with each laboratory independently conducting the complete test protocol. The coordinated efforts of these partner laboratories have been fundamental to demonstrating the method's robustness and transferability. Results from the prevalidation trials demonstrate that estimated EC50 bleaching values cluster within a relatively narrow range, providing strong evidence that the coral toxicity test method can generate comparable results independent of laboratory location or operator. This consistency in bleaching response across geographically dispersed sites demonstrates the robustness and reliability of this endpoint for inter-laboratory standardization. This prevalidation study represents a significant milestone toward establishing an international ISO standard for coral acute toxicity testing, made possible through dedicated participation of each laboratory partner. By providing a validated, reproducible framework applicable across diverse laboratory settings, standardization of this method will enhance data comparability, strengthen hazard assessment protocols, and improve our capacity to identify the effects of chemicals on coral reef ecosystems.

3.07.T-02 Neurotoxic Effects of Metal-Rich Particulate Matter on Neotropical Native Fish Brain: Bioaccumulation and Enzymatic Responses

Mariana Vitorino de Carvalho¹, Guilherme Andrade Neto Schmitz Boeing², Maira Rodrigues Lima¹, Rafaella Monteiro¹, Iara da Costa Souza¹, Julieta Griboff³, Fabiano Bendhack⁴, Magdalena Monferran⁵, Daniel Alberto Wunderlin⁵ and Marisa Narciso Fernandes¹, (1)Federal University of São Carlos (UFSCar), Brazil, (2)State University of Campinas, Brazil, (3)National Scientific and Technical Research Council (CONICET), Argentina, (4)Federal University of Paraná, Brazil, (5)National University of Córdoba, Argentina

Industrial activities in coastal areas release metal-rich settleable particulate matter (SePM) into the environment, raising significant concerns about its potential neurotoxic effects on aquatic life. Once in the water, SePM dissociates into metallic nanoparticles and becomes a source of metals/metalloids to biota, which bioaccumulate these contaminants and pose neurotoxic effects. This study investigated the biochemical and bioaccumulation responses in the brain tissue of the neotropical estuarine fish, *Centropomus parallelus*, after a 96-hour exposure to three concentrations of SePM (T1=0.01, T2=0.1, and T3=1.0 g L⁻¹) and a control group (CN).

Acetylcholinesterase (AChE) activity in the brain was measured as a biomarker of neurotoxicity, and 17 elements were quantified by ICP-MS. Principal Component Analysis (PCA) revealed distinct metal accumulation patterns among treatments, with the highest concentration (T3) strongly associated with Ce, Rb, Ni, and Zr. AChE activity remained unchanged at lower SePM levels but was significantly inhibited at the T3 concentration (1.0 g L⁻¹). This inhibition suggests a threshold beyond which neurochemical regulation is compromised. Spearman correlations identified a positive correlation with V ($\rho = 0.57$) and negative correlations with Rb ($\rho = -0.61$) and Ni ($\rho = -0.59$) on AChE activity. The findings indicate that SePM, depending on its composition and concentration, can induce early neurotoxic responses in estuarine fish, disrupt the cholinergic system, and potentially impair organismal fitness. AChE proved to be an effective biomarker for detecting sublethal effects from complex metal mixtures. These results highlight the urgent need for regulatory policies to control the release of particulate matter from industrial zones.

3.07.T-03 In-depth PFAS Characterization in Benthic and Pelagic Estuarine Food Webs: Contamination Patterns and Trophic Transfers

Ninon Serre¹, Camille Dumesnil¹, Randolph Singh², Lise Boulard¹, Catherine Munsch¹, Aurore Zalouk-Vergnoux³ and Yann Aminot¹, (1)French Institute for Ocean Science (IFREMER), France, (2)Columbia University, Mailman School of Public Health, United States, (3)University of Nantes, France

Over the past decade, emerging per- and polyfluoroalkyl substances (PFAS) have been increasingly reported in aquatic environments. Still, the environmental behavior of numerous of these emerging PFAS remain poorly understood. This study investigated trophic dynamics and contamination patterns across habitats of both legacy and emerging PFAS, in the food webs of common sole (benthic) and European sea bass (pelagic). Overall, 14 marine species, including plankton, polychaetes, shellfish, crustaceans and fish, were collected in the Seine estuary (France), a coastal ecosystem under high anthropogenic pressure. These samples were analyzed using a semi-quantitative suspect screening approach (LC-HRMS), supported by the use of an in-house suspect list of 866 compounds and AFFF as reference materials. A total of 93 PFAS belonging to 31 classes were detected, including frequently overlooked precursors such as X:2 FTAB and X:2 FTSA-HOPrS.

Some of them were detected at high concentrations, notably 6:2 FTAB, with concentrations up to five times higher (62 ng/g ww) than the highest PFOS concentration measured (12 ng/g ww). Contamination profiles appeared to be influenced by three main factors: the habitat, the trophic level and the metabolic capacities. A habitat influence was reported for the first time, with benthic organisms being mainly contaminated by long-head precursors (e.g., X:2 FTAB and X:2 FTSA-HOPrS), and pelagic organisms primarily by short head precursors (FASA and X:3 FTCA) and end products (PFSA and PFCA). Across food webs, concentrations of long-head precursors tended to decrease with the trophic level, while concentrations of end products and short-head precursors indicated biomagnification. This observation, also reported for the first time, suggested a biotransformation of long-head precursors at the highest trophic levels. Finally, species having a liver (fish) showed relatively lower levels of long-head precursors than invertebrates and crustaceans, strengthening this hypothesis of biotransformation processes. These new findings contribute to a better understanding of the environmental fate of PFAS in coastal ecosystems and call for the implementation of broader monitoring strategies and future studies on the biotransformation mechanisms of long-chain PFAS.

3.07.T-04 Land-to-Reef Pollution: Integrated Isotopic and Chemical Measurements for Ecological Impact Assessment

Nienke van de Loosdrecht¹, Petra Visser¹, Milo Leon de Baat², Mark Vermeij¹ and Jasper de Goeij¹, (1)University of Amsterdam (UVA), Netherlands, (2)Chemical Water Quality & Health, University of Amsterdam (UVA), Netherlands

Coral reefs are increasingly threatened by local stressors, particularly land-derived pollution (LDP) from excess nutrients, metals, and anthropogenic chemicals, a process often amplified by factors like rainfall and coastal development. A critical knowledge gap persists in quantifying LDP inputs and their impact on coral reef functioning, which hinders effective mitigation. To address this, the present PhD project performed an integrated approach on Curaçao's fringing reefs. This included (i) stable isotope analysis (SIA; $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$) and elemental concentration of Dictyota macroalgae for pollution tracing, supplementing this with (ii) SIA food web structure assessment, and (iii) using passive sampling with contaminant quantification and in vitro bioassays for chemical pollution monitoring and ecotoxicity assessment. The results confirmed that LDP is strongly affected by rainfall amplifying pollution runoff to nearby reefs. Macroalgal $\delta^{15}\text{N}$ values, indicating anthropogenic nitrogen input, positively correlated with elemental pollution (e.g. Cu, Pb) and coastal alteration. This anthropogenic nitrogen signal was tracked high into consumer food web at an impacted site, which also showed a compressed trophic niche and reduced carbon resource diversity. Furthermore, a wide range of anthropogenic chemicals (e.g. pharmaceutical and pesticides) were detected, with concentrations peaking in the wet season. Several of these compounds exceeded predicted no-effect concentrations, and in vitro bioassays showed responses approaching risk thresholds. The three lines of evidence confirmed that, i) land-based pollution is amplified by rainfall, ii) propagates through the food web, altering elemental and chemical concentrations, and iii) induces biological effects in coral reef ecosystems. Combined isotopic, elemental, and

ecotoxicity assessment provides a powerful framework for pollution monitoring, guiding scientifically supported mitigation and management efforts on coral reefs.

3.07.T-05 Derivation and application of effect-based trigger values for estrogen receptor-mediated activity in coastal sediments

Jiyeon Gwak, Jihyun Cha, Songyeon Lee and Seongjin Hong, Chungnam National University, Korea, Republic of

Target chemical analysis is widely used to monitor persistent toxic substances in the marine environment; however, it cannot capture contamination caused by unknown compounds. Effect-based monitoring (EBM) addresses this limitation by using in vitro bioassays to evaluate the biological activity of environmental samples, including the combined effects of known and unknown chemicals. Establishing effect-based trigger values (EBTs) is essential for implementing EBM, yet most EBT studies have focused on wastewater and surface waters, with limited attention to sediments. In this study, we derived sediment EBT values for estrogen receptor (ER)-mediated potency using three approaches (Options A–C) that incorporate relative potencies, no-effect concentrations, and mixture factors. Among the resulting thresholds, 0.062 ng E2-EQ g⁻¹ dw (Option B) was identified as the most appropriate, consistent with guideline-based EBTs for surface waters (0.009–0.049 ng E2-EQ g⁻¹ dw) and wastewater effluents (0.003–0.088 ng E2-EQ g⁻¹ dw). Applying the derived EBT to sediments from Lake Sihwa showed significant ER-mediated potency at all sites except M1 and M4. Silica gel fractionation revealed that the polar fraction (F3) contributed most strongly to ER activity. Within F3, only I2, I3, and I4 exceeded the EBT. RP-HPLC subfractionation further indicated that ER activity was concentrated in F3.3. Potency balance analysis showed that quantified target estrogens explained only 10–53% of total ER activity, suggesting substantial contributions from unidentified compounds. Nontarget screening of F3.3 from I3 and I4 identified 12 candidate ER agonists, predominantly pharmaceuticals. The six most abundant compounds were purchased for bioassay confirmation. Diethylstilbestrol (DES) and heptyl 4-hydroxybenzoate exhibited RePs of 1.5 and $1.6 \times 10^{??}$, respectively. DES accounted for ~40% of total ER activity in I3 and more than 100% in I4, indicating its importance as a major contributor. This study is the first to derive an ER EBT for sediments and apply it to evaluate sedimentary ER activity in Lake Sihwa. The results demonstrate that synthetic estrogens and pharmaceutical-derived contaminants can play a far greater role in sediment ER-mediated potency than previously recognized. These compounds should therefore be prioritized in future sediment monitoring programs and considered in management strategies to mitigate endocrine-disrupting risks in coastal ecosystems.

3.07.P Coastal Environments: At the Intersection of Human Activities and the Open Ocean

3.07.P-We213 Land Hermit Crabs as Coastal Ground Environmental Monitoring Partners

Brian Minsoo Lee¹, Holden King Ho Li², Ahjeong Son³ and Beelee Chua¹, (1)Korea University, Korea, Republic of, (2)Nanyang Technological University, Singapore, (3)Ewha Womans University, Korea, Republic of

Tropical and sub-tropical coastal ground level environment poses a challenge to aerial monitoring techniques due to the extensive vegetation coverage that creates large blind spots. Large study areas will require either an equally large array of ground level static sensors or a small group of roaming sensors. Despite the advancement in robotics, it remains cost-prohibitive to develop and operate robots to courier sensors up and down complex coastlines. They will also need to detect impending tropical storms and take shelter from surfs in order to avoid being swept out to the oceans. These specifications would invoke an astronomical amount of engineering. Here, we propose a much simpler solution by partnering with a native invertebrate: the land hermit crab. It is a pseudo-crab with that uses any appropriately sized receptacle that it can find to protect its soft abdomen, and gills (from drying out). It prefers the empty shells of turbo snails and other gastropods. When it outgrows the salvaged shell, it will look for a larger empty shell or take it from another hermit crab. Depending on species, its roaming range can be few meters from the coastline or as far as three hundred meters inland. However, it will always hug the coastline. It will also detect changes in air pressure and hides from storms in the nooks of rocks or trees. In this study, we demonstrated the possibility of partnering with the land hermit crab to courier sensors via a custom shell hugging harness. The sensor harness is shaped to conform to the spiral pattern of the gastropod shell and hence detachable. Unlike conventional animal tagging, this approach does not mandate the captivity. Instead, empty gastropod shells with sensor harness can be left on the coast and the land hermit crabs will simply pick them up during a shell swap. As a demonstration, we partnered with *Coenitobita brevimanus* to courier electronics and sensors such as solar-powered temperature and humidity sensor, and a salinity sensor (for salt water ingress monitoring) in an arena that simulate a coastal locality. We were able to remotely monitor temperature and humidity in the vicinity of the hermit crab. Furthermore, we also managed to map the border

between salt water and dry ground within the arena as the result of the hermit crab's movement. This demonstration of non-invasive partnership with local fauna for environmental monitoring will offer a sustainable alternative to robotics and drones-intensive approaches.

3.07.P-We214 Spatial Variation of Mercury Concentrations in Grey Seal (*Halichoerus grypus*) Pup Hair Across the UK

Amy Bishop¹, John Naumann¹, Madison Haumschild¹, Benjamin D Barst², Lorrie Rea³, Sean D. Twiss⁴ and Patrick Pomeroy⁵, (1)University of Alaska Anchorage, United States, (2)Earth, Energy, and Environment, University of Calgary, Canada, (3)University of Alaska Fairbanks, United States, (4)Department of Biosciences, Durham University, Durham, United Kingdom, (5)St. Andrews University, United Kingdom

Mercury (Hg) is an environmental stressor of concern in marine ecosystems, and has known negative impacts on reproduction in many species. Lanugo, or natal hair, represents a significant portion of the total body burden of Hg in young pinnipeds and likely represents an important elimination pathway for mercury. Assessments of mercury contamination for seals at coastal breeding colonies around the United Kingdom (UK) were done over two decades ago suggesting low risk for wildlife; however, these were only from a few locations and in other high latitude coastal ecosystems, fine-scale regional variation in mercury has been observed. Here we aimed to quantify the contemporary total mercury concentrations [THg] in grey seal lanugo from across the UK. From 2012-2021, lanugo samples (n=149) were collected at colonies in Scotland and England that have shown divergent growth trajectories ranging from a decline in pup-production at colonies in the western isles, to exponential growth in pup production at mainland colonies along the coast of England in the North Sea. Median [THg] (ppm, µg/g dw) was higher at the three mainland English colonies (median: 5.8 ± 2.4 µg/g Blakeney Point; 7.4 ± 3.8 µg/g Donna Nook; and 9.4 ± 4.8 µg/g Horsey) than the Isle of May (median: 3.3 ± 2.8 µg/g) and Monach Isles (4.9 ± 2.7 µg/g) breeding colonies in Scotland. The maximum [THg] in this study was 17.7ppm, which is considered low risk for individual health. We will also present results identifying whether foraging patterns contribute to any regional or sub-regional variation, and will assess for changes in [THg] over time at sites with multiple years of sampling. This study provides valuable baselines for assessing the impacts of single or multiple stressors in marine wildlife experiencing rapidly changing coastal ecosystems.

3.07.P-We215 Assessment of Multiple Stressors in a Mediterranean Coastal Lagoon, Through Toxicity Assays, Contaminants and Microbiome Analysis of Sediments.

Chiara Dettoto¹, Maria Vittoria Barbieri², Giacomo Limonta³, Matteo Oliva⁴, Matteo Bainsi³, Carlo Pretti⁴, Ethel Eljarrat⁵, Cristina Panti³ and Maria Cristina Fossi³, (1)University of Siena, Italy, (2)ONHEALTH, Institute of Environmental Assessment and Water, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (3)Department of Physical Sciences, Earth and Environment, University of Siena, Italy, (4)Interuniversity Consortium of Marine Biology of Leghorn "G. Bacci", Livorno, Italy, (5)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain

The combined effects of chemical pollution, eutrophication and climate change pose a significant risk to coastal lagoons. The Orbetello Lagoon (Tuscany, Italy) is subjected to multiple anthropogenic pressures, including urban and aquaculture discharges, legacy contaminants and emerging pollutants. This study investigates, through a multidisciplinary approach, how chemicals and physical stressors affect toxicity and microbiome composition of sediments, a crucial ecosystem component supporting the health and biodiversity of coastal lagoons. Sediment samples were collected in two different seasons (autumn and spring) at five stations.

Ecotoxicological assessments involved acute and chronic toxicity bioassays conducted at 20°C and 25°C on sediment elutriates (25%, 50%, 100%) using standardized methods with *Aliivibrio fischeri*, *Phaeodactylum tricornutum*, *Acartia tonsa* and *Ficopomatus enigmaticus*. Analysis of organic contaminants were conducted to evaluate the presence and distribution of plastic additives, including organophosphate esters (OPEs), phthalates esters (PAEs) and non-phthalate plasticizers (NPPs). The samples were processed using ultrasound-assisted extraction followed by liquid chromatography coupled to high resolution mass spectrometry (LC-HRMS). Environmental DNA (eDNA) analysis was performed using shotgun sequencing to characterize microbial biodiversity. The metagenomic analysis revealed 10 phyla and 83 species (4 Archaea and 79 Bacteria). Alpha diversity analysis highlighted differences between sampling sites, while beta diversity analysis showed different community compositions between the autumn and spring samples. Toxicity assays showed overall low toxicity, although significant effects emerged at higher elutriate concentrations at specific sites, with biological responses varying seasonally and being further influenced by the temperature of exposure. The integration of chemical, ecotoxicological and molecular data, performed through penalized linear regression, identified the relationships between contaminant concentrations (OPEs, NPPs and PAEs) and toxicity responses, and revealed how these interactions may be modulated by the bacterial communities. These data will provide a comprehensive understanding of lagoon sediments health status and how it is affected by multiple stressors, and supports the development of transferable tools for assessing and managing Mediterranean coastal environments affected by human pressures and climate change.

3.07.P-We216 Contaminant Burden of Stranded Sentinels – Maternal Transfer of Legacy and Novel Persistent Organic Pollutants (POPs)

Rebecca von Hellfeld¹, Ane Elezgarai², Belen Gonzalez-Gaya³, Mariel T.I. ten Doeschate⁴, Nicholas Davison⁴ and Andrew Brownlow⁴, (1)School of Biological Sciences, University of Aberdeen, United Kingdom, (2)University of the Basque Country, Spain, (3)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (4)University of Glasgow, United Kingdom

Oceans cover the majority of the Earth's surface and are vital in oxygen production, carbon sequestration, resources, and coastal protection. However, anthropogenic activities have introduced significant pollutants, including persistent organic pollutants (POPs), into marine ecosystems. POPs are resistant to degradation and pose severe risks to wildlife and human health by disrupting endocrine, immune, and metabolic functions. Thus, even after regulatory bans, legacy POPs persist in the environment, while emerging contaminants like UV filters and musks raise concern due to their strong bioaccumulation potential.

High trophic level animals such as marine mammals are ecosystem sentinels, integrating the temporal and spatial scale of food webs through their life history. They are also particularly vulnerable to POP bioaccumulation due to their longevity and lipid rich tissues. These pollutants can be transferred in utero from mother to offspring, as well as postnatally through milk, threatening early development. Long-finned pilot whales (*Globicephala melas*), as oceanic dolphins occupying middle trophic positions, would not be expected to exhibit pronounced exposure to coastal pollutants. This study investigates whether legacy and novel persistent organic pollutants are nevertheless present and maternally transferred in mother-foetus pairs stranded on the Isle of Lewis, Scotland, in 2023.

Liver, muscle, and skin tissues were analysed for various groups of POPs, including polyaromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), UV filters, and pesticides, addressing analytical challenges like matrix effects (i.e., the impact of matrix composition, sample preparation, and interfering compounds on the results) and recovery rates (i.e., the efficacy with which any given analyte can be extracted and quantified). Liver samples of all animals generally exhibited stronger matrix interference and overall higher contaminant accumulation, especially for lipophilic compounds. Foetus tissue samples contained a higher concentration of PAHs and selected UV-filters than then maternal matched tissue samples, as well as expressing different proportions of compound ratios. A less clear pattern was evident for PCBs and fertilisers. This highlights the importance of maternal exposure pathways in early-life pollutant accumulation, emphasising the need for further studies on the impacts of POPs on marine mammal health and their role in ocean ecosystem integrity.

3.07.P-We217 Testing environmental samples in an acute coral toxicity assay with adult *Montipora digitata* fragments

Camille Vizon¹, Valentina Di Mauro², David Brefeld¹, Laura Fiegel¹, Matthias Kellermann³, Mareen Moeller¹, Samuel Nietzer¹, Sascha Pawlowski², Laura Lütjens², Mechtild Petersen-Thiery² and Peter Schupp¹,
(1)Environmental Biochemistry Group, Institute for Chemistry and Biology of the Marine Environment (ICBM), Carl von Ossietzky University of Oldenburg, Germany, (2)BASF, Germany, (3)Planeteers GmbH, Germany

Coral reefs are increasingly facing unprecedented pressure from a wide range of anthropogenic stressors, including (untreated) wastewaters, contaminated sediments, pesticides, heavy metals as well as home and personal care products. In combination with global stressors such as ocean warming, acidification, and habitat degradation, local pollution emerges as a frequently overlooked threat, emphasizing the need for robust, reliable, and environmentally relevant coral toxicity tests. In the context of method standardization under e.g. ISO, it is essential to demonstrate its applicability towards various environmental samples. In this study, we examined multiple types of environmental samples (e.g., sediments and seawater samples) collected from different coral reef sites exhibiting varying degrees of anthropogenic influence. Both whole samples and their chemical extracts were tested across a range of concentrations using a 96-hour acute coral toxicity test with adult *Montipora digitata* fragments. Different ecologically relevant endpoints, including mortality, tissue loss, and bleaching were measured to evaluate coral responses and identify both sublethal and lethal effects of environmental samples. Preliminary results revealed toxicity associated with sediments collected from polluted sites, demonstrating that these standardized tests can successfully identify harmful environmental conditions and discriminate between sites with differing contamination levels. These findings highlight the potential applicability of such approaches for routine monitoring and for integration into future standardized methods.

3.07.P-We218 Seasonal Variations of Heavy Metal Concentration in Commercially Important Marine Fishes, Shrimps and Crabs in the Bay of Bengal Coast and the Implications for Human Health Risk in Bangladesh

Md. Sirajul Islam¹, Tanmoy Roy Tusher¹, Md. Enamul Hoq², Md. Humayun Kabir¹ and Shamim Al Mamun¹,
(1)Department of Environmental Science and Resource Management, Mawlana Bhashani Science and Technology University, Bangladesh, (2)Freshwater Station, Bangladesh Fisheries Research Institute, Bahrain

Heavy metal contamination in marine ecosystems has become a growing environmental and public health concern in Bangladesh. Industrial discharge and coastal pollution contribute to the accumulation of toxic metals in seafood, threatening food safety and human well-being. This study was conducted to investigate the occurrence and seasonal variations of heavy metal concentrations in commercially important marine fishes, shrimps and crabs from the Cox's Bazar fishing zone of the Bay of Bengal coast as well as to assess the associated human health risks, augmenting food safety/quality and seafood export in Bangladesh. Therefore, commercial marine fish samples viz. koral or vetki (seabass, *Lates calcarifer*), Ilish (ilisha shad, *Tenualosa ilisha*), rupchanda (pomfret, *Pampus chinensis*), churi (ribbon fish, *Trichiurus lepturus*), Loittyta (Bombay duck, *Harpadon nehereus*), two shrimps bagda (tiger shrimp, *Penaeus monodon*; white shrimp, *Penaeus indicus*) and swimming crab (*Portunus pelagicus*) were collected seasonally (post-monsoon, pre-monsoon and monsoon) over a whole year from both fish landing centers and fishing boats. Concentrations of four heavy metals (i.e., Cd, Cr, Pb, and Zn) in edible muscle samples were analyzed by atomic absorption spectrophotometer (AAS), while the probabilistic human health risks associated with heavy metal-contaminated seafood consumption were assessed using a standard equation-based approach. The results showed that, among the tested metals, only Zn was detected in every sample (fish and crustaceans) over the seasons. In terms of overall metal accumulation, Zn content was found exceptionally high followed by Cr and Pb, whereas Cd was below the detection limit (0.001 mg/kg). Remarkably high Zn content in seafood of Bay of Bengal coast was possibly due to the interference of huge shrimp hatcheries activities. Relatively low metal concentrations were recorded in pre-monsoon (Zn: 9.32 to 20.3 mg/kg, Cr: <0.005 to 4.24 mg/kg, Pb: <0.01 mg/kg, Cd: <0.001 to 1.12 mg/kg) followed by monsoon (Zn: 15 to 50.2 mg/kg, Cr: 1.03 to 3.95 mg/kg, Pb: 0.17 to 50 mg/kg, Cd: 0.14 to 0.58 mg/kg) and post-monsoon (Zn: 6.17 to 128 mg/kg, Cr: 1.16 to 3.62 mg/kg, Pb: 1.01 to 1.53 mg/kg, Cd: 0.11 to 0.44 mg/kg). For Zn and Pd, the values of bio-concentration factor decreased in the sequence of crab > shrimp > fish, while the values showed descending order as shrimp > crab > fish for Cr and Cd. The results also exhibited significant ($p > 0.5$) variations in metals bioaccumulation in different seasons. The calculated hazard index (HI) for the general population (adults and children) was below the maximum limiting value (i.e., <1), indicating that the seafood of Bay of Bengal is safe for human consumption and possesses a great export potential. However, the study recommends periodic monitoring of toxic heavy metals in the commercially important seafood species to avoid any unexpected health hazards caused by the toxic heavy metals via seafood consumption. The findings of this study can be applied to improve seafood safety monitoring and environmental management in coastal Bangladesh. The data on seasonal and species-specific variations in heavy metal accumulation provide a scientific basis for establishing regulatory limits and updating national seafood quality standards.

3.07.P-We219 Physiological and Ecotoxicological Effects of the Mineral Ultraviolet Filter Nano-Titanium Dioxide on Temperate Marine Microalgae

Anneliese Ananya Hodge¹, Frances Hopkins², Rachel Louise Coppock², Mahasweta Saha³ and Awadhesh Jha⁴, (1)University of Plymouth & Plymouth Marine Laboratory, United Kingdom, (2)Plymouth Marine Laboratory, United Kingdom, (3)United Kingdom, (4)University of Plymouth, United Kingdom

Ultraviolet (UV) filters are active compounds found in personal-care products (PCPs), such as sunscreens and cosmetics, to mitigate photoaging and photocarcinogenesis by absorbing, blocking or scattering UV radiation. These filters, classified as either mineral-based (inorganic) or chemical-based (organic) are considered contaminants of emerging concern (CEC) due to their extensive global use and pervasive presence in aquatic environments. Key pathways into marine systems include direct skin wash-off, wastewater effluent and industrial discharge. UV filters have been detected globally across diverse aquatic matrices, including sediments, surface and offshore waters, and within aquatic organisms. While recent media and regulatory attention has focused on coral reef impacts – prompting bans in regions such as Hawaii and Palau – the effects on temperate marine ecosystems, particularly primary producers, remain underexplored. This study addresses this gap by investigating the physiological and ecotoxicological effects of nano titanium dioxide (nTiO₂), a widely used mineral UV filter often marketed as ‘reef-safe’, on the temperate marine microalga *Isochrysis galbana*. Using a multidisciplinary approach, microalgae were exposed to environmentally relevant concentrations of nTiO₂ under UV illumination for 96 hours. Responses were assessed via growth inhibition, chlorophyll-a depletion, changes in dimethylsulfoniopropionate (DMS) levels, oxidative stress biomarkers, enzymatic activity and ultrastructural changes via electron microscopy. Results show that concentrations between 500–1000 µg/L significantly impair growth and chl-a content, elevate oxidative stress markers (e.g. lipid peroxidation, protein carbonylation), and upregulate antioxidant enzymes such as catalase and superoxide dismutase. Even low concentrations (50 µg/L) caused measurable declines in growth and chl-a within 96 hours. These findings demonstrate that nTiO₂, even at low concentrations, can disrupt key physiological functions in marine microalgae, suggesting ecological risks to coastal primary producers. Despite growing recognition that nanoparticulate mineral UV filters may not be as environmentally benign as their bulk counterparts, nTiO₂ continues to be marketed as ‘reef-safe’ due to limited regulatory oversight. This study underscores the need for broader environmental risk assessments to evaluate UV filter impacts across diverse marine environments and organisms.

3.07.P-We220 Mediterranean Seafood Under Scrutiny: Chemical Burden and Regulatory Implications

Valentina Araya Piqué¹, Maria Vittoria Barbieri² and Ethel Eljarrat³, (1)Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (2)ONHEALTH, Institute of Environmental Assessment and Water, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (3)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain

Persistent Organic Pollutants (POPs) are regulated under the Stockholm Convention due to their persistence, bioaccumulation, long-range transport, and adverse effects on ecosystems and human health. In parallel, contaminants of emerging concern (CECs) with similar properties remain largely unregulated, and occurrence data in wild seafood are still scarce. Current European legislation, including the Marine Strategy Framework Directive (MSFD), focuses primarily on legacy contaminants, potentially overlooking new or understudied substances. This study aimed to evaluate the occurrence of both POPs and CECs in Mediterranean seafood and to assess potential environmental risks and human dietary exposure, providing scientific evidence to support future regulatory prioritization.

A total of 91 samples from 13 wild-caught marine species were collected at six locations along the Catalan Mediterranean coast (Spain). Ten pollutant families were analysed, including organophosphate esters (OPEs), phthalates (PAEs), non-phthalate plasticizers (NPPs), bisphenols (BPs), UV-filters, musk fragrances, polybrominated diphenyl ethers (PBDEs), novel brominated flame retardants (NBFRs), dechloranes, and short-chain chlorinated paraffins (SCCPs). Compounds were quantified using LC-HRMS and GC-MS(/MS), depending on chemical class. Human dietary exposure was estimated through calculated Estimated Daily Intakes (EDIs), while environmental risk was evaluated using Risk Quotients (RQ = MEC/PNEC).

SCCPs dominated the total contaminant burden, showing the highest median concentration (750 ng/g wet weight), followed by PAEs and NPPs. Detection frequencies were highest for PBDEs (92.5%), OPEs (82%), SCCPs (80.7%), and PAEs (73%). Emerging substitutes for regulated flame retardants and plasticizers, such as OPEs and NPPs, were widely detected, highlighting shifts in chemical usage. Species- and site-specific differences were observed, with elevated NPP levels in European seabass and red mullet, and higher SCCP and NBFR concentrations at specific locations.

Estimated daily intakes were below established safety thresholds, but the co-occurrence of multiple POPs and CECs raises concerns regarding cumulative exposure. These findings emphasize the need to expand monitoring frameworks and consider additional contaminants, such as SCCPs, for inclusion in European seafood regulations.

Disclaimer/Disclosure:

This study has been funded by the European Union – NextGeneration EU – as part of the MITECO program for the Spanish Recovery, Transformation and Resilience Plan (Recovery and Resilience Facility of the European Union established by the Regulation (EU) 2020/2094), and was entrusted to CSIC, AZTI, SOCIB, and the universities of Vigo and Cadiz. This study has received funding from European Union's HORIZON-CL6-2023-ZEROPOLLUTION-01 under the grant agreement No. 101134929.

3.07.P-We221 Investigating The Effect of Coastal Pollution, Seasonality and Weather Conditions on The Coastal Air Composition.

Silke Lambert¹, Julie Bortier², Colin Janssen², Maarten De Rijcke³ and Jana Asselman⁴, (1)Blue Growth Research Lab, Ghent University, Belgium, (2)Ghent University, Belgium, (3)Flanders Marine Institute (VLIZ), Belgium, (4)Blue Growth Research Lab (BGRL), Ghent University, Belgium

The ocean is home to a wide range of organisms, including bacteria, microalgae, seaweed, fish, and large marine mammals. Some of these organisms and the metabolites they produce can accumulate in the sea surface microlayer—a thin layer at the ocean's surface. When waves break, air gets trapped which creates underwater bubbles. These bubbles rise to the surface where they burst, picking up these metabolites and microorganisms that are then released as sea spray aerosols into the atmosphere.

Seasonal variations influence the chemical and biological makeup of coastal ecosystems, impacting air and water quality. In addition to natural processes, human activities like coastal industry and tourism can alter the composition of seawater and consequently also sea air.

This study aims to identify key environmental and biological factors shaping the composition of coastal sea air. We integrate datasets on physical parameters (wind speed, wave height, temperature), biological indicators (phytoplankton, bacteria, chlorophyll), and microorganisms found in sea air. Pollution metrics are also considered. Multivariate analyses are used to link environmental drivers to sea air composition.

We hypothesize that both natural variability and anthropogenic pressures significantly alter coastal air microbiomes and chemical profiles. Seasonal patterns and pollution indicators are expected to correlate with shifts in microbial diversity and sea air composition. Understanding these interactions is critical for assessing implications for environmental and human health within a one health approach.

3.07.P-We222 Beyond the Turbines: Exploring Sediment Effects of Offshore Wind Farms on Marine Benthos, *Corophium volutator* and *Hediste diversicolor*

Moses Ndugwa¹, Bavo De Witte², Lieven Bervoets¹ and Gudrun de Boeck¹, (1)University of Antwerp, Belgium, (2)Flanders Research Institute for Agriculture, Belgium

Offshore wind energy is central to decarbonization. However, its expansion may introduce novel chemical stressors to offshore marine ecosystems. Measures such as cathode protection galvanic anodes and anticorrosion paint used on offshore wind turbines may leach potentially toxic chemical compounds including trace metals such as cadmium (Cd), indium (In), lead (Pb), aluminum (Al), zinc (Zn), and gallium (Ga), and organic compounds such as bisphenol derivatives and per- and polyfluorinated substances, which may negatively affect marine organisms. Besides the well-known negative effects of offshore wind farms, such as accidental birds'

collisions, electromagnetic and sound pollution, little is known about the effects of chemical leaching from the supporting infrastructure. This study investigated the potential ecotoxicological effects of sediments collected from offshore wind farms on two key bioindicator species' i.e. marine ragworms, *Hediste diversicolor* (polychaete) and mud shrimp *Corophium volutator* (amphipod). The organisms were exposed to sediments collected from six sampling locations located within offshore wind farms and two reference locations in the Belgian part of the North Sea, outside the vicinity of the wind farms. Additionally, sediments collected at the test organisms' collection location (Eastern Scheldt, Netherlands) served as a control. Organisms were exposed to sieved (500 µm) sediments of each sampling location for 28 days in a laboratory setting, after which growth rate, survival, tissue metal accumulation, and, for *H. diversicolor*, energy reserves, including lipids, proteins, and glycogen concentrations, were measured. The study revealed no statistically significant negative impacts on *H. diversicolor* and *C. volutator* from exposure to sediment collected within offshore wind farms, with physiological responses comparable to locations outside the wind farms. However, negative trends suggesting declining growth rate and elevated tissue metal levels were observed in organisms exposed to the sediments from offshore wind farms. This research contributes to understanding the potential environmental impacts of offshore wind farms, particularly in terms of chemical pollution and that may impact marine ecosystems. Such insights are crucial for integrating ecotoxicological evidence into environmental risk management for sustainable offshore wind development.

Disclaimer/Disclosure:

The study was supported by the Interreg North Sea Programme 2021–2027 co-funded by the European Union Regional Development Fund under the project ANEMOI “Chemical emissions from offshore wind farms: assessing impacts, gaps and opportunities” with the grant agreement number 41-2-13-22.

3.07.P-We223 Continuous Monitoring of Emerging Contaminants in Seawater and Oysters, Dún Laoghaire Harbour

Nicolette Sale, Patrick Sode, Fiona Regan and M. Isabel Cadena-Aizaga, Dublin City University, Ireland

Contaminants of emerging concern (CECs) are defined as compounds that pose potential risks to ecosystems and human health but are not generally monitored or regulated. These compounds can be challenging to monitor due to their diverse sources, physico-chemical properties, and ubiquitous presence in the environment at trace levels. Biomonitoring is one method for investigating contaminants in marine systems. Marine bivalves have long been recognised as crucial ecological and bioindicator species within coastal ecosystems. Their wide distribution, sedentary nature, high filtration rates, and ability to bioaccumulate various contaminants make them exceptionally suitable for monitoring CECs. In Ireland, few studies on CECs focus on monitoring their levels in seawater or comparing biota with traditional grab sampling methods.

This work aims to continuously monitor seawater and oyster samples from Dún Laoghaire harbour in Ireland, following the deployment of over 18,000 oysters in the harbour in 2025. This is part of an oyster reef development project in collaboration with Green Ocean Foundation, seeking to develop and scale oyster reef systems in Ireland.

The contaminants examined include pharmaceuticals, pesticides, per- and polyfluoroalkyl substances (PFAS), nutrients, and metals.

Both seawater and biota samples were extracted using solid-phase extraction with Oasis HLB cartridges for analysis on an Agilent 1290 Infinity II LC system coupled to an Agilent 6470 Triple Quadrupole LC/MS. Quantification was performed using MassHunter software, and a matrix-matched calibration curve was generated to assess matrix effects. Along with target analysis, three cartridges underwent non-target analysis to ascertain any additional compounds in the samples.

Preliminary results from seawater samples collected before oyster deployment indicate the presence of pharmaceuticals and pesticides across four of seven sites studied. These include antibiotics, antimicrobials, ultraviolet filters, nonsteroidal anti-inflammatory drugs, herbicides, insecticides, and fungicides. Azithromycin, carbamazepine, clarithromycin, erythromycin, mefenamic acid, trimethoprim, and venlafaxine were confirmed at every site. Pesticides fluconazole and thiabendazole were also found to be ubiquitous across sites. This baseline provides important information to track trends in marine contaminants over time and to serve as a basis for studying oyster uptake and removal of marine contaminants.

3.07.P-We224 Land-to-Sea Subsurface Flow Transports Land-Derived Metal Pollutants into Coastal Coral Reefs

Gal Vered¹, Tom Shlesinger² and Gilad Antler³, (1)Marine and Environmental Sciences Centre (MARE), Portugal, (2)The Steinhardt Museum of Natural History, Israel National Center for Biodiversity Studies, Tel-Aviv University, Tel Aviv, Israel, Israel, (3)The Department of Earth and Environmental Sciences, Ben-Gurion University of the Negev, Be'er Sheva, Israel, Israel

Land-derived pollutants can enter coastal reefs through subsurface groundwater, creating hidden, chronic exposures that are often missed by standard seawater monitoring. As these pollutants move through sediment porewater, they can reach nearby organisms. This is especially concerning for coastal coral reef ecosystems, where local stressors like nutrient enrichment and land-based pollution can affect reef resilience alongside climate-driven bleaching. Understanding these local contributions is essential for effective reef management. This study applied a multidisciplinary approach to examine a fringing reef near a black sediment zone suspected of land-based groundwater pollution. The study combined three complementary investigations: (1) sediment porewater and seawater chemistry and metal concentrations, (2) elemental and trace metal accumulation in coral tissues and skeletons, and (3) reef ecological characteristics.

Results show no detectable chemical signals in sampled seawater, while porewater from the black sediment zone showed lower salinity, Mg, K, and pH, and elevated Mn, indicating a secondary water source entering the sediments. Analysis of organic tissues of the stony coral *Stylophora pistillata* revealed higher Mn and lower Fe and As in corals near the black sediment zone compared to the control site. No differences were observed in coral cover, bleaching, biodiversity, or community composition, suggesting that these chemical signals have not yet affected reef condition. Nevertheless, a recent bleaching event, together with previously undetected subsurface pollutant inputs, highlights the need for integrated approaches to detect chronic sublethal exposures before broader ecological impacts occur.

Elevated Mn in *Stylophora pistillata* tissues confirms that subsurface inputs reach nearby corals, showing that chronic, sublethal exposures can occur without immediate effects on reef community structure. This highlights the value of multidisciplinary approaches integrating porewater analysis, coral metal accumulation, and ecological surveys to detect hidden pollutant pathways and improve risk assessment in multi-stressor coastal reef environments.

3.07.P-We225 Heavy Metals and Rare Earth Elements in Sediments and Biota of the Southwestern Iberian Peninsula: Pollution and Risk Assessment

Chiara Trombini¹, Carmen Michan², Carmen Agulló¹, Marina Barbudo-Lunar Ms.³, Veronica Inmaculada Luna-Guerrero¹, José Alhama-Carmona³ and **Julian Blasco⁴**, (1)Instituto de Ciencias Marinas de Andalucía (CSIC), Spain, (2)University of Córdoba, Spain, (3)University of Cordoba, Spain, (4)Institute of Marine Sciences of Andalusia - Spanish National Research Council (ICMAN-CSIC), Puerto Real, Cádiz, Spain

Despite their importance, coastal ecosystems are under threat due to an increasing amount of pollution resulting from human activities. Heavy metals are a global concern due to their widespread distribution, inability to degrade, high toxicity at low doses and potential for bioaccumulation and biomagnification, depending on the metal, within the food chain. On the other hand, rare earth elements are essential for many technological products, and increasing their exploitation could pose an environmental risk in coastal areas. The aim of this study is to evaluate the presence and concentration of heavy metals and rare earth elements (REEs) in surface sediments and clams (*Scrobicularia plana*) along the south-west coast of the Iberian Peninsula. This area is subject to various sources of pollution and pressure, including industrial activities, mining, and urban development. Sediment and clam samples were collected in eight sampling points in March 2024. The surface sediment samples (3 cm surface layer, three replicates from each sampling point) were freeze-dried, sieved through a 63 µm mesh, and digested (0.5 g) using a mixture of 6 mL HNO₃, 2 mL HCl, 1 mL HF, and 6 mL H₃BO₃. The soft tissues of the clams (three replicates per sampling point, with 11 organisms pooled per replicate) were freeze-dried and then digested (0.3 g) with 4 mL HNO₃ and 1 mL HCl. All digestions were carried out using a microwave digestion system (Multiwave GoPlus, Anton Paar). Metal concentrations were determined using ICP-MS (iCAP Q, Thermo Fisher Scientific). Quantification of heavy metals and rare earth elements (REEs) in sediments, together with the use of estimated pollution indices, allows the identification of the most important pollutants and the sites with the highest levels of contamination. As, Zn, Pb and Cd are the major pollutants, with Rio Piedra and Palmones being the most impacted sites. According to the pollution degree recorded in aquatic sediments, *S. plana* clams accumulated both heavy metals and REEs, making this organism an important indicator of marine pollution.

3.07.P-We226 Effects Of Gadolinium Exposure On Oxidative Stress In Two Brittle Star Species From The Ligurian Coast Of Italy

Camilla Mossotto¹, Alessia Meriardi², Alessandra Maganza¹, Antonia Concetta Elia³, Alice Gabetti², Giuseppe Esposito⁴, Marino Prearo² and Paolo Pastorino², (1)IZSPLV - Experimental Zooprophyllactic Institute of Piedmont, Liguria and Valle d'Aosta, Via Bologna 148, 10154 Torino, Italy, Regional Reference Centre for the Biodiversity of Aquatic Environments (BioAqua), Via Lino Maritano 22, Avigliana, 10051, Italy, , Italy, (2)IZSPLV - Experimental Zooprophyllactic Institute of Piedmont, Liguria and Valle d'Aosta, Via Bologna 148, 10154 Torino, Italy, Regional Reference Centre for the Biodiversity of Aquatic Environments (BioAqua), Via Lino Maritano 22, Avigliana, 10051, Italy, Italy, (3)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (4)IZSPLV - Experimental Zooprophyllactic Institute of Piedmont, Liguria and Valle d'Aosta, Via Bologna 148, 10154, Torino, Italy, Italy

Gadolinium-based compounds are widely used in medical imaging and are increasingly being detected in aquatic environments, raising concerns about their potential impact on marine organisms. Brittle stars are key benthic species that contribute to sediment turnover, nutrient recycling, and food web dynamics. However, their sensitivity to emerging contaminants, such as gadolinium, is not well understood. Although levels of gadolinium in aquatic environments have increased over the past decade, information on its physiological effects on aquatic organisms, including benthic echinoderms, is limited. This study therefore aims to evaluate the survival and oxidative stress responses of two brittle star species from the Ligurian Coast in Italy following short-term exposure to environmentally relevant and elevated concentrations of gadolinium.

A total of 270 specimens of one species and 180 of the other were collected along the Ligurian coast and kept in a controlled laboratory environment. The specimens were exposed to eight concentrations of Gd₂O₃ (i.e. 0, 1, 10, 50, 100, 250, 500 and 750 micrograms per litre) for seven days. At the end of the exposure period, specimens from each treatment group were sampled to assess potential sublethal physiological disruptions by analysing oxidative stress markers.

The analysis revealed concentration-dependent differences in oxidative stress profiles. Survival patterns showed no significant mortality across treatments. These results provide the first evaluation of gadolinium toxicity in brittle stars from the Mediterranean Sea. Furthermore, this study will contribute to our understanding of how emerging contaminants may affect the health of benthic invertebrates.

3.07.P-We227 Characterization of Emerging Contaminants in Coastal Sediments from Andalusia Using an LC-HRMS Suspect-Screening Workflow

Dana Orlando-Véliz¹, Ona Costa Parés², Rocío Inés Bonansea¹, Manuel García-Vara¹, Chiara Trombini³, Julian Blasco⁴ and Miren Lopez De Alda Villaizán⁵, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (2)University of Barcelona, Spain, (3)Institute of Marine Sciences of Andalusia - Spanish National Research Council (ICMAN-CSIC), Spain, (4)Institute of Marine Sciences of Andalusia - Spanish National Research Council (ICMAN-CSIC), Puerto Real, Cádiz, Spain, (5)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Contaminants of emerging concern (CECs) comprise a wide variety of compounds that differ in origin and chemical composition. Depending on their mobility and persistence, these substances can enter the aquatic environment and reach rivers and their interconnected ecosystems, including the coastal areas where rivers discharge. Liquid chromatography coupled with high-resolution mass spectrometry (LC-HRMS) has expanded the possibilities for CEC monitoring in recent years through the use of suspect-screening techniques.

In this study, we aimed to detect and identify CECs present in sediments from the coastal areas of eight rivers subjected to different sources of pollution in the southwestern Andalusian region. Sediment samples were extracted using an ultrasound-assisted method with different organic solvents. A suspect-screening workflow was then applied using the NORMAN Digital Sample Freezing Platform and mzCloud as the main spectral library.

The results revealed the presence of 13 CECs—including pesticides, industrial chemicals, and other compounds—with high identification confidence. A semi-quantification approach based on compound ionization efficiency was subsequently applied to estimate ecotoxicological risk. Most CECs were detected at concentrations of a few ng/g, although some samples showed substantially higher levels of certain substances (e.g., DEET reached 25 µg/g at one sampling site).

These findings highlight the value of LC-HRMS tools for characterizing potential contamination sources in

environmental matrices and guiding future efforts toward the identified pollutants and to establish the potential risk assessment.

Disclaimer/Disclosure:

We would like to thank the UE-Next Generation and PRTR and Junta de Andalucía for funding the PCM_0018_OMICHEMAR Project, and the Government of Catalonia for grant 2021 SGR 00753. OP acknowledges the JAE Intro ICU 2024 grant funded by CSIC.

3.07.P-We228 Suspect screening of contaminants of emerging concern in aquatic biota from the Andalusian Atlantic coast.

Rocío Inés Bonansea¹, Dana Orlando-Véliz¹, Ona Costa Parés², Manuel García-Vara¹, Chiara Trombini³, Julian Blasco⁴ and Miren Lopez De Alda Villaizan⁵, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (2)University of Barcelona, Spain, (3)Institute of Marine Sciences of Andalusia - Spanish National Research Council (ICMAN-CSIC), Spain, (4)Institute of Marine Sciences of Andalusia - Spanish National Research Council (ICMAN-CSIC), Puerto Real, Cádiz, Spain, (5)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

The rapid expansion of industrial activities and the introduction of new chemicals have led to the occurrence of a wide range of contaminants of emerging concern (CECs) in the environment. These compounds vary greatly in origin and structure, and for many of them, ecological risks and potential health effects remain largely unknown.

This study investigates the presence of CECs in coastal aquatic biota (the bivalve *Scrobicularia plana*) from the Andalusian Atlantic coast using a suspect screening approach. The aim was to detect and semi-quantify a broad spectrum of pollutants, including pharmaceuticals, pesticides and industrial chemicals, that may pose risks to marine ecosystems but are not routinely monitored.

Field samples were collected from eight coastal sites in southern Spain during two campaigns (winter and summer). Sample extraction was performed using an adapted version of the “QuEChUP” protocol, which combines elements of Quick, Easy, Cheap, Effective, Rugged, and Safe (QuEChERS) and Quick Polar Pesticides (QuPPE) procedures. Analyses were conducted by liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS). Compound identification relied on a suspect screening workflow supported by the NORMAN Digital Sample Freezing Platform (DSFP) and the mzCloud spectral database.

Method validation showed good recoveries for moderately polar analytes, while very polar or highly hydrophobic compounds presented analytical limitations. In biota, six compounds were confirmed and semi-quantified. Five of them were naturally occurring metabolites (4-hydroxyphenylpyruvic acid, 4-hydroxybenzaldehyde, methyl picolinate, nicotinic acid and phenylpyruvic acid), reflecting endogenous metabolic activity and minor inputs from cosmetic or food-related sources. DEET was the only clearly anthropogenic contaminant, detected between <LOD and 47 ng/g, with the highest concentration at the Guadalquivir Bajo (GS) site, suggesting localized exposure to human-derived inputs and spatial variability in bioaccumulation patterns.

Disclaimer/Disclosure:

We would like to thank the UE-Next Generation and PRTR and Junta de Andalucía for funding the PCM_0018_OMICHEMAR Project, and the Government of Catalonia for grant 2021 SGR 00753. OP acknowledges the JAE Intro ICU 2024 grant funded by CSIC.

3.07.P-We229 Human Activity in a Coastal Urban Area: Occurrence of Pesticides, Pharmaceuticals, and Sunscreen Agents in Dublin Bay

Patrick Sode¹, M. Isabel Cadena-Aizaga¹, Nicolette Sale¹, Flora Calviac² and Fiona Regan¹, (1)Ireland, (2)France

Coastal environments near major cities experience continuous exposure to chemical pollutants from multiple origins: agricultural, wastewater effluents, runoff, and recreational use. Dublin Bay is a suitable site to explore the consequences of anthropogenic activity in a coastal system. The purpose of this study was to characterise the occurrence, distribution, and partitioning between water and sediment samples of selected pesticides, pharmaceuticals, and sunscreen agents, to evaluate how their presence reflects human activity in the area. These

contaminants of emerging concern (CECs) are monitored less frequently; therefore, information on their occurrence is limited.

Surface water and sediment samples were collected from eight locations around Dublin Bay. Water samples were extracted using solid phase extraction (SPE), while sediment samples were extracted using solvent based methods followed by SPE. Target analysis was carried out using liquid chromatography coupled with a triple quadrupole mass spectrometer. Analytical performance was assessed through recoveries, matrix effects, and detection limits relevant to marine testing.

A wide range of contaminants were detected with clear geographical patterns linked to human activity in their respective area. Pesticides (MCPA, mecoprop, thiachloprid) were more abundant in northern sampling sites, linked to the agricultural activity within the area. Pharmaceuticals (carbamazepine, clarithromycin, venlafaxine) and sunscreen agents (benzotriazole and sulisobenzone) were detected at sites associated with wastewater discharge and recreational activity. Repeated detection of contaminants across various sites highlights the complex nature of the occurrence and distribution of these chemicals in the coastal environment. The CECs detected are in the ng/L range, typically below regulatory levels. However, their presence as mixtures poses a threat to the marine environment.

These findings provide a chemical profile of Dublin Bay and show how combining water and sediment analysis can lead to understanding distinct features of human activity in the coastal environment. These results can go on to influence monitoring strategies in transitional and coastal waters. Further testing could influence the classification of priority hazardous substances monitored in the Water Framework Directive, or EU watch lists, where contaminants will be subject to Union-wide monitoring to assess the risks posed to the marine environment.

Disclaimer/Disclosure:

All research was funded through the EU project - AquaBioSens.

3.07.P-We230 Flame Retardants in Dust from the Indoor Environments of Expedition Cruise Ships

Veronica van der Schyff¹, Verena Meraldi², Andrew Luke King³, Rozarka Jilkova⁴, Ondrej Audy⁴, Petr Kukucka⁴, Jiří Kohoutek⁴ and Lisa Melymuk⁴, (1)Recetox, Masaryk University, Czech Republic, (2)HX Expeditions, United Kingdom, (3)NIVA, Norway, (4)Masaryk University, Czech Republic

Flame retardants (FRs) are widely used in indoor environments to meet fire safety requirements. One understudied environment with respect to indoor chemical exposure to FRs is the maritime environment, particularly the indoor environments of cruise ships. With the continuous growth of the cruise industry, such environments with high chemical burdens can present a concern both for human exposure and environmental releases. This study presents the first comprehensive assessment of FRs in indoor dust collected from three expedition cruise ships of varying ages and refitting histories. Ten polybrominated diphenyl ethers (PBDEs), 23 alternative halogenated flame retardants, and 16 organophosphate esters (OPEs) were analyzed in dust from 12–16 locations per ship. OPEs, especially tris(1-chloro-2-propyl) phosphate (TCIPP), dominated the chemical profile, with concentrations reaching up to 1786 µg/g. Concentrations of FRs in different areas on the same ships differed greatly, sometimes by an order of magnitude. Older ships (built 2002/3) exhibited significantly higher FR levels compared to the newer vessel (Built 2020). Estimated daily intake modeling indicated that ship crew members, particularly those working in heavily furnished or electronic-rich areas, may experience elevated exposures through ingestion and dermal contact. Flame retardants have been detected in ship wastewater, suggesting potential for indoor dust as a vector for chemical contamination in marine environments. Strict performance-based fire test procedures are mandatory for all products onboard ships, but no regulations exist concerning the type of FR used or the concentrations thereof. These findings underscore the need for targeted regulation and further monitoring of chemical exposures in maritime environments, especially given the extended periods that crew members spend onboard.

Disclaimer/Disclosure:

The work was supported by Project MSCAfellow5_MUNI (CZ.02.01.01/00/22_010/0003229) financed by the Czech Ministry of Education, Youth and Sports (MEYS) (co-funded by the European Union).

3.07.P-We231 Monitoring of Contaminants of Environmental Concerns along the coastlines of the Mediterranean Sea: the ONE-BLUE project

Camilla Mariani¹, Maria Teresa Palumbo², Sara Valsecchi², Marianna Rusconi², Stefano Polesello², Maria Montserrat Sala³, Cinzia Centelleghé⁴, Marianna Pauletto⁴, Marina Brailo Šćepanović⁵, Ana Bratoš Cetinić⁵, Iva Pozniak⁶, Ivana Palunko⁶, Efthimia Cotou⁷, Marco Parolini⁸, Diego Rubolini⁸, Antonio Melley⁹, Maria Letizia Franchi⁹, Marta Llorca-Casamayor¹⁰, Marinella Farre¹⁰, Clara Sierra Sanchez¹¹, Nicole Vargas¹², Ramiro Logares³, Carles Pelejero³, Luca Ceolotto⁴ and Marco Bonato⁴, (1)State University of Milan, Italy, (2)Italian National Research Council (CNR), Italy, (3)Institut de Ciències del Mar (CSIC), Spain, (4)Dept. of Comparative Biomedicine and Food Science, University of Padova, Italy, (5)University of Dubrovnik, Department of Applied Ecology, Croatia, (6)University of Dubrovnik, Laboratory for Intelligent Autonomous Systems, Croatia, (7)Institute of Marine Biology, Biotechnology & Aquaculture (HCMR), Greece, (8)University of Milan - Department of Environmental Sciences and Policy, Italy, (9)Environmental Protection Agency of Tuscany Region - ARPAT, Italy, (10)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (11)CSIC - IDAEA, Spain, (12)Finnova Foundation, Belgium

The Mediterranean Sea is a semi-enclosed basin that is exposed to intense anthropogenic pressure. The presence of emerging contaminants in this area is a growing concern for the integrity of the ecosystem and human wellbeing. The continuous input of pollutants from coastal urbanisation, industrial activities, agriculture, maritime transport and tourism creates a dynamic and complex contamination scenario, in which many of these pollutants are not well characterised. In this context, the ONE-BLUE project aims to strengthen transnational knowledge and monitoring capacity by evaluating the occurrence and distribution of emerging contaminants across key sub-regions of the Mediterranean.

The study addresses the challenges of identifying priority contaminants, understanding their spatial patterns and supporting the development of harmonised monitoring strategies. To this end, surface and column water and sediment samples were collected in six representative Mediterranean areas: the Spanish coast, the Tyrrhenian Sea, the Ionian Sea, the Adriatic Sea and the Aegean Sea. Samples were extracted on board or in temporary laboratories near the sampling areas within 24 hours of collection to minimise degradation and ensure analytical reliability. The extracts were analysed using liquid chromatography coupled with mass spectrometry (LC-MS) to quantify a wide range of emerging pollutants, including pharmaceuticals, residues of personal care products, industrial chemicals, and other markers of human activity.

Overall, the ONE-BLUE investigation will provide a valuable evidence base for assessing environmental risk, guiding mitigation efforts, and informing policymakers on priority substances requiring targeted management.

3.07.P-We232 Behaviour-based estimates of sunscreen-derived UV filter loads to a subtropical coral-reef beach in Okinawa, Japan

Emiko Fujita¹, Yutaka Kameda¹, Hirokazu Takahashi², Rie Tai³, Wataru Naito⁴, Yoshitaka Hayashi⁵ and Hiroki Maeda⁵, (1)Chiba Institute of Technology, Japan, (2)SHISEIDO Co., Ltd., Japan, (3)Research Institute of Science for Safety and Sustainability, National Institute of Advanced Industrial Science and Technology (AIST), Japan, (4)Riss, National Institute of Advanced Industrial Science and Technology, Japan, (5)Tohoku Ryokka Kankyohozen Co., Ltd, Japan

Organic ultraviolet (UV) filters in recreational sunscreens are of concern because of their potential impacts on coastal marine ecosystems, yet quantitative links between beachgoer behaviour and UV filter inputs to seawater remain poorly constrained. Building on a monitoring campaign at a subtropical coral-reef beach in Okinawa, Japan, in summer 2024, in which we combined seawater sampling, passive samplers and a questionnaire survey, we extended this approach with a second, more detailed survey in summer 2025. In 2024, grab samples from three nearshore stations showed benzophenone-3 (BP-3, oxybenzone) concentrations up to 2.1 ng L⁻¹, with temporal changes that co-varied with bather density, tidal height and wind direction. Questionnaire responses from 169 beachgoers indicated that 75.7% used sunscreen and that six organic UV filters were present in 23 of the 28 identified products.

In 2025, we conducted structured face-to-face interviews with 302 beachgoers at the same site to obtain detailed information on sunscreen use, including frequency of application, treated body areas, product types and listed

ingredients. These data, together with time-resolved bather counts and beach geometry, were used to estimate the daily mass of sunscreen applied and the potential mass of each UV filter released to the bathing area by adapting the mass-balance framework of Labille et al. (2020), which links consumer survey data to UV filter loads and predicted environmental concentrations in beach waters.

We compare the estimated daily UV filter loads and predicted nearshore concentrations for the two survey days (2024 and 2025) and illustrate interannual and diurnal variability at this single coral-reef beach. The results provide an initial, behaviour-based quantification of sunscreen-derived UV filter inputs for Okinawa and a transferable framework to support future exposure assessments and the design of risk management options for coastal marine environments.

3.07.P-We233 Tracing the Unseen Journey of PFAS in Coastal Aerosols: Evidence from Atmospheric Deposition Studies at the Danish North Sea Coast

Theresa Döring¹, Bo Sha², Matthew Salter¹ and Ian Cousins¹, (1)Stockholm University, Sweden, (2)Environmental Science, Stockholm University, Sweden

Per- and polyfluoroalkyl substances (PFAS) are persistent and globally distributed contaminants whose environmental cycling remains unresolved. Atmospheric transport via sea spray aerosol (SSA), droplets ejected from breaking waves, may deliver PFAS from the ocean into terrestrial environments. This study investigates whether SSA drives PFAS pollution along the western North Sea coast of Denmark, where elevated PFAS levels are regularly observed in groundwater despite the absence of identifiable local sources. It is hypothesized that PFAS concentrations in atmospheric deposition decline inland, shaped by dry deposition of large SSA particles near the coast, consistent with the North Sea as the source.

A six-month field campaign along two transects extending 1 km inland employed automated wet/dry deposition samplers and bulk deposition collectors to capture continuous atmospheric PFAS inputs. Deposition chemistry was analyzed alongside dissolved organic matter signatures, meteorological observations, and nearshore aerosol particle-size distributions to characterize marine-derived contributions. Preliminary analysis of bulk deposition samples collected in November 2024 revealed an exponential decline in perfluoroalkyl carboxylic acid (PFCA) concentrations from the shoreline to 600 m inland, matching the decrease in sodium used as sea-salt tracer. PFCA concentrations reached 70 ng L⁻¹ at the coast, with perfluorooctanoic acid (PFOA) as the dominant contributor.

Although sampling is ongoing, these results already show that PFAS from the ocean can be transported inland via SSA, revealing a previously underappreciated pathway for coastal contamination. This has important implications for freshwater management, human exposure assessment, and future regulatory strategies.

3.07.P-We234 Mapping Organic and Inorganic Chemical Contamination Across the European Coastline

Lilian Greau¹, Javier Castro-Jiménez¹, Nicolas Briant¹, Bavo De Witte², Victor Manuel León León³, Steven Brooks⁴, Raffaele Siano⁵ and Aourell Mauffret¹, (1)Ifremer - Centre Atlantique, PDG-DGDS-RBE-CCEM, 44311 Nantes, France, (2)ILVO, Flanders Research Institute for Agriculture, Fisheries and Food, Animal Sciences Unit, 8400 Oostende, Belgium, (3)Centro Oceanográfico de Murcia (IEO), Spain, (4)NIVA, Norway, (5)Ifremer - Centre Bretagne, PDG-DGDS-ODE-DYNECO-PELAGOS, 29280 Plouzané, France

Chemical compounds have enhanced our quality of life, however the pollution they generate has the potential to negatively impact both the environment and human health. The chemical exposome associated with human activities includes a wide array of substances, which can be grouped into two main categories, organic and inorganic chemicals which could then both be subdivided into legacy and contaminants of emerging concern (CEC). The Traversing European Coastlines (TREC) expedition is a pan-European survey that aims to extensively study coastal ecosystems and their responses to environmental changes and pollution pressures. A collaboration has been set up between TREC and CONTRAST, a Horizon Europe project aiming to understand how chemicals of emerging concern (CECs) may harm marine ecosystems and develop solutions to reduce their impact.

The objective of the current study is to map the chemical contamination (organic and inorganic) in European coastal surface sediments. Twenty-four sampling sites across the European coastline were selected (North-east Atlantic and Mediterranean seas). An extensive list of contaminants has been monitored and analysed, including i) both legacy organic contaminants and CEC (Polycyclic Aromatic Hydrocarbons (PAHs), Polychlorinated biphenyls (PCBs), Polybrominated Diphenyl Ethers (PBDEs), Per- and Polyfluoroalkyls Substances (PFAS), Organophosphate Esters (OPE)), ii) trace metals and rare-earth elements (REEs), as well as iii) 64 unregulated CEC recently prioritized by Yulikayani et al., (2025).

We hypothesized that the contamination profiles would depend on the sampling site and nearby history of anthropogenic activities (estuary, national parks...). Indeed, some sites show a profile dominated by PAH

contamination due to their proximity to refineries and ports while others indicate a profile dominated by PFAS probably due to their proximity to industrial sites. There are also some hotspots of metal contamination found in sediments likely due to nearby mining or industrial activities. Besides, sediment properties (grain size, carbon organic) played an important role in the substance detection, highlighting the need for further adjustments in the sampling strategy to optimise the spatial scale assessment.

This study represents the first continent-wide initiative of its kind. It is then planned to link these contamination profiles to their impact on marine ecosystems biodiversity and functions.

3.07.P-We235 Fate and mobility of whale-watching vessel emissions in the marine environment and their effect on baleen whale behavior

Meem Muhtasim Mahdi¹, Charla Jean Basran² and Marianne Helene Rasmussen², (1)University of Iceland, Iceland, (2)Húsavík Research Center, University of Iceland, Iceland

The whale watching (WW) industry has been significantly contributing to coastal economic growth and fostering public engagement in marine life conservation worldwide. However, the gradual expansion of this industry has intensified environmental stress in nearshore waters, used as potential feeding zones for baleen whales (BW). Although traditional WW vessels (diesel-powered) emit harmful atmospheric and underwater emissions that adversely affect the marine environment and cetacean behavior, their associated ecological and biological risks have been inadequately quantified in previous studies. Hence, this research investigates how vessel-derived emissions disperse and accumulate under oceanographic conditions and alter respiratory and acoustic behavior in targeted BW populations in northern Iceland using the case study method. A medium-sized traditional WW vessel sailing across the Skjálfandi Bay was selected as a case ship, and its technical specification and voyaging information were obtained from its operating company and port authorities to illustrate its voyaging interface by using Seamatrix (v. 2.5.0.0) software. The STEAM model was used to calculate different particulate and gaseous emissions, and their hydrodynamic dispersion in oceanic water was illustrated using ChemicalDrift (v. 1.0) software. Finally, behavioral observations of BW towards spatial emission footprints were evaluated based on surfacing-respiration data derived from secondary literature. The preliminary results depict that different vessel-derived emissions influence the water chemistry of the nearby shore, and their dispersion in oceanic water moderately overlaps with whale-sighting hotspots. Stratified water columns and wind direction have a significant influence on pollutant persistence in feeding grounds, which elevates respiratory loads and reduces surface time in BW species. The cumulative load-level exposure may vary between peak and off-peak tour seasons, which influences habitat use and foraging efficiency. The analysis indicated that vessel-derived emissions transport a considerable amount of chemicals and non-indigenous species in ocean water, resulting in numerous environmental impacts and behavioral disruption in marine mammals. Therefore, further research is warranted to understand the transport mechanism of these pollutants while determining threshold limits for biological exposure to improve sustainable WW practices.

3.07.P-We236 Life-Long Exposure to Lower Water Quality and Enhanced Contaminant Risk May Enhance Coral Tolerance to Zinc

Verena Schoepf, Kay Watty, Maxine Mouly, Bas van Beusekom and Rene van der Zande, University of Amsterdam, Netherlands

Tropical coastal mosaics of mangrove, seagrass, and coral reefs underpin biodiversity, carbon storage, shoreline protection, fisheries, and tourism. Yet climate change, coastal development, and declining water quality increasingly threaten these systems, especially in semi-enclosed bays where pollutant loads and ecological stressors can be amplified. Despite the ecological and socio-economic importance of these habitats, the effects of coastal contaminants on marine foundation species such as reef-building corals remain severely understudied. Here, we report unexpected yet ecotoxicologically informative findings from an experiment originally designed to test climate change tolerance in the branching coral species *Porites furcata*. Colonies were collected from two contrasting habitats in Curaçao (southern Caribbean): a semi-enclosed inland bay characterized by elevated nutrients and heightened ecotoxicological risk; and a nearby fringing reef with high water quality. During the acclimatization phase in an indoor aquarium facility, we observed paling and declines in photochemical efficiency (Fv/Fm) that were most pronounced in corals from the fringing reef (-53% compared to -17% in bay-origin corals). While these changes were initially attributed to acclimation to artificial lighting, subsequent tests revealed elevated zinc concentrations (~1.57 mg L⁻¹) in the seawater supplying the facility, consistent with known negative effects of Zn on photosynthetic processes in corals.

Corals were then transferred to artificial seawater containing only trace amounts of Zn. Fv/Fm values fully recovered within 2 weeks in both reef and bay-origin corals, confirming that Zn had likely caused the stress response. While we did not directly measure seawater Zn concentrations at the corals' collection sites, other

work has shown strongly elevated Zn concentrations in seagrass leaves in the bay. These results indicate that corals chronically exposed to heightened contaminant risk, including Zn, may develop enhanced tolerance to Zn. This suggests that Zn-tolerant coral populations may also occur in other semi-enclosed coastal environments with similar local stressors. Our findings highlight the need for systematic monitoring of Zn and other trace metals in tropical bays and for standardized toxicity tests across additional coral species to better understand Zn tolerance and its implications for reef ecosystem resilience.

3.07.P-We237 Assessing the Occurrence and Drivers of Organic UV Blockers and Titanium in South-western European Coastal Waters

Mário Araújo¹, Isabel Benta Oliveira¹, Inês Soares¹, Aldo Barreiro-Felpeto¹, Antonio Moreda², Pedro Neves Carvalho³, Carlos Antunes¹ and Alexandre Campos¹, (1)Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portugal, (2)University Santiago de Compostela, Spain, (3)Aarhus University, Denmark

A large proportion of commercial sunscreens still relies on organic UV-filters, which have raised health concerns due to dermal absorption, detection in human milk, and ecological effects such as endocrine disruption. Their use has therefore been restricted in sensitive marine ecosystems. Titanium (Ti) and titanium dioxide nanoparticles (TiO₂ NPs) are increasingly promoted as “safe mineral UV-blockers”, yet their environmental risks remain poorly understood. Although Ti has been banned as a food additive in the EU, no regulatory limits currently exist for environmental concentrations of UV-filters or TiO₂ NPs, whose behavior is strongly influenced by natural factors such as salinity and organic matter. This study investigates the occurrence and co-distribution of organic UV-filters, Ti, and TiO₂ NPs along the southwestern European coast, aiming to identify key anthropogenic sources and environmental drivers shaping their presence.

Sampling was conducted in Summer and Autumn 2025 across three regions: Minho River, Ria de Aveiro, and Algarve, spanning nearly 1000 km and covering salinity gradients from freshwater to marine conditions. Ti and TiO₂ NPs were analyzed by ICP-MS and sp-ICP-MS, and organic UV-filters by LC-HRMS.

Preliminary summer results show relatively consistent coastal Ti levels (approx. 20 µg/L) and reveal strong salinity-driven aggregation of TiO₂ NPs, resulting in their low detection in marine waters. Our findings suggest that non-cosmetic Ti sources (particularly industrial activity and population density) may significantly contribute to environmental loads and pose potential risks to both ecosystems and consumers. Further ongoing assessment will support the development of monitoring strategies and regulatory frameworks for UV-filters.

3.07.P-We238 Optimization of a Method to Assess the Exposure to Emerging Pesticides in the Atlantic Blue Crab Inhabiting a Threatened Sea Lagoon

Pilar Gomez-Ramirez¹, Beatriz Fernández², Livia Spadetto¹, Francisco Acosta-Cifuentes³, Ignacio Franco⁴, Antonio Zamora-López⁵, Antonio Andres Herrero-Reyes⁵, Pedro Jiménez⁶, Juana Cava⁴, Jose Fenoll⁴ and Concepción Martínez-Gómez³, (1)Toxicology Research Group, Faculty of Veterinary Medicine, University of Murcia, Spain, (2)Spanish Institute of Oceanography - Spanish National Research Council (IEO-CSIC), Spain, (3)Oceanographic Centre of Murcia, Instituto Español de Oceanografía, Spain, (4)Instituto Murciano de Investigación y Desarrollo Agrario y Medioambiental (IMIDA), Spain, Spain, (5)Department of Zoology and Physical Anthropology, Faculty of Biology, University of Murcia, Murcia, Spain, Spain, (6)University of Murcia, Spain

Coastal ecosystems are increasingly impacted by chemical pollution, yet monitoring programs rarely include crustaceans despite their ecological relevance and capacity to accumulate contaminants. The Atlantic blue crab (*Callinectes sapidus*), an invasive species abundant in the Mar Menor Lagoon (southeastern Spain), represents a promising bioindicator for assessing exposure to contaminants of emerging concern (CECs). This study aimed to optimize an analytical method to quantify 24 emerging pesticides in crab tissues using minimal sample amounts. Haemolymph, muscle, and hepatopancreas samples were extracted following a modified protocol and analyzed by HPLC–MS/MS. Method validation demonstrated optimal recovery, repeatability, and linearity for 21 compounds across all matrices, although strong matrix effects were identified for several pesticides,

requiring matrix-matched calibration. The method was successfully applied to crabs experimentally exposed to acetamiprid and imidacloprid, with both insecticides detected in all tissues, showing highest accumulation in the hepatopancreas. These results confirm that the optimized method is robust, sensitive, and well suited for monitoring emerging pesticides in blue crabs, offering a valuable tool for future environmental assessments in threatened coastal ecosystems.

3.07.P-We239 An integrated modelling and monitoring study on the sources, pathways, and environmental fate of pharmaceuticals in the Northern Adriatic Sea

Loris Calgaro, Elisa Giubilato, Alessandro Bonetto, Pier Paolo Guolo, Laura Pagnin, Mattia Negrisola, Elena Semenzin and Antonio Marcomini, Ca' Foscari University of Venice, Italy

Chemical contamination by active pharmaceutical ingredients (APIs) has become a global environmental concern, as these compounds are only partially removed by conventional treatments and persist at low concentrations, affecting aquatic ecosystems and potentially human health. Their behaviour in coastal systems—especially semi-enclosed basins like the Northern Adriatic Sea—remains poorly understood despite high anthropogenic pressure and likely continuous inputs from rivers and wastewater.

This study quantified four key APIs—Trimethoprim (TRI), Clindamycin (CLI), Ofloxacin (OFL), and Venlafaxine (VEN)—in water and sediments by combining high-resolution modelling with seasonal monitoring. API emissions were estimated using regional consumption data, accounting for human and veterinary use and removal efficiencies. Water quality simulations were performed with the ChemicalDrift model, forced with hydrodynamic fields from SHYFEM and CMEMS. Four seasonal sampling campaigns provided data for quantitative UHPLC–MS/MS analysis.

TRI showed the highest annual load, followed by CLI, VEN, and OFL. The Po River contributed over 60% of total inputs, with secondary contributions from the Adige, Gorzone, Bacchiglione and Reno rivers, reflecting differences in local population and livestock distribution.

Model results revealed significant temporal variability in water concentrations, with localized peaks near the shore and lower backgrounds in the open sea. In some detail, CLI concentrations in water reached up to 2000 pg·L⁻¹, while TRI and VEN concentrations were generally lower (ca. 100 pg·L⁻¹), and OFL stayed mostly below 2 pg·L⁻¹. Sediment accumulation was limited to TRI and CLI, while VEN and OFL were modelled to remain largely dissolved. Spatial patterns showed consistently higher concentrations near river deltas and wastewater discharge zones, indicating dominant land-based inputs, while offshore waters and sediments exhibited low and levels of contamination.

Overall, this work highlighted the persistence, variability, and spatial heterogeneity of API contamination in the Northern Adriatic Sea, showing how the integration of modelling and monitoring can support the development of effective management strategies for the control of these chemicals' emissions.

3.07.P-We240 Use of Sea Urchin Liquid-phase Bioassays for the Ecotoxicological Analysis of Construction Products in Coastal Environments

Victoria Muñoz Ruiz¹, Eva Cifrian Bemposta², Lucía Pérez Gandarillas², Araceli Rodríguez Romero³ and Ana María Andrés Payán², (1)University of Cantabria, Spain, (2)Department of Chemistry and Process & Resources Engineering – ETSIT, University of Cantabria, Santander, Spain, Spain, (3)Institute of Marine Science of Andalusia (CSIC), Cádiz, Spain, Spain

The increasing incorporation of industrial by-products and waste-derived components into construction materials raises pressing concerns regarding their potential ecotoxicological impact on vulnerable coastal environments. These areas, situated at the intersection of human activities and open ocean dynamics, are particularly exposed to chemical leaching processes that may compromise water quality and ecosystem integrity. Within this context, standardized bioassays using marine model organisms provide a robust framework to translate chemical complexity into ecologically relevant endpoints.

In this study, we evaluated the ecotoxicity of leachates from a standardized cement (CEM V/B) incorporating blast furnace slag and metakaolin, using equilibrium leaching tests (EN 12457-1/2) at liquid-to-solid ratios of 2

and 10 L/kg. Two complementary bioassays were applied: the luminescence inhibition test with *Vibrio fischeri* and the embryonic-larval development assay with the sea urchin *Paracentrotus lividus*. Results revealed a marked influence of leachate concentration and L/S ratio on toxicity outcomes. While the bacterial assay indicated significant luminescence reduction, exceeding the toxicity threshold defined by CEN/TS 17459 at LS2 (LID = 18.83), the sea urchin assay provided a more sensitive and ecologically integrative perspective. Larvae exposed to LS10 leachates consistently reached stage 2 (four-leg development), whereas LS2 leachates at high concentrations (?75%) severely inhibited growth initiation, with significant deviations from control populations. These findings underscore the limitations of single-test approaches and highlight the necessity of multitrophic bioassay batteries for comprehensive risk assessment. The inclusion of sea urchin embryogenesis assays, a well-established marine model system, expands the interpretative scope beyond microbial endpoints, capturing developmental disruptions that are critical for population sustainability. By integrating chemical analysis with biological responses across trophic levels, this work demonstrates the relevance of harmonized ecotoxicological tools for evaluating innovative construction products in coastal zones. Ultimately, the study contributes to the advancement of standardized test systems that safeguard marine ecosystems against diffuse pollution sources, aligning with European guidelines (CEN/TR 17105) and reinforcing the role of ecotoxicology in bridging human activities with ocean health.

3.07.P-We241 Oysters as pollution sentinels in a Basque estuary (Spain): seasonal and metabolic variability

Belen Gonzalez-Gaya¹, Maddi Salvach Vilches², Iker Ugarrtemendia³, Miren Carnicero⁴, Juan Francisco Ayala-Cabrera², Oihane Diaz de Cerio⁴ and Néstor Etxebarria³, (1)Department of Analytical Chemistry & Research Centre for Experimental Marine Biology and Biotechnology, University of the Basque Country (PiE-UPV/EHU), Spain, (2)University of Basque Country, Spain, (3)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (4)University of the Basque Country, Spain, (5)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Leioa, Spain 2 Research Centre for Experimental Marine Biology and Biotechnology, University of the Basque Country (PiE-UPV/EHU), Plentzia, Spain, Spain

The use of sentinel species sensitive to chemical pollution is key to capture biological impacts in environmental monitoring programs. In particular, filter feeders are known to bioaccumulate contaminants and precisely reflect broad exposure periods in coastal areas. In this study, oysters from a moderately impacted estuary in the Basque Country (N Spain) were collected seasonally between 2023 and 2024. Oysters are considered potential substitutes for mussels as sentinel organisms in monitoring programs in this area. Therefore, this study aims to assess bioaccumulation and the occurrence of chemical contaminants in this species to correlate it with its health status. 30 oysters were collected seasonally at 4 points along the estuary, from the inner area already influenced by anthropogenic sources such as wastewater, until the mouth of the estuary on a saline environment, and biometric data was retrieved. Then, they were pooled together, freeze-dried and homogenized for the analysis of legacy and emerging semi-volatile pollutants including 16 polycyclic aromatic hydrocarbons, 8 polychlorinated biphenyls, 6 polybromated biphenyls, 34 pesticides, 6 UV filters, 7 phthalates and 8 fragrances. Samples were extracted using focused ultrasonic solid-liquid extraction, purified using 15g florisil columns and injected onto an Agilent 7890A gas chromatograph coupled to an Agilent 5975C quadrupole mass spectrometer. Preliminary results indicate positive detection of many legacy (PAHs) and emerging chemicals (UV filters, among others), suggesting relevant ecological damage as previously observed with the disappearance of other local filter feeders like mussels. The correlation between seasonal and spatial patterns will be explored willing to elucidate the insights on exposure and the biological cycles.

3.07.P-We242 Conifer Resin Acids as Indicators for Ship Coatings' Environmental Impact

Anja Prisching¹, Marten Fischer², Stefan Meinecke³, Heinz Wilkes¹ and Barbara M. Scholz-Boettcher¹, (1)Carl von Ossietzky University of Oldenburg, Institute for Chemistry and Biology of the Marine Environment (ICBM), Germany, (2)Federal Maritime and Hydrographic Agency (BSH), Germany, (3)IV 2.5, German Environment Agency (UBA), Germany

Most ships use selfpolishing antifouling coatings (SPCs), which erode evenly over time to prevent biofouling and maintain a smooth coating surface to lower fuel consumption. However, ship coatings remain an underestimated source of microplastics, nanoplastics, and associated additives (MNP&A) in the marine environment. Especially near-shore areas with strong nautical impact may experience a significant input of SPC-particles to MNP&A. To classify SPC contribution to the marine MNP load and estimate environmental impacts, a qualitative and ideally quantitative measurement variable is prerequisite.

To identify SPC-particles in the environment, a set of chemical markers commonly used across SPC products is needed. SPCs are typically based on hydrolyzable copolymers incorporating high amounts of conifer resin-related compounds (RRCs) which are either covalently or non-covalently bound. They mainly consist of natural and modified diterpene resin acids with known ecotoxicological potential and are released as SPCs disintegrate. This projects' aim is to elucidate SPC-based MNP&A input into the marine environment by i) evaluating SPCs high RRC content to find suitable chemical markers for released particles and ii) characterize leaching-based input of RRCs as potentially harmful additives.

A set of 4 representative, uncured SPC products was separated into solubility fractions to isolate potential leachate and precipitated polymers, analyzed via GC-MS and Py-GC/MS, respectively. Additional cured SPC-particles were generated and analyzed via Py-GC/MS. Finally, environmental samples (water, sediment, biota) analyzed for MNP via Py-GC/MS were screened to detect selected RRCs. Considering further leaching of RRCs as SPC-particles age, ongoing laboratory experiments are used to induce hydrolysis.

Whith one exeption, RRC composition was highly consistent across SPCs. Several RRCs were selected as potential SPC markers and partially tentatively identified via NIST library. Unknown RRCs were grouped based on key fragment ions, whith structure elucidation still ongoing. High levels of RRCs were found in both leachate and polymer binder fraction isolated from uncured SPCs. First experiments show that hydrolysis does not release all RRCs from the isolated polymer binder. A set of determined RRCs was detected in marine MNP samples (water, sediment, biota). Our preliminary results underscore RRCs' potential in unravelling the impact of ship coatings to marine MNP&A pollution.

3.08 Emerging Chemical and Microbial Threats to Drinking Water Quality: Identification, Prioritization and Risk assessment

3.08.T-01 Persistent DOM Fractions as Dominant Precursors of DBP Formation: Integrated Target and Non-Target HRMS Insights from a Full-Scale DWTP

Francisco Zafra-Navarro¹, Saida Marti¹, Simeon Schum², Pere Emiliano³, Mira Petrovic¹ and Maria José Farré¹, (1)Catalan Institute for Water Research (ICRA), Spain, (2)State University of New Mexico, United States, (3)Ens d'Abastament d'Aigua Ter-Llobregat, Spain

Chlorination remains the most widely used disinfection method in drinking water treatment due to its simplicity and cost-efficiency. However, reactions between chlorine-based disinfectants and dissolved organic matter (DOM) generate disinfection byproducts (DBPs), many of which remain poorly characterized, unregulated and potentially more toxic than those currently controlled (THMs, HAAs). In this study, we investigate DBP precursor behaviour and formation in a full-scale DWTP by integrating a multi-analytical approach based on (i) target analysis of 17 regulated and emerging DBPs, (ii) bulk measurements of adsorbable organic halides (AOX) and (iii) non-target DOM fingerprinting by high-resolution mass spectrometry (HRMS).

To assess the performance of the treatment system and the evolution of water quality throughout the distribution network, seven sampling points were selected, four treatment stages and three distribution systems. To capture seasonal variability and reduce sampling bias, six sampling campaigns were performed during three seasons (spring, autumn and winter) with two sampling events per season.

Twelve of the 17 target DBPs (four THMs, three HANs, five HAAs) were detected in finished water, with concentration ranges of 13–42 µg/L, 1–4 µg/L and 6–13 µg/L, respectively. HRMS showed that aromatic and condensed-aromatic DOM was efficiently removed, whereas aliphatic and unsaturated-like fractions persisted along the treatment train and accumulated newly formed halogenated species. AOX profiles, dominated by chlorinated organics, revealed a large pool of unknown halogenated compounds, consistent with low-oxygen unsaturated formulas in the HRMS fingerprints.

A Spearman correlation analysis highlighted 97 formulas strongly associated with DBP formation, nearly 60% of which persisted through all treatment stages. These precursors were enriched in aliphatic and low- or high-oxygen unsaturated-like van Krevelen regions; the fractions least removed by conventional treatment. Overall, our findings demonstrate that DBP formation is controlled by a narrow, structurally resilient subset of DOM. This work provides a transferable, molecular-level framework to move from bulk DOM removal towards targeted treatment strategies that selectively remove persistent DBP precursors and thereby enhance drinking water safety.

3.08.T-02 A plasmonic nano-tastebud sensor for the detection and discrimination of organic micropollutants in drinking water

Baptiste Poursat¹, Justin Sperling², Bill Sloan², William Peveler², Alasdair Clark² and Caroline Gauchotte-Lindsay³, (1)No Affiliation, United Kingdom, (2)University of Glasgow, United Kingdom, (3)James Watt School of Engineering, University of Glasgow, United Kingdom

Monitoring organic micropollutants (OMPs) in drinking water is still limited by slow, laboratory-based LC-MS/MS methods that cannot provide real-time information, especially in decentralised or rapidly changing systems. To address this gap, we developed a cross-reactive plasmonic “nano-tastebud” sensor that detects changes in water chemistry through multidimensional optical fingerprints rather than targeted analyte recognition.

The platform integrates microfluidics with 24 functionalised plasmonic metasurfaces whose localised surface plasmon resonance (LSPR) shifts respond to supramolecular interactions with waterborne compounds. We tested 11 representative OMPs, including estrogens, painkillers, antibiotics, anti-diabetics, stimulants and pesticides, spiked into tap water from 10 ng L⁻¹ to 1 mg L⁻¹. Optical responses were processed using PQN normalisation and evaluated through multivariate and machine-learning models (PCA, LDA and random forest). Independent-run validation was used to assess real-world robustness, and DOC was included as an auxiliary predictor.

The sensor consistently detected chemical changes at concentrations as low as 1 µg L⁻¹ and produced reproducible fingerprints that allowed discrimination of pollutant classes. Estrogens and painkillers generated distinctive, high-intensity responses, making them strong indicators of wastewater-related contamination. Other pollutant groups produced subtler signals but remained distinguishable from baseline water. Importantly, the platform generalised well across runs, demonstrating resilience to day-to-day drift and matrix variability, critical for field deployment.

This study provides the first evidence that a nano-plasmonic cross-reactive sensor array can rapidly detect and differentiate mixtures of OMPs in drinking water without relying on selective receptors. The approach offers a fast, field-deployable tool for early-warning detection and operational monitoring and has strong potential to complement or reduce reliance on conventional LC-MS/MS in decentralised water systems.

3.08.T-03 Exploring biodegradation potential of nitramines in drinking water, biproducts of amine-based carbon capture.

Aina Charlotte Wennberg¹, Cathrine Brecke Gundersen¹, Alexander Eiler², Merete Grung¹ and Malcolm Reid¹, (1)NIVA, Norway, (2)University of Oslo, Norway

Amine-based carbon capture plants (CCPs) can release amines that transform into carcinogenic nitrosamines (NSAs) and nitramines (NAs), potentially contaminating drinking water sources. In Norway, the strict safety threshold of 4 ng/L for these compounds poses a significant analytical challenge, making environmental modeling essential for risk assessment. Accurate models rely on precise degradation kinetics with mechanisms differing between NSAs and NAs. While photodegradation drives NSA removal, biodegradation is the dominant pathway for NAs.

This study assessed biodegradation of three representative nitramines—MEA (N-(2-Hydroxyethyl)nitramide), AMP-NO₂ (N-(1-Hydroxy-2-methylpropan-2-yl)nitramide), and NIPZ (1-Nitropiperazine)—using a modified OECD 309 test with water and sediment from Lake Elvåga, a drinking water source near a planned CCP. Experiments compared the natural attenuation in water, water-sediment inocula against adapted inocula under nitrogen-limited conditions. Primary degradation was monitored by LC-MS/MS, while microbial community changes were analyzed via flow cytometry and 16S rRNA sequencing.

Biodegradation rates proved highly compound depending: MEA degraded rapidly (DT₅₀: 7–34 days), AMP-NO₂ showed moderately (DT₅₀: 12–40 days), while NIPZ showed negligible degradation (>60 days). Sediment

addition significantly enhanced degradation compared to water alone, whereas prior adaptation offered limited increase in degradation. Abiotic processes contributed to MEA degradation in sediment. Microbial analysis revealed a decline in diversity under nitramine and phosphate exposure, yet identified no universal nitramine-degrading bacteria.

These results underscore that amine selection in CCP design is critical for mitigating drinking water risks. Furthermore, the findings suggest that microbial diversity plays a key role in regulating the persistence and degradation of nitramines in polluted recipients. Collectively, this study provides essential kinetic data for regulatory modeling.

3.08.T-04 Semi-Automated Workflow for the Identification and Screening of Active Degradation Products of Tyrosine Kinase Inhibitors After Treatment with Aerobic Activated Sludge

Nick Zwart¹, Corine J. Houtman², Timo Hamers¹ and Marja Lamoree¹, (1)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands, (2)The Water Laboratory, Haarlem/Amsterdam Institute for Life and Environment A-LIFE, VU University Amsterdam, Netherlands

Routine monitoring of drinking water sources for contaminants is commonly limited to the determination of known priority substances through chemical analysis. During the treatment of wastewater, chemicals can be transformed into other potentially hazardous and/or more mobile degradation products that remain undetected. Efforts to keep track of potential hazardous compounds released into the environment and to monitor the processes of drinking water purification depend on the ability to timely identify these compounds. This is especially important for novel pharmaceuticals with unknown impact human health. One relatively novel, expanding and structurally diverse class of (increasingly prescribed, anti-cancer) pharmaceuticals are tyrosine kinase inhibitors (TKIs). Determination of their impact depends on insight into their fate (e.g as degradation products). The advent of high-throughput effect-directed analysis (HT-EDA) provided a strategy to identify novel toxicants in mixtures by combining effect-based methods with analytical identification methods. However, HT-EDA lacks compatible bioassays for TKI screening and remains a laborious method with low identification success rate. To achieve streamlined formation, detection and improved identification of (active) TKI degradation products, an integrated workflow was developed through application of lab-scale degradations with a semi-automated identification workflow and enzymatic kinase inhibition assays. The applicability of this approach will be demonstrated by analysis of a selection of TKIs prescribed in The Netherlands. The application of lab-scale degradation together with specialized non-target screening workflows and high-resolution effect-based testing will open the way to preemptive identification of degradation products as emerging contaminants and will emphasize the importance of residues when considering environmental contaminant impacts.

3.08.T-05 Assessment of Health Risks Associated with Soluble Polymer Application in Drinking Water Production

Bianca van de Ven and Dominique Narain-Ford, RIVM, Netherlands

Synthetic polymers play an essential role in modern water treatment processes, where they are used to improve the quality and safety of drinking water. While much attention has been given to the environmental impact of insoluble polymers and microplastics, less is known about the potential human health risks associated with water-soluble polymers used in drinking water production.

This study examines the application and health risk assessment of water-soluble polymers in drinking water production. To establish a comprehensive overview, all active and recently expired certificates from the KIWA database were systematically reviewed, covering 100 dossiers. The investigation focused on polymers functioning as antiscalants, antifoaming agents, and conditioning agents. Relevant legal frameworks and guidelines were assessed to position current practices within the regulatory context.

Each polymer identified was evaluated for persistence, mobility, and toxicity (PMT) properties, with an emphasis on parameters pertinent to human health risk assessment. Data collection included both certificate information and supplementary literature review. Where available, EFSA opinions regarding food additives were consulted to support the risk estimation.

The results identified 18 distinct polymers distributed across 28 certificates, most commonly used as antiscalants. These polymers generally exhibit polydisperse molecular weight distributions and are tailored for specific roles in water treatment. For five polymers, PM properties could be identified using QSAR models; however, for the majority, the PMT/PBT scoring approach based on QSARs proved unsuitable due to identity challenges and data limitations. Additionally, the study considered potential human exposure from residual polymer content and migration from materials, particularly during the initial months following installation. These findings provide a foundation for improved human health risk assessment of water-soluble polymers in drinking water production and highlight the need for more targeted research and regulatory attention in this area.

3.08.P Emerging Chemical and Microbial Threats to Drinking Water Quality: Identification, Prioritization and Risk assessment

3.08.P-Tu209 Identification and Prioritisation of Emerging Pollutant Sources Using AI and GIS to Protect Drinking Water Wells

Shaya Algoe¹, Lout Kuiper² and Clara van der Heijden², (1)Sweco Netherlands, Department of Environmental Consultancy, Rotterdam, The Netherlands, Netherlands, (2)Sweco Netherlands, Department of Geodata Consultancy, Zwolle, The Netherlands, Netherlands

The water sector in the Netherlands faces increasing challenges due to emerging pollutants, particularly substances of very high concern (SVHCs), in waterbodies, including drinking water wells. As of January 2025, around 3,200 SVHCs and 400 potential new SVHCs have been identified. Governmental organizations aim to create a safe environment by reducing SVHCs from industrial activities. However, manual identification of sources and monitoring is time-consuming and resource-intensive, hindering effective management. This study leverages GIS datasets, AI, and FME scripts to enhance the detection and mapping of potential SVHC sources. Using AI and data-driven techniques, it assesses industrial activities and their emissions to help prioritize specific sources and develop mitigation strategies. To pinpoint industrial sources of SVHCs, FME scripts and filtering techniques were applied to the Dutch Chamber of Commerce (CoC) dataset. This dataset includes over 700,000 businesses within an area of interest of approximately 410 km². Multiple filters, derived from National Institute for Public Health and the Environment studies and expert input from in-house projects, helped identify businesses that could be potential sources of SVHCs. Non industrial sources such as (former)landfills were identified using open data and large language models for locations where firefighting foams were used. GIS is used for visualization to identify and prioritize SVHC sources near drinking water wells. A tailor made risk-matrix was used to score each source in order to prioritize them for policy making in order to protect nearby drinking water wells. The integration of multiple data sources and filtering techniques in an automated GIS workflow allowed a targeted identification of contamination hotspots. An online GIS-based dashboard provides policymakers easy access to centralized, relevant data, enhancing decision-making and response times. The study demonstrates the effectiveness of using large GIS datasets for identifying potential SVHC source locations. The centralized GIS dashboard improves efficiency and aids policymakers in making informed decisions. Future work includes adding historical SVHC measurements and developing real-time monitoring tool. The findings emphasize the importance of data integration and spatial analysis in environmental risk assessment, providing a robust framework for future investigations and helping protect drinking water wells effectively.

3.08.P-Tu210 Characterization of thyroid hormone-replacing activity in surface water using effect-directed analysis.

Jaimy de Schepper¹, Bibi van Poelgeest¹, Bram Hijzelendoorn¹, Yvonne van Oorschot¹, Timo Hamers², Marja Lamoree² and Corine J. Houtman¹, (1)Het Waterlaboratorium, Netherlands, (2)VU University Amsterdam (VU), Netherlands

Surface waters are exposed to mixtures of chemicals, many chemicals of which have been found to inhibit thyroid hormones (THs) such as thyroxine from binding to transport protein transthyretin, also called TH-displacing activity. The potential impact of TH-displacing activity on human health and the environment is of growing concern. Effect-based methods, such as in vitro bioassays, have revealed TH-displacing activity in various water matrices. Indeed, our studies have shown that TH-displacing activity is present in wastewater, surface water and also in drinking water. The environmental effect-based trigger value (EBT) for TH-displacing activity is often exceeded in surface water, indicating potential environmental risk. The chemical drivers behind this activity, however, remain largely unidentified.

This study aimed to further characterize TH-displacing activity in surface water that were known to be

contaminated with PFAS, with the expectation that we might be able to explain a large portion or even fully explain TH-displacing activity by target PFAS. Indeed, the contribution of target PFAS to TH-displacing activity was higher than found in our previous study [3]. Effect-directed analysis (EDA) was applied with nontarget screening (NTS) to identify bioactive compounds that contributed to TH-displacing activity in water to further close the gap. EDA led to the tentative identification of 12 compounds, including plant protection products and carboxylic acids, with four confirmed as contributors to TH-displacing activity. Further identification of bioactive compounds is ongoing using non-target approaches such as MS2 matching of unidentified features to those that were identified and Kendrick Mass Defect analysis. Moreover, a risk assessment will be performed on the known bioactive compounds in surface water to assess if there indeed exists an environmental risk upon exceedance of the EBT.

Ultimately, this research provides guidance to water quality managers and drinking water companies on how the FITC-T4 bioassay can be used to complement water quality monitoring for assessing environmental risk. Moreover, whether an operational response is necessary upon exceedance of the EBT to ultimately protect human health and the environment.

3.08.P-Tu212 Odour Deviations in Drinking Water Induced by Pressure Changes in the Distribution Network

Zoë Mol¹, Lore Segers¹, Herman Van Langenhove¹, Tom Vandermarliere², Bart De Gusseme¹, Christophe Walgraeve¹ and Kristof Demeestere¹, (1)Ghent University, Belgium, (2)Farys, Belgium

Drinking water providers ensure safe and pleasant drinking water through advanced treatment processes and stringent quality control. However, they sometimes receive complaints about taste and odour (T&O) in the drinking water. Since T&O are key characteristics on which people assess drinking water quality and safety, badly perceived T&O events decrease consumers' confidence in drinking water quality and cause people to choose bottled water over tap water. Production and/or release of T&O compounds during drinking water distribution should be avoided as the water is directly delivered to consumers without further treatment. Odours can be caused by leaching of compounds from pipe materials, microbial metabolism, disinfection reactions, or diffusion of odour compounds or precursors from external sources. Increasing knowledge of T&O origins is needed to better solve future problems.

Therefore, this research focuses on odour deviations related to changes in pressure during maintenance work at the high-pressure (HP) drinking water distribution system. A trace analytical method targeting 45 T&O compounds is optimized by including a derivatisation step to improve halophenol detection/quantification. Next, in a field section of a real HP pipe (± 3 km), three scenarios were systematically investigated. Lowering the overpressure in the HP pipe from 10 to 5 bar resulted in an observed bitumen/asphalt odour, which further increased in intensity after a subsequent sudden pressure drop to 2 bar. Based on the odour threshold and profile, two halophenols were detected that may have contributed to this odour observation. When the section was partially emptied, 6 halophenols and 5 other T&O compounds were identified. Our results indicate that pressure changes induce the leaching of T&O compounds from sealing materials connecting the 6m-pipe sections. This is further supported by the detection of similar T&O compounds in a water extract of the sealing materials and in an odorous household sample collected after maintenance work in the HP-network.

Overall, this study is highly relevant for identifying and quantifying key T&O compounds and their sources in (HP) drinking water distribution networks. Next to the acquired scientific knowledge, our findings have direct operational relevance, as effective pressure management during maintenance works will be a key factor for drinking water companies in preserving water quality and minimise the risk of odour-related issues in DWDS.

3.08.P-Tu213 Toxicity Prediction from MS2 Fingerprints to Support Feature Prioritization in Non-Target Screening

Miina Yanagihara¹, Nienke Meekel², Dennis Vughs¹, Astrid Reus¹, Renske P. J. Hoondert³ and Frederic Béen⁴, (1)KWR Water Research Institute, Netherlands, (2)KWR Water Research Institute, Nieuwegein, Netherlands, (3)Chemical Water Quality, KWR Water Research Institute, Netherlands, (4)VU University Amsterdam (VU), Netherlands

Non-target screening (NTS) enables the detection of large numbers of unknown features in water samples, yet interpreting their potential relevance remains challenging when structural information is limited. This study explored whether fingerprints derived from tandem mass spectra (MS2), combined with machine-learning models, can support the prioritization of features detected in NTS workflows.

Groundwater samples were collected from two locations used for drinking-water production. Samples were analysed by hydrophilic interaction chromatography (HILIC) coupled to high-resolution mass spectrometry (HRMS). Features were extracted using patRoön followed by formula and candidate generation using SIRIUS and database searches. MS2 fingerprints were generated using SIRIUS+CSI:FingerID and subsequently used as inputs for two prediction models: MLin vitroTox and deepFPlearn.

A total of 590 features were detected at Location A and 395 at Location B, with 272 features shared across both locations. After quality filtering, MS2 data were available for 280 features, and fingerprints were obtained for 163 of them. MLin vitroTox classified 158 fingerprinted features as active on at least one endpoint, covering 51 mechanistic targets. DeepFPlearn identified 11 features with a probability above 0.5 for one or more of its evaluated endpoints. An example of these preliminary outputs is shown together with relative feature abundance, to explore whether the model predictions relate to the presence of these features in the samples. These findings represent an initial step toward integrating MS2-based predictions into NTS prioritization. Future work will incorporate concentration estimates and bioassay validation to refine and evaluate this workflow as a method for supporting risk-oriented interpretation of unknown features detected by NTS.

3.08.P-Tu214 Sample preparation determines chemical characterization and in vitro responses in water sources for drinking water supply

Victoria Osorio¹, Pascal Kooij², Annemieke Kolkman³, Merijn Schriks⁴ and Stefan Kools², (1)ONHEALTH, IDAEA-CSIC, Spain, (2)KWR Water Research Institute, Netherlands, (3)Nederlands Forensisch Instituut, Netherlands, (4)Vitens N.V. Drinking Water Company, Netherlands

Chemical micro-contaminants occur in surface waters as complex mixtures, yet conventional target analysis often fails to explain the biological effects observed in water used for drinking water production. Effect-directed analysis integrates advanced chemical and bioanalytical tools to better characterize these mixtures, but sample preparation remains a critical and frequently overlooked step influencing both analytical sensitivity and bioassay performance.

We evaluated three solid-phase extraction procedures covering broad chemical domains to determine their suitability for combined chemical and toxicological assessment of contaminants of emerging concern in water sources for drinking water supply. A sequential mixed-sorbent method was compared with single-sorbent methods using Oasis Hydrophilic-Lipophilic Balance and Mixed-Mode Cation Exchange cartridges. All methods were optimized and applied to grab samples from multiple abstraction points collected during two campaigns.

Chemical analysis by liquid chromatography coupled with high-resolution tandem mass spectrometry revealed marked differences in the number and type of compounds extracted among methods, with the mixed-sorbent procedure yielding the widest chemical coverage. Concentrations varied spatially and seasonally across sampling sites. In vitro bioassays assessing endocrine, metabolic, genotoxic and oxidative stress responses confirmed that all extracts elicited biological activity, but the magnitude and pattern of responses differed among extraction methods. Variability in metabolic and anti-androgenic activities was particularly pronounced, highlighting the impact of extraction selectivity on the observed toxicity profiles.

These results demonstrate that sample preparation strongly shapes both chemical and biological outcomes in quality assessment of drinking water sources. Ongoing data treatment will investigate the extent to which each extraction method explains observed biological activity and supports mixture toxicity interpretation. Findings from this work support the need for careful method selection to ensure robust and interpretable water quality assessments.

3.08.P-Tu215 In silico toxicity assessment of data-poor substances migrating from polymer-based drinking water distribution materials

Brook F. Ashcraft¹, Astrid Reus², Miina Yanagihara³, Renske P. J. Hoondert³, Heeteak Kang⁴ and Milou M. L. Dingemans¹, (1)Institute for Risk Assessment Sciences (IRAS), Toxicology Division, Utrecht University & KWR Water Research Institute, Netherlands, (2)KWR Water Research Institute, Netherlands, (3)KWR Water Research

Institute, Netherlands, (4)Institute for Risk Assessment Sciences (IRAS), Toxicology Division, Utrecht University & LyondellBasell Industries Holdings B.V., Netherlands

Polymer-based materials, such as plastic pipes and connection parts, are widely used in drinking water distribution systems. Although safety-tested, studies show that trace amounts of chemicals can migrate from these materials into drinking water. For many of these substances, consumer exposure and potential human health or environmental risks remain unclear.

This research aimed to identify data-poor substances migrating from distribution materials and assess their mutagenic potential using in silico toxicity models. Ames bacterial mutagenicity was selected as the primary endpoint for its robust experimental data in the models used, improving prediction reliability.

A systematic literature review identified 276 distinct organic substances migrating from distribution materials, including additives, monomers, polymerization aids, and degradation products. Substances were prioritized based on legislative relevance – relating to the revised EU Drinking Water Directive – and structural alerts for mutagenicity, yielding 89 prioritized substances.

Bacterial mutagenicity predictions were generated using read-across in the OECD (Q)SAR Toolbox (v4.8) and three QSAR models from the bacterial mutagenicity model in MultiCase CASE Ultra software (GT1_BMUT, PHARM_BMUT, GT_EXPERT). Substances without experimental data (41 out of 89) received mutagenicity predictions. Among these, 26 received reliable unanimous negative predictions and are therefore unlikely to be mutagenic. None received reliable unanimous positive predictions; all positive outcomes were contradicted by at least one negative or inconclusive prediction, resulting in an overall inconclusive result. Fifteen substances had inconclusive results and were further investigated for external experimental mutagenicity data. They were categorized into high, medium, and low testing priority categories based on prediction outcomes severity to guide future testing efforts.

The findings of the current study suggest that current migration studies may overlook potentially hazardous substances due to their focus on targeted analytical methods and limited material types. The use of broader detection approaches, including non-target screening, and expanded sampling to include more material types and distribution-system-wide assessments are recommended to better capture real-world exposure.

This study was supported by the KWR Waterwijs program of Dutch and Flemish drinking water utilities.

3.08.P-Tu216 Migration of organic compounds from rubber materials in contact with water and their safety evaluation as water contact materials

Ana Isabel Penetra Dra.¹, Rui Carneiro², Cristina CM Almeida³ and Vitor Cardoso², (1)No Affiliation, Portugal, (2)Empresa Portuguesa das Águas Livres, S.A. - EPAL, Portugal, (3)University of Lisbon, Portugal

Water for human consumption comes into contact with different construction materials used in the collection, treatment, storage, and supply systems, and in the building networks up to the consumer's tap.

All the materials used in water supply structures have the potential to change water quality by leaching into the water, due to electrochemical mechanisms, biological phenomena, oxidation, corrosion, among others.

The nature of the leached compounds and the potential chemical interactions depend on the type of material used, namely, cementitious (cement, aggregates, water, additives, adjuvants, and fibers), organic (polymer matrix composites and elastomers, namely high-density polyethylene and epoxy resins) and metallic (especially stainless steel, copper, ductile iron, and metal alloys). These compounds can be harmful to human health.

The connection between the different pipework sections can be made through metal compression fittings, with the sealing being achieved by rubber sealing rings, through fittings of the same material connected by polyfusion welding.

In this work, six series of specific migrations studies from rubber materials intended for water contact have been studied. The amount of material used for each test depends on the surface-to-volume ratio (S/V) of each material and, the tests take place with a ratio S/V of 3 and 6. The experiments were carried out with ultrapure water under suitable conditions of time and temperature [1,2]. The liquid-liquid extraction of 500 mL of migration water in acid and basic conditions was used for the extraction of all potential organic compounds with 200 mL of dichloromethane. The organic extract was concentrated to 0.5 mL in a Turbovap system and analyzed by gas chromatography coupled to mass spectrometry [3]. A semi-quantitative method with ten deuterated standards was used for the quantification of all the compounds identified in migration waters. The electric conductivity, redox potential, color, pH, and the turbidity of migration waters were also performed.

More than 50 organic compounds were quantified in migration waters with a total concentration of up to 2608 µg/L. Most of the organic compounds showed concentrations lower than 10 µg/L, but some of them showed concentrations of up to 200 µg/L. The number of organic compounds and their concentrations decrease with the number of migration periods.

3.08.P-Tu217 Impact of Emerging Pollutants and Associated Health risks for Antibiotic-Resistant Bacteria and Resistance Genes in Urban Rivers

Bhawana Choudhary¹, Arun Kumar² and Patrick Gurian³, (1)Department of Civil and Environmental Engineering, Indian Institute of Technology, Delhi, India, (2)Department of Civil and Environmental Engineering, Indian Institute of Technology, Delhi, India, (3)Department of Civil Architectural, and Environmental Engineering, Drexel University, Philadelphia, United States

Antibiotic resistance in aquatic systems is rapidly increasing due to the interaction of ARGs (Antibiotic-resistant genes) with numerous environmental stressors. The continuous discharge of sewage and other contaminants creates conditions that allow antibiotic-resistant bacteria (ARB) and their genes to thrive and spread. Strong correlations between faecal indicator bacteria and ARB indicate untreated waste inputs as major contributors of resistant bacteria in the environment. Surveillance from rivers like the Ganga and the Yamuna in India has shown the presence of potential pathogenic ARB such as *Pseudomonas*, *Acinetobacter*, *Aeromonas*, *Escherichia*, *Enterobacter*, and *Klebsiella*. However, the increasing burden of ARB in aquatic systems is compounded by heavy metal contamination, continuous sewage influx, and environmental stressors that intensify horizontal gene transfer and enrich high-risk clones. Drinking-water studies globally report WHO-priority ARB such as carbapenem-resistant *Klebsiella pneumoniae*, ESBL-producing *E. coli*, multidrug-resistant *Acinetobacter* spp., *Staphylococcus aureus*, *Salmonella*, *Shigella*, and *Streptococcus pneumoniae*, all associated with significant disease burdens. Yet, despite their widespread detection, risk assessment remains limited due to the absence of suitable antibiotic-resistant dose–response models (DRMs). Traditional DRMs treat pathogens as antibiotic-susceptible and fail to capture ARB dynamics, co-selection pressures, or realistic human exposure pathways. Recent advances propose a stochastic simple death (SD) process to model ARB and antibiotic-susceptible bacteria jointly, enabling incorporation of antibiotic concentration effects, horizontal gene transfer, mixed bacterial populations, and illness treatability. A case study using gentamicin-resistant and susceptible *E. coli* demonstrated how such models can more accurately predict health outcomes across antibiotic exposure gradients. A comprehensive, next-generation DRM that integrates environmental stressors, pollutant co-selection, ARG abundance, and human exposure scenarios—such as recreational, drinking-water, or incidental ingestion—would yield far more realistic infection risk estimates. Building upon recent model innovations, incorporating ARB behaviour directly into QMRA frameworks is essential for evaluating and mitigating AMR risks in polluted urban river systems.

3.09.A Environmental Forensics: Tracking Sources and Evaluating the Effects of Chemicals in Urban and Other Environments

3.09.A.T-01 The INQUIRE project: Human exposure to indoor house dust: characterization of unknown chemical compounds and their potential sources

Stamatina Violaki, Pim Leonards, Ike van der Veen, Sicco Brandsma and Eva Sugeng, VU University Amsterdam (VU), Netherlands

Homes are small ecosystems linked to the outside world while being vastly different due to individual behaviours. Since people spend a majority of their time indoors, increasing their likelihood of exposure to hazardous chemicals. Making the indoor environment of high importance to test.

The aim of this study was to identify potentially harmful chemicals and potentially sources of them in eight European countries. The matrix used for identifying chemicals is dust, due to its complex nature and as a source of exposure.

Nearly 300 dust samples were collected, extracted and analysed with liquid chromatography high-resolution trapped ion mobility spectrometry time-of-flight mass spectrometry (LC-TIMS-TOF) for both negative and positive mode. Resulting in the detection of more than twenty thousand chemicals varying from insect repellents to plasticizers.

Country-specific trends were found that highlight the importance of improving the indoor environment and how that is reflected in legislations, or the lack thereof. Additionally, sources of chemicals could potentially be identified by questionnaires about personal habits.

The link between chemicals in consumer products sampled from the houses as potential sources is studied aiming to improve the indoor air quality and finally through legislation.

Disclaimer/Disclosure:

This project has received funding from the European Commission Horizon Europe, European health and Digital Executive Agency (HADEA), research and innovation programme under grant agreement Project No 101057499 – INQUIRE. 3.09.A.T-02 From Indoors to Surface Water: Tracking Contaminants Released From Textiles During Laundry via Target and Non-Target Screening

Anna Goellner¹, Özge Edebalı², Lisa Melymuk³, Branislav Vrana⁴, Werner Brack¹ and Martin Krauss¹,
(1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Faculty of Science, Masaryk University, Czech Republic, (3)Masaryk University, Czech Republic, (4)Recetox, Masaryk University, Czech Republic

A wide range of contaminants can be found in wastewater and surface water, of which many can contribute to mutagenic activity, but for which the sources are not well-understood. This is particularly true for indoor sources impacting on water quality. One possible pathway how indoor chemicals may reach water bodies is the emission via laundry. Accumulation of indoor contaminants on textiles and re-release via laundering was reported for phthalate esters, brominated flame retardants (BFRs) and organophosphate esters, but information for other chemical classes is scarce.

To characterise the exposure and sources of indoor contaminants in surface waters, we conducted a controlled indoor textile exposure study, from which textile extracts and laundry samples were generated. Indoor locations included (i) pubs where smoking is allowed, (ii) restaurant kitchens where most dishes consist of meat products, (iii) hair salons and (iv) flats where the residents are non-smokers and vegetarians/vegans. The samples were characterised using LC-HRMS/MS and evaluated using target and non-target screening approaches. Additionally, wastewater treatment plant (WWTP) influent and effluent samples were collected to trace the contaminants released from textiles further downstream.

Source-specific features that are present in the textile samples, representing the first step in the textile & laundry pathway were investigated. Unique features were then investigated in laundry and wastewater samples. The patterns from the textile samples can also be observed for laundry samples, albeit not for all features. From the 2335 unique features in smoking pubs filtered from textile samples 1186 were present in laundry and 329 were detected in wastewater influent. The unique features underwent hierarchical clustering to link samples that show similar occurrences, proving to be especially effective for smoking pub samples, where laundry and textile samples clustered together. Unique features that could be detected in textile, laundry, wastewater influent and effluent will be prioritised for identification using reference standards. The results will allow us not only to characterise indoor contaminants humans are exposed to from indoor environments but also to understand the extent of indoor environments as a source of contaminants in surface waters for better mitigation efforts to reduce surface water contamination.

Disclaimer/Disclosure:

This project was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – MU 4728/2-1 and the Czech Science Foundation no. GF22-06020K within the project ‘Accumulation in textiles and release by laundry as an emission pathway for aromatic amines from indoor environments to waste- and surface water’.

3.09.A.T-03 Associating point source PAH sources with vapor-phase Isotopic Carbon Ratios collected with Passive Sampling Devices

Alison Clark, Richard Scott and Kim Anderson, Oregon State University, United States

Identifying a source of an environmental pollutant such as polycyclic aromatic hydrocarbons (PAHs) can be done using chemical ratios and pinpointing characteristic PAHs. However, these techniques can be influenced by chemical degradation and weathering over time. Stable isotopic ratios are less subject to these effects. We are creating an isotopic source library for carbon isotope data from passive sampling extracts with single-source contributions from common sources of PAHs such as natural gas, vehicle exhaust, wildfires, superfund sites, etc. We have shown that we can accurately measure a carbon isotopic ratio by PAH from low-density polyethylene (LDPE) passive sampling extracts. Now we continue to put together an isotopic library to aid in differentiating PAH sources in environmental mixtures. Passive sampler data as well as available standard reference materials were analyzed for 64 PAHs via GC/MS/MS. Initial sample analysis was performed on an

Agilent 7890 GC with a 7000 QQQ MS. Detected PAHs were used to create a time reference standard to provide a comparison in retention times and analyzed using a continuous flow analyte specific GC-IRMS (thermoscientific 1310 trace Gas chromatogram with a thermoscientific Delta Q isotope ratio mass spectrometer). The GC-IRMS reference gas was calibrated to the Vienna Pee Dee Belemnite scale using secondary reference materials. Preliminary results from the analysis of NIST SRM 1991, a mixed petroleum and coal tar creosote standard, and a collected sample from creosote-impacted surface water in Northern Oregon near the Portland Harbor Superfund site show respective isotopic signatures within 1% of each other, indicating that data collected via passive sampling will return a ratio, measured by delta signatures, consistent with expected literature values for that source. Further analyses of samples from different PAH sources returns similar results, with analyzed samples including natural gas fracking sites, tobacco smoke, and the Portland Harbor Superfund site in Portland, OR. When comparisons of these point sources occur, it becomes clear that the unique combinations of detected PAHs and their delta signatures is necessary to develop a fingerprint of each source. Future sample collection and application of this method will investigate the use of isotopic mixing models to pull apart source contribution fingerprints in these samplers.

3.09.A.T-04 Identifying Contaminant Fingerprints and Endpoints-Specific Risk Drivers Pattern in Source-Related Effluents using Non-Target Screening

Alain Hoyek¹, Iker Alvarez-Mora², Carolin Huber³, Jörg Hackermüller³, Martin Krauss³ and Werner Brack³, (1)Helmholtz Centre for Environmental Research GmbH (UFZ) and Goethe University Frankfurt, Faculty of Biological Science, Germany, (2)Helmholtz Centre for Environmental Research-UFZ, Research Centre for Experimental Marine Biology and Biotechnology (PIE) and Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (3)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Source-related effluents introduce complex micropollutant mixtures into the environment. Traditional targeted monitoring captures only a fraction of these contaminants, while effect-based methods integrate biological impacts of both known and unknown compounds. Non-target screening (NTS) provides comprehensive chemical coverage but generates vast datasets requiring intelligent prioritization. This study developed a biologically guided computational workflow to identify source-specific chemical fingerprints and endpoint-specific effect drivers in effluents.

We analyzed 104 water samples from industrial and environmental sources in seven European countries. Samples underwent solid-phase extraction, LC-HRMS analysis, and testing in nine in vitro bioassays covering hormonal activity, xenobiotic receptor activation, mutagenicity, oxidative stress, PFAS-related activity, and neurotoxicity. Chemical profiling detected 154,572 features, with structural annotation performed using SIRIUS and CSI:FingerID.

To prioritize biologically relevant features, we applied MLin vitroTox predictions to estimate activation probabilities across eight bioassays for every detected feature. Features exceeding bioactivity thresholds were retained as potential risk-driver candidates, reducing the feature space while preserving toxicological relevance. Random Forest classifiers trained with leave-one-out cross-validation identified source-specific contaminants within these filtered subsets, successfully differentiating effluent groups. LASSO regression with five-fold cross-validation then linked feature intensities to measured bioassay responses, identifying statistically supported effect drivers.

The workflow generated two complementary outputs: source-specific chemical fingerprints from Random Forest classification and endpoint-specific effect-driver fingerprints from LASSO regression. Strong structure-effect relationships emerged for androgenicity, where prioritized features predominantly matched steroid and steroid-like structures including testosterone derivatives, hydroxyprogesterone, and methylated androstanes. Oxidative stress responses showed weaker correlations, reflecting non-specific pathway activation, with O-glycosides among selected features.

This integrated approach demonstrates how predicted toxicity, source identity, and measured biological effects

can be systematically connected through computational prioritization of NTS data for environmental risk assessment.

3.09.A.T-05 Sustainable green roofs for the implementation of the sponge city: Determination of ecotoxicologically safe construction products for green roofs

Elena Perabo and Christoph Hafner, Hydrotox GmbH, Germany

The consequences of climate change pose enormous challenges for urban regions. In addition to prolonged periods of heat, climate change also affects the availability of water in particular: both heavy rainfall events with flooding and droughts lead to significant damage to buildings, infrastructure and ecosystems, among other things. The sponge city concept offers various advantages for meeting these challenges: in addition to retaining rainwater, preventing flooding and relieving the burden on wastewater systems, it reduces urban heat islands through evaporative cooling and reduces drought.

This concept is to be implemented using green roofs, which utilize construction products that are regularly exposed to rainwater. These construction products may have negative impact on the retained water due to the leaching of hazardous substances, which are subsequently discharged into surface water and/ or groundwater. Thus the leaching of substances may cause ecotoxic and human-toxic effects. In the research project, building materials used for the construction of green roofs are eluted in leaching tests and the eluates are analyzed for potential negative effects on the aquatic environment using a standardized bioassay battery. Biotests offer an integrative approach to detecting the effects of undesirable substances, capturing the cumulative impact of complex mixtures, including unidentified or unexpected compounds. In the further course, a model roof is constructed on a reduced scale with evaluated building products and the retained and discharged rainwater is examined with regard to its ecotoxic effects. The aim is to define building materials that can be used safely for the sponge city concept for green roofs.

To identify such environmentally safe products, targeted ecotoxicological and analytical testing is conducted on a selection of 20 construction products. The ecotoxicological assessment follows the CEN/TS 17459 framework, which combines standardized leaching tests with ecotoxicological evaluations. Depending on the product type, two different leaching methods are applied: for flat and monolithic products, the Dynamic Surface Leaching Test (DSLTT, as per DIN EN 16637-2 is used, while granular products are assessed with the upflow percolation test (DIN EN 16637-3). The analysis of the eluates is now largely finalized. Complementary characterization was performed using various analytical methods to ensure thorough evaluation of the eluate composition.

Disclaimer/Disclosure:

The results of this contribution were developed within the project “Implementation of the sponge city: Identification of the 10 most effective levers for the necessary transformation and sustainable model solutions for roofs of the blue-green city,” commissioned by the German Environment Agency (Funding code: 3723 48 201 0).

3.09.B Environmental Forensics: Tracking Sources and Evaluating the Effects of Chemicals in Urban and Other Environments

3.09.B.T-01 Temporal Impact from PFAS Source Identification to Downstream Response- Lessons Learned and Implications

Dora Chiang¹, Jenny Zenobio¹, Jane Thrasher² and Adam Forsberg¹, (1)Jacobs, United States, (2)Jacobs, United Kingdom

One of the primary hurdles in PFAS investigations is distinguishing between overlapping sources, such as industrial and domestic discharges, atmospheric deposition, and legacy contamination from firefighting foam applications. These sources often result in complex mixtures of PFAS, including parent compounds, transformation products, and precursors, making it difficult to link contamination to specific activities or origins. This presentation aims to use a multi-year PFAS monitoring site combining with a multi-tiered approach to identify the pros, cons and limitations on PFAS forensics applied today and propose the next generation of PFAS forensic solution. Most publications on PFAS fingerprinting or forensic studies are limited to small or single sampling event at downstream receptor site/facility. Temporal datasets to observe migration and transformation over time are often recognized as data gaps. While large-scale PFAS forensic study is of interest, for a detailed assessment, this project chose a PFAS investigation site impacted by a historical fire event, paper industry and background sources. Groundwater samples have been collected across the site and also from background, upgradient and sidegradient locations since 2018. The multi-year datasets illustrated the measured PFAS compositions and concentrations changes with time and use clustering analysis to assess how the data

clusters evolve and could impact the source identification and their subsequent fate and transport. The data clusters further were used to interpret precursor transformation and PFAS sources through integration with biotransformation and source databases. Data gaps and future advancement on digital tool are identified through this project. The composition and cluster analysis are determined useful. Better streamlining of “origin” signatures to the downstream PFAS monitoring data remain challenging even when cluster analysis provides value. The nontarget analysis and TOP assay are expected to add additional lines of evidence to enhance PFAS forensics.

3.09.B.T-02 Non-target Screening and Physicochemical Profiling of Infiltrated Chemicals in Stormwater Biofilters for groundwater recharge

Sergio Santana-Viera¹, Filippo Chierchini¹, Marc Teixidó Planes² and Sandra Perez Solsona³, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (2)Geosciences, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (3)Environmental Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Urban areas with dense populations produce high pollutant loads due to intensified human activity and the prevalence of impermeable surfaces. These conditions enhance runoff and contaminant transport, as natural barriers such as vegetation and soil are largely absent. To address this, Sustainable Urban Drainage Systems (SUDS) have been introduced with the aim of reducing impervious surfaces, decentralizing runoff management, and alleviating pressure on centralized treatment facilities. Research indicates that while SUDS can effectively retain hydrophobic compounds, more persistent and mobile pollutants often bypass these systems without removal. Although the octanol–water partition coefficient (log K or log D) has traditionally been employed to assess pollutant mobility under frameworks such as REACH, recent studies are investigating alternative molecular descriptors that may better capture contaminant elution in soil environments. Given that SUDS effluents can infiltrate groundwater—recognized by the European Union as a strategic resource requiring protection—it is essential to evaluate their performance against the diverse pollutants present in urban runoff. Previous investigations have already identified highly polar compounds in groundwater that were also detected in runoff samples.

In this context, High-Resolution Mass Spectrometry combined with Non-Targeted Analysis (HRMS-NTA) was applied to detect multiple classes of compounds at trace concentrations. The study compared water samples collected before and after SUDS treatment, categorizing pollutants as retained, transmitted, or newly formed/transformed within the system. Ultimately, screening based on physicochemical properties, using both conventional and chemoinformatic approaches, enabled the identification of mobile compounds capable of percolation. Principal component analysis (PC1–PC3) provided a multidimensional representation of physicochemical diversity across the dataset. PC1 captured molecular size and flexibility, PC2 reflected structural complexity and aromatic–polar character, and PC3 described reflected the balance between lipophilicity and polarity. The observed trends suggest that the biofilter preferentially allows the passage of moderately polar and aromatic compounds containing heteroatoms or hydrogen-bonding functionalities, while more hydrophobic or rigid species are comparatively less represented.

3.09.B.T-03 POPs in Brown Waters - Revealing Spatial Patterns of PCDD/Fs, PCBs and PBDEs in Fish along Gradients in the Northern Baltic Sea

Linda Zetterholm¹, Mats Tysklind¹, Peter Haglund¹, Christine Gallampois², Per Liljelind¹ and Pär Byström¹, (1)Umeå University, Sweden, (2)Chemistry, Umeå University, Sweden

High concentrations of persistent organic pollutants (POPs) such as polychlorinated biphenyls (PCBs), polychlorinated dibenzodioxins (PCDDs), polychlorinated dibenzofurans (PCDFs) and polybrominated diphenyl ethers (PBDEs) have been found in the Baltic Sea for decades. Their lipophilic properties have resulted in elevated concentrations in fatty fish such as herring and salmon. Bioavailability of pollutants are affected by the quality of dissolved organic matter (DOM) and organic carbon is an important parameter in the cycling and

accumulation of POPs. The hypothesis is that differences in bioaccumulation patterns in fish can be observed and follow the carbon-quality gradient in the Baltic Sea. The model fish used is the three-spined stickleback (*Gasterosteus aculeatus*) having high fat content as well as a migrations pattern moving from coast to offshore and back during their lifecycle.

Sticklebacks were collected in defined bays along the Swedish and Finnish coasts as well as Offshore in the Bothnian Sea and Bothnian Bay (n=23). The fish samples were extracted, purified and target analytes were determined by HRGC-HRMS. Concentrations and congener composition of PCDDs, PCDFs, non-ortho-PCBs, indicator-PCB (I-PCB), mono-ortho PCB, and PBDE were compared and assessed by principal component analysis (PCA), across three station categories: Sweden, Finland and Offshore, for a spatial overview of concentrations.

Concentrations for PCDDs differ significantly between all three station categories ($p < 0.01$); PCDF differ significantly between Finland- Offshore stations ($p < 0.01$); PBDE differ significantly between Sweden-Finland ($p < 0.001$), and Finland- Offshore ($p < 0.001$). Though no significant differences could be seen for I-PCBs, mono-ortho PCBs or non-ortho PCBs on a larger scale, there are differences between specific stations which are more impacted by anthropogenic sources. This study suggests that the inflow of DOM from allochthonous sources via river inputs in the different coastal areas is an important regulator of the levels and composition of POPs in northern brown waters.

3.09.B.T-04 Biomineralized shells as forensic bioarchives: metal(loid) mixtures and nanoparticles from metallurgical particulate matter accumulate and persist in marine bivalves

Luisa Pimenta¹, Thales Nordi¹, Mariana Carvalho¹, Julieta Griboff², Luis Felipe de Almeida Duarte³, Helen Sadauskas-Henrique³, Magdalena Monferran⁴, Daniel Wunderlin², Camilo Pereira⁵, Marisa Narciso Fernandes¹ and Iara da Costa Souza¹, (1)UFSCar, Brazil, (2)National Scientific and Technical Research Council (CONICET), Argentina, (3)Santa Cecilia University, Brazil, (4)National University of Córdoba, Argentina, (5)UNIFESP, Brazil

Metallurgical industries release settleable particulate matter (SePM) enriched with metal(loid)s and metallic nanoparticles (NPs), which deposit into coastal waters and can interact with biomineralized structures. We evaluated two ecologically and economically important bivalves, the mussel *Perna perna* and the oyster *Crassostrea rhizophorae*, to determine how SePM-derived contaminants are incorporated and retained in their shells. Organisms were exposed for 30 days to increasing SePM concentrations (0.01, 0.1 and 1.0 g L⁻¹) and then maintained for 30 days in clean seawater to assess depuration. Scanning electron microscopy coupled with energy-dispersive X-ray spectroscopy revealed metallic particles and nanoscale aggregates embedded within calcite and aragonite layers of both species. Inductively coupled plasma mass spectrometry confirmed concentration-dependent accumulation of multiple elements, including Al, Ti, Mn, Fe, Zn, Sr, Ba, La and Ce. Although depuration reduced some element concentrations, neither species returned to baseline levels, indicating limited reversibility once contaminants are incorporated into the shell matrix. Mechanical compression testing showed that exposure to SePM reduced shell strength in both species, with *C. rhizophorae* exhibiting greater structural loss, consistent with its higher particulate retention. *P. perna* displayed faster incorporation dynamics, while *C. rhizophorae* retained a broader and more persistent elemental signature. Overall, the combined chemical, microstructural and mechanical evidence demonstrates that mussels and oysters preserve stable and source-specific particulate fingerprints derived from metallurgical emissions. These findings highlight both species as complementary forensic bioarchives for source attribution and long-term monitoring of particulate pollution in coastal ecosystems.

3.09.B.T-05 Occurrence of 7 bisphenols in surface soil and sewage sludge from Trondheim, Norway

Liang Zhao¹, Reiulf Amandus Trocio Arntsen¹, Ingrid Meltveit Aarthun¹, Susana Villa Gonzalez¹, Bo Yuan¹, Junjie Zhang², Hans Peter H. Arp³, Erlend Sørmo⁴ and Alexandros G. Asimakopoulos¹, (1)Department of Chemistry, Norwegian University of Science and Technology (NTNU), Norway, (2)MOE Key Laboratory of Pollution Processes and Environmental Criteria, Nankai University, China (Mainland), (3)Department of

Chemistry, Norwegian University of Science and Technology (NTNU), NO-7491, Trondheim, Norway; Norwegian Geotechnical Institute (NGI), Oslo NO-0806, Norway, Norway, (4)Norwegian University of Life Sciences, Norway

Bisphenols (BPs) are a series of analogues that are extensively used in the production of plastics and as additives for the manufacturing of other materials. Over years they have been detected in diverse environmental matrices like soil, biosolid etc. and exposed to human and other biota, causing both environmental and health concerns. Trondheim, the fourth largest city in Norway, has imported treated sewage sludge from local wastewater treatment plants (WWTPs) for landscaping purpose, but the levels of BPs in Trondheim soil remain largely unknown. This study collected surface soil in urban environments and sewage sludge from 2 WWTP in Trondheim, Norway from 2020 to 2024. Following solid phase extraction, BPs were analysed by ultra-performance liquid chromatography-tandem mass spectrometry. The study aims to (1) discover the BPs level in the surface soil in Trondheim, and (2) determine if local WWTPs are a source of BPs occurrence in Trondheim soil. The results unravelled alarmingly high concentration of BPs in sewage sludge in WWTPs in Trondheim, which are comparable to that found in identical type of samples in other countries. This finding underlines that WWTPs serve as a sink for contaminants of emerging concern. Besides, BPs concentration in Trondheim surface soil was lower than those found in soil internationally, and statistical test has revealed the possible land application of treated sewage sludge was not the major pollution source of BPs in Trondheim surface soil. Consequently, further research is required to investigate the sources of bisphenol pollution in the urban soil of Trondheim.

3.09.P Environmental Forensics: Tracking Sources and Evaluating the Effects of Chemicals in Urban and Other Environments

3.09.P-Tu219 Searching for unknown PFAS sources, a comparison between domestic and industrial wastewater in the Netherlands.

Erwin Roex¹ and Marcel Broekman², (1)KWR Water Research Institute, Netherlands, (2)RIVM, Netherlands

People and the environment come into contact with PFAS in various ways. Prolonged exposure to these chemicals can be harmful to health of people and the environment. To reduce this exposure, it is important to know the sources that release these substances. We know that PFAS end up in wastewater through households, for example through cleaning agents, cosmetics and washing of clothing. On the other hand, we also know that PFAS may come from industrial sources and ultimately end up in wastewater through discharges. Not much is known about PFAS from smaller industrial sources. This was reason for RIVM to study whether measurements at wastewater treatment plants (WWTP) would provide insight into unknown industrial and other sources. This turns out to be the case. The measurements revealed sources that cannot be explained by PFAS in domestic wastewater. Untreated wastewater (influent) entering a WWTP is always a mixture of domestic and industrial wastewater. The ratio of these two types of wastewater differs in each treatment. RIVM studied the influent of two groups of WWTPs in the Netherlands. The first group consisted of 11 that mainly treat domestic wastewater. The second group consisted of 6 WWTPs that treat a large amount of industrial wastewater, with possible, unknown sources of PFAS. For the first group of WWTPs, the influent was found to contain the same quantities of the same PFAS compounds. This 'pattern' can also be found in drinking water, meaning that part of these PFAS end up in the wastewater through the use of tap water. These analyses must take into account the source of the drinking water (surface water, groundwater). This is because drinking water sourced from surface water contains more PFAS than drinking water sourced from groundwater. The same pattern of PFAS compounds was also found at the WWTPs that treat industrial wastewater. However, more PFAS were found at some WWTPs than expected based on the number of local residents. This is an indication that industrial sources of PFAS yet unknown are present. Further research is needed to determine these sources.

3.09.P-Tu220 Microplastic Contamination Pathways in The Semi-Enclosed Freshwater Basin of Lake Como, Italy

Isabella Gambino¹, Benedetta Villa², Roberta Bettinetti², Elisa Terzaghi² and Antonio Di Guardo³, (1)DiSAT, University of Insubria, Italy, (2)University of Insubria, Italy, (3)Dept. of Science and High Technology, University of Insubria, Italy

Global plastic production continues to rise, and microplastics (MPs) are now widespread across environmental compartments, largely originating from land-based sources such as urban runoff, agriculture, wastewater treatment plants (WWTPs), and untreated discharges. To date, the contribution of untreated discharges during storm-related events, together with road washoff, remains poorly explored, considering that climate change is expected to increase the frequency of such events. Due to its semi-closed shape and long hydraulic residence time, Lake Como represents a particular case for evaluating how episodic untreated discharges and continuous treated effluent inputs influence contaminant dynamics. Therefore, the aim of this study is to analyze the concentration and investigate the source of MPs, as well as their fate in the semi-enclosed lake systems and to support the development of mitigation strategies. MPs were sampled from River Breggia, and from River Cosia in different hydraulic conditions, from input and output water of the Como WWTP, while lake water was sampled in stratified (summer conditions) for epilimnion and hypolimnion. Lake sediment was also sampled. MPs were extracted via oxidation with 30% H₂O₂ and density separation using ZnCl₂ (1.8 g/cm³). MPs were identified through visual observation under fluorescence microscopy, after Nile Red staining, and their polymer composition and mass were determined using Pyrolysis–Gas Chromatography–Mass Spectrometry (Py–GC–MS). Results show that storm events sharply increased MP loads in the river. In Lake Como, stratification and circulation led to very low pelagic concentrations but strong accumulation in littoral zones and sediments. Fine particles (<50 µm) and fragments dominated across matrices. PE and PP were the main polymers in waters, with SBR prominent in stormwater, while sediments and hypolimnetic samples showed greater diversity, mainly PE, PP, and N66. These findings highlight the vulnerability of semi-enclosed lakes to episodic untreated discharges and continuous effluent inputs, underscoring the need for integrated management strategies.

3.09.P-Tu221 A Systematic Comparison of Cryogenically Milled Tyre Tread (CMTT) and Tyre and Road Wear Particles (TRWP) and the Implications of Using CMTT for Environmental Studies.

Harriet Byrne¹, Bettina Seiwert², Daniel Zahn² and Thorsten Reemtsma², (1)Helmholtz Center for Environmental Research (UFZ), United Kingdom, (2)Helmholtz Center for Environmental Research (UFZ), Germany

Tyre and road-wear particles (TRWP) in the environment is receiving increasing attention due to their substantial generation (ca. 1.3 mil t a⁻¹ in EU), their diffuse release into the environment, and growing awareness of the toxicity of the compounds which leach from them. TRWP is challenging to acquire, therefore studies often use cryogenically milled tyre tread (CMTT) as a proxy, though their differences are not fully understood. This study directly compares CMTT and TRWP produced from the same 3 tyres, analysing their chemical extracts and leachates to evaluate differences in composition and the suitability of CMTT for laboratory leaching studies.

Repeated extractions and leaching were performed on both the CMTT and TRWP. Leachables and extractables were analysed by UPLC-HRMS, with target screening of 45 tyre related compounds of which 35 compounds were quantified in the extracts and 31 in the leachates. This was then complemented by a suspect- and non-target screening.

Overall, CMTT extracts contained three times higher total concentrations of target compounds than TRWP extracts. The antioxidant 6PPD dominated CMTT extracts (71%) but contributed only 11% in TRWP, with its TRWP concentration only 5% that of CMTT. Other p-phenylenediamines (DTPD, IPPD) were reduced in the TRWP. Transformation products such as 6PPD-Q and N-formyl-6PPD were enriched in TRWP, though not enough to account for the full loss of parent compounds, indicating formation of additional unmonitored transformation products. Suspect screening also suggested increased oxidative DPG transformation products in TRWP. Overall, CMTT contained more precursor compounds while TRWP was richer in transformation products, reflecting composition changes during abrasion. Leachates showed similar trends: TRWP leachates were more dominated by transformation products than leachates of CMTT. The presence of unquantified transformation products in TRWP and its leachates raises concerns about their environmental release and unknown ecological effects.

In conclusion, using CMTT as a TRWP proxy could lead to an overestimation of parent compound concentrations and underestimation of transformation products, potentially misrepresenting environmental impact. This has significant implications for chemical monitoring and toxicity studies reliant on CMTT.

3.09.P-Tu222 Evaluation of the Spatial Distribution of Microplastics Mass Concentrations in Air at a Regional Level by Means of Tree Leaves as Passive Samplers and PY-GC-MS

Antonio Di Guardo¹, Hamed Dadkhah- Aghdash¹, Lorenzo Villa¹, Isabella Gambino¹, Charlotte Lindeman², Kimberly J. Hageman² and Elisa Terzaghi¹, (1) University of Insubria, Como, Italy, Italy, (2) Utah State University, United States

Microplastics (MPs) are emerging contaminants of global concern. Recent studies show that MPs can accumulate on plant surfaces, including leaves, and enter the atmosphere through wind, dust resuspension, and urban emissions.

Moreover, rainfall can wash these particles off from leaves into terrestrial ecosystems, potentially affecting soil quality and contributing to the load of MPs in aquatic ecosystems by deposition. So far, data of MPs on leaves as well as their source, transport and behaviour are still poorly explored. The aim of this study was to evaluate the spatial distribution of MPs deposition on leaves in different selected areas at a regional level in Italy. MPs in leaf samples were characterized by Pyrolysis - Gas Chromatography and Mass Spectrometry (Py-GC-MS) for twelve polymers. The preliminary results showed a general similar trend for most polymers at a regional scale with peaks from several polymers in areas affected by intense traffic, compared to lower polluted areas (e.g., low traffic zones, green parks, forest). Most common polymer found were PET, PE, N66, PP, PS, N6, SBR, and PVC. MPs correlated with PM concentrations measured on leaves, showing peaks in high PM affected areas.

3.09.P-Tu223 Environmental exposure to tire-related pollutants in outdoor artificial turf sport centers

Intasar Ul Haq and Alberto Celma, Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden

Tire-related pollution has emerged as a significant threat to the short- and long-term sustainability of aquatic ecosystems, particularly those exposed to stormwater or street runoff. Although current research largely focuses on well-known pollution hotspots, less common sources should not be overlooked. In Europe, 52% of end-of-life tires are recycled into granulated rubber tire particles (RTP), which are commonly incorporated into cement and used in the manufacture of artificial turf. RTP is also frequently applied as infill on the surface of artificial turf sports fields to enhance grip, potentially turning these facilities into underrecognized hotspots for tire-derived pollutants. Concerns have already been raised regarding human health risks, such as exposure to carcinogenic substances in recycled rubber and increased incidences of leukemia and lymphoma among athletes; yet environmental exposure pathways remain comparatively understudied.

In this work, we investigate the presence of tire-related organic micropollutants in snow collected from outdoor artificial turf sports centers, assessing their potential to release pollutants through short-term leaching. To complement the field study, we conducted accelerated leaching experiments on RTP to evaluate their long-term contribution to aquatic contamination. Four outdoor artificial turf sports centers in the municipality of Uppsala served as case studies.

Snow samples were processed via solid-phase extraction, while RTP underwent solid-liquid extraction. All extracts were analyzed using liquid chromatography coupled to high-resolution mass spectrometry, screening for more than 130 tire-related organic micropollutants. Several compounds, including benzothiazole derivatives, urea derivatives, phthalates, benzotriazole derivatives, and 6PPD-quinone, were detected in both meltwater and RTP extracts. These findings reveal a complex mixture of tire-derived pollutants entering the environment from a previously underappreciated source.

Overall, our results highlight the need for further research into effective mitigation strategies for tire-related pollution and underscore the importance of developing alternative infill materials that minimize environmental impact while supporting sustainable urban development.

3.09.P-Tu224 Monitoring and Speciation of Road Dust Contaminants in a Perialpine French Lake

Zoé Arrigoni¹, Emilie Réalis-Doyelle² and Emmanuel Naffrechoux³, (1)EDYTEM - CARRTEL, France, (2)CARRTEL, France, (3)EDYTEM, France

Tire Wear Particles (TWPs), a major component of road dust (RD), pose a significant threat to aquatic ecosystems. Abrasion of tires on roads generates microplastic-like particles that are transported to freshwater ecosystems during stormwater runoff. These particles release multiple pollutants, including metals such as zinc (Zn) and copper (Cu), polycyclic aromatic hydrocarbons (PAHs), and organic additives like the diphenylguanidine (DPG) or 6PPD and its oxidation product 6PPD-Q. Automotive sources are estimated to contribute nearly 30 tons of TWPs per year to Lake Geneva (Lac Léman, Switzerland). Despite increasing concern regarding the ecotoxicity of these compounds, their environmental fate and speciation in lacustrine systems remain poorly documented. This research project aims to investigate the transport pathways of RD and

TWPs in freshwater ecosystems during different meteorological events and to characterize the speciation of their associated contaminants. Over an 18-month monitoring period, we will quantify the TWP and several of their associated contaminants: Zn, PAHs, DPG, 6PPD, and 6PPD-Q at both a contaminated and a reference site. The contaminated site will be located near a spillway on the shore of Lake Annecy, a highly anthropized littoral zone subject to dense road traffic. To assess speciation, contaminants will be measured across multiple environmental compartments, including runoff water, the dissolved phase of the water column, suspended organic matter, macroplankton, and lake sediments near the spillway. By combining long-term monitoring with a multi-compartment analytical approach, this study will provide new insights into the transfer dynamics of RD and TWPs within lacustrine ecosystems. The project will improve understanding of contamination processes in the littoral zone at the crucial interface between freshwater ecosystem and anthropogenic activity.

3.09.P-Tu225 Microbial Community Adaptation Enhances Biodegradation of Tire-Wear-Derived Contaminants in Urban Roadside Soils

Xiangyu Ji¹, Bettina Seiwert¹, Daniel Zahn², Anett Georgi¹, Katrin Mackenzie¹, Hauke Harms¹ and Lukas Wick¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Department of Analytical Chemistry, Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Tire and road wear particles (TRWPs) are a major source of diffuse urban pollution, continuously released from vehicles and accumulating in urban roadside soils. These soils represent both a sink and an active biogeochemical environment where contaminants may undergo transformation. In this study, we investigated the biodegradation potential of the 5 typical TRWP-derived organic contaminants 1,3-diphenylguanidine (DPG), dicyclohexylamine (DCH), hexamethoxymethylmelamine (HMMM), 6PPD-quinone (6PPDQ), and 2-mercaptobenzothiazole (2-MBT), in urban roadside soils collected along a traffic intensity gradient in Leipzig, Germany.

Batch biodegradation experiments demonstrated consistent traffic-dependent trends: soils exposed to high-traffic exhibited substantially faster and more complete degradation of the model contaminants. Non-target analysis revealed a wider variety of transformation products, appearing earlier and at higher abundance in high-traffic soils, indicating enhanced or more diverse metabolic activity. These patterns suggest that long-term exposure to traffic-derived contaminants may drive microbial community adaptation, resulting in increased enzymatic capacity for contaminant transformation.

Our findings highlight roadside soils as dynamic biogeochemical environments with significant natural attenuation capacity. Understanding how chronic exposure shapes microbial function is essential for predicting contaminant fate in urban environments and for designing nature-based stormwater treatment systems, such as tree trenches and biochar-amended filters, that harness or enhance these microbial processes.

3.09.P-Tu226 A multi-tier ecotoxicological assessment : strengthening waterbodies evaluation through in vivo, in vitro and in situ ecotoxicity tools.

Yves Marneffe, Delphine Leroy, Carole Chalon, Christopher Corin, Patricia Naport, Marcie Radoux and Vincent Rollin, Scientific Institute of Public Service (ISSeP), Belgium

The 2024 ecotoxicity surveillance network was carried out in 33 sampling locations of the Walloon WFD monitoring programme (Escaut, Meuse and Rhine basins). Its purpose is to assess how anthropogenic pressures impacted waterbodies by combining in vivo and in vitro bioassays with in situ biomarker responses in caged organisms. This five-year monitoring cycle follows the surveys conducted in 2004, 2009, 2014 and 2019. To address the need for a more integrative evaluation of toxic pressures, the programme combines acute and chronic in vivo assays (*Vibrio fischeri* (bacteria), *Pseudokirchneriella subcapitata* (algae), *Brachionus calyciflorus* (rotifer)), in vitro tests targeting endocrine and genotoxic activities (YES, YAS, anti-YES, anti-YAS, and UMU tests), and biomarker measurements in caged *Gammarus* spp. (acetylcholinesterase (AChE) inhibition, glutathione S-transferase (GST) induction, feeding rate). These biological tools complement standard physicochemical monitoring and help identify modes of action and potential long-term risks. Results show contrasted trends. Acute bacterial toxicity decreased further compared with 2019, while rotifer and algal sensitivity increased at several sites, suggesting potential emerging pressures. In vitro assays revealed widespread estrogenic activity, detected in over 90% of samples, with two-thirds of stations exceeding the

proposed EQS for 17 β -estradiol. Genotoxic responses were observed in one-third of sites. Biomarker responses in gammarus highlighted severe organism stress at several locations, including high mortality, significant AChE inhibition pointing to insecticide exposure, marked GST induction and reduced feeding activity. For each of the 33 investigated stations, a radar chart summarizes the overall ecotoxicological quality based on the results obtained from the different bioassays. Overall, the integration of multiple biological levels provides a refined understanding of toxic impacts. Stations in good chemical and ecological status generally showed low ecotoxicity, while degraded water bodies displayed consistent effects across assay types. The combined approach strengthens the assessment of ecological status and supports early detection of emerging toxic risks, guiding water-management strategies.

3.09.P-Tu227 Microbial fingerprints as forensic tools for unraveling chronic versus acute agrochemical exposure in agricultural soils

Diego Gabriel Much¹, Anabel Saran¹, Jorgelina Montoya², Sofie Thijs³, François Rineau³ and Luciano José Merini¹, (1)National Scientific and Technical Research Council (CONICET), Argentina, (2)Estacion Experimental Agropecuaria (EEA-INTA) Anguil, Argentina, (3)Centre for Environmental Sciences, Hasselt University, Belgium

Intensive agriculture introduces complex chemical mixtures into the environment, creating a pollution gradient ranging from diffuse application to acute point sources. A major challenge in environmental forensics is to distinguish, retrospectively, between the origins of such contamination, in order to tailor effective remediation strategies. This study evaluates the environmental footprint of five recalcitrant agrochemicals (atrazine, acetochlor, metolachlor, azoxystrobin and 2,4-dichlorophenoxyacetic acid) across three distinct agroecosystems in Argentina. To unravel the effects of management intensity, we utilized a stratified design comparing four scenarios per site: pristine soils, minimal intervention strategies, conventional management and machinery washing sites (acute contamination).

Our approach integrates the isolation of native degraders with high-throughput 16S rRNA and ITS2 amplicon sequencing. Restrictive physiological assays using agrochemicals as a nitrogen source successfully isolated tolerant and degrader strains, including *Rhodococcus* sp. and *Acinetobacter baumannii*, which demonstrated high efficacy (>90%) in degrading metolachlor and azoxystrobin, confirming the site-specific potential for natural attenuation.

Regarding community dynamics, we hypothesize that the distinct selective pressures of chronic versus acute exposure create unique molecular fingerprints within the microbiome. This retrospective approach is crucial in forensic contexts where chemical residues may no longer be detectable by conventional analytics due to environmental fate processes (e.g., sorption or biodegradation), yet the historical impact remains imprinted in the microbial community.

Ongoing metabarcoding analysis aims to identify specific microbial taxa that serve as differential biomarkers for each scenario. By correlating community structure shifts with chemical history, this research provides a semi-quantitative framework to track pollution sources, supporting both forensic investigations and the development of targeted bioaugmentation approaches to restore soil health.

3.09.P-Tu228 Presence and Fate of Chemicals associated with Biosolid Application to Land to Groundwater: Current Evidence and Knowledge Gaps

Sarah Roberts¹, Carolin Schultz¹, David Spurgeon¹, Dan Lapworth², Andrew C Johnson¹, Alex Mulcahy², Andrew Tye², Joel Blackburn², Raghav Patel² and Elma Lahive³, (1)United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)British Geological Survey, United Kingdom, (3)MacLean Building, United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom

Biosolids produced from wastewater treatment works (WwTWs) are applied to land as a nutrient rich soil amendment in many countries. However, the range and concentrations of contaminants found in biosolids, and underlying soil and groundwater remains poorly characterised, outside of a few well studied chemical groups. A

systematic literature review was conducted to identify and collect available data for chemicals and microplastics (MPs) present in WwTW biosolids, amended soils and underlying groundwater. Our aim was to establish their status in countries in the UK/Western Europe with developed wastewater infrastructure. Hence, data collection was focussed on these regions, except where data was limited when all available information was considered. Data of approximately 14,000 chemical or MP measurements in biosolids and biosolid-amended soils were extracted, with measurements for 786 contaminants for biosolids and 21 different contaminants for biosolid-amended soils. In soil porewaters, leachate and groundwaters, 879 measurements for 80 contaminants were retrieved. Analysis of this data showed that a broad spectrum of chemicals has been detected and measured in biosolids, with median exposure concentrations in the order of nutrients > MPs > metals/metalloids > personal care products (PCPs) > plasticisers > pesticides > pharmaceuticals > industrial solvents > persistent organic pollutants. For biosolids-amended soils and underlying groundwaters fewer studies of the associated chemicals are available, with nutrients and metals/metalloids being the major focus of research to date. Thus, there is a clear gap in the knowledge of what contaminants in biosolids are most likely to persist in treated soils and transfer to groundwater.

This review gives a first comprehensive overview of contaminants present in biosolids and the soils and groundwater below their application. Our review highlights the important need for integrated studies which examine biosolids, soils, unsaturated and saturated zones, and the expansion of monitoring efforts beyond metals to include PCP, PFAS, pharmaceuticals, plasticisers and MPs. A greater understanding of bioavailability and exposure potential, via the application of field studies, is needed to assess chemical fate and exposure in soils and groundwater, and associated risk of these WwTW biosolids derived contaminants.

3.09.P-Tu229 Tracking chromium sources in a water supply reservoir in Cape Breton, Nova Scotia, Canada: Implications for watershed and reservoir management

Ian Spooner¹, Chelsea Renaud² and Anthony Mazzocca³, (1)Earth and Environment, Acadia University, Canada, (2)Acadia University, Canada, (3)Cape Breton Regional Municipality Water Utility, Canada

Sludge produced as a waste product of water treatment at MacAskill Reservoir, Cape Breton, Canada contains elevated Cr, which is an environmental concern and a significant treatment expense. Legacy coal mining and surface processing are potential point sources of Cr. Till that incorporates coal-bearing strata and atmospheric Cr from coal power generation are also potential Cr sources. We employ a variety of investigative techniques to track the source(s) of Cr to effectively manage the watershed to minimize Cr in the water treatment processes. Cr in watershed groundwater and surface water samples was below analytical detection limits.

Paleolimnological data from a nearby reference lake recorded atmospheric pollutant impacts (Pb) but did not indicate atmospheric sources of Cr. Chromium was most prevalent in watershed soils which contained > 70 ppm Cr likely derived from Cr-bearing minerals in nearby Proterozoic bedrock; tailings from a legacy mine contained > 440 mg/kg Cr. Reservoir bottom sediment cores averaged 40 ppm Cr. Our data suggests that Cr is transferred into the reservoir as either fine-grained sediment or as stable Cr(III) that is released under reducing conditions through the interaction of till and underlying bedrock with acidic surface and groundwater. These data suggest Cr concentrations at the water treatment intake can be lowered by limiting landscape disturbances, particularly in wetlands within the watershed. Disturbance of legacy coal workings also has significant potential to release Cr into water systems and requires further assessment and monitoring to better quantify risk.

3.09.P-Tu230 Unveiling Hidden PFAS: Thermal Transformation of PVDF Binders During Lithium-ion Battery Recycling

Yuxin Wang, Tasneem Tawalbeh and Hao Liu, Binghamton University, United States

The global transition toward renewable energy has accelerated the demand for lithium-ion batteries (LIBs), which are essential for energy storage, electric vehicles, and portable electronics. Battery recycling has become a strategic priority to recover critical materials and minimize wastes. The presence of fluorinated binders, particularly poly(vinylidene fluoride) (PVDF) currently used to make battery electrodes, poses significant operational and potential environmental challenges. PVDF binder offers exceptional chemical stability but complicates its thermal removal during battery recycling, potentially generating toxic fluorinated emissions. Despite the widely used pyrometallurgical battery recycling processes, the thermal decomposition and emission profiles of the PVDF binder within spent LIBs metrics remain poorly understood. We investigated the thermal degradation of PVDF and cathode materials under representative recycling conditions. Our results revealed the generation of a diverse spectrum of fluorinated volatile, condensed, and solid-phase products, whose composition varied with temperature, oxygen availability, and cathode chemistries. We identified key temperature thresholds associated with LIBs material breakdown and the subsequent formation of fluorinated alkanes, aromatic substances, and oxygenated hydrocarbons. The findings advance the understanding of per- and polyfluoroalkyl substance (PFAS) behavior during LIBs recycling and highlight the critical needs to integrate PFAS management into sustainable battery recycling strategies.

3.09.P-Tu231 Heavy Metal Contamination in Urban Aerosols of Dhaka: Implications for Air Quality

Mir Md. Mozammel Hoque and **Suchona Surovee Tania**, *Department of Environmental Science and Resource Management, Mawlana Bhashani Science and Technology University, Bangladesh*

Sixteen (16) TSP (Total Suspended Particles) aerosol samples were collected from the rooftop of a four storied residential building of Dhaka Polytechnic Institute senior staff quarters, which is situated in Teajgaon, Dhaka. TSP samples were collected on pre-weighted glass fiber filters using a high-volume air sampler (APM 860) having flow rate 1.4 m³/min. in January, February, May and June of 2021 once a week basis and were analyzed for heavy metals including Pb, Zn, Cd, Fe, Cu, Ni and Mn using atomic absorption spectrophotometer (models: Spectra AA220 and AA240FS, Varian, Australia) equipped with electro-thermal temperature controller and flame. Abundance of heavy metals in Dhaka urban aerosols showed a distribution patterns of Zn>Fe>Mn>Pb>Cd>Cu>Ni. Concentration of Cd in Dhaka urban aerosols showed ~12 times higher concentration than that of uncovered in aerosol samples collected from Philippines and is ~13 times higher than that of Iranian aerosol. However, concentration of Ni is 327 times lower than that of measured in aerosol samples collected from Philippines, but which is 3 times higher than of Iranian urban aerosols. Enrichment factor analysis indicated that Pb, Zn, Cd, Cu and Fe are mainly emitting from anthropogenic sources. Carcinogenic risk from Ni and Cd towards different demographic level of the study area was almost same. Where we found that out of every 1000 people, on an average 14 children, males and females are at cancer risk from Dhaka urban aerosols. However, non-cancer risk induced from Zn, Cu and Mn is more significant for the children followed by adult male and female. The risk levels for the non-carcinogenic heavy metals occurred in the following order: Cu > Zn > Pb > Mn. Non-carcinogenic metals can cause harm to children more easily than those of men and women. Positive Matrix Factorization (PMF) analysis identified four major sources of these heavy metals in Dhaka urban aerosols, which includes road dust resuspension, vehicular emissions, industrial metal processing, and mixed traffic-combustion.

3.09.P-Tu232 Effects of different climatic conditions on metals from soils collected from waste disposal sites

Hussain Kaka¹, **James P. Odendaal²** and **Mark Maboeta³**, *(1)North-West University, South Africa, (2)Cape Peninsula University of Technology, South Africa, (3)Zoology, North-West University, South Africa*

Metal contamination in landfill sites poses significant environmental and public health risks. This research investigated the concentration trends of eight metals (Co, Zn, As, Sr, Ag, Cd, Sb and Pb) in soils from both legal landfills and illegal dumping locations, considering various temperature (20°C, 22°C, 25°C) and moisture conditions (30%, 50%, 60% of water-holding capacity) to replicate climatic fluctuations when exposing earthworms (*Eisenia andrei*) to the various soils. The findings indicate that both site management practices and environmental factors significantly influence the bioaccumulation of metals by earthworms in landfill settings. Illegal dumping sites pose a significantly higher risk to soil health, as earthworms accumulate alarmingly high levels of several metals. The conditions of temperature and moisture have a profound impact on the bioavailability and uptake of metals, with cooler temperatures (20°C) and lower moisture levels (30%) typically facilitating higher accumulation.

This research emphasises the environmental hazards associated with poorly managed waste disposal sites and stresses the necessity of incorporating climatic variables into ecotoxicological evaluations. The findings highlight the urgent requirement for adaptive waste management strategies to respond to climate-induced changes in contaminant behaviour. Employing standardised bioassays and *E. andrei* as a responsive bioindicator offers substantial support for regulatory measures designed to alleviate the effects of soil contamination.

3.09.P-Tu233 Assessing Metal Contamination and Ecological Risk in Vineyard Soils of Western Cape, South Africa

Krishna Gautam¹, **Hussain Kaka¹**, **Matt Dodd²** and **Mark Maboeta³**, *(1)North-West University, South Africa, (2)School of Environment and Sustainability, Royal Roads University, Canada, (3)Zoology, North-West University, South Africa*

Soil contamination by metals has become a global concern, driven by increasing awareness of risks to food safety. This study investigates the sources and spatial distribution of metals in vineyard soils (VS) across the

Western Cape, South Africa. Soil samples were collected from six vineyard farm sites (n = 42 per site; total n = 252; row and inter-row samples) for ecological risk identification. Metal concentrations were measured using a Niton XL3t GOLD portable XRF following USEPA Method 6200. Across the vineyard sites, 33 metals were detected. Mean concentrations (mg/kg) varied widely, with notable ranges for Ag (3.43–3.62), As (1.98–3.17), Ba (23.26–35.68), Cd (5.17–5.48), Cr (6.43–21.98), Cu (8.52–27.93), Fe (1464.73–16632.83), Hg (3.95–4.38), Mn (31.94–135.50), Ni (15.10–18.66), Pb (2.64–4.04), V (26.15–123.70), and Zn (8.41–33.60). When compared with FAO guideline limits, Cd, Hg, and V exceeded their respective thresholds (1.0, 0.50, and 50 mg/kg, respectively). These exceedances indicate potential risks to biota and food safety, suggesting that some sites may pose ecological and human health concerns. Ecological risk was further evaluated using the geoaccumulation index (Igeo) and pollution index (PI), based on background concentrations from pristine university garden soils as well as published values from South Africa, Canada, and the Netherlands. All vineyard sites showed low to moderate anthropogenic enrichment for the measured metals, with no consistent multi-metal pollution pattern when compared with garden soil background levels. However, when compared with background values from the Netherlands, vineyard soils showed higher pollution for Cd, V, and Hg (Igeo 1–3.3; PI 1.1–14.6). Background data from South Africa also indicated moderate to high risk for As, Cd, and Hg (Igeo 1.3–4.2; PI 1.1–27.4). Canadian reference values highlighted moderate to high contamination for Cd and V (Igeo: 4.5–4.6; PI 1.2–36.5). Overall, the vineyard soils fall within low to high contamination ranges for several metals, particularly As, Cd, Hg, and V. These findings reveal clear variations in metal loading across the region and pinpoint sites that may require closer ecological and food safety monitoring.

3.09.P-Tu234 Distribution of Potentially Toxic Elements in Sediments in Select Rivers and Creeks in Calgary, Canada

Tami Cormack¹ and Matt Dodd², (1)Royal Roads University, Canada, (2)School of Environment and Sustainability, Royal Roads University, Canada

Watersheds in Calgary, a metropolitan city in Alberta, contain mixes of varying land use including parks, residential, commercial, industrial, institutional, and agricultural. Major watersheds including Bow River, Elbow River, Fish Creek, Nose Creek, Pine Creek and the Shepard Wetland. The Bow River and Elbow River provide drinking water for the city while along with the other creeks also provide valuable habitat for fish and animal species and spaces for recreation. Surface runoff which typically empties into these watersheds can potentially introduce pollutants including various potentially toxic elements (PTEs) into sediments. Thirty-five sediment samples were collected from rivers and creeks in Calgary to assess how the surrounding land use influence PTEs distribution in the sediments. Total PTE concentrations were analyzed by x-ray fluorescence and the physicochemical properties of surface water were also determined. The mean concentrations of As (3.6), Ba (377), Cr (16), Cu (13), Fe (8720), Mn (230), Ni (14), Pb (4.7) and Zn (75) mg/kg were all below the Canadian Council of Ministers of the Environment (CCME) interim freshwater sediment quality guideline (ISQG), where available. The concentrations of Cd, Hg, Sb and Se in all the samples were below the limits of detection. As, Cr, Pb and Zn in a few sediment samples exceeded the ISQG. There were no discernible statistically significant relationships between the surrounding land use and surface water quality parameters including the pH (which ranged from 7.66 to 8.98), and electrical conductivity (485 to 2940 $\mu\text{S}/\text{cm}$). Ongoing work include determining sediment physicochemical properties such as pH and total organic carbon content following which the relationship between sediment physicochemical properties and PTEs concentrations will be explored along with how the potential ecological and human health risk associated with sediment during recreational use. The relationship between PTEs concentrations and surrounding land use will also be explored using contamination indices (enrichment factor, contamination factor, geo-accumulation indices and pollution load index), along with source apportioning through correlation and principal component analysis. Finally, recommendations on limiting exposure to potentially contaminated sediments will be developed with the aim of achieving the United Nation's Sustainable Development Goals.

3.09.P-Tu235 Pollution Sources of PCBs, HCHs, and PFASs and Potential Risks of Soil Pollution

Naila Hina and Martin Scheringer, ETH Zurich, Switzerland

Soil pollution represents a major environmental concern for maintaining soil health and soil ecosystem functioning. Among various pollutants, Persistent Organic Pollutants (POPs) are particularly problematic for soil health due to their persistence, bioaccumulation, and toxicity in soil. Various anthropogenic activities, including industrial operations, improper chemical storage and handling, and inadequate waste management, significantly contribute to soil pollution. Here we provide an overview of activities contributing to the pollution of soil by hexachlorocyclohexane (HCHs), polychlorinated biphenyls (PCBs), and per- and polyfluoroalkyl substances (PFASs), using different information sources. These sources include national databases of contaminated or remediated sites, national lists of potentially polluting activities, and relevant literature. Subsequently, EU-wide databases obtained from national and international inventories were used to map spatial

patterns and clustering of identified pollution causing activities within the EU.

The poster will present the clusters of these activities, co-occurrence of multiple pollution sources within the same geographic area at a high resolution of 1 km². The results effectively serve as a proof of concept to demonstrate the spatial co-occurrence of pollution-causing activities posing risks of co-contamination. The evidence provided by these datasets and the mapping approach used supports extensive and non-targeted soil monitoring, targeted decision-making for effective remediation, and environmental management practices.

3.09.P-Tu236 Combined laboratory and field evidence of neurotoxicity induced by metal(loid) mixtures and nanoparticles from metallurgical particulate matter

Mariana Carvalho¹, Julieta Griboff², William Fortes³, Silvia Matsumoto⁴, Magdalena Monferran⁵, Daniel Wunderlin², Marisa Narciso Fernandes¹ and Iara da Costa Souza¹, (1)UFSCar, Brazil, (2)National Scientific and Technical Research Council (CONICET), Argentina, (3)Federal University of São Carlos (UFSCar), Brazil, (4)UFES, Brazil, (5)National University of Córdoba, Argentina

Metallurgical industries emit settleable particulate matter that reaches aquatic systems and dissociates into metal and metalloid elements and metallic nanoparticles. These particles can accumulate in fish tissues and affect the cholinergic system. This study evaluated the accumulation of 27 elements and the presence of metallic nanoparticles in the brain and muscle of Nile tilapia after 96-hour exposure to environmentally relevant concentrations of particulate matter (0.0–1.0 g L⁻¹), and in fish collected from two contaminated lagoons and an aquaculture reference site in southeastern Brazil. Acetylcholinesterase activity was measured to assess neurotoxic responses.

In laboratory exposures, chromium, manganese, iron, nickel and barium increased in the brain in a concentration-dependent pattern, while aluminum, titanium, rubidium and tin increased in muscle. Transmission electron microscopy revealed iron, aluminum, copper, titanium and tin nanoparticles in both tissues of exposed fish and in field-collected animals from contaminated lagoons. In the laboratory, acetylcholinesterase activity increased in the brain at low and high particulate matter concentrations, whereas muscle activity decreased across all treatments.

Field-collected fish showed site- and year-dependent patterns. In the lagoon affected by atmospheric emissions, muscle acetylcholinesterase activity was consistently reduced, coinciding with the presence of tin and copper nanoparticles. In the lagoon receiving industrial effluents, brain acetylcholinesterase activity increased, suggesting excitatory neurotoxicity. Linear regressions revealed positive associations between brain acetylcholinesterase activity and zinc, zirconium, tin, barium and copper, and negative associations with silver and lead.

These results show that metal(loid) mixtures and metallic nanoparticles from metallurgical emissions bioaccumulate in edible fish tissues and alter enzymatic activity in both acute and chronic exposures. Such disruptions may impair behavior, swimming performance and survival, highlighting the need for regulatory control of metallurgical emissions to protect aquatic wildlife.

3.10.A Experimental, Modelling, and Monitoring approaches to assess the Environmental Fate and Exposure of Pesticides

3.10.A.T-01 Update on improving the procedure for fitting degradation rates in water sediment studies

Sevil Payvandi¹, David Patterson², Ian Hardy³, Edna Rödig⁴, Peter Rainbird⁵, Beate Erzgräber⁶, Monika Maleri⁷, Dave Nicholson⁸, Andrew Bailey⁹ and Wenlin Chen¹⁰, (1)Syngenta, United Kingdom, (2)Science Strategy, Syngenta, United Kingdom, (3)Battelle Crop Protection Solutions, United Kingdom, (4)Syngenta, Germany, (5)Syngenta, Switzerland, (6)BASF, Germany, (7)Corteva Agriscience, Germany, (8)FMC Corporation, United Kingdom, (9)Capgemini, United Kingdom, (10)Syngenta, United States

In aquatic risk assessment studies it is typical to determine total system degradation and/or dissipation half lives from water-sediment experiments rather than individual degradation rates of the water and sediment phases. The

disadvantage of this is that the use of total system half lives or dissipation half lives may mischaracterise the environmental fate processes in aquatic systems, and may lead to unrealistic outcomes, especially if behaviours over long time frames are considered (e.g. FOCUS SW repair).

The reason that compartment-specific degradation rates are often not used in aquatic risk assessments is that it is difficult to obtain statistically robust quantification of these coupled rates in the experimental system (e.g. excluding M0, four rate parameters need to be fitted from approximately 8 - 12 time points), whereas it is easier to obtain total system degradation or dissipation half lives (e.g. excluding M0, one rate parameter is fit for in single first order kinetics).

We propose to use the sediment water sorption relation (expressed as K_d) to reduce the number of fitting parameters and thus increase the reliability of statistically robust fits. This method represents a simplification of the existing fitting method in that the fitting procedure has simply been reordered but allows for the decoupling of degradation and sorption and hence more realistic parameterisation of surface water models.

In previous work we have presented this approach applied to compounds where the sediment K_d was measured, and demonstrated that this approach is successful in obtaining robust fits. This resulted in robust compartmental half lives (level PII endpoints) compared to the use of conservative 1000 d defaults (arbitrary value stated in guidance) in conjunction with the total system half life (level PI endpoints).

In this present work, we now apply the approach to a range of regulatory compounds where the sediment K_d has been extrapolated from existing soil sorption data and consider a variety of optimisation weighting functions.

3.10.A.T-02 Effect of linear and Freundlich isotherms in the prediction with VFSSMOD of pesticide residue remobilization from vegetative filter strips

Rafael Muñoz-Carpena¹, **Stefan Reichenberger²** and **Robin Sur³**, (1)Agricultural and Biological Engineering, University of Florida, United States, (2)knoell France SAS, France, (3)Bayer Research & Development Services LLC, Germany

Vegetative filter strips (VFS) are widely used at field edges to reduce surface runoff and associated eroded sediment and pesticide loads. Their mitigation effect has been incorporated into higher-tier EU FOCUS regulatory assessments through the SWAN tool, which couples the VFSSMOD model with the field runoff model PRZM and the surface water model TOXSWA. VFSSMOD is a mechanistic model that simulates runoff reduction by densely vegetated areas, accounting for VFS size, vegetation composition, hydrology, soil properties, and pesticide characteristics. The model, widely validated, estimates pesticide retention in dissolved and sediment-bound forms and considers partial remobilization of residues during subsequent runoff events, based on degradation and sorption dynamics between storms. This approach captures realistic interactions for chemicals with varying sorption and persistence.

Currently, VFSSMOD assumes instantaneous linear sorption. In this work, we incorporate the non-linear Freundlich isotherm into key VFS mitigation processes: soil leaching, event-based runoff equilibrium, inter-event soil water equilibrium, and residue remobilization. We compare predictions under linear and Freundlich assumptions across a wide range of pesticides and apply global sensitivity analysis to evaluate the importance of isotherm selection within the broader variability of VFS systems.

Results show that the maximum availability of porewater pesticide residues for remobilization in the next runoff event depends on sorption characteristics. For low K_{oc} , although the chemical is readily available in porewater, most has leached below the surface during the previous runoff event, resulting in minimal remobilization. For high K_{oc} , the chemical remains near the surface (limited leaching) but is largely unavailable in porewater, again leading to minimal remobilization. Intermediate K_{oc} values create a “sweet spot” for remobilization. However, this sweet spot shifts with isotherm type where in almost all situations the non-linear Freundlich isotherm will lead to higher sorption compared to the linear isotherm as environmental concentrations (soil runoff) typically are not be high enough to cross the intercept between both.

This study highlights the need for careful selection of pesticide sorption isotherms to realistically quantify VFS mitigation performance.

3.10.A.T-03 FOCUS Surface Water Repair Stage 2 Version Control Testing – First insights

Denis Weber¹, **Michael Brauer¹**, **Neil Mackay²**, **Peter Rainbird³**, **Beate Erzgräber⁴**, **Gerald Reinken⁵** and **Dieter Schaefer⁵**, (1)Exponent International Ltd., Switzerland, (2)FMC Agro Ltd., United Kingdom, (3)Syngenta, Switzerland, (4)BASF, Germany, (5)Bayer AG, Germany

FOCUS Surface Water Repair is a major revision of the original framework, introducing multi-year exposure calculations to capture variability in weather and application timing. It updates scenarios and aligns with regulatory developments, aiming for more realistic exposure predictions for aquatic ecosystems. Extension from one year to 20 years supports robust characterisation of annual variation in exposure peaks and patterns. In FOCUS Version Control Stage 2, the new software suite is tested according to protocol with selected test compounds and target usage patterns. This presentation offers an overview of testing status and a summary of results for a range of theoretical chemicals and uses. Testing remains ongoing and it is noted that changes to software may be required before regulatory release.

Test compounds cover a broad range of fate properties: sorption, degradation (DT50 1–10,000 days), water solubility, vapour pressure, metabolites. The illustrative testing in this abstract considers a compound characterised by highly mobility ($K_{foc} = 100 \text{ L/kg}$), impersistence in soil and sediment (DegT50 = 10 d), and persistence in water (DegT50 = 1000 d).

Seven crops were selected: potatoes, maize, cereals, apples, vines, oilseed rape, leafy vegetables. Each GAP specifies application rates, strategies (groundspray, airblast, granular), and timings (dates, intervals, growth stages).

Simulations use current test versions after Stage 1 (July 2024), including a number of adjustments since the EFSA report issued in 2020.

The multi-year framework improves characterisation of variability in exposure and patterns. Values for risk assessment depend on a currently undefined protection goal percentile metric. Maximum PEC_{sw} under FOCUS SW Repair is typically higher than current scheme; the degree of divergence from the current framework depends on percentile and conditions simulated for representative year employed in the current scheme.

A key challenge for risk managers will be interpretation of variability across scenarios and crops. Stage 2 testing contributes to consideration of percentile thresholds and potential for customisation to scenarios. Analyses here are limited to one compound; broader results will follow and will be reported in the presentation.

3.10.A.T-04 GIS based modelling of linked aquatic exposure and effect modelling considering precision application

Sebastian Multsch¹, Mike Devin Fuchs², Dirk Nickisch³, Khaled Brimo⁴, Joachim Ulrich Kleinmann¹, Sebastian Gebler¹ and Andreas Lorke², (1)BASF, Germany, (2)RPTU University of Kaiserslautern-Landau, Germany, (3)Rifcon GmbH, Germany, (4)RIFCON GmbH, Germany

Integrated landscape modelling of hydrology, chemical exposure and fate, alongside ecological effects, represents a higher-tier approach for refining surface water risk assessments of plant protection products (PPPs). Such modelling contextualises monitoring data and supports stewardship activities by incorporating local environmental and agronomic practices. Advances in digital farming and precision application techniques are increasingly relevant for regulatory risk assessment under EC Regulation 1107/2009. However, guidance on model and data selection is lacking, and further research is needed to demonstrate reliability and practicality in regulatory contexts.

This study presents a modular landscape modelling approach linking physically based exposure models with mechanistic effect models to evaluate the impact of precision application techniques, such as spot spraying, on aquatic ecotoxicological risk. The xLandscape framework was extended by integrating the Droplet and Atmospheric Dispersion drift (DAD-drift) model, which accounts for local conditions, nozzle characteristics, and agronomic practices. A statistical tool generated representative spot spray patterns based on infestation rates and patch size distribution. Surface water dynamics were incorporated to calculate realistic exposure profiles. A toxicokinetic-toxicodynamic model was adapted for Lemna sp., including habitat selection based on flow velocity.

The case study focused on early-stage herbicide application in oilseed rape within a meso-scale agricultural catchment (54 km²) in North Rhine-Westphalia, Germany. Simulations compared broadcast and spot applications (25% infestation) across 13 river segments. Standard FOCUS drift assumptions yielded PEC_{sw} up to 2.1 µg/L, whereas physically based modelling predicted concentrations below 0.1 µg/L. Spot application further reduced exposure by a factor of ~3.5. Risk assessment using EP50 values indicated failure under FOCUS assumptions but a high margin of safety for both broadcast and spot applications when using the refined approach.

This study demonstrates that linked exposure-effect modelling at the landscape scale significantly improves environmental realism and reduces uncertainty. Incorporating precision application techniques into regulatory assessments can support sustainable PPP use and local management strategies. Future work should address physical barriers and validation with monitoring data to enhance regulatory acceptance.

3.10.A.T-05 Harmonised Framework for the SETAC Spatially Distributed Leaching Modelling of Pesticides Initiative

Pavan Cornelissen¹, Aaldrik Tiktak², Anton Poot³, Bernhard Jene⁴, Gerco Hoogeweg⁵, Maarten Braakhekke¹, Louise Wipfler⁶, Judith Klein⁷, Michael Stemmer⁸, Amy Ritter⁹, Robin Sur¹⁰, Gregor Spickermann¹¹, Gerard Heuvelink¹, Gregory Hughes¹², Stephan Marahrens¹³, Stefan Reichenberger¹⁴, Nicoleta Suciul¹⁵ and Michelle Morris¹⁶, (1)Wageningen University and Research (WUR), Netherlands, (2)PBL, Netherlands, (3)Dutch Board for the Authorisation of Plant Protection Products and Biocides (Ctgb), Netherlands, (4)BASF, Germany, (5)Modeling, Corteva Agriscience, (6)Environmental Risk Assessment, Wageningen University and Research (WUR), Wageningen, Netherlands, (7)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (8)Austrian Agency for Health and Food Safety (AGES), Austria, (9)Waterborne Environmental Inc., (10)Bayer Research & Development Services LLC, Germany, (11)ADAMA, Germany, (12)GeoSpatial Analytics, United Kingdom, (13)Umweltbundesamt, Germany, (14)knoell France SAS, France, (15)Catholic University of the Sacred Heart (UNICATT), Italy, (16)Chemicals Regulation Division, Health & Safety Executive, United Kingdom

Spatially distributed leaching modelling (SDLM) of pesticides is a methodology to estimate the leaching potential over large spatial extents such as the national or European scale. While SDLM is already used for Tier 3B of the leaching risk assessment in some countries, a harmonised modelling framework for all EU member states does not yet exist. SDLM is also foreseen to be used in Tier 4 to help to select new groundwater monitoring sites in vulnerable regions and put existing groundwater monitoring sites into context. For these reasons, the SETAC-SDLM working group has recently developed a harmonised modelling framework. Two spatially distributed leaching models specifically developed for this project, based on the leaching models PEARL and PELMO, respectively. These models run up to 10,000 scenarios consisting of unique combinations of land-cover, climate, and soil data. The scenarios were derived from European soil and climate maps using k-means clustering.

At Tier 3B, these models are used to compute the 90th-percentile overall leaching concentration, which is the same exposure assessment goal as currently used in Tier 1 and 2 of the FOCUS groundwater report. The Tier 3B results have been aggregated on the FOCUS zone level and compared to Tier 1 results computed with FOCUSPEARL and FOCUSPELMO. Five example substances were tested and showed, which indicated that the leaching concentration at Tier 3B is generally lower than at Tier 1, but not for all FOCUS zones.

At Tier 4, groundwater monitoring studies must be carried out at locations that are sufficiently vulnerable in view of the existing FOCUS exposure assessment goal. The SDLM framework can play a crucial role for the selection of vulnerable regions in which to install monitoring wells and setting existing groundwater monitoring studies in context. Using site-specific soil, crop and climate data, the median annual mass flux to the groundwater can be estimated using regular leaching models. The median annual mass fluxes can then be plotted on the cumulative frequency distribution of the leached mass flux simulated with SDLM to assess whether the monitoring sites represent vulnerable locations.

3.10.B Experimental, Modelling, and Monitoring approaches to assess the Environmental Fate and Exposure of Pesticides

3.10.B.T-01 A Combined Deterministic–Stochastic Methodology for Estimating Residential Pesticide Exposure

Assif Friedman¹, DANIEL MARTINS FIGUEIREDO¹, Anke Huss¹ and Roel Vermeulen², (1)Utrecht University, Netherlands, (2)Utrecht University, Netherlands

Residential exposure to agricultural pesticides remains a public health concern in intensively farmed regions such as the Netherlands. Airborne concentrations near treated fields arise from short-term spray drift and post-application volatilization, both of which contribute to downwind transport and potential exposure at nearby homes. Existing exposure models typically focus on single events and do not capture the full variability in meteorology, application timing, and field–house configurations that shape real-world exposure patterns. We developed a modelling framework that integrates first-hour spray drift (RTDrift), volatilization up to seven days after application (PEARL), and hourly Gaussian-plume dispersion to estimate outdoor residential concentrations. Exposure was evaluated for houses within 250 m of agricultural fields using BRP (fields) and BAG (residences). Downwind alignment was assigned using hourly wind direction ($\pm 45^\circ$). Eighteen houses from the 2017 OBO study were linked to one or more of seven nearby fields that met these criteria. Model performance was first evaluated using the documented 2017 OBO application events. Each house had one measured concentration per pesticide, and RMSE, MedAE, and bias were calculated per house and summarised as medians. A second evaluation used probabilistic exposure distributions generated by simulating

all legally and meteorologically valid field–house–hour applications in 2017 (16,135 scenarios). For each house, the measured concentration was compared with the predicted median concentration across all plausible application scenarios.

For acetamiprid, evaluation against the documented application events yielded a MedAE of 3.31 ng/m³, a median RMSE of 4.68 ng/m³, and a median bias of 3.30 ng/m³. For tebuconazole, MedAE and median RMSE were 5.18 and 7.04 ng/m³, respectively. In probabilistic evaluations, predicted median concentrations closely aligned with measured values, with median errors below 0.05 ng/m³ for both pesticides.

This study presents an exposure-modelling approach capable of capturing both event-specific behaviour and the broader distribution of realistic agricultural and meteorological conditions. The framework improves representativeness across real-world variability and supports future population health assessments of residential pesticide exposure.

3.10.B.T-02 Seasonal Dynamics of Pesticide Residues in Soils: Insights from Two-years of Monitoring in Three Agricultural Settings

Romualdus Kasteel, Vanessa Reiningier and Thomas Poiger, Agroscope, Switzerland

The European Soil Monitoring Law recently adopted by the European Commission emphasized the need to monitor emerging contaminants in soils, such as pesticides, which are recognized as a major cause of chemical pollution in agricultural soils. Whilst extensive monitoring campaigns have been conducted across Europe, these typically focus on single-time sampling at numerous sites. National monitoring programs would expand these campaigns to periodic repetition on annual or multi-year intervals. Intra-annual (seasonal) dynamics of pesticide residues in soils, however, remain largely unexplored. This study addresses this gap by performing monthly soil sampling over two years at three agricultural sites in Switzerland: an apple orchard, a vineyard and arable land cropped with potatoes and winter wheat. Samples were collected at depths of 0–5 and 5–20 cm. Residues of 38 active substances and 8 metabolites were extracted from soil samples by accelerated solvent extraction using an acidified organic solvent mixture and quantified by high-performance liquid chromatography-tandem mass spectrometry. Two cases were distinguished, with active substances being applied either during (12 compounds across sites) or (long) before the monitoring study. For the first case, dissipation from the 0-20 cm layer was modeled using a modified single first-order kinetic approach to account for observed accumulation at low residue concentrations. For the second case, multiple linear regression was employed to elucidate the contribution of seasonal variations in environmental and soil properties ? soil temperature, soil moisture, total carbon content, and the gravimetric moisture content after drying at 40°C ? on variations in residue concentrations. As opposed to the vineyard and arable land, an increase in summed residue concentrations was observed in the apple orchard, also during the winter period, and mainly attributable to the fungicides. Soil temperature was the dominant factor to explain variations in residue concentrations in the apple orchard, whereas it was total carbon content in the vineyard. No significant differences were observed for arable land, probably due to the homogenization by ploughing. To conclude, monthly soil sampling revealed that seasonal variations in residue concentrations of active substances that were applied long before the monitoring campaign can be linked to variations in environmental and soil properties.

3.10.B.T-03 Agricultural Practices Drive Pesticide Residues in Soil and Earthworms

Aagje Ingetje Saarloos, Paul van den Brink, Wouter Bakker and Nico van den Brink, Wageningen University and Research (WUR), Netherlands

Farmland birds often have a sensitive conservation status and rely on agricultural landscapes where multiple pesticides are routinely applied. Despite the diversity of substances and large-scale application, direct links between pesticide usage and farmland bird trends remain poorly understood. In this study, current-used pesticide concentrations were quantified in soil derived from farmland bird habitats, and in a key dietary item: earthworms. By relating measured concentrations to site-specific agricultural practices and historic land-use, this study aims to provide insight into pesticide exposure in landscapes essential for farmland bird species. Samples were collected from 26 agricultural fields in the province Friesland, the Netherlands, in June-July 2020. The plots belonged to eight farmers and represented a gradient from extensive to intensive agricultural management. Historic land-use and management practices over the past 10 years were reconstructed through interviews with landowners. The plots consisted of four crop types: bulbs (n=4), corn (n=7), grassland (n=8) and old-grassland (n=7). All samples were screened for 648 pesticides. Fungicide concentrations were highest in bulbs, while herbicide concentrations were highest in corn. This likely reflects both crop type and timing of sampling as several corn fields were sprayed during sample collection whereas bulbs had already been harvested. Some grasslands showed fungicide levels exceeding those in corn, corresponding with past bulb cultivation and indicating long-term persistence of compounds. Bulb fields were associated with relatively high

levels of tebuconazole, hexaconazole, prothioconazole-desmethio, metazamitron and pendimethalin whereas corn was associated with dimethenamid, fluroxypyr-1-methylheptylester, foramsulfuron, fluroxypyr, and methiocarb-sulfoxide. A single pesticide was associated with old-grassland; bixafen. Insecticides were rarely detected. Although this study covered a single time point and didn't capture seasonal variability, the following conclusions can be drawn: i) crop type strongly structured pesticide profiles, ii) pesticide residues in grassland often reflect historic crop rotations, iii) management practices correlate with pesticide occurrence, and iv) quite similar patterns in soil and earthworms suggest that soil concentrations may provide a useful starting point for estimating potential pesticide exposure in farmland birds through dietary intake.

3.10.B.T-04 Determining Pesticide Concentrations in Water Framework Directive Water Bodies in the Netherlands

Almir Nunes¹, Pauline Iris Adriaanse¹, Bas Buddendorf¹, Iris Pit², Steven Kelderman², Jos van Gils², Jesse van Leeuwen² and Joost van den Roovaart², (1) Wageningen University and Research (WUR), Netherlands, (2) Deltares, Netherlands

Environmental quality standards under the Water Framework Directive (WFD) aim to protect the chemical and ecological status of European surface waters. Several active substances in plant protection products (PPPs) fall under these standards, which are often more stringent and based on different protection goals than those used in authorization procedures. As a result, PPP applications that comply with legal use conditions may still lead to exceedances of WFD standards in receiving water bodies. This work addresses the need for a method that links edge-of-field authorization assessments to expected concentrations in Dutch WFD water bodies.

We develop a rapid assessment tool that predicts how agricultural loads move from treated fields to edge-of-field watercourses, through sub-catchments, and ultimately to WFD water bodies. The approach has two components: First, it estimates local loadings entering watercourses via spray drift, runoff, erosion and drainage. Spray-drift inputs are calculated using the WUR Drift Calculator combined with high-resolution crop and watercourse maps. Runoff-related pathways follow the structure of FOCUS Surface Water Steps 1 and 2, where soil residue dynamics, crop interception, precipitation timing and degradation determine the available mass.

Loadings are allocated to watercourse segments based on treated crop area, and weekly mass inputs are generated for each sub-catchment. Second, these loadings are routed downstream using the WFD Explorer, which accounts for hydrological connectivity, transport, dilution and dissipation. A transfer-matrix approach is then used to derive maximum and average predicted concentrations for each receiving WFD water body, allowing comparison with relevant WFD environmental quality standards.

The method provides a transparent framework that links PPP use at the field level to concentrations at the scale of WFD water bodies. It enables identification of crop–substance–catchment combinations likely to exceed standards and highlights the key drivers behind high concentrations. Challenges encountered include handling substances with high sorption, managing detailed spatial datasets and aligning crop classifications across regulatory systems. Simulations for example substances illustrate how hydrology, crop patterns and substance properties influence concentration outcomes. The tool is designed to provide a basis for early regulatory risk assessment.

3.10.B.T-05 From Source to Tap: Uncovering the Origins of 1,2,4-Triazole in Flemish Drinking Water

Ingeborg Joris¹, Liesa Brosens¹, Jan Jordens¹, Ingrid Keupers², Tania Verhoeve³, Kris Van Den Belt³ and Tom Diez², (1) Flemish Institute for Technological Research (VITO), Belgium, (2) Vlaamse Maatschappij voor Watervoorziening CV (De Watergroep), Belgium, (3) Vlaamse MilieuMaatschappij (VMM), Belgium

Elevated concentrations of 1,2,4-triazole, a metabolite of a variety of substances, were detected in drinking water production centres in West-Flanders, Belgium. These facilities rely on surface water, making them vulnerable to contamination, especially in large, cross-boundary catchment areas. Identifying the origins and different transportation routes of 1,2,4-triazole to the surface water is essential to make informed decisions on mitigation strategies and to be able to assess their efficacy.

To address this challenge, a multi-method approach was applied, combining literature review, spatial modelling, targeted monitoring, and advanced analytical techniques. Potential sources and parent compounds were identified through a literature review, and pathways to surface water were mapped. A theoretical pressure map for diffuse contributions from plant protection products was developed using spatial modelling based on FOCUS Step 1 principles, incorporating crop distribution, permitted pesticide use, and chemical properties. Time-series analysis of monitoring data was combined with Non-Target Analysis (NTA).

Results revealed clear spatial and temporal patterns in 1,2,4-triazole concentrations. Point-source monitoring

identified contributions from food-processing industries and wastewater treatment plants, resulting in the highest concentrations in both surface water and treated drinking water. In areas without point sources, where agriculture was the sole contributor, minor exceedances of the drinking water limit were observed. Agriculture dominates land use in all abstraction zones, with highest diffuse pressure from plant protection products in the upstream areas linked to cereals, potatoes, and vegetables. A marked increase in 1,2,4-triazole concentrations was observed during drinking water production, with the largest increase during summer. These increases could not be explained by targeted analysis of known parent compounds. NTA revealed intermediary compounds that degrade into 1,2,4-triazole during treatment, highlighting complex transformation pathways.

This study demonstrates the value of integrating spatial modelling, targeted monitoring, and advanced analytics for source identification of newly identified micropollutants in drinking water. Furthermore, this methodology is transferable to other contaminants of emerging concern, bridging scientific research and mitigation strategies for proactive risk management.

3.10.P Experimental, Modelling, and Monitoring approaches to assess the Environmental Fate and Exposure of Pesticides

3.10.P-Tu238 Comparison of Different Approaches to Simulate Runoff and Erosion for Use in Spatially Explicit Models

Stephan Sittig¹, Matthias Konzett², Elmar M. Schmaltz², Peter Strauss², Matthias Gassmann³ and Robin Sur⁴, (1)knoell Germany GmbH, Germany, (2)Federal Agency for Water Management, Institute for Land and Water Management Research, Austria, (3)University of Kassel, Germany, (4)Bayer AG Division Crop Science, Germany

For the authorization of plant protection products, the environmental exposure assessment for runoff and erosion is conducted based on the mostly empirical model PRZM. Herein, pre-defined scenarios for location, weather, soil management and crop are used. While this being a well-established procedure, further development towards more spatial explicit modelling has gained traction in recent years. PRZM uses the runoff curve number (RCN), the models ZIN-AGRITRA, openLISEM and RZWQM2 use mechanistic approaches. That raises the question of whether and to what extent the use of more mechanistic modelling approaches in conjunction with field-specific assessments leads to a more refined exposure assessment. In the present study, we compared the capability and performance of the four models to simulate observed edge-of-field runoff and erosion. We investigated the hypothesis that an increase in model complexity implemented in the more mechanistic and comprehensive models yields to more realistic and accurate simulations. First results prove the assumption of higher accuracy due to higher resolved data and more mechanistic process implementation. However, this comes at the expense of the need for additional data that is either not available, or the model still needs to be calibrated to realize the gain in precision compared to simpler empirical models. Therefore, the analysis requires also other criteria such as scalability, technical feasibility, availability of data, desirability, and economic viability to come to a robust conclusion of the gains and limitations of field-specific modelling approaches. But this will only be evaluated in the later stages of the project. To reproduce field observations, all models often require case-by-case parameter calibration, rendering predictive assessments challenging. However, in future exposure assessments, the use of more comprehensive models is deemed to be useful as a refinement to standard calculations and for specific fields under investigation. Nevertheless, the PRZM RCN approach with the lowest number of parameters represents a reasonable trade-off between accuracy and input data demands for applications on a large scale without the possibility to acquire or calibrate additional parameters that are required by the other models.

3.10.P-Tu239 Revision of the Aged-Sorption Guidance Document

Ian Hardy¹, Wendy Van Beinum², Klaus Hammel³, Bernhard Jene⁴, Sevil Payvandi⁵ and Shiran Qiu⁶, (1)Battelle UK Limited, United Kingdom, (2)Enviresearch, United Kingdom, (3)Bayer AG, Germany, (4)BASF, Germany, (5)Syngenta, United Kingdom, (6)Corteva, United States

In the EU Aged Sorption Guidance the use of field DegT50 values in combination with aged sorption parameters is only possible to a very limited extent. If the leaching assessment for a plant protection product (PPP) is based on field DegT50 values only, it is not recommended by the current guidance to derive a DegT50_{field, equilibrium} (rescaling of DegT50_{field}) for input in exposure models in combination with from laboratory aged sorption studies derived parameters (fNE, kdes) as described for DegT50_{laboratory} values. This virtually prevents the mitigating effect of aged sorption on leaching and limits the applicability of the aged sorption guidance in combination with DegT50_{field} to very few cases.

Additional field studies were evaluated to show the relevance of aged sorption in the field. For evaluation of the field dissipation data, site-specific soil characterisation and daily climatic data for each trial were used to parameterise the FOCUS PEARL leaching model to allow detailed simulations of the transport of the PPP considered. The detailed evaluations of the datasets illustrate the relevance of aged-sorption under field conditions.

Based on the evaluation of the field datasets, revisions are proposed to the current EU Aged Sorption Guidance fully allowing for the combination of field degradation and aged-sorption data including a modified flowchart (Figure 5-4 in the Guidance Document).

The revisions are: If field and laboratory DegT50 datasets are from different populations according to the EFSA DegT50 endpoint selector, then checks are made [P5-metric or Kd_app] to test if there is evidence of aged-sorption under field conditions. If there is evidence, then the geometric mean normalised DegT50_{field, equilibrium} is used in combination with the mean laboratory aged sorption parameters, FNE and k_{des}, for the field soils. If there is no evidence of aged sorption under field conditions then field data and laboratory aged sorption parameters should not be combined in exposure assessments and Tier-1 approaches should be retained.

A report on the additional field work has been issued and the proposed revision of the EU Aged Sorption Guidance Document sent to the EU Commission and EFSA for evaluation and acceptance. The changes proposed to the GD will be discussed.

3.10.P-Tu240 Experiences with the EFSA/ECHA Water Treatment Guidance

Patrick Helmer¹, Mike Swift², Thomas Boulwood³, Michael Kubicki⁴, David Pelzer⁴ and Sonja Weishaupt¹, (1)BASF, Germany, (2)Corteva Agriscience, United Kingdom, (3)Syngenta Ltd, United Kingdom, (4)Bayer Research & Development Services LLC, Germany

In August 2023, EFSA and ECHA published a new guidance document on the impact of DWT processes on residues of PPP, biocides, and their environmental metabolites. For PPP, this guidance was entered into force in April 2024.

The guidance describes seven individual test procedures to evaluate the transformation of active substances and their metabolites under DWT processes: 1) chlorination, 2) oxidation 3) ozonation, 4) a combined process of pre-oxidation followed by chlorination, 5) UV disinfection 6) sand filtration and 7) biodegradation. These tests are to be conducted at environmental related concentrations in the range of 1-10² µg/L, with detection and identification of possible transformation products (TPs) by non-target analysis, and concentration estimation through quantification via structurally related compounds. TPs quantified above 0.075 µg/L shall subsequently undergo structure elucidation and need to be further evaluated with toxicity studies and a dietary risk assessment.

This presentation shares the experience of CropLife Europe Member Companies in the implementation of the Water Treatment Guidance, including harmonisation of experimental testing protocols for the conduction of treatments and analytics according to the new guidance, through the use of cases studies and best practice derived from ongoing experimental studies.

3.10.P-Tu241 Catchment-based Pesticide Vulnerability Mapping: Contextualizing Surface Water Monitoring Using two Methods in Flanders (BE)

Liesa Brosens¹, Jens Kiesel², Ingeborg Joris¹, Hendrik Rathjens² and Robin Sur³, (1)Flemish Institute for Technological Research (VITO), Belgium, (2)Stone Environmental, Montpelier, VT, 05602, USA, United States, (3)Bayer AG, Crop Science, Regulatory Science – Environmental Safety, Germany

Similar to other regions with intensive agricultural activity, frequent exceedances of pesticide quality standards in Flemish surface waters highlight the need for spatially explicit exposure assessment tools that go beyond

local monitoring. The susceptibility to pesticide contamination, referred to as catchment vulnerability, reflects the likelihood of pesticide transport to surface water bodies and varies significantly between catchments depending on environmental characteristics such as soil properties, topography, hydrology, and agricultural practices. While established methods exist for groundwater vulnerability assessment, comparable approaches for surface water are lacking.

This study introduces and compares two complementary methodologies for ranking catchment vulnerability to pesticide contamination in surface water: a newly developed hybrid GIS-based model and the process-based SWAT+ model. Vulnerability maps were generated for three herbicides (flufenacet, ethofumesate, metribuzin) across Flanders (Belgium) and validated against monitoring data from 237 catchments (2017–2021) and detailed time series from two intensively monitored sites.

Correlations with observed concentrations and loads were moderate to strong for flufenacet and ethofumesate, while metribuzin exhibited greater variability due to localized crop use and summer application timing. SWAT+ captured seasonal dynamics and event-driven peaks without site-specific calibration. The highest vulnerability to pesticide losses was observed in the southwestern and hillier southern parts of Flanders, driven by a combination of topography, land use, and hydrological factors. Despite using two methodologically distinct approaches, vulnerability patterns agreed well, emphasizing the robustness of the approaches.

This work addresses an important gap in surface water vulnerability assessment, where standardized comparative frameworks remain limited compared to groundwater assessment methods. By enabling a relative ranking of catchments, these methods support regional-scale risk management, facilitate selection of representative monitoring locations for regulatory purposes and allow optimized implementation of mitigation strategies to protect water quality. The methods are transferable to other regions and contribute to the growing need toward more spatially explicit and systems-based approaches in pesticide regulation.

3.10.P-Tu242 A Proposal for Harmonized Gathering of EU Surface Water Monitoring Data of Plant Protection Products

Folkert Bauer¹, Christopher Hassinger², Dirk Liss³, Monika Maleri⁴, Sarah McManus⁵, Stephan Partsch⁶, Dieter Schaefer³, Gregor Spickermann⁷ and Robin Sur³, (1)BASF, Germany, (2)BASF, United States, (3)Bayer AG, Germany, (4)Corteva Agriscience, Germany, (5)Syngenta Ireland Ltd, Ireland, (6)Global Regulatory Sciences, FMC Corporation, United States, (7)ADAMA, Germany

Surface water (SW) monitoring data play a crucial role in evaluating the ecological status of aquatic environments and identifying potential risks from chemical contaminants. In the case of plant protection products (PPPs), monitoring data are a component of renewal applications and are relied upon in emission reduction plans.

At present, there is no uniform strategy to monitor compliance of PPPs with SW environmental quality standards (EQS), i.e., no agreed essential requirements are identified for generating SW monitoring data that reliably serve this purpose, ensure data comparability across the EU, and support the development of mitigation measures to reduce surface water exposure to PPPs. This is currently reflected in the highly heterogeneous quality and quantity of SW monitoring data across the EU.

To support a reliable use of SW monitoring data of PPPs for contextualization purposes and evaluation against EQS, this poster aims to suggest a baseline for quality criteria.

This work highlights deficiencies in publicly available SW monitoring data across the EU, particularly in the context of assessing compliance of PPPs with EQS, and indicates that besides general information such as climate data, type of SW body, and flow velocities, substance-specific properties and further metadata are required to allow for a robust interpretation of the SW monitoring data and their reliable use in contextualization efforts. Proposed essential metadata include geographic coordinates, application profiles, soil types and topographical features, coverage of arable land and its spatial distribution, drainage infrastructure, potential industrial and urban emitters, and hydraulic conduits that may directly connect runoff from agricultural fields to adjacent SW bodies.

The protection of SW should be a shared interest of applicants of PPPs, competent authorities, land managers, and academia, and so should the development of a harmonized approach for generating reliable SW monitoring data to ensure data comparability and a robust assessment of compliance with EQS. Establishing harmonized monitoring practices would also support the contextualization of SW monitoring results, which, in turn, would

facilitate the development of effective mitigation measures to prevent PPP from entering into waterbodies. A coordinated SW monitoring strategy across EU Member States would significantly contribute to both regulatory consistency and environmental protection.

3.10.P-Tu243 IDENTIFICATION OF PESTICIDES ALONG THE FLYWAY: THE FIRST STEP IN A RISK ASSESSMENT FOR THE BLACK TAILED GODWIT

Bárbara Righetto, *Aagje Ingetje Saarloos, David Gomez Blanco and Nico van den Brink, Wageningen University and Research (WUR), Netherlands*

Loss of habitat is pointed out as a key driver of bird population declines worldwide, however exposure to contaminants has been shown to potentially lead to immune and reproductive alterations that can have severe long-term populational effects. However, comprehending the risks of contaminants to wildlife species is often hindered by their exposure to multiple chemicals simultaneously and, for migratory animals, by the spatial/temporal variability of exposure. Therefore, the main goal of this study is to conduct a risk assessment for pesticide exposure in black tailed godwits (*Limosa limosa*), as a proof of concept for how risk assessment can be performed for migratory species in general. The first step toward that goal is to establish to what individual compounds and mixtures godwits are exposed at different locations during migration. To accomplish that, 81 soil samples were collected in different regions of Spain (Extremadura and Doñana), France (Camargue, Vendee and Charente Maritime) and Portugal (Tejo and Sado estuaries). These regions are frequently used as stop-over sites for black-tailed godwits during their annual migration, as evidenced by previous telemetry data. Samples were freeze-dried, homogenised and underwent pesticide extraction following the QuEChERS method with slight modifications. Extracts were analysed on a LC-MS/MS using a Shim-pack Velox Biphenyl Column (Shimadzu, Japan). The used method screens for 640 current use pesticides. Individual compounds were identified through comparison of retention time and mass-to-charge ratio (m/z) of detected compounds to those of standard analytes included in the analysis. 34 different compounds were identified, encompassing fungicides, herbicides and insecticides. Only 4 of them were detected in at least one sample of each country (3-Indolyl-acetic acid, tebuconazole, DEET and azoxystrobin), while 20 compounds were detected exclusively in one of the three countries. These preliminary results suggest that pesticide use varies per region, which is in accordance with the different crops being cultivated in each location. Nonetheless, this indicates that godwit exposure to pesticide is likely dependent on migration route and reinforces the need for taking spatial variability into account when assessing the risk of chemicals to migratory animals. Next steps in this study include quantifying the pesticides detected and expanding the sampling to include also wintering and breeding grounds of the species.

3.10.P-Tu244 Fate of Nitrification Inhibitors DMPP and Nitrapyrin in Agricultural Soils – Combination of Lab and Field Study

Ulla Bollmann¹, *Erkin Gözdereliler², Linyan Zhu² and Christian Albers¹, (1)GEUS, Denmark, (2)Aarhus University, Denmark*

Nitrification inhibitors (NIs) are recommended as a solution to reduce nitrous oxide (N₂O) emissions from agricultural fields to achieve the EU target to reduce greenhouse gas emissions by at least 55% before 2030. However, their environmental fate is only rarely studied and the risk of introducing a vast amount of additional synthetic organic chemicals into agricultural soil calls for a careful environmental assessment. However, the requirements for such assessments are relatively small, as NIs are not treated as plant protection products or biocides, but falling under the fertilizer regulation in the EU. Therefore, we evaluated the environmental fate of two NIs, DMPP and Nitrapyrin, the two compounds with the highest marked share in Denmark. In a combined lab and field experiment we studied the degradation kinetics and half live in different soil depths, and evaluated the effects of the addition of manure and formulating agents. Degradation of the NIs was observed as well as formation of their transformation products. While no effect was observed from the formulating agent for DMPP, the microencapsulation of Nitrapyrin slowed the degradation. Degradation in deeper soil layers was only slightly reduced compared to top soil. Nonetheless, although fast degradation was seen in the presence of manure both in lab and field studies, observed residual concentrations of 5-15% of the active ingredient 6 Months after application, pose the risk of accumulation of NIs in the topsoils of agricultural fields.

3.10.P-Tu245 Sorption and transformation of metazachlor and its metabolites in soils and their potential to contaminate groundwater

Radka Kodesova¹, Vít Kodes², Martin Kocarek³, Daniela Tomesova⁴, Miroslav Fér³, Antonín Nikodem³ and Ales Klement⁵, *(1)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic,*

(2)Czech Hydrometeorological Institute, Czech Republic, (3)Czech University of Life Sciences Prague, Czech Republic, (4)ALS Czech Republic, Czech Republic, (5)Department of Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic

Metazachlor is a widely used herbicide that is transformed into various metabolites that are often found in groundwater. To assess their mobility in the soil environment, batch sorption experiments were performed for the parent compound and the two most frequently occurring metabolites metazachlor OA (479M04) and metazachlor ESA (479M08) and eight representative soils of the Czech Republic. The experimental sorption isotherms were fitted with Freundlich equations. The resulting Freundlich sorption coefficients (KF) were related to soil properties. The dissipation of these three compounds in five soils was further studied. During standard batch experiments, the concentrations of all three compounds and two additional metabolites (479M09 and 479M11) were always measured. The first-order kinetic model was assumed to describe dissipation profiles of the applied compounds. In addition, the rates of metabolites' formation, i.e. their fraction from the original substance, as well as their subsequent dissipation of all four metabolites were calculated.

The KF coefficient of the parent compound was an order of magnitude higher than that for the metabolites OA and ESA. Thus, while metazachlor showed high and even very high mobility in soils, both metabolites showed an extremely high mobility in the soil environment. Sorption of all compounds was mostly affected by the soil organic carbon content. The sum of fractions of all four metabolites formed from the parent compound ranged between 70 and 95%. The rate of dissipation of the metabolites OA and ESA was an order of magnitude lower than that for the parent compound. The dissipation rates of other two metabolites were generally higher than those of the metabolites OA and ESA but considerably lower than those of the parent compound. Dissipation rates were soil type dependent. The highest rates were observed in Stagnic Chernozem and the lowest in Eutric Cambisol.

Resulting sorption and dissipation characteristics and the map of agricultural soils of the Czech Republic and related database were next used to derive maps of mobility index and stability index. Finally, specific groundwater vulnerability maps for each compound were obtained by combining the DRASTIC vulnerability index and both soil indexes. The maps were confronted with the occurrence of these compounds in the groundwater of the Czech Republic.

The work was supported by the Ministry of Agriculture of the Czech Republic, project No. QL25020081.

3.10.P-Tu246 Influence of Groundwater Flow Rate on Organic Micropollutant Biodegradation in Drinking Water Aquifers

Merel Nederend¹, Silvana Ines Quito Tapia² and Nora B Sutton³, (1)Wageningen University and Research (WUR), Netherlands, (2)Wageningen University and Research (WUR), Spain, (3)Environmental Technology, Wageningen University and Research (WUR), Netherlands

Water quality in drinking water aquifers is threatened by the increasing presence of organic micropollutants (OMPs) such as pharmaceuticals, pesticides and household chemicals. Drinking water aquifers are biologically and geochemically diverse systems, where water extraction creates variations in flow rates and patterns towards extraction wells. Flow rate influences the contact time between OMPs and indigenous microbial communities mostly present as biofilm, as well as the flux of available dissolved organic carbon (DOC), nutrients and electron acceptors. Additionally, groundwater composition becomes less favorable to support microbial activity with depth, as DOC fractions and electron acceptors are preferentially consumed. In aquifers, the biodegradation of OMPs is either diffusion limited (insufficient substrate flux) or reaction limited (insufficient contact time). Little is known about the windows of opportunity in groundwater flow rate for OMP biodegradation in microbial communities across drinking water aquifers. This project aims to better understand the effect of groundwater flow rate in aquifers on OMP biodegradation. A 2D flow chamber with a glass front plate and steel frame (dimensions 130x80x15 cm) is fully saturated with wet sand and inoculated with groundwater. The reactor is run aerobically with a horizontal flow at a flow rate of 20 L/day (residence time 4 days) with 4 in- and outlets on either side. The system is operated in several different phases of 21 days where the removal of more than 20 OMPs at 1 µg/L is monitored through changes in flow rate, DOC dosing and/or oxygen spiking. Samples for OMP, DOC and microbial community analysis are taken from 16 sampling ports distributed on the glass plate and redox probes are used to monitor redox conditions. Laboratory results will be accompanied by reactive transport modelling conducted in COMSOL to give insight into reactor flow patterns and flow rates. We hypothesize that biodegradation of OMPs is influenced by variations in contact times and substrate supply,

but that the availability of oxygen is the biggest determining factor. Our findings will give insight into the fundamental physical and chemical mechanisms underlying OMP biodegradation in drinking water aquifers.

3.10.P-Tu247 Exploring the Leaching Dynamics of Aged Residues of Atrazine in Soils: Effects of Temperature and Flow Rate

Valérien zeender, Aloïs Lardinois, Ignaz Buerge, Romualdus Kasteel and Thomas Poiger, Agroscope, Switzerland

Although atrazine has not been applied to Swiss railway tracks since 1993, the herbicide and its metabolites remain detectable in many of these soils and continue to leach through these typically well-drained, low-sorption substrates. Here, we investigate how temperature and precipitation influence this leaching behaviour.

To assess atrazine and metabolite leaching under controlled conditions, we operated soil columns (ca. 20 cm² × 30 cm) packed with railway-track soil from two Swiss sites containing aged atrazine residues and its metabolites. A diluted CaSO₄ solution was pumped at varying flow rate. Each column was kept at a specific temperature, which could be changed during the experiment. Leachate was collected and analysed by LC-MS/MS. Additionally, to compare breakthrough curves of freshly added atrazine with that of aged atrazine, each column received a pulse of isotopically labelled atrazine (atrazine-¹³C₃-¹⁵N₃). Before the leaching experiments, sequential extractions with diluted CaCl₂, acetonitrile, and Soxhlet-acetonitrile were performed to characterize easily and poorly accessible residues. At the end of the experiments, acetonitrile-extractable residues were quantified again with Soxhlet in six column segments to determine the residual mass distribution and establish a mass balance.

Concentrations of atrazine and metabolites in leachate rapidly declined to <1 µg/L. Raising the column temperature led to increasing concentrations, whereas lowering had the opposite effect. A fivefold increase in flow rate (from 37 to 183 mm/day) led to lower leachate concentrations in both soils, indicating that the percolation rate exceeded the rate of desorption.

The spiked atrazine-¹³C₃-¹⁵N₃ responded similarly to temperature and flow rate changes as aged atrazine. Despite equal spike amounts, peak concentrations differed by an order of magnitude between the soils (ca. 0.7 vs. <0.07 µg/L), likely due to their different organic-carbon contents (0.37% vs. 0.79%). After approximately two months of column operation, the columns had received the equivalent of ca. 42 mm/day of rainfall, totalling ca. 2.5 m of precipitation. The organic extractions revealed that the soils still retained several times the mass of atrazine and metabolites that had leached.

The ability to characterize the leaching behaviour of long-term reservoirs of organic pollutants, such as atrazine, is essential for improving predictions of their mobility in railway-track soils.

3.10.P-Tu248 Environmental Fate of a Starch Nanocrystal Formulation for a *Bacillus thuringiensis* Biopesticide

Venla Heininen¹, Thomas Pütz² and Wulf Amelung¹, (1)Institute of Bio- and Geosciences (IBG-3: Agrosphere), Forschungszentrum Jülich, Germany; Institute of Crop Science and Resource Conservation, University of Bonn, Germany., Germany, (2)Institute of Bio- and Geosciences (IBG-3: Agrosphere), Forschungszentrum Jülich, Germany., Germany

Conventional chemical pesticides are widely used in modern agriculture. However, due to excessive use, adverse effects have been observed in both human health and the environment. Therefore, biopesticides are considered highly promising alternative, but their large-scale use is currently hampered by a lack of suitable formulations. Moreover, these formulations may contain constituents like synthetic and nanosized particles, which in turn pose an additional threat to the environment. The knowledge of the fate of these nanosized particles in an agricultural context is currently limited. It is important to consider the formulations since the environmental behaviour depends not only on the active ingredient but also on its formulation. One approach to minimizing environmental impact is to utilize bio-based formulations.

Therefore, we aim to investigate the fate of a starch nanocrystal (SNC)-based formulation for a *Bacillus thuringiensis* biopesticide using a soil column experiment in outdoor conditions. We will use the Pickering emulsion technique to encapsulate the active ingredient, with the SNCs acting as a stabilizing agent. The fate is analyzed using the radioactive carbon isotope (¹⁴C) by labelling the SNCs, which will allow us to track their transformation, distribution, and degradation. Through the application balance and the residues of the

formulation components in the different layers of soil, leachate, and plants, we will make precise statements whether the ingredients are integrated into the matter cycle of the soil, whether they are washed out, or whether they are taken up by the plants. Additionally, the impacts of formulation will be assessed on the soil enzyme activity and microbial community. An entire growing season of spring wheat (*Triticum aestivum*), including two test soils and biopesticide concentrations, ensures a wide range of environmental variability.

We hypothesize that the initial degradation of the formulation will be rapid; however, the SNCs may be taken up by the plants due to their size. As the environmental fate of bio-based nanoformulations in agricultural soil-plant systems has not been assessed before, this study will provide valuable insights into the interactions between the material and soil. The findings will provide support for regulations for biopesticides and formulations, ultimately ensuring their safe and sustainable use.

3.10.P-Tu249 Modelling Airborne Pesticide Spray Drift for Orchard Sprayers

Jenny Deng¹ and **Henk Jan Holterman²**, (1)Wageningen University and Research (WUR), Netherlands, (2)Agrosystems Research, Wageningen University and Research (WUR), Netherlands

Spray drift occurs when pesticide particles are carried away by wind from their intended target location to a neighboring area during or immediately after application. The issue of off-target spray drift with pesticides applications is a concern both to public and environmental health regarding the potential adverse health effects on humans (e.g. residents), as well as hazardous environmental impact to wildlife and water sources. Accurate drift measurement and prediction thus play a key role in risk assessment of spray applications. However, quantification of airborne spray drift is challenging because of its high variability related to environmental conditions, spray application technology, canopy structure, and measurement procedures. Over the last 30 years, a number of different approaches have been taken, mainly to modelling spray drift deposition onto the ground (i.e., dispersion models, computational fluid dynamics models, droplet tracking models and regression models), where each approach has its pros and cons. The aim of this study is to develop a model to quantify and predict non-target airborne exposures to pesticides due to spray drift from conventional cross-flow sprayers for fruit orchards. Generalized additive models (GAMs) are one of the most widely used and powerful modelling techniques in environmental studies for revealing non-linear effects of the explanatory variables on the response variable. In this study, GAMs are used to examine the relationship between downwind airborne drift concentration at different heights and meteorological conditions (i.e., wind speed and direction, relative humidity, air temperature), at various canopy growth stages of the orchard trees, and corresponding sprayer settings, by fitting the model to field trial data gathered over 20 years in the Netherlands. Model choice is via the Akaike Information Criterion (AIC) and the final model is validated in a cross-validation approach. The statistical characteristics of airborne drift concentration from the trials will be described. Next, the construction of the final model (i.e., the explanatory variables from the selection process) will be presented. The contribution of meteorological quantities and canopy development stage to the model, its validation results and goodness of the fit will be presented and discussed in detail. Main conclusions will be summarized.

3.10.P-Tu250 Enhancing Spray Drift Assessment: Integration of Vertical Drift Distribution in the Casanova Drift Model for Non-Target Organisms Risk Evaluation

Zhenglei Gao¹, **Anzhela Tamazashvili²**, **Anastasiia Bolekhan²**, **Rena Jutta Irene Isemer³**, **Jerome Goulet-Fortin⁴**, **Carola Schriever⁴**, **Marina Lauck⁵**, **Monika Maleri⁶**, **Wenkui He⁶**, **Peter Rainbird⁷** and **Edna Rödig⁸**, (1)Data Science, Bayer CropScience AG, Germany, (2)Bayer CropScience AG, Germany, (3)Crop Science, Bayer CropScience AG, Germany, (4)BASF, Germany, (5)Corteva Agriscience, (6)Corteva Agriscience, Germany, (7)Syngenta Crop Protection AG, Switzerland, (8)Syngenta Ltd, Germany

Spray drift modeling has become increasingly important in the regulatory assessment of crop protection product applications, particularly as concerns grow over the potential impacts on non-target organisms, including non-target arthropods (NTAs) and non-target terrestrial plants (NTTPs), as they play critical roles in maintaining biodiversity, ecosystem services, and agricultural productivity. Regulatory frameworks demand accurate predictions of drift behavior to ensure the safety of ecosystems adjacent to agricultural fields. Assessing the risks to NTAs and NTTPs remains challenging due to the limitations of current models, which primarily

generate spray drift deposition curves without accounting for vertical distribution of spray drift e.g. in plant canopies off-crop. This study addresses these challenges by leveraging the mechanistic Casanova spray drift model, which provides enhanced simulation capabilities to estimate not only deposition curves but also vertical drift profiles. By solving coupled ordinary differential equations (ODE) that account for drag forces, evaporation, and wind profile interactions, the model captures the complete three-dimensional transport of droplets from nozzle release through deposition. This enables extraction of vertical drift concentration profiles at specified downwind distances, providing critical exposure data for organisms residing at different canopy heights. Preliminary results indicate that the Casanova model can effectively produce short-range aerial drift patterns which could be used to predict off-crop capture by non-target species. In conclusion, the Casanova drift model represents a valuable tool for addressing the complex challenges associated with assessing spray drift impacts on NTAs and NTPs. By generating both deposition curves and vertical drift profiles, this model will aid in the development of effective strategies to protect non-target organisms in the context of crop protection applications.

The Casanova drift model was originally developed by Bayer AG. The extraction of vertical drift concentration profiles from the model was financed by CropLife Europe aisbl.

3.10.P-Tu251 From 2D to 3D: using models to increase realism in exposure assessment of NTTO

*Anastasiia Bolekhan¹, Zhenglei Gao², Jerome Goulet-Fortin³, Wenkui He⁴, **Rena Jutta Irene Isemer⁵**, Marina Lauck⁶, Monika Maleri⁴, Peter Rainbird⁷, Edna Rödig⁸, Carola Schriever³ and Anzhela Tamazashvili⁹, (1)Bayer AG, Germany, (2)Data Science, Bayer CropScience AG, Germany, (3)BASF, Germany, (4)Corteva Agriscience, Germany, (5)Crop Science, Bayer CropScience AG, Germany, (6)Corteva Agriscience, (7)Syngenta Crop Protection AG, Basel, Switzerland, Germany, (8)Syngenta Ltd, Germany, (9)Bayer CropScience AG, Germany*

EFSA has been mandated by the European Commission to revise the environmental risk assessment (ERA) for non-target terrestrial organisms (NTTO), with a particular focus on minimizing uncertainty in pesticide exposure estimates. Current regulatory approaches rely on flat surface deposition assumptions, which limit the characterization of exposure under realistic agricultural conditions (i.e. three-dimensional exposure within and beyond crop canopies). For a holistic ERA, vegetation exposure must be conceptualized as a 3D process encompassing in-field overspray with vertical dispersion and off-field spray drift involving horizontal deposition and vertical dispersion.

To tackle these gaps, the CLE NTTO Drift Ad Hoc Group launched a collaborative project with two main pillars: (1) Develop fit-for-purpose models describing droplet dispersion and spray drift at different tiers, and (2) Generate experimental data for model validation. Modeling efforts include adapting existing tools and developing new approaches, such as extending current drift deposition models for canopy-level prediction (e.g. extending Casanova) and exploring computational fluid dynamics (CFD)-based solutions for within-canopy droplet behavior. Simplified meta-models are also being designed to enable broader use. In parallel, wind tunnel experiments aim to generate quantitative data for validating these models.

This exercise faces several challenges: the complexity of simulating droplet behavior within heterogeneous canopies, the scarcity of data for model calibration, and the need to balance scientific rigor with practical usability. These challenges highlight why collaborative efforts and transparent dialogue are essential to progress.

This poster will present the rationale for this initiative, summarize the regulatory drivers for action, and describe the envisioned pathway toward harmonized, science-based NTTO exposure assessments.

3.10.P-Tu252 Land Surface and Pesticide Transport Modelling

Ali Sadrzadeh, Jan Vanderborght, Lutz Weihermüller and Stefan Kollet, Institute of Bio- and Geosciences (IBG-3, Agrosphere), Forschungszentrum Jülich (FZJ), Jülich, Germany., Germany

Soil pollution is an environmental concern in Europe. The European Commission (2020) reported that around 60–70% of European soils are unhealthy, highlighting the need to understand pollutant sources, transport processes, and mitigation strategies. The EU-funded SOILPROM project addresses this need by delivering integrated models for pollutant transport to assess the impacts of soil pollution on soil functions and ecosystem services. Our study simulates the spatial distribution and long-term evolution of pesticide concentrations in groundwater based on surface applications. Pesticide transport in the vadose zone is generally simulated using 1D models, such as HYDRUS-1D. A key challenge in vadose-zone flow and transport simulations is the accurate representation of bottom boundary conditions in the models. These boundaries are typically formulated as pressure heads corresponding to the water-table depth, which is largely unknown across Europe. To address this limitation, we use the hydrologic model ParFlow, which simulates 3D variably saturated groundwater-surface water flow in the coupled groundwater-soil-vegetation system for a domain covering Germany and neighboring regions. In the model, water table depth is a diagnostic variable that varies freely in response to 3D transient watershed hydrodynamics. We evaluate an approach that couples HYDRUS-1D simulations with ParFlow-derived water-table fluctuations. HYDRUS-1D was setup for 174 European Climate Assessment & Dataset (ECA&D) sites over Germany. We also compared the impact of selecting the atmospheric top boundary conditions, i.e., precipitation and reference evapotranspiration, in HYDRUS-1D, based on ECA&D observations or ERA5-Land reanalysis. A comparison between ERA5-Land and ECA&D evaluates the suitability of ERA5-Land for future recharge and pollution risk simulations. Results show that ERA5-Land captures temporal climate dynamics well, but smooths spatial variability. Initial HYDRUS-1D results show high spatial variability in bottom-water fluxes driven by climate, soil properties, and water-table dynamics, all of which strongly affect pesticide leaching. We will then extend the work to model pesticide transport in soil and groundwater. HYDRUS-1D will generate bottom-flux pesticide concentrations and mass fluxes, which ParFlow will use to model coupled flow and transport in groundwater, enabling a full assessment of pesticide fate in the subsurface water continuum from the surface to groundwater.

3.10.P-Tu253 Advancing Precision Application Modelling: Development of a Patch Generator for Realistic Infection Pattern Simulation

Mike Devin Fuchs¹, Sebastian Multsch² and Andreas Lorke¹, (1)RPTU University of Kaiserslautern-Landau, Germany, (2)BASF, Germany

Precision application of plant protection products is a key strategy for reducing environmental exposure while maintaining crop protection efficacy. Capturing the fine-scale spatial variability of infection and application patterns is essential for modelling precision pesticide application and associated environmental exposure. Conventional approaches often assume random or homogeneous infection distributions, which do not fully represent the spatial complexity observed in real agricultural systems. To support such analyses, we developed a Patch Generator capable of producing synthetic but realistic infection maps that capture the dual-scale (fine and broad) spatial organization of infections typically observed in agricultural fields.

The generator is defined by a set of intuitive parameters controlling infection rate, edge bias, and spatial clustering at fine and broad scales. It combines stochastic noise generation with spatial smoothing to create continuous infection patterns from discrete inputs. A micro–macro ratio parameter controls the relative contribution of small and large infection clusters, allowing the creation of maps ranging from scattered micro-spots to larger aggregated patches. This flexibility enables the generation of coherent, edge-influenced infection patterns that closely resemble those observed in field measurements.

High-resolution infection and application maps (0.25×0.25 m) were used to guide the generator's development. The observed patterns were analyzed to derive representative parameter inputs, enabling a direct link between field data and simulated maps. Visual and spatial comparisons showed that the generated maps reproduce realistic clustering and edge effects, providing robust inputs for simulation studies in fields lacking direct observations.

The Patch Generator offers a versatile and transparent method for representing infection variability within agricultural fields. By generating realistic synthetic maps from a limited set of parameters, it enables the implementation and assessment of precision application scenarios within existing modelling frameworks, enhancing the realism of spatially exposure simulations.

3.10.P-Tu254 Predicting Photodegradation of Pesticides in Swedish Waters: Validation of a Mechanistic Model

Luana de Brito Anton¹, Ida Rahu¹ and Malte Posselt², (1)Stockholm University, Sweden, (2)Department of Environmental Science, Stockholm University, Sweden

Photodegradation can be an important transformation process affecting the fate of pesticides in environmental waters, and therefore quantifying photodegradation is needed to support environmental risk assessments. However, rates of direct photolysis and indirect photodegradation – driven by photochemically produced reactive intermediates (PPRI) formed when chromophoric dissolved organic matter (CDOM) absorbs sunlight – vary depending on environmental conditions such as sunlight intensity and CDOM composition. To account for this variability in environmental conditions, mechanistic models can predict photodegradation rates across diverse waterbodies. Yet, the ability of these models to reliably predict photodegradation rates in real environmental waters remains uncertain. In this study, water samples were collected from 14 sites across the Stockholm region (including lakes, streams, and coastal waterbodies; dissolved organic carbon (DOC) = 6.2–30 mg/L) to validate a mechanistic photodegradation model. This model predicted indirect photodegradation rate constants for over 20 pesticides based on measured steady-state concentration of three key PPRI: $^1O_2$, $^{\bullet}OH$, and $^3CDOM^*$ and previously determined bimolecular reaction rate constants for each pesticide-PPRI pair. Direct photolysis predicted rate constants were calculated using previously measured quantum yields and molar absorptivity values. The combined predicted photodegradation rates were then compared with observed rates measured in all water samples. Results showed that model predictions for pesticides primarily degraded by $^{\bullet}OH$ were generally within a factor of 3 of the observed values. While the model suggested that many pesticides could also react with $^3CDOM^*$, consideration of the photochemical properties of $^3CDOM^*$ was needed to determine whether these reactions occurred in the water samples and which sensitizer should be used in the model as $^3CDOM^*$ proxy. Overall, this mechanistic photodegradation model allows estimating site-specific photodegradation rates under varying environmental conditions, providing a tool to advance our understanding of pesticide persistence in environmental waters. Integrating such approaches into regulatory frameworks could strengthen environmental risks assessments and support informed pesticide management strategies.

3.10.P-Tu255 A Higher-Tier Approach: Kinetic Evaluation of Laboratory Water/ Sediment Studies at P-II Level

Kristina Hoffmann, Jorge Olivares-Rivas, Monica Zambrano Moreno, Ruth Porschewski and Anqi Lyu, knoell Germany GmbH, Germany

P-I level (i.e. total system) endpoints are usually applied for predicting environmental concentrations of active substances in surface water and sediment in the context of the EU risk assessment of plant protection products (PPP). Standard P-II level kinetics are often limited in their applicability as refinement option due to unrealistic consideration of the exchange processes between the compartments. However, current regulatory developments (e.g. FOCUS surface water repair action and EFSA drinking water treatment assessment) require reliable P-II level endpoints to avoid over-conservative risk assessments.

In this study, we present a higher-tier approach that combines modified P-II kinetics with inverse modelling using TOXSWA v1.2 to derive reliable, compartment-specific P-II endpoints. The approach focuses on a) Determining separate DT50 values for the water and the sediment compartments; b) Accounting for adsorption through a physically consistent coupling factor that integrates sediment dry bulk density, distribution coefficient in sediment, and sediment porosity; and c) Reducing high compartment correlations.

To support this approach, a Python-based tool was developed to perform P-II level analysis (both standard and higher tier). The system solves ordinary differential equations (ODEs) as initial-value problems and minimise an ordinary least-squares (OLS) objective function using SciPy modules. The initial masses in water and sediment can be either fixed or fitted during the optimization process. Statistical parameters are handled as recommended by FOCUS degradation kinetics (2014), i.e. Chi2 is calculated, t-test is applied, and the confidence intervals are reported. The Fsed test is no longer a constraint using the modified P-II level approach. Results from the tool were validated against the widely accepted tool KinGUI for standard assessments.

Together with extrapolated (OECD 106) or optimised distribution coefficients (inverse TOXSWA) for individual sediments, the tool enables high-precision P-II level modelling for laboratory water/ sediment studies. As the higher-tier approaches are outlined in the appendices of FOCUS degradation kinetics (2014), the authors consider the described approach as an acceptable refinement in the EU risk assessment of PPPs.

3.10.P-Tu256 Identifying Model Parameter Hierarchies in FOCUS STEP 3

Dimitrios Alexander Skodras and Judith Klein, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

To standardize the role of exposure models in the European Union (EU) plant protection product authorization process, the Forum for the Co-ordination of pesticide fate models and their use (FOCUS) has established guidelines, including the FOCUS STEPS models for surface water risk assessment. Conservative scenarios representing EU member states are used, with a 4-tier approach to assess limit value exceedances. While higher-

tier calculations provide greater accuracy by requiring more information, they do not incorporate the uncertainty of model parameters, potentially leading to significant inaccuracies if sensitive parameters.

This work applies global sensitivity analysis using Sobol' indices to identify influential parameters in FOCUS STEP 3. Parameters are sampled using low-discrepancy sequences and first-order and higher-order Sobol' indices are computed to quantify main and interaction effects. STEP 3 integrates TOXSWA to calculate surface water concentrations based on pesticide inputs from drift and runoff (via PRZM) or drainage (via MACRO), across three water body types and ten representative European scenarios reflecting climatic and pedological diversity.

Both substance properties and scenario descriptors are varied to map regions of parameter space where model outputs are most sensitive. The results show that sediment-related parameters have negligible influence on predicted environmental concentrations in surface water, indicating that the sediment compartment is not a driver of exposure in STEP 3. Among substance properties, the organic carbon–water partition coefficient (K_{oc}) emerges as the only consistently influential parameter, whereas degradation half-lives are largely subdominant across scenarios. This hierarchy implies that uncertainty reduction efforts targeted at K_{oc} yield the greatest improvement in prediction reliability. For less sensitive parameters central default values may be sufficient for less sensitive properties.

Disclaimer/Disclosure:

This work was carried out in the framework of the European Partnership for the Assessment of Risks from Chemicals (PARC) and has received funding from the European Union's Horizon Europe research and innovation programme under Grant Agreement No 101057014.

3.10.P-Tu257 VERBER, a Catchment Scale Pesticide Risk Assessment Model for Surface Waters in Sweden

Anna Lindahl¹, Gustaf Boström², Mikaela Gönczi² and Nicholas Jarvis¹, (1)Department of Soil and Environment, Swedish University of Agricultural Sciences, P.O. Box 7050, SE-75007 Uppsala, Sweden, Sweden, (2)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden

Water authorities in European countries regularly need to carry out impact assessments of pesticides in their water bodies under the framework of the EU Water Directive (Directive 2000/60/EC). This requirement poses a challenge for Swedish water authorities since Sweden has up to 100,000 lakes and more than 500,000 kilometres of water courses. To support their work under the EU Water Framework Directive, we developed VERBER for surface waters, a pesticide risk management model. VERBER predicts average concentrations of active substances originating from arable fields at the outlet of sub-catchments in inter-connected networks of lakes and water-courses in Sweden. The model is intended to be used as a regional and national-scale screening-level tool to identify surface waters at risk of being affected by pesticide concentrations that pose a chronic toxicity to aquatic organisms or non-compliance with drinking water standards, and which therefore require extra attention such as monitoring.

The model calculates surface water pesticide concentrations by combining a parsimonious steady-state mass balance model with a classification tree trained on Swedish environmental monitoring data, to estimate the fraction of an applied pesticide lost to surface waters.

A comparison between average surface water concentrations predicted by VERBER and measured concentrations indicated that the model is generally realistic, but conservative in a limited number of situations.

3.10.P-Tu258 A Framework for Coupling SWAT+ Watershed Models with High-Resolution Stream Networks in xAQUATIC

Hendrik Rathjens¹, Mike Devin Fuchs², Sebastian Multsch³ and Sebastian Gebler³, (1)Stone Environmental, Austria, (2)RPTU University of Kaiserslautern-Landau, Germany, (3)BASF, Germany

The xLandscape modeling framework enables spatiotemporally simulation of pesticide fate and effects at landscape scales for regulatory risk assessment. It provides core technical functions to run multiple consecutive environmental simulation models with pre-defined scenario data (e.g., land use and cover, hydrography,

topography, crop management). xAquatic is the aquatic component of xLandscape integrating various environmental exposure and effect models. However, developing high-resolution hydrological inputs for stream networks is resource-intensive. At the same time, numerous calibrated watershed models exist, yet they often lack the resolution required for spatially explicit landscape-scale aquatic risk assessment, such as single stream segments at approximate 100 m resolution and information on edge-of-field water bodies. To address this challenge, we developed a framework that takes existing SWAT+ watershed-scale models as hydrological inputs for xAquatic scenario development, enabling high-resolution pesticide fate modeling in small streams and ditches that are critical for ecological risk assessment but typically fall below the resolution of watershed models. Integration was achieved by mapping high-resolution xAquatic reach segments to SWAT+ channels based on spatial intersection with SWAT+ landscape units. Reaches beyond SWAT+ boundaries are mapped to the SWAT+ outlet, allowing extrapolation outside the model domain. An established hydraulic scaling approach was used to estimate discharge in individual xAquatic reaches from SWAT+ channel outputs: $Q_{xAquatic} = Q_{SWAT} \times (L_{xAquatic}/L_{SWAT})^\beta$, where Q represents discharge, L is cumulative upstream length, and β is a scaling exponent accounting for nonlinear discharge-length relationships. Hydraulic parameters are calculated using the Manning equation with trapezoidal channel geometry from xAquatic reach properties. The framework was applied in the lowland Funne catchment (5,440 ha) in North Rhine-Westphalia, Germany, a predominantly agricultural basin with poorly draining clay-rich soils, low hydraulic gradients, and extensive artificial drainage. In total, 563 xAquatic stream segments were mapped to SWAT+ channels and daily outputs were transformed to hourly time steps. By enabling reuse of existing watershed models within the xLandscape architecture, this framework is intended to lower barriers for landscape-scale aquatic risk assessments and to support regulatory adoption.

3.10.P-Tu259 Mapping Crop Development as Function of Calendar Date Across the EU for Use in the EU Regulatory Framework

Mechteld ter Horst¹, Hendrik Boogaard¹, Allard de Wit¹, Herman Berghuijs¹, Steven Hoek¹, Pauline Iris Adriaanse¹, Franco Ferilli², Alberto Linguadoca², Laura Padovani² and Csaba Szentes², (1) Wageningen University and Research (WUR), Netherlands, (2) European Food Safety Authority (EFSA), Italy

EU regulations require Environmental Risk Assessments (ERA) for non-target organisms exposed to active substances in plant protection products. Accurate prediction of crop phenology across Europe is essential to improve these assessments. The presented work aims to enhance pesticide ERA by precisely mapping crop development stages (i.e., the commonly used BBCH crop growth stages) across the EU.

A harmonized database of over 1.2 million phenological observations was compiled from public sources (C2D2, PEP725, TEMPO) and literature. The C2D2 database provided broad spatial coverage, while PEP725 and TEMPO offered complementary data concentrated in Central Europe and France, respectively. To address data gaps and spatial variability, models were developed for predicting sowing dates and phenological stages. A temperature-based rule was used to predict sowing dates, supplemented by a median rule for regions strongly influenced by management practices, such as irrigated maize in Southern Europe. Crop development was simulated with the WOFOST phenology model, which describes growth using a dimensionless development stage (DVS) ranging from emergence (0.0) to maturity (2.0), accounting for temperature, photoperiod, and vernalization. Model parameters (TSUM1 and TSUM2) were calibrated using observed phenological data aggregated by agroecological zones with similar climate conditions. Intermediate BBCH stages were then linked to the DVS scale, enabling wall-to-wall predictions of development stages across a 10×10 km EU grid. After calibration, WOFOST accurately reproduced phenological development for eight major crops: spring barley, potato, sunflower, maize, winter wheat, winter rye, winter rapeseed, and winter barley. The model successfully linked observed BBCH stages to the DVS scale, capturing the expected variability and overlap among stages.

Some examples of the resulting high-resolution spatio-temporal predictions of crop growth stages will be shown. The predictions provide valuable inputs for refining pesticide risk assessments under EU regulation. This work supports more accurate estimation of pesticide application dates; improves predictions of off-target exposure, including spray drift deposition, and pollinator risks, by better characterizing crop development stages; and enhances scenario development for EU regulatory frameworks such as the FOCUS surface water models and bee-exposure scenarios. The phenology database will be released as open data.

Disclaimer/Disclosure:

This work was carried out under the Framework Partnership Agreement (GP/EFSA/PREV/2020/02) between the European Food Safety Authority (EFSA) and Wageningen Environmental Research (WENR), which aims to

advance concepts and methodologies for assessing the exposure of terrestrial non-target organisms to plant protection products.

3.10.P-Tu260 Data Availability and Quality Considerations when Collating and Harmonising EU Environmental Monitoring Data for Regulatory Purposes

Gregory Hughes¹, Dirk Liss² and Andreas Scharmüller², (1)GeoSpatial Analytics, United Kingdom, (2)Bayer AG, CropScience, Germany

Access to publicly sourced environmental monitoring data has expanded considerably over the past twenty years, largely driven by open-data policies and the requirements of the Public Access to Environmental Information Directive (2003/4/EC). These datasets are generated by a range of organisations—national and regional environment agencies, water suppliers and other public-interest bodies—each collecting samples for different regulatory, operational, or research purposes. As a result, data originate from multiple sources, collected for varying aims and with differing methodologies, making the development of a harmonised, pan-European database complex. Yet this type of integration is essential for regulatory purposes, such as evaluating chemical quality across environmental compartments within the framework of the Plant Protection Products Regulation the Water Framework Directive.

The format of online accessible chemical monitoring data varies widely—from PDFs, spreadsheets, compressed archives, to sophisticated web portals that support query functions and visualisation tools. In other cases, data must be formally requested, and access may involve administrative steps or fees. While a substantial portion is available under open-data or permissive licences, some datasets containing third-party contributions are governed by stricter use agreements. Spatial data on monitoring locations are provided in different coordinate systems and with varying degrees of positional accuracy. The heterogeneity of formats, structures and conventions means that substantial processing is required before these data can be assembled into a coherent database suitable for regulatory evaluation.

This poster outlines data availability and quality challenges in collating and harmonising environmental monitoring data using real-world examples extracted from the EnviroDataMonitor data collection and curation service B1.0.5 database and the associated Chemical Harmonisation Tool which includes >500K substance synonyms trained to facilitate this harmonisation. The work presented will highlight emerging patterns and practical considerations relevant to large-scale chemical data integration, while also identifying gaps that need to be addressed to support future regulatory assessments. This ongoing effort aims to stimulate discussion on best practices and encourage collaboration toward more consistent and interoperable environmental monitoring datasets across Europe.

3.10.P-Tu261 Inventory and Characterisation of Chemical Monitoring Data across the EU

Gregory Hughes, GeoSpatial Analytics, United Kingdom

Access to environmental monitoring data has expanded significantly across the EU in recent decades, largely driven by open-data policy developments and the increasing need for transparency in environmental decision-making. National and regional authorities (environment agencies, geological surveys, health departments) and water utilities routinely collect chemical quality data to meet diverse regulatory and operational objectives, following different sampling protocols, analytical methods and reporting standards. Consequently, although large volumes of information exist, they vary widely in quality, scope, structure and accessibility.

The assessment presented here draws on raw unaggregated chemical monitoring data gathered from countries across the EU and harmonised using the EnviroDataMonitor framework and the resulting b1.0.5 database. The work involved cataloguing monitoring providers and data sources, evaluating access routes and update frequencies, as well as characterising dataset formats, licensing conditions, and metadata completeness. Chemical and environmental dimensions were also considered, including the range of chemical classes monitored, spatial and temporal coverage, sampling matrices, analytical methods, and environmental compartments represented. Taken together, this provides an emerging evidence base on the scale, diversity and complexity of chemical monitoring information currently readily available across Europe, and the practical implications for large-scale data collation and harmonisation.

This poster presents emerging observations on the landscape of chemical monitoring data across the EU, highlighting common challenges to harmonisation and opportunities for improved data interoperability. Preliminary insights illustrate the diversity of data structures and access models encountered, and the need for coordinated approaches to make these datasets more usable for regulatory and scientific applications. The work

aims to support ongoing discussions around best practices and to lay the groundwork for more systematic data integration efforts in the future.

3.10.P-Tu262 Assessment of Pesticide Contamination in Dust from Quebec Residences based on a Method Adapted to Large-Scale Studies

Camille Pernet¹, Raphaëlle Teyssie², Maryse F. Bouchard², Benoit Barbeau³, Marc-André Verner⁴, Jacques Brodeur⁵, Amadou Diogo Barry⁶, Jonathan Chevrier⁷ and Pedro Segura¹, (1)Département de Chimie, Université de Sherbrooke, Sherbrooke, QC, Canada, Canada, (2)Unité d'épidémiologie et biostatistique, Centre Armand-Frappier Santé Biotechnologie, Institut National de la recherche scientifique (INRS), Laval, QC, Canada, Canada, (3)Département des génies civil, géologique et des mines (CGM), Polytechnique Montréal, Montréal, QC, Canada, Canada, (4)Département de santé environnementale et santé au travail, École de santé publique, Université de Montréal, Montréal, QC, Canada, Centre de Recherche en Santé Publique, Université de Montréal et CIUSSS du Centre-Sud-de-l'Île-de-Montréal, Montréal, QC, Can, Canada, (5)Département de sciences biologiques, Université de Montréal, Montréal, QC, Canada, Canada, (6)Unité d'épidémiologie et biostatistique, Centre Armand-Frappier Santé Biotechnologie, Institut National de la recherche scientifique (INRS), Laval, QC, Canada, Unité Mixte de Recherche (UMR) INRS-UQAC en santé durable, Canada., Canada, (7)Département d'épidémiologie, biostatistique et santé au travail, Université McGill, Montréal, QC, Canada, Canada

Household dust is a complex matrix that can accumulate a wide range of contaminants, including pesticides. Under indoor conditions, pesticide degradation is significantly limited by the absence of UV radiation, rainfall, and temperature fluctuations, leading to their persistence. Because people spend, on average, 90% of their lives indoors, household dust can be an important source of exposure. As global pesticide use continues to rise, there is a growing need for scalable approaches to assess pesticide contamination. This study aims to develop a contamination-free, simple, and representative sampling technique, combined with effective extraction and sensitive analysis, for quantifying pesticides in household dust, which could be easily implemented for large-scale epidemiological studies.

Dust samples were collected over 2-5 months, during the peak period of pesticide application, using Petri dishes placed inside participants' houses (n = 173) in an intensive agricultural region of southern Québec. A target list of 51 pesticides, including 18 fungicides, 19 herbicides, and 14 insecticides, was established based on their toxicity and regional use. After the accumulation period, dust was retrieved from the Petri dishes using cellulose wipes pre-moistened with isopropanol. QuEChERS was employed to quantitatively extract the pesticides from the samples, and liquid chromatography-triple quadrupole mass spectrometry was used for the analysis. This method was validated in accordance with the SANTE/11312/2021 guidelines.

Results showed that more than 97% of houses had at least one contaminant detected, and up to 17 pesticides were found in a single house. In total, 35 analytes out of 51 were detected in at least 1 Petri dish, with detection frequencies ranging from 1.3 to 69%. Fungicides were the most frequently detected pesticide class, with 16 out of 18 compounds found. Individual pesticide levels varied widely between homes, ranging from 5.9e-4 to 1.3e2 pg/cm²/day. The most frequently quantified compounds with the highest amounts were insecticides, including cis- and trans-permethrin, found in 32% and 60% of houses, respectively.

The present method provides accessible sampling and sensitive analysis suitable for large-scale studies. Furthermore, this is the first study to assess pesticide occurrence in indoor dust from residences near agricultural fields in Québec, and it will allow us to evaluate the significance of exposure to pesticides through dust.

3.10.P-Tu263 Monitoring of airborne pesticide transport and deposition in selected sampling sites in Germany between March and September 2025

Benedikt Ringbeck¹, Andreas Hentschel², Katja Hombrecher³, Margit Krapp⁴, Geraldine Knopf⁵, Bernd Göckener¹, Andrea Claus-Krupp⁶, Franziska Born-Moser⁷, Jakob Maier⁸, Achim Gathmann⁹, Roland Kubiak¹⁰ and Anna Peters⁹, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Mérieux NutriSciences, Institut Kirchhoff Berlin, Germany, (3)North Rhine-Westphalia Office of Nature, Environment and Climate (LANUK), Germany, (4)Bavarian Environment Agency (LfU), Germany, (5)Brandenburg State Office for the Environment (LfU), Germany, (6)Chamber of Agriculture North Rhine-Westphalia Plant Protection Service, Germany, (7)Brandenburg State Office of Rural Development, Agriculture and Land Consolidation, Germany, (8)Bavarian State Research Center for Agriculture, Institut for Plant Protection, Germany, (9)Federal Office of Consumer Protection and Food Safety (BVL), Germany, (10)Scientific consultant/independent researcher, Landau Germany, Germany

Airborne pesticide transport and deposition, e.g. from agricultural applications, are sparsely investigated sources of environmental contamination with potential ecotoxicological relevance for off-target organisms. To understand and quantify the entry of airborne pesticides into the environment, a monitoring campaign was performed in 2025 with a total of six sampling intervals of 4 weeks each. Pesticide concentrations in the air, as well as deposition were determined at three sites in different regions in Germany. Active air samplers were used to sample particulate matter with potentially adhering pesticides (using glass fibre filters) and volatile pesticides (using polyurethane foams). Deposition was determined using a bulk sampler to collect precipitation and dust. Samples were analysed by validated liquid- and gas-chromatography-mass spectrometry methods with limits of quantification in the low ng/L range (deposition) or in the pg/m³ range (air-concentrations). Additional experiments were performed to determine stability of the pesticides under sampling conditions for all three sample types, as well as breakthrough behaviour of the active air sampler.

Monitoring results showed trends in air concentrations and deposition of several pesticides over the sampling periods, which correlated with their typical application periods, as well as significant differences between sampling sites. Of the investigated pesticides and metabolites, dimethenamid, flufenacet, fluopyram, pendimethalin, prosulfocarb, prothioconazol-destio, terbuthylazine (and terbuthylazine-desethyl), as well as S-metolachlor were most frequently detected active substances/metabolites in these samples. The stability experiments for all samplers and breakthrough test for the active air sampler showed overall good recovery under sampling conditions. However, for individual pesticides there were significant losses by degradation, adsorption to the bulk sampler or breakthrough in the active air sampler. Overall, the results showed detectable pesticide entries into the environment potentially caused by long-distance air transport and subsequent deposition. These results may be used for a better understanding of long-distance transport and deposition of pesticides. The extent to which the results can contribute to evaluate the potential ecotoxicological risk of these pesticide entries to non-target organisms was not subject of this study and needs to be further investigated.

3.10.P-Tu264 Overcoming Phytotoxicity in Honey Studies: Insights from past Herbicide Tunnel Trials

Silvio Knaebe¹, Pierre Mack², Marina Knoll², Andreas Appeltauer² and Carmen Maria Gimeno Martos³,
(1)Eurofins Agrosience Services US, Germany, (2)Eurofins Ecotox, Germany, (3)Eurofins Trialcamp S.L.U., Spain

To establish Maximum Residue Levels (MRLs) for herbicides in honey, tunnel residue trials are the preferred methodology over open-field studies, as they ensure bees forage exclusively on the treated crop. This presentation outlines current approaches based on the SANTE 2016 guideline, specifically addressing the unique challenges of herbicide testing where the guidance left some questions open.

Unlike insecticides or fungicides, herbicides present a risk of phytotoxicity which can arrest nectar production. Consequently, trials must utilize sturdy surrogate crops. Interestingly, Phacelia, winter oilseed rape, and buckwheat have proven more robust for testing than expected, even when treated at full critical Good Agricultural Practice (cGAP) rates during flowering (BBCH 63-65).

We present data from 97 trials conducted across Central and Southern Europe. Results indicate that despite potential herbicidal effects on plant health, flowers often remain sufficiently attractive to sustain foraging. Daily monitoring of flight activity proved vital for determining the optimal sampling window, typically 7 to 10 days after application. The study confirms that valid honey samples, with sugar content and weights comparable to untreated controls, can be consistently obtained.

3.10.P-Tu265 Method Development and Determination of Pesticides in Residential Soils to Assess Human Exposure in Rural Areas of Québec, Canada

Alexandre Gagnon¹, Raphaëlle Teyssie², Maryse F. Bouchard³, Amadou Diogo Barry⁴, Benoit Barbeau⁵, Hubert Cabana⁶, Jacques Brodeur⁷, Jonathan Chevrier⁸, Marc-André Verner⁹ and Pedro Segura¹,
(1)Département de Chimie, Université de Sherbrooke, Sherbrooke, QC, Canada, Canada, (2)Unité d'épidémiologie et biostatistique, Centre Armand-Frappier Santé Biotechnologie, Institut National de la recherche scientifique (INRS), Laval, QC, Canada, Canada, (3)Unité d'épidémiologie et biostatistique, Centre Armand-Frappier Santé Biotechnologie, Institut National de la Recherche Scientifique (INRS), Laval, QC, Canada, Canada, (4)Institut National de la Recherche Scientifique (INRS), Unité Mixte de Recherche (UMR), Canada, (5)Département des génies civil, géologique et des mines (CGM), Polytechnique Montréal, Montréal, QC, Canada, Canada, (6)Département de génie civil et de génie du bâtiment, Université de Sherbrooke, Sherbrooke, QC, Canada, Canada, (7)Département de sciences biologiques, Université de Montréal, Montréal, QC, Canada, Canada, (8)Département d'épidémiologie, biostatistique et santé au travail, Université McGill, Montréal, QC, Canada, Canada, (9)University of Montréal, Integrated University Centre for Health and Social Services (CIUSSS), Canada

Pesticides are widely used to protect crops but can contaminate air, water, and soil. Populations in agricultural regions are thus more likely to be exposed to pesticides than populations in urban centers, potentially increasing the risk of acute health effects. Despite these concerns, no study has yet assessed pesticide exposure pathways in communities near agricultural fields in Québec nor Canada. Among the multiple sources of pesticides, soils are particularly important since they can act also as reservoirs that can expose populations directly by dermal contact or accidental ingestion of soil, or through air particles formed by wind erosion.

This work aims to develop an analytical method to characterize pesticide occurrence in residential soils in Montérégie, Québec's most intensive agricultural zone. Residential soil samples were collected from 78 households within 1500m of agricultural fields in the summer of 2024. We targeted a total of 49 pesticides (18 fungicides, 17 herbicides, and 14 insecticides), selected according to their use in the region and human toxicity. After collection, samples were stored at -20°C. Prior to extraction, they were air-dried for 24 hours and sieved to 2 mm. A QuEChERS extraction technique was employed, and multiple parameters (solvent ratio, salt ratio, sorbent ratio, etc.) were optimized using Design of Experiments based on the Plackett-Burman approach. Pesticide contamination was then quantified using liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS). Method performance was evaluated according to SANTE/11312/2021/v2 international standard, where linearity ($R^2 > 0.99$ and $\leq 20\%$ deviation), precision (%RSD 1-7%), trueness (-13.58-13.46%), and LOQs (1-25 ng/g) fulfilled the acceptance criteria defined in the guideline.

Preliminary results (39 out of 78 samples) show the presence of multiple pesticides, mainly atrazine, chlorantraniliprole, imidacloprid and metolachlor at concentrations ranging from 1 to 11 ng/g. As for clothianidin, it was detected at concentrations up to 24 ng/g. Detection frequencies, number of pesticides and cumulative concentrations will be presented.

This work provides a validated analytical approach and baseline data on residential soil contamination near agricultural areas, supporting future assessments of pesticide exposure and associated health risks in rural populations.

3.10.P-Tu266 Pesticides in private and community gardens

Klára Šmídová, Mária Jánošíková, Marek Šudoma and Jakub Hofman, RECETOX, Faculty of Science, Masaryk University, Czech Republic

While the soil quality, including contamination, is carefully monitored in agricultural land, the soils found in urban environments are almost entirely overlooked. At present, there is no regulation that would require the regular monitoring of urban soils or any systematic assessment of the potential risks they may pose to human health as a result of chemical or historical contamination. Yet many urban citizens who own small private gardens use them to grow fruits, vegetables, herbs, and ornamental plants. These gardeners often assume that home-grown produce is fresher, safer, and generally healthier than comparable goods purchased in supermarkets. However, this expectation may not always reflect reality. Urban soils, including those in private gardens, can suffer from reduced quality due to their complex history, previous land use, or long-term exposure to pollution sources such as traffic emissions, industrial activities, waste disposal, and the accumulation of legacy contaminants. Consequently, the produce grown in such soils may carry risks that gardeners are unlikely to be aware of.

For these reasons, we aimed to determine the overall soil quality, with particular emphasis on pesticide contamination, in typical city gardens in the Czech Republic and to discuss both the likely origins of such contamination and its potential environmental and health consequences. In total, the study includes more than 80 gardens ranging in size from 70 to 1400 m². The selected gardens are situated either adjacent to family houses or within traditional gardening colonies that are common in many Czech cities. The soils in these locations can be classified as technosols, chernozems, or fluvisols—typically loamy soils formed under a continental climate. By examining a diverse set of garden sites and soil types, the study seeks to provide an evidence-based understanding of the current state of urban garden soils and highlight the need for more systematic monitoring policies in the future.

The results indicate relatively high concentrations of p,p'-DDE (more than 0.1 mg/kgsoil in 21 cases, with concentrations exceeding 1 mg/kgsoil in 3 cases) and also significant concentrations of p,p'-DDT in some samples (more than 0.1 mg/kg soil in 7 cases). From the currently used pesticides, the highest concentration was found for azoxystrobin (more than 0.1 µg/kgsoil).

3.10.P-Tu267 A triad approach to assess the cocktail effect in surface water: a case study on the Mehaigne River (Wallonia, Belgium).

Delphine Leroy, *Yves Marneffe, Carole Chalon, Caroline Nadin and Eric Moïs, Scientific Institute of Public Service (ISSEP), Belgium*

Current monitoring of the chemical status of water bodies fail to characterize the likelihood that complex mixtures of chemicals affect water quality. In order to assess the risk induced by cocktail effect in Belgian surface waters, a transect of the Mehaigne River, which is under pressure from agriculture and untreated urban wastewater, was studied using a triad approach comprising the use of chemical analyses (100 parameters), biomarkers (feeding rate, acetylcholinesterase (AChE) inhibition, Glutathion-S-Transferase (GST) induction) and bioindication (macroinvertebrates standardized global biotic index; biological, physiological and ecological traits; and SPEAR pesticides index).

Within this framework, five caging campaigns using the amphipod *Gammarus pulex* were conducted at five sites along the Mehaigne, as well as at one reference site (Blanc-Gravier, Colonster).

An inhibition of AChE activity (>25%) was observed for two sites, one upstream in the agricultural sector, and one downstream in the urbanized sector, which suggests the presence of insecticides in the river though chemical analyses were not particularly correlated. GST activity was induced (>20%) in two sites (not statistically significant). A reduction of feeding rate was observed from upstream to downstream, showing a global degradation of water quality.

The integration of the three components (chemistry/bioassays/bioindication) allows to clarify the cause-effect relationships at each site, with a very degraded situation in the area close to the source, which is affected by toxic pressure linked to pesticides. The situation remains very degraded throughout the upstream sector. A clear improvement in the biogenic quality of the environment (microhabitats, organic pollution, eutrophication) is then observed, but the SPEAR index still indicates a significant impact related to pesticides, which is confirmed by the detection of herbicides, among other, at all the sites. Downstream, all indicators are pointing towards deterioration, which is linked to a strong urbanization of this sector promoting a supply of waste waters.

EBM tools thus constitute an interesting approach to highlight the cocktail effect of pesticides, particularly when associated with complementary approaches, and to characterize more precisely the anthropogenic pressures exerted on the river. The development of additional biomarkers associated to other modes of actions would contribute to improve this triad approach.

3.10.P-Tu268 Insecticide Bans Drive Declines in Aquatic Toxicity: Insights from 16 Years of Monitoring in Sweden

Kajsa Westlin, *Swedish University of Agricultural Sciences (SLU), Sweden*

Over the past decade, several insecticides have been banned within the EU with the aim of reducing risks to human health, protecting particularly vulnerable species and ecosystems and preventing long-term environmental contamination.

The aim of this study was to evaluate how these regulatory measures have influenced insecticide concentrations and toxicity in agricultural streams, using data from the Swedish national monitoring program for pesticides. Since 2002, the monitoring program has conducted high-frequency surface water sampling in four agricultural streams in southern Sweden. In parallel, farmers in the catchment areas are interviewed about their crop production and pesticide use.

Analyses of more than 180 substances between 2009 and 2024 show that insecticides, although typically present at lower concentrations than fungicides and herbicides, account for the largest share of toxicity in the streams. However, the long-term trend is clear: both insecticide use and the measured concentrations in surface water have declined markedly. This is also reflected in a decrease in overall toxicity in the watercourses, although some still approved insecticides — such as the pyrethroid tau-fluvalinate and the neonicotinoid acetamiprid — have increased in both use and measured concentrations following the bans.

Overall, the results show that the bans have had the intended effect. The use of many highly toxic insecticides has decreased or ceased, which is reflected in lower concentrations and reduced toxicity in the environment. This serves as a concrete example of how regulatory measures can lead to positive environmental outcomes.

3.10.P-Tu269 Collection of Sediment Data in Small Edge-of-field Watercourses and Ponds at the EU-FOCUS Scenarios Locations for use in Pesticide Registration

Wim Beltman¹, Kas Swinkels¹, Bas Jonkers¹, Sander Mucher¹, Martin Knotters¹, Steven Crum¹, Pauline Iris Adriaanse¹, Arjan Reijneveld², Almir Nunes¹ and Jan Baas¹, (1)Wageningen University and Research (WUR), Netherlands, (2)Eurofins Agro, Netherlands

In the EU the pesticides exposure to assess risks for aquatic organisms is calculated using models and scenarios. The so-called FOCUS scenarios include fifteen small edge-of-field water bodies, ditches, streams and ponds, that represent the major EU agricultural areas. Currently the sediment of all scenarios is characterized by the same properties, including a relatively low value for the organic carbon content of 5%. This low value leads to a conservative exposure in the water layer, thus a conservative risk assessment for aquatic organisms. However, it also leads to an underestimation of the exposure in sediment and thus it may underestimate risks for sediment-dwelling organisms. EFSA granted a project for a literature search and sampling campaign to collect data on sediment properties of freshwater bodies in the major agricultural areas of the European Union (project EFSA/2025/OP/0005, ongoing). The ultimate goal is to improve the sediment descriptions of the EU-FOCUS surface water scenarios to improve the quality of the aquatic risk assessment.

Locations of water bodies were selected in the vicinity (i.e., 30 km) of the existing scenario location coordinates using a waterbody map of the EESE project (contract OC/EFSA/PREV/2023/02), arable crop areas from Corine Land Cover and European Union Crop type map of 2022, and the FOCUS maps for the areas represented by the scenario. The sampling campaign took place in the spring season of each of the three regulatory zones, between April 2025 and March 2026. The sediment of 30 water bodies; 8 ditches, 16 streams and 6 ponds, was sampled. Following a randomized sampling scheme 20 cores were taken in a stretch of 100 m for ditches and streams and scaled to size for the ponds. From each core 0-2, 2-5 and 5-10-cm layers were sampled. Determined were bulk density, porosity and organic matter content. For the 5-10-cm layer also the granular composition was determined, classifying the sediment within the USDA soil classification system.

The results show, that the variation in bulk density and organic matter content within and between water bodies is very large. Examples for a pond and a stream are presented. On the basis of these data the sediment properties in the current EU-FOCUS surface water scenarios can be improved to promote a more realistic risk assessment for benthic organisms and rooted water plants in the registration procedure at EU level.

3.10.P-Tu270 Spatial analysis of vulnerability of agricultural lands to surface runoff in Europe

Penélope González Galarza, **Sebastian Multsch** and Tom Schroeder, BASF, Germany

The authorization of plant protection products requires an environmental risk assessment to evaluate potential adverse effects on non-target organisms. For aquatic organisms, risk assessment considers three main exposure pathways: runoff, drift and drainage into edge-of-field waterbodies. The FOCUS (FORum for the Co-ordination of pesticide fate models and their USE) surface water guidance provides a conceptual framework for estimating environmental exposure using simulation models, parameterization assumptions, and representative European scenarios. The FOCUS surface water scenarios (R1–R4) assume specific slope ranges (R1: 2–4%, R2: 10–15%, R3/R4: 4–10%) intended to represent realistic worst-case conditions.

This study applied geospatial analysis to quantify the extent to which actual crop fields near water bodies in the EU align with FOCUS slope assumptions. Spatial datasets of crop distribution and field slopes in the proximity of water bodies (50 m and 100 m buffers) were integrated to calculate overlap between FOCUS slopes and real-world conditions.

Results indicate that the proportion of crop area meeting both proximity (<50 m) and slope (>4%) criteria is extremely low—typically <0.4%. This demonstrates that FOCUS slopes represent only a small fraction of actual field situations adjacent to water bodies. Consequently, Tier 1 assessments based solely on these scenarios may overestimate real-world runoff exposure. Incorporating actual slope distributions into risk characterization enables more proportionate mitigation strategies.

The findings support slope-based label language (e.g., “Do not apply on soils with slope >4%”) as a targeted measure for the limited subset of fields with slopes similar to FOCUS assumptions.

3.10.P-Tu271 Comparison of FOCUS Step 4 simulations using the updated SWAN-VFSMOD scenarios with standard fixed reduction efficiencies according to FOCUS Landscape

Stefan Reichenberger¹, Robin Sur², Jorge Olivares-Rivas³, Paul Robinson⁴ and Rafael Muñoz-Carpena⁵, (1)knoell France SAS, France, (2)Bayer AG, Germany, (3)knoell Germany GmbH, Germany, (4) Dr Knoell UK Ltd., United Kingdom, (5)Agricultural and Biological Engineering, University of Florida, United States

The standardized FOCUS approach for pesticide exposure assessment in surface waters (FOCUS_{sw}) consists of four steps. Mitigation of surface runoff inputs with vegetative filter strips (VFS) can be assessed in Step 4 using the tool SWAN, which implements both fixed VFS efficiencies according to the FOCUS Landscape report and an option to apply runoff mitigation using the mechanistic, event-based model VFSSMOD. Recently a set of updated SWAN-VFSSMOD scenarios for FOCUS Step 4 has been derived. The updated scenarios are both more realistic and more protective than the previous ones and will be included in the upcoming SWAN release (v.5.3).

The objective of this study was to compare the updated SWAN-VFSSMOD scenarios with the standard fixed reduction efficiencies from FOCUS Landscape in terms of resulting exposure in surface water. For this aim, a set of FOCUS Step 4 simulations ($n = 216$) were performed (6 compounds, 2 crops, 2 application timings per crop, 2 values of VFS length in flow direction). The simulations were conducted for the two different approaches: i) “new”: new SWAN-VFSSMOD scenarios, using VFSSMOD v.4.5.2), ii) “old”: current standard approach with fixed efficiencies. Simulations were run over 20 years. Several target variables were analysed: i) pesticide load reduction efficiency (?P) for each event; ii) Predicted Environmental Concentrations (PEC_{sw}) for each event; iii) global PEC_{sw,max} for the 20-year period; iv) PEC_{sw,max} for the original 12-month period used in FOCUS_{sw}; and v) ranked annual PEC_{sw,max} and PEC_{sed,max}.

For the performed 216 simulations, the new approach yielded predominantly higher pesticide trapping and lower PEC than the old one. However, for the scenario / water body combination R1 pond (and partly R1 stream) combined with the highest simulated K_{foc} (1000 L kg⁻¹), the calculated PEC_{sw}, global PEC_{sw,max} and high ranks of annual PEC_{sw,max} and PEC_{sed,max} tended to be higher with the new approach. However, due to the limited range of sorption and degradation parameter values investigated, the results cannot be generalized to the whole substance parameter space for pesticides.

In summary, compared with the current standard fixed efficiency approach, the new approach with the updated SWAN-VFSSMOD scenarios yielded predominantly less conservative, but sometimes also more conservative ?P and PEC, reflecting the increase in realism and accuracy (and thus reduction of uncertainty) due to the use of a mechanistic, event-based model.

3.10.P-Tu272 Challenges in applying the joint ECHA & EFSA water treatment guidance document for plant protection products

Andrew Eatherall¹, Ieva Balaisyte¹, Clare Lane¹, Vera Papasova¹, Martin Tilbrook² and Charles Verity¹, (1)No Affiliation, United Kingdom, (2)ERM Europe Ltd, United Kingdom

The joint ECHA & EFSA guidance document (GD) on the impact of water treatment processes on residues of active substances, or transformation products, in water used for drinking water, was approved in July 2023 and comes into force in April 2026. This poster takes a step-by-step approach of applying the guidance to an example plant protection product with transformation products, highlighting the challenges of applying the GD. Difficulties and compromises of simulating metabolites at FOCUS Step 3 for surface water are highlighted, along with the use and derivation of zonal dilution factors and the exposure scenarios. Suggestions for changes to the process will be made for both ground and surface water.

3.10.P-Tu273 Integrating slow-release behaviour of encapsulated plant protection products into EU regulatory leaching assessment: Current knowledge and regulatory challenges

Xin You¹, Klaus Hammel², Simon Hornetz² and Dieter Schaefer², (1)Bayer AG, Monheim am Rhein, Germany, (2)Bayer CropScience AG, Germany

Plant protection products (PPPs) encapsulated in a polymer matrix, known as capsule suspension (CS) formulations can improve the functionality of active ingredients and alter product risk profiles. While CS formulations are mostly known for better targeting of pest species, increased efficacy and lower application rates, emerging evidence indicates that CS formulations also exhibit slow-release characteristics, influencing environmental fate and potentially mitigating leaching risks of PPPs. However, current EU regulatory frameworks for groundwater exposure assessment do not explicitly account for such controlled-release behaviour. To address this gap, we conducted a comprehensive review of peer-reviewed literature and EU regulatory dossiers to evaluate how CS formulation properties affect leaching potential of PPPs compared to other formulations. Our analysis focused on soil mobility, degradation kinetics and derivable release kinetics from scientific and regulatory studies conducted under realistic soil conditions. As existing leaching assessments lack parameters for slow-release kinetics, we also explored options to incorporate slow-release kinetics of CS formulations into the existing EU groundwater modelling framework to enable more realistic exposure predictions. Overall, we aimed to synthesize knowledge on the impact of slow-release behaviour of CS formulations for groundwater exposure and raise regulatory awareness that current leaching assessments may

overestimate groundwater risk of CS-formulated PPPs. Incorporating formulation-specific release behaviour into regulatory modelling could enable more realistic exposure predictions and encourage innovation in sustainable PPP formulation technologies.

3.10.P-Tu274 Bringing Rice Cultivation Practices into Environmental Risk Assessment

Anastasia Del Signore¹, Amy Ritter², Dean Desmarteau², Elisa Mascanzoni³, Wenkui He¹, Patricia Lopez-Mancisidor Romero¹ and Natalino Dalla Valle³, (1)Corteva Agriscience, Germany, (2)Waterborne Environmental Inc., (3)Corteva Agriscience, Italy

Environmental risk assessment (ERA) for pesticides in rice has historically relied on the MedRice guidance (Sanco/1090/2000 – rev.1; 2003), which assumes a static, flooded field scenario. This regulatory approach does not capture the diversity of European rice cultivation, where herbicide applications are often made to drained or semi-drained fields and water management involves multiple, dynamic flooding and drying cycles. As a result, current regulatory scenarios may miscalculate environmental exposures, potentially leading to inappropriate levels of protection for aquatic and terrestrial ecosystems.

Our study critically evaluates both the current estimates. We further assess the value of adopting physically-based models, such as RiceWQ, and the development of standardized, regionally representative scenarios. Comparative simulations were conducted using the MedRice tool and RiceWQ, parameterized with both MedRice scenarios (clay and sand soils) and new ICPS-defined country-specific scenarios (Update and harmonization of rice pesticide risk assessment and revision of European guidelines: A proposal; 2018), across major rice-growing regions including Italy, Spain, France, Greece, and Portugal. Predicted environmental concentrations (PECs) for surface water were compared to highlight the impact of scenario and model selection.

Our results show that the MedRice default scenario fails to reflect the variability of real-world practices, often leading to inaccurate exposure predictions. While the draft guidance introduces improvements—such as options for dry applications and new scenarios—it still falls short in representing regional agronomic realities. In contrast, RiceWQ, when parameterized with country-specific scenarios, yields more realistic exposure estimates.

These findings underscore the need for ERA in rice to transition toward the routine use of physically-based models like RiceWQ, supported by harmonized, regionally relevant scenarios. Enhanced collaboration among regulators, industry, and researchers will be essential to ensure scientifically robust and practically relevant risk assessments, ultimately improving both regulatory acceptance and environmental protection in rice cultivation.

3.10.P-Tu275 French Regulatory Feedback on EFSA Guidance for Predicting Environmental Concentration of Plant Protection Products in Soil: Impact Assessment of Variations in Substance-Specific Input Parameters

Arnaud CONRAD, Ysé BOULAI, Katerina SROMOVA, Martin TOURET, Pascaline VUILLEMARD, Emilie Farama and Vanessa Mazerolles, French Agency for Food, Environmental and Occupational Health & Safety (ANSES), France

The European Food Safety Authority (EFSA) has released a guidance (EFSA, 2017a) providing the methodology for calculating the predicted environmental concentrations of active substances and transformation products in soil (PECsoil) which can be used to conduct terrestrial risk assessments in the context of the Regulation (EC) No 1107/2009. This guidance on PECsoil calculations aims to ensure a more robust estimation of the exposure levels for soil organisms following application of Plant Protection Product (PPP). The methodology relies on specific soil scenarios which take into account knowledge on soil, weather and crop. The PECsoil calculations for the active substance and/or its metabolite(s) require only a few input parameters mainly related to (a) the application conditions of PPP (e.g., crop, application rate, crop growth stage, application method) and (b) the properties of the active substance/metabolite(s) (e.g., soil degradation and soil mobility). To facilitate the calculations, the analytical PERSAM tool has been released in addition to updated versions of the existing FOCUS numerical tools.

This work focuses on how variations in several input parameters related to the assessed compound (especially soil degradation half-life, DT50 and soil mobility, Koc) affect PECsoil estimates under the EFSA methodology. PECsoil were calculated for several combinations of input parameters (DT50/Koc) and different types of crops (annual and perennial), based on the recommendations of this guidance.

This work presents a first feedback on the sensitivity of the models against the selected input parameters in

order to better anticipate its use in risk assessment.
a) EFSA Journal 2017;15(10):4982

3.10.P-Tu276 Environmental Safety Considerations in EFSA's Statement of Chitosan and Chitosan Hydrochloride for Plant Protection Use

Roberto Lava¹, Franco Ferilli¹, Pauline Iris Adriaanse², Giorgia Vianello¹ and Alex Gobbi³, (1)European Food Safety Authority (EFSA), Italy, (2)Wageningen University and Research (WUR), Netherlands, (3)Council for Agricultural Research and Economics, Research Centre for Agriculture and Environment (CREA), Italy

The use of natural-based substances to improve crop quality and consequently food production was extensively developed during recent years as one of the promising approaches for more sustainable agricultural practices. Chitosan and chitosan hydrochloride, thanks to their eliciting properties, gained considerable interest in use as pesticides besides the other agricultural uses such as soil amendments or fertilisers. Both substances are approved in the EU as basic substances under certain conditions of application.

In January 2024, the European Commission asked EFSA for an opinion regarding the review of approval of chitosan and chitosan hydrochloride as per Article 23(6) of Regulation 1107/2009. In this regulatory context, it was requested to investigate whether the estimated levels of chitosan and chitosan hydrochloride resulting from the approved uses as basic substance would exceed the levels expected to occur in the environment, either naturally or derived from other uses, and consequently whether there is a need to advise on their safety to non-target species occurring in the impacted environmental compartments. To this purpose, the EFSA Panel on Plant Protection Products and their Residues (PPR) adopted a statement addressing such request accompanied by an EFSA Scientific Report outlining an estimation of the natural chitin presence in an average agricultural soil.

This poster highlights the main challenges encountered in estimating the natural levels of chitosan in the environment, starting from an assessment of its precursor chitin, and considering the rate of degradation of chitosan, strongly dependent on microbial conditions and its chemical properties. This estimation was based on the available scientific literature and derived from a polynomial function. The obtained estimation was then compared against the Predicted Environmental Concentrations of chitosan and chitosan hydrochloride calculated according to their approved uses as basic substances and the EU regulatory practices. The comparison was carried out in a quantitative and a (semi)quantitative way for the soil and freshwater compartments, respectively. Results based on the available information in ecotoxicology and environmental fate properties of chitosan, concluded that exposure levels resulting from the use of chitosan and chitosan hydrochloride as basic substance are not considered sufficient to trigger any risk for non-target organisms.

3.10.P-Tu277 Drinking Water Residue Testing: The Validation of A Positive Control Substance to Support Water Treatment Studies

Pamela More¹ and Bartek Ciszewski², (1)Environmental Fate, Charles River Laboratories, United Kingdom, (2)Charles River Laboratories, United Kingdom

The safety of an active substance is evaluated under Regulation (EC) No 1107/2009 and considers impact on the environment, animal and human health. In recent years, a data gap has emerged regarding the influence of water treatment processes on residues of active substances. This concern has led to the issuance of new guidance by the European Food Safety Authority (EFSA) and European Chemicals Agency (ECHA) on assessing the impact of water treatment processes (e.g., chlorination, ozonation) on active substances and their environmental transformation products. The guidance document sets out a tiered approach to determine if harmful substances may be formed during treatment of ground or surface water abstracted for drinking water. It is crucial that experimental methods used to determine if any treatment transformation products are formed, are robust and reproducible. A positive control substance can be useful to demonstrate the reliability of experimental methods and give confidence to data presented in regulatory studies. This presentation provides the results of screening to find, and validation of a suitable substance that can act as a positive control under all water treatment processes described in the guidance document. The validation study includes the experimental workflow, analysis of CIPAC-C water (with dissolved organic carbon) treated at a low concentration with generic compounds and subsequent stability assessments using sensitive LC-MS/MS. Also included, is the validation of a quality control procedure to demonstrate the suitability of a chromatographic method used for non-targeted screening and identification of transformation products.

3.10.P-Tu278 Novel 8-µl Blood Micro Sampling Followed by LC-MS and GC-MS Analysis Shows Low Levels of Pesticides in Farmland Birds from Sweden

Ove Jonsson¹ and Sönke Eggers², (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Swedish University of Agricultural Sciences (SLU), Sweden

Bird declines in European farmland have been linked to pesticide-driven food depletion and chronic exposure to pesticides. Yet, to what extent birds are exposed remains largely unknown, partly due to the practical and ethical aspects of collecting blood from small, wild species, but also to the analytical challenges associated with trace level determination from small sample volumes.

The Capillary Microsampling (CMS) technique was used to collect and quantitatively handle 8 µl blood samples from nestling yellowhammers *Emberiza citrinella* (N=5), nestling skylarks *Alauda arvensis* (N=40) and adult ortolan buntings *Emberiza hortulana* (N=21). With CMS an exact sample volume is collected with end-to-end glass capillaries (here after penetrating the brachial vein with a cannula) and easily treated using ordinary liquid handling.

Preparation of blood samples for LC-MS/MS analysis included addition and mixing with internal standards (ISs) and protein precipitation using acetonitrile, to a final volume of 80 µl, thus a ten-time dilution. For GC-MS, the water-based blood-IS-mixture was instead prepared by miniaturized liquid/liquid extraction using a 1:1 mixture of cyclohexane:ethyl acetate (2 x 250 µl), followed by evaporation and reconstitution in 80 µl cyclohexane:acetone 9:1. To our knowledge, this is the first report of CMS being combined with liquid/liquid extraction and GC-MS analysis.

Despite the small sample volume, the LC-MS/MS multimethod (100 compounds) showed an average detection limit of 0.77 ng/ml (range 0.016-10 ng/ml). The GC-MS method was limited to early eluting, low-boiling compounds such as chlorpyrifos, due to the complex blood matrix. For high-boiling compounds like pyrethroids, the method lacked robustness and data quality. To improve results for these compounds, additional clean-up of extracts is needed.

Pesticide residues were detected in half of the nestlings with up to 7 pesticides in a single sample (average 2). Concentrations of individual pesticides were relatively low (0.02 to 50 ng/ml) and were restricted to fungicides (N=8) and herbicides (N=5) in nestlings. Most frequently detected were the two fungicides fenpropimorph and pyraclostrobin and the herbicide tribenuron-methyl.

Our results also show that exposure of migratory ortolan buntings to the insecticide chlorpyrifos outside of Sweden can be detected in blood samples collected on their Swedish breeding grounds (7/10 tested positive; 0.25 to 0.56 ng/ml).

3.10.P-Tu279 Neonicotinoid residues in migratory birds from a key stopover site in South Korea

Syed Wasim Sardar, Mina Do and Jun-Tae Kim, Korea Institute of Science and Technology, Korea, Republic of

Neonicotinoids are widely used insecticides, and their effects on non-target species continue to raise concern. Migratory birds, which travel across diverse geographic regions and habitats, including areas with intensive pesticide use, are particularly vulnerable to exposure. Their long-distance movements and dependence on multiple stopover sites increase the chance of accumulating these chemicals from different sources, with possible consequences for their health and survival. Although the effects of neonicotinoids on invertebrates and some resident bird species are well studied, information on exposure levels in migratory birds remains limited. This study examined neonicotinoid exposure in migratory birds by measuring these compounds and their metabolites in different tissues. Feathers and muscle samples were collected and analyzed for nine neonicotinoids and eight metabolites using LC-MS/MS. Our results showed that neonicotinoid residues were present in the bird samples. Thiacloprid was the most frequently detected compound (40%), followed by acetamiprid-N-desmethyl (35%). The highest concentration was observed for nitenpyram at 14.9 ng/g, followed by thiacloprid at 2.46 ng/g. These results show that migratory birds encounter neonicotinoids during their annual cycle and highlight the potential ecological risks linked to the widespread use of these insecticides.

This work was supported by the Korea Institute of Science and Technology (KIST) Institutional Program (Grant numbers: 2E33621 and 2E33623).

3.10.P-Tu280 Integrating Chemical Diversity and Matrix Complexity: A Validated LC-MS/MS Multiresidue Framework for Realistic Exposure Assessment

Chiara Barnaba, Guilhem Zerbini, Marie-laure Bayle and Aymeric Bellemain, Rovaltain Research Staphyt, France

Realistic environmental exposure assessments require experimental designs capable of reflecting both the diversity of pesticide chemistries and the analytical complexity of agricultural matrices. In this study, we develop a comprehensive and integrative framework for evaluating a broad suite of active substances spanning multiple functional categories—including insecticides, herbicides, fungicides, plant growth regulators and safeners—and covering a wide spectrum of physicochemical profiles and modes of action. Incorporating such chemical diversity is essential to account for the range of behaviours that pesticides can exhibit once applied under field-relevant agricultural conditions, and to improve the realism of multi-residue exposure assessments.

To address the substantial variability encountered across crops, sample types were selected according to the classification logic described in SANTE/2020/12830. These include high-water-content commodities, acidic and sugar-rich materials, dry and cereal matrices, high-fat matrices, and difficult matrices such as roots and tubers. Organizing samples within this regulatory framework ensures that the study encompasses the matrix categories most commonly represented in monitoring programmes and ecological risk-assessment workflows, thereby improving the transferability and regulatory relevance of the generated data.

A harmonized LC-MS/MS multiresidue method is validated and optimized to address the diverse extraction challenges, co-extractive interferences and matrix effects associated with these SANTE-defined groups. Particular attention is dedicated to ensuring consistent analytical performance across contrasting pesticide classes and matrix types, allowing reliable, sensitive and comparable quantification of residues under realistic agricultural scenarios.

By integrating chemical breadth, matrix representativeness, validated methodology and alignment with regulatory guidance, this work establishes a robust foundation for evaluating cumulative exposure patterns in contemporary agro-ecosystems. The resulting framework is intended to support the development of more effective monitoring strategies, enhance exposure modelling efforts and contribute to more nuanced ecological risk assessments that account for the complexity of real-world multi-residue situations.

3.10.P-Tu281 METABOLOMIC ANALYSIS AND BIOCHEMICAL ANALYSES IN PLASMA, GONADS, AND LIVERS OF FISH EXPOSED TO BENTAZONE

Carlos H.L. Soares and Ivana Eunice Baptista, Federal University of Santa Catarina, CCB, Florianopolis, SC, Brazil

Bentazone is a selective herbicide, without systemic action, which is chemically a thiadiazine. It inhibits photosynthesis at Photosystem II, being effective in weed control. It is a herbicide widely used in irrigated rice crops, extensively employed in Southern Brazil. In this study, the possible deleterious effects of bentazone were evaluated in fish (*Oreochromis niloticus*), under laboratory conditions, exposed to concentrations of 170 µg/L. Fish were kept in groups of 10 individuals, control and exposed, in 300L tanks, fed with commercial feed. Blood, liver, and gonad samples were collected after a 10-day exposure period, with daily water renewal in the tanks. The obtained blood plasma was analyzed regarding total cholesterol, glucose, albumin, total proteins, AST, ALT, and alkaline phosphatase. Gonads and liver were homogenized, extracted with solvent (MTBE), and analyzed by GC/MS-TOF, in addition to the analysis of total carbohydrates and lipids. The results obtained indicated significant alterations in the levels of the enzymes ALT and alkaline phosphatase, and discrete alterations in AST. Total lipid and carbohydrate concentrations in the gonads and liver exhibited significant alterations, as well as alterations in the fatty acid, cholesterol, and carbohydrate profiles analyzed by GC/MS. A significant reduction in plasma glucose and cholesterol was observed. Total proteins and albumin did not present significant modifications. The fish exposure to bentazone provoked important metabolic alterations in the liver and gonads of the fish under study.

Keywords: bentazone, herbicide, toxicity, metabolomics, hepatic alteration.

3.10.P-Tu282 From sample to cell: Decoding Glyphosate exposure through and integrated platform

Gabriel Henrique Savietto and Marilia Cristina Oliveira Souza, University of São Paulo, Brazil

Glyphosate is one of the most widely used herbicides worldwide, and its extensive application in Brazil, raises concern about human exposure through food and environmental matrices. Accurate quantification of glyphosate

and its main metabolite, aminomethylphosphonic acid (AMPA), is essential for supporting monitoring and regulatory actions. This study developed an analytical method for determining glyphosate and AMPA in grain samples, including soybean, bean, corn, and rice. Multivariate optimization approaches were performed to streamline method development, reducing time and resource consumption while maximizing recovery rates and minimizing matrix interference.

Quantification was performed using ultra-high-performance liquid chromatography coupled with tandem mass spectrometry (UPLC-MS/MS). Chromatographic analysis employed an InfinityLab Poroshell CS-C18 column (Agilent®) maintained at 40°C, while the autosampler was kept at 8°C, using a mobile phase consist of 0.1% of formic acid in water. Residue levels will be compared to the Reg/EU 239/2013, which is used in Brazil and define maximum residues levels (MRLs) of 20.00 mg/kg for soybean, 1 mg/kg for corn, 0.10 mg/kg for rice and beans.

To assess the potential health implications, quantified residues will undergo an in vitro bioaccessibility assay using a Caco-2 cell monolayer, followed by re-quantification of the permeated fraction. Additionally, glyphosate, AMPA, and selected commercial formulations are being evaluated in cytotoxicity (MTT), genotoxicity (comet assay), and micronucleus assays across a range of concentrations, including those near regulatory limits. Preliminary MTT results indicate higher toxicity for commercial formulations compared with isolated active ingredients, underscoring the importance of continuous monitoring and regulatory vigilance to ensure food safety. Integrating chemical quantification with biological response enables a more realistic assessment of potential health risks, supporting evidence-based regulatory decisions and strengthening food safety initiatives.

3.10.P-Tu283 Optimized and Validated Novel SULLE-LC-MS/MS Method for the Determination of Neonicotinoids in Honey Samples

Robert Cholewa¹, Dawid Strzelecki¹, Paulina Łukaszewicz¹ and Łukasz P. Haliński², (1)Department of Environmental Analysis, Faculty of Chemistry, University of Gdańsk, ul. Wita Stwosza 63, 80-308 Gdańsk, Poland, (2)Department of Environmental Analysis, Faculty of Chemistry, University of Gdańsk, ul. Wita Stwosza 63, 80-308, Poland

Due to their high effectiveness, neonicotinoids (NQs) are among the most commonly used insecticides worldwide. These compounds have been repeatedly detected in aquatic environments, soil, and food, confirming their widespread distribution in ecosystems. Honeybees, thanks to their wide foraging range and continuous collection of nectar and pollen, enable the monitoring of environmental contamination. Honey can provide a matrix reflecting the accumulation of pollutants present in plants within a radius of several kilometres of the hive, making it a useful indicator of pollinator exposure to pesticides. Efficient extraction of NQs from a complex matrix such as honey remains a significant analytical challenge. Therefore, the development of sensitive and precise methods for their determination is crucial for a reliable assessment of pollinator exposure to these compounds.

In order to effectively monitor pollinator exposure to NQs, a novel method for determining residues of seven NQs in aqueous honey solutions was developed and validated. Sugaring-out liquid-liquid extraction (SULLE) with a hydrophobic modifier was used, and the analytes were determined using liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS). The extraction conditions were fully statistically optimized to maximize the efficacy of the method. Extraction effectiveness was 61-86%, depending on the compound and its concentration. The developed procedure was validated using a real matrix. Limit of detection was equal to 0.17 ng/g for majority of the compounds.. The created method was used to determine the degree of contamination of 108 natural honey samples from different regions of the world. The most frequently detected compound was acetamiprid, present in 88% of the tested samples, and followed by thiacloprid detected in 54% of honeys. The results confirmed the widespread exposure of bees to NQs in the agricultural landscape.

The developed method is characterized by high precision, accuracy, and selectivity, ensuring reliable determination of NQs in honey. Compared to the standard QuEChERS method, the modified SULLE is faster to perform, less expensive and requires fewer sample-preparation steps, making it an effective alternative in the analysis of pesticide residues in food.

3.11.A Exploring the Chemical Exposome through Advanced Target and Nontarget Screening: Bridging Occurrence, Transformation Products, and Human Health

3.11.A.T-01 Advancing the Chemical Exposome: Integrated Targeted and Non-targeted HRMS Investigation of PFAS Occurrence and Transformation in the Rhône River

Macorps Nicolas¹, Gaud Dervilly¹, Hugo Gascard¹, Jean-Pierre Faure², Brice Mourier³ and Cécile Miège⁴,
(1)ONIRIS, INRAE, LABERCA, France, (2)FDAAPPMA 69, La Tour de Salvagny, France, (3)Université Claude Bernard Lyon 1, LEHNA UMR 5023, CNRS, ENTPE, F-69518, Vaulx-en-Velin, France, France, (4)INRAE, Ur Riverly, Lyon, France, France

Per- and polyfluoroalkyl substances (PFAS) constitute a vast group of anthropogenic fluorinated compounds exceeding 7 million entries currently listed in PubChem. Targeted analysis captures only a fraction of PFAS owing to the restricted availability of commercial standards. In the southern Lyon area (France), a region marked by intense anthropogenic pressures including a major chemical industrial activity that have led to PFAS contamination and national-scale crises, local authorities implemented monitoring actions in 2022 focusing on 22 compounds in Rhône River waters, groundwaters, sediments and fish. However, contamination may have been underestimated as many emerging compounds remain unidentified. Although regional sources are mainly linked to a single fluoropolymer factory, additional inputs may also contribute. In this context, advanced non-targeted screening analysis (NTS) based on high-resolution mass-spectrometry (HRMS) is crucial for detecting both known and unknown PFAS, thereby supporting source identification. To assess the magnitude of contamination and identify compounds relevant to source tracing, this study combined a targeted analysis of 50 PFAS with NTS on the same extracts and HRMS platform (Thermo Exploris 120). Sampling of fish, sediments and groundwater (2024 – 2025) covered a longitudinal gradient including the Lyon area, with emphasis on an industrial harbour affected by a major fire (1987) and long-term aqueous film forming foam (AFFF) use. Fish were mostly contaminated with legacy PFAS, while groundwater and sediments were contaminated with both legacy and emerging PFAS, such as fluorotelomer sulfonate (FTS) and fluorotelomer sulfonamidoalkyl betaine (FTAB). Notably, 6:2 FTAB was found at concentrations comparable or even higher than those of PFOS in these matrices. Industrial harbour sediments showed the highest levels, whereas upstream of Lyon displayed significantly lower concentrations. Preliminary NTS annotations in groundwater samples revealed additional unexpected PFAS compounds spanning several classes. Our results highlight the need to complement targeted methods with non-targeted screening to achieve a broader characterization of PFAS occurrence. Emerging PFAS were seldom detected in fish, yet biotic matrices remain key to assessing contaminant transfer from abiotic compartments. Future work will refine suspect identification and semi-quantitation using structure- and ionization-matched reference standards.

3.11.A.T-02 Non-targeted screening of environmental contaminants in passive air sampler extracts from Montreal using LC-Q-TOF-MS and GC-Q-TOF-MS.

Stéphane Bayen¹, Lan Liu¹, Antoine Paul Gillet², Xianming Zhang³, David Bowman⁴, Frank Wania⁵, Philippe Apparicio⁶ and Géraldine Delbès²,
(1)McGill University, Canada, (2)Institut National de la Recherche Scientifique, Canada, (3)Chemistry and Biochemistry, Concordia University, Canada, (4)Brock University, Canada, (5)Department of Physical and Environmental Sciences, University of Toronto, Canada, (6)Sherbrooke University, Canada

Air pollution is closely associated with increased lung cancer incidence and mortality. Because many semi-volatile industrial chemicals, pesticides and combustion by-products have been classified as endocrine disrupting or genotoxic, their mixtures in urban air, even at trace levels, could have cumulative effects on human health. However, evidence for the impact of outdoor air pollution on the risk of other types of cancer and chronic diseases, remains limited, in part because the composition of such mixtures in outdoor air remains poorly characterized. Non-targeted analysis (NTA) based on high resolution mass spectrometry (MS), allows for the comprehensive analysis of contaminants in environmental samples. Previously, we developed an NTA approach to map chemical mixtures in outdoor urban air from passive air samplers (PASs) deployed during summer 2021 across the Island of Montreal, Canada, with twenty-five molecular features confirmed with analytical standards. Additional PAS sampling during different seasons and over different deployment times may yield information on the temporal pattern of the MFs of interest.

Here, we expand the previous study by deploying PASs at the same sapling sites (both residential and public area) in 2024 and 2025, to obtain spatial and temporal trends of chemical features across three different time points. Residues trapped in air samplers were extracted via accelerated solvent extraction and concentrated for LC-Q-TOF-MS analysis. Retrospective data processing and database screening were applied to characterize chemical mixtures of environmental contaminants including pesticides, flame retardants and plasticizers in outdoor urban air. Several of extracted features were successfully identified based on the accurate mass of

parent ion, isotopic patterns, retention time and multiple MS/MS fragment ions with matching abundance ratio. The temporal pattern of previous detected compounds as well as newly identified compounds were compared. This study will provide insight into risk assessment of airborne exposure to chemical mixtures and their effects related to human health.

3.11.A.T-03 Data-Driven Prioritisation of Transformation Products During Drinking Water Treatment

Ingrida Bagdonaite¹, Maria Margalef², Marja Lamoree¹ and Frederic Béen¹, (1)VU University Amsterdam (VU), Netherlands, (2)A-LIFE (Environment & Health), VU University Amsterdam (VU), Netherlands

Organic micropollutants (OMPs) are widely distributed in the aquatic environment and pose significant difficulties for (waste)water treatment. Advanced oxidation processes (AOPs), such as UV photolysis combined with hydrogen peroxide (H₂O₂), are commonly employed to degrade OMPs in water treatment. However, AOPs often generate numerous unknown transformation products (TPs), some of which may be hazardous. There is therefore an urgent need to understand how TP formation and their potential toxicity are influenced by AOP operating conditions. The main challenge in the characterization of unknown TPs consists of the development of a scalable and comprehensive method to detect and identify TPs, assess their potential (in-vitro) toxicity and link their formation to AOP. This study presents the development of a (bio)analytical platform to link the chemical and hazard space of TPs to the operational conditions of AOPs used in drinking water treatment. The workflow combines chemical analysis using orthogonal liquid chromatography (RP and HILIC), ion mobility separation with high-resolution mass spectrometry (IMS-HRMS), with computational tools to monitor TP formation and removal. Specifically, MS² similarity scores (e.g., Cosine, Tanimoto, MS²DeepScore) were used alongside analytical information (e.g., retention time, m/z, CCS) and K-means clustering to group transformation pathways. The approach was evaluated through controlled degradation experiments in both spiked and unspiked surface water using a pilot-scale AOP reactor. In addition, in vitro bioassays and in silico toxicity prediction tools are integrated to assess biological activity and prioritise compounds of concern. The prioritization workflow proved highly effective in reducing data complexity and focusing on TPs of potential concern, subsequently removing up to 98% of detected features. The prioritisation strategy highlighted distinct patterns in TP formation and persistence under different operational conditions. For example, a flame retardant and three associated TPs were tentatively identified: two TPs were confirmed via MassBankEU, while the third was assigned a probable structure using SIRIUS, CCS and MS² similarity to adjacent features. Although structural elucidation of TPs remains difficult due to the lack of reference MS² spectra and standards, this integrated approach enables a thorough evaluation of both chemical and biological risks associated with AOPs under varying operational conditions.

3.11.A.T-04 Non-target Analysis of Transformation Products in Drinking Water in and around Luxembourg

Emma Helena Palm¹, Federica Piras¹, Sara Izzo¹ and Emma Schymanski², (1)University of Luxembourg, Luxembourg, (2)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg

Drinking water is a source of human chemical exposure, yet monitoring relies on target analysis, leaving many compounds undetected. Transformation products (TPs) are especially overlooked because they often lack reference standards and may not be well documented. This is evident in Luxembourg, where only eight monitored compounds are pesticide TPs. Non-target screening aims to capture a broader range of contaminants, including TPs. This study applies non-target analysis to identify potentially hazardous TPs and precursors that are not routinely monitored in Luxembourg or neighboring regions.

Tap water samples were collected once a month over three months at 31 locations in Luxembourg and surrounds. 6 brands of bottled water were also analysed. The samples were preconcentrated using solid phase extraction and analysed with reversed phase chromatography coupled with high resolution mass spectrometry. The data analysis was performed using patRoön, while toxicity prediction for endocrine disrupting properties was performed using OPERA.

In total 171 compounds were annotated in the tap and bottled water samples in the first month of sampling. None of the compounds annotated in the bottled water samples are routinely monitored. 110 of the 131

compounds annotated in the tap water samples are also not included in routine monitoring. This shows the importance of non-target analysis to complement target analysis for identification of drinking water contaminants. 50 compounds were pharmaceuticals, indicating the need to monitor this compound class. 12 of the compounds annotated in bottled water and 16 of the compounds annotated in tap water were predicted to have endocrine disrupting properties, indicating that they pose a potential risk to human health. For the tap water samples, 10 of these compounds are not, to our knowledge, routinely monitored. 24 compounds annotated in the bottled and/or tap water were known TPs. Some of these compounds have multiple known precursors, while some of these precursors had substructures that were preserved in the TP. These persistent substructures can be used for grouping efforts in further research to identify other potential sources of these contaminants.

These results can hopefully help inform future drinking water monitoring efforts in Luxembourg as well as other EU countries and drinking water treatment research. It also provides insight into the chemical exposure via drinking water in the Luxembourg greater region.

3.11.A.T-05 Hidden Volatile Chemicals Indoors: Insights from Non-Target Analysis of European Homes

Jean Froment, Alexander Håland and Pawel Rostkowski, Department of Environmental Chemistry and Health Effects, NILU, Norway

People spend most of their time indoors, yet the mixture of airborne chemicals in homes is still poorly characterized. Many airborne compounds are linked to adverse health effects, making the identification of indoor pollutants essential. Non-target analysis provides a broad and unbiased approach to reveal the complex chemical mixtures present in indoor environments. In this study, two complementary strategies were applied to identify chemicals of concern in more than 200 European homes. Silicone foams were used to accumulate semi-volatile organic compounds, while sorbent tubes were deployed to capture volatile compounds. Foams were extracted and analyzed using gas chromatography coupled to high-resolution mass spectrometry. Volatile compounds collected on sorbent tubes were measured by thermal desorption gas chromatography. Statistical analyses were carried out to highlight characteristic indoor chemicals, and information on common uses was combined with a prioritization workflow to identify substances of potential concern. More than 800 chemicals were annotated across both analytical approaches. Most detected features occurred more frequently indoors than outdoors, underlining the significance of indoor exposure. Among the identified semi-volatile compounds, roughly half were natural products and half originated from anthropogenic sources, with many related to additives and personal care products. Plastic additives were found in nearly every home, confirming their widespread presence in indoor air. This supports growing evidence that plastics and their additives contribute not only to aquatic pollution but also to airborne contamination. Volatile organic compound (VOC) analysis revealed hundreds of chemicals in most homes, far exceeding the limited suites of compounds typically included in traditional VOC measurements. Personal care products and their additives emerged as an important class that is often overlooked in routine assessments. Overall, this study demonstrates that indoor environments contain a much broader and more complex mixture of chemicals than previously recognized. Hundreds of natural and anthropogenic compounds were detected using two complementary sampling and GC-HRMS methods, showing that exposure to additives, personal care products, and other indoor pollutants is more extensive than commonly reported.

3.11.B Exploring the Chemical Exposome through Advanced Target and Nontarget Screening: Bridging Occurrence, Transformation Products, and Human Health

3.11.B.T-01 Mapping Human Metabolism in Wastewater – An In-Depth Analysis Using Feature-Based Molecular Networking

Inga Haalck¹, Martin Krauss¹, Dennis Schmiede², Susanne Moebus², Werner Brack¹ and Carolin Huber¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Institute for Urban Public Health (InUPH) - University Hospital Essen, Germany

Human excreta and raw wastewater are complementary matrices that capture epidemiological information at the individual and population level. While both provide insights into health status, consumption behavior or

chemical exposure, their chemical complexity differs significantly. Wastewater is far more chemically complex than direct human excretion, as it captures several sources other than human excretion and is affected by dilution, matrix effects and in-sewer processes. Characterizing the overlap and transformation of chemical features from the point of excretion to their detection in wastewater is therefore essential for assessing how accurately wastewater can reflect human excretion.

This pilot study presents the first direct comparison of toilet flush samples and wastewater treatment plant (WWTP) influent using liquid chromatography-high-resolution mass spectrometry. Non-target screening in combination with feature-based molecular networking (FBMN) was applied to map and compare the broad detectable chemical space in both matrices.

Only ~25% of features overlapped between toilet flush and raw wastewater samples, showing that wastewater captures a limited portion of human excretion. FBMN further revealed patterns of feature detectability beyond their excretion, confirming the reliability of well-established WBE markers while highlighting the challenges for using phase II metabolites as potential biomarkers in WBE.

By combining NTS and FBMN, this study presents a powerful approach for mapping human-specific features in wastewater, enabling the identification of reliable biomarkers and evaluation of their stability and detectability across the sewer system. The findings provide new insights into the relationship between human excretion and wastewater influent while providing a new approach to advance WBE, improve exposure assessments, and broaden its applications in public health and environmental monitoring.

3.11.B.T-02 Characterising The Human Perinatal Chemical Exposome with Innovative Suspect and Non-Targeted Screening: Results from The PARC EU Interlaboratory Trial and Real-Case Study

Tarek MOUFAWAD¹, Kolawole Ayeni², Eirini BAIRA³, Lidia Belova⁴, Jade Chaker⁵, Clement CHALET⁶, Adrian Covaci⁴, Annelaure Damont⁶, Arthur David⁵, Mariana Fernandez⁷, Baninia Habchi⁸, Carolin Huber⁹, Tina Kosjek¹⁰, Martin Krauss⁹, Sophie Ndaw¹¹, Rosalie Nijssen¹², Herbert Oberacher¹³, Helena Plesnik¹⁰, Zan Rekar¹⁰, Elena Salamanca-Fernandez⁷, Aikaterini Termentzi³, Katrin Vorkamp¹⁴, Benedikt Warth², Linyan Zhu¹⁵, Bruno Le Bizet¹, Marja Lamoree¹⁶ and Jean-Philippe Antignac¹, (1)National Veterinary, Food and Food School of Nantes-Atlantique (ONIRIS), France, (2)University of Vienna, Austria, (3)Benaki Phytopathological Institute (BPI), Greece, (4)University of Antwerp, Belgium, (5)School of Advanced Studies in Public Health (EHESP), France, (6)Université Paris- Saclay, France, (7)University of Granada, Spain, (8)Département Toxicologie et Biométrie Laboratoire Biométrie, INRS, France, (9)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (10)Jozef Stefan Institute, Slovenia, (11)INRS, France, (12)Wageningen University and Research (WUR), Netherlands, (13)Institute of Legal Medicine and Core Facility Metabolomics, Medical University of Innsbruck, Austria, (14)Department of Environmental Science, Aarhus University, Denmark, (15)Aarhus University, Denmark, (16)VU University Amsterdam (VU), Netherlands

Early chemical exposures may predispose individuals to various health issues. Perinatal exposure assessment still remain particularly challenging, partly due to limited availability of suitable biological samples for comprehensive analysis. Suspect and non-targeted screening (SS/NTS) approaches open the door to an expanded detectable chemical space, capturing known pollutants and contaminants of emerging concern in a single run. These approaches are thus particularly suited to perinatal exposomic studies.

This work first reports an EU-wide interlaboratory trial combined with real-case profiling conducted by 11 laboratories in the frame of the PARC project. Maternal milk, serum and urine samples were collected from 30 Spanish mothers. Pooled samples of each type were prepared and spiked with 50 predefined QAQC exposure markers at 4 spiking levels. Participating lab applied their own in-house HILIC, RPLC-and/or GC- based HRMS SS/NTS workflows, from sample preparation to data processing.

The methodological assessment of the individual analytical workflows was done by comparing the detection rates and chemical-space coverages of each lab. Results demonstrated a globally good detection even at low spiking levels, and an improved coverage when complementary analytical platforms are combined. A more detailed statistical analysis was conducted by applying univariate and multivariate analysis to rely the captured chemical spaces and the detailed analytical parameters, leading to potential recommendations. A second clustering approach as well as an innovative scoring system for qualitative approaches (S-score) were also applied to describe and discuss the interlab results.

Second, the chemical profiling of all individual samples collected in the study was performed by these different partners. After 3 rounds of data consolidation and curation, more than 1000 markers of exogenous chemical exposure were identified with high confidence levels. These results documented real-life co-exposure to a wide range of compounds, including pharmaceuticals, industrial and food additives, and lifestyle markers. A larger scale real sample analyses campaign is on-going to expand these findings.

Taken together, these results demonstrate the capacity and interest of SS/NTS workflows for characterising

internal chemical exposures in human perinatal cohorts and provide practical guidance on methodological choices that enhance the captured chemical space and comparability across laboratories

This work was carried out in the framework of the European Partnership for the Assessment of Risks from Chemicals (PARC) and has received funding from the European Union's Horizon Europe research and innovation programme under Grant Agreement No 101057014.

3.11.B.T-03 Comprehensive Urinary Target and Suspect Screening of Endocrine-Disrupting Chemicals in Children and Their Association with Lifestyle Trends

Julen Segura Abarrategui¹, Nicola Montemurro², Joan O. Grimalt¹ and Sandra Perez Solsona², (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (2)Environmental Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Children are exposed daily to endocrine-disrupting chemicals (EDCs) through diet, inhalation, or dermal contact, which may pose health risks as they can interfere with estrogenic regulation, affecting child development. Urine, a non-invasive and easily obtainable matrix, is widely used to detect EDCs in exposure studies. Human biomonitoring has become a key tool for assessing exposure in populations.

The objectives of the present study were: (i) to assess exposure to 90 prioritized EDCs using a target screening (TS); (ii) to explore the presence of additional potential EDCs through a suspect screening (SS); and (iii) to examine the relationship between exposure to EDCs and various lifestyle factors (diet, body mass index (BMI), and socioeconomic status) in children.

The samples analyzed were obtained from the INMA cohort and included 350 children aged 8 years from Asturias, Spain. Additionally, 50 of these samples were randomly selected for the SS.

The TS was performed using low-resolution tandem mass spectrometry on an Agilent 6475 LC/TQ system. The SS was carried out using high-resolution mass spectrometry with an Orbitrap Eclipse™ Tribrid™ mass spectrometer, employing a suspected list of over 25,000 compounds.

In the TS, 12 compounds were detected with a frequency greater than 30 %, mostly from the bisphenol and benzophenone families. Non-parametric statistical tests were performed with these compounds to evaluate exposure trends according to lifestyle factors.

The results showed a slight correlation between urinary levels of bisphenol S and fish consumption, which was borderline significant ($p = 0.06$), indicating a trend in which higher consumption was associated with increased concentrations. A similar trend was observed for meat consumption ($p = 0.08$). No association was found with the intake of fruits and vegetables ($p = 0.56$). No significant relationships were observed between the exposure levels of any EDCs and BMI or socioeconomic status.

In the SS, six additional EDCs not included in the target list were tentatively identified with a confidence level of 2a.

These results provide a comprehensive assessment of exposure to EDCs. Furthermore, the limited number of EDCs detected in the SS, beyond those identified in the TS, suggests that the selection of prioritized compounds is appropriate and sufficiently representative. Bisphenol S showed a slight association with the consumption of animal-based foods, suggesting diet as a relevant exposure route.

3.11.B.T-04 Uncovering Environmental Drivers of Steatotic Liver Disease Through Integrated Human and Experimental Evidence

Matej Oresic¹, Shashank Gupta², Andi Alijagic³, João Marcos G. Barbosa³, Jade Chaker⁴, María Martín Grau⁵, Daniel Duberg³, Antonio Vidal Puig⁶, Stefania Carobbio⁵, Ann Daly⁷, Vlad Ratziu⁸, Jörn Schattenberg⁹, Elisabetta Bugianesi¹⁰, Quentin Anstee⁷, Jorke Kamstra¹¹ and Tuulia Hyötyläinen³, (1)No Affiliation, Sweden, (2)School of Medical Sciences, Örebro University, Sweden, (3)School of Science and Technology, Faculty of Business, Science and Engineering, Örebro University, Sweden, (4)Örebro University, Sweden, (5)Príncipe Felipe Research Center, Spain, (6)Institute of Metabolic Science, MRC MDU Unit, University of Cambridge, Cambridge, UK, United Kingdom, (7)Institute of Translational & Clinical Research, faculty of Medical Sciences, Newcastle University, Newcastle upon Tyne, NE2 4HH, UK, United Kingdom, (8)Assistance Publique-Hôpitaux de Paris, Hôpital Beaujon, University Paris-Diderot, France, (9)Department of Internal Medicine II, Saarland University Medical Centre, Homburg, Germany, Germany, (10)Department of Medical Sciences, Division of Gastro-Hepatology, A.O. Città della Salute e della Scienza di Torino, University of Turin, Turin, Italy, Italy, (11)Utrecht University, Netherlands

Metabolic dysfunction-associated steatotic liver disease (MASLD) affects about 25% of the global population and is increasingly recognised as a condition shaped not only by metabolic risk factors but also by environmental exposures. Emerging evidence suggests that endocrine-disrupting chemicals (EDCs) may contribute to MASLD development or progression, however, the specific chemicals involved and their metabolic mechanisms remain insufficiently understood. The aim of this study was to identify EDCs associated with MASLD severity and to elucidate the metabolic pathways through which they may influence liver pathology.

We performed a comprehensive exposome analysis of plasma samples from more than 1500 individuals in the European Steatotic Liver Disease (SLD) registry, integrating targeted EDC quantification with metabolomics and lipidomics using ultra-high-pressure liquid chromatography coupled to quadrupole time-of-flight mass spectrometry. Associations between chemical exposures, MASLD stages, and metabolic traits, including insulin resistance were assessed, with additional consideration of sex-specific effects. To support mechanistic interpretation, findings were compared with results from complementary in vivo and in vitro PFAS exposure models.

Perfluoroalkyl substances (PFAS) emerged as the exposure group most consistently associated with severity of liver damage. Metabolome-wide analyses identified clusters enriched in bile acids, lipid species, amino acids, and several gut microbiota-derived metabolites that mediated PFAS–liver trait relationships. In vitro models demonstrated that PFAS directly alter metabolic profiles, particularly impairing mitochondrial metabolism. Importantly, steatotic conditions combined with PFAS exposure produced substantially stronger metabolic disturbances than either PFAS exposure or steatosis alone.

In conclusion, this integrated human–experimental study identifies PFAS as key environmental contributors to severity of liver damage and highlights mitochondrial and gut–liver axis dysfunction as potential underlying mechanisms. These findings emphasise the need to incorporate exposomics into MASLD risk assessment and prevention strategies.

3.11.B.T-05 Inorganic and Organic Exposome Analysis to Investigate Placental Transfer and Pre-eclampsia

Max Lennart Feuerstein¹, Sebastian Granitzer², Simone Braeuer³, Gunda Koellensperger⁴, Claudia Gundacker² and Benedikt Warth¹, (1)Department of Food Chemistry and Toxicology, University of Vienna, Austria, (2)Medical University of Vienna, Austria, (3)Department of Natural Sciences and Sustainable Resources, Institute of Analytical Chemistry, BOKU University, 1190 Vienna, Austria, Austria, (4)Department of Analytical Chemistry, University of Vienna, Austria

The exposome, the totality of environmental and food-related exposures, is a key driver of human health and disease. Blood and tissue concentrations of chemicals are important internal exposure markers and can impact embryonic development and early life. Trace elements and metals are a crucial yet currently underrepresented part of the exposome. Furthermore, data on placental transfer of many organic chemicals and metals are still scarce, and systematic investigations are typically based on placental perfusion models.

Comprehensive characterization of the early-life exposome requires sensitive multi-analyte assays able to detect diverse chemicals at trace levels in small sample volumes. To overcome limitations of targeted human biomonitoring, we developed a workflow to identify and quantify toxicants and pollutants in low amounts of placenta, maternal blood and cord blood (i.e., 50 mg or 50 µL). Furthermore, we implemented a consistent sample preparation strategy to determine the inorganic and organic components of the human exposome from a single sample aliquot. Sensitive tandem mass spectrometry coupled to liquid chromatography (LC-MS/MS) was used for trace analysis and quantification of organic chemicals including plasticizers, perfluoroalkyl substances, personal care products, and food contaminants. Suspect screening using high-resolution mass spectrometry (LC-HRMS) further expanded chemical coverage beyond targeted analytes. Open-source software was used for data preprocessing, feature prioritization, and compound annotation. In addition, multi-element quantification was

carried out by inductively coupled plasma mass spectrometry (ICP-MS), targeting >50 elements, essential micronutrients and toxic metals.

In a pilot study, matched placenta, maternal blood and cord blood samples from participants of a cross-sectional study were analyzed and pre-eclamptic participants were compared with healthy controls. Using our novel approach for the first time, various endogenous compounds and xenobiotics including medical drugs, environmental, food, and lifestyle-related chemicals were annotated, identified and quantified in blood and placenta. The expanded analyte coverage enabled the comprehensive investigation of the metabolome and the organic and inorganic parts of the exposome and allowed assessment of the placental transfer of diverse xenobiotics and metals in real-life human samples.

3.11.P Exploring the Chemical Exposome through Advanced Target and Nontarget Screening: Bridging Occurrence, Transformation Products, and Human Health

3.11.P-Th047 Keep It Clean: Chemical Characterization of Indoor Dust Using Suspect and Non-Targeted Screening

Juan Escobar Arnanz, Covadonga Alonso, Silvia Royano, Irene Navarro, Adrian De la Torre and Maria Angeles Martínez, Center for Energy, Environmental and Technological Research (CIEMAT), Spain

Indoor dust is a complex and heterogeneous matrix containing a wide variety of organic compounds of different nature and origin. Many of these chemicals pose potential health risks to humans who are exposed to them through inhalation, ingestion and/or dermal uptake. Since population spends about 90% of its time in occupational and residential indoor environments, it is crucial to characterize pollutants present in indoor dust.

The current study proposes a comprehensive characterization of indoor dust collected from homes (n=14), offices (n=22), kindergartens (n=21) and highschools (n=26). Samples were extracted using a QuEChERS method and analyzed with gas chromatography coupled to high-resolution mass spectrometry (GC-QTOF HRMS). Dust samples were processed using a data processing workflow based on an initial suspect screening including more than 1,000 contaminants and comparing mass spectral data towards HRMS-libraries. Complementarily, those samples with a higher pollutant burden were further characterized through non-targeted screening (NTS) to identify and prioritize additional compounds.

More than 250 compounds were identified with the designed workflow at different confidence levels (Schymanski's scale), with 120 compounds being detected in 30% of the samples. Suspect screening revealed up to 61 contaminants detected in a single sample including pesticides, flame retardants and other industrial compounds. NTS aided to characterize 49-88 contaminants per sample, including other emerging contaminants (ECs) such as antioxidants (n=11) and their transformation products (n=8), non-phthalate plasticizers and plastic additives (n=10), UV filters (n=6) or photoinitiators (n=2). Some of the identified compounds, such as the transformation product of the antioxidant Irgafos 168, tris(2,4-di-tert-butylphenyl) phosphate (AO168?O), or the plastic additive 7,9-Di-tert-butyl-1-oxaspiro(4,5)deca-6,9-diene-2,8-dione, are considered pollutants of emerging concern and stood out in the analyzed samples.

In general, the developed strategy provided a more complete understanding of the presence of emerging compounds in indoor environments. Understanding indoor EC sources and their distribution is critical for assessing human exposure, especially for vulnerable who have greater dust contact.

3.11.P-Th048 Non-target Screening and Toxicity-Based Prioritization of Industrial Chemicals in Coastal Sediments

Mangong Shin¹, Seongjin Hong² and Hyo-Bang Moon¹, (1)Department of Marine Science and Convergence Technology, College of Engineering, Hanyang University, Korea, Republic of, (2)Department of Earth, Environmental & Space Sciences, Chungnam National University, Korea, Republic of

Coastal industrial regions such as Busan Bay are exposed to diverse mixtures of organic chemicals from shipbuilding, port logistics, and land-based industries. Sediments act as long-term sinks for both regulated and

emerging contaminants, making comprehensive chemical characterization essential. To achieve this, gas chromatography time-of-flight mass spectrometry (GC-TOF/MS) based non-target screening (NTS) was applied to surface sediments (n = 30) collected from shipbuilding areas, port terminals, and mixed industrial regions. Standard NTS workflows, including alignment, filtering, and spectral matching, were used to curate environmentally relevant chemicals classified into organosilicons, benzotriazole ultraviolet (UV) stabilizers, phthalates, polycyclic aromatic hydrocarbons (PAHs), heterocycles, organochlorides, and organotins.

Multivariate analysis of log-transformed intensities showed clear spatial differences. Principal component analysis (PCA) separated sediments into three groups representing shipbuilding, port logistics, and mixed regions, while hierarchical clustering (HCA) grouped chemicals according to these source influences. Organosilicons, benzotriazole UV stabilizers, and phthalates were enriched in shoreline industrial and port-associated areas, whereas PAHs, heterocycles, organochlorides, and organotins were characteristic of shipyard and industrial-complex sectors.

Relative toxic units (rTU), calculated by normalizing intensities with chronic toxicity values, showed that several subset of chemicals dominated potential toxicity. Organosilicons displayed the highest rTU values and were the strongest toxicity drivers. Organotins were the second major contributors, consistent with antifouling and ship-maintenance inputs. High-molecular-weight phthalates contributed more than low-molecular-weight plasticizers. Benzotriazole UV stabilizers showed moderate contributions, while PAHs and organochlorides contributed at secondary levels, reflecting both ongoing discharges and legacy pollution.

This study shows that combining NTS, multivariate clustering, and rTU evaluation effectively identifies characteristic chemical fingerprints and high-risk contaminants in coastal sediments. The dominant influence of organosilicons, organotins, and high-molecular-weight phthalates highlights the need for monitoring strategies addressing both emerging and persistent pollutants in industrialized marine environments.

3.11.P-Th049 Necrological pollution of the environment through human burial site leachate

Victoria Bolos¹ and Alberto Celma², (1)Research Institute for Pesticides and Water, University Jaume I, Spain, (2)Dept. Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences, Uppsala, Sweden

The environmental impacts of human burial practices remain understudied despite their potential to introduce a wide range of organic micropollutants (OMPs) into surrounding ecosystems. As populations grow and life expectancy increases, the number of individuals undergoing intensive pharmaceutical treatment at the end of life is expected to rise, raising concerns about the chemicals that may enter the environment through burial. Furthermore, traditional burial materials (including wooden coffins, varnishes, flame retardants, plasticizers, and embalming fluids such as formaldehyde) introduce additional contaminant sources that may leach into soil and water over time. This study investigates the extent of necrological pollution at the Berthåga municipal cemetery in Uppsala, Sweden, as a case-study where preliminary observations indicated abnormal toxicity and the presence of endocrine-active substances in a stormwater pond connected to a creek flowing through the burial grounds.

To evaluate the potential leaching of OMPs from the cemetery, water and sediment samples were collected at multiple points across the burial site and along upstream and downstream sections of the receiving Fyris River. Samples were subjected to solid-liquid extraction (for sediments) followed by multi-layer solid-phase extraction to cover a broad range of chemical properties and were subsequently analyzed using liquid chromatography coupled to high-resolution mass spectrometry. A suspect screening approach against pharmaceuticals, hormones, industrial chemicals, and flame retardants was used to identify potential contaminants.

The results revealed numerous OMPs in both water and sediment matrices, with two groups (flame retardants and industrial derivatives) showing particularly high occurrence within the burial site. Pharmaceuticals were also frequently detected, indicating that biological fluids from decomposing remains are reaching adjacent water bodies. Collectively, the data demonstrates that human burial sites can act as diffuse but significant sources of environmental contamination. These findings highlight the need to critically reassess burial-related infrastructure and management strategies to safeguard long-term environmental and public health.

3.11.P-Th050 Expanding the Scope of High-Throughput Effect-Directed Analysis with Orthogonal Separation Modes and Ion Mobility to Identify Endocrine-Disrupting Chemicals in Outdoor Stormwater Ponds

Lyen Marie Marcelo Castro¹, Maria Margalef², Frederic Béen³, Victoria Osorio⁴, Anna Jurado⁴, Laia Navarro-Martin¹, Marja Lamoree³ and Alberto Celma⁵, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (2)A-LIFE (Environment & Health), VU University Amsterdam (VU), Netherlands, (3)VU University Amsterdam (VU), Netherlands, (4)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (5)Swedish University of Agricultural Sciences (SLU), Sweden

High-throughput effect-directed analysis (HT-EDA) has been a powerful tool for prioritizing and identifying unmonitored endocrine-disrupting compounds in complex environmental mixtures. Its effectiveness can be greatly enhanced when coupled with multidimensional chromatography and ion mobility separation - high-resolution mass spectrometry (IMS-HRMS). This approach allows to expand chemical coverage, improve separation of coeluting and isomeric compounds, and increase confidence in compound annotation. The present study applies this expanded HT-EDA strategy to identify endocrine-active transthyretin (TTR)-binding chemicals in stormwater ponds, which are hotspots for urban-derived micropollutants. Water from outdoor stormwater ponds around Uppsala (Sweden) was collected and concentrated through solid-phase extraction (SPE). The stormwater extracts were screened on their ability to compete with thyroid hormone (TH) for binding to TTR, the TH distributor protein in plasma and cerebrospinal fluids. The extracts with higher binding affinity to TTR were selected for parallel fractionation into 96-well plates using two orthogonal separation modes: hydrophilic interaction chromatography (HILIC) and reversed-phase liquid chromatography (RP). The fractions were screened on a fluorescent competitive TTR-binding assay, and the chemical analysis of the same extracts was performed using trapped ion mobility-quadrupole time-of-flight MS. Suspect and nontarget screening was performed, and compound annotation was focused on features within fractions exhibiting high TTR-binding activity. The workflow revealed several candidates whose TTR-binding activities can be confirmed from literature, or can be prioritized for future testing. The additional dimensions in this strategy helped in addressing critical bottlenecks in EDA. Incorporating HILIC as a separation method improves the chemical coverage of EDA, allowing improved fractionation of complex mixtures containing polar or ionized compounds, which are not retained in conventional reversed-phase chromatography. In the nontarget screening of the active fractions, incorporating ion mobility as a dimension helped to distinguish analytes from coeluting matrix interferences, while acting as an additional line of evidence that increases the confidence level of the annotated features.

3.11.P-Th051 Determination of Estrogens in Drinking and Surface Water at low ng/L levels by direct injection using ACQUITY™ Premier LC System coupled to the Xevo™ TQ Absolute Mass Spectrometer **Sara Beverley, Ofure Idialu and Peter Hancock, Waters Corporation, United Kingdom**

Estrogens such as 17 α -ethinylestradiol (EE2), 17 α -estradiol, 17 β -estradiol (E2), estrone (E1), and estriol (E3) are endocrine-disrupting compounds of significant environmental concern, three (EE2, E2, and E1) with extremely low Environmental Quality Standards (EQS) proposed under the EU Water Framework Directive (WFD). Achieving these ultra-trace levels (0.017–0.36 ng/L) has traditionally required labor-intensive sample preparation steps, including derivatization and large-volume extraction (up to 1 L).

This study presents a highly sensitive LC-MS/MS method using the ACQUITY™ Premier System coupled to the Xevo™ TQ Absolute Mass Spectrometer for direct injection analysis of estrogens in drinking and surface water. Method performance was successfully evaluated using matrix-matched calibration curves, achieving excellent sensitivity (1 ng/L) and selectivity for all five target estrogens.

Baseline separation of 17 α -E2 and 17 β -E2 was obtained using a 150 mm column, with robust retention, resolution, and peak shape for all analytes within an 8-minute run time. Response was linear over a range of 1 - 500 ng/L, with ion ratios and RSD values (<10%) meeting required tolerances, demonstrating repeatability and accuracy at lowest ng/L levels. Matrix effects were evaluated (16–29%) and found acceptable for both drinking and surface water.

Increased sensitivity enables the use of reduced sample volumes (one-tenth of the previously required 1 L), significantly decreasing analysis time and chemical waste. These results confirm that this streamlined workflow supports compliance with revised EU WFD requirements while improving laboratory efficiency and sustainability.

3.11.P-Th052 Bridging Chemical Analysis and Bioassays in Breast Milk to Assess Early-life Exposure

Naroa Lopez-Herguedas¹, Georg Braun², Niklas Wojtyasiak² and Beate Escher², (1)*Helmholtz Centre for Environmental Research (UFZ)/Plentzia Marine Station (EHU), Spain,* (2)*Helmholtz Center for Environmental Research (UFZ), Germany*

Humans are daily exposed to a wide variety of chemicals, many of which are bioactive and may contribute to adverse health outcomes. Within the "One Health" framework, this study aims to develop a holistic extraction methodology for xenobiotics with diverse physicochemical properties in breast milk and to integrate it into an effect-based approach to better assess potential toxicological impacts relevant to infant development. Several extraction protocols were evaluated, using as a starting point an existing method for human plasma combining polydimethylsiloxane (PDMS) disks extraction with solid-phase extraction (SPE). Given the high lipid and protein content of breast milk, additional clean-up steps were evaluated: lipid removal using Captiva Enhanced Matrix Removal (EMR) cartridges in combination to PDMS, and a low-temperature protein precipitation (PP) with acetonitrile (AcN) and hexane. Polar and semi-polar contaminants were analyzed via liquid chromatography-high resolution mass spectrometry (LC-HRMS), while hydrophobic compounds were assessed with gas chromatography-high resolution mass spectrometry (GC-HRMS). A battery of bioassays was applied to assess developmental neurotoxicity, mitochondrial toxicity, oxidative stress response, immunosuppression and androgen receptor antagonism. Results underscored the challenges of integrating chemical analysis and bioassays into a single workflow. PDMS extraction improved the recovery of hydrophobic compounds compared to extraction with hexane, while EMR clean-up showed to be a relevant step, with around 50% of the recovered compounds falling within the acceptable recovery range (60%-140%). Largest losses were observed for hydrophobic compounds ($\log K_{ow} > 3$), although EMR clean-up slightly improved their extraction efficiency. Effect recoveries for developmental neurotoxicity aligned with the chemical recoveries, with PP using AcN and hexane performing the worst. In contrast, the combination of PDMS with PP (AcN) and EMR-SPE preserved significant fractions of bioactive chemicals, showing mean effect recoveries of around 55% and 25%, respectively. These findings suggest that hydrophilic compounds may be major contributors to the observed activity. Further experiments will include additional toxicological endpoints, like mitochondrial toxicity, oxidative stress response, immunosuppression and androgen receptor suppression, to improve toxicological coverage across a wider range of disease-related mechanisms.

3.11.P-Th053 PREVALENCE OF URINARY TRICLOSAN AMONG ADVANCED LUNG CANCER PATIENTS IN VOJVODINA

Nataša Milić¹, Danica Szadanić-Velikić², Milorad Španović³, Mirjana Ševo⁴, Jan Sudji³, Maja Milanović¹ and Nataša Milošević¹, (1)*University of Novi Sad, Faculty of Medicine, Department of Pharmacy, Novi Sad, Serbia, Serbia,* (2)*University of Novi Sad, Faculty of Medicine, Institute for Pulmonary Diseases of Vojvodina, Clinic for Pulmonary Oncology, Sremska Kamenica, Serbia, Serbia,* (3)*University of Novi Sad, Faculty of Medicine, Institute of Occupational Health Novi Sad, Novi Sad, Serbia, Serbia,* (4)*University of Novi Sad, Faculty of Medicine, Novi Sad, Serbia, Serbia*

Environmental pollution as a major risk factor alongside smoking came into focus of lung cancer studies. Urinary triclosan concentrations were significantly associated with breast cancer risk, although currently there is no direct evidence in human data establishing a link between triclosan exposure and the lung cancer development. In this research the prevalence of urinary triclosan among newly diagnosed advanced stage lung cancer patients of both genders was determined.

A total of 190 patients (44.7% female) with advanced stage (III/IV) lung cancer diagnosed at the Institute for Pulmonary Diseases of Vojvodina, Serbia, were enrolled: 61 patients with small-cell lung cancer (45.9% female), 67 patients with adenocarcinoma (41.8% female) and 62 patients with squamous cell cancer (48.4% female). Triclosan was analyzed using gas chromatography-mass spectrometry in the first morning urine sample within 24h of hospitalization.

In 29.5% (56/190) urine samples triclosan was measured above limit of quantification with average concentration 0.161 ± 0.141 $\mu\text{g/L}$ or 0.535 ± 1.070 $\mu\text{g/g}$ creatinine. There were no differences in frequency of quantification between genders (27.6% male vs. 31.8% female). However, there was 3.33 times (95%CI 1.48-7.50, $p=0.037$) higher chance of urinary triclosan quantification in adenocarcinoma patients (41.8%) in comparison to squamous cells cancer ones (17.7%) with no differences when compared to patients with small-

cell lung cancer (27.9%). This trend was more pronounced among females with adenocarcinoma (51.8%) vs. squamous cell cancer (20%) with 4.31 higher chance (95%CI 1.37-13.89, $p=0.0145$) of quantifying triclosan. The odds for triclosan presence among males with adenocarcinoma (35%) vs. squamous cell cancer (15.6%) was 2.91 times higher (95%CI 0.92-9.22, $p=0.07$). Finally, triclosan was 3.23 times more often quantified (95%CI 1.03-10.11, $p=0.044$) among females with adenocarcinoma (51.8%) vs. small-cell lung cancer counterparts (25%).

Almost one-thirds of patients enrolled in this study had triclosan in their urine sample with highest frequency of quantification among patients with adenocarcinoma. Further studies are urgent in order to determine its influence on survival rate among adenocarcinoma patients non-occupationally exposed to triclosan and detecting the probable sources of exposure.

3.11.P-Th054 Prioritisation framework to identify relevant substances for assessing the impact of environmental contaminants on human exposure

Nicole Badow¹, Elodie Bouhouille², Matteo Creta³, Valeria Dulio⁴, Ruth Moeller³, Emma Schymanski⁵, Katrin Vorkamp⁶ and Gunnar Thorsén⁷, (1)German Environment Agency (UBA), Germany, (2)Scientific Institute of Public Service (ISSeP), Belgium, (3)Laboratoire National de Santé, Luxembourg, (4)Ineris, France, (5)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg, (6)Department of Environmental Science, Aarhus University, Denmark, (7)Swedish Environmental Research Institute, Sweden

Humans are exposed to organic compounds from various sources, including indoor air, dust, drinking water, and garden soil - areas less systematically assessed than food. Chemical analyses of these matrices can provide valuable insights into which environmental sources contribute to the presence of contaminants in humans. Since monitoring studies are both resource- and time-intensive, optimising monitoring strategies is essential to ensure efforts focus on the most relevant compound groups, environmental matrices, and endpoints. Within the Horizon Europe Partnership for the Assessment of Risks from Chemicals (PARC) a multicriteria prioritisation process, inspired by the NORMAN prioritisation scheme based on action categories, was proposed to identify relevant (groups of) substances to monitor in indoor air, drinking water, indoor dust and soil, aiming to assess the impact of environmental contaminants on human exposure.

An initial list of approximately 90,000 substances was created using a comprehensive literature review, the NORMAN Suspect List Exchange and the EU LCI list as sources. Ranking criteria were developed to prioritise substances based on use, toxicity, hazardous classification, physical properties and occurrence data where available. Matrix-specific decision trees were developed for the four matrices. According to the decision trees the initial list was enriched with further data to create a master list.

As a result of the application of the decision tree, approximately 500 substances for soil, 4,800 for indoor dust, 4,000 for indoor air, and 1,700 for drinking water were prioritised and classified into two tiers: (1) targeted analysis candidates and (2) suspect/non-target screening (SS/NTS) candidates. Suspect screening can provide an initial overview of potentially present substances, enabling more focused follow-up via target analysis.

The decision tree approach was successful to prioritise relevant lists of compounds using a systematic, transparent and reproducible ranking approach. The findings from this study, together with an additional expert judgment step, will serve as recommendations for monitoring contaminant classes that are currently insufficiently investigated in the environment. This will deepen the understanding of the impact of environmental contaminants on human health.

3.11.P-Th055 Positive Control Substances for Experiments Described in the EFSA Guidance on the Impact of Water Treatment Processes

Peter Crick¹, Ivan Strepponi¹, Arnaud Serafyn¹, Andreas Irmer¹, **Peter Hvorslev, M.Sc.^{2,3}** and Neil Robinson¹, (1)IES - Innovative Environmental Services Ltd., Switzerland, (2)Eurofins IES AG, Switzerland

The European Food Safety Authority (EFSA) guidance document on the impact of water treatment processes describes a series of experiments for the generation and identification of transformation products. These processes include chlorination, chloramination, oxidation, ozonolysis, and ultraviolet light (UV) treatment.

To confirm that the test system was correctly prepared and has the potential to form transformation products, a positive control is needed. The positive control can be achieved using an indirect method, for example measurement of the reagent concentration using a colorimetric method with N,N-diethyl-p-phenylenediamine (DPD) or indophenol.

Alternatively, a direct method may be used, i.e. a compound that degrades under the reaction conditions. In this case, the selected compound(s) should have the following characteristics:

- Degrade reliably and reproducibly
- Degrade under all of the conditions to be tested
- Readily available commercially
- Relatively inexpensive
- Easy and safe to handle

Additional points may also be considered. For example, a compound that produces transformation products covering a wide range of polarities may also be used as a quality control for analytical work. Here, we present results of experiments to test various compounds for these properties.

Experiments were carried out in a standard water with addition of organic carbon obtained from the Suwannee River as defined in the guidance document. Chlorination with sodium hypochlorite was carried out at three different pH levels (6.5, 7.5, and 8.5). Monochloramine was prepared from sodium hypochlorite and ammonium chloride to carry out the chloramination experiments. For the oxidation process, an aqueous chlorine dioxide solution was obtained by addition of sulfuric acid to a solution of sodium chlorite.

Ozonolysis was carried out by treating the test substances with a freshly prepared solution of ozone in water, while the UV process was performed in an irradiation chamber fitted with a medium pressure UV lamp.

Liquid chromatography coupled with mass spectrometry (LC/MS) was used to analyse the test substances and transformation products formed in these processes. Identification of the transformation products was carried out using high resolution-accurate mass spectrometry (HRAM) with data analysis using a non-target screening workflow, while quantitative analysis was performed by HRAM or multiple reaction monitoring (MRM) on a triple quadrupole mass spectrometer.

3.11.P-Th056 Challenges in the Annotation of Environmental Contaminants with Nontarget Screening - Quality and Information of Tandem Mass Spectra

Wilco Nijenhuis¹, Kas Houthuijs², Marja Lamoree² and Frederic Béen², (1)Amsterdam Institute for Life and Environment (A-LIFE), VU University Amsterdam (VU), Netherlands, (2)VU University Amsterdam (VU), Netherlands

Advances in high-resolution mass spectrometry (HRMS) have driven a shift toward broad screening methods in environmental analysis. Central to these methods are tandem mass spectra (MS2), used for feature annotation, (sub)structure prediction, and toxicity estimation, however the MS2 data quality greatly affects this. A machine learning model was recently developed to assess MS2 quality using mathematical features. While it aligns with expert-based assessments, discrepancies remain when compared to identification scores from such as SIRIUS. To clarify these differences, this study investigates diagnostic patterns in MS2 spectra and biases across chemical space.

Machine learning models are applied to predict the probability of correct annotation and to examine how chemical-space coverage, MS2 quality, and retrieval performance relate, using experimental and library spectra from various instruments and sample types. In total, 145 mathematical MS2 descriptors were computed to characterize spectrum quality, i.e. the likelihood of successful annotation. The best model, based on 18 optimized descriptors, achieved 73% accuracy and 86% precision. Feature-importance analysis revealed clear quality-related trends, with negatively contributing effects often linked to noise or insufficient or excessive fragmentation.

Applying the model trained on neat reference standards to experimental datasets from diverse instruments and sample types revealed shifts in descriptor distributions, indicating that parts of the data fall outside the model's applicability domain. These shifts suggest that, for certain data types, MS2 quality can negatively affect

annotation outcomes. Ongoing work will investigate the causes of inconsistencies between experimental and library spectra and improve understanding of instrument- and matrix-related variability.

In conclusion, the model can prioritize spectra more likely to yield correct annotations. Understanding which spectral characteristics provide diagnostic value may improve molecule retrieval, increase library match rates, and support better-curated libraries. Filtering low-information spectra from libraries and experimental datasets can further increase annotation success, and focusing on information-rich spectra improves efficiency and reduces costs. Downstream applications such as toxicity prediction, structure annotation, and related predictive models will likewise benefit from the removal of low-informative spectra.

3.11.P-Th057 Retention index alignment algorithm for the alignment of data from different NTS studies without requiring shared standards

Alexander Becking¹, Thomas L. ter Laak¹, Rick Helmus² and Saer Samanipour², (1)KWR Water Research Institute, Netherlands, (2)University of Amsterdam (UVA), Netherlands

Non-target screening (NTS) through liquid chromatography coupled to high resolution mass spectrometry (LC-MS) is valuable to environmental monitoring because of the ability to detect a broad range of (un)known organic micropollutants (OMP's). Laboratories are frequently acquiring a lot of NTS monitoring-data of drinking-, ground- or surface-water. Comparison of their NTS-datasets allows more comprehensive analysis of OMP's occurrence, aids prioritization of unknown features, and can help identification of unknown features. The alignment of retention time is one of the key aspects to compare datasets. However, differences between batches or between laboratories, such as analytical methods and equipment, can make it impossible to compare their measured retention times, especially when their standards have little or no overlap. Recently, retention indices (RI) for LC were introduced, enabling comparison of RI values via a set of standards that is injected every batch. However, this constitutes a large and expensive challenge to jointly organize, and would exclude historic or future sample batches that do not contain the same standards.

We present a retention alignment algorithm based on predicted RI for the alignment of NTS-data across time and space without the need for overlapping standards.

To enable alignment without overlapping standards, the algorithm operates by applying a RI prediction model on a number of known analytes measured in the same analysis batch. Their retention time to RI relationships are used to build a model that maps a measured retention time to a probability distribution in the generalized RI space. The features' RI distributions are subsequently combined with their respective m/z values to align them across time and space. We explored advisable numbers of input standards, several strategies to build the retention time to RI model and several strategies to perform alignment using the RI and m/z values. The algorithm is evaluated with data from 4 laboratories across the Netherlands. Altogether, comparing of data from different methods has the potential to advance routine NTS monitoring programs.

3.11.P-Th058 A quantitative structure-response relationship model to estimate concentrations of plasticizer metabolites identified in urine using LC-HRMS without reference standards

Yong-Lai Feng¹, Anca Baesu¹, Jerrie Feng², Vanessa Martinez³ and Yan Li¹, (1)Health Canada, Canada, (2)Nanyang Technological University, Singapore, (3)University of Ottawa, Canada

Plasticizers are characterized as endocrine disruptors, and human exposure to these chemicals can adversely affect the reproductive system. Non-targeted analysis (NTA) using liquid chromatography – high resolution mass spectrometry (LC-HRMS) is a discovery-based approach for screening and identifying hundreds of compounds and metabolites in human samples without a priori knowledge of the chemical species present in the sample. However, while NTA methods need to be standardized in order to provide reliable and reproducible results on identification of unknown chemicals/metabolites, it is crucial to provide quantitative concentrations for these compounds identified in NTA to support exposure assessment. Therefore, there is an urgent need to develop quantitative NTA (qNTA) methods. Isotopically labeled internal standards (IS) are routinely used in targeted analyses to correct for the effects of sample matrix and ESI conditions but have not yet been considered for qNTA model development. In this study, we describe a quantitative NTA model using LC-electrospray ionization (ESI)-HRMS that combines quantitative structure-response relationship (QSRR), LC retention behavior, and IS for signal normalization. This relationship can be used to estimate the signal response factors of chemicals and approximate the concentrations of plasticizer metabolites without reference standards. The model consists of 12 variables, (retention time and 11 molecular descriptors), and was able to estimate response factors for eleven test chemicals with an error less than 30%. The study demonstrated that the model can be updated with routine (e.g. daily) calibration curves and estimate concentrations of unknown metabolites in urine with an error less than 50% for most compounds. The inclusion of IS in NTA workflows can reduce the variation in

results introduced during sample preparation, injection and ionization, and data analysis, thus broadening the application of models between different types of instruments (e.g. with significant response factor (RF) difference). Our approach enables a fast and simple estimation of the concentration of unknown metabolites of phthalates and their alternative chemicals without the need for respective reference standards. More importantly, the method is applicable to routine NTA studies and can be adapted to different LC-MS systems (Agilent QTOF and Thermo Orbitrap) by simply updating the model with daily calibration data without having a significant impact on its prediction accuracy.

3.11.P-Th059 Modernizing the Analysis of Flame Retardants in Environmental Matrices: Eliminating the Use of Helium Carrier Gas With Gas Chromatography Atmospheric Pressure Chemical Ionization (GC-APCI)

David Gould¹, Douglas Michael Stevens², Aron Dekkers¹ and Peter Hancock¹, (1)Waters Corporation, United Kingdom, (2)Waters Corporation, Germany

Polybrominated diphenyl ethers (PBDEs) are persistent flame retardants that undergo long range environmental transport through volatilization and deposition cycles in a process known as the grasshopper effect. This mechanism moves PBDEs from warmer to colder regions, resulting in their accumulation in air, soil, water, and biota even in areas where they were never manufactured. Their persistence and global distribution led to inclusion in the Stockholm Convention, which mandates monitoring of PBDEs and other persistent organic pollutants (POPs) across 186 countries.

Historically, PBDE analysis relied on capillary gas chromatography (GC) coupled with high resolution magnetic sector mass spectrometry (HRMS) using electron ionization (EI) for high sensitivity and specificity. However, EI GC-HRMS use is declining due to high cost, maintenance demands, and expertise requirements. This study evaluates GC atmospheric pressure chemical ionization (GC-APCI) combined with tandem quadrupole (TQ) mass spectrometry (MS/MS) as an alternative. The GC-APCI TQ system demonstrated improved speed and robustness while maintaining equal or better sensitivity and specificity compared to EI GC-HRMS. Additionally, the instrument's use of a single nitrogen supply for carrier, reagent, and collision gases supports sustainability goals.

The optimized method achieved a 27-minute runtime, with BDE 209 eluting at 22 minutes with symmetric peak shape ($a/b = 0.993$) and 10.3 s width. Calibration curves for 25 analytes were linear across three orders of magnitude (average $r^2 = 0.999885$), with parts per trillion (ppt) limits of detection. These results indicate that GC-APCI TQ MS/MS is a fit for purpose, sustainable alternative for PBDE monitoring, aligning with global regulatory requirements and advancing analytical capabilities for persistent organic pollutants.

Disclaimer/Disclosure:

3.11.P-Th060 Detection of Surfactants using Liquid Chromatography Coupled with High Resolution Mass Spectrometry

Verena Reitsam, Andreas Anwander and Wolfgang Körner, Bayerisches Landesamt für Umwelt, Germany

At the Bavarian Environment Agency each year approximately 250 to 300 incidences of local environmental accidents are elucidated analytically. In case a surface water contamination shows foam building, one focal point of analytical investigation are surfactants.

A liquid chromatograph with a RP-C18 column coupled with a high resolution mass spectrometer ($R = 120,000$) is used to analyse surface water samples for the presence of surfactants.

First step is to check the measurability of reference substances with the instrumental method and to establish a database for surfactants. With the instrumental method 76 substances within the following 7 different surfactant groups can be determined: alkyl ether sulfates, alkyl sulfates, linear alkylbenzene sulfonates, secondary alkyl sulfonates, alkyl ethoxylates, alkyl benzyl dimethylammonium compounds and alkyl trimethylammonium compounds

Due to the overall use of surfactants in different products of daily life, rather high laboratory blank values occur. Therefore, second step is to minimize blank values but also to find a strategy how to work with unavoidable blank values. A cause effect diagram is the starting point to find trigger points which cause blank values. Finally, it is aimed to express semi-quantitative results for the different surfactant groups.

3.12.A Fate and Toxicity of Metals: Recent Scientific Advancements and Their Application in Environmental Regulations

3.12.A.T-01 Source Contributions to Copper in the Danube River: Integrating Emission Apportionment with Fate Modelling

Kevin J Rader¹, Jos van Gils², Sean Comber³, Stijn Baken⁴ and Tara Miller⁵, (1)Mutch Associates LLC, (2)Deltares, Netherlands, (3)Environmental Science, University of Plymouth, United Kingdom, (4)Flemish Institute for Technological Research (VITO), Belgium, (5)International Copper Association (ICA), United Kingdom

Copper (Cu) enters European rivers from multiple sources, including agriculture, road traffic, wastewater, and natural background. Internal recycling from river sediments may also contribute to Cu levels in the water column, but the magnitude of this contribution remains uncertain. This study integrates recent country-level source apportionment for Cu loads with a river fate and transport model to assess how spatially distributed loads translate into water column concentrations in the Danube River.

Cu emissions from twelve source categories were quantified using activity rates from the Danube Hazardous Substances Model (DHSM) and emission factors developed in recent European assessments. The model predicts time-variable water column Cu while accounting for net settling of particulate Cu. To evaluate potential release of historically deposited Cu, a simplified box model was developed that incorporates settling, sediment-water diffusive exchange, resuspension, and burial. A tracer was implemented to track historical Cu released from sediment.

Spatially resolved Cu loads were applied in both models and compared with monitoring data from the Danube River Basin for 2015 to 2021. Although some deviations were observed, both models reproduced the overall magnitude of Cu concentrations along the river. The DHSM was then used to assess contributions from individual sources by running scenarios in which each source category was activated independently. Results show that road-runoff inputs, soils and natural background, and livestock manure are major contributors, with the relative importance of these sources varying between the upper and lower Danube. Preliminary results from the simplified box model indicate that the tracer approach can quantify the influence of legacy Cu released from sediments, though further refinement is needed.

This work demonstrates that country-level source apportionment can be integrated into river-scale fate and transport models to interpret observed Cu concentrations and support evaluation of sediment contributions. The combined framework provides a useful tool for managing Cu and other constituents in large river systems.

3.12.A.T-02 Accumulation, subcellular distribution and toxicity of indium in the green alga *Chlamydomonas reinhardtii*

Severine Le Faucheur¹, Sandra Mounicou², **Ophélie Fontaine²** and Emeline Delcros², (1)Ipren, University of Pau and the Adour Region, France, (2)University of Pau and the Adour Region, France

Indium (In), a trivalent hard-acid metal is increasingly used in electronic industries, yet its bioavailability and toxicity to organisms remain poorly documented. The aim of this study was to provide additional knowledge on its impact on microalgae as well as on the detoxification mechanisms developed by algae. The model green alga *Chlamydomonas reinhardtii* were thus exposed for 96 h to indium concentrations ranging from 8×10^{-9} to 4×10^{-7} M and examined for their growth and subcellular parameters. Intracellular indium concentration was also assessed following cellular washing with ethylenediaminetetraacetic acid and its subcellular fractionation was performed using differential ultracentrifugation. Indium speciation in the cytosol was further characterized using size-exclusion chromatography coupled with inductively coupled plasma mass spectrometry (SEC-ICP-MS). Furthermore, indium speciation in exposure media was calculated using thermodynamic modeling with Visual MINTEQ 4.0.

Chlamydomonas reinhardtii tolerated indium concentrations up to $36.5 \mu\text{M}$ without significant effects on growth, chlorophyll a fluorescence, cellular size, and granularity and oxidative stress. Internalized indium was observed to plateau starting at $4.2 \mu\text{M}$, while surface-adsorbed indium continued to increase with exposure. This phenomenon was explained by the extensive hydroxide precipitation of indium, limiting its bioavailability.

Internalized indium was mainly localized in granular and organelle fractions, with only minor association with heat-stable or denatured proteins, suggesting detoxification via sequestration in phosphate-rich compartments rather than thiol-based binding. Analysis of cytosol fraction with SEC-ICP-MS revealed that indium was predominantly bound to >470 kDa biomolecules and to low-molecular-weight ligands <10 kDa. Overall, indium displayed low bioavailability and limited toxicity to microalgae under near-neutral pH conditions. Its intracellular behavior closely resembles that of other hard trivalent metals, with chemical speciation, precipitation, and compartmentalization governing both accumulation and biological impact.

3.12.A.T-03 Bioaccumulation of radium-226 in the freshwater snail *Lymnaea stagnalis*: water quality effects and internal distribution

Léna Guimard, Claude Fortin and Anne Crémazy, Institut National de la Recherche Scientifique, Canada

Radium-226 (²²⁶Ra) is a naturally occurring radionuclide that may be released into aquatic ecosystems from mining operations. It may be of concern to aquatic ecosystems, because of its long half-life (1600 years), its potential for bioaccumulation and its radiotoxicity. Yet, there is currently very few ²²⁶Ra ecotoxicological data for aquatic organisms, creating uncertainties on the ecological risk assessment (ERA) of this radioelement in fresh waters. Notably, there is very a lack of knowledge on the environmental factors influencing ²²⁶Ra bioavailability to aquatic organisms. Our first objective was to evaluate how water quality may influence ²²⁶Ra bioavailability (and thus toxicity) in a model invertebrate, using the Biotic Ligand Model (BLM) framework. In the lab, we conducted aqueous ²²⁶Ra bioaccumulation experiments with the great pond snail *Lymnaea stagnalis* at varying water quality (pH, DOC, hardness and Ca). Data seem to agree very well with BLM predictions, with water hardness being by far the most important bioavailability modifying factor, as expecting from the strong analogy between ²²⁶Ra and Ca. The data suggests that, at the very least, a hardness-based water quality guideline should be considered for ERA. A second objective was to investigate the internal fate of ²²⁶Ra in juvenile *L. stagnalis* (namely its tissue and subcellular distributions), to gain insights into potential biological targets and detoxification mechanisms. We found that ²²⁶Ra was most concentrated in the Ca carbonate shell, where it is essentially detoxified. The various soft tissues (mantle, hepatopancreas, etc.) had similar ²²⁶Ra concentrations, suggesting that no particular organ can be considered a target of ²²⁶Ra toxicity. Overall, total soft tissue accumulation ²²⁶Ra was moderate compared to other trace metals tested for *L. stagnalis* under similar exposure conditions, possibly because of a tight Ca-like homeostatic control and incorporation of internalized ²²⁶Ra into the growing shell. A longer ²²⁶Ra exposure may eventually lead to relatively great ²²⁶Ra contents in the shell, but the radiological consequences of such external accumulation would likely be limited compared to a long-term ²²⁶Ra build-up within the endoskeleton of vertebrates. Subcellular distribution data are currently being collected to explore the intracellular handling of this radionuclide.

3.12.A.T-04 Mercury and Methylmercury Bioaccumulation in Caged Gammarids Across Lotic Systems of the Rhine-Meuse River Basin (France)

Victor Lachaux¹, Olivier Geffard Pr², Marina Coquery¹, Aymeric Dabrin¹, Rémi Recoura-Massaquant¹ and Ghislaine Grisot¹, (1)INRAE - RiverLy, France, (2)National Research Institute for Agriculture, Food and Environment (INRAE), France

The distribution and toxicity of mercury (Hg) in lotic ecosystems are largely determined by its chemical speciation. In the upper anoxic layers of sediments, inorganic mercury can be converted to methylmercury (MeHg), its most toxic form, which readily bioaccumulates and biomagnifies through food webs. In France, caged gammarids (*Gammarus fossarum*) are used for routine chemical monitoring, including HgT concentrations. HgT concentrations are being used as a proxy of MeHg concentration in gammarids but this relationship remains poorly documented in benthic invertebrates, raising uncertainties about the reliability of this proxy.

To address this issue, we deployed caged gammarids at 27 sites in the Rhine-Meuse watershed to assess the MeHg bioaccumulation of caged gammarids under environmental conditions, evaluate the variability of the methylmercury percentage (%MeHg) and determine the spatial variation of MeHg across sites in caged gammarids. Sites were selected to cover a wide range of HgT concentrations (<0.05 – 300 ng.g⁻¹ dw). HgT concentrations were measured by direct mercury analyzer (DMA-80) and MeHg concentrations by gas chromatography coupled to inductively coupled plasma mass spectrometry (GC-ICPMS).

The HgT and MeHg concentrations averaged respectively 39.9 ± 8.6 and 26.5 ± 4.8 ng.g⁻¹ (mean $\pm$ sd), which was in the lower range but consistent with the literature and available data. Still, both analytical methods allowed site differentiation. The methylmercury percentage varied from 49 to 93%, which suggests that

gammarids may accumulate MeHg and HgT differently depending on environmental conditions. Thus, the currently used metric HgT in caged gammarids may not be a reliable proxy of Hg contamination in streams.

To better assess site-specific effects on bioaccumulation dynamics of MeHg, we calculated the normalized difference (ND) between individuals prior to exposure (control) and those after exposure. Four significantly distinct site groups were then identified by hierarchical clustering. The spatial variability of ND MeHg was consistent with the historical metal contamination in the Rhine-Meuse river basin, mainly located within the Rhine watershed. Overall, MeHg measurement in caged gammarids showed good signs of usability as a proxy for Hg contamination in lotic systems but further investigation is needed, notably a better understanding of the MeHg toxicokinetics in gammarids.

3.12.A.T-05 Evaluating the impacts of nickel on Arctic freshwater biota, from Crustaceans to Fish

Tamzin Blewett and Connor B. Stewart, Biological Sciences, University of Alberta, Canada

Nickel (Ni) is an economically important metal used primarily in the manufacture of stainless steel and other metal alloys, with global Ni production exceeding 2.5M tonnes annually. Substantial Ni mining and processing occurs in Arctic and near-Arctic regions, with the number and scale of operations growing. Such extensive natural resource exploitation leads to release of contaminants into the environment, necessitating the evaluation of the risk these contaminants pose to biota. Biotically, the low metabolic rate and large size in Arctic animals may slow toxicant uptake, but low energy usage may limit detoxification potential. Additionally, slow growth rates mean Arctic species spend more time in sensitive larval and/or juvenile stages. Limited polar toxicity data indicates polar species have large variability in toxicant susceptibility. Therefor, we exposed juvenile Arctic char to a range of environmentally relevant Ni concentrations, ranging from 20 – 2400 µg/L for sixty days to investigate the consequences of chronic Ni exposure and the physiologic mechanisms of toxic action. This work evaluated impacts on growth and survival, respiratory toxicity via gill histology and metabolic oxygen consumption, and ionoregulatory perturbation via tissue specific ion analysis and Ni accumulation. These experiments found significant growth rate reductions with a 60-day EC20 (Ni concentration causing a 20% reduction in growth rate) of 436 µg/L and significant mortality at higher concentrations, with a 28-day LC10 (Ni concentration killing 10% of exposed organisms) of only 1,111 µg/L, a concentration well within the range of Ni observed near Arctic mines. Additionally, relevant Ni concentrations caused significant alterations to the gill structure of exposed fish. Unfortunately, the currently available results show Ni contamination poses a risk to various Arctic relevant species at concentrations well within those observed downstream of Arctic Ni mining operations. These results suggest that extrapolation of existing temperate risk assessments to Arctic systems may inadequately protect unique Arctic biota due to both high bioavailability and species sensitivity. Further research is needed to better evaluate the risks of in the Arctic.

3.12.B Fate and Toxicity of Metals: Recent Scientific Advancements and Their Application in Environmental Regulations

3.12.B.T-01 Chronic Toxicity of Metal-Organic Mixtures to *Daphnia magna*: To What Extent Can Concentration Addition and Independent Action Predict Effects?

Marius Schmitt¹, Karel Viaene², Karel Vlaeminck², Charlotte Nys², Hugo Waeterschoot³, Lara Van De Merckt⁴, Gijis Du Laing⁵ and Karel De Schampelaere¹, (1)GhEnToxLab, Ghent University, Belgium, (2)ARCHE Consulting, Belgium, (3)EUROMETAUX, Belgium, (4)AV DE TERVUEREN 168, Eurometaux, Belgium, (5)Laboratory of Analytical Chemistry and Applied Ecochemistry, Ghent University, Belgium

Freshwater systems are often exposed to a variety of different chemicals with unknown mixture effects. The mixture effects of metals and organic micropollutants (OMPs) are currently understudied. Most mixture toxicity studies focus on compounds that belong to the same or a similar chemical group. The toxicity of chemical mixtures can be predicted with two reference models, Concentration Addition (CA) and Independent Action (IA). The CA model is widely established in chemical risk assessment and assumes that all compounds in a mixture have the same Mode of Action (MoA). Mixtures with different MoA, such as metals and OMPs, are in theory better described with the IA model. In this study, we evaluated which reference model, CA or IA, describes the toxicity of metal-OMP mixtures best. Chronic *Daphnia magna* reproduction tests were performed

to test the effects of binary mixtures of one metal (Cd, Cu, Ni, or Zn) and one OMP (fenazaquin, fluoranthene, methomyl, or triclosan). To ensure the environmental relevance of the tested mixtures, combinations were selected from a previously published prioritization study that used freshwater monitoring data. The Mixture Interaction Factor (MIF) was used to quantify deviations between observed and predicted effects by dividing the observed effect concentration (EC) by the predicted EC, both being expressed as Sum of Toxic Units (?TU). For metal-OMP mixtures, CA tends to overestimate toxicity (median MIF: 1.42), whereas IA tends to underestimate mixture toxicity (median MIF: 0.84). However, IA predicted the toxicity of binary mixtures more accurately than CA. Especially when test concentrations were expressed as ?TU relative to the EC50 (median MIF, IA: 0.94, CA: 1.48), IA predicted effects more accurately than CA. Because of its greater conservatism, CA can serve as a first-tier method in chemical risk assessment of metal-OMP mixtures. At a higher tier in chemical risk assessment, IA could be used because of its greater accuracy, provided that suitable data are available. Alternatively, the median MIF values could be used as correction factors to account for potential effect overestimations by CA and underestimations by IA.

3.12.B.T-02 Beyond default Mixture Allocation Factor settings: increasing the applicability and scientific relevance of mixture risk assessments for metal(loid)s

Charlotte Nys¹, Karel Vlaeminck¹, Karel Viaene¹, Marnix Vangheluwe¹, Koen Oorts¹, Hugo Waeterschoot², Lara Van De Merckx³, Maria Laura De Donno⁴, Marius Schmitt⁴ and Karel De Schamphelaere⁵, (1)ARCHE Consulting, Belgium, (2)EUROMETAUX, Belgium, (3)AV DE TERVUEREN 168, Eurometaux, Belgium, (4)GhEnToxLab, Ghent University, Belgium, (5)Ghent University, Belgium

The impact of the combined exposure of chemical mixtures is receiving increased regulatory attention. For instance, within the Chemicals Strategy for Sustainability of the European Commission it is suggested that mixture effects will be covered by a default Mixture Allocation Factor (MAF), while also other environmental quality initiatives have considered additional safety margins. Analysis shows that the implementation of a default safety margins for the coverage of potential effects of combined exposure will have a large impact on the environmental risk assessment of inorganics (including metals and metalloids). Given that metal(loid)s are naturally occurring, the implementation of such safety margins may result in exceedances of safety limits even at natural background concentrations, suggesting the existence of combined risk. In addition, the theoretical assumptions underlying default mixture calculations and their associated conservatism are rarely evaluated. To anticipate the mixture toxicity correction in environmental regulations, a comprehensive study was set-up: the Metals Environmental Exposure Data (MEED) programme. This research programme focused on assessing existing knowledge on metal-mixture toxicity and addressing data gaps. The current study aims to summarize the learning lessons of the MEED-project in the context of risk assessment frameworks. This was done by quantifying the mixture risk associated with exposure to metal(loid)s in European freshwaters, based on monitoring data (default MAF). In addition, the conservatisms inherent to default mixture risk calculations were assessed. The conservatisms embedded in concentration addition (CA)-based risk calculations were quantified using the Margin of Safety (MoS) and the Mixture Interaction Factor (MIF). These quantify the deviation in mixture risk predictions of the assumptions I) that for all substances the same species drives the environmental threshold (MoS) and II) that all substances have the same mode-of-action (MIF). It was shown that default calculations overestimate mixture risks at the ecosystem-level on a median basis by 1.8-fold (MoS), while CA overestimates mixture toxicity of metals at the species-level by 1.3-fold (median MIF). A refined MAF should take into account the conservatisms quantified by the MoS and MIF. Supported by evidence on mixture toxicity, this refined MAF will increase the scientific relevance of mixture risk assessments for metal(loid)s.

3.12.B.T-03 A Biological Line of Evidence to Validate the Zinc Environmental Quality Standard in Europe

Charlotte Linley¹, Graham Merrington¹, Adam Peters¹, Iain Wilson¹, Christopher Cooper², Frank Van Assche²

and Howard Winbow², (1)wca environment Ltd., United Kingdom, (2)International Zinc Association (IZA), Brussels, Belgium

Under the Europe Water Framework Directive (2000/60/EC), Environmental Quality Standards (EQSs) are used to assess whether waters are meeting ‘good chemical and ecological status’. Technical Guidance is available to ensure the derivation of these EQS are evidence-driven and consistent. Biological field data can be used to validate newly derived or updated EQS. A new EQS value for Zn is proposed (11.2 µg/L), based on new bioavailability models and ecotoxicity data.

To validate its protectiveness, we analysed regulatory monitoring data (2012–2018) on freshwater macroinvertebrates in British waters using a “limiting function” approach. This method applies high-quantile regression to define the maximum achievable ecological quality at a given Zn exposure, accounting for multiple stressors. EC10 values were derived for the most sensitive taxa and compared to the proposed EQS using risk characterisation ratios (RCR).

Results show RCR values ?1 (1.03–1.26), indicating the revised EQS is protective of sensitive assemblages, though with a modest margin of safety. This field-based evidence provides a robust line of support for EQS derivation and aligns with EU Technical Guidance recommendations for uncertainty analysis. A new EQS value for Zn of 11.2 µg/L is concluded based on new bioavailability models and ecotoxicity data, which can be validated against field collected data on macroinvertebrate community responses.

3.12.B.T-04 Trophic Transfer of Lithium in Terrestrial Ecosystems

Norah Muisa¹, Martin Tsz-Ki Tsui² and Matthew Long-Hei Cheng¹, (1)School of Life Sciences, The Chinese University of Hong Kong, Hong Kong (Greater China), (2)The Chinese University of Hong Kong

Lithium (Li) is emerging as a potential environmental contaminant of concern due to its increasing global applications and production, yet it is unregulated and little is known about its bioaccumulation and trophic transfer potential in natural ecosystems. The only reported trophic transfer study of Li in complete field-based food webs was on marine ecosystems. In this work, we sampled soil, leaf litter, and ground-dwelling invertebrates from four temperate forests (the United States, US) and two subtropical forests (Hong Kong, HK), in which we analyzed their stable carbon ($\delta^{13}\text{C}$) and nitrogen ($\delta^{15}\text{N}$) isotopes to infer their energy sources and trophic positions, respectively. While we analyzed Li content for all samples. We found no significant differences in the Li levels of either soils or leaf litter between the US and HK forests ($p > 0.05$). Forest floor is clearly a net source of Li to the food webs, in which the decomposing leaf litter had Li concentrations 5- to 10-folds higher than fresh litter (Kruskal-Wallis; $p = 0.0012$). Our results demonstrated that Li bioaccumulation patterns in terrestrial ecosystems are primarily governed by the interplay between the diet and (specifically, leaf litter age), species traits (including growth stage and feeding habit), and to a lesser extent, the geographic location. For instance, by the tight coupling and consistent diminishing trend exhibited in both the $\delta^{13}\text{C}$ signatures and Li concentrations from fresh leaf litter to the strict herbivorous (i.e., Lepidoptera) order, evident in both the US and HK. This provided a clear soil-plant-primary consumer Li transfer pattern in terrestrial ecosystems for the first time. Also, by the order of median Li concentrations corresponding to leaf litter total Li contents’ differences (old > fresh leaf litter): detritivorous (e.g., earthworms; ~3,336.18 ng/g) > carnivorous, omnivorous > herbivorous > strict herbivorous (e.g., moths and butterflies; ~43.40 ng/g). While we observed trophic diminution in all forests, this pattern was only statistically significant ($p < 0.05$) in UMBS (US) and Tai Po Kau (HK) forests, and when all invertebrates (outliers included ~14 % of sample population) were considered. In summary, our study identifies the soil and decomposing litter as important sources of Li to the lower food webs through differential feeding habits. Li exhibited a weak potential in trophic transfer, which can mitigate its risk to top predators in the terrestrial biomes.

3.12.B.T-05 An approach to incorporate soil lead bioavailability in ecological risk assessment by including diet in a novel avian in vitro gastrointestinal assay

Mason Thomas Reid, Nicholas Basta and Alyssa Zearley, The Ohio State University, United States

A major challenge in ecological risk assessment is the lack of available avian toxicological data and the difficulty associated with obtaining it. Worst-case scenario estimates are often employed in situations where data is not available. When bioavailability data is not available for a chemical, it is often assumed to be 100% bioavailable, though many common contaminants of concern are in reality much less bioavailable. Overly conservative estimates of 100% bioavailability can thus result in overestimation of risk as well as unnecessarily cost- and time-intensive cleanups. Experimentally determining bioavailability directly is also unappealing as it necessitates in vivo studies which likewise raise cost and time concerns in addition to ethical ones. We report a novel in vitro method that can be used to accurately predict relative bioavailability of soil lead (Pb) to birds.

When diet is included in the novel in vitro method, in vivo-in vitro correlations were strong ($r^2 = 0.92$), showing potential for use in ecological risk assessment. Among six different avian diets, the in vitro bioaccessible Pb was strongly correlated with total phosphorus content ($r^2 = 0.78$). By including a representative diet sample in the in vitro assay, relative bioaccessible Pb can be accurately estimated while avoiding the need for animal experimentation or diet-specific adjustments for toxicity calculations. This relative bioaccessible Pb estimation can be used in ecological risk assessment to yield more true-to-life estimated exposure dose for comparison to avian toxicity reference values.

A bioavailability-based framework for avian ecological risk assessment will be presented.

3.12.P Fate and Toxicity of Metals: Recent Scientific Advancements and Their Application in Environmental Regulations

3.12.P-Mo166 Chronic Silver Toxicity to *Daphnia magna*: Development and Validation of a Bioavailability Model

Nada Bašić¹, Stephen Loftis² and Karel De Schamphelaere¹, (1)Ghent University, Belgium, (2)Lancaster Environment Centre, United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom

Widespread industrial applications of silver result in unavoidable releases to surface waters, where it exhibits toxicity to aquatic organisms even at sub- $\mu\text{g/L}$ concentrations. This raises regulatory concerns and underscores the need for scientifically derived environmental quality standards, which require an understanding of silver bioavailability across natural waters. Although an acute bioavailability model for silver exists, no chronic model is currently available, limiting our ability to assess long-term risks.

This study aimed to quantify the influence of key water chemistry variables on chronic silver toxicity to *Daphnia magna* and to develop a bioavailability model. Chronic 21-day reproduction tests were conducted in synthetic freshwaters while varying pH, calcium or magnesium concentrations across ranges representative of European surface waters. Ongoing tests will assess the influence of sodium and chloride, and tests in six natural freshwaters will further validate the model and provide insight into the influence of natural organic matter variability.

In synthetic freshwaters, calcium unexpectedly increased toxicity, reducing EC50s by a factor of approximately two (from 3.4 $\mu\text{g Ag/L}$ to 1.6 $\mu\text{g Ag/L}$) across the tested range (0.3 mM to 2.2 mM Ca), while magnesium showed no effect. Varying pH from 6.5 to 8.4 had no influence on chronic toxicity. Overall, the influence of water chemistry on chronic silver toxicity to *D. magna* was weaker than that commonly observed for other metals.

These results challenge classic assumptions in metal bioavailability modelling, particularly regarding cation competition at the biotic ligand. Ongoing validation in natural waters will determine model accuracy in natural water chemistries. The main relevance of this work lies in its applicability for regulatory purposes.

Disclaimer/Disclosure:

We wish to thank our project partners from ARCHE Consulting and UK Centre for Ecology and Hydrology as well as the European Precious Metal Federation (EPMF) for sponsoring this work.

3.12.P-Mo167 The Development and Regulatory Implementation of a Bioavailability Model for Uranium

Lucy Kennelly¹, Melanie Trenfield², Andrew Harford², Adam Peters¹, Graham Merrington¹, Stephen Loftis³, Matti Leppanen⁴, Johanna Järvisjö⁴, Karsten Liber⁵, Markus Hecker⁶, Nils Eriksson⁷, Torbjörn Karlsson⁸ and Andreas Aronsson⁹, (1)wca environment Ltd., United Kingdom, (2)Department of Climate Change, Energy, the Environment and Water (DCCEEW), Australia, (3)Lancaster Environment Centre, United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)Finnish Environment Institute (SYKE), Finland, (5)School of Environment and Sustainability, University of Saskatchewan, Canada, (6)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (7)Boliden AB, Sweden, (8)Luossavaara-Kiirunavaara AB, Sweden, (9)Andreas Aronsson Consulting AB, Sweden

In parts of Europe, including Sweden, natural background concentrations of uranium can exceed the existing Environmental Quality Standard (EQS). It is widely recognised that many biological and chemical factors can influence the behaviour and ecotoxicity of metals, including uranium, in surface freshwaters. In line with bioavailability model developments in recent years for other metals (such as copper, nickel, zinc, cobalt) we are developing the first chronic bioavailability model for uranium in freshwaters. Here, we present our approach for

the development of this model, showing results from the initial testing, outline the likely way forward and discuss how the model will be used to fit with existing regulatory approaches to ensure improved evidence-driven risk assessment of uranium.

The model development is based on the results of long-term toxicity tests with algae, aquatic invertebrates and fish, which have investigated the influence of several toxicity modifying factors including pH, dissolved organic carbon (DOC) and hardness. The model will be validated with species not used in the development tests (but in the same respective taxa), in natural field-collected waters covering a wide range of water chemistry conditions. The development tests provide the model that then can be benchmarked against the validation tests.

The development testing for algae and Hydra have been completed, whilst the development testing for fish is still in progress, expected to be completed in early 2026. Once completed, the bioavailability model will be developed. In parallel, the validation testing for all three trophic levels is underway and due to be completed in 2026. Once the model is developed and validated, it will be finalised and then applied for normalisation of the species sensitivity distribution (SSD) for waters across Europe. From this, the 5th percentile hazardous concentration (HC5) will be identified for the most sensitive region (country) and from this the EQSbioavailable will be derived. A user-friendly tool for the model, based in Excel, will also be developed.

3.12.P-Mo168 Modelling the impacts of metals and acidity on benthic invertebrates in English and Welsh freshwaters

Stephen Loftis¹, Edward Tipping² and Justyna P Olszewska², (1)Lancaster Environment Centre, United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom

Modelling the combined effects of metallic contaminants in the field represents a key challenge in metal ecotoxicology. We have previously developed the WHAM (Windermere Humic Aqueous Model)-FTOX β model quantifies combined impacts of cationic metals and acidity on biota and successfully applied it to time series recovery of lake zooplankton from past acidification and metal contamination. The purpose of this work is to apply the model to impacts in running freshwaters over a greater geographic range and to a broader expected set of significantly acting metals (Al, Mn, Ni, Cu, Zn, Cd and Pb). The model uses a dose term, FTOX, to quantify mixture effects. Metal-specific toxic potency coefficients (derived from laboratory toxicity testing) and taxon-specific sensitivity coefficients (derived from the laboratory or by optimization to field data) are combined with computed fractional occupancies of humic acid binding sites by protons and metals (computed using WHAM) to predict effects as an expected fraction of impacted taxa. We collected suitable water quality and benthic invertebrate taxon number data from 285 locations across England and Wales unimpacted by other chemical stressors and used the River Invertebrate Classification Tool (RICT) to predict the expected invertebrate taxon numbers at each location, allowing us to directly compare observed and modelled impacts. Application of a laboratory-derived distribution of organism sensitivity to metals predicted larger effects than were observed, at the most contaminated sites in the dataset. Optimization of the sensitivity distribution on the field data explained approximately half the observed variability in taxon numbers across the dataset. The optimized sensitivity distribution overlapped that derived from the laboratory but was notably broader. The model outputs allow assessment of the relative contributions of protons and each metal. Protons, Zn and Cu were the most frequent important contributors to impacts, while Cd was generally not important. There is considerable potential for further model application, for example to identify taxonomic sensitivities directly from field data.

This work was part funded by NERC under the projects NE/X015866/1 and NE/T003200/1.

3.12.P-Mo169 Effects of Water Chemistry on Cobalt, Copper, and Zinc Toxicity in Arctic-acclimated *Daphnia pulex*

Kayla Lottin¹, Ivan Cadonic², Connor B. Stewart¹, Erin M Leonard³, Anne Crémazy⁴ and Tamzin Blewett¹, (1)Biological Sciences, University of Alberta, Canada, (2)University of Alberta, Canada, (3)Wilfrid Laurier University, Canada, (4)National Institute for Scientific Research (INRS), Canada

In an effort to reduce climate change-associated impacts, the extraction of critical minerals used in green technologies is increasing globally. Sensitive environments, such as the Arctic, which contain large deposits of minerals, have an increased risk due to the region's unique physicochemical properties. Low temperatures and large variability in water hardness and pH can dictate the mobilization and speciation of metals within the environment. Furthermore, Arctic organisms possess a slower metabolic rate, extended lifespans, and limited

biological activity compared to their temperate counterparts, altering their susceptibility to metal contaminants. Current government-defined water quality guidelines are based on lower latitude organisms which may not be representative of Arctic systems. This study uses cold-adapted *Daphnia pulex*, a crustacean inhabiting both Arctic and temperate freshwater bodies, in Arctic-relevant water to determine the effects of copper (Cu), cobalt (Co), and zinc (Zn). The lethal concentration 50 (LC50) was assessed at two temperatures (8°C and 20°C) and three pHs (7.0, 7.6, and 8.2) under site-specific water hardness (10 mg/L calcium and 5 mg/L magnesium). The highest Cu toxicity was observed at pH 7.0 with an LC50 value of 10.4 µg/L (95% CI 8.59, 13.3) at 20°C and 9.86 µg/L (95% CI 9.25, 10.7) at 8°C. Arctic-acclimated *D. pulex* were also significantly more sensitive to Cu in the 8°C pH 8.2 group, with an LC50 value of 16.8 µg/L (95% C.I. 20.3, 29.5) compared to 24.2 µg/L (95% C.I. 20.3, 29.5) at 20°C. For Co, a decrease in pH unexpectedly decreased toxicity indicating the metal may have formed a complex bioavailable to the organism. Values ranged from 2.05 mg/L (95% C.I. 1.79, 2.38) for pH 7.0, and 1.11 mg/L (95% C.I. 0.97, 1.26) for pH 8.2, both at 20°C. At 8°C, using the same Co range, no LC50 values were able to be determined indicating the 48-hour test duration may be insufficient for Arctic species. Metal bioaccumulation of *Daphnia pulex* will also be measured at the two temperatures and three pHs across various timepoints (48, 96, 120, and 144 hours for 8°C and 48 hours for 20°C) to investigate potential differences in uptake rate and to determine an equivalent timepoint at 8°C. Understanding the toxicity of critical minerals using cold-adapted organisms within their relevant water chemistry will help develop Arctic-specific risk assessment models.

3.12.P-Mo170 Environmental Hazard Assessment of Cadmium in Soil. A Comparison between Toxicity to Soil Organisms and Secondary Poisoning to Wildlife.

Koen Oorts¹, Mehrnoosh Babaahmadifooladi¹, Christopher Cooper², Frank Van Assche² and Christine Spirlet²,
(1)ARCHE Consulting, Belgium, (2)International Zinc Association, Belgium

A comprehensive update of the hazard assessment of cadmium (Cd) contamination in soils was conducted, including both ecotoxicological effects on soil-dwelling organisms and secondary poisoning risks to wildlife from soil. Reliable chronic toxicity data were identified for 42 terrestrial plant species, 15 invertebrate species and 11 microbial endpoints. Chronic EC10 and NOEC values vary between 0.5 and 4596.9 mg Cd/kg dry weight (dw). Although soil properties such as pH and organic carbon influence Cd bioavailability, species-specific sensitivity was the dominant source of variation. The data were evaluated using a species sensitivity distribution (SSD), which gave a 5th percentile hazardous concentration (HC5) of 2.18 mg Cd/kg soil for direct effects. Available field data on plant growth in Cd contaminated soils confirm that this laboratory-derived threshold is protective under realistic conditions. The assessment of secondary poisoning of Cd to wildlife via predicted exposure in food is complex and the standard assumptions on soil-earthworm-predator pathway and Cd availability in diet can result in unrealistic results. Since the kidney is the critical organ for Cd toxicity in the field, an alternative approach based on critical Cd concentrations in kidneys of mammals and birds in relation to soil Cd concentrations of their foraging area overcomes these assumptions. The critical soil Cd concentration is defined as that concentration at which a critical kidney Cd concentration of 400 mg/kg dw (whole kidney) is predicted using a proportional extrapolation. Paired sets of soil Cd and kidney Cd were found for 23 mammal species and 3 bird species. Moles have the lowest predicted critical Cd concentration in soil (0.6 mg/kg dw), while deer mice have the highest predicted critical Cd concentration in soil (1813 mg/kg dw). The 5th percentile of predicted critical soil concentrations was 2.05 mg Cd/kg soil, i.e., slightly below the threshold for direct toxicity of soil Cd to soil dwelling organisms showing that secondary poisoning is indeed a critical pathway to consider for addressing the risks of cadmium contamination in soil. Overall, these thresholds exceed typical ambient background concentrations, with only ~1% of European and North American soils surpassing 2 mg Cd/kg, suggesting limited ecological risk under current ambient soil Cd levels.

3.12.P-Mo172 Different Coat, Different Interaction? Effects of Differently Coated Silver Nanoparticles on Freshwater Cyanobacterium *Synechocystis* sp. PCC 6803

Lucija Sara Kovacic¹ and Vera Slaveykova², (1)No Affiliation, France, (2)Département F.-A. Forel des sciences de l'environnement et de l'eau, University of Geneva, Switzerland

Due to their antibacterial properties, silver nanoparticles (AgNPs) represent the fastest growing class of engineered nanomaterials. The increased production and widespread use of AgNPs have raised the likelihood of these particles entering the aquatic ecosystem through accidental release or leaching. Even though the effects of engineered nanomaterials within the aquatic environment have become a subject of concern, there remains a lack of research on the impact of nanoparticle surface coatings on cyanobacteria. To address this gap, two different initial cell concentrations of *Synechocystis* sp. PCC 6803 were exposed to increasing concentrations (0–100 µg/L) of (1) 50 nm citrate-coated AgNPs and (2) 50 nm PVP-coated AgNPs. Growth inhibition was

monitored every 24 h up to 72 h via flow cytometry, while photosynthetic efficiency and photoprotection were assessed through pulse-amplitude modulated fluorometry at the 72 h. Growth inhibition was more pronounced in cultures exposed to citrate-coated AgNPs compared to equivalent concentrations of PVP-coated AgNPs, while relatively higher sensitivity was found in cultures with lower initial cell densities. Photosynthetic efficiency declined with increasing AgNP concentrations, whereas photoprotective activity rose. By examining how nanoparticle coating modulates toxicity towards primary producers in freshwater systems, the study enhances the understanding of environmentally relevant modes of action and supports more accurate ecological risk assessments of AgNPs.

3.12.P-Mo173 Exploring Dose-Dependent Effects of Copper Oxide Nanoparticles and Dissolved Copper on Photosynthesis and Growth in Freshwater Microalgae

Fiona Traber and Vera Slaveykova, Université de Genève, Switzerland

Copper oxide nanoparticles (CuONPs) are increasingly released into aquatic systems, yet their dose-dependent and sublethal effects on algal photosynthesis remain insufficiently characterised. In particular, low-dose exposures are rarely examined, which may obscure potential stimulatory or hormetic responses. This study aims to investigate the effects of a broad concentration range (0.001-100 mg L⁻¹) of 40 nm CuONPs and dissolved copper on freshwater microalgae *Raphidocelis subcapitata* and define if and under what conditions a biphasic stimulatory/inhibitory dose-response can be observed. Cultures were exposed to a wide range of copper concentrations, from low to high doses. The effects of CuONPs and ionic copper were then compared to determine whether they elicited similar or distinct impacts on photosynthesis and growth. Photosynthetic responses were assessed using chlorophyll fluorescence measurements obtained with a Pulse Amplitude Modulation (PAM) technique. Key parameters, including maximum quantum yield, photochemical and non-photochemical quenching, were evaluated to capture changes in both efficiency and protective regulation of photosystem II. Growth and pigment autofluorescence were monitored to complement fluorescence-based endpoints and provide integrative information on physiological state at the single-cell level. Nanoparticle behaviour in the exposure medium, including aggregation and dissolution, was quantified to link physicochemical properties to biological responses. The results revealed significant growth inhibition and effects on the photosynthetic apparatus following exposure to CuONPs and Cu²⁺ at high concentrations. By examining nanoparticulate and dissolved copper across a broad range of exposure, this study provides mechanistic insight into their effects on algal photosynthesis and growth. These findings will enhance our understanding of subtle, sublethal responses relevant to the ecological risk assessment of metal oxide nanoparticles.

3.12.P-Mo174 Uranium toxicity to algae and water flea in natural freshwaters. Validating Biotic Ligand Model for uranium.

Matti Leppanen¹, Heidi Ahkola¹, Johanna Järvis¹, Laura Sysoeva¹, Adam Peters², Graham Merrington², Lucy Kennelly², Stephen Loft³, Melanie Trenfield⁴, Andrew Harford⁴, Karsten Liber⁵, Markus Hecker⁶, Nils Eriksson⁷, Torbjörn Karlsson⁸ and Andreas Aronsson⁹, (1)Finnish Environment Institute (SYKE), Finland, (2)wca environment Ltd., United Kingdom, (3)Lancaster Environment Centre, United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)Department of Climate Change, Energy, the Environment and Water (DCCEE), Australia, (5)School of Environment and Sustainability, University of Saskatchewan, Canada, (6)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (7)Boliden AB, Sweden, (8)Luossavaara-Kiirunavaara AB, Sweden, (9)Andreas Aronsson Consulting AB, Sweden

Water chemistry significantly influences the bioavailability of metals in freshwaters. Bioavailability models have been developed for several metals, such as Cu, Ni, Zn, and Co, and are used to derive safe surface water

concentrations. All models must be validated through toxicity tests conducted under various natural water chemistry conditions. Typically, three trophic levels (algae, invertebrates, fish) are selected for these tests. The test-based effect concentrations are then compared to the model-based concentrations during the validation process.

Our objective is to generate toxicity data that will be used to validate a chronic bioavailability model for uranium in freshwaters. We collected five natural water samples from Finland and Sweden, representing the water chemistry conditions under which the model was developed. The standard test species chosen include green algae (*Raphidocelis subcapitata* SAG 61.81 strain originally from Norway) and water flea (*Daphnia longispina*, sourced from a nature conservation area in Finland). These organisms will be exposed to uranyl nitrate hexahydrate ($\text{UO}_2(\text{NO}_3)_2$) in chronic tests. Non-linear regression models will be employed to estimate the effective concentrations (EC10) for algae growth rates and water flea reproduction. The results are expected to be available early 2026.

3.12.P-Mo175 Metal accumulation and Metallothionein responses in the Mediterranean invasive blue crab (*Callinectes sapidus*) across salinity regimes

Beatriz Fernández¹, Pilar Gomez-Ramirez², José María Aparicio³, Antonio Zamora-López⁴, Ignacio Franco³ and Concepción Martínez-Gómez³, (1)Spanish Institute of Oceanography - Spanish National Research Council (IEO-CSIC), Spain, (2)University of Murcia, Spain, (3)Oceanographic Centre of Murcia, Instituto Español de Oceanografía, Spain, (4)Department of Zoology and Physical Anthropology, Faculty of Biology, University of Murcia, Spain

The blue crab (*Callinectes sapidus*), an invasive species expanding across Mediterranean coastal lagoons, tolerates salinities from near-freshwater to hypersaline. In invaded ecosystems, it alters food webs as an omnivorous top mid-predator, scavenger, and prey, including as a human seafood resource. Salinity strongly influences metal bioaccumulation and detoxification in aquatic organisms, yet the physiological mechanisms regulating ion transport, gill permeability, and metabolism in highly euryhaline crustaceans remain poorly understood. Salinity also shapes prey communities, modifying trophic exposure, so metal bioaccumulation reflects both environmental chemistry and food web shifts. Essential metals are physiologically regulated, whereas non-essential metals accumulate with exposure. Metallothioneins (MTs), cysteine-rich proteins key to metal detoxification and sequestration, mediate metal homeostasis. In *C. sapidus*, multiple MT isoforms bind Cu, Cd, Hg, and Zn. Establishing baseline MT levels across salinity regimes is essential to accurately interpret metal exposure and detoxification in this euryhaline species.

We measured metals (Cd, Cu, Pb, Zn, As, Ni, Cr, Co, Mn, Tl) and MTs in *C. sapidus* from two contrasting Mediterranean ecosystems: the hypersaline Mar Menor lagoon and low-salinity El Hondo wetland. Metals were quantified in gills, hepatopancreas, haemolymph, and muscle; MTs were measured in gills and hepatopancreas. We analyzed spatial, tissue-specific, and sex-related patterns, and correlated metal and MT levels with physicochemical and biological variables.

This study investigates the role of blue crabs as vectors of metal contaminants across coastal ecosystems and assesses ecological risks and human exposure through consumption. The use of MTs as biomarkers of metal exposure is evaluated, highlighting their potential in integrated environmental monitoring programs in Mediterranean ecosystems affected by invasive species.

Funded by the Spanish Ministry of Science, Innovation and Universities and the Spanish State Research Agency (MICIU/AEI/10.13039/501100011033; CRABMEDPOL project (PID2022-138720OA-I00))

3.12.P-Mo176 One lake, two worlds? – Mercury dynamics in food webs from two basins in human-impacted Lake Vesijärvi, Finland

Alexander Piro¹, Jan Weckström¹, Tommi Malinen¹, Katja Kulo² and Kimmo Kalevi Kahilainen¹, (1)University of Helsinki, Finland, (2)Natural Resources Institute Finland (Luke), Finland

Clean lakes and resilient food webs are vital to maintaining biodiversity and ecological integrity, however, pressures on these important ecosystems are numerous. The VesiMon project aims to develop and test methods to holistically understand aquatic ecosystems, identify pressures on them, and make the monitoring of water bodies more accurate and cost-effective. In this study, primary producers, pelagic and benthic invertebrates, and the fish community were sampled in the Enonselkä and Kajaanselkä basins of Lake Vesijärvi in southern Finland. These basins represent different levels of productivity and human-impact, with the Enonselkä basin

being more eutrophic due to a history of municipal sewage inputs. The aquatic community of these basins was assessed regarding stable isotopes of nitrogen ($\delta^{15}\text{N}$) and carbon ($\delta^{13}\text{C}$), total mercury content [THg] (mg/kg) and bioaccumulation of THg in different fish species, and biomagnification of THg through the entire food web. The [THg] was highest in piscivores and generalists, and lowest in benthivores and planktivores, without consistent significant differences detected between the basins. Bioaccumulation regression slopes between [THg] and fish length were most elevated in planktivorous fish in both basins, and species-specific differences between basins were apparent. Biomagnification of THg, defined as the regression slope between [THg] and $\delta^{15}\text{N}$, was significant in both basins but did not differ significantly between them. Stable isotope analyses indicated higher $\delta^{13}\text{C}$ in the Kajaanselkä basin and higher $\delta^{15}\text{N}$ in the Enonselkä basin, thus indicating the higher nutrient status of the latter basin. Overall, THg analyses indicated that although variations in [THg] and bioaccumulation were apparent in fish, these differences were more closely related to species characteristics than to any systemic differences between the basins. While these methods provided a wealth of information on the food webs of these basins, the basins are notably similar in mercury metrics, while differences in stable isotope ratios represent the shifting energy sources of the Enonselkä basin.

3.12.P-Mo177 Challenges in Applying Metal Environmental Quality Standards in Freshwater: Estimation of Natural Background Concentrations in Flanders.

Karolien Bijns, Hilda Witters, Eef De Clercq and Stijn Baken, Flemish Institute for Technological Research (VITO), Belgium

In Flanders, the Flemish Environmental Agency has developed environmental quality standards (EQS) for various metals in freshwater systems. The derivation follows the methodology outlined in the EU Technical Guidance Document No. 27 (2018). Metals represent a particular challenge in the derivation and application of EQS due to their natural occurrence in the environment, their essentiality for certain species, and their complex behavior as function of physico-chemical properties in aquatic systems. As a result, metal-specific EQS values are often associated with considerable uncertainty.

To address these issues, EU Guidance Document No. 38 (2019) provides additional recommendations for deriving metal EQS, including the consideration of natural background concentrations (NBCs).

Based on this guidance document, we estimated regional NBCs for several metals (arsenic, barium, cobalt, iron and vanadium) in Flemish freshwater ecosystems. The application of these NBCs and their implications within the EU Water Framework Directive are discussed.

3.12.P-Mo178 Zinc in German Freshwaters: Searching for Ecological Signals in Real-World Monitoring Data and Evaluation of a Bioavailability-Based Environmental Quality Standard (EQS)

Gareth Le Page¹ and Christopher Cooper², (1)Enviresearch Ltd., United Kingdom, (2)International Zinc Association (IZA), United States

Zinc occurs naturally in freshwater systems and is essential for many biological processes, but higher concentrations can lead to ecotoxicological effects. Zinc has numerous applications across many industries and, as such, it is critical to understand the potential risk of increased concentrations of zinc to environmental health. One key regulatory tool to support safe use of substances such as zinc is an environmental quality standard (EQS) compliance assessment. A bioavailability-based EQS for zinc has been derived for regulatory use in Europe, yet there is still relatively little information on how well real-world monitoring data reflect possible ecological responses to zinc. In this project, we examine whether existing German monitoring datasets offer any evidence of zinc influencing biological communities, particularly at or around the bioavailable-EQS.

To do this, we brought together bioavailable zinc measurements from several German Länder and combined them, where possible, with corresponding biomonitoring data for fish, macrozoobenthos, phytoplankton and macrophytes/phytobenthos. The focus of the analysis is on exploring patterns in community metrics in relation to zinc concentrations, recognising the challenges posed by combining data from different monitoring programmes. This required harmonising disparate datasets, aligning sampling locations, and applying spatial and temporal matching rules to ensure that chemistry and biology data were meaningfully comparable. Where the data allows, community metrics such as richness, abundance, and other established assessment indices are examined in relation to bioavailable zinc concentrations and acknowledging (or where possible, accounting for)

the presence of multiple environmental pressures. The study offers a weight-of-evidence perspective that may inform on the protectiveness of the bioavailable Zn EQS to real world communities.

3.12.P-Mo179 Metalloids Monitoring in Offshore Produced Water: Analytical Insights and Environmental Implications

Neri Bonciani, Ma¹, Karen Feilberg² and Martin Mørk Larsen³, (1)Technical University of Denmark (DTU), Denmark, (2)DTU Offshore, Technical University of Denmark (DTU), Denmark, (3)Aarhus University, Denmark

Produced water (PW), the largest waste stream from offshore oil and gas production, is almost entirely discharged to the sea. It contains complex organic and inorganic pollutants, including toxic metalloids such as mercury (Hg), arsenic (As), antimony (Sb), and selenium (Se). These elements pose ecological and human health risks, particularly in fish-rich marine environments like the North Atlantic. Despite their relevance, comprehensive temporal data on metalloid concentrations in North Sea PW are lacking. Analytical quantification is challenging due to PW's high salinity (~70‰), hydrocarbons, and production additives, which can interfere with conventional measurement techniques. For this reason, the presented study evaluates cold vapor atomic fluorescence spectrometry (CV-AFS) and inductively coupled plasma mass spectrometry (ICP-MS) for ultra-trace metalloid detection in PW and presents a multi-year dataset (2022–2024) from four mature North Sea chalk oilfields.

Field-average Hg measured in PW by CV-AFS exceeded both North Atlantic background levels and predicted no-effect concentrations (PNECs). This was not in agreement with commercially reported values (often obtained with standard ICP methods). Concentrations indeed varied across fields and throughout time, influenced by production practices, sampling approaches, and matrix complexity. However, CV-AFS demonstrated superior sensitivity for hydride-forming elements, minimizing over- or underestimation caused by ICP-MS matrix interferences. Risk assessment revealed that instantaneous PEC/PNEC ratios for Hg and Se exceeded 1 in multiple fields, indicating potential localized ecological impacts even at moderate discharge volumes. Correlations with outlet temperature and oil-in-water content suggest that current discharge controls do not sufficiently mitigate metalloid risk.

The results emphasize the critical need for optimized sampling protocols, acid-washed glassware, airtight seals, and rapid analysis to reduce variability and improve analytical accuracy. Integration of metalloid monitoring with existing oil-in-water discharge regulations is recommended to strengthen environmental risk management of offshore PW. By providing validated analytical methods and evidence-based risk insights, this study supports regulatory decision-making and operational practices to mitigate metalloid impacts in marine environments.

3.12.P-Mo180 Photochemical, Abiotic, and Microbial Pathways of Mercury Reduction in Aquatic Environments

Yong Cai¹, Guangliang Liu¹, Samuel Sunday Ogunsola¹ and Peter Olusakin Oladoye², (1)Florida International University, (2)Florida International University (FIU) Institute of Environment

Mercury (Hg) is a global health concern due to the long-range intercontinental transport of elemental Hg (Hg(0)) in the atmosphere and microbial methylation of inorganic Hg to produce highly toxic and bioaccumulative methylmercury in aquatic environments. Biogeochemical cycling of Hg in the environmental media (air, soil, water, and sediment) involves various transport and transformation processes, among which reduction of divalent Hg (Hg(II)) to Hg(0) in aquatic environments is a critical step as it controls the air-water Hg exchange and the pool of inorganic Hg available for methylmercury production. Photochemical reaction has been extensively studied as a dominant pathway for the reduction of Hg(II) to Hg(0) in sunlit environments such as surface water. The reduction of Hg(II) in the environment with limited light penetration (e.g., aphotic water layer and sediment) can be attributed to microbial and dark chemical processes. It is well known that Hg-resistant bacteria can use the MerA pathway to reduce Hg(II), which is usually mediated by aerobic heterotrophic microbes in Hg-contaminated areas. In anaerobic zones, Hg(II) reduction can occur through the activities of some heterotrophic and chemotrophic microorganisms, e.g., the dissimilatory iron (Fe) reduction bacteria. The widely present ferrous Fe (Fe(II)) species, including aqueous Fe(II) and especially solid phase Fe(II) such as magnetite, green rusts, and mackinawite, may be a critical driving force for dark chemical reduction of Hg(II), although their exact roles in Hg redox transformation in aquatic environments warrant further investigation. We present here a comprehensive review of aquatic Hg(II) reduction by synthesizing previous information and highlighting future research needs.

3.12.P-Mo181 Organometallics in Commerce: A Scoping Review of Environmental Fate and Behavior

Matthis Schüfer¹, Bernd Nowack² and Zhanyun Wang¹, (1)ETH Zurich, Switzerland, (2)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland

In recent years, the synthesis and assessment of chemical inventory data have greatly advanced our understanding of the composition of the global chemical market. A landmark contribution to this effort was made by Wang et al. (2020), who compiled a unified global chemical inventory encompassing over 350,000 chemicals and mixtures. Within this landscape, organometallic compounds emerge as a particularly significant class of chemicals, with over 10,000 identified.

Evidence from well-studied examples, like those containing lead, mercury, and tin, demonstrates that many of these substances can be persistent, bioaccumulative, and toxic. Yet only a limited number of organometallics appear to have been thoroughly studied or publicly assessed with respect to their environmental fate and behavior, with existing information often highly fragmented. In response to this situation, this poster presents the first structured overview of data relevant for the environmental assessment of organometallics in commerce.

Using structural filters, we extracted 10,613 organometallic substances from the latest version of the global chemical inventory and assembled a PostgreSQL database integrating data from 25 regulatory, scientific, and industrial sources. CAS Registry Numbers were used as the common identifier to link inventory chemicals to the respective sources. The final database includes harmonized structural identifiers, production and use information, hazard classifications, and available physicochemical properties. Using these data, we further characterized and mapped the chemical space of organometallics through cheminformatic analyses and categorized substances based on use patterns and hazard classifications wherever possible.

Our findings point to substantial data gaps across all dimensions investigated, with information heavily skewed toward main-group organometallics. Even so, we identified approximately 600 substances of potential concern, including several high-production-volume chemicals used in applications with high exposure potential. In contrast, only a small fraction of organometallics could be sufficiently characterized in terms of their properties, hindering environmental assessment for most substances. Overall, our work highlights organometallics in commerce as an overlooked systemic issue and identifies strategic needs that require attention from both researchers and policymakers to advance future evaluation and regulatory decision-making.

3.12.P-Mo182 Isotope-Tracing of Tin Methylation and Degradation in Marine Sediments

Ivna Vrana¹, Anđela Bačinić¹, Ines Sviličić Petrić¹, Goran Palijan², Maja Ivanić¹, Mavro Lučić¹ and Martina Furdek Turk¹, (1)Ruder Boskovic Institute, Croatia, (2)Josip Juraj Strossmayer University of Osijek, Croatia

The methylation of tin (Sn) is environmentally significant because it converts inorganic, non-toxic and low-mobility Sn species into soluble, mobile and harmful methyltin compounds (MeTs). Trimethyltin (TMT) is a particularly potent neurotoxin widely used as a model compound in neurotoxicity studies. Despite their relevance, the formation pathways and environmental behavior of MeTs remain poorly understood, and their concentrations in marine environments are rarely reported. Although MeTs are known to occur in seawater and sediments, in situ evidence of Sn methylation is scarce, making it unclear whether detected MeTs originate from natural processes or anthropogenic inputs.

This study investigated the formation and degradation of MeTs in 16 marine sediments under oxic and anoxic conditions. Sediments were spiked with isotopically enriched inorganic Sn (Sn119) and enriched mono- and dimethyltin (MMT116, DMT116). Transformations were monitored over 180 days. Comprehensive sediment characterization (grain size, mineralogy, elemental composition, TOC, carbonate content) and amplicon-based microbial community profiling were performed to identify factors controlling MeTs dynamics. Transformation rate constants were calculated from concentration changes over time.

The results showed that MMT116 and DMT116 degraded efficiently in all sediments, decreasing by 20–40% over 180 days, with faster degradation under oxic conditions. Formation of TMT116 through methylation of MMT116 occurred only in one anoxic sediment (K-A), reaching 11 ng/g after 180 days. Although the first step of inorganic Sn methylation to MMT was not observed, further methylation to DMT was detected exclusively in sediment MAN-O, where DMT119 formed under oxic conditions after 180 days. MAN-O is a partially oxygenated clayey silt with moderate organic matter and microbial communities including early-stage sulfate-reducing bacteria, enabling a short “hot moment” of methylation. In contrast, K-A is a sandy silt that developed strongly reducing conditions and a consortium dominated by metal- and sulfate-reducers, fermenters and methanogens, enabling efficient methylation.

Overall, the results demonstrate that Sn methylation can occur in marine sediments, although degradation

generally prevails. Nonetheless, under specific sedimentological and microbial conditions, toxic MeTs, including TMT, may form.

3.12.P-Mo183 Stress Responses and Toxicity Associated with Exposure of *Acanthamoeba castellanii* (Amoebozoa; Acanthamoebidae) to Trace Metals

Raul M. Hilder¹, **Ronnie Mooney**², **Mhairi Alexander**¹, **Kiri Rodgers**¹, **Fiona Henriquez**² and **Beric M. Gilbert**¹, (1)School of Health and Life Sciences, University of the West of Scotland, United Kingdom, (2)Department of Civil and Environmental Engineering, University of Strathclyde, United Kingdom

Despite their natural occurrence in the environment, many metals are known to become toxic to organisms at elevated concentrations. With changes in industrial processes and technological developments, novel elements are now being released into aquatic ecosystems. Free-living protists, such as amoebae, perform critical roles in aquatic environments as both bacterial grazers and microbial reservoirs, including potential pathogens. Few studies, however, have compared the toxicity and responses of protists to metals routinely released into natural environments through anthropogenic activity. This is despite some metals such as silver being well-known for having antimicrobial properties. The present study aimed to compare the toxicity and morphological changes in the free-living protist and opportunistic pathogen, *Acanthamoeba castellanii* when exposed to aluminium, silver, and vanadium metals. Exposures were carried out under controlled conditions for two replications. *Acanthamoeba castellanii* (ATCC 50370) were cultured in peptone glucose medium and exposed to varying trace metal concentrations. These metals were chosen given their use in new and developing technologies such as renewable energy storage. All metals induced a dose-dependent response in *A. castellanii*, characterised by increased mortality and enhanced cyst formation. Mortality was quantified using Alamar Blue assays and verified through morphological assessment, while mature cysts were stained using Calcofluor White. These results indicate that *A. castellanii* responds to metal stress through encystation, enabling survival under otherwise toxic conditions. Such shifts towards cyst dominance could disrupt microbial interactions, alter grazing dynamics, and ultimately influence wider ecosystem functioning in metal-impacted environments.

3.12.P-Mo184 Uranium Toxicity to Zebrafish in Reconstituted Freshwater at Different pH and Ionic Composition

Karsten Liber¹, **Markus Hecker**², **Som Niyogi**³, **Adam Peters**⁴, **Graham Merrington**⁴, **Lucy Kennelly**⁴, **Stephen Lofts**⁵, **Matti Leppanen**⁶, **Johanna Järvisjö**⁶, **Melanie Trenfield**⁷, **Andrew Harford**⁷, **Nils Eriksson**⁸, **Torbjörn Karlsson**⁹ and **Andreas Aronsson**¹⁰, (1)School of Environment and Sustainability, University of Saskatchewan, Canada, (2)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (3)University of Saskatchewan, Canada, (4)wca environment Ltd., United Kingdom, (5)Lancaster Environment Centre, United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (6)Finnish Environment Institute (SYKE), Finland, (7)Department of Climate Change, Energy, the Environment and Water (DCCEEW), Australia, (8)Boliden AB, Sweden, (9)Luossavaara-Kiirunavaara AB, Sweden, (10)Andreas Aronsson Consulting AB, Sweden

Water quality characteristics influence the aqueous bioavailability and hence toxicity of many metals and radionuclides, including uranium. Past research has shown that pH is among the most relevant variables in those relationships. Additional variables such as water hardness, alkalinity and dissolved organic carbon can also play important roles. However, surprisingly little is known about the toxicodynamic relationships between these water quality parameters and uranium in key aquatic receptors, hampering environmental risk assessment efforts and guidelines development. This research project is part of a larger effort to generate the data needed to develop a generalized bioavailability model for uranium toxicity to aquatic organisms. The research presented here will focus on the chronic toxicity of uranium to zebrafish (*Danio rerio*), a model test species, at different aqueous pH levels. Specifically, zebrafish are sub-chronically exposed to incremental concentrations of uranium for 28 d starting with 724 hr old embryos. Primary biological endpoints include hatching success, survival at swim-up (approx. day 6), and survival, growth and teratogenicity at 28 d. Tests are conducted at six pH levels

(6.0, 6.5, 7.0, 7.5, 8.0, 8.5) covering a range of values representative of natural waterbodies. All tests are conducted in reconstituted freshwater with average hardness and alkalinity of approx. 50 mg/L as CaCO₃ each and no DOC. Four additional tests will be conducted with different concentrations of Ca, Mg and DOC. Tests conducted at very low alkalinity proved unsuccessful due to a reduced ability at maintaining dissolved uranium (added as uranyl nitrate) at nominal levels. Tests conducted to date show that uranium toxicity to early life stage zebrafish falls in the 0.2 to 2.0 mg U/L range (hatching success and lethality). Preliminary data also suggests that there is an influence of pH on U toxicity. Additional results on survival, growth and developmental deformities across the full suite of water quality variables investigated will be presented (experimentation still in progress).

3.12.P-Mo185 Ecotoxicity of Environmentally Realistic Metal-Organic Mixtures to the Freshwater Algae *Raphidocelis subcapitata*

Maria Laura De Donno¹, Hugo Waeterschoot², Lara Van De Merckt³ and Karel De Schamphelaere⁴,
(1)GhEnToxLab, Ghent University, Belgium, (2)EUROMETAUX, Belgium, (3)AV DE TERVUEREN 168, Eurometaux, Belgium, (4)Ghent University, Belgium

Environmental risk assessment frameworks still predominantly follow a substance-by-substance approach, even though chemical contamination in the environment typically occurs as complex and often unknown mixtures. Regulatory agencies are increasingly recognising the need to assess the risks associated with chemical mixtures and to systematically integrate combined exposure and effects into chemical risk assessments. In this study, we investigate the aquatic toxicity of environmentally realistic mixtures containing both metal and organic contaminants.

We selected four representative real-world mixtures from the European freshwater monitoring database, focusing on combinations of five metals and four organic compounds. Monitoring database (EU Waterbase) analysis showed that five metals and five organics were sufficient to explain 90% of the overall mixture risk in 90% of samples. For each of the four metal-organic mixtures, we conducted 72-hour growth inhibition tests with the freshwater algae *Raphidocelis subcapitata*, following the OECD 201 guideline. We first performed range-finding tests to estimate the toxicity of the reconstituted metal mixtures and organic mixtures by testing them at different relative enrichment factors (REF). The REF is the metric used to express the concentration or dilution of a mixture of contaminants relative to their environmental levels, while maintaining their relative proportions constant. We then conducted binary mixture toxicity tests to assess any interactions between the metal and organic mixture groups.

Our specific experimental design aimed to address 2 main research questions: i) which mixture model, independent action or concentration addition, predicts more accurately the toxicity of environmentally realistic metal-organics mixtures, and ii) whether complex organic mixtures present below no-effect concentrations influence metal toxicity, and vice versa. If no influence is observed, it would suggest that metals and organic chemicals could be assessed independently in regulatory frameworks; vice versa, if an influence is observed, it would suggest that they should be considered jointly.

We aim that this study would provide relevant experimental data to improve our understanding of the joint toxicity of environmentally and regulatory relevant metal-organic mixtures, allowing a scientifically more robust risk assessment of chemical mixtures in aquatic environments.

3.12.P-Mo186 Influence of Environmentally Realistic Organic Micropollutant Mixtures on Metal Mixture Toxicity: Toward More Ecologically Relevant Risk Assessment

Matthieu Gallin¹, Marius Schmitt², Charlotte Nys³, Hugo Waeterschoot⁴, Lara Van De Merckt⁵ and Karel De Schamphelaere¹,
(1)Ghent University, Belgium, (2)GhEnToxLab, Ghent University, Belgium, (3)ARCHE Consulting, Belgium, (4)EUROMETAUX, Belgium, (5)AV DE TERVUEREN 168, Eurometaux, Belgium

Substance-by-substance risk assessments may underestimate mixture or combined exposure effects. Hence, a mixture assessment factor (MAF) is proposed as a default approach to address potential mixture effects, particularly given the limited understanding of how environmentally realistic organic micropollutant (OMP) mixtures may influence metal toxicity.

This study investigates whether an organic-metal MAF is needed and seeks to quantify its value by conducting 21-day reproduction tests with *Daphnia magna* (OECD 211). If realistic organic mixtures do not influence the toxicity of realistic metal mixtures, this could indicate that organics and metals can be regulated independently

within environmental risk assessment frameworks in respect to mixture toxicity.

To construct realistic exposure scenarios, metals in river samples were prioritized to reconstitute a quinary metal mixture representing environmentally relevant conditions. Organic compounds were extracted from wastewater treatment plant (WWTP) effluents using large-volume solid-phase extraction (LVSPE) to obtain a representative organic mixture. The metal mixture concentration series were then combined with varying amounts of this organic extract to quantify potential interaction effects. The experimental setup was replicated for 3 different river systems in Flanders: Dommel, Grote Struisbeek and Grote Nete.

Preliminary comparisons of metal mixture dose–response curves with various levels of added OMP indicate that organic mixtures exerted slight antagonistic to negligible effects on metal mixture toxicity. This interaction was both location - and concentration-specific. In most treatments, no significant influence of the OMP mixture was observed; only at certain organic–metal concentration combinations did a modest antagonistic effect occur. A possible explanation is that organic compounds in general may form complexes with metals, thereby reducing their bioavailability and mitigating toxicity.

Based on these findings, a specific organic–metal mixture assessment factor (MAF) does not appear necessary. Thus, LVSPE-extracted OMP influences on metal mixture toxicity may be considered negligible within the current environmental risk assessment framework for metals. Further replication of this experiment with additional test species and targeting other organics is required to validate whether the observed mechanism applies across multiple trophic levels and a broader set of organic-mixtures.

3.12.P-Mo187 Street-Level Contamination: Heavy Metal Pollution and Human Health Implications in South African Urban Soils and Sediments

Veronica Ngole-Jeme and Chinemerem Ruth Ohoro, University of South Africa (UNISA), South Africa

Highways are major sources of inorganic contaminants in urban environments, particularly in South Africa, where poor road conditions, heavy traffic, engine emissions, overloaded vehicles, industrial activities, and inadequate waste management contribute to elevated heavy metal pollution. These pollutants accumulate in street-level soils, creating exposure pathways like dermal contact, inhalation, and ingestion that pose significant health risks to pedestrians and street vendors. This study investigated the concentrations of priority heavy metals (As, Cd, Cr, Cu, Pb, Hg, Zn, Mn, Co, and Ni) in urban roadside soils from Johannesburg, Randburg, and Thohoyandou, selected to represent contrasting levels of traffic density, industrialization, and urban development. Results revealed unexpectedly high contamination levels in shaded soils of Thohoyandou, which, despite being a moderately trafficked and less industrialized town, recorded the highest concentrations of Pb (2261.98 mg/kg), Cr (179.23 mg/kg), Cu (260 mg/kg), Mn (899.81 mg/kg), and Co (44.35 mg/kg). Conversely, unshaded soils of Johannesburg displayed the highest Ni (330.05 mg/kg) and Hg (1762.41 mg/kg) levels, consistent with its intense urban and industrial activity. These findings indicate that heavy metal pollution is not solely driven by large-scale urbanization but can also be exacerbated by rapid town development, unregulated vehicle conditions, and inadequate environmental management practices. The elevated metal concentrations observed suggest potential ecological and human-health risks that warrant urgent attention. We recommend periodic monitoring of roadside soils, enforcement of vehicular emission standards, improved waste-management strategies, and targeted risk assessments for vulnerable populations living or working near busy roadways.

3.12.P-Mo188 Research on Source Analysis and Background Value Determination of Heavy Metals in Soil of Lead Zinc Mining Area in Southern Gansu Province

Yufeng Xie, Nanjing Institute of Environmental Sciences, Ministry of Ecology and Environment, China (Mainland)

In order to scientifically determine the background values of heavy metals in the soil of the Chengxi lead-zinc ore belt in southern Gansu, this study systematically collected multiple representative soil samples from the region and measured the contents of seven heavy metal elements, including As, Cd, Cu, Hg, Ni, Pb, and Zn. We adopted various internationally recognized methods such as traditional mathematical statistics, median $\pm$ 2MAD method, normalization processing method, and cumulative frequency curve method, and based on this, we developed a "robust iteration geochemical method" to comprehensively determine the soil background value range of each element. The sources and spatial differentiation characteristics of heavy metals were explored through correlation analysis and principal component analysis (PCA). The results indicate that the content of

Cd, Pb, and Zn in the soil of the study area is significantly higher than the national soil background values, showing obvious geochemical characteristics of mineralization. Correlation analysis and principal component analysis revealed three main sources of heavy metals: associated elements of lead-zinc mineralization (Cd, Pb, Zn), parent material sources of soil formation (Ni, Cu, As), and independent high background sources of mercury. The consistency of the background value range determined by multiple methods is strong, among which the new method is recommended as the best representation of the background value in the region due to its robustness. This study provides important benchmark data and scientific methods for accurate evaluation of environmental quality, pollution risk assessment, and ecological restoration in high background value areas.

3.12.P-Mo189 Copper Pollution in the Arctic - An Aggregate Exposure Pathway for Understanding Sources, Sinks, and Bioavailability

Sam Welch¹, Pierre Blévin², Camden Karon-Klefbom¹, Anita Evensen² and Knut Erik Tollefsen¹, (1)Norwegian Institute for Water Research, Norway, (2)Akvaplan-NIVA, Norway

Copper is both a vital nutrient and material in biota and industry, and a classical stressor for wildlife and the natural environment. Growing demand for copper and increasing Arctic industry will likely increase both copper emissions and concurrent stressors. A more comprehensive understanding of pollutant dynamics will aid academics and regulators in understanding pressures on this sensitive and rapidly changing region.

Aggregate Exposure Pathways (AEPs) provide a comprehensive, weight-of-evidence based framework for characterising chemical exposure to wildlife of interest. Although copper is among ecotoxicology's most studied pollutants, an overall assessment of copper pollution in the Arctic has not been conducted. AEPs are well suited to mapping the profile of Arctic copper pollution thanks to their support for synthesis of available literature and regulatory data with weight-of-evidence assessment. Thus, information on occurrence and dynamics can be integrated into a source to dose pathway description that identifies current knowledge and data gaps.

We present our work on developing an AEP for copper pollution and exposure to wildlife in and around the Arctic circle, based on a systematic review of scientific literature and an assessment of Norwegian environmental monitoring data. We assess sources, receiving compartments, flows, and biota exposure to copper in our qualitative based mapping. By comparing measured concentrations to background levels, we establish a threshold above which chemical analysis data can be considered evidence of contamination. By applying the Criteria for Reporting and Evaluating Exposure Datasets (CREED) to evidence lines we quantify the confidence in each line of evidence.

Our work advances the understanding of copper pollution in Scandinavia and the AEP concept, integrating best practice in exposure assessment, systematic literature, and weight-of-evidence assessment to take the paradigm to its next logical step. Additionally, it will serve as the basis for quantification and modelling of copper fate that can be used for environmental risk assessment as part of the Source to Outcome Pathway (STOP) concept.

3.13.A Harnessing Nature: Innovative Bioremediation and Phytotechnologies for Contaminant Removal and Ecosystem Recovery

3.13.A.T-01 Nature's Clean Up Crew: A System's Approach to Halogenated Contaminant Biotransformation

Gerardo Aguilar Jr¹, Andrew Ball¹, Leadin Khudur¹ and Attila Tottszer², (1)RMIT University, Australia, (2)ALS Global, Australia

Emerging contaminants, including per- and polyfluoroalkyl substances, pesticides, and legacy chlorinated solvents continue to persist and accumulate across ecosystems. Existing abiotic treatment technologies are costly, energy-intensive, require toxic inputs, produce secondary waste, and often incomplete in mixed-contaminant settings. Bioremediation research has historically focused on bacteria, leaving fungal pathways under explored despite their known oxidative and reductive enzymatic capabilities. This study addresses this gap by evaluating filamentous fungi as nature-based biocatalysts for halogenated contaminant transformation and establishing an integrated experimental-mechanistic-genomic workflow to characterise fungal dehalogenation capacity.

Bench-scale microcosms were constructed using white-rot and dematiaceous fungi exposed to halogenated nitrophenols as model substrates. Transformation products were monitored using GC–MS for volatile metabolites and ion chromatography for fluoride and chloride release. Abiotic and biological controls were included to quantify fungal contributions. Complementary bioinformatic analyses (Pfam/HMM domain mining, VCPO/CPO signature screening) were incorporated to identify putative oxidative, reductive, and vanadium-dependent enzyme systems linked to halogen metabolism.

Fungal cultures demonstrated clear transformation of both chlorinated and fluorinated substrates, with stoichiometric halide release confirming active dehalogenation. Toxicity assays indicated ~80% reduction in parent-compound toxicity and near-complete mineralization without detectable intermediates, contrasting with partial transformation typically reported for bacterial systems. Species-specific differences suggest concurrent oxidative and reductive mechanisms operating within fungal metabolism. These findings highlight a distinct and underutilized functional space for fungi in contaminant degradation.

The results provide a mechanistic foundation for integrating fungal biocatalysis into nature-based remediation systems, including engineered wetlands, fungal-amended biofilters, and organic-amendment matrices. Coupling fungal biochemistry with advanced analytical and genomic tools enables the development of scalable, low-impact treatment strategies aligned with sustainable environmental management.

Disclaimer/Disclosure:

Some genomic and enzyme-prediction data remain in preparation for publication and will be presented in summarized form.

3.13.A.T-02 Two complementary ways to overcome bioavailability restrictions in bioremediation: direct enhanced desorption and solubilization

Rosa Posada, Alicia Fernández-Vázquez and Jose Julio Ortega-Calvo, IRNAS-CSIC, Spain

The biodegradation of slowly desorbing polycyclic aromatic hydrocarbons (PAHs) in contaminated soils remains a major challenge in bioremediation. Biosurfactants offer a sustainable strategy to enhance pollutant bioavailability. While microbial biosurfactants like rhamnolipids are well-established, phytogenic surfactants such as saponin present a cost-effective, environmentally friendly alternative. Saponin is a non-ionic biosurfactant with excellent solubilization capacity for hydrophobic contaminants. This study investigates how saponin promotes PAH biodegradation through two complementary mechanisms: direct enhanced desorption and micellar solubilization. We employed a creosote-polluted soil containing 3,902 mg kg⁻¹ total PAHs. After 56 days of biostimulation, when most environmentally bioavailable PAHs were depleted, saponin was applied to mobilize the slow-desorbing fraction. Desorption kinetics of nine indicator PAHs were determined by Tenax extraction. Micellar solubilization was investigated in a NAPL/water biphasic system using ¹⁴C-labelled phenanthrene and pyrene at saponin concentration of 1 g L⁻¹ (above its critical micelle concentration of 0.1 g L⁻¹). Mineralization kinetics were correlated with PAH partitioning using the soil microbial community as inoculum. Results showed that direct enhanced desorption is the primary mechanism for enhanced biodegradation of slow-desorbing PAHs. Saponin sorption to soil aggregates swells the sorbent, enhancing intra-aggregate PAH diffusion and desorption. In biphasic systems, saponin induced contrasting effects: enhanced pollutant partitioning but inhibited microbial adhesion to the NAPL–water interface. Without saponin, phenanthrene mineralization rates exceeded partitioning rates. With saponin, mineralization kinetics shifted to linear rates corresponding to partitioning rates. We conclude that an initial biostimulation stage followed by saponin addition to degrade residual slow-desorbing PAHs is the most effective approach for improving soil bioremediation, and that balancing enhanced pollutant partitioning with inhibited microbial adhesion is critical for optimizing biosurfactant use in NAPL systems. These findings reinforce green chemistry approaches in bioremediation. Enhanced desorption by biosurfactant-containing biological fluids may increase PAH bioavailability in exposure scenarios such as earthworm gut and human respiratory tract, with implications for health effects.

3.13.A.T-03 Biological Granular Activated Carbon As A Reactive Barrier To Clean Up Groundwater Contaminated By PAHs.

Joy Ginika-Osuorji, Russell Davenport and David Werner, Newcastle University, United Kingdom

Background and Aim: Polycyclic aromatic hydrocarbons (PAHs) are persistent groundwater contaminants that demand long-term, sustainable remediation strategies. Permeable reactive barriers (PRBs) containing activated carbon (AC) are often used for PAH removal because of their strong adsorption capacity; however, this capacity is limited, leading to saturation, frequent media replacement, and reduced cost efficiency. To address the limitations, the present study investigates whether bioaugmented activated carbon (BAC), enriched with PAH-degrading microbial biofilms, can enhance PAH removal in PRBs by integrating adsorption with biodegradation. In BAC systems, saturated AC serves as a substrate for microbial colonisation, allowing microorganisms to utilise adsorbed organic matter as a nutrient source. As the biofilm matures across the carbon's pores and surfaces, it facilitates the biodegradation of both trapped and incoming contaminants. The goal of this study is to determine whether this self-cleaning mechanism can extend the operational lifespan and improve the overall performance of PRB systems used in groundwater remediation.

Methods: Batch experiments were conducted to compare pristine AC (adsorption only) and BAC (adsorption + biodegradation). A passive dosing approach using low-density polyethylene (LDPE) sheets preloaded with phenanthrene, pyrene, and perylene simulated gradual PAH release into groundwater. PAH concentrations were quantified using GC-MS following solvent extraction and nitrogen blowdown. The initial 28-day batch was followed by a 16-week extended experiment to observe long-term interactions.

Results: LDPE dosers released PAHs consistently, while pristine AC showed rapid initial adsorption approaching equilibrium after 42 days. In contrast, BAC maintained continuous pollutant removal beyond this point, suggesting biological removal, i.e. biodegradation. Among the tested compounds: Phenanthrene, pyrene and perylene, phenanthrene exhibited the highest biodegradation rate, achieving approximately 75% removal by day 6 in BAC systems.

Conclusion: BAC demonstrated superior and sustained removal of PAHs compared with pristine AC, confirming the potential for combined adsorption and biodegradation to occur in reactive barriers. The integration of BAC into PRBs offers a promising, sustainable solution for long-term groundwater remediation. Ongoing work involves column and microcosm studies to simulate realistic flow and PRB operating conditions.

3.13.A.T-04 Are there sustainable alternatives to biochar for reducing pollutant bioavailability? A look at biosealing bacteria

Bryan Martínez Monzón¹, José Luis García², Yair Cruz Narváez¹, José Javier Castro Arellano¹, Rosa Posada² and Jose Julio Ortega-Calvo², (1)Academia de Química Analítica y Análisis Instrumental, Escuela Superior de Ingeniería Química e Industrias Extractivas, Instituto Politécnico Nacional, Mexico, (2)Institute of Natural Resources and Agrobiology of Seville - Spanish National Research Council (IRNAS-CSIC), Spain

Immobilisation of organic pollutants is currently regarded as an effective strategy to mitigate chemical risks in soil by significantly reducing their bioavailability. This study evaluates whether *Bacillus subtilis* biosealing can serve as a sustainable alternative to traditional sorbents such as biochar, sand, and montmorillonite clay for reducing the bioavailability of hydrophobic organic pollutants. Naphthalene was used as a model contaminant to assess both adsorption and diffusion-limiting mechanisms. First, adsorption experiments in glass test bottles were conducted using equal masses of each material. Naphthalene concentrations were quantified by liquid scintillation, and Freundlich isotherms were constructed to compare sorption performance. All materials followed the Freundlich model with good agreement, confirming their capacity to immobilize naphthalene to varying degrees.

Second, diffusion through micrometre-scale pores was examined using membrane bioreactors equipped with 3 µm track-etched membranes. *B. subtilis* was applied on top of the membranes to induce pore clogging through biofilm formation. Naphthalene diffusing from the lower reservoir volatilized into the headspace and was trapped in cyclodextrin for daily quantification. The presence of *B. subtilis* markedly reduced naphthalene transport compared to bacteria-free controls, indicating effective biosealing of the pores. When combined with sorbents, diffusion decreased even further, with montmorillonite showing the strongest immobilization effect. Diffusion differences became evident after 2–3 days, consistent with the expected timeframe for bacterial deposition and pore clogging. Overall, the results demonstrate that *B. subtilis* biofilms can significantly limit contaminant mobility by physically obstructing pore spaces. When paired with clay or other sorbents, this strategy produces a synergistic reduction in naphthalene bioavailability, with sealing performance that surpasses conventional biochar in limiting naphthalene mobility through microporous media. These findings highlight biosealing as a promising, sustainable mechanism for mitigating pollutant spread in soils and porous media, potentially offering an alternative or complement to carbon-based amendments.

3.13.A.T-05 Metabolic pathways for biotransformation of benzalkonium compounds in fungal- and bacteria-based biofilm reactors

Yrsa Larsson¹, Marcell Nikolausz², Vaidotas Kisieličius³, Hnerik Bjarne Møller⁴, Ulrich Gosewinkel⁴ and Kai

Bester³, (1)ENvironmental Sciences, Aarhus University, Denmark, (2)Department of Microbial Biotechnology, Helmholtz Centre for Environmental Research–UFZ, Germany, (3)Environmental Science, Aarhus University, Denmark, (4)Aarhus University, Denmark

Benzalkonium compounds are a biocidal disinfectant and can accumulate in sewage sludge and manure, where its persistence and transformation pathways remain poorly understood. This study addresses how different biological treatment systems degrade benzalkonium compounds and how microbial communities respond to exposure. To investigate this, biofilm reactors were operated in three setups: water, a fungal system using *Trametes versicolor*, and manure. Reactors were spiked with benzalkonium chloride and monitored for chemical transformation, metabolite formation, and microbial community shifts. Sampling was performed over time to assess degradation kinetics, transformation pathways and community adaptation through chromatography, high-resolution mass spectrometry and sequencing of ribosomal RNA genes. All systems degraded benzalkonium compounds but with distinct kinetics. Wastewater originating biofilms showed rapid removal through oxidation of the alkyl chain, followed by additional oxidation steps. The fungal system performed only partial oxidation, while the manure reactors exhibited the broadest range of metabolites, including benzylic transformations and dealkylation reactions. These differences reflect the influence of microbial diversity on degradation routes as microbial community analysis demonstrated clear differentiation between systems. In water, oxidative degradation was dominating. In manure, genera previously associated with transformation of quaternary ammonium compounds were enriched, coinciding with the appearance of manure-specific metabolites. Across all systems, benzalkonium chloride exposure did not consistently increase the abundance of the antibiotic resistance genes that were screened. Overall, this work demonstrates that biodegradation of benzalkonium chloride depends strongly on environmental matrix and microbial community composition, leading to distinct removal efficiencies and metabolite profiles. These findings improve understanding of disinfectant fate in biological treatment systems and support more effective management of quaternary ammonium compounds in wastewater and manure treatment.

3.13.B Harnessing Nature: Innovative Bioremediation and Phytotechnologies for Contaminant Removal and Ecosystem Recovery

3.13.B.T-01 VIRTUE: A Virtuous Cycle of Phytoremediation, Pyrolysis and Biochar Applications towards Safe PFAS Levels in Soil, Feed and Food

Gerard Cornelissen¹, Erlend Sørmo², Nicolas Estoppey¹, Raoul Wolf¹, Nathalie Briels³, Thomas D. Bucheli⁴, Daniel Rasse⁵, Hans Peter Schmidt⁶, Emma Knight⁷ and Hans Peter H. Arp⁷, (1)Norwegian Geotechnical Institute (NGI), Norway, (2)NMBU, Norway, (3)ARCHE Consulting, Belgium, (4)Environmental Analytics, Agroscope, Switzerland, (5)NIBIO, Norway, (6)Ithaka Inst, Switzerland, (7)NGI, Norway

Many agricultural, natural and urban areas are PFAS-contaminated from sewage sludge, fire-fighting foam and industry. This causes large economic and societal damages in many countries but remediation is challenging. The overall research need is a method for remediation for diffuse PFAS contamination without negative tradeoffs. We propose a Virtuous Cycle by combining phytoremediation to accumulate short-chain PFAS, then destroying them by pyrolytic treatment, and applying the resulting PFAS-free biochar as a sorbent to immobilize long-chain PFAS in soil and stormwater. We will present investigations of PFAS contamination of agricultural, urban and natural areas in Norway. We will also present data on uptake in plant species suitable for phytoremediation. We refined earlier work on pyrolysis conditions optimal for PFAS destruction and effective biochar sorbents and will show data on >99% reduction in PFOS leaching with 1.5-5% biochar made from local plants. The layout of a full LCA quantifying positive environmental impacts will be presented, as well as the principles of human exposure modelling and a Bayesian network approach to aid in optimal implementation scenarios. The data will be coupled to results from the ARAGORN project where remediation is tested for 9 contaminated sites across Europe, and both phytoremediation and biochar amendment are tested for PFAS and other types of chemicals (heavy metals, OCBs, PAHs). We aim to provide partners and society with a practical solution for the enormous problem of PFAS soil pollution, applicable to other contaminants.

Disclaimer/Disclosure:

Funding was obtained from the Research Council of Norway, project VIRTUE (#357871) and the European Commission, project ARAGORN (#101112723).

3.13.B.T-02 Biochar as Efficient Sorbents for the Retention of Road Runoff Pollutants in Tree Trench Biofilters

Xiangyu Ji, Anett Georgi, Lukas Wick, Katrin Mackenzie and Hauke Harms, Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Blue-green infrastructures, such as tree trench biofilters, have untapped potential to reduce subsurface contamination by road runoff pollutants. Runoff is characterized by highly variable quantities and chemical loads that may overwhelm microbial transformation and lead to pollutant transfer to the subsurface. Augmenting biofilter systems with carbon-based sorbents may allow for fast transitory retention of pollutants in high load periods and continuous slow release for long-term biodegradation.

Wood-based biochar thereby emerges as a sustainable and cost-effective sorbent. However, the role of physicochemical biochar properties for efficient transitory retention and slow pollutants release for subsequent biodegradation is still poorly understood.

Here, we compare untreated wood-derived biochar (BC) and gas-activated biochar (BAC) with respect to the retention of four typical road-runoff pollutants: naphthalene (NAPH), methyl tert-butyl ether (MTBE), 1,3-diphenylguanidine (DPG) and perfluorooctanoic acid (PFOA). Batch experiments were used to derive sorption isotherms and sorption kinetics; Flow-through retention was evaluated in small columns and compared with FAST 2.0 and AdDesignS predictions based on batch-derived isotherm and diffusion parameters; Pilot-scale tests were conducted in a 1 m³ IBC unit subdivided into four compartments with identical substrate and gravel layers, but different top layers (soil, soil with grass, soil with BC, soil with BAC).

From the batch experiments, all pollutants showed substantially higher adsorption on BAC than on BC, with more than an order of magnitude increase in capacity despite an only 2.4-fold increase of its surface area. Kinetic data revealed strong diffusion limitations in BC, while mesopores in BAC enabled markedly faster intraparticle transport. Column experiments confirmed rapid initial DPG removal by BC followed by early breakthrough (about 40 pore volumes), whereas model simulations predicted more than 70% sustained removal for BAC over 500 pore volumes. Pilot-scale results corroborated these trends: BAC achieved the highest pollutants retention, whereas BC performed similarly to the grass and soil treatment. Overall, BAC proved to be the most suitable amendment for tree trench biofilters, as confirmed across batch tests, column experiments, modelling, and pilot-scale test systems. This integrated approach provides a robust framework for scenario-based design of biochar-amended biofilter systems.

3.13.B.T-03 Comparative Study of Nature-Based Reclamation of Distinct Greywater Streams

M. Eugenia Valdés¹, Lucas Leonel Alonso¹, Esther Mendoza¹, Massimiliano Riva¹, Maria Pau Garcia-Moll², Joaquim Comas³, Meritxell Gros¹, Sara Rodriguez-Mozaz¹ and Gianluigi Buttiglieri⁴, (1)Catalan Institute for Water Research (ICRA), Spain, (2)Catalan Institute for Water Research (ICRA), University of Girona (UdG), Spain, (3)Catalan Institute for Water Research (ICRA), LEQUIA-Institute of the Environment (UdG), Spain, (4)Quality Area, Catalan Institute for Water Research (ICRA), Spain

Water reuse is increasingly prioritised in the Mediterranean region, despite technical, social and safety barriers. Nature-based solutions, e.g. green walls, offer environmentally friendly options for water reuse, nutrient recovery and urban agriculture. However, their performance is still insufficiently documented, particularly for greywaters. This study aimed at evaluating: (i) the treatment efficiency of two full-scale demonstration green wall facilities operating with real greywater, and (ii) the suitability of their effluents for reuse. The first system, GRETA (Sant Quirze del Vallès, Spain), has operated since April 2023 treating up to 220 L·day⁻¹ of shower, sink and rainwater using 8 planted modules (substrate perlite, gravel, LECA with 24 plant species), horizontal flow and an ozonation step. The second facility, the experimental green wall (EGF) at ICRA (Girona, Spain), has operated since January 2025 treating 180 L·day⁻¹ of kitchen and sink greywater with four modular sectors combining vertical and horizontal flow, LECA–perlite substrates and 5 plant species. Water quality was monitored for 3-4 weeks at both systems, analysing regulated parameters and contaminants of emerging concern. Samples were extracted by SPE and analysed by LC-MS/MS (PPCPs, EDCs, plastic additives) and LC-HRMS (suspect screening). Environmental safety was assessed through risk quotients and current regulations. Both systems showed good physicochemical and microbiological performance. GRETA achieved high removals of ammonia (99%), total nitrogen (80%), E. coli (>99%), organic matter (80-98%) and TSS (96%). EGF removed 80–90% of organic matter without increasing alkalinity or TSS. GRETA showed high removal of several pharmaceuticals (ibuprofen, acetaminophen 99–100%; valsartan 88%; fluoxetine 100%), while others improved after ozonation (carbamazepine 20–93%). Caffeine was frequently detected yet efficiently removed (94%). Some antibiotics showed negative removal in the first step but were eliminated by ozonation. Chemical analyses and risk assessment for EGF are ongoing. Overall, green wall systems

demonstrate strong potential for treating greywater in urban buildings, meeting reuse standards and effectively removing organic micropollutants. These results support the development of innovative, decentralized and cost-effective water reuse schemes that contribute to water-scarcity resilience and sustainable circular water systems.

3.13.B.T-04 Remediation of PFAS Contaminated Soil Using Sorbent Stabilization with Activated Carbon and Sewage Sludge Biochar: Insights on Plant and Earthworm Uptake and Ecotoxicity

Ingrid Rijk¹, Felicia Frederiksson², Christina Prevazi², Maria Larsson³, Dan Berggren Kleja⁴, Anja Enell⁵, Maria Florberger⁶, Alf Ekblad⁷, Susanne Karlsson⁸, Matilda Wiberg⁹, Erlend Sørmo¹⁰, Katinka Muri Krahn¹¹ and Anna Kärrman¹, (1)Orebro University, Sweden, (2)Örebro University, Sweden, (3)MTM Research Centre, Örebro University, Sweden, (4)Swedish Geotechnical Institute, Sweden, (5)Swedish Geotechnical Institute, Sweden, (6)Geosyntec Consultants AB, Sweden, (7)School of Science and Technology, Örebro University, Sweden, (8)Structor Miljö Öst, Sweden, (9)Structor Miljöteknik, Sweden, (10)Norwegian University of Life Sciences, Norway, (11)Lindum, Norway

Two potential effective (bio)char types for remediation of soils contaminated with per- and polyfluoroalkyl substances (PFAS) are activated carbon (AC) [2] and sewage sludge-based biochar (BC-SS) [3]. Both have demonstrated similar, large sorption capabilities for longer chain PFAS, however, sorption of shorter chain PFAS may be less effective and only few studies have investigated sorbent effects on zwitterionic PFAS. Furthermore, the profound effects that these sorbents can have on uptake by plants and earthworms and potential ecotoxic effects also remain an area requiring further research.

Two PFAS-contaminated soils (“Med PFAS” 750 µg ΣPFAS kg⁻¹ soil; “High PFAS” 2000 µg ΣPFAS kg⁻¹ soil) were collected from former firefighting areas in Sweden. The soils were treated either without any additions (Control); 1% (w/w) compost (+ fertilizer in plant test) (FC); 1% compost and 2% of a wood-based commercially available AC (BC-AC), or 1% compost and 2% BC-SS (BC-SS). The mixtures were tested for PFAS solubility using a batch leaching test, plant growth and PFAS uptake in perennial ryegrass *Lolium perenne*, and acute toxicity, reproduction and PFAS uptake in earthworms *Eisenia fetida*. Up to 54 neutral, anionic, cationic and zwitterionic PFAS were targeted and analyzed using UPLC MS/MS.

Both biochars resulted in very effective in stabilization of PFAS in the soils. In the Med PFAS soil, ΣPFAS decreased with 95.7% in the leachate with BC-SS and 99.6% with BC-AC, with compost contributing to the retention. Plant growth increased with compost, biochar and fertilizer addition, with the highest biomass observed using BC-SS. Uptake of PFAS in earthworms and plants was highly reduced in BC-AC treatments (resp. 97% and >99% reduction of ΣPFAS). BC-SS treatments showed similar reduction of PFAS uptake in earthworm (95%) but some remaining short-chain PFAS uptake in plants (75% reduction of ΣPFAS). However, BC-AC and in a lesser extent also BC-SS decreased earthworm biomass and reproduction. In conclusion, we show that these biochars are effective PFAS stabilizers and provide a promising approach to stabilize PFAS in situ. However, there is a need to balance sorbent addition with potential negative side-effects to biota.

3.13.B.T-05 Pilot Scale Study for a Green Recovery of a Construction Site Area

Anna Barra Caracciolo¹, Ludovica Rolando¹, Rodolfo Gentili², Antonio Finizio², Chiara De Carolis¹, Alessandra Narciso¹ and Paola Grenni³, (1)Italian National Research Council (CNR), Italy, (2)University of Milano Bicocca, Italy, (3)Water Research Institute, Italian National Research Council (CNR), Italy

Tunnelling projects can significantly affect natural ecosystems, causing habitat loss and degradation as result of extensive surface soil removal for setting up a construction site. The soil is piled up for long time up, with a consequent loss of vegetation cover at the construction site. Moreover, millions of cubic metres of soil excavated (spoil material, SM) are generated for tunnel implementation. Although SM can be valorised and reused (in accordance with circular economy principles), its chemical stabilization with lime (LSM) for facilitating its handling, owing to high pH values, can influence its use for greening purposes.

This work reports a case study related to the A1 highway tunnel construction (Apennine Mountains near Florence, Italy), where a revegetation planning is underway. Four-year mesocosms consisting of mixed SM with surface soil and different organic amendments (compost, pomace and digestate) tested the growth of five native tree/shrub species: *Ostrya carpinifolia* (black hornbeam), *Quercus pubescens* (downy oak), *Fraxinus ornus* (ash),

Olea europaea (olive) and *Corylus avellana* (hazel). The mesocosms consisted of a topsoil layer (0–30 cm depth, initial pH: 8), an intermediate layer (35–50 cm depth) consisting of LSM amended with compost or pomace or digestate and a deeper LSM layer (50–60 cm, depth pH: 11–12). Two control conditions (only topsoil and untreated SM) were also set-up. Plant survival and growth, soil parameters (e.g. pH and organic carbon) and microbial community abundance and activity were evaluated over time. Organic amendments improved soil quality, thanks to the introduction of active microbial populations if compared with controls. At 48 months, pH values were comparable both in the amended and non-amended conditions, indicating that microorganisms played a key role in moderating the alkaline conditions of SM and facilitating its mitigation. In fact, microbial taxa, which have in their functional profile genes involved in pH homeostasis, have been identified. Moreover, tree mortality was quite low (15%) and mostly affected oaks (*Quercus pubescens*, 38%). Tree performances among different amendments did not show statistical differences, except one species (*Olea europaea*) grown on surface soil (control) which had the best performance because the pH was lower than 8 in all layers.

3.13.P Harnessing Nature: Innovative Bioremediation and Phytotechnologies for Contaminant Removal and Ecosystem Recovery

3.13.P-We243 Assessment via Target and Suspect Screening of the Fate of Mobile Organic Contaminants and Transformation Products in Sustainable Urban Drainage Systems

Filippo Chierchini¹, Sergio Santana-Viera², Marc Teixidó Planes³ and Sandra Perez Solsona⁴, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (2)Instituto Universitario de Estudios Ambientales y Recursos Naturales (i-UNAT), Universidad de Las Palmas de Gran Canaria, Spain, (3)Geosciences, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (4)Environmental Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Rapid urbanization and climate change are driving a transition from grey infrastructure to nature-based solutions like Sustainable Urban Drainage Systems (SUDS) for stormwater management. While effective for filtering conventional pollutants (e.g., metals, solids), their efficacy against mobile organic contaminants remains elusive. In particular, due to high water solubility and low sorption, polar Persistent, Mobile, and Toxic (PMT) substances often bypass biofiltration. Furthermore, biological activity within SUDS may facilitate incomplete degradation, generating Transformation Products (TPs) that could be more persistent or toxic than their precursors and are not included in standard monitoring.

This study assesses the fate of mobile contaminants across the urban infiltration pathway in Barcelona. The objectives were to: i) develop a targeted HPLC-QqQ method for 52 contaminants (pesticides, industrial chemicals, tyre-related compounds, and PPCPs); and ii) analyze known and in-silico predicted TPs via HRMS suspect screening. Sampling campaigns covered first-flush stormwater, SUDS effluents, and groundwater. A specialized sample preparation protocol using lyophilization and reconstitution was validated to overcome SPE limitations for hydrophilic substances, yielding recoveries of 70–120%.

Analysis revealed a high occurrence of polar anthropogenic contaminants in street runoff, with concentrations reaching 10 µg/L. Comparing influents with effluents showed that while SUDS significantly reduce the total contaminant load, specific polar compounds exhibit "breakthrough" behavior. Notably, hazardous PMTs such as TCPP and Melamine were found enriched or poorly retained in effluents. Additionally, suspect screening will tentatively identify TPs formed during infiltration.

These findings indicate that SUDS, while promising, may act as source of mobile chemicals into the underneath zone. This underscores the necessity of integrating advanced monitoring to evaluate the chemical security of green infrastructure and protect groundwater resources.

3.13.P-We244 Links Between Environmental Heterogeneity, Microbial Community Assembly, and Micropollutant Removal in Constructed Wetlands

María José Monge Salazar¹, Joeselle Serrana², Arild Gustafsson¹ and Malte Posselt³, (1)Stockholm University,

Sweden, (2)Department of Environmental Science, Stockholm University, Stockholm, Sweden, (3)Department of Environmental Science, Stockholm University, Sweden

Constructed wetlands (CWs) are widely used as nature-based solutions to improve water quality. In urban areas, they often receive stormwater or treated wastewater discharged directly from wastewater treatment plants. CWs receiving treated effluents play a crucial role in intercepting micropollutants, such as pharmaceuticals, personal care products, and pesticides. Despite their importance, the mechanisms through which CW design, vegetation structure, and habitat heterogeneity shape microbial communities and facilitate micropollutant removal remain poorly understood. This knowledge gap limits our ability to optimize CW performance for eliminating organic contaminants that persist after conventional wastewater treatment. Although CWs are less heterogeneous than natural lakes or rivers, they contain substantial small-scale variability. Differences in ponds shape, pollutant loads, plant species, and vegetation cover create environmental gradients that generate diverse microhabitats. These microhabitats can influence microbial community assembly and, in turn, affect the capacity of CWs to attenuate organic micropollutants. We therefore hypothesize that CWs with greater within-system heterogeneity will support more taxonomically and functionally diverse microbial communities, resulting in enhanced micropollutant biodegradation. Previous research has largely relied on laboratory studies to evaluate microbial and micropollutant dynamics, but these controlled settings rarely capture the shifting environmental conditions and complex chemical mixtures present in full-scale systems. As a result, our understanding of how full-scale CWs function at the microbial level remains incomplete. This study aims to investigate how environmental heterogeneity across and within CWs influences microbial community composition and micropollutant attenuation. Fieldwork was conducted between June and October 2025. During this period, water and sediment samples were collected from nine horizontal surface-flow CWs in Sweden to profile microbial communities and quantify organic micropollutants. Additionally, plant composition and vegetation cover were assessed through field surveys, environmental DNA analysis, and aerial imagery. The results will highlight how engineered ecosystems can be designed or managed to maximize micropollutant removal and support the development of more effective and ecologically grounded wastewater treatment.

3.13.P-We245 From pilot to deployment: a high-efficiency, nature-based technology for contaminant removal and ecosystem recovery

Nooshin Barzegar Marvasti¹, Rhys Coldrick², Iestyn Stead², Muhammad Abdullahi Mr³, William A. Stubbings Dr⁴, Mohamed Abou-Elwafa Abdallah Dr⁴, Karl D. Dearn², Robert G. Lee⁵ and **Luisa Orsini**⁶, (1)University of Birmingham, United Kingdom, (2)Department of Mechanical Engineering, and Centre for Environmental Research and Justice, University of Birmingham, United Kingdom, (3)Biosciences, University of Birmingham, United Kingdom, (4)School of Geography, Earth, and Environmental Sciences, University of Birmingham, United Kingdom, (5)Birmingham Law School and Centre for Environmental Research and Justice, University of Birmingham & Daphne Water Solution Limited, United Kingdom, (6)School of Biosciences and Centre for Environmental Research and Justice, University of Birmingham, United Kingdom

Water pollution is a defining environmental and public health challenge. Conventional wastewater treatment plants (WWTPs) were never designed to remove persistent, mobile, and toxic (PMT) chemicals, such as pharmaceuticals, pesticides, microplastics, and PFAS. These chemicals, some known as “forever chemicals”, pass largely untreated through current systems, accumulate in surface and groundwater, and eventually return to our table through the food chain. Their growing presence threatens drinking water security, degrades ecosystems, increases human health risks, and raises regulatory pressures on utilities and industries.

Daphne Water Solutions (DWS) Ltd. addresses this gap with a patented, nature-based tertiary treatment technology developed over more than a decade of research. The system harnesses the biofiltration capacity of *Daphnia* (water fleas), freshwater organisms long used as sentinel species in ecotoxicology. Unlike many nature-based approaches, which are slow and infrastructure-intensive, the DWS system is engineered for speed and scalability. It operates within the hydraulic retention times of municipal WWTPs, removing contaminants in hours rather than days. It is modular, retrofittable, and produces no toxic by-products.

Here, we report results from near real-world demonstrations, including a 12-month continuous operation of a 2.7 m³ prototype treating secondary effluent. The system achieved removal efficiencies of up to >93% across 32 target contaminants, including PFAS and microplastics. Based on these outcomes, DWS has advanced to commercial-scale pilots at large WWTPs and decentralized deployments in rural and heritage sites, testing the system under diverse operational and regulatory conditions.

A recent life cycle assessment (LCA) further quantified the environmental benefits of the technology, showing a 20% reduction in freshwater ecotoxicity potential and an 8% reduction in eutrophication risk compared to conventional and nature-based tertiary treatments. These improvements make the DWS technology a game changer for enhancing water quality while actively protecting biodiversity and human health.

The platform offers a scalable, energy-efficient, and low-impact solution that aligns with circular water strategies and accelerates progress toward Net Zero environmental goals.

3.13.P-We246 Lignosulphonate, A Green Surfactant-Driven Bioavailability to Accelerate Bioremediation: A Circular Strategy to Address Recalcitrant Contaminants in Polluted Soils and Sediments

Muneeswari Rajasekaran, Mohammad Sadia, Gabriel Dupaul and Gabriela Lucia Paladino, Mid Sweden University, Sweden

Bioremediation-oriented clean-up technologies offer a viable solution for the removal of persistent organic pollutants (POPs) and reclamation of polluted soil and sediments. However, the limited bioavailability of POPs within the complex environmental matrices remains a key bottleneck in achieving successful bioremediation. Enhancing bioavailability substantially improves microbial access to recalcitrant pollutants, thereby accelerating biodegradation and resulting in effective clean-up. Recently, surfactant-aided strategies have shown promise in enhancing the bioavailability of hydrophobic organic contaminants, aiding microbial metabolic breakdown and accelerating the rate of bioremediation. Despite their advantageous role, the environmental drawbacks of chemical surfactants and the expensive manufacturing cost associated with biosurfactants demand the need for viable, sustainable alternatives. In this context, the present study focuses on investigating the potential of lignosulfonate, a sulphite pulping by-product comprised of lignin and sulphonate functional groups that confer surface-active characteristics, as an environmentally friendly surfactant for enhancing the pollutant bioavailability during bioremediation. In addition, its established application in soil stabilisation signifies its suitability as a potential safer candidate for environmental applications, while its origin as an industrial side stream contributes to resource circularity. In this study, the impact of lignosulphonate surfactant on the bioavailability of a broad spectrum of emerging contaminants, including Polychlorinated biphenyls, polycyclic aromatic hydrocarbons, dioxins and related hydrophobic pollutants present in aged, contaminated soil and fibre-rich sediments will be evaluated. Then, the lignosulphonate performance will be systematically compared with different classes of other green surfactants—such as rhamnolipid, Eco-Tween 80, and saponin. The surfactant-mediated enhancement in contaminant bioavailability will be further benchmarked against the environmental bioavailability of POPs determined by the standardized desorption extraction method using TENAX, which is a valuable tool used in environmental risk assessment. The study is anticipated to explore how lignosulphonate can act as a safe, low-cost green surfactant that improves bioremediation efficiency, thereby advancing the successful mitigation of hazardous pollutants and the restoration of contaminated environments.

3.13.P-We247 Removal of per- and polyfluoroalkyl substances in a Multifunctional Decentralized Wastewater Treatment System

Anne Röhrig¹, Qiuguo Fu², Petra Ariette Schierz², Martin Krauss², Khaja Rahman², Lucie Moeller² and Nico Grasse², (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Department for Environmental Analytical Chemistry, Germany, (2)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Water scarcity and the need for resilient water management are driving interest in local wastewater reuse. Per- and polyfluoroalkyl substances (PFAS), particularly ultra-short-chain compounds such as trifluoroacetic acid, persist through conventional treatment and pose environmental and human health risks. This study evaluates a pilot-scale, multifunctional, decentralized system that combines an aerated vertical-flow constructed wetland with an activated carbon filter derived from sewage sludge, with the aim of enhancing PFAS removal.

The treatment train for municipal wastewater treatment at the BDZ site in Leipzig included primary sedimentation in a three-chambered septic tank, an aerated vertical-flow constructed wetland (supporting plant-microbe interactions) for secondary treatment, and additional tertiary treatment steps (optional): slow sand filtration, ultraviolet irradiation, and activated carbon filtration. Composite samples were collected over five weeks across the three treatment steps. PFAS, from ultra-short to long-chain compounds including precursors, were quantified using targeted liquid chromatography-mass spectrometry.

The biological treatment in the constructed wetland only achieved limited PFAS removal, with some increases potentially due to precursor transformation. Tertiary treatment steps incrementally improved removal performance, while activated carbon achieved the highest removal for short and long-chain PFAS. Certain ultra-short PFAS showed partial reduction, whereas trifluoroacetic acid and trifluoromethanesulfonic acid remained persistent. Overall, the integrated system outperformed conventional centralized wastewater treatment plants for removing most of the PFAS.

These findings demonstrate that decentralized, multifunctional systems integrating engineered natural processes with waste-derived activated carbon can enhance PFAS elimination, support safer wastewater reuse (e.g., agricultural irrigation purposes), and offer a scalable, low-impact alternative to conventional treatment. Ongoing work also investigates plant uptake and optimization to address persistent ultra-short PFAS, highlighting the potential of nature-based strategies for sustainable contaminant management and ecosystem protection.

3.13.P-We248 Two stage biological removal of chlorophenoxy acid pesticides combining moving bed biofilm and biofiltration reactors from contaminated groundwater. A pilot-scale study

Andrea Mongelli¹ and **Kai Bester²**, (1)Environmental Chemistry and Toxicology, Aarhus University, Denmark, (2)Environmental Science, Aarhus University, Denmark

Across Europe, groundwater is increasingly affected by complex mixtures of legacy and emerging contaminants, including pesticides and their transformation products from production residues. Within this context, nature-based and low-impact remediation systems provide promising alternatives to conventional treatments. A pilot study was conducted at the Stengården landfill, which was loaded with municipal wastes as well as production residues of pesticides site in Denmark to evaluate a biologically driven treatment process for pesticide-contaminated groundwater under high iron concentrations.

The pilot system combines Moving Bed Biofilm Reactors (MBBR) and biofilters, representing an engineered natural system designed to enhance microbial degradation while minimizing energy and chemical inputs. The study aimed to quantify removal efficiencies for the herbicides mecoprop, dichlorprop and their metabolites, as well as to investigate how environmental and process factors such as iron, hydraulic retention time, dissolved oxygen and temperature influence biotransformation pathways. Monitoring included targeted chemical analyses and operational parameters to assess performance under realistic field conditions.

The system achieved high removal of the parent pesticides (85 percent on average) and moderate removal of the metabolites (60 percent). Effluent concentrations of mecoprop and dichlorprop consistently met the European Union drinking water limit of 0.1 µg/L, while metabolite concentrations remained above the threshold. Removal efficiencies showed positive correlations with dissolved oxygen in the biofilter. Elevated iron levels, approximately 30 mg/L, inhibited mecoprop degradation, suggesting an interaction between redox dynamics, microbial activity and contaminant transformation.

This work demonstrates how engineered biological systems can support the treatment of groundwater impacted by emerging contaminants, offering a scalable and energy-efficient nature-based solution. The findings improve understanding of pesticides from production residues degradation under variable environmental conditions and contribute to the development of sustainable remediation strategies aligned with the principles of the European Green Deal and ecosystem restoration initiatives.

3.13.P-We249 Plastic additive enrichment drives shifts in microbial communities with traits of plastic degradation

Matthew Tarnowski, Andy Stawowy and Eva C. Sonnenschein, Swansea University, United Kingdom

Plastics incorporate numerous chemical additives that improve material performance but also contribute to environmental contamination due to their persistence and tendency to leach. Microbial degradation provides a promising route to mitigate these pollutants, though effective screening approaches for active degraders remain limited. This study combined biochemical assays with 16S rRNA amplicon sequencing to identify microbial communities capable of degrading common plastic additives. Microbial inocula from contrasting environments – natural (Chessel Bay, Swansea Bay) and anthropogenic (wastewater treatment and recycling plants) – were enriched for 22 days using di(2-ethylhexyl) phthalate (DEHT), tetradecane, or a no-additive control. High-throughput assays were adapted to quantify community-level growth, cell death, redox potential, and esterase activity across treatments. DEHT cultures supported the greatest microbial growth, while tetradecane exposures showed enhanced redox activity, suggesting distinct metabolic responses to ester versus alkane additives. Sequencing revealed 957 amplicon sequence variants across 36 cultures, with PERMANOVA indicating that substrate type explained 39–63% of the variance in community composition. Both additives enriched bacterial taxa with recognized plastic-degrading potential, such as Nocardiaceae, which correlated with elevated esterase activity. Intriguingly, families not previously linked to plastic degradation, including Vermiphiliaceae, also increased in relative abundance, suggesting untapped biodegradative capacities within environmental microbiomes. Overall, these results demonstrate that diverse microbial communities from natural and engineered systems can metabolize ester- and alkane-based plastic additives. The integrated biochemical–molecular approach developed here enables scalable identification of biodegradative consortia and holds promise for advancing microbial bioremediation of plastic-associated pollutants.

3.13.P-We250 Role of plant leaves in the degradation of airborne pollutants: biodegradation vs. photodegradation of Polycyclic Aromatic Hydrocarbons

Elisa Terzaghi¹, Corinne Bertipaglia¹, Elisabetta Zanardini¹, Davide Siniscalchi¹, Renzo Bagnati², Alice Passoni², Laura Rampazzi³, Cristina Corti⁴, Jose Julio Ortega-Calvo⁵, Rosa Posada⁵ and Antonio Di Guardo¹,
(1)Department of Science and High Technology, University of Insubria, Como, Italy, Italy, (2)Department of Environmental Health Sciences, Istituto di Ricerche Farmacologiche “Mario Negri” IRCCS, Milan, Italy, Italy, (3)Department of Human Sciences and Innovation for the Territory, University of Insubria, Como, Italy, Italy, (4)CRIETT, University of Insubria, Italy, (5)Institute of Natural Resources and Agrobiology of Seville - Spanish National Research Council (IRNAS-CSIC), Spain

Polycyclic aromatic hydrocarbons (PAHs) constitute a class of organic contaminants, that can derive from the incomplete combustion of wood and fossil fuels and vehicular traffic. Once emitted they can be found in the atmosphere in gaseous form or associated to particulate matter. Plants can remove PAHs from the air through the so called Forest Filter Effect (FFE) accumulating these compounds in leaves and transferring them to soil. Moreover, the phyllosphere host significant amounts of bacteria that can contribute to the biodegradation of PAHs producing metabolites such as OH-PAHs. However, no studies are available so far about the presence and source of PAH metabolites in plant leaves. Just few works reported data about their photodegradation on leaf surfaces.

In this work, new aspects of FFE were investigated through several laboratory experiments of increasing ecological complexity. More specifically, the study was designed to evaluate for the first time the contribution of light and phyllosphere microbial communities of *Quercus ilex* leaves to the degradation of deuterated PAHs (naphthalene-d₈, acenaphthene-d₁₀, phenanthrene-d₁₀, pyrene-d₁₀, chrysene-d₁₂, and perylene-d₁₂). Such degradation was investigated by observing the production of deuterated PAH hydroxy metabolites (OH-PAHs). This was performed through target and suspect screening analyses of PAH metabolites using an UHPLC-HRMS (LC-Orbitrap).

OH-PAHs were produced both in light and dark conditions (generally after 7 days), while their appearance in sterile controls was negligible. The number of PAH metabolites and their isomers increased when entire leaves were used rather than the inoculated phyllosphere microorganisms only, confirming the degradation ability of native phyllosphere microbial communities. Although preliminary, these results showed that FFE can be enhanced by photo- and biodegradation processes, because these degradation reactions could help to maintain a high air to leaf PAH gradient, since these compounds could be continuously removed. Additionally, the metabolites produced, being more polar and less hydrophobic, may likely be washed off during rainfall events, and be transported to the terrestrial environment, restoring the PAH gradient.

Further and more realistic studies are necessary to better quantify the contribution of phyllosphere biodegradation and photodegradation on PAH removal from air (phylloremediation) and their precise role in FFE.

3.13.P-We251 Iron-Enriched Biochar for the Removal of Mn(II) and Ni(II) from Drinking Water

Juliette Lepley¹, Nikolas Hagemann², Thomas D. Bucheli³ and Roland Kallenborn⁴,
(1)Environmental Analytics, Agroscope, Zürich, Switzerland & Faculty of Chemistry, Biotechnology and Food Science,

Norwegian University of Life Sciences (NMBU), Switzerland, (2)Ithaka Institute, Goldbach, Germany & Environmental Analytics, Agroscope, Zürich, Switzerland, Germany, (3)Environmental Analytics, Agroscope, Switzerland, (4)Faculty of Chemistry, Biotechnology and Food Science, Norwegian University of Life Sciences (NMBU), Norway

Highly-contaminated drinking water with Mn(II) and Ni(II) poses public health risks, including adverse neurodevelopmental effects and eczematous flare-ups in children. Efficient removal of these Potentially Toxic Elements (PTEs) is crucial to ensure safe drinking water consumption, as described by the UN Sustainable Development Goal 6: Clean Water and Sanitation. Iron-based materials have emerged as low-cost, effective, and clean alternatives to activated carbon for water treatment; however, their application is limited by aggregation, surface passivation, and low selectivity. Biochar has increasingly been used as a carrier material to mitigate these limitations due to its high specific surface area, functional groups, and conductivity. However, no studies have evaluated the efficiency of iron-enriched biochar for Mn(II) and Ni(II) removal from synthetic aqueous solutions or real drinking water. The aim of this study is to assess the efficiency of iron-enriched biochar for Mn(II) and Ni(II) removal from synthetic solutions and highly-contaminated drinking water from Longyearbyen, Svalbard. Iron-enriched biochars will be produced by co-pyrolysis of Brewer's Spent Grains and hematite (Fe₂O₃) at 400, 500, 600, and 700°C, and tested in batch experiments using synthetic solutions and contaminated drinking water samples. Adsorption experiments will be conducted under various conditions (temperature, pH, contact time, and sorbent dosage) to determine removal efficiencies, kinetics, and isotherm behavior. Iron-enriched biochar characterization (elemental analysis, FTIR, XRD, SEM-EDS, etc.) will be exploited to link material properties, iron species formation, and surface chemistry to observed removal mechanisms. We expect that increasing pyrolysis temperature will enhance biochar conductivity; thus increasing electron-transfer rates for removal of Mn(II) and Ni(II). However, higher temperatures are also expected to decrease the abundance of surface functional groups; thus reducing metal-ion complexation. The overall removal efficiency will therefore depend on the balance between these two temperature-dependent effects. The results of this study will provide insight into the suitability of iron-enriched biochar as a low-cost, environmental-friendly technology for Mn(II) and Ni(II) removal from real drinking water, and contribute to future work on urban farming in the Arctic and its potential application to soils to limit plant uptake of PTEs and heavy metals.

Disclaimer/Disclosure:

The study was funded by the EU HORIZON 2.6 Programme (ArcSolution, grant-ID: 101135051)

3.13.P-We252 Uptake and Depuration of Short- and Long- Chain Per- and Polyfluoroalkyl Substances in Submerged, Floating and Emergent Aquatic Plants

Michael Deligiannis¹, Adamantia Kampioti², Anna Huang¹, Ruben Meine Kause², Jan Baas¹, Stefan van Leeuwen², Steven Droge¹ and Ivo Roessink¹, (1)Wageningen University and Research (WUR), Netherlands, (2)Wageningen Food Safety Research (WFSR), Netherlands

Per- and polyfluoroalkyl substances (PFAS) are persistent anthropogenic chemicals, widely used in industrial and consumer products for their water and grease-resistant properties. They are major pollutants of water bodies and, due to their persistence and bioaccumulation, they pose a danger to aquatic organisms. Aquatic plants can remove PFAS from contaminated water through uptake and potential enzymatic degradation. Different wetland species vary in their PFAS uptake capacity, influenced by plant type and biomass per water volume. PFAS can enter plants through roots or the entire plant structure in submerged species, floating plants are in contact with the upconcentrated levels at the air-water boundary, and emerging plants translocate PFAS out of the water into their leafy and reproductive tissues. Aquatic plants are a potential, cost-effective solution for the remediation of polluted water bodies and a nature-based alternative to costly conventional treatment methods. For this purpose, three types of plants were tested with two PFAS, through an uptake and elimination phase, one submerged plant (*Elodea canadensis*), one floating (*Salvinia natans*) and one emerging (*Glyceria maxima*). To evaluate the role of chain length in uptake, one long-chain (PFUnDA) and one short-chain (TFA) PFAS compound were utilised in two concentrations (50 µg/L and 1000 µg/L). In the uptake phase (lasting 14 days) the plants were exposed to the PFAS, while in the depuration phase (14 days) the plants were transferred to clean medium, to assess pollutant uptake and release. Sampling was performed on days 0, 1, 4, 11, 14, 15, 20, and 28 and the internal concentrations were measured in different plant compartments (e.g., roots and shoots). Additionally, for the emergent plant, the shoots were divided into the parts below and above the water. The internal concentration results from each plant compartment were further analysed using a toxicokinetic model. This study aims to advance understanding of how aquatic plants can mitigate PFAS pollution by examining species-specific

differences in uptake, translocation, and depuration of short- and long-chain PFAS. The comparison of submerged, floating and emerging species can clarify the role of plant morphology and exposure pathways of each specific compound on PFAS removal efficiency. The findings will contribute to the development of nature-based, low-cost phytoremediation strategies for PFAS pollutants in aquatic environments.

3.13.P-We253 Degradation and formation of PACs during the bioremediation of creosote-polluted soil combined with toxicity and microbial community analysis

Maria Jordán¹, Kevin Rocco², Pol Martín¹, Anna Kärrman², Maria Larsson², Magdalena Grifoll¹ and Joaquim Vila¹, (1)Department of Genetics, Microbiology and Statistics, Faculty of Biology, University of Barcelona, Spain, Spain, (2)MTM Research Centre, School of Science and Technology, Örebro University, Sweden, Sweden

PAH-contaminated sites typically contain highly complex contaminant mixtures that include not only PAHs but also a range of other substituted polyaromatic compounds (PACs), such as alkylated-PAHs, NSO-heterocyclic PACs and oxygenated PAH transformation products (oxy-PAHs). Oxy-PAHs may also form during bioremediation treatments and are known to potentially increase soil genotoxicity despite effective PAH removal. A central challenge in the bioremediation of PAH-contaminated soils is to elucidate the actual in situ processes by analyzing microbial communities as functional systems and broadening risk assessment beyond the traditional 16 US-EPA priority PAHs. In this work, we evaluate how microbial biostimulation influences the fate of more than 80 analytical targets and soil toxicological endpoints, and we identify the microbial processes that drive the formation and eventual subsequent degradation of toxic transformation products.

Soil slurry microcosms were set up using a heavily creosote-polluted soil and incubated for 50 days under different biostimulation regimes (with or without nutrient addition). Soil extracts were obtained using a Dionex ASE 350 with in-cell basic silica clean-up. To recover a wider range of polar transformation products, aqueous samples were extracted using a combined neutral and acidic SPE extraction workflow developed in this study. Soil and neutral aqueous extracts were analyzed by GC-LRMS, whereas acidic extracts were analyzed by LC-HRMS. Toxicological risks were evaluated through cell line-based CALUX® bioassays. Microbial community dynamics involved in PAC degradation were examined by tracking structural changes at both genomic and transcriptomic levels using 16S rRNA gene sequencing.

The native soil microbial communities responded to bioestimulation by removing more than 80% of PAHs when nutrients were supplied. In the absence of nutrients, degradation of high-molecular-weight PAHs (HMW-PAHs) was limited, and these compounds tended to leach into the aqueous phase. Notably, an increase in toxicity was observed after 20 days, coinciding with maximum PAC biodegradation rates. This suggests that transformation products, not included in our extensive analytical target list, contributed to the increase in toxicity. Total and active microbial communities exhibited clearly distinctive compositions, and nutrient addition modulated the succession of active taxa associated with PAC biodegradation.

3.13.P-We254 Organic Micropollutant Transformation Products in *Brachypodium distachyon*

Selina Ilchmann, Rumyana Karlova, Stefan van Leeuwen, Nora B Sutton and Thomas Wagner, Wageningen University and Research (WUR), Netherlands

Organic micropollutants (OMPs) are a global environmental concern posing a threat to water quality. Plants are intentionally or unintentionally exposed to OMPs during water purification purposes (constructed wetlands) or food production (pesticide application; irrigation with treated effluent), respectively. Although the potential of plants to biotransform xenobiotic chemicals is known, there is little knowledge of the chemical identity of actual in-plant transformation products (TPs). Many aspects play a role when it comes to OMP TPs in plants, starting with the bioavailability of OMPs (i.e. not sorbed to soil), plant uptake behavior and plant defense mechanisms. The low concentrations at which OMPs occur in the environment, the potentially lower concentration of TPs in plants, and the complex plant matrix make the identification and quantification of OMP TPs in plant material challenging. To evaluate the fate of OMPs in plants and, more specifically, their spatial distribution within

plants, it is crucial first to identify TPs. The study aims to provide insight into the fate and transformation of a variety of OMPs with different chemical properties after their uptake in the plant. It was hypothesized that plant uptake is OMP specific. In case of uptake, not all OMPs will be transformed. If TPs are formed, we expect them to undergo a similar transformation, including hydrolysis, oxidation, and glycosylation. To identify TPs, we exposed model plant species *Brachypodium distachyon* to different OMPs in a hydroponic growth set-up. Targeted liquid chromatography-tandem mass spectrometry (LC-MS/MS) analysis was performed to quantify OMP uptake into roots and potential transport into the shoots. In addition, non-targeted LC-HRMS analysis on shoot and root material were performed to provide insights into TPs formed in-plant, and to reveal changes in overall plant metabolite composition and hence plant wellbeing. The data processing tools GNPS and patRoom were used for data analysis. Valuable insights are gained from the explorative approach, adding experimental data to OMP in-plant alteration model. In summary, with this poster presentation, I will present an experimental design that allows for the investigation of plant OMP uptake, transportation and transformation. This knowledge allows further investigation into in-plant mode of action or risk assessment of OMPs in the environment.

3.13.P-We255 Harnessing Recycled Manganese/Iron Oxide Sand In Constructed Wetlands For Enhanced Organic Micropollutant Removal

Han Liu¹, Thomas Wagner², Roel Meulepas¹ and Nora B Sutton³, (1)Wetsus, Netherlands, (2)Wageningen University and Research (WUR), Netherlands, (3)Environmental Technology, Wageningen University and Research (WUR), Netherlands

Managed aquifer recharge (MAR) with surface water in the Netherlands is hampered by the presence of organic micropollutants (OMP) in this surface water. As a result, Dutch drinking water companies are testing constructed wetlands as an innovative pretreatment strategy before MAR. While conventional constructed wetland designs effectively remove COD and nutrients, they fail to sufficiently remove all OMP.

To overcome this, we propose integrating manganese/iron oxide (MnOx/FeOx) sand recycled from drinking water treatment plants as the substrate in constructed wetlands. This recycled MnOx/FeOx sand is biologically generated as a byproduct of microbial oxidation of dissolved Mn²⁺ and Fe²⁺ in groundwater-based drinking water production plants.

These biogenic oxides offer three potential OMP removal mechanisms: 1) Chemical Oxidation: Electron transfer from OMP to the highly reactive MnOx matrix. 2) Biodegradation: Degradation and MnOx regeneration mediated by manganese-oxidizing bacteria (MnOB) embedded in the biofilms. 3) High adsorption capacity: Biogenic MnOx possesses a δ -MnO₂ crystalline structure to enhance OMP adsorption.

To validate the concept, batch OMP removal experiments will be performed with 24 OMPs, including Glyphosate, Sulfamethoxazole, Diclofenac, Sucralose, etc. Controlled mixtures of recycled MnOx/FeOx sand and mature sand from running constructed wetlands will be used as an inoculum and tested under 1) Inhibited Systems (4°C): Isolating abiotic processes (adsorption + oxidation, 2) Biotic Systems (20°C): Enabling all three mechanisms. The OMP removal efficiency will be tested under both strict aerobic and anaerobic environments for 28 days and monitored using LC-MS/MS. In addition, high-resolution LC-MS will be used for non-target screening to identify transformation products.

By performing these batch experiments, we hypothesize that we will be able to determine the contribution of MnOx/FeOx sand to the overall OMP removal efficiency and identify the respective contributions of biodegradation, adsorption, and chemical oxidation.

The findings of these batch experiments aim to provide valuable insight into the critical parameters that significantly impact the interaction of MnOx with OMP removal, ultimately affecting OMP removal efficiency. The result will be consecutively used in the design of lab-scale and pilot-scale MnOx-mediated wetland construction, such as the oxygen level (water saturation zone) and hydraulic retention time, etc.

3.13.P-We256 Plant-microbe interplay influencing urban pollutant transformation in percolation systems

Karolin Seiferth¹, Mia Schumacher², Steffen Kümmel³ and Marie Muehe¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Department of Applied Microbial Ecology, Germany, (2)University of Tübingen, Germany, (3)Helmholtz Centre for Environmental Research GmbH (UFZ), Department of Technical Biogeochemistry, Germany

Urban runoff transports diverse organic pollutants that threaten urban waters and soils. Blue-green infrastructures such as tree trenches help to mitigate these impacts. Yet, the biological contribution of the rhizosphere to pollutant transformation remains understudied. We ask whether plant-microbe interactions and low molecular weight carbon amendments can stimulate pollutant transformation under realistic conditions. We hypothesize that low molecular weight carbon can stimulate microbial activity and support co-metabolic

degradation. To test this hypothesis, we established an outdoor mesocosm experiment. Trees (*Tilia cordata*) were planted in 1000 L containers that simulate a real tree trench in Leipzig, Germany. The systems received a mix of pollutants commonly found in urban runoff waters (naphthalene, bis(2-ethylhexyl) phthalate, methyl tert-butyl ether, and 1,3-diphenylguanidine). We added by-products from industries (molasses, whey) as low molecular weight carbon to stimulate microbial processes. We also applied four surface cover treatments: biochar, activated biochar, grasses, and an uncovered control. We monitored key biogeochemical and biological indicators. These include pH, redox potential, nitrogen and carbon species, 16S rRNA genes and transcripts, and functional genes involved in pollutant degradation. This approach allows us to assess both general microbial responses and the activation of specific degradation pathways. The chemical fate of the added pollutants is also being quantified. The analytical work has only recently begun and laboratory processing is still ongoing. Early observations show that organic priming increases microbial activity. First signals also indicate shifts in carbon cycling. These responses suggest that priming can enhance conditions that support co-metabolic degradation. Full chemical and molecular analyses will confirm whether these biological changes translate into higher transformation rates.

This work provides new insights into how biological mechanisms influence contaminant fate in tree trenches. Understanding these interactions supports the design of blue-green infrastructures that not only retain pollutants but also promote their transformation. This contributes to more resilient and sustainable urban water management.

3.13.P-We257 A trend prediction model of natural attenuation in groundwater based on machine learning and microbial community

Xiaodong Zhang¹, Ran YU², Tao Long¹ and Xin Zhu¹, (1)*Nanjing Institute of Environmental Sciences, Ministry of Ecology and Environment, China (Mainland)*, (2)*Southeast University, China (Mainland)*

Natural attenuation combined with long-term monitoring (known as monitoring natural attenuation, MNA) has been proven to be a resultful remediation technology in petroleum-contaminated sites in which the biodegradation was the main study conducted at contaminant removal. Trends analysis and prediction are important segments for MNA application, in which complex biotic and abiotic factors need to be considered. Microorganisms also could be regarded as “first responders” to environmental changes, and carries additional information about environmental conditions that should be of great advantage in simplifying natural attenuation predictions.

In this work, the long-term monitoring of BTEX/CAHs and microbial community in the groundwater of a pesticide plant was conducted. A machine learning approach for natural attenuation prediction was developed with RFC model followed by either RFR or ANN model, utilizing both microbial information and contaminant attenuation rates for model training and cross-validation. The performance of the models in the prediction of the feasibility and/or rates of natural attenuation of BTEX and CAHs was subsequently evaluated and compared. Results showed that the RFC model could achieve high accuracy (above 99%) for the feasibility prediction of natural attenuation for both BTEX and CAHs, and could successfully identify the key functional microbial genera. The RFR model was sufficient for BTEX natural attenuation rate prediction, and the MAPE was 8.1% ~ 19.6%. However, the predicted natural attenuation rates of CAHs by RFR were unreliable, with the MAPE as high as 22.0% ~ 153.9%. The ANN model showed better performance in the prediction of attenuation rates for both BTEX (with MAPEs from 2.1% to 4.6%) and CAHs (with MAPEs from 6.9% ~ 19.7%). Based on the assessments, a composite modeling method of RFC and ANN models was proposed, which could reduce the MAPE to as low as 2.1% ~ 4.6% for BTEX and 6.9% ~ 19.7% for CAHs. This study reveals that the combined machine learning approach under synergistic use of site microbial data has promising potential for predicting natural attenuation.

3.13.P-We258 In-Situ Remediation of Contaminated Sediments in Open Waters and Wetlands

Charlie Menzie, *Exponent Inc., United States*

Over the past two decades there have been several developments in in-situ remediation of soils and sediments for petroleum hydrocarbons (including PAH compounds), PCBs, dioxins, and metals (especially lead and arsenic). In-situ treatment amendments have included activated carbon (granular and powdered), organoclay, highly concentrated microbial inoculants for bioremediation, and geochemical modifications for reducing metal bioavailability. This paper provides an overview of the developments using case studies for PCBs, dioxins, and lead. In-situ remediation for PFAS in soils and sediments is relatively new, and the presentation will provide a status. Because in-situ remediation involves a range of considerations including addressing potential for adverse impacts and addressing factors affecting efficacy, the utility of in-situ remediation methods for soils and sediments will be presented within the broader context of remedial decision-making.

3.13.P-We259 Unravelling Steroid Hormone Transformation Pathways in a Natural Wastewater Treatment System Through High-Resolution Suspect Screening

Rayco Guedes-Alonso¹, Giulia Bonaccorso², José Alberto Herrera-Melián¹, Zoraida Sosa-Ferrera¹, Massimo Del Bubba² and José Juan Santana-Rodríguez¹, (1)University of Las Palmas de Gran Canaria (ULPGC), Spain, (2)University of Florence, Italy

Steroid hormones are environmentally relevant endocrine disruptors that undergo extensive biotransformation during wastewater treatment, yet most of their transformation products (TPs) remain unidentified. Natural treatment systems such as macrophyte pond–constructed wetland configurations are increasingly adopted as low-energy solutions, but their ability to degrade or generate TPs is still unclear. This study provides the first comprehensive characterisation of TPs derived from testosterone, levonorgestrel, and cortisone in a full-scale natural system treating urban wastewater.

Using a highly selective molecularly imprinted SPE protocol combined with ultra-high-performance liquid chromatography and high-resolution quadrupole time-of-flight mass spectrometry, we applied a suspect-screening workflow integrating accurate mass, MS^E fragmentation, elemental composition, and automated spectral matching. More than 30 TPs were detected across influent, intermediate, and effluent samples, revealing a complex network of reductive, oxidative, hydroxylation, and ring-cleavage pathways. Aeration strategies implemented in the pond–constructed wetland system markedly altered transformation dynamics. Testosterone was efficiently removed under aerobic conditions, with enhanced formation of oxidised and ring-opened intermediates. Levonorgestrel showed no detectable parent compound but produced persistent hydroxylated and reduced TPs, indicating stable precursors or strong sorption–desorption behaviour. Cortisone generated numerous polyoxygenated derivatives, many structurally novel and tentatively annotated, several of which persisted through the final effluent.

Overall, the system demonstrated a strong capacity to transform steroid hormones, but also produced a chemically diverse suite of TPs with varying persistence. These findings highlight that “removal” of parent compounds does not necessarily equate to detoxification and reinforce the need to evaluate TPs when assessing the performance and environmental safety of nature-based treatment technologies.

Disclaimer/Disclosure:

3.13.P-We260 Enhancing Steroid Hormone Removal in a Natural Wastewater Treatment System Through Biosorbent Substrates and Aeration

Rayco Guedes-Alonso, David Arocha-Espiau, José Alberto Herrera-Melián, Zoraida Sosa-Ferrera and José Juan Santana-Rodríguez, University of Las Palmas de Gran Canaria (ULPGC), Spain

Steroid hormones are potent endocrine disruptors frequently detected in municipal wastewater effluents at concentrations capable of inducing adverse effects on aquatic biota, even at the ng·L⁻¹ level. Their recognised ecological relevance has led the European Commission to include key representatives in the Water Framework Directive and successive Watch Lists, highlighting the need for treatment technologies capable of achieving near-complete removal. Natural wastewater treatment systems (NWTs) offer a sustainable and low-energy alternative for small or isolated communities, but their performance regarding the full spectrum of steroid hormones remains insufficiently resolved.

This study investigates the presence, removal, and optimisation potential of steroid hormones in a full-scale macrophyte pond–constructed wetland system located on a university campus. Fifteen hormones from all major families were monitored over five months at three treatment stages. Under baseline operation, nine compounds—including testosterone, boldenone, estrone, 17β-estradiol, progesterone, megestrol acetate, cortisone, prednisone and prednisolone—were detected in influent waters at concentrations from 10 to 600 ng·L⁻¹. The facultative pond achieved removals >85% for most compounds, and only five hormones persisted in the final effluent at <30 ng·L⁻¹, demonstrating the intrinsic capacity of NWTs to attenuate high-impact contaminants.

Two enhancement strategies were evaluated: (i) replacing traditional substrates with locally sourced palm-tree residues (*Phoenix canariensis*), and (ii) continuous aeration of constructed wetland channels. The biosorbent substrate provided retention comparable to conventional media, offering a circular-economy alternative with minimal degradation after months of operation. Aeration yielded the most substantial improvement, driving the

complete elimination of nearly all detected hormones, strongly suggesting stimulation of aerobic biodegradation pathways.

These findings confirm that optimised NWTs can achieve removal efficiencies aligned with EU environmental policy objectives and can represent a robust option for regions with limited energy or infrastructural capacity. The demonstrated effectiveness of aeration and low-cost biosorbents provides a practical path for upgrading existing nature-based systems to meet future regulatory thresholds for endocrine-disrupting compounds.

Disclaimer/Disclosure:

3.13.P-We261 A site-specific diagnostic framework for immobilization of metals and metalloids using dolomite-modified biochar in alkaline soils

Sampriti Chaudhuri¹, Carlotta Carlini², Oliver Mann³, Thilo Hofmann⁴ and Gabriel Sigmund⁵, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)University of Bologna, Italy, (3)ESW Consulting Wruss Ziviltechniker GmbH, Austria, (4)University of Vienna, Austria, (5)EDGE, Wageningen University and Research (WUR), Wageningen, Netherlands

Soil amendments, such as biochar, are increasingly used to stabilize metals and metalloids to sustain healthy soil functions. However, their sorptive performance is highly site-specific, with strong controls by soil pH, carbonate-buffering capacity, organic matter, and Fe/Mn (oxyhydr)oxide content. Here, we evaluated a dolomite-modified biochar (DMB) (Carlini et al., 2021, Patent No. 102021000014195*), produced by co-pyrolysis of wood and dolomite, as a low-cost, mineral modified amendment to support in-situ immobilization of metals and metalloids in nine contaminated Austrian soils, differing in pH, total organic carbon (TOC), total inorganic carbon (TIC), Fe/Mn oxides, and contaminant load. Harmonized batch leaching and column percolation tests were used to quantify amendment effects on trace metals (Co, Ni, Zn, Cd, Tl, U, Cu, Pb) and oxyanions (As, Sb, Cr, Mo) relative to high temperature wood-based biochars and activated carbons. Across soils, trace metals were generally immobilized, but Cu and Pb showed pronounced, soil-dependent mobilization: Cu increased in organic-rich, weakly buffered soils via dissolved organic carbon-mediated complexation, whereas Pb was mobilized in carbonate-dominated soils with low TOC/TIC ratios and high total Pb, which is consistent with the formation of soluble Pb-carbonate/hydroxide complexes. For the oxyanions, DMB substantially reduced As and Sb leaching in carbonate-buffered, Fe/Mn-oxide-rich soils, but mobilized them in organic-rich, weakly buffered soils where elevated pH promoted DOC release and Fe oxide dissolution. Cr and Mo remained persistently mobile under alkaline conditions, highlighting a trade-off when multiple oxyanions co-occur.

From these patterns, we derived a diagnostic framework based on TOC, TIC (and their ratio), soil pH, Fe/Mn oxide content and total contaminant load to predict when carbonate-rich biochar will act as a beneficial, sustainable amendment and when it may pose mobilization risks. In suitably buffered alkaline soils, DMB can therefore stabilize residual contamination and support long-term ecosystem recovery, while emphasizing that heavily contaminated hotspots require prior removal or isolation.

*Carlini, C., Primante, A., Greggio N. (2021). Metodo per la fabbricazione di un materiale composito per il recupero di nutrienti e/o inquinanti da acque reflue, materiale composito ottenuto e relativo uso.

3.13.P-We262 EVALUATION OF SUNFLOWER CAPABILITY IN RECOVERING A MULTI-CONTAMINATED SOIL MIXED WITH POLYCHLOROBYPHENIL POLLUTED MARINE SEDIMENT

Aurora Rutigliano¹, Anna Barra Caracciolo², Melissa Sardano³, Paola Grenni⁴, Pietro Cotugno⁵, Ilaria Savino², Angela Gatto⁶, Livia Mariani⁶, Ludovica Rolando² and Valeria Ancona², (1)University of Bari, Italy, (2)Italian National Research Council (CNR), Italy, (3)Università degli Studi di Bari - Aldo Moro, Italy, (4)Water Research Institute, Italian National Research Council (CNR), Italy, (5)Univeristà degli Studi di Bari - Aldo Moro, Italy, (6)Consiglio Nazionale delle Ricerche (CNR), Italy

Nature-Based Solutions have emerged as effective, sustainable and cost-effective strategies for recovering contaminated environments from organic and inorganic contaminants. Among these strategies, Plant-Assisted Bioremediation (PABR) represents a methodology which decontaminates soil, sediments and water via the synergistic interactions established between plants and rhizosphere microbial communities. Sunflower (*Helianthus annuus* L.) has demonstrated a high capacity to remove pollutants, especially heavy metals. In this

work, the capability of Sunflower (*Argentario* var) to decontaminate a multi-contaminated soil was assessed in greenhouse microcosms. For this purpose, aliquots of soil collected from a polychlorinated biphenyl (PCBs) and heavy metal (HMs) contaminated site were mixed with those of a PCB polluted marine sediment (from the Mar Piccolo). The area studied was located in Taranto (Apulia Region, Italy). The contaminated substrate was used for setting up microcosm experiments with sunflower in absence/presence of a municipal waste compost. Moreover, control microcosms (without plants) were also performed. Soil chemical-physical parameters (e.g. pH, EC, etc), contaminant analytical determinations and microbiological analyses (microbial abundance and dehydrogenase activity) were carried out at 45 and 90 days. Moreover, qPCR analysis was performed for assessing the microbial community composition and ecotoxicological tests were carried out to assess the efficacy of the PABR technology.

The main results obtained in sunflower planted microcosms evidenced that soil PCB concentration reduced at end of the experiment (90 days) strongly in presence of sunflower and compost, while in the unplanted microcosms PCB removal was observed only if the compost was added. Microbial abundance and dehydrogenase activity highly increased in all the sunflower planted microcosms and the highest values were in the planted microcosms treated with compost. Further investigations are on-going to characterize sunflower's root exudates and rhizosphere microbial community structure and composition.

3.13.P-We263 Nature-based Remediation of Metal Pollutants in Nature Areas (NARMENA): An Ecological Modelling Approach

Karel Vlaeminck¹, Karel Viaene¹, Marnix Vangheluwe¹ and Froukje Kuijk², (1)ARCHE Consulting, Belgium, (2)OVAM, Belgium

The EU-LIFE project NARMENA (Nature-based Remediation of Metal pollutants in Nature Areas to increase water storage capacity) aims to evaluate the efficacy of Nature-Based Remediation (NBR) techniques in mitigating metal pollution in soil and sediment within select nature reserves in Flanders. Focus is on three target sites that have been selected for their historical contamination with metals. The Grote Calie is contaminated with chromium, the Winterbeek is strongly contaminated with metals and chlorine, and the final site, the Grote Laak contains high levels of cadmium and arsenic.

NBR techniques were implemented at these target sites. At the Grote Calie, a combination of Bacteria-Assisted Phytostabilisation (BAP) and constructed wetlands (CW) was employed to reduce metal contamination. Specifically, applying BAP will reduce metal bioavailability by stabilising and/or fixating the metals in the soil, rhizosphere, or through absorption by plants and accumulation in (underground) plant biomass. CW were employed by flooding the land or keeping the contaminated areas below the water level, creating artificial wetlands. Submersion leads to reduction of metal ions in the soil which reduces metal bioavailability and immobilizes the contaminants.

To support the ecological impact assessment of remediation measures, an ecological modelling approach was developed. This tool allows to predict the impact of remediation techniques on the ecotoxicity of specific contaminants. The model was developed based on laboratory toxicity testing for three species (i.e., *Hyaella azteca*, a freshwater amphipod, *Lemna minor*, a macrophyte, and *Daphnia magna*, the water flea). The ecological modelling approach allows to simulate the influence of physicochemical parameters affecting bioavailability on populations of these three indicator species. The impact of different remediation scenarios at the target sites could be assessed, differentiating between no action, conventional excavation approaches, and NBR techniques (BAP and CW). The NARMENA tool provides insight into the potential of NBR techniques to effectively reduce metal pollution in nature reserves, while also promoting sustainability and improving local water retention. This tool highlights the added value of ecological modelling in supporting nature conservation and remediation initiatives.

3.13.P-We264 Reducing Antibiotic Resistance Genes via vermiremediation in soils treated with Oxytetracycline, Sulfamethoxazole, and Enrofloxacin

Camila F. Rutkoski¹, Erik Urionabarrenetxea², Nerea Garcia-Velasco², Lur Epelde³, Carlos Garbisu³, Eduardo A. Almeida¹ and Manuel Soto², (1)Department of Natural Science, University of Blumenau, Blumenau, SC, Brazil, Brazil, (2)Research Centre for Experimental Marine Biology and Biotechnology (PiE-EHU/UV),

Antibiotic resistance genes (ARGs) are recognized as emerging microbial pollutants that threaten human and animal health by contributing to the spread of antibiotic-resistant bacteria and diminishing the efficacy of current antimicrobial treatments. This study assessed the capacity of *Eisenia fetida* to reduce ARGs associated with the antibiotics oxytetracycline (OTC), sulfamethoxazole (SMX), and enrofloxacin (ENR) in agricultural soil through a vermiremediation approach. Initially, environmentally relevant concentrations of these antibiotics (4.21 mg/kg OTC; 2.21 mg/kg SMX; 1.61 mg/kg ENR) and levels comparable to those found in animal manure (42.1 mg/kg OTC; 22.1 mg/kg SMX; 16.1 mg/kg ENR) were applied to soil under controlled laboratory conditions for 136 days to induce ARG development. Subsequently, *E. fetida* earthworms were introduced into the contaminated soils for 28 days to evaluate their remediation potential. Amplicon sequencing of 16S rRNA and high-throughput quantitative PCR (HT-qPCR) revealed that *E. fetida* modified both the soil bacterial community structure and the resistome. Dominant phyla across treatments included Actinobacteriota, Proteobacteria, Firmicutes, Planctomycetota, Verrucomicrobiota, and Gemmatimonadota. Among genera with relative abundance >0.5%, *Bacillus*, *Candidatus Udaebacter*, *Gemmatimonas*, JG30-KF-AS9, *Streptomyces*, and *Paenibacillus* were most prevalent. The highest antibiotic mixture stimulated an increase in genes conferring resistance to sulfonamides (*sul1*) and multidrug efflux systems (*acrA*, *tolC*, *mdtH*, and *mdtE/yhiU*). Vermiremediation mitigated all these genes except *mdtH*. Genera JG30-KF-CM45, KD4-96, and TK-10 showed positive correlations with most ARGs, suggesting they may act as reservoirs. In conclusion, these findings indicate that vermiremediation using *E. fetida* is a promising strategy for reducing ARGs from multiple antibiotic classes in agroecosystems. Partially funded by Joint Research Laboratory on Environmental Antibiotic Resistance (Euskampus), “Coordenação de Aperfeiçoamento de Pessoal de Nível Superior, CAPES” (001) and “Conselho Nacional de Desenvolvimento Científico e Tecnológico, CNPq” (307390/2017-9) Brazil. Funded by the Basque Government: CBET+: IT1743-22 Consolidated Research Group.

3.13.P-We265 Assessing the toxicity of phytoremediated mining soils on *Eisenia fetida* and *Lactuca sativa*

Erik Urionabarrenetxea¹, Ann S. Brückner¹, Anthony J. Fow¹, Meagan E. Mehlhop¹, Nerea Garcia-Velasco¹, Manuel Soto¹, Beñat Zaldibar² and Helena Moreira³, (1)Research Centre for Experimental Marine Biology and Biotechnology (PiE-EHU/UV), University of the Basque Country, Spain, (2)University of the Basque Country, Spain, (3)BIOPOLIS Program in Genomics, Biodiversity and Land Planning, CIBIO, Campus de Vairão, Portugal

Soil contamination by metals derived from mining activities represents a persistent environmental challenge due to their persistence, stability and toxicity. These pollutants accumulate in soils, creating long-term ecological risks. Phytoremediation has emerged as a cost-effective and environmentally friendly approach, and the use of sunflowers combined with pollutant-resistant bacteria is considered promising for enhancing metal uptake and plant resilience. However, its efficiency remains uncertain, as benefits vary across biological levels. To evaluate this strategy, mining soils from Lanestosa (Spain) and Sentein (France) were treated with sunflowers stabilized with bacterial inoculants. Six treatments per site were applied under blind conditions with 4 replicates each. Toxicity was assessed at organism level using *Eisenia fetida* and *Lactuca sativa* through soil and leachate bioassays, and at cellular level via coelomic fluid analyses (cell viability and fluorescence biomarkers: riboflavin and calcein). These indicators provide complementary insights into oxidative stress and membrane integrity. Results showed no significant differences in earthworm survival or weight change, and lettuce germination exceeded 70% across treatments, suggesting low acute toxicity. Root elongation varied within sites but lacked consistent effects related with treatment. Cellular assays revealed more nuanced responses: riboflavin concentrations were higher in bacterial inoculation treatments, suggesting reduced oxidative stress, whereas calcein fluorescence indicated greater membrane stability in untreated soils after 14 days. These contrasting trends imply that bacterial inoculation may mitigate certain stress pathways without uniformly improving soil quality. Overall, organism-level endpoints suggest limited remediation benefits, while cellular biomarkers highlight complex physiological interactions. Although phytoremediation supported by bacteria shows potential for reducing sublethal toxicity, its effectiveness as a comprehensive remediation strategy remains inconclusive. Future research should extend exposure periods, integrate soil physicochemical analyses, and refine bacterial consortia to enhance ecological relevance and optimize remediation outcomes. Funded by: PhytoSUDOE-SOE1/P5/E0189. *A. Brückner, A. Fow, and M. Mehlhop are supported by the Erasmus+ Student Scholarship ECT+ EMJMD "European MSc in Environmental Contamination and Toxicology" 2022-2024.

3.13.P-We266 Anaerobic biodegradation by microbial fuel cell of the insecticide imidacloprid for the production of sustainable energy.

Eliane Pedroso¹, Gilmar Silva², Giovani Valdeirão¹, Yago Avancini¹, Teresa Paiva¹ and Flávio Teixeira da Silva¹, (1)University of São Paulo, Lorena Engineering School, Brazil, (2)UFF- Universidade Federal Fluminense, Brazil

The Imidacloprid is an insecticide widely used worldwide in agricultural activities to combat pests. Its extensive use has raised concerns regarding the environment due to contamination of soil and water bodies, through soil washout by runoff and atmospheric deposition by spraying. So, in recent years, the need for studies that promote the generation of clean energy through sustainable means has grown. This study aims to develop a microbial fuel cell using the bacterium *Shewanella oneidensis* for the treatment of wastewater contaminated with the insecticide by oxidative cleavage and that is capable of generating sustainable energy as a product. A double-compartment microbial fuel cell was constructed with an anode containing the bacterial biofilm and a cathode, both consisting of platinum separated by a Nafion proton exchange membrane and a stainless steel current collector. The treatment of a solution containing 100 mg.L⁻¹ of imidacloprid was performed in triplicate for three days with an external resistance of 220 Ω. Then, 5 mL of the treated samples underwent an organic phase extraction for subsequent analysis of the by-products generated and compared with the control samples by gas chromatography coupled to mass spectrometry (GC-MS). For this, this study too develop and validate analytical methodologies for the efficient detection and quantification of imidacloprid and its metabolites in anaerobic biodegradation by microbial fuel cells using gas chromatography coupled with mass spectrometry (GC-MS). Was carried out 32 different approaches were analyzed at concentrations of 10, 5, and 0.5 mg/L using a commercial standard of imidacloprid. However, through laboratory validations, only 8 methods were refined and tested at lower concentrations (0.3-0.1) mg/L. Among them, only one method was selected based on the peak integration area, column preservation, absence of baseline noise in the chromatogram and energy efficiency. The collected samples from the fuel cells were subjected to an organic phase extraction process using dichloromethane (CH₂Cl₂) with the purpose of extracting imidacloprid and its possible by-products from the reaction medium, such as Imidacloprid-urea. Subsequently, the samples were rotary evaporated and dissolved in acetone prior to GC-MS analysis. The chromatographic results confirmed the efficiency of anaerobic biodegradation within microbial fuel cells, demonstrating its potential for IMI degradation and environmental remediation.

3.13.P-We267 Integrating Molecular and Geochemical Evidence of Biodegradation during Bioremediation of a Linear Alkylbenzene-Impacted Aquifer with a tailored native microbial consortium
Pol Martín¹, Pablo de la Ossa², David Gramunt², Alfredo Pérez de Mora³, Magdalena Grifoll¹ and Joaquim Vila⁴, (1)University of Barcelona, Spain, (2)TAUW Iberia S.A.U, Spain, (3)TAUW GmbH, Germany, (4)Genetics, Microbiology and Statistics, University of Barcelona, Spain

In 2016, the aging of a high-voltage cable resulted in the release of more than 30,000 L of insulating dielectric oil rich in linear alkylbenzenes (LABs) into a fractured coastal calcarenite aquifer in Spain. After light non-aqueous phase liquid (LNAPL) physical removal, a bioaugmentation approach using a native tailored microbial consortium and aerobic biostimulation were implemented to treat the contaminant plume.

A specialized LAB-degrading microbial consortium was enriched from the indigenous microbiota (GWP-F1) demonstrating complete degradation of the dielectric oil components. After detailed community analysis, consortium GWP-F1 was scaled up for field application.

Following successful pilot testing, a full-scale bioaugmentation strategy was implemented consisting in a series of groundwater recirculation cells equipped with infiltration–extraction wells connected to an aeration system enabling nutrient addition and oxygenation of the recirculated water to support biostimulation. Treatment cycles consisted of oxygenation followed by nutrient and inoculum injection.

Microbial dynamics and biodegradation processes were monitored through MPN counts, qPCR targeting key consortium phylotypes (*Sphingobium*, *Hydrogenophaga*, and *Gordonia*), and functional genes involved in LAB degradation (P450 cytochrome monooxygenases, AlkB alkane hydroxylases, and biphenyl/toluene dioxygenases). Changes in microbial community structure were evaluated using 16S rRNA amplicon sequencing. Hydrocarbon degradation was further assessed through GC-MS analysis of LAB isomer-specific diagnostic ratios.

The bioaugmentation strategy resulted in substantial reductions in groundwater LAB concentrations and induced a pronounced restructuring of the microbial community. Targeted consortium-associated 16S rRNA biomarkers and functional genes exhibited a robust enrichment of 1–2 orders of magnitude across the treated areas,

maintaining stable abundances over time. GC-MS analysis confirmed a significant reduction in the most biodegradable LAB isomers, providing strong and consistent evidence of active in situ biodegradation.

3.14.P Improving Understanding and Modelling of the Partitioning, Mobility, and Bioavailability of Highly Polar and Ionisable Substances in the Environment

3.14.P-Th061 Is the Organic Carbon Normalised Partition Coefficient the most Appropriate Measure of Partitioning for Substances that are Highly Mobile in the Environment?

Adam Peters¹, Michael Hüben², Dieter Hennecke², Benedikt Ringbeck³, Steph Jones⁴ and Pippa Kate Curtis-Jackson⁴, (1)wca environment Ltd., United Kingdom, (2)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (4)Environment Agency United Kingdom, United Kingdom

Several studies have applied screening level assessment approaches to identify substances that could potentially be mobile in the environment. Due to the lack of suitable alternative metrics, these prioritisation exercises have generally been based on the organic carbon normalised partition coefficient (KOC), considering it the principal indicator of substance mobility in the environment. However, concerns have been raised about the appropriateness of the KOC concept to indicate the potential for substances to be mobile in the environment. The partitioning and binding of substances to components of soils and sediments is an important aspect of their environmental fate and can determine both their mobility and bioavailability. However, tests using defined natural soils do give variable results due to the extremely diverse nature of soil characteristics in terms of their contents of organic carbon, clay, and iron and aluminium (oxy)hydroxides, as well as their cation exchange capacity and pH. There are three principal mechanisms that contribute to the overall retention of substances in soils and other sub-surface media. These are phase partitioning, cation binding, and anion binding. There are several components of soils and other subsurface media that can be involved in one or more of these mechanisms; for example soil organic matter is important in phase partitioning for hydrophobic and nonpolar substances, but can also be important for the binding of cations. The extremely high variability of the overall distribution coefficient KD between different soils limits its usefulness as an inherent measure of the environmental fate of a substance. It may be possible to define partition coefficients for interaction mechanisms, such as cation or anion exchange (e.g., producing KCation and KAnion, respectively) that could then be applied collectively to consider all of the individual partitioning mechanisms, including the KOC value, to derive an overall partition coefficient. The need to include characteristics of the medium will improve the relevance of partitioning information for hazard and scenario-specific exposure assessment purposes, although it will also require that reference conditions are defined to allow comparisons to be made between different substances. Improved approaches are likely to need to take account of the local environmental conditions, and this will improve the relevance of the information especially for site-specific risk assessments.

3.14.P-Th062 Experiments on the Retention Behaviour of Ionic Organic Substances on Mixed-Mode HPLC Columns for the Future Expansion of OECD 121

Michael Hüben¹, Adam Peters², Benedikt Ringbeck³, Dieter Hennecke¹, Richard Gibson⁴, Steph Jones⁴, Hattie Brunning⁴ and Pippa Kate Curtis-Jackson⁴, (1)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)wca environment Ltd., United Kingdom, (3)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (4)Environment Agency United Kingdom, United Kingdom

The partitioning and binding of substances to components of soils and sediments is an important aspect of their environmental fate and mobility. Screening level assessment approaches to identify potentially mobile substances have generally been based on Koc, because organic matter plays a dominant role in the adsorption of many substances to surface soils. However, concerns have been raised about the appropriateness of the Koc concept to indicate the potential mobility of substances, principally because: (1) adsorption to organic matter is a less important adsorption mechanism for some ionisable substances; and (2) levels of organic matter in subsurface soils are much lower than in surface soils, so other interactions may be more dominant in those media. Currently, there is a lack of suitable alternative metrics by which the other interactions between substances and components of soils and sediments can be measured.

The OECD TG 121 screening method for the measurement of Koc on an HPLC system is often carried out as a simple, quick and cheap method that provides directly comparable results. The cyanopropyl stationary phase allows for the interaction of polar and non-polar groups of a test substance, but it does not include other interactions that may be influential in determining the adsorption properties of more polar and ionisable

substances, including ion exchange interactions and some polar interactions.

It may be possible to extend the general concept of the OECD TG 121 screening test to consider additional interactions that occur in soils and other subsurface media, which are especially relevant for polar and ionisable substances. This work investigated whether state-of-the-art mixed mode stationary phases could act as surrogates for surfaces where adsorption occurs in soils or sediments reflecting such interactions.

The most promising HPLC solid phases for the intended purpose were identified. Following a method development phase, tests were performed with 56 substances using strong cation exchange (SCX) and weak cation exchange (WCX) columns, both combined with reversed phase material. Retention of the cationic test substances was observed; the results are promising and indicate that we could develop an extension to the OECD TG 121. This multi-year project is intended to provide a step towards a possible solution to improve the mobility assessment of polar and ionic substances in low organic carbon soils and subsurface media.

3.14.P-Th063 Evaluation of Prediction Methods for the Mobility Criterion KOC

Stefan Trapp¹, Klaus Mosthaf¹, Anders Nyeggen¹, Prasit Shrestha² and Dieter Hennecke², (1)Technical University of Denmark, Denmark, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

With the new PMT (persistent mobile toxic) classification of chemicals by the EU since 2024, the partition coefficient between organic carbon and water K_{oc} received increased attention. Several prediction tools for this property have been developed. The Technical Guidance Document for REACH (TGD) lists log K_{ow} – log K_{oc} regressions for various substance groups. For acids and bases, Franco and Trapp developed regressions using pH of soil. A regression by Ecetoc uses log D as predictor for the adsorption of bases, while that of Droge and Goss for cations relies on molar volume and the number of hydrogen atoms at the charged nitrogen. Li et al. developed six new regressions for the distribution coefficient K_d of acids, weak and strong bases and neutral chemicals. The K_{oc} was also estimated by the machine learning tool implemented in Opera, listed in CompTox. Using experimental data sets from literature, we tested accuracy (sum of residues SU) and precision (log mean absolute error log MAE) of these prediction methods for neutrals chemicals, acids, bases and zwitterions. The experimental data set of Li et al. (2021) contains 689 measured K_d-values for 54 chemicals (pharmaceuticals, half of them bases) in eight soils and five sediments. Soils and sediments were characterized by an array of data, such as pH, TOC, CEC, %clay, %silt, and content of K, Mg, Na.

The K_{oc} of neutral pharmaceuticals was well predicted except for a few polar chemicals (about factor 10 average error). Adsorption of acids was even better predicted, best by the regression equation of Li et al. with less than factor 3 absolute error. The K_{oc} of bases, mostly present at cations, was widely underpredicted and with less precision (0.82 ? log MAE ? 1.40). Zwitterions were among the chemicals with the highest and the lowest K_{oc} and those with the widest range. No method could predict adsorption of zwitterions satisfyingly (avg. error > factor 25). CompTox gave good K_{oc} values for the bulk of chemicals but had a few high outliers, which increased average error and lowered reliability.

Among properties of the soil, pH had the most significant impact on K_d and K_{oc}, followed by TOC and CEC. The choice of method depends on the availability of such input data: methods requiring more data generally performed better, but those data are not always at hand, while generic estimation methods, such as CompTox/Opera or the TGD regressions, can be used without knowledge of the soil properties.

3.14.P-Th064 An Approach for Accounting for Structural Similarity in Reference Substance Selection for Highly Mobile Test Substances in HPLC based Fate Studies

Charlotte Linley, Iain Wilson and Adam Peters, wca environment Ltd., United Kingdom

In this presentation, we outline an approach for applying structural similarity profiling to improve the selection of reference substances for screening tests of the environmental partitioning and mobility of substances using HPLC based methods calibrated with reference substances. The structural similarity profiling approach uses publicly available tools, such as the OECD QSAR Toolbox, so that structurally similar reference substances can be identified for test substances to use for calibration of the methods, potentially enhancing the reliability and relevance of KOC and mobility testing for chemicals. Hypothetical examples are used due to the lack of reliable partitioning data for these substances.

Seventeen ionizable cationic substances with the potential for high mobility in the environment were selected for assessment. Because no distinction between reference and test substances was possible, a subset of the test

substances were tested together, and the similarity of each substance in the suite was assessed against two of the individual substances, propranolol and tryptamine. To evaluate the applicability of using the OECD QSAR Toolbox for this purpose, an initial structural similarity assessment was conducted.

The reference substances were tested against a set of potential test substances using the Dice coefficient similarity measure and the PubChem molecular features system.

Substances were considered to be potential reference substances where they had a structural similarity of at least 60% when compared to the hypothetical test substances. For propranolol six potential reference substances were identified (2,2'(benzylimino)diethanol, atenolol, benzyltrimethylammonium chloride, lidocaine, methylephedrine, and serotonin). For tryptamine seven potential reference substances were identified (2,2'(benzylimino)diethanol, benzyltrimethylammonium chloride, ciprofloxacin, cotinine, florasulam, lidocaine, and serotonin). This demonstrates that it is possible to evaluate the structural similarity of test and reference substances using free publicly available software. However, given the limited number of substances for which reliable environmental partitioning information is available the application of this approach to identify suitable reference substances could significantly reduce the number of reference substances available.

3.14.P-Th065 Development of column testing approach for the mobility assessment of chemicals during river-bank filtration.

Prasit Shrestha¹, Dieter Hennecke¹, Simone Küpers², Stefan Hahn³, Dimitrios Alexander Skodras², Stefan Trapp⁴ and Klaus Mosthaf⁴, (1)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Lower-Saxony, Fraunhofer Institute for Toxicology and Experimental Medicine (ITEM), Germany, (4)Technical University of Denmark (DTU), Denmark

River-bank filtration (RBF) is a widely used technique which utilizes the natural filtration capabilities of sediment and gravel to remove impurities and contaminants in the extracted water. However, there are potential risks, as certain non-degradable and highly mobile chemicals can pass through the filtration system and contaminate the drinking water sources. Existing regulatory tests do not include methods to evaluate the mobility of polar chemicals in usually very low/no organic carbon RBF materials. This study aimed to create a column testing approach with aquifer materials accompanied by a transport modelling approach to assess the mobility of polar chemicals during RBF.

In this study, two sandy aquifer materials from Haltern am See and Berlin (Germany) with variable cation exchange capacity, content of organic carbon, texture and porosity were selected. Three test substance 1) nitrophenol (classified as potential PMT & vPvM)1, 2) melamine (classified as PMT & vPvM)1 and 3) carbamazepine (detected in groundwater and drinking water)1 were used in this study.

A column test setup with water saturation in up-flow condition similar to DIN 19528 was used as a basis for the development of this testing approach. For this study, columns with diameter 14 cm were filled with aquifer material to a height of 40 cm and were initially saturated with tap water. A flow rate of 1.1 mL/min was used and the test was conducted at 20°C in the dark. As a first step, the test substance and the tracer (KBr) were loaded as eluent (dissolved in tap water) into the saturated column at substance concentrations of 0.1 mg/L and tracer/KBr concentration of 0.2 mg/mL. This loading step was carried out for 3 d and was followed by a washing step where the eluent was exchanged with tap water that was flushed through the column for 2 d at a similar flow rate. For both loading and washing steps, the concentrations of test substances along with other phys-chem parameters of the eluate such as pH and electrical conductivity were measured. The results obtained from these column studies will be presented.

3.14.P-Th066 A workshop to engage with stakeholders, identify data gaps and establish research priorities for the development of a screening test to assess the mobility of polar and ionisable substances

Pippa Kate Curtis-Jackson¹, Michael Hüben², Adam Peters³, Benedikt Ringbeck⁴, Dieter Hennecke², Dimitrios Alexander Skodras⁵, Steph Jones¹, Richard Gibson¹ and Hattie Brunning¹, (1)Environment Agency United Kingdom, United Kingdom, (2)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)wca environment Ltd., United Kingdom, (4)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (5)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

The partitioning and binding of substances to components of soils and sediments is an important aspect of their environmental fate and can determine both their mobility and bioavailability in the environment. Screening level assessment approaches to identify and prioritise potentially mobile substances are generally based on the organic carbon normalised partition coefficient (KOC) as the principal indicator of substance mobility; this is because organic matter plays a dominant role in the adsorption of many substances to surface soils. The OECD Test Guideline (TG) 121 screening method for the measurement of KOC benchmarks the relative retention time of a test substance with a series of reference substances on an HPLC system using a cyanopropyl stationary phase; this allows for the interaction of polar and non-polar groups of a test substance but does not include other interactions that may be influential in determining the adsorption properties of more polar and ionisable substances, including ion exchange interactions and some polar interactions. It may be possible to extend the general concept of the OECD TG 121 screening test to consider additional interactions that contribute to the overall retention of substances in soils and sub-surface media. Following an evidence review and experimental phase investigating the potential to extend the general concept of the OECD TG 121, a workshop was undertaken to engage with stakeholders, secure support, identify data gaps and uncertainties, and understand the best way forward with this work. The workshop included a series of presentations and breakout groups, which encouraged discussion and comment, on the historical background of the OECD TG 121, the evidence review, the experimental work and potential next steps. In general, an extension to the OECD TG 121 that enables the consideration of interactions between substances and components of soils and sediments, beyond those associated with organic carbon, was supported. Key outcomes included increased awareness and interest in moving the work forward; external influence on the project direction; clarity on the data gaps and experimental work that is needed; and potential collaborations to progress this work. The workshop has provided the basis from which a road map for future development can be established. Presenting this workshop will provide a valuable learning exercise in how to work with key stakeholders to improve regulatory acceptance.

3.14.P-Th067 Taking Account of Bioavailability in Assessing the Potential Risks Posed by Diclofenac in European Surface Waters

*Adam Peters, Iain Wilson, Rebecca Jayne Brown and **Dean Leverett**, wca environment Ltd., United Kingdom*

The nonsteroidal anti-inflammatory drug diclofenac has widespread use and can enter the environment via wastewaters. Diclofenac is a monocarboxylic acid with a pKa value of approximately 4, meaning that at pH 4 diclofenac will be present in approximately equal amounts in both ionised and unionised forms. At pH 6 approximately 99% of diclofenac will be present in the ionised form, and at pH 7 approximately 99.9% of diclofenac will be ionised. The physicochemical properties of diclofenac indicate that the substance is water soluble, ionised in aqueous environmental media, and unlikely to undergo significant environmental partitioning due to its presence in an anionic form in the environment. Diclofenac environmental behaviour is therefore typical of many other human pharmaceuticals. It readily ionises, is water soluble, and shows a limited tendency to partition to environmental matrices, which is unsurprising as these are often clinical design requirements for medicines. It has recently been proposed that Environmental Quality Standards (EQS) for diclofenac should take account of its ionisation, and consider differences in the uptake and toxicity of the ionised and unionised forms. Normalisation of toxicity data for diclofenac based on pH has been reported to reduce heterogeneity in acute data and improve the Species Sensitivity Distribution (SSD) of chronic data. Bioavailability based approaches for EQS derivation are usually based on the normalisation of toxicity data to a consistent set of water chemistry conditions, and the calculation of a site-specific SSD. However, in cases where all species in the ecotoxicity database use the same bioavailability normalisation approach it may be possible to apply a bioavailability correction to an HC5 value derived from a bioavailability normalised SSD. Water chemistry conditions vary widely across Europe, and EQS values that take account of this variation have been set within Europe for over a decade and are now widely implemented. This presentation considers the variation in local pH conditions of surface waters across Europe to identify differences in the relative sensitivity of areas to diclofenac toxicity.

3.14.P-Th068 Prediction of the mobility of gabapentin, tramadol, diclofenac, acesulfame, and methamphetamine in soils based on their properties

***Radka Kodesova**¹, Alina Sadchenko², Martin Kocarek³, Vit Kodes⁴, Miroslav Fér³, Helena Švecová², Ales Klement⁵, Antonín Nikodem⁵, Jindrich Zelinka³ and Roman Grabic², (1)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (2)University of South Bohemia Ceske Budejovice, Czech Republic, (3)Czech University of Life Sciences Prague, Czech Republic, (4)Czech Hydrometeorological Institute, Czech Republic, (5)Department of Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic*

Agricultural soil can be contaminated by various micropollutants. One source of these micropollutants is contaminated river water or even treated wastewater used for irrigation, or sludge from wastewater treatment plants used to enrich the soil with organic matter and nutrients. Compounds occurrence in soil or their leaching from soil and migration towards groundwater depend on the climatic conditions, properties of the vadose zone environment and behavior of a particular compound, i.e., its sorption onto soils and sediments, and stability in the environment. The five compounds, i.e., gabapentin, tramadol, diclofenac, acesulfame, and methamphetamine, that are frequently found in the water environment were selected. To determine their behavior in different soil environments, standard sorption experiments were performed for each of them in eight representative soils of the Czech Republic. The Freundlich sorption isotherms were calculated to express relationships between concentrations in solution and sorbed onto soil particles. Multiple linear regressions were used to derive equations for predicting the Freundlich sorption coefficient (KF) using the properties of tested soils, e.g., organic carbon content, clay content, soil pH, cation exchange capacity, and wettability index. These equations and the maps of soil properties were used to predict the KF value distributions within the agricultural soils of the Czech Republic and subsequently to delineate classes of compounds' mobility in the soil environment. The standard dissipation tests in three soils were also conducted to determine their persistence in soils. Next, specific groundwater vulnerability maps for each compound were obtained by combining the DRASTIC vulnerability index, mobility index and stability index.

The work was supported by the Ministry of Agriculture of the Czech Republic, project No. QL24010384.

3.14.P-Th069 Testing the Applicability of Diffusive Gradients in Thin-Films (DGT) to Assess Pesticide Bioavailability in Soil

Dora Fleten¹, Felix E. Wettstein², Juliane Hollender³ and Thomas D. Bucheli², (1)Agroscope, ETH Zürich, Switzerland, (2)Agroscope, Switzerland, (3)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

The growing global demand for food results in an increased use of pesticides in agricultural production to ensure corresponding crop yields. Once applied, pesticides enter the environmental matrix of soil, where they undergo a range of processes e.g., sorption, microbial degradation, and ageing. In conventional risk assessment, the total extractable concentration of pesticides in soil is typically used as the standard for exposure. However, this method anticipates the most adverse circumstances and does not account for environmental processes that modify pesticide fate and thereby influence their (bio)availability. Consequently, determining pesticide bioavailability is essential for risk assessment, remediation strategies, and related decision-making. In this project, we focus on determining pesticide bioavailability using passive sampling. Although the diffusive gradients in thin-films (DGT) technique has demonstrated strong validity and performance for a wide range of metals, metalloids, and other inorganic substances, its application to organic compounds such as pesticides remains relatively novel. Therefore, while the use of DGT for determining pesticide bioavailability in soil might be an innovative extension of this method, it still requires thorough investigation. We will evaluate DGT performance under controlled conditions with water-saturated soils, compare it with other passive sampling techniques (e.g. silicone-based materials) and test whether it provides valid results as a proxy for the actual pesticide exposure. If so, current risk assessment frameworks may get more environmentally meaningfully refined.

3.14.P-Th070 Leaching of heavy metals, nicotine, and other organic compounds from spent disposable e-cigarettes and their environmental implications

Lillian N Tran, Gregory Wang, Constantino Neri, Anna Kim, Wonsik Woo, Michael Lum and Ying-Hsuan Lin, University of California, Riverside, United States

The use of disposable e-cigarettes is widespread and increasing globally. Disposable vape products are designed to be single-use devices that are discarded after the e-liquid is exhausted. Due to a lack of standardized recycling procedures, most spent disposable e-cigarettes end up in municipal waste. The hazardous chemicals leaching from these spent disposables into landfills and the nearby surrounding environment pose significant environmental concerns. This study aims to characterize the leaching of heavy metals, nicotine, other polar organic contaminants, and potential nicotine transformation products from the spent disposable devices (NJOY Menthol) in different aqueous environments at different pH, including (1) deionized water, (2) synthetic leachate, and (3) simulated rainwater. Samples were collected at six time points, every 48-72 hours, spanning from 0 to 11 days. Environmental matrices influenced the leaching rates, causing an increase in nicotine,

menthol, and heavy metals over time in all conditions. Nicotine reached a plateau in both synthetic leachate and simulated rainwater conditions, whereas the observed increase of nicotine and anabasine could be explained by possible transformations into other forms of nicotine. These findings indicate a potential rise in pollution and ecotoxicity associated with improper disposal of the spent disposable e-cigarette devices and highlight urgent needs for regulatory measures governing the use of these products.

3.15.P Innovative Approaches to Groundwater Quality Monitoring: From Detection to Policy

3.15.P-Th071 Relationship Between the Occurrence of Organic Micropollutants and Groundwater Conditions in Drinking Water Aquifers: The Netherlands as a Case Study

Merel Nederend¹, Tim Zonjee¹, Silvana Ines Quito Tapia² and Nora B Sutton³, (1)Wageningen University and Research (WUR), Netherlands, (2)Wageningen University and Research (WUR), Spain, (3)Environmental Technology, Wageningen University and Research (WUR), Netherlands

The occurrence of organic micropollutants (OMPs) in drinking water aquifers has been widely documented. Physiochemical, hydrogeological and biological processes influence the fate of OMPs in the environment, mainly through biodegradation and sorption. Biodegradation and sorption potential is OMP specific, through differences in physio-chemical properties of OMPs interacting with groundwater chemistry and the soil matrix. OMP occurrence in drinking water aquifers is a complex interplay of different mechanisms, and it is challenging to predict the prevalence for a given aquifer. This research aimed to study relationships among the occurrence of OMPs in drinking water aquifers and groundwater conditions as well as the role of OMP-specific properties, with the Netherlands as a case study. The data set covered 286 individual extraction wells distributed over 23 extraction fields in the eastern and northern part of the Netherlands. Macrochemistry data (pH, electron acceptor and dissolved organic carbon (DOC) concentrations) and OMP concentrations were measured by a Dutch drinking water company over a 9-year period (2016 to 2025). This data shows that pesticide transformation products are detected most at extraction wells. 2,6-dichlorobenzamide (BAM), transformation product (TP) of the pesticide dichlobenil, is the most frequently detected compound at the extraction wells (46%). The TPs of other pesticides also have a higher presence than their parent compounds, showing the persistence of these TPs. The data shows that OMP charge state is predictive for OMP occurrence, with a lower occurrence of positively charged OMPs (N = 15 wells) than neutral (N = 245) / negatively charged (N = 223) OMPs. Electrostatic interactions, such as attraction between positively charged OMPs and negatively charged soil particles is a process likely to contribute to limited transport of positively charged OMPs. Lastly, the data shows a positive trend between the concentration of DOC (mg/L) and summed concentration of PFAS (ng/L) in individual extraction wells, if PFAS is detected. These new insights on the factors influencing OMP occurrence at extraction wells contribute to improved prediction and management of OMPs in drinking water sources.

3.15.P-Th072 PFAS Levels in Soil and Groundwater Profiles: Implications for Drinking Water Production from Groundwater

Floris Naus¹, Remco Vis¹, Louise M. van Mourik¹, Bas van der Grift², Bahareh Kianfar², Johan van Leeuwen² and Arjen Wintersen¹, (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)KWR Water Research Centre, Netherlands

Per- and polyfluoroalkyl substances (PFAS) are highly fluorinated chemicals that have been produced and used on a large scale in various industries and products since the 1950s. During the production and application of PFAS, these substances have also been diffusely distributed via the air and associated atmospheric deposition. As a result, they are present almost everywhere in the soil at low concentrations. A significant part of the total PFAS load is still present in the unsaturated zone of the subsurface. From the unsaturated zone, PFAS migrate to the groundwater, which is extracted for drinking water production. However, there is still insufficient generic knowledge about the presence and distribution of PFAS in the soil, and how and when PFAS will spread to drinking water sources that utilize groundwater. This is especially true for the relatively low concentration ranges which are found in diffusely PFAS-contaminated areas. In this study, the presence and fate of PFAS in the subsurface is further researched.

The monitoring part of the study maps the concentration depth profile of 34 PFAS in the unsaturated zone and in groundwater. For this, samples of soil in the unsaturated zone were taken at 101 locations at multiple depths. Additionally, samples of groundwater at multiple depths were taken at 24 locations. There were approximately

seven filters per well, with depths ranging between 3 and 10 m below surface level.

The results of the monitoring study confirm that legacy PFAS in the subsurface are still largely contained within the unsaturated zone. This raises further questions about the dominant transport processes of PFAS in the subsurface. If the peak of PFAS production and atmospheric deposition was in the past, the largest peak would not have been in the topsoil but a bit further down. Therefore, the results will be used to improve modelling by providing an estimation of the environmental behavior of PFAS in the soil and of the diffuse PFAS load that is still on its way from the soil to ground- and drinking water.

3.15.P-Th073 Uncovering PFAS in Groundwater: Occurrence, Hotspots and Health Risks Implications

Meritxell Gros¹, Natalia Sáez Rosique¹, Teresa Garrido², Marta Expósito², Josep Fraile², Yolanda Soriano³, Julian Campo³, Mira Petrovic¹ and Josep Mas-Pla¹, (1)Catalan Institute for Water Research (ICRA), Spain, (2)Catalan Water Agency (ACA), Spain, (3)Desertification Research Center, University of Valencia, Spain

Groundwater is a key resource for urban and agricultural water supply, yet its quality is increasingly threatened by industrial, urban and agricultural activities, and by over-extraction that may enhance pollutant mobilization. Emerging contaminants (ECs), particularly per- and polyfluoroalkyl substances (PFAS) raise particular concern due to their persistence, mobility and potential health impacts. Upcoming revisions of the EU Water Framework Directive and Groundwater Directive, including the establishment of a Groundwater Watch List (GWWL), reflect the need for harmonized monitoring and regulation across Europe.

To support these initiatives, the Catalan Water Agency (ACA) implemented a regional monitoring network to assess the occurrence, hotspots and potential risks of relevant ECs, including PFAS and pharmaceuticals (PhACs), in groundwater. Between 2022 and 2024, 94 groundwater sites impacted by urban and industrial activities across Catalonia were analyzed. Twelve PFAS, including perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkyl sulfonic acids (PFSA), and eleven PhACs, were quantified using UHPLC-HRMS and UHPLC-MS/MS, respectively. Environmental risks were evaluated using hazard quotients ($HQ = MEC/PNEC$) using data from the NORMAN database, while human health risk followed the EFSA guidance based on the summed intake of four PFAS (PFOA, PFNA, PFHxS and PFOS).

PFAS were widespread, with detection frequencies above 89% for PFPeA, PFOA and PFOS. Concentrations ranged from sub ng/L to several hundred ng/L, reaching 773 ng/L for PFOS. Short-chain PFCAs and PFSA dominated, particularly near industrial areas. Many sites exceeded the 100 ng/L threshold for the sum of 20 PFAS set in Spanish drinking water regulations. PhACs such as carbamazepine, sulfamethoxazole, amidotrizoic acid and primidone were also detected, sometimes above 100 ng/L, and even exceeding 1000 ng/L for amidotrizoic acid. Environmental risk assessment revealed moderate to high risks ($HQ > 0.1-1$) at many sites, primarily driven by PFOA and PFOS. Human health assessment showed that summed HQs for the four PFAS often exceeded 1, with some surpassing 10, indicating potential health concerns if groundwater were used for consumption of drinking water without treatment. Overall, PFAS are the most critical contaminants due to their ubiquity, persistence and strict regulatory limits, highlighting the need for harmonized monitoring, pollution control and targeted groundwater remediation.

3.15.P-Th074 A Comprehensive Assessment Framework for Chemical Mixtures in Urban Groundwater

Santiago Gómez-Herrera¹, Estanislao Pujades¹, Naroa Lopez-Herguedas², Monica Enrich³, Anna Jurado¹ and Victoria Osorio¹, (1)Institute for Environmental Assessment and Water Research, IDAEA-CSIC, Jordi Girona 18-26, 08034 Barcelona, Spain., Spain, (2)Research Centre for Experimental Marine Biology and Biotechnology (PIE), University of the Basque Country, Spain, (3)Barcelona Cicle de l'Aigua SA (BCASA), Spain

Urban groundwater (GW) is increasingly considered a strategic alternative water resource for cities facing population expansion, recurrent droughts, and intensification of climate change effects. However, its suitability for drinking purposes remains uncertain due to the presence of complex mixtures of organic contaminants. This study presents a comprehensive assessment framework that integrates target analysis, suspect and non-target screening (NT/SS), human-health risk evaluation, and numerical mixing modelling to characterize and prioritize contaminants in an urban aquifer. In this context, six monthly sampling campaigns were conducted collecting 48

GW samples from eight wells/piezometers in the Poble Sec pilot zone of Barcelona (Spain), an area where oxic aquifers are strongly influenced by urban activities. Samples were concentrated and analysed by LC-HRMS, enabling the quantification of 123 target compounds spanning pharmaceuticals, industrial chemicals, pesticides, transformation products, food additives, and drugs of abuse. Complementary, NT/SS is ongoing to explore additional substances/candidates not included in the target list. Overall, 108 compounds were detected at least once, and 45 were ubiquitous across all campaigns, suggesting a chemically diverse mixture influenced by multiple urban sources. Total concentrations were dominated by industrial chemicals, followed by pharmaceuticals and food additives, with compounds such as tris(chloropropyl) phosphate and melamine capable of migrating and persisting through the subsurface. Spatial and temporal patterns indicated contamination hotspots as well as attenuation processes along the flow path. Human-health evaluation using consumption rates posing health risk revealed the presence of potential risk compounds (e.g., Docusate or Pentobarbital) that fell into high-priority categories, whereas most contaminants exhibited values related to low concern under typical GW consumption scenarios. Finally, a mixing-modelling employing MIX code is being applied to quantify recharge-source contributions and prioritize contaminants as potential tracers in the urban aquifer. This multi-tiered approach (combining chemical screening, risk prioritization, and modelling) provides a robust basis for assessing the implications of chemical mixtures in GW and supports its future evaluation as a complementary drinking-water resource.

3.15.P-Th075 Characterising Emerging Contaminants in a Groundwater Catchment Using Advanced Screening Approaches

Nonito Ros Ros Berja¹, Anna Menció², Ruben Gil-Solsona³, Josep Mas-Pla² and Meritxell Gros⁴, (1)Catalan Institute for Water Research (ICRA), Spain, (2)Grup de Recerca GAiA-Geocamb, Department of Environmental Sciences, University of Girona, Spain, (3)Spanish National Research Council (CSIC), Spain, (4)Catalan Institute for Water Research (ICRA-CERCA), Spain

Groundwater is essential for sustaining urban, agricultural and ecological needs, especially in Mediterranean regions facing prolonged droughts. Reduced recharged and intensified pumping may alter stream-aquifer interactions and open new pathways for emerging contaminant (EC) infiltration, such as pharmaceuticals (PhACs), endocrine disrupting chemicals (EDCs), PFAS, pesticides and other anthropogenic chemicals. These ECs reach aquifers at low ng/L levels, challenging groundwater quality assessment. Recent advances in European groundwater policy, that introduce new quality standards for some ECs, underscore the need for monitoring approaches that capture a broader spectrum of ECs. While targeted analysis may underestimate contaminant occurrence, HRMS-based suspect screening can detect a wider range of ECs, and their combined application offers a more comprehensive assessment framework. In this context, the present study integrates advanced target and suspect screening methods to characterise ECs in the drought-affected Onyar River aquifer, and to demonstrate the added value of using these combined strategies for groundwater monitoring.

Groundwater and river samples were collected during two campaigns (2021–2023) under contrasting hydrological conditions. Target LC–MS/MS analysis focused on 45 PhACs, 9 metabolites and 32 EDCs, while HRMS-based suspect screening (Orbitrap Exploris 120) was applied to broaden chemical coverage. Target analysis detected only a small subset of compounds, mainly PhACs and selected EDCs, typically below 20 ng/L, with higher concentrations in sites near the river and attenuation was observed at depth. In contrast, suspect screening revealed a much wider chemical profile, identifying 67 compounds including additional PhACs, metabolites, pesticides, and multiple transformation products, indicating active degradation and natural attenuation processes in the aquifer. The limited overlap between both approaches demonstrates that each framework captures different fractions of the contaminant spectrum.

These results show that integrating targeted and suspect screening methodologies provides a more complete assessment of groundwater pollution under drought-intensified conditions that enhance the mobility and diversity of ECs. This combined strategy improves the detection of contaminants relevant to current and future

European groundwater quality standards and supports more effective monitoring in vulnerable Mediterranean aquifers.

3.15.P-Th076 Bridging Polarity Gaps in Groundwater Contaminant Analysis with a Hybrid SPE Approach Combined with Non-Targeted Analysis

Francesc Labad Roig, Ulla Bollmann and Nanna Hjort Vidkjær, Geological Survey of Denmark & Greenland (GEUS), Denmark

Urban groundwater is increasingly viewed (and even used) as a strategic resource for future drinking-water supplies, especially under growing climate pressures and the need for resilient water systems. Ensuring its long-term safety requires monitoring strategies capable of capturing a broad spectrum of contaminants. While routine surveillance typically focuses on nutrients, heavy metals, and microbiological indicators, this approach overlooks the diverse range of organic micropollutants introduced by human activities. Sources such as wastewater leakage, agricultural inputs, surface water infiltration, or urban runoff contribute complex mixtures of both well-known and emerging organic compounds. Consequently, relying solely on target-based analytical lists provides an incomplete understanding of groundwater quality and may underestimate potential risks.

Non-target analysis (NTA) using liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS) offers a powerful alternative, enabling the detection of thousands of features without predefined analyte selection. Nevertheless, achieving broad chemical coverage remains challenging due to the diverse physicochemical properties of groundwater contaminants, including their polarity, molecular size, ionisation behaviour, and sorption affinities. A single extraction or chromatographic method often fails to capture the entire polarity range.

To address this limitation, we developed a multi-layered solid-phase extraction (mLSPE) approach that integrates sorbents with complementary retention mechanisms, aiming to maximise the extraction of both polar and non-polar organic compounds within a single workflow. Extracts were analysed using two orthogonal chromatographic modes, hydrophilic interaction chromatography (HILIC) and reversed-phase liquid chromatography (RPLC), coupled to a timsTOF Pro 2 high-resolution mass spectrometer (Bruker Daltonics). This dual-LC strategy expands the detectable chemical space and enhances molecular coverage in NTA workflows.

The combination of multi-layer SPE with complementary LC-HRMS separations significantly widens the analytical window accessible for non-target screening of urban groundwater. This integrated approach supports a more comprehensive characterisation of contamination patterns, provides deeper insight into pollutant sources, and strengthens the overall framework for groundwater protection and risk assessment.

3.15.P-Th077 Advancing Non-Target Screening for Groundwater Monitoring: Combining Reversed Phase and Hydrophilic Interaction Chromatography for Broader Contaminant Coverage

Nanna Hjort Vidkjær and Ulla Bollmann, Geological Survey of Denmark & Greenland (GEUS), Denmark

Groundwater provides nearly half of the world's drinking water, making its protection critical for public health. Organic micropollutants (OMPs)—including pharmaceuticals, pesticides, industrial chemicals, and their transformation products—pose emerging challenges due to their persistence and potential toxicity even at trace concentrations. Traditional monitoring relies on targeted analytical methods optimized for specific compounds, but these approaches may provide an incomplete OMP profile and underestimate risks.

To address this gap, non-target screening (NTS) using liquid chromatography coupled with high-resolution mass spectrometry (LC-HRMS) is increasingly implemented in monitoring. However, the diversity of OMP physicochemical properties complicates comprehensive detection. Implementing both reversed phase (RP) and hydrophilic interaction liquid (HILIC) chromatography methods will likely improve compound coverage, especially for highly polar compounds ($\log D < 0$).

The Aquaplexus project aims to develop robust LC-HRMS NTS workflows for routine groundwater monitoring in Denmark. We evaluated five LC methods (four RP and one HILIC) coupled to a Bruker timsTOF Pro2 HRMS. Nine groundwater samples were concentrated by vacuum-assisted evaporative concentration (VEC). Pooled samples were spiked post-VEC with 205 OMPs ($\log D_{pH7}$: -16.9 to 7.8).

Method performance was assessed based on number of compounds detected, peak characteristics and intensity, retention time range, and matrix effects. Additionally, data from unspiked samples were analyzed in a non-target workflow to compare chemical fingerprints and OMP identifications across methods. The first results showed significant differences in peak intensities but few differences in OMP coverage between methods. Combining RP and HILIC resulted in a minor increase in OMP detections but a significant increase in sensitivity. Assessments of matrix effects and NTA comparisons will provide a more comprehensive foundation for selecting the best method combination for Danish groundwater monitoring. This work advances NTS implementation for environmental surveillance and informs future monitoring programs aimed at safeguarding drinking water resources.

3.16.A Integrating Genomics, Metabolomics, and Control Strategies to Address Harmful Algal and Cyanobacterial Blooms

3.16.A.T-01 Mixture Toxicity of Guanitoxin and Organophosphates in Zebrafish: From Developmental and Neurobehavioral Phenotypes to Transcriptomic Responses

Larissa Souza Passos¹, Melissa von Wyl², Elisabeth Janssen², David Lopez Rodriguez², Colette vom Berg² and Ernani Pinto³, (1)University of São Paulo (USP), Brazil, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Center for Nuclear Energy in Agriculture (CENA), University of São Paulo (USP), Brazil

Guanitoxin, a neurotoxin produced by cyanobacteria and the only known naturally occurring organophosphate, poses environmental risks comparable to synthetic organophosphate insecticides. Its effects on aquatic organisms, particularly in combination with other compounds sharing similar mechanisms of action, remain poorly understood. This study evaluated the developmental toxicity of guanitoxin, produced by *Sphaerospermopsis torques-reginae* ITEX-024, alone and in combination with the organophosphate insecticides malathion and trichlorfon in zebrafish (*Danio rerio*) larvae. Embryos were exposed for 120 hours to individual compounds and binary or tertiary mixtures at environmentally relevant concentrations using the Fish Embryo Toxicity test. Multiple endpoints were assessed to evaluate developmental and molecular effects. All compounds exhibited dose-dependent toxicity, with mixtures significantly enhancing both lethal and sublethal effects. The trichlorfon + guanitoxin combination was particularly potent, causing high rates of embryo coagulation, cardiac arrest, hatching failure, and pericardial swelling exceeding 600%. Sublethal effects were observed in all mixtures, including edema, craniofacial malformations, muscle disorganization, and pronounced hypoactivity under dark conditions, with locomotion reduced by ~80% in larvae exposed to guanitoxin + malathion. Transcriptomic profiling revealed downregulation of genes critical for muscle contraction, synaptic signaling, energy metabolism, and oxidative stress. The highest number of differentially expressed genes was observed in the trichlorfon + guanitoxin mixture (1,348 genes), followed by guanitoxin + malathion (513). Synergistic interactions in multiple mixtures indicate that guanitoxin, alone or combined with synthetic organophosphates, exerts severe neuromuscular and developmental toxicity. These findings highlight the ecological risks of pollutant mixtures in freshwater systems affected by agricultural runoff and cyanobacterial blooms, emphasizing the need to integrate mixture effects into environmental monitoring and risk assessment.

3.16.A.T-02 Herbicide Exposure Alters Transcriptomic Responses in a Bloom-Forming Cyanobacterium and Its Chytrid Parasite

Alice Balard¹, Jürgen F. H. Strassert², Justyna Wolinska² and **Erika Martinez-Ruiz²**, (1)University College London, United Kingdom, (2)Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Germany

Metolachlor (MET) is a widely used herbicide of the chloroacetanilide family that poses risks to freshwater ecosystems. Beyond its direct toxicity, MET can disrupt ecological interactions such as those between cyanobacteria and their chytrid parasites. Chytrids are zoosporeic fungi ubiquitous in aquatic environments that lethally parasitize phytoplankton, thereby influencing bloom dynamics by delaying or suppressing bloom formation. While previous studies have shown that MET affects cyanobacterial growth and metabolism, as well as chytrid fitness, the molecular mechanisms underlying these effects remain poorly understood. This study investigated the transcriptional responses of the toxigenic cyanobacterium *Planktothrix agardhii* and its obligate chytrid parasite *Rhizophydium megarrhizum* exposed to an environmentally relevant concentration of MET using a dual-transcriptomic approach. MET modulated the expression of genes associated with key physiological processes in both organisms, including photosynthesis in the host, *P. agardhii* and developmental transitions in the parasite *R. megarrhizum*. Furthermore, MET altered host-parasite co-expression patterns, indicating a coordinated molecular response to herbicide exposure. Our findings reveal the molecular basis of MET-induced disruption of cyanobacteria–chytrid interactions, providing new insights into how anthropogenic pollutants can reshape microbial relationships and influence freshwater bloom dynamics.

3.16.A.T-03 Silent Killers on the Riverbed: Episodic Anatoxin Bursts from Benthic Cyanobacterial Mats in Swiss Waters

Simon Grundmüller¹, Kim Ngoc Tram Luong² and Elisabeth Janssen¹, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Benthic cyanobacteria form cohesive mats on river and lake beds that can remain unnoticed until detached fragments accumulate along recreational shorelines. These mats may contain variably high concentrations of neurotoxic anatoxins and have been linked to rapid dog fatalities after contact with stranded material. In September 2024, several dogs showed lethal neurotoxic symptoms within minutes after bathing and drinking in the River Rhine near Schaffhausen (Switzerland), whereas benthic mats observed at the same reach in March 2025 were not associated with intoxications. This contrast illustrates the episodic and site-specific nature of the risk and the limitations of monitoring strategies that focus mainly on pelagic blooms.

We investigate benthic cyanobacterial mats from river Rhine and selected lakes in northeastern Switzerland using an integrated field and laboratory approach. Mats are sampled as floating and bottom-attached material, and lyophilised biomass is analysed by liquid chromatography–high-resolution tandem mass spectrometry (LC-HRMS/MS) for anatoxins, microcystins and other cyanopeptides, complemented by suspect screening against CyanoMetDB. Parallel DNA analyses (16S rRNA amplicon sequencing and toxin biosynthesis marker genes) provide community composition and the potential for toxin production.

We observe seasonal shifts in both anatoxin load and dominant genera, with *Microcoleus*-dominated mats in late summer exhibiting much higher anatoxin concentrations than *Oscillatoria*-dominated mats the following spring at river Rhine. These findings suggest that acute shoreline risk is strongly strain-dependent and can vary by orders of magnitude over time. By linking environmental conditions, community structure and toxin profiles across sites, this work aims to identify environmental “hot spots” and “hot moments” of anatoxin production and to support more targeted surveillance and timely risk communication for bathing and dog-walking areas.

3.16.A.T-04 Ecophysiological Experiments on *Prymnesium parvum*: Environmental Conditions Favoring Growth

Tümer Aykut, Robin Thoo, Agnieszka Rudak and Iwona Jasser, University of Warsaw, Poland

Invasive and toxic algae threaten ecosystems and public health by spreading rapidly, outcompeting native species, and releasing harmful metabolites. This study examines environmental factors regulating the growth of two harmful genera, *Prymnesium* and *Raphidiopsis*. *Prymnesium parvum* is a toxic, bloom-forming haptophyte that produces ichthyotoxins responsible for major fish kills and food-web disruption while *Raphidiopsis raciborskii* is a filamentous cyanobacterium capable of forming dense, toxin-producing blooms that degrade water quality and endanger aquatic life and human health. Together, these species illustrate the increasing challenges posed by harmful algal blooms in freshwater and coastal systems. Two strains of *P. parvum* (from Poland and Scotland) and one strain of *R. raciborskii* from northeastern Poland were used to assess growth under controlled conditions. Cultures were established through single-cell or single-filament isolation and expanded in climate-controlled chambers. *R. raciborskii* was maintained in WC medium, while *P. parvum* was grown in F/2 medium. Growth was evaluated across a wide range of environmental conditions, including temperatures from 12.5 to 30 °C, conductivities of 750–13,500 µS/cm, pH values of 6.5–8.5, total nitrogen of 1.0–5.0 mg/L, total phosphorus of 0.5–2.5 mg/L, and iron concentrations of 0.1–0.6 mg/L. Experiments were conducted in 100 ml flasks containing 70 ml of medium and 5 ml of culture per strain and were monitored over a 15-day period. Daily, 5 ml subsamples were analyzed for cell abundance and replaced with fresh medium. Although *R. raciborskii* trials have not yet begun, the *P. parvum* experiments show distinct strain-specific responses. The Scottish strain grew best at 13,500 µS/cm, while the Polish strain peaked at 10,500 µS/cm. Both strains performed optimally at pH 6.5–7.0, though maximum cell densities differed. High nitrogen favored the Scottish strain, whereas phosphorus stimulated growth in both; the Scottish strain responded most strongly to the highest concentrations, while 2.5–3.0 mg/L was optimal for the Polish strain. Growth also increased with rising iron levels, with the Polish strain reaching the highest abundances. Temperature experiments for *P. parvum* are ongoing, and identical environmental gradients will be applied to *R. raciborskii* to support the development of effective management strategies. The study also highlights the need to develop strain-specific mitigation strategies.

Disclaimer/Disclosure:

Abstracts have been prepared for *Prymnesium parvum* and *Raphidiopsis raciborskii*. *R. raciborskii* is currently being isolated; if successful, a growth-rate experiment will be conducted. Otherwise, the presentation will focus on two strains of *P. parvum*. Additionally, the temperature experiment for *P. parvum* is ongoing, so its results are not yet included.

3.16.A.T-05 Dual Roles of Cyanobacterial metabolites: As Enzyme Substrates and Inhibitors

Xuejian Wang, Elena Lippuner and Elisabeth Janssen, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Cyanobacterial blooms release toxic and bioactive secondary metabolites that threaten both ecosystem and human health. Biotransformation plays an important role in determining the environmental fate of these metabolites in surface waters. Research on the biotransformation of cyano-metabolites has focused primarily on microcystins, however, much less is known about other coproduced metabolites such as anabaenopeptins, cyanopeptolins, and microginins. The toxic mode of action of these bioactive metabolites often involves the inhibition of functional enzymes. Yet our understanding of their inhibitory effects on aquatic enzymes involved in biotransformation remains limited. In this study, we investigated the dual roles of cyano-metabolites as enzyme substrates and enzyme inhibitors. Using fractionated cyanobacterial extracts, we examined their reactions with commercial peptidases, the enzyme pool of aquatic biofilms, and a heterologously expressed multicopper oxidase from wastewater activated-sludge communities. Regarding the role as enzyme substrates: carboxypeptidase Y degraded two linear microginins by removing their C-terminal tyrosine residues. The aquatic enzyme pool degraded a wide of cyano-metabolites mainly through peptide-bond hydrolysis, tyrosine oxidation and arginine deamination. Cyano-metabolite containing tyrosine residues were labile when incubated with the multicopper oxidase in the presence of ABTS as a mediator, whereas tyrosine-free congeners remained stable. Regarding the role of enzyme inhibitors: cyanopeptolins inhibited trypsin (IC₅₀ = 53.75 nM), chymotrypsin (IC₅₀ = 2.20 µM) and peptidase activity in aquatic enzyme pool, but not carboxypeptidase Y. Microginins and anabaenopeptins showed mild inhibition towards carboxypeptidase Y and little effects toward the other enzymes. Overall, cyano-metabolites can act both as substrates and inhibitors of environmental relevant enzymes, and the diverse interactions shaping cyano-metabolite fate in surface waters requires further investigation.

The authors thank Swiss National Science Foundation (SNF) for funding this project (CRSII5_202290).

3.16.B Integrating Genomics, Metabolomics, and Control Strategies to Address Harmful Algal and Cyanobacterial Blooms

3.16.B.T-01 Profiling the Metabolomic Response of *Microcystis aeruginosa* PCC7806 to UV-A and UV-B Irradiation Stress

Eleni Aidini¹, Sevasti-Kiriaki Zervou¹, Triantafyllos Kaloudis², Christine Edwards³, Linda A. Lawton³, Dimitris Kletsas⁴, Maria Antonopoulou⁵, Theodoros Triantis¹ and Anastasia Hiskia¹, (1)Institute of Nanoscience and Nanotechnology, NCSR "Demokritos", Athens, Greece, Greece, (2)AquOmixLab, Athens Water Supply & Sewerage Company (EYDAP SA), Greece, (3)School of Pharmacy and Life Sciences, Robert Gordon University, United Kingdom, (4)Institute of Biosciences and Applications, NCSR "Demokritos", Athens, Greece, Greece, (5)Department of Sustainable Agriculture, University of Patras, Agrinio, Greece, Greece

Understanding the metabolic response of the bloom-forming cyanobacterium *Microcystis aeruginosa* to UV irradiation, a crucial component of sunlight, is essential for assessing ecological impacts and water quality. This study investigates the differential metabolomic profiles of the toxicogenic model strain PCC7806 following exposure to distinct UV-A (320–400 nm) and UV-B (280–320 nm) irradiation treatments.

We employed an integrated untargeted LC-HRMS and a computational pipeline to analyze intracellular metabolites. Cultures were subjected to UV-A (8 h/day for 4 days, sampled after 4 days) or UV-B (15 or 60 min, sampled after 1 and 4 days) and compared to non-irradiated controls. Raw data were processed using *mzmine* for feature detection and precursor-matching against CyanoMetDB, followed by molecular networking and annotations in the Global Natural Products Social Molecular Networking platform (GNPS2) and SIRIUS for in silico annotations. FBMNstats was used for uni- and multivariate statistics.

Statistical evaluation revealed the differential abundance of over 150 annotated features, including cyanotoxins (i.e., MC-LR, [D-Asp3]MC-LR, MC-HiLR), UV-protective mycosporine-like amino acids (i.e., shinorine, porphyra-334, mycosporine-glycine-alanine), and bioactive peptides (aerucyclamides, cyanopeptolins). We observed a marked difference in stress response with UV-A irradiation acting as a stimulant, causing a statistically significant increase in secondary metabolites and overall cell growth (as indicated by higher optical density). Conversely, UV-B induced dose-dependent effects, where short exposure (15 min) resulted in stable or slightly elevated metabolite levels, while prolonged exposure (60 min) caused a significant decrease. These findings provide molecular insights into the complex mechanisms governing *M. aeruginosa* survival and metabolic potential in UV-rich freshwater environments.

3.16.B.T-02 Evaluation of Ultrasound for Cyanobacteria Suppression Using a Field Unit in a Laboratory Anechoic Tank

Linda Weavers¹, Elyse Bonner¹, Shannon Thayer¹, Zuzana Bohrerova¹ and Elizabeth Crafton-Nelson², (1)Ohio State University, United States, (2)Hazen and Sawyer, United States

Cyanobacteria dominate harmful algal blooms (cyanoHABs) in freshwater sources, including Ohio drinking water reservoirs. Hydrogen peroxide (H₂O₂) is considered an environmentally friendly algacide because it decomposes into water and oxygen and selectively suppresses cyanobacteria. Ultrasound has also been proposed as a non-chemical alternative for cyanoHAB control, with manufacturers claiming it reduces buoyancy and photosynthesis. However, laboratory sound pressures and frequencies often differ from field conditions, complicating translation of results. This study examined whether ultrasound induces sonoporation—temporary openings in cell membranes—and whether this enhances H₂O₂ effectiveness at low concentrations. Experiments were conducted in a 1.2 m cube anechoic tank (1,800 L) lined with acoustic tiles to simulate a reservoir. A commercial ultrasound unit cycled through 24–205 kHz frequencies. Sound pressures were measured with a hydrophone. Cyanobacteria (*Microcystis*, *Anabaena*) were tested at 10⁷ and 10⁸ cells/mL. Sonoporation was assessed using DAPI and SYTOX Green stains quantified by flow cytometry. Synergy tests combined ultrasound with 0, 2, and 4 mg/L H₂O₂. Samples were submerged in Whirlpak bags under controlled light and temperature. Sonoporation experiments lasted up to 4 hours; H₂O₂ treatments were monitored for 48 hours. Algal reduction was measured via cell counts and chlorophyll-a/pheophytin-a fluorescence; residual H₂O₂ was analyzed by UV-Vis spectrophotometry. Ultrasound produced peak sound pressures of 4.3 kPa, below cavitation thresholds, and did not induce sonoporation in *Microcystis* cells. Combining ultrasound with H₂O₂ did not enhance cyanoHAB suppression. At 10⁷ cells/mL, chlorophyll-a was higher with ultrasound after 48 hours, suggesting a protective response to sound, as observed in other bacteria. At 10⁸ cells/mL, no significant differences were found between treatments. Overall, ultrasound did not improve H₂O₂ efficacy and may even promote growth at certain conditions.

This research was funded by the U.S. Army Engineer Research Development Center, Aquatic Nuisance Species Research Program's HAB Research & Development Initiative, grant W912HZ2120012 and the Ohio Water Development Authority (OWDA) under grant 7517. Hydro Bioscience LLC kindly donated an ultrasonic transducer to Ohio State University.

3.16.B.T-03 ANTIMICROBIAL RESISTANCE IN CYANOBACTERIA: AN EXPERIMENTAL AND GENOMIC APPROACH

Gloria Bianchi¹, Daniela Fortini², Isabella Marcucci³ and Maura Manganelli³, (1)Italian National Institute of Health, Dept. Environment and health (Rome, Italy), University of Tuscia (Viterbo, Italy), Italy, (2)Italian National Institute of Health, Dept. Infectious Diseases (Rome, Italy), Italy, (3)Italian National Institute of Health, Dept. Environment and health (Rome, Italy), Italy

In 2015, the World Health Organization (WHO) declared antibiotic resistance (AR) as one of the main threats to public health. Therefore, the WHO has promoted a Global Action Plan to combat AR using a One Health approach, which emphasizes the close link between human, animal, and environmental health. In the past decade, it has become clear that the environment influences the spread and transmission of antibiotic-resistant bacteria (ARB) and antibiotic resistance genes (ARGs) through various mechanisms. Cyanobacteria, photosynthetic prokaryotic organisms, are naturally present in almost all terrestrial and aquatic habitats and a growing number of studies highlight some role for cyanobacteria in the spread of AR in freshwater environments. In our study, we tested the susceptibility/resistance of four cyanobacterial strains to environmentally and health-relevant classes of antibiotics at concentration that reproduce the low environmental levels (0.0008 - 0.8 mg/L). We determined the minimum inhibitory concentration (MIC) of two strains of unicellular cyanobacterium *Microcystis aeruginosa* (CCAP1450/6 and CCAP1450/16 from Culture Collection of Algae and Protozoa) and two strains of the filamentous cyanobacterium *Planktothrix rubescens* (F1 and F9 isolated in our laboratory from Flumendosa Lake, Sardinia, Italy), using the microdilution method on 96-well plates. The results showed inter- and intraspecific variability among cyanobacteria with filamentous strains generally more resistant than unicellular ones. Genomic analysis confirmed the MIC tests results: *P. rubescens* strains exhibit antibiotic resistance mechanisms (e.g., the presence of β -lactamase) that explain their greater resistance compared to *M. aeruginosa*, in which no ARGs have been found, demonstrating the genetic susceptibility of both unicellular strains to the tested antibiotics.

Genomic analysis also revealed the presence of mobile genetic elements (plasmids and transposons), suggesting potential mechanisms of horizontal gene transfer responsible for the environmental spread of antibiotic resistance genes.

In conclusion, our results contribute to clarify the potential role for cyanobacteria as reservoirs and vectors of ARGs in aquatic ecosystems.

3.16.B.T-04 Uncovering the cytotoxicity of secondary metabolites from *Microcystis* extracts on two fish cell lines

Aurore Huré¹, Iris Barjhoux¹, Damien Rioult², Claudia Cosio¹, Manon Quiquand³, Benjamin Marie³ and Emilie Lance¹, (1)Université de Reims Champagne-Ardenne, UHLN, INERIS, Normandie Univ, SEBIO, UMR-I 02, Reims, France, France, (2)Université de Reims Champagne-Ardenne, UHLN, INERIS, Normandie Univ, SEBIO, UMR-I 02, Reims, France / URCATech Plateforme Mobile de Cytométrie Environnementale (URCATech-MOBICYTE, URCA, Reims, France), France, (3)UMR 7245 MNHN/CNRS Moécules de Communication et Adaptation des Micro-organismes (MCAM), Cyanobactéries et Environnement (CYANO) (MNHN, Paris, France), France

Cyanobacterial blooms in freshwater ecosystems have intensified globally due to climate change and eutrophication. *Microcystis* is particularly concerning for producing microcystins (MCs), regulated cyanotoxins. However, other metabolites (e.g., aeruginosins, microginins, microcyclamides) have sublethal to lethal effects, yet remain incompletely characterized and unregulated.

This study screened 14 *Microcystis* strains with distinct metabolite profiles for ecotoxicity using in vitro fish cell lines: rainbow trout liver-waterloo 1 (RTL-W1) and common carp leukocyte (CLC). Flow cytometry assessed cell mortality and growth after 24 h and 48 h. A Weight-of-Evidence-based method integrated toxicity data into a ToxHQ index normalized between reference, methanol control, and 3,4-dichloroaniline (3,4-DCA), a cytotoxicity positive control (OECD-recommended positive control). Cell cycle and energy metabolism (glycolysis and mitochondrial stress) were analyzed by flow cytometry and Seahorse. Metabolomic analyses were performed by LC-MSMS.

Extracts induced cell mortality ranging from 5% to 47% and growth inhibition from 0.41 to 0 day⁻¹ compared to the 89% of cell mortality and 0 day⁻¹ of growth inhibition in the positive control (3,4-DCA), particularly the CLC cell line. PMC 815.12 extract ranked in “moderate” toxicity associated with a higher ToxHQ Index than PMC 570.08 (36.7% vs. 20.9%), which also produced emerging cyanopeptides, including cyclamides and cyanopeptolins. Five additional extracts showed slight effects (ToxHQ Index 8 to 13%), producing MCs and/or emerging cyanopeptides (aeruginosins, cyanopeptolins, cyclamides, microguanidines), alongside non-peptide and unknown metabolites. These findings raise questions about which metabolites – and/or variants- drive these effects and suggest potential molecular interactions. Sublethal effects were investigated, including cell cycle analysis and energy metabolism. Some extracts (cyclamides, microginins, microcystbiopterins, cyanopeptolins, aeruginosins) inhibiting the growth rate, affected cell proportions in G1, S, and G2 phases. A few extracts were tested for metabolism (glycolysis and mitochondrial stress) showed no significant effect. Effect-Directed Analysis will fractionate toxic extracts to identify causative metabolites. Additional sublethal endpoints would refine toxicity assessment and improve understanding of mixture effects on aquatic organisms

3.16.B.T-05 Bioprospecting Microcystis-Dominated Toxic Biomass For Valuable Compounds And Biopesticidal Activity

Judita Koreivienė¹, Daiva Burokienė², Dovilė Čepukoitė², Jūratė Karosienė¹, Karina Šmeliova¹, Jūratė Kasperovičienė¹, Sofia Iliakopoulou³, Angelika-Ioanna Gialleli⁴, Anastasia Hiskia⁵ and Triantafyllos Kaloudis³, (1)Laboratory of Algology and Microbial Ecology, State Scientific Research Institute Nature Research Centre, Lithuania, (2)Laboratory of Plant Pathology, State Scientific Research Institute Nature Research Centre, Lithuania, (3)Institute of Nanoscience & Nanotechnology, NCSR Demokritos, Athens, Greece AquOmixLab, Athens Water Supply and Sewerage Company, Athens, Greece, Greece, (4)AquOmixLab, Athens Water Supply & Sewerage Company (EYDAP SA), Greece, (5)Institute of Nanoscience & Nanotechnology, NCSR Demokritos, Athens, Greece, Greece

Climate change and eutrophication are intensifying toxic Microcystis blooms, posing threats to freshwater ecosystems and public health. While mechanical harvesting reduces acute risks, sustainable management requires economic valorization of the collected biomass in line with circular economy principles. This study aimed to identify valuable compounds in Microcystis-dominated biomass and assess the potential of its extracts as bio-based pesticides against plant pathogens.

Cyanobacterial biomass was harvested from the Kaunas Reservoir, Lithuania (2020–2024), using AS-L/AS-LAND prototypes. Freeze-dried samples were analyzed for macromolecular content (proteins, pigments, carbohydrates, lipids). Individual compounds were identified via LC-qTOF in 70% methanol extracts. The antagonistic activity of four extract types (water, methanol, acetone–ethanol, phycocyanin) was tested against the oomycete *Phytophthora cactorum* and seven fungal pathogens (including *Fusarium*, *Botrytis*, and *Alternaria* spp.). Pathogen growth on extract-amended media was assessed over 14 days.

Proteins were the most abundant component in the biomass (45.9 ± 9.5 mg/g), significantly exceeding lipids and carbohydrates. LC-qTOF analysis revealed a diversity of bioactive non-ribosomal peptides, including anabaenopeptins, cyanopeptolins, microginins, and oscillamides. Methanol extracts were dominated by microcystins (21.4–47.1%) and pigments (13.7–56.4%). In bioassays, aqueous extracts were ineffective or stimulatory to pathogen growth. Conversely, methanol extracts demonstrated strong inhibitory activity, reducing *Fusarium culmorum* growth by up to 22.5% and *Phytophthora cactorum* by up to 44.6% after one week. Morphological changes were also observed in *Alternaria alternata* and *Botrytis cinerea*.

Harvested Microcystis biomass is a rich source of proteins and bioactive peptides. While aqueous extracts showed limited utility, methanol extracts effectively suppressed specific plant pathogens. These findings highlight the potential for valorizing toxic cyanobacterial blooms into biopesticides, transforming an environmental hazard into a valuable resource.

3.16.P Integrating Genomics, Metabolomics, and Control Strategies to Address Harmful Algal and Cyanobacterial Blooms

3.16.P-Tu284 Mass Spectrometry Query Language (MassQL) - Driven Pipeline for Comprehensive Detection of Structurally Diverse Cyanopeptides in Environmental Datasets.

Sofia Iliakopoulou¹, Sevasti-Kiriaki Zervou¹, Angelika-Ioanna Gialleli², Theodoros Triantis¹, Anastasia Hiskia¹ and Triantafyllos Kaloudis², (1)Institute of Nanoscience & Nanotechnology, NCSR Demokritos, Athens, Greece, Greece, (2)AquOmixLab, Athens Water Supply & Sewerage Company (EYDAP SA), Greece

Cyanobacteria produce a structurally diverse array of secondary metabolites, including potent toxins and bioactive molecules. Rapid and accurate detection of these compounds in complex environmental and biological matrices using mass spectrometry (MS) is essential for environmental hazard assessment and natural product discovery. However, the high structural variability within major cyanopeptide classes (e.g., microcystins, anabaenopeptins, microginins, cyanopeptolins) often leads to incomplete detection when relying solely on matching with publicly available spectral libraries, which are limited and incomplete.

To address this gap, we have developed a computational screening approach which begins with feature-based molecular networking (FBMN) to map and categorize known and potential cyanopeptide families within the MS datasets. While FBMN successfully reveals clusters of related compounds, this project develops class-specific mass spectrometry query language (MassQL) queries, deployed within the Global Natural Products Social Molecular Networking (GNPS2) ecosystem for sharing and community curation of mass spectrometry data, to provide a robust, complementary, and transferable methodology for comprehensive screening across diverse MS2 datasets.

Our approach centers on developing class-specific MassQL queries by systematically identifying and incorporating the minimal set of required and excluded MS2 fragmentation patterns (diagnostic fragment ions and neutral losses). The core objective is to simultaneously minimize Type A errors (false negatives), ensuring near-comprehensive coverage of structural analogs, and Type B errors (false positives), maximizing specificity against unrelated compounds.

The resulting MassQL queries are designed for direct implementation across both proprietary in-house libraries and vast publicly accessible metabolomics repositories. This work demonstrates the power of a standardized, pattern-matching query language to transform high-throughput screening, providing the environmental and public health communities with a much-needed tool for rapid and comprehensive detection of structurally diverse cyanopeptides.

3.16.P-Tu285 Chemodiversity of Microginins and Aeruginosins in Greek Freshwater Bodies: Elucidation of Novel Linear Peptides

Sevasti-Kiriaki Zervou¹, Triantafyllos Kaloudis², Spyros Gkelis³, Theodoros Triantis¹ and Anastasia Hiskia¹, (1)Institute of Nanoscience and Nanotechnology, NCSR “Demokritos”, Athens, Greece, Greece, (2)AquOmixLab, Athens Water Supply & Sewerage Company (EYDAP SA), Greece, (3)School of Biology, Aristotle University of Thessaloniki, Thessaloniki, Greece, Greece

Cyanobacteria form Harmful Algal Blooms (HABs) that are occurring with increasing frequency and intensity in recent years, often lasting for extended periods as a consequence of climate change. The production of cyanotoxins such as microcystins during HABs poses a major threat to freshwater ecosystems and public health. Along with well-known cyanotoxins, cyanobacteria produce other bioactive metabolites which are often overlooked.

This study focuses on investigating the presence and chemodiversity of the bioactive linear cyanopeptides belonging to the microginin and aeruginosin classes in freshwater bodies of Greece. Samples were collected during HAB events and analyzed using liquid chromatography – high-resolution mass spectrometry (LC-HRMS) with data dependent acquisition (DDA). Acquired data were processed using a comprehensive pipeline of open-access software and platforms, including mzmine for feature detection and searching to CyanoMetDB compound database, MetFrag for in-silico fragmentation of possible structural candidates, GNPS for feature-based molecular networking and spectral library matching as well as SIRIUS for formula prediction and structure annotation. Feature-based molecular networking successfully revealed the molecular networks of microginins and aeruginosins. This advanced data analysis approach enabled the elucidation of numerous known and new congeners of these linear peptides, significantly contributing to the understanding of the metabolic potential of bloom-forming cyanobacteria. Results reveal a previously underestimated chemodiversity within the linear peptide profile of cyanobacterial blooms. Furthermore, this approach was proven efficient for the characterization of other overlooked metabolites in complex natural product mixtures particularly when hindered by the absence of reference standards and open-access reference fragmentation spectra.

3.16.P-Tu286 Grazer pressure and its influence on growth and toxin dynamics in harmful algae: insights from copepod interactions

Wenxin Liu¹, Timon Van Renterghem¹, Ilias Semmouri¹, Colin Janssen¹ and Jana Asselman², (1)Ghent University, Belgium, (2)Blue Growth Research Lab (BGRL), Ghent University, Belgium

Harmful algal blooms (HABs) can pose significant ecological and socio-economic risks by producing toxic metabolites that accumulate in food webs, as such impacting fisheries, aquaculture, tourism, and human health. Anthropogenic pressures, including greenhouse gas emissions and nutrient enrichment, have intensified climate change and eutrophication, altering key abiotic factors such as water temperature, pH, salinity, and nutrient ratios. These changes have been demonstrated to influence HAB dynamics, and were identified as critical drivers of growth and toxin production. Previous studies suggest HAB toxins deter grazing from predators, but the reciprocal effects of grazers on HAB physiology remain underexplored. Current evidence is limited but suggests that certain chemical cues released by grazers - such as copepodamides excreted by copepods - can trigger toxin production in harmful algal species like *Alexandrium* and *Pseudo-nitzschia*. The mechanisms driving this phenomenon remain poorly understood, as does its consistency across diverse algal species and grazer-derived chemical signals. It is also unknown whether these interactions are modulated by environmental conditions. Furthermore, broader physiological responses and comparative effects among other grazer groups (e.g., bivalves) are poorly understood.

To address these knowledge gaps, we examined both direct and indirect effects of grazer pressure on HAB growth and toxicity. Two HAB species - the dinoflagellate *Alexandrium minutum* (a saxitoxin producer) and the estuarine cyanobacterium *Microcystis aeruginosa* (a microcystin producer) - were exposed to (1) live copepods, (2) copepod extracts, and (3) copepod culture medium filtrates (potentially containing chemical cues). We quantified growth rates, intracellular and extracellular toxin concentrations, and photosynthetic pigment profiles as indicators of algal physiological status. Copepod grazing rates were also assessed. Comparative experiments included three copepod species *Nitokra spinipes*, *Acartia tonsa*, and *Temora longicornis*, the dominant North Sea species. This study provides novel insights into grazer-HAB interactions and advances our understanding of feedback mechanisms that influence bloom dynamics under changing environmental conditions.

3.16.P-Tu287 Cyanobacteria Blooms in Shallow Urban Ponds: Insights from Seasonal and Bi-Monthly Sampling in 20 Ponds in Brussels (Belgium)

Laure Roman¹, Jean-Pierre Descy², Alberto Borges² and Nathalie Gypens¹, (1)Université Libre de Bruxelles (ULB), Belgium, (2)Université de Liège (ULg), Belgium

Small, shallow urban lakes provide important ecosystem services, such as biodiversity support and recreational opportunities, which are closely linked to phytoplankton biomass and community composition. In several Brussels ponds (Belgium), potentially harmful cyanobacteria blooms (cHABs) are recurrently observed. This study aims to describe and compare cyanobacteria dynamics across twenty urban ponds, addressing the challenge of identifying appropriate methodological strategies to efficiently capture changes in phytoplankton assemblages. We combined a single year of seasonal sampling across all twenty ponds with more than two years of (bi)monthly sampling in a subset of four ponds. Phytoplankton dynamics were assessed using multiple complementary approaches: chlorophyll *a* measurement as a proxy for total phytoplankton biomass, chemotaxonomic pigment analysis to estimate major phytoplankton groups, microscopy for cross validation of cyanobacteria identification, and 16S ribosomal DNA (rDNA) sequencing with cyanobacteria-specific primers. Seasonal sampling was useful for identifying ponds with low biomass and low risk of cHABs, but proved insufficient to capture cyanobacteria dynamics. Chlorophyll *a* concentration alone did not reliably indicate cyanobacteria biomass, as high values frequently reflected blooms of other phytoplankton groups, particularly cryptophytes and chlorophytes. Chemotaxonomic analysis efficiently captured cyanobacteria evolution, revealing elevated biomass especially during summer, but lacked fine-scale taxonomic resolution. Microscopy offered direct and timely identification but was constrained by its labor intensive and operator dependent nature. In contrast, 16S rDNA sequencing provided finer taxonomic resolution, including the detection of picocyanobacteria not visible under standard microscopy, yet remains inadequate for routine monitoring. Results showed that cHABs were mainly dominated by the genera *Dolichospermum*, *Microcystis*, and *Aphanizomenon*, all associated with potentially toxic strains. Overall, our findings highlight the need for combining multiple monitoring approaches to assess cyanobacteria dynamics in urban ponds.

Disclaimer/Disclosure:

Laure Roman received funding from Institute for the Encouragement of Scientific Research and Innovation (Innoviris) of the Brussels-Capital Region as part of the Smartwater project (RBC/2020-EPF-6 h) and from the 'Fonds pour la formation à la Recherche dans l'Industrie et dans l'Agriculture' (FRIA, Belgium).

3.16.P-Tu288 Diversity, Toxicity, and Chemical Characterization of Marine Benthic Cyanobacterial Mats from Florida Coastal Ecosystems

David Berthold¹, Forrest Lefler¹, Jessica Moretto¹, Maximiliano Barbosa¹, Katherine Hubbart², Rosa Hunter³, Megan Schulz³, Melissa Peacock³, Véronique Savar⁴, Laura Biessy⁵, Clarisse Hubert⁵, Philipp Hess⁴, Manoëlla Sibat⁴ and Dail Laughinghouse¹, (1)University of Florida, United States, (2)Florida Fish and Wildlife Conservation Commission, (3)Northwest Indian College, United States, (4)Ifremer, France, (5)Cawthron Institute, New Zealand

Marine cyanobacteria are diverse and widespread across estuaries and bays to open oceans, producing a wide range of secondary metabolites including cyanotoxins. Benthic cyanobacterial mats (BCMs) are increasingly reported in marine environments, partly driven by nutrient loading and climate change. Along Florida coasts, BCMs have proliferated across mangroves, seagrass beds, and coral ecosystems, demonstrating the urgency in understanding the diversity, physiology, and toxicity of this growing environmental health hazard. Between 2022 and 2024, BCMs were sampled to investigate their diversity and toxin production. Environmental samples underwent eDNA extraction with amplification of 16S rRNA for bacteria including cyanobacteria, and 18S rRNA for associated eukaryotes. Individual strains representing novel and published species were isolated and cultured for morpho-molecular characterization. Metagenomes of select field samples and individual strains, along with nutrient and metal analyses were investigated. Sequencing revealed that BCMs are diverse communities primarily composed of large filamentous cyanobacteria including *Dapis*, *Okeania*, *Lyngbya*, *Sirenicipillaria*, and *Moorena* while also acting as reservoirs for several bloom-forming dinoflagellates including *Amphidinium* and *Alexandrium*. Toxin profiles were determined using complementary analytical approaches. Targeted screening by LC-MS/MS focused on ~40 characterized cyanotoxins including paralytic shellfish toxins (PSTs), anatoxins, cylindrospermopsins, microcystins, and lyngbyatoxins. Samples showed the presence of anatoxin-a, dihydroanatoxin-a, cylindrospermopsins, and microcystins. A dmMC-RR analogue was detected in two *Moorena* species. For lyngbyatoxins, a specific analytical method was developed in-house based on a contaminated sample from New Zealand, enabling their identification and quantification. Results indicate that Florida's benthic cyanobacterial mats represent complex, diverse communities producing multiple known and potentially novel toxins and secondary compounds. Further assessment is needed to fully characterize their cyanobacterial and eukaryotic community structure, toxin production capabilities, and ecological drivers, emphasizing the importance of continued monitoring of these proliferating marine cyanobacteria.

3.16.P-Tu289 Monitoring Harmful Algae Blooms In Ecuador: Challenges And Search For Solutions

Christine Van der heyden¹, Byron Briones², Niels De Troyer¹, Bjorge Decostere¹, Luis Dominguez³ and Julio Bonilla², (1)University of Applied Sciences and Arts HOGENT, Belgium, (2)Centro de Investigaciones Biotecnológicas del Ecuador (CIBE), Escuela Superior Politécnica del Litoral (ESPOL), Ecuador, (3)Centro de Agua y Desarrollo Sustentable (CADS), Escuela Superior Politécnica del Litoral (ESPOL), Ecuador

Cyanobacterial blooms and its toxin production represent a growing environmental and public health concern in Ecuador. Conventional toxin detection methods such as HPLC and ELISA are expensive and logistically challenging in this region. We use environmental DNA (eDNA) as alternative approaches for monitoring potential (toxic) bloom events. A longitudinal and temporal analysis of water samples between 2022-2025 was performed, targeting five strategic locations along the Daule's river basin; and seven water reservoirs. Using eDNA, three microcystin synthesis genes (*mcyA*, *mcyB*, and *mcyE*) and two cylindrospermopsin synthesis genes (*cyrA* and *cyrC*) were monitored. Also, cyanobacteria-specific primers were employed to demonstrate their presence/absence. We detected distinct spatiotemporal distribution patterns of the cyanotoxin genes: microcystin-related genes were detected more frequently lotic sites, while cylindrospermopsin-genes showed higher prevalence in lentic water bodies. These results indicate a habitat preference: microcystin-producing species predominantly occur in riverine systems, while cylindrospermopsin-producing species dominate in reservoir environments. The observed distribution patterns suggest that cyanobacterial species composition is significantly influenced by water body type and associated environmental factors. Furthermore, as microcystin standards are absent in Ecuador, we focused on the development of a biosensor using the bacteria *Sphingosinicella microcystinivorans*. Several strategies were elaborated consisting of transforming *S. microcystinivorans* on the one hand and using its microcystin degradation gene cluster for

transforming *E. coli* on the other hand.

This study demonstrated molecular technologies as sensitive methods for early detection and monitoring of (harmful) algal blooms, presenting a viable alternative to traditional analytical approaches in resource-constrained environments.

3.16.P-Tu290 Non-Targeted Analysis Based on High-Resolution Mass Spectrometry for the Simultaneous Detection of Cyanotoxins and Synthetic Emerging Pollutants in Water Reservoirs

Angelika-Ioanna Gialleli, Sofia Hliakopoulou, Anastasia Kagiara, Phani Miskaki and Triantafyllos Kaloudis, AquOmixLab, Athens Water Supply & Sewerage Company (EYDAP SA), Greece

Water resource depletion and increasing drought frequency are critically elevating the need for systematic quality monitoring of drinking water sources. These environmental stressors often concentrate emerging contaminants, leading to complex mixtures where natural toxins converge with anthropogenic chemicals. In this study, we applied a Non-Targeted Analysis (NTS) workflow to investigate its capability for early detection of natural and synthetic pollutants at trace levels in two key reservoirs supplying the Attica region: Lake Yliki and Lake Marathonas.

Samples collected from diverse locations (water-intake towers, pumping stations, and stream inflows) were analyzed using Liquid Chromatography-Quadrupole Time-of-Flight (LC-qTOF-MS) utilizing both Data-Dependent (DDA) and Data-Independent Acquisition (DIA). The computational pipeline included data preprocessing in MZmine, Feature-Based Molecular Networking (FBMN) on the GNPS platform, and downstream multivariate statistical analysis.

The analysis revealed a co-occurrence of biogenic compounds (cyanotoxins, cyanopeptides) alongside anthropogenic pollutants (pesticides, pharmaceuticals). However, it is important to note that the concentrations of these detected compounds were extremely low (ng/L range). Consequently, the analysis provides solid proof that raw water quality is suitable for drinking water production following standard treatment processes, ensuring that concentrations of pesticides, pharmaceuticals, and cyanotoxins remain well below the established parametric values in accordance with the EU Drinking Water Directive (2020/2184) and World Health Organization (WHO) guidelines.

The critical advantage of this HRMS-based methodology is the capacity to monitor a wide range of natural and synthetic compounds simultaneously, starting from very low levels (ng/L). Unlike traditional targeted monitoring, this approach captures the full spectrum of the chemical cocktail, serving as a powerful tool for early-warning management and environmental forensics, allowing for timely interventions. This high-sensitivity screening enables a proactive system to safeguard water quality, identifying potential contamination pathways—such as agricultural runoff or wastewater inputs—before they pose a significant risk to public health.

3.17.A Integrating Polymer Analytics, Plastic Additives, and Micro/Nanoplastics for Risk Assessment and Regulation

3.17.A.T-01 Rubber additives are bioaccessible and rapidly released from respirable particulate matter in the lungs

Anya Sherman¹, Emily Roche² and Thilo Hofmann², (1)IDAEA-CSIC, Spain, (2)University of Vienna, Austria

Airborne tire-wear particles generated during driving are ubiquitously present in urban particulate matter and are inhaled by urban residents. These particles contain several rubber additives and their transformation products (rubber-derived compounds, RDCs), many of which are of toxicologic concern to humans. However, the extent to which inhalation of tire-wear particles contributes to RDC exposure depends on RDC bioaccessibility, i.e., whether they are released from particles before particles are expelled from the lungs or destroyed. In this study, we isolated respirable particulate matter (aerodynamic diameter < 4.5 µm) and conducted leaching experiments with simulated epithelial lung fluid and phagolysosomal lung fluid to simulate conditions on the lung surface, and following engulfment by phagocyte cells. RDCs with a wide range of physicochemical properties including hydrophobicity (log D from 0.9 to 4.9), charge state (neutral and positive), and compound stability were bioaccessible in the lungs, although the total bioaccessible fraction varied between compounds, and between simulated lung environments. Bioaccessibility in lung fluids was higher than reported in other aqueous environments, due to the unique composition of lung fluids (high organic content and presence of pulmonary surfactants which enhanced leaching especially for hydrophobic RDCs), as well as the inherently small size of respirable particulate matter. Such fine particles have a low intraparticle diffusion distance, and a high surface area to volume ratio contributing to RDC release. For all bioaccessible RDCs, release kinetics were rapid, reaching equilibrium concentrations in lung fluids within ten minutes. These rapid kinetics were due to small particle size, and high local solid to liquid ratios within the lungs. Fast leaching kinetics imply that RDCs will

be released during rubber particles pulmonary residence time. Inhalation of rubber particles is therefore an important source of RDC exposure.

3.17.A.T-02 A Fingerprint Analysis Approach Towards Identification and Quantification of Additives in Plastics

Jan-Hendrik Arndt, Frank Malz and Robert Brüll, Fraunhofer Institute for Structural Durability and System Reliability LBF, Germany

Plastics development used to be all about creating new base polymers. Now, the focus has shifted towards creating new formulations, i.e., combinations of base polymers and functional additives. These additives are crucial for adjusting the properties of plastics, such as resistance to degradation, flame retardancy or flexibility. Given legal requirements, modern formulations also often mandatorily contain recycled plastics, increasing the overall need for those. Preferentially, plastics for recycling are sourced from applications where low additive contents are needed, such as packaging waste, to minimize issues with residual additives.

For example, the regulations regarding flame retardants (FR) have become increasingly strict in recent years and plastics being now recycled often still contain formerly allowed but now highly regulated FR. Issues such as this prevent the recycling of many of the available plastics, with electronic waste being a particularly prominent case where lots of material would be available but recycling efforts are severely hampered by concerns regarding additive content. Increasing the use of these raw material streams in recycling will require suitable analytical approaches for fingerprinting additives in plastics at the recycling site.

While established methods, typically based on chromatography/mass spectrometry exist, these methods suffer from high cost, long analysis times and require a suitable lab. In comparison, ion mobility spectrometry (IMS) offers a highly promising alternative for determining the additive profiles of recycled plastics. It provides high sensitivity, short analysis times, portability, and relatively low costs (both in terms of purchase and operation). Furthermore, it has already demonstrated its immense potential in many areas, particularly in security checks (e.g., explosives detection at airports). Applications such as in environmental analysis further underscore the high sensitivity and specificity of the method in mobile applications. And the general applicability regarding additives, particularly FR, was similarly shown recently. Still, there have been no applications of IMS established with regards to recycled plastics, yet.

The presentation will outline an IMS-based approach towards on-site fingerprinting of additives in recycled polymers. It will detail the necessary steps in method development, foreseen challenges and mitigating approaches as well as initial results.

3.17.A.T-03 Fate of industrial polypropylene pellets in the environment: influence of additives on the release of degradation by-products

Amandine Passin¹, Célia Arib¹, Thierry Falher², Véronique Montembault¹ and Fabienne Lagarde¹, (1)Institut des Molécules et Matériaux du Mans, IMMM - UMR 6283 CNRS, Le Mans Université, Avenue Olivier Messiaen, Le Mans Cedex 9 72085, France, France, (2)CT-IPC Centre Technique Industriel de la Plasturgie et des Composites, Pôle Universitaire de Montfoulon, France

Plastic pollution encompasses a wide range of emerging contaminants, including additives, microplastics, nanoplastics, as well as volatile and soluble species produced during polymer degradation. Although these compounds are now found in aquatic, terrestrial, and biological environments, their contribution to plastic pollution remains widely underestimated and insufficiently characterised. Additives, incorporated to facilitate processing, improve material properties, or extend durability, can leach during use and markedly influence degradation pathways and kinetics. Yet, environmental samples do not allow the initial composition or true exposure conditions of plastics to be determined, making controlled laboratory studies essential to link formulation, ageing mechanisms, and the nature of emitted by-products.

In this work, polypropylene (PP) pellets containing controlled amounts of additives commonly used in commercial plastics were subjected to accelerated ageing protocol combining UV exposure and moderate mechanical stress. Their behaviour was compared with that of additive-free pellets. Mass loss, surface oxidation, and changes in crystallinity were monitored during UV ageing. Volatile by-products were inferred from gravimetric measurements, while particulate and soluble degradation products were quantified using morphometric analysis and total organic carbon measurements in the aqueous phase.

Our results show that polypropylene degradation generates volatile, soluble, and solid by-products regardless of formulation. Additives do not suppress the formation of these species but significantly delay their appearance.

While volatile and soluble compounds are ultimately produced at levels similar to those of neat PP, the generation of microplastics is much more strongly inhibited. Additives shift the degradation mechanism towards surface-limited oxidation and delamination, reducing overall fragmentation favouring the realisation of small

uniform particles. These findings underline the key role of formulation in the environmental ageing of polyolefins and highlight the importance of considering additive effects in future plastic design strategies and pollution assessment frameworks.

3.17.A.T-04 Multi-class Organic Contaminants in Brain and Muscle of Mallorcan Fish

Valentina Araya Piqué¹, Carme Alomar², Maria Vittoria Barbieri³ and Ethel Eljarrat⁴, (1)Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (2)Instituto Español de Oceanografía (IEO) Centro Oceanográfico de Baleares, Palma de Mallorca, Spain, Spain, (3)ONHEALTH, Institute of Environmental Assessment and Water, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (4)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain

Plastic additives and personal care product chemicals are widely used in consumer products and can exhibit toxic effects, raising concerns for environmental and human health. Despite growing awareness, information on their tissue-specific distribution and bioaccumulation in wild marine fish remains limited. This study investigated the occurrence and distribution of a broad range of plastic additives, bisphenols, UV-filters, and synthetic musk fragrances in brain and muscle tissues of two Mediterranean fish species commonly consumed by humans: European hake (*Merluccius merluccius*, n = 18) and striped red mullet (*Mullus surmulletus*, n = 8), collected off the coast of Mallorca (Spain).

Concentrations of 20 organophosphate esters (OPEs), 12 phthalates (PAEs), 11 non-phthalate plasticizers (NPPs), 4 bisphenols (BPs), 2 UV-filters, and 1 musk fragrance were quantified using liquid chromatography–high resolution mass spectrometry (LC-HRMS). Results were lipid-normalized to compare tissue distribution between brain and muscle.

PAEs were the predominant compounds, with maximum concentrations reaching 3.82×10^2 ng/g lipid weight in mullet brains and 1.38×10^2 ng/g lipid weight in hake brains. Detection frequencies differed markedly between tissues. Brain tissues showed high detection of DIPA, DEHP, and TCIPP, while muscle tissues were dominated by tonalide, DiBP/DNBP, DEHP, and high-molecular-weight phthalates. Overall, concentrations were generally higher in brain than muscle for compounds detected in both tissues, though clear species-specific trends were observed. Notably, bisphenol A, TPHP, and DINCH were exclusively detected in brain tissue, whereas bisphenol S, octocrylene, TCEP, and DEHP were mainly associated with muscle.

These findings demonstrate compound- and tissue-specific accumulation patterns, with brain tissues accumulating potentially neurotoxic chemicals and muscle tissues representing a relevant pathway for human exposure through seafood consumption. Accounting for tissue-specific distribution is essential for accurate environmental and human health risk assessments.

This study has been funded by the European Union – NextGeneration EU – as part of the MITECO program for the Spanish Recovery, Transformation and Resilience Plan (Recovery and Resilience Facility of the European Union established by the Regulation (EU) 2020/2094), and was entrusted to CSIC, AZTI, SOCIB, and the universities of Vigo and Cadiz. This study has received funding from European Union's HORIZON-CL6-2023-ZEROPOLLUTION-01 under the grant agreement No. 101134929.

3.17.B Integrating Polymer Analytics, Plastic Additives, and Micro/Nanoplastics for Risk Assessment and Regulation

3.17.B.T-01 Applying Effect-Based Testing to Develop Safer Polymers: Case Study with Flame-Retardant, Reprocessable Vitrimers

Rafael Reis¹, Arvinth Sekar², Cédric Hervieu², Sabyasachi Gaan² and Ksenia J Groh³, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Swiss Federal Laboratories for Materials Science and Technology (Empa), Switzerland, (3)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

The transition toward Safe and Sustainable by Design (SSbD) materials requires early integration of hazard assessment alongside the analysis of functional performance to support material optimization. For novel or

highly engineered polymers, conventional chemical analyses and risk-based exposure assessments may not capture complex or unexpected biological effects arising from leaching substances such as additives, degradation products, or processing-related by-products. Effect-based bioassays offer a valuable alternative strategy as they directly measure biological responses to mixtures of often unknown chemicals, enabling more comprehensive evaluation of potential human and ecotoxicological hazards at early innovation stages. Here, we present a case study on the aquatic toxicity of a newly developed vitrimer material that incorporates dynamic covalent bonds within highly crosslinked networks. This design provides mechanical strength, reprocessability, and inherent flame retardancy, all of which are essential for both high performance and circularity. Phosphorus-containing polymers are particularly promising, since phosphorus contributes to flame retardancy while also establishing dynamic bond exchange. Unlike traditional thermosets where phosphorus is added as an external additive that can increase leaching risk and compromise mechanical properties, our approach aims to embed phosphorus directly into the polymer backbone to provide inherent flame retardancy and reprocessability. Early toxicity assessment is essential to ensure material safety and to guide iterative improvements. To address this need, we applied a fish cell based acute toxicity assay (OECD Test Guideline 249), miniaturized from a 24-well to a 96-well format to increase throughput while maintaining sensitivity, cell viability, and reproducibility. A set of monomers, polymers, and material leachates was evaluated to systematically investigate the influence of formulation, curing, and reprocessing cycles on aquatic toxicity. Combined with material performance data, these effect-based toxicity results supported iterative material optimization, thus showing that integrating bioassays into early research and development can complement or in some cases even replace conventional chemical characterization and help advance SSbD material development.

3.17.B.T-02 Plastic Product-Specific Degradation Pathways and Quantification of Release Species: Towards Systematic Assessments for Material Comparison and Harmonization

Patrizia Marie Schmidt¹, Immanuel Willerich¹, Lars Meyer¹, Till Gründling¹, Denis Botin², Wendel Wohlleben¹ and Andreas Künkel¹, (1)BASF, Germany, (2)Analytical and Material Science, BASF, Germany

During their use phase, polymer-based products (including paints and textiles) age, fragment and release different materials at rates that vary by many orders of magnitude, depending on the exposure scenario and on the material composition. Consequently, fragmentation and degradation products are released, such as microfibers and -particles, fillers, additives, and/or low-molecular-weight organic species. The rates and profiles of these releases vary significantly depending on the material composition and exposure scenario. Comprehensive assessment of these emissions is essential, not only to quantify solid fragments (e.g., micro- and nanoplastics), but also to capture dissolved degradation products and additives.

To address current analytical limitations – especially in distinguishing different types of release species – novel workflows and analytical protocols have been developed for the cases of paints and textiles. For textiles, full-scale washing machine tests with in-line filtration and Raman microscopy (>50 µm) were combined with batch abrasion simulations. Analytical ultracentrifugation (AUC) and thermogravimetric analysis (TGA) enabled the differentiation between various release species.

Similarly, for paints and coatings, artificial weathering and mechanical stress in the presence of water were applied to facilitate the release of fragments and degradation products. A unified protocol employing Pyrolysis Gas Chromatography Mass Spectrometry (pyr-GCMS), Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES), and dissolved organic carbon (DOC) measurements allowed for the quantification of dissolved degradation species and additives, solid polymers, and inorganic or composite particles. These methodological advances enable a holistic and comparative assessment of micro- and nanoplastic releases from polymer-based products. The differentiation and quantification of different types of release species is still challenging and requires the use of several analytical techniques in parallel. The resulting insights provide a foundation for the targeted development of new materials with minimized environmental release profiles.

3.17.B.T-03 Development, Validation, and Application of a Method for the Quantification of Micro- and Nanoplastics in Human Bile

Federica Nardella¹, Martin Van Velzen¹, Henk Roest², Luc van der Laan² and Marja Lamoree¹, (1)VU University Amsterdam (VU), Netherlands, (2)Erasmus MC Transplant Institute, University Medical Center Rotterdam, Netherlands

Micro- and nanoplastics (MNPs) have recently been identified and quantified in human tissues and fluids, raising concerns about potential health implications and highlighting the need for reliable biomonitoring methods. Human bile is a relevant but largely unexplored matrix for assessing internal exposure, as it is a key medium for the excretion of exogenous substances entering the body via ingestion. Its complex composition, together with the difficulty of preventing external plastic contamination during clinical handling, has limited its

use in MNP research. This study aims to address these challenges by developing and validating a method based on pyrolysis–gas chromatography–mass spectrometry (Py-GC-MS) for the quantitative determination of six common polymers, namely polymethyl methacrylate (PMMA), polypropylene (PP), polyvinyl chloride (PVC), polyethylene terephthalate (PET), polystyrene (PS) and polyethylene (PE), in human bile. In addition to method development, the study also aims to assess the suitability of routinely collected clinical material for MNP biomonitoring. Archived bile samples stored under standard clinical conditions will be evaluated alongside bile collected and processed under strictly plastic-free protocols. This comparison will allow us to identify potential contamination sources associated with common storage conditions and to determine whether existing biobank materials can be reliably used for retrospective analysis of MNP exposure. Bile samples collected during liver transplantation procedures were processed using plastic-free protocols and rigorous QA/QC procedures. Method validation was performed by evaluating all relevant analytical figures of merit, confirming the robustness and suitability of the approach for quantitative MNP analysis in bile. The validated method was applied to an initial set of human bile samples, with PVC identified as the most frequently detected polymer. These findings demonstrate the applicability and potential of the method, which will be extended to a larger dataset and archived clinical material to support future evaluations of internal exposure and the suitability of existing clinical storage conditions for retrospective MNP biomonitoring.

3.17.B.T-04 So You've Eaten a Microplastic – Where Does it Go? The First Human Microdosing Study

Luke Parker¹, Anne-Eva Nieuwelink¹, Maria M. Kloukinioti¹, Hedwig Braakhuis¹, Lora-Sophie Gerber¹, Rianne de Lig¹, Esther van Duijn¹, Wouter Vaes¹, Maya Al Sid Cheikh², Marlou Dirks³, Silvie Timmers³, Hans Bouwmeester³ and Ingeborg Kooter¹, (1)TNO, Netherlands, (2)University of Edinburgh, United Kingdom, (3)Wageningen University and Research (WUR), Netherlands

Human exposure to microplastics is increasingly recognised as a global concern, yet a human risk assessment remains challenging. This is in part due to the lack of biokinetic data on the adsorption, distribution, metabolism and excretion (ADME) of microplastics in the human body. Current evidence for the absorption of microplastic particles upon ingestion is based on in vitro and in vivo rodent studies. The biological relevance of this data is, however, questionable due to the simplicity of the models and potential interspecies differences. In this study, 1 μ m 14C-polystyrene particles and Accelerator Mass spectrometry (AMS) were used to perform the world's first human microdosing study, filling a major data gap by providing biokinetic data on microplastics in the human body.

In this work, we use 14C-labelled polystyrene - which accurately mimics the chemical and physical properties of unlabelled polystyrene - to perform the first human microdosing study. Our approach utilizes a state-of-the-art Accelerator Mass Spectrometer (AMS) which is able to detect trace-levels of 14C. This innovative approach allows detection of PS with high sensitivity in complex matrix samples upon exposure to very low doses, without altering particle behaviour. This overcomes the limitations of conventional spectroscopic or mass-based methods that require fluorescently-labelled or metal-doped particles.

Six healthy normal weight volunteers between 21 and 36 years of age (three males and three females) received a single oral microdose (100 μ g) of 14C-labelled polystyrene incorporated in yoghurt. Blood, urine, and feces samples were collected over a five day period to characterise the absorption and excretion rate of polystyrene microplastics. The clinical trial was successfully performed and preliminary AMS results indicate the presence of 14C in the blood, the quantification and interpretation of which is currently ongoing, along with analysis of urine and feces.

This first-of-its-kind experiment represents a large step towards facilitating a human risk assessment of microplastics by delivering essential, robust biokinetic data in vivo in humans. The methodology - combining isotopic labelling with AMS - also offers a framework for future research as it can be adapted for many polymer types, morphologies and particle sizes.

3.17.P Integrating Polymer Analytics, Plastic Additives, and Micro/Nanoplastics for Risk Assessment and Regulation

3.17.P-Tu291 Evaluating microplastic particles as vectors of exposure for plastic additive chemicals using a food web model

Todd Gouin¹ and **Michael Whelan²**, (1)TG Environmental Research, United Kingdom, (2)University of Leicester, United Kingdom

Micro- and nanoplastic particles (MNPs) represent potential hazards for humans and wildlife, including as vectors for chemical exposure (e.g. plastic additives and pollutants sorbed from the surrounding environment). The leaching of chemicals from MNPs has been identified as a potential exposure pathway but the relative magnitude of this pathway under environmentally relevant conditions remains unclear. Here, we describe a modification of the ACC-HUMANSTEADY bioaccumulation model to include dietary exposure to MNPs containing either accumulated chemicals from the surrounding environment or embedded plastic additive chemicals (PACs). Chemical transfer to humans and wildlife is described using two-film resistance concepts assuming spheroidal or cylindrical particles of different sizes. The relative contribution of MNPs and environmental media to the estimated daily chemical intake in humans was assessed in various exposure scenarios, for a range of hypothetical chemicals with varying octanol-water and air-water partition coefficients (KOW and KAW, respectively; i.e. $0 < \log KOW < 8$ and $-5 < \log KAW < 3$). Results imply that MNPs could act as sources of exposure to chemical additives when the ingestion rate of 1 μm MNPs is $>10 \text{ mg d}^{-1}$, and the concentration of hydrophobic plastic additive is $>5\% \text{ wt wt}^{-1}$. The contribution made by MNPs as vectors of exposure decreased with increasing particle size and decreasing ingestion rates of MNPs. Human health risks were evaluated for four specific PACs to illustrate the application of the model for risk assessment. Risks were negligible when the ingestion rate of MNPs was $<100 \mu\text{g d}^{-1}$. Uncertainties are high regarding the characterization and quantification of ingestion of MNPs by humans and wildlife, including particle sizes and polymer composition, as well as on the presence of PACs in MNPs. These data gaps need to be addressed if the issue of MNPs as vectors of chemical exposure is to be fully understood. The work illustrates that mechanistic models, which account for all major exposure pathways, can be used to identify the importance of different exposure pathways, help prioritize research needs and support decision making.

3.17.P-Tu292 Understanding Human Exposure to Plastic Additives – A Systematic Review Protocol

Lara Cioni¹, **Valentina Araya-Piqué²**, **Maria Vittoria Barbieri³**, **Judith Desmet²**, **Julio Fernández-Arribas²**, **Daniel Rozúa¹** and **Ethel Eljarrat²**, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (2)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (3)ONHEALTH, Institute of Environmental Assessment and Water, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Plastic additives include a wide variety of chemicals which are added to plastics to confer them specific properties such as flexibility, resistance, and toughness/softness. With over 16 thousand plastic additives in use, there are three classes of these chemicals that are receiving growing international attention given their widespread use and detection in the environment: phthalates (PAEs), organophosphate esters (OPEs) and non-phthalate plasticizers (NPPs). Several PAEs and OPEs are associated with adverse effects, such as endocrine disruption, immunotoxicity and carcinogenic effects. For NPPs, which are often used as alternatives to PAEs, toxicological information is still lacking. Nonetheless, some recent studies are showing that these compounds might also have harmful effects in neurodevelopment and on the endocrine system. Due to these health concerns, the number of studies investigating human exposure to these chemicals has been growing in recent years, highlighting that humans can be exposed to PAEs, OPEs and NPPs through diet, dust, air, and consumer products. However, a critical question remains: which is the major route of exposure to these chemicals? To address this question, we designed a systematic review protocol to systematically find and select peer-reviewed literature reporting quantitative data for one or more exposure pathways to PAEs, OPEs, and NPPs. The first step of the protocol consists of searching literature data in various databases (PubMed, Science Direct, Scopus, Web Of Science, Wiley Online Library) and one literature search engine (Google Scholar) using specific keywords for PAEs, OPEs and NPPs in combination with keywords for different exposure pathways (diet, dust, air inhalation, dermal uptake). Duplicates are removed, and the second step consists of a screening based on title and abstract. During this step, each publication is reviewed by at least two reviewers with defined exclusion

criteria to remove all publications without human exposure data on selected plastic additives. The final step consists of reviewing the publications in full text and selecting those for data extraction. In this step, only publications with quantitative estimates of at least one human exposure pathway are included. This systematic review protocol will provide an evidence map to assess if currently available literature is sufficient to define the primary exposure routes for PAEs, OPEs and NPPs, and to identify critical knowledge gaps.

3.17.P-Tu293 Temporal Patterns of Bisphenol Exposure in the Czech Population Within the Framework of Regulatory Measures

Daria Sapunova¹, Klára Komprdová¹, Jiří Kohoutek¹, Vladimíra Puklová², Andrea Krsková², Milena Černá², Martin Zvonář¹, Zdenko Reguli³, Lenka Andryšková¹, Pavel Piler¹, Petra Příbylová¹, Jana Klanová¹ and Jiří Kalina¹, (1)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (2)National Institute of Public Health, Czech Republic, (3)Faculty of Sports Studies, Masaryk University, Czech Republic

Background: Bisphenol A (BPA), widely used in plastics and epoxy resins, has raised concern due to its ability to leach and act as an endocrine disruptor. In response, regulatory measures in Europe have increasingly restricted its use. However, since the 2010s manufacturers have started replacing BPA with analogs such as bisphenol S (BPS) and bisphenol F (BPF), which show similar endocrine activity.

This study examined temporal trends in bisphenol exposure in the Czech population and assessed whether regulatory actions targeting BPA have resulted in reduced exposure, alongside increasing exposure to its substitutes.

Methods: Urinary BPA, BPS and BPF were analyzed in two Czech cohorts sampled in 2011–2012 (DEMOCOPHES-CZ: 116 mothers, 118 children) and 2019–2020 (CELSPAC: 195 school children, 299 teenagers, 305 young adults). Statistical comparisons were made between periods and across subgroups. Population reference values were derived, and measured concentrations were compared with available health-based guidance values to evaluate potential health risks.

Results: BPA concentrations significantly decreased over time (?29% in adults; ?48% in children), while BPS concentrations increased (+121% in adults; +90% in children). Children consistently showed higher BPA levels than adults. A moderate correlation between mothers and children ($\rho = 0.34$) suggests shared household exposure. Higher levels of BPA were found in smokers in the CELSPAC adults, and children had higher levels of BPA in the warm season of the year. Additionally, females had higher BPS levels compared to males. Reference values were calculated for the Czech population. All BPA values exceeded the BPA health-based guideline value (GV) of 0.0115 µg/L and 1%-8% of BPS values exceeded the GV of 1.0 µg/L depending on cohort and age.

Conclusions: The decline in BPA and rise in BPS over time may reflect a response to BPA regulation. However, it also demonstrates the need for policy frameworks that prevent regrettable substitutions. Higher bisphenol levels in children indicate greater exposure in this group and highlight the importance of continued monitoring. Hence, human biomonitoring is essential for evaluating regulatory performance, protecting vulnerable groups such as children, and guiding future chemical policy and risk management.

3.17.P-Tu294 Beyond Small Molecules: Adsorption Behavior of High-Molecular-Weight Polymers in Soil **Sebastian Schmiedt, Lena Mayer and Paul Bendig, Eurofins Agroscience Services, Germany**

Understanding the adsorption and desorption behavior of chemicals in soil is critical for assessing their environmental fate, including potential accumulation in soil, sediment, or sludge. OECD Guideline 106 provides a standardized approach to determine adsorption coefficients, which are essential for predicting mobility, persistence, and bioavailability of substances. These data form the basis for regulatory frameworks such as REACH to evaluate ecological risk and ensure safe chemical use.

In this study, an adapted method based on OECD Guideline 106 was applied to investigate the adsorption behavior of high-molecular-weight polymers in soils. Polyethylene glycol (PEG 1500) served as a model compound and was tested across twelve well-characterized reference soils. The adapted approach demonstrated reproducibility, enabling reliable determination of adsorption coefficients.

Results indicate that adsorption strength increases with polymer chain length and is influenced by soil properties such as texture, organic carbon content, and pH. However, due to the complexity of these factors, no clear predictive relationships could be established, indicating that polymer adsorption cannot yet be reliably predicted and must be experimentally assessed through further systematic testing.

3.17.P-Tu295 Applicability of OECD Test Guideline 120 to Various Polymers: A Comparative Evaluation and Practical Guidance

Friederike Luenne¹, Nora Melchin², Boris Meisterjahn³, Sabine Gaul⁴, Thomas Sadler⁵, Stefanie Bilke⁶, Sebastian Schmiedt⁷ and Harmanna Henderiks⁸, (1)BASF SE, Limburgerhof, Germany, (2)BASF, Germany, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Clariant, Germany, (5)Currenta, Germany, (6)Evonik Operations GmbH, Germany, (7)Eurofins Scientific, Germany, (8)Covestro, Netherlands

Polymers are widely used in consumer and industrial products including textiles, paints, detergents, coatings, adhesives, and medical devices. The EU market comprises tens to hundreds of thousands of distinct polymer types. Under the EU's Chemicals Strategy for Sustainability, the Commission has proposed revising REACH to extend information and registration requirements to polymers, including standardized reporting of physicochemical properties and solubility behavior.

Existing REACH information frameworks are typically based on OECD Test Guidelines (TG). Polymers exhibit distributions of chain lengths, varied end groups, and diverse architectures. These inherent features limit the technical applicability of many current TGs and increase the risk of producing inconsistent or non-reproducible data. Polymer-specific characteristics must be explicitly addressed when applying analytical methods.

Although the OECD TG 120 on solution/extraction behavior in water focusses on polymers, it covers only certain polymer types and shows critical gaps e.g. regarding sample preparation techniques for non-solid polymers. Further standardization of the methodologies is necessary to produce consistent and comparable data sets for characterization and hazard assessments.

This comparative round robin test evaluates the applicability of the OECD TG 120 (Solution/Extraction Behaviour of Polymers in Water) to six representative polymers and polymer products, including highly viscous, liquid, and waxy materials.

Sample preparation strategies, solubility/extractability workflows, and analytical feasibility were assessed.

Technical limitations were identified and adaptations proposed to ensure robust data generation for regulatory purposes.

3.17.P-Tu296 From Calibration to Compliance - Addressing Analytical Gaps in Size Exclusion Chromatography of Polymers

Alexander Eifert¹, Andre Striegel², Beate Fresenborg³, Cynthia Mitchell⁴, **Jana Falkenhagen⁵**, Jurgen Schroeyers⁶, Matthias Pursch⁷, Patrice Castignolles⁸, Ron Peters⁹ and Timo Florian Beskers¹⁰, (1)Wacker Chemie AG, Germany, (2)National Institute of Standards and Technology (NIST), United States, (3)Tesa SE, Germany, (4)ExxonMobil Technology and Engineering, United States, (5)Federal Institute Materials Research and Testing (BAM), Germany, (6)ExxonMobil Chemical Europe, Belgium, (7)DOW, Germany, (8)Sorbonne University, France, (9)Covestro, Netherlands, (10)BASF, Germany

Size Exclusion Chromatography (SEC) is a cornerstone analytical technique for determining the molar mass distribution and oligomer content of polymers, which is increasingly critical as regulatory frameworks such as REACH consider extending registration requirements to polymers. Despite its widespread use, SEC faces technical limitations, which need to be considered in the context of polymer safety assessment and regulatory compliance.

This contribution, developed by the ECETOC Polymer Analytics Task Force, provides a comprehensive overview of the current state of SEC methodology for polymer analysis. We discuss the challenges associated with accurate molar mass determination, including large error margins—especially in the low molecular weight range—stemming from instrument calibration, detector limitations, and sample preparation. The recent round robin test highlighted substantial inter-laboratory variability not only for the number-average molar mass (Mn) but also the oligomer contents. These findings underscore the urgent need for harmonized protocols.

Solubility and partial solubility of polymers present further analytical challenges, as incomplete dissolution or

the presence of insoluble fractions can bias SEC results. The interference of non-polymer components, such as additives and residual monomers, complicates the quantification of low molecular weight species (<500 g/mol and <1000 g/mol), which are key parameters for regulatory thresholds. Calibration standards, experimental conditions, and detector response factors influence the accuracy and comparability of SEC data when non-polymer components are present in the sample. Which in many cases cannot be avoided for industrial samples. Based on these insights, we recommend a set of best practices for SEC analysis, including solubility assessment, careful selection of calibration standards, and subtraction/correction for side components. The harmonization of SEC methodologies and the development of standardized guidelines are essential to ensure reliable polymer characterization for regulatory and safety assessments and consequently for a safe and sustainable use of polymers in diverse applications.

3.17.P-Tu297 A Sandboxing Experiment: What if there were no Guidelines to Assess the Solubility of Polymers?

Joachim Venzmer, Research Interfacial Technology, Evonik Operations GmbH, Germany

The solubility in water is a necessary requirement for both the determination of other phys-chem parameters such as surface activity or logKow and a meaningful assessment of environmental fate. Therefore, the solubility of polymers in water has been identified as the most pressing topic the Workstream “Phys-Chem Properties and Methods” of the ECETOC Polymer Analytics Task Force has to take care of.

Since the existing guidelines are known to be not fit-for-purpose, I would like to take the opposite approach: What if there were no guidelines, but only polymer know-how and experience in the field of colloid science to study and evaluate the water solubility of polymers? This will be discussed for four different representative classes of polymers: very hydrophilic, completely water-soluble polymers, hydrophobic polymers known to form microplastic particles, polymer dispersions, and amphiphilic polymers having surfactant properties. It will be shown that one crucial requirement for the assessment of solubility of polymers in water is know-how about polymer and colloid science. Additionally, information about the composition of the polymer must be utilized to choose a suitable method – there is just no “one-method-fits-all” approach for polymers possible. This is not too surprising taking the extremely broad range of different polymer structures and properties possible into account.

3.17.P-Tu298 Uncertainty in SEC: Round Robin Test with Real-Life Polymer Samples

Jana Falkenhagen¹ and Timo Florian Beskers², (1)Federal Institute Materials Research and Testing (BAM), Germany, (2)BASF, Germany

Size Exclusion Chromatography (SEC) remains the most widely applied technique for determining molar mass averages and molar mass distributions of polymers. By separating molecules according to their hydrodynamic volume using a porous stationary phase, SEC provides a chromatogram that, when calibrated with standards of known molar mass, yields a relative molar mass distribution curve. From this curve, key parameters such as number-average molar mass (M_n), weight-average molar mass (M_w), and oligomer content—defined as fractions below 1000 g/mol and 500 g/mol—can be derived. These low-mass fractions are of particular regulatory interest because they represent mobile species with potentially higher bioavailability and toxicity. However, SEC is not without limitations. While error margins of 10–20% for molar mass determination across laboratories and instruments are well documented, variability in oligomer quantification may be even greater. Influencing factors include solvent choice, column configuration, dissolution behaviour, and baseline integration settings. Current DIN and ISO standards, developed from earlier interlaboratory studies, do not adequately address these challenges, especially under conditions relevant to real-life polymer samples.

To quantify these uncertainties, a comprehensive round robin test was conducted between June 2024 and February 2025 with 35 laboratories worldwide. Unlike previous studies focused on narrowly dispersed standards, this initiative included complex real-world samples such as copolymers, blends, and dispersions with gel content as a material exhibiting partial solubility. Analyses were performed in three solvent systems (THF, DMAc/DMF, and water) to reflect diverse application scenarios. The results reveal significant interlaboratory variation, particularly in the low molar mass region, with deviations exceeding 50% for M_n and even higher for oligomer content in challenging matrices. These findings underscore the urgent need for harmonized protocols, improved calibration strategies, and clear guidance on solubility and sample preparation.

This contribution presents results of the round robin study. Example cases will be discussed and interpreted to allow recommendations for method harmonization. Reducing variability in SEC polymer characterization and increasing the comparability of results are critical steps toward reliable data for regulatory compliance and polymer safety assessment.

3.17.P-Tu299 Investigating the use of Hansen Solubility Parameters for Grouping of Polymers for REACH Registration

Helen Jane Disley and Ben Barnes, Vitis Regulatory, United Kingdom

Although the Registration of polymers is not currently required under EU REACH, it is expected that the Commission may present legislative proposals for selecting polymers for registration in the coming years. Given the huge number of polymers on the EU market (one estimate suggests between 400,000 and >1,000,000 polymers), grouping polymers for Registration is essential to avoid placing undue burden on industry and regulators. However, no detailed proposal for how groups are to be created or validated has been put forward by the Commission.

In this work we explore the hypothesis that Hansen Solubility Parameters (HSP) may be useful in the grouping of polymers, specifically that polymers within the same structural class and in similar Hansen space will have similar (eco)toxicological properties. Developed in the 1960s, the HSP method represents solvents as points in a three-dimensional space (based on three key parameters) to predict whether one substance will dissolve in another. It has been used in the polymer industry for identifying suitable solvents for polymers. It has more recently been applied more broadly to characterise similarity between substances and how this can be used to predict their interactions with different matrices.

Hansen Solubility Parameters were calculated for various polymers including alcohol ethoxylates and methacrylates. Data visualization techniques were used to investigate potential groupings. Where available, these were compared to published classifications and/or (eco)toxicological property data.

Initial findings indicate that HSP calculations have potential to differentiate between structurally similar polymers with, for example, different molecular weights, functional group equivalent weight or oligomer content. The need for good quality (eco)toxicological data for structurally defined polymers to validate potential groupings is highlighted and the uncertain reliability of current classifications of polymers is identified as a key variable.

3.17.P-Tu300 Integrating Safe and Sustainable by Design Criteria for Regulatory Assessment of Emerging Biopolymers in Packaging Applications

Javier Alcodori¹ and Arantxa Ballesteros Rianza², (1)Processes and Products Safety Unit, ITENE Research Centre, Valencia, Spain, (2)Processes and Products Safety Unit, ITENE research centre, Valencia, Spain

The transition toward biodegradable polymers requires robust and integrated approaches to ensure that new materials are safe, high performing and environmentally sustainable. The Be-UP project addresses this challenge by developing innovative biopolyesters, materials and packaging prototypes and evaluating them through a comprehensive Safe and Sustainable by Design (SSbD) methodology. A major barrier to the adoption of biodegradable polymers is the absence of harmonised frameworks that link material performance with environmental fate, human health considerations and circularity. Be-UP aims to overcome this gap by implementing a full SSbD assessment, integrating environmental, economic, social and safety dimensions. The SSbD Framework is applied from early development to final demonstrators, defining criteria for safety, sustainability, recyclability and risk assessment. A multi-criteria decision tool is being developed to combine information on environmental impacts, human health risks and life cycle performance, enabling dynamic comparison of materials and guiding design choices for researchers and industry. Complementary studies assess techno-economic feasibility across the value chain, including market context, mass and energy balances and economic performance supported by life cycle costing. Sustainability performance is addressed through life cycle assessment and social life cycle assessment, comparing conventional production and end-of-life scenarios with the novel Be-UP approach.

Recyclability is evaluated through mechanical and chemical routes, assessing material integrity over repeated processing cycles and the potential for depolymerisation and re-polymerisation into high-quality products. Risk assessment integrates toxicity testing of additives and final materials and ecotoxicity studies in aquatic and terrestrial environments. It also considers the potential release of micro- and nanoplastics and their role in biodegradation processes and biological interactions.

Together, these activities deliver a harmonised framework for assessing biodegradable polymers, linking fate, performance and sustainability. The results will support the safe implementation of new bioplastics and inform future best practices for polymer design and regulation.

3.17.P-Tu301 Pitfalls of Ambiguity in the Development of Safe and Sustainable Biobased Plastics: How Can Industry and Regulators Better Navigate this Landscape?

Fiorella Pitaro¹, John D. Hader¹, Nadia Ilaria Malinverno², Bernd Nowack¹ and Claudia Som², (1)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (2)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland

Plastics regulation in the European Union has expanded rapidly in response to growing concerns about pollution, human exposure, and the rise of alternative materials. Yet, definitions of plastics, polymers, and biobased materials remain fragmented and sometimes ambiguous, creating uncertainty for scientists and developers. This study examines how plastics and biobased plastics are defined and regulated within the EU, with the aim of clarifying key terms and helping researchers navigate the policy landscape more effectively. We first map all relevant EU regulations that apply to plastics across major sectors and identify where biobased and biodegradable materials are treated similarly or differently from conventional plastics. We then analyse how regulatory definitions, such as “polymer,” “plastic,” “biobased,” “natural polymer,” and “chemically modified” are applied across policies. Building on two existing classification frameworks, we develop a simplified decision tree that helps determine whether a material qualifies as a plastic under EU law and whether it falls under the microplastic restriction.

To test its usefulness, we apply the decision tree to several emerging biobased materials, including cellophane, protein-based polymers, lignin, biobased microcapsules, and rubber. These case studies reveal where regulatory interpretations diverge and where chemical modification becomes a decisive factor.

Our results show that most biobased polymers are regulated in the same way as conventional plastics unless they meet strict criteria for being natural and not chemically modified. This highlights the importance of early regulatory consideration during material design. With the decision tree we aim to propose a practical tool to support this process by making regulatory boundaries more transparent. Overall, the study contributes to clearer communication between regulators and innovators and supports the development of safer and more sustainable biobased materials within a rapidly evolving policy landscape.

This project received funding from the ETH Board of Switzerland in the framework of the Join Initiative: Proteins for a Sustainable Future.

3.17.P-Tu302 Are bioplastics safer: An in vitro approach

Laura Rama, Mónica Almeida, Maria de Lourdes Pereira and Miguel Oliveira, University of Aveiro, Portugal

Nanoplastics are emerging environmental contaminants, and humans are a potential target of their effects. These particles are ubiquitous in the environment and have been detected in food items (e.g., seafood) and beverages, including drinking water, with evidence of human exposure demonstrated by their presence in urine, stool, blood, and tissues such as the lung, liver, and brain. One of the major limitations in the current research addressing the potential effects of nanoplastics is the predominance of studies using pristine polystyrene (PS) nanoplastics, which fail to account for the diversity of polymer types found in the environment. There is a clear need to assess the potential of biopolymers as a safer alternative to the classic fossil-based polymers.

This study focused on the effects of polyethylene terephthalate (PET) (fossil-based) and polyhydroxybutyrate (PHB) (bio-based) nanoplastics on HepG2 (hepatocyte-like – to assess effects on a metabolic model) and HCT116 (intestinal epithelium – representing a critical barrier against their systemic entry into the body). PET is one of the most produced polymers worldwide and the polymer most used for water bottles, whereas PHB is a biodegradable polymer (made by bacteria) marketed as environmentally friendly, although its effects have not been thoroughly studied.

Cells were incubated with PET (191 nm) and PHB (195 nm) at the concentrations ranging from 100 to 0.0064 mg/L and from 50 to 0.0032 mg/L, respectively (5-fold dilution factor). Effects on cell viability (MTT and LDH assays) were assessed at 24, 48 and 72h. Overall, LDH levels in the media were not significantly different in any of the conditions, showing no significant cell death. The MTT results indicated a gradual decline of cell metabolism at 24 and 48h but recovered at 72h. In HepG2, PHB nanoplastics elicited a higher impact than PET nanoplastics.

Overall, these preliminary findings indicate transient stress, without cell death, and suggest that biopolymers are

not risk-free. Ongoing essays aim to clarify these effects, examining how these particles influence overall cell function.

3.17.P-Tu303 Biopolymers: Ecotoxicological Risks of Micro and Nanoplastics Aquatic Organisms

Ana Patrícia Gonçalves¹, Isabel Lopes² and Miguel Oliveira², (1)CESAM, University of Aveiro, Portugal, (2)University of Aveiro, Portugal

Intense plastic production and poor waste management are promoting the widespread accumulation of microplastics (MPs) and nanoplastics (NPs) in aquatic ecosystems. These size fractions, that disperse through the water column, sediments and biofilms, display high mobility, environmental persistence, and bioavailability, enabling uptake by diverse aquatic taxa, ranging from plankton to higher trophic levels (e.g. fish and humans). The reported effects on aquatic organisms include feeding disruption, oxidative stress, inflammation, metabolic dysregulation, and reproductive impairment. The reported effects on aquatic organisms include feeding disruption, oxidative stress, inflammation, metabolic dysregulation, and reproductive impairment. NPs, due to their small size, ability to penetrate cells, form eco-coronas, and facilitate co-transport of sorbed contaminants, are considered potentially more hazardous to biota.

Biopolymers such as polyhydroxyalkanoates (PHAs) and polylactic acid (PLA), derived from renewable, biological feedstocks, are increasingly proposed as sustainable alternatives to fossil-based polymers. Although expected to degrade in the environment, their degradation rates remain highly context dependent, and environmental fragmentation can still generate micro- and nano-sized particles. As industry moves toward nanoscale formulations, nano-biopolymers introduce new exposure pathways for freshwater organisms. The available studies on nano-biopolymers have reported size- and surface-dependent uptake, interactions with epithelial and digestive tissues, and potential oxidative or inflammatory responses. Critical knowledge gaps persist regarding environmental transformation, environmental levels, biodegradation kinetics and trophic transfer potential of nano-biopolymers in freshwater ecosystems. Furthermore, comparative ecotoxicological data on nano-biopolymers relative to synthetic NPs remain scarce. This study aims to synthesize available evidence on the ecotoxicological impacts of nano-biopolymers in freshwater organisms and evaluate if these polymers are in fact safer and more sustainable than conventional fossil-based.

3.17.P-Tu304 Understanding Life-Stage Susceptibility to Biodegradable Nanoplastics: A Case Study in Hediste diversicolor

Adília Pires, Nídia dos Santos, Beatriz Neves, Valéria Giménez, Mónica Almeida and Miguel Oliveira, University of Aveiro, Portugal

Biodegradable polymers have been proposed as more alternatives to conventional plastics. However, growing evidence suggests that their fragmentation into micro- and nanoplastics (NPs) raising significant concern about potential ecological risks. Polyhydroxybutyrate (PHB), a prominent biopolymer of the polyhydroxyalkanoate family, can generate NPs whose effects on key aquatic organisms remain poorly understood. This study investigated the impacts of PHB NPs exposure on juvenile and adult polychaete *Hediste diversicolor*, a key bioturbator species in estuarine ecosystems. Organisms were exposed for 14 days to sediments spiked with PHB NPs (103.9 ± 5.07 nm) at 0, 0.5, 2, 8, 32, 128 mg PHB/kg sediment. Behavioral (feeding, burrowing, light

avoidance, bioturbation) and physiological (regenerative capacity) endpoints were assessed, after exposure and a 7 day depuration in clean sediment.

The results demonstrated that PHB NPs exposure altered behavior in both life stages, with juveniles showing higher sensitivity and reduced resilience. Feeding activity was significantly impaired in exposed polychaetes, with juveniles requiring more time to detect and capture food. Burrowing activity was impaired in juveniles (32 mg/kg) and in adults (128 mg/kg), though both stages recovered after depuration. Light avoidance responses were significantly delayed in juveniles and adults, with juveniles failing to recover at the highest concentration. Regarding bioturbation activity, sediment remobilization was significantly reduced across all juveniles' treatments, and persisted after the recovery period, compromising sediment oxygenation and nutrient cycling in estuarine habitat. Adults exhibited significant reductions at high concentrations, with partial recovery. Regarding regenerative capacity, adults exposed to PHB NPs regenerated fewer segments and showed reduced overall regeneration percentage across all treatments.

Overall, the findings highlight that PHB NPs impacted behavioral and physiological endpoints in *H. diversicolor*, with juveniles exhibiting reduced resilience and being unable to completely recover after 7 days. These findings demonstrate that even biopolymer particles can pose ecologically relevant risks at the nanoscale, potentially compromising sediment dynamics, nutrient cycling, increasing vulnerability to predators and population fitness.

3.17.P-Tu305 Synthesis of Metal-Embedded Nanoplastics as Test Materials and Quantification by spICP-MS

Hyojung Choi, Keun-Bai Yoo, Seon-jin Yang, Sang Don Kim and Byung-Tae Lee, Gwangju Institute of Science and Technology (GIST), Korea, Republic of

Conventional approaches for characterizing nanoplastics and assessing their behavior in environmental matrices have primarily relied on commercially available plastic particles and analytical techniques such as dynamic light scattering (DLS), scanning electron microscopy (SEM), transmission electron microscopy (TEM), μ -FTIR, and Raman spectroscopy. However, these methods face significant limitations in complex environmental samples, particularly in distinguishing nanoplastics from background particles or carbon-based materials and in accurately quantifying particle number concentration (PNC). Recently, a new analytical strategy has emerged in which nanoplastics are labeled with metals and quantified using single-particle inductively coupled plasma mass spectrometry (spICP-MS), allowing the determination of particle size distribution (PSD) and PNC based on individual metal-derived signal events. This study aims to synthesize metal-embedded nanoplastics (Me-NPs) and establish a quantitative analytical method utilizing their metal signatures. Me-NPs were produced by incorporating metals (e.g., tantalum (Ta), gold (Au)) into commonly used polymer resins, including polystyrene (PS), polyvinyl chloride (PVC), and polypropylene (PP). To fabricate these materials, both top-down approaches (e.g., cryogenic milling, chemical fragmentation) and bottom-up approaches (e.g., oil-in-water (O/W) emulsion solvent evaporation, antisolvent nanoprecipitation) were employed. Using the element specificity of spICP-MS, we developed an analytical framework capable of determining the PSD and PNC of the synthesized Me-NPs. These Me-NPs are expected to serve as test materials that can be utilized in future investigations aimed at examining the environmental behavior of nanoplastics—such as weathering, aggregation, dispersion, and mobility—under various environmental conditions.

3.17.P-Tu306 Nanoplastics in agriculture: ingestion and impacts on arthropods in food webs

Yurika Tokunaga¹, Denise Mitrano², Roman Schefer³, Shouta Nakayama⁴, Mayumi Ishizuka⁴ and Michael Peter Meissle⁵, (1)Hokkaido University, Switzerland, (2)ETH Zurich, Switzerland, (3)Environmental Systems Science, ETH Zurich, Switzerland, (4)Hokkaido University, Japan, (5)Research Division Agroecology and Environment, Agroscope, Switzerland

Nanoplastics (NPs) are of growing concern due to their uptake by organisms, ability to cross biological barriers, and potentially greater toxicity compared to microplastics. Although awareness of their ecological risks is increasing, the ingestion and impacts of NPs within terrestrial ecosystems remain poorly understood, especially compared to aquatic systems. Assessing NP exposure in soil-dwelling organisms is particularly challenging because of methodological limitations in quantifying NPs at low concentrations and the complexity of exposure routes. Building on our previous development of a palladium (Pd)-doped NP exposure system for agricultural food webs, this study expands the approach to additional arthropod species. We established NP exposure assays for four representative terrestrial arthropods: an omnivorous rove beetle (*Dalotia coriaria*), a carnivorous devil's coach-horse rove beetle (*Ocypus olens*), a herbivorous mealworm beetle (*Tenebrio molitor*), and a detritivorous springtail (*Folsomia candida*). Adult rove beetles, mealworms, and springtails were exposed to Pd-doped NPs via spiked dry yeast feed for short-term (up to 1 week) and/or long-term (up to 6 weeks) durations, while rove

beetle larvae were exposed throughout their developmental period. Larvae of the devil's coach-horse beetle were additionally fed NP-exposed mealworms for up to 1 week. NPs in all species were quantified using inductively coupled plasma–mass spectrometry (ICP–MS), with Pd serving as a tracer. Using these measurements, we compared NP burdens across species to evaluate bioaccumulation and assess toxicity via biological endpoints including growth, reproduction, and mortality. We also compared NP burdens across developmental stages to examine changes associated with metamorphosis, and between predator–prey pairs to evaluate the potential for trophic transfer and to estimate biomagnification factors. This study provides new insights into the fate and effects of NPs in arthropods within agricultural food webs, demonstrating the utility of Pd-doped NPs and supporting the development of ecological risk assessment frameworks in terrestrial environments.

3.17.P-Tu307 Assessment of Nanoplastic Pollution in Aquatic Systems from Wastewater Sources in Eastern Germany

Neha Parashar and Dušan Materić, Helmholtz Center for Environmental Research (UFZ), Germany

The unchecked littering and mismanagement of plastics, coupled with their rising production and usage, have escalated them into one of the most pressing environmental pollutants. Among them, microplastics (<5 mm) and nanoplastics (<1 µm) have emerged as critical contaminants, with NPs posing the greatest risks due to their ability to penetrate and contaminate water sources. While MPs are globally found to contaminate every freshwater ecosystem, it is reasonable to expect NPs to be similarly widespread as a result of MPs degradation with impacts still unknown. Wastewater systems such as wastewater/sewage treatment plants (WWTPs/STPs) are increasingly recognized as major pathways for nanoplastics, facilitating their re-entrance into river systems. Importantly, such land-based discharges of nanoplastics into rivers ultimately contribute to the growing plastic pollution load in oceans, linking inland sources directly to marine contamination. Globally, numerous studies have examined the abundance, pathways, and removal efficiencies of microplastics in WWTPs/STPs; however, systematic assessments of nanoplastics remain scarce. In Europe, despite increasing awareness of microplastic pollution in rivers like the Rhine, Elbe, and Danube, no study to date has focused on the occurrence, size-wise distribution, and fate of nanoplastics in wastewater systems and river water. Henceforth, the present study aims to address this gap by investigating nanoplastic pollution in raw and treated wastewater from WWTPs in Leipzig, which ultimately discharge into the Elbe River, using highly sensitive techniques such as thermal desorption–proton transfer reaction–mass spectrometry (TD-PTR-MS). By establishing the first comprehensive dataset of nanoplastic concentrations in these environmental matrices, the study will generate new insights into their fate and transport, inform technological upgrades in treatment systems, and guide policymakers in developing evidence-based regulations and guidelines to mitigate nanoplastics pollution.

3.17.P-Tu308 Ultra-sensitive quantification of mixed nanoplastic particles from environmental water samples through magnetic enrichment using custom-designed bifunctional peptides

Maochao Mao, Marisa Sárria Pereira de Passos and Ulrich Schwaneberg, RWTH Aachen University, Germany

Plastic materials such as PE, PP, PS, and PET are extensively used and increasingly discarded into the environment. The degradation of synthetic polymers in a circular polymer economy inevitably leads to the formation and widespread release of micro- and nanoplastics (MP/NPs), making the management of plastic contamination in aquatic environments crucial. NPs under 1 µm pose specific risks due to high surface area and colloidal stability, especially with those under 20 nm capable of crossing biological barriers. Detection and quantification of these small particles, especially those smaller than 5 nm, remain major analytical challenges acknowledged by the EU Commission, hindering the establishment of effective regulatory policies. Conventional techniques such as FTIR, Raman, and dynamic light scattering are limited in sensitivity or polymer specificity. On the other hand, membrane-based separations often fail to capture the smallest NPs, underestimating total loads. To overcome these limitations, we developed a magnetic enrichment platform by functionalizing Fe₃O₄ superparamagnetic nanoparticles (SPION) with custom-designed bifunctional peptides capable of binding a broad range of polymer types, followed by analysis via Py-GC/MS. We assessed enrichment efficiency, adsorption kinetics, adsorption isotherms, and salt effects using model NP suspensions, and further evaluated real-world applicability by spiking mixed NPs into 1 L environmental water samples, followed by analysis of seven types of environmental waters (river, lake, seawater, wastewater). The system achieved over 96 % recovery for PS, PP, PE, and PET NPs, with a maximum adsorption capacity of 3.95 ± 0.14 g NPs · g⁻¹ adsorbent for PS-COOH500 nm. Adsorption was enhanced by salt ions, where hydrophobic interactions served as the primary driving force for NPs binding, demonstrating the platform's versatility across diverse aqueous environments. The method successfully enriched, detected, and quantified mixed NPs - including PP, PE, PS, PET, PMMA, PC, nylon 6, and nylon 66 - from complex water matrices, with a detection limit down to 0.061 µg for PS, demonstrating broad applicability for environmental monitoring. This work presents a sensitive, versatile, and efficient approach for isolating and quantifying NPs in aquatic environments,

thereby supporting improved assessment of nanoscale plastic pollution and informing regulatory and mitigation strategies.

3.17.P-Tu309 Physiological and Compositional Effects of Poly(3-Hydroxybutyrate) and Polymethyl Methacrylate (PMMA) Nanoplastics in Invertebrates

Abdulshakur Isah Lawal¹, Isabel Benta Oliveira¹, Antonio Cascajosa Lira², José A. González Pérez³, Maria Paula Gomez¹, Miguel Oliveira⁴, Alexandre Campos¹ and Mário Araújo¹, (1)CIIMAR, Portugal, (2)Area of Toxicology, Faculty of Pharmacy, University of Sevilla, Spain, (3)IRNAS-CSIC, Spain, (4)CESAM, University of Aveiro, Portugal

Micro- and nanoplastics (MNPs) are ubiquitous in marine systems, arising from diverse sources, such as the fragmentation of larger plastic debris, direct emissions from industrial processes and consumer products, and biological activity. However, the toxicokinetics and physiological impacts of both conventional and biodegradable polymers remain poorly understood. In this study, we evaluated the toxicokinetics and biological responses of the mussel "*Mytilus galloprovincialis*" to two environmentally relevant nanoplastics: polyhydroxybutyrate (PHB, 200 nm) and polymethylmethacrylate (PMMA, 250 nm) following a preliminary investigation of their effects on the microalga "*Tetraselmis suecica*".

No acute toxicity to the microalgae was observed across a wide concentration range of both MNPs (4.69–150 mg/L²¹). However, All nanoplastic treatments resulted in stoichiometric disruptions after 24h, with co-exposure of both nanoplastics showing a 30% reduction in nitrogen content, elevated C:N ratios, and $\delta^{13}\text{C}$ enrichment consistent with photosynthetic stress. In mussels, gene expression responses were tissue- and polymer-specific: CAT was upregulated in the digestive gland after PHB and remained elevated under co-exposure, while GST- π in gills responded only to the mixture. PHB and PMMA induced distinct biological effects with PMMA particularly triggering oxidative pathways. Py-GC/QTOF-MS detected both polymers in faeces but not in tissues, indicating rapid elimination and limited short-term bioaccumulation.

Our findings underscore the need for integrated stoichiometric, transcriptomic, and chemical approaches to assess ecological risks of emerging nanoplastics under realistic exposure scenarios.

3.17.P-Tu310 Flow Cytometry as a Non-Destructive Tool for Detecting Micro- and Nanoplastics in Complex Biological Samples

Inês Santos¹, Frank G.A.J. Van Belleghem², Lee Bouwman³, Daan van Twist⁴ and Mathie Leers¹, (1)Dept. of Clinical Chemistry & Hematology, Zuyderland Medical Center, Sittard-Geleen, The Netherlands and Dept. of Environmental Sciences, Faculty of Science, Open University, Heerlen, The Netherlands, Netherlands, (2)Department of Environmental Sciences, Open University, Netherlands, (3)Dept. of Vascular Surgery, Zuyderland Medical Center, Sittard-Heerlen, The Netherlands, Netherlands, (4)Dept. of Internal Medicine, Zuyderland Medical Center, Sittard-Heerlen, The Netherlands, Netherlands

Micro- and nanoplastics (MNPs) have been detected in human tissues and biological fluids, including blood, yet little is known about their distribution in the body or how they interact with immune cells. Current analytical methods rely on harsh digestion or high temperature procedures that destroy cellular structures, making it impossible to study particle-cell associations in intact biological samples. To address this challenge, our objective was to develop a sensitive, non-destructive method capable of detecting MNPs in biological matrices while preserving immune cell architecture. We established a flow cytometry assay using optimized Nile Red fluorescence to detect MNPs in blood while maintaining intact immune cells. Validation was performed with polystyrene particles of 0.5, 1, and 3 μm , and ongoing work extends the method to additional polymers, including polyethylene and poly(methyl methacrylate). Analytical performance metrics - limit of detection, limit of quantification, sensitivity, and specificity - are being determined to support comparison with pyrolysis-gas chromatography-mass spectrometry. Although initially developed for blood, the assay is being adapted to other clinically relevant matrices, including atherosclerotic plaques, to enable the study of particle-cell associations across different tissue environments. Its compatibility with multiparameter immunophenotyping will support future assessments of whether MNPs preferentially associate with specific immune cell subsets or inflammatory profiles. The assay reliably identifies polystyrene particles with clear separation from background signals, and validation across multiple particle sizes demonstrates robustness. Establishing sensitivity and specificity supports applicability for trace-level biomonitoring across diverse sample types. This non-destructive flow

cytometry approach provides a practical and accessible tool for detecting MNPs in complex biological samples while preserving immune cell structure. Because flow cytometers are routinely available in clinical laboratories, the method can be readily integrated into existing workflows for large-scale human monitoring. Extending this assay to vascular tissues such as atherosclerotic plaques will support studies exploring potential links between particle presence and inflammatory processes, advancing research on human exposure and the health impacts of plastic pollution.

3.17.P-Tu311 Museum Foraminifera Archive Historical Marine Plastic Pollution

Marco Mattonai¹, Laura Cotton², Ronnie N. Glud³, Francesca Modugno¹, Moriaki Yasuhara⁴ and Elvis Genbo Xu⁵, (1)Department of Chemistry and Industrial Chemistry, University of Pisa, Italy, (2)Natural History Museum Denmark, Denmark, (3)Danish Center for Hadal Research, University of Southern Denmark, Denmark, Denmark, (4)School of Energy and Environment, State Key Laboratory of Marine Environmental Health, City University of Hong Kong, Hong Kong (Greater China), (5)Department of Biology, University of Southern Denmark, Denmark

Historical reconstruction of marine plastic pollution is essential for understanding long-term ecological impacts, yet suitable natural archives remain scarce. Agglutinated foraminifera, benthic protists that incorporate surrounding sediment into their shells (tests), offer untapped potential to record the emergence and rise of micro(nano)plastics in marine systems. The goal of this study was to determine whether foraminiferal tests preserve quantifiable plastic-derived polymers and to evaluate their suitability as century-scale plastic pollution indicators. Using pyrolysis–gas chromatography–mass spectrometry with matrix-matched calibration, we analyzed historical agglutinated foraminifera samples (*Rhabdammina discreta*, *Astrorhiza furcata*, *Conglophragmium* sp., and *textulariid*) collected from Departure Bay, the Norwegian Sea, and the Puerto Rico Trench between 1911 and 1952. Procedural blanks, solvent-free preparation, and polymer-spiked controls were used to assess contamination risk, instrument sensitivity, and method performance. Quantified plastic-derived polymers exhibit a temporal increase consistent with global trends in plastic production. By 1952, elevated concentrations were observed, including PE at up to 78.7 µg/g, PS at up to 0.9 µg/g, and PET at up to 45.0 µg/g. Our findings establish foraminifera as potential indicators of past pollution, providing a rapid, novel method for tracking long-term marine pollution using historical museum specimens and enhancing global environmental monitoring.

3.17.P-Tu312 Temporal variability and risk assessment of microplastics in surface water from a coastal lagoon, southern Gulf of Mexico

Mitzi Ariadna Sánchez Campos, Guadalupe Ponce Vélez, Laura Sanvicente Añorve and Hugo F. Olivares Rubio, National Autonomous University of Mexico (UNAM), Mexico

This study assesses the abundance, characteristics, and ecological risk of microplastics (MPs) in the Sontecomapan Lagoon System (SLS), a RAMSAR site in the southern Gulf of Mexico. MPs, defined as particles <5 mm, are emerging pollutants that can carry toxic substances and cause sublethal effects in aquatic organisms. In tropical regions, their concentration varies seasonally, increasing during the rainy season due to greater continental runoff and atmospheric precipitation.

The lagoon was sampled on three occasions: during the rainy season (June 2018, October 2019) and the dry season (March 2023) at ten stations within the lagoon and the rivers that flow into. MPs were obtained by sieving, organic matter digestion, and density separation, and were characterized by microscopy and attenuated reflectance Fourier transform infrared spectroscopy (µFTIR-ATR). Ecological risk was assessed using the PLI, PHI, and PERI indices. Concentrations were higher in June (7.5 items/L) than in October (1.7 items/L) and March (1.5 items/L), confirming an increase during the rainy season. Inland tributaries registered 5.2 items/L, highlighting their role as entry points for plastic pollution into the lagoon. Particles smaller than 1000 µm were dominant (58–83%), increasing their bioavailability to zooplankton. Fibers were the most frequent form (56–95%), mainly associated with textiles and fishing activities, and the color blue predominated in all sampling campaigns. While the PLI indicated a low pollutant load, the PHI and PERI indices revealed risks ranging from

low to extremely high, mainly due to the presence of hazardous polymers such as acrylic. High risk levels imply a high probability of adverse effects on pelagic organisms, altering population structure and dynamics, and ultimately disrupting the functioning of the food web. In conclusion, despite their low abundance, microplastics (MPs) pose a significant risk due to their chemical composition and spatial distribution. Priority areas for monitoring and mitigation are identified, and it is emphasized that the risk posed by microplastics should be assessed not only by quantity but also by the material's hazardous nature.

3.17.P-Tu313 Microplastic-Biofilm as Hotspots for Antibiotic Resistance in Hospital Wastewater: An Emerging Environmental Health Concern

Jana Asselman¹, Maaïke Vercauteren², Tom Coenye³, Ting Zhang⁴ and Sari De Schipper¹, (1)Blue Growth Research Lab (BGRL), Ghent University, Belgium, (2)Blue Growth Research lab, Ghent University, Belgium, (3)Laboratory of Pharmaceutical Microbiology, Ghent University, Belgium, (4)Ghent University, Belgium

The intersection of plastic pollution and antimicrobial resistance (AMR) in hospital wastewater (HWW) poses a growing threat to public health. These effluents are known to contain a high load of both antimicrobials and pathogens. Additionally, microplastics (MP) have been reported to be stable substrates allowing the attachment of microorganisms, referred to as the plastisphere. By offering both a substrate for increased horizontal gene transfer and a protective niche for biofilm formation, the presence of MP in the HWW could accelerate the spread of AMR. Despite the high risks associated with untreated clinical discharge, the specific role of MPs as vectors for resistance in hospital wastewater remains poorly understood. This research investigates the chemical nature of MPs in these effluents and their capacity to support resistant microbial communities.

Using untreated wastewater samples from a major hospital, we collected parallel samples to conduct chemical and biological analyses independently. In this study we characterized the MP pollution profile via 10% KOH digestion and FTIR spectroscopy, and determining microbial DNA concentrations following 16S/18S rRNA PCR amplification. Microorganisms were isolated from MPs and their antibiotic susceptibility profile was determined. FTIR analysis and cultured- based assays suggest detailed insights into the size distribution of these vectors, the extent of eukaryotic vs. prokaryotic colonization, and the comparative resistance profiles of attached vs. free-living bacteria will be further analyzed. Overall, this research bridges environmental chemistry and microbial ecology to reveal how plastic pollution intersects with antimicrobial resistance in clinical effluents, underscoring a pressing need for One Health-oriented wastewater mitigation strategies.

3.17.P-Tu314 Screening Level Environmental Risk Assessment of Microplastics in Dutch Waters

Joris T.K. Quik¹, Peter van Breemen¹, Anne Hids¹, Svenja Mintenig², Sam van Loon¹, Elmer Swart¹ and Albert Koelmans², (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Wageningen University and Research (WUR), Netherlands

Microplastics by now seem to be ubiquitously present in our environment. Tackling plastics pollution requires effective mitigation measures. One common way of prioritising such measures in chemical regulatory frameworks is to base them on the outcomes of environmental risk assessments. This is not common practice yet for microplastics, although the first risk assessments are already available in scientific literature. For this reason we performed a screening level study into the environmental risk of microplastics in Dutch waterbodies. This was done to learn about the best practices to perform a regulatory relevant environmental risk assessment (RIVM report 2025-0095) and to get a better understanding of the extent of microplastic pollution in the Netherlands. To this end, we used existing environmental measurements, both spectroscopic and pyrolysis-based. These were recalibrated to the 1 to 5000 µm size range and compared to literature reported HC5 levels that were derived for the same range of particle sizes based on volume or surface area as the environmentally relevant metric. Several challenges are identified, e.g. in recalibration of pyrolysis based data for comparison to HC5 levels. This work illustrates the need for a better understanding of microplastics size distributions in the environment and the need for more refined measurements spanning a larger size range of microplastics.

3.17.P-Tu315 Toxicological Interactions Between Polystyrene Microplastics and Coastal Pollutants in the Marine Bivalve *Crassostrea gigas*

Hoon Choi¹ and **Moonjin Lee²**, (1)Korea Resrach Institute of Ships & Ocean Engineering, Korea, Republic of, (2)Korea Institute of Ships & Ocean Engineering, Korea, Republic of

This study investigated the toxicological interactions between microplastics and representative coastal environmental pollutants, specifically cadmium (Cd) and phenanthrene (PhA), to better understand the potential environmental risks posed by microplastics through combined toxicity.

Exposure experiments using the marine bivalve *Crassostrea gigas* were conducted to assess fertilization rate, D-shape embryogenesis incidence, and survival rate. Microplastics alone did not exhibit any significant toxic effects on these three biological endpoints across all tested concentrations.

However, both Cd and PhA showed clear concentration-dependent toxic effects, following a sigmoidal dose-response curve. When exposed to Cd alone, the EC50 values for fertilization rate, D-shape embryogenesis, and survival rate were $12.768 \pm 0.256 \text{ mg}\cdot\text{L}^{-1}$, $3.592 \pm 0.136 \text{ mg}\cdot\text{L}^{-1}$, and $> 40 \text{ mg}\cdot\text{L}^{-1}$, respectively. In contrast, co-exposure to Cd and microplastics resulted in EC50 values of $14.429 \pm 0.206 \text{ mg}\cdot\text{L}^{-1}$, $3.899 \pm 0.083 \text{ mg}\cdot\text{L}^{-1}$, and $27.500 \pm 1.804 \text{ mg}\cdot\text{L}^{-1}$ for the same endpoints, indicating a slight reduction in Cd toxicity in early life stages but a significant increase in toxicity at the adult stage. This suggests that microplastics may facilitate Cd bioavailability by acting as vectors or carriers.

Similarly, exposure to PhA alone resulted in EC50 values of $0.038 \pm 0.015 \text{ mg}\cdot\text{L}^{-1}$, $0.006 \pm 0.001 \text{ mg}\cdot\text{L}^{-1}$, and $> 0.2 \text{ mg}\cdot\text{L}^{-1}$ for fertilization, embryogenesis, and survival, respectively. When PhA and microplastics were co-exposed, the EC50 values changed to $0.076 \pm 0.033 \text{ mg}\cdot\text{L}^{-1}$, $0.022 \pm 0.001 \text{ mg}\cdot\text{L}^{-1}$, and $> 0.2 \text{ mg}\cdot\text{L}^{-1}$, respectively. Interestingly, in contrast to Cd, the presence of microplastics appeared to decrease PhA toxicity in both larval and adult stages.

These results indicate that microplastics may modulate the toxicity of co-existing pollutants depending on their chemical properties. Hydrophobic contaminants such as PhA may show reduced toxicity through sorption to microplastics, whereas metals like Cd may exhibit increased toxicity due to facilitated transport and bioaccumulation. Thus, microplastics could act as both passive carriers and active participants in pollutant dynamics, ultimately influencing the ecological risk to marine organisms such as *C. gigas*.

3.17.P-Tu316 Analyzing the Effect of UV-C Exposure on the Microplastics Particles from Wind Turbine Blades

Firdha Cahya Alam, **Alvise Vianello**, **Hery Mitsutake** and **Jes Vollertsen**, Department of the Built Environment, Aalborg University, Denmark

Wind turbines are among the leading renewable energy sources in Europe and have expanded significantly over the past few decades. One of the main challenges associated with wind energy is the continuous operation of turbines under varying environmental conditions, including high-speed rain, strong winds, and UV radiation. Repeated exposure to these conditions can affect the coating surface of the blades. This coating has the potential to degrade into microplastics, which can then disperse into the air and eventually deposit in the marine environment. However, there is still limited research analyzing the behavior of these microplastics in the environment and their effects at the microscopic level. In this study, we aimed to analyze the fate of microplastics from wind turbine blades under accelerated aging conditions using UV-C exposure. We used ground material from the maintenance of wind turbine polyurethane coatings, representing microplastic particles released from the blades. These polyurethane particles were then placed in artificial seawater to evaluate the effects of UV exposure. The experiments were conducted for 7, 14, and 28 days of UV-C exposure, corresponding to approximately 25, 50, and 101 days of natural sunlight exposure. Samples were then analyzed with micro-FTIR-imaging spectroscopy. Preliminary results revealed that after 28 days of UV-C exposure, the particles exhibited visible yellowing and chemical changes consistent with the breakdown of the polyurethane structure. This degradation was indicated by increased absorbance at 1714 cm^{-1} and 3343 cm^{-1} , along with decreased peaks at 2924 cm^{-1} and 2825 cm^{-1} . These findings indicate that UV exposure accelerates the deterioration of polyurethane coatings, leading to the formation of more oxidized and potentially more fragile

microplastic fragments. Understanding these degradation mechanisms is therefore essential for evaluating the full life-cycle impacts of wind turbine materials and for guiding the development of more durable and environmentally sustainable coatings for next-generation renewable energy infrastructure.

3.17.P-Tu317 Monitoring the Release of Plastic Chemical Additives from Conventional and Biodegradable Microplastics using Outdoor Mesocosms

Santiago Virseda-Mayoral¹, Juan Carlos García-Mesa¹, Laura Cherta-Cucala², Virtudes Martínez-Hernández² and Paula Redondo-Hasselerharm², (1)Imdea Water Institute, Spain, (2)IMDEA Water Institute, Spain

The extended use of plastics in agriculture has led to the release of large concentrations of microplastics (MP) into freshwater ecosystems through surface runoff, throughflow, or windthrow. However, the release of plastic chemical additives (PCAs) from conventional and biodegradable MPs in aquatic ecosystems remains poorly understood. PCAs comprise a variety of organic compounds with different physical-chemical properties, functional groups, and molecular sizes. This, combined with the vast number of chemical compounds classified as PCAs, underscores the need for robust methodologies to study exposure to these contaminants and to assess the associated risks to environmental and human health. The objective of this work was to monitor the release of PCAs from conventional (polyethylene) and biodegradable (polybutylene adipate terephthalate) MPs generated from mulch films used in agriculture using a realistic setup. For this purpose, both MPs were separately added to 1m³ fiberglass outdoor mesocosms at environmentally relevant concentrations for three months. To identify the presence of PCAs in both polymer types, MPs were first analysed by pyrolysis coupled to gas chromatography-mass spectrometry (Py-GC-MS) without any sample treatment. The pyrolysis temperature was set at 450°C, which allow to adequately identify PCAs without interferences coming from the pyrolysis fragments of the plastic polymers. As a result, the number of PCAs detected in MPs was as follows: 10 in bioplastic mulch, 19 in polyethylene mulch, and only one detected in both two materials. Fatty acids were the predominant PCAs present in both materials. Phosphated and nitrogenated PCAs were only identified in polyethylene mulch. A total of 15 PCAs detected in MPs were chosen to develop a quantitative method in PCAs release to the water by extraction with stir bar sorptive and subsequent analysis by GC-MS. This method will be applied to analyse PCAs in the water samples collected over time.

3.17.P-Tu318 Influence of Combustion Scale on Size-Resolved PAH Emissions and Cytotoxicity from Polystyrene Fires

Chia-Ho Tung¹, Li-Hsin Cheng², Ming-Jen Chen², Kuang-Chung Tsai³, Chi-Fu Yeh⁴, Chia-Wen Tsai⁵ and Hui-Tsung Hsu⁶, (1)Department of public health, China Medical University, Taiwan, Taiwan (Greater China), (2)Department of Occupational Safety and Hygiene, Fooyin University, Taiwan (Greater China), (3)Department of Safety, Health and Environmental Engineering, National Kaohsiung University of Science and Technology, Taiwan (Greater China), (4)Hwa-Ying Environment Technical Consultants Co., Ltd., Taiwan (Greater China), (5)Department of Nutrition, China Medical University, Taiwan, Taiwan (Greater China), (6)Department of Public Health, China Medical University, Taiwan, Taiwan (Greater China)

Plastic waste combustion is a major source of hazardous emissions, yet its health impacts remain insufficiently understood. Polystyrene, widely used in packaging and consumer products, releases substantial soot and polycyclic aromatic hydrocarbons (PAHs) during burning. These particles can penetrate deep into the lungs and induce oxidative stress, inflammation, and respiratory injury. However, the toxicological properties of PAH mixtures generated from polystyrene under realistic fire conditions have not been systematically characterized. This study evaluated how combustion scale affects PAH emissions and cytotoxicity. Polystyrene was burned in an ISO 9705 fire test room using 20-cm and 60-cm pans. Aerosols were collected with an eight-stage cascade impactor and separated into coarse and fine fractions. Extracts were analyzed for total PAHs, compositional

profiles, benzo[a]pyrene equivalents, and excess lifetime cancer risk. Human bronchial epithelial BEAS-2B cells were exposed to the extracts, and 24-hour cytotoxicity was measured using the MTT assay. PAH concentration differences were assessed with the Mann–Whitney U test, and cell viability with the t-test, both conducted in R 4.5.0.

Fine particles were the dominant carriers of PAHs at both combustion scales. In the 20-cm fire, fine-fraction PAH levels were four to five times higher than those in the coarse fraction, while in the 60-cm fire they were roughly twice as high. Scaling combustion from 20 to 60 cm substantially increased PAH concentrations across all size fractions. Fine particles were enriched with four- and five-ring PAHs, whereas coarse particles contained lower proportions of these high-molecular-weight compounds. Corresponding benzo[a]pyrene equivalents indicated lifetime cancer risks of ~10⁻⁷ for the 20-cm fire and ~10⁻⁸ for the 60-cm fire. BEAS-2B cells exposed to 0.5% extracts showed 10–20% viability loss for 20-cm combustion and 40–50% for 60-cm combustion. Future work will incorporate PAH diagnostic ratio analysis, evaluation of combustion parameters and size-resolved mass distributions, and quantification of inflammatory cytokines—including IL-6 and aryl hydrocarbon receptor-associated proteins (AHR, CYP1A1, CYP1A2, CYP1B1)—via western blot to develop a more comprehensive toxicological profile.

3.17.P-Tu319 Combustion-Generated Phthalates and PAHs from Polypropylene: Size-Dependent Chemical Profiles and Lung Cell Toxicity

Han-Hsiang LIN¹, Hui-Tsung Hsu², Chia-Wen Tsai³, Li-Hsin Cheng⁴, Kuang-Chung Tsai⁵, Chi-Fu Yeh⁶ and Ming-Jen Chen⁴, (1)Department of public health, China Medical University, Taiwan, Taiwan (Greater China), (2)Department of Public Health, China Medical University, Taiwan, Taiwan (Greater China), (3)Department of Nutrition, China Medical University, Taiwan, Taiwan (Greater China), (4)Department of Occupational Safety and Hygiene, Fooyin University, Taiwan, Taiwan (Greater China), (5)Department of Safety, Health and Environmental Engineering, National Kaohsiung University of Science and Technology, Taiwan, Taiwan (Greater China), (6)Hwa-Ying Environment Technical Consultants Co., Ltd., Taiwan (Greater China)

Open burning of plastic waste emits hazardous organic pollutants, including polycyclic aromatic hydrocarbons (PAHs) and phthalate esters (PAEs). Although research has largely focused on PAH toxicity, emerging evidence indicates that PAEs can persist under incomplete combustion and contribute to oxidative and inflammatory effects. This study characterized pollutants produced from polypropylene combustion and assessed their cytotoxic and pro-inflammatory potential in BEAS-2B lung epithelial cells. Combustion tests were conducted at the Fire Laboratory of the National Kaohsiung University of Science and Technology following ISO 9705 procedures. Emissions were sampled at 20 cm and 60 cm above the flame, extracted with organic solvents, and analyzed using gas chromatography–mass spectrometry. BEAS-2B cells were exposed to the extracts for 24 hours, and cytotoxicity was measured using the MTT assay. Statistical analyses were performed in R version 4.5.0.

Chemical profiles varied by sampling height and particle size. While total particle mass did not differ significantly, fine particles at 60 cm contained higher PAH concentrations, especially 4–5 ring species such as fluoranthene and pyrene. Phthalate esters showed similar enrichment, with di(2-ethylhexyl) phthalate concentrated in fine particles at 60 cm, suggesting preferential condensation of high-molecular-weight compounds. MTT results demonstrated dose-dependent reductions in BEAS-2B viability, with the strongest effects observed in fine-particle extracts collected at 60 cm. However, non-cancer risk assessment showed hazard quotients for diethyl phthalate, dibutyl phthalate, and di(2-ethylhexyl) phthalate were all below 1, indicating low expected risk under environmental exposure conditions.

The next phase of this work will examine inflammatory responses induced by phthalate esters in lung epithelial cells. Interleukin-6 secretion will be quantified using ELISA, and Western blotting will evaluate CYP1A1, CYP1A2, CYP1B1, and aryl hydrocarbon receptor expression. These analyses will clarify inflammatory pathways and determine whether AhR-mediated signaling contributes to IL-6 regulation following phthalate exposure.

3.17.P-Tu320 The Trojan Horse: Exploring Release of Chemicals from Plastics into the Ocean

Jiazhe Chen, Jianguo Liu and Zhichun Zhang, Peking University, China (Mainland)

The extensive global production and use of plastics and chemicals have led to increasing triple planetary crisis. Large quantities of chemicals in plastics are transported into natural environments through plastic leakage and eventually into the oceans, posing long-term risks to marine ecosystems. However, their environmental burden remains unquantified globally. This study developed a mass transfer model to quantify the release of chemicals from plastics into the oceans based on Fick's diffusion law, incorporating the impact of plastic aging. A assessment framework was established through coupling the mass transfer model and dynamic material flow

analysis (DMFA). It was then applied to quantify the global release of nine chemicals of concern (CoCs) from plastics into the oceans, including Penta-BDEs, Octa-BDEs, Deca-BDEs, HBCD, DEHP, DINP, SCCPs, MCCPs and TCPP.

The results show that, between 2000 and 2020, the global mass of nine CoCs embedded in leaked plastics increased from 0.30 Mt to 0.53 Mt, leading to the cumulative releases of 89.7 kt (95% CI: 42.4-259.7 kt) in the ocean by 2020. Their releases are highly concentrated in the tropical and subtropical regions of Asia, which accounted for 49.9% of the global mass. They are all classified as lower middle-income countries (LMCs). A cross-sectional analysis among countries reveals an inverted U-shaped relationship between the per-capita mass of CoCs embedded in leaked plastics and per-capita gross domestic product (GDP), consistent with the Environmental Kuznets Curve (EKC) hypothesis. The inflection point occurs at a per-capita GDP of approximately 2,208 dollars. By 2020, about 73.5% numbers of countries have surpassed this threshold. However, the decoupling currently stems primarily from improved waste management systems, rather than decrease in chemical use. The scenario analysis reveals that, relying solely on either reducing plastic consumption or optimizing waste management will partially curb the increase in the release of CoCs, while reducing chemical use will substantially mitigate the releases, with annual release peaking in 2071 before declining. The results highlight the importance of reducing use of CoCs to curb their long-term environmental impact in the ocean.

This study provides scientific evidence for understanding plastic pollution in the marine environment, and offers decision support for sound management of chemicals, particularly for the upcoming global plastics treaty.

3.17.P-Tu321 Endocrine disruptive potential of a new bisphenol A substitute DD-70

Larisa Đurić¹, Jana Pavlović², Damir Pinter¹, Maja Milanović¹, Nataša Milošević¹ and Nataša Milić¹,

(1)University of Novi Sad, Faculty of Medicine, Department of Pharmacy, Novi Sad, Serbia, Serbia,

(2)University of East Sarajevo, Bosnia and Herzegovina

The increasing number of evidences about the endocrine disruptive effects of bisphenol A (BPA) have led to its replacement with insufficiently explored structural alternatives. DD-70 (1,7-bis (4-hydroxyphenylthio)-3, 5-dioxaheptane) belongs to the novel BPA substitutes mainly found in thermal paper. Having bisphenol structure, DD-70 could have the similar estrogenic profile as BPA. Hence, the aim of this study was to investigate the endocrine disruptive potential of this compound using in silico tools.

SwissADME was used for the calculation of molecular properties and the prediction of gastrointestinal absorption of DD-70 whereas GOLD software was applied for molecular docking. The binding affinity of DD-70 towards estrogen receptor alpha (ER α , pdb: 7UJO), beta (ER β , pdb: 5TOA) and gamma (ER γ , pdb: 6KNR) was evaluated in comparison to BPA using ChemPLP as a scoring function.

Based on the analyzed molecular properties, DD-70 met Lipinski's rule of five criteria for good oral bioavailability as well Veber's rule with predicted high gastrointestinal absorption. The obtained ChemPLP scores of DD-70 for ER α , ER β , and ER γ were 83.92, 71.04, and 73.28, respectively, in comparison to co-crystallized ligand scores of 99.97 (ER α), 67.46 (ER β), and 116.35 (ER γ). However, when compared with the ChemPLP scores obtained for BPA (ER α 60.36, ER β 55.54, and ER γ 59.83), DD-70 had much higher binding affinity. The obtained results suggest DD-70 high potential for impairment of normal estrogen signaling through the interactions with estrogen receptors.

In silico results imply health risks associated with the exposure to DD-70 as xenoestrogen. Both in vitro and in vivo studies are needed in order to better understand the endocrine disruptive potential of this new BPA alternative.

3.17.P-Tu322 Persistent Organic Pollutant Signatures in Cory's Shearwater Exposed to Plastic Ingestion

Dulce Soliz Rojas¹, Natalia Baena², Gema Paniagua², Juan Carlos Bravo², Rosa María Garcinuño², Beneharo Rodríguez³, Airam Rodríguez⁴, Begoña Jiménez¹, Pilar Fernández-Hernando² and Juan Muñoz-Arnanz¹,

(1)Institute of Organic Chemistry - Spanish National Research Council (IQOG-CSIC), Spain, (2)National

University of Distance Education (UNED), Spain, (3)Grupo de Ornitología e Historia Natural de las islas Canarias (GOHNIC), Spain, (4)Departamento de Ecología Evolutiva, Museo Nacional de Ciencias Naturales (MNCN-CSIC), Spain

Plastic ingestion by seabirds is widely recognized as a physical threat, yet its role as a vector of organic contaminants remains insufficiently characterised under real environmental conditions. This study evaluates the occurrence and profiles of persistent organic pollutants (POPs) in Cory's shearwater (*Calonectris borealis*) in relation to previously and fully characterised plastic and microplastic loads detected in their proventriculus and ventriculus.

A subset of 57 fledglings stranded during rescue campaigns in Tenerife (Canary Islands, Spain) in 2022 and 2023 were examined and analyzed for POP concentrations in ingested plastics, liver, and, in some cases, adipose tissue. Up to 53 compounds were determined, including polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs) and organochlorine pesticides (OCPs), by means of a validated analytical method based on ultrasound-assisted extraction, gel permeation chromatography clean-up and GC-qqq-MS/MS, with additional purification steps for tissues when required. The method showed recoveries of 60–95%, high reproducibility (RSD <8%) and limits of quantification below 1 pg g⁻¹ for most target compounds.

Concentrations were generally higher in plastic particles than in liver on a fresh weight (f.w.) basis, whereas values were comparable when normalized to lipid content. Distinct congener patterns were observed between matrices: plastics were dominated by PBDE-209 and lower-chlorinated PCBs, while liver samples showed prevalence of PCBs-153/138, PBDEs-47/99/100 and p,p'-DDE, reflecting selective bioavailability, transformation processes and additional dietary sources. Moderate monotonic correlations were detected between POP loads in plastics and ΣPCB concentrations in liver on a f.w. basis, but not when expressed on a lipid basis. Moreover, the total mass of ingested plastics showed a negative logarithmic relationship with ΣPCB concentrations.

These results support a multifactorial exposure scenario rather than a single direct transfer pathway from plastics to tissues. The combined assessment highlights the relevance of Cory's shearwater as bioindicator and provides robust evidence to inform integrated monitoring strategies addressing both plastic pollution and chemical contamination, particularly in the Canary Current ecosystem, an area of high ecological and socioeconomic importance.

3.17.P-Tu323 Distribution Characteristics and Risk Assessment of Phthalic Acid Esters in Groundwater from Hetao Irrigation District

Gaofeng Zhao, Chinese Academy of Agricultural Sciences (CAAS), China (Mainland)

Hetao Irrigation District is a major grain and oil seed production region and one of the top three largest irrigation districts in China, which is facing complex challenges for green development of agriculture. The long-term large-scale use of agricultural mulch film in Hetao irrigation district results in residues of plasticizers such as phthalic acid esters (PAEs) in the irrigation district, while pollution in groundwater caused by PAEs from agricultural mulch film was lack of systematic research. In order to investigate the distribution characteristics of PAEs in groundwater from the irrigation district. Wuyuan County was selected as the objective area, which was one of the first pilot areas of agricultural non-point source pollution control and supervision guidance in China. Groundwater samples were collected before spring irrigation, after spring irrigation, before autumn irrigation, and after autumn irrigation, respectively, and PAEs in these samples were analyzed by gas chromatography-mass spectrometry. The results showed that the concentration of PAEs in these samples ranged from 0.14 µg•L⁻¹ to 9.80 µg•L⁻¹ during the two irrigation periods. Diethyl phthalate and dimethyl phthalate were the major constituents in groundwater during spring irrigation. Dibutyl phthalate and di(2-ethylhexyl) phthalate became the major PAE constituents in groundwater after autumn irrigation. The concentration of PAEs in groundwater increased by 20.3% after spring irrigation and by 115.5% after autumn irrigation. The infiltration of irrigation water containing PAEs into the groundwater environment is an important reason for the increase of PAEs concentration after irrigation. Iso-octyl phthalate was a major high-risk pollutant, and its annual risk factor value far exceeds the safety threshold, mainly due to its high lipophil and low degradation, leading to prominent bioaccumulation risk. The results will provide a cutting-edge research basis for preventing and controlling PAEs pollution in the irrigation district.

3.17.P-Tu324 Tire wear particles (TWPs) as a vector for chemicals from urban environments

Dorte Herzke¹, Natascha Schmidt¹, Claudia Halsband² and Kristin Galtung³, (1)Norwegian Institute for Air

Research, Norway, (2)Akvaplan-NIVA, Norway, (3)Norwegian Institute for Water Research, Norway

Tire wear particles (TWP) are formed through the abrasion of tire treads during driving. They represent a specific form of microplastic (MP) pollution and contribute to an essential portion of the overall MP emissions, with around 6 million tons of TWP emitted annually across the world and therefore ranked as the second most abundant source of primary MP to the world's oceans. Antioxidants and antiozonants play crucial roles in preventing degradation of the tire material during use. These additives can constitute between 5-10% of the weight of the tires. Paraphenylenediamines (PDs) are commonly used as additives with N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD) being one of the most widely used PDs. These chemicals and their transformation products, especially PD-quinones, have been shown to be bioavailable and toxic to a range of aquatic organisms. Because of their complex composition, TWP not only disrupts natural systems as anthropogenic particles, but also as a source of harmful soluble additives. These additives create additional environmental and human health concerns due to their leaching potential.

Total deposition samples were collected during 2022 – 2025 at two remote locations (Svalbard, Zeppelin station and Birkenes station) and two urban locations (Oslo and Trondheim) in Norway. To evaluate the ability of TWP chemicals to be taken up by recipients of emissions to the marine ecosystem, a variety of marine species were sampled along sites with known TWP pollution as well as reference sites. In addition, exposure experiments in blue mussels, a commonly consumed seafood species, were conducted to better understand the uptake kinetics of TWP chemicals.

Based on our findings of TWP in urban deposition samples and marine species impacted by tire rubber pollution, evidence for both airborne as well as dietary human exposure to TWP and related chemicals were found in our study. Bioavailability of selected TWP chemicals, the PDs, could be shown in both exposure experiments as well as field samples. Elimination capability of PDs exposure seems to vary between marine species, posing unknown longterm risks together with potential dietary exposure risks to humans. For additional human health considerations, especially urban settings, with a high occurrence of atmospheric TWPs can be potential high exposure risk to both PM10 sized (and smaller) particles and related chemicals.

3.17.P-Tu325 Quantification of Tyre Wear PM10 Microplastics From Recycled Rubber Flooring With Pyrolysis-Gas Chromatography Coupled With Mass Spectrometry (Py-GC-MS)

Daniel Rozúa¹, Teresa Moreno¹, Ethel Eljarrat¹ and Stephanie Wright², (1)Institute of Environmental Assessment and Water Research, Spanish Research Council, Barcelona, E-08034, Spain, (2)Environmental Research Group, School of Public Health, Imperial College London, United Kingdom

Non-exhaust vehicle emissions are the main source of tyre wear microplastics, mainly made of natural rubber (NR) and artificial rubber, its main constituent being styrene-butadiene rubber (SBR), but recent years have seen a growing concern regarding other sources, like the photooxidative, chemical and mechanical wear of recycled rubber surfacing, found in playgrounds and sport facilities. Due to the proximity and physical activity of pitch users in sport facilities, and the higher effect of exposure for children in playgrounds, these sources represent an acute and significant exposure to tyre wear microplastics to their users.

On top of the known challenges microplastic analysis poses, like difficulty to isolate from the environment and low analytical selectivity for most methods, tyre NR and SBR are subjected to a vulcanization process during synthesis, binding polymer strands with sulphur bonds to give these materials the durability tyres require. Vulcanization makes these microplastics remarkably inert, making their analysis more challenging, and requiring long and complex sample treatment.

To bypass this issue, a new method was developed, consisting in pyrolysis-gas chromatography coupled to mass spectrometry (py-GC-MS). The high temperature of the pyrolysis furnace is able to decompose vulcanized rubber material back into its oligomeric constituents with minimal sample treatment, thus providing a simple and reproducible analytical method for NR and SBR monitoring.

8 sampling sites were studied in the city of Barcelona, where deposited PM10 was sampled using a portable vacuum sampler with separation chamber in PM10-selective regime. Suspended PM10 was also studied in one sampling site, using PM10-selective air pumps. Corresponding field and method blanks were taken and analysed as well. A py-GC-MS method was optimized for the analysis of NR, also known as polyisoprene, and SBR, using selective markers for quantitation and internal standard calibration. Analysis of mock samples was made to ensure the devulcanization of rubber microplastics under pyrolysis and acceptable recoveries.

Results show NR and SBR have been detected in deposited PM10. They were, however, not detected in suspended PM10 significantly above blank samples. Results prove the method's effectiveness in detecting tyre wear microplastics, simplifying the complex analytical problem vulcanized rubber poses when using conventional sample treatment and extraction.

This work is supported by the Spanish Ministry of Science and Innovation (Project EDGE PID2022-140801OB-I00) and by the Spanish Research Council ("Ayuda Mención de Excelencia-IDAEA" and "Ayuda para Estancias Breves del CSIC iMOVE2025").

3.17.P-Tu326 Trace elements in plastics – an environmental case study of sorption and release

Tristan Zimmermann¹, Hanna Buschmann², Lars Michael Hildebrandt³, Ole Klein² and Daniel Pröfrock¹, (1)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (2)Helmholtz-Zentrum Hereon, Germany, (3)Department of Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany

Global plastic pollution poses a major environmental challenge. An often-overlooked danger lies in the chemical additives of the plastics. A variety of additives are mixed into plastics during manufacture to give them specific properties such as color, stability, or flexibility. However, these can be released from the material under environmental influences such as UV radiation and/or contact with water. To understand the extent of this problem and to enable sound risk assessments, it is crucial to investigate the behavior of additives under real environmental conditions.

Therefore, we deployed plastic sheets made from widely used polymers (PE, PET, PVC) with defined additives containing elements like Mg, Ca, Zn, As and Sb, at a research platform in the North Sea. Polymer plates with defined mass fractions of target metals were custom made by SKZ – Das Kunststoff Zentrum (Würzburg, Germany). The plates were deployed between December 1, 2023, and November 20, 2024, at a research platform in Cuxhaven (Germany). Polymer types included with known amounts inorganic and organic additives. Samples of the polymer plates were taken after 7, 15, 22, 30, 36 and 51 weeks.

After deployment approx. 200 mg of the plates were acid digested using a microwave-assisted acid digestion (MWAD) protocol (6 mL HNO₃ and 2 mL HCl; 220 °C). Quantification of 55 elements was performed using an ICP-MS/MS system (8800 Triple Quadrupole ICP-MS, Agilent Technologies, Tokyo, Japan). The analytical process was validated using the reference materials NMIJ CRM 8123-a (PVC), NMIJ CRM 8133-a (PP), BAM-H010 (ABS), ERM-EC680m (PE) and ERM-EC681m (PE).

Depending on the polymer type and element different sorption/desorption behaviors were observed. We observed mainly sorption of selected elements like Mn and Fe to the surface likely caused by precipitation and or biofilm growth. For elements with high mass fractions like Sb in PET or Zn in PVC that were added during the manufacturing process, leaching effects could be observed. These elements are of special interest, as they are also highly abundant in consumer plastics due to their usage as catalyst (Sb in PET) or additive (Zn-stearate in PVC).

This pilot study highlights the complex nature of sorption and desorption processes of inorganic elements from custom made plastics under real world conditions. Understanding these processes is key to mitigate the environmental impact of plastic products during their lifetime and following disposal.

3.17.P-Tu327 Assessing the Environmental Persistence of Commercial Phenolic Antioxidants

Cleo Amelia Maria Soldini¹, Janis Anthamatten¹, Carolin Seller-Brison¹ and Kathrin Fenner², (1)University of Zurich, Switzerland, (2)Environmental Chemistry, University of Zürich, Switzerland

Synthetic phenolic antioxidants are widely used as plastic additives to maintain polymer integrity under oxidative stress. Despite their extensive use and frequent detection in various environmental matrices, data on their environmental fate and (eco-)toxicity remain limited. This work aims to address this hazard assessment gap by investigating the environmental persistence and sorption behaviour of 60 commercially available phenolic antioxidants using activated sludge biotransformation assays.

To this end, a targeted ESI-LCMS method was developed to quantify dissolved and total concentrations in activated sludge. Compounds were tested in mixtures at environmentally relevant concentrations, and biotransformation tests were conducted over 72 hours. By analysing both supernatant and ethanol-extracted sludge samples, the extent of partitioning between the dissolved phase and the activated sludge was assessed. Observed biotransformation rate constants of parent antioxidants were determined assuming first-order degradation kinetics. The experimental data collected will be used to further infer sorption coefficients and biomass- and bioavailability-corrected biotransformation rates.

Observed biodegradation in activated sludge depends on both the compound's intrinsic biodegradability and its bioavailability to the microbial community. Across the selected set of antioxidants, some compounds exhibited very low dissolved fractions, indicating that adsorption to the sludge flocs strongly influences their fate in activated sludge. For those antioxidants, quantifying the partitioning between the dissolved phase and the activated sludge is essential for interpreting the results of biotransformation experiments. Therefore, the efficiency of the sludge extraction procedure was assessed for all selected antioxidants, yielding a mean extraction efficiency of 75%. For antioxidants with higher bioavailability, observed biodegradation rate constants were derived based on dissolved concentrations.

Overall, this study fills an important knowledge gap in the environmental hazard assessment of synthetic

phenolic antioxidants. The testing workflow and the generated data can be integrated into early stages of the chemical development process for new, emerging antioxidants, thus providing essential information for designing safe and sustainable chemicals and materials. Future work will focus on coupling activated sludge biotransformation assays with in vitro (eco-)toxicity assays.

3.17.P-Tu328 Analysis of Antioxidants and UV Absorbers in Forty-Four Recycled Plastic Pellets

Naohide SHINOHARA, Naoya KOJIMA, Tomoko OGURI, Kyoko ONO, Isamu OGURA and Masashi GAMO, National Institute of Advanced Industrial Science and Technology, Japan

Introduction

To achieve a low-environmental-impact circular plastic economy, expanding the use of recycled plastics is essential. However, their safety has not been fully evaluated, particularly regarding residual or unintentionally introduced additives. Antioxidants and UV absorbers prevent thermal and photodegradation, but some persist, migrate, or show toxicity. Yet, unlike flame retardants and plasticizers, information on them remains limited. This study quantified these additives in recycled polyethylene and polypropylene pellets.

Methods

Eight antioxidants and eight UV absorbers were analyzed in 44 samples of recycled plastic pellets collected from 10 recycling plants in Japan. Approximately 200 mg of pellets were treated with 10 mL of cyclohexane at 150 °C for 4 h in a high-pressure vessel to extract additives. After centrifugation, the supernatant was filtered and concentrated to 1.0–1.5 mL by nitrogen blowdown at 30 °C, then diluted to 10 mL with methanol to reprecipitate the resin. The solution was centrifuged, filtered, concentrated to ~1.0 mL, internal standards were added, and the volume was adjusted to 3.0 mL with dichloromethane. The extracts were analyzed using GC–MS.

Results

The most frequently detected antioxidant was pentaerythritol tetrakis[3-(3,5-di-tert-butyl-4-hydroxyphenyl)propionate] (Irganox 1010), found in 98% of samples (<0.3 to >403 µg/g). Octadecyl 3-(3,5-di-tert-butyl-4-hydroxyphenyl)propionate (Irganox 1076) was detected in 39% (<2.0 to >265 µg/g). 2,4-Di-tert-butylphenol (Prodox-146) and butylated hydroxytoluene (BHT) were detected in 34% (<0.3–39.3 µg/g) and 14% (<0.3–83.2 µg/g), respectively. Among UV absorbers, UV770 was detected in 6.8% (<3.5–76.5 µg/g), while UV327 and UV329 were each observed in only one sample (48.6 and 1.14 µg/g, respectively).

Discussion

Because the EU Persistent Organic Pollutants Recast Regulation will restrict UV328 in recycled products to <1 µg/g as an unintentional trace contaminant (UTC) by August 4, 2029, all analyzed pellets were within this requirement (all samples were below the limit of quantification: 0.3–0.7 µg/g). Other UV absorbers of regulatory concern, such as UV-329, UV-320, and UV-350, are listed as Substances of Very High Concern (SVHC) in Europe and might be subject to future restrictions; however, only a small number of samples contained detectable amounts. In contrast, the antioxidants were detected more frequently and at higher concentrations than the UV absorbers.

Disclaimer/Disclosure:

Part of this study was based on results from the “Circular Economy System” project of the Cross-ministerial Strategic Innovation Promotion Program, Cabinet Office, Japan commissioned by the Environmental Restoration and Conservation Agency.

3.18.A Microplastics Research: Beyond Fear-Mongering, Towards Trustworthy Science

3.18.A.T-01 Addressing Matrix Effects in Micro- and Nanoplastic Quantification Using Pyrolysis-GC-cIMS-HRMS

Kas Houthuijs¹, Justine Bissonnette², Nikita Harvey³, Marja Lamoree¹, Karl Jobst³ and Frederic Béen¹, (1)VU University Amsterdam (VU), Netherlands, (2)Memorial University of Newfoundland, Canada, (3)Chemistry, Memorial University of Newfoundland, Canada

Studies reporting the presence of micro- and nanoplastics (MNPs) in human biological samples are increasing, raising concerns about exposure and potential health effects. Current exposure assessment commonly relies on

pyrolysis coupled to gas chromatography – mass spectrometry (Py-GC-MS), where quantification is based on the detected abundance of polymer-specific markers. However, a key limitation of Py-GC-MS is its potential for polymer overestimation when non-plastic matrix components form identical markers during pyrolysis. Such interferences complicate toxicological interpretation and contribute to public concern. At the same time, quality assurance and control practices to mitigate such misidentifications are not consistently implemented, making the reliability of reported exposure data uncertain.

A recent advancement in the quantification of MNPs is the use of cyclic ion mobility spectrometry (cIMS) hyphenated to high-resolution MS (HRMS). The improved separation and resolution of Py-GC-cIMS-HRMS provide additional analytical specificity by reducing spectral background, thereby preventing false-positive detections. In this study, we applied a non-target approach to identify MS features that uniquely correlate with the polymers PE, PP, PS, PET, PVC, and PMMA. Across all samples, peak picking yielded 35,365 MS features for which linear calibration models were fitted. Based on each model's coefficient of determination (R^2), for each polymer optimal markers were identified that remained robust in the presence of sample matrix.

Our preliminary findings indicate that PE quantities can be overestimated when commonly used short-chain α -alkene markers are employed, whereas long-chain α -alkenes or α,ω -alkadienes remain robust with limited matrix effects. For PET, potential underestimation may occur due to co-pyrolysis with matrix residue. The stronger matrix effects observed here compared to earlier reports likely result from the use of single-shot pyrolysis, the standard approach for MNP quantification. Instead, in double-shot pyrolysis, volatiles are removed prior to polymer pyrolysis, thereby reducing the formation of nonspecific fragments such as α -alkenes and limiting co-pyrolysis with more reactive polymers like PET. Together, these results demonstrate the value of Py-GC-cIMS-HRMS for improving marker selection and strengthening the reliability of MNP exposure assessments.

3.18.A.T-02 Best practices for the detection and quantification of micro- and nanoplastics in biological tissues

Willie Peijnenburg, University Leiden, Netherlands

Micro- and nanoplastics (MNP; 1 nm–5 mm) have become a major environmental and public-health concern. While numerous studies have documented their occurrence in various ecosystems and biological matrices, methodological inconsistency continues to undermine data comparability and risk interpretation. This contribution presents an internationally validated framework of 28 best practices for the detection and quantification of MNP in biological tissues. Developed through an expert-reviewed consensus process, this framework represents a globally harmonized foundation for methodological reliability.

Each recommendation was derived from a systematic review of 46 interlaboratory comparison studies, validated by independent experts, and grouped into four pillars: Quality Assurance and Quality Control (QA/QC), Sample Collection, Particle Quantification and Qualification, and Data Handling and Reporting. Although the primary focus lies on biological tissues such as blood, muscle, and organ samples, the same principles apply broadly to environmental and industrial matrices. The aim is to increase reproducibility, minimize contamination, and enable transparent cross-study comparison.

3.18.A.T-03 Identification of Unknowns using Vibrational Spectroscopy – A Case Study of Microparticles in the Environment

Matthew Wagner, The Procter & Gamble Company, United States

The rapid expansion of micro- and nanoplastic (MNP) research has created a need for robust analytical methods to ensure the accuracy of findings. This presentation reviews analytical approaches for identifying environmental MNPs, using vibrational spectroscopy as a case study to highlight common challenges and best practices. While techniques like Fourier transform infrared (FTIR) and Raman spectroscopy are powerful tools for chemical identification, over-reliance on automated software and Hit Quality Index (HQI) metrics for spectral matching can lead to misidentification. A case study demonstrates how different software packages can yield conflicting results for the same material, underscoring the critical role of the experienced analyst in interpreting spectral data. Accurate identification in complex environmental matrices requires a commitment to analytical rigor, including thorough sample preparation, an awareness of spectral library limitations, and the application of complementary, multimodal analytical techniques to confirm findings. Advancing the scientific understanding of MNPs demands a holistic approach that goes beyond advanced instrumentation to include improved data analysis, a critical evaluation of results, and the development of standardized methods to enhance data reliability.

3.18.A.T-04 Reliable Riverine Microplastics Monitoring: Improvement and Harmonization of Sampling, Analysis and Reporting

Guidrun Obersteiner, Reinhold Ottner, Sabine Lenz and Christian Zafiu, University of Natural Resources and Life Sciences (BOKU), Austria

Despite growing attention to microplastics, methods for detecting them in river ecosystems remain heterogeneous. Differences in sampling, preparation, and analysis make comparability difficult. Partners from seven countries in the Danube basin worked to improve and harmonize existing monitoring approaches to enable reliable statements about the distribution of microplastics.

Since varying infrastructure of participating organizations, a common methodological framework was developed, tested, and adapted to local conditions. Two comparative sampling campaigns provided important insights into the handling of different pump and net systems and enabled harmonized procedures on site. Standardized protocols ensured that all partners recorded comparable metadata such as flow velocity and hydrological conditions. Pre-treatment and analysis were carried out according to sample type, laboratory equipment, and budget. Various sample splitting methods were tested for representativeness.

Scientifically, a combination of pump and net sampling is recommended, as both methods cover different particle size ranges and can be used simultaneously. This allows a representative water volume to be recorded and different analysis parameters (mass, particle count, polymer type) to be addressed flexibly. Standardized application improves comparability, supports the identification of hotspots, and provides a basis for effective mitigation measures. The results show that analytical methods—especially FTIR methods and databases used—can have a significant impact on particle counts.

The following key challenges were identified: representative sampling, harmonized metadata collection, standardized pretreatment and analysis, uniform reporting, and quality assurance.

These aspects are taken into account to formulate standardized protocols. Complete standardization remains difficult due to varying resources and issues. In the future, however, key parameters like mandatory size fractions should be introduced. In addition to the particle count, the determination of mass as a stable parameter is particularly relevant above 500 µm. A new measurement parameter focussing on the area of plastic could also be introduced, especially for analysis methods where the plastic particles are scanned over a large area, in order to avoid overestimating the particle count. Interlaboratory studies and suitable reference materials are urgently needed to improve the comparability of polymer identifications.

3.18.A.T-05 Index-based Environmental Risk Assessment of Micro- and Nanoplastics: Handbook for Conscious, Accurate, and Standardized Use

MANUELA PICCARDO and Stanislao Bevilacqua, University of Trieste, Italy

Pollution from micro- and nanoplastics currently represents one of the main environmental challenges, raising concerns both for its ecological consequences and for the potential risks to human health. After two decades of data collection since the first appearance of the term “microplastic” in the scientific literature, research is moving toward a new direction — that of assessing ecological and human health risks. In this perspective, a rising interest is converging on the use of indices, which may represent an effective tool for describing environmental quality in a clear and straightforward manner.

This contribution, based on the systematic review of 316 papers collected from the Web of Science database, aims to examine the use of indices for environmental risk assessment from both an editorial perspective (when the first publication dates back to, how the topic has evolved over time, and which publishers and journals have shown the greatest interest) and a technical point of view (which and how many indices have been proposed to date, which environmental matrices have been considered, and which geographical areas have received the most attention). Furthermore, what limitations does each index present, and how can they be improved? The goal is to gather and summarize all information on the topic, which to date remains somewhat fragmented, and propose a roadmap to guide researchers and practitioners through an informed, accurate, and standardized use of indices for ecological risk assessment of microplastic pollution.

3.18.B Microplastics Research: Beyond Fear-Mongering, Towards Trustworthy Science

3.18.B.T-01 Distinguishing the Aqueous behaviour of Water Soluble Polymers from Nano-plastics with Advanced Analytical Techniques

Kevin Goodall¹, Vincenzo Agostiniano¹, Jeremie Gummel¹, Jan Claussen² and Yuri Roiter³, (1)Procter & Gamble, Belgium, (2)Procter & Gamble, Germany, (3)Procter & Gamble, United States

The widespread use of the term “nano-plastics” risks implying every polymer to be classed as a nano-plastic, despite general academic consensus and adoption into regulatory frameworks of micro/nano-plastic definitions.

This risk is acute with water soluble polymers. A single macromolecule chain of a water soluble polymer is nano-sized in solution, but does it behave the same properties as a “small nano-sized microplastic” dispersed in water? This is important for classifications, and to ensure the right methods are applied to the relevant species to assess environmental risk.

Water soluble polymers have been studied for a number of years to determine their water binding preferences. Environmental aspects of such polymers is now also in focus.

We studied Polyethylene Glycol (PEG), Polyvinyl Alcohol (PVA) (across grades of solubility) and Polystyrene (PS). From simple filtrations, we have expanded to the aqueous nanoscale using Small Angle X-ray Scattering (SAXS), Dynamic Light Scattering (DLS), and Atomic Force Microscopy (AFM). The resultant structures show different single macromolecule conformations (for soluble materials), or hard spheres. It validates prior academic work using other techniques. The structures seen give insights into predicted environmental fate, eg contaminant adsorption or degradation.

We are extending the techniques to study if water soluble polymers could exhibit nano-plastic characteristics in the aqueous environment. From simple filtration experiments, we expanded to SAXS and DLS to look at individual or mixed water soluble polymers in various simulated environmental conditions. With complex systems, including mixture with surfactants, low water environments, we developed GPC and NMR to study hydrogel formation and solubilization behaviour. Results will be shared from our recent work, showing when formation of nano/microplastics is possible.

This work expands the toolbox to understand how water soluble polymers behave in water compared to nano-plastics. They demonstrate difference in solution conformation depending on structures or conditions. It can also provide insights for regulators to classify polymers as soluble or nano-plastic, to ensure subsequent application of the correct risk assessment procedures.

3.18.B.T-02 Beyond Size and Shape: Characterising Physicochemical Properties of Microplastic Test Materials Generated by Cryomilling

Lucy Howarth-Forster¹, Robyn Barrett¹, Rob Clough¹, Jack Allen², Chris Powell², Lee Durndell¹, Susan Ferrier³, Richard C. Thompson¹, Lisbet Sorensen⁴, Matthew Cole⁵ and Michael Wilde¹, (1)University of Plymouth, United Kingdom, (2)University of Leicester, United Kingdom, (3)Fugro, United Kingdom, (4)Norwegian University of Science & Technology, Norway, (5)Plymouth Marine Laboratory, United Kingdom

Cryomilling is a widely adopted method of generating microplastic test materials for environmental studies: however analysis of these test materials is often limited to size and shape, and it is assumed other physical, chemical and thermal properties are preserved. Here, this assumption is challenged to provide insight into the effect of cryomilling on physicochemical properties which can influence microplastics behaviour and impact.

A comprehensive analysis of several virgin polymer pellets, including low-density polyethylene, polypropylene, polylactic acid and polybutylene succinate, and a weathered agricultural mulch-film, was performed before and after cryomilling. Scanning electron microscopy and particle size analysis showed that particle size and shape were influenced by milling parameters, such as chamber size, and polymer type. Surface-specific additives identified by FTIR spectroscopy were redistributed throughout the milled material, but weathering-induced changes were preserved. Bulk polymer chemistry was maintained after milling, confirmed by pyrolysis gas-chromatography mass spectrometry. However, polymer-specific changes in crystallinity were demonstrated using thermogravimetric analysis with differential scanning calorimetry. Contamination from metal and plastic milling components was concluded to be minimal. These results show that it cannot be assumed that physicochemical characteristics are preserved during cryomilling and therefore should be considered when characterising microplastic test materials used in environmental studies. Furthermore, characterising these materials beyond size and shape allows for a more realistic comparison between microplastic test materials and environmental plastics.

3.18.B.T-03 The Plastic in Microplastics

Heinrich Dahms¹, Magdalena Vanek², Francesca Vallefuoco³, Daniele Ricaldone³, Richard Greenfield⁴ and Roberta Bottarin³, (1)EurAc Research, Italy, (2)University of Innsbruck, Italy, (3)Eurac Research, Italy, (4)University of Johannesburg, South Africa

Microplastics (MPs) are tiny synthetic particles ranging between 5 mm and 1 µm. Each particle can consist of one of a variety of synthetic materials, produced from a series of polymer chains and chemical additives, to impart the characteristics needed for the final use of each plastic material. This leads to particles having unique characteristics between polymers and within each polymer. When these particles enter the environment, they undergo further physical and chemical alterations. Surface fracturing, volume and density changes, biofilm growth, and the ability to release and absorb toxicants from the surrounding environment lead to a scenario in which each MP particle may have unique traits and how they could impact organisms. These points lead to particles that are difficult to sample, analyse, characterise, and assess their impact on biota. In this study, MPs in rivers and streams in the Autonomous Province of Bolzano were investigated. Ten sites were selected where nine replicate sediment samples were collected to determine the MP content. These consisted of three bank replicates, three instream at 20 cm deep, and three instream at 5 cm deep to report a more representative abundance of MPs. The sediment was then dried, and MPs were separated through density separation with ZnCl₂ and centrifugation. Particles were then filtered, quantified through stereomicroscopy, and characterised with a Shimadzu ATR-FT-IR with Labotech software and compared to spectra of both organic, additive, and polymer libraries. The mean concentrations varied between 38.85 ± 22.23 particles per kg in spring and 32.59 ± 10.94 particles per kg in autumn. Concentrations ranged between 16.65 and 79.55 particles per kg in the spring and 12.96 and 46.29 particles per kg in the autumn. Polymer analysis found that Polyester was the most prevalent polymer type. Other materials included polypropylene, polyacrylic, and other artificial natural fibres such as Bemberg. Some chemical additives were also identified; however, these can only be hypothesised, with more formal analysis required to concretely determine the type and concentrations of each additive present. Fifty additive signatures were detected, including 16 which are described as toxic to the aquatic environment, and more than half with no toxicological data available. This highlights not only the importance of studying MP abundances, but also the additives and other toxicants which may be bound to these particles.

3.18.B.T-04 Towards Standardized and Open Data Reporting on Litter Monitoring in Inland and Transitional Waters

Maria Kazour¹, Mariana Nogueira Miranda², Charlotte Dhondt¹, Therese Nitschke¹, Nelle Siele Meyers³, Liesbeth De Keukelaere⁴, Gita Maas⁵, Daniel González Fernández⁶, Miguel J. Sánchez-Guerrero Hernández⁶, Luca Muth⁷, Stephan Wagner⁸, Marko Petelin⁹, Samuel Zidaric⁹, Jana Asselman¹⁰, Rachid Amara¹¹, Perine Doyen¹², Guillaume Veillet¹³, Patricia Martin Cabrera¹⁴, Jelle Rondelez¹, Lisa Inès Devriese¹⁵, Gert Everaert¹⁵ and Ana Isabel Catarino¹, (1)Flanders Marine Institute (VLIZ), Belgium, (2)Research Department, Ocean and Human Health, Flanders Marine Institute (VLIZ), Belgium, (3)Ocean and Human Health, Flanders Marine Institute (VLIZ), Belgium, (4)Flemish Institute for Technological Research (VITO), Belgium, (5)Stichting De Noordzee, Netherlands, (6)University of Cádiz, Spain, (7)University of Applied Science Fresenius, Germany, (8)Institute for Analytical Research, University of Applied Science Fresenius, Germany, (9)Infodata Sistemi (INFOR), Italy, (10)Blue Growth Research Lab (BGRL), Ghent University, Belgium, (11)Universiy of the Littoral, France, (12)UMRt 1158 BioEcoAgro, France, (13)University of the Littoral, France, (14)International Oceanographic Commision (IOC)- Ocean Best Practices System Manager, UNESCO, France, (15)Ocean & human health, Flanders Marine Institute (VLIZ), Belgium

Litter surveying and monitoring in the aquatic environment still relies on disparate reporting methodologies. While the Marine Strategy Framework Directive (MSFD) provides guidance for marine environments, comparable requirements are limited under the Water Framework Directive (WFD) and have not been implemented yet, resulting in heterogeneous datasets and reduced comparability across studies. To address this gap, we developed FAIR-compliant and openly accessible dataset templates for micro-, meso-, and macrolitter monitoring that align with existing international best practices for gathering and managing metadata and data, including the guidelines of the European Marine Observation and Data Network (EMODnet). A structured development workflow was followed, informed by European directives, technical guidance documents, and controlled vocabularies. The templates were tested using pilot datasets and refined through multiple local and European projects (e.g., PLUXIN, PLASTFLOW, TREASURE, INSPIRE) to ensure applicability across diverse sampling environments and methods. Delivered in a machine-readable format (*.CSV), the templates capture campaign-level metadata (e.g., geographical and temporal coverage, environmental setting, and responsible institutions) as well as detailed methodological information such as sampling approach, equipment, and processing workflows. Litter observations are reported at the sample or item level, with standardized descriptions of material, size, count, morphology, and other key characteristics. These harmonized templates

enhance transparency, interoperability, and long-term reusability, enabling more reliable spatial and temporal assessments of litter pollution in aquatic environments. By translating policy needs into practical data structures, this work supports a consistent, FAIR, and open workflow for litter monitoring and reporting in inland and transitional waters.

3.18.B.T-05 Do Current Microplastic Data From Global Karst Groundwater Show Real Environmental Contamination or Methodological Bias?

Syeda Maria Zainab¹, Dan Lapworth², Richard Cross³, Katherine Pond⁴, Monica Felipe-Sotelo⁵ and Louise Maurice², (1)School of Engineering, University of Surrey, United Kingdom, (2)British Geological Survey, United Kingdom, (3)UK Centre for Ecology & Hydrology, United Kingdom, (4)Department of Civil and Environmental Engineering, University of Surrey, Guildford GU2 7XH, UK, United Kingdom, (5)School of Chemistry and Chemical Engineering, University of Surrey, United Kingdom

Microplastics have been found in karst groundwater in several regions, but the overall picture is still unclear. Most studies come from only a few countries and focus on caves, whereas springs and wells in many karst areas remain unexplored. Reported concentrations vary from low to extremely high, but it is not always clear how much of this variation reflects the hydrogeology, contamination sources and how much comes from the methods used.

To clarify this, we compiled published studies on microplastics in karst groundwater and examined how methodological choices shape the results. We compared the main approaches used for sampling, particle extraction and identification, and considered how these choices affect what each study detects. Variation in detection limits, polymer confirmation methods, and contamination control helps explain the high variation in number of particles detected between studies. For instance, Raman or micro-Fourier Transform Infrared Spectroscopy detect many more small particles and a wider range of polymers, while studies that rely mainly on visual identification using microscopy or sodium chloride for density separation are biased toward larger or low-density particle fragments and fibres.

To assess how comparable the available data are, we applied existing quality assessment criteria for microplastics. This helped show where analytical biases are likely to happen and where results are better supported by stronger QA/QC. It not only helps us identify uncertainties but also shows where studies are directly comparable despite using different methods. Although some studies report using basic contamination control and limited spectroscopic confirmation, recovery tests are never carried out, and visual identification is still common practice, restricting the types of microplastics that can be confidently identified, typically towards larger plastic fibres.

By putting the published evidence into context, we show that many of the differences between studies reflect methodological bias rather than differences in environmental contamination. By linking the results published so far to their sampling and analytical choices, it becomes clearer where studies can genuinely be compared and where methodological artefacts limit what can be concluded. This supports more realistic communication of microplastic exposure in karst groundwater and highlights the benefit of moving towards more consistent and standardised approaches in future work.

3.18.P Microplastics Research: Beyond Fear-Mongering, Towards Trustworthy Science

3.18.P-Mo190 Beyond Polystyrene: Precipitation-Based Production of Pristine Micro- and Nanoplastic (MNP) Test Materials

Oliver Kretschmar¹, Kathrin Harre², Lucas Kurzweg³, Keno Herzog¹ and Günther Auernhammer⁴, (1)University of Applied Sciences Dresden (HTW Dresden), Germany, (2)Agriculture/Environment/Chemistry, University of Applied Sciences Dresden (HTW Dresden), Germany, (3)Chemical Engineering, University of Applied Sciences Dresden (HTW Dresden), Germany, (4)Leibniz Institute of Polymer Research Dresden, Germany

Polystyrene remains the dominant focus of ecotoxicological micro- and nanoplastic (MNP) research, despite representing only a minor share of global plastic production. Environmentally relevant test materials from polymers such as LDPE, PET, PA6 and PP remain scarce, particularly below 20 µm.

A fast and straightforward precipitation-based approach is presented in this work for producing pristine MNP reference materials from these polymers using tailored solvent–nonsolvent systems. The method enables the generation of irregular and spherical particles within a reproducible micro- and nanoplastic size range, yielding LDPE (0.5–10 µm), PET (0.4–4 µm), PA6 (0.6–6 µm) and PP (0.2–6 µm). Polymer-specific yields of 250–920 mg of MNP material can be achieved in a single run.

Accelerated UV ageing was applied to mimic environmentally relevant processes, with the precipitated particles being photo-oxidized and subsequently characterized by FT-IR and zeta-potential measurements. Pristine particles showed strong agglomeration tendencies, whereas the UV-aged materials exhibited enhanced colloidal stability in aqueous systems, with zeta potentials below -30 mV at pH 7, significantly reducing their propensity to cluster. A concept for producing pristine MNP particles containing polymer additives is furthermore introduced.

This study ultimately provides two key advancements: (1) a precipitation-based route for generating polymer-diverse reference materials for MP/MNP characterization, and (2) an ageing procedure that enhances environmental relevance by modifying particle surface chemistry and dispersion behavior.

3.18.P-Mo192 Towards fit-for-purpose monitoring of microplastics

Richard Cross¹, Sarah Roberts¹, Michael Greenop¹, Heather Carter², M. Gloria Pereira², Godfred Amankwa¹, Festus Asaaga¹, Lee Walker², Peter Henrys¹ and Andrew C Johnson², (1)UK Centre for Ecology & Hydrology, United Kingdom, (2)United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom

The past 20 years of research has left us in no doubt that microplastics are ubiquitous across the globe.

However, whilst we are not lacking in data, we are limited in generalising insights from the extensive observational studies to date. Uncertainty is inherent to the measurement of any chemical. Whilst not unique to microplastic research, it is proving particularly challenging when communicating the risks of microplastic emissions. Standardisation of measurements is often cited as a solution. However, standardisation can only occur once the field has matured sufficiently to guide which of the available methods can deliver relevant data and meet the needs of the many stakeholders who will rely on these measurements.

Many approaches have been used to measure microplastics in the environment. These range from the relatively cheap, looking for easy to spot large particles, to more expensive analyses, targeting challenging particles only a few microns in size, or identifying polymers themselves. No single method is quantitative of microplastics across their entire diversity of size, shape and chemistry. However, if we consider specific monitoring scenarios, we can begin to identify and develop methods which are “fit-for-purpose”.

Any candidate method consists of a series of steps: sample collection, preparation, analysis and interpretation. There is variation associated with each of these steps, which in combination establishes the total uncertainty. When considering wide scale monitoring, the suitability of candidate methods can be considered a balance between the accuracy and precision of the data generated (the “uncertainty”), versus the costs, throughput and readiness of these methods for deployment at scale.

Here, we present a framework to identify fit-for-purpose monitoring for microplastics (UKWIR, EQ/01/A/279). Taking the hypothetical scenario of national monitoring for microplastics in wastewater effluent, we show how uncertainty, sample number, confidence and costs are linked and can be combined in an evaluative framework, to select suitable methods to develop or deploy at scale. This framework would allow candidates to be ranked, cost efficiency to be considered and recommendations for targeted research to reduce uncertainty or validate specific elements of the method(s) to be identified. In this way, the framework acts as a harmonised, structured approach, applicable to many scenarios, to support the development of fit-for-purpose monitoring.

3.18.P-Mo194 Assessing Sampling Effort Needed to Detect Microplastic Declines in the Scheldt Estuary for Policy Support

Nelle Siele Meyers¹, Jana Asselman², Ronny Blust³, Hanne Diels³, Erik Toorman⁴, Nithin Achutha Shettigar⁴, Boudewijn Decrop⁵, Theofano Koutrouveli⁵, Els Knaeps⁶, Arne Van Overloop⁶, Lisa Inès Devriese⁷, Carina Lalyer⁸, Larissa Bonifacio⁸, Jelle Rondelez⁸, Charlotte Dhondt⁸ and Ana Isabel Catarino⁸, (1)Ocean and Human Health, Flanders Marine Institute (VLIZ), Belgium, (2)Blue Growth Research Lab (BGRL), Ghent University, Belgium, (3)University of Antwerp, Belgium, (4)KU Leuven, Belgium, (5)IMDC, Belgium, (6)Flemish Institute for Technological Research (VITO), Belgium, (7)Ocean & human health, Flanders Marine Institute (VLIZ), Belgium, (8)Flanders Marine Institute (VLIZ), Belgium

Monitoring plastic pollution in estuarine environments is complicated due to high natural variability and multiple interacting physical, chemical, and biological processes affecting transport and retention. In the Scheldt

Estuary in Belgium, tidal dynamics, freshwater discharge, rainfall, sediment resuspension, vegetation, organic matter, and industrial activity introduce variability that can obscure temporal trends. Historical accumulation and burial-resuspension cycles of older plastics further complicate distinguishing new pollution. Following recent policy measures to reduce microplastic emissions, the PLASTFLOW project (2024–2025) aimed to update microplastic abundance estimates and evaluate the sampling effort required to detect policy-driven changes. Building on a 2020–2022 baseline study, sampling campaigns were conducted across eight estuarine sites during different seasons, collecting surface and water-column samples at multiple depths. Preliminary results confirm previously identified accumulation zones, particularly upstream of Doel and in the Antwerp region, with surface concentrations ranging from 25–28 particles/m³ and water-column concentrations from 93–122 particles/m³. Downstream locations generally exhibited lower concentrations, though Zeebrugge showed elevated water-column levels likely influenced by coastal inputs or dredge disposal. To inform monitoring design, a power analysis is currently being performed using observed variability to determine the number of samples per estuarine segment and season needed to detect policy-relevant changes ($\alpha = 0.05$, power = 0.8). Initial observations suggest substantially higher sampling intensity than currently implemented is required, which emphasizes the influence of both spatial and temporal variability on monitoring outcomes. By combining updated concentration data with statistical power assessment, PLASTFLOW will provide guidance for robust long-term monitoring frameworks, enabling reliable evaluation of mitigation efforts under the EU Green Deal's Zero Pollution Action Plan.

3.18.P-Mo195 Minimizing Biogenic Interference in Microplastic Quantification: Evaluation of Digestion Protocols and Counterstaining Strategies

Le Hoang Yen Nguyen¹, Adrian Covaci², Giulia Poma² and Mik Van Der Borgh³, (1)KU Leuven, University of Antwerp, Belgium, (2)University of Antwerp, Belgium, (3)KU Leuven, Belgium

Microplastics characterization in organic waste remains a major analytical challenge due to the complexity of the matrix. The main issues arise from the high loads of biogenic materials, which can persist through multiple sample preparation steps. While chemical digestion has been studied to reduce organic content in various environmental matrices, complete removal has not been achieved without compromising polymer integrity. Residual natural particles can exhibit optical properties similar to those of plastics, leading to a substantial overestimation during microscopic-based quantification. In this study, we evaluated the efficiency of multiple digestion protocols for organic waste and introduced a subsequent two-step staining procedure to better visualize and distinguish microplastics from inorganic and biogenic particles. Since Nile red can fluorescently stain both plastic and certain natural particles, a counterstaining step using a water-soluble dye was introduced to mask and suppress the fluorescence signal from the biogenic interferences. The proposed workflow aims to minimize matrix-derived interferences and improve the reliability of microplastic analysis in organic waste.

3.18.P-Mo196 Development of a Portable Hollow-Fiber System for Sampling and Quantifying Microplastics Larger Than 1 µm

Yutaka Kameda, Chiba Institute of Technology, Japan

Microplastics (MPs) in treated drinking water have emerged as a regulatory concern, particularly in the European Union where routine monitoring is mandated, and in California where tap-water monitoring guidelines have recently been proposed. Although these frameworks outline recommended sampling and analytical approaches for both raw and treated water, their implementation remains impractical. Current protocols require prolonged sampling and the use of large, costly concentration systems capable of processing several hundred liters of water in situ, presenting significant technical and logistical barriers. Moreover, multiple studies suggest that MPs detected in tap water may originate from post-treatment contamination within distribution systems rather than from water purification facilities, underscoring the need for point-of-use measurements. To accurately evaluate human exposure and associated health risks, reliable and scalable methods are needed to quantify MPs—including their concentrations, size distributions, and polymer chemistries—directly at consumer endpoints.

Here, we present a newly developed portable hollow-fiber concentration system (Mitsubishi Chemical Cleansui Corporation) designed for rapid sampling of MPs >1 µm in tap water. The system is compact and installation requires only attachment to a standard faucet, comparable to operating a household shower head. Sampling several hundred liters of tap water can be completed within 30 minutes automatically, and MPs are retained within a dedicated concentration chamber integrated into the shower-head unit. The retained fraction is subsequently digested using 30% hydrogen peroxide and further concentrated onto a 1 µm silicon membrane filter. Identification and quantification are performed using micro-Raman spectroscopy coupled with imaging-based particle recognition.

This presentation will demonstrate the system's contamination control and will report an example of measured MP concentrations, size distributions, and polymer compositions from a faucet. The results highlight the capability of this field-deployable method to enable scalable, regulatory-relevant monitoring of microplastics in drinking water at the point of human exposure.

3.18.P-Mo197 Validation of a pyrolysis - gas chromatography – mass spectrometry method for the determination of microplastics and its application in an interlab study

Myrthe van der Kolk¹, Martijn Korporaal², Fatma al Manji³ and Eva de Rijke⁴, (1)University of Amsterdam (UvA), Netherlands, (2)Wageningen Food Safety Research (WFSR), Netherlands, (3)Institute of Environmental Sciences Leiden (CML), Netherlands, (4)University of Amsterdam (UVA), Netherlands

Micro- and nanoplastics (MNP) are of health and environmental concern but little is known about the extent of the problem (1). Analytical techniques to reliably quantify MNP in environmental matrices are still under development. This is crucial to understand the concentrations we are exposed to and to devise mitigation strategies. Thermoanalytical techniques quantify MNP from nano- to millimeter size (2), however they are prone to disturbances from matrices, and the effect of polymer composition and weathering are not yet understood. These disturbances and uncertainties can lead to unreliable results causing misjudgment of human exposure.

In the pyHarmony project, which is part of the MOMENTUM consortium, we are developing reliable methods and performing interlab studies to gain knowledge on these topics. In this study, different commonly occurring MNP, i.e. polyethylene (PE), polypropylene (PP), polystyrene (PS), polymethylmetacrylate (PMMA), polyvinylchloride (PVC), polyethylene terephthalate (PET), nylon6 (N6) and styrenebutadienerubber (SBR) using the Frontier standard mixture were investigated. A pyrolysis GC-MS method was developed and validated and applied to fiber material from a washing machine filter, sand and river sediment samples spiked with PE, PP, PS and SBR from the interlab study. For all MNP three indicator pyrolysis products were found and limits of detection were below 1 ng absolute in all cases, with R2 values ranging between 0.990 and 0.999, recoveries between 80% and 120%, repeatability <20% and reproducibility <30%. With the optimized py-GC-MS method, PE, PP, PS and SBR were successfully identified and quantified in the sand and sediment samples and PET was identified in the fiber sample.

3.18.P-Mo198 Adapting Raman microspectroscopy to different analytical aims for detecting microplastics in biological systems

Alena Vdovchenko¹, Julia Laskowska¹, Eric Auyang² and Stephanie Wright³, (1)Imperial College London, United Kingdom, (2)School of Public Health, Imperial College London, ., United Kingdom, (3)School of Public Health, Imperial College London, United Kingdom

Plastic pollution represents a pressing environmental challenge. Micro/nanoplastics (MNPs) can form through environmental fragmentation or be intentionally produced, subsequently leaking into the environment. MNPs infiltrate food, water, and air, and can enter the human body through ingestion and inhalation. Understanding whether these particles are absorbed into the bloodstream and whether they reach specific tissues is critical for predicting toxicity.

Detecting and identifying MNPs in biological samples remains technically challenging due to their low concentrations and biological interferences. Raman microspectroscopy offers a label-free method for chemical imaging, enabling detection of submicron particles that are more likely to cross biological barriers and accumulate in human tissues.

This work explores how Raman microspectroscopy can be adapted to different analytical objectives—quantification, localisation, and biochemical assessment—across distinct biological systems. Three experimental examples illustrate the analytical trade-offs associated with each objective.

In the first example, quantification of MNPs in human blood focuses on identifying MNPs in digested samples, where low particle concentrations require matrix removal and concentration steps. The method was applied to

the analysis of blood from healthy donors ($n = 5$). Several polymer types were detected at low counts (< 10) and were absent in procedural blanks, suggesting their association with the blood matrix.

In the second example, cell culture experiments using THP-1 macrophages exposed to polyethylene terephthalate and polyamide MNPs demonstrate that Raman microspectroscopy enables localisation of particles inside cells.

In the third example, analysis of human tissue samples addresses both localisation and quantification. Here, a combined approach of digestion and cryosection analysis was applied to evaluate the feasibility of detecting MNPs within complex tissue structures.

Together, the results highlight how improving the likelihood of detecting MNPs often requires sacrificing spatial information about their location within the biological matrix. Rather than a single workflow, effective MNP detection requires tailoring Raman protocols to the specific biological question—whether quantification, localisation, or biochemical characterisation. Overall, this work defines methodological boundaries and optimisation strategies for Raman-based MNP detection in biological samples.

3.18.P-Mo199 Advancing the Analysis of Micro- and Nanoplastics Using Multimodal Sub-Micron Optical-Photothermal Infrared (O-PTIR) and Simultaneous Raman Microscopy with Co-located Fluorescence

Carolin Borbeck¹, Miriam Unger¹ and Dieter Fischer², (1)Photothermal Spectroscopy Corp., Germany, (2)Leibniz Institute of Polymer Research Dresden, Germany

Detection and characterization of microplastics (1 μm to 1 mm) and nanoplastics ($< 1 \mu\text{m}$) are crucial to monitor their prevalence and determine potential threats caused due exposure to these particles. Nanoplastics are particularly hazardous as they can penetrate biological barriers and absorb toxic compounds, which is facilitated by their small size and large surface-to-volume ratio. Traditional Fourier-transform infrared (FTIR) spectroscopy can only detect particles larger than $\sim 10 \mu\text{m}$, while Raman spectroscopy can identify particles down to 1 μm – and sometimes even 300–500 nm – but often suffers from fluorescence interference. This highlights the need for novel methods enabling adequate characterization of plastic particles in the sub- μm range.

Using Optical Photothermal Infrared (O-PTIR) spectroscopy, the accepted limitations of traditional IR microscopy are broken, providing for true submicron spatial resolution operating in contact-less reflection mode (as opposed to ATR), whilst providing for FTIR transmission/ATR-like data quality. Furthermore, it bridges the gap between conventional IR microspectroscopy and nanoscale IR spectroscopy. Now, for the first time, it also enables IR+Raman - simultaneous IR and Raman measurements at the same time, from the same spot and the same resolution. The complementary information gained by both IR and Raman scattering spectroscopy allows for cross-validation of results between different techniques. Additionally, the measurements can be combined with co-located widefield fluorescence microscopy, facilitating the identification of regions of interest and the localization of particles to be characterized. The measurements can be automated employing an algorithm called *featurefindIR®*, which enables fast evaluation of samples, both quantitatively and qualitatively.

Several applications of how O-PTIR can advance analytics of micro- and nanoplastics will be highlighted. O-PTIR has been applied in the characterization of particles extracted from water and consumer products like beer and yoghurt as well as embedded in various organic matrices.

3.18.P-Mo200 Identification of microplastics using Nile Red microscopy: case studies on wastewater and effluents from treatment plants

Audrey Joris, Aymeric Nagant and Laurence Haouche, ISSeP, Belgium

The determination of microplastics (MPs) in the environment is a growing concern. There is still no real consensus on the preparation and analysis methods to be used. Each laboratory applies the method it has developed. There are a lot of sources of error and misidentification in MPs analysis. This is due, on the one hand, to the complexity of this pollutant, its nature, its origins, its degradation in the environment and its affinity with other pollutants that adsorb onto these particles. On the other hand, there is a lack of comparability between the results obtained by different methods and different laboratories. This observation was made during interlaboratory studies as the Missouri project.

Identifying MPs using Nile red microscopy is an initial approach to observe MPs particles from 100 μm to 1 mm. It's a simple and inexpensive method for determining the presence of MPs in water. However, this method

has certain drawback. Observing the different areas of the filter is very time-consuming. This drawback can be reduced by using counting software.

The study concerned highlights the difficulties encountered when observing water samples and identifies the errors that can occur when applying this method. Despite the prior removal of organic matter (MO), MO remains a significant source of interference. MO causes either an overestimation because it fluoresces in the same way as MPs.

Observations confirms that this method has proven useful in the context of an exploratory study as an initial approach to determining the presence of microplastics in raw water and effluent from treatment plants. Analytical methods can provide more precise results, for example microFTIR or pyrolysis GC-MS. These techniques are more expensive, but provide more accurate data on the presence of MPs, including the type of plastic, the quantity and the concentration in the sample. More effective is the preparation sample phase, more accurate will be the MPs measure. There is a real need for CRM based on aged plastics in order to calibrate measurement methods more accurately.

3.18.P-Mo201 Development of a High-Resolution Analytical Method for Detecting Biodegradable Microplastics (>20 µm) in Surface Waters and Sediments Using Micro-FTIR Imaging

Yutaka Kameda, Chiba Institute of Technology, Japan

Production and commercial use of biodegradable plastics—including polylactic acid (PLA), polyhydroxybutyrate (PHB), polybutylene adipate terephthalate (PBAT), and polybutylene terephthalate (PBT)—have expanded rapidly as policy-driven substitutes for traditional polyolefins. In Japan, for example, agricultural films, seedling pods, and protective field materials are increasingly manufactured from these polymers, and governmental guidelines explicitly encourage their adoption to mitigate polyolefin-derived MP emissions to marine ecosystems. Biodegradable polymers are commonly assumed to mineralize into carbon dioxide and water via hydrolysis and microbial activity within soil or compost environments over timescales ranging from months to several years. However, emerging evidence suggests that their degradability in aquatic environments—including surface waters, sediments, and low-nutrient marine systems—may be substantially reduced. Several recent experimental and field studies indicate that these materials may persist for extended periods, and in some cases fragment into microplastic forms more rapidly than conventional polymers. This raises the possibility that biodegradable MPs may exhibit higher environmental mobility, broader dispersal potential, and distinct exposure-based ecological risks compared with traditional microplastics. Despite these concerns, virtually no systematic monitoring data exist regarding the environmental occurrence, distribution, or physicochemical characteristics of biodegradable polymer-derived MPs in aquatic systems. To address this critical gap, this study proposes and validates a high-resolution analytical workflow capable of detecting and identifying biodegradable MPs >20 µm in both surface water and sediment samples. The method integrates automated particle isolation with micro-Fourier transform infrared imaging, enabling polymer-specific mapping, size determination, and compositional classification of PLA, PHB, PBAT, and PBT particles with high reproducibility and spectral accuracy.

This presentation describes the development, optimization, and application of this analytical approach and discusses its potential for establishing baseline occurrence datasets and supporting future environmental risk assessments of biodegradable microplastics in freshwater and marine ecosystems.

3.18.P-Mo202 Biodegradability of Polymers in Aquatic Test Systems: ISO 14852 - Feasibility Study for Different Concentrations of Test Item and Inoculum

Andrea Brunswik-Titze, Jessica Buehler and Marie Canon, Hydrotex GmbH, Germany

Polymers are a product group that is increasingly becoming the focus in the topic of biodegradability and persistency. Due to their broad spectrum of properties, both synthetic and natural polymers play essential roles in everyday life. Guideline EN ISO 14852: Determination of the complete aerobic biodegradability of plastic materials in an aqueous medium — Method using analysis of the released carbon dioxides (July 2021) is one out of several to proof biodegradability of polymers in aquatic test systems. According to the Official Journal of the European Union, Entry 78, the EN ISO 14852 is one of the permitted test methods, to demonstrate that the polymer is degradable (group 4, three compartments).

The ISO 14852 guideline follows the OECD 301B guideline very closely in terms of testing principles, but the permitted concentration range of the test concentration and inoculum concentration is much larger (test concentration: 30 - 2000 mg L⁻¹ TOC (OECD 301B: 10 - 20 mg L⁻¹ TOC), inoculum concentration: 30 - 1000 mg L⁻¹ dry solids (OECD 301B: 30 mg L⁻¹ dry solids). Furthermore, according to the Official Journal of the EU, the test duration may be extended up to six months.

According to a ring test mentioned in the ISO Guideline, e.g. CO₂ evolution has only been determined in the

lower inoculum concentration range of 30 mg L⁻¹ dry solids. The study results presented here are intended to show the extent to which the range of permitted concentration levels (test item and inoculum) and test duration can be exploited while still complying with the validity criteria like CO₂ evolution in the blank controls or variation between the replicates. The results are from initial tests carried out with a water-soluble polymer, testing three different test item concentrations and three different inoculum concentrations with prolonged test duration. The resulting effect on the validity parameters required by the Guideline EN ISO 148521, but in particular on the biodegradability behaviour of the polymer, are presented.

3.18.P-Mo203 Fate of microplastic carbon: UV-radiation enhanced biodegradation of polyethylene and polystyrene traced with ¹³C isotopes in freshwater and Baltic Sea water

Noora Risku¹, Jussi Vesamäki¹, Benjami Laine¹, Anssi Vähätalo¹ and Sami Taipale², (1)University of Jyväskylä, Finland, (2)Department of Biological and Environmental Science, University of Jyväskylä, Finland

Plastic pollution is perhaps among the most visible markers of human-driven environmental change in the Anthropocene. While plastic persists in the environment, it also fragments into micro- and nanoplastics that can eventually undergo microbial biodegradation to CO₂ and biomass. This disintegration depends on environmental factors like UV light and microbial communities. While these factors are recognized, their relative contributions to plastic degradation remain poorly quantified, especially in less-studied environments like freshwater and brackish waters. We used ¹³C-labelled polyethylene (PE) and polystyrene (PS) microplastics along with ¹³C-labelled starch as a positive control, to investigate plastic biodegradation and carbon pathways in humic lake water and Baltic Sea water over two months. Prior to incubation, labeled microplastics were irradiated in a solar simulator, with UV-A and UV-B daylight spectrum, corresponding to one summer of natural solar radiation in the Northern Hemisphere. Stable-isotope analyses of CO₂, dissolved organic carbon (DOC), dissolved inorganic carbon (DIC), and microbial phospholipid fatty acids (PLFA) enabled precise quantification of plastic biodegradation and tracing carbon pathways. Additionally, we conducted microbiome analysis with 16S rRNA and analyzed microbial enzyme activity. UV exposure had a significant and systematic effect on plastic biodegradation in both waters, with largest response observed for PS in lake water. A notable fraction of labeled carbon resulted in DOC, indicating leaching before microbial assimilation. DOC from both plastic and starch was higher in Baltic Sea water than in lake water, possibly suggesting less efficient microbial uptake and processing in the brackish environment. Overall, both UV-light and water type affected plastic biodegradation rate, but UV-light had a more profound effect.

3.18.P-Mo204 Effects of Climate zones on plastic film degradation – Arctic to Tropic

Karin Mattsson¹, Juliana Aristéia de Lima², David Lecchini³ and Marc Metian⁴, (1)Marine Sciences, University of Gothenburg, Sweden, (2)University of Gothenburg, Sweden, (3)Laboratoire d'Excellence 'CORAIL', French Polynesia, (4)IAEA Marine Environment Laboratories, Monaco

Plastics are recognized as an environmental threat and have been detected all over the planet. Plastics in the environment will degrade and fragment due to physical, chemical and/or biological forces, creating smaller-sized particles, including micro- and nanoplastics. Information regarding how plastic degrades and fragments in the environment is lacking.

Polyethylene (PE), Polypropylene (PP), and Polylactic acid (PLA) plastic film were produced from pellets without adding additives. The films with a thickness of 40–50 µm were exposed to summer outdoor conditions for 46 days in different climate zones, including Arctic, Tropic, Nordic, and Mediterranean zones. After exposure, the films were analyzed using Fourier Transform Infrared Spectroscopy (FTIR), tensile strength, and imaged using Scanning Electron Microscopy (SEM).

Preliminary results indicate the highest degradation for PP followed by PE, and there is no sign of degradation for PLA in the tested conditions. Moreover, we see a relation between temperature, sun intensity and the level of degradation.

3.18.P-Mo205 Environmental Aging and Cellular Interactions of Biodegradable Microplastics from PLA and PBS

Konstantin Malafeev¹ and Susanna Miettinen², (1)Tampere University, Faculty of Engineering and Natural Sciences, Tampere Institute for Advanced Study, Finland, (2)Tampere University, Adult Stem Cell Group, Faculty of Medicine and Health Technology, Finland

Biodegradable polymers such as polylactic acid (PLA) and polybutylene succinate (PBS) are increasingly used as alternatives to conventional plastics. However, like other polymers, they may fragment into biodegradable microplastics (BioMP) during the degradation process when exposed to environmental conditions. Their aging behavior and potential interactions with living cells remain insufficiently understood.

This study investigated how environmental aging influences the structural, thermal, and chemical properties of BioMP generated from PLA and PBS, and how aged particles interact with human fibroblasts in vitro. PLA and PBS pellets were ground into ~1 mm particles, and the grinding process increased their crystallinity. The crystallized BioMP were subjected to accelerated aging combining UV exposure (855 MJ/m²), a black standard temperature of 60 °C, and controlled humidity. Particle properties were analyzed using differential scanning calorimetry (DSC), Fourier-transform infrared spectroscopy (FTIR), thermogravimetric analysis (TGA), and scanning electron microscopy (SEM).

To evaluate biological interactions, aged BioMP were tested in WI-38 fibroblasts proliferation and viability assay. This model enabled assessment of cell responses to particles that had undergone different aging conditions. Under the tested conditions, aging did not lead to detectable changes in the thermal transitions, chemical structure, or morphology of PLA and PBS BioMP. Preliminary in vitro results with WI-38 fibroblasts similarly indicated that aging did not influence the cellular response, as cells proliferated equally in the presence of both initial and aged samples over the 7-day experiment. These findings describe the behavior of PLA- and PBS-derived BioMP under specific laboratory conditions and provide a basis for future studies exploring broader environmental scenarios, extended aging periods, additional biological models, as well as the potential influence of additives and supramolecular structure on BioMP formation, aging, and biological interactions.

3.18.P-Mo206 Aged Biobased Microplastics Release Toxic Compounds that Impair Early Algal Development

Simon B. Redlich¹, Paula Walz², Marius Hermesdorf², Laura Calderón-Rodríguez³, Marcus Franke², Desirée Leitschneider², Quirina Roode-Gutzmer², Felix H. Schacher³, Michael Stelter⁴, Thomas Wichard¹ and Patrick Bräutigam¹, (1)Friedrich Schiller University Jena, Institute of Inorganic and Analytical Chemistry, Germany, (2)Friedrich Schiller University Jena, Institute of Technical Chemistry and Environmental Chemistry, Germany, (3)Friedrich Schiller University Jena, Institute for Organic Chemistry and Macromolecular Chemistry, Germany, (4)Friedrich Schiller University Jena, Institute of Technical Chemistry and Environmental Chemistry, Center for Energy and Environmental Chemistry, Germany

Biobased plastics are increasingly adopted as alternatives to petroleum-based polymers due to their perceived environmental benefits. However, their degradation in marine environments may generate unknown transformation products with potential ecotoxicological relevance. This study examines how photochemical aging affects the toxicity of biobased microplastics and their released degradation compounds toward early developmental stages of *Ulva mutabilis*, a representative of the widely distributed *Ulva* genus that contributes to coastal primary production and nutrient cycling.

Microplastic particles of polylactic acid, polyhydroxybutyrate and cellulose acetate (1.125 mm) were aged under simulated sunlight in artificial seawater, and both particles and leaching extracts were tested in standardized algal bioassays. Toxicity was assessed using survival rate and chlorophyll a fluorescence of developing gametophytes. To further explore potential degradation-derived compounds, leaching extracts of aged cellulose acetate were analyzed using high-resolution mass spectrometry.

All polymers exhibited intrinsic toxicity, which substantially increased following aging. Photodegradation reduced median effect concentrations by factors of 4 to more than 10, with aged cellulose acetate producing the most toxic responses at < 1 mg/mL levels. High-resolution mass spectrometry revealed that aged cellulose acetate released a markedly broader suite of dissolved organic compounds than its nonaged counterpart, including numerous low molecular weight substances absent prior to aging. The emergence of these newly formed degradation products coincided with strong toxicity responses, indicating that transformation products, rather than solely pre-existing compounds, play a key role in the observed effects. Furthermore, toxic substances continued to leach after photodegradation had ceased, demonstrating persistent release beyond the exposure window.

These results demonstrate that biobased polymers can pose polymer-specific hazards after UV aging and challenge the assumption that biodegradability equates to ecological safety. The findings highlight the need to incorporate aging-related transformation products into environmental risk assessment of bioplastics and suggest

that regulatory evaluation should consider both inherent toxicity and degradation-dependent leaching in marine environments.

3.18.P-Mo207 Does Environmental Weathering Alter the TED-GC/MS Fingerprints of Microplastics?
Sevda Eryilmaz Soydan¹, Patrick Bauerlein², Merle de Kreuk³ and Kim Maren Lompe⁴, (1)Delft University of Technology and KWR Water Research Institute, Netherlands, (2)KWR Water Research Institute, Netherlands, (3)Delft University of Technology, Netherlands, (4)Delft University of Technology, Delft, Netherlands

Microplastic (MP) particles present in the environment exhibit considerable variability in size, morphology, and chemical composition due to the processes of aging and weathering. This variability complicates the analytical detection and identification of these particles, posing challenges for researchers and environmental monitoring efforts. Aging processes such as UV exposure, oxidation, mechanical abrasion and biological activity modify the physical and chemical properties of polymers, so that environmental MPs differ markedly from pristine reference materials. While thermoanalytical techniques have been used to study polymer aging, most work has focused on idealised systems and does not capture the complexity of real environmental samples. In this study, we apply thermal extraction–desorption gas chromatography–mass spectrometry (TED-GC/MS) in combination with laser-direct infrared (LDIR) imaging to pristine and environmentally weathered polymers (PS, PE, PET, PA-6,6, ABS, PVC, PP, CR) in order to (i) quantify the impact of weathering on thermal degradation kinetics and fingerprint intensity and (ii) assess how these changes affect the robustness of fingerprint-based polymer identification in complex matrices. Polymers were exposed to natural outdoor conditions using four different weathering procedures, including deployment on a rooftop and in a freshwater pond, with sampling after 3 and 6 months. Pristine and weathered polymer samples were subsequently characterised by TED-GC/MS and LDIR, and the resulting datasets were compared. The approach allows us to link changes in thermal degradation behaviour to alterations in chemical fingerprints and to evaluate to what extent environmental aging compromises, or preserves, the diagnostic value of TED-GC/MS for MP identification.

3.18.P-Mo208 Mapping the European Microplastic Landscape: Regional Emission Signatures, Pathway Effects, and the Mass-Number Discrepancy
Yichen Sun¹, Jikke van Wijnen² and Ad M. J. Ragas³, (1)Environment Science, Radboud University, Netherlands, (2)Open University, Netherlands, (3)Environmental Science, Radboud University, Netherlands

Mitigating microplastic pollution requires comprehensive, source-specific baselines that capture the distinct structural drivers across different geographies. This study presents a harmonized emission inventory for the EU-27, quantifying releases from seven major sources, spanning transport (tyres, road markings), industry (pellets), and consumer products (textiles, paints, scrubbing agents), using a systematic "Activity Level × Emission Intensity" framework. We estimate total annual emissions at 877 kt (536–1429 kt), corresponding to a per capita emission of 1.96 kg/year. On a mass basis, emissions are unequivocally dominated by tyre wear particles (87%) and pre-production pellets (7%), highlighting the critical footprint of the transport and industrial sectors. However, a paradigm shift occurs when emissions are assessed by particle count: textile microfibers emerge as the overwhelmingly dominant source (>99%), underscoring a fundamental disconnect between mass-based inventories and particle-driven ecological risks. Spatially, we identify distinct regional emission signatures, such as climate-induced road abrasion hotspots in Nordic countries and industrial pellet leakage in Western Europe. Furthermore, modeling of environmental pathways reveals that national wastewater infrastructure plays a critical role in mediating aquatic pollution; notably, Italy and France emerge as the largest contributors to surface water loads despite Germany being the largest generator. These findings demonstrate that a single metric is insufficient for risk assessment. We advocate for a dual-metric policy approach (mass and number) and regionally tailored interventions to effectively mitigate the diverse microplastic burden across Europe.

3.18.P-Mo209 Microplastics concentration in outdoor air: detection, quantification, identification

Carmen Wolf^f, Aline-Kathrin Andert¹, Mahleh Eghbalinejad², Christine Kube¹, Christian Laforsch², Martin G.J. Löder² and Anke Nölscher³, (1)IUTA e.V., Germany, (2)University Bayreuth & BayCEER, Germany, (3)FZ Jülich, Germany

Research on atmospheric microplastics (MP) remains limited compared to aquatic and soil studies. Early work relied mainly on particle-based spectroscopic polymer identification and passive sampling, reporting deposition rates of 29–1008 particles/m²/day, but long-term datasets are scarce. Compared to spectroscopic particle-based techniques, thermoanalytical methods offer faster quantification but with lower sensitivity.

This project aims to measure, quantify, and identify airborne MP and its sources using PM10 filter and deposition samples from rural background stations. Sampling is conducted every 2 weeks over two years at sites operated by the German Federal Environment Agency, representing coastal, lowland, forest, upland, and alpine environments. Deposition samples are collected at six stations using stainless-steel passive samplers, while PM10 samples are taken at three stations with small filter devices. Sampling began in November 2025, with first analyses scheduled for early 2026.

Sample preparation focuses on reducing matrix components that may interfere with detection. Deposition samples are sieved (<5 mm) and filtered (0.8 µm). If high amounts of pollen or organic debris are present, samples are gently dried and subjected to oxidative digestion. For PM10 samples, a key challenge is separating particles from the filter material; this is achieved through density separation using sodium iodide solution (1.8 g/cm³), allowing lighter MP particles to float and be isolated.

Analysis is carried out using thermo-extraction desorption gas chromatography–mass spectrometry (TED-GC-MS). This method enables identification of polymers, quantification of their mass fractions, and detection of tyre abrasion—which is difficult to assess with spectroscopic particle-based methods.

First results of these measurements will be presented along with the monitoring and sample preparation strategy.

3.18.P-Mo210 Global Review of Microplastic Occurrence, Sources, and Methodological Gaps in Mountain Ecosystems

Magdalena Vanek¹ and Heinrich Dahms², (1)University of Innsbruck, Italy, (2)Eurac Research, Italy

Abundant even in remote mountain regions, yet their occurrence, sources, and impacts remain poorly understood. Mountainous ecosystems are highly vulnerable to climate-driven changes and anthropogenic pressures, making accurate monitoring essential. We conducted a systematic review of 70 peer-reviewed studies covering more than 900 sampling sites across global mountain systems to synthesise patterns of microplastic occurrence, sampling approaches, and methodological discrepancies. Water and sediment were the most studied compartments, while snow, ice, biota, and atmospheric fallout remain underrepresented. Reported microplastic abundances vary widely, often correlating with human accessibility rather than elevation alone. Analytical methods differ across matrices, including extraction techniques and polymer identification protocols, limiting comparability. Most studies report particle shapes and sizes, but fewer provide polymer composition or standardised units, complicating cross-study synthesis. Human Footprint Index (HFI) analysis revealed a strong bias toward pressured landscapes: ~75 % of studied sites were urbanised (HFI > 7), ~13 % moderate (4–7), and only ~9 % remote (HFI < 3), indicating that >90 % of investigations occurred near anthropogenically impacted areas. Tourism and atmospheric deposition were cited mostly as dominant sources at high altitudes. Our findings highlight critical gaps: lack of studies in several continents, non-harmonised methodologies and limited multi-compartment sampling. Addressing these gaps through standardised protocols and integrated monitoring is essential for assessing cumulative risks and informing conservation strategies for mountain ecosystems, which provide vital biodiversity and water resources for human health.

3.18.P-Mo211 Mitigating Microplastic Loads in Wastewater Treatment Plants Serving Alpine streams

Magdalena Vanek¹, Heinrich Dahms², Francesca Vallefuoco³, Daniele Ricaldone³, Birgit Sattler⁴ and Roberta

Bottarin³, (1)University of Innsbruck, Italy, (2)EurAc Research, Italy, (3)Eurac Research, Italy, (4)University of Innsbruck, Austria

Alpine streams, often considered pristine, are increasingly impacted by climate change, land-use alterations, and emerging pollutants such as microplastics (plastic particles smaller than 5 mm). These particles originate mainly from wastewater effluents, urban runoff, and agricultural activities, posing ecological risks to freshwater ecosystems. However, monitoring microplastics remains difficult due to variations in sampling methods and reporting units, which limit comparability across studies. To improve monitoring and evaluate mitigation strategies, we tested a novel filtration system in three wastewater treatment plants (WWTPs) in South Tyrol, Italy, using a Before-After-Control-Impact design. We combined a rapid habitat sampling method with a microplastic discharge unit (MDU) calculation to assess changes in microplastic abundance in river water, sediment, and macroinvertebrates upstream and downstream of WWTPs before, during, and after filter installation. Microplastics were detected in all compartments, with fibres as the dominant type. Preliminary results indicate spatial differences in concentrations and suggest that discharge variability influences reported abundances. The filtration system demonstrates potential for mitigating microplastic loads, supporting compliance with the new EU Urban Wastewater Treatment Directive. These findings contribute to improving monitoring approaches and inform strategies to protect Alpine freshwater ecosystems, which are biodiversity hotspots and providers of essential ecosystem services.

3.18.P-Mo212 Quantifying Loads and Removal Efficiencies of Elastomeric Particles, Including Tire- and Road-Wear Particles, in Two Municipal Wastewater Treatment Plants in Japan

Yutaka Kameda and Emiko Fujita, Chiba Institute of Technology, Japan

Understanding the environmental behavior and pathways of tire and road wear particles (TRWPs) in urban systems is essential for mitigating their discharge to aquatic environments. Previous studies indicate that urban road runoff can contain high concentrations of TRWPs, particularly during rainfall events. In cities with combined sewer networks, such runoff is transported to wastewater treatment plants (WWTPs), whereas in separate systems it may bypass treatment and enter receiving waters directly. In addition, other elastomer-derived particles, including degradation products of 6-N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD), are generated during the use and abrasion of rubber products. These fine particles can enter stormwater, atmospheric dust, and municipal wastewater even under dry conditions, suggesting continuous input to WWTPs irrespective of rainfall. Despite increasing concern, quantitative data on the loads, fate, and removal efficiencies of elastomer particles and TRWPs in WWTPs remain scarce. In particular, time-resolved measurements are lacking, hindering accurate estimation of emission factors and environmental transfer pathways.

In this study, influent and effluent waters from two WWTPs—one operating a combined sewer system and the other a separated system—were sampled hourly during dry weather using automated samplers. Fine particles (>20 µm) belonging to nine elastomer polymer classes, including TRWPs, were identified and quantified using a micro-Fourier transform infrared spectroscopy method developed for this study. Concentrations in sewage sludge were also measured to characterize partitioning behavior and assess retention during treatment. The resulting datasets provide new insights into temporal variability, influent loading trends, and polymer-specific removal efficiencies of elastomeric particles in contrasting wastewater treatment configurations. These findings improve understanding of the role of WWTPs in the urban lifecycle of rubber-derived particulate pollution and contribute essential parameters for predicting their fate in aquatic environments.

3.18.P-Mo213 Binding Properties of Heavy Metals on Tire and Road Wear Particles in the Aquatic Environment

Angus Rocha Vogel¹, Svetlana Swonarjow² and Wolf von Tümpling³, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Helmholtz Center for Environmental Research (UFZ), Germany, (3)Central Laboratory for Water Analytics and Chemometrics, Helmholtz Center for Environmental Research (UFZ), Germany

Tire wear particles (TWP) are an emerging environmental issue associated with growing ecotoxicological concern. In response the European Parliament has introduced the Euro 7 regulation, which will establish limits for tire abrasion. Simulations estimate that more than 100,000 tons of tire wear particles are released in Germany every year, representing roughly one third of all microplastics entering the environment. These

emissions are expected to rise due to increasing vehicle numbers.

Tire and road wear particles (TRWP), formed by friction between tires and the road surface, consist of elongated rubber particles (10–350 µm) that incorporate additional particles from the road. TRWP contain Zn (from the manufacturing process) as well as heavy metals like Cr, Ni, Cu, Cd and Pb, which originate mainly from road traffic. Rainfall mobilizes these composite particles and transport them into the aquatic environment via gullies and drainage systems, where TRWP may release incorporated heavy metals into the surrounding water, potentially making them bioavailable to aquatic organisms.

To assess the risk of heavy metal release from TRWP and their potential bioavailability, we applied a sequential extraction procedure (Community Bureau of Certified References, BCR) to TRWP samples collected from a highway tunnel and go-kart tracks. This extraction method includes three steps simulating different aquatic conditions: slightly acidic (readily available elements, aerobic, F1), reducing (metal oxides, anaerobic, F2), and oxidising (bound to organic matter, F3) and a residual fraction (F4).

TRWP from the Elbe tunnel exhibited high bioavailability of Cd and Zn (> 50% in F1), while Pb was predominantly mobilized under reducing conditions (> 70% in F2). The investigated trace elements followed the mobility ranking: Zn > Pb > Cd >> Cu > Co > As >> Ni > Cr. Furthermore, incubation of TRWP with river water from the Freiburger Mulde (high heavy metal concentrations) revealed that newly adsorbed Cd and Zn to TRWP from the surrounding water were only weakly bound and easily bioavailable (> 95% Cd, > 85% Zn). These findings indicate that TRWP can significantly influence the mobility and bioavailability of heavy metals in aquatic systems. This has important implications for evaluating ecological risks and for understanding the role of TRWP as vectors transporting toxic metals to aquatic biota.

3.18.P-Mo214 Microplastics Monitoring in the Dutch Rivers - Small Temporal and Spatial Variations in Microplastic Concentrations in Suspended Matter

Christa van Oversteeg and Ivo Freriks, Rijkswaterstaat, Netherlands

Over the past 5 years, Rijkswaterstaat developed and validated sampling and analysis methods for the monitoring of microplastics in the Dutch rivers. To sample suspended particulate matter (SPM), including microplastics, from rivers in a representative way, the performance of two sampling methods, both suited to sample large water volumes, was evaluated. First, time-integrated samples were taken by continuously pumping water through a sedimentation box for periods of 2 to 4 weeks. The performance of the method was evaluated by sampling with 2-4 set-ups at the same location during the same period, showing good reproducibility and reproducible retention of SPM. In addition, the influence of sampling depth was studied by sampling at different depths (10-290 cm). The second sampling method studied was SPM sampling using a continuous flow centrifuge. With this discrete sampling method, large water volumes can be sampled in short periods of time (hrs). The composition (particle size and microplastic composition) of SPM collected by both methods were compared and showed only small variation. Particle size distributions of the SPM sampled by sedimentation box or flow centrifuge, from different sampling locations and different sampling periods were similar: over 90% of the sampled SPM was smaller than 75 µm. Large, visible microplastics were rarely found.

Microplastic concentrations in samples collected at multiple locations along the Dutch sections of the Meuse, Rhine and Scheldt were measured using thermal extraction desorption gas chromatography – mass spectrometry, using a validated method with a reproducibility below 20%. In all samples, polyethylene and styrene-butadiene rubber were the most abundant polymers. Polypropylene, polystyrene and natural rubber were also detected at concentrations above the limit of quantification in most samples. Microplastic concentrations in SPM sampled by time-continuous sampling with the sedimentation box or discrete sampling with the flow centrifuge showed only small variations. While SPM concentrations (mg/L) show large variations in time and space, microplastic concentrations within the SPM (g/kg) show only minor temporal and spatial variations. No correlation between microplastic concentration and river discharge was found. These findings suggests that SPM based monitoring could provide a reliable approach to assess microplastic pollution in riverine environments.

3.18.P-Mo215 Polymer-Specific Characterization of Microplastics (>20 µm) in Surface Waters of the Klang River, Malaysia, and Their Estimated Flux to the Coastal Ocean

Emiko Fujita¹, Yutaka Kameda¹, Yuka Motohashi¹, Gakushi Fujimura¹, Mariatti Jaafar², Danial Shafiq², Amir Muhammad² and Asiah Binti Mahamood², (1)Chiba Institute of Technology, Japan, (2)Universiti Sains Malaysia, Malaysia

Rivers are now recognized as major pathways transporting land-based microplastics (MPs) to marine ecosystems, yet quantitative field measurements describing their fluxes—particularly from large tropical rivers in rapidly developing regions—remain limited. Southeast Asia, where plastic consumption, population density,

and watershed connectivity converge, represents a critical but undercharacterized source region. To address this gap, we conducted a systematic assessment of the abundance, polymer composition, and size distribution of MPs in the surface waters of the Klang River, Malaysia, and developed a first-order estimate of their export flux to the adjacent coastal sea.

Surface water samples were collected at 19 sites along a ~90 km transect spanning the system from the upper reaches of the Batu River, through the midstream Klang River corridor, to the tidal estuary at Port Klang. Sampling was conducted during the local dry season (June 2025) to capture low-flow transport conditions. At each site, 10–50 L of surface water were filtered in situ using a 10 µm plankton net, and river discharge was quantified via the velocity–area method based on cross-sectional geometry and float-derived surface flow velocity.

In the laboratory, retained material was rinsed from the net, subjected to oxidative digestion using hydroperoxide solution, and subsequently processed by density separation in sodium iodide. The supernatant was recovered in triplicate, combined, and filtered onto silicon membranes. Particles larger than 20 µm were analyzed using micro-Fourier transform infrared (micro-FTIR) imaging spectroscopy to identify 16 polymer types, enabling polymer-specific quantification.

Near the river mouth during low tide, surface water contained 38 MP particles L⁻¹. When scaled using discharge measurements, this concentration corresponds to an estimated export flux of 2.3×10^7 particles s⁻¹, equivalent to approximately 30 g s⁻¹ of plastic transported toward the coastal ocean. These results demonstrate that a single urban river system can deliver tens of millions of microplastic particles per second under typical hydrological conditions, highlighting the significance of riverine pathways in sustaining marine plastic pollution. The findings underscore the urgency of improving watershed-scale waste management and monitoring frameworks in rapidly urbanizing tropical regions.

3.18.P-Mo216 SPATIOTEMPORAL PATTERNS IN MICROPLASTIC MORPHOLOGY AND COLOR IN THE PARAÍBA DO SUL RIVER AND THEIR ECOLOGICAL IMPLICATIONS

Bárbara Geraldino, Patrícia dos Santos and Daniele Maia Bila, Universidade do Estado do Rio de Janeiro, Brazil

Microplastic ingestion has been documented across various trophic levels. Mechanisms include misidentification of food and trophic transfer. Physical characteristics such as size, shape, color, and buoyancy significantly influence the likelihood of interaction. The present study characterizes the morphology and color of microplastics (MPs) in the Paraíba do Sul River during sampling campaigns in May and September 2025. The study focuses on spatiotemporal variation and the potential ingestion risk to aquatic biota.

Microscopic analysis identified particles ranging from 50 to 500 µm, including fragments, fibers, films, foams, and granules. In May, fragments constituted 66% of the total, while fibers accounted for 22.7%. Transparent, black, and blue particles were most frequently observed. Sampling points 8, 9, and 10 exhibited the highest particle counts (150, 121, and 115, respectively). Notably, downstream locations displayed higher concentrations but reduced color diversity. In comparison, the September sampling revealed a substantial increase in the total amount of microplastics compared with May. This rise can be attributed to periods of intense rainfall, which elevate microplastic loads in water bodies by mobilizing accumulated urban waste. Consequently, between the first and second sampling campaigns, the total number of microplastics increased markedly across all sites, rising from 26–150 particles per point to 87–230 particles per point. There was substantial growth in all morphological categories, with pronounced increases in transparent (+75.2%) and black (+101%) particles, and the emergence of orange particles, which were absent in the first campaign. These observed spatiotemporal changes suggest hydrodynamic, anthropogenic, and seasonal influences. Particles in this size range are ingested by zooplankton, mollusks, aquatic insect larvae, and small fish. This may interfere with feeding, promote satiety, disrupt digestion, and hinder growth. Higher concentrations downstream show that these areas accumulate pollutants. Different polymers show distinct ingestion and retention patterns. Biomagnification speeds contaminant transfer and increases ecological risks at higher trophic levels.

3.18.P-Mo217 Plastic pollution in urban freshwater systems: characterization in two contrasting lagoons of Buenos Aires, Argentina.

Yamila Belén Díaz¹, Cinthia Terlecki¹, Luz Allende¹, María Soledad Fontanarro², Javier Montserrat¹ and Giselle Berenstein³, (1)Universidad Nacional de General Sarmiento, Argentina, (2)Universidad Nacional del Centro de la Provincia de Buenos Aires (UNCPBA)- CONICET, Argentina, (3)Rheinland-Pfälzische Technische Universität / Universidad Nacional de General Sarmiento/ CONICET, Germany

Plastic pollution in freshwater systems is an emerging environmental issue, particularly in densely populated urban areas. Urban lakes and lagoons in Argentina have been shown to contain microplastics, but integrated

assessments of macro- and microplastics, their weathering state, and associated risks remain scarce. This study characterizes plastic pollution in two contrasting urban lagoons in Buenos Aires Province: one highly urbanized lagoon in the Buenos Aires Metropolitan Area (AMBA) (high anthropogenic pressure, HU) and one moderately urbanized lagoon in Tandil (lower anthropogenic pressure, LU). The objectives were to: (i) monitor the presence and polymer composition of macro- and microplastics; (ii) quantify the degree of surface weathering of collected plastics; (iii) assess the ecological risk of these lagoons in relation to plastic pollution. Macro- and microplastics were collected from the water column and littoral zones, classified by morphology and polymer type, and analysed using Fourier Transform Infrared Spectroscopy with Attenuated Total Reflectance (FTIR-ATR) to calculate carbonyl (CI), hydroxyl (HI), and silicon (SI) indices as proxies for environmental weathering. An ecological risk index for microplastics (RI) was estimated for each lagoon to quantify plastic-related ecological threats.

The HU lagoon showed higher contamination, with microplastic abundances of 9 ± 4 items/L and macroplastics of 0.6 ± 0.3 items/m², compared with 1.4 ± 0.7 items/L and 0.1 ± 0.1 items/m² in the LU lagoon. Polyethylene (PE), polypropylene (PP), and polyethylene terephthalate (PET) were the most abundant macroplastic polymers, with PE exceeding 35% in both lagoons. PP was the predominant polymer among microplastics in both lagoons. PE macroplastics from HU exhibited significantly higher weathering, reflected in elevated CI, HI, and SI values, whereas no consistent differences were detected for PP or PET. The average ecological risk index for microplastics was 38.7 ± 23.4 (low to high risk) in LU and 134.0 ± 76.8 (high to extremely high risk) in HU, highlighting the influence of urbanization on both plastic loads and associated risks.

These findings show that urban intensity shapes the quantity, composition, and degradation state of plastic debris in small freshwater systems and provide a risk-based framework to inform monitoring, mitigation, and management of plastic pollution in urban water bodies across South America.

3.18.P-Mo218 How Do Microplastics Distribute Through Freshwater Ecosystems? The Search for a Bioindicator Species

Heinrich Dahms¹, Shako Senyolo², Simone Dahms-Verster³ and Richard Greenfield², (1)EurAc Research, Italy, (2)University of Johannesburg, South Africa, (3)University of the Witwatersrand, South Africa

Microplastics (MPs) have been detected in the freshwater ecosystems globally. Microplastics are tiny synthetic materials usually between 5 mm to 0.01 mm. Although research on MPs in freshwater ecosystems lagged behind that in the marine environment, this gap has narrowed over the last decade. When MPs enter freshwater environments, they do not simply transport downstream; MPs' distribution is impacted by the naturally heterogeneous physical characteristics of rivers. Abiotic components, such as depth, discharge, velocity, and sediment grain size, and biotic components, such as vegetation and biota, can all affect how MPs distribute through a river system. This in turn changes the MP load available to biota and their ability to ingest higher quantities of these particles. Microplastics have also been detected in almost all major animal groups, including freshwater invertebrates, fish, reptiles, amphibians, birds, and mammals. Globally, fish have been among the most investigated groups, with over 100 species studied. This group was closely followed by invertebrates, then birds, and, lastly, reptiles, mammals, and amphibians, which were the least investigated groups. Concentrations found within biota varied greatly from 1 particle per animal to over 50 particles. The foundational information of animals that ingest MPs is key to determining whether a species can be considered a bioindicator for MPs in freshwater environments. Given the wide variety of methods for sampling MPs in rivers, a bioindicator species might bridge the gap created by differences in sampling and reporting methods. Currently, fish species such as *Cyprinus carpio* and *Oreochromis niloticus*, which are widely distributed, omnivorous, invasive, and easily identified, have been found to ingest MPs across multiple continents and could be good bioindicator species. Other animals, such as chironomid larvae, oligochaetes, freshwater mussels, clams, and other filter-feeding invertebrates, have also been suggested as bioindicator species. With MP research ready to turn to more monitoring-style research, a good bioindicator species could yield more representative and comparable data across study locations globally; however, more research is required. Final considerations, such as increased research on underrepresented groups, such as birds, amphibians, and reptiles, must be made to understand their interactions with MPs, which is still unknown.

3.18.P-Mo219 Assessment of Polymer-Specific Deposition Dynamics of Microplastics (>20 µm) Using Sediment Traps in a Eutrophic Lake

Yutaka Kameda and Emiko Fujita, Chiba Institute of Technology, Japan

The vertical transport and deposition dynamics of microplastics (MPs) represent a critical yet insufficiently resolved component of their environmental fate in aquatic ecosystems. Understanding when, how, and which polymers transition from the water column to benthic environments is essential for predicting long-term accumulation, ecological exposure, and biogeochemical implications. Although most synthetic polymers—particularly polyolefins—exhibit densities comparable to or lower than freshwater and seawater, numerous studies now suggest that aggregation processes can facilitate particle settling. Interactions with suspended inorganic minerals, microbial biofilms, phytoplankton, and extracellular polymeric substances can modify the physicochemical properties of MPs, effectively increasing particle density, hydrodynamic drag, and settling efficiency. However, key knowledge gaps remain regarding the polymer-specific characteristics of MP aggregates—including their size distributions, composite densities, and morphological features—that govern deposition rates and fluxes across diverse aquatic settings. Despite growing concern, empirical field observations of MPs >20 µm settling in natural waters remain limited, particularly in eutrophic lake systems where elevated primary productivity and high organic matter concentrations may accelerate aggregation and deposition relative to marine systems. Eutrophic lakes therefore represent ideal natural laboratories to assess polymer-dependent sedimentation behavior under biologically enhanced particle collision environments. In this study, we present results from a field monitoring program designed to quantify the deposition behavior of MPs larger than 20 µm in one of Japan's most eutrophic freshwater lakes. Sediment traps were deployed at 1.0, 2.5, and 4.5 m depths and retrieved at two-month intervals to capture temporal variation in deposition fluxes. Retrieved particles were analyzed using micro-Fourier transform infrared imaging, enabling polymer-specific identification of 16 different materials. In addition to polymer classification, the workflow allowed measurement of size distributions of MP-containing aggregates and characterization of polymer-dependent deposition patterns.

3.18.P-Mo220 Polymer-Specific Density Distributions of Microplastic Aggregates Reveal Their Differential Settling Behaviors in Tokyo Bay Seawater

Yutaka Kameda and Emiko Fujita, Chiba Institute of Technology, Japan

Understanding the fate of microplastics (MPs) in marine environments remains challenging, particularly due to the limited availability of long-term, high-resolution observational datasets. A persistent discrepancy exists between global MP load estimates and concentrations reported by field monitoring programs. In particular, in situ quantification of settling fluxes and deposition velocities is technically difficult, as sediment-trap deployments require substantial cost, labor, and long-term maintenance. Consequently, many previous studies have relied on theoretical sedimentation models—most commonly Stokes-type equations—to infer MP depositional dynamics. However, these models require accurate measurements of particle size and effective density in situ, and such datasets are scarce, especially for MP-containing aggregates in coastal seawater. In this study, we present the first monitoring results characterizing both size distributions and in situ density spectra of MP-bearing aggregates (>20 µm) in the seawater of Tokyo Bay. Aggregates were collected using a 10-µm plankton net and subsequently fractionated into discrete density classes via cascade density separation using sodium iodide solution. Each density fraction was digested using a modified Fenton reaction, and MPs >20 µm were identified, quantified, and polymer-typed using imaging micro-Fourier transform infrared spectroscopy. Microscopic imaging prior to digestion enabled direct measurement of aggregate dimensions, providing pair-matched datasets of size, density, and polymer composition. Using these empirically derived values, polymer-specific deposition velocities were estimated based on theoretical settling models. The resulting deposition patterns were further compared with polymer compositions of MPs in seabed sediment samples from Tokyo Bay to evaluate consistency between predicted and observed depositional signatures. This integrated monitoring and analytical framework provides rare observational evidence for polymer-dependent settling behavior of MP-containing aggregates in a semi-enclosed coastal system and offers a methodological pathway to reduce uncertainty in global MP fate modeling.

3.18.P-Mo221 Half-century record of coastal microplastic fluxes (>20 µm) in a sediment core from Nanao Bay, Japan

Emiko Fujita¹, Yutaka Kameda¹, Shinya Ochiai² and Seiya Nagao², (1)Chiba Institute of Technology, Japan, (2)Kanazawa University, Japan

Microplastics (MPs, $\geq 20 \mu\text{m}$) preserved in dated sediment cores provide a means to reconstruct temporal trends in plastic contamination. We analyzed MPs in a gravity core collected from western Nanao Bay, a semi-enclosed coastal embayment on the Sea of Japan. The core was sliced at 1–2 cm resolution and dated using ^{210}Pb (CFCS model) with support from ^{137}Cs . After removal of organic matter and density separation, particles 20–5000 μm were collected on 5 μm silicon filters and identified by micro-FTIR imaging. For each slice, MP fluxes were calculated by multiplying dry-weight concentrations (items g^{-1}) by layer-specific dry mass accumulation rates ($\text{g cm}^{-2} \text{yr}^{-1}$). Across the 1960–2012 record, MP fluxes ranged from 4.2 to 122.4 items $\text{cm}^{-2} \text{yr}^{-1}$, which is within the range reported for microplastics in Great Lakes sediment cores.

Total MP fluxes in the Nanao Bay core increased from about 4.2 items $\text{cm}^{-2} \text{yr}^{-1}$ around 1960 to 45.8 items $\text{cm}^{-2} \text{yr}^{-1}$ around 1980, broadly paralleling the rapid growth of plastic production and use in Japan. In contrast, fluxes during 1990–2000 decreased to 11.3–16.1 items $\text{cm}^{-2} \text{yr}^{-1}$, similar to levels in the mid-1960s. This decline is consistent with changes in plastic consumption patterns in the catchment, the expansion of municipal wastewater treatment plants around 1990, improvements in solid-waste collection, and rising public concern about litter and waste management. Superimposed on these long-term trends, several core slices show fluxes approximately one order of magnitude higher than adjacent layers; these peaks coincide with years when major typhoons affected the Nanao Bay region, indicating short-term event-driven increases in MP delivery to the seabed.

Overall, the Nanao Bay record shows that temporal variability in MP fluxes to coastal sediments is broadly consistent with the historical trajectory of plastic production, and is also consistent with possible influences from patterns of use, wastewater and solid-waste management, public awareness, and episodic extreme weather events such as typhoons.

3.18.P-Mo222 Transformation Patterns of Environmental Plastic Pellets

Hanne Diels¹, Joaquim Sanctorum², Johan Blom³, Raewyn M. Town¹ and Ronny Blust¹, (1)ECOSPHERE, University of Antwerp, Belgium, (2)DynXLab, University of Antwerp, Edegemsesteenweg 202, Antwerp, Belgium,, Belgium, (3)SuPAR, University of Antwerp, Belgium

Since the 1970s the widespread presence of industrial plastic pellets have been observed in surface waters and beaches all over the world. In the port of Antwerp (Belgium), located in the Scheldt estuary, pellets are being unintentionally released whereafter they are exposed to a variety of environmental stressors (temperature, UV radiation, salinity, water, oxygen, biological activity, and mechanical stress) causing various patterns of physical and chemical degradation. Our aim is to identify transformation patterns of released pellets to better understand the mechanisms underlying their breakdown.

Plastic pellets were collected in the port area (road and roadside) and throughout the Scheldt estuary (riverbank, soil, water and sediment) between 2022 and 2025. Confocal microscopy ($n = 78$) and MultifileAnalyzer were used to examine the pellet's surface roughness. Micro-CT scanning ($n = 24$) and DragonFly World were used to examine the interior of the pellets.

Pristine pellets (polyethylene/polystyrene) from Antwerp producers were used as reference materials and showed clean-cut edges, smooth surfaces and texture lines. Four transformation patterns were identified: (1) accumulation of contaminants, (2) textural changes in terms of increased surface roughness or abrasion, (3) the formation of cracks and (4) the formation of internal holes. Environmental pellets showed higher surface roughness than pristine ones. Cylindrical pellets exhibited less uniform texture and less additional surface area compared to their pristine counterparts. Polystyrene pellets are more likely to release smaller particles due to texture abrasion, while polyethylene pellets lose smaller particles via external cracks.

Transformation processes start from the moment a pellet enters the environment. Material exchange occurs between the plastic and its environment: the pellet's chemical structure breaks down into micro- or nanoparticles, potentially releasing polymer additives, and environmental substances enter the pellet.

Degradation processes reinforce each other: increased surface roughness enhances the possibility of retaining contamination and the release of smaller plastic particles.

The next step in this research will be to determine the polymer types and the oxidation indices. This will allow us to better understand the polymer-specific breakdown mechanisms— both in terms of transformation patterns and chemical breakdown due to oxidation – in order to assess their potential risk.

3.18.P-Mo223 Polyolefin-based coated fertilizer fragments ($\geq 20 \mu\text{m}$) as microplastics in rivers and a coastal bay in Japan

Emiko Fujita and Yutaka Kameda, Chiba Institute of Technology, Japan

Polymer-coated fertilizers are increasingly used to reduce labour input and enhance nutrient-use efficiency through controlled nutrient release. In many formulations, fertilizer granules are encapsulated by a polyolefin-based shell that undergoes gradual degradation in soils and surface waters, allowing dissolved nutrients to diffuse outward over time. As the shell cracks and delaminates, coating fragments detach from the granules and can persist as microplastic particles. Coated fertilizers are therefore a plausible primary source of microplastics to agricultural soils and hydrologically connected waters. Yet, despite this concern, field observations that unambiguously identify microplastics derived from coated fertilizer coatings, particularly in the 20 µm size range, remain very scarce.

Chandra et al. (2019) estimated that coated fertilizers account for only about 0.25% of total fertilizer use globally and about 8–10% and 1% of fertilizer use in Europe and the United States, respectively. In Japan, an ageing agricultural workforce has driven demand for labour-saving fertilization practices, and the use of coated fertilizers is expected to increase accordingly. This trend heightens the need to understand the environmental fate of polyolefin coatings and their contribution to microplastic loads.

This study investigates the occurrence and abundance of polyolefin-based coated fertilizer fragments (20 µm) in riverine and coastal environments in Japan. Environmental samples were collected in September 2025 from four sites along the Kumaki River, one site along the Otsu River and one site in Nanao West Bay. For all six sites, the presence and abundance of polyolefin-based coated fertilizer particles >20 µm were confirmed and quantitatively assessed.

By providing site-resolved data on coating-derived microplastics in both rivers and a semi-enclosed coastal bay, this work identifies polyolefin-based coated fertilizers as a diffuse agricultural source of microplastics that directly links fertilization practices to microplastic contamination. These findings support the inclusion of coated fertilizer use and management in future source apportionment and risk assessments of microplastics in intensively farmed regions.

3.18.P-Mo224 Microplastic Formation from Biodegradable and Conventional Mulching Films: Soil Degradation Study

Sevil Vafadar Afshar¹, Majda Nikezić², Janja Vidmar², Dimitrios Savvas³, Filippa Maniour³, Nanna B. Hartmann⁴ and Konstantina Argyropoulou³, (1)Technical University of Denmark (DTU), Denmark, (2)Jožef Stefan Institute, Slovenia, (3)Agricultural University of Athens, Greece, (4)DTU Sustain, Technical University of Denmark (DTU), Denmark

Agricultural mulching films contribute significantly to microplastic contamination in soils. In this study, the degradation and release of microplastics from three mulching films were investigated over 180 days in a soil matrix under environmentally relevant conditions. Tested materials included two conventional LDPE films (black and transparent), one biodegradable PBAT/starch film. Pristine and UV-weathered forms of each film were included. Additionally, a field-weathered black LDPE film.

Degradation of plastic fragments > 2 mm was quantified via weight loss, while the soil fraction < 2 mm was collected for microplastic analysis. A method for extracting microplastics from soil was optimized by combining oleo-extraction with an additional density separation step. Extracted particles were characterized using FTIR and LDIR chemical imaging to determine their polymer composition, particle count, and particle size distribution.

After 180 days, biodegradable films showed the highest degradation (up to 15 % weight loss), whereas conventional films exhibited minimal fragmentation (< 5 %). UV pre-treatment slightly increased the fragmentation of biodegradable films. Microplastic analysis revealed higher particle counts from biodegradable mulching films compared to conventional mulching films.

These findings demonstrate that biodegradable mulching films degrade more rapidly than conventional mulching films, producing measurable microplastics under realistic soil conditions. Optimized extraction and characterization methods provide robust tools for quantifying microplastic generation and evaluating the environmental implications of biodegradable agricultural plastics.

3.18.P-Mo225 Challenges to determine polymers in soil by Py-GC/MS

Martin Hoppe¹, Georg Scheeder¹, Zacharias Steinmetz², Carmen Wolf³, Aline-Kathrin Andert³ and Kristof Dorau⁴, (1)BGR, Germany, (2)RPTU University of Kaiserslautern-Landau, Germany, (3)IUTA e. V., Germany, (4)MU, Germany

Plastics in the environment are a major global challenge of the 21st century. Large amounts enter the soil in various ways. Relevant entry paths include tire abrasion, sewage sludge, mulch films, and compost. Sample preparation and analysis of plastics, especially in the <1 mm fraction (SMPs, small microplastics), is subject to various analytical and methodological challenges.

The project “SOSMA” (soil sampling for microplastic analysis) investigated the entry of plastics into an arable soil (Cambisol) via the compost pathway. A total of 173 samples were analyzed for macroplastics (MaPs, >5 mm) and large microplastics (LMPs, 5-1 mm). A subset was examined for SMPs (<1 mm). First, the focus was on sample preparation and the determination of recovery rates using pyrolysis gas chromatography coupled with mass spectrometry (Py-GC/MS). The samples (master sample = 2 L, tested subsample 500 g) were treated with density separation and Fenton digestion after dry sieving. Cryogenic grinding was also performed for homogenization as the particulate plastics were inhomogeneously distributed in the samples after processing. The recovery rates of spiked plastics (polyethylene (PE), polyethylene terephthalate (PET), polypropylene (PP), polystyrene (PS)) were determined using Py-GC/MS from the solids and after solvent extraction. Second, both methods were applied to the unspiked soil samples.

Further homogenization by cryo-milling reduced the inhomogeneity for PP and PS. However, grinding may lead to a larger mineral surface area, which can result in lower recovery rates due to changed pyrolysis conditions (PE). The recovery of PET was at a low level, which is why no data interpretation is provided for PET. The recovery rates of the common three (PE, PP, PP; 0% - 225%) show partly acceptable but method and polymer specific results. Hence, no combination of methods (unmilled/ cryomilled; solid/ solvent extraction) provides the perfect result to determine all investigated polymers.

The results for the unspiked soil samples show higher polymer concentrations after solid matter measurement compared to the measurement after solvent extraction. More results regarding the unspiked samples will be available at the time of the conference. However, for a representative and reliable quantification of plastics in soils, it is necessary to better understand the polymer specific causes of sample preparation and matrix effects on the analysis results derived by Py-GC/MS.

3.18.P-Mo226 Down Profile Migration of Microplastics in Agricultural Soils Amended with Composted Municipal Solid Waste: Influence of Soil Type, Application Method and Temporal Dynamics

Nivetha Sivarajah¹, Matthew Tighe¹, Sara Bayat¹, Brian Wilson¹, Fiona Tang² and Susan C Wilson¹, (1)School of Environmental and Rural Science, University of New England, Australia, (2)Department of Civil and Environmental Engineering, Monash University, Clayton, Victoria 3800, Australia, Australia

Applying composted municipal solid waste (MSW) to agricultural soils can enhance soil health and crop productivity. However, the presence of microplastics (MPs) has raised concerns about potential adverse effects on soil systems and food security. Despite these concerns, the migration of MPs in different soil types, under different compost application methods and over temporal scales remains poorly documented. Our study focused on the vertical distribution of MPs derived from composted MSW applied to three soil types: silty loam, sandy loam, and clay. A controlled glasshouse column experiment was conducted using soil columns (0.85 m length × 0.15 m internal diameter). Composted MSW was applied at 50 t/ha using two methods: surface application and incorporation to 15 cm depth. Columns were watered to maintain 60% field capacity. Soil samples were collected at 5 cm depth intervals up to 50 cm at 12 and 18 months. The MPs were extracted using H₂O₂ (30%) digestion and ZnCl₂ density separation, then quantified and characterised using stereoscopic zoom microscopy. Surface application of composted MSW resulted in high retention (>44%) of MPs within the 0–5 cm layer across all three soils at both time points. In the incorporated treatment, MPs were largely retained within the top 15 cm (30–40% in 0–5 cm and 5–35% in 5–10 cm). Higher MP counts were observed in the sandy loam compared to similar depths for other soils, but this was influenced by the higher MP recovery from this soil. Below 20 cm depth, a higher number of MPs (3–49) were detected in incorporated compared with surface applied (1–17) across all soil types at 12 and 18 months. Surface application resulted in higher MP accumulation in the 0–5 cm layer, whereas incorporated MSW showed greater extent of vertical MP migration for all three soils. A small fraction of MPs was detected at 50 cm depth in all soil types under both application methods at the two sampling times. Morphological analysis showed that MP fibres were the most common, comprising 52–60% in surface treatments and 36–48% in incorporated. Size fraction analysis indicated that particles ranging 0.1–1 mm were most abundant, representing 44–55% of MPs across all treatments and depths. This study demonstrates that MPs in soil amended with MSW mobilise down profile and raises concerns regarding soil health, groundwater contamination, and off-site environmental impacts of MPs when utilising composted waste materials in agricultural applications.

3.18.P-Mo227 Earthworm-Facilitated Transport of Microplastics in Soil: A Small-Scale Field Lysimeter Study

Durađ Milošević¹, Saša Stanković¹, Milica Stojković Piperac¹, Vladimir Pešić² and Dragana Aščerić¹, (1)University of Nis, Serbia, (2)University of Montenegro, Montenegro

The application of plastic mulching films in agriculture is increasing, leaving persistent microplastic particles in soil where they are difficult to remove. Earthworms can mix soil and litter and may transport microplastics vertically, but evidence from realistic field conditions is still limited and sometimes inconsistent. We established a small-scale field experiment in Podgorica, Montenegro, to investigate how local earthworms affect the vertical transport of microplastics originating from aged mulching films. Cylindrical PVC tubes were used to construct small-scale lysimeters (110 mm inner diameter, 250 mm height), installed flush with the soil surface and connected to a smaller lower tube that served as a passive leachate reservoir, separated by a metal mesh and a layer of gravel. The upper part was filled with local field soil and covered with turfgrass collected on site. Aged mulching film was cut and shredded into four size fractions and applied on the soil surface (0.3 grams per lysimeter) under the turfgrass. Two treatments were used: with and without local earthworms, each with three replicates. The experiment ran for three months under semi-passive conditions, relying on natural rainfall supplemented by occasional irrigation events to support earthworm activity. At the end of the exposure, lysimeters were retrieved. Soil columns were sectioned into depth intervals, leachate was collected from the reservoirs, and all earthworms were recovered where possible. Microplastics were extracted using density separation with saturated salt solution and quantified by stereomicroscopy; leachate samples were filtered and examined for the presence of particles. We hypothesize that earthworm activity will enhance downward transport of mulching film microplastics compared with controls, but that the overall penetration depth will remain modest under field conditions relative to laboratory soil column studies. We expect most particles to remain in the upper soil layers, with limited detection in leachate and a stronger downward shift in smaller size fractions. Final quantitative data on vertical microplastic profiles, leachate, and earthworm responses will help clarify how microplastics are likely to move in agricultural soils and whether they represent a realistic pathway towards deeper soil layers and groundwater.

3.18.P-Mo228 Comparative ecotoxicological assessment of microplastics across multiple species from marine and freshwater environments

Rita Fernandes¹, Diana Isabel Oliveira Carneiro², Madalena Filipa Moreira Vieira¹, Joana Figueiredo¹, Caio Cesar-Ribeiro³, Maria Fernanda Palanch⁴, Carlos Marques⁵ and Roberto Martins⁶, (1)University of Aveiro, Portugal, (2)CESAM & Department of Biology, University of Aveiro, Portugal, (3)CCMAR - Center for Marine Sciences, Brazil, (4)Universidade Federal Fluminense, Brazil, (5)CICECO, University of Aveiro, Portugal, (6)CESAM - Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal

Humans have introduced numerous contaminants into ecosystems, including microplastics (MPs), raising major concerns regarding the health of natural ecosystems and organisms at various biological levels. This study assessed the potential effects and environmental hazard of polystyrene (PS), polyvinyl chloride (PVC), polyethylene terephthalate (PET) and high-density polyethylene (HDPE) on six freshwater and marine model species: the microalgae *Raphidocelis subcapitata* and *Tetraselmis chuii*, the crustaceans *Daphnia magna* and *Artemia salina*, the bivalve *Mytilus galloprovincialis* and the fish *Danio rerio*.

All four MPs were tested on the six species at the same concentration range, 1 to 100 mg/L. The microalgae *T. chuii* and *R. subcapitata* were exposed to 72 h (ISO 10253; OECD 201, respectively). Immobilization of *A. salina* and *D. magna* was assessed after 48 h (ASTM E1440-91 adapted; OECD 202, respectively). In *M. galloprovincialis*, mortality and oxidative stress and neurotoxicity-related biomarkers were evaluated following the ASTM E729-96 (adapted). Finally, the *D. rerio* embryo toxicity test (OECD 236) aimed to record acute effects, malformations, and hatching delay over 96 h, and biochemical effects on larvae exposed until 120 h. No significant growth inhibition effects were detected in any microalgae species (*T. chuii* and *R. subcapitata*), nor immobilization on crustaceans (*A. salina* and *D. magna*), nor mortality on mussels *M. galloprovincialis* and *D. rerio* fish larvae (EC50 values > 100 mg/L). Nevertheless, significant biochemical responses indicated that, despite the absence of individual-level toxicity, subcellular effects were triggered.

Regarding biochemical effects on *D. rerio* larvae, PVC induced the most significant responses, increasing catalase, glutathione peroxidase and glutathione reductase, indicating antioxidant defense activation. In *M. galloprovincialis*, across digestive gland, gills and muscle tissues, the most relevant effects were linked to PS

and HDPE. HDPE clearly caused neurotoxicity in gills and muscle, and oxidative stress with antioxidant defense activation in the digestive system and gills. PS mainly affected antioxidant biomarkers, consistently in both digestive system and gills.

This study evidenced how different MPs interact across different trophic levels and environmental compartments, which is critical for a more comprehensive environmental risk assessment.

3.18.P-Mo229 Using bivalves to assess the risks of microplastics and associated pollutants: the case of the Loire River, France

Evan Bossard¹, Antoine Le Guernic², Isabelle Métais², Aurore Zalouk-Vergnoux³, Laurence Poirier³, Célia Arib⁴, Fabienne Lagarde⁴, Alain Geffard Pr⁵, Mélissa Palos-Ladeiro⁶ and Amélie Châtel², (1)Université Catholique de l'Ouest, laboratoire BIOSSE, Angers, 49000, France, (2)Université Catholique de l'Ouest, laboratoire BIOSSE, Angers, 49000, France, (3)Université de Nantes, laboratoire ISOMer, Nantes, 44000, France, (4)Université du Mans, laboratoire IMMM, Le Mans, 72000, France, (5)University Reims, France, (6)Université de Reims Champagne-Ardenne, laboratoire SEBIO, Reims, 51100, France

Aquatic environments represent the ultimate sink for many contaminants, posing a risk to organisms and ecosystems. Among these pollutants, microplastics (MPs) are emerging contaminants that are still rarely integrated in risk assessment while their toxic effects towards aquatic organisms have been largely demonstrated. However, linking these effects to ecological consequences observable in the field remains a major challenge. The ability of MPs to adsorb, transport and release toxic chemicals, further complicates the assessment of their actual impacts.

To quantify the effects of MPs within a risk assessment framework, new strategies have to be developed. In this context, an innovative experimental design was set up to evaluate the Loire river contamination and its biological impact on bivalves from different habitats, including some never been employed in biomonitoring programs. The objective was to establish an integrated biomarker response (IBR) index that summarizes biomarker variations, facilitating risk assessment.

For this purpose, four bivalve species were selected: two marine bivalves (*Scrobicularia plana*, *Mytilus edulis*) and two freshwater (*Corbicula fluminea*, *Dreissena polymorpha*), encompassing both water column and sediment compartments. Individuals were placed for three weeks in plastic-free cages in the downstream of the Loire river, from Angers to Saint-Nazaire. Caging was carried out in spring and autumn 2025. Variations in the response of several selected biomarkers observed were used to develop an IBR index. Biomarker variations were correlated with chemical contamination in the sites and pollutants bioaccumulation within organisms. Results highlighted a site-dependent contamination by pollutants such as MPs, that differentially bioaccumulated within organisms depending on their habitat. In addition, differences in biomarker responses at multiple organizational levels (immunological, biochemical and molecular) observed could be correlated to the presence of pollutants.

The study demonstrates that the use of caging approach combined with an IBR determination strategy allowed consideration of both multichemical exposure together with responses at multiple levels of the biological organization. In addition, as this double approach can be applied to different environments (freshwater, marine systems), and various matrices (water column, sediment), it represents a potentially valuable strategy for ecological risk assessment.

3.18.P-Mo230 Toxicity of microplastics as single and mixture stressors to *Lumbriculus variegatus* in sediment exposures

Victor Carrasco Navarro¹, Ahlam Mohamed-Benhammou², Jussi V.K. Kukkonen¹ and Jose-Luis Martinez-Guitarte², (1)University of Eastern Finland, Finland, (2)National University of Distance Education (UNED), Spain

Sediments are sinks to microplastic particles, although most of ecotoxicity studies that have been performed so far are related to the water column. In freshwater environments, levels in sediment were orders of magnitude

higher than in water, what is a concern for biota inhabiting these environments. In our study, the toxicity of polystyrene (PS) and polybutylene succinate (PBS) microplastics and polyester (PES) microfibers was assessed using the benthic invertebrate *Lumbriculus variegatus* (Oligochaeta) as model organism. *Lumbriculus variegatus* is a widely used organism in toxicity tests and a key link between contaminants present in sediments and upper trophic levels. The materials were spiked to natural lake Höytiäinen sediment at two concentrations (0.5 and 5% of sediment dry weight), including additional food in form of *Urtica* spp. (0.5%). In addition to the single stressors, exposures to mixtures of all the materials were also set (33.33% of each material). Water parameters, including oxygen, conductivity and pH were monitored. Ten worms were added, and they were exposed during 28d following guidelines. Endpoints that were monitored at 28d were growth (dry weight) and reproduction (number of worms). These variables were compared using one way ANOVA or Kruskal Wallis methods for parametric or non-parametric data. The results obtained showed that only the PES microfibers at the highest concentrations (5%) caused an effect in both endpoints. This is in accordance with other studies that indicate a higher toxicity of microfibers compared to microparticles due to the food dilution effect. Interestingly, mixtures of the three materials did not cause harm to the worms. The gut content of the worms was also collected and will be analyzed for microplastics content. Potential degradation and formation of biofilm will be monitored with SEM. Overall, the present study adds valuable and missing information that could be used to determine the thresholds for sediment content regarding microplastics. The results could also be used to compare different materials that are widely used. They include a traditional thermoplastic, a supposedly biodegradable plastic in the form of particles and a microfiber.

3.18.P-Mo231 Toxicological Effects of Microplastic and Nanoparticles Contaminated Fish Feed on *Cyprinus carpio* Growth and Oral/Intestinal Microbiome

Nishita Narwal¹, Shi Xiaotao² and Mian Adnan², (1)Guru Gobind Singh Indraprastha University, India, (2)China Three Gorges University, China (Mainland)

Microplastic (MP) and nanoparticle (NP) contamination in fish feed threatens aquacultural productivity and food security. In this study we assessed the effects of dietary exposure to MP, NP, and their combination (MNP) on *Cyprinus carpio* growth and oral/intestinal bacterial composition. Contaminated feed significantly reduced weight gain and feed efficiency ($p < 0.05$), with MNP causing the most severe impacts on fish weight gain. Moreover, 16s rRNA sequencing revealed a significant shift in bacterial taxa, marked by pathogenic *Aeromonas* and *Vibrio* enrichment and commensal reduction, particularly in the intestines ($p < 0.001$). Beta diversity confirmed taxonomic shifts (PERMANOVA: $R^2 = 0.248$, $p = 0.001$), with intestinal bacteria more sensitive than oral bacteria. *Aeromonas* abundance correlated strongly with growth impairment (Mantel $p < 0.05$; $R^2 > 0.5$), indicating that it is a key growth-limiting pathogen and is elevated by contaminated feed. These findings highlight the dual risk of MNP-contaminated feed that disrupts the microbiome and decreases growth performance. Strategies to mitigate these effects are urgently needed to secure aquaculture feed.

3.18.P-Mo232 Nondestructive Flowcytometric Method for the Detection and Interaction of Micro and Nano Plastics in Bonemarrow.

Rinaldo van Meel¹, Mathie Leers¹, Ines Santos² and Frank G.A.J. Van Belleghem³, (1)Department of Clinical Chemistry & Hematology, Zuyderland Medical Center, 2 Department of Environmental Sciences, Faculty of Science, Open Universiteit, Heerlen, Netherlands, (2)Department of Clinical Chemistry & Hematology, Zuyderland Medical Center & Department of Environmental Sciences, Open Universiteit, Netherlands, (3)Department of Environmental Sciences, Faculty of Science, Open Universiteit, Heerlen, The Netherlands,, Netherlands

Introduction:

Microplastics and nanoplastics (MNPs) have recently been identified in several human tissues, yet their presence and potential effects in bone marrow remain largely unexplored. Existing detection methods rely on destructive analytical techniques, which limit the study of MNP–cell interactions. This work describes the ongoing development of a non-destructive flow cytometric approach to detect MNPs alongside bone marrow cells.

Methods:

Bone marrow samples obtained from femoral heads were spiked with various plastic types and particle sizes. In addition, THP-1 monocytic cells were included as an exploratory control model, exposed to the same plastic to acquire cell internalization and interaction controls. Samples were fluorescently labelled and analyzed by multiparameter flow cytometry. Data processing in Infinicyt, including the use of principal component analysis (PCA), was explored to assist in separating cellular events from microplastic particles.

Results:

Preliminary findings indicate that labelled microplastics can be distinguished from bone marrow cells using combined scatter and fluorescence characteristics. Initial analyses suggest that PCA may enhance separation between particle populations, though optimization is ongoing. Early experiments using THP-1 cells provide a controlled reference context, helping assess the reproducibility of plastic-associated signatures. In addition using a mix of plastic labelling agents can assist in uniquely fingerprinting the microplastic.

Conclusion:

This non-destructive flow cytometric strategy shows promise for detecting MNPs within complex biological matrices and for probing their interactions with cells. Ongoing work aims to further refine the PCA-based analysis, expand the range of tested polymers and particle sizes, and integrate additional cellular markers, including more detailed evaluations using THP-1 and primary bone marrow populations. Which could lead to a high throughput clinical analysis method for investigating the presence and interactions of MNPs.

3.18.P-Mo233 Health impacts of microplastics and nanoplastics: consensus on research needs

Jane Muncke¹, Raymond Pieters², Tanja Cirkovic Velickovic³, Alba Hernández⁴, Mark David Morrison⁵, Rudolf Reuther⁶ and Roel Vermeulen⁷, (1)Food Packaging Forum, Switzerland, (2)Institute for Risk Assessment Sciences, Utrecht University, Netherlands, (3)University of Belgrade, Serbia, (4)Autonomous University of Barcelona (UAB), Spain, (5)Optimat Ltd., United Kingdom, (6)ENAS Environmental Assessments, Germany, (7)University Medical Center Utrecht, Netherlands

Identifying the human health risks of exposure to micro- and nanoplastics (MNPs) is an urgent priority due to first findings of MNPs in human tissues and the increasing prevalence of plastics in society. From 2021 to 2026, the European Union funded five Horizon 2020 research projects under the CUSP cluster with the aim of supporting human health risk assessment for MNPs. One output of this work is the CUSP Roadmap detailing research needs for health risk assessments of MNPs in Europe, outlining short, mid-term and long-term needs until 2032 for five transversal themes: Materials and Methods, Hazard Assessment, Exposure Assessment, Risk Assessment Frameworks, and Mitigation Measures. The CUSP Roadmap sets clear priorities for research, policy, and outreach, and provides the evidence base needed to guide regulation and innovation. It identifies the need for policymakers, scientists, and industry to work together strategically to reduce risk, accelerate the transition toward safer and more sustainable alternatives, and ultimately protect public health from the harm caused by MNPs.

3.18.P-Mo234 Microplastic fibers – double trouble in environmental monitoring

Lina Büngener, Dora Mehn, Guillaume Bucher and Douglas Gilliland, European Commission - Joint Research Centre (JRC), Italy

Ongoing standardization and regulatory activities are trying to address microplastics (MPs) in the environment, and to enable comprehensive monitoring of this pollutant of emerging concern by establishing guidelines for sampling, sample preparation and analysis. Meanwhile, it is becoming evident that MPs in the form of fibers likely will need to be looked at separately. While they are a highly abundant form of MPs in the environment, especially in atmospheric and wastewater samples, several issues surrounding sample preparation and analysis persist: Because of their dimensions, it is difficult to ensure that fibers are captured representatively during MP sampling, which usually involves sieves. MP fibers are often a major contaminant of procedural blanks.

Analysis methods depending on the automated analysis of (optical) images, such as Raman micro-spectroscopy or FT-IR micro-spectroscopy, usually have difficulties to accurately identify and measure fibers. And finally, MP fibers could exhibit a different environmental fate compared to “round” MP particles.

This presentation outlines the major challenges encountered related to the environmental monitoring of MP fibers as a particular group of MP particles, and some experimental results exploring potential solutions are presented for discussion.

3.19.A Out of the Norm: Assessing Fate, Safety, and Sustainability of Biodegradable Polymers

3.19.A.T-01 Soil Biodegradation of Biobased Polyesters: Towards Structure-Reactivity Relationships

Thijs Vangeel and Michael Sander, ETH Zurich, Switzerland

Biodegradable polymers are essential for advancing a circular plastic economy, particularly when designed to reintegrate into natural elemental cycles through industrial composting or environmental biodegradation. Aliphatic–aromatic copolyesters, such as poly(butylene adipate-co-terephthalate) (PBAT), are widely used due to their mechanical performance and biodegradability, yet they typically rely on fossil-derived monomers. Substituting these components with renewable alternatives – most notably 2,5-furandicarboxylic acid (F) – offers a pathway toward fully bio-based, biodegradable materials.

In this study, 28 fully bio-based F-containing aliphatic–aromatic copolyesters were synthesized by systematically varying the diol, aliphatic diacid, and aromatic diacid components, as well as the aromatic-acid content (30–70%). Thin films (~30 µm) were prepared and evaluated for soil biodegradability using controlled laboratory incubations (~400 vessels). Residual polymer was periodically extracted via Soxhlet extraction and quantified by ¹H-NMR, which also provided insight into compositional changes during degradation.

To disentangle the effects of molecular structure, soil type, and degradation kinetics, the experimental design was divided into three targeted subsets. Subset A assessed one representative F-containing polyester across six standard soils, benchmarked against PHBH as a positive control. Subset B examined biodegradation dynamics for nine structurally varied polyesters through five time points. Subset C compared the complete set of synthesized copolyesters in a single standard soil (LUFA 6S) at two incubation durations.

Across all subsets, clear trends emerged linking biodegradability to copolyester molecular features, including the nature of the aromatic and aliphatic diacids and the diols, as well as the aromatic-acid content. These findings establish structure–biodegradability relationships that can guide the design of next-generation fully bio-based, soil-biodegradable aromatic–aliphatic copolyesters.

3.19.A.T-02 Soil Biodegradation of a Rice Dust-Based Bioplastic and Its Effects on Microbial Communities

Catarina Correia de Lemos Malheiro¹, Rui G. Morgado¹, Paulo Brites¹, İrem Ö. Ufuk², Nicolas Joly³, Patrick Martin³, Amparo López-Rubio⁴, Martinho Oliveira¹, Idalina Gonçalves¹ and Susana Loureiro⁵, (1)University of Aveiro, Portugal, (2)Gebze Technical University, Portugal, (3)Université d'Artois-UniLasalle, France, (4)IATA-CSIC, Spain, (5)CESAM-Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal

Soil is a major reservoir for plastic disposal, which can interfere with the biogeochemical processes, thereby impacting soil multifunctionality and productivity. Conventional plastic replacement with bioplastics, particularly those developed from low-value natural by-products, emerged as a promising strategy to tackle this global challenge, one that promotes circularity, reduces dependence on fossil fuels, lowers greenhouse gas emissions, and mitigates the impacts on ecosystems. However, assessing the effects of bioplastics on the functioning of soil ecosystems remains paramount. In this study, the impact of a rice dust-based bioplastic on soil functioning was assessed during the defragmentation stage of the biodegradation process. The experimental design comprised two treatments: i) with bioplastic (BIO) and ii) without bioplastic (CT). At each sampling time (days 0, 7, 14, 28, 42, 56, and 84), three replicates were destructively sampled, and a comprehensive set of analyses was conducted, including soil enzymatic activities, multiple soil nutrient fractions, and soil properties. The bioplastic piece was also recovered, gently cleaned, oven-dried, and reweighed to assess mass loss. Biodegradation results showed almost complete defragmentation. Model-based estimation of the half-life for Lufa 2.2 soil-incubated bioplastics was approximately 15 days. The results of soil functioning tests showed that the bioplastic induced significant changes in certain soil enzymes and nutrient fractions. The transient spike in dissolved organic carbon observed at the beginning of the experiment led to consistently higher values of microbial biomass carbon. On the contrary, soil incubated with bioplastic showed significantly less content in inorganic N (mainly nitrates) and total dissolved N, but similar values of microbial biomass nitrogen. Urease activity was significantly higher in soil incubated with bioplastic, suggesting a requirement for additional N mining by soil microbial communities. Likewise, bioplastic incubations led to reduced inorganic P and ultimately to significantly different microbial biomass phosphorus over time. Overall, the bioplastic appears to have triggered a positive priming effect, requiring additional action from the microbial community to extract native N from the soil organic matter. A similar situation appeared to occur for P. Further work should focus on structural alterations in soil microbial communities.

3.19.A.T-03 Chemical complexity and ecotoxicological effects of leachates from bioplastic and conventional plastic products

Sevil Vafadar Afshar¹, Bina Bhattarai², Katrin Loeschner¹ and Nanna B. Hartmann³, (1)Technical University of Denmark (DTU), Denmark, (2)DTU Food, Denmark, (3)DTU Sustain, Technical University of Denmark (DTU), Denmark

Bioplastics (bio-based and/or biodegradable) are often promoted as environmentally safer alternatives to conventional plastics (fossil-based and non-biodegradable), yet their chemical complexity may present ecotoxicological risks. This study compared water-based leachates and methanol-based extracts from five commercial plastic products, including conventional plastic and bioplastic bags. Polymer composition was verified via FTIR and DSC, while elemental composition was measured using ICP-MS/OES. Non-target analysis (HR-LCMS) characterized unknown organic constituents, and ecotoxicity was assessed using marine bacteria (*Aliivibrio fischeri*), freshwater algae (*Raphidocelis subcapitata*), and *Daphnia magna*.

Results showed that biodegradable plastics released a more chemically diverse array of organic compounds and, in some cases, higher concentrations of metals (e.g., Zn and Fe) than conventional plastics and non-biodegradable bioplastics. Chemical profiles differed between water- and methanol-based extractions, and products with the same base polymer exhibited distinct leachate compositions and ecotoxicity responses, emphasizing the importance of assessing finished products rather than base polymers alone. Bioplastic leachates caused stronger ecotoxic effects, particularly inhibiting algal growth by up to 80 %. In contrast, *D. magna* was sensitive only to a bio-based, non-biodegradable bag, while marine bacteria showed slightly higher sensitivity to bioplastics compared to conventional plastics.

These findings suggest that bioplastics can release organic compounds and metals at levels comparable to or exceeding those of conventional plastics, thereby challenging the assumption of their inherent environmental safety and underscoring the need for comprehensive chemical and ecotoxicological evaluations.

3.19.A.T-04 Water-soluble polymers in the aquatic environment – Lessons learned from two case studies with Polyethylene glycole and polyquaternium polymers

Daniel Zahn¹, Maximilian Steuernagel², Eva-Maria Burkhardt³ and Gabriele Treu³, (1)Department of Analytical Chemistry, Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (3)German Environment Agency (UBA), Germany

The field of water-soluble polymers (WSPs) comprises neutral, anionic, and cationic polymers with estimated individual annual production volumes in the range of hundreds to hundreds of thousands of tons. Unlike conventional solid polymers for which an increasing share is recycled or incinerated, many WSP applications do not facilitate recollection. While environmental occurrence data for WSPs is exceedingly scarce first evidence indicates that this combination of high production volumes, widespread applications, and low potential for recollection can result in substantial emissions into the environment in the µg/L or near sources even mg/L range. Yet, assessment of WSPs in the environment is still in its infancy coping with severe analytical challenges and an at best rudimentary understanding of the environmental fate and effects of WSPs. Herein we compare the results from two case studies, one analyzing polyethylene glycol (PEG) a very high production volume but readily biodegradable WSP in surface water and wastewater treatment plants with another study analyzing four polyquaternium (PQ) polymers in surface water, highlighting challenges and knowledge gaps in the environmental assessment of WSPs.

PEG was analyzed for in 18 surface water samples and two wastewater treatment plants. Despite its inherent biodegradability, PEO concentrations ranged from <LOD to 11 µg/L for surface waters (11/18 samples >1 µg/L). A molecular weight fraction between 1.3 and 4 kDa was dominant in wastewater treatment plant effluent and most surface waters, likely due to molecular weight dependent sorption and biodegradation processes. Four PQs (PQ-2, 6, 7, and 10) were analyzed for in 15 surface water samples, which led to the widespread

detection of PQ-2 (13/15 samples) after direct injection and the detection of PQ-7 and PQ-10 in samples with a strong urban impact after freeze drying (20-fold enrichment). Due to the lack of well-characterized standards and strong interactions with humic acids accurate quantification of PQs is not possible with the current iteration of the method. Nevertheless, PQ-concentrations were estimated in the tens to hundreds of µg/L for many of the investigated samples, partially exceeding concentrations for which ecotoxicological effects have been reported. These results indicate that a shift towards degradable WSPs is required.

Disclaimer/Disclosure:

The authors thank the German Environment Agency for granting the project “Analysis of Polyquaternium Compounds in Environmental Samples through non-target Screening” (FKZ 181180) and the Federal Ministry for the Environment, Nature Conservation and Nuclear Safety for its funding.

3.19.B Out of the Norm: Assessing Fate, Safety, and Sustainability of Biodegradable Polymers

3.19.B.T-01 Screening Biodegradation Tests: History, Predictive Value, and Clarification of Common Misconceptions in Environmental Persistence Assessment

Drew McAvoy, University of Cincinnati, United States

Screening biodegradation tests have been a foundational component of environmental fate assessment for more than forty years, yet their purpose, limitations, and predictive power are often misunderstood. These tests originated during the regulation of surfactants in the 1970s, when regulators and industry required harmonized and reproducible methods for identifying chemicals capable of rapid biodegradation under aerobic conditions. The test development originated with surfactant regulations, and culminated in the Organization for Economic Cooperation and Development (OECD) tiered biodegradation framework established in 1981, which introduced Ready biodegradability tests, Inherent biodegradability tests, and Simulation test. These tests are now embedded in regulatory frameworks across the world.

Ready tests are intentionally designed as stringent stress tests. They rely on low, unacclimated microbial densities typically between ten thousand and one hundred thousand colony-forming units per milliliter high chemical-to-biomass ratios, and mineralization endpoints such as carbon dioxide evolution or oxygen consumption. The goal is to evaluate whether a substance possesses the inherent capacity for rapid aerobic biodegradation under conservative test conditions.

A substantial body of empirical evidence confirms the predictive value of Ready test outcomes. This includes studies of environmental half-lives, and comparative tests across sludge and river water tests. This presentation discusses frequently cited concerns such as the sixty-day duration for enhanced ready tests, the so called “missing 40%”, and perceptions on poor waste water treatment plant performance. Many of these concerns arise from the challenge of communicating a complex scientific topic in simplified form to external audiences. Recent work from both industry and academia, including environmental monitoring studies, further reinforces the historical basis for the applicability and predictability of OECD tests, even for more complex substances such as polymers and chelants. The ongoing challenge for academia is to ensure robust communication of these concepts within regulatory frameworks and risk assessments. This presentation will review the underlying science and invite discussion on how to reassure and effectively explain the science to non-scientific audiences.

This presentation is of the sole opinion of the author.

3.19.B.T-02 Towards an Integrative Assessment of Polymer Biodegradation

Kathleen McDonough¹, Jennifer Menzies², Ashley Wilcox², Nigel Yates², Taylor Neal², Sandra Isaacs², Spiro Stilianoudakis², Mark Sivik², Maura Hall², Kristin Connors², Susan A Csiszar¹ and Lijuan Li², (1)Procter & Gamble, Mason, United States, (2)Procter & Gamble, United States

Significant focus has turned to the development of biodegradable water soluble polymers for use in products disposed of down the drain into the sewer system. In addition, there is renewed regulatory focus on methods for assessment of polymer biodegradation as the EU Commission evaluates new approaches to register polymers under the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH). Polymers are

composed of structurally similar molecular chains with varying molecular weights (MW) typically >1000 Da and complex structural features. Biodegradation of polymers is more complex than for lower MW molecules due to the need for extra-cellular enzymatic cleavage of the polymer into smaller oligomeric fragments that are able to be transferred intra-cellular in order for complete mineralization to occur. The high MW and complex nature of the starting test substance and the fragmentation into many additional transformation products, results in significant analytical hurdles for quantifying biodegradation potential, biodegradation pathways, and rates of primary and ultimate biodegradation in a robust manner. Limited polymer biodegradation assessments have been conducted with actual test data across different biodegradation assays (screening, simulation, novel test setups) and with inoculum from different environmental compartments to quantitatively evaluate whether a polymer is biodegradable. This research developed an integrated approach to evaluate the biodegradation potential of different complex water soluble polymers that are used in down the drain products. For each polymer under investigation, this research evaluated known biodegradation pathways and biodegradation potential based on a variety of screening and simulation type studies with mixed microbial communities from activated sludge and river water compartments. This research further explored the impact of test design (test chemical concentrations, inoculum concentration and handling) on study results. These data were assimilated to evaluate the biodegradation potential and pathway of each polymer in activated sludge wastewater treatment and freshwater compartments.

3.19.B.T-03 Stable isotope labeling in polymer biodegradation assessment: from research to regulation

Michael Sander¹, Flora Wille¹, Kevin Kleemann¹, Michael Zumstein² and Aaron Kintzi³, (1)ETH Zurich, Switzerland, (2)University of Vienna, Austria, (3)Environmental Geoscience, University of Vienna, Austria

Biodegradability is a desirable trait for many structural, water-soluble, and water-dispersible polymers used in diverse applications. It ensures that polymers can undergo complete microbial metabolic utilization in natural (soil, water) or engineered (wastewater, compost) environments, forming CO₂ and microbial biomass. Biodegradability therefore is a critical safe-and-sustainable by-design criterion to prevent the formation and accumulation of persistent polymers, including stable micro- and nanoplastics, in the environment.

Biodegradation is commonly assessed by incubating polymers in the desired matrix (e.g., soil, compost, sludge inoculum) coupled with respirometric analysis of polymer-derived CO₂ formation (i.e., mineralization). While such analyses provide direct evidence for biodegradation, several interpretational challenges remain. First, standard mineralization measurements can be affected by ‘priming’, a substrate-dependent artifact for which substrate-free control incubations cannot fully correct. Second, incubations often need to be conducted at high polymer concentrations to generate sufficient signal above background CO₂ formation from natural organic matter (e.g., for compost). Alternatively, the background is diluted and/or enrichment inoculae need to be used for incubations (as in the case of sludge). Third, the non-mineralized fraction of the polymer carbon cannot be quantified as residual polymer carbon cannot be delineated from background natural organic matter carbon in the incubation matrix. Therefore, mass balances on polymer carbon cannot be closed. Finally, the relative contributions of residual polymer and microbial biomass derived from polymer carbon remain uncharacterized. This contribution demonstrates how the above challenges can be addressed and new fundamental insights into biodegradation obtained using stable isotope-labeled polymers in incubation studies. The interpretational power of this approach is illustrated through selected studies with ¹³C-labeled structural and water-soluble polymers. Beyond highlighting its value for academic research, the contribution discusses the unique role of stable-isotope labeling in future regulatory assessments of polymer biodegradability, noting commonalities with, but also advantages over, radioisotope labeling approaches.

3.19.B.T-04 Biodegradability of Polylysine in Wastewater: Identification of Key Microbial Degradors and Enzymatic Mechanisms

Soumya Daturpalli¹, Jervis Vermal Thevathasan², Sebastian Groß¹ and Andreas Künkel¹, (1)BASF, Germany, (2)Research Biopolymers, BASF, Germany

Polylysines are widely used in personal care formulations due to their antimicrobial activity, film-forming ability, and moisturizing properties. To further develop this versatile class of polymers, and since they are released into wastewater streams, it is important to understand their biodegradability in this environment. In this study, we aimed to identify key microbial degraders capable of utilizing polylysine as a sole carbon source. Therefore, we established an enrichment cultivation protocol using an activated sludge sample from a wastewater treatment plant. Subsequently, a metagenomic analysis was conducted to identify candidate microbial degraders that were enriched during the cultivation. Selected microbes were obtained from public microbial collections and modified standard biodegradation tests confirmed the ability of these strains to mineralize polylysine into carbon dioxide. A proteomics analysis performed at specific time points during the

biodegradation test revealed key enzymes implicated in polylysine degradation. These findings advance our understanding of polylysine biodegradation and may inform future strategies to mitigate bioaccumulation in wastewater environments.

3.19.B.T-05 Towards Holistic Approaches to Modeling Polymer Biodegradability

Susan A Csiszar¹, Chengrui Lin², Kathleen McDonough¹, Jennifer Menzies³, Ashley Wilcox³, Nigel Yates³, Mark Sivik³, Luke Zannoni³ and Huichun Zhang², (1)Procter & Gamble, Mason, United States, (2)Case Western Reserve University, United States, (3)Procter & Gamble, United States

A key aspect of sustainable innovation involves designing polymers that can biodegrade within their receiving environments. An important element in assessing, understanding, and forecasting biodegradability is the application of computational tools. While there are established methods for predicting the biodegradability of small molecules, the development of models for polymers is still in the early stages. Additionally, there are several methods to assess and measure polymer biodegradation in aqueous media such as (but not limited to) enzymatic assays, screening studies, simulation studies, all of which provide a range of insights from impacts of increasing environmental realism and enzymatic and microbial transformation pathway and kinetic information. Furthermore, adaptation of these methods to polymers is an active research area, allowing for greater availability of insights and data to build predictive and understand biodegradation mechanisms. As such, a holistic framework to modeling polymer biodegradability is recommended that leverages both mechanistic, kinetic, and data-based approaches that can be integrated across experimental assays and studies. Mechanistic and kinetic modeling techniques can be used, for example, to link and understand differences across assay results. Data-based approaches such as machine learning can integrate structural descriptors of polymers with experimental results, and can be combined with the mechanistic-based approaches. A practical starting point for building machine learning models leverages screening biodegradation assay results where there is currently sufficient existing data to build frameworks and models, which can then be extended to other assay types. As part of the holistic modeling approach, we present a machine learning model that leverages data from polymer screening biodegradation studies and recent advances in polymer informatics. The approach includes a framework for consistent polymer representation across several water soluble polymer classes including copolymers, allowing for data across classes to drive predictions. The model was built using publicly available data and was evaluated using an independent test set of recently generated screening biodegradation data.

3.19.P Out of the Norm: Assessing Fate, Safety, and Sustainability of Biodegradable Polymers

3.19.P-We268 Improved Digital Representation of Polymers for Better Biodegradation Assessment

Jessica Mugleston¹, Volker Settels², Juan de Pablo³, Yuan Tian³, Patrizia Marie Schmidt², Glaucio Battagliarin⁴ and Gervasio Zaldivar³, (1)BASF, United Kingdom, (2)BASF, Germany, (3)New York University, United States, (4)Research Biopolymers, BASF, Germany

A key tool in the in-depth assessment of how polymers break down in the environment will be the use of predictive modelling. For the assessment of small molecules, it has proven an invaluable addition to standard lab-based methods, and can give additional insights into breakdown products, toxicity, pathways and enzyme binding. The advent of more complex modelling techniques and supercomputing capacity, together with the slow expansion of openly available datasets has allowed many accurate models to be developed which meet specific requirements of regulators (for example the recent QSAR Assessment Framework guidelines). The relative simplicity of describing small molecules to computers here has also facilitated such development.

The development of accurate predictive models specifically for polymer biodegradability is however an altogether more complex hurdle. One of the main issues contributing to the absence of accurate models here is a lack of accurate representation methods to describe polymer structure. Traditional techniques fail to include structural polymer properties which are important for development of accurate models. Although many techniques are already available which describe the chemical nature of polymers (repeating units, end groups, branching, etc), none so far have been able to accurately encompass the stoichiometric nature of polymers; namely, molecular weight distribution and wider polymer microstructure. For prediction of biodegradation, it is crucial this information is included, as so many of these processes are directly affected by such information – it is widely understood that increased molecular weight and crystallinity affect biodegradation due to uptake and accessibility constraints.

Here, we will present a new advanced polymer representation method which comprises chemical as well as stoichiometric data. This method is based on the G-BigSMILES techniques outlined by Schneider et al in 2024.

With the additional stoichiometric data, we further propose how this can be used to accurately represent real-life polymers, and how this can be applied to biodegradation prediction. By offering better, more accurate predictions of how polymers biodegrade in various environments, we hope that this can further the discussion on how fate of polymers can be better assessed.

3.19.P-We269 Water Soluble and Dispersible Polymer Biodegradation and Transformation Pathway Data Curation to Enable the Development of Modelling Tools

Susan A Csiszar¹, Marlies Bergheim Sr M², Harald Streicher³, Glauco Battagliarin⁴, Jessica Mugleston⁵, Guillaume Cottin⁶, Michael Sander⁷, Jasmin Hafner⁸, Thomas Hofstetter⁹, Kathrin Fenner¹⁰, Ryan Heisler¹¹ and Amelie Ott¹¹, (1)Procter & Gamble, Mason, United States, (2)Corporate Scientific Services, Henkel AG & Co. KGaA, Germany, (3)Beiersdorf AG, Germany, (4)Research Biopolymers, BASF, Germany, (5)BASF, United Kingdom, (6)L'Oréal, France, (7)ETH Zurich, Switzerland, (8)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (9)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (10)Environmental Chemistry, University of Zürich, Switzerland, (11)International Collaboration on Cosmetics Safety (ICCS), United States

We present a framework for a new initiative from the International Collaboration on Cosmetics Safety (ICCS) to enhance the development of in silico tools and methods for polymer biodegradation. Modeling and computational tools for estimating polymer biodegradation are key aspects to better understand, predict, and support grouping, weight-of-evidence, and read-across assessments of the biodegradability of polymers. While there are several modeling techniques available for small molecules, models for polymers are still in the early stages, and model development relies on experimental data to build the models and to evaluate them. This project emphasizes the collection, curation, and assessment of experimental data related to polymer biodegradation, including transformation pathways and enzymatic assays, to inform the development of robust predictive models. By addressing identified gaps in data reporting and availability, this initiative seeks to facilitate the creation of a comprehensive database, prioritize modeling methodologies, and highlight future data generation needs. The focus is on water-soluble and dispersible polymers within environmentally relevant compartments, particularly wastewater treatment and aqueous environments, to support the ongoing ICCS collaborative research activities in polymer biodegradation.

3.19.P-We270 High Throughput Automation Modifications to OECD 302B Biodegradation Assay Using Robotic Interface

Yu Xue¹, Aschwin van der Horst¹, Thomas Ravensbergen¹, Imane Garcia² and Sang-Tae Kim³, (1)Ashland Central R&D Team, Netherlands, (2)Ashland Regulatory Affairs and Toxicology, France, (3)Ashland Regulatory Affairs and Toxicology, United States

The OECD 302B (Inherent Biodegradability: Zahn-Wellens/ EVPA Test) is a screening test for inherently biodegradable materials that uses activated sludge as an inoculum source and measures the biodegradation through analysis of dissolved organic carbon (DOC). This assay is a powerful tool for analyzing the fate and biodegradation potential of both small molecules and polymers used in various applications, including pharmaceutical, personal care, and industrial products that are released into domestic or industrial wastewater treatment facilities. In this assay, samples must be taken from the bottle at the sampling timepoint, filtered, and then analyzed with a total carbon analyzer (TOC) or CHNS machine. This process can be labor intensive and time consuming and therefore may be a limiting factor for the test material numbers that can be analyzed during a given trial. To mitigate this issue and make this assay higher throughput, a robot was designed in collaboration with Synchron, Etten-Leur, Netherlands. The setup for this system is five trays of 12 test bottles, arranged in a row along a lab bench. There is an overhead track on which the robotic sample arm moves down the row. The automated series for sampling is as follows: (1) The robot uses first a pH probe to record the pH into its internal computer; (2) the robot picks up a sample from the test bottle and then a filter (3) the filtrated sample is deposited into a test tube; (4) the filter is released into a disposal area (5) the needle is rinsed and cleaned; and (6) the bottle is refilled with deionized water to its original amount. The study operator will then take the prepared test tube samples and be able to place them directly to the TOC for analysis of the carbon content by TOC measurements. The OECD 302B analysis method is now fully operational by a robotic interface enhancing degradation measurements on a daily basis with low labor cost and improved high throughput capabilities.

3.19.P-We271 Improving Polymer Biodegradability Assessments with the Probabio Method

MICKAEL CREGUT¹, Thomas Louineau², Anaëlle Torres³, Alicia Lessentier⁴, Maël Guedj⁴, Valérie Jomain⁴, Gerald Thouand⁵ and James Wilson³, (1)syensqo, France, (2)University of NANTES, France, (3)SYENSQO, France, (4)Syensqo, France, (5)Univ Nantes, France

Introduction

Water-soluble and water-dispersible polymers are essential in many formulations, such as Home and Personal Care and agricultural products. As sustainability becomes a priority, accurate biodegradation assessment methods are needed. Current OECD guidelines, designed for simple substances, do not fully address the environmental fate of complex polymers, which often degrade via pathways not covered by standard tests.

Objective

This study evaluates polymer biodegradation under diverse biotic and abiotic conditions, aiming to improve classification and labeling of polymer ingredients based on biodegradability.

Materials and Methods

Five polymers were tested under 400+ conditions. Standard OECD tests (301, 306, 302) were performed in various environments: wastewater treatment plants (WWTPs), freshwater, soil, seawater, and sediments. Inoculum sources included:

WWTPs: La Roche-sur-Yon (80,000 PE), Bellevigny (4,000 PE)

Lagoon: Bellevigny (250 PE)

Soils: organic and intensive (La Roche-sur-Yon)

Freshwater: l'Yon, La Loire

Sediments: Loire

Seawater: Atlantic coast

Tests used two temperatures (12°C, 24°C) and two inoculum concentrations (standard and 10x higher).

Experimental Design

A Design of Experiments (DOE) approach, Probabio, was used to systematically vary biotic (inoculum composition, diversity, density) and abiotic (chemical properties, exposure) factors, reflecting environmental heterogeneity.

Results and Discussion

Biodegradation was measured at 28 and 60 days. Key findings:

Inoculum Composition/Density: Presence and diversity of degraders were critical.

Inoculum History: Pre-exposure to the polymer or similar compounds enhanced degradation.

Chemical Properties/Exposure: Polymers with greater environmental exposure had higher biodegradation due to pre-adapted microbes; novel substances degraded less.

Lab vs. Environment: Laboratory conditions (e.g., Food-to-Mass ratios) often differed from real environments.

Stochastic Variability: Sampling differences affected results, highlighting the need for representative samples.

Conclusion

Biotic and abiotic factors significantly influence polymer biodegradation. Using a comprehensive DOE framework, this study proposes a refined labeling system: readily biodegradable, enhanced ready, ultimately inherent, or not biodegradable. This approach supports improved environmental assessment of complex polymers, aligning with sustainability goals.

3.19.P-We272 Investigating Freshwater Microbial Communities and Their Potential for Biodegradation of Water-Soluble Polymers

Anika Mikes¹, Patrick Schacksen¹, Sebastian Groß², Glauco Battagliarin², Andreas Künkel² and Michael Zumstein¹, (1)University of Vienna, Christian Doppler Laboratory for Biodegradation of Water-Soluble Polymers, Division of Environmental Geosciences, Centre for Microbiology and Environmental Systems Science, Austria, (2)BASF, Germany

Water-soluble polymers (WSPs) are providing key functions in numerous consumer products, including those used for home and personal care. After use, WSPs can enter natural aquatic environments (e.g. rivers) – mostly via wastewater treatment plant effluents. Biodegradation is a key process controlling the fate of WSPs in these systems and biodegradability a key desired feature of sustainable WSPs. Standardized biodegradation screening tests are typically performed under closed-bottle conditions over several weeks. The results of such tests can vary considerably depending on the composition of the sampled microbial community used as inoculum. Moreover, closed incubation can induce community shifts, sometimes referred to as “bottle effects”, as microbial communities adapt to confined conditions and resource limitations. Grazing by eukaryotes can further influence these dynamics by selectively removing certain bacterial taxa, thereby shaping community structure and potentially altering biodegradation outcomes. Understanding the variability of sampled microbial communities and the shift of these communities during laboratory biodegradation testing is important for further

improving biodegradation tests with respect to reproducibility and environmental relevance. In this study, we analyzed the composition and dynamics of riverine microbial communities sampled for WSP biodegradation testing using 16S rRNA gene amplicon sequencing. Water samples were sampled at different locations along the Danube. Microbial community shifts were monitored during incubation experiments to examine how natural communities change under closed-bottle conditions typically used in biodegradability testing. Furthermore, we assessed the impact of eukaryotic grazers on bacterial community dynamics during these incubations. Selected WSPs (i.e., polyamino acids, polysaccharides, polyethylene glycol, and polyvinyl alcohol) were incubated with freshwater microbial communities and biodegradation was assessed in respirometric laboratory tests. Together, our experiments provide insights into the natural and induced variability of freshwater microbial communities and their potential to biodegrade WSPs in riverine systems.

3.19.P-We273 Applicability and Improvements of OECD (bio)degradation Testing for Water-soluble Polymers

Boris Meisterjahn¹, Glauco Battagliarin², Elaine Jennings³, Stefan Hahn⁴, Dieter Hennecke⁵ and Christopher B Hughes⁶, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Research Biopolymers, BASF, Germany, (3)Ricardo-AEA Ltd, United Kingdom, (4)Lower-Saxony, Fraunhofer Institute for Toxicology and Experimental Medicine (ITEM), Germany, (5)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (6)Embark Chemical Consulting, United Kingdom

Biodegradation screening testing and more complex biodegradation simulation studies are requested under regulatory frameworks such as REACH for persistency assessment of low molecular weight (“small”) molecules. While polymers and polymeric substances were initially exempted from REACH, this will change in the near future, and implementation of polymer-specific modifications of the respective ordinances and guidance are necessary. In this context, the question arises whether standard test guidelines used for the determination of small molecules degradability are appropriate for polymers. These guidelines might need modifications to obtain meaningful data on the biodegradation of polymers in environmental compartments. Possible modifications are not limited to the test setup and technical aspects, but are concerned more with degradation endpoints, which will have to be different compared to small molecules (e.g. changes of the molecular weight distribution, definition of primary degradation). While there is much attention paid to degradation of plastics due to the microplastic restriction, so far studies on water-soluble polymers such as e.g. PEGs or PVOHs are largely missing, especially with regard to higher-tier biodegradation simulation studies. The CEFIC LRI ECO64 project makes a start to close these gaps. In a first step 14C-radioactive CMC with different degrees of substitution will be synthesized. With these compounds available, their biodegradation in the four most important biodegradation simulation tests (soil, sediment, surface water and WWTP-simulation) should be investigated. In parallel these compounds will also be applied to standard screening tests for comparison reasons. In addition to the aforementioned substances, also a radiolabelled biocidal polymer was already tested in soil, water/sediment and WWTP simulation tests. Using the specificity of the radioactive labelling, endpoints possibly relevant for polymer biodegradation beyond the parameter mineralisation will be investigated. Based on the results of the biodegradation simulation and screening tests, recommendations for polymer testing and also appropriate reference substances should be derived.

3.19.P-We274 Inter-laboratory testing of two polyurethane dispersions according to the enhanced OECD 301 F test guideline

Christopher B Hughes¹, Niels Timmer², Olive Nkundwakazi³, Emma Danby⁴, Kristina Miller⁵, Ute Hammesfahr⁶, Cristina Lavilla Aguilar⁷, Daniela Knopp⁸, Hannah Schumacher⁸ and Michael Bunge⁸, (1)Embark Chemical Consulting, United Kingdom, (2)Charles River Laboratories, Inc., Netherlands, (3)Normec OWS, Belgium, (4)Scymaris Ltd., United Kingdom, (5)Noack Laboratorien, Germany, (6)ibacon GmbH, Rossdorf, Germany, (7)Covestro, Netherlands, (8)Covestro, Germany

Biodegradability of polymers is a desirable trait to prevent long-term impacts to the environment. Furthermore, degradability is an important consideration in regulation of polymers, such as within the EU REACH restriction on synthetic polymer microparticles. Polyurethane dispersions (PUDs) are polyurethane polymer resins dispersed in water and are used in a variety of applications, including agriculture (e.g. as binders for coatings, seed treatment adjuvants and others). In agricultural applications, environmental release of polyurethanes is

effectively inevitable, via deposition of treated materials onto soils and plants. In line with the principles of safe and sustainable by design (SSbD), modifications such as for the backbone and segment architecture (e.g. cleavable motifs, altered crosslinking) allow for adjusted chemical properties and also largely influence their biodegradability potential. An inter-laboratory comparison was performed on two PUDs to assess their biodegradability according to the enhanced OECD 301 F test guideline. The ring test involved six laboratories from four countries and followed a specific protocol to investigate inter- and intra-test variability. Tests included microcrystalline cellulose as an additional positive control and three replicates per treatment. Test results indicated that both PUDs were extensively biodegradable, with biodegradation exceeding 60% after either 28 days or 60 days in all labs. The first test item was slower to degrade than the second, but both polymers showed similar biodegradation extents by day 60. Considerable variability in the evolution of biodegradation between replicates was observed, although results converged within an acceptable range by the end of the test. The results of this inter-laboratory comparison demonstrate the potential variability between replicates and across laboratories when conducting ready biodegradability testing of polymer dispersions, and the importance of extended test durations. Preliminary results of investigations into inoculum characterisation, preservation and re-use will also be presented.

3.19.P-We275 Evaluating Analytical Tools for Assessing the Degradation of Polysaccharide-based water-soluble polymers

Prabodhi Preethika Dehiwalage Dona¹, Russell Davenport¹, Jennifer Menzies² and Kathleen McDonough³,
(1)Newcastle University, United Kingdom, (2)Procter & Gamble, United States, (3)Procter & Gamble, Mason, United States

Biodegradable polymers are promoted as alternatives to poorly degradable materials, yet their environmental fate and transformation processes remain insufficiently understood. Their high molecular weight and structural diversity make them analytical outliers that often fall outside standard biodegradation tests, highlighting the need for methods tailored to characterising degradation pathways and intermediates.

This study develops and evaluates a multi-technique workflow to quantify and interpret the enzymatic degradation of polysaccharides with varied chemical modifications and degree of substitutions (DS).

Unmodified pullulan and dextran, along with modified carboxymethyl cellulose (CMC) with DS from 0.6 to 1.2, were degraded in assays using substrate-specific enzymes to compare their relative degradation extent and pathways.

Degradation was assessed using complementary analytical approaches. Thin-layer chromatography (TLC) enabled rapid qualitative detection of degradation intermediates, while Ultra-High Performance Liquid Chromatography coupled with Charged Aerosol Detection (UHPLC-CAD) enabled quantitative detection of mono/di saccharides. UHPLC-CAD offered improved sensitivity and reproducibility, with detection and quantification limits of 15 and 20 µg/mL.

The workflow resolved key degradation steps and revealed that higher substitution reduced enzymatic efficiency in converting CMC into glucose, cellobiose, and celotriose. These results will be compared to published OECD 301 and 314B data of the same materials. Pullulan and dextran showed greater conversion into glucose and related intermediates, indicating the method's applicability to other polysaccharides.

Additional methods, including infrared spectroscopy, derivatisation-based mass spectrometry (MS), are being optimised to improve detection of intermediates in complex matrices. Together, these approaches provide a scalable framework for evaluating the biodegradable potential of polysaccharide polymers and their transformation products, supporting stronger interpretation of standard biodegradation tests. Scalability can be achieved through a tiered strategy, utilising TLC-UHPLC-CAD for quantification in high-concentration assays and integrating sensitive methods such as MS to characterise trace intermediates in environmentally realistic samples. Overall, this work provides a robust analytical approach that informs biodegradable polymer design and refinement of fate assessment strategies.

3.19.P-We276 Rapid Screening Tool to Assess Likelihood of Degradation for Research Samples

Christine McInnis¹ and Katharine Minker², (1)International Flavors & Fragrances Inc. (IFF), United States, (2)International Flavors and Fragrances (IFF), United States

The demand for non-persistent polymers with a lower carbon footprint has accelerated the search for new bio-based biodegradable polymers that meet or exceed the performance over existing incumbents. Where the performance of natural biopolymers falls short, researchers have focused on designing new scaffolds and backbone modifications to maintain or introduce biodegradability while meeting performance criteria. Obtaining biodegradability measurements is a critical step of this design cycle, yet traditional screening tests (e.g., OECD 301 Test for Ready Biodegradability) take 28–60 days and are too slow for rapid innovation. We have now developed a higher throughput miniaturized assay to provide researchers faster feedback and enable prioritization of incoming samples in full scale tests. While this test cannot quantify percent biodegradability, it serves as an excellent starting point to rank molecules of interest based on their likeliness to degrade. Furthermore, this assay can provide researchers insights into the impact chemical modifications are having on biodegradability in as early as five days.

3.19.P-We277 Bridging Laboratory and Environmental Relevance: Soil Biodegradation of Polymers via Oxygen Consumption Monitoring (ISO 17556)

Anaëlle Torres¹, Maël Guedj², MICKAEL CREGUT³ and James Wilson¹, (1)SYENSQO, France, (2)Syensqo, France, (3)syensqo, France

The environmental fate of biodegradable polymers is a growing concern for both regulators and industry, requiring reliable and relevant assessment methods. This work presents a comprehensive methodology for evaluating polymer biodegradability in soil, developed in alignment with ISO 17556:2019. The approach utilizes indirect measurement of microbial activity by monitoring oxygen consumption in soil microcosms with pressure sensors. Changes in pressure and CO₂ capture are continuously recorded, providing a sensitive, real-time quantification of oxygen uptake by soil microorganisms as they mineralize test polymers.

Indeed, OECD 301 and 302 are considered screening tests, meaning they are first-tier assays that are easy to perform, cost-effective, and suitable for upscaling. Their main advantage lies in their stringency: they are highly selective and generally provide conservative biodegradation profiles. Thus, when a substance is classified as readily biodegradable according to these tests, it is generally assumed that it is unlikely to persist in the environment.

OECD 302 tests, which assess inherent biodegradability, further enhance the identification of a substance's potential for biodegradation or mineralization. However, they still lack environmental representativeness. In summary, while these screening tests efficiently address biodegradability criteria, they do have certain limitations regarding their environmental relevance. This is why, for second-tier testing, it is important to focus on the potential for biodegradation under actual environmental conditions, particularly by considering the impact of the matrix (e.g., soil or sediment) on the biodegradation process.

The soil test bridges this gap by simulating realistic soil conditions, enabling the assessment of polymer mineralization and persistence in a more environmentally relevant context. The protocol is versatile, accommodating various polymer types including (i) non-soluble microplastics, (ii) hydrosoluble polymers in formulations (iii) and adsorptive polymers as well as different soil matrices. It supports extended incubation periods for comprehensive monitoring. The data generated provide critical insights for regulatory submissions, product development, and sustainability assessments.

By advancing our understanding of polymer biodegradation in soil, this methodology supports Syensqo's mission to drive sustainable innovation and create solutions that benefit both humanity and the planet.

3.19.P-We278 From Functional Lifetime to Soil Breakdown: A Field Realistic Degradation Method

Pia Borelbach and Mona Duhme, Fraunhofer Institute for Environmental, Safety and Energy Technology UMSICHT, Germany

From Functional Lifetime to Soil Breakdown: A Field Realistic Degradation Method

Biodegradable plastics are routinely assessed either by artificial weathering without soil contact or by standardized biodegradation assays that require shredding and intimate mixing with a test substrate. Neither approach reflects the coupled action of solar radiation, soil microbiology, and moisture cycles under use, nor do they capture the critical window in which abiotic damage (e.g., photo oxidation, hydrolysis, embrittlement) triggers loss of function long before complete mineralization. To close this methodological gap, Fraunhofer UMSICHT has developed a non standard, yet rigorously controlled, degradation test that simultaneously exposes intact specimens to real soils, sensor controlled moisture regimes, and adjustable UV irradiation. A modular rig allows six parallel trials with independent registers. UV lamps there while address two registers each. Watering is solved via drip irrigation and magnet valves maintain setpoints. Soil temperature, UV dose and ambient conditions are logged continuously. This design enables reproducible comparisons across materials

and conditions while preserving application relevant interfaces and synergies.

We will present the method and its application to BioVlies, a project targeting bio-based, biodegradable nonwovens for crop protection as alternatives to polypropylene nonwovens. Although initially developed for mulch films, the protocol readily transfers to plates and nonwovens. Within BioVlies, polymer blends identified for spinnability and mechanical performance are processed into staple fiber nonwovens. Our degradation assay complements these trials by aging the samples in a laboratory controlled, similar to real field setting. This aging gives more detailed ideas and information how biodegradable plastic nonwovens perform within their application purpose.

By providing actionable metrics that connect application performance with degradability in soil, the assay supports eco design and offers an evidence base for future standardization. We argue that field realistic, non standard testing is essential to minimize microplastic release during use while ensuring agronomic efficacy, and we invite dialogue on integrating such methods into certification and product development workflows for biodegradable plastics.

Disclaimer/Disclosure:

This project is funded by the Federal Ministry of Research, Technology and Space (BMFTR) of the Federal Republic of Germany under grant agreement (031B1484B).

3.19.P-We279 From Fragmentation to Complete Biodegradation: Understanding the Fate and Timescales of Biodegradable Polymer Fragments in the Environment

Patrizia Marie Schmidt¹, Markus Rückel¹, Lars Meyer¹, Kai Oliver Siegenthaler², Glauco Battagliarin², Wendel Wohleben¹, Sam Harrison³, Cansu Uluseker³ and Andreas Künkel¹, (1)BASF, Germany, (2)Research Biopolymers, BASF, Germany, (3)UKCEH, United Kingdom

The environmental impact of plastic pollution has driven the development and adoption of biodegradable polymers, particularly for applications where post-use recovery is impractical. The loss of the structural integrity of these materials, however, is an inevitable part of the biodegradation process and leads to an interim formation of fragments. Here we present a comprehensive investigation into the fragmentation and biodegradation behavior of both industrially compostable polymer blends and certified soil-biodegradable mulch films, integrating advanced experimental techniques with mechanistic modeling.

In several independent biodegradation studies, various biodegradable polymer blends were subjected to industrial composting (ISO 14855) or soil biodegradation (ISO 17556). Fragmentation pathways were elucidated using fluorescence, FTIR and Raman microscopy. The results revealed that blend morphology, phase separation, crystallinity, and microbial colonization are key factors influencing fragmentation kinetics. Notably, fragmentation is not merely a surface phenomenon but is driven by inhomogeneities within the bulk material and by the accessibility of degraders. The experimental data were used to parameterize the open-source FRAGMENT-MNP model, enabling the prediction of fragmentation and dissolution rates, fragment size distributions, and the conversion of polymer mass into CO₂ during biodegradation. It was demonstrated that fragmentation is a transient phase: particle counts peak and then decline as mineralization proceeds, with over 90% of polymeric carbon ultimately converted to CO₂. Modeling confirmed that residual fragments do not persist as microplastics, with predicted concentrations dropping below one particle per gram of soil within 600–700 days.

Overall, these studies provide mechanistic and quantitative evidence that certified biodegradable polymers, when properly designed and tested, do not contribute to persistent microplastic pollution. The integration of experimental and modeling approaches offers a robust framework for guiding polymer design and regulatory assessment, supporting the transition to more sustainable plastic use in agriculture and packaging.

3.19.P-We280 Polymer Biodegradability and the Link Between Abiotic and Biotic Degradation

Christian-Sebastiano Toppi¹, Arnaud Martel¹, Guillaume Cottin², Samia Boudah², Alaa Bensetra³, Elsa PAIVA², Xavier Schultze², Fabienne Lagarde¹, Pascal Pandard² and Cyril Sweetlove², (1)Le Mans University, France, (2)L'Oréal, France, (3)Analytical chemistry, L'Oréal, France

Polymer persistence is a growing environmental concern, and current biodegradability tests are often designed for small molecules and may not adequately capture the complexities of polymer degradation. This study introduces a novel, integrated approach combining accelerated abiotic degradation pathways with advanced analytical techniques and standard biodegradability tests. Our aim is to identify specific degradation products, thereby elucidating a polymer's biodegradability mechanisms and a potential rapid screening test for polymers.

Polyhydroxybutyrate (PHB) and polylactic acid (PLA) served as model biodegradable and non-biodegradable polymers, respectively. To simulate and accelerate relevant hydrolytic degradation processes, polymer particles (1-10 µm) underwent hydrothermal aging at 130°C for various durations (1-120 hours). Following the abiotic treatment, the resulting water-soluble degradation products were analyzed directly by Liquid Chromatography-High Resolution Mass Spectrometry (LC-HRMS) to characterize the initial breakdown products.

Complementary OECD 301F biodegradability tests were conducted on pristine PHB and PLA. To comprehensively analyze degradation products from these biotic tests, a study of three selected Solid Phase Extraction (SPE) cartridges (Oasis HLB, C18 and StrataX) was employed to optimize the sample preparation and handle the analytically complex biodegradability medium before LC-HRMS analysis. The feasibility of employing Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF) was also explored, providing preliminary insights into identifying additional degradation products complementary to LC-HRMS.

This study introduces a novel approach, deploying applied analytical and sample preparation methods to successfully identify relevant polymer degradation products generated by the herein presented abiotic degradation method for the selected polyesters, notably correlating with those found in biodegradation media. Building on these promising findings, with our upcoming work we aim to further develop a suitable MALDI-TOF method. In parallel, our work intends to focus strategically on the in-depth exploration of novel abiotic techniques, particularly promising hydrothermo-oxidative conditions with the aim of mimicking observed biodegradation kinetic rates. These combined efforts are aimed at refining a potential predictive screening approach for polymer biodegradability.

3.19.P-We281 Assessing aqueous photo-degradability of novel polymers containing hydrolysable additives or oxidizable functional groups

Kiara Baker¹, Danny Bonomo¹, Jessica Vinskus¹, Andrew Ashmar¹, Jason Orlando², Sunny Suprenant¹, Kevin Noonan¹, Daphne Chan¹, Stefanie Sydlik¹ and Ryan Christopher Sullivan¹, (1)Carnegie Mellon University, United States, (2)Carnegie Mellon Institute, United States

Novel polymer materials designed to enable aqueous (photo)degradation pathways have been developed at Carnegie Mellon University through an NSF ECO-CBET team project. The central hypothesis we are exploring is that aqueous (photo)degradation pathways enabled by incorporating additives or labile functional groups will then enable biodegradation pathways not possible for commodity polymers. These new materials include polymers conjugated to graphene oxide, containing protein fibril additives, or oxidizable disulphide functional groups. We have developed accelerated aging methods to evaluate the degradability of these new materials under aqueous environmental conditions involving photo-oxidation or hydrolysis transformation pathways. The degradation rate and alteration of the original monomer or polymer material is evaluated along with determining the soluble transformation products and microplastic particles produced. LC-MS/MS, GC-MS, NMR, and Raman spectroscopy are the main analysis methods being deployed. Graphene oxide (GO) was found to produce significant singlet O₂ under UV illumination, a powerful selective oxidant that can drive oxidation of the polymer material covalently bound to the GO. Graphene oxide also enables aqueous degradation pathways. Protein fibril additives should enable aqueous degradation pathways of the composite material through oxidation or hydrolysis. The disulfide functional groups incorporated into polyethylene are vulnerable to oxidation by singlet oxygen and hydroxyl radicals, producing sulphonic acids that open new degradation pathways of the polyethylene. Molecular probe experiments were used to quantify the photo-oxidants produced by the polymer materials themselves (in the case of GO) or by chemical reagents representative of common environmental precursors (H₂O₂, HCO₃⁻, NO₃⁻).

3.19.P-We282 Development and Validation of a Laboratory Protocol to Assess Biodegradability and Ecotoxicity of Per- and Polyfluoroalkyl Substance Alternative Polymers and Their Transformation Products

Qiyun Zhang, Ph.D. candidate¹, Sebastiaan Lichtert¹, Pegah Zahedifar², Gertrude Kignelman², David De Smet² and Karel De Schamphelaere¹, (1)Laboratory of Environmental Toxicology and Aquatic Ecology (GhEnToxLab), Department of Animal Sciences and Aquatic Ecology, Belgium, (2)Centexbel, Belgium

Per- and polyfluoroalkyl substances (PFAS) have been extensively used due to their chemical stability and surfactant properties. However, these same characteristics also contribute to their extreme persistence, leading to their widespread occurrence and accumulation in aquatic ecosystems, and increasing regulatory scrutiny. In response, research efforts toward PFAS-alternative polymers have accelerated, with a focus on materials that

can retain performance characteristics while offering improved environmental profiles, particularly reduced persistency.

Despite this progress, standardized methods to evaluate the environmental safety of these novel polymers remain limited. While assessing the degradability of PFAS-alternative polymers is critical, there is also a need to understand whether the transformation products formed during degradation might cause ecotoxicological effects on non-target organisms.

This study aims to develop and validate a reproducible laboratory protocol for evaluating the biodegradability and ecotoxicity of PFAS-alternative polymers. Biodegradation was monitored using a ready biodegradation test based on the standard Organisation for Economic Co-operation and Development (OECD) guideline 301.

Transformation products generated during the BOD test were subsequently isolated by testing out and optimising a variety of separation techniques. The ecotoxicity was assessed using the *Daphnia magna* immobilization test (OECD 202) and the algae growth inhibition test (OECD 201), to evaluate ecotoxicological responses at different trophic levels. The protocol allows quantifying changes in ecotoxicity between the parent compound and its transformation products.

Our research contributes a practical, scientifically grounded testing framework for early-stage environmental screening of fluorine-free polymeric PFAS alternatives. By integrating biodegradation and ecotoxicity endpoints, this protocol supports the advancement of Safe and Sustainable by Design (SSbD) innovation in fluorine-free chemistry.

3.19.P-We283 Comparative Ecotoxicological Assessment of Microplastics Derived from Biodegradable and Conventional Plastics

Norihisa Tatarazako, Ryotaro Kanefuji and Yukiyo Okazaki, Ehime University, Japan

Marine pollution caused by plastics remains a critical global environmental issue.

Biodegradable plastics, which ultimately decompose into water and carbon dioxide in the environment, are considered a promising solution to the plastic waste problem. However, challenges such as limited recyclability still hinder their widespread adoption.

In our previous work, we proposed a practical ecotoxicological assessment method for intermediate degradation products of biodegradable plastics, referencing ISO 5430 (Ecotoxicity test for marine biodegradation) while aligning the procedure with Japan's chemical regulatory framework.

In the present study, we compared the ecotoxicological effects of microplastics (MPs) generated from both biodegradable and conventional plastics using acute toxicity tests with *Daphnia magna*. Direct toxicity of MPs alone was not detected; therefore, we investigated changes in toxicity when MPs coexisted with environmental pollutants. Zinc and pyrene were selected as representative contaminants. Polyethylene was used as a conventional plastic, whereas PBHB, PGA, PCA, and PBA were used as biodegradable plastics.

The results indicate that differences in pollutant adsorption capacities among plastic types alter the toxicity profiles during co-exposure. These findings highlight the importance of considering interactions between MPs and environmental contaminants when evaluating their ecological risks.

Disclaimer/Disclosure:

This presentation is based on results obtained from projects subsidized by the New Energy and Industrial Technology Development Organization (NEDO) and granted by the JCIA-LRI.

3.19.P-We284 Ecotoxicity of Biopolymers – Learnings from the Lab to the Field Scale

Marie Winter¹, Gabriele Broll², Bodo Philipp³, Cecilia Diaz⁴, Sebastian Eilebrecht⁵ and Karsten Schlich⁶, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME); University of Osnabrueck, Germany, (2)Institute of Geography, University of Osnabrück, Germany, (3)Institute of Molecular Microbiology and Biotechnology, University of Münster, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (6)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Biopolymers are considered as sustainable alternatives to synthetic, non-degradable polymers for use in agrotechnical products. Therefore, biopolymers remain unregulated, whereas synthetic microparticulate polymers got restricted under EC 2023/2055. However, ecotoxicity data supporting the exclusion of biopolymers from regulation is missing. This three-year study investigated: I) Whether biopolymers cause ecotoxic effects potentially linked to their substance properties, II) Which ecotoxicological methods best assess biopolymer ecotoxicity and III) The suitability of laboratory tests for predictions on the field scale (laboratory vs. outdoor

field study).

Four aquatic (e.g. OECD TG 201, transcriptomic analysis of fish embryo) and seven terrestrial test methods (e.g. ISO 15685, OECD TG 222) were selected to examine the ecotoxicological responses of six biopolymers and modified natural polymers (e.g. alginate, chitosan, CMC). The dataset generated was used to identify sensitive methods based on a LOEC (Lowest Observed Effect Concentration) comparison as well as OECD TG 216 threshold ($\pm 25\%$ deviation of treatment to control activity) analysis for soil microbial functional tests. To validate laboratory tests for field scale predictions, the identified sensitive test methods were applied in a one-year laboratory and outdoor field study (single substances/ substance mixtures).

Biopolymer exposure impaired microbial-driven soil cycles, such as potential nitrification (ISO 15685) and extracellular enzymatic activities (ISO 20130), with both inhibitory and stimulatory effects $>25\%$ depending on substance and concentration. Collembola and earthworm-related endpoints were mainly unaffected. Aquatic test results indicated that physicochemical properties (e.g. solubility, ionic charge) can be linked to the ecotoxicological outcome of the test.

For the laboratory and outdoor field study, ISO 15685 and ISO 20130 were performed. Extracellular enzymatic activity data showed a correlation between lab and field incubated samples, while potential nitrification activity correlated poorly over time. This could be linked to the degree of specialization of the microbial groups relevant to maintaining the soil functions.

Overall, biopolymers can cause ecotoxicological responses and should not be excluded from regulation without further evaluation. Incorporating soil microbial functional tests alongside aquatic tests is recommended for a comprehensive polymer assessment.

3.19.P-We285 Ecotoxicity assessment of Seaweed-Based Packaging Materials using *Capitella teleta*

Timpy Timpy¹, Eda Duranay¹, Stive Pregent², José María Martín-Durán³, Ruth Sarah Rose³ and Marina Resmini¹, (1)School of Physical and Chemical Sciences, Queen Mary University of London, United Kingdom, (2)Notpla Limited, United Kingdom, (3)School of Biological and Behavioural Sciences, Queen Mary University of London, United Kingdom

Biodegradable and bio-based materials, such as those derived from seaweed, corn, cellulose and other natural polymers, are being developed as sustainable alternatives to petroleum-based plastics. However, their increased use has not been matched by in-depth research on their environmental fate and potential ecotoxicological risks. To address this knowledge gap, this study evaluated the impact of brown seaweed-based single-use food packaging materials on *Capitella teleta*, a marine invertebrate often used as a relevant model organism for assessing ecotoxicity. The first part of the work focused on the characterisation of commercially available brown seaweed-based single-use boxes using Fourier Transform Infrared Spectroscopy (FTIR), Scanning Electron Microscopy (SEM), and contact angle. The data provided insights into the surface chemistry, morphology, microstructure, and hydrophobic character of these materials. In the second part, exposure experiments with *Capitella teleta* were done using two approaches: 1) disc material (3 mm) and 2) crushed fibre (sieved to 1000 μm). The experiments were conducted over six weeks by incubating 120 mg of samples in 12g of sediment in the artificial seawater. The measured endpoints included initial adult count (number of males and females), adult survival during each sift, time to sexual maturity, time to first reproduction, number of reproductive events, eggs per brood tube, and stages of the eggs produced in the brood tube.

Key findings from the chemical characterisation using FTIR confirmed the functional groups, as expected, while SEM imaging provided evidence of the surface coating. Contact angle measurements indicated a highly hydrophilic nature. A series of experiments was also conducted to obtain statistical data, and these provided evidence of uniformity in the coating of the commercial boxes and confirmed high data reproducibility. Ecotoxicity tests with *Capitella teleta* offered preliminary insights into the impact of these materials. This work contributes to the broader understanding of the environmental fate and potential risks associated with seaweed-derived packaging materials, supporting evidence-based evaluation of their suitability as sustainable alternatives to petroleum-based plastics.

Disclaimer/Disclosure:

This project, GreenX3, is funded by the European Union Horizon Europe MSCA Doctoral Network programme under EC Grant Agreement 101120061 and by UK Research and Innovation (UKRI) under the UK government's Horizon Europe funding guarantee [grant number EP/Y032039/1].

3.19.P-We286 Development and demonstration of sustainable bio-based materials for the marine environment

Nelle Siele Meyers¹, Ana Isabel Catarino², Jens Vroman³, Isabel De Schrijver³, Maelenn Le Gall⁴ and Maria El

Rakwe⁵, (1)*Ocean and Human Health, Flanders Marine Institute (VLIZ), Belgium*, (2)*Flanders Marine Institute (VLIZ), Belgium*, (3)*Centexbel, Belgium*, (4)*IFREMER, France*, (5)*IFREMER, France*

Polymer-based applications are increasingly used across marine sectors, yet their fossil-fuel-based origins are considered unsustainable. The SeaBioMat project explores bio-based alternatives that could replace conventional materials while maintaining their performance. Building on earlier findings that PLA-flax composites perform well and generate fewer microplastics than polypropylene, SeaBioMat aims to advance these materials to higher TRL levels and explore additional bio-based and biodegradable polymers for composite and textile use. The project considers the entire life cycle and potential environmental interactions, such as microplastic formation and its effect on the marine environment, to ensure a lower ecological footprint. A key research task is to assess micro- and nanoplastic generation from the degraded materials, their effects on marine organisms, and material behaviour under realistic environmental conditions. To properly understand these degradation processes, the newly developed materials will undergo accelerated ageing under controlled but representative marine conditions, where extrinsic factors such as water, oxygen, microbial activity, mechanical abrasion, and UV radiation will be decoupled. Ageing will be followed by detailed mechanical and physicochemical characterisation, including tensile testing, crystallinity and molecular-weight analysis, FTIR/RAMAN spectroscopy, and gravimetric measurements. Within this framework, we will assess the potential impacts of the developed materials, focusing on their durability, degradability, and ecotoxicological effects compared to current synthetic-based materials. We will specifically focus on understanding how exposure to UV radiation, mechanical stress and temperature may lead to the formation of micro- and nanoplastics, and on determining the potential toxic effects of these microplastics on aquatic organisms such as microalgae, and benthic invertebrates such as copepods and bivalves. Microplastics generated during ageing and abrasion will be analysed using RAMAN/FTIR spectroscopy and Nile Red staining, and their ecotoxicity will be assessed through targeted bioassays. Leaching of substances from bio-based materials and their ecotoxicological impacts on the marine environment will also be studied. The expected outcomes will provide valuable insights into the environmental compatibility of bio-based polymers and support the development of sustainable materials for marine applications.

3.19.P-We287 Biodegradable Safe and Sustainable by Design Polymers for Packaging of Oily Food and Cosmetic Products

Arantxa Ballesteros Ríaza¹ and Javier Alcodori², (1)Processes and Products Safety Unit, ITENE research centre, Valencia, Spain, (2)Processes and Products Safety Unit, ITENE Research Centre, Valencia, Spain

Biodegradable polymers offer promising alternatives to conventional plastics, yet their adoption requires robust methods to assess safety, environmental fate and overall sustainability. The E-OILÉ project addresses this need by developing and validating new biodegradable materials for monodose packaging of oily foods and cosmetic products while applying a fully integrated Safe and Sustainable by Design (SSbD) framework. The project focuses on understanding regulatory requirements, identifying data needs, and ensuring that new materials comply with safety, performance and environmental criteria across their entire life cycle.

A key challenge is that biodegradable polymers do not behave like conventional plastic materials and therefore require adapted methodologies for characterisation, biodegradation and risk assessment. To address this, the project combines early-stage regulatory review, requirements definition, and targeted data collection for modelling. High-quality experimental information on material properties, toxicity, and environmental degradation will support the development of digital twins capable of predicting biodegradation processes.

The safety assessment integrates new in vitro methods to evaluate potential hazards to human health, including cytotoxicity, genotoxicity, skin irritation and inflammation using relevant human cell models. Environmental safety is addressed through ecotoxicological testing in freshwater, marine and terrestrial systems. Suitability for food and cosmetic contact is evaluated through migration testing and risk assessment based on European legislation.

Sustainability is examined through LCA, S-LCA and LCC, complemented by circularity indicators to capture resource efficiency, end-of-life performance and potential environmental benefits compared to fossil-based packaging.

Overall, this work provides a comprehensive framework for evaluating biodegradable polymers that integrates regulatory compliance, mechanistic understanding of biodegradation, human and environmental safety and holistic sustainability. The results will support the safe implementation of biodegradable packaging and offer transferable approaches for the broader assessment of emerging polymer materials.

This project received funding from the Horizon Europe research and innovation programme under grant agreement N° 101177771.

3.19.P-We288 Safe and Sustainable by Design Development of Next-Generation Biodegradable Polymers for Circular Packaging Applications

Arantxa Ballesteros Riaza¹, Javier Alcodori² and María Rivero García³, (1)Processes and Products Safety Unit, ITENE research centre , Valencia, Spain, (2)Processes and Products Safety Unit, ITENE Research Centre , Valencia, Spain, (3)ITENE Research Centre , Valencia, Spain

The transition towards safer, more sustainable packaging materials requires new biodegradable polymers that combine high technical performance with improved end-of-life fate. Despite increasing market demand, most current biodegradable plastics are still limited by suboptimal degradation in real environments, insufficient barrier or mechanical properties, and the lack of harmonised methodologies to assess their safety and sustainability. In this context, BioPackMan aims to design and demonstrate new biodegradable polymer materials for packaging applications by applying a fully integrated Safe and Sustainable by Design (SSbD) framework, supporting the deployment of circular biobased solutions.

The project explores an extended space of biodegradable polymers, including PHAs, PLA, PBS/PBSA and tailored copolymers, combined with sustainable additives such as natural nanocellulose, nanolignin and plant-derived functional ingredients. BioPackMan focuses on the development of at least four innovative biodegradable formulations and multiple additive systems to enhance mechanical performance, barrier properties and controlled biodegradation. Two advanced processing technologies will support the production of both rigid and flexible packaging formats.

A central objective of BioPackMan is to apply SSbD principles from early design stages onwards, integrating hazard assessment, human and environmental safety, exposure considerations and life-cycle sustainability, enabling iterative feedback loops between material development, safety assessment, performance testing and sustainability evaluation. This ensures that the selected formulations and processing routes are aligned with regulatory expectations, minimise potential hazards, optimise resource efficiency and deliver favourable end-of-life scenarios. Packaging demonstrators for food, home-care and personal-care applications will validate industrial relevance and allow benchmarking against conventional fossil-based packaging.

BioPackMan will generate scientific and technical evidence to support the design, assessment and demonstration of safe, sustainable and circular biodegradable polymers. The project will contribute to refining SSbD implementation for emerging biobased materials, provide methodologies for robust biodegradation and safety assessment, and deliver demonstrators and recommendations that facilitate the uptake of next-generation biodegradable packaging solutions in European value chains.

This project received funding from the Horizon Europe research and innovation programme under grant agreement N° 101178576.

3.19.P-We289 Safe and Sustainable Bio-based Polymers: Assessing safety and environmental impact of 5-(Hydroxymethyl)furfural Derivates in the CERISEA Project

Javier Alcodori¹, Pau Camilleri² and Arantxa Ballesteros Riaza³, (1)Processes and Products Safety Unit, ITENE Research Centre , Valencia, Spain, (2)ITENE Research Centre, Spain, (3)Processes and Products Safety Unit, ITENE research centre , Valencia, Spain

The CERISEA project is a pioneering large-scale initiative within the European bio-based chemical sector, dedicated to establishing a sustainable and circular production pathway for 5-Hydroxymethylfurfural (5-HMF). Sourced from non-food biomass side streams, 5-HMF serves as a versatile platform chemical for producing polymers, resins, and crop science solutions. Fully aligned with the European Green Deal, CERISEA's core innovation is its comprehensive application of the Safe and Sustainable by Design (SSbD) framework to systematically assess and mitigate the safety and environmental impacts across the entire value chain, from initial feedstock to final product.

The project's methodology is built on a structured, iterative application of SSbD principles. This begins with a detailed scoping analysis to define system boundaries and characterize the potential environmental fate of HMF and its derivatives. The safety assessment pillar rigorously follows OECD guidelines and REACH standards to proactively identify and mitigate hazards for human health and the environment, ensuring regulatory compliance from the outset. Concurrently, the environmental sustainability is evaluated through Life Cycle Assessment (LCA) to quantify the project's footprint, demonstrating a targeted reduction of 10,200 tons of CO₂ emissions annually compared to conventional fossil-based production. A key aspect of the environmental work involves using advanced predictive and mechanistic models to understand the biodegradation pathways and exposure potential of the resulting bio-based polymers, ensuring they break down safely without leading to persistent accumulation in ecosystems.

By seamlessly integrating cutting-edge production technology with rigorous, tiered SSbD assessments and strong stakeholder engagement, the CERISEA project successfully validates an economically viable and industrially scalable model for bio-based chemical production. It conclusively demonstrates that high-volume manufacturing can be achieved without compromising on safety or sustainability, thereby paving the way for a greener, more resilient, and circular European chemical industry.

Disclaimer/Disclosure:

Abstract written thanks to funding from the European Union, within the Circular Bio-based Europe Joint Undertaking (CBE-JU) under grant agreement No 101214076. The JU receives support from the European Union Horizon Europe research and innovation programme and the Bio Based Industries Consortium.

3.19.P-We290 Connecting Disciplines to Shape Sustainable Bioplastics Futures: A System-Dynamics Meta-Framework

M.T. (Marieke) Brouwer¹, E.U. (Ulphard) Thoden van Velzen¹, J. (Judith) Van Leeuwen², W.S. (Wei-shan) Chen², D.P.B.T.B. (David) Strik² and Y.B. (Yme) Van Lith², (1) Wageningen Food & Biobased Research, Netherlands, (2) Wageningen University and Research (WUR), Netherlands

The environmental and societal impacts of plastics necessitate a transition to a sustainable plastic system; however, the complexity and limited understanding of this system hinder effective interventions. Interventions tend to focus on technology or policy, often overlooking broader, interconnected sustainability challenges within plastic systems. There is a need to shift from fragmented approaches to holistic plastic-transition studies. To address this, the Plastic Transition Meta-Framework (Plastic TMF) was developed and presented as a comprehensive framework for analyzing plastic systems and transition dynamics through an interdisciplinary lens. The framework aims to clarify transition complexities and guide future research by integrating sustainability dimensions (people, planet, profit) into an assessment of the system dynamics of the plastic system. Developed through a multi-step process, it builds on a thorough PRISMA-based literature review and integrates existing system and transition dynamics frameworks. The framework incorporates specific components and related indicators to operationalize six interconnected systems: socioeconomic, technological, ecological, driving forces, societal goals, and planned interventions. This structure enables a detailed assessment of system dynamics and clarifies the connections between them. By distinguishing the status quo, system dynamics, and transition dynamics, this framework provides deeper insights into plastic transitions. This interdisciplinary approach addresses key gaps in the existing literature by integrating and advancing diverse perspectives. While its comprehensive nature offers new insights, the framework's applicability may vary depending on specific contexts and practitioners' needs. A complementary case study was conducted to implement the framework. The study explores future development pathways for PHA bioplastics through dynamic material flow analysis, assessing potential technological and legislative interventions and their impacts. All in all, it demonstrates how the framework links current system assessments with future sustainability transitions in plastics. This contribution advances the field by providing a conceptual tool for navigating the complex challenges of plastic sustainability in the future.

3.20.A PFAS in Terrestrial & Aquatic Ecosystems: Advances in Understanding of Fate and Effects

3.20.A.T-01 Sea Spray Aerosols and other Per- and Polyfluoroalkyl Substances (PFAS) Sources on an Arctic Volcano

William Hartz¹, Nora Larsson², Pontus Larsson², Ingrid Ericson Jogsten³, Leo Yeung⁴, Stine Eriksen Hammer⁵, Stephan Weinbruch⁶ and Roland Kallenborn⁷, (1)Örebro University & NILU, Norway, (2)Örebro University, Sweden, (3)MTM Research Centre, Örebro University, Sweden, (4)Örebro University, Sweden, (5)Norwegian Coastal Administration, Norway, (6)Technical University of Darmstadt, Germany, (7)Norwegian University of Life Sciences, Norway

Per- and polyfluoroalkyl substances (PFAS) are a diverse group of organofluorine contaminants found worldwide, including in the remote Arctic. While long-range atmospheric degradation of precursors has become established as a major contributor to PFAS deposition in remote environments, the role of sea spray aerosols (SSAs) remains poorly understood in the field. SSAs, generated by wave action and bubble bursting, may provide an additional significant pathway for PFAS transfer from ocean to atmosphere.

This study investigated PFAS deposition on Jan Mayen, a remote Arctic island in the North Atlantic, to evaluate the potential influence of SSAs alongside other sources. Surface snow samples and surface water samples on the island were collected for this investigation. Ten snow samples were collected inland along a transect (2.5 – 6.8 km from the coast) up the world's northernmost active volcano (2277 m.a.s.l.). Melted snow and water samples were analysed for PFAS, and used to investigate local activities, glacier runoff, atmospheric precursor degradation and SSAs as sources of PFAS in the remote Arctic coastal environment.

Results indicated that local sources were spatially limited (<0.5 km). As such the transect up the volcano represented just processes of the remote Arctic environment. At higher elevations on the transect, PFAS profiles were dominated by trifluoroacetic acid and perfluoropropanoic acid and perfluorobutanoic acid, consistent with atmospheric precursor degradation. Some PFAS concentrations decreased with lower elevation due to increased summer snowmelt, with glacier runoff transferring PFAS to downstream aquatic ecosystems. In contrast, several longer chain perfluoroalkyl acids, including perfluorooctanesulfonic acid and perfluorooctanoic acid, were still elevated in surface snow <500 m.a.s.l., coinciding with elevated sodium ion concentrations, suggesting SSA influence from nearby wave action on the coastline (<4.2 km away). These chain length dependent results confirm existing knowledge that only those most surface active PFAAs are expected to be enriched in SSAs.

These results demonstrated the importance of SSAs as a source of PFAS in coastal areas, whereas the atmospheric degradation of precursors dominated as a PFAS source at locations removed from maritime air mass influence at higher elevations. Understanding SSA as a PFAS source is important for assessing PFAS exposure in coastal ecosystems/agriculture and drinking water sources.

3.20.A.T-02 Environmental and Human Health Risks of Short-Chain PFAS Falling Under the Purview of the Montreal Protocol and Amendments

Keith R. Solomon¹, Mark L. Hanson², Mads Peter Andersen³ and Timothy Wallington⁴, (1)University of Guelph, Canada, (2)University of Manitoba, Canada, (3)California State University, Northridge, United States, (4)University of Michigan, United States

Trifluoroacetic acid (TFA) is a breakdown product of several refrigerant gases that fall under the purview of the Montreal Protocol (MP) and amendments. Perfluoro propionic acid (PFPrA) and perfluoro butanoic acid (PFBA) are short-chain PFAS that are used as blowing agents for insulation and also fall under the purview of the MP. TFA is widely used in industry as a precursor for synthesis and a reagent and large quantities are released into the environment. It is also a final residue of some agrochemicals and pharmaceuticals containing the CF₃ group. The -CF₃ group, a pseudohalogen, confers beneficial properties to these chemicals, but they could degrade to produce TFA. These three perfluorinated acids have low pK_a values and accumulate as salts in terminal sinks like the oceans and endorheic lakes with no outflows. They are globally distributed in surface waters. With the possible exception of TFA, they are anthropogenic and are persistent in the environment. Their intensive properties, particularly their solubility in water allows them to be easily excreted by animals and, unlike the longer-chain PFAS, they are not bioaccumulative in food-webs. However, their persistence has raised concerns for potential adverse effects in the environment. This presentation is the culmination of an extensive characterization of environmental fate and effects of these acids in the environment and humans. We have used probabilistic approaches such as species sensitivity distributions combined with cumulative frequency

distributions of environmental concentrations to characterize hazards and risks to humans and the environment. The results of this analysis suggest that predicted amounts to be released in the next 75 years through from the degradation of compounds related to the Montreal Protocol, are of de minimis risk to ecosystem and human health. However, the same is not necessarily true for other sources in the environment.

3.20.A.T-03 Small Creatures, Big Contaminants: PFAS uptake in macroinvertebrates

Adele Romagnano¹, Vincent J. Pettigrove² and Claudette Kellar¹, (1)RMIT University, Australia, (2)Aquest Research Group, RMIT University, Australia

Per- and polyfluoroalkyl substances (PFAS) are widely distributed in freshwater ecosystems and can enter the environment through point sources, such as wastewater treatment facilities, or diffuse sources, such as urban runoff. While research has primarily focused on the impact of point-source PFAS, the effect of diffuse sources on biota remains poorly understood; despite urban environments being associated with elevated PFAS. Macroinvertebrates are well-suited to biomonitoring because they live within the water column and occupy key positions in aquatic food webs, providing insight into bioaccumulation across trophic levels. Typical assessments include surface water or sediment samples, which provide a static reading, while macroinvertebrates offer a unique temporal evaluation of contamination. This study quantified PFAS accumulation in freshwater macroinvertebrates from urban and non-urban streams to evaluate diffuse PFAS and characterise pollution profiles across urban and non-urban environments.

Macroinvertebrates were collected from 29 sites in urban and non-urban areas. Concentrations of 25 PFAS congeners were measured and correlated with catchment imperviousness, dominant land use (%), and distance from the largest city to predict PFAS accumulation and congener distribution.

PFAS were detected extensively across all sites, with twenty PFAS congeners detected in 82% of the macroinvertebrate samples. PFOS was the most dominant and was detected at the highest concentrations at 73 ng/g ww. Urban sites exhibited higher median concentrations, although PFOS, PFDoDA, PFTeDA, and ?29PFAS were the only congeners where levels were significantly elevated. PFOS was positively correlated with the percentage of residential and industrial land cover and was negatively correlated with the percentage of non-urban land. The number of PFAS and long-chain congeners had a positive association with the percentage of residential land, while showing a negative association with the percentage of non-urban land.

This study provides the first evidence of PFAS accumulation in macroinvertebrates from Australian freshwater streams, demonstrating that diffuse urban sources can contribute substantially to trophic exposure, even in areas where point sources are limited. These findings advance our understanding of PFAS behaviour and environmental distribution, highlighting the importance of biota in biomonitoring the accumulation of PFAS to guide chemical management strategies.

Disclaimer/Disclosure:

This study was funded by Ecology Australia (Holsworth Wildlife Grant).

3.20.A.T-04 Covering 57 PFASs in One Shot: An Expanded LC-MS/MS Method for Contaminant Tracing Through the Otter Food Web

Ling Chen¹, Ruben Meine Kause², Bas van Dijk², Nico van den Brink³ and Stefan van Leeuwen², (1)Wageningen Food Safety Research (WFSR), China (Mainland), (2)Wageningen Food Safety Research (WFSR), Netherlands, (3)Toxicology, Department of Agrotechnology and Food Sciences, Wageningen University and Research, Netherlands

With the ongoing phase-out of legacy per- and polyfluoroalkyl substances (PFASs), numerous emerging and precursor compounds have been introduced as replacements. In this study, we developed and validated a sensitive and robust liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) method for the simultaneous quantification of 57 PFASs compounds, including legacy substances, precursors, and emerging PFASs such as chloroperfluoropolyether carboxylates (ClPFPECAs) and perfluoroethylcyclohexane sulfonate (PFECBS). The method achieved limits of detection (LOD) as low as 0.01 ng/g, demonstrating its suitability for trace-level analysis in complex biological matrices. It was further applied to several aquatic species within the otter's food web, enabling comprehensive assessment of PFASs distribution, environmental fate, and bioaccumulation in freshwater ecosystems.

3.20.B PFAS in Terrestrial & Aquatic Ecosystems: Advances in Understanding of Fate and Effects

3.20.B.T-01 PFAS in Fire Foam Contaminated Soils – The Importance of Precursors and Leaching for Risk Assessment

Patrick van Hees¹, Patrik Karlsson² and Maja Milosevic Puhacin², (1)Eurofins Food & Feed Sweden AB/Örebro University, Sweden, (2)Eurofins Food & Feed Testing Sweden AB, Sweden

Per- and polyfluoroalkyl substances (PFAS) comprise a chemically diverse group that includes ultrashort chains and high-molecular-weight polymers, posing challenges for environmental risk assessment. Historically, regulations have focused on a limited set of terminal PFAS, overlooking precursor compounds that transform into persistent perfluoroalkyl acids. Aqueous film-forming foams (AFFFs), widely used for fire suppression, are major sources of these precursors, which exhibit strong sorption and some also long-term stability in soils. This study investigates PFAS concentrations, composition and leaching behavior in source-zone soils from Swedish airports to give input to risk assessment strategies. Soils were analyzed using extended target lists, total oxidizable precursor (TOP) assay, and suspect screening to identify both original AFFF constituents and possible degradation products. Batch leaching tests (L/S=10) were performed to evaluate mobility. Results show that fluorotelomer-based precursors, particularly 6:2 FTAB, dominate PFAS profiles, with concentrations up to 8,100 µg/kg dry matter. A number of C5-C8 sulphonamides were also identified but at moderate concentrations. TOP assay confirmed precursor presence and transformation potential, with perfluoroalkyl carboxylate (PFCA) increases up to 12,000 µg/kg. Many of the precursors showed structures with quaternary nitrogen head-groups. Leaching tests revealed substantial mobility, with up to 79% of PFAS content released, and branched forms leaching slightly more than linear forms. Sorption coefficients (Log KOC) indicate significant soil retention for major contaminants as PFOS and 6:2 FTAB, but air-water interface effects may further influence adsorption.

Findings highlight that precursor compounds often exceed regulated PFAS concentrations and significantly contribute to long-term groundwater risk. Incorporating precursors and potential transformation products into analytical and regulatory frameworks is essential for accurate risk assessment and effective remediation planning. The work contributes with insights to guide future contaminated land management and risk evaluation.

3.20.B.T-02 Dynamics of emerging PFAS in a contaminated terrestrial ecosystem

Oliver Salangad, Francesca Cappelli, Fabian Simon, Jodie Buytaert, Marcel Eens, Lieven Bervoets, Thimo Groffen and **Adrian Covaci**, University of Antwerp, Belgium

Previous studies near a fluorochemical plant near Antwerp (Flanders) revealed some of the highest PFAS concentrations ever reported in soils, invertebrates, and songbird eggs. However, these studies mainly focused on a set of legacy PFAS. The main objective was to investigate the occurrence and fate of emerging PFAS identified with non-target analysis in soil and the corresponding accumulation of these compounds in songbird eggs.

Surface soil samples (n=30) were collected in 2024 close to and were pooled into 7 composite samples. Eggs from great tits (*Parus major*) (n=29) and blue tits (*Cyanistes caeruleus*) (n=10) were collected from the same sites in April-May 2022.

Suspect and non-target screening (SS/NTS) analyses were carried out using LC-QTOF-MS. Additionally, ~30 PFAS were analysed by target LC-MS/MS to quantify the most common PFAS, including sulfonates, carboxylates, sulphonamides and their derivatives.

In both soil and eggs, legacy PFAS classes were identified, such as long-chain sulfonates (PFSA), including homologues (up to C16) previously unreported. SS/NTS identified emerging PFAS classes (CL2-3), including pentafluorosulfide-perfluoroalkyl sulfonic acids (SF₅-PFSA), ether-substituted carboxylic acids (PFECAs) and sulfonic acids (PFESA), and keto-PFSA. Certain homologues of SF₅-PFSA (C6, C11), PFECA (C11-C12), and PFESA (C6-C9, C11, C13, C15) were present in eggs, but not in soil, suggesting biotransformation of SF₅-PFSA in birds to shorter homologues.

PFSA were the major PFAS, comprising 24 % of the total PFAS in soil and 86 % in eggs. In both matrices, PFOS was the most predominant (up to 1,030 ng/g in soil and 51,000 and 3,600 ng/g ww in great tit and blue tit eggs, respectively). Yet, the prevalence of FASA (FOSA; 2301 ng/g) and FASAA (Et-FOSAA; 7108 ng/g) was observed in soil. SF₅-PFSA (3900 ng/g; 2% of total PFAS) and keto-PFAS (<1%) were both previously identified in soils impacted by AFFF. In great tit eggs (more contaminated than blue tit eggs), total SF₅-PFSA level reached up to 6200 ng/g, corresponding to 5% of the total PFAS burden. Among SF₅-PFSA, the C9-homologue was the most predominant in both matrices, followed by the C8-homologue.

The comparison of biotic and abiotic matrices showed some overlaps but also differences in contamination profiles and homologue distributions. This emphasizes that SS/NTS approaches have the potential to identify overlooked PFAS to better understand and mitigate adverse effects.

3.20.B.T-03 Linking PFAS Structure to Plant Uptake: Differential Accumulation in Root and Fruit Crops
Rebecca E Yates¹, Zhaoyang Liu² and Jay Gan¹, (1)University of California, Riverside, United States, (2)Huazhong Agricultural University, China (Mainland)

Since the early 2000s, restrictions on legacy PFAS such as PFOS and PFOA have driven the development of novel PFAS incorporating shorter chains, ether groups, or halogen substitutions; however, emerging evidence suggests several novel PFAS may equal or exceed their legacy counterparts in persistence and bioaccumulation. As practices such as treated wastewater irrigation and biosolids application expand, understanding how structural modifications influence plant uptake of PFAS is critical. This study aimed to evaluate structural drivers of PFAS bioaccumulation in edible crops and support the development of mechanistic models to inform future agricultural practices. Tomatoes (*S. lycopersicum*) and carrots (*D. carota*) were grown in hydroponic solution containing ten representative PFAS (5 µg/L each). Leaves and edible tissues were sampled every 9 d to monitor PFAS accumulation over time, and whole plants were harvested at maturity for quantification of PFAS in roots, shoots, leaves, and fruits, with corresponding bioaccumulation factors (BAFs) calculated. In tomato roots, 6:2 Cl-PFESA accumulated to the highest extent (1040.8 µg/g), exceeding but followed by PFOS (745.4 µg/g). PFASs accumulated more strongly than PFCAs of equal chain length, and short-chain PFAS showed relatively low root retention, consistent with high mobility. Similar patterns were observed in shoots, with 6:2 Cl-PFESA reaching 889.5 and PFOS 341.4 µg/g. Leaves displayed a distinct distribution, with ADONA accumulating most strongly (5202.9 µg/g in young leaves; 1776.3 µg/g in old leaves), followed by PFOA (2431.4 and 1500.5 µg/g), GenX (1538.8 and 1321.3 µg/g), and PFBA (1503.5 and 1265.9 µg/g). In fruits, accumulation also favored smaller and ether PFAS, with GenX reaching 966.3, PFBA 701.1, PFBS 447.7, and PFHxA 381.9 µg/g. Larger, more hydrophobic PFASs and Cl-substituted PFAS were detected at very low levels in fruits. Calculated BAFs reinforced these trends, with long-chain, Cl-substituted PFAS exhibiting higher BAFs in roots and shoots, while smaller and ether-containing compounds showed enhanced translocation and higher BAFs in leaves and fruits. Ongoing carrot analyses and equation modelling are expected to refine these structure–uptake relationships in a root vegetable system. A better understanding of how specific molecular features help govern plant PFAS bioaccumulation may guide safer chemical design and management strategies to reduce dietary exposures from crop consumption.

3.20.P PFAS in Terrestrial & Aquatic Ecosystems: Advances in Understanding of Fate and Effects

3.20.P-Tu329 Evaluation of the CTC PAL RSi online SPE system for PFAS analysis in environmental water matrices

Sara Beverley and Peter Hancock, Waters Corporation, United Kingdom

Per- and polyfluoroalkyl substances (PFAS) are persistent environmental contaminants requiring robust analytical workflows for trace-level detection in complex water matrices. This study evaluates the CTC PAL RSi autosampler configured for online solid-phase extraction (SPE) coupled to a Waters Xevo™ TQ-Sµ triple quadrupole mass spectrometer for the analysis of PFAS. Included are the list of 48 PFAS in UK Drinking Water Inspectorate (DWI) including the 20 PFAS contained in the 2020 EU Drinking Water Directive (EU 2020/2184) and emerging zwitterionic/cationic species associated with aqueous film-forming foams (AFFFs) totalling 55 analytes.

To address zwitterionic and cationic PFAS species, the method employs rapid polarity switching during MRM acquisition, leveraging the TQ-Sµ's fast polarity switching capability (15 ms) to ensure accurate detection across diverse PFAS chemistries.

Using Oasis™ HLB SPE chemistry in a single-column setup, the system demonstrated suitability for quantitative analysis of most target PFAS across drinking water, groundwater, river water, and surface water matrices, with limitations observed for PFBA and neutral PFAS. The workflow operates in trap-and-elute mode,

enabling large-volume injections (up to 5000 µL) and sequential sample processing.

Key considerations include minimizing carryover through solvent blanks and maintaining low system background via PFAS-free components and rigorous cleaning protocols. The platform offers flexibility for multiple sample introduction techniques and enhanced contamination control, making it well-suited for high-throughput PFAS monitoring in relatively clean water samples.

3.20.P-Tu330 Sustained Accuracy in PFAS Analysis: Robust Instrument Performance for Environmental Monitoring

David Gould¹, Aron Dekkers¹ and Peter Hancock², (1)Waters Corporation, United Kingdom, (2)Waters Corporation, Germany

Per- and polyfluoroalkyl substances (PFAS) are persistent contaminants of growing regulatory concern, requiring accurate identification, quantification, and confirmation across diverse environmental matrices. In a robustness study exceeding 17,500 injections, the Xevo™ TQ Absolute XR Mass Spectrometer was evaluated for long-term performance using landfill leachate, biosolids, and river water samples.

Eleven PFAS residues were consistently detected in leachate extracts, including PFBA and PFPeA - compounds traditionally considered challenging to confirm due to limited product ion availability. Sensitive detection of the m/z 19 product ion enabled reliable confirmation within standard multiple reaction monitoring (MRM) acquisition, supported by enhanced low-mass transmission in waters_connect™ for Quantitation Software. The Totals feature in waters_connect facilitated streamlined reporting of branched, linear, and total concentrations for PFHxS and PFOS, ensuring compliance with evolving regional requirements.

Over 120 days, the system demonstrated exceptional robustness, consistent quantitation, and minimized unscheduled maintenance, highlighting its suitability for high-confidence PFAS analysis without secondary confirmation methods. This capability supports laboratories in meeting stringent and rapidly changing regulatory frameworks, reducing the need for additional confirmatory techniques and accelerating compliance reporting.

3.20.P-Tu331 Simulation-based Evaluation of Long-term Trends in Environmental PFOS and PFOA Concentrations Across Japan Using the Multimedia Fate Model (G-CIEMS)

Yoshitaka Imaizumi, Yosuke Koyama, Noriyuki Suzuki and Koichi Ohno, National Institute for Environmental Studies (NIES), Japan

Many studies have been conducted to estimate environmental levels of per- and polyfluoroalkyl substances (PFAS), a group comprising more than 10,000 compounds. This issue originated with the production of perfluorooctane sulfonate (PFOS) and perfluorooctanoate (PFOA) for applications such as textiles and packaging materials since the 1950s. PFOS was listed under Annex B (Restriction) of the Stockholm Convention in 2009, and PFOA under Annex A (Elimination) in 2019. In Japan, a maximum limit of 50 ng/L for the combined concentration of PFOS and PFOA in drinking water was established in June 2025, and the same limit will be applied as an environmental quality standard for water pollution from April 2026. To estimate PFOS and PFOA concentrations in rivers and their temporal trends, several monitoring campaigns have been conducted in Japan. However, distinguishing sampling sites influenced by upstream point sources from those affected by “ordinary sources,” such as households and general human activities, remains challenging. This study provides a comprehensive evaluation of baseline PFOS and PFOA concentrations in Japan’s environment over the past five decades using the multimedia fate model G-CIEMS. To construct long-term emission data, we analyzed multiple monitoring datasets useful for estimating representative temporal trends of PFOS and PFOA emissions, including sediment core samples and flux estimations based on observed concentrations. By integrating historical monitoring data and sediment core analyses, we reconstructed emission trends and simulated their long-term environmental fate. Finally, by comparing simulated concentrations with observed data in the atmosphere, river water, and river sediments, we assessed the reliability of the emission dataset and the simulated long-term trends across Japan.

3.20.P-Tu332 Environmental Fate and Effects of Low Molecular Weight Perfluoropolyether (PFPE) fluids: a Weight of Evidence approach

Eleonora Simonini, Ilaria Colombo and Pier Antonio Guarda, Syensqo, Italy

Perfluoropolyethers (PFPEs) are a family of liquid perfluoropolymers characterized by a carbon backbone with repeating ether units, in which all hydrogen atoms are replaced by fluorine. Low molecular weight (MW) PFPEs exist as low-viscosity fluids and, due to their combination of dielectric and mechanical properties, are essential materials for heat transfer and testing applications in the semiconductor industry.

In this work, new data and existing information were combined using a WoE approach to assess the environmental fate of a specific family of low MW PFPEs, commercially known as Galden®.

The assessment covers three Galden® grades with the same structure but different MWs (410, 610, 870 Da), allowing trend evaluation within the product family. Data include measured physicochemical properties for each grade (in order of increasing MW: vapor pressure 14,800, 560, 15 Pa; water solubility 0.5, 1.0, 2.1 ppm; LogKow 5.6, 2.3, 2.4). LogKoc was calculated for all grades (4.6, 2.0, 2.0), while LogKoa was measured for the lowest MW (0.9) and calculated for the others (0.2, 1.9). The dataset also includes experimental partitioning tests (sediment, water, air), environmental distribution modeling, and results of standard ecotoxicological tests, all showing no signs of acute toxicity.

All evidence consistently shows that environmental distribution is strongly dominated by volatility, with the atmosphere being the primary compartment for all three products (? 99.9%). Partitioning into other compartments (water, sediments, soil) increases slightly with increasing MW, which corresponds to a decrease in volatility; however, distribution in these compartments remains very limited (< 0.1%). Distribution in biota is predicted to be negligible. Although Kow alone, as an indicator of bioaccumulation in aquatic life, might suggest that the grade with the lowest MW has potential for bioaccumulation, this potential is neutralised by the substance's high volatility, which prevents exposure of aquatic organisms. For the same reason, aquatic toxicity in natural systems is not considered critical.

This outcome highlights the importance of considering multiple pieces of evidence when assessing the environmental fate of chemicals, especially for volatile substances. It also demonstrates that, depending on its environmental distribution, some hazard properties may be of limited significance for the overall hazard assessment of a chemical.

3.20.P-Tu333 PFAS enrichment in the surface microlayer and lake foam: a multi-lake study in the Finger Lakes of NY

Yuxin Wang¹, Tasneem Tawalbeh¹, Richard Smith², Stella Woodard¹ and Lindsay McMillan³, (1)State University of New York at Binghamton, United States, (2)Global Aquatic Research LLC (GAR), (3)Finger Lakes Land Trust, USA, United States

Per- and polyfluoroalkyl substances (PFAS) are surfactants that can accumulate at the air-water interface, resulting in elevated PFAS levels at the water's surface. In recent years, large quantities of surface foam have been observed on many of the Finger Lakes in the United States. The 11 Finger lakes provide drinking water to over 2 million people and are home to world-renowned wineries. Because foam forms from water at the surface microlayer (SML, top 1mm), both foam and the SML might contain elevated PFAS levels compared to water below. Preferential partitioning of PFAS into foam and the SML could pose higher risks for wildlife and humans that frequently interact with the water's surface. The foam also accumulates along shorelines, exposing lakeshore properties. We surveyed 40 PFAS compounds and their concentrations in lake foam, the SML, and water column of five of the larger, lower-nutrient (oligotrophic to mesotrophic) Finger Lakes. Our results show total PFAS enrichment in foam relative to the underlying water, with some PFAS compounds detectable only in foam. PFAS in the SML are variable, and likely dependent on the formation of surface slicks. Our results advance the understanding of PFAS fate and transport in aquatic systems, as well as how different PFAS compounds partition and accumulate in foams. In collaboration with lake associations, we also developed and distributed a web-based foam reporting platform. Other watersheds can easily adapt the reporting tool to increase documentation of surface foams in natural waters.

3.20.P-Tu334 Tracing PFAS in Lake Como Basin: from WWTPs to Rivers and The Lake

Isabella Gambino¹, Elisa Terzaghi² and Antonio Di Guardo², (1)DiSAT, University of Insubria, Italy, (2)Dept. of Science and High Technology, University of Insubria, Italy

Per- and polyfluoroalkyl substances (PFAS) are persistent and mobile contaminants. Owing to their extensive use and persistent nature, PFAS are now widespread into aquatic environments, ending directly by PFAS containing coatings (e.g., paper and textile coatings) and indirectly coming from leachate from landfills and effluent of wastewater treatment plants (WWTP). The persistence and high mobility of PFAS in water bodies, along with their potential to bioaccumulate in aquatic organisms, have made these ecosystems a major focus of scientific research, especially considering the crucial ecological role that surface water play. This study provides a comprehensive assessment of PFAS contamination in surface waters of the Como basin, with a focus on the effects rainfall events. Lake Como, due to its morphological characteristics and slow water renewal rate, is a sensitive environment. Since it receives inputs from two WWTPs through minor tributaries, it is potentially vulnerable to chemical pollution.

Overall, around 20 PFAS compounds were found in both riverine and lacustrine environments under normal and overflow conditions. Results highlight the changing profile from river samples before and after the Como WWTP, and then in lake samples. Lake water sampled in littoral and pelagic areas in epilimnion and also in hypolimnion (-40m) showed a slightly different chemical fingerprint, likely influenced by dilution from water coming from northern areas of the lake, and other processes.

3.20.P-Tu335 Assessing Multiple PFAS Collectively: Insights from a Scenario-Based Analysis using Multimedia Exposure Model

Monami Kondo¹, Kazuya Inoue¹, Shigeki Masunaga² and Wataru Naito³, (1)National Institute of Advanced Industrial Science and Technology, Japan, (2)Yokohama National University, Japan, (3)Riss, National Institute of Advanced Industrial Science and Technology, Japan

Growing scientific and regulatory attention has highlighted the urgent need to better characterize the environmental and human-health implications of per- and polyfluoroalkyl substances (PFASs). To prioritize PFASs for future risk management, exposure assessment and risk assessment based on realistic environmental scenarios are essential. Under thousands of PFAS compounds said to exist, rapid assessment requires effective analytical modelling alongside advances in monitoring and analytical techniques. In this study, we aimed to verify whether significant differences among PFAS compounds could be identified through a consistent analytical procedure and attempted to visualize these differences to explore the possibility of grouping structurally or behaviorally similar compounds. We also employed a well-developed multimedia model to identify exposure pathways for expert selected multiple PFAS under a specific use scenario. Our results revealed both the effects of individual substances and the effects of selecting functional use categories, demonstrating the complexity of simultaneously analyzing multiple types of PFASs. Moreover, our results suggested that classification based on exposure characteristics is feasible; for instance, the atmospheric distribution-dominant substance group exhibited significantly lower total exposure levels than the soil and water distribution-dominant substance groups. Our findings highlighted the need of precariousness in regulating multiple PFAS collectively and demonstrated the necessity for individual exposure assessments and comparative evaluations. In our presentation, we will discuss the advantages of model-based PFAS exposure assessment, along with scenarios and substances selected, and outline future directions for advancing PFAS evaluation.

3.20.P-Tu336 Flushed Through the System: A Sub-Kilometer Investigation of PFAS Pathways from Urban Rivers to Coastal Waters

Helen Burke¹, Leila Bowe², Yulong Ma³, M. Isabel Cadena-Aizaga⁴, Stuart Harrad³ and Fiona Regan¹, (1)Dublin City University (DCU), Ireland, (2)DCU Water Institute, Dublin City University (DCU), Ireland, (3)University of Birmingham, United Kingdom, (4)Dublin City University, Ireland

Per- and polyfluoroalkyl substances (PFAS) are a large group of man-made chemicals, defined by the Organisation for Economic Co-operation and Development (OECD) as any compound with a (-CF₃) or (-CF₂-) moiety. This strong carbon-fluorine bond renders these compounds resistant to degradation and impacts

hydrophobic and oleophobic properties.

These physico-chemical properties are highly attractive to industry, with PFAS being utilised in a range of industrial sectors including chemical manufacturing, electronics, pharmaceuticals, and firefighting foams as well as coatings on consumer goods. However, these same properties contribute to the persistence of PFAS in the environment. Widespread use and resistance to degradation have resulted in PFAS becoming ubiquitous in the natural environment. Even in areas without fluorochemical production, such as Ireland, PFAS can enter the environment through industrial and municipal wastewater, firefighting activities, and urban runoff, often travelling through stormwater networks before being discharged to surface waters.

This study aimed to explore the influence of stormwater outfalls on the concentration of 33 PFAS in the Liffey Estuary, Dublin, Ireland. Sub-kilometer sampling was conducted at individual outfalls along the river to assess variability in PFAS loadings.

Water samples were extracted by solid phase extraction using Oasis WAX cartridges, and analysed by high-pressure liquid chromatography (Sciex Exion) coupled with time-of-flight mass spectrometry (Sciex 5600+ triple TOF-MS).

Twenty-four PFAS were detected across the estuary, including long-chain compounds and their short-chain replacements. Total PFAS concentrations ranged from 6.20 to 91.48 ng/L, with highest total concentrations downstream of waste treatment facilities. Spatial variation in PFAS class profiles was evident across the upper and lower estuary, with the number of PFAS detected ranging from 2 to 14 compounds. Detections and concentrations varied markedly between outfalls within a few hundred meters of each other. Multivariate analysis indicated that stormwater outfalls act as a diffuse source of PFAS in the Liffey Estuary, along with unique PFAS profiles being attributed to localised inputs such as waste facilities and marina activities.

These findings highlight the need for high-resolution spatial monitoring to improve PFAS source attribution and understanding of mobility pathways in urban surface waters.

3.20.P-Tu337 PFAS Partitioning in the Mississippi River

Alison Ling¹, Alicia Erickson¹ and Summer Streets², (1)University of St Thomas, United States, (2)Minnesota Pollution Control Agency, United States

The present study uses publicly available PFAS data collected from surface water, pore water, sediments, surface microlayers, and fish tissue in Pool 2 of the Mississippi River to estimate partitioning coefficients across a broad range of PFAS, including FASAs and ultrashort-chain PFAS, some of which have limited fate and transport data reported in freshwater systems. Sorption coefficients (K_d and K_{oc}), microlayer enrichment factors (EF), and bioaccumulation factors (BAF) reported here can inform considerations for environmental fate and transport modelling, risk assessment, and treatment technologies.

This study reports on field observations of partitioning between surface water, sediment, pore water, surface microlayer, and fish tissue across 46 measured PFAS. The data includes 56 locations sampled for PFAS in surface water, pore water, sediment, and surface microlayer and 865 fish samples during the summer of 2021.

PFAS with detections in at least 80% of samples for at least one media are PFBA, PFBS, PFHxA, PFHxS, PFOA, PFOS, PFPeA and TFA. PFAS with detections in at least 50% of samples in at least one media are TFSI, N-EtFOSAA, PFHpA, PFPA, and TFMS. TFA was the most abundant PFAS in surface water samples by about one order of magnitude, with values detected in the single-digit parts per billion. Other short-chain and ultra-short chain PFAS, including TFMS, TFSI, PFBA, also dominated surface water samples. Sediments and pore water more reflected impact from legacy PFAS such as PFOA and PFOS.

K_d values increase with increasing chain length for both PFCAs and PFSAAs, especially for compounds with more than 6 carbons. There was limited difference between the two classes, except for PFOS, which has partitioning coefficients 0.5 to 1.0-log higher than those for PFOA. BAFs observed in this study were similar to other studies for PFAAs, and reflect an early report of BAFs in ultra-short TFA, TFMS, and TFSI, all with values similar to those for PFBA. Partitioning from surface water to microlayer is limited to a factor of 1 to 10 for most PFAS, with more partitioning to microlayer for long-chain PFAAs over short-chain PFAAs. The FASAs detected in microlayer samples, N-EtFOSA, N-EtFOSAA, and PFOSA, all have much higher microlayer concentration factors than other PFAS, around 1,000x (3-log), more similar to sediment K_d values than other microlayer EFs.

3.20.P-Tu338 A 25-year study of the presence of PFAS in wild little penguins (*Eudyptula minor*) from around Sydney, Australia

Jorge Lejo-Santiago¹, Sara Ghorbani Gorji², Jane Hall³, Chris Doyle⁴, Alison Rubie³, Purificación López-Mahía¹, Soledad Muniategui-Lorenzo¹, Kevin Thomas⁵ and Sarit Kaserzon⁵, (1)University of A Coruña, Spain, (2)Queensland Alliance for Environmental Health Sciences, Australia, (3)Australian Registry of Wildlife Health, Australia, (4)New South Wales Department of Climate Change, Australia, (5)University of Queensland, Australia

Per- and polyfluoroalkyl substances (PFAS) are persistent organic pollutants designed to be highly stable, making them widespread and enduring in the environment. Their presence in water bodies is concerning because they bioaccumulate, yet few studies have examined their occurrence in Australian aquatic organisms. To assess long-term PFAS exposure in a native Australian species residing off the east-coast of Australia, little penguins (*Eudyptula minor*) were chosen as indicator species. Little penguins are the only penguin species to breed on the mainland in the state of New South Wales (NSW), where only one mainland colony is located at Manly Cove in Sydney Harbor National Park. This colony is classified as endangered due to threats from predators, urban development, and human disturbance. More broadly, little penguins across NSW are also in decline. The short lifespan and strong site fidelity of the species make them ideal for studying temporal changes.

The presence of 71 PFAS was investigated in little penguin livers using a rapid sonication-based extraction followed by solid phase extraction for purification. Analysis was performed via liquid chromatography coupled to triple quadrupole mass spectrometry (LC-MS/MS, Qtrap). The study analysed 93 wet liver samples, as part of an opportunistic collection and storage program spanning 25 years (1998–2023). These samples were obtained from wild penguins found across Sydney area and other regions of NSW. Age, sex, collection location, and cause of death including apparently healthy individuals and ill penguins was recorded for each sample.

42 PFAS were detected at concentrations ranging from 41 ng/g to 3130 ng/g (total PFAS). PFOS was present in all samples, consistently alongside at least one other PFAS, and was the most abundant compound detected in the penguins. PFHxS, 6:2 FTS, PFHpS and PFDODA were found in more than 50% of samples. Temporal variations were observed over the 25-year period for five PFAS compounds, including PFOS, with a decline in PFOS concentrations between 2009 and 2023. Male penguins exhibited statistically higher total PFAS concentration levels than females. No significant differences were detected between juveniles and adults. Although PFAS concentrations in liver tissues have declined over time, the little penguin population remains exposed to appreciable levels, highlighting the need for further research and continued protective measures for the colony, and the species more broadly.

3.20.P-Tu339 Evaluation of PFAS in Higher Trophic Level Bird Eggs

Christopher J McCarthy¹, Shaun A. Roark², Gary Santolo², Jenny Zenobio², Chris Heron², Suz Ball², Chris DeSorbo³ and Micah Miller³, (1)Jacobs, (2)Jacobs, United States, (3)Biodiversity Research Institute, United States

Perfluoroalkyl substances (PFAS) are widespread in aquatic food webs, yet information on PFAS in bird eggs remains limited for most species. Eggs of piscivorous birds provide an integrated measure of exposure during pre-laying foraging and can offer insight into background levels and potential ecological risk. The objective of this study was to characterize PFAS in eggs of three piscivorous bird species and to evaluate how measured concentrations compare with published toxicity thresholds for perfluorooctane sulfonate (PFOS).

Eggs of common loon, osprey, and double-crested cormorant collected from sites in Maine and New Hampshire were analyzed for 40 PFAS using liquid chromatography coupled with quadrupole time-of-flight mass spectrometry. Samples represented multiple nesting periods and were derived from homogenized archived eggs. Spatial differences were observed within species, with common loon eggs in Maine showing significant variation among locations. PFOS was the dominant compound in all species. Trends over time were assessed for

Maine common loon eggs, showing declining concentrations of 7:3 fluorotelomer carboxylic acid and variable patterns for several long-chain acids. Osprey eggs exhibited declines for multiple PFAS, although site coverage limited interpretation.

Background concentrations were estimated using distributional approaches and indicated higher PFOS levels in New Hampshire relative to Maine. When compared with available PFOS toxicity thresholds for bird eggs, a portion of samples from both states exceeded the lowest published value, while none approached higher thresholds. Population data available for common loons suggest that the lowest threshold may be conservative relative to observed field conditions.

Overall, PFAS levels were greatest near denser human activity and closer to known sources. This work highlights the need for additional field-based studies to determine what dietary exposure levels and egg concentrations may indicate risk for piscivorous bird populations. Findings support improved interpretation of biomonitoring data and provide initial background values for species with limited prior reporting.

3.20.P-Tu340 Integrated monitoring and toxicological assessment of PFAS in aquatic ecosystems: Human exposure risks in UK and Spanish populations and insights from cellular bioenergetic profiling

Eva Junque¹, Emilie Brun¹, Marta Llorca-Casamayor², Arianna Bautista³, Jon Barber⁴, Mael Exner¹, Heather Mercer⁵, Francesco Dondero⁶, Marinella Farre², Jonathan Barlow¹ and Iseult Lynch⁷, (1)University of Birmingham, United Kingdom, (2)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (3)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (4)CEFAS, United Kingdom, (5)Sandia National Labs, United States, (6)Department of Science and Technological Innovation (DISIT), University of Eastern Piedmont, Alessandria, Italy, (7)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom

Per- and polyfluoroalkyl substances (PFAS) are widespread contaminants characterised by extreme persistence, environmental mobility and documented biological effects. Their presence in aquatic environments raises concerns for ecosystem integrity and human exposure through fish consumption. This study combines large-scale monitoring with mechanistic in vitro assays to assess PFAS occurrence, toxicological behaviour and potential exposure risks in the United Kingdom and Spain. Between 2020 and 2024, more than 10,000 surface water, groundwater and saline water samples, together with 288 edible fish from 16 species, were analysed for 47 PFAS using targeted LC-MS/MS and LC-HRMS suspect screening. PFAS were frequently detected in all matrices. Spanish fish showed elevated levels of long-chain PFAS and emerging PFAS such as PFNA and 6:2 FTS, whereas UK fish were dominated by PFOS. In contrast, UK waters displayed higher proportions of PFOA and short-chain PFAS (e.g., PFPeA, PFHxA), consistent with their mobility and ongoing inputs. Estimated dietary exposure via fish exceeded the EFSA TWI (4.4 ng/kg bw/week) by more than five-fold in Spain, indicating concern for frequent consumers. Spatial analysis revealed a hotspot in Moreton-in-Marsh (UK), where high PFAS in freshwater suggest localised sources requiring investigation. To evaluate mechanistic toxicity, zebrafish fibroblast (ZF4) cells were exposed to 19 PFAS (10–1000 µM), and bioenergetic function was assessed using Seahorse XF analysis and CCK-8 viability assays. PFAS exposure produced clear, structure-dependent effects: mid- and long-chain PFAS reduced maximal respiration and spare capacity while increasing glycolysis, indicating a compensatory shift in energy metabolism. Long-chain PFAS caused the strongest decreases in viability and mitochondrial performance, aligning with known structure-activity trends. These findings support the use of bioenergetic assays as New Approach Methodologies (NAMs) for mechanistic PFAS hazard characterisation. Overall, this assessment highlights significant PFAS contamination in aquatic environments, dietary exposure risks, the presence of localised hotspots and mechanistic evidence of mitochondrial disruption. Together, the results strengthen the basis for integrated ecological and human-health risk assessment and emphasise the need for targeted actions to mitigate PFAS contamination in freshwater and marine systems.

Disclaimer/Disclosure:

We also acknowledge the Environment Agency for providing fish and water data and DEFRA for their support.

3.20.P-Tu341 Toxicological Assessment of PFOA and PFOS in a Bottlenose Dolphin Fibroblast Cell Line

Silvia Iori, Antonella Molinari, Valentina Zappulli, Mery Giantin, Cinzia Centelleghes and Marianna Pauletto, Department of Comparative Biomedicine and Food Science (BCA), University of Padova, Italy

Due to their persistence and bioaccumulative behaviour, Perfluorooctanoic acid (PFOA) and Perfluorooctane sulfonic acid (PFOS) pose significant risks to marine species. Bottlenose dolphin (*Tursiops truncatus*), as apex predator that inhabits coastal regions and frequently interacts with human activities, is particularly susceptible to the accumulation of these pollutants. Consequently, the development of assays for accurately assessing the biological effects of these anthropogenic chemicals in this species appears essential.

This study investigated the toxicological responses of a bottlenose dolphin fibroblast cell line to PFOA and PFOS. Initial cytotoxicity tests, conducted using a luminescent cell viability protocol, assessed half-maximal inhibitory concentrations (IC₅₀) following 24, 48, and 72 hours of exposure to increasing concentrations of each compound. Subsequent experiments examined early apoptosis and necrosis (Annexin V Apoptosis and Necrosis Assay), late apoptosis (Caspase 3/7 Assay), and oxidative stress (Glutathione Assay) at three sub-cytotoxic concentrations (? IC₂₅).

PFOS cytotoxicity was higher than that of PFOA, showing IC₅₀ values around 230 µM at all the examined time points, indicating that the compound's potency is stable over time. Conversely, PFOA IC₅₀ at 24, 48, and 72 hours of exposure resulted in 934, 837.5 and 695.2 µM, respectively. While necrosis was not evident, early apoptosis and oxidative stress were appreciated at concentrations well below the IC₅₀, (i.e. 100 and 300 µM for PFOS and PFOA, respectively). This evidence demonstrated that, although the observed IC₅₀ were quite high (but almost comparable to those reported for these compounds in human cells), both PFAS might elicit subtle effects preceding overt cytotoxicity in this cell model.

This study demonstrated that cetacean in vitro systems represent a valid tool for studying the cellular effects of contaminants of environmental concern (CECs) and advancing understanding of pollutant impacts on marine mammals and ecosystem health.

Disclaimer/Disclosure:

This study has received funding from the European Union's Horizon Europe research and innovation programme under grant agreement No.101134929 (ONE-BLUE - Integrated approach to assess the levels and impact of contaminants of emerging concern on blue health and biodiversity modulated by climate change drivers).

3.20.P-Tu342 Influence of DOC and Microplastics on PFAS Bioavailability and Ecophysiological Effects on Zebrafish (*Danio rerio*) Embryos

*Alexander Maria Pape*¹, *Giovanna Mottola*², *Eeva-Riikka Vehniäinen*³, *Céline Arzel*³ and *Katja Anttila*¹,
(1)University of Turku, Finland, (2)University of Eastern Finland, Finland, (3)Department of Biology, University of Turku, Finland

Over the last two decades, per- and polyfluoroalkyl substances (PFAS) have gained increased focus as more and more evidence of their biological effects in different biota has been demonstrated; examples in fish include malformations and behavioural aberrations. Globally, the contamination with this class of persistent organic pollutants (POPs) is particularly high in the aquatic environment due to their longevity. Moreover, little is known about their effects in presence of environmental vectors, which have been shown to change bioavailability of POPs by adsorption.

Therefore, the goal of this study is to strengthen knowledge on how climate change and the increasing presence of vectors affect the toxicity of PFAS on the aquatic environment. To this purpose, the effect of four PFAS (PFOA, PFUndA, PFHpA, PFHxDA) were studied in zebrafish embryos, both alone and in combination with one of two vectors. The chosen vectors were dissolved organic carbon (DOC) and microplastics. DOC is a major factor of water brownification, which affects aquatic ecosystems globally. A commercially available fertiliser was used as a DOC proxy due to its high content of humic and fulvic acids. Polyethylene was chosen for the microplastic exposure, as it plays a significant role in single use plastics and can be found in large amounts in the aquatic environment.

To evaluate potential interactions between pollutant and vector, the acute toxicity of PFAS was tested singularly and together with either vector to establish the EC₅₀. In a second step, embryos were exposed to sublethal concentrations until 120hpf and subsequently used to evaluate their thermal tolerance as well as several biomarker assays to measure oxidative stress, dioxin-like activity and metabolic stress. Preliminary results show that the addition of DOC leads to higher acute toxicity, as well as a decrease in the average thermal maximum of zebrafish embryos, suggesting that brownification might increase PFAS toxicity in aquatic organisms and weaken their response to environmental changes.

3.20.P-Tu343 Assessing the Toxicity of PFAS to *Enchytraeus crypticus* – Can Compound Structure be Used to Classify Relative Toxicity?

Emily Eagles¹, Amaia Green Etxabe¹, Stephen James Short², Heather Carter¹, M. Gloria Pereira¹, Jacob Bundy³, Tomas C. Barker Tejada³ and David Spurgeon¹, (1)UK Centre for Ecology & Hydrology, United Kingdom, (2)Pollution, UK Centre for Ecology & Hydrology, United Kingdom, (3)Imperial College London, United Kingdom

Per- and poly-fluoroalkyl substances (PFAS) are contaminants across ecosystems with multiple known release pathways into terrestrial systems, yet the understanding of risks posed to terrestrial organisms is lacking. The vast number of PFAS compounds requires development of approaches to aid in classifying the relative hazard posed across this growing group of contaminants. This study will establish a ranking of lethal concentration data for selected PFAS compounds and form the basis of future work to understand the potential correlations between the structure, chemical properties and toxicological effects of PFAS. We consider the survival effects in the annelid *Enchytraeus crypticus*, a model soil organism, using an acute aquatic toxicity set up to allow survival through time to be monitored over 96 h. The selection of PFAS used were chosen based on evidence of use and environmental presence whilst ensuring there was representatives from four classes with differing functional groups in their structure: perfluorocarboxylic acids, perfluorosulphonic acids, perfluorosulfonamides and fluorotelomers, and within these classes there was at least one short chain and one long chain PFAS selected. Preliminary data support the hypothesis that lethal concentrations will vary depending on the structure of the PFAS, with variation in toxic response seen between the classes of PFAS. Subsequent analysis of internal organism PFAS concentration, from the end of exposures, will assess the uptake of PFAS and determine any toxicokinetic variation. Further work will develop on this to understand toxicodynamics, by assessing PFAS interactions within the organisms during exposure.

3.20.P-Tu344 Multigeneration toxicity and accumulated adverse effects of perfluoro(4-methyl-3,6-dioxaoctane) sulfonate in *daphnia magna*.

GISU PARK, Shinhye Park and Youngsam Kim, KIST-EUROPE, Germany

Structural alternatives of per- and polyfluoroalkyl substances (PFASs) have been widely used in industry, resulting in their ubiquitously distributed presence in the environment and biological system. Among these alternatives, perfluoroalkyl ether sulfonic acid (PFESAs) emerged as next-generation PFAS replacements and increasingly detected in aquatic environments and consumer products. While assumed to be a safer alternative, potassium perfluoro(4-methyl-3,6-dioxaoctane) sulfonate (PFMDS) may pose delayed and generationally compounding risks in aquatic ecosystems. PFMDS shares the specific 'ether-sulfonate' structural motif with 6:2 Cl-PFESA (F-53B), a potent toxicant known for its high bioaccumulation and endocrine-disrupting potential. With growing concerns over ecotoxicological effects, this study presents the comprehensive evidence that PFMDS exhibits transgenerational toxicity amplification. We evaluated toxicity of PFMDS on the keystone model organism *Daphnia magna*, integrating multigenerational and acute with physiological endpoints with transcriptional profiling. Acute exposure yielded a 48-h EC50 of 22.25 mg/L and induced a significant elevation in reactive oxygen species (ROS) levels in adults after 24 hours of exposure. In the chronic test, the first generation (F0) exposed to concentrations up to 10.0 mg/L showed no significant changes in reproduction or growth. However, the second generation (F1) exhibited remarkable physiological impairment at the same concentration. Consequently, reproductive output decreased by over 20%, and significant growth retardation was also observed in the third generation. This pattern of multigenerational toxicity accumulation indicates that adverse effects of PFMDS becomes more pronounced across generation. In understanding of further mechanisms of toxicity, transcriptional analysis was conducted on both chronically and acutely exposed adults and neonates. The expression levels of antioxidant-related gene (SOD, CAT, GST, Hr3) and ecdysteroidogenesis-related gene (Vtg1/2, EcR-A/B, JHE) were examined in chronic exposure, JHE and Vtg expression levels were significantly downregulated. Similarly, in both 24-hour exposed adults and neonates, Vtg expression was also significantly downregulated. Collectively, these findings provide a comprehensive assessment of PFMDS toxicity and demonstrate its amplified adverse effects across generations in *D. magna*, emphasizing important concerns about the long-term ecological safety.

3.20.P-Tu345 Early-Life Transcriptomic Disruptions in Zebrafish Exposed to GenX, NBP2, PFOS, and their Mixture Reveal Chemical- and Dose-Specific Neurodevelopmental toxicity

Shaloo Singh¹ and **ANBUMANI SADASIVAM²**, (1)No Affiliation, India, (2)Council for Scientific and Industrial Research (CSIR) India, India

Per- and polyfluoroalkyl substances (PFAS) and their emerging alternatives present growing environmental and human health concerns. *Danio rerio* embryos exposed to PFOS, NBP2, GenX, and their mixture (0.1–30 µg/L) did not show morphological deformities upon static exposure. However, biochemical assays revealed a significant increase in reactive oxygen species (ROS), antioxidant enzymes, and acetylcholinesterase (AChE) activity, indicating cellular stress. To understand the mechanistic pathways underlying these responses, *D. rerio* larvae were exposed from 0 to 96 hpf to PFOS, NBP2, GenX, and their binary mixture at concentrations of 0.3 and 30 µg/L and subjected to transcriptome profiling (fold change ≥ 1.5 ; FDR < 0.05). PFOS induced a dose-dependent transcriptional effect aligned with biochemical outcomes. Low-dose PFOS (0.3 µg/L) disrupted synaptic vesicle fusion and glutamatergic/GABAergic transport (*cplx2b/3a/4a*, *syt11b*, *slc17a6a/7a*), while high-dose PFOS (30 µg/L) enhanced dopaminergic GPCR signalling, glutamate biosynthesis, and GABAergic regulation (*drd4a*, *gnal*, *gls2a*, *npas4a*), consistent with elevated ROS and AChE activity. NBP2 at 30 µg/L altered CNS neuron differentiation (*wnt8b*, *nr4a2b*, *lhx6a*) and auditory visual sensory pathways (*trpa1b*, *pcdh15a*, *exorh*, *tmc1*), supporting its neurotoxic potential. GenX showed distinct dose responses: 0.3 µg/L GenX enriched glutamatergic synaptic transmission (*gria2a/3/3b/4a*, *slc17a6a/b*, *grin2bb*), whereas 30 µg/L activated enzyme-linked receptor signalling and oxidative stress pathways, mirroring elevated antioxidant enzyme activities. The mixture exposure elicited the broadest disruptions. At 3 µg/L, it altered mechanosensory behaviour and sensory system development (*scn8aa*, *pkd2l1*, *cib2*). At 30 µg/L, strong endocrine and hormone-responsive pathways (*esr1/2b*, *thrb*, *fgf19/23*, *nr4a2a/b*, *stat5b/6*) were activated, aligning with severe oxidative stress markers. qPCR and behavioural assays (locomotor activity and startle response) corroborated the transcriptomic changes, revealing neurodevelopmental impairments induced by legacy and alternate PFAS. The multi-tiered biochemical, transcriptomic, qPCR, and behavioural analysis demonstrates PFOS, NBP2, GenX, and their mixtures induce oxidative stress-mediated neurodevelopmental toxicity in zebrafish. These findings emphasise the urgent need to integrate molecular endpoints and mixture toxicity considerations into ecological risk assessment for emerging PFAS.

3.20.P-Tu346 From Farm to Table: Field and Laboratory Insights into Bioconcentration, Uptake Kinetics, and Consumer Risk of Per- and Polyfluoroalkyl Substances in Kelp

Justin Sankey¹, **Jitka Becanova²**, **Simon Vojta²**, **Johanna Ganglbauer²** and **Rainer Lohmann²**, (1)University of Rhode Island - Graduate School of Oceanography, United States, (2)University of Rhode Island, United States

Macroalgae such as the native New England kelp, *Saccharina latissima*, represent the fastest-growing sector of aquaculture, providing an increasingly important source of income as climate change impacts traditional fisheries. Because aquaculture farms are predominantly located in estuarine and coastal waters, understanding the influence of environmental contaminants on cultivated kelp is essential. Although previous studies have demonstrated bioaccumulation of heavy metals and legacy pollutants such as Polychlorinated biphenyls (PCBs) in kelp, data is limited for the uptake of emerging contaminants such as per- and polyfluoroalkyl substances (PFAS). PFAS are ubiquitous, environmentally persistent chemicals used in firefighting foams and stain-, water-, and grease-resistant coatings, and are associated with a range of adverse health effects. This study quantifies the bioconcentration potential of *S. latissima* and assesses potential harm to consumer by establishing field-based bioaccumulation factors (BAFs), laboratory-derived bioconcentration factors (BCFs), characterizing kinetic uptake rates for an 11-compound mixture of perfluoroalkyl acids (PFAAs), an anionic class of PFAS, and deriving estimated daily intakes and hazard ratios for different demographics based commercially available seaweed products. Determining BAFs, BCFs and uptake kinetics for *S. latissima* will support evaluations of kelp's potential role as a sink for PFAS in the coastal environment and inform monitoring programs for aquaculture operations to assess potential exposure risks to crops. Additionally, we contextualize the contamination in Rhode Island-sourced kelp to that of other seaweeds available in the global market and provide actionable data to inform risk communication for the consumptions of seaweeds.

3.21 Pharmaceuticals in the Environment – Innovations in Risk Assessment, Regulation, and the Science Globally

3.21.T-01 Connecting the Dots in Terrestrial Pharmaceutical Fate: Towards a Prioritisation Framework

Nahum Ashfield¹, **Jun Li²** and **Alistair Boxall³**, (1)Department of Environment and Geography, University of York, United Kingdom, (2)University of York, United States, (3)University of York, United Kingdom

Pharmaceuticals are now widespread contaminants, yet their behaviour in terrestrial systems remains poorly characterised compared to aquatic environments. The heterogeneity of soils, and resulting variation in physical and chemical properties, complicates predictions of pharmaceutical fate, transport and bioavailability. Continued use of wastewater sludge and reclaimed water in agricultural practises, alongside regulatory shifts that place greater emphasis on chemical persistence and mobility, highlight the urgent need for approaches that can fill data gaps and support prioritisation of high-risk substances.

The framework presented combines data from sludge sorption studies, soil mobility modelling, earthworm uptake experiments, and spatial evaluation of risk in Europe. Experimental work produced 178 linear sorption coefficients for 48 pharmaceuticals across four sludge types, covering a range from 1.3 to 21,846 L/kg. These values showed up to four orders of magnitude variation between compounds and up to two orders of magnitude variation across sludge matrices for individual substances. A machine learning soil mobility model was developed and optimised using random forest algorithms, trained on existing soil sorption data, to predict organic carbon normalised sorption coefficients for more than 1500 human and veterinary pharmaceuticals across seven OECD 106 representative soils. The model performed strongly during cross validation ($R^2 = 0.93$) and external testing (Literature $R^2 = 0.58$, Industry $R^2 = 0.29$) and allowed mobility classification under new European regulatory criteria, with more than half of all assessed substances predicted to be mobile or very mobile. A QuEChERS based method for 41 pharmaceuticals in earthworm tissues and soils achieved recoveries between 50 and 150 percent and supported a reduced scale OECD 317 uptake study design. This generated kinetic soil bioaccumulation factors and porewater bioconcentration factors across five soils, supporting the assessment of pH and organic carbon effects on bioavailability in *Eisenia fetida*.

Predicted mobility outputs were combined with European soil and land use data, and pharmaceutical consumption patterns to map spatial variation in terrestrial exposure, identifying regions with elevated mobility and potential for groundwater contamination.

Together, these components form a practical and scalable framework for assessing and prioritising pharmaceutical exposure and risk in terrestrial systems.

3.21.T-02 Advancing Drug Emission Modelling Through Systematic Derivation of Human Drug Metabolism and Excretion Data from Regulatory Sources and Mass Balance Study Publications

Frank Klont, University of Groningen, Netherlands

Background: Pharmaceutical pollution is a growing concern, with potential risks to both human health and aquatic ecosystems. With the growing diversity of drugs, empirical biomonitoring is becoming increasingly challenging. Hence, emission prediction methodologies based on drug utilization data are gaining importance. A key parameter across many of these models is the so-called excretion fraction (f_{ex}). This factor aims to correct for the fact that many administered drugs, commonly referred to as parent drugs, are not always excreted (entirely) in their unchanged form but rather (partly) as drug metabolites, which can be pharmacologically active or inactive. Deriving f_{ex} can, however, be challenging due to the complexity of human metabolism and the fact that available data on drug metabolism and excretion are not always reported in a consistent or complete manner. **Methods:** With a team of specialists from various domains, we established a systematic pharmacokinetic data retrieval and assessment framework. It considers Summary of Product Characteristics (SmPC) documents as a principal source of up-to-date drug information due to their regulatory status. SmPCs subsequently aid in the identification of detailed data on drug metabolism and excretion, mostly in marketing authorization documents and scientific study publications. Relevant information can then be extracted following the structured assessment process we developed and tested using various therapeutic drugs of environmental interest. **Results:** Our workflow was successfully developed and tested, demonstrating its use in extracting and interpreting pharmacokinetic information relevant for deriving f_{ex} . During testing, however, several considerations emerged, including: whether to use f_{ex} in the first place, incomplete recovery and healthy (male) volunteer bias in mass balance studies, and an apparent underreporting of phase II metabolites in older mass balance studies. A preliminary comparison between f_{ex} values derived using our approach and those used in recent drug emission studies furthermore revealed substantial differences in the values obtained, despite all approaches relying on SmPCs as key source documents. **Conclusion:** We developed a systematic workflow to extract human pharmacokinetic data from regulatory documents and mass balance study publications. This workflow allows for transparent derivation of excretion fractions for use in drug emission models.

3.21.T-03 Degradation products of siRNAs and ASOs following incubation in sewage sludge

Laura Garcia Barcia, Harvey Andersen, Alec Bell, Ryan Hill, Christopher Wiethoff and Alison Nimrod Perkins, Lilly, United States

Small interfering RNAs (siRNAs) and antisense oligonucleotides (ASOs) are two types of a new pharmaceutical modality. These oligonucleotide therapeutics feature chemical modifications such as 2'-O-methyl and 2'-fluoro substitutions, Locked Nucleic Acid (LNA) bases, phosphorothioate linkages, and 5-methyl cytosine, that improve stability and reduce nuclease susceptibility, with potential implications for environmental persistence following excretion into wastewater systems.

We first conducted a miniaturized study in microtubes to assess degradation under realistic wastewater conditions. A GalNAc-conjugated siRNA duplex targeting HPRT and its antisense strand were incubated in sewage sludge (2500 mg TSS/L) in non-aerated microtubes for 7 days. Fluorescent probes confirmed active endonuclease and exonuclease activity. High-resolution mass spectrometry showed the siRNA duplex disappeared by 93.6% within 24 hours and was undetectable by Day 7. The antisense strand exhibited similar disappearance (98.2% on Day 1) and was also undetectable by Day 7. Mass-MetaSite analysis identified 25 fragments (5–23 nucleotides), confirming enzymatic cleavage.

To validate these findings and assess biodegradability, we initiated 28-day OECD 301B and 314B studies. Test substances included the HPRT siRNA duplex, its antisense strand, and a MALAT1-targeting ASO, all with chemical modifications. Sludge concentrations were 30 mg TSS/L for 301B and 2500 mg TSS/L for 314B. Samples were collected at multiple time points throughout the 28-day period for HRMS analysis (pending final results).

Nuclease activity was consistently higher in 314B sludge. In OECD 314B, endonuclease activity was $6.58 \times 10^{??} \mu\text{mol}/\text{min}$ —comparable to the preliminary study ($1.34 \times 10^{??} \mu\text{mol}/\text{min}$)—demonstrating little evidence of seasonal variability. 301B sludge showed much lower activity ($2.94 \times 10^{??} \mu\text{mol}/\text{min}$), ~22-fold lower than 314B, likely due to the diluted sludge.

Chemically modified oligonucleotides were not readily biodegradable by OECD 301B criteria, showing negligible CO₂ evolution despite ready biodegradability of unmodified RNA controls. However, realistic wastewater conditions (2500 mg TSS/L) and analysis by HRMS demonstrated that chemically modified therapeutic oligonucleotides are highly susceptible to rapid, repeated primary degradation by both endo and exonucleases.

3.21.T-04 Projected Ecotoxicological Risks from Pharmaceuticals in German Rivers by 2050

Shixue Wu¹, Peter Krebs² and Rohini Kumar¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Dresden University of Technology, Germany

The European Union (EU)'s zero-pollution ambition targets a toxic-free environment by 2050, but an aging population and a warming climate increase disease prevalence and pharmaceutical use, leaving future pollution levels and the route to this goal uncertain. Using a node-link model informed by Representative Concentration Pathways (RCP) and Shared Socioeconomic Pathway (SSP) scenarios, we projected concentrations of five pharmaceuticals and their ecological risks to three aquatic species in 1-km river stretches across Saxony, Germany, by the 2050s. Signal-to-noise ratios ranged from 4.49 ± 1.30 (carbamazepine) to 7.68 ± 2.22 (ciprofloxacin), showing an agreement across 15 climate models. Under SSP5–8.5, pharmaceutical concentrations varied from ~98% (sulfamethoxazole) to 192% (gabapentin) without policy intervention in pharmaceutical prescribing, and from ~60% (carbamazepine) to ~23% (metformin) with stringent policy intervention, relative to the 2010s baseline. Rivers under at-risk toxicity from pharmaceutical mixtures increased by 7.7% (algae) to 12.4% (daphnia) without intervention, but decreased by 6.5% (daphnia) to 6.8% (fish) with intervention. To reach no-harm targets for the ecosystem from pharmaceutical mixtures at the moderate-risk, 21% (with intervention) to 33% (without intervention) of wastewater treatment plants require full upgrades for all pharmaceuticals. This study consolidates knowledge on the gaps to EU's zero-pollution goals amid socioeconomic and hydroclimatic changes.

3.21.T-05 A Framework to Identify High-Priority Legacy Active Pharmaceutical Ingredients for Environmental Risk Assessment

Cristiana Cannata¹, Erika Colombo², Ashenafi Legehar³, Irene Bramke⁴, Annika Buck⁵, Anja Coors⁶, Melvin Faber⁷, Gemma Janer⁸, Samuel K Maynard⁹, Rhys Whomsley⁵, Caterina Zillien¹⁰, Caroline Moermond¹¹ and Ad M. J. Ragas¹, (1)Environmental Science, Radboud University, Netherlands, (2)Istituto di Ricerche Farmacologiche Mario Negri IRCCS, Italy, (3)University of Helsinki, Finland, (4)AstraZeneca, Netherlands, (5)European Medicines Agency (EMA), Netherlands, (6)ECT Oekotoxikologie GmbH, Germany, (7)National Institute for Public Health and the Environment (RIVM), Netherlands, (8)Novartis Pharma, Spain, (9)Environmental Protection, Global Sustainability and SHE, Operations, AstraZeneca, United Kingdom, (10)Radboud University, Netherlands, (11)Centre for Safety of Substances and Products (VSP), National Institute for Public Health and the Environment (RIVM), Netherlands

Active Pharmaceutical Ingredients (APIs) from human medicinal products are detected in surface waters globally, but the full extent of their impact remains insufficiently understood. Conducting environmental risk assessments (ERAs) including experimental studies for all pharmaceuticals is considered unfeasible, particularly for legacy APIs approved before the ERA became a mandatory requirement in the European Union. This challenge can be addressed by prioritising legacy APIs for ERA, as highlighted by the European Commission's recent proposal for a revised EU pharmaceutical legislation, stating the need to establish scientific criteria to prioritise legacy APIs, using a risk-based approach.

In line with this, we present a risk-based prioritisation framework to identify high-priority legacy APIs for further testing and ERA, which we applied to a dataset of 1,687 APIs. Predicted environmental concentrations in surface waters (PEC_{sw}) were estimated using European consumption data from 2019 to 2023. Effect concentrations were predicted using multiple approaches, including Quantitative Structure-Activity Relationship (QSAR) models, and Theoretical therapeutic Water Concentrations (TWCs). To validate these predictions, QSAR and TWC values were compared against empirical ecotoxicity data for a subset of data-rich APIs. Results showed that QSAR models, which generally show acceptable statistical performance, tend to underestimate the effects of highly toxic pharmaceuticals. In contrast, TWC values were more conservative but exhibited greater variability in performance. Exposure and effect concentrations were combined into preliminary risk quotients (pRQs), which were ranked and subsequently benchmarked against a reference ranking for validation. In the final step, multiple pRQs were combined into a single risk-based ranking. This list, along with a summary of ERA data availability for the included APIs, can serve as a starting point for stakeholders, such as industry and regulators, to screen legacy APIs for data gaps, guiding decisions on which substances require a further ERA, possibly involving testing, and what types of studies are needed.

3.21.P Pharmaceuticals in the Environment – Innovations in Risk Assessment, Regulation, and the Science Globally

3.21.P-Tu347 A Step Towards Understanding the Global Environmental Distribution of Aquatic Exposure from Consumer and Institutional Pharmaceutical Usage

Christopher M Holmes¹, Elizabeth Tandy¹, Claire Holmes¹, Thomas Austin² and Scott Oram³, (1)Applied Analysis Solutions LLC, United States, (2)Haleon, Switzerland, (3)Haleon, United Kingdom

Improved environmental risk assessment and regulation for pharmaceuticals requires that we are better able to predict and mitigate movement into surface water. It is important to ensure that water stewardship, problem identification, prioritization and action are science based. The pharmaceutical industry faces scrutiny regarding the environmental impact of APIs that can enter water systems from consumer use at home, institutional uses in hospitals, manufacturing sites, and animal health uses. Companies must be aware of the eventual emissions and potential impacts of ingredients. Mapping of detailed water network emissions empowers companies to predict the distribution of their ingredients in various aquatic ecosystems. This prediction helps in developing robust environmental risk assessments and management plans ensuring readiness for increased regulations and mandatory disclosure. Accurate and robust information on water vulnerability supports regulatory agencies in their remit for the protection of human and environmental health. We developed a globally consistent, spatially explicit freshwater exposure model for down-the-drain substances, with an initial focus on pharmaceuticals. The EmiE model (Evaluating Micropollutants in the Environment) is built upon established datasets at global and national levels, spatially linking sources of pharmaceutical uses, emissions and receiving water systems. Beyond consumer uses, we have added the ability to model localized high-intensity emissions from hospitals and other institutions. The model has been designed for extensibility, with an eye towards including manufacturing emissions as well as diffuse source emissions (e.g., from veterinary uses). This holistic view of emissions enhances our understanding of potential environmental impact, allowing for more proactive management and more localized and effective mitigations. While the model operates at the finest level of hydrologic resolution (the river segment), embedded tools supply seamless aggregation to multiple basin levels using a choice of

metrics, allowing for direct linking of model results to other existing environmental protection efforts. Whether mitigating pollution, ensuring compliance, optimizing resource management, or protecting ecosystems, trusted and transparent maps and predictive tools are indispensable for businesses committed to operating responsibly in an evolving global landscape.

3.21.P-Tu348 Case study on the significance of persistent and mobile pharmaceutical active substances in drinking water from bank filtrate – against the backdrop of the Urban Waste Water Treatment Directive

Ursula Karges¹, Verena Becker² and Christian März², (1)IWW Water Research Institute, Germany, (2)Bonn University, Germany

Innovations in European water legislation may have a long-term positive impact on the entire water cycle, provided they are properly implemented in the Member States. With the latest versions of the EU Urban Waste Water Treatment Directive (UWWTD) and the EU Drinking Water Directive (DWD), which now also emphasises the importance of drinking water catchment areas, ‘from source to tap’ seems to be more relevant than ever in terms of water quality. UWWTD states that human pharmaceutical and cosmetic products are particularly problematic in terms of the formation of micropollutants in water bodies.

In our case study, we thus investigated the actual influence of upstream waste water treatment plants (WWTP) on the pharmaceutical spectrum throughout the entire water cycle at a bank filtrate-fed drinking water production site: from the WWTPs effluents through the receiving river and the bank filtrate to the finished drinking water. Due to their different dimensions, the respective WWTP are not yet equally affected by the requirements of the UWWTD, but already differ significantly in the treatment technology applied. Water samples taken from wastewater effluents, surface water, groundwater, abstraction wells and treated drinking water were analysed using high-performance liquid chromatography coupled with tandem mass spectrometry. A total of around 30 pharmaceutical active substances were analysed, with the focus later being placed on examining the occurrence and behaviour of five representative compounds, that were particularly prominent in drinking water samples, including the metabolite oxipurinol. Individual pharmaceutical residues were detectable throughout the entire water cycle, right up to the finished drinking water.

The results provided evidence of the contamination pathway from the sewage treatment plant to the drinking water for the case study area. Persistence and mobility proved to be particularly relevant properties for this contamination pathway, with the persistent and mobile oxipurinol and the UWWTD indicator substance carbamazepine epitomising this problem.

Although bank filtration offers significant natural protection against certain trace substances, pharmaceutical residues, waste water discharges remain the main source of river contamination and, subsequently, the groundwater system. These results are highly relevant to the implementation of the revised UWWTD, which prioritises an additional fourth treatment stage to be implemented.

3.21.P-Tu349 Environmental Occurrence and Antimicrobial Resistance Potential of Carbapenems – Last-Resort Antibiotics

Vaidotas Kisielius, Alba Martinez i Quer, Anders Johansen and Pedro Neves Carvalho, Aarhus University, Denmark

The misuse of antibiotics in human and veterinary medicine is a major driver of antimicrobial resistance (AMR). Although antibiotics are widely detected in aquatic environments, monitoring of the last-resort β -lactam antibiotics – carbapenems – remains extremely limited. Their structural similarity to penicillins and partial excretion in humans suggest that carbapenems enter wastewater and surface waters, potentially exerting selective pressure that promotes environmental AMR. However, empirical evidence has been scarce.

In this study, we developed and validated a sensitive liquid chromatography–tandem mass spectrometry (LC-MS/MS) method to quantify six carbapenems (biapenem, doripenem, ertapenem, faropenem, imipenem and meropenem) in environmental waters. Applying this method to Danish hospital effluents and surface waters.

Because carbapenems are chemically unstable and may form biologically active transformation products (TPs), we further examined their fate under environmentally relevant conditions. TPs of ertapenem, faropenem, imipenem and meropenem were observed, and their potential contribution to AMR is under evaluation.

By analyzing both parent compounds and transformation products, this work provides new evidence of the overlooked environmental persistence and transformation of carbapenems. These findings highlight their potential role in sustaining selective pressure for AMR in aquatic environments.

3.21.P-Tu350 State of Pharmaceutical Pollution in Italian Waters and Estimation of the Load Discharged from Rivers into Coastal Waters

Stefano Polesello¹, Giacomo Bonacina², Marianna Rusconi¹, Claudio Roscioli¹, Sara Valsecchi¹, Luisa Mattoli², Mattia Gianni², Giada Fodaroni² and Vitalia Murgia³, (1)Istituto di Ricerca sulle Acque, CNR, Italy, (2)Aboca SpA, Italy, (3)Associazione Italiana Medici per l'ambiente ISDE Italia, Italy

In recent decades, the combination of “pharmaceuticals” and “personal care products” (PPCPs) has been recognised as a contaminant of “emerging concern” due to their persistent presence in the environment. As part of a study on the risk assessment of PPCPs in Italian waters, we conducted a sampling campaign to detect the presence of pharmaceutical compounds, including active ingredients and excipients, in Italian waters. We collected more than 150 samples of surface water (rivers, lakes and reservoirs), groundwater and spring water at approximately 120 sites. Approximately 30 rivers flowing into the Tyrrhenian Sea, the Adriatic Sea and the Ionian Sea in 12 Italian regions from north to south were sampled at the end of the basin, near the river mouth, in order to estimate the overall drug load in rivers flowing into Italian coastal waters. We developed a screening method based on solid-phase extraction and high-resolution HPLC (Orbitrap) mass spectrometry to assess the presence of pharmaceuticals, followed by the quantitative determination of over 80 compounds. The picture that emerged from the study showed that the problem of pharmaceuticals is widespread throughout the country, with some compounds (e.g. metformin, caffeine, sucralose and carbamazepine) often determined at microgram-to-tens of microgram levels. The combination of screening and quantitative determination methods made it possible to assess the state of pharmaceutical pollution in Italian waters and to highlight the different sources, including urban and hospital wastewaters. In addition, the quantitative data were compared with the available PNECs in order to assess the specific risk of the monitored sites and using the risk quotient approach.

This work has been funded by the European Union through the Next Generation EU program. PNRR, Mission 4, Component 2, Investment 1.4 - National Biodiversity Future Center (NBFC) – CUP n° B63D21015220004, and the Horizon Europe ONE-BLUE project.

3.21.P-Tu351 A Pragmatic Approach to Determine Rapid Degradability of Cosmetic and Pharmaceutical Substances Under the European Union's Urban Wastewater Treatment Directive

Sagar Thakali¹, Jennifer K. Saxe² and Stella Wang², (1)R&D, Kenvue, United States, (2)Kenvue, United States

The European Union's new Urban Wastewater Treatment Directive (UWWTD) will require extended producer responsibility (EPR) fees for companies in the pharmaceutical and cosmetics sectors when their products contain substances defined as “micropollutants.” However, the Directive's definition of micropollutants excludes “rapidly degradable” substances. For the definition of “rapidly degradable” substances, the Directive refers to the Classification, Labelling and Packaging (CLP) Regulation. However, the application of the CLP definition for the purposes of implementing the UWWTD lacks clarity. Therefore, we will assess the CLP definition, the underlying test methods, and associated data to determine “rapidly degradable” substances for the UWWTD and provide a pragmatic approach to avoid unnecessary testing burden while ensuring environmental protection.

We propose a tiered approach to exclude substances from the UWWTD's scope due to biodegradability using the results of first, screening tests and second, simulation tests. Abundant Ready Biodegradability study results exist for many substances, which can provide valuable insights. Instituting completely new testing methods solely for the UWWTD, as some stakeholders have suggested, would require considerable resources to standardize these methods and conduct tests on numerous substances that already have biodegradability data available. Ready (and Inherent) Biodegradability tests are screening tests that are designed to be stringent and difficult to pass and are intended as indicators of rapid and ultimate degradation in most environments, including biological wastewater treatment plants (WWTPs). Therefore, some substances that fail these screening tests may actually be rapidly degradable under more favorable conditions of typical WWTPs. Consequently, assigning EPR fees simply based on the failure to meet the ready biodegradability criteria would be inappropriate, violating the polluter pays principle, i.e., the polluter should bear the expenses of preventing and controlling pollution. We advocate for the possibility of stakeholders to perform more realistic higher-tier studies that can override lower-tier screening studies. These optional higher-tier studies should be based on either (1) well-established simulation tests (e.g., OECD Methods 303A and 314b), or (2) a combination of in silico models (e.g., SimpleTreat) and environmental monitoring at the outfall of properly operating tertiary WWTPs.

3.21.P-Tu352 Photocatalytic removal of aqueous PPCPs with In(OH)3-InVO4 modified carbon nitride
Xin Zhu¹ and Yfei Miao², (1)Nanjing Institute of Environmental Sciences, Ministry of Ecology and Environment, China (Mainland), (2)Hohai University, China (Mainland)

In recent years, environmental problems caused by medicines and personal care products (PPCPs) have attracted much attention. Heterogeneous photocatalytic technology has become a research hotspot due to its characteristics of not requiring the addition of soluble oxidants and efficient degradation of PPCPs. In this study, the In(OH)3-InVO4/g-C3N4 catalyst was synthesized by the hydrothermal method. It presented a mesoporous structure. Compared with g-C3N4, the functional groups did not change significantly, but the specific surface area increased significantly. The light absorption capacity, light response performance and separation efficiency of photogenerated carriers were all significantly enhanced. The removal efficiency of OTC after 60 minutes of light exposure reached approximately 91%. The coexistence of HCO3⁻ significantly enhances the removal efficiency of OTC by promoting the generation of carbonate radicals. Meanwhile, a higher pH can promote the generation of superoxide free radicals ($\cdot\text{O}_2^-$), thereby enhancing the treatment efficiency. The active species capture experiment confirmed that holes (h^+) and $\cdot\text{O}_2^-$ were the dominant active species in the system. Based on the characterization analysis and inference, the construction of the S-type heterojunction promotes the effective separation of electrons (e^-) of the g-C3N4 conduction band and holes of the In(OH)3-InVO4 valence band. h^+ directly participates in the oxidation of pollutants, and the edge potential of the g-C3N4 conduction band is greater than the potential of $\text{O}_2/\cdot\text{O}_2^-$ (-0.33 eV). Further drive e^- to reduce O_2 to $\cdot\text{O}_2^-$, synergistically enhancing the degradation of pollutants.

3.21.P-Tu353 Distribution and Ecological Risk Evaluation of Pharmaceuticals in Catalanian Rivers (Spain)

Maria Olivella Martí¹, Xavier Ortiz Almira¹ and Cristian Gómez-Canela¹, (1)Department of Analytical and Applied Chemistry, School of Engineering, Institut Químic de Sarrià-Universitat Ramon Llull, Via Augusta 390, 08017 Barcelona, Spain, Spain, (2)Environmental Laboratory, Institut Químic de Sarrià-Universitat Ramon Llull, Spain

Pharmaceutical residues are increasingly detected in surface waters due to growing consumption and the limited removal capacity of conventional wastewater treatment plants. Their persistence can affect aquatic organisms and may compromise ecosystem functioning. Catalonia, a region with high population density and diverse river basins, has not previously been studied at this extent. Most research has focused mainly on the Besòs and Llobregat because of their proximity to the Barcelona metropolitan area. Understanding the extent of contamination and its ecological implications is essential for improving water quality management.

This study aims to characterise the occurrence of pharmaceutical residues in Catalanian rivers and evaluate their ecological risks. To achieve this, a broad monitoring campaign was conducted across 14 major rivers, encompassing 52 sampling locations from sources to mouths. In total, 72 pharmaceuticals and five metabolites were quantified using liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) to detect trace concentrations. Ecological risks were assessed through risk quotients, calculated for algae, invertebrates and fish, providing an integrated view of potential impacts across trophic levels.

Pharmaceuticals were detected in almost all rivers, although eight compounds were not found in any sample. The highest concentrations occurred in basins influenced by urban, industrial or wastewater discharges, particularly the Besòs and Tordera. Several pharmaceuticals exceeded ecological risk thresholds, especially for algae, which emerged as the most sensitive group. Pentoxifylline and fluoxetine showed the greatest risk potential, while levofloxacin was the main concern for invertebrates. Areas of elevated risk were mainly located at river mouths or downstream of densely populated zones.

The study concludes that pharmaceutical contamination is widespread and ecologically relevant. These findings provide evidence to support improved water management in Catalonia. The results identify priority compounds and highlight specific locations where mitigation or enhanced monitoring should be implemented. By providing the first region-wide overview of pharmaceutical pollution, this work advances understanding of the issue and offers practical guidance for authorities and water managers to develop effective measures to protect river ecosystems.

3.21.P-Tu354 Can Bioaccumulation Screening Based on Log KOW Associated with the Neutral-Only Forms for Ionizable Substances Drive Unnecessary Fish Testing?

Jennifer K. Saxe¹, Sagar Thakali² and Stella Wang¹, (1)Kenvue, United States, (2)R&D, Kenvue, United States

The European Medicines Agency (EMA) Environmental Risk Assessment (ERA) Guideline requires pH-corrected octanol-water distribution coefficients (Dow) for ionizable active pharmaceutical ingredients (APIs) to be compared against octanol-water partition coefficient (Kow) screening criteria for bioaccumulation assessments. Given that the Dow for ionizable APIs are determined at three pH levels sufficiently encompassing the environmentally relevant pH range, concerns were raised with the Agency that further pH-correction is not justified and leads to unnecessarily conservative screening and subsequent need for redundant animal testing. However, the regulatory requirement remains in effect. Furthermore, EMA provides a specific approach for pH-correction only for monoprotic APIs (i.e., with a single dissociation constant) and not for APIs with multiple dissociation constants.

This study will evaluate the validity of the rationale requiring pH-correction of the log Dow values determined at three pH levels encompassing the environmentally relevant range (pH 5 to 9) for ionizable APIs with both single and multiple dissociation constants. Publicly available log Dow and bioaccumulation data will be evaluated, as well as recent literature on conceptually similar pH-correction applied to ecotoxicity of ionizable substances. Additionally, this study will show how the narrower optimal pH range for definitive in vivo test organisms for bioaccumulation testing (e.g., OECD Methods 305 and 321) may limit the practical usefulness of the currently required screening over a wider pH range.

The results of our evaluations will inform a more appropriate bioaccumulation screening approach based on log Dow values for ionizable substances.

3.21.P-Tu355 Assessing the Environmental Fate of a New Promising Antimicrobial Peptide

Owen DANIEL¹, Thomas Thiebault¹, Fabrice Alliot², Mabia Hossain Shetu¹ and Elodie Guigon², (1)Sorbonne University, France, (2)Practical School of Advanced Studies (EPHE), France

Antibiotics are widely used in human and veterinary medicine, and have contributed significantly to the increase in human lifespan over the last century. However, their overuse has led to the development of antimicrobial resistance (AMR), a major global health threat. Once excreted, antibiotics and their transformation products are emitted into the environment, where they can impact human and environmental health by promoting AMR or by exerting other hazardous impacts. Characterization of their environmental fate allows to evaluate such effects and is therefore required. As with others organic contaminants, the fate of antibiotics in ecosystems is driven by processes such as hydrolysis, photolysis, biodegradation or adsorption. In order to tackle AMR, it is necessary to develop new antibiotics less susceptible to create resistance. A promising antimicrobial peptide, Pep16, was synthesized for this purpose. Its environmental fate and transformation products were characterized using batch experimentations simulating environmental conditions, to ensure that the possible future large-scale use of this compound will not present risks to human and environmental health. Among the investigated processes, hydrolysis was not observed in ultrapure water, but was observed in river water. Water matrix constituents are responsible for this difference, especially Cu²⁺ which was shown to catalyze Pep16 degradation. Direct and indirect photolysis of Pep16 were assessed, and the effect of light attenuation depending on immersion depth in river water will be further characterized for better environment representativeness. Adsorption was shown to be important on the tested sediments. Kinetics and isotherms variations were highly depending on their physicochemical properties. Biodegradation of Pep16 by microbial communities from river water and raw wastewater was relatively fast and was found to be fluctuating with season and experimental conditions variations. The applied methodologies are contributing to the evaluation of Pep16 environmental fate. The knowledge acquired on the processes related to the fate of Pep16 is sufficient to predict its persistence, which will be relatively limited and controlled by the physicochemical properties of the environment, and its mobility, which will be limited due to strong adsorption. This work is therefore essential for evaluating the potential impacts of Pep16 on human and environmental health if it were to be marketed.

3.21.P-Tu356 Challenges of pH adjustment of toxicity tests for ionisable pharmaceuticals

Rebecca Jayne Brown¹, Dean Leverett¹, Thomas Austin² and Tracey Jayne Goodband³, (1)wca environment Ltd., United Kingdom, (2)Haleon, Switzerland, (3)Smithers, United Kingdom

New guidance for the environmental risk assessment (ERA) of pharmaceuticals was published in February 2024. As many pharmaceuticals are ionisable across an environmentally realistic pH range, and because

bioavailability and therefore toxicity may vary with pH, the new guideline includes a requirement for toxicity testing to be conducted “at a stable pH consistent with the most bioavailable form of the test chemical”. This will usually be the neutral or non-dissociated form. Standardised ecotoxicity tests have been optimised to be conducted under water quality conditions which maximise survival and performance of the test organisms within the assays. Some of the challenges that have been encountered when attempting to adjust the pH of media in a fish early life stage (ELS) test and a sediment water toxicity test with *Chironomus riparius* will be discussed. For the example test chemical the aim was to maintain the pH in the test system between pH 6 and 7. In the ELS the pH of the dilution water was adjusted to 6 using 37% hydrochloric acid to reduce the pH of the stock dosing solutions. During the test the pH of test vessels was maintained between 6.65 to 6.92. The test validity criteria were met but post hatch survival was 76% (guideline criteria is 75%). This is lower than is typical for the laboratory (historical control value is 79-97% (mean = 90%) for the last 11 studies). For the chironomid tests adjusting the pH of the test media alone was insufficient to maintain the test pH. The sediment was therefore also adjusted to pH 6 (sediment pH during the test was 6.43-6.48). However, the test validity criteria were not met for this test indicating that the test organisms did not tolerate the lower pH. In addition, the sediment carbon concentrations did not meet the levels recommended for the test because sediment pH is adjusted using calcium carbonate (i.e. an additional carbon source). There is a fine balance between conducting ecotoxicity tests at a pH consistent with the most bioavailable form of the test chemical and fulfilling test validity criteria. In addition, it can also be unclear if any increased sensitivity observed in the tests is due to maximised test substance bioavailability or because the test animals are under additional stress. pH adjustment of toxicity tests is expected to lead to more repeated tests which has ethical implications for vertebrate testing.

3.21.P-Tu357 pH-Dependent Toxicity of the Ionisable Pharmaceutical Ibuprofen in Aquatic Environments

Sefi Butler, Jonathan Burke, Sarah Dore, Trannum Rahim and Joanna Rowland, Reckitt Benckiser Group PLC, United Kingdom

Concern around the toxicity of ionisable molecules in relation to the pH of environmental lotic waters compared to testing media has been raised under regulatory frameworks (e.g. EMA ERA guidelines and Water Framework Directive EQS derivations), and in the scientific literature. For example, studies such as Chang et al. 2021 have raised this concern in relation to several active pharmaceutical ingredients including ibuprofen, although these findings were based on fish gill cell culture model and little data exists in intact organisms in environmentally relevant conditions. Given that the EMA ERA guidelines and EQS conclusions have significant regulatory impacts, further studies are useful to fully contextualise risk.

In EU lotic waters, pH typically ranges from 6 to 8, with more than 93% of sites above pH 7. Conducting aquatic toxicity assessments under altered pH conditions in laboratory settings is often impractical and experimentally complex. Such modifications can result in non-compliant tests because permissible pH ranges for test media are constrained by OECD guidelines and may vary according to species-specific or media-specific requirements. As a result, studies on aquatic organisms completed as part of regulatory processes consider the toxicity at species specific pH, usually around pH 7.

Since ibuprofen is a weak acid with a pKa of 5.15, its toxicity could theoretically increase with decreasing water pH. It should be noted that in any environmentally relevant EU lotic water ibuprofen will never reach 50% ionisation nor be fully ionised. To investigate the effect of modulating pH on ibuprofen toxicity to intact organisms, several studies were conducted. Fish, the most sensitive aquatic organism to ibuprofen, were tested in an OECD 236 fish embryo toxicity test with media adjusted to environmentally relevant pH levels. Two OECD 211 daphnia reproduction studies were also conducted with test media at varying pH levels and provide supplementary information.

Across all studies, ibuprofen toxicity was unaffected by variations in test media pH, indicating no biologically or statistically significant increase in toxicity within environmentally relevant pH ranges. Since these studies were all OECD guideline compliant and to GLP and C1, R1 according to CRED evaluation, the results also provide robust regulatorily relevant endpoints for consideration under ERA and EQS evaluations of ibuprofen in the future.

3.21.P-Tu358 Innovating Aquatic Toxicology: Lessons Learned from a Novel Full Life Cycle Fish Study

Sefi Butler, Jonathan Burke, Sarah Dore, Trannum Rahim and Joanna Rowland, Reckitt Benckiser Group PLC, United Kingdom

Robust chronic ecotoxicological data are critical for pharmaceutical registration within the EU, as outlined by the European Medicines Agency (2024), and plays a pivotal role in policy development and regulatory decision-making. The EQS dossier SCHEER (2023) and Faber et al. (2023) highlights that although several freshwater toxicity studies on ibuprofen exist, many fail to meet CRED scoring criteria, resulting in notable gaps and uncertainties when assessing and drawing conclusions on the chronic aquatic toxicity profile of Ibuprofen. Oldenkamp et al. (2022) similarly stressed the importance of high-quality, accessible ecotoxicity data on pharmaceuticals to support scientific research, regulatory frameworks, and public awareness.

The authors used a collaborative approach that included consultation with leading academic experts and regulatory authorities to develop a full life cycle test suitable for investigating the toxicological effects of Ibuprofen to fish (fathead minnows, *Pimephales promelas*) with the intention to continuously expose F0 embryos (<24-hours old) through all growth and reproduction stages to the production and growth of F1 juveniles.

The full life-cycle study on fathead minnows was conducted in compliance with Good Laboratory Practice (GLP) and, where applicable, OECD guidelines to ensure methodological rigor. Given the novelty of this approach, the study provided a unique opportunity to observe fathead minnows over an extended duration in the laboratory. The extensive dataset generated encompassed biological and behavioural parameters as well as operational aspects of the test system. These observations offer valuable insights for the design and execution of future long-term studies as well as interpretation of the results observed. Several challenges encountered during the study prompted consideration of procedural refinements, while others emerged from the interpretation of behavioural data, informing potential considerations of aspects of the study guidelines. The poster discusses these challenges and proposes solutions and recommendations for subsequent research.

3.21.P-Tu359 Ecotoxicological Impacts of the Painkiller Indomethacin on *Procambarus clarkii*: Tissue-specific Cytotoxic and Oxidative Responses

Alessandra Maganza¹, Federica Impellitteri², Camilla Mossotto¹, Annalisa Cotugno¹, Alice Gabetti¹, Antonia Concetta Elia³, Monia Renzi⁴, Francesca Provenza⁵, Giuseppe Esposito¹, Marino Prearo¹, Alessia Merialdi¹, Valerio Matozzo⁶, Caterina Faggio⁷ and Paolo Pastorino¹, (1)The Veterinary Medical Research Institute for Piedmont, Liguria and the Aosta Valley, Italy, (2)Department Veterinary Sciences, University of Messina, Italy, (3)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (4)Department of Life Sciences, University of Trieste, 34127, Trieste, Italy, (5)Bioscience Research Center srl, Italy, (6)Department of Biology, University of Padova, Italy, (7)Department Veterinary Sciences, University of Messina, 98166, Messina; Department of Eco-sustainable Marine Biotechnology, Stazione Zoologica Anton Dohrn, 80121, Napoli, Italy

Non-steroidal anti-inflammatory drugs (NSAIDs) are increasingly acknowledged as emerging contaminants in freshwater environments, but their impacts on aquatic invertebrates are still not well understood. This study provides the first combined assessment of cellular and biochemical responses in the red swamp crayfish (*Procambarus clarkii*) following long-term exposure to indomethacin, a commonly used NSAID. Individuals were exposed for 28 days to concentrations of 2.5, 5, and 10 mg/L, and a suite of cytotoxicity and oxidative stress biomarkers was examined.

Cell viability in hemolymph and hepatopancreas was evaluated using Trypan Blue and Neutral Red assays, while oxidative stress indicators were measured in hepatopancreas, gills, and muscle: superoxide dismutase (SOD), glutathione peroxidase (GPx), glutathione S-transferase (GST), and malondialdehyde (MDA). Results showed that indomethacin elicited notable cytotoxic and oxidative responses that varied across tissues. Importantly, hepatopancreas cell viability declined significantly at lower concentrations, with partial recovery at the highest dose, suggesting a potential hormetic effect. Oxidative stress markers showed concentration-dependent shifts: SOD and MDA were significantly modified in the hepatopancreas, GST activity changed in the gills, and GPx activity increased in muscle at the highest concentrations. Hemocyte viability remained stable, indicating a degree of resilience in circulating cells. The Integrative Biomarker Response-Threshold (IBR-T) index revealed both hormetic and traditional dose-response patterns depending on the tissue. From an ecological standpoint, these findings indicate that *P. clarkii* may withstand relatively high levels of indomethacin without undergoing systemic oxidative failure, potentially contributing to its persistence and competitive success in contaminated environments. However, the sensitivity of the hepatopancreas points to possible sublethal metabolic disturbances that could influence long-term fitness and population dynamics. Overall, this research offers new insights into the ecotoxicological effects of indomethacin in a key invasive species and underscores the value of tissue-specific biomarker approaches in environmental risk assessment.

3.21.P-Tu360 Consumption of Microalgae Exposed to Diclofenac Affects the Survival and Reproduction in the Cladoceran *Ceriodaphnia dubia*

Miriam Hernández-Zamora, Laura Martínez-Jerónimo and **Fernando Martínez-Jerónimo**, INSTITUTO POLITECNICO NACIONAL, ESCUELA NACIONAL DE CIENCIAS BIOLÓGICAS, Mexico

Diclofenac (DCF) is a nonsteroidal anti-inflammatory drug (NSAID) with antipyretic and analgesic effects; worldwide, its approximate annual consumption is 2,400 tons. DCF is the most widely used NSAID in humans and animals for treating muscle pain and inflammatory conditions. It is marketed as oral tablets or topical gel and is sold over the counter under various brand names. Urban and hospital wastewater are the primary sources of DCF release. Its presence in water bodies is not regulated, and concentrations ranging from 0.02 ng/L¹ to 216 µg/L¹ have been detected, which can negatively impact aquatic biota and its trophic structure. Therefore, the objective of this study was to evaluate the effect of food exposed to diclofenac and potentially contaminated by this drug, on the reproductive parameters of *Ceriodaphnia dubia*. The microalga *Pseudokirchneriella subcapitata* was exposed to different concentrations of DCF (12.5, 25, and 50 mg L⁻¹) in Bold Basal Medium for 7 days, and subsequently used as food for *C. dubia*. The median lethal concentration (LC50) of DCF was determined in the cladoceran at 48 h. Subsequently, a 15-day chronic bioassay was performed, supplying *C. dubia* 1 x 10⁷ cells mL⁻¹ of *P. subcapitata* without diclofenac (control) and 1 x 10⁷ cells mL⁻¹ of *P. subcapitata* as the intoxicated food obtained from each DCF concentration. Survival and reproductive responses of *C. dubia* (total progeny, age at first reproduction, and number of clutches) were evaluated daily. The LC50 of diclofenac for *C. dubia* was 58.56 mg L⁻¹. Cladoceran survival decreased by 10% with the contaminated feed. Reproduction (total progeny) of *C. dubia* decreased significantly compared to the control in treatments fed with microalgae exposed to DCF, and the age at first reproduction was delayed by up to 1 day at the highest concentration (50 mg L⁻¹). These findings highlight the importance of considering the effects of emerging contaminants, such as DCF, on the trophic structure of the aquatic environment. The planktonic cladocerans, as non-selective filter feeders, are directly exposed to toxic substances in the water and, indirectly, through the ingestion of microalgae that are also exposed to and possibly affected by these chemical pollutants, which can act as toxic carriers and become an additional environmental stressor.

3.21.P-Tu361 Temperature Affects the Toxicity of Amoxicillin in *Microcystis aeruginosa* and Modifies the Toxicogenicity of This Cyanobacterium

Miriam Hernández-Zamora, Marlene Mesías-García, Miriam Z. Silva-Preciado and **Fernando Martínez-Jerónimo**, INSTITUTO POLITECNICO NACIONAL, ESCUELA NACIONAL DE CIENCIAS BIOLÓGICAS, Mexico

The quality and availability of freshwater are currently severely affected by population growth, urbanization, and intensified agricultural practices, which lead to excessive discharge of mineral nutrients into aquatic environments. This, coupled with climate change, contributes to increased intensity and frequency of harmful cyanobacterial blooms, mainly dominated by *Microcystis aeruginosa*, with negative repercussions for aquatic life and humans due to the synthesis and release of cyanotoxins. Furthermore, contaminants of emerging concern, such as pharmaceuticals and especially antibiotics, influence cyanobacterial growth. Globally, in 2024, the production of amoxicillin trihydrate was estimated at approximately 69,000 tons for use in human and veterinary medicine. This antibiotic has been detected in aquatic ecosystems at concentrations ranging from ng to µg L⁻¹. Therefore, the objective of this study was to evaluate the effect of amoxicillin and two temperatures (25 and 30 °C) on the growth and concentrations of photosynthetic pigments, phycobiliproteins, and cyanotoxins of *M. aeruginosa*. The Median Inhibitory Concentration (IC50) was determined according to OECD Protocol 201. Subinhibitory bioassays were performed with 50,000 cells mL⁻¹ in BG11 medium at two temperatures (25 °C and 30 °C), exposing the cells to amoxicillin concentrations of 102, 188, and 426 ng L⁻¹, with constant aeration and continuous illumination at 30 µmol photons m⁻² s⁻¹ for 96 h. The IC50 of amoxicillin in *M. aeruginosa* was 544.53 ng L⁻¹. In bioassays evaluating the effect of temperature on amoxicillin toxicity, cell growth was comparatively more inhibited at 30 °C, but pigment synthesis, particularly carotenoids, phycocyanin, and allophycocyanin, was significantly stimulated. Regarding cyanotoxin synthesis, the highest concentration of microcystins was recorded in *M. aeruginosa* at 30 °C when exposed to the highest amoxicillin concentration (426 ng/L). Our results demonstrate that amoxicillin alters the development of *M. aeruginosa* and that higher temperatures intensify these effects, favoring the synthesis and accumulation of microcystins, which pose a potential risk to biota and humans. Therefore, the importance of considering the combined effects of pharmaceutical contaminants and global warming in freshwater toxicity studies is highlighted, as these factors can influence other processes, such as eutrophication, which, in turn, can amplify the impacts of emerging contaminants.

3.21.P-Tu362 Cytostatic pharmaceuticals: from regulatory dossiers to real ecotoxicity data.

Alejandra Pérez-Vázquez¹, Micaela Faria², Nathalie Chèvre², Paul Thomas³, Floriane Larras³, Christelle Margoum⁴, M. Carmen Casado-Martinez⁵ and Benoît J.D. FERRARI⁶, (1)KREATiS, France, (2)Faculty of Geosciences and Environment, University of Lausanne, Switzerland, (3)KREATiS SAS, France, (4)UR Riverly, INRAE, Villeurbanne, France, (5)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Switzerland, (6)Ecotox Centre, Switzerland

Pharmaceuticals are widespread in aquatic ecosystems. This unintended load is known to potentially affect aquatic organisms. To control the entry of pharmaceuticals in the market in the European Economic Area (EEA) authorization is a mandatory prerequisite, including an Environmental Risk Assessment (ERA) of the active pharmaceutical ingredients (APIs).

Antineoplastic agents have been among the most frequently authorized APIs in the EEA over the past decade, these are mainly use in cancer treatment. However, the ecotoxicological information included in their authorization dossiers remains limited, resulting in a lack of regulatory-compliant ecotoxicological data for these APIs.

This work focuses on cyclophosphamide and ifosfamide which are classified as cytostatic antineoplastics APIs, which generally intervene in cell division, and their main role is to inhibit or completely block the replication of DNA. The toxicity of these two cytostatic substances will be assessed by using single-species bioassays guidelines for different model organisms, in order to represent the effects in the ecosystem at different trophic levels.

In aquatic organisms the toxicity on primary producers growth inhibition has been assessed in *Pseudokirchneriella subcapitata* following OECD 201 guidelines. Also, acute and chronic toxicity on secondary producers has been assessed using *Daphnia magna*. For the acute toxicity the target endpoint was survival following OECD 202 guideline. As for the chronic toxicity were survival, reproduction and growth by following OECD 211 guideline. Additionally, sediment effect assessment has been assessed in chironomids emergence following OECD 218 and ostracods survival and growth according to ISO 14371.

The aim of this study is to understand the potential toxic effects of cytostatic substances in the aquatic ecosystems. Also, to provide good quality and regulatory compliant ecotoxicity data for model organisms.

3.21.P-Tu363 Ecotoxicological Effects of Natural Antimicrobial Terpineol on Soil Bioindicators and Microbial Communities

Laura Botello-Morte, Antonio Valenzuela, Elisa Langa, Pedro Rodríguez-López, Diego Ballester and María Rosa Pino Otín, San Jorge University, Spain

Terpineol (TN) is a monoterpene naturally present in essential oils (EOs) from aromatic plants or obtained through biotransformation. Its aroma and solvent properties make it a popular in both the chemical and food industry as an ingredient and additive, respectively. Furthermore, it presents some therapeutic properties such as antimicrobial activity against pathogenic or multidrug resistant (MDR) bacteria.

As a result, global demand is increasing and despite being generally recognized as safe (GRAS) compound for humans, information regarding the potential environmental impact is still scarce. Since it is assumed to be fully biodegradable in water, it would be interesting to evaluate the impact of the use of terpineol over soil. In this study, the ecotoxicity of terpineol using key soil bioindicator organisms (*Allium cepa* and *Eisenia fetida*) and soil microbial communities was assessed.

The *A. cepa* assay yielded a 72 h EC₅₀ of 50.555 (40.807-63.574) µg/mL, while the 14-day *E. fetida* assay resulted in a LC₅₀ of 55.791 (47.769-62.141) mg/kg, suggesting a moderate toxicity of TN towards individual soil bioindicators, that increased in a dose-dependent manner. Additionally, the effects of TN on soil microbial communities were evaluated to provide a more ecologically relevant perspective. Terpineol at 10 and 100 µg/mL significantly reduced microbial growth after 72 h hours of incubation. Additionally, TN caused a dose-dependent reduction in microbial metabolic activity, presenting statistical significance when amines or amides were used as carbon source at 10 µg/mL ($p < 0.05$) and 100 µg/mL ($p < 0.01$) of TN added.

These results highlight that TN, despite being considered biodegradable and low-risk for humans, may pose ecological risks when released into soil environments. Regulatory consideration and further research are needed to better understand its long-term environmental effects and to support safe use guidelines.

3.21.P-Tu364 Enhanced Ecotoxicity of Synergistic Antibiotic and Natural Compound Combinations: An Aquatic Outlier

Natalia Ferrando¹, María Rosa Pino Otín¹, Manuel Arruebo², Laura Botello-Morte¹, Diego Ballesterio¹ and Elisa Langa¹, (1)San Jorge University, Spain, (2)Instituto de Nanociencia y Materiales de Aragón (INMA), Aragon Health Research Institute and University of Zaragoza., Spain

The widespread emergence of antibiotic-resistant bacteria has driven the search for alternatives, including the synergistic use of commercial antibiotics (ATBs) and natural compounds (NCs). Although promising against pathogens, their combined environmental fate and ecotoxicity on non-target aquatic organisms remain largely unknown. This research addresses the critical ecotoxicological risk posed by seemingly benign NC-ATB combinations.

This study aimed to evaluate acute aquatic ecotoxicity of four synergistic NC-ATB combinations compared to individual compounds, identifying synergistic toxic effects on non-target organisms. The tested combinations, previously validated against human bacteria, were cinnamaldehyde (CIN) with amoxicillin (AMO), CIN with gentamicin (GTM), eugenol (EUG) with GTM, and EUG with tetracycline (TC). Ecotoxicity assays were carried out using three bioindicators: luminescence inhibition of *Aliivibrio fischeri*, immobilization of *Daphnia magna*, and community-level physiological profiling (CLPP) via Biolog AWCD on river microbiota. Tests were performed at Minimum Inhibitory Concentrations of isolated (MIC_{iso}) and combined components (MIC_{comb}). Results showed synergistic combinations generally had higher ecotoxicity than isolated ATBs on *A. fischeri* and *D. magna*. For example, the CIN-AMO combination's *D. magna* EC₅₀ was 16.191 mg/L, markedly lower than individual components at similar doses. Conversely, toxicity toward aquatic microbiota was comparable to isolated ATBs at MIC_{iso} and lower than isolated NCs at MIC_{iso}. Notably, EUG-TC was the most toxic to river microbiota, reducing AWCD almost to zero, implying a strong impact on bacterial metabolism. Differences between toxicity in simple organisms and complex microbiota suggest toxic effects could be masked in natural communities due to resistant bacterial species proliferation, consistent with findings in other chemical combination studies.

Though environmental concentrations are low compared to EC₅₀ values, NC-ATB synergies are not ecologically innocuous for selected non-targets, showing unexpectedly enhanced toxicity. The substantial ecotoxicity increase over individual ATBs, especially for *A. fischeri* and *D. magna*, is a critical anomalous challenge that current risk assessment models do not consider because those assume low risk from NCs and focus on isolated antibiotics. Future environmental impact assessments of novel antimicrobial strategies must consider synergistic effects.

3.21.P-Tu365 Ecotoxicological Effects of a Thymol–Chloramphenicol Synergistic Antimicrobial Combination on *Daphnia magna* and River Microbial Communities

Cristina Gan-Oria, Elisa Langa, Laura Botello-Morte, Diego Ballesterio and María Rosa Pino Otín, San Jorge University, Spain

The extensive use of antibiotics has led to their persistent release into aquatic environments, raising concerns about resistance development and toxicity to non-target organisms. Combining natural compounds with conventional antibiotics is emerging as a sustainable approach to reduce antibiotic doses while retaining antimicrobial effectiveness. However, the environmental consequences of such synergistic antimicrobial combinations (SACs) remain poorly characterized. This study investigated the ecotoxicity of a thymol–chloramphenicol SAC previously shown to exert potent antimicrobial activity against *Acinetobacter baumannii* but whose effects on aquatic organisms and microbial communities had not been examined.

Acute immobilization assays with *Daphnia magna* were conducted according to OECD Guideline 202, using five dilution levels (100%, 50%, 25%, 12.5%, and 6.25%) of the SAC. The undiluted mixture contained 31.25

µg/mL thymol and 7.8 µg/mL chloramphenicol. Immobilization increased with concentration and exposure time, with 48-hour EC50 values indicating moderate acute toxicity. Predictive mixture models (Concentration Addition and Independent Action) revealed that the observed toxicity closely matched the expected response derived from the individual substances, suggesting no synergistic or antagonistic effects on *D. magna*. To assess potential impacts on microbial communities, water from the Gállego River (Spain) was exposed to 31.25 µg/mL thymol, 7.8 µg/mL chloramphenicol, their combination (SAC), and the individual compounds at their respective minimum inhibitory concentrations (MICs; thymol 125 µg/mL, chloramphenicol 62.5 µg/mL). Microbial metabolic activity was evaluated with Biolog EcoPlate™, assessing the ability of native microbial assemblages to utilize 31 carbon sources. Significant reductions in average well color development (AWCD) were observed at MIC levels of the individual compounds, showing stronger inhibition than that produced by the SAC. At synergy concentrations, both thymol and chloramphenicol exhibited much lower toxicity, and the thymol response was similar to the negative control. Overall, the thymol–chloramphenicol combination preserved potent antimicrobial activity while markedly reducing the individual compounds' toxicity. These findings support the potential of natural–antibiotic synergistic formulations as environmentally safer alternatives to mitigate the ecological impact of antibiotic usage

3.21.P-Tu366 Ecotoxicological Assessment of Synergistic Antimicrobial Combinations of Antibiotics with Tannic Acid (SACTA) and Nerol (SACNE) on Aquatic Bioindicators and River Microbial Communities *Guillermo Lorca, Diego Ballester, Laura Botello-Morte, Pedro Rodríguez-López, Elisa Langa and María Rosa Pino Otín, San Jorge University, Spain*

Synergistic combinations between antibiotics (ATB) and natural products (NP), such as tannic acid (TA) and nerol (NE), are promising strategies to reduce antibiotic doses and mitigate antimicrobial resistance and environmental contamination. However, their ecotoxicological impacts on aquatic systems and microbial communities remain poorly understood.

This study assessed six synergistic combinations: SACTA1 (TA 46.87 + chloramphenicol, CHL 3.91 mg/L), SACTA2 (TA 46.87 + ampicillin, AMP 7.81 mg/L), SACTA3 (TA 40.62 + CHL 1 mg/L), SACNE1 (NE 125 + streptomycin, STM 1.17 mg/L), SACNE2 (NE 125 + gentamicin, GTM 0.78 mg/L), and SACNE3 (NE 250 + STM 31.25 mg/L), using *Daphnia magna*, *Aliivibrio fischeri*, and microbial assemblages from the Gállego River (Spain).

For *D. magna*, toxicity decreased in the order SACNE3 > SACNE2 > SACNE1 > SACTA3 > SACTA2 > SACTA1; for *A. fischeri*, SACNE2 > SACNE3 > SACNE1 > SACTA2 > SACTA1 > SACTA3, confirming higher toxicity of NE-based mixtures. Antibiotic EC50 values in combinations (0.03–5.47 mg/L) were 100–10,000 times lower than their individual LC50 values (STM 772, GTM 840, AMP 4324, CHL 285 mg/L), demonstrating the co-adjuvant effect of NPs. Despite increased mixture potency, antibiotic concentrations remained below therapeutic MICs, ensuring environmental safety. NP doses (NE 1–14.6 mg/L; TA 18.12–43.17 mg/L) were below or near LC50 levels. Overall, synergistic use reduced antibiotic requirements by up to 90%, decreasing selective pressure and resistance risk.

At the community level, TA-based mixtures (SACTAs) reduced microbial growth and degradation of polymers and carbohydrates, whereas NE-based (SACNEs) caused milder effects, with SACNE1 eliciting a hormetic response enhancing growth and amino acid metabolism. Higher TA toxicity reflected disruption of ecological and metabolic interactions, while NE had direct membranolytic effects. SACNE1, SACNE3, SACTA1, and SACTA2 were 16–32% less inhibitory than individual antibiotics at MIC, SACNE2 matched antibiotic toxicity, and SACTA3 was 71% more toxic.

These findings show that ecotoxicity of natural–antibiotic synergies depends on composition. The limited impact and resilience of microbial communities support their potential as safer antimicrobial alternatives, inviting further validation in realistic environmental scenarios.

3.21.P-Tu367 A Cocktail a Day Keeps the Doctor Away - How to Consider Potential Additive Mixture Toxicology within Veterinary Pharmaceutical Legislation

Louis-Marvin Sander¹, Thomas Backhaus², Jan Pridöhl³, Ute Kühnen³ and Gerd Maack⁴, (1)German Environment Agency (UBA), RWTH Aachen University, Germany, (2)RWTH Aachen University, Germany, (3)Pharmaceuticals, German Environment Agency (UBA), Germany, (4)German Environment Agency (UBA), Germany

Conventional ecotoxicological assessments typically focus on assessment of single substances or of fixed mixtures in combination products. Those are mostly ignoring and thus underestimating the effects of additive or synergistic mixture toxicology in the environment. Among others, this is true in the context of the assessment of pharmaceuticals. Therefore, this study assesses how a Mixture Assessment Factor (MAF), based on data for veterinary pharmaceuticals might statistically be defined, considering the extensive variety of chemical mixtures possible, and what role single substance tests and measured environmental concentrations (MECs) can play in this process.

The proposed approach includes publicly available databases, such as the Pharms-UBA (PU) for MECs and the European Medicines Agency's public assessment reports for effect data. The latter were supplemented by internal data from the German Environment Agency. Based on that dataset, four questions were posed: (1) Which mixtures are found in the environment, and in what range are the additive MECs? (2) Are there any substances and mixtures that raise concerns due to potential $RQ_{real} = MEC/PNEC$ (real world RQs)? (3) Which MAF_{max}, MAF_{weighted}, and MAF_{exact} can be derived? (3) Based on additive effects, what would be a generally applicable MAF suggest?

The effect dataset contains 51 AS, which can theoretically form 4.22×10^{66} mixtures. Thus, the most relevant mixtures need to be found. The PU MEC database shows that, only based on soil and veterinary pharmaceuticals, 34 different AS can be found with theoretical 8.03×10^{38} mixtures possible. The articles contained 219 study sites where mixtures actually occurred in the environment. Mixture sizes ranged from 2 to 17 with additive MECs from ng up to mg/kg soil.

In summary, our analysis demonstrates that mixtures in the environment already are a cause for concern and should be addressed in Environmental Risk Assessment. Based on veterinary and dual-use AS, it highlights the need for an extra safety factor due to already elevated mixture exposure. This suggests a similar approach for human pharmaceuticals, identifying relevant mixtures, risk drivers, their occurrence, risk potential, and possible regulatory adaptations to align with environmental protection goals.

3.21.P-Tu368 The Missing Pieces for a Monography System – Prioritizing Substances for Pharmaceutical Environmental Risk Assessment

Louis-Marvin Sander¹, Daniela Gildemeister², Arne Hein³, Thomas Backhaus⁴ and Gerd Maack³, (1)German Environment Agency (UBA), RWTH Aachen University, Germany, (2)Pharmaceuticals, German Environment Agency (UBA), Germany, (3)German Environment Agency (UBA), Germany, (4)RWTH Aachen University, Germany

In order to minimize risks posed by pharmaceutical residues in the environment, it is necessary to understand the potential effects on organisms and the fate of these substances in the environment. Especially for substances authorized before 2005 for use in veterinary medicinal products (VMP) and in 2006 for use in human medicinal products (HMP) respectively, such data are often missing. Even for products approved after the relevant guidelines come into effect, data gaps are quite common. In 25 % of substances authorized, no final assessment is possible. Incomplete dossiers due to tests with insufficient data quality further reduce the ability to estimate the potential environmental impact. In Article 23 of the proposed revision of Directive 83/2001, a program for legacy medicinal products authorized before 2005 is planned. Therefore, a prioritization scheme will be needed to unveil the most important substances connected to eventually occurring adverse environmental effects. For that, publicly available data from (European) Public Assessment Reports will be supplemented by confidential data from the German Environment Agency. Predicted Environmental Concentrations will be generated and supplemented with available refined PECs. The analysis starts with a holistic approach, where

active substances of both HMPs and VMPs are examined with respect to their main entry pathways, regardless their indication or anatomical therapeutically group. For calculations including MECs, among others, the Pharms-UBA-Database will be used.

Following an evaluation of the criteria, the final step will be the creation of a prioritisation scheme for such a programme. This will include a list of active substances that are of environmental concern and/or for which data is missing. It will also highlight the amount of already available data, where generation of the proposed substance monographs (Article 24 of proposed new Directive) is a low-hanging fruit. The objective is building a strong data foundation for adequate risk assessment in the regulation and use of pharmaceuticals. This helps to avoid redundant work in substance evaluations, facilitates product substitution and enables the implementation of safety precautions during production and use. Combining such a foundation in form of a monograph system and explicit data-sharing guidelines aids process simplification in preventing unnecessary multiple assessment and mitigates resource consumption for all stakeholders involved.

3.21.P-Tu369 Application of Toxicogenomics in Ecotoxicological Model Organisms for Monitoring Pharmaceutical Residues as Relevant Trace Compounds in Aquatic Environments

Melina Schöpker¹, Karsten Schlich², Christoph Schaefer² and Sebastian Eilebrecht³, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Relevant trace substances, such as nanoparticles, per- and polyfluoroalkyl substances (PFAS) and pharmaceuticals, enter wastewater systems through domestic wastewater, industrial discharges, or rainwater and, if not efficiently removed, can contaminate rivers, lakes and even drinking water. Pharmaceuticals as highly potent substances pose a significant threat to aquatic compartments and their communities. The effects on aquatic organisms range from acute to chronic toxicity, sometimes even at environmentally relevant concentrations. Moreover, pharmaceuticals often occur as complex mixtures whose combined effects may exceed those of their individual components. A major challenge in monitoring pharmaceuticals in aquatic systems is their presence at very low concentrations, which makes analytical detection difficult. Targeted analytical methods are limited to known compounds, whereas non-targeted approaches often lack sensitivity, especially for compounds in complex mixtures. Detecting transformation products is particularly challenging, as little data is available on them.

The aim of this study is to investigate the applicability of toxicogenomic methods for detecting the molecular effects of pharmaceuticals as trace substances in aquatic environments. Based on this, a mechanism-sensitive monitoring approach will be developed and applied to pharmaceutical mixtures and real water samples to detect compounds by their mode of action (MoA).

Relevant OECD guideline tests will be combined with transcriptomic methods using the aquatic model organisms *Danio rerio* (embryo) and *Raphidocelis subcapitata*. Single substances as well as simple and complex mixtures will be tested, starting with preliminary tests to determine sublethal effect concentrations, followed by testing down to the environmentally relevant concentration range. Transcriptome analysis, transcriptomic-point-of-departure (tPOD) calculation and bioinformatic evaluation will be used to investigate method sensitivity and identify molecular signatures of the MoA of the tested pharmaceuticals. This approach will then be applied to mixtures and water samples, such as effluents from wastewater treatment plants.

Overall, the results of this study could enable the applicability of molecular methods for monitoring pharmaceuticals in environmental samples to be investigated, supporting both environmental monitoring and risk assessment.

3.21.P-Tu370 A Novel Secondary Poisoning Model for Pharmaceutical Bioaccumulation in Aquatic, Terrestrial, and Hybrid Food Webs

Charlie Davey¹, Ad M. J. Ragas² and Jan A.J. Hendriks¹, (1)Radboud University, Netherlands, (2)Environmental Science, Radboud University, Netherlands

Pharmaceutical pollution has become a salient issue in recent years, where contamination is not only limited to the aquatic environment, but also terrestrial and subterranean environments. However, due to the scarcity of data when compared to the large number of pharmaceuticals and biota that can be affected, secondary poisoning models can be deployed to fill in these data gaps both in terrestrial and aquatic environments. Yet many models have limited applicability, either by their limited species scope or by not considering physicochemical properties such as ionisation, which is specifically important for pharmaceuticals. Therefore, a novel secondary poisoning model would need to account for both the complexity and diversity of the ecosystem it is modelling, and the diversity of physicochemical properties that pharmaceuticals particularly may have. To this end, a new secondary poisoning model was developed and validated that covers the aquatic, terrestrial, and subterranean food webs, as well as combinations.

The model expands on previous models by including ionisation and ionisation-based phase partitioning using logDOW and poly-parameter linear free energy relationships (pp-LFERs). The model covers multiple species groupings (algae, plants, worms, molluscs, arthropods, fish, birds, and mammals) across three environments (aquatic, subterranean, and terrestrial) while correcting for mass, blood type, diet, and internal pH. The model was validated using 75 pharmaceuticals spanning 55 studies, 330 compounds, and 445 species from recent literature. Fold errors showed that 81% of aquatic data had been within a factor of 100, while 50% was within a factor of 10. Preliminary results for the terrestrial model indicate that 71% of predicted data were within a factor of 100, while 51% were within a factor of 10. Algae, was consistently under predicted by the model, indicating that cell wall interactions may need to be modelled differently. Individual compounds such as caffeine and sulfamethoxazole also routinely were underpredicted, with sulfamethoxazole being a prime example of a compound with multiple ion species and zwitterions, which the model does not account for. Furthermore, terrestrial data were only limited to 3 studies, indicating that improvements to the terrestrial and subterranean parts of the model could be made with the availability of more data.

3.21.P-Tu371 K drugs: Eco/genotoxicological Characterization of the synthetic Cannabinoid MDMB-4en-PINACA

Gabriely Fernanda Groto Militão, José Luiz da Costa and Gisela Umbuzeiro, State University of Campinas (UNICAMP), Brazil

The use of chemical substances to alter mental states and sensory perception dates back centuries. New Psychoactive Substances (NPS) are compounds designed to modulate the central nervous system. Synthetic cannabinoids (SC), popularly known as “K drugs” (K2, K4, K9), represent the group with the highest number of substances detected worldwide since 2008. MDMB-4en-PINACA stands out for its strong affinity to CB1 receptors in the central nervous system. Data on the ecotoxicity, genotoxicity, and behavioral effects of NPS remain scarce, limiting our understanding of their environmental impacts. This work aims to characterize the eco/genotoxicological hazards of the synthetic cannabinoid MDMB-4en-PINACA. MDMB-4en-PINACA was dissolved in Dimethylsulfoxide (DMSO) at the limit of solubility (11.26 µg/µL). Acute toxicity was performed with *Daphnia similis* (2 to 11 mg/L) and *Parhyale hawaiiensis* (2 to 11 mg/L). A miniaturized version of the Salmonella/microsome mutagenicity test (Microplate agar, MPA) was tested in concentration-response from 0.14 to 2.25 µg/µL. Five strains (TA100, TA98, TA97a, TA102, and TA1535) were used with and without metabolic activation (rat liver S9 5% PB-induced). DNA damage in *P. hawaiiensis* sperm cells was evaluated using the comet assay at three concentrations (0.5, 1.6, 5.0 mg/L), along with negative (DMSO 0.01%) and positive controls (Ethyl methanesulfonate, EMS). Sixteen males were individually exposed for 96h. Testes were collected, slides prepared and stained with ethidium bromide. One hundred comets per gel were analyzed (%DNA in tail) using Comet Score 2.0. Acute toxicity was observed in both organisms, *D. similis* (EC50 3.77 mg/L) and *P. hawaiiensis* (LC50 2.91 mg/L). MDMB-4en-PINACA did not showed mutagenic effects in any Salmonella strain, regardless metabolic activation, but increased sperm DNA damage at 5.00 mg/L. This work provides new data on the eco/genotoxic hazard characterization of the synthetic cannabinoid MDMB-4en-PINACA. *P. hawaiiensis* proved to be a suitable invertebrate model for assessing sperm DNA damage after 96 h exposure to MDMB-4en-PINACA. Using invertebrates as alternative models helps reduce ethical and social concerns associated with mammalian testing. To complete the mutagenic evaluation, we are testing it for micronucleus in hemocytes of *P. hawaiiensis*.

3.21.P-Tu372 Environmental Risk Assessment of Generic Human Pharmaceuticals

Martin Bowyer¹, **Emilie Vizade²** and **Tom Hargreaves¹**, (1)Blue Frog Scientific Limited, United Kingdom, (2)Blue Frog Scientific Limited, France

Following adoption of the updated environmental risk assessment (ERA) guidelines by the European Medicines Agency (EMA) the assessment of generic human pharmaceuticals is entering a new era of scrutiny. Both the EMA and the UK Medicines and Healthcare products Regulatory Agency (MHRA) are increasingly requiring full environmental data packages for generic pharmaceutical applications, an evolution that reflects the growing priority placed on environmental protection under EU and UK frameworks.

Historically applications for generic products could avoid in-depth ERAs by arguing that authorisation would not lead to increased environmental exposure. However, this approach is now only accepted under the new guideline if a full ERA is available for the reference drug product. In cases where no previous ERA is available, e.g. original submission occurred before 2006, or the previous ERA does not meet the requirements of the current guidelines, new or updated ERAs will need to be submitted.

This shift aligns with broader environmental objectives across the EU and UK, ensuring that all pharmaceuticals are assessed for their potential impact on ecosystems, consistent with guidance under Directive 2001/83/EC and UK Human Medicines Regulations 2012.

With the adoption of the updated EMA guidelines many generic pharmaceutical manufacturers find themselves requiring extensive ERAs, including significantly laboratory testing, to fulfill their submission requirements. For generic manufacturers margins are tight and the requirement for laboratory testing often exceeding €300,000 may make some products financially unviable. The aim of this work is to discuss the strategies available to manufacturers of generic pharmaceuticals to satisfy the requirements of the EMA guidelines and highlight the benefits of data sharing and collaboration during data generation.

Overall, the implementation of the mandatory environmental risk assessment for pharmaceuticals products is leading to a strong increase of new experimental studies for complex endpoints. To avoid unnecessary animal testing and ensure harmonization of ERAs on the same active substances, generic manufacturers must be aware of the options available and the benefits of collaboration through development of consortium and data sharing agreements.

3.21.P-Tu373 Should Peptide-Based Radioligand Therapeutics be Exempt from an Environmental Risk Assessment under the EMA Guideline for Human Medicinal Products?

Gemma Janer¹, **Stephane Rodde²** and **Milica Glogovac²**, (1)Novartis Pharma, Spain, (2)Novartis Pharma, Switzerland

A radioligand therapy is a precision-based approach for cancer treatment. Peptide-based radioligands include a peptide-based targeting compound, a linker, and a complexing agent to chelate a radioactive isotope. The ligand binds to a specific cell marker of the target cancer cells to deliver the radioisotope, destroying these cancer cells while having limiting impact on nearby healthy cells. The radioisotopes used have short decay half-lives (e.g., in the order of a few hours to a few days) to minimize long-term exposure.

Risks related to the radioactive properties of these therapies are governed by separate regulatory frameworks. In addition, the EMA guideline (EMA/CHMP/SWP/4447/00 Rev. 1- Corr.*), does not exempt radioligands from an environmental risk assessment. The assessment starts by estimating predicted exposure concentration (PEC) and determining n-octanol:water partitioning coefficients (log Dow) at environmentally relevant pHs.

The therapeutic doses are defined based on radioactivity rather than mass. As a worst-case scenario, the maximum mass content of the chemical precursor (typically at levels of µg per dose) can be used in the PEC calculation. The resulting PEC, considering also the dose regimen and the default market penetration factor (1% of the population per year) leads to PECs several orders of magnitude below 0.01 µg/L, the phase II ERA threshold. Additionally, if the PEC was refined by prevalence of the target indications, it would be even lower. The log Dow values are to be compared with a threshold of log Kow > 4.5, as a trigger for a persistence-bioaccumulation-toxicity assessment. Peptide-based radioligands have predicted log Kow values in the negative range, driven by both the peptide and the chelator hydrophilicity. Handling of the radioligand to generate experimental log Dow data would be technically challenging and unnecessary given the hydrophilicity of the radioligand.

Given 1) the extremely low predicted environmental exposure, 2) the short decay half-life of radioligands and consequent rapid loss of pharmacological activity, 3) the fact that a large fraction of their molecular mass corresponds to the peptide, which is expected to readily biodegrade, and 4) the high hydrophilicity of peptide-based radioligands, we consider that peptide-based radioligands should be exempted from the preparation of an environmental risk assessment.

3.21.P-Tu374 Environmental Risk Assessment of the New Pharmaceutical Imlunestrant, a Selective Estrogen Receptor Degradar

Alison Nimrod Perkins, Laura Garcia Barcia and Michael Lee, Eli Lilly and Company, United States

Imlunestrant is a novel, small molecule estrogen receptor degrader that has recently been approved to treat breast cancer. To fulfill the Environmental Risk Assessment (ERA) requirement, studies to characterize the physical chemical properties, environmental fate and ecotoxicity of imlunestrant were conducted. The results of these studies were used to predict the distribution, persistence and effects of imlunestrant amongst environmental compartments. A fish full- life cycle toxicity test was included based on the mechanism of action at the estrogen receptor. A high adsorption coefficient to sewage sludge ($K_{FOC} = 29600 \text{ L}\cdot\text{kg}^{-1}$) indicates that imlunestrant could be transferred to soil via land application of biosolids; therefore, the toxicity to terrestrial species was evaluated. Imlunestrant is hydrophobic (at pH 5, 7, 9 $\log K_{ow}$ is 3.29, 5.13, 5.55, respectively) so a bioconcentration study in fish was conducted. Risk assessments were conducted for the sewage treatment plant, surface water, sediment and soil. Risk Quotients (PEC:PNEC) were all less than 1 and demonstrated that there is no risk to species in the environment. While the BCF_{kgL} was determined to be 274 to 500 $\text{L}\cdot\text{kg}^{-1}$, preclinical toxicity data was evaluated to show that imlunestrant does not pose a risk for secondary poisoning. Additionally, imlunestrant is not classified as PBT or vPvB. Conduct of the ERA followed the framework of the updated EMA ERA guidance (2024) and learnings with the new guidance are discussed.

3.21.P-Tu375 Environmental Risk assessment of Pharmaceuticals in river catchment areas – case study of Latvia

Ieva Putna-Nimane¹, Ineta Liepina-Leimane¹, Evita Strode¹, Lauri Äystö², Wojciech Artichowicz³, Alena Seidenfaden⁴ and Jens Tränckner⁴, (1)Latvian Institute of Aquatic Ecology, Latvia, (2)Finnish Environment Institute (SYKE), Finland, (3)Gdansk University of Technology, Faculty of Civil and Environmental Engineering, Poland, (4)Rostock University, Germany

Pharmaceuticals are the backbone of therapeutic medicine, improving quality of life and extending life expectancy worldwide. However, there is growing concern about their environmental impacts—both during manufacturing and after the post-consumption excretion of the more than 4,000 unique active ingredients currently listed by DrugBank. While the EU has established several frameworks and directives to support the removal and monitoring of micropollutants (including pharmaceuticals), there remains no harmonized or clearly defined approach for evaluating environmental risks beyond individual substance assessments. To address this mixture-based challenge, we propose a cumulative risk-calculation approach based on risk-quotient (RQ) aggregation with adjusted logistic function in a descriptor the authors coined component cumulative risk index (CCRI). The CCRI provides a more scaled estimate of mixture risk than the simple sum of RQs. While sum of RQ increases linearly and can therefore overestimate risk when many substances are present at low levels, the CCRI moderates this inflation and is interpretable across different sites and seasons.

To test the robustness and practical relevance of this approach, we analyse a case study using real measured concentrations of 10 pharmaceuticals in Latvian surface across all four seasons.

A seasonal trend was evident throughout study period with the concentrations decreasing from winter to summer. The overall RQ-sum values were highest during November 2024, moderately elevated in February 2025, and mostly lower in May 2025. Natural waterbodies—upstream sampling sites, reservoirs, and river mouths—consistently exhibited low risk values, typically below an RQ of 1. Downstream sites receiving WWTP discharge showed higher RQ sums than natural waters, but these values were still substantially lower than those measured directly in WWTP effluents, which were often one to two orders of magnitude greater. This trend was also reflected in the cumulative risk assessment based on CCRI, which showed that a small subset of pharmaceuticals—diclofenac, clarithromycin, estrone, sulfamethoxazole, and venlafaxine—consistently dominated the total RQ contribution across sites and seasons.

The results highlight the importance of mixture-based evaluation such as the CCRI, showing that a small number of high-impact pharmaceuticals can disproportionately shape environmental risks and should be prioritized in monitoring and management strategies.

3.21.P-Tu376 Addressing Public Data Deficiency: Evaluation of AI-Tool "TRIDENT" for the Generation of Ecotoxicological Data in Context of Pharmaceutical Environmental Risk Assessment (Art. 57(2) EC

No. 726/2004)

Jan-Derek Tiedemann¹, Louis-Marvin Sander² and Carolin Floeter³, (1)University for Applied Sciences Hamburg (HAW), Germany, (2)German Federal Environmental Agency, Germany, (3)Environmental Engineering, Hamburg University of Applied Sciences (HAW), Germany

Medicines that were approved for the EU market before 2005 were not required to undergo an environmental risk assessment (ERA) as part of the EU approval process. Even with the current European legislation, data that is collected remains not sufficiently accessible to the public. This results in a data gap as described by Spilsbury et al. (2024), among others. This has led scientists to explore other methods to assess the environmental impact of the active pharmaceutical ingredients (APIs) in medical products able to help close the knowledge gap. The emergence of AI models offers new opportunities for in silico modelling of ecotoxicological endpoints. This study uses the AI-based tool TRIDENT, which, according to Gustavsson et al. (2024), delivers more reliable results and has a broader range of applications than conventional in silico methods based on quantitative structure-activity relationships. This study modelled and validated predicted ERA endpoints for the aquatic toxicity of environmentally relevant pharmaceuticals approved for sale in the EU in accordance with Article 57(2) of Regulation (EC) No. 762/2004. A possible assessment factor is determined by comparing the modelled results from TRIDENT with available empirical data. APIs were then prioritized based on these results and compared with existing lists of priority substances. Furthermore, the underlying training data is evaluated to determine which factors are critical for more reliable prediction data prioritization efforts for pharmaceuticals.

3.21.P-Tu377 Too Safe for Comfort? Examining the Conservatism in Sediment Risk Assessment of APIs

Irene Bramke¹, Samuel K Maynard², Rachel Moreby³ and Stewart Owen³, (1)AstraZeneca, Netherlands, (2)Environmental Protection, Global Sustainability and SHE, Operations, AstraZeneca, United Kingdom, (3)AstraZeneca, United Kingdom

The EMA Phase 2 sediment environmental risk assessment derives predicted sediment concentrations (PEC_{sediment}) from surface water predictions (PEC_{surface water}) using an equilibrium partitioning method (EPM) at Tier A. Tier B refinements address only the PEC_{surface water} input and no guidance is provided for incorporating degradation in water or sediment or adsorption-desorption kinetics to improve the realism of sediment exposure prediction. Using AstraZeneca's EcoPharmacoVigilance dataset, approximately 200 matched literature pairs of measured concentrations in surface water (MEC_{surface water}) and sediment (MEC_{sediment}) were compiled. MEC_{surface water} values were used to derive, for comparison PEC_{sediment} according to EMA ERA. EPM-based PEC_{sediment} systematically exceeded MEC_{sediment}, demonstrating added conservatism beyond the already conservative PEC_{surface water} under the current sediment RA approach. For the three most data-rich APIs, the predicted-to-measured ratios were high: "API A" averaged a 48-fold overestimate; "API B" averaged a 300-fold overestimate; and "API C" averaged a 2-fold overestimate, with 9 of 49 pairs for "API C" only (and 9 of 177 pairs in total) showing MEC_{sediment} higher than PEC_{sediment} (all underpredictions being less than fivefold). These findings indicate the current approach necessarily overestimates sediment organism exposure for Phase 2 APIs that undergo any degradation in water, sediment, or both, potentially flagging unwarranted sediment risks. With anticipated GPL revisions that may tie environmental risk to approval timelines or mitigation requirements, relying on the unrefined EPM may lead to unnecessary mitigations. Incorporating available water-sediment degradation data (e.g., DT₅₀ values) from OECD water-sediment tests offers potential refinement options to differentiate risks driven by overly conservative assumptions from genuine potential risks and improve the realism and regulatory relevance of sediment exposure predictions.

3.21.P-Tu378 A Scientifically Robust and Regulatory Critical Fish Full Life Cycle Study with Ibuprofen: Fulfilling Chronic Toxicity Data Gaps to Support Informed Environmental Risk Assessment

Jonathan Burke¹, Sefi Butler¹, Trannum Rahim¹, Joanna Rowland¹ and Richard John Maunder², (1)Reckitt Benckiser Group PLC, United Kingdom, (2)Scymaris Ltd., United Kingdom

Robust chronic ecotoxicological data are critical for pharmaceutical registration within the EU, as outlined by the European Medicines Agency (2024), and plays a pivotal role in policy development and regulatory decision-making. The Environmental Quality Standard (EQS) dossier SCHEER (2023) and Faber et al. (2023) highlights that although several freshwater toxicity studies on ibuprofen exist, many fail to meet CRED scoring criteria, resulting in notable gaps and uncertainties when assessing and drawing conclusions on the chronic aquatic toxicity profile of Ibuprofen. Oldenkamp et al. (2022) similarly stressed the importance of high-quality, accessible ecotoxicity data on pharmaceuticals to support scientific research, regulatory frameworks, and public awareness.

Due to the considerable time, complexity and expenditure involved in conducting fish full life cycle tests, most current fish toxicity studies such as Constantine et al. (2020) focus primarily on early life-stage development or sensitive developmental stages in isolation rather than considering the reproductive output across generations which could prove more relevant for understanding population level effects and support well informed environmental risk assessments when scientifically appropriate.

The authors used a collaborative approach that included consultation with leading academic experts and regulatory authorities to develop a full life cycle test suitable for investigating the toxicological effects of Ibuprofen to fish (*Pimephales promelas*) with the intention to continuously expose F0 embryos (<24-hours old) through all growth and reproduction stages to the production and growth of F1 juveniles.

This test represents the first full life cycle test conducted with ibuprofen in accordance with Good laboratory Practice (GLP). This study holds high significance and provides the most sensitive aquatic endpoint from a comprehensive series of environmental toxicology tests conducted by the authors between 2019 and 2025. This test provides robust endpoints considered critical for understanding effects of ibuprofen to fish and enables well informed environmental risk assessments. This study builds on earlier work published by Constantine et al. (2020), and presents the first scientifically relevant and reliable Fish Full Life Cycle Study with ibuprofen (CRED C1, R1; Moermond et al., 2016).

3.22 PMT/vPvM Substances: Advances in Identification, Prioritisation, Risk Assessment and Regulation

3.22.T-01 Percentage Leached as a Function of Koc and DT50 – a Scientific Indication of True Mobility *Sevil Payvandi¹, Siul Ruiz², Jose Luis Gomez-Eyles¹, Paul Sweeney¹ and Tiina Roose², (1)Syngenta, United Kingdom, (2)University of Southampton, United Kingdom*

Many factors are involved in the leaching of substances to groundwater, e.g. substance properties, emission at the soil surface, and environmental conditions. Of the substance properties, the degradation half-life and sorption partition coefficient are the most important, and represent key inputs into regulatory environmental risk assessments as well as many empirical indices of leaching.

In terms of assessing hazards (as opposed to assessing risk), mobility in soil represents the hazard of leaching, where mobility has been defined by REACH Annex II, as ‘the potential of the substance...to move under natural forces to the groundwater or to a distance from the site of release’. In Europe, the organic carbon-water partition coefficient (Koc) alone has been proposed as the basis of the mobility hazard classification. However, whilst Koc is clearly important for leaching, this approach ignores the other critical substance property that governs true mobility and leachability – the soil degradation half-life (DT50). Here we present how a simple ratio of sorption and degradation can be used to provide a more robust hazard assessment of mobility based on substance properties.

We extend previous work where leaching concentrations were estimated analytically. In that work, to enable analytical progress, we considered the steady state solution of the leaching concentration as a function of depth under constant effective water flux conditions and used European FOCUS scenarios. Variability of weather conditions was accounted for by sampling over the weather files. To now address the estimation of percentage leached, we adapt the previous work and as an example we consider all European FOCUS scenarios. However this method could be rapidly applied to any representative region or a combination of regions as the solutions are analytical. We then derive critical thresholds of Koc/DT50 and analyse how these could be used as hazard criteria.

The ratio of Koc/DT50 represents a simple but scientific extension of the hazard concept of mobility by combining half-life and sorption while still retaining the conservatism of the original concept of using sorption alone, and the extent of leaching is considered and not just the extent of sorption. In addition, we will also address how to use this methodology for higher tier refinements and weight-of-evidence cases e.g. modelling approaches to integrate aged sorption data into mobility hazard assessments.

3.22.T-02 Advancing Multi-Model Screening of Persistent, Mobile and Toxic Chemicals: Application to the DSSTox Database

Eric Verbruggen¹, Emiel Rorije², Tjebbe Janson¹, Pim Wassenaar¹, Roel Schreurs¹, Johannes Meesters¹, Jaap Slootweg¹, Arjen Wintersen¹, Andre Bannink³, Harrie Timmer⁴ and Julia Hartmann¹, (1)National Institute for

Public Health and the Environment (RIVM), Netherlands, (2)Centre for Safety of Products and Substances, National Institute for Public Health and the Environment (RIVM), Netherlands, (3)Association of river water works - section Meuse (RIWA Meuse), Netherlands, (4)Association of Dutch Water Companies (Vewin), Netherlands

Persistent, Mobile, and Toxic (PMT) substances, as well as very Persistent and very Mobile (vPvM) substances can cause long-lasting and diffuse contamination of water resources. To facilitate early identification and prioritization for regulatory action, the Dutch National Institute for Public Health and the Environment (RIVM) developed a novel screening method in 2023, initially applied to over 6,000 chemicals. Each substance receives a continuous score (0–1) for persistence (P), mobility (M), and (human) toxicity (T), which are aggregated into an overall PMT score. These data are made accessible to permit officers, risk assessors, water suppliers, industry, and other stakeholders via an RIVM-hosted website.

Currently, RIVM is refining and expanding this approach based on stakeholder feedback and recent scientific insights. Key improvements include: extending the method to the Distributed Structure-Searchable Toxicity (DSSTox) Database (>1 million substances), incorporating a broader set of models for P, M, and T estimation, and explicitly addressing uncertainties. Furthermore, RIVM is moving the workflow from Excel to R and Python, enhancing reproducibility, scalability, and transparency, and enabling on-demand model execution.

As the revised method is still in development, results are pending. The presentation will focus on methodological improvements and application to the DSSTox database. Comparisons with known and suspected PMT-substances from priority lists and monitoring programs from drinking water companies will also be presented.

The improved screening approach and expanded database increase usability for regulators and stakeholders in identifying and managing environmentally relevant chemicals. This tool serves as an initial step, guiding further investigation of high-scoring substances and supporting safe-by-design strategies to prevent the development of new PMT chemicals.

3.22.T-03 Prioritization of PMT Chemicals during Agricultural Water Reuse – Potential for Human Exposure and Groundwater Contamination

Alina H. Seelig¹, Annika görnt², Mogens Thalmann², Veikko Junghans³, Daniel Dittmann², Aki Ruhl², Thorsten Reemtsma¹ and Daniel Zahn⁴, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)German Environment Agency (UBA), Germany, (3)Humboldt University of Berlin, Germany, (4)Department of Analytical Chemistry, Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

With increasing water stress agricultural water reuse is becoming more prevalent worldwide, which leads to higher demands on wastewater quality to minimize detrimental effects of human and environmental exposure with contaminants. Persistent and mobile (PM) chemicals are difficult to remove from the water cycle. If these chemicals are also toxic (T), they may pose a threat to human and environmental health. Consequently, these PM(T) chemicals seem highly relevant for water reuse, yet little is known on their up-take by and distribution in plants or infiltration into groundwater. In this study, two exposure pathways during agricultural wastewater reuse are studied for 60 PM(T) chemicals: (I) the potential for human exposure through crop consumption is investigated by studying plant uptake by and distribution in rocket in pot experiments in a greenhouse, and (II) infiltration into groundwater is simulated with soil-filled columns over a duration of 37 weeks. Combined, these results aid in prioritizing potentially problematic PM(T) chemicals during agricultural water reuse and demonstrate which exposure pathway is most relevant for these chemicals.

The relative uptake (% RU – fraction of maximum uptake over experiment duration) by rocket exceeded 10% RU for 18 PM(T) chemicals and reached up to 64% RU for perfluoropropionic acid (PFPrA). Carbamazepine, a well-studied pharmaceutical known for its very high plant uptake showed a plant uptake of 28% RU. To investigate the distribution of PM(T) chemicals in arugula the translocation factor was calculated. More than 60% of the studied chemicals showed a translocation factor above 1, which indicates accumulation in the rocket leaves with individual chemicals reaching a translocation factor of up to 100.

A total of 87% of the target compounds were detected in the column effluent. The results showed that 23 analytes experienced virtually no retardation (retardation coefficient $RD < 1.5$ relative to bromide tracer, Figure

1), 6 analytes exhibited moderate retardation (RD 1.5–5), and 28 PM chemicals eluted markedly delayed (RD > 5). Ultrashort-chain perfluoroalkyl substances, such as PFPrA, trifluoroacetic acid, and bistriflimide, broke through rapidly and were detected in the effluent at more than 40% of the applied mass. Based on these findings and median concentrations in urban effluent a human exposure potential and a ground water exposure potential were calculated aid in prioritization for risk assessment.

3.22.T-04 Identifying Persistent and Mobile Substances with the SIN List

Hanna Holmquist¹, Hans Peter H. Arp², Sivani Baskaran³, Romain Figuière⁴, Sarah Hale⁵, Jonatan Kleimark¹, Jerker Ligthart¹, Michael Neumann⁶, Emma Helena Palm⁷, Silvia Rigatti¹, Hilma Samuelsson¹, Ivo Schliebner⁸ and Daniel Sättler⁸, (1)ChemSec, Sweden, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Norwegian Geotechnical Institute (NGI), Canada, (4)Department of Environmental science, Stockholm University, Sweden, (5)DVGW - Technologiezentrum Wasser, TZW, United Kingdom, (6)IV 2.3 Chemicals, German Environment Agency (UBA), Germany, (7)University of Luxembourg, Luxembourg, (8)German Environment Agency (UBA), Germany

The Substitute It Now! (SIN) List is an early-warning phase-out list of chemicals that, according to the non-governmental organisation ChemSec, meet the regulation on the registration, evaluation, authorisation and restriction of chemicals (REACH) criteria for substances of very high concern (SVHC). In October 2025, the SIN List was updated with 18 new persistent, mobile and toxic (PMT) and very persistent and very mobile (vPvM) entries as part of the Zero Pollution of Persistent, Mobile Substances (ZeroPM) project.

Persistent and mobile substances threaten water resources, including drinking water, as their continued release leads to an increase in contamination. In 2023, the Classification, Labelling and Packaging (CLP) regulation introduced PMT/vPvM as new hazard classes. This development represents an important initial step towards acknowledging the urgency of regulating chemicals that contribute to water resource contamination. The current inclusion of 53 PMT/vPvM entries on the SIN List further substantiates this urgency and provides industry and other stakeholders with a relevant tool for chemical substitution.

The PMT/vPvM substances were assessed through a weight-of-evidence approach based on the CLP criteria. Data were retrieved from REACH registration dossiers, other authorities' publicly available sources, and scientific literature.

The new SIN List entries have a variety of characteristics, both in terms of chemical groups (mainly nitrogen compounds, but also halogenated, aromatic and heterocyclic compounds, and hydrazines), and production volumes (from ? 1 to < 10 tonnes per annum for dichlorodifluoromethane, to exceeding 10 000 tonnes per annum for 1,3-dioxolane, acryloyldimethyltaurates (AMPSA), cyanoguanidine, cyanuric chloride and methenamine). The substances are in both industrial and consumer use. Some have very specific technical functions (i.e. benzotriazoles and methylated benzotriazoles are anti-corrosion agents) while others are more versatile and can have multiple functions (e.g. methenamine, cyanoguanidine).

The full list of PMT/vPvM entries can be found on the SIN List (<https://sinsearch.chemsec.org/>).

3.22.T-05 Protecting Drinking Water Sources from PMT-substances

Tineke Slootweg¹, Harrie Timmer² and Andre Bannink³, (1)Water Laboratory, Netherlands, (2)Vewin, Netherlands, (3)RIWA, Netherlands

Protection of drinking water sources is part of the so-called Multi-Barrier Approach To Safe Drinking Water. One important barrier is source water protection, which may sound obvious but can get very complicated in a densely populated area with multiple uses such as the Meuse river basin. Drinking water companies extract around 460 million cubic metres of water from the Meuse every year to supply drinking water to around 7 million people in the Netherlands and Belgium.

One of the components of source water protection is monitoring and for compliance checks monitoring results need to be compared to norms or standards set by legislation. But not all substances that can be monitored have legal standards set. This is specifically the case for a wide variety of persistent, mobile and toxic substances which are hard to remove with most regular water treatment techniques. Therefore 170 drinking water companies from 18 EU countries have set target values for unregulated parameters in the European River Memorandum.

The drinking water companies that use the river Meuse as a source for drinking water production monitor several hundreds of parameters. Every three years the monitoring results are evaluated against the ERM target values. The latest evaluation was done in 2024. More than 282,000 measurements were evaluated based on concentration, frequency of detection and intrinsic properties that hinder sustainable production of drinking water. In total 37 substances were prioritised as relevant, meaning that they hinder sustainable production of drinking water using the river Meuse as a source. However, the first of the 37 substances is a group of 20 per- and polyfluoroalkyl substances which are currently mentioned in the EU Drinking Water Directive. In addition to the Meuse River Dossier and its Program of Measures that were initiated in the Netherlands to better protect this source for drinking water under the Water Framework Directive, the Clean Meuse Water Chain was started. It is a cooperative venture of Dutch drinking water companies and water authorities as well as the Ministry of Infrastructure and Water Management. Since 2015 the initiative has been working on reducing pharmaceutical residues and industrial substances ending up in the river Meuse.

3.22.P PMT/vPvM Substances: Advances in Identification, Prioritisation, Risk Assessment and Regulation

3.22.P-We291 The impact of Standards in Mobility testing - a case of fragrance materials

Aurelia Lapczynski, Research Institute for Fragrance Materials, United States

New hazard classification for the European Union (EU) Classification Labelling and Packaging Regulation (CLP) were recently introduced implementing a new hazard class of Persistent (not or hardly degradable in the environment) Mobile (well soluble in water and therefore easily transported through the environment) and Toxic (toxic to ecosystem) - PMT as well as very Persistent and very Mobile (vPvM) chemicals. The combination of P and M properties of chemicals enable them to be transported over long distances from the point of emission, pass natural and artificial barriers and enter drinking water sources causing a high concern with consequent exposure to humans and other organisms. To assess the potential of the material to be mobile, standardized methods have been developed and include estimating the adsorption/desorption behavior of chemicals on a different soil types (OECD 106) and/or estimating an adsorption coefficient (K_{oc}) in soil and in sewage sludge using HPLC method (OECD 121). In effort to understand and select the most appropriate approach for evaluating the potential Mobility of a material, a number of fragrance materials with various physical chemical properties were selected and evaluated first in the OECD 121 method followed by the OECD 106. During the OECD 121 evaluation it was noted that the standards selected for the screening could potentially have an impact on the results – and this was further investigated and the results are presented in this poster

3.22.P-We292 Applying In silico Models to Screen Persistent Mobile and Toxic Substances in Waste Water Treatment Plants Worldwide

Arianna Sgariboldi¹, Elena Posté¹, Nicola Chirico¹, Alessandro Sangion², Marco Evangelista¹, Cristiana Morosini³, Andrea Re⁴ and Ester Papa¹, (1)DiSTA, University of Insubria, Italy, (2)Arnot Research & Consulting (ARC), Canada, (3)DiSAT, University of Insubria, Italy, (4)Xylem Water Solutions, Italy

The new update to the European CLP regulation (EU 2023/707) introduces the PMT and vPvM hazard classes, namely persistent, mobile, and toxic substances and very persistent and very mobile substances, requiring proper management to protect the environment and drinking water. Among emerging contaminants, pharmaceutical and personal care products (PPCPs) may show persistence, mobility, and toxicity, as has been highlighted by several studies. To support PMT identification, regulatory frameworks encourage the use of in silico approaches, such as QSAR models, which can predict multiple properties and activities of chemicals. This presentation summarizes a recent study to investigate PPCPs detected in waste water treatment plants (WWTP)

effluents worldwide, and to assess their PMT properties using various in silico tools. The study reviewed literature from 2014 to 2019, which led to the collection of removal efficiency (RE) data, in different WWTPs worldwide, for 251 PPCPs, and to the classification of these chemicals, according to their RE. PMT properties were assessed using 15 QSAR models. Only reliable predictions were used to identify PMTs according to regulatory criteria. Finally, predicted toxicities and experimental data were combined to calculate the potential environmental risk, for each chemical, following the approach suggested in the OECD-TGD. More than 200 PPCPs were analyzed in more than 70 WWTPs. The application of QSAR models identified 11 PMTs, including antibiotics, psychiatric drugs/antidepressants and a herbicide, which were recognized also among the most persistent classes in WWTPs on the basis of RE data. Limitations in the application of QSARs in this context include the lack of models for the prediction of long-term toxicity, Log_PD, and Log_PK_{oc}, as well as unclear applicability domains. The analysis of potential risk in the aquatic environment led to the identification of 77 individual chemicals posing potential risk in at least one of the different locations included in the study. These results highlight how integrating different in silico models with experimental data can support the identification of PMT chemicals at the screening level. They also highlight critical areas of the chemical domain where substances may exhibit borderline behaviour and QSAR approaches can still be improved to provide more reliable predictions.

3.22.P-We293 Behaviour of Persistent and Mobile Chemicals (PMs) in Aquifer Sediment Microcosms under Different Redox Conditions

Tianqi Li¹, Till Meier¹, Carsten Vogt² and Qiuguo Fu¹, (1)Department of Environmental Analytical Chemistry, Helmholtz Centre for Environmental Research – UFZ, Germany, (2)Department of Technical Biogeochemistry, Helmholtz Centre for Environmental Research – UFZ, Germany

Persistent and mobile compounds (PMs) pose an increasing challenge to the long-term quality of groundwater and the safety of drinking water supplies. Chemical persistence is a key factor in understanding their environmental fate, potential exposure, and associated risks to the environment and human health. However, the persistence and degradability of PMs in groundwater remain poorly understood. Commonly used OECD 308 and 309 simulation tests are primarily applied to surface water and associated sediments, hence most available persistence data are confined to surface water conditions. Compared to surface water, groundwater typically has limited oxygen, reduced microbial activity, and restricted light exposure, which may lead chemicals to behave even more persistently. To address this knowledge gap, we established a 120-day degradation simulation test in aquifer sediment microcosms to evaluate the persistence and biodegradability of 24 groundwater-relevant PMs under three different redox conditions. Additionally, we compared our experimental persistence results with predictions from five commonly used models, as well as available data from surface waters where applicable. 1 mL supernatant was taken from 10 time points, and PMs were quantified using supercritical fluid chromatography coupled with triple quadrupole mass spectrometry. In our study, 22 PMs exhibited half-lives exceeding 40 or 60 days under at least one redox condition, which meets the REACH criterion for chemical persistence in freshwater/marine environments, whereas 12 PMs were persistent under all three tested redox conditions over 120 days. Certain sulfonic acids (i.e., methanesulfonic acid, p-toluenesulfonic acid, and benzothiazole-2-sulfonic acid) were biotransformed only at aerobic conditions and nitrate availability enhanced the biotransformation of two 2-pyrrolidones in anoxic groundwater environment, highlighting the critical role of redox state in persistence assessment. Besides, the five commonly used predictive models exhibited variable performance and low accuracy, likely due to redox-driven or compound-specific degradation behaviour, or the limited availability of relevant experimental data. Our findings emphasise that groundwater compartments with different aquifer properties and prevailing redox regimes should be considered for PMs' regulatory decision-making and in improving modelling prediction.

3.22.P-We294 Overcoming Chromatographic and Extraction Challenges for the Determination of PMT/vPvM Substances in Water

Natalia Sáez Rosique¹, Jing Ma², Jelena Radjenovic², Josep Mas-Pla², Meritxell Gros² and Sara Rodriguez-Mozaz², (1)University of Girona, Spain, (2)Catalan Institute for Water Research (ICRA), Spain

The occurrence of persistent, mobile, and toxic (PMT) and very persistent and very mobile (vPvM) substances in the aquatic environment has gained growing attention within the scientific community due to their potential impact on environmental and human health. Their high polarity and strong ionisation mean that many of these substances are poorly retained in most natural attenuation processes. At the same time, routine monitoring programmes still rely largely on analytical methods that are not well suited to the most mobile compounds, and show limited retention for the “gap compounds”. There is therefore a clear need to develop and apply dedicated analytical approaches that can reliably capture these highly polar PMT and vPvM substances in real environmental samples.

This study addresses this challenge by developing and optimising a robust ultra-high-performance liquid chromatography–tandem mass spectrometry (UHPLC–MS/MS) method for the identification and quantification of representative PMT and vPvM substances in water, and by applying it to groundwater monitoring in Catalonia (north-eastern Spain). A set of 55 substances was selected to represent a broad range of physicochemical and ionic properties. Compounds with logDow < 0 and no robust methods available were deliberately included to challenge method performance. Different chromatographic columns were evaluated and optimised exploring the effects of pH, buffer concentration and aqueous content. In parallel, three water preconcentration strategies were assessed: mixed-mode solid-phase extraction, hydrophilic–lipophilic balanced solid-phase extraction and lyophilisation.

The optimised workflow, with a mixed-mode chromatography, significantly improved retention and peak shape for the most mobile analytes and enabled the determination of previously problematic PMT substances. Application to groundwater samples from the Baix Fluvià alluvial aquifer and the Llobregat River Basin aquifer confirmed the presence of several PMT substances in different hydrogeological sectors, highlighting their relevance in regional water resources. Overall, the study demonstrates that dedicated chromatographic and extraction strategies are essential to close current analytical gaps in groundwater monitoring and to provide more reliable occurrence data for the identification and prioritisation of PMT and vPvM substances in environmental protection and water-management frameworks.

3.22.P-We295 Persistent and Mobile Chemicals in Groundwater: An Overlooked Challenge for Drinking Water Quality

Xiaojing Zhu and Thorsten Reemtsma, Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Persistent and mobile (PM) chemicals are of particular relevance for groundwater used for drinking water production, as their mobility and low removability allow them to pass through aquatic systems and treatment steps. In our recent screening of 82 groundwater samples from 25 groundwater bodies in Saxony, Germany, 163 PM chemicals were detected, including 72 chemicals reported for the first time in groundwater. Many of these are widely used industrial compounds that have not previously been included in groundwater monitoring. Considering that around 70% of drinking water in Germany originates from groundwater, their presence raises important questions about treatment effectiveness and exposure. To examine their removals during oxidation treatment, a set of priority PM chemicals (selected based on their PMBT, detection frequency, and concentrations) was subjected to Fenton reaction experiments. Several chemicals, including trifluoroacetic acid (TFA), perfluoropropionic acid (PFPrA), and melamine, showed no degradation, demonstrating extreme resistance even under strong oxidation. Some chemicals formed substantial numbers of transformation products (TPs); for example, dibutylamine produced 38 TPs, many of which were probably identified for the first time. In the case of 4-hydroxy-1-(2-hydroxyethyl)-2,2,6,6-tetramethylpiperidine (HHTMP, one of those first-time reported in groundwater), TPs, which are more persistent than the parent compound, including triacetaminine (also found in groundwater) and several additional newly found TPs, were generated. These results suggest that oxidation-based treatment does not reliably mitigate the risk posed by PM chemicals in drinking water and may

rather introduce additional problematic chemicals. Overall, these findings highlight the need for protecting drinking water resources from contamination by PM chemicals rather than relying on technical barriers to remove them.

3.22.P-We296 Leveraging mass spectrometry data for predicting chemical persistence and mobility via transformer models

Yingxiao Yan¹, Anneli Krüve² and Jonathan W Martin², (1)Stockholm university, Sweden, (2)Stockholm University, Sweden

Untargeted high resolution mass spectrometry (HRMS) is widely used for molecular identification and structural characterization, yet only 1–20% of spectra from environmental samples match HRMS/MS libraries (e.g., NIST), leaving most compounds as “molecular dark matter”. Reducing exposure to hazardous substances requires rapid, high-throughput identification of potentially toxic, persistent, or mobile substances. A prior proof-of-concept work (MS2Tox) showed machine learning can predict acute toxicity of unidentified substances from molecular fingerprints predicted from the MS2 data. Building on this, we leverage data-rich HRMS MS2 data directly for property prediction, reducing error propagation and enabling more robust workflows. Beyond predicting toxicity, early detection of environmentally persistent and mobile substances is critical for proactive risk management.

We aim to develop deep learning models that predict environmental persistence and mobility directly from MS2 data acquired in environmental samples, thereby enhancing untargeted screening for deleterious substances. Specific objectives include model development using curated MS2 data, benchmarking against fingerprint-based models, and validation with experimental MS2 data.

HRMS MS2 data were sourced from MassBank (2025.10) and persistence and mobility endpoints from Arp and Hale (2022), based on degradation half-lives and organic carbon-water partitioning (KOC). Compounds with spectra and endpoints were stratified by ionization mode and split into training, validation, and testing sets. Spectra were encoded as m/z-intensity pairs and processed using a transformer architecture inspired by MS2Prop (Voronov et al., 2024). An MS2-derived fingerprint-based QSPR benchmark was implemented for comparison. Predictions on HRMS datasets (e.g., strategic water monitoring) were cross-validated against empirical measurements and PubChem.

We expect MS2-based models outperform fingerprint-based approaches by reducing structural annotation errors and that compounds predicted as persistent or mobile will correspond to known substances documented in literature or databases. This work introduces a novel strategy for predicting persistence and mobility directly from MS2 spectra, advancing quantitative spectra–activity relationships (QSPAR). The approach enhances untargeted screening of environmentally hazardous compounds and may extend to other physicochemical, environmental and biologically-relevant endpoints.

3.22.P-We297 Development and validation of a GC–MS/MS method for the determination of EPA priority PAHs and metabolites in marine sediments

Dulce Soliz Rojas¹, Begoña Jiménez² and Juan Muñoz-Arnanz¹, (1)Institute of Organic Chemistry - Spanish National Research Council (IQOG-CSIC), Spain, (2)Spanish National Research Council (CSIC), Spain

Polycyclic aromatic hydrocarbons (PAHs) are widespread contaminants in marine sediments and pose significant environmental and toxicological concerns due to their persistence and potential carcinogenicity. Reliable monitoring of the 16 PAHs prioritized by the US Environmental Protection Agency (EPA), together with relevant metabolites, is essential to clarify contamination sources, transformation processes and ecological risks. Nevertheless, their determination in sediment matrices remains analytically demanding because of concentration levels (high and low simultaneously), matrix complexity and the need for high selectivity.

This study describes the development and optimisation of a sensitive GC–MS/MS method using an Agilent system composed of a 7010B triple quadrupole mass spectrometer equipped with a high-efficiency electron impact (EI) source, coupled to a 7890B gas chromatograph fitted with a programmable temperature vaporization (PTV) inlet. The method targets 17 PAHs, including the 16 US EPA priority compounds, together with 20 associated metabolites, such as methylated, dimethylated and trimethylated derivatives, allowing a more comprehensive assessment of degradation pathways, source apportionment and environmental weathering processes. A commercial mixture of six deuterated PAHs was employed as surrogate standards to assess extraction efficiency and method recovery, while a separate mixture of six deuterated compounds was used as injection standards for instrumental variability control.

Chromatographic separation was achieved on an HP-5 column using helium as carrier gas at 1.2 mL min⁻¹. A 1 µL injection volume was applied in splitless mode, with a purge flow to split vent of 50 mL min⁻¹ at 0.75 min. The oven temperature programme was optimized from 100 °C to 300 °C to ensure effective resolution of structurally similar analytes. Acquisition was performed in multiple reaction monitoring (MRM) mode, divided into five-time segments, to enhance sensitivity and discrimination under complex matrix conditions.

The method will be applied to the analysis of marine sediment samples from different locations, providing robust data on spatial distribution and contamination profiles. Particular emphasis was placed on overcoming challenges related to sensitivity, co-elution and matrix effects, demonstrating the suitability of the proposed approach for high-quality monitoring of PAHs and their metabolites in marine sediments.

3.22.P-We298 Monitoring Data as a Tool for Chemical Mobility Assessment: Opportunities, Challenges and Ways Forward

Chesney Swansborough, Claire Gibson and Connor Powell, Vitis Regulatory, United Kingdom

Understanding and assessing the mobility of chemicals in the environment is a critical component of risk assessment, particularly for substances that may pose risks to drinking water sources. Recent developments under EU chemicals legislation, including the inclusion of PMT (Persistent, Mobile, and Toxic) and vPvM (very Persistent, very Mobile) criteria within the CLP Regulation and emerging considerations under REACH, have intensified the need for robust evidence to evaluate the behaviour and impact of mobile substances in the environment and inform regulatory decision-making.

Monitoring data provide essential, real-world evidence of a chemical's presence, transport and persistence in the environment, complementing standard laboratory testing and modelling approaches. Such data can reveal patterns of contamination, identify vulnerable catchments, and highlight exposure pathways that may not be captured through conventional assessments. Despite these advantages, the use of monitoring data in regulatory risk assessment remains limited. Challenges include questions around data quality, representativeness and how monitoring data can be meaningfully integrated into weight-of-evidence approaches.

This poster presentation explores how monitoring data can support, inform and complement the risk assessment of mobile chemicals. This includes:

- Identify key scientific and regulatory barriers to the use of monitoring data, including data quality issues and regulatory acceptance.
- Discuss opportunities to address these barriers through improved data reporting and transparent interpretation and documentation practices.
- Present case studies illustrating how monitoring data may inform assessment of mobile substances.
- Propose a conceptual framework for integrating monitoring data into regulatory decision-making processes and weight-of-evidence approaches.

By stimulating discussion within the SETAC community, this poster aims to contribute to evolving discourse on how monitoring data can be leveraged to strengthen evidence-based mobility assessment and support future regulatory needs under EU chemicals legislation.

3.22.P-We299 Developing a Basin-Scale Environmental Exposure Model for Persistent, Mobile, and Toxic (PMT) substances with Melamine as a Validation Case

Jianguo Liu, Shaoxuan Zhang, Rongjing Lu, Zhichun Zhang and Jiazhe Chen, State Key Laboratory of

The widespread distribution of Persistent, Mobile, and Toxic (PMT) substances is posing increasing threats to human health and aquatic ecosystems. River basins are a major environmental distribution space for PMT substances. Conventional fugacity-based models struggle to accurately describe the environmental behaviour of PMT substances due to their high ionizability and hydrophilicity. Existing activity-based models still use a traditional grid-cell simulating approach that does not adequately match the transport and distribution dynamics of PMT substances in the environment. This study developed a nationwide exposure assessment model for PMT substances based on chemical activity and basin-scale simulation. By establishing basin-scale emission scenarios of PMT substances with 7,388 key parameters related to the industry, population, wastewater treatment and reclamation, and environmental exposure scenarios with over 6,240 key parameters related to the meteorology, hydrology, and multimedia environment in totally 80 secondary basins across China, the model could conduct a national, regional or basin-wide emission and exposure simulation for PMT substances. The model was applied to melamine, a typical PMT substance with a high detection rate in water systems, and validated through nationwide melamine monitoring supplemented by existing monitoring data from 2010 to 2024. The model revealed a pronounced spatial distribution pattern of the emissions and the environmental exposure of melamine across China, and increasing trends in exposure levels across the multimedia environment over the past 26 years. The environmental exposure levels of melamine in regions are strongly related to the activities of major melamine emission industries, such as papermaking and textiles. Areas with higher melamine levels in the environment are clearly reflected through model simulations, i.e., the coastal areas of the Shandong Peninsula, the Taihu Lake Basin, and the Haihe River Basin in the Beijing-Tianjin-Hebei region, suggesting that local governments and the community should give due attention to these findings.

3.22.P-We300 PMT substances in the Human Food Chain: Methodologies for Assessing their Occurrence and Fate

Stefan van Leeuwen, Bas van Dijk, Serena Rizzo, Ruben Meine Kause, Karsten Beekmann, Lianne bouwman, Leonieke van den Bulk and Katja CW van Dongen, Wageningen Food Safety Research (WFSR), Netherlands

Persistent, Mobile, and Toxic substances (PMTs) pose concerns for both the environment and food production. Increasing evidence shows that this class of compounds is present in various water sources. Because water is essential for food production, it is important to understand the occurrence and fate of PMTs in food production systems. Using PMT-contaminated water, such as for irrigation, may ultimately result in PMTs being present in food products. However, many knowledge gaps remain before a conclusion can be drawn regarding these risks.

In this work, we take initial steps to fill such knowledge gaps by (i) taking published PMT prioritisation lists, (ii) establishing analytical chemical analysis approaches based on suspect screening, (iii) studying PMT occurrence in surface water, and (iv) exploring the uptake of PMTs in food crops. Here, we report on steps (i) to (iii). A database containing prioritisation scores for around 10,000 compounds (approach by Hartmann et al. (2023)) was made available by the Dutch National Institute for Public Health and the Environment (RIVM). The scores were calculated based on QSAR predicted scores for P, M, and T properties. Compounds with a PMT-score ≥ 0.33 were considered for chemical analysis.

To prepare for chemical analysis (i.e. suspect screening), relevant information was collected from databases such as CompTox, AMOS (Analytical Methods & Open Spectra), and the Norman SusDat database. Information on liquid chromatography (LC) amenability and electrospray ionisation (ESI) properties was collected, including predicted ions (e.g., $[M+H]^+$, $[M-H]^-$) when experimental data were unavailable. The resulting suspect list, comprising approximately 2,100 compounds, was used both as an inclusion list of masses prioritised for fragmentation during instrumental acquisition on a Thermo Scientific Orbitrap IQ-X Tribrid mass spectrometer and, after acquisition, as a mass list for data analysis to screen for PMTs in Dutch surface water samples.

To avoid selectivity bias, the water samples were only filtered, without further clean-up. Nearly 100 substances were detected, and several of these could be confirmed at confidence level 1 (Schymanski et al. 2014). The results were compared with available occurrence data for Dutch surface waters, such as those reported by RIWA Rijn and RIWA Maas. Future work will study if, and how much PMTs are taken up by food crops. Such data will support risk assessment of PMTs in food production.

3.22.P-We301 Making the EU's Common Data Platform's database of alternatives to substances of concern an effective tool for substitution of PMT/vPvM substances

Hans Peter H. Arp¹, Sarah Hale², Lise Oules³, Hanna Holmquist⁴, Jonatan Kleimark⁴, Emma Schymanski⁵, Romain Figuière⁶ and Raoul Wolf¹, (1)Norwegian Geotechnical Institute (NGI), Norway, (2)DVGW: TZW, Germany, (3)Milieu Consulting, Belgium, (4)ChemSec, Sweden, (5)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg, (6)Department of Environmental science, Stockholm University, Sweden

Providing information on existing alternatives to hazardous substances is a key action to support companies in transitioning to safer alternatives. Although alternative databases developed by researchers and NGOs exist, such as Chemsec's Marketplace, the ZeroPM Database of alternatives to PMT/vPvM substances, or the SUBSPORTplus portal, there is currently no EU database aggregating existing information on alternatives to hazardous substances. The current provisional agreement in the EU to establish a common data platform on chemicals however provided that the future platform to be set up and maintained by ECHA will contain 'data on alternatives to substances of concern' and on alternative technologies or materials not requiring such substances (<https://data.consilium.europa.eu/doc/document/ST-10883-2025-ADD-1/en/pdf>).

Data on alternatives to substances of concern in the common data platform could serve two purposes: supporting the work of ECHA's Socio-economic assessment committee (SEAC) in the assessment of the socio-economic impacts of restrictions and applications for authorisation; and supporting companies in finding relevant alternatives for PMT/vPvM substances. To make the platform an effective tool for substitution, it should provide the right information, be designed in a user-friendly way, and contain effective search functions to allow identifying relevant alternatives. It should also allow for scientists and other experts to upload data, so that the platform can be democratized. Herein we present our recommendations for this development in the EU's upcoming common data platform on chemicals.

3.22.P-We302 Application of a screening level multimedia activity model for evaluating the fate of persistent mobile organic chemicals

Todd Gouin, TG Environmental Research, United Kingdom

In recent years there has been increasing interest to screen and prioritize chemicals used in commerce with respect to their potential to contaminate drinking water sources. The German Environment Agency (Umweltbundesamt – UBA), for instance, has proposed screening criteria to identify chemicals that may pose hazards to drinking water. The hazard criteria aim to prioritize chemicals that are persistent, mobile and toxic (PMT) or very persistent and very mobile (vPvM). The development and application of exposure assessment tools would thus support prioritization activities. This study summarizes the development of a multimedia environmental fate and transport model, which supports the exposure assessment of persistent mobile organic chemicals (PMOCs) under a variety of scenarios, including under steady-state, equilibrium and non-steady-state and non-equilibrium conditions. The developed model includes multilayer soil and aquifer compartments (unsaturated and saturated), which is used to enable a screening level estimate of exposure to PMOCs. Model results, based on an assumption of equilibrium and steady-state, provide an illustrative example regarding the relative importance of including a saturated compartment for screening and prioritizing PMOCs in groundwater that might be used for drinking water, whereas dynamic results provide a relative evaluation of the time needed to exceed toxicological thresholds of concern. Sensitivity and uncertainty analysis demonstrate the importance of system dependent variables, specifically the relationship between the hydrological residence time of an aquifer and the time to exceed threshold values.

3.22.P-We303 Machine learning coupled with causal inference to identify persistent, mobile and toxic pharmaceuticals and disinfectants

Biao Jin¹, Min Han¹ and Hans Peter H. Arp², (1)Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, China (Mainland), (2)Norwegian Geotechnical Institute (NGI), Norway

Various pharmaceuticals and disinfectants are utilized in large quantities, with some of these chemicals likely rising concerns on drinking water sources. Persistent, mobile, and toxic (PMT) substances have been recognized as a threat to drinking water resources. Identifying the pharmaceutical and disinfectant compounds of high drinking water concern remains a challenging task due to the lack of high-quality experimental data required for PMT assessment. To solve this problem, we developed and applied a machine learning approach to identify the PMT substances among pharmaceuticals and disinfectants. We constructed and compared different machine learning models by combining molecular description methods, data balancing approaches and machine learning algorithms¹. The optimal model achieved an accuracy of 90.6% based on external test data. Moreover, model interpretation and causal inference indicated that our approach successfully captured the causal relationships between PMT properties and molecular descriptors². Notably, the screening results showed that over 60% of the target pharmaceutical and disinfectant compounds are potential PMT substances, providing a list of prioritized contaminants to prevent unnecessary environmental emission as well as to develop efficient treatment techniques.

3.22.P-We304 Assessing the State of Science and Developing Best Practices for Mobility Assessment of Difficult-to-Test Substances

Christopher B Hughes¹, Marlies Bergheim Sr M², Judith Kaumanns³, Katharina Sessler⁴, Harald Streicher⁵, Ryan Heisler⁶ and Amelie Ott⁶, (1)Embark Chemical Consulting, United Kingdom, (2)Corporate Scientific Services, Henkel AG & Co. KGaA, Germany, (3)Product Safety & Regulatory Affairs, Wella Company, Germany, (4)Wella Company, Germany, (5)Beiersdorf AG, Germany, (6)International Collaboration on Cosmetics Safety (ICCS), United States

The assessment of substance mobility in the environment has recently become a key regulatory requirement under the European Union's Classification, Labelling and Packaging (CLP) Regulation, following the introduction of new hazard classes for persistent, mobile and toxic (PMT) and very persistent, very mobile (vPvM) substances. These classifications aim to identify chemicals that, due to their persistence and ability to move freely through environmental compartments, may contaminate groundwater and drinking water sources, posing long-term risks to human and ecological health.

Mobility (M/vM) is usually assessed based on the organic carbon-normalized soil–water partition coefficient (KOC). KOC values can be determined through experiments or computer models, but acquiring accurate data is often challenging for many chemicals.

A review has been conducted to assess current methods for mobility assessment, emphasizing the specific challenges presented by two types of substances: charged or ionizable substances and unstable or reactive substances. Charged and ionizable substances undergo complex interactions with soils, including both electrostatic and hydrophobic interactions. Their speciation varies with environmental pH, complicating testing and modeling. Similarly, unstable or reactive substances may transform during testing, making it difficult to determine a meaningful KOC for the original compound and their transformation products.

To address these issues, regulatory experience and scientific literature has been synthesized to offer recommendations for improving the assessment of charged, ionizable, and unstable/reactive substances. Key needs include further investigating the suitability of KOC as a universal indicator of mobility, developing and validating alternative descriptors and test methods for challenging substances, and further guidance for substances that form transformation products. Broader research priorities are also identified, such as improving experimental designs and improving the mechanistic understanding and predictive capability of sorption and transformation processes.

By filling these scientific and methodological gaps, regulators, researchers, and safety assessors can increase confidence in identifying substances with genuine mobility concerns and ensure that the PMT/vPvM framework is applied consistently and defensibly across all relevant chemical classes.

3.22.P-We305 Comparative Evaluation of Koc Determination Methods for Fragrance Ingredients Under New EU Mobility Criteria

Arturo Mendoza¹, Maureen Le Moan², Gordon Sanders³, Georg Kreutzer⁴, Heike Laue² and Thomas Dutriez², (1)Environmental, RAPS Analytical, Givaudan, Switzerland, (2)Givaudan, Switzerland, (3)Product Safety Sciences, Givaudan, Switzerland, (4)RAPS, Givaudan, Switzerland

In April 2023, the European Commission introduced a new environmental mobility classification criterion, adopted by the EU Parliament in December 2023, defining substances as Mobile (M) when $\log K_{oc} < 3$ and very Mobile (vM) when $\log K_{oc} < 2$. These thresholds significantly reduce the number of fragrance ingredients classified as M or vM compared to the original proposal ($\log K_{oc} < 4$ for M and < 3 for vM), which would have impacted a higher number of substances.

This project evaluates the applicability of the OECD 121 HPLC screening method for $\log K_{oc}$ determination against a higher-tier approach using freeze-dried sewage sludge as a solid environmental matrix, following OPPTS 835.1110 “Activated Sludge Isotherm” guideline. The objectives are to determine whether sludge-based testing provides more realistic sorption estimates for borderline cases and to assess its applicability for substances with $\log K_{oc}$ values above 3, supporting improved wastewater treatment plant removal predictions in environmental risk assessments.

The experimental setup involves sludge preparation by decantation, centrifugation, freeze-drying, and thermal desiccation. Tests are conducted using varying concentrations of the test substance. Preliminary results indicate that sludge-based isotherm testing often yields higher $\log K_{oc}$ values than HPLC screening, potentially reducing predicted environmental concentrations in surface waters compared to standard *in silico* models.

This work advances K_{oc} determination strategies for fragrance ingredients, enabling more accurate mobility classification and supporting robust environmental risk assessments under evolving EU regulatory frameworks.

3.22.P-We306 The Non-Extractable Residue Problem in Kinetic Analysis

Vera Papasova and Clare Lane, No Affiliation, United Kingdom

The assessment of the persistence of an active substance for the purposes of hazard assessment is of increasing significance considering the new hazard classes being introduced via CLP guidance. In particular, the interpretation of bound residue deviates between guidance introduced by FOCUS and the PBT guidance by ECHA, creating a significant disconnect between evaluations, potentially on the same active substance. Here, a number of datasets are evaluated to highlight the impact of applying different handling approaches for NER and discuss the appropriateness of some approaches.

3.22.P-We307 Improving the Determination of the Organic Carbon – Water Adsorption Coefficient (K_{oc}) for Down-the-Drain Chemicals Using a Sewage Sludge Adsorption Assay

Gordon Sanders¹, Georg Kreutzer¹, Heike Laue², Arturo Mendoza³ and Maureen Le Moan³, (1)Givaudan International SA, Switzerland, (2)Givaudan, Switzerland, (3)Givaudan Suisse SA, Switzerland

Mobility, under EU CLP legislation, is described as a function of the organic carbon-water adsorption coefficient (expressed as $\log K_{oc}$). Whereas the K_{oc} may be used for non-polar chemicals at a screening level, the K_{oc} remains a simplistic metric and does not consider the full spectrum of complex sorption behaviours that substances can undergo upon contact with environmental matrices. Tier I testing to measure K_{oc} uses the OECD Test Guideline (TG) 121 HPLC method employing a moderately polar stationary phase. The retention time of the test item is compared against that of a range of reference substances, which may or may not be of comparable chemistry. The current Tier II refinement approach OECD TG 106 involves performing adsorption-desorption investigations using a range of soils and/or sediments of different characteristics (at least 5 individual matrices). Although more realistic than Tier I, this approach is time and resource intensive. Furthermore, guidance is required on which K_{oc} value derived from the numerous soils / sediment matrices tested should be adopted as the “representative” K_{oc} value.

Chemicals incorporated within consumer goods, which undergo down-the-drain disposal, will transit via a waste-water treatment plant (WWTP) prior to the effluent entering a waterway. For such products, contact with sewage sludge is the most important adsorption interaction process. Sewage sludge physico-chemical characteristics, including organic-carbon content, tend to be relatively stable in comparison to that of soils and sediments and, therefore, represent a reliable test matrix.

The OPPTS 835.1110 – Activated Sludge Sorption Isotherm TG, therefore, represents a valid Tier II test alternative. It is also representative of the most relevant exposure scenario for down-the-drain chemicals.

Besides establishing a K_{oc} value, this approach also permits calculation of a K_d value (adsorption-desorption distribution coefficient) as well as the direct calculation of a % removal-rate for sewage sludge.

This poster will discuss the relevance and advantages of using the OPPTS 835.1110 TG for the determination of adsorption of down-the-drain chemicals and will compare results derived using the OECD 121 and the OPPTS 835.1110 for a series of fragrance molecules and interpret these results in a legislative and risk assessment context.

3.22.P-We308 OECD TG 309 and the validity criteria for the reference substance: Is there a good season to collect the surface water?

Aminé Tchéré Kakia, Dirk Scheerbaum, Christian Maeß and Kristina Miller, Noack Laboratorien, Germany

For a reliable assessment of the simulation test in surface water (OECD 309), a sufficient microbial activity of the used water should be confirmed. For this purpose, the parallel testing of a reference substance is required and considered for the validity assessment of an OECD 309. The expected time interval for the degradation is usually less than 2 weeks. The challenges around the fulfilment of this validity criterion are well known and most recently subject of discussion.

In this presented work, the mineralization of the reference substance aniline was tested monthly over a period of 14 months (from January 2024 to February 2025) with surface water from the same origin. The purpose was to assess the seasonal difference of the quality (microbial activity) of the surface water and thus its influence on the mineralization rate of aniline.

The aerobic mineralization was performed with radiolabeled aniline over a period of approx. 2 weeks.

The water was collected from the surface of a nature-protected river in Lower Saxony. The tests always started within the sample collection day.

The investigation resulted in different mineralization rates for aniline. The biodegradation data and the associated weather conditions at the time of the sampling are presented and evaluated.

3.22.P-We309 Linking Structure and Hazard: Acute Ecotoxicity of Triazine PMT and PMT-like Compounds

Natalia Karadimitriou¹, Bianca Stadelmann², Milo Leon de Baat³ and Lisa Annie Baumann⁴, (1)No Affiliation, Netherlands, (2)University of Amsterdam (UVA), Netherlands, (3)Chemical Water Quality & Health, University of Amsterdam (UVA), Netherlands, (4)VU University Amsterdam (VU), Amsterdam, Netherlands

Persistent, Mobile and Toxic (PMT) substances are increasingly recognised as a threat to water resources. Triazine-based PMT substances are widely used as herbicides and industrial additives, and closely related analogues and degradation products are now detected alongside them in surface and groundwater. It remains unclear whether officially recognised PMT substances are generally more acutely toxic than their structural analogues, or whether structural differences on the triazine ring could predict toxicity.

We addressed this question using acute toxicity tests with zebrafish (*Danio rerio*) embryos and the invertebrate *Daphnia magna*. Thirteen triazine-based compounds were selected around four substances classified as PMT by the German Environment Agency and grouped into three structural classes: methylthio-triazines, chloro-triazines, and melamine-type triazines. In the zebrafish embryo test (ZFET), mortality and malformations were scored at 96 h. *Daphnia magna* immobilization tests were conducted and scored for immobilization at 48 h. Concentration–response models were used to derive median lethal concentrations (LC₅₀; ZFET) and effect concentrations (EC₅₀) for malformations (ZFET) and immobility (*Daphnia*).

The LC₅₀ results support a toxicity ranking among the three structural groups, with methylthio-triazines being the most toxic, chloro-triazines intermediate, and melamine-type triazines the least toxic. These patterns indicate that simple ring features—particularly the position-2 substituent and the presence or absence of N-alkyl side chains—help predict relative acute toxicity among structurally related PMT and PMT-like compounds. Grouping triazine PMT and PMT-like substances by structure can guide early prioritisation but should be complemented by targeted toxicity tests and computational models to distinguish closely related analogues. Together, these insights support structure-informed testing and prioritisation of PMT candidates and can inform the design and selection of safer alternatives.

3.23.P Polychlorinated N-Alkanes – Current State, Challenges and the Way Forward

3.23.P-Th078 Fast Screening of Polychlorinated Alkanes via In-Source Chloride Ion Detection

Ingus Perkons¹, Natalija Galuza² and Laura Lazdina², (1)Institute of Food Safety, Animal Health and Environment BIOR, Latvia, (2)Institute of Food Safety, Animal Health and Environment BIOR, Riga, Latvia, Latvia

Polychlorinated alkanes (PCAs) are high production volume chemicals and globally widespread contaminants, yet their determination remains analytically challenging due to the extreme complexity of technical mixtures. As a result, routine monitoring still lacks fast and broadly applicable screening tools capable of estimating total PCA load without elaborate quantification workflows. This study evaluates whether in-source chloride

formation can provide a faster, more robust, and operationally simple route to quantifying total PCAs in environmental samples.

We developed a liquid chromatography-tandem mass spectrometry (LC-MS/MS) method that uses in-source fragmentation to generate the diagnostic chloride ions at m/z 35 and m/z 37 from all PCA ions entering the electrospray interface. In-source fragmentation energy and ESI conditions were systematically optimized to maximize the combined chloride-ion signal. The approach was then assessed using commercial single-chain PCA standards (C10-C17; 43-71% Cl) to characterize how chain length and chlorination degree influence fragmentation behavior. As expected, both parameters increased the chloride-ion response, yet all standards provided clear and reproducible signals at low concentrations. Preliminary tests on technical mixtures and spiked environmental samples yielded recoveries of approximately 60–120% relative to high-resolution MS values, demonstrating that the method is suitable for screening-level semi-quantification across diverse matrices.

These findings demonstrate that in-source chloride-ion monitoring allows reliable and efficient estimation of total PCA content, significantly simplifying the analytical workflow. Ongoing work is extending the method to long-chain PCAs, assessing matrix interferences, and further lowering the time of chromatographic separation to support high-throughput environmental monitoring.

Disclaimer/Disclosure:

This work was supported by the Latvian Research Council project “PARAFood: Prioritizing Analytical Rigor and Addressing Gaps in Data for Understanding Chlorinated Paraffins in Food” under the grant agreement No. lzp-2023/1-0559.

3.23.P-Th079 Advanced LC/QTOF-MS Approach for Chlorinated Paraffins: Combining Online SPE and Non-Targeted Screening

Shaun Reeksting¹, Marcus James Chadha¹ and Christian Hegmanns², (1)Agilent Technologies, United Kingdom, (2)Agilent Technologies, Germany

Chlorinated paraffins (CPs), widely used as flame retardants and plasticizers, pose environmental and health concerns due to their persistence and bioaccumulation potential. This study presents a high-resolution LC/QTOF-MS workflow for simultaneous quantitation and screening of short-chain (SCCPs) and medium-chain chlorinated paraffins (MCCPs) in water samples, employing an online solid-phase extraction (SPE) configuration for large-volume injections (500 μ L). The method demonstrated excellent linearity ($R^2 \geq 0.995$) across a seven-point calibration range (0.15–10 $\text{pg}/\mu\text{L}$) and achieved method detection limits below 1 $\text{pg}/\mu\text{L}$ for most congeners, with relative standard deviations $\leq 20\%$. No SCCPs or MCCPs were detected in surveyed river, tap, and treated water samples; however, non-targeted screening revealed surfactants and fatty acids. The workflow enables sensitive CP detection and retrospective analysis, addressing limitations of traditional GC-based approaches for complex CP mixtures. Future work will incorporate isotopically labeled standards and expand to indoor dust and food matrices, supporting comprehensive monitoring strategies for regulated CPs.

3.23.P-Th080 Uncovering the Relative Importance of Chemical Emissions Arising from the Application as Plastic Additives

Chengkang Chen and Frank Wania, Department of Physical and Environmental Sciences, University of Toronto, Canada

Synthetic chemicals can be used simultaneously in various applications including as plastic additives. With the rapid rise in plastic production and the associated pollution, it is vital to investigate the relative contribution of the application as plastic additives to chemical emissions and subsequently to human and wildlife exposure. We select four groups of chemicals, i.e., polychlorinated n-alkanes (PCAs), polychlorinated biphenyls, polybrominated diphenyl ethers, and organophosphate esters, and apply the dynamic substance flow analysis model (CiP-CAFE) to revisit their global historical emissions. We compare emissions of these chemicals arising from their application as additives in plastic products with those from other applications. Using the derived emission estimates as input, we further apply the chemical fate model BETR-Global to assess to what extent emissions arising from plastic additive applications contribute to the environmental exposure to these chemicals globally. Our findings uncover a large contribution of application as plastic additives to total emissions. Taking PCAs as example, 20% of PCA global historical emissions during 1930-2020 are attributed to the use as plastic additives, with this contribution varying between regions and with time. PCA emissions from plastic additives application are more likely to lead to PCA emissions into the atmosphere, while emissions from other

applications are more likely to be to fresh water and soils. Accordingly, plastic additive use of PCA makes a large contribution to global atmospheric contamination. For example, over 60% of short-chain PCAs (SCCPs) in the global atmosphere are attributed to the emissions of SCCPs as plastics additives. This percentage is even higher in China where ~90% of SCCP use is as additive. This work advances our understanding of the vital importance of plastic additives to the emissions of, and therefore ultimately to the human exposure to, many contaminants.

3.23.P-Th081 Tracking Real and Virtual Flows of Polychlorinated n-Alkanes Associated with International Trade Between China and Rest of World

Chengkang Chen and Frank Wania, *Department of Physical and Environmental Sciences, University of Toronto, Canada*

Since the 2000s, China has become the dominant producer, user, and exporter of polychlorinated n-alkanes (PCAs). By 2020, Chinese PCA production accounted for ~40% of global cumulative production. On the one hand, China has exported PCAs and PCA-containing products (e.g., plastics) to the rest of the world, resulting in real flows to, and emissions of PCAs in, other regions (flow 1 (F1)). Also, some PCAs emitted in China are transported to other regions via environmental long-range transport in the atmosphere and marine currents (F2). On the other hand, commodities whose production requires the synthesis and use of PCAs in China are exported to meet consumer demand elsewhere, leading to a virtual emission transfer from consumption regions to China (F3). Finally, some PCA-containing products may be imported into China from consumption regions at the end of their useful lifetime, thus leading to potential emissions during the waste disposal phase (F4). We seek to track and quantify these real and virtual flows of PCAs associated with the international trends of chemicals, products and waste. We apply the dynamic substance flow analysis model (CiP-CAFE) to calculate the global flows and emissions of PCAs for the period from 2000 to 2020 in two scenarios, i.e., with and without considering the trade of PCAs and PCA-related products and wastes between China and other regions. By comparing these two scenarios, we can quantify the impacts of F1, F3, and F4 processes on the emissions in China and other regions. Furthermore, we apply the multimedia fate model BETR-Global to simulate the fate and transport of PCAs, with the derived global emission estimates as input. Again two simulations are performed, i.e., including and excluding Chinese emissions. By comparing these two simulations, we can calculate the magnitude and directions of F2 from China to other regions. The model results shed light on the role of international trade of chemicals and products in transferring globally the emissions of PCAs and therefore the risks associated with exposure to PCAs.

3.24 Recent Advances in Sample Preparation and Related Analytical Methods in Environmental Monitoring

3.24.T-01 Comparing Innovative Sorbents Performances for Passive Sampling of Polar Organic Contaminants through Target and Non-target Screening

Camille Richer¹, Thomas Thiebault² and Fabrice Alliot³, *(1)Sorbonne University, France, (2)No Affiliation, France, (3)Practical School of Advanced Studies (EPHE), France*

Passive sampling use for monitoring of surface waters presents a valuable alternative for tracking water quality, offering cost-effective time-averaged concentration data, and lowering limits of quantification. Recent studies questioned devices type as criteria of sampling performance, but fewer are considering receiving phase material, apart from the usual HLB sorbent. Targeting polar organic contaminants encompasses a broad range of compounds, including ionized or highly hydrophilic ones. Considering these physicochemical properties is crucial to maximize analytes recovery. Therefore, the development of passive sampling devices filled with cutting edge sorbents mixture appears as a promising approach of passive sampling.

This study investigated the implementation of several combinations of sorbents (ion-exchange and neutral sorbents) in passive sampling devices aimed at polar organic contaminants and particularly the most hydrophilic ones (i.e., drugs, pharmaceuticals and biomarkers). To assess the kinetic parameters of the sorbents mixtures and therefore determine the sampling rates of the tested devices, POCIS were exposed for varying periods (1, 2, 4, 7, 11, 15 and 21 days) in the Seine river, Paris. Grab samples were also collected and extracted through acidic and basic elution steps. Analysis of samples was performed by target HPLC-MS/MS (45 targeted contaminants) and non-target LC-QTOF-MS.

The performance of sorbent combination regarding different target contaminants was assessed. Accumulation of compounds highlights the selectivity of each sorbent combination and enables the estimation of in situ contaminants concentrations. Ion-exchange sorbents performed better with ionized and highly hydrophilic molecules. These are however very selective and exhibit rapid accumulation kinetics, making them less suited to

target a broader range of compounds.

The in-situ calibration of POCIS enabled the determination of sampling rates for a wide range of compounds. The dispersion of values highlights the varying degrees of affinity between compounds and receiving phases. Samples were analysed through non target screening to first compare the detected and identified compounds between the samples within the exposure duration, showing increased detected signals from passive samples with the most extended deployment periods.

Disclaimer/Disclosure:

This study is supported by the WHAOU project (24-PEVD-0006) within the France 2030 initiative, and Sorbonne University provides a Ph.D. grant to CR.

3.24.T-02 Innovative Supramolecular Solvent Platforms for Comprehensive Sample Preparation in the Analysis of Chemical Exposomics

Noelia Caballero-Casero and Soledad Rubio, Analytical Chemistry, University of Córdoba, Spain

Characterizing the chemical exposome requires analytical workflows capable of handling vast numbers of structurally diverse contaminants spanning wide ranges of polarity, abundance, and matrix complexity. Liquid chromatography-high-resolution mass spectrometry (LC-HRMS) has become the preferred strategy for this purpose. However, the complexity of the analyses and the strong potential for matrix effects, particularly when electrospray ionization is used, make sample preparation the critical step of the analytical process. Conventional organic solvent-based extractions and solid-phase approaches provide partial and biased coverage, depend heavily on analyte polarity, and often require sequential or parallel workflows that compromise throughput and hinder comprehensive chemical elucidation. As a result, large numbers of chemicals are excluded during sample treatment, preventing their detection and ultimately limiting chemical exposome investigation.

Supramolecular solvents are nanostructured liquids formed through the spontaneous self-assembly of amphiphiles. Their intrinsic coexistence of multiple microenvironments, combined with the ability to tune nanostructure, polarity domains, and binding sites, enables the simultaneous solubilization and preconcentration of compounds across wide physicochemical ranges. Evidence from applications in water, indoor dust, urine, and food matrices demonstrates that supramolecular solvents can efficiently extract chemicals across broad polarity ranges, including persistent organic pollutants, pharmaceuticals, flame retardants, bisphenols, and other emerging contaminants. These capabilities directly address the key requirements for exposome-oriented sample preparation: broad chemical coverage, matrix independence, and minimal manipulation.

This work highlights recent advances in the fundamental understanding of supramolecular solvent generation, including the factors governing their synthesis, structural organization, and the modulation of their physicochemical properties. Emphasis is placed on how these insights support the development of extraction processes capable of accommodating contaminants spanning wide polarity and structural ranges. Remaining challenges for widespread routine adoption in analytical laboratories are also discussed, together with the opportunities that supramolecular solvents offer to expand the accessible chemical space and streamline analytical workflows.

3.24.T-03 Volumetric Dried Blood Spot (DBS) microsampling as smart tool for human biomonitoring of PFAS exposure

Martina Galletto and Alberto Salomone, University of Turin, Italy

Exposomic is a recent concept defining the integrated compilation of physical, chemical, biological, and psychosocial influences that impact biology. The complexity of measuring the human exposome throughout the lifespan has become evident.

For purpose of human biomonitoring, blood is a particular useful matrix since it allows the detection of biologically relevant circulating xenobiotics. However, sampling of venous blood presents several drawbacks

which can now be overcome by the use of Dried Blood Spot (DBS) microsampling.

This study aimed to develop, optimize, and validate a streamlined analytical workflow based on DBS combined to UHPLC-MS/MS detection of 25 per-fluoro alkyl substances (PFAS), a well-known class of environmental pollutants of concern because of the numerous adverse health effects associated with its acute or chronic exposure.

The sampling approach was based on Capitainer B device, which ensures the collection of a volumetric sample of 10 μL through a microfluidic channel. The extraction is carried out by 30 minutes of sonication after addition of 500 μL of methanol and internal standards. The extract is then centrifuged for 10 minutes, evaporated, and reconstituted by 20 μL of 75:25 aqueous: organic mobile phases. Finally, 3 μL are injected to UHPLC-MS/MS for target analysis. The range of calibration (2.0 – 100 ng/mL) was selected according to clinical guidelines with reference to potential toxicity for human health.

The developed method was validated in terms of specificity, sensitivity (LOD 0.4-1.0 ng/mL), accuracy and precision, fulfilling the acceptability criteria ($\pm 20\%$). Extraction recovery demonstrated excellent values (above 80%), whereas matrix effect reported ion enhancement for 13 molecules ($>50\%$). Lastly, stability testing by ANOVA clearly showed a non-statistically significant difference comparing three levels of temperature (-20°C , 4°C , 25°C) and storage time (1 week, 2 weeks, 1 month).

As proof-of-concept, the method application was performed with a cohort of 10 volunteers residing in Piedmont (Italy). Non-alarming concentrations have been found (ΣPFAS 0.74 – 3.38 ng/mL, mean 1.52 ng/mL).

The minimal invasive volumetric DBS combined with the optimized extraction methodology and a sensitive detection method, reveals to be innovative, rapid, and cheap, and particularly suitable to large biomonitoring campaigns focused on at-risk populations because of occupational exposure or vulnerable-stage of life.

3.24.T-04 Indications towards cooperative degradation of micropollutants in biofilms by mass spectrometric imaging

Min Qui¹, Yrsa Larsson², James McKenzie³, Vaidotas Kisieličius⁴, Nicole Strittmatter¹ and Kai Bester⁴, (1)TU Munich, Germany, (2)ENvironmental Sciences, Aarhus University, Denmark, (3)Imperial college, United Kingdom, (4)Environmental Science, Aarhus University, Denmark

There is one major question on biofilm reactor operation: Why are biofilm reactors able to conduct more degradations of pollutants than planktonic/sludge reactors. To answer this question, we degraded benzalkonium compounds in moving bed biofilm reactors (MBBRs). The kinetics of the degradation and the metabolic pathways were elucidated by means of HPLC-HRMS from the bulk water.

The than-known metabolites were targeted for by mass spectrometric imaging (MSI) at the surface of the biofilms with a spatial resolution of 50 μm . Even though, the distribution of the parent compounds was not very homogenous, probably due to different properties of the biofilm surface, be it in charge or in lipophilicity, there were clear maxima of metabolite formation:

A) Several reactions can be localized. It can thus be concluded that the few microorganisms that can metabolize these pollutants are not evenly distributed over the biofilm.

B) The different biotransformations have different reaction centers, especially i) the oxidation of the terminal C by ω -oxidation, followed by both α - and β -oxidation, and ii) the second hydroxylation to form bis-hydroxy derivatives are located differently. Thus, these two different reactions are conducted by different microbial niches. These niches further differed in their lipid patterns, which were measured in the same MSI analysis.

As the different steps of the metabolic chain are located differently, it can be concluded, that different organisms cooperate in this process and probably share the invests into degradation enzymes and possibly the utilisation in energy and carbon harvesting.

Disclaimer/Disclosure:

This study was made possible by the support of the Danish Independent Research Fond (DFF) through project BIOMAN as well as through the European Commission through the project SYBERAC.

3.24.P Recent Advances in Sample Preparation and Related Analytical Methods in Environmental Monitoring

3.24.P-Th082 Intensive Sampling With Ceramic Passive Samplers to Measure Contaminants of Emerging Concern in the Besòs River Delta Groundwater in Barcelona, Spain

Giacomo Moro, Sandra Pérez and Silvia Lacorte, Department of Environmental Chemistry, IDAEA-CSIC, c/Jordi Girona 18, 08034 Barcelona, Spain, Spain

Groundwater is an increasingly important source of drinking water in Europe, but contaminants of emerging concern (CECs) including pharmaceuticals, personal care products and industrial chemicals are only recently being detected, despite their potential harm for the environment. Traditional grab sampling provides only a snapshot of contamination, often missing temporal fluctuations caused by variable river flows, industrial discharges or precipitation events. Passive sampling offers an alternative by integrating contaminant uptake over days to weeks, providing more representative, time-weighted concentrations. Ceramic passive samplers (CPSs) are particularly promising due to their simplicity, robustness, low cost and high sorptive capacity.

In this study, CPSs were successfully calibrated for 54 of 63 target CECs using controlled spiked water experiments, establishing compound-specific sampling rates (R_s) and identifying chemicals with insufficient uptake, such as highly polar compounds or those prone to degradation. Calibrated CPSs were deployed in duplicate in 12 wells and two river sites in and around the Besòs River in Barcelona for 14 days. Grab samples were collected simultaneously at all sites, with two wells sampled intensively seven times during the deployment period to enable direct comparison of time-averaged concentrations.

A wide range of contaminants were successfully detected in the extracts of CPSs, including compounds such as acetaminophen and mecoprop that were undetectable by grab sampling. For other substances, such as 2,4-dichlorophenol and hexamethoxymethylamine, CPSs achieved lower detection limits, enabling measurement where grab sampling failed. Comparison of averaged grab-sample and CPS concentrations in the intensively-sampled wells showed strong agreement: over 80% of compounds matched within the same order of magnitude, with several detected exclusively by CPSs.

These results demonstrate that CPSs can provide a sensitive, reliable and practical tool for monitoring CECs in groundwater, complementing traditional sampling methods. Their ability to capture time-integrated concentrations enhances our understanding of contaminant occurrence and variability in aquifers, supporting improved water quality assessment and management strategies.

3.24.P-Th083 Hydrophobic deep eutectic solvent-liquid phase microextraction as a green method for analyzing environmental contaminants in urine

Nicola Garofalo¹, Julen Segura Abarrategui², Sandra Perez Solsona³, Paride Papadia¹ and Nicola Montemurro³, (1)Dipartimento di Scienze e Tecnologie Biologiche ed Ambientali (DiSTeBA) University of Salento, Italy, (2)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (3)Environmental Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Urine is widely used for biomonitoring due to its easy collection, but only a limited range of compounds, due to their low levels, can be reliably measured without extensive preparation. Hydrophobic deep eutectic solvents-Liquid-phase microextraction (HDES-LPME) provides greener and more versatile extraction. This study evaluated menthol:octanoic acid 2:1 (M:C8 2:1), menthol:decanoic acid 2:1 (M:C10 2:1), thymol:octanoic acid 2:1 (T:C8 2:1), and thymol:decanoic acid 2:1 (T:C10 2:1) extraction efficiency of 83 environmental contaminants from human urine. Among them, menthol:octanoic acid 2:1 showed the highest extraction efficiency and was selected for further optimization and validation at four concentration levels (0.5, 1.0, 5.0, 10.0 $\mu\text{g L}^{-1}$), followed by LC-MS/MS quantification through HPLC-MS/MS 1290 Infinity II HPLC system coupled to an Agilent 6475 Triple Quadrupole Mass Spectrometer. HDESs were prepared by stirring the components at 60°C to obtain eutectic liquids. Firstly, 1 mL of urine was pretreated with β -glucuronidase. For the LPME, 300 μL of HDES was added to urine, sonicated for 10 min and 5 min centrifuged at 10,000 rpm. Thus, 100 μL of 1.5 M NaOH was added dropwise to the HDES layer, and the mixture was manually shaken. Then 100 μL of 0.5 M citric acid was added. The mixture was again centrifuged for 10 min at 10,000 rpm to separate the phases. Finally, 150 μL from the HDES phase was diluted 5-fold with methanol before the injection. M:C8 2:1 showed average recovery ($80 \pm 22\%$) and extraction ability (58 out of 83 analytes with recoveries above 75%), higher than M:C10 2:1 and the thymol-based HDESs, and was chosen as the most effective extraction solvent. The trueness of the procedure was estimated by the recoveries for a contaminant-free urine, spiked with four concentration levels of analytes. For all concentration levels, a large part of the recoveries span a range of 60 to 120%. A certain variability was observed for organophosphates (30-118%) and pyrethroids (17-101%). Recovery rates for Chlorophenoxypropionic acids and neonicotinoids were lower than 60%. The method was applied to 22 adolescent and 8 adult urine samples from the Barcelona metropolitan area. Bisphenols, benzophenones, and parabens were detected at 0.15–9.15, 0.01–2.52, and 0.02–9.10 $\mu\text{g L}^{-1}$, respectively. Overall, the HDES-LPME procedure using M:C8 2:1 proved effective for broad-spectrum contaminant extraction from urine and was suitable for real biomonitoring applications.

3.24.P-Th084 An Optimized Spectrophotometric Approach Based on p-Dimethylaminobenzaldehyde for Reliable Urea Monitoring in Environmental and Industrial Samples

Reliable quantification of nitrogenous compounds such as urea is critical for both environmental assessment and industrial process control. In this study, an optimized spectrophotometric method was developed using p-dimethylaminobenzaldehyde (PDAB) as a derivatizing reagent under controlled acidic conditions. The approach was designed to overcome reproducibility issues related to the aging of acidic PDAB solutions, variations in analytical parameters, and the detection of low urea concentrations. The color reagent was prepared by dissolving PDAB in a 1:1 (v/v) mixture of glacial acetic acid and water, followed by the addition of concentrated sulfuric acid (H₂SO₄). A Central Composite Design (CCD) within the framework of Response Surface Methodology (RSM) was employed to optimize the reagent composition, identifying an optimal PDAB:H₂SO₄ molar ratio of 1:0.89, which produced the maximum absorbance at 430 nm for a 10 mg L⁻¹ urea concentration. Kinetic evaluation confirmed the stability of the chromogen formed at low urea levels, supporting high-throughput laboratory operation. The method was validated according to the Standard Methods for the Examination of Water and Wastewater (Part 1040), exhibiting excellent linearity ($R^2 > 0.99$), precision indicated by inter-laboratory relative standard deviations below 5 %, and recovery between 90 % and 110 % at three concentrations (10, 50, and 100 mg L⁻¹). The limits of detection and quantitation were 2.2 mg L⁻¹ and 10 mg L⁻¹, respectively. The procedure demonstrated strong robustness with minimal sensitivity to experimental variations and provided an efficient means to minimize interferences from ammonia and hydrazine compounds commonly present in fertilizer effluents. Overall, this enhanced PDAB-based approach provides a simple, sensitive, and reproducible analytical tool for the monitoring of urea in diverse matrices. Its adaptability for both environmental samples and fertilizer industry applications makes it a practical and sustainable alternative to more time-consuming conventional techniques.

3.24.P-Th085 Determination and Occurrence of Ethylene Oxide and 2-Chloroethanol in Foods

Yunjia Yao¹, Wen-Ting Szu¹, Chun-Hui Chiu², Yu-Tsung Lee², Deng-Jye Yang¹ and Yi-Jun Lin¹, (1)Institute of Food Safety and Health Risk Assessment, National Yang Ming Chiao Tung University, Taiwan, Taiwan (Greater China), (2)Research Center for Food and Cosmetic Safety, Chang Gung University of Science and Technology, Taiwan (Greater China)

Ethylene Oxide (EtO) is a gaseous compound permitted as a fumigant for certain crops in several countries, including the United States, Canada, and India. Owing to its carcinogenic and mutagenic effects, the European Union (EU) has banned its use as a pesticide since 1991, and Taiwan likewise prohibits its residues in foods. Since 2020, the EU has reported numerous incidents of EtO contamination, mainly involving nuts, soybeans, and wheat products, which are important dietary staples and major imported food items in Taiwan. EtO readily reacts with chloride ions and water in food matrices to form 2-Chloroethanol (2-CE). Accordingly, the EU defines the residue level as the sum of EtO and 2-CE, expressed as EtO equivalents. Building on the currently adopted regulatory approach, this study refined and extended the analytical methods to nuts, soybeans, and wheat products, and investigated their EtO and 2-CE concentrations using a representative sampling design based on the core food approach. Matrix-matched calibration curves for each food type showed linearity, recovery, and relative standard deviation values that complied with regulatory validation criteria. The method detection limits for 2-CE ranged from 0.002 to 0.01 mg/kg, corresponding to 0.001–0.0055 mg/kg as EtO equivalents. Concentrations in sesame, nuts, dried tofu, soy milk, cookies, and noodles were all within regulatory limits. This study combined a refined analytical method with a representative sampling design to enhance accuracy and reliability of EtO and 2-CE residue monitoring in foods.

3.24.P-Th086 Revealing Hidden Thiol-Containing Molecules in Sediments: A Novel Extraction Strategy Based on Thiol–Disulphide Exchange and Its Application to OECD 219 Tests

Chiara Barnaba, David Bernard, Marie-laure Bayle and **Aymeric Bellemain**, Rovaltain Research Staphyt, France

Environmental pollutants such as pharmaceuticals, personal care products, and pesticides are a growing concern worldwide due to their potential effects on ecosystems and human health. Assessing their behaviour in soil and sediment environments requires a combination of chemical and biological analyses, which can be time-consuming and resource-intensive. Quick, comprehensive, and cost-effective methods are therefore needed to improve environmental monitoring and risk assessment—especially for compounds that can strongly interact with sediment matrices.

Among these, thiol-containing molecules represent a particular challenge. Due to their high reactivity, they can form disulphide bonds with naturally occurring thiols in soil and sediment, leading to incomplete extraction and underestimation of their environmental concentrations. To address this issue, we developed a novel extraction method based on the thiol–disulphide exchange reaction, enabling recovery of both free and bound thiol species. As a case study, the extraction method was optimized and validated for Thiorphan, the active thiol metabolite of the pharmaceutical Racecadotril, within the framework of the Sediment-Water Chironomid Toxicity Using Spiked Water (OECD 219). Using β -mercaptoethanol as a reducing agent, the approach efficiently releases sediment bound Thiorphan, which is then extracted and quantified via HPLC–TQ in MRM mode. The method exhibited excellent analytical performance, with a linear range of 10–1000 $\mu\text{g/L}$, a detection limit of 10 $\mu\text{g/L}$, 95% accuracy, and 2.6% precision (RSD).

This approach provides a new analytical tool for detecting reactive thiol-containing pollutants in soil and sediment. It is particularly relevant for ecotoxicity studies in soil and sediments (e.g. OECD 219 test), in which it will support a better understanding of pollutant fate, persistence, and bioavailability.

3.24.P-Th087 Fast und automated Microplastics Analysis in Carbonated Beverages by QCI based LDIR- A critical Evaluation of Spectral Range Selection and Size Detection Limits

Andreas Kerstan¹ and **Wesam Alwan²**, (1)Agilent Technologies, Germany, (2)Agilent Technologies, Australia

Microplastics have become an unwelcome ingredient in food and drink, raising concerns about how plastic materials contribute to contamination. This study demonstrates a rapid, automated approach for detecting and characterizing microplastics in carbonated beverages and apple juice using an Agilent 8700 Laser Direct Infrared (LDIR) chemical imaging system. Samples packaged in various materials such as plastic, glass, aluminum cans, and multilayer cartons were analyzed directly on aluminum-coated filters, a process requiring minimal sample preparation. Using the Particle Analysis method and inbuilt microplastics spectral library within the Agilent Clarity software, microplastics were detected in all beverage types. Polyvinyl chloride (PVC) and polyethylene terephthalate (PET) were identified as the most prevalent polymers. The workflow, including robust quality control and direct-on-filter analysis, highlights the suitability of the 8700 LDIR for microplastics monitoring in food and beverage applications.

Furthermore, critical aspects such as the selection of the spectral range and the influence of interferences such as natural PA and Mg stearate will be examined and critically discussed in this presentation. The LDIR 8700 was compared with other systems such as the Cary 620 FPA Imaging System and the Cary 630 FTIR spectrometer, and the spectral range was compared to the fingerprint range for all systems. In all cases, polymers were identified with high HQI. The presentation will also demonstrate strategies to identify PA in presence of PA naturally occurring and Mg Stearate in presence of PE.

3.24.P-Th088 Development of Green, Comprehensive Analytical Methods for Monitoring Organic and Inorganic Disinfection By-Products in Drinking Water

Despo Fatta-Kassinos, **Photini Papaioakeim**, **Efstathios A. Elia**, **Panagiota Fella**, **Eleni Maragkou**, **Costas Michael** and **Agapios Agapiou**, University of Cyprus, Cyprus

Disinfection of drinking water, while essential for public health, results in the formation of a complex mixture of regulated and emerging disinfection by-products (DBPs). The new European Union (EU) regulation (EU 2020/2184) requires improved analytical capacity for DBP surveillance. This work addresses the challenge of developing sensitive, high-throughput, and sustainable analytical strategies for the determination of diverse DBP classes: volatile organic trihalomethanes (THMs), polar organic haloacetic acids (HAAs), and inorganic anions (IAs).

To analyze THMs, three advanced green microextraction techniques were investigated: high-capacity sorptive extraction (HiSorb), thin film-solid phase microextraction (TF-SPME), and stir bar sorptive extraction (SBSE). Among these, the headspace (HS)-HiSorb method coupled with Thermal Desorption-Gas Chromatography-Mass Spectrometry (TD-GC-MS) was optimized. Although the combined use of TF-SPME and SBSE yielded a

synergistic effect, achieving the highest extraction efficiency for THMs, the optimized HiSorb method-using a polydimethylsiloxane (PDMS) sorbent- offered the best balance between high performance and practical suitability for routine, automated monitoring.

For the analysis of nine HAAs and the three inorganic anions (chlorite, chlorate, and bromate), two separate Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS) methods were successfully developed. This approach eliminated the traditionally required time-consuming derivatization or extensive sample pretreatment steps for GC-MS analysis of HAAs, simplifying the workflow significantly. Both LC-MS/MS methods achieved satisfactory low limits of quantitation (LOQ) (e.g., bromate: 5 ppb; HAAs: 5-50 ppb) and demonstrated high linearity ($R^2 > 0.99$), ensuring compliance with EU regulatory limits.

This integrated analytical strategy provides a robust and validated toolbox for the concurrent quantification of a wide range of organic and inorganic DBPs. The demonstrated utility of combined green microextraction with direct LC-MS/MS analysis represents a significant advancement toward sustainable, high-throughput environmental monitoring in water quality assessment.

3.24.P-Th089 Novel Untargeted Two-Dimensional Mass Spectrometry Based Environmental Analysis

William Dixon, Steven Wright and Tim Wilson, Verdel Instruments, United Kingdom

Environmental pollution is hazardous to human health with wide ranging impacts on the biosphere in general. One of the key challenges of understanding environmental pollution is the complexity of the sample. These samples are composed of thousands of compounds, which interact with each other to further increase the complexity of the sample as it ages. The majority of components are routinely missed by targeted analyses, which results in poorer understanding of environmental pollution.

To overcome these limitations, untargeted analysis combining chromatography and high-resolution spectrometry are commonly employed. However, it can be time-consuming to develop suitable chromatographic methods, requiring experienced scientists, and the cost of acquiring appropriate hardware such as Fourier-transform ion cyclotron resonance mass spectrometers (FT-ICR MS) or orbitrap mass spectrometers is very high. This reduces the accessibility of untargeted analysis to many labs.

Two-dimensional mass spectrometry (2D-MS) is an emerging technique that performs rapid, untargeted analysis of complex unknown samples without the need for chromatography. Instead, 2D-MS employs encoding techniques to correlate precursor compounds with their fragments without prior precursor isolation. Quadrupole two-dimensional mass spectrometry (Q-2DMS) enables 2D-MS on benchtop instruments such as quadrupole time-of-flight (Q-ToF) mass spectrometers, reducing the cost and increasing the accessibility of 2D-MS.

In this work we apply this novel technique to multiple environmental applications with a view to demonstrating a lower-cost approach to untargeted analysis and increase its accessibility. Samples were acquired from different environmental sources using simple, low-cost methods and minimal sample clean-up to maximise the number of components identified in samples. Additionally, work is ongoing to use unique fingerprint patterns in the data-rich 2D-MS plots for source attribution.

3.24.P-Th090 Comprehensive Identification of Emerging Contaminants in Tap Water from 12 Countries Combining Supramolecular Solvent Extraction and Suspect Screening Analysis

Luis Muñiz-Bustamante¹, Noelia Caballero-Casero² and Soledad Rubio², (1)University of Cordoba, Spain, (2)Analytical Chemistry, University of Córdoba, Spain

The growing production of chemical compounds has led to the massive release of substances into the environment, including a wide range of organic pollutants detected in wastewater effluents. Many of these compounds lack chemical and toxicological information and are therefore classified as emerging contaminants (ECs). Wastewater effluents are discharged into various water bodies, serving as an entry pathway for ECs into the hydrological cycle and promoting their global dispersion. Since drinking water treatment plants rely on these water bodies and are equipped with treatment processes designed to remove only specific contaminants, the presence of ECs in tap water must be assessed.

High-resolution mass spectrometry (HRMS), due to its high mass accuracy, enables the identification of compounds without the need for analytical standards. However, the success of non-targeted HRMS

methodologies depends on the implementation of extraction techniques capable of covering compounds with high structural diversity and a wide polarity range. Water analysis using conventional solvent-based methods is limited to the extraction of non-polar and medium polar ECs and requires additional purification steps to achieve adequate selectivity.

In this context, the use of supramolecular solvents (SUPRAS) was proposed as a strategy for the multiextraction of ECs in 53 tap water samples collected from 12 countries. The intrinsic properties of SUPRAS combined with suspect screening analysis (SSA) enabled the tentative identification of 33 ECs across a wide polarity range (logP -1.3 to 16.2), belonging to different chemical classes, including cleaning and household care products, industrial chemicals and intermediates, personal care products, plasticizers, stimulants, surfactants, and others. Most of these ECs have not been previously reported in tap water. These results highlight the remarkable extraction capabilities of SUPRAS, offering a broad-spectrum, streamlined, and efficient alternative to conventional protocols. This innovative methodology reinforces the advantages of supramolecular solvents as a versatile tool for identifying overlooked contaminants and exploring new exposure pathways in urban environments.

3.24.P-Th091 DPX-Based Sample Cleanup for the Analysis of Emerging Contaminants in European Eel Brain

Abril Lan Frias Amigo¹, Marc Roca Aracil¹, Marc Ordeix Rigo², Sandra Perez Solsona³ and Nicola Montemurro³, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (2)Centre d'Estudis dels Rius Mediterranis (CERM) - University of Vic, Spain, (3)Environmental Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

Since the mid-20th century, the European eel population has been reduced to a minimal presence worldwide. It is estimated that in the last 50 years the effects of this extremely vulnerable species have been reduced to less than 95%. The main causes include overfishing, disruption of ecological connectivity, and parasitic infections from bacteria, viruses, and macroparasites. Climate-driven changes linked to industrialization and globalization have further accelerated the decline of Mediterranean eel populations.

Recently, the high chemical contamination of water including the presence of heavy metals, drugs and pesticides seems to be implicated in the decline of European eel stocks in the last decades. Many of these pollutants can alter the normal functioning of the nervous system, induce lesions and behavioral deficits that affect migration and reproduction. However, information on levels of potentially neurotoxic pollutants in the eel brains is still very scarce.

The goal of this work to investigate the bioaccumulation of several neurotoxic pollutants including pharmaceuticals, pesticides, and drugs of abuse in European eel brain samples from the Pyrénées-Orientales. For the extraction approximately 20-200 mg of brain tissue was homogenized with a bead beating machine using 0.5 mL of cold acidified acetonitrile/methanol, followed by a 15-min ultrasonic bath and centrifugation. For purification, the effectiveness of dispersive pipette extraction (DPX) cleanup was evaluated using the HybridSPE DPX Tips. To increase throughput and reduce manual errors, the Hamilton Robotics platform was employed, requiring low volumes of sample and organic solvents, time, and less sample manipulation. The method was applied to samples from the lower part of the Têt y Tech rivers and the Verdoube river, Canet-Saint-Nazaire and Salses-Leucate lagoons, lower part of Llança river, Els Aiguamolls de l'Alt Empordà lagoons, and Aiguamolls del Baix Ter Girona) and Barcelona (lower parts of Tordera and Besòs rivers and Llobregat Delta river ponds).

Identification and quantification of compounds were carried out by liquid chromatography coupled to Thermo Orbitrap Xploris 240 mass spectrometry system, by applying sophisticated wide-scope target screening workflows.

The automated DPX tip cleanup procedure was very fast allowing for simultaneous analysis of many samples in few minutes. Results revealed the presence of several pollutants, especially pesticides, in eel brain tissues.

3.24.P-Th092 Development of a method for quantifying essential and toxic elements in whole blood for biomonitoring studies

Livia Bossi Val, Fernando Barbosa Júnior and Vitor Luiz Caleffo Piva Bigão, University of Sao Paulo, Brazil

Essential and potentially toxic elements play critical roles in metabolic processes and are closely associated with the prevention or onset of various health disorders. Biomonitoring studies help define safe reference values, which are crucial to guide effective public health policies. However, the analysis of blood requires robust method development to overcome matrix complexity and ensure reliable quantification of these challenging trace elements.

This study aimed to develop a simple dilute-and-shoot Inductively Coupled Plasma – Tandem Mass Spectrometry (ICP-MS/MS) method capable of simultaneously quantifying essential and toxic elements in whole blood with high sensitivity. To enhance method reliability, validation will be conducted following the International Council for Harmonisation (ICH) M10 guideline for bioanalytical method validation.

The methodology involves a mild digestion and dilution step (dilute-and-shoot) using 0.5% (v/v) nitric acid and 0.01% (v/v) Triton X-100. Different instrumental conditions, including collision/reaction cell gases, internal standards, and dilution strategies, were evaluated to improve accuracy in this complex matrix. Method development included assessment of potential matrix effects, evaluation of linearity, limits of detection, instrumental and analytical precision, and accuracy studies using certified reference materials.

The method enabled the quantification of 13 essential and toxic elements with improved detectability and reduced matrix-induced suppression. Polyatomic interferences were effectively minimized through the use of reaction and collision gas modes, producing results suitable for biomonitoring applications.

This straightforward dilute-and-shoot approach demonstrates strong potential for routine multielement analysis in whole blood and can support large-scale biomonitoring efforts, contributing to the establishment of robust reference values and supporting public health decisions related to nutritional status and chemical exposure.

3.24.P-Th093 TIMFIE Sampling Offers Time-Integration and Quantitative Determination of Multiclass Organic Micropollutants in Whole Water

Ove Jonsson, Oksana Golovko and Mikaela Gönczi, Swedish University of Agricultural Sciences, Department of Aquatic Sciences and Assessment, Sweden

Organic micropollutants, e.g. pesticides, pharmaceuticals and PFASs pose a risk to aquatic organisms, ecosystems and their functions. Their presence and concentrations in the environment vary over time and sampling techniques that enable determination of average levels in whole water are vital to estimate chronic exposure of biota and assess waterbody status.

Time-Integrating, Micro Flow, In-situ Extraction (TIMFIE) is a novel sampling technique that meets the need for: whole water analysis, quantitative methods possible to validate according to established principles, fully time integrated from continuous active sampling, low cost and flexible use.

TIMFIE samplers are made from inexpensive laboratory consumables and requires no battery or power supply. A 120-mL syringe is set under negative pressure by pulling and locking the piston with a nail. A flow restrictor (narrow bore PEEK tube) enables a low water flow through one or more solid phase extraction (SPE) cartridges, where target compounds are continuously extracted in situ over one or two weeks. The extracted sample volume is accurately determined which is fundamental for subsequent quantitative analysis. Sampling flow rate (and thus possible sampling time) is easily controlled by varying flow restrictor back pressure.

Two polymer columns in series with a weak anion exchange material (HR-P, HLB, HR-XAW, Macherey-Nagel) were chosen to enable broad extracting capability. The SPE assembly was handled as one unit during conditioning and elution steps, and final extract split for subsequent analysis with four LC-MS/MS multimethods for different compound classes (here 119 pesticides, 66 pharmaceuticals, stimulants, industrial chemicals and personal care products, and 30 PFASs). Methods were validated with a 50 mL sample volume and a final extract volume of 0.5 mL resulting in a theoretical concentration factor of 100.

The SPE cartridge format, with Luer connections in both ends, enables automation of conditioning and elution steps using in-house made manifolds and a stand-alone LC-pump. This significantly reduces tedious lab-work and minimizes handling variability and errors.

Due to its compact and robust design, the TIMFIE sampler can be deployed using various methods, with

submerged placement being preferable since it provides more stable environmental conditions and minimizes visibility to passersby.

3.24.P-Th094 Determining Water Solubility of Poorly Soluble Liquids; Beyond OECD 105

Bryony Retter, Scymaris Ltd., United Kingdom

Water solubility of compounds is an essential parameter to understand how a chemical behaves in the environment and any hazards that may be associated with it, while also being a requirement in global chemical assessments and regulatory submissions. The OECD 105 guideline currently uses two methods for determining water solubility: shake-flask and column elution. Both methods have their limitations, with shake-flask being suitable for compounds with a preliminary solubility of >10 mg/L, while column elution is suitable for low solubility compounds (<10 mg/L), but is unsuitable for testing liquids.

Here we present a successful case of determining water solubility using an alternative, slow stir method. This method uses principles taken from the OECD 123 guideline (partition coefficient; slow stir method), along with criteria taken from the OECD 105 guideline, to determine the water solubility of a poorly soluble, liquid compound. A previous study demonstrated the effectiveness of this methodology for determination of water solubility for a medium-chain saturated hydrocarbon compound; in this case, however, it was applied to measure the solubility of a long-chain fatty acid methyl ester. So far, experimental investigations have focused on compounds with densities lower than 1 g/mL, however with appropriate modifications to the experimental design, this method may also be applied to compounds with densities greater than that of water.

For substances with densities of less than 1 g/mL, the compound is directly dosed onto the surface of the water in an appropriate vessel, stirred slowly until a minimal vortex is formed, and sampled at relevant time points until an equilibrium is reached. Analysis and data handling followed the recommendations described in the OECD 105 guideline. The work therefore presents suitable methodology for the determination of poorly soluble liquids.

Disclaimer/Disclosure:

3.24.P-Th095 Evaluating a New Polymer-Based Device for Dried Urine Microsampling of Environmental Organic Contaminants

Vítor Luiz Caleffo Piva Bigão¹, Gabriel Henrique Savietto¹, Livia Bossi Val¹, Nathalia de Assis Aguilar Duarte¹, Marília Cristina Oliveira Souza¹, Mariana Zuccherato Bocato², Anthony Alexandre Weil², Silvana Ruella de Oliveira¹ and Fernando Barbosa Júnior¹, (1)University of São Paulo, Brazil, (2)Reload Health, Brazil

Microsampling strategies have become practical alternatives for biological sample collection in remote or logistically constrained settings. Although dried blood formats are well established, dried urine microsampling remains underexplored, particularly for the determination of environmental organic pollutants. The newly developed Ouro Health Polymer, created by Reload Health in collaboration with the Analytical and Systems Toxicology Laboratory (ASTox – USP), offers a novel platform for passive urine adsorption, drying, and field-ready biomonitoring.

This study evaluates the analytical feasibility of the Ouro Health microsampler for detecting multiple classes of environmental pollutants in dried urine, aiming to develop and optimize a polymer-based method for their quantitative determination.

Synthetic urine was spiked with target pollutants and absorbed onto the polymer by immersion during 5 min with gentle agitation. The multilayer structure enables passive drying at room temperature in 12 hours. Extracts were recovered using 7 mL of solvent, followed by SPE cleanup. After derivatization, samples were analyzed by GC-MS to assess recovery and detectability of bisphenols, parabens, and benzophenones. Chromatographic separation was carried out on a DB5-MS column. The oven temperature of the chromatographic column was initially maintained at 70 °C for 2 min, followed by a heating ramp from 15 °C/min to 210 °C, with a subsequent increase of 20 °C/min to 280 °C, holding for 5 min. Finally, a rise of 10 °C/min to 300 °C, was held for 10 min. UPLC-MS/MS will also be tested to expand the evaluation of polymer performance.

We hypothesize that the polymer provides efficient adsorption, stabilization, and extraction of organic pollutants, supporting sensitive GC-MS quantification and improved analytical performance through optimized extraction and instrument conditions.

This work represents the first evaluation of the Ouro Health polymer for environmental biomonitoring, demonstrating its potential applicability not only to dried urine but also to other non-biological liquid samples, such as environmental water. The results highlight its potential for low-infrastructure sampling, particularly in remote areas where conventional urine collection, refrigeration, and transport remain challenging.

3.24.P-Th096 Automation of SVOCs Analysis in Water Using EPA 8270: A High-Throughput Workflow with GC-MS/MS and Robotic Sample Preparation

Janina Kornas¹ and Anna Cali², (1)Agilent Technologies, Germany, (2)Agilent Technologies, Italy

Monitoring semi-volatile organic compounds (SVOCs) in water is critical for environmental compliance and public health. Traditional EPA 8270 workflows rely on manual sample preparation, which is time-consuming, solvent-intensive, and prone to variability. We present a fully automated solution integrating robotic sample preparation with Agilent 8890 GC and 7010C triple quadrupole MS/MS for the analysis of a great number of compounds, including PAHs, PCBs, pesticides and chloronaphthalenes. The method employs two optimized workflows—acidic for most analytes and basic for amines—combined with matrix-matched calibration to ensure regulatory compliance with EPA 8270 performance criteria. Results demonstrate excellent linearity ($R^2 > 0.99$), recovery (70–130%), and precision (RSD $< 10\%$ for most compounds), even at trace levels (5–10 ppt for PAHs and PCBs). Automation significantly reduces solvent use, waste generation, and operator exposure while improving throughput and reproducibility. This robust, high-sensitivity approach enables cost-effective, scalable SVOC monitoring in environmental water matrices.

3.24.P-Th097 Development and optimization of a sample preparation method for the determination of organic micropollutants in soil samples using GC-APCI-QTOF MS

Nikolaos Boinis¹, Nikolaos Dragazis², Eleni Panagopoulou², Georgios Gkotsis² and Nikolaos S. Thomaidis², (1)Chemistry, National and Kapodistrian University of Athens, Greece, (2)National and Kapodistrian University of Athens, Greece

Growing awareness of organic micropollutants (OPs) in soil necessitates robust analytical methods, as complex matrices and diverse OP mixtures often lead to underestimated concentrations without comprehensive chemical coverage. Wide-scope sample preparation enables simultaneous analysis of emerging and legacy OPs, increasing analytical efficiency while reducing environmental impact. Gas chromatography with atmospheric pressure chemical ionization quadrupole time-of-flight mass spectrometry (GC-APCI-QToF MS) offers high sensitivity and selectivity, while enabling wide-scope screening for monitoring soil quality. The scope of this study was the development of a generic sample preparation protocol aimed at OPs in soil samples, maximizing the capabilities of cutting-edge instrumentation. Thus, three sample preparation methods, Accelerated Solvent Extraction (ASE), Ultrasonic Assisted Extraction (UAE), and modified QuEChERS (mQuEChERS), were tested using a smart validation scheme of 38 compounds selected as representative OPs across major pollutant classes: polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polychlorinated naphthalenes (PCNs), and organochlorine pesticides (OCPs). The mQuEChERS method emerged as the most suitable, employing solid-liquid extraction assisted by sonication, followed by phase separation and solid phase extraction purification, leading to optimized analyte recovery and matrix interference reduction. The mQuEChERS protocol was validated for 75 analytes spanning emerging and legacy OPs, including 16 PAHs, 19 PCBs, 5 PCNs, 16 OCPs, and 19 pesticides. The method demonstrated excellent linearity over 30–300 $\mu\text{g/kg}$, achieved recoveries of 70–120%, and maintained high precision (RSD below 11%). The final validated method was applied to real-world soil samples collected from Attica, Greece, and analyzed via GC-APCI-QToF MS. In total, 31 OPs were detected at ultra-trace levels, 16 PAHs, 2 PCBs, 5 OCPs, plus 8 pesticides. PAHs displayed the highest concentrations, with phenanthrene, pyrene, and naphthalene being the most prevalent. Pesticides, like Pendimethalin and Amitraz, followed, while OCPs like DDT were present at lower levels. Results reflected the impact of local industrial and agricultural activities on the environmental contaminant profile. The validated

mQuEChERS stands out as a robust, efficient, and environmentally friendly method, expanding monitoring capabilities worldwide when combined with GC-HRMS.

3.24.P-Th098 Passive Sampling of PFAS Across the Water Cycle: Calibration, Matrix Effects, and Source Identification

Kristina Mraz¹, Antonin Halek¹, Veronika Svobodova¹, Vaclav Janda¹, Jana Pulkrabova¹, Jakub Hejnic², Martin Srb², Darina Dvorakova¹ and Vojtech Kouba¹, (1)University of Chemistry and Technology Prague, Czech Republic, (2)Prague Water Supply and Sewerage Company (PVK), Czech Republic

In the recent years passive samplers have become a powerful tool to detect per- and polyfluoroalkyl substances (PFAS). In contrast to grab sampling, passive sampling can provide time weighted average concentrations and is particularly suitable for detecting low and fluctuating concentrations of the target analytes. However, there remain uncertainties of applying passive samplers for PFAS in complex water matrices, such as wastewater (WW). This study aims to address the matrix effects, evaluate their influence on the PFAS sorption and calibrate the passive sampler in the field, to enable source identification across diverse aquatic environments. We have conducted laboratory experiments to test the matrix effects of pH, salinity, humic acids and organic matter of the PFAS sorption on a weak anion exchange sorbent. Increased PFAS sorption was observed at moderately elevated pH, salinity, and humic substances within the tested ranges, whereas the lowest sorption occurred at the lower ends of these ranges. Finally, polar organic chemical integrative samplers (POCIS) with our chosen sorbent were deployed long-term deployment in surface and drinking water and short-term deployment in WW. In-situ calibrations were performed under linear uptake conditions to obtain sampling rates for the different water matrices and the time-weighted average concentrations were determined. This combined laboratory and field approach improves our understanding of matrix effects during PFAS monitoring and allows deviations from optimal conditions to be accounted for during in-situ application. Overall, our findings extend the applicability of passive samplers to complex water matrices and thereby contribute to comprehensive PFAS source identification.

3.25 Safe Organic Waste Circularity: Monitoring and Managing Contaminants in Valorisation Processes

3.25.T-01 A Smelly Situation – Assessing Pollutant Profiles of Sweden’s Most Used Organic Waste-Based Fertilizers with an Accelerated Solvent Extraction, GC-HRMS, and CALUX® Bioassay-Based Combination Method

Rhayn Werz¹, Kevin Rocco², Maria Larsson², Anna Kärrman¹ and Anna Maria Rotander¹, (1)Örebro University, Sweden, (2)Orebro University, Sweden

Reusing organic waste-based fertilizers is promoted to return key nutrients (phosphorus, nitrogen, organic matter) to agricultural soils, yet emerging micropollutants, particularly in sewage sludge, raise concerns. This study compares pollutant profiles of the three most used organic waste fertilizers in Sweden: sewage sludge, agro industrial waste fermentate and cow manure. 12 sludge samples from Swedish wastewater treatment plants (WWTPs) with varying catchment sizes and treatments (n=3) as well as 5 fermentate samples and 5 manure samples were included.

Using a previously developed, comprehensive method, samples were lyophilized, extracted using accelerated solvent extraction with a n-hexane and dichloromethane mix and analyzed by GC HRMS with suspect and non target screening (NTS). DR and Nrf2 CALUX® bioassays measured activation of the aryl hydrocarbon receptor and oxidative stress, expressed as Bio TEQs and Bio CEQs based on 2, 3, 7, 8–TCDD and curcumin standards respectively.

A first assessment with suspect screening at confidence level 1 indicates a higher overall pollution of sewage sludge than agro-industrial fermentate and manure. We screened for 46 compounds including polychlorinated biphenyls (PCBs), dioxins and furans (PCDD/Fs) as well as polycyclic aromatic hydrocarbons (PAHs), phthalates, siloxanes and plastic additives using native batch standards. The phthalate DEHP occurred in all sludges and fermentates, while DIDP appeared only in sludges. Plastic additives were present in sludges and fermentates. Manure showed a single detection (siloxane D5).

DR CALUX® activities expressed as Bio-TEQs were highest in sludge (0.5–15.3ng/g), followed by fermentates

(0.3–1.7ng/g) and lowest in manure (0.3–0.8ng/g). Yet, no PCBs or PCDD/Fs were detected; among nine PAHs screened, anthracene, chrysene, and benzo[a]pyrene occurred in some sludges, underscoring the value of complementary bioanalytical tools. Nrf2 Bio CEQs ranged 152–1216µg/g in sludges and were lower in fermentates (153–856µg/g) and manures (65 and 121µg/g), with 3 manure samples <LOQ. Sludges from city WWTPs showed the strongest responses in both assays.

Overall, sludge, particularly from cities, exhibited the highest DR and Nrf2 activity as well as a higher number of detected pollutants than fermentates and manure. No clear trend in detected pollutants or activity was observed across sludge treatments. Suspect and NTS with in-house libraries are ongoing and will be presented at SETAC.

3.25.T-02 Total Oxidizable Precursor (TOP) Assay as a Tool to Assess Transformation and Mineralization of PFAS in Sewage Sludge Treatment

Erlend Sørmo¹, Liang Zhao², Hans Peter H. Arp³, Pia Nystu², Gerard Cornelissen⁴, Gabriela Castro⁵, Nicolas Estoppey³, Junjie Zhang⁶ and Alexandros G. Asimakopoulos², (1)NMBU, Norway, (2)NTNU, Norway, (3)Norwegian Geotechnical Institute (NGI), Norway, (4)NIBIO, Norway, (5)University of Santiago de Compostela, Norway, (6)University of Copenhagen, Norway

The presence of per and polyfluorinated alkyl substances (PFAS) and precursors in sewage sludge from wastewater treatment plants (WWTPs) has raised concern as it limits reuse. Knowledge gaps exist with regard to precursor transformation during traditional sludge treatment, such as anaerobic digestion (AD) and novel approaches, such as pyrolysis, and how it affects environmental impact of these processes. Therefore, the total oxidizable precursor (TOP) assay was applied to sludge samples from before and after AD from 3 WWTPs, and to 6 sludges and the 23 biochars resulting from full-scale relevant pyrolysis treatments at various conditions (500-800 °C; 5-50 min retention time (RT)). Mean target ΣPFAS37 concentrations in raw sludge (RS) ranged from 184 to 258 ng g⁻¹. RS contained the highest precursor loads as the TOP assay resulted in a 2-5 times increase in ΣPFAS37. A relative reduction of ΣPFAS37 in digested sludge (DS) compared to RS indicated transformation of precursors during AD which could indicate gaseous emissions and/or unmonitored congeners in DS. Both scenarios would lead to an underestimation of the environmental impact of the digestion process. Mean concentrations of ΣPFAS37 were 5.58±6.21 ng g⁻¹ in the 23 biochars produced. There were no significant correlations between PFAS concentrations and temperature or RT. The TOP assay indicated significant precursor presence in some sludge biochars with ΣPFAS37 >20 ng g⁻¹. Still, the mean removal effect (RE) across all conditions tested, was high for both target PFAS and precursors (>98%). The levels of residual PFAS detected in some biochar samples when using the TOP assay (>20 ng g⁻¹) warrant further assessment and demonstrates the need to consider non-target PFAS compounds when assessing destructive treatments. Although the TOP assay is a semi-quantitative method, it proved useful studying the effect of sludge treatments. However, optimization towards specific matrices is needed to produce more reliable data.

3.25.T-03 From Soil to Water: Comparing Insect Frass and NPK Fertilisers in Plant Performance and Environmental Safety

Diogo Filipe Nunes Cardoso¹, Ana Eduardo Rodrigues¹, Inês Bento Cruz², José Nereu Pinto³, Amid Mostafaie¹, Catarina Correia de Lemos Malheiro³, Pedro Monteiro¹, Ana Rita R. Silva¹, Ivã G. Lopes⁴, Glória Pinto¹, Clarice C e Souza⁵ and Susana Loureiro¹, (1)University of Aveiro, Portugal, (2)Department of Biology, University of Aveiro, Portugal, (3)CESAM & Department of Biology, University of Aveiro, Portugal, (4)Department of Biosystems and Technology, Swedish University of Agricultural Sciences (SLU), Sweden, (5)Centro de Investigação Interdisciplinar Egas Moniz (CiiEM) & Ingredient Odyssey SA–Entogreen, Portugal

Insect frass from *Hermetia illucens* is emerging as a circular and bio-based alternative to mineral fertilisers, yet comparative assessments focused on plant-level responses and environmental safety remains limited. This study evaluates two types of insect frass (cereal-based and olive pomace-based) against a conventional NPK regime using Integrated soil–plant assays and soil column leaching experiments. Brassica rapa was grown for two full life cycles under equivalent nitrogen inputs, and plant performance, soil biochemical functioning, and soil ecotoxicity (using *Enchytraeus crypticus* and *Folsomia candida*) were assessed. Additionally, leaching assays simulated intense

rainfall to quantify nutrient losses (NH_4^+ , NO_3^- , PO_4^{3-}) and the ecotoxicity of leachates to freshwater organisms (*Raphidocelis subcapitata*, *Lemna minor*, *Daphnia magna*) was determined.

Across soil–plant systems, frass-based fertilisation supported plant development comparably to the 100% NPK treatment. While exclusive frass applications produced slightly lower early-stage biomass, plant physiological and biochemical markers (including chlorophyll, pigment indices, sugars, and antioxidants) remained stable across all treatments, indicating an absence of metabolic stress. Frass amendments improved soil functioning by maintaining or enhancing enzyme activities related to carbon, nitrogen, and phosphorus cycles, and by promoting more balanced ammonium–nitrate dynamics. Soils reused for a second crop cycle (without additional fertilisation) still supported plant growth where frass was previously present.

Soil ecotoxicology tests revealed no adverse effects of frass on the reproduction or adult survival of *E. crypticus* or *F. candida*, demonstrating that both frass types are compatible with the functioning of the soil ecosystem. In leaching assays, frass amendments exhibited clear environmental advantages. Compared with mineral NPK, frass substantially reduced nutrient losses, with nutrients being more strongly retained in the upper soil layers due to the stabilizing influence of organic matter and chitin. Leachates from frass-treated soils caused no toxicity to algae, macrophytes, or crustaceans, while NPK leachates inhibited algal growth due to elevated nitrogen concentrations.

Frass, therefore, represents a viable, safe, and environmentally advantageous fertilisation strategy within circular and climate-smart agricultural systems.

3.25.T-04 Sewage sludge application as biofertilizer: microbial effects and preliminary persistence assessment of quaternary ammonium biocides in soil

Sophie Lennartz¹, Maria Carolina Santos², Ricardo Veiga Leitão², Jose Paulo Sousa², Luis Cunha² and Kai Bester³, (1)Aarhus University, Denmark, (2)University of Coimbra, Portugal, (3)Environmental Science, Aarhus University, Denmark

Quaternary ammonium compounds (QACs) are high production volume cationic surfactants and biocides entering wastewater treatment plants after application in healthcare, consumer products, industry or agriculture. While typically > 90% of QACs are removed from wastewater, a significant fraction sorbs to sewage sludge with concentrations reaching up to 10^2 mg/kg. Consequently, high amounts of QACs can enter agricultural soils when sludge is used as biofertilizer. However, so far little is known about the fate and effects of sludge-borne QACs in soil ecosystems. QACs are aerobically degradable in surface water and sludge, but strong adsorption to organic matter and clay minerals may result in incomplete degradation and long-term persistence in soil. As QACs are broad-spectrum antimicrobials, exposure may negatively impact the diversity and function of the soil microbiome. This study therefore investigated the fate and effects of QACs in sludge-amended agricultural soil.

To this end, we investigated the dissipation and microbial community effects of structurally diverse QACs in controlled lab-scale soil microcosm experiments. QAC parent compounds were quantified by UPLC- MS/MS and effects on soil microbial communities investigated by 16S rRNA gene metabarcoding. QACs showed limited degradation after 28-day incubation in soil microcosm, indicating potential for persistence. They altered bacterial richness, evenness, and β -diversity in dose-dependent manner at exposure concentrations between 0.001-100 mg/kg. Alkyltrimethylammonium compounds induced a monotonic decrease in α -diversity, while benzalkonium compounds showed a toxicity threshold at 0.01 mg/kg soil dry weight, corresponding to realistic soil concentrations after sludge application.

Sewage sludge application is a major emission pathway for QAC biocides into agricultural soils. Our findings show that this may lead to (semi-)persistent contamination, negative effects on soil microbial diversity and altered microbial functions at realistic exposure levels. Further research should clarify the biotransformation of QACs, mobility and potential uptake of metabolites by field crops, as well as cumulative effects from repeated applications. These findings highlight the need to consider QAC input via sludge in future risk assessment to better evaluate potential impacts on soil ecosystems and human consumers.

3.25.T-05 Fate of Micropollutants in Sludge Treatment Reed Beds: Removal Efficiency, Persistence, and Risk Assessment for Agricultural Reuse

Alba Martinez i Quer¹, Amir Gholipour², Gregor Plestenjak³ and Pedro Neves Carvalho⁴, (1)Department of Environmental Science, Aarhus University, Denmark, (2)Aarhus University, Denmark, (3)University of Ljubljana, Slovenia, (4)Environmental Science, Aarhus University, Denmark

Sludge Treatment Reed Beds (STRBs) are nature-based systems widely used for sustainable sludge management, offering effective dewatering and mineralization. However, the fate of organic micropollutants such as pharmaceuticals, pesticides, and biocides in these systems remains poorly understood, limiting safe reuse of biosolids in agriculture.

This study aimed to evaluate the removal efficiency and persistence of micropollutants in pilot-scale STRBs and assess potential ecological risks associated with land application of treated sludge.

Nine pilot beds planted with *Miscanthus × giganteus* were operated outdoors for 16 months under three aeration regimes: non-aerated control, passive aeration, and active aeration. Sludge from a municipal wastewater treatment plant was loaded every 40 days at an annual rate of 16 kilograms of dry matter per square meter.

Forty-nine micropollutants were monitored using liquid chromatography coupled with tandem mass spectrometry, and a preliminary risk assessment was performed using predicted environmental concentrations and no-effect thresholds for soil organisms.

Results showed that 43 compounds were detected at least once, with pharmaceuticals dominating. Most compounds exhibited strong removal trends: 34 were completely removed and 21 achieved approximately 99 percent reduction, regardless of aeration type. Aeration did not significantly influence removal, while environmental factors such as temperature and moisture played a greater role. Three compounds—benzalkonium chloride, carbamazepine, and propranolol—persisted or accumulated, raising concerns about long-term environmental impact. Risk assessment indicated that most compounds posed low ecological risk, but antibiotics trimethoprim, azithromycin, and erythromycin exceeded safety thresholds for soil microbes.

These findings demonstrate that STRBs can effectively mitigate micropollutant loads, supporting circular economy goals. However, persistent compounds and antibiotic-related risks require improved monitoring and risk assessment frameworks to ensure safe agricultural reuse.

3.25.P Safe Organic Waste Circularity: Monitoring and Managing Contaminants in Valorisation Processes

3.25.P-Th099 Fate of four ¹⁴C-labelled organic trace contaminants brought in tropical and temperate agricultural soils with organic wastes

Antoine SPAUDO¹, Claire-Sophie HAUDIN², Valérie DUMENY², Léa ARMAND², Pierre Benoit², Marjolaine DESCHAMPS², Marion COLLINET¹ and Frédéric FEDER¹, (1)UPR Recyclage et Risque, CIRAD, France, (2)Ecologie Fonctionnelle et écotoxicologie des agroécosystèmes – Université Paris-Saclay, INRAe, AgroParisTech, UMR ECOSYS, France

Organic trace contaminant (OTC) fate in agricultural soils amended with organic waste products (OWP) has been widely studied under temperate conditions, whereas little to no data exist for tropical pedoclimatic contexts.

In this study we focused on the following question: what is the impact of OW, soil properties and time on the fate of various OTC in a soil/OW mix under controlled conditions? Our hypothesis for this experiment were:

- OTC properties will influence their fate in soil along the experiment, especially their log K_{ow}
- The quality of organic matter in OW and soil will influence the fate of OTC more than the quantity
- OTC extractability will decrease over time due to OW and soil properties

A 49-day microcosm incubation was conducted using 5 g of soil mixed with 150 mg of OWP spiked with 50 µL of ¹⁴C-labelled OTC: linear alkylbenzene sulfonate (LAS), phenanthrene (PHE), carbamazepine (CBZ), and azithromycin (AZI). Two soils with contrasting pedoclimatic origins, a Nitisol (Réunion Island, RUN) and a Luvisol (Yvelines, QA) and two OWP types (biosolids, BS ; pig slurry, PS) were tested. Mineralisation was

monitored via ^{13}C -CO₂ capture using lime traps. At days 0, 7, 28, and 49, microcosms were sacrificed for sequential extraction (CaCl₂ and methanol) to quantify readily and poorly available contaminant fractions. Methanol extracts were analysed by HPLC to identify potential degradation products.

Extraction yields decreased over time for all OTC except AZI, for which yields were too low for reliable interpretation, mainly due to adsorption mechanisms to plastic tubes. LAS and PHE were the only compounds that mineralised within the experimental timeframe, with mineralisation rates markedly higher in BS than in PS, and greater in RUN than in QA. CBZ displayed contrasting dynamics across soils: in RUN, the decrease in readily available CBZ corresponded to an increase in the poorly available fraction, whereas in QA this decrease was mainly associated with the formation of non-extractable residues. CBZ was also the only OTC that remained more available in RUN/OWP mixtures than in QA/OWP mixtures. HPLC analysis of CBZ methanol extracts showed that some degradation products were formed even if mineralization was very low. In QA/BS modality, the degradation product represented up to 90% of the radioactivity at day 49.

3.25.P-Th100 Frass for grass: *Acheta domesticus* frass effects on soil functions and organisms

José Nereu Pinto¹, Sara Dias², Francisca Fortes², Inês Bento Cruz¹, Fábio Yu Chen¹, Diogo Filipe Nunes Cardoso¹ and Susana Loureiro³, (1)CESAM, University of Aveiro, Portugal, (2)Department of Biology, Campus Universitário de Santiago, University of Aveiro, Portugal, (3)Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Portugal

Insect frass has garnered considerable attention as a sustainable, organic fertiliser and soil amendment.

Compared to traditional animal-based or mineral/chemical fertilisers, frass is a more sustainable option, being generally considered safer because it is organic, low in pathogens, and can boost soil health by adding beneficial microorganisms and chitin that support plant defences. But, as with all manures, its specific properties depend on the producing species. Therefore, this study focused on the house cricket *Acheta domesticus*, a potential manure producer (frass) that remains significantly understudied compared to other alternatives such as *Hermetia illucens*. Despite this gap, *A. domesticus* is a promising candidate capable of upcycling diverse substrates into valuable biomaterials, including frass, protein, lipids, and chitin.

Before frass can be widely used in agricultural soils, it is essential to assess both its safety for soil organisms and its influence on soil functioning. This study evaluated two aspects of frass application: (1) ecotoxicological effects on representative soil organisms and (2) soil enzymatic activities related to nutrient cycling. Ecotoxicity was assessed using the soil invertebrates *Enchytraeus crypticus* and *Folsomia candida*. Organisms were exposed to six frass concentrations in soil (0 – 1.045%), from a reference application rate of 0.261 % (3.47 tons/ha prepared according to the nitrogen needs of *Avena sativa*, equivalent to 130 kg N/ha) and an estimated frass mineralisation coefficient of 50%. Soil biochemical functioning was assessed by measuring the activities of Urease (UA), Dehydrogenase (DHA), Basic- and Acidic-phosphatase (B-, A-P), Arylsulfatase (AS), and β -glucosidase (β G) in amended LUFA 2.2 soil.

At agronomically relevant application rates, cricket frass did not induce mortality in *E. crypticus* or *F. candida*. It significantly increased the reproductive output of the former, matching the responses previously observed with other types of insect frass. Soil enzymatic activities showed no statistically significant changes within these relevant concentrations, indicating that frass did not disrupt or improve key soil biochemical processes in the short exposure time. Taken together, these results suggest that cricket frass can be safe for soil invertebrates, and importantly, it does not impair nutrient-cycling processes.

3.25.P-Th101 Black Soldier Fly Frass from Olive Pomace as a Sustainable Soil Amendment in Cabbage Production

Amid Mostafaie¹, José Nereu Pinto², Ana Eduardo Rodrigues¹, Inês Bento Cruz³, Ana Rita R. Silva¹, Rui G.

Morgado¹, Catarina Correia de Lemos Malheiro², Pedro Monteiro¹, Diogo Filipe Nunes Cardoso¹ and Susana Loureiro¹, (1)University of Aveiro, Portugal, (2)CESAM & Department of Biology, University of Aveiro, Portugal, (3)Department of Biology, University of Aveiro, Portugal

Synthetic nitrogen fertilizers supply ~80% of global agriculture but generate substantial environmental costs (€35–230 billion annually in Europe). Circular bioeconomy approaches, valorizing agro-industrial waste, offer alternatives. Black soldier fly (*Hermetia illucens*, BSF) larvae efficiently bioconvert organic residues into nutrient-rich frass suitable for agricultural use. Olive pomace residue of the olive oil industry (exceeding 15 million tonnes/year globally), containing phytotoxic phenolic compounds and a low pH, presents both a waste management challenge and an opportunity for circular valorization. We assessed olive pomace and cereal-derived BSF frass as partial NPK substitutes in cabbage (*Brassica oleracea* var. *capitata*) production within a comprehensive environmental and agronomic framework. A greenhouse study (90 days, n = 5 replicates per treatment, 100 cabbages per treatment) compared six treatments: UF = unfertilized control; NPK = 100% NPK fertilizer; OP25 = 25% olive pomace-derived BSF frass + 75% NPK; OP50 = 50% olive pomace-derived BSF frass + 50% NPK; C25 = 25% cereal-derived BSF frass + 75% NPK; C50 = 50% cereal-derived BSF frass + 50% NPK. All fertilized treatments received the same amount of nitrogen (150 kg N ha⁻¹). We measured crop yield, soil biological activity (MacFayden mesofauna extraction, bait lamina feeding tests, and enzymatic activities), decomposition kinetics (Tea Bag Index), plant physiology (gas exchange and pigments), and environmental safety (*Daphnia magna* - acute toxicity on soil elutriate). An increased marketable yield (28-31%) was observed in the frass treatments compared to the unfertilized treatment, and a difference of (-3% to +9%) was noted compared to the 100% NPK treatment. Soil mesofauna was significantly higher in the treatment with 50% of BSF substitution to NPK fertilizer. Additionally, significantly higher feeding activity was observed in the BSF frass-treated samples, and no aquatic toxicity was detected in the soil elutriate. BSF frass from olive pomace and cereal substrates demonstrates promise as a partial NPK substitute, enhancing soil biological activity and ecosystem services while maintaining crop productivity and environmental safety. These findings support the use of circular bioeconomy approaches for valorizing agro-industrial residues such as olive pomace using insects as bioconverters.

3.25.P-Th102 Assessment of Animal Manures as Sources of Microplastics and Phthalates in Agricultural Soils

Sheharyar Farid, Mark Gerard Healy, Ana R. Marques Mendes and Liam Morrison, University of Galway, Ireland

Plastics and their associated chemicals are widespread across environmental compartments. The land application of animal manures raises concerns about the contribution to microplastics (MPs) and plastic-derived chemicals such as phthalates contamination in soils. Once present, these contaminants may persist, interact with soil biota, and enter food and water pathways, posing risks to environmental and human health. Nevertheless, the sources, behaviour and fate of MPs and phthalates introduced to agricultural environments via organic amendments remain poorly characterised.

This study investigates manures from bovine, ovine, chicken, duck, and pig production systems in Ireland to assess their potential contribution to MPs and phthalates in agricultural soils. Representative manure samples were collected from farms across the country. The research is currently in its method development phase, focusing on analytical techniques for the extraction, isolation, and quantification of MPs and phthalates. This includes optimisation of organic digestion and filtration methods for MPs and solvent extraction, followed by gas chromatography–mass spectrometry for phthalates. Once validated, these methods will be applied to characterise and quantify MPs and phthalates in the collected manure samples

The outcomes will provide baseline data on the occurrence and variability of MPs and phthalates in different manure types and offer insight into their potential contribution to soil contamination and subsequent exposure pathways within an Irish context. This work will contribute to a better understanding of how agricultural recycling of organic materials may act as a vector for plastic-associated pollutants and influence human

exposure through the soil–food–water nexus. The findings will inform future risk assessments and support the development of mitigation strategies for sustainable agricultural practices.

3.25.P-Th103 Assessing Metal Risks in Circular Insect Farming Using a Toxicokinetic Framework

Ana Eduardo Rodrigues¹, José Nereu Pinto², Ana Rita R. Silva³, Patrícia Veríssimo Silva⁴, Diogo Filipe Nunes Cardoso³ and Susana Loureiro³, (1)Department of Biology & CESAM-Centre for Environmental and Marine Studies, University of Aveiro, Portugal, (2)CESAM & Department of Biology, University of Aveiro, Portugal, (3)University of Aveiro, Portugal, (4)Department of Biology, University of Aveiro, Campus Universitário de Santiago, University of Aveiro, Portugal

Under the Novel Food Regulation (EU) 2015/2283, the yellow mealworm (*Tenebrio molitor*) is one of the four insect species currently approved for human consumption in the European Union. Its ability to grow on diverse organic waste streams supports circular food production, but also raises questions regarding contaminant transfer and safety. Although metal accumulation has been reported in edible insects, most studies rely on single-endpoint measurements, providing limited insight into how contaminants actually behave within insect tissues. A toxicokinetic (TK) approach is therefore essential to determine whether accumulation is temporary or persists despite depuration. To address this gap, we quantified the uptake and elimination kinetics of cadmium (Cd), arsenic (As), and lead (Pb) in *T. molitor* larvae. Organisms were fed metal-spiked semolina wheat for a period of 21 days (uptake phase), followed by a 21-day on unspiked food (elimination phase). Control groups were fed clean substrate throughout the experiment. Targeted exposure concentrations matched EU feed limits (Directive 2002/32/EC): 2 mg Cd/kg, 2 mg As/kg, and 10 mg/Pbkg. Organisms were sampled on days 0, 1, 3, 7, 14, 21, 22, 24, 28, 36, and 42; lyophilised, and their metal content was then analysed using inductively coupled plasma mass spectrometry. Accumulation in *T. molitor* was metal-specific. At the last day of exposure (day 21), Cd (2.6 ± 0.3) g Cd/kg; bioaccumulation factor [BAF]=2.03 and As (7.03 ± 1.05 g As/kg; BAF=32.82) exceeded the regulatory limits for feed in the EU after exposure. In contrast, Pb accumulated to a lesser extent (2 ± 0.62 mg Pb/kg; BAF=0.24). Cd was quickly eliminated and reached internal levels in larvae below the threshold after 1 day in the clean substrate, with half of the compound (DT50) being eliminated in 6.87 days. In turn, internal concentrations of As exceeded EU feed limits during the entire experiment, revealing a DT50 value of 94 days, whereas accumulated Pb was promptly eliminated (DT50=2.12 days). These findings suggest that safety cannot be inferred from exposure levels alone and must also account for depuration dynamics. TK parameters provide a predictive tool for regulatory decision-making by highlighting contaminants retained in insects after depuration. Integrating TK models into edible insect safety procedures is thus crucial to ensure that circular production systems are not only sustainable, but safe.

3.25.P-Th104 From Printed Disposable Wearable Electronics to Waste: Oxidation, Microbial Inhibition, and Environmental Impact of Copper, Silver, and Carbon Inks on Paper Substrates by Life Cycle Analysis

Margreet de Kok¹, Theresa Seeholzer², Minna Vikman³, Kirsi Immonen⁴ and shavini stuart⁵, (1)TNO, Netherlands, (2)infineon, Germany, (3)Technical Research Centre of Finland Ltd. (VTT), Finland, (4)VTT Technical Research Centre of Finland Ltd, Finland, (5)TNO Nederland, Netherlands

In the Sustronics project, funded by the EU, a smart wound dressing based on printed electronics has been developed that integrates a disposable electronic sensor built on sustainable substrates and comprising more sustainable electronic materials. The dressing is designed to electronically monitor pH and temperature to flag infection, enabling timely therapy adjustment and supporting improved patient outcomes . Flexible printed electronics based on printable inks on sustainable substrate materials like paper and biobased

plastics have several advantages over the conventional electronic technology which applies rigid FR4 boards and subtractive technology with considerable environmental impact.

Flexible printed electronics are expected to be more frequently integrated into products like clothing, health care wearable and consumer products. Therefore, these materials will increasingly enter hospital waste streams and municipal waste streams, with potential contact with nature through applications of bottom ash from waste incineration or via landfilling. This paper will use a biodegradation study of electronics in compost comprising Cu, Ag and Carbon particles on a paper substrate to apply first insights into exposure of nature to these new material combinations and provide insights to the LCA study of the End-of-Life Scenario. The metals showed inhibition in biodegradation of the substrate in contrast to carbon and more severely for the Cu filled material. Analysis of the compost after the biodegradation experiment suggested that the difference in inhibition is caused amongst others by the oxidation potential of the metals: less noble metals oxidise more readily and after being leached out into the compost inhibit microbes. These findings provide first insights into exposure risks from emerging material combinations in flexible electronics.

Modelling the end of life scenario's by LCA is presented but the background information for this phase of the life cycle is limited. The results underscore the need for dedicated inventory data and impact characterization tailored to printed electronics, and indicate that material selection (e.g., favoring carbon-based conductors over Cu) can reduce potential environmental burdens at end of life. This work contributes initial empirical evidence and methodological input to support future LCA of flexible electronics, and aims to steer the development of materials and designs that are more compatible with natural systems.

3.25.P-Th105 Emerging Pollutants in Walloon Sewage Sludge: Towards an Integrated Methodology to Evaluate Health and Environmental Impacts of Farmland Spreading

Cecile Kech, Stephanie Bemelmans, Carole Chalon, Yves Marneffe, Pierre Jacquemin and Caroline Nadin, Scientific Institute of Public Service (ISSEP), Belgium

In Wallonia (Belgium), farmland spreading is the main solution for sludge management. Prior to land application, regulatory quality control covers only a few parameters, including common organic pollutants. However, emerging substances in sewage sludge have been poorly explored to date.

The main objective of the study was to assess the impact of sludge farmland spreading on human health and the environment, with a focus on some endocrine disruptors (EDCs) and pharmaceutical products. Following a prioritization of relevant substances and a selection of Walloon Waste Water Treatment Plants (WWTPs), chemical and ecotoxicological characterization of sludges was carried on. Finally, a health risk was assessed. The aim of the prioritization was to highlight the substances likely to be found in sludges and potentially having the highest hazards for humans and the environment. The methodology was based on physico-chemical properties and regulatory criteria. Presence in Walloon sludges was then confirmed using high-resolution chromatography techniques, and a specific chemical characterization was carried out. At the same time, an ecotoxicological characterization assessed the intrinsic toxicity of raw sludge and the effect of sludge mixed with soil using a battery of tests. The scope of this battery meant that all aspects are covered: terrestrial and aquatic ecosystems, different trophic groups, complementary forms of toxicity, direct and indirect exposure routes. In addition, the endocrine disruption potential was characterized using in vitro YES/YAS tests. Finally, the assessment of the health risks associated with the use of WWTP sludge in agriculture was conducted by modelling exposure doses on the basis of the chemical results.

In conclusions, prioritization step sets up a list of 69 substances, and 29 representative WWTPs with authorisation to spread the sludge in Wallonia. The specific chemical characterization was carried out based on 160 sludges. The EDCs analyzed belong mainly to the chemical families of alkylphenols, chlorophenols, phthalates, perfluoroalkyl compounds (PFAS) and personal care products. A general frequency of 36% was observed with two EDCs over 95%. The ecotoxicological characterization on 29 sludges shows six sludges with high effects (indirect and direct exposure). And finally, based on some assumptions, results of the risk assessment show that a risk associated with PFOS and PFOA in WWTP sludge farmland spreading cannot be excluded.

3.25.P-Th106 Risk Assessment of Organic Contaminants in Sewage Sludge Applied to Agricultural Soil
Trine Eggen¹, Stefan Trapp², Christian Vogelsang³, Merete Grung³, Christiane Kruse Fæste⁴, Aksel Bernholft⁵, Gunnar Sundstøl Eriksen⁵, Veronika Sele⁶, Belinda Flem⁷, Håvard Steinshamn¹, Robert Barneveld¹, Carl Einar Amundsen⁸, Barbara Alexandra Bukhvalova⁹ and Tron Øystein Gifstad⁹, (1)NIBIO Norwegian Institute of Bioeconomy Research, Norway, (2)Department of Environmental and Resource Engineering, Technical University of Denmark, Denmark, (3)NIVA, Norway, (4)Norwegian Veterinary Institute, Norway, (5)VI Norwegian Veterinary Institute, Norway, (6)HI Institute of Marine Research, Norway, (7)NGU Geological Survey of Norway, Norway, (8)Retired, Norway, (9)VKM Norwegian Scientific Committee for Food and Environment, Norway

The Norwegian Scientific Committee for Food and Environment (VKM) has on request from The Norwegian Food Safety Authority (NFSA) performed a risk assessment of organic contaminants in sewage sludge. Norway is an elongated country where climate precipitation and temperature vary highly, and thus also agricultural cropping systems and practice. Five municipalities/regions across North, South, East, and West were chosen to capture climate and agricultural differences and thus used in the risk assessment.

In the present risk assessment NFSA asked for evaluation of many scenarios including today's common sludge application according to today's the Norwegian fertiliser regulation in terms of amount of sewage sludge, application time before cultivation or harvesting. In addition, it was asked for an evaluation of new ways of application of sewage sludge and of sewage sludge-based products as biochar, ash and struvite and some other sludge-based products. Application methods (effect on soil depth and soil mixing or not), and shorter period from application before cultivation and harvesting, were also included.

A science-based risk assessment was conducted, consisting of the four steps: i) identifying hazards (measured data), ii) description and characterisation of the hazards (from literature), iii) assessment of exposure/intake of the hazard (modelling), and iv) description/characterization of risk (Comparing exposure to toxic effect level). Target organisms in the risk assessment included environmental living organisms in water and soil, farm animals – including grazing animals, and humans. Due to lack of knowledge, risk towards farm animals and humans were not a proper risk assessment but an evaluation of likelihood for increased exposure over years of sewage sludge application (up to 100 years). In addition, for selected contaminants terrestrial secondary poisoning of mammals and bioaccumulation in fish and potential transfer to humans and up in the food web were evaluated.

The number of organic contaminants in sewage sludge is large, around 1000 different compounds have been analysed for in Norwegian sewage sludge, and a prioritisation of contaminants were performed, following same approach as JRCs screening for organic contaminants in wastewater from 2022.

Highlights from the risk assessment will be presented, as well as some urgent knowledge gaps in order to develop robust and reliable risk assessments.

3.25.P-Th107 The impact of pyrolytic conversion and biochar amendments on metal exposure and mobility in soil

Kristin Ivanova Kostadinova¹, Clara Benedikte Mader Lade¹, Flora Anna Zentai¹, Heidi Birch² and Philipp Mayer¹, (1)Technical University of Denmark (DTU), Denmark, (2)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark

Over the last two decades, pyrolytic conversion and biochar amendments have emerged as promising technology within waste management, resource recovery and contaminant remediation. More recently, large scale biochar amendments have been suggested as an important pillar for carbon capture within the green transition of Danish Agriculture, which has triggered concerns and discussions about the associated contamination risks. This concern is particularly relevant for metals, which are known to up-concentrate in biochar. However, pyrolysis also promotes the formation of mineral phases which enhances metal retention in the solid phase, thereby reducing aqueous metal concentrations and hence metal mobility. These changes would then be reflected in a higher solid–water distribution coefficients (KD values). This raises critical questions regarding the environmental fate of metals in biochar-amended soils, including their mobility, leaching potential, and long-term impacts on soil and water quality.

This study addresses these concerns by investigating the behavior of metals in biochar, with a focus on their exposure and mobility under varying pH conditions. Carefully paired samples from wastewater treatment plant (WWTP) sludge and biogas residue fiber, along with their corresponding biochars, were obtained from full-scale pyrolysis plants in Denmark. Aqueous-phase metal concentrations in equilibrium with the feedstocks and their derived biochars were analyzed, covering a wide range of elements, including rare earth elements (REEs). To further assess metal partitioning between solid and aqueous phases, solid–water distribution coefficients were determined with two different approaches. Finally, column experiments were conducted to determine the

metal leaching from soils at varying amendments of biochar from straw, biogas residue fiber and WWTP sludge.

3.25.P-Th108 Reduced Leaching of PFAS and Polar Organics from Biochar: The Combined Effect of Pyrolytic Removal and Increased Sorption

Clara Benedikte Mader Lade¹, Kristin Ivanova Kostadinova¹, Svante Rehnstam², Benjamin Schneider¹, Heidi Birch³, Wolfgang Stelte¹, Lutz Ahrens⁴ and Philipp Mayer¹, (1)Technical University of Denmark (DTU), Denmark, (2)Lennart Hjelm's väg 9, Swedish University of Agricultural Sciences (SLU), Sweden, (3)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark, (4)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden

The Danish Government has presently a strong focus on pyrolysis as a key technology in the green transition in Denmark. This is due to its potential and increasing applications within circular economy, carbon sequestration, soil improvement, and contaminant removal. Sewage sludge (SS) from wastewater treatment plants (WWTPs) and biogas residue fiber (BRF) from biogas production offer high nutrient content that makes them promising candidates as fertilizers. However, the presence of heavy metals and organic pollutants such as per- and polyfluoroalkyl substances (PFAS) in the feedstock or contaminants produced during pyrolysis, has raised concerns regarding its safe utilization as biochar fertilizer. The critical question is therefore: How does the pyrolytic conversion of feedstock to biochar (BC) affect the exposure, mobility and potential impact of pollutants in the environment?

The first aim of this study is to determine the overall effect of the pyrolytic conversion of WWTP sludge and biogas residue fibers to biochar on the leachability, exposure and mobility of PFAS and polar organic contaminants. We hypothesize that pyrolysis substantially decreases aqueous concentrations for most if not all organic contaminants due to (1) pyrolytic removal and (2) increased matrix to water distribution coefficients. Dewatered SS and BRF were used as model feedstocks, with carefully matched samples of feedstock and BC obtained from different full-scale pyrolysis plants in Denmark. Equilibrium batch tests with feedstock and corresponding BC suspended in water were conducted, followed by up-flow column percolation tests with BC and soil mixtures. Aqueous concentrations from both experiments were measured across a broad range of polar organic chemicals including PFAS, utilizing advanced analytical techniques such as LC-HRMS. To comprehensively assess the impact of pyrolytic conversion on various pollutants, non-target analysis was conducted in addition to targeted PFAS analysis. The results from the batch equilibrium tests show exposure and leachability reductions of polar organic contaminants in BC relative to the corresponding feedstocks. The outcomes of this study will inform regulators on the potential environmental impact of biochar application in agriculture.

3.26 Soil–Plant Transport and Mineral Weathering: Spatiotemporal Environmental Implications

3.26.T-01 The Effects of Ageing and Heterogeneous Distribution of Perfluoroalkyl Acid (PFAA) in Soil on Their Uptake by Allotment Vegetables

Arne Vangansbeke¹, Jan Vanderborgh² and Erik Smolders¹, (1)KU Leuven, Belgium, (2)KU Leuven, FZ Jülich, Belgium

Home-grown vegetables are a known pathway for human exposure to per- and polyfluoroalkyl substances (PFASs). Although bioconcentration factors (BCFs; -) are available to relate soil contamination to plant concentrations, these values are often deduced under laboratory conditions and fail to take into account key environmental factors from the field. With PFAS contaminations often being decades old and concentrated in the upper part of the soil, this study assessed the effect of the ageing and heterogeneous distribution of the most widespread perfluoroalkyl acids (PFAAs) on their BCF in common allotment vegetables. To study ageing, a small pot trial was set up in which ¹³C-labeled PFAA components were added to three historically contaminated soils, on which celery and radish were planted. Results showed significantly higher BCF values for the ¹³C spiked compared to ¹²C aged PFAAs, with values decreasing with increasing chain length, irrespective of the contaminants' suspected age. To study the effect of heterogeneous PFAA distribution, the lower part of PVC pots (30-40 cm in height) was filled with uncontaminated soil, while historically contaminated soils were used for the upper part. Besides the aforementioned vegetables, also lettuce and hemp

were planted, the latter for its phytoremediation potential. While lettuce and celery have a shallow fibrous root system, radish and hemp have a deeper taproot system. This experiment is ongoing and results will be communicated at the conference. We speculate that root distribution critically explains the plant-specific BCFs in this setup. This study is anticipated to lead to more field-relevant BCF values than those based on spiked and homogenized soils.

3.26.T-02 A Novel Workflow to Identify the Environmental Fate of Emerging Contaminants in the Wastewater – Soil – Plant Continuum

John Nightingale¹, Laura Carter², Eyyatar Ben Mordechay³ and Benny Chefetz⁴, (1)University of Leeds, United Kingdom, (2)The University of Leeds, United Kingdom, (3)The Hebrew University of Jerusalem, Israel, (4)The Volcani Institute, Israel

The reuse of treated wastewater (TWW) for irrigation represents an important pathway through which emerging contaminants enter agroecosystems. Although environmental monitoring campaigns continue to expand, their success remains constrained by the performance and selectivity of multi-residue analytical techniques, which routinely overlook lesser-known chemicals in terrestrial matrices. Advances in environmental fate modelling and non-targeted screening (NTS) offer new opportunities to characterise contaminant behaviour across the wastewater–soil–plant continuum; however, the high cost, time demands, and methodological limitations of NTS restrict its widespread application. Here, we present a validated modelling framework and an accompanying Python workflow that integrates NTS data from wastewater treatment plant influents and effluents with advanced fate modelling tools. Model evaluation using targeted datasets (n = 69 chemicals; 9 Zea mays fields; 12 Solanum lycopersicum fields) demonstrated strong predictive performance, with 90.5% and 89.2% of measured concentrations meeting “good match” criteria for maize and tomato fruits/grains, respectively. When semi-quantified TWW concentrations were used to simulate PEC_{grain}, 88.89% of predicted values for Zea mays grains fell within one order of magnitude of semi-quantified measurements, including 17β-estradiol, carbamazepine, di(2-ethylhexyl) phthalate, dodecyl sulphate, N,N-diethyldodecanamide, N-phenyl-1-naphthylamine, octyl hydrogen phthalate, and venlafaxine. Model simulations further identified high-priority contaminants within plant tissues. In maize leaves, the top five emerging contaminants were 4-nitrophenol > fexofenadine > atenolol > octyl hydrogen phthalate > lidocaine, with a similar ranking observed in grains alongside PPG n4, 4-formylaminoantipyrine, carbamazepine, N-phenyl-1-naphthylamine, and tris(2-butoxyethyl) phosphate. Pharmaceuticals were prevalent across TWW and plant matrices, with compounds such as estriol, carbamazepine, atenolol, 11-ketotestosterone, flecainide, trenbolone, atomoxetine, climbazole, and artemotil detected in both leaves and grains. Collectively, these results demonstrate that coupling NTS outputs with mechanistic modelling offers a scalable and transferable approach for predicting contaminant fate under real-world irrigation scenarios, while revealing overlooked chemicals of emerging concern in agroecosystems.

3.26.T-03 Quantifying the Impact of Plant Uptake on Watershed-Scale Pesticide Concentration in Flowing Water Bodies

Jens Kiesel¹, Hendrik Rathjens², Gerald Reinken³ and Robin Sur³, (1)Environmental Systems Modeling, Stone Environmental Inc., Germany, (2)Stone Environmental Inc., Austria, (3)Bayer Research & Development Crop Science, Germany

SWAT (Soil and Water Assessment Tool) is a widely used tool for modeling pesticide transport through agricultural watersheds. It is, however, currently lacking plant uptake functionality, although plants absorb chemicals from the soil, particularly persistent compounds that remain in the root zone due to slower soil degradation or reduced mobility. This represents a significant gap in simulating chemical fate processes, as plant uptake can remove substantial amounts of pesticides from soil systems during growing seasons. In this work we updated the SWAT code to include plant uptake, building on recent improvements in the representation of subsurface chemical transport pathways including tile drain and groundwater flow. Our approach calculates uptake based on plant water consumption patterns, compound-specific resistance terms, and chemical concentrations in soil water. The implementation ensures that uptake occurs only during active plant growth periods and follows established water uptake distributions with depth. We tested the updated model in two European agricultural watersheds using a stable pesticide transformation product that is taken up by plants according to laboratory-derived uptake factors. Incorporating plant uptake reduced predicted concentrations of

the simulated metabolite in streamflow by 5 to 17%, with differences between catchments attributed to variations in agricultural land use intensity and cropping patterns. This indicates that plant uptake is an important removal pathway for slowly degrading compounds and provides improved capability for evaluating farming practices and mitigation strategies. The enhanced model demonstrates very good performance while providing more mechanistically complete representation of chemical fate processes. We provide the new functionality for both SWAT2012 and SWAT+, enabling watershed managers and researchers to better assess pesticide environmental fate in agricultural systems.

3.26.T-04 Integration of Prospective Environmental and Economic Impact Assessment for Emergent Mineral Carbonation of Steel Slags Process Design in Agriculture

Ponnapat Watjanatepin¹, Lola Eelen¹, Laura Steinwilder², Nina Miladinović¹, Luka Ceyssens¹, Tom Van Duyse¹, Sara Vicca², Tom Van Gerven¹ and Karel Van Acker¹, (1)KU Leuven, Belgium, (2)University of Antwerp, Belgium

Emerging technologies are often characterized by low Technology Readiness Levels (TRLs), which present challenges such as limited life cycle inventory data, high uncertainty in available datasets, and unknown economy-of-scale effects. These factors complicate the assessment of environmental and economic impacts. However, low TRL stages also offer opportunities for design flexibility and performance optimization, enabling improvements in both technological efficacy and sustainability outcomes compared to mature technologies. This study proposes an integrated framework for prospective environmental and economic assessment of emerging technologies. The framework combines Life Cycle Assessment (LCA) and Life Cycle Costing (LCC) with Multi-Criteria Decision Analysis (MCDA) using the Analytical Hierarchy Process (AHP) to evaluate trade-offs and identify optimal scenarios. Prospective LCA (pLCA) is employed as a scenario analysis tool to determine key technological parameters influencing global warming potential (GWP) and overall environmental performance. The approach is demonstrated through a case study on mineral carbonation of steel slags as a carbon capture, utilization, and storage (CCUS) technology. Results identify optimal carbonation conditions based on environmental and economic criteria, estimate ideal process durations, and highlight carbonation efficiency as a critical parameter for reducing GWP. This framework provides actionable insights for guiding the development of emerging technologies toward environmentally and economically sustainable pathways.

3.26.T-05 Fate of Pharmaceuticals and Human Health Risk Assessment in Agricultural Water Reuse: Case Studies in Greenhouse and Soil Cultivation.

Birte Raes¹, Josephine Vosse², Gianluigi Buttiglieri², Birgit De Bock¹, Ado Van Assche³ and Joris De Nies³, (1)AquaFin, Belgium, (2)ICRA-CERCA (Catalan Institute for Water Research), Spain, (3)Proefstation voor de Groenteteelt vzw, Belgium

Water scarcity in agriculture is increasing due to changing climate conditions, driving interest in reclaimed water as an alternative irrigation source. The LIFE ACLIMA project demonstrates climate-adaptive solutions for horticulture and agriculture in Flanders, including reuse of municipal wastewater treatment plant (WWTP) effluent. EU Regulation 2020/741 sets minimum requirements for agricultural water reuse regarding e.g. pathogens, but micropollutants such as pharmaceuticals lack target values and require risk-based evaluation. In Flanders, the Decision of the Flemish Government provides detailed guidance for environmental risk assessment of micropollutants. However, human health risk assessment (HHRA) remains undefined, creating uncertainty and acting as a barrier to circular water adoption in agriculture. The LIFE ACLIMA project addresses this gap by evaluating the fate of pharmaceuticals and associated human health risks in two effluent-irrigated systems: (i) greenhouse bell pepper cultivation and (ii) open-field soil cultivation. Pharmaceuticals were detected in irrigation water and, at low concentrations, in greenhouse fruits and leaves. Soil trials as well confirmed pharmaceutical uptake in the fruits in low concentrations. HHRA was performed by estimating daily intake (EDI) from measured crop concentrations and comparing it to acceptable daily intake (ADI). To ensure a precautionary approach, multiple ADI values are generated based on various thresholds and the most conservative ADI values were applied in all calculations. Under these assumptions, consumer exposure remained well below thresholds of concern, indicating negligible health risk for the tested scenarios. These findings provide critical evidence for regulatory frameworks and risk communication. While pharmaceuticals can enter the food chain through reclaimed water irrigation, current data suggest minimal human health risk when conservative assumptions are used. Further research on additional crops, long-term soil dynamics, and cumulative exposure is recommended to strengthen confidence in safe water reuse practices.

3.26.P Soil–Plant Transport and Mineral Weathering: Spatiotemporal Environmental Implications

3.26.P-Th109 Assessment of Organic Contaminant Uptake in Field-Grown Fruits Irrigated with Recycled Water and Amended with Class A Biosolids

Audrey Jeanne Braun, Nicole M Dennis Ph.D, Rebecca E Yates and Jay Gan, University of California, Riverside, United States

As pressures on freshwater resources intensify, recycled water and Class A biosolids are gaining recognition as valuable inputs for sustainable agriculture, offering agronomic benefits such as improved soil quality, enhanced plant growth, and nutrient recycling. However, both recycled water and biosolids can contain trace concentrations of unregulated organic chemicals (UOCs), including pharmaceuticals, personal care products, plasticizers, flame retardants, and per- and polyfluoroalkyl substances. Despite growing interest in repurposing these waste-derived materials, data on plant accumulation of UOCs and subsequent human dietary exposure remain limited, particularly under field conditions.

To address these knowledge gaps, a large-scale field study was conducted in semi-arid Southern California using integrated recycled-water irrigation and biosolids fertilization. Four staple fruit crops, i.e., apple, avocado, mandarin, and peach, were grown using standard agronomic practices, with tertiary treated wastewater as the sole irrigation water source and Class A biosolids partially or fully replacing synthetic fertilizers. A list of 24 UOCs were targeted for analysis using UPLC-ESI-MS.

In our previous study on vegetable crops, 20 UOCs were detected at concentrations from 0.93 to 455 ng/g dry weight (d.w.). Dietary intake estimates for these UOCs, based on U.S. EPA reference consumption rates, suggested an adult annual intake of 4880 µg, equivalent to < 0.2 µg/kg body weight per day for a 70 kg person. Compared with available acute toxicity data, these exposures are several orders of magnitude below levels known to cause adverse effects. We therefore hypothesize that concentrations in fruit trees, given their greater biomass and longer growing season, will be even lower, supporting the sustainable reuse of large volumes of biosolids.

These findings provide field-based insights into the environmental behavior and food-chain transfer potential of UOCs in agricultural systems, suggesting that treated municipal wastewater and biosolids can be safely integrated into food production within a circular economy framework. Future work will expand these investigations to long-term and multi-season trials that assess cumulative effects of repeated applications. Collectively, these studies will inform human health and ecological risk assessments and support best management practices for the responsible and sustainable reuse of treated waste-derived resources in agriculture.

3.26.P-Th110 Environmental Distribution and Soil-Plant Transfer of Carbon Based Nanomaterials

Siyaari Jamatia, Arun Kumar and Arya Vijayanandan, Indian Institute of Technology Delhi, India

Carbon-based nanomaterials (CBNMs), such as carbon nanotubes (CNTs) and fullerenes, are widely used in industrial products, textiles, coatings, batteries, and electronics. Their growing use has increased their release into the environment, with untreated wastewater contributing up to 99% of CNT emissions. Environmental fate studies also show that soils receive the largest share of these materials (about 91.2%), followed by freshwater systems (about 2.8%). Understanding how CBNMs accumulate in soil and how they move into edible plants is therefore important for assessing human exposure and potential health risks.

In this study, concentrations of CNTs and fullerenes in soils and sludge-treated soils were collected from the literature to develop realistic exposure ranges. The data were log transformed and analyzed using the mean, standard deviation, standard error, and two-tailed 90% confidence intervals (CI), which were later back-transformed to original units. CNT concentrations were consistently higher than those of fullerenes in both soil types. In sludge-treated soils, CNTs had a mean concentration of 59.13 ng/kg (90% CI: 37.35–93.63), which was about 18 times higher than fullerenes (3.29 ng/kg; 90% CI: 1.12–9.64). In natural soils, CNT concentrations (1.88 ng/kg; 90% CI: 0.99–3.58) were around 31 times higher than fullerene levels (0.06 ng/kg; 90% CI: 0.025–0.142), indicating that CNTs are more persistent in the environment.

Root–shoot transfer factors (TFs) were compiled across plant species to assess internal mobility. CNTs exhibited very low transfer, with TF values ranging from 0 to 0.10, whereas fullerenes showed significantly

higher mobility, with TF values ranging from 0.049 to 1.156. The highest fullerene TF was roughly 12 times greater than the maximum CNT TF, and the average fullerene mobility was 10-15 times higher. Overall, CNTs tend to remain in soil for longer periods, while fullerenes move more easily within plant tissues. These contrasting behaviors highlight the need for more accurate exposure assessments of CBNMs in agricultural environments.

3.26.P-Th111 Refining The Hydroponic Method For Determining Plant Root Uptake Of Chemicals: An Evolved Ring Test Design

Maximilian Küppers and Marc Lamshöft, Bayer Research & Development Services LLC, Germany

Uptake of soil chemicals into plants critically shapes environmental fate and is quantified in models like PEARL and PELMO via the Transpiration Stream Concentration Factor (TSCF). Hydroponic studies isolate root uptake from soil effects (sorption, degradation), revealing a compound's intrinsic uptake potential. An earlier OECD round robin test using a prior design showed substantial inter-laboratory variability. Building on those findings, the CLE/IVA Working Group "Plant Uptake" developed an evolved hydroponic protocol to target key sources of variation.

Key refinements to reduce variability

- Growth stage standardization: Plant age is replaced with BBCH growth stages (e.g., BBCH 12–13 and 21–24) to improve physiological uniformity across labs.
- Environmental control: Light is specified by PPFD within 150–550 $\mu\text{mol}/\text{m}^2/\text{s}$, a biologically relevant metric, instead of illuminance (Lux).
- Chemical/analytical precision: Nutrient solution pH tightened to 5.5–6.0; mass balance recovery constrained to 95–105%.

Validation via ring test A five-laboratory inter-laboratory ring test was initiated using 1,2,4-triazole as the test item. Preliminary results from one lab show excellent intra-laboratory precision:

- BBCH 11–12: Mean TSCF ? 0.46, 0.47, 0.43 at 0.1, 1, and 10 $\mu\text{mol}/\text{L}$.
- BBCH 21–24: Mean TSCF ? 0.57, 0.58, 0.55 at the same concentrations.

Early data suggest the refined protocol produces robust, reproducible TSCF measurements across concentrations and growth stages. The forthcoming full presentation will deliver a comprehensive statistical analysis from all five laboratories, quantify improvements in inter-laboratory reproducibility relative to the previous study, and provide a formal validation of the evolved test design.

3.26.P-Th112 Upward Movement of Dimethylsilanediol (DMSD) in Soil-Plant Systems

Jaeshin Kim¹, David Adrian², Shihe Xu³ and Marc-André Courtemanche², (1)Dow Chemical Company, Midland, United States, (2)Dow Chemical Company, United States, (3)Tridge Environmental Consulting LLC, United States

Methylsiloxanes, both polymeric and oligomeric, are widely used in consumer and industrial products. Their environmental degradation, particularly following land application of wastewater sludge, leads to the formation of smaller degradation products. Among these, dimethylsilanediol (DMSD) is a key monomeric hydrolysis product. Although DMSD is known or expected to occur in soil, its transport behavior has yet to be comprehensively characterized. To address this, we developed a dynamic model to estimate DMSD formation and movement under varying weather scenarios. Model parameters were optimized using experimental data

from bench-scale soil column studies. In these experiments, octamethylcyclotetrasiloxane (D4), a parent compound, was spiked into the topsoil to simulate realistic conditions and track DMSD behavior. The model confirms that DMSD generation from D4 increases as soil moisture decreases and that DMSD migrates upward with water and volatilizes at the soil surface during dry conditions. It also enters plant roots and translocates through the stem to the leaves, facilitated by its high water solubility and low affinity for plant tissues. Unlike typical soluble pesticides found in agricultural soils, DMSD can volatilize from leaf surfaces without accumulating in the plant, due to its relatively low KOA value. These results suggest that DMSD primarily moves upward in soil and plants, with volatilization to air being a dominant pathway. Downward transport toward groundwater appears unlikely. Understanding this behavior is essential for assessing environmental exposure and potential risks associated with siloxane degradation products.

3.26.P-Th113 Four years of monitoring the behavior of micropollutants whose source is treated wastewater or sludge from wastewater treatment plants in the soil-water-plant system

Radka Kodesova¹, Alina Sadchenko², Ales Klement³, Miroslav Fér⁴, Helena Švecová², Antonin Nikodem⁴, Jindrich Zelinka⁴ and Roman Grabic², (1)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (2)University of South Bohemia in České Budějovice, Czech Republic, (3)Department of Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (4)Czech University of Life Sciences Prague, Czech Republic

To assess the behavior of selected micropollutants in the soil-water-plant system, nine raised beds were installed in March 2021 at the wastewater treatment plant for ?eské Bud?jovice WWTP in the Czech Republic. Two beds contain soil taken from the surface horizon of the Arenic Regosol and seven beds contain soil from the surface horizon of the Eutric Cambisol. Several scenarios were implemented: A. irrigation with drinking water (control); B. irrigation with treated wastewater; C. application of treated sewage sludge; and D. application of composted sewage sludge. In 2021, either corn or a mixture of different types of vegetables (lettuce, onions, carrots) was grown on the beds. Results from this year have been published by Kodešová et al. (<https://doi.org/10.1016/j.scitotenv.2023.167965>). The experiment continues and other types of crops are grown in the beds. Both biosolids are applied every year before planting or sowing plants. Since 2022, the beds with composted sewage sludge have been additionally irrigated with treated wastewater, and since 2023, the beds have been roofed so that the behavior of micropollutants is not affected by rainwater. Initially, attention was paid primarily to pharmaceuticals, and later other substances were included in the monitoring, such as those found in tires, surfactants, dyes, fire-fighting foams, disinfectants and cleaning products. In general, compounds of high sorption and high stability in the environment were accumulated in the soils. Mobile compounds were found in the water drained from the beds, taken up by plants and accumulated in the leaves. Less mobile compounds remained mainly in the underground parts of the plants. However, it was also found that some compounds, despite being highly sorbed in the soil environment and having a low potential to be transported in plants due to their properties, were accumulated in the leaves or were leached from the beds. Compost reduced the leaching and uptake of compounds from wastewater. After the roof was installed, the concentrations of substances in the monitored system increased and more compounds were quantified than in the first two years.

3.26.P-Th114 Dynamic Modeling of Pesticide Uptake From Coated Seeds Into Maize Plants and Translocation to Pollen

Arno Rein¹, Stefan Trapp², Klaus Hammel³ and Peter Fantke⁴, (1)Chair of Hydrogeology, TUM School of Engineering and Design, Technical University of Munich, Germany, (2)Department of Environmental and Resource Engineering, Technical University of Denmark, Bygningstorvet 115, DK-2800 Kgs. Lyngby, Denmark, Denmark, (3)Bayer AG, Crop Science Division, Environmental Safety, Germany, (4)substitute ApS, Graaspurvevej 55, 2400 Copenhagen, Denmark; Department for Evolutionary Ecology and Environmental Toxicology, Goethe University, 60438 Frankfurt am Main, Germany; Department of Environmental Sciences, College of Agriculture and Environment, Denmark

Agricultural insecticides are often applied via seed coating. The resulting chemical residues can potentially impact pollinating insects, an important aspect currently not included in evaluating the environmental performance of product and technology life cycles. Here, we propose a dynamic mechanistic model for chemical

plant uptake from soil and translocation to nectar and pollen, for simulating residue concentrations in soil and plant parts as a function of time. Modeling results were compared with concentrations of different insecticides observed in field experiments with seed (or soil) and spray application.

Observed concentrations could be explained well by modeling. Highest concentrations in stem, leaves, flowers and thus also pollen were seen during times of intense growth and small plant mass: at the beginning of the exponential growth phase, when intense fluxes by transpiration and assimilate stream meet small compartment volumes. Degradation rates were calibrated with the model, which exceeded dissipation rates directly fitted to measured concentrations. This can be explained by the continuous delivery of chemical mass predicted by the model due to translocation from roots via stem to leaves, flowers and pollen, which cannot be considered by empirical methods. Simulated dissipation encompasses growth dilution, degradation and (if relevant) volatilization with half-lives of 0.17-0.53 days for pollen, close to half-lives observed for pesticides applied via spraying. In the simulated field tests, 1 mg imidacloprid was applied per seed (11.9-13.5 mg/m²) with resulting pollen concentrations of 0.001-0.012 mg/kg fresh weight during the pollen shed period. Corresponding RUD (residue per unit dose) values are 0.0083-0.1 mg/kg per kg applied on one ha, which is low compared to the median RUD reported for spray application (26 mg/kg). Hence, seed coating is an effective application method for insecticides, but the drawback is the presence of toxic residues during the whole growth period, endangering visiting insects, such as pollinators, which can potentially be exposed.

In conclusion, our model predicts translocation of mobile, persistent and non-volatile chemicals from soil to pollen. This holds also for PMT (persistent, mobile, toxic) compounds present in reclaimed wastewater for irrigation and in sewage sludge applied to fields. Our model can be incorporated into existing frameworks to consider exposure and life cycle impacts on pollinating insects.

3.26.P-Th115 Plant uptake of Organic Chemicals from Sewage Sludge applied to Norwegian Fields – Part of a Risk Assessment

Stefan Trapp¹, *Christian Vogelsang², Merete Grung² and Trine Eggen³*, (1)Technical University of Denmark (DTU), Denmark, (2)Norwegian Institute for Water Research, Norway, (3)Norwegian Institute of Bioeconomy Research, Norway

The Norwegian authorities commissioned a risk assessment of organic micropollutants in sewage sludge applied on agricultural fields. To this end, results from chemical analysis of sludge from the Norwegian sewage treatment plants were collected, together with soil properties and crop rotation data for Norwegian regions. Chemical data were downloaded from CompTox, additional physico-chemical properties were estimated with ACD. The median value of the 90%-percentiles of the measured sludge concentrations at individual sludge facilities divided by PNEC soil was employed to pre-select and reduce the number of chemicals to 301. This includes 95 medical drugs, 47 chemicals in cosmetics (among them siloxanes and benzalkoniumchlorides), 16 flame retardants (hereof 7 polybrominated), 14 PAH, 20 pesticides, 13 per- and polyfluorinated compounds, 16 plasticisers and 29 other chemicals added to plastic, six rubber chemicals, 17 surfactants, plus fragrances, solvents, antioxidants, coatings, corrosion inhibitors and others.

K_d and K_{oc} were determined for typical soils from five regions. Measured values were preferred, else, regressions (TGD for neutral chemicals, Franco and Trapp for acids and bases) were used. Bioconcentration factors in carrots, potatoes, grass and cereals were calculated with crop-specific plant uptake models. Concentrations in soil are calculated following the approach in TGD, but modified for Norwegian scenarios. Biodegradation rates are estimated with Biowin, unless measured high-quality data are found in literature. Results were sorted for bioconcentration factors (BCF), and for (preliminary) concentrations in crops. These preliminary results indicate that many chemicals well known from field studies rank high in the list of plant uptake, among them carbamazepine, caprolactam, triclosan, TCPP, TBEP, acetylsalicylic acid, benzalkoniumchlorides and fluorinated compounds. All top 100 chemicals with highest BCF have K_{oc}-values below 1000 L/kg (M, mobile), and many below 100 L/kg (vM, very mobile). However, also the very lipophilic chemicals, such as PAH, PBDE and siloxanes can pose a risk due to soil attachment and grazing animals. Calculated concentrations in crops will further be processed to calculate risks for humans, farm animals and wildlife under various scenarios of sludge application. The results will serve to decide about permitted application schemes in Norway.

3.26.P-Th116 Can Oil (Palm) and Water Mix? Ecological Risk of Heavy Metals in an Oil Palm Plantation
Nicholas Porter¹, Elma Lahive², M. Gloria Pereira¹, Emily Forbes³, Susan Zappala³, Claus Svendsen¹, Peter Kille⁴, Jason Weeks⁵ and Benoit Goossens⁶, (1)United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)MacLean Building, United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Joint Nature Conservation Committee (JNCC), United Kingdom, (4)Cardiff University, United Kingdom, (5)Joint Nature Conservation Committee (JNCC), ., United Kingdom, (6)Cardiff University, Danau Girang Field Centre (DGFC), United Kingdom

The high yield potential of oil palm, alongside ever-increasing demand for palm oil derivatives, drives frequent agrochemical use to maximise productivity. Agrochemicals, such as fertilisers, can contain impurities such as heavy metals. These unintentional releases of heavy metals can cause toxic effects in organisms and pose a threat to health of the wider ecosystem. With over 30 million hectares planted with oil palm globally, and ongoing expansion in many places, understanding the ecological risk of such pollutants is critical knowledge that will underpin future management strategies to promote sustainable production. In this study, an ecological risk assessment was performed for aquatic species in water bodies receiving inputs from an oil palm estate in Sabah, Malaysia. Concentrations of 11 metals were measured in a total of 86 water samples collected from subsidiary drains (within planted blocks), boundary drains (surrounding planted blocks), and nearby tributaries. Predicted No Effect Concentrations (PNECs) for freshwater organisms were extracted from the Norman Network Ecotoxicology Database of lowest PNECs. The total dissolved concentrations of trace elements were then compared to PNECs to assess risk using a risk quotient approach. A risk quotient >1 indicates that aquatic organisms may be at risk of toxic effects. Across these 11 metals, risk quotients ranged from <0.0001 (seen for molybdenum) suggesting negligible risk, to 138.7 (seen for cobalt) suggesting high risk. Notably, As, Co, Cu, Ni and Zn showed risk quotients >1 for 44%, 67%, 59%, 80% and 52% of samples respectively. This suggests possible risk of aquatic toxicity from multiple metals in oil palm influenced waterbodies. Furthermore, the trend in risk for the majority of elements followed the pattern: subsidiary drains > boundary drains > tributaries likely due to a combination of proximity to sites of agrochemical application and dilution. This study presents a risk assessment of heavy metals in waterbodies of oil palm plantations, revealing that metals may pose a risk to aquatic organisms. Future work should investigate how metal translocation and risk varies over time as well as the direct contribution of agrochemical use to dissolved metal concentrations. Finally, the PNEC values used here are for temperate species, therefore, the relative sensitivity of analogous native species is needed to account for sensitivity differences and determine real world risk in these ecosystems.

3.26.P-Th117 Transformations of ZnO ENPs Change Everything: Bioaccumulation, Plant Health, and Soil Microbiome Response

Anna Ziarkowska, Mikołaj Feculak and Izabela Joško, University of Life Sciences in Lublin, Poland

Engineered nanoparticles (ENPs) released into the environment, including soil, undergo physical, chemical, and biological transformations that alter their properties, mobility, and bioavailability in the soil-plant system. Pristine (p-ENPs) and transformed (trans-ENPs) ENPs differ in solubility, sorption, and bioaccumulation potential, which may promote plant growth or cause toxicity at higher concentrations. Significant knowledge gaps remain regarding the accumulation of Zn released from ZnO ENPs in edible plants. Furthermore, the impact of multiply transformed forms of ZnO ENPs on Zn bioavailability in soil and its subsequent transfer through the food chain remains unknown. The aim of this study was to determine the effect of ZnO ENP transformation on Zn accumulation in lettuce and spinach and to assess plant health indicators (chlorophyll, MDA level), with particular emphasis on potential risks to consumers. The next step was to determine the effect of ZnO ENPs on the activity of extracellular enzymes in soil and to determine the copy numbers of bacterial genes involved in C, N, and P cycling. Plants were grown in LUFA 2.3 soil enriched with p- or trans-ZnO ENPs or ZnSO₄ (20 and 200 mg Zn/kg). Chemical modification of ZnO ENPs involved sulfidation of ENPs (sulf-ZnO ENPs) by aging in sulfide ion solutions. Biological modification of ENPs consisted of protein-coated BSA (BSA@ZnO ENPs). Doubly converted ZnO ENPs were obtained by forming a protein corona on the sulfided ENPs (BSA@sulf-ZnO ENPs). The results show that Zn bioavailability in soil depends on the dose and form of ZnO ENPs, and accumulation in plants also depends on the species. The highest Zn concentrations in roots were observed after p-ZnO, and the lowest after ZnSO₄. Furthermore, p-ZnO demonstrated limited translocation, while ZnSO₄ demonstrated greater mobility. All risk indices (EDI, HRI, THQ) were <1, indicating no health

risk. Chlorophyll and MDA content depended primarily on the type of ENPs. Analysis of soil enzyme activity indicates that microorganisms adapt to ZnO ENPs, and longer exposure may even increase the activity of organic matter-degrading enzymes. It is worth emphasizing that trans-ZnO ENPs exhibit a different pattern of accumulation in soil and exert a different effect on plants and soil microbiota than p-ZnO ENPs. These findings represent an important step towards understanding the fate and effects of trans-ZnO ENPs in the soil-plant system.

These studies were carried out as part of the project titled “Chemical and biological transformations of metal-based nanoparticles and their role in the transmission of emerging contaminants from soil to the human diet” funded by National Science Centre (2021/43/B/NZ9/02857).

3.26.P-Th118 Potential risks of enhanced weathering for climate, human health, and ecosystems

Selene Cobo¹ and **Gonzalo Guillén-Gosálbez²**, (1)University of Cantabria, Spain, (2)ETH Zurich, Switzerland

Enhanced weathering has recently gained attention as a promising CO₂ removal (CDR) practice, but previous analyses are based on theoretical assumptions that differ substantially from experimental observations and overlook the risks of heavy metal emissions. Here, we draw on the results of existing experimental studies to conduct a prospective life cycle assessment of alternative enhanced weathering scenarios. We find that initial CDR is insufficient to counterbalance greenhouse gas emissions occurring throughout the rock supply chains in some scenarios, only achieving net removal one to four decades after rock particles are applied on inland areas. Moreover, our results indicate that enhanced weathering could entail substantial damage to human health and ecosystems. Initially, these impacts are mainly linked to the rock transportation and quarry operations, but in subsequent years health risks could arise due to the potential release of toxic heavy metals. Contrary to the prevailing assumption, we find that zinc emissions from basalt could pose a greater health threat than nickel release from dunite. These preliminary results highlight the need for additional research—prioritizing non-agricultural areas to avoid food chain contamination—to demonstrate the short-term net climate benefits of enhanced weathering before CDR credits are commercialized.

S.C. thanks the Spanish Ministry of Science, Innovation and Universities for her Ramón y Cajal fellowship (RYC2022-035377-I). G.G.G thanks the Horizon 2020 program (grant agreement No 869192).

3.26.P-Th119 Arsenic bioaccumulation in alder trees (*Alnus* spp) from gold mine tailings, Nova Scotia, Canada: Implications for phytoremediation and environmental risk assessment

Ian Spooner¹, **Eve Pole²**, **Sarah Hines³** and **Nelson J O'Driscoll²**, (1)Earth and Environment, Acadia University, Canada, (2)Acadia University, Canada, (3)K.C. Irving Environmental Science Centre Acadia University, Canada

Speckled alder (*Alnus incana* subsp. *rugosa*) is a subspecies of *Alnus incana* with a wide range across the cooler regions of Northern America. Speckled alder provides essential habitat for a variety of wildlife and serves as a food source for small mammals and birds. Speckled alder commonly becomes established at mining and industrial sites however little is known about its phytoremediation potential or the metal bioaccumulation risk it may pose. We examine concentrations of arsenic (and other metalloids) in speckled alders that have become naturally established at a legacy gold mine tailings impoundment in Nova Scotia, Canada. Field sampling involved collecting alder leaves, catkins, and branches, as well as associated tailings soil, and surface and groundwater samples, which were analyzed for metals using X-ray fluorescence (XRF) and inductively coupled plasma spectrometry (ICP-MS). Arsenic concentrations in tailings impoundment soil (100- 3200 ppm), surface water (352 -3440 ppb) and groundwater (4320 - 5620 ppb) exceeded Canadian environmental guidelines (12 ppm soil, 5 ppb water). Average arsenic concentrations were 1362 ppb in catkins, 914 ppb in leaves and 313 ppb in wood. Our data suggests that speckled alder growing on legacy gold mine tailings tolerates high concentrations of arsenic and, as it is endemic to the area, may be an effective phytoremediator. However, preliminary data from alder growing on nearby but undisturbed soil indicates much lower As levels suggesting the increased potential for As in speckled alder growing on mine tailings to bioaccumulate in local wildlife. Further sampling is underway to provide guidance on determining bioconcentration factors to more accurately assess both phytoremediation potential and environmental risk to biota in the region.

3.26.P-Th120 Industrial chemicals in irrigated agricultural soils: a case study on the Great Bačka Canal, Vojvodina Province, Serbia

Nataša Đurišić-Mladenović¹, Igor Antić², Maja Buljovčić², Dušan Rakić² and Jelena Živančev², (1)University of Novi Sad, Faculty of Novi Sad, Serbia, (2)University of Novi Sad, Faculty of Technology Novi Sad, Serbia

Industrial chemicals, together with other micropollutants, are increasingly found in agricultural soils, mainly due to irrigation with surface waters receiving wastewater discharges, as well as the use of treated wastewater or sludge in crop production. In Serbia's intensively cultivated Vojvodina Province, irrigation practices often rely on water from the Danube-Tisa-Danube Hydro-System. Within this canal network, the Great Bačka Canal represents one of the most contaminated stretches due to a prolonged history of industrial and municipal effluents. Continuous use of the Great Bačka Canal water for agricultural irrigation creates conditions in which soils may act as long-term repositories for a broad spectrum of different contaminants. Thus, the objective of this study is to characterise the occurrence and distribution patterns of industrial chemicals in soils exposed to irrigation with water from the Great Bačka Canal.

To assess this potential occurrence, 100 soil samples were collected from four agricultural fields regularly irrigated with water from Great Bačka Canal. The samples were processed using the QuEChERS extraction protocol and analysed by liquid chromatography - high-resolution mass spectrometry. A comprehensive suspect-screening workflow was implemented to identify industrial chemicals repeatedly occurring in the soil samples. Contaminants were ranked according to detection frequency and annotation confidence, after which selected candidates were quantified using reference standards. Among detected compounds were triphenyl phosphate, tributyl phosphate, dodecyl sulfate, 2,5-di-tert-butylhydroquinone, triethyleneglycol bis(2-ethylhexanoate), dibutyl phosphate, triethyleneglycol bis(2-ethylhexanoate), and triphenylphosphine oxide with maximum concentrations up to 300 ng/g. The results highlight the importance of robust monitoring schemes that capture realistic exposure scenarios in agricultural areas affected by contaminated water sources, thereby supporting more reliable ecological and human health risk evaluations.

3.26.P-Th121 Pesticide Profiles in Irrigated Agricultural Soils from the Northern Serbian Province of Vojvodina

Jelena Živančev, Igor Antić, Maja Buljovčić, Dušan Rakić and Nataša Đurišić-Mladenović, University of Novi Sad, Faculty of Technology, Serbia

The presence of pesticide residues in agricultural soils reflects not only their field application but also the quality of water used for irrigation, which may serve as an additional pathway of contamination. In the northern Serbian Province of Vojvodina, farmers frequently rely on surface-water irrigation, and long-term use of water from impacted waterways can gradually alter the chemical status of soils. One such water source is the Great Bačka Canal (GBC), a section of the Danube-Tisa-Danube network historically burdened by diverse pollutant inputs. While its water quality has been studied extensively, much less is known about how irrigation with GBC water influences the pesticide residue patterns in surrounding soils.

To address this gap, this study investigated the occurrence of pesticide residues in soils collected from four agricultural sites that regularly rely on GBC irrigation. A total of 100 samples were analysed. Soil extracts were prepared using a QuEChERS-based procedure and analysed by liquid chromatography-high-resolution mass spectrometry. The analytical strategy combined broad suspect screening with targeted quantification of confirmed pesticide candidates.

Multiple pesticides were detected, including carbaryl, pyrimethanil, fluopyram, bentazone, metalaxyl, fluxapyroxad, metamitron, chloridazon, prometon, metolachlor and azoxystrobin, with concentrations reaching 201 ng/g. The distribution of residues points to the dual influence of agricultural use and long-term exposure to canal water. These findings emphasise the need to consider irrigation water quality when assessing pesticide accumulation in soils, particularly in regions dependent on surface water irrigation.

Disclaimer/Disclosure:

3.26.P-Th122 Remediation of Pesticides by Vegetation Strips: the Uptake and Impact of Azoxystrobin, Diflufenzuron and 2,4-Dichlorophenoxyacetic Acid on the Species *Arabidopsis thaliana*.

Lucia Rodriguez-Freire¹, Shannon Flynn¹, Patricia Lopez-Calcano¹, Alwin Jose¹ and Freya Thornley², (1)Newcastle University, United Kingdom, (2)No Affiliation, United Kingdom

England is experiencing a river water quality crisis, with the Environment Agency (EA) classifying 85% of rivers as failing to achieve good ecological status in 2022. Pesticide contamination from agricultural pollution is a key contributor to impaired streams and is harmful to ecosystem health. This project aims to understand plant pesticide interactions, including uptake, and their impacts on plant growth and health. Additionally, we investigated pesticide adsorption rates to soils of varied composition to assess environmental bioavailability. Three pesticides were selected based on EA analysis of English rivers, prioritising pesticides by concentration and ecotoxicological risk. Initial experiments examined the uptake and plant response to azoxystrobin, diflufenzuron, and 2,4-Dichlorophenoxyacetic acid (2,4-D) by the model plant *Arabidopsis thaliana*. Pesticide exposures were conducted at three concentrations, 2.5, 5, and 10 µg/l, in controlled tissue culture experiments in ½ strength Murashige and Skoog Medium (0.75% agar) to investigate pesticide degradation rates, plant uptake, and plant stress responses. Each individual pesticide exposure had 6-8 replicate vessels, with 2 plants per 150ml of media, grown with 12:12 day: night light at 25°C and 70% relative humidity. Following 6 weeks of growth, plant stress was measured using ImageJ to determine plant leaf surface area and chlorophyll fluorescence to measure chlorophyll death. A pesticide mass balance was calculated using LC-MS measurements of pesticide concentrations in the media, root, and shoot biomass. Additionally, pesticide uptake, degradation, and diffusion rates in the media were calculated. Utilising the largely annotated *A. thaliana* genome, global proteomic and metagenomic analyses were carried out to determine plant pesticide response and the up and down regulation of plant stress response systems. Further experiments investigated pesticide bioavailability in varied soil types using ratios of organic matter to clay with partitioning experiments at 2.5, 5 and 10 µg/l. Solid phase extractions and LC-MS analysis were used to quantify the pesticide soil adsorption, and bioavailability. Vegetation strips are a valuable protection strategy for river water quality against agricultural pesticide pollution. With further understanding of plant pesticide uptake and their impact on plant health at a metabolic level, vegetation strips can be better designed to improve plant uptake.

3.26.P-Th123 Tracking Environmental Organic Micropollutants in Soils and Traditional Catalan Calçots (green onions)

Lucas Leonel Alonso¹, Maria Pau Garcia-Moll¹, Romane Tanneau², Gianluigi Buttiglieri³ and Sara Rodriguez-Mozaz¹, (1)Catalan Institute for Water Research (ICRA), Spain, (2)Department of Fundamental and Applied Sciences, University of Poitiers, France, (3)Quality Area, Catalan Institute for Water Research (ICRA), Spain

Agricultural production is increasingly affected by global stressors such as population growth and climate change. Although several strategies have emerged, as the use of reclaimed water or the composting of WWTP's sludge, both may introduce OMPs into agricultural soils. This study investigates the presence of pharmaceuticals, antibiotics, plastic additives and other OMPs in calçots, a traditional winter onion grown in Catalonia, from diverse agricultural settings, including fields irrigated with groundwater, tap water, reclaimed water and those amended with composted sludge. Samples were collected during the 2024–2025 harvest, separated into roots, bulbs and leaves, freeze-dried and extracted by bead beating with acetonitrile. Targeted UHPLC-QTRAP analysis was conducted for 9 samples of soils and calçots from different farms from Catalonia. The target analysis enabled the detection of 109 compounds across the four matrices. Soils exhibited the highest diversity of contaminants, with recurrent detection of caffeine (8 samples), tolyltriazole (7), BPA (6), 6PPD-q (6), TCEP (4) and various pharmaceuticals. Roots showed fewer detections overall but consistent presence of TCEP and DPG in all samples, caffeine in 7, and β-blockers such as nadolol and propranolol in 6. Bulbs displayed an intermediate pattern dominated by methylparaben (8 detections), DPG (6), BPA (4) and tolyltriazole (4). Leaves showed frequent detections of TCEP (9), DPG (7), benzophenone-3 (7), caffeine (6) and occasional TBEP and ibuprofen metabolites. These patterns aligned with accumulation factors: several compounds exhibited mean ratios >1 in at least one comparison, including TCEP, BPA, DPG and caffeine for root/soil and bulb/soil; and caffeine, DPG and benzophenone-3 for leaf/soil. Conversely, many pharmaceuticals (e.g., azithromycin, trimethoprim, diclofenac) remained largely confined to soils, with ratios consistently <1. Overall, the results indicate that while most contaminants remain predominantly in soil, a subset of environmentally relevant OMPs—including TCEP, DPG, caffeine, BPA and benzophenone-3—can be detected

across plant tissues and may accumulate to higher levels than in soil. Ongoing wide-scope screening and a community survey to understand citizen perspective on micropollutants will further refine the interpretation of contaminant sources and help contextualize their relevance within current calçot production practices.

3.26.P-Th124 Fate of Tire Wear-Derived Contaminants in Tire Wear Particles-Soil-Plant System

Chao Gao¹, Vered Mordehay¹, Anya Sherman², Luzian Elijah Hämmerle², Thilo Hofmann², Tamara Polubesova¹, Benny Chefetz¹ and Evyatar Ben Mordechay¹, (1)The Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Israel, (2)Department of Environmental Geosciences EDGE, Center for Microbiology and Environmental Systems Science, University of Vienna, Austria

Tire wear particles (TWP) are continuously introduced into soils through atmospheric deposition, road runoff, and biosolid application. TWPs consist of polymers, carbon black, and numerous additives, referred to as 'tire wear-derived contaminants' (TWCs). Once in the environment, TWCs can be released from the TWPs into soil, taken up by crops, and pose health concerns to ecosystems. Despite increasing evidence of TWCs in soils and plants, their fate in the environment, specifically, their release from TWPs and subsequent uptake by plants and metabolism, remains insufficiently understood. Current studies on plant uptake of TWCs were conducted under hydroponic conditions and/or using elevated TWCs concentrations and therefore do not reflect environmentally relevant cases. To address these gaps, this study examined the fate of six representative TWCs: benzothiazole (BTZ), 2-aminobenzothiazole (A-BTZ), 1,3-diphenylguanidine (DPG), hexa(methoxymethyl)melamine (HMMM), N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD), and 6PPD-quinone, as well as their transformation product in soils mixed with TWPs (0, 0.1, 1, and 2.5%) serving as the source of TWCs for plant uptake.

Our data show that both alfalfa and lettuce were contaminated with TWCs originating from TWPs. Among the detected TWCs, DPG exhibited the highest concentrations in alfalfa and lettuce (168 and 454 ng/g, respectively), and the greatest number of transformation products (14 out of 21). BTZ and its transformation products were not detected in plant tissues, likely due to rapid in-plant metabolism. TWPs' level in soil affected the overall TWCs taken up; for example, DPG's concentration increased from 41 ng/g (0.1% TWPs) to 168 ng/g (2.5% TWPs) in the 1st alfalfa harvest. Additionally, TWCs concentration in the alfalfa shoot decreased over the growing season during the alfalfa growth period, which was harvested five times at the shoot base. For example, the concentration of A-BTZ in alfalfa grown in soil amended with 2.5% TWPs decreased from 33 ng/g in the 1st harvest to 4 ng/g in the 5th harvest. This decline is consistent with the rapid release of TWCs from freshly added TWPs and is further supported by the sequential water-extraction data. This study demonstrates that TWPs are a major source of tire wear chemicals in soils. Recognizing this consequential exposure pathway is vital for regulatory decision-making, environmental risk assessment, and food-safety protection.

3.27.A Strategies for PFAS, Organic Micropollutants & Their Persistent Products: Analysis, Assessment & Treatment Across Environmental Media

3.27.A.T-01 Understanding PFAS Exposure: Wide-scope Suspect Screening Reanalysis of High-resolution Mass Spectrometry Data from Exposomics Studies

Lapo Renai, Federica Calabrò and Saer Samanipour, University of Amsterdam (UVA), Netherlands

Per- and polyfluoroalkyl substances (PFAS) encompass thousands of structurally diverse anthropogenic compounds varying in fluorination, chain length, and functional groups. Their extreme stability and widespread use lead to a constant human exposure, yet poorly understood. Targeted studies focus mainly on about 30 regulated PFAS, capturing only a minimal fraction of the true PFAS exposome. Advances in high-resolution mass spectrometry (HRMS) have enabled non-targeted analysis (NTA) workflows, which exploit accurate mass, fragmentation patterns, and neutral losses to broaden the coverage of PFAS chemical space. However, NTA data processing remain biased toward common structural motifs and homologue series, uncovering atypical PFAS such as fluorotelomers or ethers. Plus, many exposomics studies focus narrowly on regulated PFAS, neglecting the broader spectrum of relevant homologs that may occur in study samples.

Retrospective analysis (reanalysis) of archived HRMS datasets using broad and chemically informed suspect lists has the potential to overcome these limitations. In this context, we propose a retrospective wide-scope suspect screening tool tailored for PFAS exposomics studies. The extensive suspect list was curated from experimental data on standard mixtures and the OECD PFAS inventory, filtered for compatibility with reversed-phase LC (> 1600 entries). Each suspect entry was paired with structural descriptors, predicted retention indices (RIs), and MS² fragments sourced from standards or, when unavailable, databases and literature data, also assigning relative identification confidence levels. Candidate features are prioritized by precursor accuracy, isotope, and MS² matching, while a curated filtering strategy based on spectral similarity, intensity, and identification confidence ranking minimized redundancies. PFAS identification accuracy was further refined by a method-dependent retention time-RI regression model.

Reanalysis by wide-scope suspect screening of LC-HRMS data on human serum from general and PFAS-exposed cohorts confirmed not only legacy perfluoroalkyl acids (e.g., PFOS, PFHxS, and PFNA) but also a wider list of unregulated PFAS isomers previously neglected—including fluorotelomer ethers, alcohols and acetates, unsaturated PFAS, sulfonamidoacetic acids, and amines—thereby broadening prior exposure assessments (about 6.5-fold increase compared to former identifications) and the knowledge on PFAS chemical coverage in exposomics.

3.27.A.T-02 Monitoring of PFAS in Urban and Industrial Wastewater via Sum Parameter and Target Analysis: The Critical Role of Particulate Load

Philipp Roesch, Ronny Wischer, Jennifer Bartz and Ulrike Braun, German Environment Agency (UBA), Germany

Since the initial reports indicating the potential of sum parameters of adsorbable organic fluorine (AOF), extractable organic fluorine (EOF), and total fluorine (TF) to detect and survey large quantities of unidentified organofluorine compounds in environmental matrices, their utilization has become a valuable addition to conventional PFAS analytical methods. The sum parameter AOF was the first parameter to become standardized through the DIN EN ISO 18127:2024-08-Entwurf standard. The EU-Wastewater Treatment Directive (EU-UWWTD) demands the implementation of a monitoring program for per- and polyfluoroalkyl substances (PFAS) in wastewater nationwide by 2027, following its enactment in late 2024. To date, only a limited number of studies have demonstrated the feasibility of sum parameter analysis in wastewater samples.

Herein, we investigated several wastewater treatment plants (influent and effluent) from urban areas as well as selected PFAS manufacturing industries. All wastewater samples were sampled via 24-h sampling auto-samplers or via qualified random sampling and subsequently worked, based on state-of-the-art extraction and measurement protocols. In order to obtain further information regarding the distribution of analytes in the wastewater matrix and to assess the applicability of the standard methods for "PFAS Total" and "Sum of PFAS", we applied target analysis by Liquid Chromatography Coupled Tandem Mass Spectrometry (LC-MS/MS) and AOF sum parameter analysis by Combustion Ion Chromatography (CIC). The evaluation of the data indicates the presence of significant trends, which can contribute to the selection of appropriate harmonized methods and strategies for future PFAS monitoring in WWTPs.

Overall, we demonstrated that a majority of PFAS in WWTP streams gets discarded in sludge sedimentation. However, highly soluble, short-chain compounds leave the treatment process untreated. Moreover, our study showed that sum parameter analysis combined with various extraction methods enables a thorough examination of PFAS-containing wastewater matrices and can be employed to evaluate PFAS levels in influent and effluent samples from urban and industrial wastewater streams. Since Trifluoroacetic acid (TFA), the major PFAS degradation product, was quantified in significant amounts for all samples investigated, an additional monitoring of WWTP effluents is highly recommended.

3.27.A.T-03 Long-Term Study of River Spree With Insights on Pollutions Situation With a Focus on PFAS

Pia Schünemann¹, Stephanie Spahr², Tobias Goldhammer³, Thomas Sommerfeld¹, Jan Lisec¹ and Björn Meermann¹, (1)Federal Institute for Materials Research and Testing (BAM), Germany, (2)Ecology and Biogeochemistry, Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Germany, (3)Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Germany

Per- and polyfluorinated alkyl substances (PFAS) are environmental pollutants of concern regarding their persistency and bioaccumulation properties and impact on human health. Due to the wide range of existing physicochemical properties of PFAS molecules it is difficult to detect all compounds with one single method. In

Target Analysis missing analytical standards poses a problem. Additional measurement time and manual effort for data assessment create difficulties in Non-Target Screening. Within our study complementary sum parameter tools (extractable organic fluorine, EOF) were developed as a fast-screening tool for river water samples.

Through a long-term study of River Spree, we receive insights into the pollution situation regarding organic fluorinated compounds and organic trace substances. EOF measurements and subsequent complementary Target and Non-Target PFAS analysis give a more detailed insight into the environmental pollution situation with fluorinated compounds. Correlation assessment between fluorinated organic compounds and organic trace substances was conducted. The idea here was that, in the event of a correlation, it would be possible to infer exposure to PFAS from exposure to organic pollutants. Correlation tests showed increase of fluorinated compounds are coming with an increase of organic trace substances. However, the influence of season and weather (warm, dry, wet) leads to inconsistency of the significance of the correlation. Therefore, this study provides EOF as a Hot-Spot Screening Tool, shows the importance for improvement of analytical methods for PFAS detection and underlines the importance of long-term environmental studies as the time of sampling has an impact on their concentration.

3.27.A.T-04 Mineralization of Per- and Polyfluoroalkyl Substances at a Municipal Solid Waste Incinerator

Anna Holfelder¹, Daniel Wohter², Ragnar Warnecke³, Hans-Joachim Gehrmann¹, Dieter Stapf¹ and Peter Quicker², (1)Karlsruhe Institute of Technology, Germany, (2)RWTH Aachen University, Germany, (3)Gemeinschaftskraftwerk Schweinfurt GmbH (GKS), Germany

Per- and polyfluoroalkyl substances (PFAS) in municipal waste poses challenges for safe disposal and circular economy objectives. To address methodological limitations in previous studies, a PFAS measurement campaign was conducted at a municipal solid waste incineration (Gemeinschaftskraftwerk Schweinfurt, GKS). The aim of the campaign was to investigate the thermal decomposition of PFAS in the grate furnace and the efficiency of the flue gas cleaning system. Three test scenarios were established: municipal solid waste (MSW) as the reference scenario, MSW mixed with PFAS-contaminated soil, and MSW with manually added PFAS-containing materials as a worst-case scenario. Input and output streams were sampled and analyzed. Regarding the gaseous emissions, U.S. EPA methods OTM-45 and OTM-50, variations of the OTM-45 and fourier-transform infrared spectroscopy (FTIR) and tunable diode laser (TDL) measurements for volatile PFAS and hydrogen fluoride (HF) were carried out.

Analyses of the MSW indicated PFAS concentrations of 40–50 µg/kg (sum of 43 substances), approximately half of it attributed to trifluoroacetic acid (TFA). The primary air contained 2–3 ng/m³ of 35 ionic PFAS, while process water contained 2 µg/L TFA and 6 ng/L other ionic PFAS.

The flue gas measurements showed total polar and semi-volatile PFAS concentrations of 0–22 ng/m³. Respectively no significant increase was caused through PFAS addition. It is likely that TFA emissions in the flue gas originated from pre-contaminated scrubber water rather than incomplete combustion. Carbon tetrafluoride (CF₄) emissions (FTIR: 1–2 mg/m³, OTM-50: 0.5 mg/m³) were observed only during PFAS addition, while other products of incomplete combustion were undetectable. Concentrations of PFAS in bottom ash residues were below 5 µg/kg.

3.27.B Strategies for PFAS, Organic Micropollutants & Their Persistent Products: Analysis, Assessment & Treatment Across Environmental Media

3.27.B.T-01 Biotransformation of Eight PFAS Classes in Three Fungal Cultures and Sewage Sludge – Impact on Primary Degradation and Transformation Product Formation

Ann-Cathrin Krause¹, Emily Lichtenwald¹, Lukas Wick¹, Dietmar Schlosser¹, Thorsten Reemtsma¹ and Daniel Zahn², (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Department of Analytical Chemistry, Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Per- and polyfluoroalkyl substances (PFAS) are a class of over 4,700 synthetic chemicals, many of which are either highly persistent or can form persistent transformation products, contributing to global environmental contamination. While regulatory monitoring focuses on legacy compounds, thousands of per- and

polyfluoroalkyl substances remain understudied, with PFAS sum parameters indicating large amounts of unidentified organic fluorine.

Fungi are abundant in soils and wastewater systems and possess unique enzymatic capabilities. Yet, their role in per- and polyfluoroalkyl substance transformation remains poorly explored.

This study investigated the biotransformation of nine structurally diverse per- and polyfluoroalkyl substances belonging to eight substance classes in three fungal cultures, *Pleurotus ostreatus*, *Gloeophyllum trabeum*, and *Phoma* sp. UHH 5-1-03 as well as in activated sludge. The studied PFAS classes included perfluoroether carboxylic acids, a perfluorinated phosphinic acid, a fluorotelomer carboxylic and sulfonic acid, a side-chain fluorinated aromatic compound along with two sulfonamide derivatives. The analytes were spiked into the cultures as a mixture and the time points were sampled sacrificially. High-resolution mass spectrometry was used to track parent compound depletion and transformation product formation.

Five of the nine compounds showed no biotransformation across tested cultures, indicating limited biodegradation potential for many modern PFAS classes. Rapid biotransformation of 6:2 fluorotelomer carboxylic acid was observed in all cultures with half-lives below 20 hours. 6:2 fluorotelomer carboxylic acid also displayed a culture-specific formation of transformation products. The side-chain fluorinated aromatic compound was also biotransformed quickly. Notably, only *Pleurotus ostreatus* transformed perfluorobutane sulfonamide forming alcohol- and carboxylic acid conjugated metabolites that resemble phase II transformation products observed in mammals.

The results demonstrate that fungal species differ in transformation capacity and pathway selection leading to distinct transformation product profiles.

3.27.B.T-02 Sewage sludge derived carbons as circular sorbents for the removal of persistent and mobile organic compounds

Sampriti Chaudhuri, Jonas Koehne, Ariette Schierz, Anett Georgi and Martin Krauss, Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Persistent and mobile organic compounds (PMOC) such as pharmaceuticals, personal care products, PFAS, industrial chemicals and their transformation products escape conventional wastewater treatment, challenging the new EU Urban Wastewater Treatment Directive. We tested whether wet wastes such as sewage sludge, after phosphorus (P) recovery via hydrothermal carbonization (HTC), can be converted into efficient sorbents by steam activation for advanced treatment. Hydrochars were produced from sewage sludge with or without lignocellulosic (bark, foliage, green waste) or nutrient-rich (manure) co-substrates, then steam-activated under varying temperatures and durations, including Fe-enriched and pyrolyzed controls. Sorbents were comprehensively characterized, and batch adsorption experiments were performed with real tertiary effluent from a decentralized wastewater treatment pilot (aerated constructed wetland, sand filter, UV) containing >200 PMOC (including transformation products) quantified by LC-HRMS. Molecular descriptors were computed (RDKit, ChemAxon) and linked to removal using correlation analysis, Logistic Regression and machine-learning models (Random Forest, XGBoost).

Steam-activated hydrochars from sewage sludge+bark removed up to twice as many PMOC as the corresponding biochar, driven by ~5-fold higher surface area, higher microporosity and basic mineral surface functionalities that support π - π , hydrophobic and H-bond interactions. Moderate activation temperature (800 °C) combined with longer duration maximized microporosity and sorption, whereas higher temperature (900°C), manure co-substrates and Fe-enrichment all reduced removal due to ash-driven pore blockage. Transformation products such as gabapentin-lactam and guanylurea were more strongly retained than their parents, consistent with reduced polarity.

Across >200 PMOC, hydrophobicity descriptors correlated positively with removal, while polarity descriptors correlated negatively. Ionization descriptors showed that neutral or protonated species sorbed best.

Classification models consistently identified lipophilicity (at pH 7), apparent aqueous solubility (at pH 7), aromaticity, polarizability, pKa(s) and solvent accessible surface area of PMOC as top features affecting sorption. HTC of sewage sludge, coupled with steam activation of the hydrochar, provides a promising pathway to recover P while producing a circular sorbent capable of meeting future EU micropollutant removal targets.

3.27.B.T-03 Browsing FAIR Transformation Product Information with FAIR-TPs

Bashir Mayahi¹, Emma Helena Palm¹ and Emma Schymanski², (1)University of Luxembourg, Luxembourg, (2)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg

From identifying transformation products (TPs) in samples using mass spectrometry (MS) to incorporating them into chemical regulation, scientists still face significant challenges integrating TPs into environmental research. Yet, sharing information on TPs is more important than ever in the AI era. The FAIR-TPs website, presented here, lets users examine publicly accessible TP data gathered from various literature sources. The underlying data comes from several datasets on the NORMAN Suspect List Exchange (NORMAN-SLE) as well as ChEMBL, all accessible via PubChem. An open source workflow is used to compile the data, which are archived and versioned on Zenodo under a CC-BY license, and then processed and visualized on FAIR-TPs. At present, FAIR-TPs contains 11,082 reactions, involving 9,404 compounds from 11 sources.

The FAIR-TPs website is designed to make transformation knowledge reusable, testable, and accessible, providing features to investigate and produce outputs suitable for scientific dissemination. Because compounds and their reactions are highly interconnected, the data are stored in a graph-based structure and visualized through an interactive interface with statistics and several search options. The transformation data come from the “Transformations in PubChem – Full Dataset” hosted on Zenodo, including compound-level information (CID, InChI, InChIKey, SMILES, molecular formula, exact mass, xlogP, names/synonyms) and reactions-level data (biosystem, enzyme, transformation, massDiff, xlogpDiff and reference metadata).

During a chemistry-aware Transform step, identifiers are homogenized, names are normalized with a majority-vote method and long or problematic names are trimmed. In the Load step, the data are stored in a Neo4j graph compounds as nodes and each reaction as a directed edge, allowing efficient navigation of multi-step reaction networks. A Django interface renders structures, performs depth-limited traversals, and provides CSV/XLSX/patRoon/MetFrag downloads for MS workflows, plus image downloads. After statistics are verified for completeness, the site is deployed on a virtual machine, available at <https://fairtps.lcsb.uni.lu>. FAIR-TPs helps researchers connect precursors, intermediates and end products by facilitating the browsing, comparison, and reuse of transformation knowledge. This improves the basis for analysis, assessment, and treatment across environmental media, where understanding reaction pathways is essential.

The authors thank the NORMAN Suspect List Exchange contributors and community members providing open transformation data, and colleagues at the Luxembourg Centre for Systems Biomedicine and PubChem for their support. This work was funded in part by the EU Horizon 2020 programme (Grant Agreement 101036756, ZeroPM).

3.27.P Strategies for PFAS, Organic Micropollutants & Their Persistent Products: Analysis, Assessment & Treatment Across Environmental Media

3.27.P-Mo235 Destruction of Per- and Polyfluoroalkyl Substances Containing Emerging Aqueous Film-Forming Foam in a Full-Scale Hazardous Waste Incinerator

Peter Leube¹, Christian Vogel², Eric Kennedy³, Michael Stockenhuber³, Tai Troung⁴, Anthony Rappé⁵, Olaf Holm⁶, Wenchao Lu⁷ and Jens Blotevogel⁷, (1)Federal Institute Materials Research and Testing (BAM), Germany, (2)Division 4.3, Federal Institute Materials Research and Testing (BAM), Berlin, Germany, (3)University of Technology Sydney (UTS), Australia, (4)Ventia, Australia, (5)Colorado State University (CSU), United States, (6)Thomé-Kozmiensky Verlag – vivis, Germany, (7)Commonwealth Scientific and Industrial Research Organisation (CSIRO), Australia

Per- and polyfluoroalkyl substances (PFAS) are among the environmental contaminant groups that have received the most attention in recent years. The heightened concern arises from the fact that their unique molecular peculiarity responsible for widespread use, including in critical applications, simultaneously account for their environmental persistence.

The safe destruction of PFAS in various matrices, such as waste streams, is of great importance to prevent the impact on the environment and human health. The volume of such waste increased following the phase-out regulations of PFAS containing aqueous film-forming foams (AFFF) in numerous countries. Originally intended for firefighting, they are now classified as hazardous/ toxic waste that must be properly destroyed.

Incineration shows high potential for destruction of PFAS in impacted wastes since it can break the strong carbon-fluorine bond. This could potentially lead to completely mineralization of PFAS. However, previous experience with halogenated waste incineration has shown that products of incomplete destruction (PIDs) can be formed if the incineration conditions are insufficient.

In the project „Investigating the Thermal Decomposition of PFAS in a Full-Scale Commercial Hazardous Waste Incinerator” funded by the U.S. Department of Defense’s Strategic Environmental Research and Development Program (SERDP), German, Australian and American partners examine the treatment of PFAS containing waste streams in a full-scale hazardous waste incineration plant to demonstrate the readiness, viability, and level of safety of this destruction method.

Here, we present the results of our first campaign. We focused on the incineration of a contemporary fluorotelomer-based AFFF under varying conditions to evaluate the completeness of PFAS destruction and the potential formation of PIDs. In addition to solid samples (slag, boiler ash and dust) and liquid samples (slag cooling water and scrubber water), flue gas was sampled and analysed.

3.27.P-Mo236 Analysis of per- and polyfluoroalkyl substances (PFAS) in atmospheric deposition

Ahmad El Masri¹, Jessica Queron², Jean Pierre Blanquet³ and Hervé Adrien³, (1)PhD student, France, (2)Ms, France, (3)Mr, France

The monitoring of per- and polyfluoroalkyl substances (PFAS) in the environment is of great interest due to their toxicity and persistence. Recent research has predominantly focused on measuring PFAS in soil and water, while studies analyzing PFAS in air—such as through stack emissions, ambient air, and atmospheric depositions—remain limited. This gap is partly due to the wide variety of physico-chemical properties among PFAS compounds and the need for diverse sampling techniques and analytical approaches. This study aims to evaluate the efficiency of a sampling technique for the atmospheric deposition of various PFAS, including polar, non-polar, volatile, and semi-volatile compounds. Tests were conducted in both real and controlled environments to assess the suitability of the method for PFAS with carbon chains ranging from C1 to C18. In addition, this work compares different analytical approaches for sample preparation and analysis as conducted by three independent laboratories.

3.27.P-Mo237 Advanced Ozone and Activated Carbon Operational Strategies for Enhanced Micropollutant Removal from Secondary Wastewater Effluent

Zoë Mol, Tao Zhang, Kristof Demeestere and Stijn Van Hulle, Ghent University, Belgium

Water resources are threatened given the fact that (emerging) contaminants are continuously introduced into water bodies. In view of providing safe water to humans and our aquatic ecosystems, current policy and legislative frameworks are stressing the need for advanced yet cost-effective water treatment approaches. Advanced oxidation processes are key in this context, but their performance is often limited by interactions between the organic matrix components (e.g. humic acids), the target micropollutants (μPs) and the added or generated oxidants. Ozonation is one of the most performant technologies, yet its dosing must be carefully optimized to avoid excessive energy use and undesirable by-products such as bromate. Combining ozonation with activated carbon (AC) adsorption can enhance μP removal while mitigating these drawbacks, though determining the optimal dosing control and sequencing of both processes remain challenging.

This study investigates various ozone and powdered AC (PAC) dosing strategies, with a focus on their sequential order. When applying ozonation first, or when combined with simultaneous AC addition, the μP removal efficiency increases by 5–10 % and the time to achieve 80 % removal halves, compared to the situation where AC is dosed prior to ozone addition. Pre-ozonation modifies the properties of effluent organic matter (EfOM) (e.g., hydrophobicity), reducing its competition with μPs for AC adsorption sites, while AC pre-adsorption shows limited benefit on the subsequent ozonation process. These findings support applying ozonation (optimal dose of 0.5 mg O₃/mg DOC) before or simultaneously with AC addition, followed by an AC polishing step, to achieve efficient μP removal while minimizing the formation of by-products.

Reliable real-time monitoring is essential for effective process control. Although an optimal ozonation dose of ~0.5 mg O₃/mg DOC is recommended, current practice lacks reliable strategies to balance O₃ and AC dosing in real time, often leading to overdosing, increased costs and carbon footprint, or insufficient μP removal.

Although surrogate parameters have shown promise in stand-alone ozonation or AC systems, integrated monitoring of the combined process is still scarce. This study therefore establishes a whole-process surrogate strategy for real-time optimization of O₃ and AC dosing, enabling more efficient control and supporting the broader implementation of intelligent tertiary treatment for micropollutant removal.

3.27.P-Mo238 Comparing Oxidative Treatments of Triazole Fungicides and Their Persistent Transformation Products in Wastewater

Nikoline Marxen¹ and Gabriel Sigmund², (1) Wageningen University and Research (WUR), Netherlands, (2)EDGE, Wageningen University and Research (WUR), Wageningen, Netherlands

Degradation of micropollutants often results in the formation of intermediate transformation products (TPs). Many micropollutants are classified as persistent, mobile and toxic (PMT) or very persistent and very mobile (vPvM), reflecting limited degradation under natural environmental conditions. Despite this, they can still form TPs through, for example, oxidation processes used in advanced water treatment. These TPs may be more persistent, mobile, and toxic than the parent compounds making their formation and accumulation particularly concerning. Triazole fungicides are a group of micropollutants characterised by a 5-membered ring containing three nitrogen and two carbon atoms, which is responsible for their antifungal and toxic properties. During degradation of triazole fungicides, TPs typically retain the triazole ring or form 1,2,4-triazole as a standalone compound. Both photodegradation and biodegradation have limited effects on the 1,2,4-triazole ring. Although chemical oxidation processes may initiate reactions that promote ring opening and degradation of the 1,2,4-triazole ring, their ability to fully mineralise triazole fungicides remains unclear. Additionally, knowledge on the TPs formed during chemical oxidation processes, especially concerning the 1,2,4-triazole ring, is limited. In this study we aim to compare oxidative treatment of wastewater using ozone and heat-activated persulfate to provide insight into the ability of different radical species ($\text{OH}^\bullet$ and $\text{SO}_4^{\bullet-}$) to degrade and mineralise 1,2,4-triazole and its precursors. We will also investigate potential variations in degradation pathways between the two oxidation methods. TPs will be detected and measured via a suspect screening using high resolution mass spectrometry. The analysis will progress from simplified model water matrices to real and complex wastewater effluent matrices. We hypothesise that the two oxidation processes will produce distinct transformation pathways and TPs. We also expect that the increasing complexity of the water matrix will lead to a higher diversity of TPs. The findings will provide insight into the fate and persistence of triazole fungicides during chemical oxidation treatments.

3.27.P-Mo239 Mitigating the Ecotoxicity of Bentazone and Glyphosate using Combined Vacuum UV and UV-C Treatment of Contaminated Water

Paolo Taborelli, Christian Gøthgen Madsen, Andreas Langwithz Kruse, Sofie Knop Lund, Marc Bello Pintor and Peter Roslev, Aalborg University, Denmark

Bentazone and glyphosate are examples of widely used herbicides that are frequently detected as contaminants in groundwater and surface waters. Bentazone (3-isopropyl-1H-2,1,3-benzothiadiazin-4(3H)-one 2,2-dioxide) is a selective herbicide that inhibits photosynthesis in target plants, and glyphosate (N-(phosphonomethyl)glycine) is the most common active ingredient in non-selective broad-spectrum herbicides. The environmental toxicity of these herbicides to non-target organisms is considered moderate but adverse effects have been observed in aquatic organisms from different trophic levels including bacteria, algae, invertebrates, amphibians, and fish. Environmentally friendly methods for mitigation are therefore in demand. This study investigated the potential of combined vacuum UV (185 nm) and UV-C (254 nm) irradiation (VUV-UVC) as a mitigation method to degrade bentazone and glyphosate and thereby decrease their ecotoxicity. VUV treatment is an advanced oxidation process that degrades many aquatic contaminants, but the efficiency and the toxicological profile of the process is often underinvestigated. In this study, the UV mediated photolysis of bentazone and glyphosate was quantified by LC analysis, and the potential ecotoxicity of UV treated herbicides was examined using a battery of test organisms from different trophic levels including the yeast *Saccharomyces cerevisiae*, the microalga *Raphidocelis subcapitata*, the crustacean *Daphnia magna*, and selected annual broadleaf non-target plants. In addition, mesocosm with freshwater plankton was examined before and after exposure to UV treated herbicides. Different bioassays were included to better assess adverse effects of bioactive products in UV treated samples including herbicide transformation products. The study showed that combined VUV and UVC irradiation facilitated rapid photolysis within minutes of aqueous bentazone and glyphosate, and that the degradation was related to UV fluence (Joule/cm^2) and flow regimes. UV treatment of water contaminated with bentazone or glyphosate resulted in significant decreases in potential ecotoxicity due to complete mineralization or formation of less toxic transformation products. The results are relevant for assessing sustainable treatment of herbicide contaminated water with before discharge into environmental waters.

Disclaimer/Disclosure:

This study is funded by the European Union under the Marie Skłodowska-Curie Actions (MSCA) – Doctoral Networks (HORIZON – MSCA –2022-DN-JD-101119555): “Human footprint on water from remote cold areas to the tropical belt. INtegrated Approach TO secure water QUALity by exploiting Sustainable processes” (IN2AQUAS).

3.27.P-Mo240 The Importance of Non-Targeted PFAS Analysis: Identifying Non-Regulated PFAS in UK Freshwater Samples by LC/QTOF

Jonathan Spencer¹ and Christian Hegmanns², (1)Agilent Technologies, United Kingdom, (2)Agilent Technologies, Germany

Per- and polyfluoroalkyl substances (PFAS) represent a vast and diverse group of chemicals, yet most environmental monitoring programs rely on limited target lists, potentially leaving many PFAS undetected. This study demonstrates the value of non-targeted PFAS analysis through a case study of five surface water samples collected near a UK fluorochemical plant. These samples were analyzed using liquid chromatography coupled with quadrupole time-of-flight mass spectrometry (LC/QTOF MS), supported by FluoroMatch and MassHunter software for comprehensive annotation. Across the samples, 43 PFAS were identified at confidence level ≥3, spanning five structural classes, including perfluorocarboxylic acids (PFCAs), hydrogen- and chlorine-substituted PFCAs, perfluoroether carboxylic acids (PFECAs), and a suspected group of unsaturated PFECAs (UPFECAs). Notably, only eight of these compounds appear on the UK Drinking Water Inspectorate target list, representing just 17% of the total PFAS peak area detected. These findings highlight the limitations of targeted monitoring and underscore the importance of incorporating non-targeted screening to inform regulatory frameworks and ensure comprehensive environmental PFAS assessment.

3.27.P-Mo241 Fast Fluorine Screening Method for Sealing Materials via High Resolution-Continuum Source-Graphite Furnace Molecular Absorption Spectroscopy

Sebastian Kampf¹, Ronya Mona Wallis², Lennart Gehrenkemper¹ and Björn Meermann¹, (1)Federal Institute for Materials Research and Testing (BAM), Division 1.1 – Inorganic Trace Analysis (ITALab), Germany, (2)German Environment Agency (UBA), FG II 2.5 “Laboratory for Water Analytics”, Germany

Elastomers commonly used as sealing materials are highly networked rubbery polymers. They are often produced using per- and polyfluoroalkyl substances (PFAS) either during manufacturing or as additives to enhance their performance during applications in harsh environments. Due to the lack of reliable recycling strategies without compromising the resulting polymer-quality, sealing materials are often disposed of in landfills. Thus, they represent a possible source of continuous PFAS contamination of both the immediate environment and surrounding ground water reservoirs through landfill leachates. To assess the scope of fluorine content, we developed a potential Standard Operating Protocol (SOP) to allow for subsequent fluorine/PFAS determination in various blends of sealing materials. Optimizations were aimed for time efficiency and robustness of results. The SOP entails a shredding sequence from roughly cutting to sieving. Optimal results were obtained for the fraction size between 125-250 µm. Extractions performed with either acidified methanol or ultra-pure water proved reproducibility of results and revealed high extractable fluorine concentrations for most sealing materials investigated. The high fluorine concentrations extracted by water further puts emphasis on the risks associated with leaching from microplastics generated by material abrasion during their lifetime and within landfills. The SOP can easily be expedited by implementation of additional sample preparation steps such as Solid Phase Extraction (SPE) to explicitly measure extractable organofluorides. In prospect of the broad ban of PFAS proposed by the European Chemical Agency (ECHA), it will be imperative to reliably screen products for fluorine and PFAS and scan for future compliance. Regarding the derogations discussed for certain applications such as Nafion proton exchange membranes and sealants in industrial sites, the SOP will allow for the fast screening of fluorine leaching to help advance the development of materials safe and sustainable by design.

3.27.P-Mo242 Metrology to support the analysis of per- and polyfluoroalkyl substances from industrial emissions (MetZeroPol)

Christian Vogel¹, Christian Piechotta² and Junchi Lu², (1)Division 4.3, Federal Institute Materials Research and Testing (BAM), Berlin, Germany, (2)Federal Institute Materials Research and Testing (BAM), Germany

The EU’s Zero Pollution action plan aims at reducing pollution in air, water and soil to levels no longer considered harmful to health and natural ecosystems. As part of this, the Industrial Emissions Directive was

revised in 2024 which includes a magnitude reduction in the permissible associated emission level of a range of pollutants, affecting many industrial processes. Pollutants such as perfluoroalkyl and polyfluoroalkyl substances (PFAS) are increasingly causing concern. Up to now there is only little knowledge on which industrial processes emit PFAS, at what concentrations, and no European standard exists (only national standard in Belgium and France) for measuring PFAS emissions. Therefore, the Euramet project MetZeroPol will develop methods to measure PFAS and used to identify key PFAS species from real industrial processes. Furthermore, the members are involved in the new CEN/TC 264/WG 48 - “Emissions and ambient air - Determination of PFAS” group in order to uniformly regulate the standardization of analysis methods for PFAS emissions from industrial plants.

3.27.P-Mo243 Enhancing Per- and Polyfluoroalkyl Substances (PFAS) Pollution Retention by Superabsorbent Polymer (SAP) amended to a Grass Swale Prototype of Green Infrastructure

Delezia Singh¹, Karolina Nowak² and Martin Krauss³, (1)University of Koblenz, Koblenz, Germany, (2)University of Koblenz, Germany, (3)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research (UFZ), Germany

Per- and polyfluoroalkyl substances (PFAS), or “forever chemicals”, are contaminants of escalating global concern. Superabsorbent polymers (SAPs), known for their high-water retention capacity, offer a potential new approach for enhancing PFAS removal within green stormwater infrastructure (GSI), like grass swales, particularly in the face of climate change-driven weather events in urban environments. Through the support of the Marie Skłodowska-Curie Actions European Union Programme, this project (PFAS-RETENT) will focus on evaluating the retention potential for a group of highly mobile, short-chain PFAS, using a biological (lignin)-based, superabsorbent polymer (SAP) integrated into a grass swale framework or prototype. To accomplish this, these specific objectives (OBJs) will be employed: OBJ1—evaluation of the retention-release processes of the SAP for the PFAS in focus (short-chain: perfluorobutanoic acid (PFBA), hexafluoropropylene oxide dimer acid (HFPO-DA), 4,8-dioxa-3H-perfluorononanoic acid (DONA), ultra short-chain: trifluoroacetic acid (TFA)), using batch retention experiments (simplified framework); OBJ2—assessing the efficacy of the SAP for removing these PFAS, when incorporated into lab-scaled, grass-planted microcosms (basic framework of a grass swale system); OBJ3—assessing the efficacy of the SAP in removing these PFAS when incorporated into flow-through, grass-planted mesocosms (‘real-world’ framework of a grass swale system). The methodology will follow a 3-stage stepwise approach, beginning with simple designs (batch experiments—OBJ1, microcosms—OBJ2), then increasing in complexity to a nearly real-world scenario (flow-through mesocosms—OBJ3). For OBJ2 and OBJ3 experiments, percolation and drought simulations will be applied in order to evaluate the SAP retention performance for PFAS under these conditions. SAP integrated into swale substrates could serve as a temporary “removal” barrier for short-chain PFAS during storm runoff, thereby limiting their distribution throughout urban water systems and the water cycle. During drought periods, PFAS trapped in the water-saturated gel phase of the SAP (along with the water) could be taken up by the vegetation within swale GSIs, thus reducing their release to nearby water bodies and minimizing contamination risks to urban water resources.

Disclaimer/Disclosure:

This project has been accepted, and is funded, by the Horizon Europe Marie Skłodowska-Curie Actions (MSCA) European Fellowship Programme (HORIZON-MSCA-2024-PF-01-01). Project number and name: 101207331—PFAS-RETENT. The main hosting institution is the University of Koblenz, along with a secondment host institute, the Helmholtz Centre for Environmental Research (UFZ).

3.27.P-Mo244 Quantification of Perfluorocarboxylic Acids in Water Samples via Static Headspace Gas Chromatography Coupled to Mass Spectrometry

Christian Vogel¹, Peter Leube² and Maren Riedel², (1)Division 4.3, Federal Institute Materials Research and Testing (BAM), Berlin, Germany, (2)Federal Institute Materials Research and Testing (BAM), Germany

Perfluorocarboxylic acids (PFCAs) are one of the most prominent and studied subgroups of per- and polyfluoroalkyl substances (PFAS), which have attracted great interest in environmental and toxicology research due to their intensive use in combination with their persistence, mobility and potential threat to ecosystems and human health. The standard method to quantify PFCAs in water samples is liquid chromatography. For quantification of ultrashort-chain PFCAs (carbon chain length of two or three carbon atoms) often hydrophilic interaction liquid chromatography or ion chromatography coupled with mass spectrometry is used (e.g. DIN 38407-53). However, there are a lot of laboratories using mass spectrometry coupled to headspace gas chromatography systems (HS-GC-MS), usually to quantify a wide range of volatile organic compounds. While PFCAs themselves are difficult to measure with HS-GC-MS in water samples, this challenge can be solved by

derivatizing the acids to more volatile compounds, like esters. This approach could enable laboratories using HS-GC-MS to analyse and monitor PFCAs in environmental water samples. By following this idea, we successfully developed a HS-GC-MS method to quantify PFCAs in ultrapure water. Trifluoroacetic acid (TFA), perfluoropropionic acid (PFPrA), perfluorobutanoic acid (PFBA) and perfluorooctanoic acid (PFOA) served as exemplary analytes of PFCAs, which were derivatized with methanol and concentrated sulfuric acid to form methyl esters. The method was optimized by varying different preparation and measurement parameters, leading to limits of detection and quantification in the two-digit ppt-range for all four analytes. The method was then tested on various real water samples, including tap and surface water, groundwater, landfill leachate, treated wastewater and impinger water from a sewage sludge incineration experiment. TFA was the most frequently detected PFCA, with concentrations in the ppt and low ppb range. The detection and quantification of the remaining three PFCAs vary with the sample types and sampling location.

3.27.P-Mo245 Emerging Topics in the Monitoring of Organic Micropollutants in Surface Waters

Milan Koželuh, Lenka Sikorová and Lumír Kule, Povodí Vltavy, State Enterprise, Prague, Czech Republic

Driven by recent discoveries about the environmental impact of widely used organic chemicals, the EU has introduced new regulations for municipal wastewater treatment (UWWTD, 2024) and drinking water production (DIRECTIVE (EU) 2020/2184). Our team has responded flexibly by developing and innovating reliable analytical methods to detect emerging or previously undetectable organic micropollutants. The methods are suitable for routine analysis of various water types. Our presentation highlights four highly topical issues affecting water quality.

The revised Urban Wastewater Treatment Directive mandates the monitoring of 12 pharmaceutical and personal care products (PPCPs) commonly detected in wastewater. These substances are classified into two categories: easily treatable substances and easily disposable substances.

1,2,4-triazole is a persistent organic compound primarily found in the environment as a degradation product of various triazole fungicides commonly used in agriculture. It is also a key component in various pharmaceuticals, including antifungal, antiviral and antibacterial drugs.

Trifluoroacetic acid (TFA) has a wide variety of recognized anthropogenic sources in the environment. TFA arises from the degradation of previously used refrigerants and enters the environment through atmospheric deposition. Moreover, it is also a degradation product of long-chain PFAS. Regardless of its source, TFA ultimately accumulates in surface waters, reaching concentrations of units to tens of µg/l.

Chlorothalonil, a widely used fungicide that was banned in the EU in May 2020, had an estimated total consumption of 500 tonnes in the Czech Republic between 1997 and 2020. Initial results show that chlorothalonil 471811, a key metabolite, occurs year-round in surface waters of agriculture areas, reaching concentrations of several hundred ng/l. Removing this metabolite during drinking water production is challenging due to insufficient capture on granular activated carbon.

3.27.P-Mo246 Monitoring of Perfluorinated Compounds (PFAS) in Waters of the Vltava River Basin

Lumír Kule, Lenka Sikorová and Milan Koželuh, Povodí Vltavy, State Enterprise, Prague, Czech Republic

PFAS (Per- and polyfluoroalkyl substances) constitute a large group of synthetic chemicals (nearly 15 000, over 4700 with CAS numbers) with diverse physicochemical properties. Their high stability, resulting from the robust carbon-fluorine bond, combined with useful physicochemical properties has led to widespread use in various industrial and consumer products, including food and beverage packaging, clothing, cookware, cosmetics, paints and coatings, lubricants and firefighting foams. Nevertheless, these same properties now raise concerns about environmental pollution and human health. People are exposed to PFAS mainly through food and water, leading to bioaccumulation. The toxicity and health hazards associated with PFAS exhibit significant variability. Certain PFAS are suspected carcinogens and reproductive toxicants. The ability of modern analytical techniques to determine PFAS at trace concentrations has increased the importance of monitoring these persistent organic pollutants in the environment. Recent toxicological studies have led to a significant reduction in the acceptable daily intake levels for certain PFAS in human consumption. Consequently, both European and Czech legislation are being updated to reflect these new scientific findings.

The water management laboratories of the Vltava River Basin have been monitoring selected PFAS in surface and wastewater since 2023. A direct injection LC-MS/MS method for 20 PFAS, with detection limits of 0.5 to 6 ng/l, has been developed and validated to comply with Czech regulations. A parallel off-line SPE method using a Labtech XANA and D-EVA system was subsequently developed to achieve significantly lower detection limits required by stricter European directives.

The article presents and statistically analyzes the findings of perfluorinated compounds in waters within the

Vltava River basin in 2024. The obtained results most frequently showed the presence of perfluoroalkyl acids (PFOA, PFHxA, PFHpA and PFPeA).

3.27.P-Mo247 Development and Application of an Accurate Mass PFAS Library for GC/Q-TOF Analysis in Environmental Samples

Janina Kornas¹ and Sofia Nieto², (1)Agilent Technologies, Germany, (2)Agilent Technologies, United States

Per- and polyfluoroalkyl substances (PFAS) are persistent environmental contaminants detected in water, soil, and biota, posing significant analytical challenges due to their chemical diversity and volatility. We report the creation of an accurate mass Personal Compound Database and Library (PCDL) for PFAS analysis using high-resolution GC/Q-TOF instrumentation. The library comprises ~150 EI spectra with accurate m/z values, retention times, and structural identifiers, enabling both targeted and non-targeted workflows. Soil and drinking water samples were extracted using optimized solid-phase and solvent-based methods as well as SPME, followed by full-spectrum acquisition and screening. The PFAS PCDL facilitated confident identification of multiple PFAS classes, including fluorotelomer alcohols and perfluoroalkyl ethers, in environmental matrices. Additionally, complementary screening using NIST and pesticide libraries revealed co-occurrence of pesticides, PAHs, flame retardants, and industrial by-products. This approach demonstrates the utility of accurate mass libraries for comprehensive contaminant profiling and supports regulatory monitoring of emerging pollutants in complex environmental samples.

3.27.P-Mo248 Analyzing Ultra-short To Long Chain PFAS In Water Samples In A Single LC-MSMS Method With Maximized Sensitivity

Christian Hegmanns and Matthias Kamuf, Agilent Technologies, Germany

Christian Hegmanns, Matthias Kamuf

Agilent Technologies, Hewlett-Packard-Strasse 8, 76337 Waldbronn, Germany

The analysis of per- and polyfluorinated alkyl substances (PFAS) in aquatic matrices has significantly evolved in recent years. The chemical properties of the analytes of interest are covering a very broad range, including highly polar analytes such as trifluoroacetic acid (TFA) to very non-polar analytes like perfluorooctadecanoic acid (PFOcDA). Classic reversed-phase LC columns with C18 stationary phases work very well for separating homologous rows of PFAS analytes from medium to low polarities and even their branched isomers, but highly polar analytes are not retained sufficiently and therefore cannot be separated properly. On the other hand, HILIC columns can be used to retain and separate highly polar PFAS analytes, while the non-polar long-chain PFAS remain unseparated.[1]

With recommended drinking water concentration limits are getting even lower, lately,[2] there is a need for increased sensitivity, allowing lower quantification and detection limits.

Here we show how a specially designed mixed-mode stationary phase LC column can be used to achieve good retention and separation across the full range of polarity of PFAS analytes. This allows the analysis of water samples from different types of sources, using a single chromatographic method.

Furthermore, we demonstrate maximized sensitivity in case of SPE sample preparation prior to analysis, as well as in a dilute-and-shoot application.

3.27.P-Mo249 Ecotoxicogenomic Hazard Assessment of the Sweeteners Saccharin and Cyclamate for *Daphnia magna* and Investigation of Their Biodegradability

Jule Bucker¹, Alexandra Loll¹, Franziska-Frederike Wege¹, Bodo Philipp² and Sebastian Eilebrecht¹, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Faculty Biology, University Munster, Germany

Artificial sweeteners such as saccharin and cyclamate are widely used as food additives because they provide high sweetness with low calorie intake. Both compounds are characterized by high water solubility and chemical stability, which contributes to their incomplete removal in wastewater treatment plants. Consequently, saccharin and cyclamate are frequently detected in treated effluents and surface waters at concentrations up to the microgram-per-liter range. Their persistence and mobility in aquatic environments raise concerns about potential ecological effects due to long-term environmental exposure. Although previous studies have indicated microbial involvement in their degradation, the identity of the responsible species remains insufficiently understood. The sweetener sucralose has previously been shown to alter the swimming behavior of *Daphnia*

magna, while comparable data for saccharin and cyclamate are largely lacking, and ecotoxicological information on these compounds remains scarce.

The aim of this project is twofold: First, to contribute to the hazard assessment of saccharin and cyclamate by addressing the data gap regarding their toxicological properties, using *Daphnia magna* as a model organism. Behavioral and acute immobilization tests were conducted across environmentally relevant and high exposure concentrations. First results showed that saccharin and cyclamate do not cause significant changes in swimming activity and lethality of *D. magna*. Extracted RNA was then sequenced to identify possible gene expression alterations caused by the sweetener.

Second, it seeks to identify microorganisms capable of degrading these sweeteners. This research will contribute to efforts aimed at reducing the abundance of saccharin and cyclamate in aquatic ecosystems. To investigate the degradability of saccharin and cyclamate, solutions containing each sweetener as the carbon source were inoculated with sewage sludge from a wastewater treatment plant. Actively growing cultures could be enriched for both sweeteners. In the following steps, these will be identified after enrichment by colony PCR and 16S sequencing.

This integrated approach, combining ecotoxicological hazard assessment with microbial degradation studies, will not only enhance the understanding of the environmental impact of saccharin and cyclamate but also support the development of effective bioremediation strategies.

3.27.P-Mo250 Elucidating Organohalogen Micropollutant Interactions with Clay Minerals: High Adsorption Indicates Relevance for Environmental Fate Processes

Leonard Böhm¹, Martin H. Gerzabek² and Daniel Tunega², (1)Technische Universität Braunschweig, Germany, (2)BOKU University, Austria

Hydrophobic halogenated micropollutants widely show persistent, bioaccumulative, and toxic characteristics that lead to adverse effects on humans and other biota. The knowledge of sorption processes is highly relevant to estimate their mobility and retention and thereby to assess their environmental fate and risk. Their interactions with organic matter are intensively studied, whereas data on interactions with clay minerals (CM) are still scarce, especially for neutral, hydrophobic organohalogen compounds (OHC). To mechanistically elucidate OHC–CM interactions, we combined laboratory experiments with molecular modeling.

We studied OHC–CM interactions with five halogenated benzenes (log KOW 2.6–6.5) as well as twelve pure phyllosilicate CMs and 21 smectite-rich bentonites as mineral phases in laboratory adsorption experiments. Molecular modeling was performed at the density functional theory (DFT) level for the same five OHCs and montmorillonite models of varying mineral structure with and without explicit solvation.

Our results show that OHCs can adsorb to clay minerals to a relevant extent, with a strong mutual influence of OHC and CM properties on the extent of adsorption. Expectedly, the hydrophobicity of the OHCs played a crucial role for the extent of adsorption but can be outweighed by mineral properties. Results from molecular modeling did align well with laboratory results but partly deviated based on hydration state.

In particular, our results i) show the relevance of CMs for OHC adsorption with a wide variation of solid-liquid adsorption coefficients over orders of magnitude (log K_d <1.0 to >5.0); ii) provide mechanistic understanding of the influence of CM characteristics such as layer charge, exchangeable cations, particle size, and pore size distribution on adsorption; and iii) elucidate the hydration state to be critical both for the extent of adsorption energies and the type of interaction processes.

Overall, our results suggest a strong influence of specific OHC–CM interactions on the environmental distribution of OHCs and challenge the widely accepted paradigm that neutral (highly) hydrophobic compounds are (almost) exclusively sorbed to organic matter.

Thereby, our results highlight the relevance of minerals for the fate, transport, and retention of OHCs in the environment, e.g. for the elucidation of long-term source/sink phenomena in soils and sediments as well as for applications in water treatment and landfill sealing.

3.27.P-Mo251 From Paper Food Contact Materials to Human Exposure: Characterizing PFAS Contamination, Migration Dynamics, and Health Risks

Paper-based food contact materials (FCMs) have been found to contain per- and polyfluoroalkyl substances (PFASs). Under high-temperature short-time (HTST) and long-term storage (LTS) conditions, PFASs from paper FCMs can migrate into dry and lipophilic foods. However, apart from using food simulants like 50% ethanol, there is a lack of research on the representativeness of other simulants, such as vegetable oil and Miglyol 812, for lipophilic foods. The objective of this study was to assess PFAS migration from paper FCMs to lipophilic foods under both HTST and LTS conditions. This study compiled occurrence data on per- and polyfluoroalkyl substances (PFASs) in FCMs from domestic and international sources collected between 2013 and 2024. The materials examined included paper bags, boxes, cups, plates, and grease-resistant paper, with a focus on perfluorocarboxylic acids (PFCAs, C4–C18), perfluorosulfonic acids (PFSAs, C4–C10), and PFAS precursors. To bridge regional monitoring gaps, 45 paper bag and box samples were collected from various retail channels in Taiwan. Samples were extracted using ultrasonic-assisted methanol extraction (60°C) and analyzed by LC–MS/MS and GC–MS/MS, following the CEN/TS 15968:2010 standard for targeted screening. Method validation confirmed recovery rates of 70–130% and detection limits of 0.5 µg/m². AKTS SML software was employed to simulate migration under HTST and LTS conditions. Migration simulations were conducted in accordance with EU and U.S. FDA regulations. The relative potency factor (RPF) approach was applied to convert individual PFAS exposures to PFOA equivalents for assessing human health risks. The results showed that precursors, specifically 8:2 fluorotelomer alcohol (8:2 FTOH), dominated in paper bags, significantly exceeding PFCAs, PFSAs, and other classes of compounds. Conversely, paper boxes showed markedly lower levels, indicating that paper bags were the primary source of concern. Under HTST conditions (175°C, 2 h), 50% ethanol proved to be the most effective extraction method, with precursor migration rates observed in paper bags. Crucially, LTS conditions (25°C, 15 months) resulted in 57% precursor migration, substantially surpassing standard simulation predictions (40°C, 10 days). This suggests current protocols may underestimate cumulative exposure risks. Exposure assessment confirmed HTST contact as a critical scenario, with 8:2 FTOH in paper bags presenting the highest exposure load.

This study was provided by a grant from the National Science and Technology Council, Taiwan (NSTC 110-2222-E-019-003-MY3; NSTC 113-2221-E-019-008-MY3).

3.27.P-Mo252 Method Validation for the Analysis of per- and polyfluoroalkyl substances (PFAS) in Water Samples using Solid Phase Extraction and Liquid Chromatography coupled to Tandem Mass Spectrometry

Ana Isabel Penetra Dra.¹, Vitor Cardoso², Rui Carneiro² and Andreia Videira², (1)ADP, Portugal, (2)Empresa Portuguesa das Águas Livres, S.A. - EPAL, Portugal

PFAS are a group of persistent chemicals widely used in various industrial and consumer products. Due to their persistence and potential adverse health effects, rigorous and sensitive analytical methods are needed that can monitor these compounds [1].

The Council Directive 2020/2184 of 16 December 2020 regarding the quality of water intended for human consumption states the parametric value for “Sum of 20 PFAS” of 0,1 µg/l and that the analytical methods should allow the quantification for “Sum of 20 PFAS “ at 30% of the parametric value [2].

The objective of this work was the implementation and validation of an analytical method for analysing the “Sum of 20 PFAS” in raw water and water for human consumption, namely: PFBA, PFPeA, PFBS, PFHxA, PFPS, PFHpA, PFHxS, PFHpS, PFOA, PFOS, PFNA, PFNS, PFDA, PFDS, PFUnDA, PFUnDS, PFDoDa, PFDoDS, PFTrDA and PFTrDS. The method was validated by applying several statistical tests: linearity, precision, accuracy, method quantification limit and matrix effects. Simultaneously, the prevention and mitigation of cross-contamination of these compounds in the laboratory was also studied.

Mass spectrometer parameters were optimized for each PFAS and two different MRM transitions were selected. Some compounds showed significant ion suppression effects (-57,5% for PFBA, -49,5 for PFPeA, -40,6% PFHxA, - 33,6% for PFHpA). For those compounds surrogate labelled compounds were used for results correction. This method showed excellent linearity ranges for all compounds (between 0,150 and 1,500 µg/L), with correlation coefficients greater than 0,9993. Recovery studies in several matrices with different fortification levels were performed using solid phase extraction with recoveries between 68% (PFDoDs) and 102% (PFOS) with RSD lower than 14,9% (PFBS). The Method Reporting Limit set for all compounds was 1,5 ng/L. The expanded uncertainty (k=2) of the analytical method was below 34,9% (PFBS). Interlaboratory studies showed

good performance for this method with z-scores of -0.5 for PFOS and -1.87 for PFOA.

Between 2023 and 2025 an extensive monitoring campaign was carried out in the EPAL and Águas do Vale do Tejo (AdVT) supply system to investigate the occurrence of PFAS in drinking water, surface water and groundwater. The compounds that were commonly found in drinking water and surface water were: PFBA, PFPeA, PFBS, PFHxA, PFHxS, PFOA and PFOS. None of the monitored PFAS were found in groundwater samples.

3.27.P-Mo253 Dissolved Organic Matter Accelerates the Aquatic Photochemistry of the Rubber Additive Diphenyl Guanidine (DPG)

Shira Joudan¹, Nipuna Senanayake², Samantha Burke² and Summer Scott², (1)Chemistry, University of Alberta, Canada, (2)University of Alberta, Canada

Diphenyl guanidine (DPG) is a widely used rubber vulcanizer that has emerged as an environmental contaminant of concern. While attention has focused on phenylenediamines like 6PPD and their toxic transformation products, DPG has been detected at relatively high concentrations in diverse environmental matrices. Despite its abundance, little is known about the environmental fate, transformation pathways, and toxicity of DPG. This study aims to address critical knowledge gaps by investigating the direct and indirect photochemical degradation pathways and kinetics of DPG in aqueous systems. Aqueous photochemistry experiments were performed using lamps centred at UV-B in solutions with and without dissolved organic matter (DOM) to explore the difference between direct and indirect photochemistry. DPG quantitation was performed with high-performance liquid chromatography with UV detection. We found that DOM from the Mississippi River increased the removal rate of DPG in a concentration dependent manner by up to 8x. Transformation products were identified using Orbitrap high resolution mass spectrometry. Phenylguanidine was formed in experiments both with and without DOM and confirmed with a standard. We tested the photochemical rate constant of phenylguanidine and found it was twice as fast as DPG. In direct photochemistry experiments, an oxygen addition transformation product [DPG+O] was identified. Ongoing work will explore the structure of this oxidation product; chromatographic peaks imply there are multiple sites of oxidation on structure. These findings have implications for understanding the environmental persistence and risks associated with DPG as a rubber-related chemical, as well as its transformation products, which are generally more water soluble and thus more mobile.

3.27.P-Mo254 Ecotoxicological Monitoring of the Photocatalytic Degradation of Micropollutants by Nano Metal-Oxide Based Photocatalysts

Judit Háhn, Balázs Göbölös, Gergő Tóth, Illés Bock, Zsolt Csenki-Bakos, István Szabó, Balázs Kriszt and Edit Kaszab, Hungarian University of Agricultural and Life Sciences (MATE), Hungary

Within the framework of the circular economy, it is essential to identify and develop technologies capable of treating wastewater generated by various industrial activities so that the treated and recovered water meets the quality requirements for agricultural reuse. However, current wastewater treatment processes often fail to remove numerous micropollutants, which—upon entering the environment—may harm ecosystems, disrupt biological functions, and bioaccumulate in organisms. Although several emerging processes can remove micropollutants, they may also generate metabolites or by-products with toxicity comparable to, or even exceeding, that of the parent compounds. Ecotoxicological assays therefore provide an excellent tool for monitoring treatment performance and evaluating whether degradation processes truly reduce environmental hazards.

In this work, we investigated the efficiency of pollutant photodegradation by 3D-printed photocatalysts containing nano-metal oxides, using aquatic ecotoxicological assays representing three trophic levels. We assessed the biological effects of the nano-metal oxides themselves, the photocatalysts produced from them, and the residues originating from the degradation of rhodamine B and paracetamol using the *Aliivibrio fischeri* cytotoxicity test, the *Daphnia magna* immobilization assay, and the zebrafish (*Danio rerio*) embryo (ZETA) test. This integrated approach enabled us to evaluate both the direct toxicity of the materials and the ecological relevance of the treated effluents.

Our results clearly showed that nano-metal oxides exhibit toxicity toward all test organisms, whereas the 3D-printed structures exerted substantially lower effects, indicating that sintering reduces the biological impact of the catalytic components. For rhodamine B solutions treated with the printed structures, a marked decrease or even complete elimination of toxicity was observed, confirming effective detoxification alongside photodegradation. These metal-oxide composite-based structures therefore mitigate the negative effects associated with metal-ion release and efficiently photooxidize and detoxify micropollutants. Overall, our findings highlight the importance of combining advanced treatment technologies with ecotoxicological

assessment to ensure that wastewater treatment processes targeting micropollutant removal are both effective and environmentally safe.

This research was carried out within the framework of the Water4All Co-funded Partnership. The project was supported by the National Research, Development and Innovation Office (NKFIH) under project ID 2023-1.2.2-HE_PARTNERSEG-2023-00009.

3.27.P-Mo255 PFAS in Brazilian Citrus Commodities: Levels, Sulfluramid as a Key Precursor, and Human Health Risk Implications

Pedro Neves¹, Gabrielle Nascimento¹, Gabriel Henrique Savietto² and Marilia Cristina Oliveira Souza¹, (1)University of São Paulo, Brazil, Brazil, (2)University of São Paulo (USP), Brazil

Brazil is the world's largest consumer of pesticides, and sulfluramid (EtFOSA) is extensively used to control leaf-cutter ants. Its aerobic degradation produces perfluorooctanesulfonic acid (PFOS) and, through indirect aqueous photolysis, perfluorooctanoic acid (PFOA), two persistent and bioaccumulative per- and polyfluoroalkyl substances (PFAS). Despite evidence that PFAS can migrate through soils, water, and food webs, data on their occurrence in tropical agricultural commodities and transfer across interconnected environmental and biological matrices remain limited. Within a One Health framework, assessing PFAS exposure is critical, as it integrates environmental persistence, crop uptake, food and water contamination, and potential impacts on human and animal health. High exposures to PFOS and PFOA have been linked to immunotoxic, carcinogenic, metabolic, and developmental effects. Yet, dietary exposure data from major food-producing regions in the Global South are scarce.

This study developed an analytical methodology for detecting PFOS and PFOA, originating directly or via sulfluramid degradation, in Brazilian citrus commodities. Using ultra-high-performance liquid chromatography coupled to sequential mass spectrometry (UPLC-MS/MS) with QuEChERS sample preparation, 60 citrus samples from São Paulo were analyzed, the state that represents approximately two-thirds of the planting territory and three-quarters of the production of this citrus fruit of Brazil. The calibration curve ranging from 0.001 to 100 ng/mL. PFOA was detected in 100% of samples, and PFOS was the second most prevalent compound, while sulfluramid was detected in some samples, likely due to rapid transformation into its degradation products. Estimated daily intake, hazard quotient (HQ), and cancer risk (CR) assessments revealed $HQ > 1$ and $CR > 10^{-6}$ for PFOA, highlighting potential health risks for domestic consumers and international importers.

The methodology proved reliable and reproducible despite analytical challenges, providing crucial data from an underrepresented region. These findings underscore the need for regulatory monitoring of PFAS in Brazilian food and contribute to understanding PFAS dynamics across environmental, animal, and human health interfaces under the One Health paradigm.

3.27.P-Mo256 Children's Exposure to Airborne Chemicals in Danish Schools and Homes

Paula Guedes¹, Maria A. Aretaki², Rossana Bossi³, Judith Desmet², Barend L. van Drooge⁴, Ethel Eljarrat⁴, Louise Frederickson¹, Patrik Fauser¹, Andreas Massling³, Mar Viana⁴, Heidi Salonen⁵ and Katrin Vorkamp³, (1)Aarhus University, Denmark, (2)Institute for Environmental Assessment and Water Research (IDAEA-CSIC) & Department of Analytical Chemistry and the Environment, PhD program of University of Barcelona (UB), Spain, (3)Department of Environmental Science, Aarhus University, Denmark, (4)Institute for Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (5)Aalto University, Department of Civil Engineering & Queensland University of Technology, International Laboratory for Air Quality and Health, Finland

Indoor air quality assessments often overlook chemical mixture complexity, limiting comprehensive health risk evaluations for vulnerable groups like children. This study addresses this gap by analysing fluorotelomer alcohols (FTOHs; known PFAS precursors), biocides, plasticisers, polycyclic aromatic hydrocarbons (PAHs), and brominated and organophosphorus flame retardants (BFRs and OFRs) in air and dust samples from Danish

homes and schools. The chemical data is integrated with results from a walkthrough survey for the characterisation of classrooms, buildings, and surroundings.

Samples were collected at five schools, one school gym, and five homes between October 2024-2025, with two sampling periods per site. Air samples were collected using low-volume pumps (4.0 L min⁻¹) during school hours and overnight/weekends in homes, with dual Isolut® ENV+ SPE cartridges. After sampling, cartridges were spiked with labelled standards and extracted using group-specific solvents. Extracts were analysed for FTOHs and BFRs by GC/MS, biocides by LC-MS/MS, PAHs by GC-MS/MS, and OFR and plasticisers by LC-MS/MS coupled with turbulent flow chromatography (TFC) for online purification. Dust was collected via gravitational settling over five months and by vacuum sampling.

Preliminary data show the presence of FTOHs in all air samples, dominated by 6:2 and 8:2 homologues.

Concentrations ranged between 258–10,959 pg m⁻³ in schools, with homes showing significantly higher levels (up to 49,641 pg m⁻³), likely due to lower nighttime ventilation and more emission sources. PAHs also showed higher levels in homes (1,694–104,398 pg m⁻³) compared to schools (1,701–41,358 pg m⁻³). Five of the 12 biocides were detected in air, with DEET reaching 215,472 pg m⁻³ in one school sample. Other biocides appeared less frequently and at lower levels (5–648 pg m⁻³). BFRs were below detection limits in air. Analysis of the other chemical groups is ongoing, and dust samples are being processed.

These preliminary findings confirm high indoor chemical concentrations in some Danish homes and schools. Elevated FTOH and PAH levels in homes highlight ventilation and emission source roles. The results support comprehensive risk assessments that consider combined chemical burdens rather than individual compounds. By integrating chemical data with environmental and behavioural walkthrough surveys, this study aims to guide evidence-based exposure reduction strategies, emphasising emerging pollutants.

Disclaimer/Disclosure:

This work was part of the project InChildHealth (grant agreement ID: 101056883), funded by the European Union. The authors would like to thank Birgit Groth and Annegrete Ljungqvist (Aarhus University) and Roser Chaler and Alex Garcia (IDAEA-CSIC) for technical assistance in the laboratory.

3.27.P-Mo257 Robust Methodology for Hyperspectral Characterization of PFAS in Plant Matrices Using AI

Delfin Rodriguez Minguez¹ and Carmen Fernandez Lopez², (1)Politechnic University of Cartagena (Spain), Spain, (2)University Defense Center, (CUD), Spanish Air Force Academy, MDE-UPCT, Spain

Per- and polyfluoroalkyl substances (PFAS) are persistent contaminants with severe environmental and health implications. Traditional detection methods are costly and spatially limited, creating an urgent need for scalable, non-invasive solutions. This study has developed a robust methodology for hyperspectral characterization of PFAS in plant matrices (focus on *lactuca sativa*), enabling indirect detection of soil contamination through vegetation.

The central hypothesis was that PFAS uptake induces physiological stress in plants, altering leaf optical properties and generating distinctive hyperspectral patterns. To test this, lettuces (*Lactuca sativa*) have been grown under controlled hydroponic conditions with graded PFAS concentrations and extracted by means of liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS). Physiological indicators (e.g., stomatal conductance, chlorophyll fluorescence) have been monitored alongside hyperspectral signatures across VIS–NIR and red-edge regions. These data have been used to train AI models to identify spectral markers linked to PFAS accumulation.

The outcomes include validated algorithms capable of discriminating PFAS-induced spectral changes from other stressors, ensuring specificity and robustness. The methodology could be scaled to UAV and satellite imagery for operational monitoring. This approach addresses a critical knowledge gap by linking PFAS bioaccumulation to plant spectral response, offering a transferable protocol for precision agriculture and environmental surveillance. Its relevance lies in reducing monitoring costs, enabling dynamic risk mapping, and supporting regulatory compliance in sensitive areas. By integrating hyperspectral sensing with AI-driven analytics, this research advances remote contamination detection and strengthens strategies for sustainable soil management and food safety.

3.27.P-Mo259 PFAS in Elemental Analysis: Towards a Routine Screening Method for Total Fluorine

Alexander Köhrer¹, Matthias Schmitt¹, Friederike Luenne² and Martin Wende¹, (1)BASF, Germany, (2)BASF SE, Limburgerhof, Germany

The European Union aims to impose restrictions on the use of per- and polyfluoroalkyl substances (PFAS) across various products and processes. Among other analytical challenges, the feasibility of the approach is heavily dependent on fast screening methods as over 10,000 substances fit the common PFAS definitions. Here, elemental analysis of fluorine can serve as an effective tool. By careful consideration and selection of methods like Graphite-Furnace Molecular Absorption Spectrometry (GF-MAS) or Combustion Ion Chromatography (CIC) as well as suitable sample preparation methods, several sum parameters can be determined, offering flexibility and applicability to a wide range of samples and matrices.

Two major analytical challenges were addressed in this study. First, the differentiation between inorganic and organic fluorine species was investigated by applying mass balancing approaches and selective enrichment. Second, species-specific response behaviors in fluorine quantification were eliminated through systematic comparison of digestion methods. This is particularly important for samples with unknown fluorine species composition. The most effective digestion approach was implemented in a semi-automated system, reducing manual workload and delivering substantial time savings while maintaining analytical reliability.

3.27.P-Mo260 Assessment of Health Risks from Polycyclic Aromatic Hydrocarbons and Their Halogenated Derivatives in Residential Indoor Environments

Tetsuya Takikawa, Kazushi Noro and Takashi Amagai, University of Shizuoka, Japan

Polycyclic aromatic hydrocarbons (PAHs) and their halogenated derivatives (XPAHs) are emerging persistent organic pollutants with potential carcinogenicity. Their occurrence in indoor environments remains largely unexplored. We measured 26 PAHs and 40 XPAHs in indoor air and house dust from 45 residences in Toyama, Shizuoka, and Kanagawa, Japan (2022–2024). XPAHs were detected at all sites, with concentrations 10^3 – 10^4 times lower than PAHs but with similar size distributions and compositions, suggesting analogous atmospheric behavior. Homes using unventilated wood stoves exhibited indoor/outdoor ratios >10 for high-molecular-weight PAHs, notably benzo[a]pyrene, indicating strong indoor sources. Cancer risk assessment showed inhalation as the dominant exposure pathway, with 95th percentile incremental lifetime cancer risk exceeding 1×10^{-6} in several areas, surpassing safety thresholds. These results demonstrate that indoor exposure to PAHs and XPAHs may pose non-negligible health risks and underscore the need for mitigation strategies, such as PM_{2.5} reduction, to protect public health.

3.27.P-Mo261 Towards accurate estimation of extractable (organic) fluorine (EOF)

Johannes Kikuchi-McIntosh¹, Malin Montelius², Gustav Sporre¹, David Bastviken¹ and Teresia Svensson¹, (1)Linköping University, Sweden, (2)Swedish Geotechnical Institute, Sweden

Given the complexity and abundance of fluorinated organic compounds in the environment, broader analytical methods like extractable organic fluorine (EOF) and adsorbable organic fluorine (AOF) with combustion ion chromatography, are now commonly employed to assess contamination levels across various matrices. Although it is well-known that fluoride in sample extracts can lead to overestimation of EOF as the measurement does not inherently distinguish between organically bound fluorine and inorganic fluorine (i.e. fluoride), it is still largely neglected primarily due to lack of adequate analytical approaches. In this study, we investigated the presence of fluoride (F-) in EOF-extracts and designed and validated a method for fluoride determination in small aliquots (~250 µL) of complex aqueous- and solvent matrices. The method is based on derivatization of fluoride to triphenylfluorosilane (TPSiF) with gas-chromatographic tandem mass spectrometry analysis (GC-MS/MS). Calibration was linear from 1–1000 µg/L ($R^2 > 0.99$) and the limit of detection (LOD) and quantification (LOQ) was 0.98 and 4.5 µg F-/L respectively. The relative standard deviation (RSD) was below 7% across the calibrated range. Certified reference material (CRM River water) and fluoride spiked minced meat were used to assess fluoride recovery to $103 \pm 3\%$ ($p = 0.10$) and $95 \pm 6\%$ ($p = 0.31$) of certified/spiked concentrations. Analysis of sample extracts showed that (1) solid phase extraction (SPE)-extracts of river water, (2) solvent extracts from aqueous-film-forming foam (AFFF)-impacted soil, and (3) extracts of a fish sample contained 29–49, 61 ± 4.7 , and 17–90 µg F-/L respectively. F- accounted for 3–59% of the measured EOF, indicating substantial overestimation. Therefore, the analysis and discount of F- in EOF-extracts is essential for accurate EOF determination by CIC. This study highlights the risk that past analyses may have overestimated EOF concentrations, in some cases as much as by 750%. Mitigating such large biases are important for accurate monitoring of environmental concentrations and for the evaluation of remediation strategies to remove PFAS in soils and waters, particularly in light of current regulatory development concerning EOF and PFAS. As such, we recommend that F- determinations of extracts are routinely employed to improve accuracy of the fluorine mass balance calculation and avoid overestimation of the EOF-content.

3.27.P-Mo262 Ecotoxicogenomic Evaluation of the Photodegradation Products of Acesulfame-K

Rachael Inegbedion¹, Alexandra Loll², Benedikt Ringbeck³, Susanne Baldermann⁴ and Sebastian Eilebrecht³, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME) & Food Metabolome, Faculty Life Sciences, University of Bayreuth, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME) & Faculty Biological Sciences, Goethe University Frankfurt, Germany, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Food Metabolome, Faculty Life Sciences, University of Bayreuth, Germany

Sugars provide essential dietary energy, but excessive intake is linked to several cardiometabolic conditions, prompting increased use of low-calorie artificial sweeteners. Acesulfame-K (Ace-K) is highly stable and minimally metabolized, leading to its frequent detection in aquatic environments, especially downstream of wastewater treatment plants. This persistence raises concerns about the formation of photodegradation products, such as sulfamic acid, during ultraviolet disinfection or from sunlight exposure. Although sulfamic acid is used in various household and industrial applications, its presence in surface waters may pose ecological risks. This study assessed the formation of Ace-K photodegradation products under simulated sunlight and UV irradiation. Also, acute toxicity was assessed using *Danio rerio* embryos and *Daphnia magna* according to the Organisation for Economic Cooperation and Development (OECD) test guidelines. Thereafter, transcriptome responses were evaluated to identify sub-lethal and molecular-level impacts. For the photodegradation experiments, Ace-K at pH 4, 7, and 9 was irradiated with simulated sunlight (>290 nm) for 20 days or UV light (254 nm) for 30 minutes. Samples were analyzed to quantify Ace-K and detect transformation products. For ecotoxicogenomic tests, *Daphnia magna* and *Danio rerio* embryos were exposed to fully degraded Ace-K and its known transformation product; sulfamic acid. RNA was extracted and sequenced. Statistically significant differentially expressed genes (DEGs) were identified using DESeq2, followed by over-representation analysis (ORA) using clusterProfiler. In this study, Ace-K was found to be stable in the UVB/UVA and visible light spectrum (>290 nm) but it is rapidly degraded under UVC, forming some transformation products such as hydroxyl-acesulfame and sulfamic acid. Ecotoxicology tests on *Danio rerio* revealed no significant morphological effects at low (10 µg/L) or high (100 mg/L) exposures. Ongoing molecular analysis will further explore potential effects on gene expression. Further insights are to be gained through the ecotoxicology experiments with *Daphnia magna*. These findings improve understanding of Ace-K environmental fate and highlight the importance of considering transformation products in risk assessment.

3.27.P-Mo263 Leveraging AFFFs to support suspect screening of PFAS in marine biota of low trophic level

Ninon Serre¹, Randolph Singh², Catherine Munsch¹, Aurore Zalouk-Vergnoux³ and Yann Aminot¹, (1)French Institute for Ocean Science (IFREMER), France, (2)Columbia University, Mailman School of Public Health, United States, (3)University of Nantes, France

Per- and polyfluoroalkyl substances (PFAS) are synthetic chemicals extensively used for their unique properties, which have led to widespread environmental contamination, including in marine ecosystems. Notably, a wide range of PFAS is used in aqueous film-forming foam (AFFF) formulations, which are well-known sources of PFAS contamination. This study explores the use of AFFFs as qualitative reference materials to support suspect screening of PFAS in organisms of low trophic level.

Mussels and oysters were sampled in 2021 from 23 sites along the French coast. Samples were extracted using methanolic potassium hydroxide and purified through solid-phase extractions (WAX and ENVI-Carb-SPE). Analyses were performed using a LC-QTOF (Agilent Technologies). Suspect screening was conducted using EI-MAVEN software and an in-house suspect list of 866 PFAS. To enhance detection and annotation, 14 different AFFFs were analyzed as reference materials. Two types of AFFFs were included: FT-AFFFs, which contain mainly polyfluoroalkyl compounds, and ECF-AFFFs which predominantly contain perfluoroalkyl compounds.

Overall, 79 PFAS from 29 chemical classes were detected including non-biotransformed precursors. Most of the compounds detected in the bivalves were also detected in AFFFs. This work demonstrates the effectiveness of using AFFF formulations as reference material in PFAS suspect screening workflows. Co-analysis with biological extracts greatly assisted peak attribution, as a high number of features is found in these complex matrices increasing the likelihood of false-positive annotations. Applied to low trophic level species, such as mussels and oysters, this approach enhanced the detection of precursor compounds that might otherwise be biotransformed and undetected in higher trophic levels. In this study, AFFF played a key role by helping recover

low-intensity signals in biota samples, thereby improving detection sensitivity. In several cases, they were also essential for distinguishing between candidate isomeric structures, either with the characteristic FT-AFFF/ECF-AFFF composition pattern, or by providing key MS/MS information. This methodology highlighted numerous unregulated and not routinely monitored PFAS, some of which are, to the best of our knowledge, reported for the first time in marine organisms (e.g., X:2 FTSAm). The approach presented here offers a practical and informative strategy for expanding PFAS monitoring efforts in marine environments.

3.27.P-Mo264 Nontarget screening workflow for the analysis Per-and-polyfluoroalkyl substances in environmental samples using a benchtop multi-reflecting Time-of-flight mass spectrometer

Hania Hollins, Sara Beverley, Richard Lock, Isabel Riba and Jayne Kirk, Waters Corporation, United Kingdom

The widespread use of per and polyfluoroalkyl substances (PFAS) in industrial processing and manufacturing over the last decades has led to global environmental and health concerns. As the number of these compounds continues to increase, it is becoming a challenging task to monitor PFAS using the traditional targeted methods. A screening workflow using High Resolution Mass Spectrometry (HRMS) is an ideal bridge for monitoring the regulated PFAS and detecting non-regulated PFAS.

Here, PFAS content in river, biosolid and river leachate was determined. PFAS extractions were performed following the EPA 1633 guidance. 2 µL of both samples and standards were analyzed using an ACQUITY™ Premier UPLC™ system coupled to a benchtop multi-reflecting time-of-flight (MRT) mass spectrometer (Xevo™ MRT). Data were acquired in negative ionization mode at 20 Hz scan speed, using MSE, a data independent mode of acquisition.

The levels of sensitivity and dynamic range were evaluated for at least 30 PFAS standards. Non-Target screening (NTS) workflow within waters_connect software along with the PFAS libraries (in-house Waters generated and an online version of the NIST PFAS library), enabled the identification and quantification of at least five compounds with a mass measurement of <500 ppb and mass resolution of >60,000 FWHM, in river, biosolid and leachate samples. The samples tested contained varying amounts of PFAS.

The work described highlights the exceptional mass accuracy, sensitivity, high mass resolution, and dynamic range of the Xevo MRT MS system for PFAS analysis. For most of the tested compounds the limits of detection were in the low ng/L range (< 5 ng/L). The dynamic range spanned at least four orders of magnitude from 1 to 10,000 ng/L. The screening workflow is based on accurate mass, fragment ion information, isotopic matching and mass defect, this coupled with high mass resolution, fast scan speeds and exceptional levels of mass precision of the. Using the NTS workflow allowed the detection of PFAS compounds that were not incorporated into the PFAS libraries. Xevo MRT mass spectrometer significantly reduces false positives and enables rapid, confident assignment and identification of PFAS related compounds.

3.27.P-Mo265 Concentrations and Profiles of Per- and Polyfluoroalkyl Substances (PFAS) in Dust and Drinking Water from the United Kingdom: Implications for Human Exposure

Liu Yang, Stuart Harrad, Mohamed Abou-Elwafa Abdallah and Daniel Drage, University of Birmingham, United Kingdom

Per- and polyfluoroalkyl substances (PFAS) have found extensive application in a wide range of manufacturing industries and commercial products due to their water and grease proofing properties. Several legacy PFAS have been listed as persistent organic pollutants (POPs) for restriction and ultimate elimination under the Stockholm Convention, leading to the introduction of a growing number of novel PFAS as substitutes. However, both the extent of novel PFAS contamination in indoor environments of the United Kingdom (UK) and the associated exposure levels of the population are still poorly understood. Therefore, our study aims to explore a suite of 44 PFAS in indoor dust and drinking water and to conduct a preliminary exposure and risk assessment of the UK population to PFAS. Indoor dust and drinking water samples were collected from households and offices in the West Midlands, UK, followed by quantitative analysis using ultra-performance liquid chromatography coupled to quadrupole time-of-flight mass spectrometry. PFAS were detected in all samples, with the median total concentration of 114 and 84.8 ng/g in home dust and office dust, 2.26 ng/L in household tap water and 1.54 ng/L in office drinking water, respectively. The estimated daily intakes of PFAS through dust digestion and water consumption were 0.07 and 0.14 ng/kg body weight/day for adults and 0.42 and 1.34 ng/kg body weight/day for toddlers, under average and high exposure scenarios, respectively. Household tap water

represented the primary contributor to the median daily PFAS intake for adults (54.4%), whereas home dust ingestion was the dominant source for toddlers (69.9%). Our study highlights the widespread occurrence of legacy and novel PFAS in the UK indoor environment and underscores the need for continued monitoring and prompt regulatory actions to reduce the risk of PFAS to human health and the UK environment.

3.27.P-Mo266 PFAS Measurements in Complex Environmental Samples (Biosolids, Soil, Sediment, Wastewater) with Enhanced Matrix Removal and Automation

Mike Chang, Matthew Giardina and Limian Zhao, Agilent Technologies, United States

Recent method development efforts to measure PFAS compounds in various sample matrices led to testing standards including but not limited to those published by USEPA, ASTM, ISO and many other agencies and institutions. PFAS testing has evolved to measure down to ng/L (or pg/L) in drinking water and ng/mg in other solid environmental samples. While expanding testing protocols to more complex matrices outside drinking water samples, one of the most challenging aspects of the analytical workflow lies in the effectiveness of sample matrix cleanup. Matrix interferences coming from the complex sample matrices can not only damage the instruments requiring more frequent maintenance on them, but also inconsistent data can result in false positives/negatives.

To address this issue for complex environmental sample preparation, greatly enhanced cleanup approach is applied streamlining the workflow and minimizing human errors resulting in consistent data meeting USEPA 1633A requirements with soil and biosolids

3.27.P-Mo267 Investigating the Organofluorine Load in a UK Wastewater Treatment Plant

Rafael Georgiou¹, Crispin Halsall¹, Jon Barber², Sara Losada² and Jonathan P. Benskin³, (1)Lancaster University, United Kingdom, (2)Centre for Environment, Fisheries and Aquaculture Science (Cefas), United Kingdom, (3)Stockholm University, Sweden

Poly- and Perfluoroalkyl Substances (PFAS) are a diverse group of persistent and bioaccumulative synthetic chemicals found in numerous consumer products due to their thermal and chemical stability, and water- and grease-resistant properties. Their extensive applicability, detection in many environmental media, toxicity and ubiquitous occurrence, has led to significant regulatory responses to manage PFAS pollution by replacing legacy PFAS with novel alternatives. Eventually, these substances find their way into the environment throughout their life cycle from manufacture to waste disposal. PFAS and other fluorinated substances enter wastewater and runoff streams and eventually end up in rivers and estuaries. However, PFAS represent only a fraction of the organofluorine present in wastewater with other sources including pharmaceuticals, pesticides and polymer-derived fragments. Because many of these substances lack standards and established analytical methods, targeted methods likely underestimate the amount of organic fluorine burden in WWTPs. To address this a combined mass balance approach integrating targeted analysis, Extractable Organic Fluorine (EOF) and Total Fluorine (TF) was utilised to investigate the organofluorine loads in a UK WWTP. Diffusive gradient in thin films (DGTs) passive samplers were deployed across treatment stages and sludge samples were collected to characterise the extractable organofluorine in the aqueous and solid compartments, respectively. Initial results showed that PFAS accounted only for 8% of the EOF for the aqueous compartment, while sludge-extractable organofluorine accounted only 0.2% of the TF. These findings reveal that the vast majority of the organofluorine in the WWTP is unidentified demonstrating the need for future developments of new holistic and sensitive analytical methods to better characterise the organofluorine burden in WWTPs.

3.27.P-Mo268 PFAS in Air: Regulatory and Standards Landscape, Method Development, and Workflow Guidance

Chris Llewellyn¹, Caroline Widdowson², Laura Miles² and Aaron Davies², (1)Business Development, Markes International Ltd, United Kingdom, (2)Markes International Ltd, United Kingdom

PFAS (per- and polyfluoroalkyl substances) are a group of highly persistent chemicals that are now recognized as a global concern. While much attention has focused on water and soil, PFAS can also be emitted into the air during industrial processes, product use, and waste handling. Once airborne, they may travel long distances, making air a critical pathway for dispersion and exposure.

Testing for PFAS in air is challenging. They can exist both as vapours and bound to particles, they occur at very low concentrations, and background contamination can easily compromise results. For industry and environmental consultants tasked with source emission testing and environmental monitoring, understanding these challenges and the expectations of regulators is essential.

This presentation is designed to give a clear overview of the current landscape for monitoring PFAS in air. It will outline practical considerations for sampling and analysis, highlight the importance of contamination control, and provide updates on U.S. and international efforts toward method development, standardization, and regulatory guidance. Example workflows using thermal desorption coupled with gas chromatography-mass spectrometry (TD-GC-MS) will also be discussed, showing how these techniques can be applied to real-world testing of PFAS in air.

3.27.P-Mo269 Hydrodynamic Modelling of Pharmaceuticals and PFAS in a Swedish Lake: Spatiotemporal Variations

Ekaterina Sokolova¹, Mikael Gustavsson² and Jorrit Mesman³, (1)Department of Earth Sciences, Uppsala University, Sweden, (2)University of Gothenburg, Sweden, (3)Uppsala University, Sweden

Human-derived micropollutants such as active pharmaceutical ingredients (APIs) and per- and polyfluoroalkyl substances (PFAS) are continuously released to surface water sources, mainly via wastewater and riverine inputs. Conventional monitoring typically provides sparse data in space and time, making it difficult to characterise concentration dynamics and to support risk assessment and drinking water protection. This work addresses the challenge of predicting spatiotemporal variations in micropollutant concentrations at the scale of whole lakes. We develop and apply a modelling framework that combines emission modelling from human activities with three-dimensional hydrodynamic transport modelling, and evaluate it for APIs and PFAS. The hydrodynamic model was set up for Lake Ekoln in Sweden, and validated against observed water temperatures. For APIs, emissions from a wastewater treatment plant were estimated from prescription data for >500 substances and coupled to the hydrodynamic model. The emission estimates were validated against monthly effluent measurements of 10 APIs; 102 of 103 measured concentrations were predicted within a factor of 10. Modelled lake concentrations were compared with 321 historical measurements of 20 APIs; 73% and 99% of predictions were within a factor of 10 and 100 of observations, respectively. For PFAS, emissions from the wastewater treatment plant and the lake's main inflow were represented in the model based on available measurements, and the simulated lake concentrations were generally consistent with the limited observational data. The modelling results confirmed that the main inflow to the lake is the dominant PFAS source. The model revealed pronounced seasonal and spatial variability. Our results demonstrate that relatively simple emission estimates, when combined with hydrodynamic modelling, can reproduce observed micropollutant patterns and reveal concentration gradients that routine monitoring would miss. This approach can guide targeted monitoring, inform mitigation of dominant sources, and support risk management for aquatic ecosystems and drinking water sources.

3.27.P-Mo270 Enhanced performance for FOSA and FOSEs analysis with an ultra-sensitive PFAS-multiclass method in environmental samples.

Om Shrestha¹, Toshiya Matsubara², Kazuhiro Kawakami¹ and Ruth Marfil-Vega³, (1)Shimadzu Corporation, Japan, (2)Shimadzu Scientific Instruments, Inc., (3)Marketing, Shimadzu Scientific Instruments

With the increasing regulatory drivers and public pressure for managing PFAS in the environment, foods, and consumer and industrial products, laboratories are in need of efficient multiclass-PFAS methods that enable routine ultra-sensitive quantitation. As the classes of PFAS to be monitored expand the instrument performance may be compromised for specific compounds as their ionization efficiency changes based on their physico-chemical properties. In this work we validated a LC-MS/MS method (LCMS-8065 XE, Shimadzu Corporation) for a multiclass-PFAS panel including PFCAs, PFSAs, FTSSs, FOSAs, FOSAs, FOSEs, FTCAS, PFESAs and PFECAs across matrices of environmental relevance (drinking water, wastewater, tissue...). Sample preparation varied depending on the matrix of interest: co-solvation and direct injection for drinking water, and pre-concentration (either Solid Phase Extraction or solvent extraction) for other sample types. Method Detection Limits (MDLs) were below 1 ng/L in drinking water for all targeted compounds. In solid samples, MDLs ranged from <0.05 to 0.2 ng/g for PFCAs, PFSAs, PFESAs and PFECAs, < 0.5 ng/g for FTSSs and FTCAS, and < 0.6 ng/g for FOSAs, FOSAs, and FOSEs. In this presentation we will share the detailed results of the method validation, with emphasis on classes of PFASs that are historically worse performers in multiclass-PFAS methods, such as FOSAs and FOSEs.

3.27.P-Mo271 Analysis of Neutral PFAS in Ambient Air Using Thermal Desorption Gas Chromatograph-Mass Spectrometry.

Riki Kitano¹, Nami Iwasa¹, Yui Higashi¹ and Ruth Marfil-Vega², (1)Shimadzu Corporation, Japan, (2)Marketing, Shimadzu Scientific Instruments

In response to the tightening of PFAS regulations, analytical methods have been developed targeting non-

volatile (ionizable) PFASs for various matrices such as water, soil, and food using liquid chromatography-mass spectrometry (LC/MS/MS). However, for the analysis of semi-volatile or volatile neutral PFAS gas chromatography-mass spectrometry (GC/MS) is the most effective technique.

In this study, nine semi-volatile and volatile neutral PFASs including four fluorotelomer alcohols (FTOHs), three fluorotelomer acrylates (FTACs), and two perfluoroalkyl sulfonamides (FOSAs), were targeted with a method for air samples using thermal desorption GC-MS (TD-GC/MS), without the need of solvent-based sample extraction.

A TD-GC/MS (GCMS-QP2020 NX coupled with TD-30R, Shimadzu Corporation). A preliminary study was conducted to select the most suitable sample tubes: Tenax TA and Tenax TA/Carboxen 1000 were evaluated. A mix of the targeted compounds were spiked onto the sample tube to achieve 0.05 to 12.5 ng of each compound, and the sample was purged with nitrogen gas to be used for the calibrations. Based on the results from the sample tube evaluation, the two-layer type sample tube of Tenax TA/ Carboxen 1000 was selected for further method evaluation. For the recovery test using air samples, 4 FTOHs were added to the sample tube at 10 ng, 3 FTACs and 2 FOSAs at 1 ng, and 20 L of air was collected at 100 mL/min. The measurement of standard samples for the nine PFAS components showed that for all compounds, measurement was possible from 0.05 ng, and good linearity was confirmed in the range from 0.05 to 12.5 ng with a correlation coefficient of $R > 0.998$ for the calibration curve. Furthermore, the area value and concentration %RSD ($n=3$) < 6 at 0.2 ng confirmed good reproducibility. The results of the additive recovery test using air samples showed that the additive recovery was 77 to 106 % and the concentration %RSD ($n=3$) < 8 , which were generally good results. In this presentation we will share the detailed results from the evaluation of different sample tubes and the overall performance of the TD-GC/MS method developed in this work for the simultaneous analysis of FTOHs, FTACs and FOSAs in air samples.

3.28 Trifluoroacetic Acid in the Environment – Here Today, More Tomorrow

3.28.T-01 Atmospheric passive sampling of gaseous perfluorinated carboxylic acids dominated by trifluoroacetic acid (TFA)

Trevor VandenBoer¹, Irina Nistorescu², Daniel Persaud², Eric Vanhauwaert², Alex Kasperkiewicz³, Amandeep Saini³, Chubashini Shunthirasingham³, Hayley Hung⁴ and Cora Young², (1)Chemistry, York University, Canada, (2)York University, Canada, (3)Environment and Climate Change Canada (ECCC), Canada, (4)Air Quality Processes Research Section, Environment and Climate Change Canada (ECCC), Canada

Atmospheric oxidation of volatile perfluorinated alkyl substances (PFAS) is a major source of gaseous perfluorinated carboxylic acids (PFCAs). Their abundance and deposition after formation controls their subsequent impacts on the global environment. For example, atmospheric formation leads to observed parts-per-trillion mixing ratios of TFA in the gas phase, as well as $\mu\text{g per L}$ concentrations in Arctic ice caps. There are numerous precursors that can form mostly TFA, but also other short chain PFCAs (C_6 or smaller) through atmospheric oxidation, including chlorofluorocarbon replacements.

Active atmospheric sampling methods for PFCAs have the potential for substantial analytical artifacts and are yet to be subject to rigorous validation experiments, such as calibration with gaseous analytes or method intercomparisons. Passive sampling methods have similar limitations and have treated PFCAs as traditional persistent organic pollutants instead of targeting their acid functionalities to elicit method specificity.

As a result, insights into the abundance, phase distribution, and spatial and temporal variability of atmospheric PFCAs has been limited. Here we demonstrate a calibrated passive sampling technique for gaseous PFCAs based on long-established acid sampling strategies using nylon filters in a low cost diffusion-driven sampler. These were deployed in several large field campaigns in Canada from weeks to months timescales to study controls on the formation and fate of TFA and other atmospheric PFCAs.

In nearly all cases, TFA was the most abundant of the analyzed homologue suite, present at hundreds of parts per quadrillion to parts per trillion by volume mixing ratios (ppqv - pptv). When measured with seasonal time resolution, TFA abundance increased when the abundance of atmospheric precursors and oxidants are also expected to maximize. When measured with spatial resolution, heterogeneity in TFA levels was observed within urban landscapes and along urban-to-rural transects, suggestive of hotspots for direct emissions or atmospheric transport. Measurements we conducted within a wastewater treatment plant found TFA as the most abundant gaseous PFCA and prior knowledge of these facilities as point sources in the urban environment. The emerging landscape of atmospheric TFA will be discussed alongside limitations and knowledge gaps from these first measurements across a wide variety of atmospheric environments.

3.28.T-02 Advancing Our Understanding of the Sources of Atmospheric TFA

Cora Young¹, Shira Joudan², Amy Lees³ and Peter Edwards³, (1)York University, Canada, (2)Chemistry, University of Alberta, Canada, (3)University of York, United Kingdom

Atmospheric formation is a major source of perfluoroalkyl carboxylic acids (PFCA) to the environment. The number of potential fluorinated precursors is inversely related to chain length, with the shortest PFCA, trifluoroacetic acid (TFA), having numerous potential precursors. Atmospheric formation can explain observed levels of TFA in diverse locations, including urban air Arctic ice caps. There are numerous precursors that can form TFA through atmospheric oxidation, including chlorofluorocarbon replacements, such as hydrofluorocarbons (HFCs) and hydrofluoroolefins (HFOs). While certain mechanisms that form TFA as a major product have been well studied (e.g., HFC-134a), there has been less focus (and a great deal of confusion) on mechanisms that form TFA and as minor products. For example, HFC-125 (CF₃CHF₂) has been the subject of conflicting reports on its TFA formation. This confusion stems, in part, from the dependence of the yield on nitric oxide (NO) and peroxy radical (RO₂) ratios. In addition, formation of TFA is typically reported as a molar yield of the precursor product. This chemical yield is not readily digestible by non-chemists. With a detailed re-evaluation of the chemistry that forms TFA from precursors, here we demonstrate that we can more accurately predict the formation of TFA. We also propose a new metric, the atmospheric PFCA formation potential (APFP) that can be used by policymakers. This mass-based definition is more consistent with other metrics used by policy makers, including the global warming potential. This new metric allows for better assessment of the overall impacts of TFA precursor chemicals. For example, this allows emissions of precursor chemicals, typically reported in mass units, to be directly related to the mass of TFA that will be formed from their ultimate atmospheric degradation. In addition, the trade-offs between climate and TFA formation can be readily assessed. Examples of how the APFP can help in our evaluation of precursor usage will be presented.

3.28.T-03 Rising TFA Concentrations in Danish Groundwater: Atmospheric and Agricultural Sources

Christian Albers and Anders Johnsen, Geological Survey of Denmark & Greenland (GEUS), Denmark

TFA is widespread in the environment, including in groundwater, where it is found in concentrations hundreds or even thousands of times higher than any other PFAS. Due to its high chemical and biological stability and its low sorption to soil, TFA can be considered to move conservatively with groundwater. Under these assumptions, we have demonstrated that the concentration of TFA in groundwater has risen from non-detectable levels in Danish groundwater formed before 1960 to detectable levels in all Danish groundwater formed after 1980, with a consistent increase that appears to be ongoing.

There are likely two major sources contributing to this rise in TFA, and in both cases TFA is a degradation product—either from fluorinated gases in the atmosphere or from pesticides used in agriculture. In Denmark, the latter source has been considered somewhat hypothetical, since only a few pesticides have been shown to form TFA during degradation, none of which have been used in Denmark. We therefore conducted a degradation study using seven common pesticides that contain a C-CF₃ group, all of which were found to form TFA in three agricultural soils.

Taken together, the available evidence suggests that rising atmospheric input currently contributes approximately 0.5 µg/L TFA to Danish groundwater. In areas with conventional agriculture, there is an additional TFA input from pesticides, with a magnitude similar to or greater than the atmospheric input. This source has also been increasing over the past decades but is expected to decline in the future due to a recent, Danish ban on many C-CF₃ pesticides.

The results of our work can inform ongoing discussions about regulations of fluorinated gases and pesticides, as well as discussions about future legal threshold values for TFA in the environment and in drinking water.

3.28.T-04 Widespread Trifluoroacetic Acid (TFA) Pollution in UK Surface Waters

Jun Li¹, Alistair Boxall², **Rowan Stanforth³**, Megan Kirton³ and Hannah Evans³, (1)University of York, United States, (2)University of York, United Kingdom, (3)Fidra, United Kingdom

Trifluoroacetic acid (TFA; CF₃COOH) is now recognised as the most abundant of per- and polyfluoroalkyl substances (PFAS) in the global environment. Its formation from longer-chain PFAS, combined with extreme solubility and mobility, leads to diffuse inputs to aquatic systems from multiple pathways. Despite international evidence of increasing TFA concentrations in water systems, and growing concern over potential health and environmental impacts, our work is the first to determine the presence and potential drivers of TFA pollution in UK surface water.

We quantified TFA in repeat samples collected from 54 river monitoring sites (214 total samples) spanning a

broad range of UK catchments and supplemented this with 19 sites in Yorkshire, where monthly composite samples were collected using automatic samplers (268 total samples). TFA concentrations were determined by direct-injection (40 µL) high-performance liquid chromatography–tandem mass spectrometry (HPLC-MS/MS). We extracted environmental variables for each of the catchments, including the percentage of arable land, population sum and exposure to landfill sites, military bases and airfields, golf courses, industrial sites and wastewater treatment plants. We examine how these variables relate to TFA flux via General Additive Modelling (GAM).

TFA was detected at 97% of sites during the national sampling campaign, and in 99% of samples in the regional campaign, demonstrating widespread contamination across the UK. We recorded the second-highest level of TFA pollution ever reported in surface water globally (River Kelvin, Glasgow), while the mean UK concentration of 2,211 ng/L aligns with observations from other European and international studies. Further analysis has highlighted the percentage of arable land within the catchment (EDF = 2.1, $p < 0.01$) and exposure to golf courses (EDF = 1.463, $p < 0.001$) as two significant non-linear predictors of TFA flux.

This first national baseline of TFA in UK surface waters reveals widespread contamination, underscoring the chemical's persistence and suggests substantial inputs from TFA precursors across UK catchments. Our review of environmental variables aims to shed light on potential influences of TFA pollution such as industrial pollution, wastewater treatment, and use of PFAS pesticides. Our findings highlight the need for strengthened evaluation and control of TFA and wider PFAS-precursor emissions in the UK.

This research was completed by the University of York and Fidra. Fidra is an endowment funded SCIO and Scottish registered charity (SC043895). Fidra's accounts are published on the OSCR website.

3.28.T-05 Trifluoroacetic Acid Formation in Potato Cultivation: Impact of Fluazinam, Fluopicolide and Oxathiapiprolin Degradation

Patrick van Hees¹, Lars Wiik², Cristian Nilsson³, Helena Aronsson⁴, Ludmila Bucuricova⁵ and Torbjörn Synnerdahl⁵, (1)*Eurofins Food & Feed/Örebro University, Sweden*, (2)*The Rural Economy and Agricultural Societies, Skåne County, Sweden*, (3)*The Rural Economy and Agricultural Societies, Halland County, Sweden*, (4)*Dept. Soil and Environment, Swedish University of Agricultural Sciences, Uppsala, Sweden*, (5)*Eurofins Food & Feed Testing Sweden AB, Sweden*

Trifluoroacetic acid (TFA) is a highly persistent and mobile compound formed as a quasi-terminal degradation product of substances containing trifluoromethyl groups (CF₃). These moieties are common in agrochemicals, making pesticides a significant source of TFA, often referred to as “PFAS pesticides.” TFA is increasingly detected in environmental and food matrices, raising concerns about its accumulation and potential risks to ecosystems and human health. Despite its relevance, knowledge gaps remain regarding the fraction of applied pesticides converted to TFA and its distribution across soil, water, and crops under field conditions.

This study investigates TFA formation and fate in a multi-matrix field experiment involving potato cultivation with and without PFAS-containing fungicides. The trial was conducted at Lilla Böslid, Halland, Sweden, using twelve plots arranged in three treatments: untreated control, non-PFAS fungicides, and “PFAS pesticides” (fungicides fluazinam, fluopicolide and oxathiapiprolin). Sampling included drainage water, adjacent stream water, precipitation, irrigation, soil, foliage, and tubers over one growing season, with continued water and soil monitoring planned until spring 2026. Chemical analyses include TFA, four additional ultrashort PFAS, other PFAS and pesticide residues.

Preliminary results indicate background TFA concentrations in drainage water of $1,300 \pm 110$ ng/L, soil levels averaging 0.68 µg/kg dry matter and 35-80 µg/kg in foliage before pesticide treatment. Theoretical calculations suggest that full conversion of applied pesticides could yield TFA concentrations of 170,000 ng/L in drainage, highlighting its potential significance as a source. Further evaluation will address TFA distribution in crops, seasonal variation, and relative contributions from precipitation versus pesticide degradation. Additional objectives include constructing a CF₃-moiety budget and assessing potato yield and disease incidence. This research will provide critical insights into TFA dynamics in agriculture, supporting mitigation strategies and informing regulatory frameworks. Findings will help quantify the environmental burden of PFAS pesticides and guide sustainable crop protection practices.

3.28.P Trifluoroacetic Acid in the Environment – Here Today, More Tomorrow

3.28.P-We310 Occurrence of Trifluoroacetic Acid in Surface Water and Groundwater from Swedish Agricultural Areas

Gustaf Boström, Bodil Lindstrom, Kajsa Weslien and Mikaela Gönczi, Department of Aquatic Sciences and Assessment, SLU Centre for Pesticides in the Environment, Swedish University of Agricultural Sciences, Sweden

Several active substances in plant protection products approved in the EU fall under the OECD definition of PFAS. Many of these PFAS pesticides can degrade to the ultrashort-chain transformation product trifluoroacetic acid (TFA), a very persistent compound. Because TFA originates from multiple environmental sources, including pesticides, its presence and potential accumulation in surface water and groundwater are of increasing concern.

This study aims to characterize the occurrence and concentrations of TFA in agricultural surface water and shallow groundwater in Sweden and to evaluate these concentrations in relation to ecological and groundwater quality thresholds.

Water samples collected in 2021, 2022 and 2025 within the Swedish national monitoring program were analyzed for TFA. In 2021-2022, 20 surface water samples and 12 groundwater samples were analyzed for a set of 67 pesticide metabolites, including TFA. In 2025, we collect 50 additional surface water grab samples (May–Oct, biweekly) and 40 groundwater samples from the same areas and analyze them for three ultrashort-chain PFAS, including TFA. The full dataset will include 70 surface water samples from long-term agricultural monitoring sites, 4 samples downstream of greenhouses and orchards, and 52 samples of shallow groundwater (2–8 m depth) from field-edge monitoring wells.

To date, 88 samples have been analyzed. TFA was detected in all surface water samples and in all but a few groundwater samples (reporting limit 0.05 µg/L). Surface water concentrations (0.38–2.4 µg/L) were well below the predicted no-effect concentration reported in the REACH registration dossier for TFA (560 µg/L), but relatively high compared to other detected pesticide metabolites in agricultural streams. Concentrations in shallow groundwater (0–5.4 µg/L) frequently exceeded the 0.1 µg/L threshold value applied to individual pesticides and their metabolites in groundwater, indicating a potential long-term contribution of agricultural recharge to TFA levels in groundwater. Detailed pesticide use data from the long-term monitoring catchments enable further assessment of possible sources of TFA.

Final results from the study will be reported to the Swedish Environmental Protection Agency in March 2026. Overall, this work advances understanding of the occurrence of TFA in agricultural landscapes and supports ongoing evaluation of pesticide-derived TFA and their relevance for groundwater risk and aquatic risk assessment.

The study was financed by the Swedish Environmental Protection Agency. Samples from 2021 and 2022 were analyzed by DVGW Technology Centre for Water (TZW), Karlsruhe, Germany. Samples from 2025 were analyzed by Eurofins.

3.28.P-We311 Occurrence of trifluoroacetic acid and other ultrashort-chain PFAS in groundwater

Elvio D Amato and Dennis Vughs, KWR Water Research Institute, Netherlands

Trifluoroacetic acid (TFA) is a very mobile and persistent perfluorinated compound. It is often present in water at concentrations orders of magnitude higher than those of other per- and polyfluorinated substances (PFAS) and is also increasingly being detected in drinking water. However, little is known about the occurrence of TFA and other ultrashort-chain PFAS ($C < 4$) in groundwater. In this study, existing and newly collected monitoring data were used to investigate the occurrence of TFA and other ultrashort-chain PFAS (Figure 1) in groundwaters characterized by different degrees of vulnerability. TFA was detected in 89, 41, and 15% of the sites from aquifers categorized as ‘vulnerable’ ($n = 74$), ‘moderately vulnerable’ ($n = 22$), and ‘not vulnerable’ ($n = 20$), respectively (Table 1). Six other ultrashort-chain PFAS mostly occurred below the limit of quantification (0.0005–0.002 µg/L), but PFPrA and TFMS were detected in 17 and 13% of the samples, respectively. TFMS was detected at levels < 0.060 µg/L, and PFPrA below 0.025 µg/L, respectively. Both TFMS and PFPrA occurred only in ‘vulnerable’ and ‘moderately vulnerable’ groundwaters. A correlation was found between the percentage of water younger than 25 or 50 years in groundwater sources and the concentration of TFA in the

abstracted groundwater ($r = 0.77$, with a few outliers excluded), indicating input from diffuse sources with a peak between 1975 and 2000. The highest concentrations were found at abstraction sites with a large proportion of infiltrated surface water. The contribution of TFA (and other ultrashort-chain PFAS) to the weighted toxicological impact as part of a mixture of various PFAS requires further investigation, as TFA and other ultrashort-chain PFAS pose a risk to groundwater quality.

3.28.P-We312 Monitoring Ultra-Short Chain PFAS in Flanders: Occurrence, Patterns, and Tracing TFA

Karel Vlaeminck¹, Nathalie Briels¹, Karel Viaene¹, Marnix Vangheluwe¹, Frederik Verdonck¹, Maarten De Jonge² and Ann De Meester², (1)ARCHE Consulting, Belgium, (2)Flanders Environment Agency (VMM), Belgium

Ultra-short chain PFAS (USC PFAS, ΣC_3), such as trifluoroacetic acid (TFA), are characterised by high environmental mobility combined with strong persistence. To better understand their occurrence in Flanders, the Flanders Environment Agency conducted a large-scale monitoring campaign assessing USC PFAS in wastewater, surface water, and groundwater. In the initial campaign, 49 PFAS, including 7 USC PFAS, were investigated in wastewater and surface water. A second, follow-up campaign focused on USC PFAS in rural areas (with particular emphasis on TFA), with targeted sampling in surface and groundwater. In parallel, PFAS pesticides (i.e., plant protection products suspected of degrading into TFA) were also sampled to explore potential links with the environmental occurrence of TFA.

Based on the results of the first campaign, USC PFAS were widely detected across Flanders, with TFA present in 74% of wastewater and 88% of surface water sites. The USC PFAS in surface water showed consistently elevated concentrations in urban, rural and diffuse areas, indicating a widespread distribution throughout the region.

The second campaign similarly revealed a substantial contribution of TFA to the overall PFAS burden at rural sites. TFA was detected in 36 of 40 surface water sites and in 267 of 272 groundwater sites. The median TFA concentration in surface water was 2.3 $\mu\text{g/L}$, with peak values up to 13 $\mu\text{g/L}$. Among PFAS pesticides, fluopicolide and fluopyram occurred at the highest concentrations in surface water, with median values of 0.025 and 0.031 $\mu\text{g/L}$, respectively. In groundwater, the median TFA concentration was 2.8 $\mu\text{g/L}$ with a maximum of 30 $\mu\text{g/L}$. Detections of PFAS pesticides in groundwater were very low. Fluopicolide was detected the most (in 25 of the 272) and was quantified in the highest concentration (max. 1.5 $\mu\text{g/L}$).

Statistical analyses consistently showed a positive relationship between TFA and the pesticide fluopicolide in surface waters. The observed associations between TFA concentrations and specific crop types were weaker and should be treated as exploratory, given the absence of detailed pesticide use data. The monitoring dataset has some limitations, particularly the low sampling frequency, which prevents a reliable assessment of seasonal variability in TFA concentration or pesticide application patterns. Even so, the high detection frequency of TFA in surface and groundwater indicates a broadly diffuse occurrence across rural areas in Flanders.

3.28.P-We313 TFA Analysis in Drinking Water

Carlos Bueno¹, Aidan Harrison², Michael Scherer³ and Jianru Stahl-Zeng³, (1)Sciex Spain, Spain, (2)SCIEX UK, United Kingdom, (3)SCIEX Germany, Germany

Trifluoroacetic acid (TFA, CF_3COOH) is a low molecular weight perfluorinated carboxylic acid formed as a breakdown product of various industrial chemicals, including refrigerants and pesticides. Found increasingly in surface water, groundwater, and drinking water, it has raised environmental and health concerns due to its resistance to degradation and removal.

Toxicological concerns have prompted the European Food Safety Authority (EFSA) to propose an acceptable daily intake (ADI) of 0.03 mg/kg body weight per day, expressed as sodium trifluoroacetate.¹ This value is undergoing consultation¹ due to emerging data suggesting potential classification of TFA as a Reproductive Toxicant Category 1B and a very persistent, very mobile (vPvM) substance under REACH.

This poster describes a robust and ultra-fast method for the analysis of trifluoroacetic acid (TFA) in multiple water sources using the SCIEX 7500+ system, enabling high-throughput workflows with minimal sample handling. The method, which includes confirmation with both a quantifier and qualifier transition for confirmation, achieves a rapid turnaround time of just 4 minutes and 30 seconds between samples, allowing for the processing of 40 samples—including blanks and standards—in under four hours.

An injection volume of just 5 μL was required to achieve a lower limit of quantitation of 10 ng/L ensuring

sensitive detection with low contamination of mobile phases and a TFA-free blank when internal standard (IS) was excluded. The robust analytical method was shown with batch analysis of >90 successful injections without signal degradation or significant change in baseline noise.

Retention time stability across the sequence was excellent with a %RSD of 2.32% across the 71 injections. Internal standard recoveries were tracked across the entire sequence and were between 80 and 120% of the mean

3.28.P-We314 The Prevalence of Trifluoroacetic Acid in Drinking Water Supplies across England and Wales

Simon Gutierrez¹, Kate Schofield², Nathan Hobbs², Javier Soto², Ben Thorpe³, Elaine Jennings¹ and Jacob Smith², (1)Ricardo-AEA Ltd, Spain, (2)Ricardo-AEA Ltd, United Kingdom, (3)UK Department for Environment, Food and Rural Affairs. Drinking Water Inspectorate, United Kingdom

Trifluoroacetic acid (TFA), an ultrashort-chain perfluoroalkyl acid (PFAA), is a highly mobile and persistent chemical within the per- and polyfluorinated substances (PFAS) family. Recent studies have reported its widespread occurrence in environmental matrices at concentrations exceeding other PFAS compounds. The presence of TFA in drinking water is an emerging concern across Europe, with many regulatory bodies taking action to address the issue, however despite this threshold concentrations remain poorly defined and data on its prevalence is limited. This study, led by the UK's Department for Environment, Food and Rural Affairs (DEFRA) aims to address this knowledge gap by characterising TFA's occurrence in England and Wales drinking water sources.

Therefore, we conducted a literature review compiling existing data on prevalence and sources of TFA in this region. Spatial insights guided site selection for a targeted monitoring program at four drinking treatment works, enabling comparison of urban and rural catchments and allowing the evaluation of the prevalence of TFA across England and Wales. In addition, samples were taken at multiple stages of the treatment process (raw, partially treated, and final effluent) to assess the effectiveness of current and advanced treatment technologies in removing TFA.

Findings from the literature review found a notable lack of data on environmental prevalence in England and Wales, underscoring the need for targeted monitoring. This study therefore presents preliminary monitoring results from the first coordinated effort to map TFA in drinking water supplies across these regions. This will include the influence of different sources on TFA concentration, including those from local inputs such as pesticides, industrial runoff, and emissions from fluorochemical industries, as well as more diffuse contributions from the atmospheric degradation of HFCs or HFOs used in refrigeration and cooling systems.

Findings from this study will help identify drinking water catchments most at risk of TFA contamination, provide evidence on the effectiveness of current treatment processes in removing or degrading TFA, and highlight any unintended consequences within treatment systems that could further increase concentrations. Furthermore, the results will underpin risk assessments for TFA exposure in drinking water supplies and provide a robust evidence base to guide future regulatory standards and local policy decisions.

3.28.P-We315 Trifluoroacetic Acid (TFA) in the Environment: Multiple Sources and Regulatory Challenges

Giuseppe Granato¹, Gianluca Maschio¹, Simone Marzeddu¹, Dania Esposito² and Emanuela Pace¹, (1)Hazardous Substances Section, Service for environmental education and training and for the technical coordination of Directorate activities (DG-TEC), Italian Institute for Environmental Protection and Research (ISPRA), Italy, (2)Italian National Institute for Environmental Protection and Research (ISPRA), Italy

Trifluoroacetic acid (TFA) is an extremely persistent and highly mobile fluorinated compound, increasingly detected in aquatic environments, soils, and biota worldwide. As the smallest short-chain perfluoroalkyl carboxylic acid, TFA combines a $-\text{CF}_3$ group with a carboxyl function, conferring complete water miscibility and exceptional chemical stability. These properties result in resistance to natural degradation and conventional water treatment, leading to accumulation in the water cycle and wide-scale dispersion.

TFA originates both from direct emissions during fluorochemical production and from the degradation of numerous precursors, including hydrofluorocarbon refrigerants such as R1234yf, blowing agents, plant protection products, pharmaceuticals, and biocides. Key entry pathways include atmospheric deposition, agricultural leaching, industrial discharges, and wastewater treatment. Over the years, TFA has become the most widespread water contaminant and one the main sources is due to PFAS pesticides, the use of which involves

deliberate dispersion in agricultural fields. EFSA has identified at least 56 PFAS pesticides under the ongoing peer review process and 12 PFAS active substances shown to produce TFA in soil and/or groundwater. Other anthropogenic sources remain poorly quantified, complicating source attribution and environmental modelling. Emission data are fragment and vary across regions and sectors.

Monitoring across Europe indicates that TFA is widely detectable in surface waters, groundwater, soils, crops, and food products, suggesting progressive environmental transfer. Although toxicological effects occur only at concentrations far above current environmental levels, the combination of extreme persistence, mobility, and ongoing precursor use implies continued growth of environmental loads in the coming decades. This raises potential conflicts between drinking water production, agricultural practices, and ecosystem protection. Regulatory measures are currently fragmented and lack harmonized limits. Evaluation processes in different regulatory areas can lead to different conclusions regarding the use of PFAS. European initiatives, including proposed PFAS restrictions under REACH (Reg. EC 1907/2006), aim to reduce inputs, yet coverage of major TFA precursors remains uncertain.

3.28.P-We316 Policy Analysis for the Identification and Quantification of European Sources of Trifluoroacetic acid

Rachel Lucy London, *Institute for Biogeochemistry and Pollutant Dynamics, University of Amsterdam (UVA), Netherlands*

Trifluoroacetic acid (TFA) is very mobile, contaminates drinking water, is difficult to remediate, and is reprotoxic to humans (category 1B). It is also an anthropogenic pollutant, widespread throughout the environment, whose concentration is increasing. Understanding the relative size of different TFA sources to the environment is important. This will help assess the effectiveness of current regulatory efforts in reducing TFA emissions and inform targeted future regulatory efforts. This policy analysis seeks to complement existing environmental monitoring campaigns by determining the annual volumes of TFA and TFA precursors being placed on the European market.

TFA precursor volumes were determined using import, export, manufacturing, and sales data from the European Economic Area (EEA). The amount of TFA emitted to the environment was calculated for different uses: TFA as a basic chemical, PFAS (per- and polyfluoroalkyl substances) uses covered by the European Union's proposed REACH restriction (divided into fluoropolymers, fluorinated gases, PFAA and PFAA precursors), human medicinal products, veterinary medicinal products, and plant protection products. This data was combined with molecular mass, number of C-CF₃ groups, TFA molar yield, and emission factors. Where data was available, substance specific calculations were performed, otherwise grouped values were used. Uncertainty was quantified through a bounding analysis, so as to generate a best-case, and worst-case scenarios.

The results show the annual input of TFA to the environment from different sources in the EEA. For certain uses, country specific calculations are also included for comparison (Germany, Netherlands, and Switzerland). The largest TFA sources from the EEA are fluorinated gases (REACH uses) and plant protection products. Although it was the smallest source investigated, this study is also the first one to quantify TFA emissions from veterinary medicinal products, filling a data gap previously identified by European regulators.

This study supports the hypothesis that the REACH restriction should be effective in reducing TFA emissions to the environment (if implemented in its current format). However, this alone would be insufficient to eliminate emissions to the environment, as other sources (such as plant protection products) lie outside the scope of the REACH restriction. If TFA emissions to the environment are to be minimised, further regulatory action should be taken.

3.28.P-We317 Derivation of Guidance Values Under the EU Drinking Water Directive: the Case Study of Trifluoroacetic Acid

Derek Wallace¹, **Richard Bartlett**², **Bastian Becker**³, **Anja Hueser**³, **Felix Kluxen**⁴, **Volker Laabs**⁴, **Jyotigna Mehta**⁵, **Stephanie Melching-Kollmuss**⁴, **Ursula Sauer**⁶, **Emily Scorgie**⁷ and **Robin Sur**⁸, (1)ISK Biosciences Europe N.V., United Kingdom, (2)Syngenta, United Kingdom, (3)Bayer AG, Germany, (4)BASF, Germany,

(5)ADAMA, United Kingdom, (6)Scientific Consultancy - Animal Welfare, Germany, (7)Syngenta, Netherlands, (8)Bayer Research & Development Services LLC, Germany

The definition of a 'relevant metabolite' in water intended for human consumption (as per Drinking Water Directive) is based on risk, i.e. the function of hazard and exposure, whereas the definition of a 'relevant metabolite' in groundwater is based on human health hazard alone ("has certain toxicological properties that are considered unacceptable") in Article 3(32) of the Plant Protection Product Regulation, which is also applicable in the context of the Ground Water Directive. Therefore, a metabolite of a pesticide that is considered relevant under the PPP Regulation and under the GWD, is not necessarily also a relevant metabolite under the DWD, and the DWD does not include any guidance value for substances that are identical with drinking water relevant metabolites of PPPs but that are present in the drinking water due to such other uses and/or sources. As a consequence, different Member States may define different guidance values for a given substance.

In order to explore this topic, the case study of trifluoroacetic acid is considered. TFA is a metabolite of several active substances in PPPs that contain a C-CF₃ moiety and is also the terminal degradation product of a range of commercially used substances, such as next-generation refrigerants and propellants in spray cans. Since an EU-harmonised concept for the derivation of drinking water guidance values for TFA is unavailable, various guidance values have been proposed or implemented on the Member State level for drinking water which may cause uncertainty with respect to the adequacy of such values. As such, the scientific rationale underlying health-based guidance values for TFA in drinking water that have been set or proposed on the Member State level are reviewed in this study.

Finally, a science-based approach for deriving guidance values for substances in drinking water is proposed. Application of this approach to TFA as an example yields a health-based guidance value of 294 µg/L TFA in drinking water, and a supplementary guidance value of 56 µg/L to cover specific vulnerable population groups. Scientists from relevant stakeholders like executive and regulatory bodies, academia, water supply companies and industry are encouraged to align on an EU-harmonised approach to derive scientifically justified and robust guidance values for substances in drinking water to adequately protect consumers.

3.28.P-We318 Structural Impact on the Aquatic Fate of Aryl-CF₃ Contaminants: Persistence, Defluorination, and Formation of TFA

Shira Joudan¹, Zhefei Guo² and Genevieve Tremblay³, (1)Chemistry, University of Alberta, Canada, (2)Department of Chemistry, University of Alberta, Canada, (3)University of Alberta, Canada

The substitution of fluorine atoms in organic molecules results in advantageous properties for applications in industrial, household, health and agricultural applications. However, once in the environment, these compounds, many of which are considered per- and polyfluoroalkyl substances (PFAS), can be persistent and cause harmful effects. In the pharmaceutical and agrochemical industries, fluorine atoms are added either directly to an aromatic ring as a single fluorine (aryl-F) or as trifluoromethyl groups (aryl-CF₃). Our interests in aryl-CF₃ chemicals in the environment are threefold. First, these chemicals are of interest because they are designed to be biologically active and thus may have unintended biological impacts if they persist in aquatic ecosystems. Second, some aryl-CF₃ can form trifluoroacetic acid (TFA) in the environment, which is considered the smallest PFAS. Sources of TFA are poorly constrained and environmental concentrations continue to grow. The contribution of aryl-CF₃ to environmental TFA concentrations is unknown. Third, complete mineralization of anthropogenic organofluorine compounds is the goal after desired usage. As many aryl-CF₃ undergo defluorination in the environment, we aim to understand why certain structures undergo more defluorination than others to help inform the design of greener chemicals. This presentation will report our results of kinetics and products of hydrolysis and aquatic photochemical reactions of a suite of aryl-CF₃ to understand how their structure impacts persistence, defluorination, and formation of TFA. Some aryl-CF₃ form up to 10% TFA due to photochemistry, while the remainder of the aryl-CF₃ undergoes defluorination to fluoride. Conversely, some undergo full defluorination and do not form TFA, while others are stable at the C-F bond. Our use of ¹³C isotopic labels and high-resolution mass spectrometry allowed for the tracking of sequential oxidations to the aromatic ring resulting in ring cleavage to form TFA.

3.28.P-We319 Atmospheric Deposition of TFA from Urban, Rural, and Remote Regions

Daniel Persaud¹, Trevor VandenBoer², Heetasmin Singh³ and **Cora Young¹**, (1)York University, Canada, (2)Chemistry, York University, Canada, (3)University of Guyana, Guyana

The dominant fate of atmospheric trifluoroacetic acid (TFA) is wet and dry deposition. Comprehensive monitoring of this deposition is needed to understand its spatial and temporal variation. We have deployed custom atmospheric deposition samplers in various locations in Canada (e.g., urban Toronto, rural Ontario) to characterize spatial variability in a region. We have also deployed the samplers in Georgetown, Guyana, an area in which pollutants are rarely reported. All samplers were deployed for at least one year with samples collected approximately monthly. Samples were analyzed using ion chromatography coupled to mass spectrometry. Concentrations and fluxes in atmospheric deposition will be presented, as well as the implications for TFA sources and fate.

3.28.P-We320 Bioaccumulation and Toxicity of Trifluoroacetic Acid (TFA): Weight-of-Evidence for Environmental Risk Assessment

Christopher J McCarthy¹, Jenny Zenobio², John Gondek², Victoria Lydy² and Dylan Ricke², (1)Jacobs, (2)Jacobs, United States

Trifluoroacetic acid (TFA) is an ultrashort-chain fluorinated acid increasingly detected in rainwater, surface waters and groundwater worldwide. Its extreme persistence, high mobility and rising environmental concentrations have prompted regulatory interest, yet its behavior in aquatic organisms remains less well characterized than other per- and polyfluoroalkyl substances (PFAS). A clearer understanding of its bioaccumulation potential and aquatic toxicity is needed to support environmental risk assessment and the development of scientifically grounded water-quality benchmarks and standards.

The purpose of this work was to compile and evaluate available information on bioaccumulation and aquatic toxicity for TFA, and to integrate these data into a weight-of-evidence evaluation relevant to regulatory frameworks. A systematic literature review was performed to identify measured bioaccumulation factors and bioconcentration factors for fish and shellfish, as well as acute and chronic toxicity endpoints for algae, invertebrates and fish across freshwater and marine systems. All studies meeting minimum quality standards were compiled into a harmonized dataset for cross-species comparison and interpretation.

The available evidence indicates that TFA exhibits negligible bioaccumulation in aquatic organisms, consistent with its ultrashort-chain structure, and rapid elimination kinetics. The one published study of bioaccumulation in the aquatic macrophyte *Lemna minor* reported bioconcentration factors ranging from 1 to 1.6 indicating essentially no bioaccumulation. Aquatic toxicity studies across algal, invertebrate, and fish species show low sensitivity to TFA, with effect concentrations typically reported in the mg/L range.

Although the overall dataset supports a low hazard profile relative to other PFAS, notable uncertainties remain. Chronic toxicity data are limited, analytical confirmation is inconsistent in older studies, and marine taxa are underrepresented. The weight-of-evidence evaluation highlights the need for standardized chronic testing with analytical verification, updated fish bioaccumulation studies using modern methodologies, and expanded datasets across additional species and exposure conditions.

3.28.P-We321 Aerosol Microdroplet Photochemistry Enables Unexpected Transformations of Polyfluorinated Alkyl Contaminants that Produce Ultra-Short PFAS

Ryan Christopher Sullivan¹, Dennis Doyle¹, Riley Madison Weatherholt¹, Bailey Bowers² and Kaitlyn L Chung¹, (1)Carnegie Mellon University, United States, (2)Oberlin College, United States

Transformations of PFAS under treatment or environmental conditions often result in shorter-chain perfluorinated alkyl chains. The high surface activity of PFAS allows their concentration to be enhanced through aerosolization in both a water treatment and sea spray aerosol context. This places the contaminants in a unique chemical environment at the air–water interface that can accelerate degradation kinetics and alter the transformation reaction pathways. We explored this using an oxidation flow reactor that exposed PFAS-containing aerosol droplets to 185 or 254 nm UV radiation. This generates gas-phase ozone as well as gas and aqueous-phase hydroxyl radicals relevant to both water treatment and tropospheric chemistry without requiring addition of chemical reagents. We compared substrate degradation rate and extent, defluorination, and transformation products between aerosol microdroplets and bulk using both targeted and nontargeted high-resolution mass spectrometry. Chemical ionization mass spectrometry using iodide as the reagent ion enabled real-time observations of a series of small volatile fluorinated reaction products not captured by LC-MS analysis. We observed fluoride production and a homologous series of perfluorocarboxylic acid (PFCA) transformation products, indicating perfluoroyl chain-shortening of the 6:2 FTCA in addition to removal of the –CH₂C(O)OH head group. Aerosol microdroplets produced much faster oxidation kinetics and deeper degrees of transformation and defluorination, all the way down to TFA from a C₆ perfluoro alkyl precursor. The reactants were produced by VUV photolysis of O₂ and H₂O using 185 nm, or of hydrogen peroxide under 254 nm illumination relevant to cloud water chemistry.

These findings could provide a lower-cost PFAS remediation and mineralization approach, which can enable water treatment and reuse by removing ultrapersistent micropollutants. We will present recent work evaluating the transformations of ultra-short PFAS such as TFA, where treatment of PFAS often gets stuck and become a source of ultra-short PFAS. These findings also imply that PFAS may experience unexpected transformations in atmospheric aerosol driven by photo-generated hydroxyl radical and interfacial chemistry. This may represent an additional secondary source of ultrashort PFAS such as TFA which is routinely measured in the troposphere and surface waters.

3.28.P-We322 Analytical Development for the Qualification and Quantification of Environmentally Relevant Concentrations of Trifluoroacetic Acid (TFA)

Rory Mumford¹ and Philip Rooney², (1)Environmental Fate and Metabolism, Smithers, United Kingdom, (2)Smithers, United Kingdom

Trifluoroacetic acid (TFA) is an environmental contaminant of increasing focus, arising as a terminal degradation product of fluorinated substances. Its ubiquity and chemical persistence present analytical challenges, particularly when quantifying environmentally relevant concentrations during sample analysis from simulation studies. This work presents the development and validation of a robust analytical framework for the qualification and quantification of TFA across multiple environmental matrices.

Method development focused on differentiation of sample-derived TFA from background residues through the use of ¹³C-labelled TFA as a stable isotope reference standard. Quantitative performance was assessed using a quantitative triple quadrupole mass spectrometer, while complementary qualitative assessments of method selectivity and molecular confirmation were conducted on a Thermo Eclipse Orbitrap high-resolution mass spectrometer. Sensitivity studies demonstrated sub-nanogram per litre detection limits, with reproducible quantification achieved across complex matrices following tailored sample preparation and ion suppression control strategies.

The analytical methods enable confident identification and quantification of substance derived TFA at environmentally relevant concentrations, addressing a key analytical barrier in assessing its occurrence, persistence, and potential ecological impact. This work contributes to improving trace-level detection to support environmental risk assessments of organic compounds containing trifluoromethyl functional groups which have the potential to generate TFA as a terminal metabolite.

Track 4: Ecological and Human Health Risk Assessment of Chemicals, Mixtures and Stressors and Risk Mitigation Strategies

4.01.A Advancing the Environmental Risk Assessment and Management of Cosmetics, Sunscreens and Personal Care Products

4.01.A.T-01 Combining SCCS And BPR Product Type 1 Exposure Frameworks To Derive Consumer Based Environmental Risk Assessment For Cosmetic Ingredients

Zakaria Naddi, Harald Streicher and Diego Robles, Beiersdorf AG, Germany

Cosmetic products can contribute to emissions to wastewater during normal use as they are disposed down-the-drain. However, environmental exposures are regulated via REACH and not the Cosmetic Product Regulation. Hence, no dedicated environmental exposure approach exists for cosmetics. We propose to use a combination of two approaches which are both well-grounded in existing regulations but in their combination new to cosmetics. We use the Scientific Committee on Consumer Safety (SCCS) Notes of Guidance for input calculation assuming all cosmetics are washed-off. For exposure, we use the Biocidal Products Regulation (BPR) Product Type 1 (PT 1) guidance which also is a down-the-drain scenario established for estimating releases from human hygiene products to wastewater. We adapt the structured exposure logic developed under the BPR, where environmental risk assessment is used to demonstrate that uses do not cause “unacceptable effects” on the environment, to build a transparent emission basis for cosmetic ingredients.

Our method integrates SCCS default parameters with PT 1 emission equations. For each category, SCCS values for amount per use are combined with ingredient concentrations to calculate daily emissions to wastewater. The method quantifies the emissions entering wastewater during consumer use. These emissions serve as inputs in EUSES, where they are converted into Predicted Environmental Concentrations for surface waters (PEC –

surface water).

Case examples using typical cosmetic ingredients (e.g. UV-filters, Preservatives) illustrate how the method captures differences in product occurrence and consumer use patterns, enabling more realistic and transparent emission estimates.

The combined SCCS–PT 1 framework provides a reproducible, well-documented and regulation-consistent basis for estimating emissions of cosmetic ingredients, helping to close a key gap in cosmetic environmental assessment.

4.01.A.T-02 Commercial Organic UV filters in Sunscreens and their Ability to form Novel Disinfection By-products

Joy Amadi¹, Leanne Powers², Andrew Heyes¹, Carys Louise Mitchelmore³, Philippe Schmitt-Kopplin⁴ and Michael Gonsior⁵, (1)University of Maryland Center for Environmental Science (UMCES), United States, (2)SUNY College of Environmental Science and Forestry, United States, (3)University of Maryland Center for Environmental Science, (4)Helmholtz Munich, Germany, (5)ICRA, Spain

Organic UV filters and their toxicity have been the focus of research in recent years. However, their degradation and transformation products remain largely undefined. Here we show a systematic non-targeted approach to discover disinfection by-products (DBPs) that are produced upon chlorination of UV filters with free chlorine at different doses. Non-targeted ultrahigh resolution 12 Tesla Fourier transform Ion Cyclotron Resonance Mass Spectrometry (FT ICR MS) was used to discover novel DBPs arising from commercial organic UV filters in sunscreens that also have been found in reasonably high concentrations in the aquatic environment where people are bathing. As expected, the susceptibility of direct chlorination of these aromatic organic compounds depends on the activation of the aromatic ring structure. However, diverse DBPs were discovered which raise concerns in creating high molecular weight DBPs of currently unknown toxicity. These DBPs have the potential to be abundant in chlorinated outdoor swimming pools, as well as in treated and disinfected wastewater. For example, avobenzone seemed relatively inert to chlorination, but octocrylene showed the consistent production of 7 abundant DBPs containing up to three chlorine atoms in negative mode electrospray ionization. DBPs formed from homosalate, octisalate and OD-PABA were also evaluated. The obtained data confirmed that rather diverse DBPs form from these compounds upon chlorination and that further evaluations in real word scenarios are needed to address this potential risk and exposure. The persistence of these DBPs are currently unknown, but all these DBPs accumulated over chlorination time and dose, suggesting that these are end-products and not intermediate compounds.

Disclaimer/Disclosure:

This research project was funded by the US National Science Foundation, Environmental Chemical Sciences (award 2302575).

4.01.A.T-03 How time and place define the concentration of UV filters off a recreational beach in Florida, USA

Carys Louise Mitchelmore¹, Andrew Heyes², Michael Gonsior³, Dorothy-Ellen Abigail Renegar⁴, Iain Davies⁵ and Stefanie Landeweer², (1)University of Maryland Center for Environmental Science, (2)University of Maryland Center for Environmental Science, United States, (3)Catalan Institute for Water Research (ICRA), Spain, (4)Nova Southeastern University, United States, (5)Science, Personal Care Products Council (PCPC), United States

Ultraviolet (UV) filters are a diverse group of organic and inorganic chemicals that have a wide range of commercial applications, including as sunscreen active ingredients, and have been found in coastal locations reflecting the extent of recreational activity. Despite the potential for recreational source inputs to vary over the day, typically monitoring programs only analyze one or a few discrete samples and do not capture this temporal variation. To investigate this, 3 composite samples were collected along 2 100m transect locations at different distances from the shore (T1; nearshore in the bathing zone and T2 ~50m from the shoreline) at multiple times over 24-hours. Samples were immediately processed by filtering (GFF) and solid phase extraction to prepare the 'dissolved fractions'. The GFF filters were frozen and later extracted via hexane to prepare the 'particulate' fractions. All extracts were analyzed quantitatively for 12 organic UV filters using LC-MS/MS.

Oxybenzone (BP-3), octocrylene (OC), homosalate, octisalate, avobenzone, octinoxate, and, OD-PABA were measured in all samples, with higher levels in May, reflecting higher numbers of recreational users. Concentrations were higher at T1 and reduced significantly at T2. All UV filters and the septic-tracer caffeine

followed similar temporal trends with peak concentrations detected in the mid afternoon, reflecting recreational use. This dataset allows for the calculation of time weighted average concentrations (TWAs). Higher concentrations of OC were observed in the 'particulate' phase reflective of its lower solubility and higher logKow, whereas, BP-3 concentrations were nearly all in the 'dissolved' phase matching their physio-chemical properties. Concentrations of the lower solubility UV filters were not as different between March and May as the more soluble BP-3 concentrations were suggesting concentration saturation.

Overall, these results indicate that aquatic organisms in popular recreational areas may encounter UV filter concentrations that are highly variable over a 24-hour period rather than a steady environmental exposure, and that concentrations rapidly decline in the bathing zone after people leave. These results highlight that both location and time is important in environmental risk assessments for UV filters. Furthermore, to understand total concentrations and exposure routes it is important to conduct assessment of partitioning by filtering samples.

This research was funded by a standard research grant to the University of Maryland Center for Environmental Science to Mitchelmore, Gonsior and Heyes from the Personal Care Products Council (PCPC), Washington, D.C.

4.01.A.T-04 Spatial and Seasonal Variations in Concentrations of UV Filters and Preservatives Across Yorkshire's Rivers Revealed by Continuous River Monitoring

Jun Li¹, Leuan Roberts², Angelica Pardo Islas², Alejandra Bouzas-Monroy², Harald Streicher³ and Alistair Boxall², (1)Department of Environment and Geography, University of York, United Kingdom, (2)University of York, United Kingdom, (3)Beiersdorf AG, Germany

Ultraviolet (UV) filters and preservatives are widely used in personal care products. Their extensive use and continuous release into aquatic systems have led to widespread occurrence and raised concerns about environmental impacts. Although many studies have investigated their occurrence, few have achieved the temporal resolution needed to capture seasonal variations or identify key drivers of concentration differences. To address this gap, we conducted a one-year, high-resolution monitoring campaign across 19 sites in nine river catchments in Yorkshire, United Kingdom, spanning land uses from densely populated urban areas to rural arable and livestock regions. Sampling was performed every six hours using automatic samplers, and composite samples were prepared every four weeks. Thirteen target chemicals were selected for monitoring, and their concentrations were analysed using liquid chromatography–tandem mass spectrometry or gas chromatography–mass spectrometry. Ultraviolet filters were detected more frequently than preservatives, with Ensulizole showing the highest detection frequency and mean concentration. Preservatives such as parabens and phenoxyethanol were present at lower levels. Significant differences were observed among land-use categories and seasons for both chemical classes. For UV filters, peri-urban catchments exhibited the highest flow-corrected fluxes, exceeding those in arable, livestock, and urban areas. Preservative fluxes were higher in city, peri-urban, and market-town catchments than in agricultural areas. Both patterns reflect the impact of mixed residential and light-industrial activities through domestic wastewater, urban effluents, and surface runoff associated with personal care product usage. Significant seasonal variation was also observed. UV filter fluxes peaked in spring, exceeding other seasons, whereas preservative fluxes were highest in summer. These patterns indicate that elevated fluxes during warmer months reflect increased product consumption and enhanced releases via domestic wastewater and urban effluents. The strong temporal coupling at certain sites further suggests overlapping emission pathways and shared hydrological controls. These findings provide insights into the behavior and sources of personal care product-related contaminants, supporting improved regional water quality management and regulatory strategies.

4.01.A.T-05 Application of Probabilistic Emissions Modelling to Estimate UV Filter Concentrations at a Recreational Beach in Florida

Margaret Fleming¹, Thomas Federle², Donald Versteeg³, Michael Gonsior⁴, Andrew Heyes⁴, Carys Louise Mitchelmore⁵ and Iain Davies⁶, (1)Personal Care Products Council (PCPC), United States, (2)Thomas W Federle LLC, United States, (3)Ecostewardship LLC, United States, (4)University of Maryland Center for Environmental Science, United States, (5)University of Maryland Center for Environmental Science, (6)Science, Personal Care Products Council (PCPC), United States

UV filters (UVFs), the active ingredients in sunscreen products, are subject to scrutiny from the scientific and regulatory community due to their potential risk to organisms in aquatic compartments. To assess this risk,

environmental exposures are best characterized by combining exposure modelling with well-designed monitoring studies. While properly conducted monitoring studies provide the most definitive exposure data, they are snapshots of individual scenarios in time and space. Modelling has the potential to assist in extrapolating monitoring data to additional sites with similar visitation patterns and hydrology. To support UVF risk assessment, a probabilistic model incorporating environmental fate processes and consumer habits and practices was developed to represent the recreational beach exposure pathway and predict the UVF emissions due to direct release of skin-applied sunscreen products to aquatic environments. A joint monitoring and modelling study of UVF concentrations at Calusa Beach in Bahia Honda State Park in the Florida Keys was conducted to elucidate spatial and temporal UVF concentration trends and to provide a case study to evaluate the predictive ability of the probabilistic UVF emissions model. Measured UVF concentrations were highest in the afternoon, when the number of swimmers/bathers peaked. Subsequently, as recreational activities declined, UVF concentrations significantly decreased due to dilution/dispersion. Model performance was represented by the ratios of the predicted median values (describing the log-normal distributions of modelled concentrations) to the average concentrations measured in triplicate water samples. The UVF emissions model performed well (i.e., within a factor of 4) at predicting measured concentrations for the five UVFs during peak recreational activity at two sampling sites. On average, the model overpredicted the measured values by a factor of 1.8. The reasonable agreement between the predicted and measured values indicates the probabilistic emissions model can be a useful tool for characterizing aquatic UVF exposure at recreational beaches.

4.01.B Advancing the Environmental Risk Assessment and Management of Cosmetics, Sunscreens and Personal Care Products

4.01.B.T-01 Integrated Approaches to Assess Bioavailability and Bioaccumulation of Water Soluble Polymers

Maura Hall¹, Vincenzo Agostiniano², Kevin Goodall² and Christopher Ruark¹, (1)Procter & Gamble, United States, (2)Procter & Gamble, Belgium

Water soluble polymers possess structural and physicochemical features that inherently limit biological uptake, yet current regulatory expectations increasingly call for clear and transparent demonstration of their bioavailability and bioaccumulation behavior. Their large molecular size, extensive hydration, low lipid affinity, and limited membrane permeability contribute to minimal internal exposure across human and environmental pathways.

This presentation outlines a weight of evidence framework that integrates mechanistic principles of bioaccumulation, toxicokinetic information from mammalian and environmental systems, and emerging analytical approaches to assess the bioavailability and bioaccumulation potential of water soluble polymers. The approach considers attributes such as molecular size, hydrodynamic diameter, solubility behavior and links these properties to expected uptake constraints. Empirical indicators and toxicokinetic observations are used to demonstrate the consistently low internal exposure observed for representative examples of water soluble polymers, reinforcing their low potential for bioaccumulation. New methods and approaches including solvent partitioning, and approaches to simplify testing compared to expensive fish studies (eg sharpening toxicokinetic studies with CaCo2 assays) will be shared.

Together, these elements provide a coherent and scientifically grounded basis for evaluating water soluble polymers. Importantly, many of these approaches are referenced in existing regulatory approaches around the world- albeit not all the same. However, this link and references do create an ability to link the mechanistic, and new analytical approaches within a modern regulatory context. We propose a framework and toolkit which illustrates how mechanistic understanding and empirical evidence can be combined to assess bioaccumulation potential in a manner that reflects the unique properties of these materials and supports transparent, science based assessments.

4.01.B.T-02 Risks of Mixtures of UV Filters to Freshwater Algal and Cyanobacterial Species

Lalita Chomphen¹, Alejandra Bouzas-Monroy¹, Jun Li¹, Harald Streicher², Amy Rose Ockenden³, Lorraine Maltby³ and Alistair Boxall¹, (1)Environment and Geography Department, University of York, United Kingdom, (2)Environmental Safety, Beiersdorf AG, Germany, (3)School of Biosciences, University of Sheffield, Sheffield, United Kingdom

UV filters (UVFs) are extensively used in personal care products and have been increasingly detected in aquatic environments worldwide. Although the toxic effects of individual UV filters on standard aquatic

ecotoxicological test species have been studied, the understanding of their effects on species more widely, as well as their combined effects, remains limited. This study explored the risks of five commonly detected UVFs, homosalate, octocrylene, benzophenone-3, ensulizole, and avobenzone, to freshwater algal and cyanobacterial species. Laboratory bioassays were conducted using twelve phytoplankton and periphyton species (five chlorophytes, two cyanobacteria, and five diatoms) using single UVFs and mixtures of UVFs with growth inhibition employed as the toxicity endpoint. Bioassay results were used to evaluate the concentration addition (CA) and independent action (IA) mixture toxicity models for predicting mixture effects. The models were then used, alongside an extensive monitoring dataset for UVFs in Yorkshire's rivers, to establish the potential risks of these chemicals to freshwater systems. Results from single-compound tests demonstrated pronounced interspecific and higher taxonomic rank variability in sensitivity, with diatoms generally exhibiting higher susceptibility to UVF exposure than chlorophytes and cyanobacteria. Among the tested species, the diatom *Aulacoseira granulata* was identified as the most sensitive. Model evaluation using the model deviation ratio (MDR) indicated that the CA model provided consistently more accurate predictions of observed mixture toxicity compared to the IA model indicating that the toxicological interaction of the tested UVFs is predominantly additive. Use of the CA model alongside UVF monitoring data yielded mixture risk quotient values below 1, indicating that the selected UV filters currently pose a low risk to aquatic environments in the study region under typical exposure conditions.

4.01.B.T-03 Aquatic Risk of Fragrance Materials: Advancing Prioritization in Aquatic Systems

Aurelia Lapczynski¹ and **Heather Summers²**, (1)Research Institute for Fragrance Materials, United States, (2)Integral Corp, United States

For more than 50 years, the Research Institute for Fragrance Material (RIFM) has led programs to demonstrate the human and environmental safety of more than 3,000 fragrance materials manufactured and used by their members. The Environmental Program sponsors testing and academic research on the fate and effects of fragrance materials in aquatic compartment. In addition, RIFM conducts environmental risk assessments and screens fragrance materials using the RIFM Environmental Framework published almost 20 years ago (Salvito et al. 2002. Environ. Toxicol. Chem., 21: 1301-1308). While the Framework has proved to be an effective tool, its scope was limited to the United States and Europe. RIFM recognized the need to expand the geographic scope of those assessments to include regions with rapidly expanding usage of fragrance materials. Also, advances in environmental exposure science and ecological hazard characterization over the past two decades offer an opportunity for the Framework to showcase cutting edge science and data analytics. This presentation will highlight recent advances of the Framework that feature expanded geographies, real-time access to the most current population and hydrological data, mechanism of action material categorization and the ability to reassess the entire inventory of fragrance materials nearly instantaneously at the push of a button.

4.01.B.T-04 Advancing Environmental NGRA: Transferring a 10-Step Read-Across Framework for Cosmetic Ingredients

Harald Streicher, Zakaria Naddi and Diego Robles, Beiersdorf AG, Germany

Next-Generation Risk Assessment (NGRA) provides a structured, mechanistic, and non-animal approach for chemical safety evaluations. While NGRA concepts are increasingly established in human safety assessment, their application to environmental safety remains at an early stage. This work demonstrates how a 10-step NGRA framework, originally developed for human safety evaluations of cosmetic ingredients, can be systematically adapted for environmental risk assessment.

Using triclosan as a data-rich model compound, we assessed how the framework performs when environmental exposure, fate, and hazard information are integrated with New Approach Methodologies (NAMs). The adapted workflow covers scenario definition and data curation (Tier 0), bioavailability modelling and mode-of-action hypothesis building (Tier 1), and the derivation of environmental points of departure from NAM datasets (Tier 2). Mechanistic information from transcriptomics, high-throughput bioactivity assays, and metabolic and endocrine-related pathways was combined with QIVIVE and bioaccumulation models to identify sensitive biological targets and derive NAM-based PNEC values, which subsequently allow the calculation of a risk quotient and thereby a complete environmental risk assessment.

Applying the framework to triclosan resulted in NAM-derived PNECs that align with—and in part are more protective than—existing regulatory PNECs. The case study confirms that environmental NGRA can generate transparent and biologically meaningful evidence for risk characterisation without new vertebrate testing.

This work illustrates the feasibility of translating a human-safety NGRA framework to environmental safety and highlights its potential for broader implementation across sectors. Strengthening data integration, mechanistic interpretation, and cross-species extrapolation will be key steps towards establishing NGRA as a future-ready paradigm for environmental protection.

4.01.B.T-05 Cosmetics Claims: Need for Enhanced Risk Communication on Cosmetic Ingredients

Cristiana Gheorghe¹, Jon D. Oldfield¹ and Iseult Lynch², (1)University of Birmingham, United Kingdom, (2)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom

Cosmetic products are a notable source of chemical exposure in daily life, as consumers use multiple products daily (e.g., shampoo, toothpaste, deodorant, moisturiser), each containing complex mixtures of ingredients. Cosmetics exposure is directly through skin contact, and indirectly via inhalation of volatile components, eye and oral routes. Despite extensive exposure, information available to the public about cosmetic ingredients, their potential hazard for human health and real-world risk is fragmented, highly technical and uneven in quality. The EU's regulatory database and opinions are publicly accessible but are written for experts. Smartphone apps have emerged as an easy way for consumers to access information, but it is unclear what data is used, the basis for their scoring and whether they differentiate between hazard and risk.

To gain a better understanding of the effectiveness or otherwise of these "scoring" approaches for risk communication to consumers, a systematic analysis of the apps available in English and their scoring systems was performed, supplemented by an online survey of general public opinion on the information available regarding ingredients in cosmetics and what drives their purchasing choices.

A structured search of Smartphone apps was performed in Nov. 2025 on Google Play/Apple App Store to aggregate all consumer facing cosmetics scoring apps into one dataset. The review used the PRISMA workflow, predefined keyword combinations and inclusion/exclusion criteria, identifying >150 mobile apps that display ingredient- or product-level scores to users in a standardised format (numeric, colour code, icons or labels). The survey of consumer perceptions was carried out May-Nov. 2025 and examined the key factors influencing purchasing decisions, the relevance of product claims and labels, and the role of digital tools in shaping choices. >300 responses were collected and results indicate that consumers reported moderate to very concerned regarding cosmetic product safety. Presence of controversial ingredients (e.g., parabens), absence of safety certifications or testing and negative social media or negative product reviews are among the factors that drive consumer perception of a cosmetic being potentially hazardous.

The results show a clear need for much stronger management of communication of risks from cosmetics / cosmetic ingredients to the public, ideally via establishment of an independent body to oversee such communication.

4.01.P Advancing the Environmental Risk Assessment and Management of Cosmetics, Sunscreens and Personal Care Products

4.01.P-Mo272 Spatio-Temporal Patterns of UV Filters in the Baltic Sea and Their Distribution at Different Depths

Harshada Sakpal¹, Marion Kanwischer², Detlef Schulz-Bull² and Kathrin Fisch¹, (1)Julius Kühn-Institut (JKI), Institute for Ecological Chemistry, Plant Analysis and Stored Product Protection, Germany, (2)Leibniz Institute for Baltic Sea Research Warnemünde (IOW), Germany

The occurrence of organic ultraviolet (UV) filters is of increasing scientific concern due to their potential as endocrine disruptors and their ability to bioaccumulate in the environment. Globally, the use of organic UV filters as active ingredients in sunscreens, personal care products, and industrial materials is growing exponentially. The Baltic Sea, with its unique topography and freshwater input that carries pollutants from human activities in the catchment area, is recognized as one of the most heavily impacted regional seas in terms of chemical pollution. One group of these pollutants is UV filters, which primarily enter the Baltic Sea through river inflows, wastewater treatment plants, and recreational activities. Previous studies have highlighted the presence of UV filters in the coastal areas of the Baltic Sea, particularly in the surface waters around the Warnow Estuary and other coastal sites. The main objective of this study is to determine if increasing levels of UV filters in the coastal Baltic Sea are transported into offshore waters and to identify the areas with the highest levels of pollution. Water sampling conducted during the spring-summer and autumn-winter seasons of 2023

and 2024 were used to evaluate the seasonal variability of UV filter concentrations across the Baltic Sea. This study also provides a comprehensive comparison between the distributions in the coastal areas and the open sea, while considering variations across different depths in the open waters. Among the UV filters detected, octocrylene (OC), PBSA, and UV-P were the most prevalent. The highest concentrations of OC were found in water samples from coastal areas during the summer, reaching as high as 162.6 ngL⁻¹. The peak concentration of PBSA, at 732.8 ngL⁻¹, was recorded in the coastal area in November, while the highest concentration of UV-P, measured at 34.3 ngL⁻¹, was found in the open sea during the same month. Other UV filters, such as BP-4, were detected at notable concentrations in coastal areas. No significant differences in UV filter concentration distributions across different depths were observed, indicating a uniform distribution of UV filters throughout the water column in the open sea of the Baltic Sea. In conclusion, UV filters were found in both the open sea and coastal regions of the Baltic Sea throughout the year. These findings provide clear evidence of the widespread occurrence and distribution of UV filters in the Baltic Sea.

4.01.P-Mo273 Environmental occurrence of octocrylene in marine and freshwater systems: A critical review

Todd Gouin, TG Environmental Research, United Kingdom

The use of octocrylene has come under regulatory scrutiny, with concerns regarding its potential environmental risk. A main challenge in assessing environmental risk relates to uncertainties associated with exposure quantification, specifically with the use and release of octocrylene into marine and freshwater systems. A systematic and critical literature review is conducted in this study, consistent with the Criteria for Reporting and Evaluating Exposure Data (CREED), with the primary aim to collate measured environmental concentrations (MECs) of octocrylene in surface water systems. The results of the study, consequently, include considerations regarding the reliability and usefulness of the available data, to quantify and/or represent reasonable approximations of environmentally relevant exposure to octocrylene. Significant procedural and methodological inconsistencies were involved among the available studies regarding surface water and sediment sample collection, processing, and analyses. Therefore, accompanying discussion in this study draws attention to the need for well-defined monitoring studies capable of acquiring concentration data that are representative of environmental systems and the need to either increase the number and frequency of samples collected or to consider the adoption of time-weighted passive sampling methods at sites to account for spatial, diurnal, and seasonal variabilities. Nonetheless, the existing data provides some understanding of central tendencies in MECs, which may be useful in ground truthing ongoing regulatory environmental risk assessments. The geometric mean concentrations for octocrylene in surface water reported at sites associated with recreational activities are similar in freshwater (30 ng/L) and marine (37 ng/L) systems. Similarly, the geometric mean concentrations of octocrylene in sediments influenced by potential sources of octocrylene are also relatively consistent for samples collected from both estuarine (6.9 ng/g dw) and freshwater riverine (4.3 ng/g dw) systems.

4.01.P-Mo274 ChemRadar: Detecting Chemical Hazards on the Horizon

Renske P. J. Hoondert¹, Daniel Joao Silva Tavares Duarte² and Thomas L. ter Laak³, (1)Chemical Water Quality, KWR Water Research Insititute, Netherlands, (2)KWR Water Research Institute, Netherlands, (3)KWR Water Research Insititute, Netherlands

ChemRadar is a forward-looking initiative aimed at improving the detection and prioritization of emerging chemical threats in the drinking water sector. Traditional monitoring systems are often reactive, focusing on known contaminants, which leaves utilities vulnerable to unforeseen risks. ChemRadar addresses this gap by introducing a structured workflow that integrates existing tools and data sources into a flexible, adaptive system.

The workflow is organized into three analytical stages: screening, signaling, and prioritization. Screening involves collecting broad information on chemical occurrence and emissions, even if data is incomplete or noisy. Signaling interprets patterns and trends to identify potential threats, while prioritization ranks substances based on factors such as exposure relevance, toxicity, persistence, and mobility. This non-linear approach allows users to start at any stage depending on their context and needs.

ChemRadar recognizes four distinct user domains—scientific, industrial, societal, and policy—each with unique perspectives and requirements. For example, scientists may focus on analytical methods and data gaps, while policymakers prioritize regulatory trends. Practical applications range from laboratory analysts detecting unknown contaminants to strategic managers planning long-term water safety measures.

The framework leverages a wide array of resources, including scientific databases, regulatory platforms, industrial data, and societal tools. It also incorporates computational models and text-mining techniques to enhance foresight. Two complementary implementation strategies are proposed: a top-down approach, which scans broad chemical space for preventive insights, and a bottom-up approach, which focuses on contaminants detected in drinking water for immediate relevance. Combining these strategies improves predictive power and reduces blind spots.

In the next phase, we are evaluating the system for a series of potential threats, ranging from individual chemical groups to more generic trends in uses /applications of groups of chemicals to generic trends and changing activities that can lead to emission of chemicals. These cases are used evaluate the value and applicability of the ChemRadar concept/workflow in collecting information, identifying knowledge needs and gaps and supporting the evaluation of the risk for the drinking water sector. Preliminary results of a selection of these cases will be presented

4.01.P-Mo275 Filling Data Gaps in Chemical Risk Assessment: Multi-Trophic Evaluation of Cinchonidine and Its Production Byproducts

Fábio Yu Chen¹, Ingrid Peralta¹, Sara Bragança¹, Madalena Filipa Moreira Vieira¹, Patrícia Veríssimo Silva² and Susana Loureiro¹, (1)University of Aveiro, Portugal, (2)Department of Biology, University of Aveiro, Campus Universitário de Santiago, University of Aveiro, Portugal

Cinchonidine is a quinoline alkaloid and a common chiral synthetic intermediate in pharmaceutical synthesis, which can enter wastewater through laboratory use, drug manufacturing, or disposal of reaction residues, potentially exposing aquatic organisms to this compound. Although structurally related to regulated antimalarial compounds increasingly used in drug production, ecotoxicological data for cinchonidine remain extremely limited. The toxicity assessment of waste generated during the production of the active pharmaceutical ingredient (API) is a key strategy for advancing green pharmaceutical manufacturing. In this study, pure cinchonidine and cinchonidine-containing waste residues generated at different stages of API production, supplied by a pharmaceutical company (AstraZeneca), are being evaluated in aquatic model organisms: *Aliivibrio fischeri* (MicroTox), *Saccharomyces cerevisiae* (Yeast Estrogen Screen Assay), *Raphidocelis subcapitata* (OECD Test No. 201: Freshwater Alga and Cyanobacteria, Growth Inhibition Test), *Daphnia magna* (OECD Test No. 202: *Daphnia* sp. Acute Immobilisation Test), and *Danio rerio* (OECD Test No. 236: Fish Embryo Acute Toxicity (FET) Test). Results from this case study will help clarify the environmental hazards associated with cinchonidine-containing wastes and support the industry's greener pharmaceutical development, highlighting the need for environmental risk assessment approaches that explicitly consider the toxicity of production residues, such as cinchonidine. Moreover, this work highlights the importance of collaboration between academia and the pharmaceutical industry for the development of greener pharmaceuticals.

4.01.P-Mo276 Chemical Contaminant Inhibition of Settlement and Survivorship in Caribbean Corals

Dorothy-Ellen Abigail Renegar¹, Ellen Regina Englert Skelton² and Carys Louise Mitchelmore³, (1)National Coral Reef Institute, Nova Southeastern University, United States, (2)Nova Southeastern University, United States, (3)University of Maryland Center for Environmental Science

Early life stages of scleractinian corals are generally regarded as more sensitive to contaminants compared to adults. Spawning and larval development of most coral species on Florida's Coral Reef occurs through the summer and fall, which coincides with substantial rain-event driven events associated with risk of exposure to chemical contaminants in the water column and sediment/substrate. The inhibition of larval settlement and/or metamorphosis, which are crucial developmental steps and ultimately determine survival, have been examined for only a very limited range of chemical contaminants and coral species.

Montastraea cavernosa and *Pseudodiploria clivosa* larvae were exposed to contaminants as nominal dissolved concentrations or pre-contaminated settlement tiles, and tiles checked for settlement and metamorphosis daily

for 96 hours or until no observable swimming larvae are found (i.e. either settled or perished). Chemicals included metals (copper, arsenic, zinc), hydrocarbons (chrysene, fluoranthene, pyrene, phenanthrene), and common organic pollutants (tributyltin, diuron, and octocrylene) as these chemicals are waterborne and/or sediment-associated contaminants recognized for potential toxicity. These contaminants were identified in a recent metanalysis as contaminants of potential impact as they have been detected at concentrations which exceed both EPA water quality standards and State of Florida threshold and/or probable effects levels in waters and sediments across the southeast coast of Florida.

For *M. cavernosa*, significant reductions in settlement were observed for dissolved exposures to fluoranthene, phenanthrene, pyrene, diuron, octocrylene, and tributyltin and for settlement tiles contaminated with zinc, pyrene, and octocrylene. Non-significant dose-related reductions in settlement were also observed for other dissolved and contaminated tile exposures. The test methodology consistently met or exceeded the typical 20% laboratory settlement success rate for *M. cavernosa*.

This study has thus far identified preliminary thresholds of effect for common inorganic and organic chemical contaminants exposure for settlement in Atlantic corals, and provided a framework for the establishment of standardized toxicity test methods for coral early life stages which are a current need and essential for determining the environmental risk of chemical contaminants on coral reefs.

This research was made possible by funding provided by the Florida Department of Environmental Protection's Coral Protection and Restoration Program to DA Renegar and CL Mitchelmore.

4.01.P-Mo277 Polyvinyl Alcohol-induced Cytotoxic and Oxidative Responses across Tissues of the Blue Crab *Callinectes sapidus*

Alessandra Maganza¹, Camilla Mossotto¹, Annalisa Cotugno¹, Giorgia Zicarelli¹, Alice Gabetti¹, Alessia Merialdi¹, Antonia Concetta Elia², Caterina Faggio³, Monia Renzi⁴, Francesca Provenza⁵, Giuseppe Esposito¹, Marino Prearo¹ and Paolo Pastorino¹, (1)The Veterinary Medical Research Institute for Piedmont, Liguria and the Aosta Valley, Italy, (2)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (3)Department Veterinary Sciences, University of Messina, 98166, Messina; Department of Eco-sustainable Marine Biotechnology, Stazione Zoologica Anton Dohrn, 80121, Napoli, Italy, (4)Department of Life Sciences, University of Trieste, 34127, Trieste, Italy, (5)Bioscience Research Center srl, Italy

Polyvinyl alcohols (PVAs) are synthetic water-soluble biopolymers produced from polyvinyl acetate and widely used in industrial, medical, and personal care applications, including packaging films, detergents, contact lenses, and cosmetics. Over 65,000 tonnes enter aquatic ecosystems annually, and their slow degradation under limited environmental conditions raises concerns about their effects on marine fauna.

This study investigated the effects of PVA exposure on the blue crab *Callinectes sapidus*, an alien species in the Mediterranean Sea. Three exposure concentrations (0.5, 5, and 25 mg L⁻¹) and a control were used, and crabs were exposed for 10 and 20 days. Haemolymph was collected with sterile syringes, and after euthanasia in ice water, muscle, gill, and hepatopancreas tissues were dissected for analysis. Oxidative stress was assessed through the activities of antioxidant enzymes: superoxide dismutase (SOD), glutathione S-transferase (GST), glutathione peroxidase (GPx) and lipid peroxidation levels. Cell viability in haemolymph and hepatopancreas was evaluated, while statistical differences among treatments were analysed using the Kruskal–Wallis test followed by Dunn's post hoc comparisons. The overall biochemical response was interpreted using the Threshold-based Integrated Biomarker Response (IBR-T) index.

Results revealed a greater sensitivity of hepatopancreas cells to PVA exposure compared to haemolymph cells. Prolonged exposure induced clear oxidative stress, with increased antioxidant enzyme activity and lipid peroxidation, particularly at higher concentrations. After 10 days, the IBR-T index rose with exposure level in all tissues, reaching its highest values in the higher PVA concentration group, indicating early activation of antioxidant and detoxification processes. After 20 days, IBR-T values remained elevated, especially in muscle and hepatopancreas, suggesting cumulative stress effects. Overall, the study demonstrated a concentration and time dependent biological response to PVA, highlighting significant physiological alterations at the highest exposure level. These findings contribute to a better understanding of PVA–organism interactions and emphasise the need for further research on their environmental implications.

4.01.P-Mo278 Freshwater Toxicity of Polymer-Surfactant Mixtures Across Trophic Levels

Ana Rita Santos¹, Luís Alves², Isabel Lopes¹ and Cátia Venâncio¹, (1)University of Aveiro, Portugal, (2)University of Coimbra, Portugal

The development of advanced materials, particularly for application in personal care products (PCP), is shifting due to growing environmental concerns. Continuous release into wastewater systems makes them prone to become pseudo-persistent pollutants. Current regulatory assessments focus on individual compounds, but commercial formulations are complex mixtures in which components interactions can unexpectedly affect freshwater life.

This study, based on an industry-academia partnership, aimed to investigate the ecotoxicological behavior of three quaternized hydroxyethyl cellulose polymers common in PCPs (SoftCAT™ SK-M, SK-MH, and SL-5) alone and in combination with three surfactants: Sodium Lauryl Ether Sulfate (SLE2S), Alkyl Amido Propyl Betaine (APB), and Tallow Ester Quat (EQ). The cellulose polymers were tested at pre-established HC₅ values (Hazardous Concentration for 5% of species) from previous research: 0.00354 mg/L (SK-M), 0.00127 mg/L (SK-MH), and 95.5 mg/L (SL-5). Surfactants were used at 33-fold higher concentrations to maintain the typical 1:33 polymer-to-surfactant ratio found in commercial formulations. Eight treatments were used per polymer in each assay, including a negative control, individual compounds (polymer at HC₅; surfactants at 33 × HC₅), and their binary mixtures. Toxicity assessment comprised a battery of assays with freshwater organisms covering different trophic levels: the producer *Lemna minor* (yield and growth), primary consumers *Brachionus calyciflorus* and *Daphnia magna* (mortality and reproduction), and the secondary consumer *Danio rerio* (mortality, malformations, heart rate, body length).

Toxicity profiles were polymer- and species-specific. Combined and individual exposure of *D. rerio* to SK-M and surfactants altered the cardiac function, with combined exposures producing different effects than single compounds. SK-MH altered cardiac function only in combination with APB, where the mixture response was different from that of the polymer and surfactant alone. No significant effects were detected for *L. minor*, *D. magna*, or *B. calyciflorus* for SK-M and SK-MH. On the other hand, SL-5 led to high mortality in *D. rerio* and pronounced growth inhibition in *L. minor*, with the strongest effects produced by SLE2S and APB (alone and combined with SL-5). These results show that interactions among PCP ingredients can markedly change toxicity, suggesting current single-compound testing frameworks may underestimate mixture-related risks.

4.01.P-Mo279 Natural complex substances: An experimental & in silico combination approach to evaluate ecotoxicity

Paul Thomas¹, Floriane Larras¹, Nicolas Delpit², Lise Mata³, Marine Canton⁴ and Sylvain Antoniotti⁴,
(1)KREATiS SAS, France, (2)SGS France laboratoire de Rouen, France, (3)Laboratoires des Pyrénées et des Landes, France, (4)University Côte d'Azur, Institut d'Innovation et de Partenariats Arômes Parfums Cosmétiques, France

Natural complex substances (NCSs) are botanical extracts of unknown or variable composition containing long chain substances that are very difficult or impossible to identify,

The recommended approach to perform an environmental aquatic hazard assessment for UVCBs is water accommodated fraction (WAF) toxicity assays. Such methodologies have been used for the fragrance industry's essential oil products (termed Type 1 or NCS1. However, WAF lacks mechanistic interpretability. Its application in hazard and risk assessment is therefore questioned.

Bicherel and Thomas (2021) published an in silico method for toxicity estimation for complex mixtures using an equivalent of the WAF methodology deemed applicable to non-polar narcotic mixtures such as essential oils (NCS1). This in silico method mimics WAF studies for nonpolar narcotic mixtures using chemical activity principles. It accurately predicts acute and chronic ecotoxicity lethal or effect loading rate. Nevertheless, until now, the method had not been used for toxicity estimation of more complex substances than NCS1, e.g. NCS2 substances containing large fractions of unidentified constituents.

In this study the NCS was separated into three fractions: 1) "volatile," 2) "non-volatile but potentially bioavailable," and 3) potentially "inert" and analytically define them. The whole substance (WS) and each fraction were tested as water accommodated fractions (WAFs) for acute and chronic ecotoxicity to algae and daphnids. Their toxicity was predicted using (a) an in silico method adapted for mixture toxicity testing and (b) the additivity Classification Labelling and Packaging/Global Harmonised System (CLP/GHS) method, based on analytically determined composition.

The study demonstrated the importance of combining in silico and experimental approaches, especially for

complex substances such as NCS2. The fractionation approach provided quality empirical toxicity study results and these are in agreement with the in silico predictions. Thus it can be concluded that the experimental data validate the results of the in silico prediction while the latter support and thermodynamically explain the empirical results from the studies. On the other hand, CLP does not predict toxicity in any of the studies. The implication of these conclusions will be discussed.

4.01.P-Mo280 In Silico Eco/Tox Prediction Using Triad of QSAR model, Toolbox read-across and expert knowledge. Application for skin sensitization

Hristiana Stoyanova (Ivanova), Gergana Dimitrova, Kalin Kirilov and Ovanes Mekenyan, Laboratory of Mathematical Chemistry (LMC) Prof. Assen Zlatarov Burgas State University, Bulgaria

Across the variety of industrial sectors, including pharmaceuticals, cosmetics and personal care products, food additives and their associated regulatory assessments, there is a need to develop robust and reliable methods to reduce or replace animal testing. It is generally recognised that no single alternative method will be able to provide a one-to-one replacement for assays based on more complex toxicological endpoints. Hence, information from a combination of techniques is required. The current work suggests a combination of Quantitative Structure-Activity Relationship (QSAR) predictions, read-across (RA) analogues approach and expert knowledge for providing mechanistically reliable predictions. The combined approach is called “QSAR Triad” and will be demonstrated for predicting skin sensitization potential of a case study chemical. The first pillar of the QSAR Triad includes QSAR prediction from the OASIS TIMES software which is justified by identification of analogues supporting the prediction and analogues supporting the simulated metabolic pathway responsible for the metabolic activation. In addition, the system allows to consider the toxicokinetics of adduct formation and to quantify the extent of damage that could be caused to macromolecules (i.e., to skin proteins). All supporting information is automatically organized and could be reported via the software according to the QSAR Assessment Framework (QAF) approach. The second pillar of the QSAR Triad relies on RA prediction obtained in QSAR Toolbox and is based on selection of mechanistically and structurally similar analogues. Along with the selection of analogues, the Toolbox provides a functionality (called Alert performance), which could be used to estimate the percentage of positive and negative analogues available within the Toolbox databases and sharing the same mechanism(s) of interaction with macromolecules as the target chemical. The third pillar of the QSAR Triad is associated with the expert approval of the results obtained in the previous stages, which is an important step for verification of final prediction based on external knowledge. In general, the suggested reliability workflow is applicable for any (eco)toxicological endpoint with known mode of action and clear mechanisms of interaction with macromolecules.

4.01.P-Mo281 Exposure Driven Environmental Risk Assessment - A Case Study on Fragrance Materials.

Samantha Crotty, Marissa Guttenberg and Aurelia Lapczynski, Research Institute for Fragrance Materials, United States

Fragrance materials are ubiquitous in the environment due to pervasive uses in cosmetics, consumer products, and other daily use items. Over the past 20 years, the Research Institute for Fragrance Materials (RIFM) has been the leader in conducting environmental risk assessments on more than 3,000 fragrance materials. It has been with this mission that RIFM has developed an updated three-tiered framework that utilizes exposure-based modeling for assessing and ensuring the safe use of these materials. The recent updates to this framework allow for the more accurate assessment of fragrance materials by employing new approach methodologies (e.g., mode-of-action based ecological thresholds) to limit the use of animal testing, covering more geographical regions, and yielding realistic exposure concentrations (e.g., using updated IFRA Volume of Use surveys). The RIFM Environmental Risk Assessment determines exposure concentrations by using now available data on region-specific water usage, wastewater treatment models, river dilution, and measured biodegradation and ecotoxicity data. In addition, a hazard assessment is evaluated alongside the risk assessment, to ensure the safety of the fragrance material. The hazard assessment is conducted by using available measured or modeled persistence, bioaccumulation, and toxicity data. Following the completion of a risk and hazard assessment of a fragrance material, a four-to-five-year maintenance cycle begins which allows RIFM to re-evaluate the material to maintain and update RIFM's previous conclusion. This poster highlights a case study in which the step-by-step approach of exposure-based risk assessment of a fragrance material is employed. By using RIFM's conclusions drawn from the updated framework, manufacturers and regulators are able to create accurate science-based decisions to ensure the safe use of fragrance materials.

4.01.P-Mo282 New Training Course on Environmental Safety for Cosmetic Safety Assessors

Marlies Berghem Sr M¹, Iain Davies², Alessia Giorgis³, Melanie Gross⁴, Joachim Kremer⁵, Aurelia

Lapczynski⁶, Andreas Picker⁷, Amelie Ott⁸, Véronique Poulsen⁹, Klaus Rettinger¹⁰, Harald Streicher¹¹, Nathalie Vallotton¹², Adriana Wigh⁵ and Johannes Tolls Dir¹, (1)Corporate Scientific Services, Henkel AG & Co. KGaA, Germany, (2)PCPC, United States, (3)knoell Germany GmbH, Germany, (4)Coty Inc., United States, (5)Henkel AG & Co. KGaA, Germany, (6)RIFM, United States, (7)ADA Cometics, Germany, (8)ICCS, Belgium, (9)L'Oréal, France, (10)IKW, Germany, (11)Beiersdorf AG, Germany, (12)DOW, United States

Cosmetic safety assessors are increasingly confronted with questions relating to the environmental safety of cosmetic products.

Trained according to traditional curriculum in chemistry, human toxicology, dermatology and cosmetic legislation, they often lack the necessary background to address these emerging concerns.

To address this gap, a new online training course module will be launched in 2026 to include environmental safety assessment into the qualification scheme for cosmetic safety assessors.

Developed in collaboration with industry professionals and association experts, the course provides fundamental knowledge on environmental safety assessment of chemicals used in cosmetic products. It introduces essential concepts, regulatory frameworks, and practical methodologies relevant to evaluating the environmental impact of cosmetic ingredients.

4.02 Beneath the Surface: Advancing Soil Ecotoxicology and Risk Assessment for Realistic and Sustainable Ecosystem Protection

4.02.T-01 Recovery of earthworm populations in field test plots through migration?

Silvio Knaebe¹, Tobias Vollmer², Anja Hamberger² and Olaf Klein², (1)Eurofins Agroscience Services US, Germany, (2)Eurofins Ecotox, Germany

Earthworm field tests are used as highest tier in the risk assessment for in-soil organisms. Differences in earthworm populations (population size and composition) of test item treated and untreated field plots are assessed at different timings after application of the test item, thus covering short-term effects (1 month after application) as well as medium to long-term effects (6 months, 12 months after application) including recovery. If full recovery is observed after a one-year trial period, the risk is estimated to be low (De Jong et al., 2006; EFSA, 2017). The test (ISO guideline 11268-3, ISO 2014) is typically carried out on plots with a minimum size of 10x10 m that are separated from each other by untreated strips.

It is known that earthworms are capable of active dispersal (e.g. EFSA 2017, Grigoropoulou & Butt 2010, Emmerling & Strunk 2012) and it could thus be postulated that migration could lead to an overestimation of the recovery potential of earthworm populations when studying small experimental plots – especially when the distance to potential “source areas” for migration (untreated areas) in relation to the potential dispersal rate is much smaller than in real world field situation with much larger distances to untreated areas (field margins etc.). A series of field experiments was set up in order:

- to estimate the contribution of migration from untreated areas to the recovery of strongly damaged earthworm populations and

- to evaluate whether migration could be reduced by either setting up mechanical barriers at the plot borders or by separating the plots from untreated areas by strips of intensively cultivated soil.

Additionally, data from >50 earthworm field studies following ISO 11268-3 with pairs of toxic standard and water-treated plots were evaluated.

Results of these field experiments and data assessments will be presented and discussed.

4.02.T-02 From In vitro to Field: Comparison of Results from Tests of different Levels of Realism for Arbuscular Mycorrhizal Fungi

Ulrich Menke¹, Anna Manukyan², Julia Spell³ and Michael Thomas Marx¹, (1)Bayer AG, CropScience, Germany, (2)University of Thessaly, Biopolis, Department of Biochemistry and Biotechnology, Larissa, Greece, (3)knoell Germany GmbH, Germany

Arbuscular mycorrhizal fungi (AMF) form mutualistic associations with many crop species and can play an important role in nutrient uptake and soil health. AMF were identified as focal organism group for future soil risk assessment [EFSA, 2017]. Our objective is to compare own and literature results of lab experiments, greenhouse-based, semi-field and field tests and to evaluate effects of model substances on AMF colonization under different exposure conditions. A potential tiered testing and risk assessment approach is discussed.

From three separate research groups, pre-symbiotic laboratory experiments with spore germination tests in medium acc. to ISO 10832:2009, performed with several fungicides and on different AMF species were analysed. Only the two AMF species *Rhizophagus intraradices* and *R. irregularis* showed a sufficient dose-response and can be considered reliable for inclusion into regulatory testing. Overall the ISO 10832 medium test with the right species is well suitable to differentiate under worst case conditions regarding effects on spore germination and hyphae elongation providing a good tier 1.

Performing tests that include the symbiosis between AMF and a host plant represents a major step towards more realistic conditions. In symbiotic tests performed in small pots in the greenhouse with barley and maize plants, a differentiation between the substances dependent on dose, route and timing of exposure was evident. The magnitude of effects was reduced compared to the medium tests. These test systems can be considered an intermediate-tier (tier 2) test systems between lab and field but still using a defined AMF species.

In a semi-field test with natural AMF population and natural soil in larger containers, with the exception of one product, the tested fungicides showed no significant effect on the mycorrhization process within the host plant. This semi-field test could act as possible tier 3 or higher-tier test system, still below a full field test design.

Ecotoxicological data from field-tests with AMFs, providing the highest tier, are limited. Available literature indicates that effects observed in the lab and greenhouse are attenuated in the field.

In conclusion, our results show that test designs with different levels of realism are available, providing sufficient sensitivity and clear dose-dependent effects for AMF. These could be used to develop a tiered testing scheme for AMF.

4.02.T-03 Experimental Validation of Mixture Toxicity Models for Pesticides in Soil

Micha Wehrli¹, Andreas Maccagnan², Aline de Courten³, Mathieu Renaud⁴, Marion Junghans⁴, Kathrin Fenner⁵ and Miriam Langer³, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag) & University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Switzerland, (4)Swiss Centre for Applied Ecotoxicology, Switzerland, (5)Swiss Federal Institute of Aquatic Science and Technology (Eawag) & University of Zurich, Switzerland

Pesticides are widely applied to protect crops, yet their biologically active nature can harm non-target soil organisms. Current risk assessments focus on single substances, ignoring realistic mixtures that persist in agricultural soils for decades. This gap raises concerns about cumulative effects on soil fauna, such as springtails, which play a key role in nutrient cycling. Our study aimed to validate mixture toxicity models for terrestrial ecosystems experimentally, specifically the concentration addition (CA) model, which is established for aquatic systems but unvalidated in soils. We selected five commonly detected pesticides, two herbicides, two fungicides, and one insecticide, based on Swiss soil monitoring data and toxicity profiles. Using OECD232 reproduction tests with *Folsomia candida*, we assessed single formulations and mixtures of five formulations at environmentally relevant concentrations. All soil treatments (8 treatments for single substances and 21 for mixtures) were measured at the start and at the end of the test. This study is the first study to track a complex mixture of pesticides in springtails. Internal pesticide concentrations, for all 5 active substances and two metabolites, were measured to evaluate uptake and elimination over 28 days and analyzed with a Toxicokinetic (TK) model in the Build Your Own Model (BYOM) platform. Results indicate that CA predictions align closely with observed mixture effects, suggesting its applicability for soil organisms. These findings support the development of mixture-based risk assessments, improving ecological protection under real-world exposure scenarios.

4.02.T-04 Entry of Pesticides From the Air Into Soils far Away From Agricultural Areas as Potential Stress Factors for Soil Organisms

Stefan Rhiem¹, Benedikt Ringbeck², Uwe Bieling¹, Helena Pannekens¹, Astra Segelcke¹ and Katja Hombrecher¹, (1)North Rhine-Westphalia Office of Nature, Environment and Climate (LANUK), Germany, (2)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany

The atmospheric transport of pesticides is an area of growing concern due to environmental entries at larger distances from agricultural land. Pesticide deposition (wet and dry) was investigated monthly over a period of one year at eight locations in agricultural and non-agricultural areas in North Rhine-Westphalia, Germany. A total of 18 active substances and metabolites were detected in self-constructed bulk samplers. At all sites, there were inputs not only in spring/summer, but also in autumn/winter. At non-agricultural sites, fewer substances and lower deposition rates were found. The herbicides prosulfocarb, flufenacet, terbuthylazine and its metabolite terbuthylazine-desethyl, as well as prothioconazole-desethyl were detected at all locations. In order to determine

the residues of pesticides deposited on the soil, samples were taken from the upper soil layer at one selected agricultural and one non-agricultural site. Sampling took place in June, September, November and February of the following year. All ten pesticides analysed were detected in the upper soil layers (0-2 cm and 2-10 cm). The highest concentrations were measured in June, but residues were detected at all sampling times, confirming persistence of pesticide residues in the soil. The results were used to calculate the mixture toxicological stress for soil organisms (earthworms, springtails and predatory mites), with earthworms exhibiting the highest stress. The drivers of the mixture toxic stress were terbutylazine, terbutylazine-desethyl, fluopyram and prothioconazole-desethio. In summary, atmospheric deposition is a significant entry route for pesticides into soils and subsequently a potential stressor for soil organisms. As protective approach for determining mixture toxic stress levels, soil concentrations can be estimated from depositions rates and used for calculating stress potential, which was also done with these data. However, field data show a more realistic picture as it includes residues of persistent substances and as it covers all further pathways of environmental fate of these substances. The results indicate the times of the year, which are important for measuring pesticides introduced via deposition. This will improve planning of future monitoring campaigns. In addition, the results indicate those pesticides, which are drivers of mixture toxicological stress for soil organisms.

4.02.T-05 Copper in Plant Protection: Long-Term Field Evidence on Earthworm Recovery and Soil Accumulation

Apostolos Koutsaftis¹, Matthias Weidenauer², Daniele Ruccia³ and Olaf Klein⁴, (1)ERM Europe Ltd, Netherlands, (2)Crop Protection, Battelle, Switzerland, (3)ERM Europe Ltd, France, (4)Eurofins Scientific, Germany

Copper-based plant protection products (PPPs) are essential in organic and integrated farming due to their broad-spectrum efficacy and lack of resistance development. However, copper does not degrade and can accumulate in soils, posing risks to soil organisms. EU renewal in 2018 highlighted high earthworm risk at Tier 1 based on chronic lab studies. A unique long-term (ongoing since 2003) field study in two sites in Germany, on grassland assessed three rates (4, 8, 40 kg/ha/year) and derived a NOAEC at 4 kg/ha/year considering only transient effects on earthworm abundance and biomass. Results support restricted use conditions: a maximum of 28 kg/ha over 7 years (24 kg/ha/year) with mitigation measures, ensuring no unacceptable environmental effects.

In autumn 2003 a GLP compliant earthworm field study was started on two grassland field sites located in Southern Germany. Naturally occurring field populations of earthworms present at the field sites were evaluated. The test item Copper hydroxide WP (500 g Cu/kg) was applied at nominal target rates of 4 (T1), 8 (T2) and 40 (T3) kg a.s./ha/year divided into three applications per year (e.g. for T1 an application in October, December and March at 1.5, 1.5 and 1 kg a.s./ha, respectively). T3 was not applied further than the 7th year. Following the demonstration of population sensitiveness and toxic reference efficiency, this was not applied after 8 years. Earthworms were sampled regularly to assess any effects on the earthworm population and to determine copper residue levels. Soil samples were taken and analysed for total and bioavailable copper residue levels in two different soil depths (0-5 cm and 5-30 cm). Statistical analysis were performed on the obtained results to demonstrate significant differences between test item treatments and control along the years.

Across several years of monitoring, earthworm populations at two field sites remained generally high, with only transient treatment-specific reductions. 4 and 8 kg/ha/year showed minimal long-term impact, while 40 kg/ha/year caused marked but partially reversible effects on certain taxa. Soil copper concentrations declined slowly in surface layers but remained elevated compared to baseline. Earthworm residues decreased over time, indicating limited bioaccumulation. Overall, the study shows gradual recovery of earthworm communities and stabilization of copper residues, with persistent localized effects at high application rates.

4.02.P Beneath the Surface: Advancing Soil Ecotoxicology and Risk Assessment for Realistic and Sustainable Ecosystem Protection

4.02.P-Th125 Modelling the impact of earthworm movement on pesticide exposure estimates for row crops

Quentin Devalloir¹, Raphaël Royauté², Carole Bedos², Olivier Crouzet¹, Colette Bertrand², Pierre-François Staub¹, David Crevoisier², Pierre Benoit² and Cécile Dagès², (1)Office Français de la Biodiversité (OFB), France, (2)National Research Institute for Agriculture, Food and Environment (INRAE), France

Current Environmental Risk Assessment (ERA) of pesticides relies mainly on plot-scale approaches and often overlooks both landscape processes and organism behaviour, limiting realistic exposure estimates for soil organisms. This shortcoming is particularly critical in intensively treated systems such as vineyards, where spatial heterogeneity and species traits influence contact with contaminants. This study investigates how earthworm movement alone can shape exposure patterns under identical contamination conditions. We developed an individual-based model to simulate the movements of two ecologically contrasted earthworm species: the endogeic *Aporrectodea caliginosa* (low mobility, soil-confined) and the anecic *Lumbricus terrestris* (higher vertical and horizontal mobility). A spatially heterogeneous contamination pattern was implemented to represent localized soil hotspots found in row-crop systems, and this same contamination layer was applied to both species. As a first proof-of-concept, simulations were run under a fixed “worst-case” configuration with persistent hotspots, while additional scenarios accounting for temporal dissipation and degradation processes or ignoring spatial heterogeneity are in development. For each individual, we calculated a Potential External Exposure Index, defined as the cumulative sum of pesticide concentrations in all grid cells visited along the individual’s trajectory. This movement-based index is a proxy of cumulative external exposure, allowing comparison of species-specific movement. Under this configuration, pronounced interspecific differences were observed. *Lumbricus terrestris* displayed higher and more variable Potential External Exposure Index values than *A. caliginosa*. Its greater mobility and frequent horizontal and surface movements increased the likelihood of encountering and revisiting highly contaminated zones, raising exposure and inter-individual variability. In contrast, the more restricted and soil-confined movements of *A. caliginosa* resulted in lower and more homogeneous exposure patterns. These findings demonstrate that exposure is not solely determined by environmental concentration levels, but is also strongly modulated by ecological traits such as movement behaviour and habitat use. Ultimately, this framework supports the future coupling of the earthworm models with the MIPP pesticide fate model to generate spatially explicit and ecologically realistic exposure estimates for ERA in row-crop systems.

Disclaimer/Disclosure:

The authors thank the project PARC 6.4.4.e for the funding of this work.

4.02.P-Th126 The FORESEE Earthworm Model – from Conceptualisation to Completion

Vanessa Roeben¹, Gregor Ernst¹, Andre Gergs², Natalie Albrecht³ and Kim Rake³, (1)Bayer CropScience AG, Germany, (2)Bayer Research & Development Services LLC, Germany, (3)gaiac eco assessment GmbH, Germany

Soil risk assessment of plant protection products is based on a two-tiered approach, where if the Tier 1 is not passed, field studies can be conducted to demonstrate that soil organisms are not at long-term risk. Field studies are time- and labour-intensive, and can only represent a snapshot of conditions, i.e., the tested climatic conditions, soil properties, and species composition. Mechanistic population models are a promising tool to extrapolate from these studies to different populations and environmental conditions.

For the past 7 years, we worked on an earthworm population model, namely the FORESEE, to establish such a tool. The model was setup through collaborative efforts of experts from many disciplines, reaching from earthworm ecologists, fate and risk assessment experts to modellers, to ensure a scientifically sound model with the help of the combined expertise and broad stakeholder engagement. The model integrates state-of-the-art concepts, such as dynamic energy budget and toxicokinetic-toxicodynamic theory, in a modular approach to provide a generic model, which supports a quick and easy change of species, ecological type and environmental conditions. In this modular approach the different model assumptions are readily interchangeable, which makes it a flexible tool for intermediate and higher tier risk assessment applications.

To encourage and inspire the set-up of more such models and enhance acceptability of these for soil risk assessment, we present the time course and important milestones of our project from first ideas collected in a workshop in 2018 to the final model validated with a field study to be published in 2026.

4.02.P-Th127 Applying the 2023 Central Zone Guidance: Challenges in Soil Analytical Verification for Rapidly Degrading Actives

Ricardo Petersen¹, Ieva Balaisyte², Ana Raquel Sales³ and Ana Pereira³, (1)ERM - Environmental Resources Management, Portugal, (2)ERM - Environmental Resources Management, Ireland, (3)Ascenza Agro, S.A., Portugal

In the European Union, the assessment of soil risk for plant protection products has historically relied on the Terrestrial Guidance Document (SANCO/10329/2002). This framework calculates toxicity exposure ratios

(TER) by comparing laboratory-derived toxicity endpoints, typically based on nominal test concentrations, with modelled maximum predicted environmental concentrations in soil (PEC_{max}). While this approach has provided a standardized method for evaluating potential risks to soil organisms, it does not account for the complexities introduced by substances that degrade rapidly in soil.

The 2023 Central Zone Working Document introduces a novel approach specifically targeting active substances with DT90 values shorter than the standard test durations for key soil invertebrates—earthworms, springtails, and soil mites (56, 28, and 14 days, respectively). Under this guidance, analytical verification of soil concentrations throughout the study is required, and when measured concentrations fall below 80% of nominal, endpoints must be expressed as time-weighted averages (TWA) or geometric means. This methodological shift has significant implications: TER calculations now combine modelled PEC_{max} peaks with long-term measured endpoints, potentially leading to overly conservative risk predictions that may not reflect real-world exposure scenarios. In the absence of available intermediate-tier refinements, this approach may increase the need for extensive, complex field studies to satisfy regulatory requirements.

This poster presents a case study comparing soil ecotoxicological datasets evaluated under the traditional SANCO (2002) approach—where endpoints were derived from nominal concentrations—with those assessed under the 2023 Central Zone framework, incorporating analytically verified concentrations. The analysis explores how different exposure metrics (PEC_{max} versus PECTWA) and sampling strategies influence TER outcomes and highlights the practical challenges of implementing the new guidance. The poster also discusses practical testing challenges and potential solutions for a more pragmatic, scientifically robust soil risk assessment framework that balances regulatory rigor with feasibility.

4.02.P-Th128 Revising guidance on pesticide risk assessment for soil organisms – considerations from an user perspective

*Agnes Schimera¹, Michael Thomas Marx², Melanie Bottoms³, **Gregor Ernst⁴**, Stefan Kimmel⁵, Amanda Sharples⁶, Frank Staab⁷, Kate Brougham⁸, Vanessa Roeben⁴ and Stephanie Tokar⁹, (1)ADAMA, Germany, (2)Bayer Research & Development Services LLC, Germany, (3)Syngenta Ltd, United Kingdom, (4)Bayer CropScience AG, Germany, (5)Corteva Agriscience, Germany, (6)FMC Corporation, United States, (7)BASF, Germany, (8)Nufarm, United Kingdom, (9)UPL NA Inc., United States*

Under Regulation (EC) No 1107/2009, pesticide approval requires demonstrating the absence of unacceptable environmental effects. For soil organisms, the EFSA has to review the soil risk assessment currently based on the terrestrial ecotoxicology guidance (SANCO/10329/2002). CropLife Europe (CLE) provides considerations to support EFSA and national authorities in developing an aim-oriented, pragmatic and protective soil risk assessment. This poster outlines the scientific investment projects undertaken by the CLE ad-hoc soil expert group from the past years, and presents a set of user-oriented priorities or ‘wish list’ to be considered in the development of an updated soil risk assessment guidance.

The conclusions from the CLE soil group have led to the following recommendations:

? Alignment between the new EFSA (2017) soil exposure guidance and the future soil risk assessment is essential, without introducing an unjustified increase in conservativeness[1].

? The implementation of workable intermediate tier options should be promoted once the relevant data gaps have been addressed[2], and

? the inclusion of additional organism groups should only be considered if validated test protocols (including higher-tier options) are available, which is currently not the case, e.g., for mycorrhizal fungi[3].

? Assessment factors in a tiered risk assessment scheme should be based on data-based calibration following a transparent methodology[4].

? Fixed effect thresholds (e.g., 10%) for (semi-)field studies are unrealistic and scientifically unreasonable. Relevant threshold values can only be considered biologically relevant when they are above typical occurring natural variabilities[5] and species-specific responses. Instead, medium to large temporary effects should be acceptable for soil-function-relevant groups if recovery occurs within an agreed timeframe and effects are outside natural occurring variation[6].

The poster aims to serve as a basis for scientific discussion and foster the development of a data-based, practical, and cost-effective approach that strikes a balance between food security and the protection of soil fauna in agricultural landscapes.

4.02.P-Th129 Development of workable Specific Protection Goals for pesticide risk assessment for soil organisms

Agnes Schimera¹, Michael Thomas Marx², Melanie Bottoms³, **Gregor Ernst⁴**, Stefan Kimmel⁵, Amanda Sharples⁶, Frank Staab⁷, Kate Brougham⁸, Vanessa Roeben⁴ and Stephanie Tokar⁹, (1)ADAMA, Germany, (2)Bayer Research & Development Services LLC, Germany, (3)Syngenta Ltd, United Kingdom, (4)Bayer CropScience AG, Germany, (5)Corteva Agriscience, Germany, (6)FMC Corporation, United States, (7)BASF, Germany, (8)Nufarm, United Kingdom, (9)UPL NA Inc., United States

Under Regulation (EC) No 1107/2009, pesticide approval requires demonstrating the absence of unacceptable environmental effects. For soil organisms, the European Commission has mandated EFSA (EC Mandate M-2024-0086) to review the soil risk assessment methodology as part of revising the terrestrial ecotoxicology guidance document (SANCO/10329/2002). CropLife Europe (CLE) provides considerations to support EFSA and national authorities in developing scientifically robust and operational SPGs for future risk assessment. SPGs should be defined for key ecosystem services (ESS) delivered by non-target soil organisms in production and non-production areas, distinguishing between primary and supportive ESS. For in-field areas, the primary ESS—agricultural production—must remain central, as acknowledged in EFSA (2017)¹, irrespective of potential conflicts with other ESS (e.g. biodiversity). Therefore, trade-offs between ESS should be explicitly addressed, prioritizing primary ESS for decision-making to ensure food security under increasing global pressures. SPG setting is only feasible for organism groups with established test protocols (earthworms, collembola, mites). While for newly proposed taxa, data generation is a prerequisite. Fixed effect thresholds (e.g., 10%) should be omitted as they are scientifically unjustified and impractical for (semi)field studies due to high natural variability². Overmore, Pamminger et al (2021)³ indicate that even large transient effects on abundance may not impair critical soil functions such as organic matter degradation. Therefore, medium to large temporary effects should be acceptable if recovery occurs within an agreed timeframe and within typical occurring natural variability, requiring clear definitions and methodologies. For off-field areas, diverse land uses and overlapping regulations (e.g., Sustainable Use Directive, Habitats Directive, Nature Restoration Regulation) complicate SPG development. Establishing realistic SPGs at landscape scale requires definition of land use scenarios and an understanding of spatial and temporal variability of soil communities within these—a current research gap. CLE emphasizes that SPG development must integrate ecological science, sustainability objectives, and practical feasibility to maintain agricultural productivity while meeting regulatory protection goals.

¹ EFSA Journal 2017;15(2):4690; ² Schimera et al (2024) IEAM in press 10.1093/inteam/vjaf171; ³ IEAM 18(5) pp 1423-1433

4.02.P-Th130 Ecological Profiling of Taxa for Risk Assessments

Melanie Hagen-Kissling¹, Rik Delhem¹, Matthias Grove¹, Andre Grove¹, Livia De Felici¹, Josep Roig Garriga² and Bogdan Dehelean¹, (1)Eurofins MITOX, Netherlands, (2)Eurofins MITOX FOPSE, France

Ecological profiling of taxa can improve pesticide risk assessment by integrating species-specific ecological traits—such as habitat use, feeding behaviour, and life-cycle characteristics—into exposure and effect evaluations.

Springtails (Collembola), among the most abundant soil arthropods and indicators of soil health, show strong spatial and temporal variation linked to humidity, organic substrates, and microclimatic conditions. These dynamics influence the representativeness of field samples, which is essential for assessing the effects of plant protection products (PPP) on springtail communities.

In a pilot study, we examined (relatively) small-scale spatial dynamics in springtail composition, and how these shape the observed effects of a PPP treatment on the populations. Using a checkerboard design, we assessed how patchy PPP applications translate into direct and indirect impacts on springtail populations. Because springtails move horizontally as well as vertically, we used aspirator (soil-surface) and mine trap (in-soil) sampling methods, to capture the community dynamics in three dimensions, with a special focus on identifying potential source-sink dynamics of springtails and their spatial ranges.

Besides spatial dynamics, springtail communities show temporal dynamics, e.g. seasonal or even diurnal. We investigated, if we can find remarkable differences in springtail community composition between climatic regions (Central vs. Southern). We focused on identity, abundance and ecological types of taxa: euedaphic, hemiedaphic, epedaphic. Particular focus was given to short-term (diurnal) temporal variation in community composition especially in warm dry habitats. These can influence the representativeness of field samples, which are critical for assessing the effects of PPPs. For example, using aspirator sampling during the day in a warm dry environment, might not lead to an exhaustive sample of the springtail community present in that habitat, since springtails move between soil layers (vertical stratification).

Through this comparative approach, we aim to develop tailored sampling strategies for Collembola that account

for spatial and temporal ecological dynamics and thereby enhance the reliability and ecological relevance of PPP risk assessments under different climatic conditions.

4.02.P-Th131 Implementing Arbuscular Mycorrhiza Fungi in an Environmental Risk Assessment – Case Study with Benomyl considering Effects on Spore Germination and Symbiosis

Laura Petry, Ruben Schlinkert, Marie Winter and Karsten Schlich, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Arbuscular mycorrhizal fungi (AMF) are ubiquitous in terrestrial ecosystems and form symbioses with most plants, thereby can enhance nutrient uptake, pest tolerance, and yield. Despite their ecological importance, AMF have been recognized as non-target soil organisms relevant for environment risk assessment (ERA) of plant protection products (PPP) within the EFSA soil opinion (2017). The current OECD nitrogen transformation test (OECD Test Guideline (TG) 216), used to assess PPP effects on soil microorganisms, does not address impacts on AMF.

To close this gap, the UBA project MICROSOIL proposes to include a spore germination test (ISO 10832) as a Tier 1 screening method. However, this method does not capture the symbiosis between AMF and host plants. Therefore, a symbiosis-test-method was developed within the UBA project ERAMYC for assessing the effects of PPP on the symbiotic phase of AMFs. In our study, we observed the effect of a PPP in artificial and natural soil on AMF using both methods.

Preliminary experiments using *Funneliformis mosseae* confirmed sufficient spore germination in artificial soil and the reference soil RefeSol 02A, which were selected as substrates for all further test systems. The fungicide Benomyl was used as a reference substance and showed a clear dose–response relationship on spore germination in two independent experiments. In the spore germination tests an EC₅₀ of 4.5 mg/kg dry weight (dw) soil in artificial substrate and of 3.23 mg/kg dw soil in natural soil were determined. The ISO 10832 states that the EC₅₀ should be between 1 and 10 mg/kg dw soil and therefore the results show that the test worked well in the natural soil.

In the subsequent Tier 2 symbiosis test, *Allium ampeloprasum* (leek) serves as the host plant with *F. mosseae* as the fungal partner. After a 56-day exposure, endpoints include intraradical colonization, extraradical mycelium production, and plant biomass. In parallel, the OECD TG 216 test is conducted to compare AMF sensitivity to the standard soil microbial assay used in ERA. The experiments on the symbiosis of AMF were initiated in September/October 2025. The tests will be terminated and evaluated in January 2026, the results will be presented on the poster.

Results from all tests will be analyzed to evaluate sensitivity, ecological relevance, and potential regulatory applicability.

4.02.P-Th132 AM fungi – which species should be tested in laboratory tests for soil ecotoxicological risk assessment of plant protection products and their active substances

Fritz Oehl¹, Javier Palenzuela², Mike Anderson Corazon Guivin³, Álvaro López García² and Ewald Sieverding⁴, (1)Agroscope, Switzerland, (2)Spanish National Research Council, Estación Experimental del Zaidín (EEZ-CSIC), Soil and Plant Microbiology, Granada, Switzerland, (3)Universidad Nacional de San Martín, Laboratorio de Biología y Genética Molecular, Morales, Peru, (4)University of Hohenheim, Germany

Glomeromycota comprises the arbuscular mycorrhizal (AM) fungi, which occur in all agricultural soils worldwide with varying abundance and richness depending largely on climate, soil, crop/vegetation and land use intensity. They are of major significance for ecosystems, as they improve plant growth, suppress pathogens and enhance soil fertility & stability and water infiltration. AM fungi comprise > 350 species divided into 3 classes, 9 orders, 26 families and >60 genera. They are at risk due to excessive soil cultivation or application of plant protection products. We ask, which taxa are appropriate to be tested in dose-response ecotoxicological laboratory experiments with plant protection products (PPP) and their active substances (AS). Different AM fungal taxa are clearly seasonal or not, have specific life cycles, hyphal networks and spore formation characteristics. Spores, or ‘fruit-bodies’, are differentiated within weeks, only after months or years, and sometimes not at all. They are formed singly, in clusters or huge agglomerations, in soils or preferably in plant roots, either perfectly mature, or as early aborted spores without any germination capacity and function. Estimations can be made about the beneficial performance of well-studied AM fungal taxa or about their sensitivity in different soil management or cropping systems and agricultural land use intensities.

Glomeromycetes species have increased beneficial potentials, with respect to plant growth promotion, plant health, soil structure formation or soil health. Some species are commercially available, for bio-remediation, as bio-pesticides or bio-fertilizers. Genera with most positive ecological value, or highest benefits for plants or soils either belong to Glomerales, Entrophosporales, Diversisporales, Acaulosporales or Gigasporales. In

contrast, Archaeosporales or Paraglomerales spp. were rarely shown to have positive effects on plants or soils, while Pacisporales and Sacculosporales spp. have rarely been cultured. It is however a black box, which of all these taxa might be more or less sensitive to herbicides, insecticides or even fungicides. Here, we aim to identify those AM fungi with different traits, properties and ecological benefits, but also most suited for ecotoxicological tests with AS or PPP. Our criteria are based on the knowledge on fungal structures, culturability, significance as non-target organisms and especially as ‘improvers’ of plant growth & health and soil fertility.

4.02.P-Th133 Toxicity of Azoxystrobin to Arbuscular Mycorrhizal Fungi Assessed across Soil, Drench, and Foliar Exposures in a Controlled Intermediate-Tier Greenhouse Test System

Anna Manukyan¹, Ulrich Menke², Emilia Hilz² and Michael Thomas Marx², (1) Plant and Environmental Biotechnology Laboratory, University of Thessaly, Biopolis, Larissa, Greece, (2) Bayer AG, CropScience, Germany

Arbuscular mycorrhizal fungi (AMF) are widespread plant symbionts that play key roles in nutrient acquisition, soil functioning, and crop performance. Their ecological relevance has been recognised by the European Food Safety Authority (2017), which designated AMF as a focal non-target organism group for future soil risk assessment. Current testing is largely based on ISO 10832:2009, a Tier 1 in vitro assay targeting spore germination. A second Tier would need to include AMF responses during functional symbiosis. This study aimed to establish a greenhouse-based test system to evaluate the effects of a model substance on AMF colonization under defined exposure routes, providing an intermediate tier between laboratory and field studies.

A standardized pellet-based *Rhizoglyphus irregularis* inoculum ensured precise and homogeneous AMF input into natural agricultural soil planted with maize. Plants were grown under controlled greenhouse conditions. The commercial azoxystrobin formulation AMISTAR® (250 g/L) was applied (i) via soil mixing at planting, (ii) soil drenching, or (iii) foliar spraying with soil protection at single, double, and 20-fold field rates. A full-factorial greenhouse experiment with five biological replicates was conducted in a randomized design. Plants were sampled 15, 30, and 45 days after planting. AMF colonization was quantified by colonization frequency (F%), indicating the proportion of colonized root segments, and colonization intensity (M%), describing colonization within affected segments. The abundances of arbuscules, vesicles, and intraradical hyphae were assessed to characterise structural composition.

At day 15 there was no AMF colonization, independent from azoxystrobin. At days 30 and 45, marked dose-dependent reductions in both F% and M% were observed, with the highest dose eliminating colonization. Drench applications allowed partial colonization but reduced F% and M% compared with the control, whereas foliar exposure resulted in only mild suppression. Structural analysis showed differences in sensitivity among AMF structures: arbuscules and intraradical hyphae declined most strongly, while vesicles were less affected and more variable.

This greenhouse-based approach offers a practical intermediate-tier test system that increases ecological realism and allows early observation of colonization and recovery, while keeping variability low enough to derive statistically robust endpoints.

4.02.P-Th134 Toxic Cocktails in Soils : Assessing Fungicide-Insecticide Mixture Effects on Earthworm Reproduction

Lisa Gollot¹, Cleo Tebby², Laura Frattaroli³, Rémy Beaudouin⁴, Raphaël Royauté³ and Juliette Faburé³, (1) Université Paris-Saclay, INRAE, AgroParisTech, UMR EcoSys, 91120 Palaiseau, France & Experimental Toxicology and Modeling Unit, INERIS, 65550 Verneuil en Halatte, France, France, (2) Experimental Toxicology and Modeling Unit, INERIS, France, (3) Université Paris-Saclay, INRAE, AgroParisTech, UMR EcoSys, 91120 Palaiseau, France, France, (4) Experimental Toxicology and Modeling Unit, INERIS, & Institut national de l'environnement industriel et des risques, Université de Reims Champagne-Ardenne, Université Le Havre Normandie, Normandie Univ, UMR-I 02 SEBIO, 60, France

Soils are crucial reservoirs of biodiversity and providers of essential ecosystem services, yet they are increasingly threatened by agricultural intensification and pesticide use. Pesticide residues frequently persist in soils as complex mixtures, whereas environmental risk assessments typically focus on single compounds, thereby overlooking potential mixture effects. Earthworms play a key role in soil functioning and are particularly vulnerable to pesticide contamination. We investigated the combined effects of two persistent compounds frequently detected in agricultural soils, epoxiconazole (a fungicide) and imidacloprid (an insecticide), on life-history traits of *Aporrectodea caliginosa*. Based on their known modes of action, synergistic

interaction could theoretically occur, with triazole-mediated inhibition of detoxification pathways potentially enhancing imidacloprid toxicity. In a first experiment, each compound's relative potency was estimated by characterizing the dose–response relationship for cocoon production, following an adaptation of OECD guideline 222. In a second experiment, mixture effects were assessed using a fixed-ratio ray design across five concentration ratios and 36 conditions ($n = 8$ per condition). Adult growth and cocoon production were monitored for 28 days, followed by hatching assessment over 56 days. Both pesticides exhibited significant toxicity. Imidacloprid was markedly more potent ($EC_{50} = 0.55$ mg/kg) than epoxiconazole ($EC_{50} = 126.8$ mg/kg). Mixture analyses using Jonker's interaction models showed significant deviation from concentration addition suggesting synergistic interactions. This conclusion is in accordance with potential metabolic interactions reported in the literature. Environmental risk assessment revealed concerning exposure scenarios, particularly for imidacloprid, as maximum detected soil concentrations (0.16 mg/kg) approach effect thresholds with safety margins of only 1.8 to 3.4 fold, below typical regulatory factors. A key knowledge gap remains as to whether the hypothesized metabolic interference mechanisms occur in earthworms. Dedicated toxicokinetic and biomarker investigations are therefore required to quantify internal exposure and assess the plausibility of such mechanisms.

4.02.P-Th135 Evaluation of an AI-based Software System for Counting and Body Size Measurement of the Springtail *Folsomia candida* in OECD 232 Reproduction Tests

Eiko Wagenhoff¹, Benjamin Höferlin², Markus Höferlin² and Andreas Duffner¹, (1)Eurofins Agrosience Services Ecotox GmbH, Germany, (2)Visionanalytics, Benjamin Höferlin & Markus Höferlin GbR, Germany

The springtail reproduction test (OECD 232, 2016) with *Folsomia candida* is a key component of the test battery for environmental risk assessment of plant protection products in the soil compartment.

Although the validity criterion requires a minimum of 100 juveniles per control replicate after the 28-day test period, actual juvenile numbers are often much higher—frequently exceeding 1000. After extraction from the test soil using dyed black water, the white adult and juvenile springtails float on the water surface and can be counted either directly under a binocular microscope or via photographs taken from the water surface. Both approaches, however, are time-consuming, labor-intensive, and prone to human error.

To streamline, accelerate, and standardize this process, the software FOLSOMIACOUNTER was developed to enable automated juvenile counting from photographs. An integrated AI-based feature also estimates body size for both adults and juveniles, supporting the detection of sublethal effects beyond reproduction. Over recent years, the AI has been continuously trained and refined using photographs of varying quality.

We present a comparison of manual versus software-based juvenile counts using photographs from annual toxic reference item studies (2023–2024), which were excluded from the software's training dataset. The poster discusses results in terms of:

- (a) time savings achieved,
- (b) counting accuracy,
- (c) impact on the main ecotoxicological endpoint (EC_{50}), and
- (d) potential of body size measurement as an additional sublethal parameter.

In addition, the current extension of this approach to earthworm counting, and the associated challenges will also be presented.

4.02.P-Th136 Neonicotinoid insecticide residues in agricultural soils in Germany

Benedikt Ringbeck¹, Dimitrios Alexander Skodras², Pia Kotschik³, Stephan Marahrens³, Ricardo Schöps³, Bernd Göckener² and Karlheinz Weinfurter², (1)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)German Environment Agency (UBA), Germany

Neonicotinoids are among the most widely used insecticides worldwide. The use of some neonicotinoids was largely banned in the European Union several years ago due to adverse effects on the nervous system of bees and other pollinators and, in the case of thiacloprid, due to carcinogenic and reproductive toxic effects on humans. However, due to the very long half-lives of some of these active substances in soil, significant and long-lasting contamination of agricultural soils on which they have been applied is expected, despite restrictions on their use.

Between 2021 and 2024, a Germany-wide study was conducted in which soil samples were taken from 100 areas under agricultural use at soil depths of 0–5 cm and 5–20 cm. The aim of the study was to record the level of chemical residues in agricultural soils. The subproject presented here investigated the soil residues of

neonicotinoids. For this, a highly sensitive analytical method was developed using QuEChERS processing and UHPLC-MS/MS detection with limits of quantification (LOQ) of 10 ng/kg for the five most important active substances within this group of substances: imidacloprid (IMI), thiamethoxam (THIAM), clothianidin (CLO), acetamiprid (ACE), and thiacloprid (THIAC). The results show extensive contamination of the soils examined, with detection rates > limit of detection (LOD) of 17% (ACE), 44% (THIAC), 36% (THIAM), 95% (IMI), and 86% (CLO) in arable land, for example. The spatial distribution of residues was examined with respect to the main land-use types (arable land, wine-growing areas, orchards, and grassland), geographical distribution, soil depths, and temporal trends. Despite comprehensive bans on the use of four of the investigated active substances, the data demonstrate the persistence and widespread distribution of neonicotinoid residues in agricultural soils across Germany. The results serve as a basis for assessing the actual environmental risk in the soil from the cumulative chemical contamination. In addition, the findings help to close existing gaps in the risk assessment of chemicals and form the basis for a prospective risk assessment with regard to adverse effects on soil biodiversity.

This study was funded by the German Environment Agency (Grant no. FKZ 3720 63 4020).

4.02.P-Th137 Influence of Hydrogel Soil Amendments on Lambda-Cyhalothrin Toxicity in Two Standard Soil Mesofauna Bioindicators

Meena Pandey¹ and Kayode Jegede², (1)University of California Davis (UC Davis), United States, (2)University of California Davis (UC Davis)

Hydrogels are increasingly incorporated into agricultural soils to improve water retention and crop resilience under drought, yet their interactions with pesticide fate and soil invertebrate toxicity remain poorly understood. This study investigates how a representative hydrogel influences the toxicity of the pyrethroid lambda-cyhalothrin to two standard soil mesofaunal bioindicators, *Folsomia candida* and *Oppia nitens*. We hypothesize that hydrogel supplementation will reduce effective exposure by enhancing sorption and altering soil water dynamics, thereby mitigating toxicity relative to non-amended soils; moreover, effects may differ between the natural and artificial soils due to contrasting textures and organic matter contents. To do this, the experiment was conducted using one hydrogel type, six pesticide concentrations (including control), and two contrasting soils: a natural loamy sand and OECD artificial soil. Hydrogels were homogenized into each soil at an agronomically relevant rate and equilibrated 7 days prior to pesticide application. Standardized 28-day reproduction tests were performed separately for *F. candida* and *O. nitens* following OECD 232 and ISO 23266 respectively, to assess adult survival, reproduction, and growth. The soil moisture, pH, and lambda-cyhalothrin residues in soil and porewater, will be measured, to quantify hydrogel-driven changes in pesticide bioavailability. Data will be analyzed using GLMs, two-way ANOVA, and correlations linking biological responses with measured residues. Dose-response of lambda-cyhalothrin will be assessed using non-linear regressions in R. This study will help to see the combined effects of soil amendments and pesticide stressors on soil mesofauna, informing sustainable pesticide management and soil-amendment strategies under climate-resilient agriculture. The test is ongoing.

4.02.P-Th139 Eco-Toxicological Assessment of Hydrocarbon-Contaminated Soil Recovery Using Plant and Earthworm Bioassays

Sulaiman Alrumman, College of Science, Biology Department, King Khalid University, Saudi Arabia

Hydrocarbon contamination poses significant risks to soil health, yet chemical analysis alone cannot reliably assess ecological recovery because it overlooks bioavailability and biological responses. This study aimed to identify sensitive and reliable bioassays for evaluating the recovery of kerosene- and diesel-contaminated soils using plant and earthworm responses. Three soil types were amended with 1% hydrocarbons and subjected to non-incubated and incubated treatments to simulate freshly contaminated and remediated conditions. Bioassays included seed germination, root elongation, shoot height, germination index for mustard and wheat, and 14-day survival of earthworms. Results showed strong soil-dependent response patterns. Mustard root elongation was highly sensitive to contamination and effectively detected residual toxicity, while wheat shoot height was the best indicator of soil recovery. In contrast, seed germination showed low sensitivity across treatments. Earthworms exhibited complete mortality in freshly contaminated soils but could not distinguish between incubated and non-incubated treatments, indicating persistent toxicity. Overall, plant growth parameters were the most informative indicators of both contamination levels and recovery status. The study demonstrates that a multi-bioassay approach offers a more comprehensive and ecologically relevant assessment of hydrocarbon-

contaminated soil recovery compared with chemical analysis alone, supporting improved ecological risk assessment and remediation evaluation.

4.02.P-Th140 Is biochar toxic to soil organisms? Standard tests with enchytraeids, springtails and earthworms

Marianne Bruus, Aarhus University, Denmark

The few existing studies of biochar impact on soil fauna report varying effects, i.e. both negative and positive effects have been seen. As biochar characteristics vary not only between feedstocks, but also between batches, the variation in organism responses may not come as a surprise. Nevertheless, assessing possible risks to soil organisms is crucial to secure safe use of biochar, which is, by some politicians and administrators, seen as an obvious tool for combining climate change mitigation and improvement of agricultural soils.

As an initial assessment of the possible toxic effects of biochar made from straw and biogas digestate, respectively, OECD reproduction tests were performed with the enchytraeid *Enchytraeus albidus*, the spring-tail *Folsomia candida* and the earthworm *Eisenia fetida*, all organisms used in standard testing of e.g. pesticides. To ensure maximum exposure, biochar pellets were ground and mixed into the test soil. Based on results from a range-finding test, test concentrations in the range 0-10 and 0-100 mg/kg soil were applied. High biochar concentrations affect soil moisture, and to omit this factor from the test and concentrate on possible toxic effects, soil moisture levels were carefully adjusted for each biochar concentration level.

Adult survival of the three test species was not significantly affected by the tested biochar concentrations. The reproductive output of enchytraeids was slightly increased at the higher biochar concentrations, whereas no effects were seen on springtail reproduction. For the earthworms, high biochar concentrations seemed to delay the reproduction process; the total reproductive output (no. cocoons + no. juveniles) was hardly affected, but the ratio cocoons:juveniles was increased.

The outcome of this study suggests that further studies involving repeated biochar application, other feed-stock types and more agriculturally relevant conditions should be performed. Fortunately, a long-term field study has been established to do exactly that: At four experimental stations, four types of biochar will be applied for at least five years to study long-term effects on crop yield, soil physio-chemistry and leaching, and soil organisms. Apart from elucidating the potential toxicity of selected biochar products to soil fauna etc., the projects can also serve as basis for establishing procedures for future risk assessment of biochar.

4.02.P-Th141 Ecotoxicological Assessment of Excavation Material Contaminated by Munitions and Explosives Residues

Renée Wouters¹, Florian Breider², Benoît J.D. FERRARI¹ and Mathieu Renaud¹, (1)Ecotox Centre, Switzerland, (2)Swiss Federal Institute of Technology Lausanne (EPFL), Switzerland

In Switzerland, as in other parts of the world, military activities such as training exercises, storage, and accidents have led to the contamination of soil with munitions and explosives, resulting in environmental pollution.

However, in this research project, primary ecotoxicological tests revealed very low toxicity in plant germination and invertebrate reproduction despite very high concentrations of metals, polycyclic aromatic hydrocarbons and explosives, exceeding Swiss remediation thresholds. The main theoretical explanation for this lack of effects is assumed to be the low overall bioavailability of these chemicals.

The ongoing aim of this research project is to bridge the gap between chemical analysis and ecotoxicological testing by focusing on bioavailability as the key driver of exposure. By adapting existing standardized soil ecotoxicity methods to enable the recovery of organisms after exposure, internal contaminant concentrations from exposed organisms and plants will be quantified and linked to their biological responses. In parallel chemical analysis of the total contaminants' concentrations in soil will allow to evaluate the link between total and internal concentrations, and how well these different fractions of contaminants correlate with ecotoxicological effects.

This integrated chemical-biological approach will help gain insights into bioavailability and help explain why high contamination levels do not necessarily translate into measurable toxicity. Future work may extend these methods to contaminated field sites, validating laboratory approaches through internal concentrations in field-collected organisms. Ultimately, this research aims to improve the assessment of risks posed by munition and explosives by focusing on the bioavailable fraction that truly drives ecological impacts.

4.02.P-Th142 BioDive4Soil – A systematic assessment of soil biodiversity

Martina Roß-Nickoll¹, Karsten Schlich², Alexander Bach¹, Cecilia Diaz², Klaus Peter Ebke³, Elke Eilebrecht², Carsten Haub⁴, Stephan Jänsch⁵, Carolin Kaufmann-Boll⁶, Pia Kotschik⁷, Christian Ristok⁸, Ina Schäfer⁹, Lucas Stratemann⁷, Andreas Toschki¹⁰, Karlheinz Weinfurter² and Silvia Pieper⁷, (1)Institute for Environmental

Research, RWTH Aachen University, Aachen, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)MESOCOSM GmbH, Institut fuer Gewaesserschutz, Germany, (4)EFTAS Fernerkundung Technologietransfer GmbH, Germany, (5)ECT Oekotoxikologie GmbH, Germany, (6)ahu GmbH Wasser Boden Geomatik, Germany, (7)German Environment Agency, Dessau-Rosslau, Germany, (8)German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Germany, (9)Senckenberg Biodiversity Climate Research Center, Frankfurt am Main, Germany, (10)gaiaac – Research Institute for Ecosystem Analysis and Assessment, Germany

The decline in biodiversity in conjunction with global change poses a severe threat to ecosystem functioning and long-term resilience. Soils host around 60 % of all species on earth but our knowledge of soil biodiversity across different land-use types and its drivers remains limited. Recognizing its importance, the German Environment Agency (UBA) has launched a high-impact research program in collaboration with the Fraunhofer-Gesellschaft and ten other institutions. The project is funded by the Natural Climate Protection Action Program (ANK) of the Federal Ministry for the Environment (BMUKN).

Here, we present an overview of the recently initiated German BioDive4Soil project – a large-scale systematic assessment of soil biodiversity. In BioDive4Soil, we will assess soil biodiversity across Germany, covering different habitats, land-use types, and soil regions. We will sample in near-natural ecosystems and across a gradient of increasing land-use intensity.

We will establish baseline knowledge of soil communities by determining morphological, functional, and molecular diversity of soil microorganisms and fauna. We will perform eDNA-metabarcoding and barcoding of individual species across different soil taxa to improve genomic reference data of soil organisms. We aim to identify soil biological reference values indicative for healthy soils and important drivers of soil community composition, such as land-use management, soil type, and pollution.

Taken together, BioDive4Soil aims to close existing knowledge gaps and to improve our understanding of the diversity of soil organisms in Germany, changes in their composition, their main drivers and possible approaches for the protection and restoration of soils and soil biodiversity.

To date, an initial draft of the overall concept for the baseline survey has been developed and is being continuously refined over the coming month in close collaboration with other national monitoring programs and with consideration of the European soil monitoring law. Areas were identified for an initial sampling campaign, and samples were taken from 10 out of a total of 250 sites in autumn 2025.

Disclaimer/Disclosure:

The project BioDive4Soil is financed by the German Federal Ministry for the Environment, Nature Conservation, Nuclear Safety and Consumer Protection, Aktionsprogramm Natürlicher Klimaschutz; FKZ: 3724 NK 601 0.

4.03.P Chemicals and Biodiversity in Managed Landscapes: Systems Thinking, Spatial Scales and Sustainable Solutions

4.03.P-Th143 Rehabilitating contaminated soils via phytomanagement for circular bio-Based applications: A Belgian field Case

Cécile Nouet¹, Enrica May Hedgecock², Pierre Lejeune², Marc Hanikenne², Quentin Douhard² and Viktoria Gross², (1)University of Liège, Belgium, (2)University of Liege, Belgium

As part of the IASIS project, the University of Liège is conducting a field case study in Wallonia (Belgium), a former industrial site contaminated with hydrocarbons and heavy metals. Funded by Horizon Europe and the CBE JU, IASIS is exploring phytomanagement as a sustainable strategy for the remediation of contaminated and saline soils across Europe.

The IASIS project advances phytomanagement strategies for rehabilitating contaminated and saline soils, with a particular focus on tailored microbial consortia. These approaches are tested and validated at both laboratory and field scales. Eight Field Case Studies (FCSs) have been established across Europe, four on contaminated sites and four on saline soils, where eight high-yielding, non-food industrial crops are cultivated using low-input, sustainable practices. The project supports the development of bio-based products through two main crop categories: oilseeds and lignocellulosic species, integrated into cascading biorefinery value chains.

The Belgian FCS involves cultivating three plant species on a 2-hectare site using low-input agricultural practices, including plant-based fertilizers, microbial consortia, and minimal mechanization. The field is

structured into crop- and treatment-specific plots, replicated across the site and over three growing seasons to ensure robustness and reproducibility of results.

First a pot experiment in greenhouse was conducted to select the soil amendments and test plant growth on contaminated soils collected from the field site. Following soil preparation, the first field trial was launched under low-input conditions. Soil health indicators, including microbial diversity and pollutant concentrations, have been evaluated. Biomass development had been monitored using drone imaging, and harvested samples are undergoing analysis to assess quality parameters relevant to downstream applications. A second growing season is scheduled for spring 2026. The poster will present data analyses from the pot experiment and the first growing season, along with preliminary observations from the second.

4.03.P-Th144 Assessing Channelisation Impacts on Benthic Macroinvertebrate Assemblages of a Lowland Agricultural Catchment

Elena James, University of Birmingham, United Kingdom

Following legacies of hydromorphological alteration, lowland rivers are highly threatened by multiple, often synergistic pressures including pollution, invasive species, and anthropogenic climate change. Hydromorphological degradation undermines river ecosystem integrity often through habitat homogenisation to the detriment of ecosystem services. The European Union Water Framework Directive was introduced partly to alleviate hydromorphological degradation and support surface water bodies in achieving 'good' ecological status.

The research project aimed to assess the impact of channelisation on benthic macroinvertebrate assemblages of a lowland agricultural catchment by comparing kick-sampled macroinvertebrates between good and poor morphology reaches. The study also included physicochemical site assessment using handheld sensors, Modular Physical River Habitat surveys, and field observations. There was an additional focus on invasive *Dikerogammarus* distributions within the catchment considering possible habitat homogenisation induced by channelisation for poor morphology reaches.

The results demonstrated macroinvertebrate assemblages were alike between morphology types, highlighting macroinvertebrates can recover from anthropogenic disturbances depending on local catchment characteristics. Well-established channelisation was identified as weakly influencing macroinvertebrate assemblages, especially where local restoration measures improved diversity of formerly degraded reaches with good colonisation potential.

It was concluded long-term monitoring, for which the scope improves with citizen science, is essential to fully understanding macroinvertebrate responses to hydromorphological change considering invasive species and anthropogenic climate change impacts.

This study valuably assessed multiple stressors acting on the study system. It examined how far habitat can be modified before ecosystem integrity is undermined and ecological effects are detrimental. It affirmed biological and physicochemical river health assessments remain highly relevant for river degradation evaluations, especially applied long-term, over multiple spatial scales to inform adaptive management, which can assist future management decisions to support ecosystem services. Research gaps addressed also included whether channelisation facilitated biotic invasions of *Dikerogammarus* within a lowland agricultural catchment and Site of Special Scientific Interest.

4.03.P-Th145 Lithium mining could threaten hundreds of vulnerable and endangered species

Shyam Sharma¹, Jacqueline Edge², Gregory Offer¹, Charlotte Miller³, Will Pearse¹ and Guy Woodward¹, (1)Imperial College London, United Kingdom, (2)University of Birmingham, United Kingdom, (3)Independent Consultant, United Kingdom

Electric vehicles (EVs) are being rapidly deployed as a technological solution to the climate crisis. Mineral extraction to supply EV battery production can cause serious ecological harm, threatening global biodiversity.

Lithium, a key EV battery component, is expected to experience an enormous mining boom. This increased mining could significantly threaten nearby species, potentially driving some to a higher extinction risk.

Using the IUCN Red List, we assessed how 400 operational and prospective lithium mines could threaten their surrounding species. First, we determined each mine's coordinates using company reports and academic literature. Then, we applied 50 km buffers around each site, representing the total area in which both direct and indirect mining impacts could harm local species. Next, we assessed how much the buffered mines overlap with each Red List species' range, from 0 to 100 %. We then weighted each overlap percentage by the species' extinction probabilities to compute threat scores for the mines. We also developed a global list of species that could be under the greatest threat from lithium mining, considering various scenarios for future mine construction. Additionally, using the Red List's categorisation criteria, we identified range-restricted species that could be at risk of being pushed to more severe threat categories than they are currently classified in.

We found that Australian lithium mines pose the greatest threat by a large margin. Globally, we identified up to 193 threatened species could be significantly impacted by lithium mines. Additionally, we noted at least 184 range-restricted species could face higher-than-expected extinction risks. Red List species ultimately represent one of many facets of global biodiversity. While mitigating harm to these species is critical, it is futile to attempt to protect them alone without also safeguarding the wider ecosystems they depend on. Future work on this topic should involve developing a broader, more robust framework to capture and mitigate the totality of each mine's potential impacts on surrounding ecosystems.

Disclaimer/Disclosure:

4.03.P-Th146 What is biodiversity and why should we be measuring it?

Aaron Stoler and William L. Goodfellow, No Affiliation, United States

Businesses are facing increasing pressure from regulators and investors to disclose their impacts and dependencies on biodiversity. However, "biodiversity" is nebulously defined as all variability in the natural world, according to the United Nation's Convention on Biological Diversity. Not surprisingly, this has generated significant confusion over what businesses should be measuring – and how they should be measuring it. This presents a particular challenge for regulators seeking to understand the chemical thresholds necessary to protect the environment and its myriad processes. This poster will discuss the history of biodiversity as a concept, walk through recent attempts to synthesize and standardize biodiversity (e.g., TNFD, CSRD, GEOBON's Essential Biodiversity Variables), and examine how the new ISO Biodiversity Standard (ISO 17298) alters the playing field. In addition, we will revisit central research themes that are increasingly omitted from the conversation, including the relationship between biodiversity and ecosystem function, the need for biodiversity as insurance against future disturbances, and the overwhelming – albeit generally overlooked – importance of functional trait diversity.

4.03.P-Th147 The challenge of the ATAT indicator for the Global Biodiversity Framework: Good Intentions hampered by unscientific metrics

Thomas G. Preuss¹, Christian Bogen¹, Lucie L'Hotial Million², Peter Campbell³, Helen Thompson³, Neil Mackay⁴, Nevena Hristozova⁵, Ximena Patino⁶, Mick Hamer⁷, Bernhard Jene⁸, Mark Thomas⁹, Anne Alix¹⁰, Paul Whatling¹¹, Steven Levine⁹ and Christoph Neumann⁵, (1)Bayer AG, Germany, (2)Syngenta, Germany, (3)Syngenta Ltd, United Kingdom, (4)FMC Corporation, Germany, (5)CropLife International, Belgium, (6)Bayer SA, Colombia, (7)Syngenta Ltd, Germany, (8)BASF, Germany, (9)Bayer AG, (10)Corteva Agriscience, United Kingdom, (11)FMC Corporation, United States

The Kunming-Montreal Global Biodiversity Framework (GBF) is a recently adopted agreement that supports the Sustainable Development Goals and builds on the previous Strategic Plans of the Convention of Biological Diversity. There are several indicators that are relevant for agro-chemicals, among them those of the GBF Target 7. The overarching aim of Target 7 is to reduce pollution risks and their negative impacts on biodiversity and ecosystem functions to levels that are not harmful by 2030. This target is divided into reduction of nutrient pollution (Target 7.1) and reduction of risk from pesticides and hazardous chemicals (Target 7.2). The Aggregated Total Applied Toxicity (ATAT) is one of the proposed headline indicators (7.2) to measure progress

towards this specific goal focusing on pesticides. However, there has been no validation to determine the extent to which the methodology will result in an actual risk reduction, e.g. when one substance is substituted by another.

According to OECD and EFSA guidance, a methodology must be validated before used in a regulatory system. The first important step for validation of new approaches or model calculations is to conduct a verification, so the aim is reflected correctly in the mathematical equations. Already this first verification step fails for the ATAT since unsimilar units are added up to each other. Therefore this indicator is not scientifically sound nor the results easy to interpret. One of the further verification calculations indicates that the ATAT is sensitive to areas with low risk (high RTL) and not to the risk assessments areas which actually drive the risk to biodiversity. While there appears to be a disconnect between the ATAT indicator, the current toxicity assessments and actual effects on biodiversity, a more integrated approach could be a solution.

4.04 Environmental Hazard and Risk Assessment of UVCBs and Complex Mixtures: From Scientific Challenges to Regulatory Solutions

4.04.T-01 How can simple data facilitate the assessment of data-poor complex substances? Application of baseline (Tier 0) data for UVCB evaluation

Erin Maloney¹, Cameron Hunter Collins², Emma Schymanski³, Julie Krzykwa⁴ and Sandrine Estelle Deglin⁴, (1)Shell Global Solutions International B.V., Netherlands, (2)Shell Global Solutions International B.V., United States, (3)Luxembourg Centre for Systems Biomedicine, University of Luxembourg, Luxembourg, (4)Health and Environmental Sciences Institute (HESI Global), United States

The evaluation of substances of Unknown or Variable composition, Complex reaction products and Biological materials (UVCBs) is often complicated by the lack of a consistent, reliable and well-curated source of data. This can introduce challenges when attempting to conduct substance prioritizations, evaluations, or hazard/risk assessments. To address this gap, the UVCB Committee of the Health and Environmental Sciences Institute (HESI Global) developed a pilot database (the 'PULSE' database) of baseline ('Tier 0') data for 109 UVCBs. This contribution describes various use cases for data from PULSE, highlighting challenges associated with UVCB evaluation and the opportunities that Tier 0 data present to fill some of these data gaps. To demonstrate database functionality, two UVCB substances were selected, and data availabilities and limitations were explored across PULSE. Two case studies were then conducted to demonstrate the utility of Tier 0 UVCB data for data gap filling and substance evaluation, using PULSE as the primary source of data. In the first case study, Tier 0 data were used to group 14 metal naphthenates (based on structural characteristics and manufacturing process), and environmental fate data of 6 'data-rich substances' was read-across to fill data gaps for 8 data poor substances. This demonstrated that metal naphthenates may contain both (readily) degradable and non-degradable fractions and display low bioconcentration factors. In the second case study, available data for 88 UVCB substances included on the Canadian Domestic Substances list were extracted from PULSE. Substances were prioritized based on exposure characteristics and then hazard (persistence, bioaccumulation, toxicity). This prioritized 5 UVCBs with high tonnages and widespread use, that contained varied limitations in the breadth of available hazard data, highlighting areas that could be prioritized for data gap filling or in-depth hazard assessment. Overall, these case studies are conducted with Tier 0 data, thus require further investigation to confirm hypotheses. However, they serve to demonstrate how simple data available in the PULSE database can be used to highlight and fill data gaps, drive hypotheses, prioritize and augment existing hazard and risk assessments for UVCBs. Ultimately this work demonstrates the need for an expert-curated database containing detailed, publicly accessible information for UVCBs to advance the science for these complex substances.

4.04.T-02 Integrated Hazard Assessment of Permanent Aquatic Storage Strategy-Treated Fluid Tailings in a Canadian Pilot-scale Oil Sands Pit Lake

Immanuela Oluchi Ezugba¹, Lorne Doig², Banamali Panigrahi³, Catherine Davila-Arenas⁴ and Karsten Liber⁵, (1)Toxicology, University of Saskatchewan, Saskatoon, Canada, (2)Toxicology, University of Saskatchewan, Canada, (3)University of Saskatchewan, Canada, (4)University of Saskatchewan, Canada, (5)School of Environment and Sustainability, University of Saskatchewan, Canada

Long-term management of fine tailings and oil sands process-affected water remains a significant challenge for reclamation in the Alberta oil sands (AOS) region of western Canada. Pit lakes are one option to address this

issue, provided they achieve chemical stability and support aquatic life. Lake Miwasin, constructed as a Permanent Aquatic Storage System (PASS), contains alum and polymer-treated fluid tailings. This study integrated multiple sediment toxicity assessments to assess the potential effects of the lake's bottom substrate on *Chironomus dilutus* larvae and characterize the hazards associated with polymer-treated tailings. Standard whole-sediment toxicity tests conducted in 2020 using deep-littoral and limnetic sediments showed toxicity in both zones, with survival ranging from 5 to 15%. A Phase I Sediment Toxicity Identification Evaluation demonstrated that ammonia and organic compounds likely contributed to the observed toxicity, particularly in the limnetic sediment. Polymer characterization and subsequent toxicity tests confirmed that the amphoteric polymer used during the PASS process did not contribute to toxicity to *C. dilutus* larvae, indicating that the polymer concentration in the expressed water was not a source of toxicity. Porewater tests conducted in 2021 and 2022 provided insight into spatial and temporal changes in sediment toxicity. The 2021 porewater test showed that the deep-littoral sediment porewater (0 to 3.33%) was more toxic than the limnetic porewater (16 to 53%). In contrast, the 2022 porewater test showed improved survival (>60%) in both zones, suggesting diminishing toxicity over time. An additional sediment depth horizon assessment was conducted in 2022 using limnetic sediment layers (0-2 cm versus bulk 0-10 cm) and in 2023 (0-2 cm, 2-5 cm, and bulk 0-10 cm). Generally, the results showed that the surficial sediment (0-5 cm) was less toxic than the bulk sediment in both years, indicating decreasing toxicity in the surficial sediment layer. *Pimephales promelas* early-life stage tests conducted with surface water samples collected in 2023 demonstrated that near-bottom water was toxic. EcoToxChip, a molecular tool for detecting changes in gene expression, will further determine the biological pathways of the complex mixture present in the lake water to help assess potential aqueous risk. Overall, these findings will help inform future sediment sampling and monitoring in this and similar pit lakes in the AOS region.

4.04.T-03 Environmental Risk Assessment of UVCBs: The Value of Multi-Generational Exposure Tests
Benedetta Ponti¹, Claudia Ferrario¹, Marco Bonaldo¹, Francesca Noè¹, Desirée Garagna¹, Girolamo Teresi² and Ilaria Geremia³, (1)LabAnalysis, Italy, (2)Italmatch Chemicals S.p.A, Italy, (3)TEAM mastery S.r.l., Italy

Substances of unknown or variable composition, complex reaction products and biological materials (UVCBs) pose unique challenges to regulators and product registrants, who are required to characterize their environmental fate and toxicity, specifically, it makes toxicity, environmental behaviour, risk, and classification evaluations arduous.

Due to the analytical challenges posed by UVCBs, ecotoxicity testing must be carefully designed to maximize the solubility and maintaining stable exposure concentrations. Achieving consistent concentrations in laboratory testing is complicated by degradation, volatility and adsorption to test vessels or organisms.

In the present study, we report results from a UVCB case study in which different aquatic toxicity tests were performed to evaluate reproductive endpoints: a standard chronic test on *Daphnia magna* and a non-commonly required life-cycle test on the benthic organism *Chironomus riparius*. Analytical checks of test concentrations in relevant matrices were performed to determine actual exposure.

In the chronic *D. magna* test, no substantial negative effects were recorded. Maintaining stable exposure concentrations during the test was challenging despite precautions such as solvent carriers and pre-conditioning of test vessels.

The life-cycle test with *C. riparius* revealed generational effects: an increase in fecundity at the highest concentrations in the first generation, followed by a decrease in emergence and altered sex ratio in the second generation. The test was performed by spiking sediment with a solvent carrier and adding food directly to the sediments in view of the high log K_{ow} of the UVCB. The concentrations decreased over the 58-day test period. However, the mass-balance analysis, including sediment, water and porewater compartments, allowed to confirm the UVCB affinity for sediment and to verify organisms' exposure.

Our results confirm the challenges associated with aquatic exposure assessment of UVCBs, particularly the difficulty of maintaining stable test concentrations. While no adverse effects were observed in the *Daphnia magna* reproduction test, the *Chironomus riparius* life-cycle test revealed generation-dependent effects at the highest concentrations. These findings highlight the importance of multigenerational sediment-based tests for identifying risks that may not be evident in standard aquatic toxicity assays.

4.04.P Environmental Hazard and Risk Assessment of UVCBs and Complex Mixtures: From Scientific Challenges to Regulatory Solutions

4.04.P-Th148 The Challenges of Aquatic Classification of Unknown or Variable composition, Complex reaction products or Biological materials (UVCBs) and Complex Mixtures in Lubricant Additive Packages

Leon Rockett¹, Mark Cobb¹, David Davies¹, Wayne Kennedy², Ravi Menon², Neal Smith¹ and Virginia Payne²,
(1)Afton Chemical, United Kingdom, (2)Afton Chemical, United States

Lubricant additive packages have a wide range of applications in industrial, professional and consumer settings. These packages typically consist of a complex mixture of poorly water soluble, difficult to test mono-constituent, multi-constituent substances and Unknown or Variable composition, Complex reaction products or Biological materials (UVCBs). Whilst regulatory programmes such as the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) require aquatic toxicity data for determination of the hazard classification of the individual substances within these lubricant additive packages, there is no equivalent requirement for hazard classification of the whole mixture. However, Safety Data Sheets (SDSs) require hazard classification of the whole lubricant additive package. As such, lubricant additive packages are seldom classified based on the whole mixture, but instead by calculation from summation of the intrinsic hazards of all the individual substances in that mixture.

Many of the individual constituents of a lubricant additive package are considered toxic or very toxic to the aquatic environment, and in some cases, with long-lasting effects. However, many of these substances do not have a complete aquatic toxicity dataset; long-term aquatic toxicity data is rarely available. Therefore, chronic aquatic hazard classification is based on short-term aquatic toxicity data in accordance with Table 4.1.1(b)(iii) of the Global Harmonized System of Classification and Labelling of Chemicals (GHS). Furthermore, summation does not inform on how the individual constituents of a mixture can interact.

As such, there is an inherent uncertainty in the hazard classification of complex mixtures by summation approaches. Aquatic toxicity testing of lubricant additive packages, and classification based on these whole-mixture test data can provide a more robust approach to hazard classification. This poster will present several case studies of aquatic testing of lubricant additive packages, addressing the challenges of difficult-to-test substances, and provide a comparison of aquatic classification by both the summation and whole-mixture testing approaches. In many cases, data generated from mixture testing indicates lower hazardous classification compared to summation approaches, indicating the value of whole-mixture testing.

4.04.P-Th149 Integrating Spatial-Temporal-Extent Prioritization and a Tiered Mixture Framework: A Regulatory Strategy for Managing PPCPs in Korean Rivers

Jun Yub Kim¹ and Sang Don Kim², (1)School of Earth Science and Environmental Engineering, Gwangju Institute of Science and Technology (GIST), Korea, Republic of, (2)Gwangju Institute of Science and Technology (GIST), Korea, Republic of

The continuous release and pseudo-persistence of Pharmaceuticals and Personal Care Products (PPCPs) in aquatic environments pose significant ecological risks often underestimated by traditional single-compound assessments. This study established an integrated risk management framework by evaluating the spatiotemporal dynamics and mixture toxicity of 137 PPCPs across four major South Korean rivers (Han, Geum, Yeongsan, and Nakdong). A year-long LC-HRMS monitoring campaign detected 120 compounds. While ubiquitous compounds like metformin dominated in concentration (up to 42.7 µg/L), they posed negligible risks. Conversely, a conventional Risk Quotient (RQ) approach flagged broad ecological concerns but lacked discrimination for priority management. To address this, we applied the Spatial-Temporal-Extent (STE) prioritization methodology, integrating detection frequency and temporal persistence. This multidimensional approach refined the priority list, reclassifying specific stressors such as clotrimazole, fluoxetine, and olmesartan as primary ecological drivers warranting regulatory attention. Cumulative risks were assessed using a conservative Concentration Addition (CA) model. The Hazard Index (HI) and Risk Quotients based on the Sum of Toxic Units (RQ_STU) consistently exceeded safety thresholds, identifying fish as the most vulnerable trophic level (RQ_STU up to 24.2). Risks were significantly amplified during low-flow winter and spring periods, highlighting the influence of dilution capacity. Crucially, Maximum Cumulative Ratio (MCR) analysis categorized the majority of mixtures as Group I. This indicates that cumulative toxicity is predominantly driven by one or two high-potency chemicals rather than by the combined effect of many low-level substances. In conclusion, integrating STE prioritization with component-based mixture modeling offers a scientifically robust strategy superior to simple concentration-based monitoring. These findings provide essential evidence for establishing site-specific water quality criteria and targeted management policies for unregulated micropollutants.

4.04.P-Th150 A proposal for categorizing UVCBs for aquatic ecotoxicity testing

Benedikt Ringbeck¹, Karsten Schlich², Claire Elisabeth MacKenzie¹, Elke Eilebrecht², Sebastian Eilebrecht³,

Maria Vogt², Lena Kosak², Christoph Schaefer⁴, Bernd Göckener¹ and Matthias Teigeler², (1)Department Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, Germany, (2)Department Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, Germany, (3)Department Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Substances of ‘Unknown or Variable composition, Complex reaction products or Biological materials’ (UVCBs) are an increasingly important group of substances registered under the REACH regulation. These substances are complex mixtures that often do not have a fixed or well-defined chemical composition and consist of various constituents. UVCBs are considered “difficult-to-test substances” according to OECD 23 “Guidance Document on Aquatic Toxicity Testing of Difficult Substances and Mixtures”. Standard aquatic ecotoxicity tests, developed for the testing of soluble substances, often prove to be not applicable for UVCBs as the individual constituents have different physico-chemical properties, which complicates the application to aqueous media. Furthermore, selective and sensitive analytical verification, and interpretation of measured exposure concentrations for these complex mixtures is difficult and lacks standardization. E.g., for UVCBs containing various constituents varying in their water solubility, an effect assessment can be difficult. Based on our practical experience on UVCB testing and to address these challenges, we propose a categorization system for UVCBs based on chemical similarity of constituents and based on difficulties for test application in aqueous media. This proposal focuses on complex chemical reaction products rather than biological materials which are all categorized as UVCB. In a first step, the substances are categorized into three categories according to their chemical complexity with regards to chemical structure and physico-chemical properties of the constituents. Following analytical considerations for method development and quantification strategies, the substance groups are further categorized by their applicability in aqueous test systems for reaching stable and uniform exposure concentrations. Eventually, different perspectives on data evaluation and discussion of analytical results and the ecotoxicological assessment are given for these subgroups. This categorization is intended to bring more clarity and uniformity in the performance and interpretation of ecotoxicological studies on UVCBs. Furthermore, it shall give guidance on whether testing of the whole substance or fractions/representative constituents of the UVCB may be reasonable. Eventually, these considerations may help regulators and other stakeholders with comparison between studies and overall evaluation of these studies within the REACH framework.

4.04.P-Th151 Organotin compounds in dust from Colombian: Concentrations, urban influence, environmental conditions, and socio-demographic factors

Dairo Meza-Morelo¹, Boris Johnson-Restrepo¹ and Gilberto Fillmann², (1)Environmental Chemistry Research Group, School of Exact and Natural Sciences, University of Cartagena, Colombia, (2)Laboratorio de Microcontaminantes Orgânicos E Ecotoxicologia Aquática, Instituto de Oceanografia, Universidade Federal Do Rio Grande, Brazil

Organotin compounds (OTs), widely used as stabilizers in PVC, catalysts, and biocides, represent a persistent class of semi-volatile indoor contaminants. Although their occurrence has been documented in household dust in Europe, North America, and Asia, data from tropical and Andean Latin American regions remain extremely limited. This study quantified monobutyltin (MBT), dibutyltin (DBT), and tributyltin (TBT) in household dust from 30 homes in Cartagena, Medellín, and Bogotá, representing distinct climatic, geographic, and urban environments, as well as household socio-demographic tiers (low-, mid-, and high-income households). Phenyltins were also analyzed but remained below detection limits. Bogotá, a cold high-altitude Andean city (~2600 m) characterized by reduced natural ventilation and dense vertical housing, exhibited the highest concentrations of the sum of butyltins ΣBTs (667–2428 ng Sn/g). Cartagena, a coastal tropical city with high humidity and a mix of traditional and modern housing, presented intermediate levels (54–1140 ng Sn/g). Medellín, located in a temperate valley with moderate building density and favorable airflow, showed the lowest and most homogeneous concentrations (5–879 ng Sn/g). High-income households showed significantly higher ΣBTs, consistent with greater prevalence of PVC and synthetic laminated materials. MBT was the dominant compound, mirroring patterns reported in the USA and Europe. These findings highlight that indoor exposure to OTCs in tropical developing countries results from an interplay of urban form, climate, ventilation patterns, and material use, which extends beyond socioeconomic factors alone. This study establishes the first baseline for OTCs in Colombian indoor environments.

4.04.P-Th152 UVCB Substances: Methodology for Substance Identification, Generation of Constituents and Selection of Representative Samples

Stela Kutsarova, Darina Yordanova, Yordan Karakolev and Ovanes Mekenyan, Laboratory of Mathematical Chemistry (LMC) Prof. Assen Zlatarov Burgas State University, Bulgaria

A thorough characterization of UVCBs (substances of Unknown or Variable composition, Complex reaction products, or Biological materials) has always been difficult due to the complex nature of their origin and/or unknown or variable composition. A well-defined substance identification is an essential precondition for a substance to satisfy the requirements of implementation of any chemical related legislation. The incomplete structural characterization also hinders an in silico hazard assessment, which role could become crucial for substance assessment when experimental data is not available. A methodology for definition of an unambiguous structural description was developed to address those issues. The methodology allows for the coding of constituents, their generation, calculation of important properties of UVCB constituents, and selection of representative samples. Two formats are developed: Generic Simplified Molecular-Input Line-Entry System (G SMILES) and Generic Graph (G GRAPH). G SMILES is a SMILES-based single line notation used for coding fixed and variable structural features of UVCBs. G GRAPH allows generation of constituents coded in G SMILES, calculation of physicochemical properties, simulation of reactions, selection of constituents and their storage in a text file. Two main types of selection of constituents are developed. The first one is an endpoint driven selection based on ranges of a defined physicochemical property, e.g., logKow values are critical when assessing acute aquatic toxicity. The second approach is a statistical selection of the minimum number of generated constituents which could be considered as representing the UVCB. This representative sample is selected in such a way that the structural variability and the properties of concern of the UVCB are estimated within a predefined tolerable error. The aim of the statistical selection is to enable the assessment of UVCB substances by reducing the number of constituents that need to be evaluated. The procedure has been applied successfully on theoretical examples and on real case studies.

4.04.P-Th153 Evaluation of the RTgill-W1 Cell Line Assay (OECD TG 249) for Predicting Acute Fish Toxicity of Surfactants

Jayne Roberts¹, Roman Li², Helena Villuendas Garcia², Liesa-Kristin Beuter³, Jens Bietz⁴, Kristin Connors⁵, Jay Dawick⁶, Marc Geurts⁷, Geoff Hodges¹, Erin Maloney⁸, Lauren McAnally⁶ and Frank Seitz⁹, (1)Unilever, United Kingdom, (2)aQuaTox-Solutions GmbH, Switzerland, (3)Nouryon Specialty Chemicals B.V., Sweden, (4)Clariant, Germany, (5)Procter & Gamble, United States, (6)Innospec, United Kingdom, (7)Nouryon Specialty Chemicals B.V., Netherlands, (8)Shell Global Solutions International BV, Netherlands, (9)Sasol Germany GmbH, Germany

Understanding short-term toxicity in fish is a key endpoint requirement in global regulatory frameworks and environmental risk assessment. Commonly this endpoint is fulfilled by the OECD TG 203 fish acute toxicity test. However, evolving legislation under the Chemical Strategy for Sustainability (CSS) attempts to reduce vertebrate animal testing. To achieve this ambition whilst ensuring environmental safety, robust, reliable, and regulatory-compliant alternatives are required. The RTgill-W1 Fish Cell Line Acute Toxicity assay (OECD TG 249) is proposed as an alternative. This assay has previously been shown to have good correlation with existing in vivo acute fish data for a variety of chemicals. However, to date only a limited number of surfactants have been tested using this assay and a clear applicability domain for this group of chemicals has not been definitively established. Surfactants often exist as multi-constituent or UVCBs (Substances of Unknown or Variable Composition) due to the variation in alkyl chain length and branched/linear structure. Their 'surface-active' nature, solubility, lipophilicity, and presence of ionizable headgroups also makes standard (or adapted) test methodologies challenging. Therefore, it is essential to evaluate the suitability of in vitro test designs for this chemical class. Here we present the results from an Environment and Health – Risk Assessment & Management (ERASM) Task Force, established to address these uncertainties. Initially, existing in vivo and in vitro experimental data (OECD TG 203, OECD TG 249) were collected from external sources for a range of nonionic, anionic, cationic, and amphoteric surfactants. Correlation analysis demonstrated strong agreement between in vivo and in vitro results, with the majority falling within one order of magnitude of the line of unity. Surfactants with high-quality compositional and in vivo data (specifically 2 nonionic, 2 cationic, 2 amphoteric,

4.04.P-Th154 Environmental Hazard Assessment of a UVCB under the REACH Regulation – Regulatory and Practical Perspectives

The environmental hazard assessment of UVCB substances poses significant challenges under regulations such as REACH. UVCBs are complex mixtures containing dozens to hundreds of constituents, often with unknown structures and variable composition. Current REACH guidance provides only limited direction for the analytical characterization required to ensure regulatory acceptance of ecotoxicity test results. Key challenges include verifying the UVCB analytically due to diverse physical-chemical properties of the constituents, such as solubility, degradation, and interactions with the test systems. An increased diversity in the properties of individual constituents makes it increasingly challenging to analyze representative constituents using a single analytical approach.

Hazard characterization of UVCBs is limited by technical feasibility, time, and cost. Regulatory and practical requirements frequently diverge, which necessitates case-by-case assessments for each substance. These challenges mean that registrants of UVCBs often face higher costs than those registering mono- or multi-constituent substances, resulting in an uneven playing field. Clear, harmonized regulatory criteria for selecting representative constituents and assessing technical feasibility are needed. Current guidance requires registrants to conduct extensive analyses before claiming that testing is technically not feasible, so efforts often resemble research rather than routine testing. A balanced approach between regulatory requirements and scientific considerations is essential to support UVCB registrants and restore fair competition.

Héloïse Thouément, Julie de Vriendt and Berend Mensink, Haskoning Nederland B.V., Netherlands

Essential oils contain multiple constituents, notably terpenes and terpenoids, with varying toxicities and behaviors. Concentrations range from trace level ($<0.1\%$) to major fractions ($>50\%$, some $>90\%$) of an essential oil. The composition of each essential oil batch varies, notably with plant growth conditions. Consequently, essential oils are considered as “unknown or variable compositions, complex reaction products or biological materials” (UVCBs). UVCBs pose challenges for environmental risk assessments as described in recent reviews.

SETAC Europe 36th Annual Meeting

We illustrate differences in risk assessment results using a hypothetical citrus oil case-study, identifying the drivers of variability and assessing the applicability of the methods. This study will be relevant to the regulators as much as to the industry, as environmental risk assessments affect permissible production and use volumes under EU regulations. Comparing methodologies is particularly relevant with the current implementation of the One Substance, One Assessment approach.

4.04.P-Th156 Chemical Mapping of Naturals Constituents through the Persistence, Bioaccumulation, Mobility and Toxicity (PBMT) Prism: Qualitative Analysis as a Precursor to Literature Data

Kevin Bonnot¹ and *sylvia gimenó²*, (1)DSM-Firmenich SA, Belgium, (2)Firmenich, Belgium

Ingredients from natural sources, in particular essential oils, are widely formulated in consumers products such as cosmetics, perfumery, and household products. Understanding the environmental and ecotoxicological impact of those Natural Complex Substances (NCS) has become a priority, notably with the implementation of the More than One Constituent Substances (MOCS) concept under the recent update of the EU Classification, Labelling and Package Regulation (EC No 1271/2008). However, the complex and variable composition of NCS presents a unique challenge for the assessment of their environmental impact. We will make use of the information gathered on over 1,000 naturals constituents, as to their Persistence, Bioaccumulation, Mobility and Toxicity potential and statistical analyses that will help understand and predict the fate and effects of naturals constituents.

The first part of the study presents an innovative method of Hierarchical Clustering on Principal Components (HCPC), based on chemical families. The HCPC approach is particularly well-suited to the classification of complex substances, as it allows for the identification of distinct chemical families based on both structural similarities and environmental properties. This method clusters molecular fragments (qualitative data) and 2D descriptors (quantitative data), and is enriched by unsupervised statistical analysis methods such as Partial Least Squares (PLS) regression and sparse PLS. These advanced techniques enable us to uncover patterns in the molecular structures of naturals constituents and establish correlations with key environmental parameters, such as persistence, bioaccumulation, mobility, and toxicity. In the second phase, a visualization based on regulatory thresholds for PBT/PMT is used to categorize clusters of components according to CLP criteria.

This study, by focusing on molecular structure, enables the qualitative prediction of the environmental impact of substances. From the clusters created and the descriptors and fragments characterizing these groups, we will identify key molecular descriptors critically for the assessment of naturals constituents. These findings are crucial for advancing the understanding of the environmental fate of these substances and the applicability of the MOCS concept to substances of botanical origin, for which there is a 5-year derogation.

4.04.P-Th157 Evaluating mitigation strategies to reduce chemical and biological pollutant transfer in biosolid-amended agricultural systems.

Morgan Giacomoni, *Jessica Subirats Medina and Victor Matamoros*, *Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain*

The application of biosolids in agriculture provides nutrients and improves soil properties but can introduce emerging contaminants (ECs) and antibiotic resistance genes (ARGs), posing environmental risks. This study evaluated the fate of ECs, heavy metals, and ARGs in wheat cultivated in silty clay loam and sandy soils under five fertilization strategies: biosolids, biosolids amended with 10% biochar, biosolid-derived compost, inorganic fertilizer, and an unfertilized control. ECs were monitored at application, 30 days, and harvest (140 days), while ARGs were quantified in soil, straw, and seeds, and heavy metals were analyzed in soil. Biochar amendment accelerated EC degradation, reducing half-lives from 65 to 35 days and lowering ARGs abundance in soil and straw. Composting reduced the initial ECs and ARGs load but some compounds persisted longer in soils. Heavy metal concentrations remained below regulatory limits, and no ECs or ARGs were detected in seeds, indicating negligible transfer to edible tissues. These findings demonstrate that composting and biochar effectively mitigate chemical and biological contaminant persistence and mobility, enhancing the environmental safety of biosolid application in agricultural systems.

4.04.P-Th158 Tracking alkylated decalins during biodegradation of a complex hydrocarbon substance to derive primary half-life data

J. Samuel Arey¹, Martin Lommatzsch² and Delina Lyon³, (1)Oleolytics, United States, (2)Laboratory Lommatzsch & Säger, Germany, (3)CONCAWE, ., Belgium

Assessing the biodegradability of complex hydrocarbon substances for chemical registration—such as under the REACH regulation—requires evaluating hundreds to thousands of individual constituent chemicals. A practical alternative to testing multiple individual constituents is to test a whole complex hydrocarbon substance and derive the primary biodegradation half-lives of individual constituents by tracking the observed decay of signal peaks in GCxGC-FID data obtained from successively biodegraded samples, as previously demonstrated by the authors. In this work, the authors focused on generating primary biodegradation half-life data for one representative group of hydrocarbons: the alkylated decalins. The eventual goal is to determine how structural features, particularly branching, influence primary biodegradation rates.

In previous work, GCxGC-FID data provided limited information about the chemical identities of the separated constituents, and these studies encountered challenges when attempting to associate the GCxGC-FID peaks with corresponding GCxGC-TOFMS peaks that could be further identified by Non-Target Analysis (NTA) techniques. For several of the studied constituents, chemical identity information from GCxGC-TOFMS data could not be clearly attributed to the calculated primary biodegradation rates from GCxGC-FID data. To address these limitations, we explored methodological adaptations to the analytical and data processing approaches, including:

1. Analyzing a series of successively biodegraded samples by reversed-phase GCxGC-TOFMS, including a prefractionation step to remove the aromatic fraction
2. Tracking the decay of the quantified peak signal of selected ions diagnostic of alkylated decalins in the GCxGC-TOFMS data obtained from the successively biodegraded samples
3. Using existing Non-Target Analysis work-flows on the co-located TOFMS mass spectrum to identify chemical structure information for each selected ion peak that was tracked. We also consider the GCxGC retention time relative to other alkylated decalin peaks.

This improved workflow would enable the targeted identification and characterization of alkylated decalin structures in a straight-run gas oil sample that had been previously tested.

4.04.P-Th159 Defining aquatic toxicity endpoints for pesticide mixtures – Why the “cat must chase its own tail”

Gero Eck¹ and Katie Jo White², (1)Exponent, Switzerland, (2)Exponent, United Kingdom

Detailed guidance on deriving aquatic toxicity endpoints for pesticidal products containing multiple active substances or toxicologically relevant co-formulants is provided by EFSA (2019). However, feedback from Competent Regulatory Authorities on the acceptability of endpoints reported in studies has been inconsistent, suggesting that the current guidance leaves some room for interpretation.

While such variability may be undesirable when seeking universally accepted approaches, a certain degree of flexibility can be useful to support scientifically robust data interpretation. The EFSA framework adopts a conservative stance by defining toxicity solely on the basis of analytical recovery in the test matrix, but without accounting for the toxicity of individual components. This method yields meaningful endpoints only when all critical components are similarly persistent and toxic. Conversely, it may overestimate actual toxicity if a component with low stability and limited toxicological relevance is present.

Greater scientific rigor is therefore needed to derive meaningful endpoints for combination products, ensuring risk assessments are protective without being excessively conservative. In environmental risk assessment, measured product toxicity is also used to evaluate the predictive value of modelled mixture toxicity using Concentration Addition (CA), including the derivation of Model Deviation Ratios and the identification of potential synergistic effects that may occur due to the combined exposure to multiple constituents present in the formulation. Although measured product toxicity is valuable for detecting synergisms, careful judgment should be applied in its calculation.

While empirical toxicity data inform on the applicability of CA, CA together with the identification of toxicity drivers should also be employed to scrutinize the way aquatic endpoints are defined, emphasising the circular nature of this reasoning while maintaining a sense of proportion to ensure meaningful risk assessments for aquatic organisms.

4.04.P-Th160 Dioxins in Food and Feed: Update of the 2018 EFSA Risk Assessment

Ron (Laurentius) Hoogenboom¹ and **Luisa Bordajandi²**, (1)*Wageningen University and Research (WUR), Netherlands*, (2)*European Food Safety Authority (EFSA), Italy*

The European Food Safety Authority (EFSA) was established in January 2002 as an independent body providing scientific advice and communication on risks associated with the food chain (Regulation (EC) No 178/2002).

Polychlorinated dibenzo-p-dioxins and furans (PCDD/Fs) and dioxin-like polychlorinated biphenyls (DL-PCBs) do still occur in the environment and may enter the food-chain and as a result accumulate in humans. In 2018, the EFSA Panel on Contaminants in the Food Chain published an Opinion on the health risks for humans and animals related to the presence of PCDD/Fs and DL-PCBs in food and feed. A Tolerable Weekly Intake (TWI) of 2 pg Toxic Equivalents (TEQ)/kg bw per week was derived for humans, expressed using the Toxicity Equivalency Factors set by WHO in 2005. Average and high exposures were, respectively, up to five and 15 times the new TWI in adolescents, adults and the elderly, while toddlers and children up to 10 years of age had a similar range of exceedances of the TWI. The EFSA Opinion recommended, among others to re-evaluate the 2005 WHO-TEFs in order to take into account new in vivo and in vitro data (in particular, more insight into the reported lower relative potency of PCB-126 in humans).

In 2024, WHO published its updated WHO-TEF values. Following this publication, the European Commission requested EFSA for an update of the scientific Opinion on the risk for animal and human health related to the presence of PCDD/Fs and DL-PCBs in feed and food on the basis of the new 2022 WHO-TEF values.

In addition to the existing data, all relevant toxicological information in experimental animals and humans published since the 2018 Opinion was taken into account for the hazard and risk characterisation. An update of the dietary exposure assessment was also performed considering the occurrence data on PCDD/F and/or DL-PCBs in food submitted to EFSA between 2013 and 2023. The draft updated scientific Opinion underwent public consultation from November 2025 until January 2026.

All aspects of the risk assessment where the new 2022 WHO-TEFs would have an impact will be presented. These include the hazard characterisation, e.g. the derivation of the health-based guidance value (Tolerable Weekly Intake (TWI)), as well as the changes in occurrence in food and dietary exposure assessment expressed in TEQ following the use of the 2022 WHO-TEFs compared to the use of the 2005 WHO-TEFs.

4.04.P-Th161 High-Throughput Assessment of Predicted Hydrocarbon Degradation Products Using Integrated QSAR Workflows and Applicability Domain Analysis

Elaine Jennings¹, **Javier Soto¹**, **Simon Gutierrez²**, **Yves Verhaegen³**, **Sandrine Sourisseau⁴** and **Delina Lyon⁵**, (1)*Ricardo-AEA Ltd, United Kingdom*, (2)*Ricardo-AEA Ltd, Spain*, (3)*European Fuel Manufacturers Association Division Concawe, Belgium*, (4)*TotalEnergies, France*, (5)*European Fuel Manufacturers Association Division Concawe, Brussel, Belgium*

Petroleum substances, particularly those classified as substances of unknown or variable composition, complex reaction products or biological materials (UVCBs), present a significant challenge for environmental hazard assessment due to their complex and variable chemical profiles. One requirement under the European REACH and CLP chemicals regulations is the identification and evaluation of the persistence, bioaccumulation, mobility, and toxicity (PBMT) of their expected degradation products, which are often more structurally diverse than the parent compounds, including more polar and potentially charged compounds.

To address this, we developed a high-throughput computational workflow to assess over 6.45 million predicted degradation products of >127,000 hypothetical parent structures. To manage datasets of this magnitude, the team developed a high-throughput, reproducible data-processing architecture using Polars as the central analytical engine. The design emphasizes scalability, traceability, and regulatory compliance within a unified QSAR/QSPR framework. We integrated multiple QSAR models, including OPERA, to predict PBMT endpoints, and evaluated the applicability domains of each model and identified gaps where polar or charged metabolites fall outside existing QSAR coverage.

Preliminary results generated with a subset of the data show that a substantial proportion of metabolites (approximately 33%) are outside the applicability domains of commonly used OPERA models, especially for bioaccumulation and mobility endpoints. A subset of compounds was not covered by any model, indicating the potential need for targeted experimental testing. This work demonstrates the importance of combining multiple QSARs and applicability domain analyses to ensure robust hazard assessment of complex petroleum-derived substances and their transformation products.

Our findings support the development of more inclusive and scalable computational tools for regulatory

chemical assessment and provide a framework for identifying data gaps in UVCB metabolite evaluation. By enabling high-throughput screening of structurally-diverse hydrocarbons (including polar/ionised species) in a reproducible data-engineering environment, the platform contributes to the field of environmental chemistry, hazard and exposure assessment, facilitating modelling of chemical behaviour across compartments, monitoring-modelling integration and evidence-based decision support.

4.04.P-Th162 MEED: Finalization of the Multiyear Metals Environmental Exposure Data Collection program Anticipating the Challenges of the EU Zero Pollution Ambition Policy and the Combined Exposure to Mixtures

Hugo Waeterschoot¹, **Marnix Vangheluwe²**, **Charlotte Nys²**, **Karel Viaene²** and **Lara Van De Merckt³**,
(1)EUROMETAUX, Belgium, (2)ARCHE Consulting, Belgium, (3)AV DE TERVUEREN 168, Eurometaux, Belgium

The Chemicals Strategy for Sustainability (CSS) is a key pillar of the EU Zero Pollution Ambition (ZepA), and a building block of the Green Deal. This policy aims for reaching good quality status of the environment by achieving exposure levels of chemicals that are no longer being harmful to health and the environment. This challenges environmental and chemicals regulations given focused on substance specific risk assessments and limits. The effects of combined exposure of mixtures and ensuring they do not affect biodiversity are therefore new areas of concern in regulatory risk assessments. The introduction of a Mixture Allocation Factor (MAF) to demonstrate safe use of chemicals and lack of impact of mixtures on ecosystems, is a default approach considered by regulators. This poses a significant scientific challenge particularly for metals, given their natural occurrence and broad and growing use in Green Deal applications such as electric vehicle batteries, solar cells, ... This complex challenge drove the sector to conduct a comprehensive “Metals Environmental Exposure Data” (MEED) gathering programme, including the development of scientific concepts and targeted test work to assess combined mixture exposure. MEED ran for 4 years, built on 6 interlinked projects. The first was the identification of metals that contribute the most to the combined risks to the environment, followed by an extensive investigation of today’s regional background levels of metals, and an update on the STP emissions contributions as a key source of consumer input. A review and reappraisal of existing knowledge on metals mixtures and metals-organics mixtures interactions allowed to define data gaps and to perform gap-filling research for their toxicity and interactions. Next, this evidence was used in a tiered assessment system for local and regional biodiversity impact assessment, including biomonitoring and environmental DNA screening for specific organism groups. Finally, the outcomes were used to design a science-based concept to improve the assessment of combined effects for regulatory schemes like REACH. This poster presents the overall process, main outcomes and conclusions of MEED, while detailed assessment are presented in complementary posters and presentations. MEED delivered a large amount of data and relevant concepts for use in chemicals registration and environmental permit updates, key to assess progress with the EU ZepA policies in a scientific way.

4.04.P-Th163 Assessment of Structural and Functional Changes to the Microbiome of Aquatic Microcosms Caused by Heavy Metals in E-waste: Cerium and Lanthanum

Veronica Inmaculada Luna-Guerrero¹, **Alba Moreno-Camacho²**, **Chiara Trombini³**, **Marina Barbudo-Lunar Ms.⁴**, **Inmaculada Osuna-Jimenez²**, **Carmen Michan⁵**, **Julian Blasco⁶** and **José Alhama-Carmona²**, (1)Instituto de Ciencias Marinas de Andauca (CSIC), Spain, (2)University of Cordoba, Spain, (3)Instituto de Ciencias Marina de Andalucía (CSIC), Spain, (4)Biochemistry and Molecular Biology, ceiA3, University of Cordoba, Spain, (5)University of Córdoba, Spain, (6)Institute of Marine Sciences of Andalusia - Spanish National Research Council (ICMAN-CSIC), Puerto Real, Cádiz, Spain

Technological development is increasing the consumption, use and subsequent disposal of electronic objects, generating a new and worrying type of waste known as e-waste. It is estimated that e-waste production will reach 74 million tonnes by 2030. This presents a significant global environmental problem, as many of these products contain toxic metals that can leach into aquatic ecosystems and cause environmental and health problems. This study aims to determine the impact of the various metals present in e-waste on aquatic ecosystems by evaluating changes in microbial populations in both biotic and abiotic matrices. To this end, artificial microcosms containing sediment and water, along with the bioindicator organism *Scrobicularia plana*, have been designed and placed under controlled conditions. The effects of the metals cerium (Ce) and lanthanum (La) were studied both individually and as a mixture (Ce+La). The microbiome of the sediment and digestive gland of *S. plana* was identified by isolating genomic DNA from these matrices and sequencing their 16S rDNA. The most abundant phyla in the sediments were Proteobacteria, Actinobacteria, and Bacteroidetes, whereas the most abundant phyla in the digestive gland of *S. plana* were Tenericutes, Proteobacteria, and

Firmicutes. At a lower taxonomic level, the Ectothiorhodospiraceae family was most abundant in the sediments, whereas the Mycoplasmataceae family was most abundant in the digestive gland of *S. plana*. All results were statistically evaluated. Additionally, alpha and beta diversity, as well as microbiome functionality using the FAPROTAX database, were analysed. The results obtained reveal the effects of metals on microbiome structure and its consequences. Our ultimate goal is to identify future exposure biomarkers for these contaminants.

4.04.P-Th164 Establishing a Robust Boundary Composition taking the Example of a Complex UVCB Substance: Analytical and Regulatory Challenges

Johanna Becker¹, Frederik Simon Hermann¹, Matthias Karl¹, Torsten Schardt¹ and Indra Conen², (1)Currenta GmbH & Co. OHG, Germany, (2)indra.conen@currenta.de, Germany

Accurate substance identification is a central requirement under REACH. However, UVCB substances often lack robust, standardized analytical frameworks to define their boundary composition, which summarizes and comprises the composition in set boundaries. A representative UVCB substance was selected to illustrate the challenges associated with deriving a robust boundary composition. The complex mixture is the reaction product of a condensation reaction resulting in a wide range of molecules from volatile constituents with low molecular weight to oligomers with high molecular weight. Because of this inherent variability, defining a reliable boundary composition is essential to ensure regulatory compliance and to support a scientifically sound Substance Identity Profile (SIP). According to the European Chemicals Agency (ECHA) guidance “Identification and naming of substances under REACH and CLP”, all relevant constituents—regardless of their abundance—must be identified and quantified down to the respective reporting thresholds, particularly when they may influence classification or PBT assessment. Inconsistent or incomplete analytical data, such as reporting vague concentration ranges, undermines regulatory acceptability and the scientific integrity of the SIP. For such complex UVCB substances, conventional material balance approaches are not directly applicable due to the inherently diverse composition. This work outlines the analytical challenges encountered and presents a multitechnique strategy developed to achieve reliable quantitative characterization, while relying on a practical, low-effort analytical workflow that allows data to be obtained with minimal resource expenditure. The integrated approach combines LC-UV fingerprinting as key element, sulfated ash determination, and Karl Fischer water analysis, supplemented when needed by LCMS and gel permeation chromatography (GPC). Together, these methods provide a reproducible, sensitive, and comprehensive analytical dataset across laboratories.

We describe the data evaluation concept enabling consistent quantification of relevant constituents and discuss the regulatory context in which these analytical requirements are embedded. The proposed methodology strengthens characterization standards for UVCB substances and offers a transferable framework for addressing similar complexities in boundary composition definition and SIP development.

4.05 Environmental Risks of (New) Chemicals Used in Maritime Transport

4.05.T-01 Bringing circularity and sustainability into the maritime antifouling coatings industry by reusing dead batteries

Guillermo López¹, Diogo Gomes², Diana Isabel Oliveira Carneiro³, Luis Miranda⁴, M. Margarida Almeida³, Natalia Belloti¹, Frederico Maia⁵, Miguel Peluso⁶ and Roberto Martins³, (1)Research and Development Center in Paint Technologies, Argentina, (2)Department of Biology, University of Aveiro, Portugal, (3)CESAM, University of Aveiro, Portugal, (4)CESAM, University of Aveiro, Federal University of Paraná, Brazil, (5)Smallmatek – Small Materials and Technologies, Lda., Rua Canhas, 3810-075, Aveiro Portugal., Portugal, (6)UPL Laboratory, Argentina

Alkaline batteries are used in various electronic devices and when they are discarded, they pose a threat to the environment and human health. ZnO is a semiconductor with a band gap of 3.37 eV and a high excitonic binding energy of 60 meV. These properties give it important technological applications, among them, ZnO has antimicrobial and antifouling activity that can be used to bioactive coating formulations. Marine biofouling on ship hulls decreases speed and increases fuel consumption and greenhouse gas emissions. The present study aims to propose a method to revalorize the Zn present in the alkaline batteries by developing an active nanoform, incorporating it in coatings, and assessing its anti-fouling efficacy and ecotoxicity. Briefly, zinc was

recovered through an acid leaching process using biogenerated H_2SO_4 ($\text{H}_2\text{SO}_4\text{b}$). Once the Zn^{2+} ions were dissolved, a Na_2CO_3 solution was added. The resulting precipitate was dried and separated into two fractions: one was calcined at 500 °C for 2 hours (C-ZnO), and the other, the uncalcined fraction (WC-Zn), was doped by wet impregnation with H_2SO_4 , followed by calcination, and designated WC-ZnO/S. The solids were characterized by ICP-OES, XRD, SEM, and TEM. Three self-cleaning antifouling paints (P) were formulated with a 7% concentration of a biocidal additive: P_C-ZnO, and P_WC-ZnO/S plus a biocide-free control (P_CTL). The antibiofilm and the short-term ecotoxicity of the coatings with the additives were evaluated. Quantitative determination of the components present in C-ZnO and WC-ZnO/S using ICP showed that zinc (Zn) is the major element, along with sulfur (S), sodium (Na), and iron (Fe). The predominant phase of the solids was zincite (ZnO). SEM analysis showed morphological differences between the two solids: C-ZnO exhibited a nanorose-like shape, while WC-ZnO/S had a star-like shape. TEM analysis revealed particle sizes greater than 20 nm for C-ZnO and 50 nm for WC-ZnO/S. Bioassays suggest that the studied solids are potential antifouling agents and that their incorporation into paints would help prevent the adhesion of microorganisms. In this context, zinc recovery and the manufacture of new materials with potential applications as environmentally friendly antifouling additives represent significant waste valorization with clear environmental benefits by fostering circularity and sustainability, particularly in the maritime industry.

4.05.T-02 Ecotoxicological and Biodegradability Assessment of Antifouling Paints for Marine Applications (PROJECT - NAUTILUS)

PATRICIA SOLORZANO¹, Virginia Cazzagon², Rubén Francisco Martínez López², Melissa Diogo Faria³, Verónica Gonzalez-Andres², Elena Cerro-Galvez², Nélida Gimeno⁴, Elisabet Fernández⁴, Pilar Salsé⁵, Belén Pascual⁵ and Socorro Vázquez-Campos², (1)Hehs, Leitat Technological Center, Spain, (2)Leitat Technological Center, Spain, (3)Environmental Chemistry, Leitat Technological Center, Spain, (4)HEMPEL, Avda. Sentmenat 108, Polinyà, Spain., Spain, (5)ERCROS, Spain

Biofouling negatively affects marine infrastructures and leads to substantial economic costs. Conventional antifouling paints used on boats contribute to marine pollution by releasing microplastics and toxic biocides, potentially harming marine species. Additionally, fossil-based paints increase greenhouse gas emissions and deplete finite resources. The NAUTILUS project, funded by the Spanish Ministry of Science and Innovation, aims to develop safer and biodegradable alternatives by designing new biobased and biodegradable antifouling paints.

Four biobased formulations based on biodegradable polymers such as PHA and PLA were developed without biocides to reduce their ecotoxicity potential. A tiered assessment was conducted, including ecotoxicity and biodegradability testing, to select the most promising alternatives. The same approach was applied to seven acrylic-based commercial paints to identify a commercial benchmark for comparison.

Physicochemical tests using FTIR, TGA, and ICP-MS evaluated paint degradation and substance release during seawater exposure. Copper-based commercial paint showed high Cu release (0.29 mg/L) and DCOIT-based paint released 39.3 mg/L, leading to their exclusion as safe options. Based on degradation and surface roughness results, a biobased, biocide-free PHA paint was selected.

Biodegradability assessments following OECD 301F confirmed one acrylic-based biocide-free paint as readily biodegradable (>60% in freshwater after 28 days). Under ISO 18830 marine conditions, two commercial paints and the PHA-based paint achieved >60% biodegradation after 120 days, meeting the standard criteria.

Ecotoxicity testing across multiple marine species revealed that paints containing DCOIT had the highest toxicity, with effects observed in algae, crustaceans, and bioluminescent bacteria. Both acrylic and PHA polymers were evaluated to confirm their safety. The biocide-free PHA paint demonstrated lower ecotoxicological impact compared to traditional commercial paints containing biocides.

In conclusion, the NAUTILUS project successfully developed a biobased antifouling paint using a PHA matrix. The new formulation is biodegradable and does not cause significant ecotoxic effects on tested marine organisms. Ongoing physicochemical research aims to further understand the substances released during the

paint's lifespan in seawater, supporting its potential as a sustainable alternative to conventional antifouling coatings.

4.05.T-03 Environmental Safety Assessment of Liquid Organic Hydrogen Carriers for Energy Transport: Towards Benign-by-Design Solutions

Marta Markiewicz¹, Georgios Tzortzinis², Bruno Guilherme Christoff², Maik Gude² and Stefan Stolte³, (1)Dresden University of Technical, Germany, (2)Dresden University of Technology, Germany, (3)Institute of Water Chemistry, Dresden University of Technology, Germany

The maritime industry's transition from fossil fuels to renewable energy faces significant challenges. While wind and solar power are being developed, their intermittent nature and geographical limitations necessitate efficient energy storage solutions. Hydrogen has emerged as a promising energy carrier, with multiple storage approaches available. Liquid Organic Hydrogen Carriers (LOHCs) offer advantages over compressed (CGH₂) and liquefied (LH₂) hydrogen by eliminating high-pressure or cryogenic storage requirements. However, LOHCs require energy-intensive hydrogenation/dehydrogenation processes and present potential environmental hazards that remain poorly characterized.

As LOHC technology evolves, multiple carrier molecules are being evaluated for maritime applications, creating opportunities to select environmentally acceptable options alongside technologically efficient ones. This study provides a comprehensive preliminary environmental hazard assessment of 24 LOHC carrier systems across four key categories: persistence, bioaccumulation potential, aquatic toxicity, and mobility. Environmental hazard profiles were systematically evaluated for each LOHC system in both hydrogen-lean and hydrogen-rich forms. Results revealed that most LOHC systems exhibit at least one form that is either bioaccumulative or mobile in aquatic environments. Critically, the hydrogen-rich form typically demonstrates poor biodegradability, identifying biodegradation potential as a key design parameter for developing new LOHC carriers. Structure-Activity Relationships (SARs) were developed from the compiled dataset, enabling identification of molecular features associated with specific hazards. Common hazard patterns, critical knowledge gaps, and recurring shortcomings across LOHC systems were systematically characterized. Two oxygen-containing LOHC systems are identified as promising low-hazard alternatives. This proactive environmental assessment framework supports informed carrier selection, enabling the maritime industry to pursue energy transition goals while minimizing ecological risks associated with emerging hydrogen storage technologies.

4.05.T-04 Ammonia as a Maritime Fuel: A Review of Environmental Risk Dynamics during Bunkering and Shipping Spills

Edwin Foekema¹, Tim Wijgerde² and Michael Yeboah³, (1)Marine Animal Ecology, Wageningen University & Research, Netherlands, (2)Wageningen Marine Research, Netherlands, (3)Wageningen University and Research (WUR), Netherlands

Ammonia is a promising carbon-free maritime fuel because of its high energy-to-volume ratio. However, it also poses risks to human health and marine ecosystems, hampering its regulatory and social acceptance. In the absence of robust data on high-volume ammonia spill risks, this review evaluates the existing knowledge of marine-related hazards unique to large- and small-scale accidental spills. The main challenge is to understand how different forms of ammonia, release conditions, environmental processes, and mitigation strategies combine to determine the overall risk in marine spaces. To address this challenge, evidence is synthesised from its historical application as an industrial chemical, theoretical studies on large-scale releases, documented physical and chemical behaviour, and ecological impact. Ammonia has primary hazards, including toxicity, flammability,

and explosiveness, and secondary hazards arise from combustion byproducts and biological transformation. Storage and wind under general atmospheric conditions strongly influence spill behaviour. The fully refrigerated ammonia form has reduced airborne dispersion, thereby enhancing human safety. This property increases the likelihood of high-concentration contamination in water, intensifying local ecological impacts. Wind speed disperses ammonia, reducing the local risk, but can occasionally intensify the risk to distant areas under light wind speeds and stable atmospheric conditions. Spills can cause acute toxicity and disrupt the natural biological pathways that convert ammonia into less harmful nitrogen forms. Under limited dilution, transformative products such as nitrites can reach toxic levels. Non-toxic ammonia, nitrite, and nitrate levels can stimulate harmful algal blooms. Regarding mitigation-related insights and risks, spills are expected to result from human error or equipment failure. Existing mitigating strategies for airborne ammonia may occasionally lead to conflict between human and ecological safety, highlighting the need to reduce overall risks through improved operational procedures, engineering design, ammonia-absorption technologies, and integrated approaches to hazard management. Overall, the physical, biological, and operational components of ammonia must be integrated for risk evaluation, as this will support the development of effective regulatory measures and mitigation strategies as ammonia becomes increasingly important in maritime energy systems.

4.05.T-05 Nature-based Antifouling Strategies Using *Posidonia oceanica* Leaf Extracts in Silicone Coatings for Marine Aquaculture

Bianca Gabrielli¹, Donatella Degl'Innocenti², Marzia Vasarri², Elisa Martinelli³, Matteo Oliva⁴ and Carlo Pretti¹, (1)Department of Veterinary Sciences, University of Pisa, Italy, (2)Department of Experimental and Clinical Biomedical Sciences, University of Florence, Italy, (3)Department of Chemistry and Industrial Chemistry, University of Pisa, Italy, (4)Interuniversity Consortium of Marine Biology and Applied Ecology "G. Bacci" (CIBM), Italy

In aquaculture, various approaches have been used to address biofouling, including mechanical net cleaning, biological control, and chemical antifoulants. However, chemical antifoulants may release organic and/or toxic solvent-based contaminants into the environment. Therefore, sustainable aquaculture promotes the use of antifouling polymers that incorporate naturally derived bioactive compounds in netting materials. *Posidonia oceanica*, a Mediterranean seagrass, is rich in primary and secondary metabolites such as terpenes, flavonoids, and phenolic compounds. It has demonstrated strong antifouling performance among its applications in human activities. Alcoholic extracts of *P. oceanica* leaves were prepared and added to a silicone-based polymeric matrix (PDMS) at concentrations of 0, 90, 135, and 180 mg L⁻¹. These composite materials were applied to 5 × 5 cm Dyneema® net samples using dip-coating. To test their efficacy, all samples, including untreated Dyneema® nets as controls, were mounted on a rigid frame and immersed in seawater at Livorno touristic Harbor (Italy). The nets were monitored every two weeks for 14 weeks, from early March to late June 2025, with photographic documentation. At the end of the exposure, efficacy was assessed by cleaning the samples with a high-pressure water jet (150 bar, 50 cm distance) for 10, 20, 60, and 90 seconds. Photographic data were analyzed using ImageJ software to quantify fouling coverage, mesh occlusion, and cleaning efficiency. The results showed that nets treated with PDMS-based coatings were more effective than controls in reducing surface coverage, occlusion, and improving cleaning efficiency. Of all treated samples, the coating with 180 mg/L *P. oceanica* extract was the most effective across all parameters. This improvement was particularly evident up to the sixth week, with significant reductions in fouling coverage and mesh occlusion compared to all other treated nets, and higher cleaning performance even after 90 seconds of water-jet exposure. These findings highlight the potential of *P. oceanica* leaf extracts as bioactive additives in silicone coatings. This approach provides a nature-based antifouling strategy for sustainable aquaculture and offers opportunities for further study through laboratory tests.

4.05.P Environmental Risks of (New) Chemicals Used in Maritime Transport

4.05.P-We324 Ecotoxicity and circular revalorization of Bio-Sourced and Thermosetting Polymeric Coatings

Mariana Bruni Marques do Prado e Silva¹, Diogo Filipe Nunes Cardoso², Victor Neto² and Roberto Martins³, (1)CESAM & Department of Biology, University of Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)CESAM - Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal

Protective coatings are among the most widely used and industrially relevant coatings, and within this category, those based on synthetic polymers are a key class of materials that can be broadly divided into thermoplastic and thermosetting materials. However, coatings, especially the thermosetting ones used in high-performance applications, pose significant environmental concerns. Given the unlikely elimination of polymers from our

society, it is crucial to better understand the environmental risks associated with coatings and to develop strategies to revalorize and upcycle end-of-life polymeric materials, which are currently treated as non-added-value waste. Therefore, this work aims to present a holistic framework along with the very first results of the assessment of the environmental hazard of innovative bio-sourced coatings (alkyd-based) and conventional thermosetting coatings (polyurethane-based). This assessment involves standard ecotoxicological assays exposing eight different marine species to the compounds' leachates over time, evaluating endpoints such as growth inhibition, embryotoxicity, air survival, condition index, and biochemical biomarkers. The revalorization potential of end-of-life polymeric materials will also be evaluated through additive manufacturing using degraded materials in the matrix to produce 3D printing filaments, as well as through bioconversion methods based on the capacity of yellow mealworms (larvae of *Tenebrio molitor*) to digest these materials. This includes assessing their survival, growth and bioconversion rates to create novel add-value eco-products, contributing to the reduction of coatings' environmental footprint and a "zero" pollution environment.

4.05.P-We325 Are Innovative Ultra-Low Friction Silicone Foul-Release Coatings Viable Green Alternatives?

Diogo Gama¹, Joana Figueiredo², Anand Lopez³ and Roberto Martins², (1)Department of Biology, University of Aveiro, Portugal, (2)CESAM, University of Aveiro, Portugal, (3)GIT Coatings, Canada

The colonization and adhesion of fouling organisms to submerged metal infrastructure pose a persistent challenge for the global maritime sector, with profound economic and environmental implications. Conventional approaches, centered on biocidal antifouling coatings, have been adopted to mitigate this phenomenon; however, their toxic impact has not been sufficiently explored. The main active components of these polymeric antifouling coatings, such as organic or metallic biocides, demonstrate toxicity to several non-target species. In this context, silicone-based foul-release coatings (FRCs) emerge as an alternative due to the absence of biocides in their formulation and the surface characteristics that hinder adhesion or facilitate the removal of organisms. The present study aims to evaluate the ecotoxicity of leachates from four commercial FRC coatings from the company GIT (XGIT-FUEL Black, XGIT-FUEL Blue, XGIT-FUEL Red, and XGIT-FUEL White), comparing them with a commercial paint containing copper. The coatings were applied to microscope glass slides (n=3 for each coating) and immersed in aerated artificial seawater for up to one year, with periodic collection of water aliquots containing the coatings' leachates for physical-chemical analysis and ecotoxicological testing. To assess ecotoxicity, three species of microalgae were tested (*Chaetoceros calcitrans*, *Phaeodactylum tricornutum*, and *Tetraselmis chuii*; ISO 10253), a rotifer (*Brachionus plicatilis*; ISO 19820), and a crustacean (*Artemia salina*; ASTM E1440-91). The results showed that globally the tested FRC coatings did not have a significant effects on the four species tested over time (when significant effects were detected, they were limited to a maximum of +20% relative to the negative control). However, the commercial self-polishing coating (SPC) containing copper caused acute toxicity in *Brachionus plicatilis* after just one day of immersion, associated with the release of a high amount of copper. Overall, these results suggest that the FRCs currently marketed by GIT are promising alternatives, with a lower environmental impact than the most commercially successful category of antifouling coatings /Cu-based SPC) worldwide.

4.05.P-We326 Biodiesel Produced in Brazil as Candidate Low-Carbon Fuel for Maritime Transportation under the International Maritime Organization Strategy on Reduction of Greenhouse Emissions from Ships

Lucas Pereira¹, Nilza Patrícia Ramos¹, Priscila Sabaini¹, Wellington dos Santos² and Marília Folegatti¹,
(1)Embrapa Environment, Brazil, (2)Embrapa Agroenergy, Brazil

The International Maritime Organization (IMO) has launched a strategy to reduce greenhouse gas (GHG) emissions from ships, which account for 3% of global emissions, in support of the UN Sustainable Development Goal 13 (take urgent action to combat climate change and its impacts). Projections indicate that 64% of the reduction by 2050 will be achieved using low-carbon fuels, such as biodiesel, of which Brazil is the world's third-largest producer, with 9.1 billion liters produced by 58 plants in 2024. Its origin from renewable biomass and residues, combined with significantly lower GHG emissions compared with conventional fuels, makes biodiesel an important contributor to the country's energy matrix and a valuable candidate low-carbon fuel for maritime transportation.

Our study assessed the GHG emissions of biodiesel from soybean and beef tallow, which account for 72.4% and 6.4% of the feedstock used in Brazil in 2024, respectively, following the methodological rules set in the IMO Life Cycle Assessment Guidelines. The scope included the biofuel production to the end-use (Well-to-Wake or WtW), which is the combination of scopes Well-to-Tank (WtT) (from primary production to the transportation of the fuel to the ship's tank) and Tank-to-Wake (TtW) (from the ship's fuel tank to the exhaust). For soybean biodiesel, the WtT scope encompasses soybean production, the extraction of vegetal oil and its conversion to biodiesel, and the transportation stages. For tallow biodiesel, in addition to the conversion to biodiesel, the industrial stage includes the treatment of tallow, a by-product of the slaughterhouse.

Results indicate GHG emissions for biodiesel of 9.78 (WtT for tallow), and 23.84 (WtT for soybean, not including land use change), plus 4.18 g CO₂e/MJ (TtW for both feedstocks). We found that fossil CO₂, from methanol used during the transesterification process in all biodiesel plants in Brazil, released during fuel combustion on the ship (TtW), has a significant impact of 3.74 g CO₂e/MJ. Using ethanol instead of methanol could reduce the impact to 0.48 (TtW). Overall, biodiesel compares favorably with heavy fuel oil, a conventional maritime fuel with emissions of 91.60 g CO₂e/MJ (WtW).

Biodiesel, which is a well-established biofuel in Brazil with a capacity capable of providing a large increase in production, can be a valuable piece of the IMO's strategy to reduce the GHG emissions from ships globally.

4.05.P-We327 Environmental Risk Assessment of 'Green' Fuels in shipping

Janne Fritt-Rasmussen, Kim Gustavson, Christian Juncher Jørgensen, Ane Lopez de Gamiz Zearra, Sofie Amalie Sønderby Rask and Anne Sofie Lansø, Aarhus University, Denmark

International shipping is currently undergoing a profound transformation driven by the global ambition to achieve climate neutrality. Central to this transition is the replacement of conventional fossil fuels with alternative energy to fossil fuels often referred to as 'green' fuels. While the climate benefits of adopting green fuels are evident, particularly in terms of lowering CO₂ emissions to the atmosphere, the broader environmental implications remain insufficiently understood. Unlike conventional fossil marine fuels, which have well-documented spill scenarios and established response strategies, green fuels present novel challenges and a need for a systematic assessment of environmental risks associated with accidental spills, operational discharges, and long-term exposure in marine ecosystems.

Our research addresses this knowledge gap by conducting a comprehensive environmental risk assessment of spill and operational discharges of the green fuels ammonia and methanol intended for maritime use. The present assessment integrates literature values on chemical property analysis, and an ecotoxicological evaluation, with a comprehensive scenario-based modeling to estimate dispersion and concentrations in seawater and air under different spill conditions and localities in Danish waters. By simulating worst-case scenarios and operational leakage/discharges events, we aim to identify critical thresholds for toxic effects on marine organism and seabirds and inform the development of mitigation strategies.

4.05.P-We328 Effects of Ammonia Fuel Spills on Marine Microorganisms: Initial Insights from a Mesocosm Experiment.

Julie Svendsgaard, Janne Fritt-Rasmussen, Kim Gustavson, Christian Juncher Jørgensen, Hans Jakobsen and Sofie Amalie Sønderby Rask, Aarhus University, Denmark

Ammonia (NH₃), projected to become a dominant marine fuel by 2050, is a well-known inorganic nitrogen compound with documented toxicity to aquatic organisms. However, knowledge of its behaviour, ecological effects and potential cumulative impacts under high-concentration spill scenarios remains limited. Because microorganisms play a key role in biogeochemical cycling, understanding their response to NH₃ spills is critical for assessing ecosystem-level impacts.

We conducted a 14-day in situ mesocosm experiment in a Danish fjord (summer 2025), exposing natural microbial assemblages (<200 µm) to seven pulse additions of NH₃ across a concentration gradient (2–200 mg NH₄OH-N/L). Changes in phytoplankton and heterotrophic bacterial populations were assessed using flow cytometry, while nutrient speciation, pH, and oxygen dynamics were monitored. Preliminary results indicate that concentrations >20 mg NH₄OH-N/L suppressed phytoplankton growth throughout the experiment, with phytoplankton fluorescence recovery observed at 20 mg NH₄OH-N/L after 12 days. During the first week, growth inhibition occurred at 4–9 mg NH₄OH-N/L.

Our preliminary findings suggest that NH₃ spills at the tested concentrations may pose lethal risks to lower trophic levels in coastal marine ecosystems. Pending our chemical and community composition data, we expect to gain further insights into exposure thresholds and community recovery dynamics. Ultimately, our goal is to quantify the ecotoxicity of NH₃ spills at phytoplankton and bacterial population level and assess their implications for coastal marine ecosystem functioning.

4.06 Filling the Gap: Solutions for Monitoring, Modelling and Assessment of Chemical Pollution Under Data Scarcity and Low-Capacity Conditions

4.06.T-01 Fuelwood Consumption Patterns and Spatial Distribution of PM_{2.5} and PM₁₀ Emissions in Thulamela Municipality, Limpopo Province, South Africa.

Ibironke Titilayo Enitan¹, Stuart Piketh² and Joshua Edokpayi¹, (1)Department of Geography and Environmental Sciences, University of Venda, Thohoyandou 0950., South Africa, (2)Unit for Environmental Sciences and Management, North-West University, South Africa

Fuelwood remains a dominant household energy source in Thulamela Municipality, contributing significantly to fine particulate pollution and associated health risks. This study examines household fuelwood consumption patterns and maps the spatial distribution of PM_{2.5} and PM₁₀ emissions resulting from residential wood combustion (RWC). Fuelwood activity data were obtained through scale-based measurements from households in Gondeni and Lunungwi villages. A bottom-up emission estimation approach was applied, integrating seasonal activity data with established emission factors, and allocating emissions across the municipality at 1-km resolution. The results show clear seasonal variation in daily fuelwood use, with households consuming 7.27 kg/day in summer, 10.33 kg/day in autumn, 12.92 kg/day in winter, and 7.61 kg/day in spring. Winter exhibited the highest levels of both wood consumption and particulate emissions. Average annual household emissions were estimated at 5.34×10^{22} t/year for PM_{2.5} and 6.04×10^{22} t/year for PM₁₀. Spatial analysis revealed distinct emission hotspots in the municipality's southwest and northwest, aligning with densely populated settlements that rely heavily on fuelwood. This study provides the first spatially resolved baseline for PM_{2.5} and PM₁₀ emissions in Thulamela Municipality, South Africa, related to the RWC. The findings fill a critical data gap in rural household energy emissions and offer a valuable decision-support tool for clean-cooking initiatives, targeted air-quality management, and future exposure-risk modelling in low-income communities.

Keywords: Residential wood combustion (RWC); PM_{2.5} and PM₁₀ emissions; Fuelwood consumption; Spatial distribution; Bottom-up emission approach; Thulamela Municipality; South Africa; Air-quality management.

This research was supported by the National Research Foundation (NRF) through the NRF Postdoctoral Fellowship Award (grant number PSTD240502217020); the Eskom Power Plant Engineering Institute (ESKOM, grant number E349); and the Research and Publications Committee (RPC) of the University of Venda (project number SES/19/ERM/11).

4.06.T-02 Toxicity assessment of sediments under the influence of submarine outfalls along the coast of São Paulo, Brazil.

Karin Cristine Baldauf¹, Josiane Vendemiatti¹, Anjaina Fernandes de Albuquerque¹, Gabriely Fernanda Groto Militão², Eliezer Oliveira³, Bianca Ferreira da Silva³, Leandro Hantao³, Amanda dos Santos⁴ and Gisela Umbuzeiro¹, (1)State University of Campinas (UNICAMP), Brazil, (2)State University of Campinas - Unicamp, Brazil, (3)Universidade Estadual de Campinas, Brazil, (4)Universidade Estadual Paulista – Unesp, Brazil

Combining toxicity and genotoxicity tests, along with chemical analysis, is a solid strategy to assess the quality of sediment samples affected by submarine outfalls. This study aimed to evaluate the quality of sediment samples collected in areas impacted by these discharges along the São Paulo coast in Brazil. Acute and chronic tests were conducted using the tropical epibenthic organism *Parhyale hawaiensis*, as well as the *Salmonella*/microsome assay. Non-target chemical analysis was also performed. Sediment samples were collected from areas subjected to three wastewater submarine outfalls (Praia Grande, Praia das Cigarras, and Santos). Mortality (96h) and reproduction inhibition (49d) tests with *P. hawaiensis* were performed with whole sediment. The *Salmonella*/microsome was performed using a miniaturized protocol with strains YG1041, TA98, and TA100, in the absence and presence of metabolic activation. An exploratory non-target screening of organic fractions was conducted using UHPLC–Orbitrap HRMS. Low mortality was observed only for Praia Grande. In the reproduction test, organisms exposed to sediments from Praia Grande and Praia das Cigarras produced fewer neonates per surviving female than those exposed to Santos's sediment, and all sediment samples resulted in fewer neonates than the control. Sediments from Santos and Praia Grande were mutagenic for strain YG1041 with and without metabolic activation, while Praia das Cigarras showed mutagenicity only with metabolic activation, suggesting the presence of mutagenic substances related to aromatic amines and nitrocompounds in Praia Grande and Santos, and mainly aromatic amines in Praia das Cigarras. A total of 82 compounds were identified in at least one sediment extract: 32 in Praia das Cigarras, 14 in Santos, and 39 in Praia Grande. These compounds were classified into three categories: Pharmaceuticals and Personal Care Products (PPCPs), Industrial, and Others. Santos' sediment consisted mainly of sand and had the fewest detected compounds, possibly due to its lower organic matter content. These results indicate that higher organic matter content may contribute to greater retention and diversity of chemical compounds in the sediments. These results highlight not only the need for continuous monitoring but also the inadequacy of relying solely on primary treatment and dilution at sea, reinforcing the urgency for improved wastewater management strategies to reduce ecological risks in coastal environments.

4.06.T-03 From source to solution: understanding antibiotic residues in an Indonesian reservoir

Miranti Ariyani, Milou G.M van de Schans, Pieter van Oel and Nynke Hofstra, Wageningen University and Research (WUR), Netherlands

The presence of antibiotic residues in the tropical reservoirs remain largely unknown. Lack of understanding is particularly clear in regions where the types, patterns, and sources of antibiotics are poorly documented. Understanding the occurrence and sources of antibiotics is essential for designing effective management strategies. This study assessed the occurrence, sources, future impacts, and mitigation strategies for antibiotics in the Cirata reservoir, Indonesia. In total 21 of 65 targeted residues were detected in water of the reservoir belonging to six different classes: sulfonamides, diaminopyrimidines, lincosamides, tetracyclines, fluoroquinolones, and amphenicols. Ecotoxicological risks ranged from medium to critical, particularly for the antibiotic residues: sulfamethoxazole, ciprofloxacin, norfloxacin, lincomycin, with ciprofloxacin posing the greatest threat to cyanobacteria. Moreover, the class of fluoroquinolones may also promote the selection of antibiotic-resistant bacteria. Based on their occurrence and risk, 12 antibiotics were prioritized. By developing and using the improved MARINA-Antibiotics model, we assessed the sources, future state, and effectiveness of management strategies. Direct animal manure discharge, primarily from sheep, cattle, and broiler farming, was identified as the dominant source of antibiotics. Under an economy-driven, strong climate change scenario (SSP5–RCP8.5), antibiotic concentrations were projected to remain ecologically risky. Strategies targeting livestock, crop, and aquaculture production, as well as human-derived sources, were evaluated for their potential to reduce antibiotic concentrations. Due to the link between antibiotic residues and nutrients, commonly used nutrient-based strategies were modeled to evaluate their potential in mitigating antibiotic residue levels. These

strategies could lower concentrations by up to 41% by 2050, and reductions of up to 70% become achievable when combined with antibiotic-specific measures. This study represents an important step toward a comprehensive understanding of antibiotic occurrence and sources in Indonesian reservoirs, offering critical insights to inform targeted interventions aimed at mitigating ecological risks and the long-term impacts of antibiotic residues on the reservoir. Moreover, this study can be helpful for developing management solutions for other reservoirs facing similar socio-environmental and climate-hydrological challenges.

4.06.T-04 Global Pilot Study: Monitoring Chemical Pollution under Low-Capacity Conditions

Saskia Finckh¹, Arundhati Tewari², Faith Kandie³, Christian Schmidt¹, Saeed S. Albaseer⁴, Iker Alvarez-Mora⁵, Natalie Aneck-Hahn⁶, Sara G. Chemical pollution is a global challenge. Composition, sources, and impacts vary regionally, posing significant risks to water resources, human health, and ecosystems. Although data on chemical pollution are rapidly increasing in high-income regions, such as Europe and North America, information from low- and middle-income countries in Africa, Asia, and Central and South America remains scarce. Nevertheless, awareness of chemical pollution is growing worldwide, and dedicated scientists and practitioners are prepared to address these challenges within their countries.

In this context, a global pilot study emerged from the workshop “Solutions for the ONE WORLD: Monitoring Chemical Pollution under Low-Capacity Settings”, held in September 2025 at the Helmholtz Centre for Environmental Research (UFZ) in Leipzig, Germany, in partnership with the International Panel on Chemical Pollution (IPCP) and the World Water Quality Alliance (WWQA). The workshop brought together international experts in chemical monitoring, with a particular focus on the Global South, who established a global network to advance solutions to chemical pollution.

The overarching aim of the pilot study was to demonstrate the potential of chemical pollution monitoring under low-capacity conditions. Therefore, 300 water samples from urban, agricultural and pristine rivers (as a control) in 29 countries worldwide were investigated for approx. 500 target substances using liquid chromatography high-resolution mass spectrometry (LC-HRMS). The countries from which samples were collected include Argentina, Australia, Brazil, Canada, China, Costa Rica, Czech Republic, Ethiopia, France, Germany, Ghana, India, Italy, Japan, Kenya, Lebanon, Malaysia, Mexico, New Zealand, Nigeria, Pakistan, Republic of Korea, Serbia, South Africa, Spain, Sri Lanka, Sweden, Tanzania, and USA. Preliminary results show substantial variation in the occurrence and concentrations of organic micropollutants across the sampled sites.

In summary, the present study advances our understanding of micropollutant impacts by conducting the first coordinated global monitoring initiative in rivers with varying degrees of anthropogenic impact. Our vision is to contribute to the establishment of a growing global chemical monitoring network that enables more consistent data generation, fosters capacity-building, and supports the development of solution-oriented strategies to reduce chemical pollution worldwide.

4.06.T-05 Beating data-hungriness: How molecule, company, catchment and organism dimensions facilitate derivation of principles and parameterisation of models in risk and life cycle assessment

Jan A.J. Hendriks¹, Félix Leiva², Bingqing Lu³, Luke Ockhuijsen², Jasmijn Polinder², Louise Schreyers², Jie Xiong² and Filippos Zisopoulos², (1)Radboud University, Netherlands, (2)Department of Environmental Science, Radboud University, Nijmegen, Netherlands, (3)Department of environmental science, Radboud University, Netherlands

Setting: Over the last decades, anthropogenic pressures on the environment have dramatically intensified and diversified. Nowadays, we have to deal with 100,000+ pollutants, sites and species.

Relevance: While models are available, application to thousands of cases is severely limited by data gaps due to financial, ethical, disciplinary and other constraints. As an alternative, missing information can be obtained by linking parameters to well-known chemical, hydrological, socio-economic and biological characteristics, in particular size (e.g., molecular mass, company revenue, catchment area, body weight).

Objectives: Consequently, the overall aim of the present study is to obtain a cross-disciplinary suite of statistical and mechanistic relationships for environmentally relevant parameters (quantities) in assessment models as a function of size and other descriptors, underpinned by overarching scaling principles. We focus on pollutants, covering emission and fate in catchments and cities, accumulation in organisms and effects on communities.

Methods: Based on data from reviews, databases and articles, we derive empirical and theoretical relationships for rate, time, density and other quantities Y (parameters) as a power ($Y = a \cdot X^b$) function of company, catchment, organism and community size X . We cover e.g., emission of waste from companies, transport of water in river basins, circulation of blood in organisms and transfer of biomass in communities including the pollutants these processes generate, carry and degrade.

Results: First, we will report examples of statistical regressions obtained. For instance, emission of pollutants is related to engine, company and city size, comparing scaling of fossil fuel combustion to biomass respiration.

Flow of water through lakes, rivers, plants and animals is linked to their volume as well. Perfusion of organs by blood is an allometric function of body weight. Size distributions of micro- and macroplastic particles in water are compared those of organisms in aquatic systems (usually called size spectra). Most of the variability is explained by size but other global variables like temperature can contribute as well.

Conclusions: Identifying overarching principles based on shared system characteristics (e.g., size, dimension), the integrated suite of theoretical and statistical relationships obtained 1) profoundly advances our understanding and 2) crucially reduces data-hungriness of assessment tools.

4.06.P Filling the Gap: Solutions for Monitoring, Modelling and Assessment of Chemical Pollution Under Data Scarcity and Low-Capacity Conditions

4.06.P-Th165 Low-Budget Field SPE Kit for Water Sampling

Isaac Cheruiyot Tanui¹, Faith Kandie², Saskia Finckh¹, Werner Brack¹ and Martin Krauss¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Moi University, Kenya

Continuous releases of complex chemical mixtures have made the comprehensive monitoring and assessment of organic micropollutants in water resources more urgent than ever. Yet, the monitoring of organic micropollutants remains constrained by analytical, logistical, and financial limitations. Even in Europe, monitoring programs typically target only a limited number of regulated substances, leaving many chemicals unassessed. In the Global South and other regions, monitoring is even more scarce due to restricted access to advanced instrumentation (GC-MS, LC-MS/MS), high operational costs, and other resource-related barriers. Conventional approaches for analyzing organic micropollutants involve typically laboratory-based extraction after sampling, that can be prohibitively expensive, particularly for developing economies. This presentation highlights the development of a cost-effective sampling method that uses easily accessible devices and is suited for regions with limited resources. Because this method is considerably cheaper than existing alternatives, it can be implemented globally, allowing datasets to be compared across regions and providing valuable insight into the occurrence of chemical mixtures in the environment. The goal of this study was to develop and evaluate an inexpensive, reliable method for monitoring organic contaminants in water using a low-budget field sampling kit. During the method development, we (i) assessed chemical losses due to filtration using the kit, (ii) evaluated recoveries for the combined filtration and solid-phase extraction (SPE) step, and (iii) examined the stability of compounds stored on SPE cartridges under different temperature and storage durations

4.06.P-Th166 Monitoring Fuel-related Volatile Organic Compound exposure in Low-Capacity Contexts: Lessons from Petrol Filling Stations in South Africa

Suranie Horn, Stefan Linde, Lize Van Der Westhuizen and Jeanre Deysel, North-West University, South Africa

Petrol, diesel, and their emissions release various hazardous chemical agents, including volatile organic compounds (VOCs) such as benzene, toluene, ethylbenzene, and xylene (BTEX) into the surrounding air. Petrol filling attendants and the public are exposed to these hazardous chemical agents (HCAs), many of which are linked to adverse health effects. Regulatory guidelines in the form of occupational exposure limits (OELs), such as those outlined in the South African Regulations for Hazardous Chemical Agents, 2021 (RCHA) for VOCs, aim to minimise risk for workers. Despite international research on fuel-related exposures, data from South African contexts remain limited. This study was conducted at a petrol filling station, where personal exposure to VOCs among petrol filling attendants was assessed using TraceAir® II passive badges placed in the breathing zone, following the NIOSH 1500/1501 method. Environmental monitoring was also performed by placing TraceAir® II passive badges on tripods positioned at 1.5 meters from the ground to measure VOC concentrations. The TraceAir® II badges were analysed for BTEX. Environmental conditions were also monitored during the sample collection period, and measured airflow, temperature, relative humidity and carbon monoxide. In addition, the cancer risk and hazard quotient (HQ) (non-cancer risk) were calculated according to USEPA guidelines. All measured BTEX 8h-TWA concentrations were below the regulatory limits set by the RCHA (2021). Personal exposure to BTEX was higher ($p < 0.05$) compared to area exposure monitoring results. All benzene samples under the low exposure scenario (3 days) exceeded the lifetime cancer risk threshold as set by the USEPA. Under the high exposure scenario (5 days), the majority of the samples also exceeded this threshold. Hazard quotient values for toluene and ethylbenzene were below 1, indicating minimal non-cancer risk. Xylene HQ values ranged from 0.695 to 3.517, suggesting potential non-cancer health concerns in some cases. Although BTEX levels were within regulatory limits, chronic low-level exposure and cancer risks from benzene, alongside xylene's non-cancer hazards, highlight the need for improved exposure control measures. These findings provide baseline data to support informed decision-making on worker safety.

4.06.P-Th167 A Passive Sampling Study of Volatile Organic Compounds in Skopje: Seasonal Trends and Potential Emission Sources

Volatile organic compounds (VOCs) represent important urban air pollutants, contributing to photochemical smog formation and posing risks to human health. Skopje, the capital of Macedonia, is often ranked among Europe's most polluted urban centers due to consistently poor air quality. Using the passive sampling approach, this study demonstrates a practical method for VOC monitoring under data-scarce, resource-limited conditions. It provides the first comprehensive, year-long assessment of VOCs in Skopje's ambient air, conducted at five representative sites using Radiello passive samplers to evaluate monthly average concentrations, seasonal patterns, probable primary sources, and ozone formation potential (OFP). VOCs from different chemical classes were detected, including aliphatic and aromatic hydrocarbons, terpenes, and hydrocarbon derivatives. VOC levels were highest in winter, driven by traffic, domestic heating, and industrial activity, while summer concentrations were lower due to photochemical degradation and enhanced atmospheric dispersion. Analysis of BTEX, including toluene/benzene (T/B) ratios and correlation patterns, indicated that traffic was the dominant emission source, with additional contributions from industrial activities and waste management at specific locations. Principal component analysis further identified six source-related factors: mixed traffic, solvent and industrial emissions, biogenic sources, fuel evaporation, personal care products, and industrial/petroleum-related VOCs. Meteorological parameters also played a role in VOC levels and trends, with aromatic and aliphatic compounds showing negative correlations with temperature, UV radiation, and ozone, while fine particulate matter (PM_{2.5}) correlated positively with aromatic compounds and terpenes. OFP analysis indicated that highly reactive species, such as toluene, xylenes, C₆–C₃ substituted benzenes, and n-tetradecane, contributed disproportionately to ozone formation despite their lower ambient concentrations. Overall, this study provides essential baseline data on VOC levels, sources, and atmospheric behavior in Skopje, supporting evidence-based air quality management and targeted emission controls. The results underscore the need to address both mobile and stationary sources and are relevant for other urban areas in Macedonia and the Western Balkans. Future work in Skopje should expand monitoring to additional sites and assess health risks from long-term VOC exposure.

Disclaimer/Disclosure:

Support for this study was gratefully provided by the Macedonian Ecological Society within the project "Development and application of methods for monitoring of volatile and semi-volatile organic compounds in the air of Skopje", financed under the "Intermediate Grants Program for Young Ecologists".

4.06.P-Th168 Legacy and Emerging Pesticides in Fish from the Letaba and Inkomati Catchments in Southern Africa.

Victor Wepener¹, Marelize Marsay¹, Chinemerem Ruth Ohoro², Collins Nimako³, Yoshinori IKENAKA⁴, Yared Yohannes⁴, Nicholas J Smit¹ and Mayumi Ishizuka⁴, (1)North-West University, South Africa, (2)University of South Africa (UNISA), South Africa, (3)No Affiliation, United States, (4)Hokkaido University, Japan

The rapid population growth across Africa has increased the demand for food production, resulting in increased pesticide use. South Africa is among the top four pesticide importers in Sub-Saharan Africa, raising significant concerns regarding the contamination of freshwater ecosystems. Organochlorine pesticides (OCPs), historically used for agriculture and vector control, persist in the environment due to their high lipophilicity and long half-lives. Despite bans on many OCPs, residues remain in aquatic systems, potentially affecting non-target organisms such as fish. Similarly, neonicotinoids, introduced as safer alternatives, are now linked to adverse effects on aquatic biota, yet little is known about their bioaccumulation in wild fish species in Southern Africa. This study investigated 13 neonicotinoids and 19 OCPs in fish muscle tissue from the Inkomati and Letaba catchments. Only two OCPs, p,p'-DDE and p,p'-DDD, were detected, likely due to ongoing DDT use in malaria control. Concentrations were generally low and varied between sites, with higher values found in the Letaba catchment. Neonicotinoids were detected at low concentrations, with acetamiprid and imidacloprid being the most prevalent, although the concentrations were lower than those reported globally. Muscle tissue, representing long-term exposure, may underestimate total pesticide burdens due to lower lipid content. Findings suggest historical contamination and ongoing inputs from agricultural and disease control practices. Although concentrations were below levels of concern for vertebrates, this study highlights the need for continued monitoring and expanded tissue analysis to better understand bioaccumulation and ecological risks in Southern African freshwater systems.

Keywords: neonicotinoids, OCP, DDT, freshwater fish, bioaccumulation

4.06.P-Th169 From Monitoring to Human Health Assessment: Contaminant Burdens and Nutritional Benefits in Azorean Fish under the MoniPOL Programme

Joana Da Rosa, Joana Goulart, Sofia Oliveira, Inês Duarte and Inês Martins, Institute of Marine Sciences - Okeanos, University of the Azores, Portugal

Long-term contaminant monitoring programmes are essential for safeguarding public health in remote regions with high fisheries dependency. In the Azores, where fish consumption exceeds national and European averages and where volcanic and hydrothermal processes influence metal availability, robust baseline information on contaminant burdens in seafood remains scarce. At the same time, fish provides key nutritional benefits, reinforcing the need for integrated risk-benefit assessment.

The MoniPOL programme was established in 2022 to address this information gap by systematically evaluating both contaminant loads and nutritional quality in regionally important species. Species were selected according to landing prevalence, consumer preference and biological traits linked to contaminant uptake. Muscle and liver tissues were analysed for cadmium, mercury, lead and arsenic, alongside energy content, total fat, protein and moisture. This combined dataset enables the identification of sentinel species, supports long-term surveillance and provides evidence required for consumer guidance and policy development.

Marked interspecific variability was observed. Mercury concentrations exceeded EU limits in some deep-dwelling species, and cadmium levels in the Azorean limpet, a highly valued regional delicacy, surpassed the maximum regulatory threshold for molluscs by 137%, indicating a potential dietary risk for frequent consumers. Arsenic was consistently the most abundant element, especially in demersal species, reflecting natural geochemical conditions and indicating the need for continued assessment. Nutritional profiles also varied widely: some species exhibited favourable protein and energy content with comparatively low contaminant levels, whereas others combined lower nutritional value with elevated contaminant burdens, reducing their suitability from a risk-benefit perspective.

By generating the first integrated contaminant-nutrient baseline for Azorean fish, MoniPOL provides a practical and scalable framework for chemical pollution assessment in data-poor, low-capacity regions. The programme strengthens the scientific basis for transparent risk-benefit communication, supports fisheries and public health policy, and contributes directly to SETAC's objectives on improving human exposure assessment and enabling evidence-based regional management.

4.06.P-Th170 Sharing the experience from the Spanish Monitoring Programme on POPs in Support of the Stockholm Convention

Maria Angeles Martínez¹, Pere Colomer Vidal², Adrian De la Torre³, Juan Muñoz-Arnanz², Irene Navarro¹, Jose Luis Roscales², Covadonga Alonso¹ and Begoña Jiménez², (1)Center for Energy, Environmental and Technological Research (CIEMAT), Spain, (2)Institute of Organic Chemistry - Spanish National Research Council (IQOG-CSIC), Spain, (3)Unit of POPs and Emerging Pollutants in the Environment, Department of Environment, Spain

Effective environmental policies are mandatory in order to protect the environment from chemical pollutants. The Stockholm Convention is a legally binding treaty signed in 2001 with the aim to protect the environment and human health from Persistent Organic Pollutants (POPs). Long-term monitoring of POPs based on a coordinated network, with consistent methodology and analytical procedures, is highly valuable for understanding the spatial distribution of these contaminants and for establishing a baseline to evaluate the effectiveness of regulatory measures. This study aims to assess in Spain the distribution and chemical profiles of POPs in core environmental matrices (air and water) proposed by the Global Monitoring Plan in support of the SC. The assessment is based on a single coordinated sampling network: the Spanish Monitoring Programme on POPs. To date, passive air (PUF-PAS) monitoring data from 23 locations across Spain between 2008-2023 and surface water monitoring data from 8 sites in the Tagus and Douro River basins collected between 2013-2024 have been assessed.

Air monitoring sites represented a wide range of environmental settings, including remote, rural and urban areas, which allows for the evaluation of the anthropogenic pressure influence on POP levels and profiles. Higher concentrations were observed in urban and suburban areas compared to rural and remote sites, along with significant decreasing trends for most legacy compounds (PCDD/Fs, PCBs, PBDEs, DDTs, HCB), indicating the effectiveness of existing regulatory measures. Yet, slow decline rates for certain substances suggest ongoing environmental persistence. Surface water monitoring revealed marked spatial variability in PFAS concentrations, with higher levels at sites influenced by urban activity. While stable or decreasing trends were observed for some compounds, increasing patterns at specific locations point to potential ongoing inputs or

delayed responses to regulatory controls.

The assessment strategy of the SMP-POPs highlights the complementary value of air and water monitoring for characterizing pollutants' behavior, identifying hotspots and supporting integrated risk management strategies. This data set from Spain serves as a baseline for future assessments of temporal and spatial trends at global scale. Our findings reinforce the need for sustained and harmonized monitoring to track long-term trends and guide effective environmental policies under international objectives.

4.07 From Complexity to Clarity: Next-Generation and AI-Driven Approaches for Smarter Assessment and Regulation of Chemical Mixtures

4.07.T-01 Strategies for Chemical Mixtures Assessment in Consumer Products: Integrating Realistic Exposure and Toxicity Mechanisms Using Korean Product Data as a Case Study

Gaeul Yang¹, Yongmin Jung¹, Keon Kang², Donghyeon Kim³, Ajaya Kumar Sahoo⁴ and Jinhee Choi¹, (1)University of Seoul, Korea, Republic of, (2)School of Environmental Engineering, University of Seoul, Korea, Republic of, (3)Department of Applied Biosciences, University of Seoul, Korea, Republic of, (4)University of Seoul, India

Humans are routinely co-exposed to complex chemical mixtures through consumer products. However, traditional toxicity assessments typically focus on single chemicals, limiting our understanding of mixture toxicities. To make mixture studies applicable to risk management, both real-world exposure—including realistic combinations of chemicals and their mixing ratios—and the mechanistic basis of mixture toxicity need to be considered, rather than simply reporting mixture effects. This study aimed to develop an assessment strategy for chemical mixtures in consumer products that integrates both realistic exposure and toxicity mechanisms.

We first identified chemical combinations actually present in Korean consumer products and selected Triclosan and 1,2-Benzisothiazol-3(2H)-one (BIT), two widely used preservatives, as case studies. Cytotoxicity was evaluated using four human cell lines representing key target systems: HepG2 (liver), BEAS-2B (respiratory), SH-SY5Y (nervous), and Jurkat (immune). Predicted cytotoxicity of mixtures was estimated using concentration addition (CA) and independent action (IA) models. The observed effects of mixtures were then compared with predicted values through the model deviation ratio (MDR) approach.

For the realistic-exposure track, we combined cytotoxicity testing of 1:1 equimolar mixtures with exposure assessment based on the tested ratios to characterize product-related risks. Seven combinations exhibited synergism in one or two cell lines. Exposure assessment was then performed for consumer products containing these synergistic mixtures, including cleaners, laundry detergents, and deodorizing agents. For the mechanistic track, we tested EC20-based equitoxic mixtures together with mode-of-action analysis. Sixteen combinations exhibited synergism in one or two cell lines, and mixture effects were highly cell line-dependent. Synergism was more frequently observed in SH-SY5Y and Jurkat cells, likely reflecting differences in metabolic and antioxidant capacity and membrane-related toxicokinetics.

This study proposes an integrated framework for assessing mixtures in consumer products using two complementary tracks. By integrating the results from both tracks, this approach helps identify the mechanisms underlying mixture effects in products and assess whether these effects are likely to occur at realistic exposure levels, thereby informing the prioritization of mixtures for risk management.

4.07.T-02 BPA-Equivalents: An Effective Tool to Assess Mixture Toxicity and Substitution Scenarios of BPA and its Alternatives

Vanessa Srebny¹, Beate Escher², Georg Braun² and Niklas Wojtysiak², (1)Eberhard Karls University of Tübingen, Germany, (2)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

Bisphenol A (BPA) is an industrial chemical and endocrine disruptor phased out in Europe and therefore replaced by often structurally very similar alternatives. Monitoring data revealed that humans and the environment are already exposed to mixtures of BPA substitutes. Due to their shared structure and estrogenic activity, concentration-additive effects are expected for such mixtures.

We designed seven multi-component mixtures of BPA and up to nine alternatives based on European surface-water concentrations and tested them in five in vitro assays that are relevant for BPA and its substitutes.

Measured mixture effects aligned well with predictions for concentration addition for cytotoxicity, estrogenicity, and mitochondrial toxicity. Therefore, BPA-equivalents (BPA-EQ) could be used as a simplifying metric for interpreting mixture effects and for substitution scenarios.

Adding the five most frequently detected bisphenols to BPA increased total concentrations nine-fold but raised BPA-EQs 24-fold for estrogenicity and 12-fold for cytotoxicity and mitochondrial toxicity. Substitution simulations showed that meaningful reductions in BPA-EQ were only achieved with near-inert alternatives.

As BPA alternatives accumulate in mixtures, it is important to assess their risks to the environment and to humans as a group. The BPA-EQ approach helps translate chemical exposure data to mixture toxicity and allows easier interpretation and communication of mixture effects to regulators. Bioanalytical equivalent concentrations referenced to phased-out chemicals also offer a simplified way to assess and evaluate the risks of different substitution scenarios.

4.07.T-03 Assessment of the Ecotoxicity of 600 000 Mixtures Reveals only Negligible Differences Between Concentration Addition and Independent Action

Katja Schröder¹, Richard Ottermanns² and Thomas Backhaus¹, (1)RWTH Aachen University, Germany, (2)Environmental Biology and Chemodynamics, RWTH Aachen University, Germany

For predicting mixture toxicity, normally the Concentration Addition model (CA) is used. It assumes, for a mixture of substances, that they are acting in the same manner on the measured endpoint. It is unclear how high the deviation to reality can be where some compounds can affect the same endpoint through different modes of action. The model for dissimilarly acting substances is Independent Action (IA). Which model predicts higher toxicity, depends on the distribution function that is assumed, its slope and the mixture concentration. In practice the knowledge to apply IA for prediction is often missing though, as it requires full concentration-response curves to be available for every compound, which are rarely reported. Obtaining an IA prediction and the toxicity for the present substances for organisms from the aquatic trias of algae, invertebrates and fish, is limited by the scarce availability of dose-response parameters for single substances.

This study established a database of concentration-response relationships from standard assays with algae, daphnids and fish, to estimate the maximum and likely difference between the mixture toxicity predictions by CA and IA for real-world mixtures, compiled from large-scale monitoring databases. Toxicity prediction modelling was applied to derive chronic EC10 values for all mixture compounds for algae, daphnids and fish. For all mixture components, a random CRC-slope was sampled from the empiric distribution in a Monte-Carlo simulation. The simulation was built to obtain a realistic distribution of ratios between the EC10 values predicted by CA and IA.

The slope draws for all 610.326 mixtures show a similar distribution of IA/CA ratio across databases and organisms. In about 80% of cases CA is more conservative.

In reality most mixtures will most probably contain some chemicals acting similarly and some that are not. That means it is highly likely that the real prediction error is even smaller than what was found in the simulation. The selection between CA or IA, thus becomes largely irrelevant in view of other sources of uncertainty, like EC10 and concentration determination, and considering the underlying exposure dynamics. In that regard, our simulation results support the notion to use CA as the default first approach.

4.07.T-04 Making sense of chemical monitoring data for environmental risk assessment: a stepwise scenario-based approach

Thomas Backhaus¹, Werner Brack², Wibke Busch², Benjamin Daniels³, Pedro A. Inostroza⁴, Jan Koschorreck⁵, Richard Ottermanns⁶, Katja Schröder¹ and Eric Winter⁵, (1)RWTH Aachen University, Germany, (2)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (3)Toxrat GmbH, Germany, (4)Biological and Environmental Sciences, RWTH Aachen University, Germany, (5)German Environment Agency (UBA), Germany, (6)Environmental Biology and Chemodynamics, RWTH Aachen University, Germany

Modern analytical methods produce extensive datasets on the occurrence and co-occurrence of chemicals in the environment. Modern analytical methods generate extensive datasets on the occurrence and co-occurrence of environmental chemicals, yet this wealth of information remains underused for understanding chemical pollution. We propose a systematic, scenario-based evaluation of exposure data that clarifies whether specific environmental compartments are at risk, identifies suitable mitigation options, and provides strategic guidance for future monitoring and ecotoxicological research.

The approach starts with a rigorous problem formulation that distinguishes several key assessment questions. Risk quantification supports site comparison and ranking, with Concentration Addition serving as a robust first-tier model where data permit. Identification of risk drivers is essential for source allocation and targeted mitigation; component-based methods provide transparent rankings of each chemical's contribution. The framework further enables the identification of sensitive taxonomic groups, informing group-specific protection strategies. A comparison of analytical detection limits with hazard profiles highlights chemicals requiring improved analytical methods, while *in silico* tools such as validated QSARs help to flag chemicals lacking empirical ecotoxicity data. For components identified as potential risk drivers, experimental follow-up is warranted.

Current environmental risk assessments often hinge on a binary distinction between “risk” and “no risk,” still shaped by long-standing guidance documents. However, to support robust decision-making, it is crucial to delineate the uncertainty space between these categories. This is best achieved through contrasting scenario analyses that explore different assumptions and create edge-case boundaries for plausible outcomes. Wide divergences between scenarios indicate insufficient robustness or incomplete datasets, whereas minimal differences strengthen confidence in the conclusions.

Overall, the proposed framework maximises the value of existing monitoring data, supports mixture-aware and uncertainty-informed environmental risk assessments, and provides a flexible structure that can also be adapted to other complex exposure situations, including human health assessments.

4.07.T-05 Combined Toxicity and Mechanistic Insights of Common Heavy Metal Mixtures

Masato Ooka and **Menghang Xia**, National Center for Advancing Translational Sciences, United States
Heavy metal contamination of soil, water, and air is widespread near manufacturing facilities, processing plants, landfills, and mining sites, leading to chronic exposure for surrounding communities. Although individuals are routinely exposed to mixtures of heavy metals, the combined toxic effects of these exposures are not well understood. In this study, we evaluated the toxicity of metal compound mixtures commonly detected at contaminated sites. Our results show that mixtures of nickel/arsenic/cadmium and beryllium/arsenic/cadmium exhibit greater toxicity than their individual components, indicating potentiated effects in combination. Mechanistic studies revealed that cadmium-containing mixtures significantly increased oxidative stress compared to single compounds, resulting in greater DNA damage. Furthermore, these mixtures induced higher levels of interleukin-8 secretion and promoted angiogenesis more than their respective components. These findings provide important insights into the enhanced toxicity of heavy metal mixtures prevalent at contaminated sites and underscore the need for further research on mixture-specific mechanisms to improve risk assessment and remediation strategies.

4.07.P From Complexity to Clarity: Next-Generation and AI-Driven Approaches for Smarter Assessment and Regulation of Chemical Mixtures

4.07.P-Mo283 Alternative Assays for Routine Toxicity Assessment

Kirit Wadhia¹ and **Wouter Lanneau**², (1)National Oilwell Varco (NOV), United Kingdom, (2)MicroBioTests Inc., Gent, Belgium

Substantial number of aquatic toxicity tests exist and are deployed in particular frameworks. However, for routine screening of environmental samples and potential chemical formulation investigations, these conventional assays are not practical and hinder expeditious progress. The development of alternative small-scale bioassays referred to as microbiotests has significantly advanced throughput strategies. The microbiotest technology has several advantages in comparison to the “traditional” tests based on laboratory cultures, especially its independence of the stock culturing burden.

The Daphtoxkit is a prime example of a microbiotest that has been effective and has enabled implementation of projects worldwide otherwise not doable and has accelerated the advancement of research & development programs. Microbiotests offer new opportunities for effects monitoring of chemicals and environmental matrices (effluents, leachates, interstitial waters, etc). These can also contribute to increasing the cost efficiency and diagnostic potential of hazard assessment schemes.

Use of *Daphnia* microbiotests is continuing to gather momentum for application in regulatory frameworks.

Aquatic microbiotests like Daphtoxkit, invaluable for screening and ranking ecotoxic effects, their intrinsic features can contribute to novel applications enabling rapid detection and enhanced throughput.

Biological testing, and microbiotesting in particular, will undoubtedly increase significantly in environmental protection activities in the future. International recognition of biotesting, and more critically owing to limitations in regional testing infrastructure (lack of laboratories and culturing facilities), the implementation scope is globally significantly enhanced to facilitate environmental policies, regulations and guidelines. The imperative need for cost efficiency in environmental assessment continues to fuel the need for R & D concerning microbiotesting.

4.07.P-Mo284 Microbial Assays for Risk Assessment to Evaluate Toxicity of Chemicals and Environmental Samples

Michelle Robertson¹ and **Kirit Wadhia**², (1)Energy & Environmental Microbiology Services, NCIMB, United Kingdom, (2)National Oilwell Varco (NOV), United Kingdom

Benefits of microbial bioassays

Bacteria are good candidates for ecotoxicity testing because of number of factors that include small size, rapid growth rate and ease of handling. The use of bacterial bioassays to assess toxicity is well established attributed to the rapidity of ascertaining results and convenience of use.

Single species bacterial tests have been in common use across a wide range of industry and environmental applications.

The best known tests make use of the naturally luminescent bacteria *Aliivibrio fischeri* (previously known as *Vibrio fischeri*). These tests are based on the rationale that exposure to toxins disrupts the bacterial respiratory processes, which in turn results in a reduction in light output. Reduction in light output is a relatively simple response to measure which can then be calibrated to convey toxicity of the test sample.

MARA and LumiMARA bioassays with the incorporation of genetically diverse multiple strains combination have significantly advanced microbial assays from single species utilisation.

Bacterial testing is generally based around assessment of the acute toxicity response of a single marine species. In contrast, testing using both MARA and LumiMARA gives a measure of acute and chronic toxicity, encompassing marine, freshwater and terrestrial species of prokaryotic microorganisms (bacteria) and additionally eukaryotic single-celled microorganism (yeast).

MARA

The MARA test assesses toxicity by measuring the growth of ten bacterial species and one yeast, following 18 hours of incubation in the presence of a concentration gradient of the test sample.

LumiMARA

LumiMARA assesses toxicity on the basis of the reduction in luminescence of 11 species of bacteria following exposure to a concentration gradient of the test sample. The test includes nine marine and two fresh water species from a variety of habitats.

Application in the oil and gas industry

The Oslo and Paris Commission (OSPAR) Recommendation 2012/5 requires contracting parties, of which the UK is one, to implement a risk-based approach for the management of produced water from offshore oil and gas

installations. MARA and LumiMARA bioassays are recommended by UK's Department for Energy Security and Net Zero (DESNZ) guidance integral to the regime of tests to be utilised.

4.07.P-Mo286 Smart Assessment of MASLD-Relevant Endocrine Disruptor Mixtures Using a Definitive Screening Design

You Song¹, Jorke Kamstra², Julie Maassart³, Tuulia Hyötyläinen⁴, Matej Oresic⁵ and Maria T. Hultman¹, (1)Norwegian Institute for Water Research, Norway, (2)Institute for Risk Assessment Sciences (IRAS), Utrecht University, Netherlands, (3)Institut national de la santé et de la recherche médicale (Inserm), France, (4)School of Science and Technology, Örebro University, Sweden, (5)School of Medical Sciences, Örebro University, Sweden

Metabolic dysfunction-associated steatotic liver disease (MASLD) is one of the most widespread chronic liver disorders globally, and growing evidence suggests that exposure to endocrine disruptors (EDC) may contribute to its initiation and progression. Understanding the effects of complex mixtures is difficult because the number of possible combinations is large, their relative potencies vary widely, and potential interactions can obscure the identification of toxicity drivers. Efficient strategies are therefore needed to prioritise mixtures and to determine which individual EDCs most strongly influence biological responses relevant to MASLD. In this study, we developed a stepwise and resource-efficient workflow for mixture assessment based on in vitro screening combined with a Definitive Screening Design (DSD), a statistical design-of-experiments approach that allows detection of main effects, nonlinearities and selected interactions using relatively few tests. The zebrafish liver cell line (ZFL) was used as the biological model because of its suitability for evaluating metabolic and toxicological responses. For each chemical, concentration-response data were used to derive effect concentrations, which were then applied as standardised forcing levels in the mixture design. The DSD was constructed to explore mixture behaviour in only 17 experimental runs, and cytotoxicity following 48-hour exposure was quantified. Statistical model fitting was used to estimate the contribution of each chemical to the overall response. A demonstration study was conducted using a mixture containing perfluorooctanoic acid (PFOA), p,p'-dichlorodiphenyldichloroethylene (p,p'-DDE) and allyl hexanoate (AHC). The workflow successfully distinguished the relative influence of each chemical and clearly identified perfluorooctanoic acid as the dominant driver of cytotoxicity, whereas the other two chemicals showed little to no effect within the tested range. No substantial nonlinear or interaction effects were detected, indicating that the mixture response was governed primarily by the linear contribution of PFOA. This proof-of-concept demonstrates that the integration of in vitro assays with a DSD provides a powerful and scalable strategy for early-stage mixture assessment. The approach is well suited for prioritising more complex mixtures relevant to MASLD and will be extended in future work using 3D spheroid cultures and mixtures identified through cohort studies.

4.07.P-Mo287 AI-Aided Meta-Analysis on Global Change Drivers-Triggered Airborne Microplastics-Related Human Pulmonary Toxicity

Si-Yu Chen¹, Szu-Chieh Chen² and Chung-Min Liao¹, (1)Department of Bioenvironmental Systems Engineering, National Taiwan University, Taiwan (Greater China), (2)Department of Public Health, Chung Shan Medical University, Taichung 40201, Taiwan and Department of Family and Community Medicine, Chung Shan Medical University Hospital, Taichung 40201, Taiwan, Taiwan (Greater China)

Anthropogenic global change had substantially led to a surge in airborne microplastics (MPs). The potential human health implications, particularly the side effects on the lungs, are a growing concern. However, the magnitude and determinants of MPs-induced respiratory effects remain uncertain. While numerous studies have investigated this issue, a comprehensive understanding of the overall risk is lacking due to the heterogeneity of methodologies and outcomes. This study applied an artificial intelligence (AI)-assisted multilevel meta-analytic framework to systematically synthesize experimental findings from in vivo and in vitro studies published up to June 2025. Study quality was rated using a standardized risk-of-bias assessment tool. A total of 40 studies satisfying the eligibility criteria with low to moderate bias risk were included for the calculation of summary effect size. We found that the most significant increases of effective effect size were observed in inflammatory response following airborne MP exposure, with substantial heterogeneity across endpoints. Meta-regression analyses indicated that smaller MPs size, higher exposure concentrations, and longer exposure durations were key moderators of toxicity. Furthermore, random forest modeling identified MPs size as the primary predictive driver of pulmonary toxicity. Overall, the findings uncovered by this meta-analysis quantitatively demonstrate that airborne MP exposure elicits measurable pulmonary toxic responses across the biological models. Our findings provide crucial information for prioritizing and developing risk-based policies and protection mechanisms to safeguard public health on human pulmonary toxicity responses attributed to anthropogenic amplification of airborne MPs variability.

4.08 From Nanomaterials to Advanced Materials: Ensuring Safety in Innovation

4.08.T-01 Imogolites for agriculture & environmental plant protection; a challenge to assess and regulate

Mona Connolly¹, Lars Skjolding², Fabienne Testard³, Dorra Garouri³, Arianna Filoramo³, Anders Baun² and Jose María Navas¹, (1)INIA CSIC, Spain, (2)Technical University of Denmark, Denmark, (3)Université Paris-Saclay, France

Imogolite (Imo) is a natural clay mineral with tubular morphology composed of aluminum hydroxide (Al(OH)₃) and oxo-hydroxysilicate anion (SiO₃)OH. However, synthesised and modified versions have emerged of nanohybrids with organic and inorganic components used to fine tune inner and outer surfaces and properties. Hydroxylated Imo (Imo-OH) and methylated Imo (Imo-CH₃) with hydrophilic and hydrophobic inner surfaces, respectively, as well as hybrid materials functionalized with copper/copper oxide nanoparticles are such examples. These materials have been synthesized by CEA Paris-Saclay to explore their potential as plant protection products/fungicides in agricultural applications. Safety considerations early in the design process will ensure their safe use for protecting human health and the environment. However, introducing an added layer of complexity for regulators and assessors to determine potential risk is that these materials are advanced, multi-component, nano-enabled and also can act as nanocarriers. In aqueous solutions and test media strong Imo inter-nanotube interaction occurred leading to gel formation at concentration >0.5 mg/L. Unique direct interactions of this Imo gel with algae and *Daphnia* sp. resulted in organisms being trapped and such physical effects resulted in toxicity being recorded for the endpoint of immobilisation to *Daphnia* sp. (OECD TG 202) and growth inhibition in algae (OECD TG 201). For *Daphnia* sp., immobilization and physical entrapment occurred at concentrations >6.25 mg/L. Algal growth inhibition was also measured at concentrations of 3.1 mg/L. At the cellular level significant reductions in RTgill-W1 fish cell viability were only measured for the Imo-CH₃ materials. The interaction of the gel caused disruption of the plasma membrane, however EC₅₀ values were all above 100 mg/L indicating an overall low hazard potential for both the Imo-OH and Imo-CH₃ materials. Under these conditions the Imo presents a hazard through physical interaction effects rather than inherent chemical toxicity. Modifications of the material through Cu nanomaterial hybridization however introduced an additional hazard from this chemical component. Risk assessments, and indeed SSbD assessments, of these materials may require additional considerations to overcome challenges when hazard and fate testing (e.g. stability issues/gel formation/multi-component aspect) to ensure the generation of robust and relevant data to meet regulatory needs.

4.08.T-02 Lights, Camera... Action? Challenges for *Daphnia* during Advanced Materials ecotoxicity testing

Katie Reilly¹ and Iseult Lynch², (1)University of Birmingham, United Kingdom, (2)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom

Daphnia have been historically used for ecotoxicity assessments, including nanomaterials and microplastics, establishing an extensive understanding of toxicity and range of endpoints for comparison. As a result, a range of test guidelines have been established, including the OECD 202 acute immobilisation, and OECD 211 for reproduction (or chronic exposures). However, these standardised and widely used test guidelines, are likely to need adaptation to ensure they are accurately assessing advanced materials due to the complex nature of the materials in the exposure scenarios.

Commercial formulations of advanced materials have been used in the Macrame project, to explore risk assessments and toxicity endpoints of advanced materials in complex product matrices (AdMa@CM). Here, we highlight the use of some commercial dry lubricant sprays (for example for use on bicycle chains) and how these can impact *Daphnia* to feed into an environmental risk assessment for the product. Initial toxicity assessments were undertaken in flat bottom glass tubes, following the OECD 202 guideline of 5 neonates in 10mL of exposure solution with 4 replicates per exposure. For this material, we trialled adding the aliquot of toxicant to the test vessel before topping up with medium and adding the neonates, in addition to adding the toxicant last to determine if exposure order has a significant impact on the observed endpoints. In addition, we also trialled different ages of the *Daphnia* (4-6 days old) to determine if a larger individual is a) more visible and b) more likely to survive the exposure due to different developmental stages. Initial observations of the exposure to the panel of AdMa@CM showed nearly 100% mortality in all groups, excluding the control. When observed

under the microscope, the exposed Daphnia were still alive and attempting to move but couldn't due to the physical nature of the toxicants. This was observed in the majority of exposures, including at the highest concentrations, leading to adaptation to the test design to explore this further.

Highlights from this work include the systematic exploration of the challenges the AdMa@CM can present in acute aquatic exposures. Immobilisation of Daphnia exposed to mixtures of graphene based AdMa are readily immobilised due to the physical impendence of movement, as opposed to the typical toxicant response.

4.08.T-03 Animal-Free Computational Pipeline for Deriving In Vivo Nanoparticle Safety Thresholds from In Vitro Data

Jimeng Wu¹, Peter Wick² and Bernd Nowack², (1)Swiss Federal Laboratories for Materials Science and Technology (EMPA), St. Gallen, Switzerland, (2)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland

Ensuring the safe use of nanoparticles requires exposure limits that are biologically meaningful and human health relevant. Yet most existing safety thresholds are derived from animal studies, which are costly, time-consuming, ethically constrained, and available only for a subset of substances. Meanwhile, in vitro assays generate abundant toxicity data but lack a direct quantitative linkage to in vivo doses. As innovation accelerates, there is a critical need for scientifically justified methods that extrapolate in vitro responses of nanoparticles to organism exposure levels, enabling early-stage safety evaluations aligned with Safe and Sustainable by Design (SSbD) principles.

We present an integrated in vitro to in vivo extrapolation framework that translates in vitro nanoparticle toxicity into organism relevant exposure limits using harmonized dose–response modeling and physiologically based pharmacokinetic (PBPK) simulation. We compiled and harmonized nanoparticle toxicity datasets across mouse and human cell systems, yielding 72 human and 38 mouse dose–response experiments after rigorous pre- and post-dose response modeling screening. Using the dose response curve, we estimated BMD₁₀ potencies from each in vitro toxicity experiment.

To enable translation, we converted in vitro BMD₁₀ values ($\mu\text{g}\cdot\text{mL}^{-1}$) into organism level equivalent doses ($\text{mg}\cdot\text{kg}^{-1}$ body weight) using PBPK-derived delivery efficiencies. These translated values were benchmarked against 33 harmonized mouse in vivo studies, showing strong material-dependent quantitative alignment, especially for graphene oxide. Deviations for silica and TiO₂ reflected differences in particle size distributions and endpoint types between in vitro and in vivo experiments. Finally, applying the human PBPK model, we derived nanoparticle-specific human exposure limits. These predicted thresholds represent biologically plausible, human-relevant safety ranges directly grounded in in vitro data.

By linking harmonized in vitro assays with PBPK-driven in vitro to in vivo extrapolation, this work provides a transparent, reproducible, and animal-free pathway for deriving protective exposure limits for nanoparticles. The framework supports SSbD initiatives by enabling early-stage safety evaluation for nanoparticle innovations.

4.08.T-04 Ensuring Safe Advanced Materials – MACRAMÉ Recommendations for Test Guideline Development and Standardisation

Elisabeth Heunisch¹, Daniel Haase², Anna Pohl¹, Eric A. J. Bleeker³, Samia Ouahjji³, Blanca Suarez Merino⁴, Rayen Chantal Mentler⁴, Iseult Lynch⁵, Thomas Exner⁶, Luis Mauricio Ortiz-Galvez⁷, Tommaso Serchi⁸, Martin Wiemann⁹, Alberto Katsumiti¹⁰, Klaus-Michael Weltring² and Steffi Friedrichs¹¹, (1)German Federal Institute for Occupational Safety and Health (BAuA), Germany, (2)Gesellschaft für Bioanalytik Münster e.V. (BioMS), Germany, (3)National Institute for Public Health and the Environment (RIVM), Netherlands, (4)TEMAS Solutions, Switzerland, (5)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom, (6)7P9, Germany, (7)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (8)Luxembourg Institute of Science and Technology, Luxembourg, (9)IBE R&D Institute for Lung Health gGmbH, Germany, (10)GAIKER Technology Centre, Spain, (11)AcumenIST, Belgium

Innovation of advanced materials (AdMas) and application of AdMas-enabled products is rapidly increasing. Besides their exceptional properties and functionalities, AdMas raise scientific questions about their behaviour, safety and transformation along their life cycle. Advanced test methodologies for physico-chemical characterisation, safety testing and detection and quantification along the life cycle of AdMas and AdMas-enabled products are urgently needed to gain insights for scientists, innovators and also regulators. To keep pace with innovation, testing methodologies need to be developed or adapted in a timely manner, proven to be fit-for-purpose and advanced towards harmonised and standardised methods.

The EU-funded project MACRAMÉ gained valuable scientific and technical experiences during the development of methods for assessing inhalable carbon-based AdMas of various morphologies and commercial AdMas-enabled products. MACRAMÉ is fully aligned with the EU ambitions to secure the safety and sustainability of new chemicals, materials, products and processes striving for zero pollution and toxic-free environments.

Based on its experiences, MACRAMÉ has developed Informed Recommendations on the Needs for Test Guideline Developments and the Standardisation of Test Methods that go beyond the state-of-the-art developed methods. Diverse stakeholder groups were consulted to provide feedback in multiple ways to these informed recommendations. The recommendations are in line with the identified needs and gaps towards regulatory and policy requirements for AdMas, captured by MACRAMÉ in the Needs Assessment Report on Regulatory & Policy Frameworks. Needs and challenges mainly lie in addressing the whole life cycle of (products containing) AdMas. This requires combined imaging and analytical approaches to quantify transformed AdMas in situ in products and following release along the product life cycle. In addition, this requires life cycle thinking in material design and the development of sector-specific methodologies as well as tools for Safe-and-Sustainable-by-Design (SSbD), along with incentives to encourage their use.

The overarching goal of the MACRAMÉ Informed Recommendations is to clarify the specific need for test method development and standardisation of methods for use with AdMas. This should then enable regulatory testing of AdMas that is manageable by industry, acceptable to regulators and can ensure the trust of other stakeholders.

4.08.P From Nanomaterials to Advanced Materials: Ensuring Safety in Innovation

4.08.P-We329 Exposure Alteration of Silver Nanoparticles by Key Member *Sphingomonas* in *Daphnia magna*

Jesse Ouwehand¹, Bregje Brinkmann², Willie Peijnenburg³ and Martina G. Vijver¹, (1)Leiden University, Netherlands, (2)Environmental Biology, Leiden University, Netherlands, (3)National Institute for Public Health and the Environment (RIVM), Netherlands

Host-associated microbiomes often contain bacteria capable of interacting with metal ions in their local environment. This capability could play a fundamental role in shaping exposure to soluble nanomaterials as silver nanoparticle. This study investigated whether silver-resilient microbiome members influence the response of *Daphnia magna* to soluble silver nanoparticles (AgNPs), aiming to clarify how the microbiome shapes nanoparticle exposure and toxicity. Acute toxicity tests were performed using axenic, mono-associated, and naturally colonized *D. magna* neonates. Microbiome depletion increased neonate sensitivity to AgNPs, demonstrating a protective role of the microbiome. Two silver-resistant bacteria, *Sphingomonas yanoikuyae* and *Microbacterium* sp., were isolated from the *Daphnia* microbiome. *S. yanoikuyae* exhibited enhanced uptake of silver ions, whereas *Microbacterium* showed limited ion accumulation. Mono-association with *S. yanoikuyae* restored AgNP tolerance to levels comparable to naturally colonized neonates, while *Microbacterium* provided only transient protection, maintaining tolerance for 24 hours but not at 48 hours. Toxicity in naturally colonized and *S. yanoikuyae*-associated neonates was primarily driven by the particulate species, whereas axenic neonates showed a dominant contribution from ionic silver. Mono-association with *Microbacterium* slightly reduced ionic toxicity but did not fully restore the natural phenotype. Overall, our findings reveal that host-associated bacteria modulate AgNP toxicity through active silver uptake and alteration of ionic species. This active uptake hence shape the exposure to host and affects sensitivity of silver nanoparticles. This highlights the microbiome as a

crucial factor in nanoparticle ecotoxicology and emphasizes that host-microbe interactions influence the outcome of nanoparticle exposure.

4.08.P-We330 Surface Coatings Regulate the Biodynamics and Trophic Transfer of Silver Nanoparticles: Insights from Au@Ag Core-Shell Nanoparticle

Yufei Zhao¹, Wenhong Fan¹, Xiaomin Li¹, Ying Wang¹ and Xiaoli Zhao², (1)School of Materials Science and Engineering, Beihang University, China (Mainland), (2)State Key Laboratory of Environmental Criteria and Risk Assessment, Chinese Research Academy of Environmental Sciences, China (Mainland)

Silver nanoparticles (AgNPs) is widely used in production and daily life, and its potential risks to the aquatic environment should be further monitored. The most directly related to the toxic effect is the biokinetic process within aquatic organisms. At the same time, when AgNPs enter the organism, they undergo a series of migration and transformation, especially the release of silver ions, which is considered the key mechanism of toxicity. Therefore, this study constructs a typical aquatic food chain (*Escherichia coli*-*Tetrahymena thermophila*) to explore the influence of surface coating on the biokinetic process under direct exposure in water phase and indirect exposure in food phase. In addition, by synthesizing Au@AgNPs with different surface coatings, this study can better distinguish the accumulation and transfer processes of particulate and released silver ions in organisms. The results show that surface coating regulates the surface charge of Au@AgNPs, which significantly affects its biokinetic and trophic transfer processes. In water phase exposure, the PEI-coated Au@AgNP accumulates the most in *T. thermophila* due to electrostatic interaction, and the particulate silver is more easily excreted than the released silver ions. In the food chain transfer, the PEI-coated Au@AgNP achieves the transfer from *E. coli* to *T. thermophila* in a relatively complete particulate form, showing the highest relative transfer efficiency of gold. However, the silver and gold transfer efficiency of PVP-Au@AgNP is the lowest, indicating a lower bioavailability, less transformation, and higher excretion efficiency. Moreover, the released silver ions show higher bioavailability than the particulate form in both exposure pathways. In conclusion, this study demonstrates that surface coating regulates the surface charge of AgNPs, affecting their biokinetic and transfer processes in both water phase exposure and food chain transfer. At the same time, when assessing the ecological risk of nanomaterials, the differences in the behavior of particle and ionic forms and the potential amplification effect through the food chain must be considered.

4.08.P-We331 Toxicity Assessment of Silver Nanoparticles in Aquatic Organisms from Different Trophic Levels

Ismael Alberto Ortiz-Ramos, Roberto Carlos Valerio-García, Roberto Rico-Martínez, Mario Alberto Arzate-Cárdenas and Ana Laura Carbajal-Hernández, Universidad Autónoma de Aguascalientes, Mexico

Silver nanoparticles (Ag-NPs) are widely used in medical, pharmaceutical and industrial applications, and pose a potential risk to aquatic ecosystems due to their possible release into the environment. Their presence in surface waters may negatively affect organisms from different trophic levels, including microalgae, rotifers and fish. This study evaluated the toxicity of Ag-NPs in three representative biological groups to characterize their differential sensitivity and the potential ecotoxicological effects associated with these nanoparticles. Toxicity tests with microalgae (*Raphidocelis subcapitata* and *Chlorella vulgaris*) and rotifers (*Brachionus calyciflorus* and *Lecane quadridentata*) were conducted in 24-well polystyrene plates using five concentrations prepared in species-specific media. Microalgae were incubated for five days and rotifers for one day. Embryo toxicity tests with zebrafish (*Danio rerio*) followed OECD Guideline 236, evaluating mortality, morphological alterations and hatching inhibition. Median lethal or inhibitory concentrations (LC50 or IC50) were calculated, and potential morphological alterations in rotifers were documented. Ag-NPs caused toxicity in all species tested. *D. rerio* embryos were the most sensitive (LC50 = 7.38 mg L⁻¹), followed by *C. vulgaris* (IC50 = 8.26 mg L⁻¹) and *R.*

subcapitata ($IC_{50} = 13.53 \text{ mg L}^{-1}$). Among rotifers, *B. calyciflorus* was more sensitive ($LC_{50} = 14.53 \text{ mg L}^{-1}$) than *L. quadridentata* ($LC_{50} = 18.87 \text{ mg L}^{-1}$). Reproductive rates decreased from 0.9 mg L^{-1} in *B. calyciflorus* and 2.35 mg L^{-1} in *L. quadridentata*. Microscopic observations revealed structural deformities in microalgae, alterations in the lorica and body constrictions in rotifers, and reduced hatching and multiple malformations in fish embryos. Overall, the results indicate differential toxicity across trophic levels and highlight the high sensitivity of early fish developmental stages. The observed morphological alterations, reproductive impairment and sublethal effects demonstrate that Ag-NPs pose a relevant ecotoxicological risk to aquatic organisms. These findings emphasize the need for responsible management of reactive nanoparticles to minimize their release into freshwater ecosystems.

4.08.P-We332 Evaluation of the acute toxicity of six nanoparticles used in industry and cosmetics in *Danio rerio* and *Chlorella vulgaris*

Carlos Manuel Valadez-Valadez¹, Ana Laura Carbajal-Hernández², Roberto Carlos Valerio-García², Mario Alberto Arzate-Cárdenas², Martha Stephanie Pérez-Mendoza³ and Alfredo Rafael Vilchis-Nestor⁴, (1)Universidad Tecnológica Metropolitana de Aguascalientes, Mexico, (2)Universidad Autónoma de Aguascalientes, Mexico, (3)Centro Conjunto de Investigación en Química Sustentable UAEM-UNAM, Mexico, (4)Faculta de Química, Unidad Colón, UAEM-UNAM, Mexico

Nanoparticles widely used in the medical, cosmetic, food, textile, and energy sectors include silver particles (AgNPs), copper oxide (CuONPs), zinc oxide (ZnONPs), titanium oxide and dioxide (TiONPs and TiO₂NPs), as well as hydroxyapatite nanoparticles (HAp NPs). In cosmetics, ZnONPs and TiO₂NPs are frequently used due to their ability to block ultraviolet radiation in sunscreens. Their increasing use raises the likelihood of release into the environment, making it necessary to assess their potential toxic effects on aquatic organisms. The objective of this study was to determine the acute toxicity and median lethal concentration of six types of nanoparticles in early stages of *Danio rerio* fish and *Chlorella vulgaris* microalgae. All nanoparticles were characterized using scanning electron microscopy, energy dispersive X-ray spectroscopy, hydrodynamic diameter, and zeta potential. Fertilized *D. rerio* eggs less than 2 h post-fertilization and axenic cultures of *C. vulgaris* were used, exposing them to five concentrations of each nanoparticle and a control. The bioassays were performed according to OECD guidelines (236 and 201) for acute toxicity in fish embryos and algae, and the median lethal and inhibitory concentrations (LC_{50} and IC_{50}) were determined at the end of the tests. In *C. vulgaris*, only hydroxyapatite nanoparticles did not induce population growth inhibition. AgNPs and ZnONPs showed the highest toxicity, with median inhibitory concentration (IC_{50}) values of 3.06 and 4.23 mg L^{-1} . In *D. rerio*, only AgNPs and TiONPs caused mortality, teratogenic effects, and hatching inhibition. CuONPs, TiO₂NPs, ZnONPs, and HAp NPs caused hatching inhibition at concentrations of 3.12, 6.25, 12.5, 25, and 50 mg L^{-1} , but showed low mortality (?15%) at the highest concentrations evaluated. These results highlight important differences in the sensitivity of aquatic organisms exposed to nanoparticles widely used in industry and cosmetics and provide relevant information for risk assessment and the development of regulations aimed at minimizing their environmental impact.

4.08.P-We333 Environmental Implications of Nano-Enabled Rapid Antigen Test Kits: A Cross-Species Ecotoxicological Assessment

Rorisang Malatsi¹, Fanelesibonge P Vilakazi¹, Christene Goldman¹, Daniela Maria Pampanin² and Tarryn Lee Botha¹, (1)University of Johannesburg, South Africa, (2)Chemistry, Bioscience and Environmental Engineering, University of Stavanger (UiS), Norway

Nanogold (nAu) is the most researched advanced material in biomedicine due to its unique physicochemical properties, modifiability, and perceived biocompatibility. Colloidal gold rapid test kits (RATs), including those for pregnancy testing, ovulation monitoring, drug use screening, HIV diagnostics, and more recently, large scale screening during the Covid-19 pandemic, are one of the most common applications of nAu due to their sensitivity and ease of use. However, as the use of such test kits and other sources of advanced materials increase, so does the prevalence of these materials in the environment, which could potentially threaten aquatic and human health. Despite this, there exists a large knowledge gap regarding the bioaccumulation, potential immunotoxicity, and stress-related effects of leached nAu. This study aimed to assess the characterization, toxicity, biodistribution, and physiological impact of nAu leached RATs in *Daphnia pulex*, *Daphnia magna* and zebrafish (*Danio rerio*) embryos using a OECD guidelines. Dynamic light scattering, Fourier-transform infrared spectroscopy (FTIR), dynamic light scattering (DLS) and inductively coupled plasma mass spectroscopy was used to characterise the nAu leached. Zebrafish embryos had several lethal endpoints at low dose exposures, while behaviour was significantly affected in all species assessed. The brand of RAT used within the same test type affected the toxicity level. The primary gold nanomaterial (nAu) particle size was found to be 2-16 nm,

surface functionalization of the RATs shifted after use, and the concentration of nAu exhibited almost double leaching potential from conjugated pad after buffer addition (pH 4.5) in used RATs compared to the unused ones. Notably, no significant difference was observed in the leaching of used and unused kits at alkaline pH. These findings strongly suggest that RATs can significantly contribute to nano-waste pollution but highlight how minor changes within their development and production can be harnessed to ensure the safe and sustainable design of advanced materials.

4.08.P-We334 Hormetic Responses of *Raphidocelis subcapitata* to TiO₂ Nanoparticles: Role of Reactive Oxygen Species and Metabolic Reprogramming

Mariam Bakir¹, Angelica Guitierrez², Arturo Keller² and Vera Slaveykova¹, (1)Environmental Biogeochemistry and Ecotoxicology, Department F.-A. Forel for Environmental and Aquatic Sciences, University of Geneva, Switzerland, (2)Bren School of Environmental Science & Management, University of California, United States

Ecological risk assessment (ERA) of ENPs typically focuses on toxicity, yet evidence shows that low concentrations can stimulate growth. Predicted environmental levels of engineered nanoparticles (ENPs) often fall within these sub-toxic ranges. Hormesis, stimulatory effects at low doses, could occur below conventional toxicity thresholds, but its prevalence and mechanisms in photosynthetic microorganisms remain largely unexplored. We investigated the biphasic dose-response of the green alga *Raphidocelis subcapitata*, a typical species used in ecotoxicity tests, exposed to TiO₂ nanoparticles (TiO₂-NPs) with concentration ranging from 0.5 to 100 mg L⁻¹ for 24, 48, and 72 h and assessed growth and reactive oxygen species (ROS) generation. Biphasic dose-response curves were observed at 48 and 72 h, but not at 24 h, with EC₅₀ values increasing from 16.2 ± 0.4 mg L⁻¹ at 24 h to 28.3 ± 1.16 mg L⁻¹ at 72 h, likely due to NP aggregation, sedimentation, and shifts in the cell-to-nanoparticle ratio over time. At 72 h, TiO₂-NPs induced a pronounced hormetic response, with maximal growth stimulation (MAX) at 13 mg L⁻¹, enhancing up to 60% of the population, a zero-effect point (ZEP) of 0.5 mg L⁻¹, and a no-observed-adverse-effect concentration (NOAEC) of 21 mg L⁻¹. ROS measurements indicated mild oxidative stress at low TiO₂-NP doses, which was mitigated by cellular antioxidant defenses at stimulatory concentrations. Targeted metabolomics revealed dose-dependent reprogramming of amino acids, nucleotides, fatty acids, carboxylic acids, and antioxidants. At ZEP, metabolites associated with amino acid metabolism, the TCA cycle, and antioxidant pathways accumulated, whereas at NOAEC, these metabolites were depleted. Notably, depletion of TCA intermediates, amino acids, and nucleotides began at MAX and intensified at higher TiO₂-NP concentrations. These findings support the hypothesis that mild oxidative stress drives hormesis growth stimulation, with ROS accumulation and metabolic adjustments acting as key mediators. Overall, this study highlights the ecological relevance of sub-toxic stimulatory effects in microalgae and provides mechanistic insights into how TiO₂-NPs modulate growth, oxidative stress, and metabolism. By providing a rigorous and comprehensive evaluation of the response to ENP exposure by phytoplankton, the base of the food chain, we aim to provide the basis for improved ERA and safer-by-design nano-enabled products.

4.08.P-We335 Ecotoxicity, Ingestion and Depuration of Nano-Enabled Fertilizers in Algae (*Raphidocelis subcapitata*) and Crustaceans (*Daphnia magna*)

Katerina Giaki¹, Angel Yedra Martínez², Inmaculada Ortiz Gómez², Steffen Foss Hansen¹ and Lars Michael Skjolding¹, (1)DTU Sustain, Technical University of Denmark (DTU), Denmark, (2)Centro Tecnológico (CTC), Spain

Controlled release nano-fertilizers (NF) are a promising alternative for improving nutrient use efficiency and soil quality. However, nanoforms remain a challenge due to their dynamic behavior in test systems. Consequently, careful characterization of the exposures is pivotal for correct interpretation of the test results. In this work, we assess the ecotoxicity and bioaccumulation potential of two nanocarriers (nanoclay bentonite & silicon dioxide) with two individual fertilizers (NH₄NO₃ & KCl) all functionalized with hydrophobic deep eutectic solvent (HDES). Suspensions of the nanoforms were prepared following OECD TG 318 and particle size and zeta-potential were characterized with Dynamic Light Scattering (DLS). Exposure concentrations were quantified using inductively coupled plasma mass spectrometry (ICP-MS). For ecotoxicity, each component was evaluated individually and in combination using the freshwater algae (*Raphidocelis subcapitata*) and the

crustacean (*Daphnia magna*) with OECD TG 201 and 202 respectively. Bioaccumulation potential was assessed in *D. magna* neonates using an uptake period of 24h, following depuration for 24h, and an additional 24h depuration period in the presence of a food source (*R. subcapitata*).

Stable suspensions of nanocarriers were prepared in MilliQ with z-average in range from 200-250 nm and a PDI of 0.4-0.6. However, the suspensions of the final formulations were heterogeneous with ranges from 600 to 2700 nm and PDI between 0.8-1. Additionally, visible sedimentation was observed after addition to media indicating an unstable exposure. Nanocarriers inhibited the growth of algae ($EC_{50} = 237$ mg/L and 107 mg/L for NCB and SiO₂, respectively) while no immobilization of *D. magna* was found for exposure concentrations up to 1000 mg/L. No effects were observed for HDES, fertilizers, and fertilizer-impregnated carriers. The final NFs showed growth rate inhibition of algae (EC_{50} values ranging from 33 to 94 mg/L) and immobilization of *D. magna* (EC_{50} values ranging from 27 to 68 mg/L). The mixture toxicity of the final formulations (toxic units) was calculated based on experimental and theoretical values for the individual substances. Assuming concentration addition, 64% of the response could not be explained. Further studies are necessary to investigate the discrepancy between the individual substances and the final formulations especially focusing on potential particle-specific effects.

4.08.P-We336 Safety and sustainability of innovative materials – the communication and knowledge base MANTRA

Dana Kühnel¹, Katja Nau², Matthias Finkbeiner³, Harald F. Krug⁴, Andreas Mattern⁵, Nadja Möller⁶, Simone Rogg⁶, Jessica S. Wilk³, Lilla Nikl⁶ and Alexis Bazzanella⁶, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Karlsruhe Institute of Technology, Germany, (3)Technische Universität Berlin, FG Sustainable Engineering, Straße des 17. Juni 135, 10623 Berlin, Germany, (4)NanoCASE GmbH, Switzerland, (5)Helmholtz Centre for Environmental Research (UFZ), Department Ecotoxicology, Germany, (6)Society for Chemical Engineering and Biotechnology e.V. (DECHEMA), Germany

Innovative materials are needed to remediate environmental pollution, or secure green energy transition, to give just a few examples. Specifically, innovative membranes allow the removal of hazardous substances from waste streams, and catalysts enable the low energy production of green hydrogen. Novel materials and technologies are also needed to replace or reduce the use of rare or otherwise critical elements in industrial catalysts.

However, it is not enough to consider only the efficacy and efficiency of novel materials; their safety for humans and the environment, as well as their overall sustainability, must also be guaranteed.

The project MANTRA (Data on Innovative Materials for Sustainability and Transfer) supports research teams in developing promising materials and processes for membranes and catalysis. MANTRA supports activities in science communication, networking, public relations, the systematic selection and application of established sustainability indicators, LCA, advice on material safety, and the transfer of results to industry and practice. MANTRA also provides knowledge about the health effects and sustainability of new catalytic and membrane materials accessible to the public. This is achieved through a dedicated website (<https://materialneutral.info/en/>), brochures, information flyers, regular status meetings, workshops, and participation in conferences. These activities facilitate the exchange of information on material safety and sustainability among all relevant stakeholders, from material developers to end users.

The proposed contribution will present the MANTRA knowledge platform, introduce the scientists behind the project, and outline the goals and methods used to communicate the safety and sustainability of innovative materials.

Key messages:

1. Innovative, safe, and sustainable materials are essential for tackling today's societal challenges
2. The MANTRA project supports the development and adoption of such materials for membranes and catalysis
3. MANTRA addresses human and environmental safety of innovative materials, and the need to select appropriate, multidimensional sustainability indicators

4.08.P-We337 Ecotoxicological effects of fibrous and platelet-shaped advanced materials on *Daphnia magna*

Dana Kühnel¹, Gail Rinda Djeukem Ghogo², Karsten Schlich³, Burkhard Stahlmecke⁴ and Carmen Wolf⁴, (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)Helmholtz Center for Environmental Research (UFZ) / University of Hasselt, Belgium, (3)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Institute for Environment & Energy, Technology & Analytics - IUTA e.V., Germany

The growing use of advanced materials (AdMas) raises concerns about their ecological impact, and the applicability of existing test guidelines to this specific group of materials. Fibrous and platelet-shaped materials represent advanced materials for which a reliable environmental hazard assessment based on the available test methods is challenging.

The project “FaPlaN” therefore aims to obtain information on the mechanisms of action (MoA) and thus a mechanistic understanding of potential toxic effects on aquatic organisms as green algae, cyanobacteria and daphnids exerted by fibrous and platelet-shaped advanced materials.

This contribution focusses on Boron nitride nanotubes (BNNTs), Boron nitride platelets (BNPs), silica carbide nanotubes, and MXenes regarding acute and sublethal toxicity in *Daphnia magna*. Alongside the incorporation of agitation to OECD test guideline 202, to enhance dispersion of materials during the test, feeding inhibition and oxidative stress biomarkers are assessed as additional endpoints. Further, the influence of particle morphology, developmental stage of the test organism, and exposure conditions on toxicity is evaluated. All test materials were fully characterized prior to testing, and material uptake was quantified to address size and shape-dependency, as well as dependency on daphnia life-stage. Miniaturized assays in 24 well plates were performed under static and dynamic conditions (shaking at 150 rpm), addressing limitations of the standard test guideline. Results showed that BNNTs induced the highest overall toxicity, while MXenes, although causing only minimal immobilization, led to significant feeding inhibition and redox imbalance, effects that would be missed by standard tests. Dynamic conditions generally increased toxicity by enhancing particle dispersion; however, this effect was not significant for all endpoints, particularly for BNNTs and BNPs. Age-dependent sensitivity was also evident, with 24 and 48 h neonates showing heightened more pronounced effects, compared to 4 d old neonates.

These results advocate for revising the current OECD TG 202 with regard to dynamic test conditions, to provide more continuous exposure of neonates to the test materials throughout the experiment. Further suggestions include to incorporate age-stratified testing, improved exposure scenarios, and multi-endpoint approaches.

4.08.P-We338 Ecotoxicological Effects of Fibrous and Platelet-shaped Advanced Materials on Freshwater Algae and Cyanobacteria

Karsten Schlich¹, Dana Kühnel², Burkhard Stahlmecke³ and Carmen Wolf³, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (3)Institute for Environment & Energy, Technology & Analytics - IUTA e.V., Germany

Advanced materials (AdMa) are a very heterogeneous group of materials and used in many applications. It is unclear, whether OECD test methods in the field of ecotoxicology (including those already adapted for testing nanomaterials) may be applicable for this class of materials. Due to their special morphology, fibrous and platelet-shaped materials represent advanced materials that might exhibit a specific mechanism of action (MoA) is unknown and a reliable assessment of an environmental hazard based on the available test methods is challenging.

Our project aims to check the feasibility of OECD test methods for AdMa und to receive information on their MoA for aquatic organisms as green algae, cyanobacteria and daphnids exerted by fibrous and platelet-shaped advanced materials.

Boron nitride nanotubes and platelets, a silica carbide (SiC) nanowire and a titanium carbide (TiC) MXene were tested to investigate potential MoA of the materials to algae. All materials were fully characterized. Preliminary tests were performed to consider shading effects at the fluorescence measurement to determine cell density.

Finally, the effect of the four materials on the growth of the green algae *Raphidocelis subcapitata* and the cyanobacteria *Synechococcus leopoliensis* was observed following the OECD Test Guideline (TG) 201 and the recommendations of the OECD Guidance Document (GD) 317. Next to effects on regular endpoints as growth

rate and yield, agglomeration behaviour between algae or cyanobacteria and the advanced materials was observed.

Only SiC nanowires and the TiC MXene had an impact on both green algae and cyanobacteria, indicating that green algae were more sensitive. Attachment of particles to algae appeared to be the most relevant MoA. Test methods (OECD TG 201, OECD GD 317) appeared to be feasible. However, at a high concentration of 100 mg/L a direct effect of the test material on the fluorescence measurement and therefore on the determination of the cell density could be observed. The measurement was impacted by around 20 to 40%. While there is a chlorophyll extraction method for the green algae *Desmodesmus subspicatus*, there is none for *R. subcapitata*. As a simple transfer of the method seems not feasible, there is the need for a broader discussion on the adaptation need of applying *R. subcapitata* in TG 201 to investigate the aquatic toxicity of advanced materials interfering with the measurement system.

4.08.P-We339 An Integrated Approach to Evaluate the Safety of Innovative Materials for Water Treatment According to the SSbD Framework

Beatrice Negrini¹, Patrizia Bonfanti¹, Anita Colombo¹, Beatrice Anna Brugger², Maurizio Gualtieri¹, Massimo Perrucca³ and Paride Mantecca⁴, (1)University of Milano-Bicocca, Italy, (2)Swiss Federal Laboratories for Materials Science and Technology (Empa), Switzerland, (3)Project HUB 360, Italy, (4)University of Milan, Italy

As nanomaterials (NMs) gain widespread use, quantitative frameworks integrating functionality, safety and sustainability considerations across their life cycle are needed. Since current sustainability methods overlook nano-specific hazards, strategies to incorporate toxicity data into Life Cycle Assessment (LCA) are required. Approaches based on Key Decision Factors (KDFs) and Key Performance Indicators (KPIs) allow linking design options to multidimensional performance, supporting early identification of safer and more sustainable configurations.

This study applies such a methodology, focusing on safety aspects, to novel NMs applicable to nano-enabled products (NEPs) such as water filtration membranes (WFM), and proposes a preliminary strategy to integrate the data into sustainability frameworks. Two case studies are presented: nanoforms and NEPs based on copper oxide nanoparticles (CuO NPs) and perovskite nanoparticles (Pv NPs), both applicable for antimicrobial/antifouling filtration systems. CuO-enabled WFM with or without a chemical binding (PVB) represent two design options, while four Pv NP types were analysed based on different synthesis parameters, defined according to a design of experiment (DoE).

Aquatic toxicity was assessed using zebrafish embryos (OECD 236) and larval behavior assays, while in vitro skin sensitization (OECD 442D) was also evaluated for CuO-WFM. The analyses generated primary data to support the development of nano-specific Effect Factors (EFs) for LCA. Interpreted through the KDF–KPI perspective, results indicate the PVB-containing WFM as the best design option. PVB enhanced antibacterial stability, improved NPs retention within the polymeric matrix and reduced in vitro toxicity while maintaining ecotoxicological safety. All tested Pv nanoforms showed promising application potential due to their favorable safety profile.

The findings show how structured KDF–KPI analyses enable comparison of design alternatives also according to a DoE, while the generated toxicity data build the quantitative basis needed for future nano-specific impact categories in LCA. Integrating a DoE approach into the KDF–KPI framework could further relate NM performance to synthesis-related KDFs, improving the derivation of EFs for LCA studies considering different synthesis routes.
