Jesse Ouwehand¹, Willie Peijnenburg² and Martina G. Vijver¹, (1)Leiden University, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands

Advances in sequencing and computational tools have greatly improved our ability to study the microbiome. Because the microbiome can either support or impair host health, understanding its role when exposed to emerging materials, such as nanomaterials, becomes increasingly important in grasping toxicity. Aforementioned, we conducted a systematic review and meta-analysis to identify common patterns in how nanomaterials affect host-microbiome systems across diverse models. This systematic review and meta-analysis of available 16S rRNA datasets revealed strong functional redundancy within microbiomes, meaning that microbial species can shift without corresponding changes in functional pathways. This underscores that function, not composition, may provide more meaningful insight into microbiome-mediated effects meaning that the microbiome cannot be another endpoint measured. Ample studies have tried to find causal relationships between host adverse outcome and the microbiome via gnotobiotic techniques. These studies hint at the direct influence of microbiome during exposure with nanomaterials yet it still remains a black-box on what mechanism are at stake. Furthermore, the often-used gnotobiotic organisms have their limitations as they are hard to maintain and cannot be generated for every model system. To further develop a mechanistic view of the microbiome in nano-ecotoxicology, we propose the use of microbial metabolite supplementation. The current study aims to deepen understanding of bioenergetic adverse outcome pathways during nanomaterial exposure and to examine how microbial signal molecules influence key events. This approach seeks not only to clarify gaps in the current bioenergetic AOP but also to assess whether supplementation is a viable tool for the microbial ecotoxicologist's toolkit.

4.08.P-We341 A Regulatory Framework for Assessing the Variability & Safety of Nanoforms

Kai Benjamin Paul¹, Carolin Schultz², Richard Cross², Gerogia Tsiliki³, Alex Zabeo⁴, Elisa Moschini⁵, Vicki Stone⁵, Wendel Wohlleben⁶, Virginia Unamuno⁷, Wim De Coen⁷, Diana Mestre⁷, Laurence Deydier Stephan⁷, Mateusz Trochowski⁷, Radek Bombiera⁷ and Cyril Jacquet⁷, (1)Blue Frog Scientific Limited, United Kingdom, (2)United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Purposeful IKE, Greece, (4)GreenDecision Srl, Italy, (5)Heriot Watt University, United Kingdom, (6)ECETOC, Belgium, (7)European Chemicals Agency (ECHA), Finland

The ECHA-funded project, "Nanomaterial Risk Assessment: A Regulatory Way Forward for Sameness and Grouping Approaches," seeks to create a regulatory framework that efficiently accounts for nanoform (NF) variability while ensuring comprehensive hazard evaluation and regulatory compliance, to streamline regulatory submission and evaluation.

Stage one of the project gathered existing frameworks and data and formed a draft decision-tree framework for identifying the acceptable variation of nanoform characterisers (e.g. size, surface area, surface functionalisation) that would lead to undifferentiable hazard, exposure and risk. Unlike sets of similar nanoforms, the developed framework aimed to only require nanoform characteriser information to group these nanoforms into a single nanoform.

Here we will present the decision-tree framework and its intended use. The framework was tested with case studies and external validation and results of both will be briefly presented here.

Further, we will take you on a "tour de nanoform" under the REACH regulation highlighting robust elements as well as some of the key areas for improvement. Covering in general data curation, data variability, the ECHA database, information type and information patterns as well as the perceived usefulness of some of the decision-trees.

It is clear from this research that substantial work is still required to form a robust framework for regulatory purpose, but also that the current framework builds a strong foundation by building upon previous work (e.g. NanoApp & GRACIOUS).

4.08.P-We342 Integration of the Eco-corona into Regulatory Nanomaterial Ecotoxicity and Fate Testing

Maria Bille Nielsen, Technical University of Denmark (DTU), Denmark

Nanomaterials acquire a so-called eco-corona on their surface when entering natural environments. This eco-corona, consisting of environmental biomolecules, can significantly impact the nanomaterial's fate and toxicity. The European chemicals legislations REACH requires nanomaterial manufacturers and importers to report on how nanomaterials transform in the environment. In the regulatory guidance, eco-corona formation is acknowledged as an important transformation process, yet no regulatory guidance is provided on how to test it. In this study, we identify and map methods for characterizing and testing effects of eco-corona, based on the findings from the MISTRA Environmental Nanosafety project, and provide recommendations for their integration into regulatory nanomaterial test guidance. We identified methods to study eco-corona formation outside organisms in solutions with natural organic matter or animal secretes (ex vivo) and bio-coronas formed inside organisms when passing through them (in vivo). We propose updating the regulatory guidance on nanomaterial ecotoxicity and fate testing with these methods and methodological considerations. Furthermore, we recommend including eco-corona considerations in the persistency, bioaccumulative and toxicity (PBT) assessment required by REACH. Jointly, this could support the implementation of information requirements on nanomaterial transformation, make nanomaterial ecotoxicity tests more environmentally relevant and lower the uncertainties in data extrapolation.

4.09 From Outliers to Insights: Transforming Environmental Risk Assessment through Effect Modelling

4.09.T-01 Movement for landscape models - Is now the time for a universal framework?

Pernille Thorbek¹, Joachim Ulrich Kleinmann², Luke Evans³ and Thomas G. Preuss⁴, (1)BASF, United Kingdom, (2)BASF, Germany, (3)Butterfly Conservation, United Kingdom, (4)Bayer Research & Development Services LLC, Germany

Ecological risk assessments of plant protection products assess both exposure and effects. Much effort has gone into improving the modelling of both. However, the location of the individual relative to the area of application largely controls the exposure of the individual, and movement controls location. For many species movement means that exposure is not static, but highly heterogeneous over time. Specifically for non-target terrestrial organisms (NTTO) the selection of microhabitats through movement plays a crucial role for their exposure to plant protection products. While recommendations for good modelling practice have been issued for TKTD models, population models, and mechanistic effect models in general, the development of movement modules is often ad hoc. Here, we present the continuation of the developments of a framework for movement modelling since SETAC 2024, where a general framework for movement modelling was first presented.

Especially NTAs are a very diverse group and also exhibit diverse movement patterns. Moreover it has been found, that for NTAs the specific microhabitat which individuals use is crucial for their exposure to PPPs. A literature review showed that seven factors (Direction, Speed, Motivation, Energetics, Memory, Response to landscape features, Response to other organisms) cover most movement processes included in the models. However, not all models included all factors and model complexity ranged from no movement to correlated random walks and further to sophisticated models including responses to landscape elements and other organisms. Overall, models for terrestrial species were more complex than aquatic species and vertebrate models were more complex than invertebrates. This diversity to some extent reflects the ecology of the species modelled, and the role movement plays in exposure assessment.

During a workshop at ECEM2023, attended by ecological modellers with a broad range of expertise, a preliminary universal framework for movement modelling has been formulated and afterwards extended. This universal movement modelling framework will help the development and assessment of models. It is not the intention that all movement models must include all factors, but rather that it will help the modellers make informed decisions about what to include and what to exclude. When factors are excluded, justification should be given for why the factors are not considered to be important.

4.09.T-02 Margins-of-safety Predictions for the Risk of Measured Pesticide Mixtures from German Streams by Using GUTS Models

Paula Scharlach¹, Florian Schunck² and Andreas Focks³, (1)FB06, University of Osnabrueck, Germany, (2)Institute of Mathematics, University of Osnabrueck, Germany, (3)FB06/Institute of Mathematics, University of Osnabrueck, Germany

Pesticide mixtures in the environment are attracting increasing attention for risk assessment. A monitoring study detected multiple active substances in small German streams with fluctuating pesticide levels that could influence effects on aquatic organisms. This study assesses the impact of measured pesticide mixtures on aquatic macroinvertebrates by using GUTS models. We applied the concept of concentration addition for

substances with similar modes of action (MoA) to account for cumulative effects, and the concept of independent action for those with different MoA. In total, we included 19 substances with three MoA covering a selection of insecticides and fungicides from the monitoring in our study. We considered neuromuscular and neuroactive substances as well as sterol biosynthesis inhibitors. Due to limited sampling in time, we developed three exposure scenarios with different assumptions about pesticide concentrations between samplings. The GUTS models are calibrated to one substance per MoA group and extrapolated across the entire MoA group using equivalence factors that represent differences in sensitivities. LP50 values quantified the risks of single substances and pesticide mixtures.

We observe an increase in risk of one to two orders of magnitude for substances within each MoA group relative to the reference substance. Generally, insecticides pose higher risks, especially neuroactive substances, than sterol biosynthesis inhibitors. The assumptions in the different exposure scenarios strongly influence risk predictions, and potential risk drivers across the included substances and monitoring sites were identified. Although we only cover a part of real-world substance mixtures by considering 19 of 75 measured active substances from the monitoring study, risk has already been identified. This highlights the importance of considering mixture effects in a future environmental risk assessment.

4.09.T-03 Holistic Evaluation of Aquatic Data for Advancing Species Sensitivity Distribution Models

Dominic Englert¹, Dirk Nickisch², Alexander Singer³, David Schneider¹, Heike Fremdt¹ and Thomas G. Preuss¹, (1)Bayer Research & Development Services LLC, Germany, (2)Rifcon GmbH, Germany, (3)RIFCON GmbH, Germany

Species Sensitivity Distributions (SSDs) are central to ecological risk assessment. However, the construction of SSDs can be compromised by fundamental assumptions about test designs and test species. We reveal potential problems and demonstrate how to resolve them through modelling.

Firstly, constructing SSDs often suffers from inconsistencies among toxicity endpoints (e.g., measured after differing exposure durations). The General Unified Threshold Model of Survival (GUTS) can harmonize exposure durations and account for sensitivity differences across exposure profiles. We analyzed datasets of three insecticides to calibrate GUTS-RED models across aquatic invertebrates and predicted EP50 values, exposure profiles causing 50% mortality, under different scenarios to construct scenario-specific SSDs. We show that exposure profiles influence species sensitivity rankings due to differences in uptake and elimination rates.

Secondly, SSDs assume that the sensitivity of a few tested species represents equal shares of sensitivities across a taxon. This assumption is questionable without prior understanding of the relationships among different species' sensitivities. To test the assumption, we applied multiGUTS, which extends GUTS by incorporating known relationships of GUTS parameters that link the survival responses of species sharing receptors and pathways. From a multiGUTS calibrated to eight test species, we simulated the survival response of the whole taxon (represented by 10,000 hypothetical species). The artificial SSD directly reflects the sensitivity of the taxon and reveals the representativeness of the eight test species. We compared the artificial SSD to the conventional SSD approach applied in risk assessment. In our example, most tested species consistently fell in the sensitive range, indicating they are representative for risk assessment.

Our study underscores the value of integrating empirical test results with suitability checks from modelling to enhance confidence in ecological risk assessments. Our modelling approaches support harmonizing toxicity tests across designs and species. This allows for a more comprehensive understanding of species sensitivity.

4.09.T-04 A-priori predictions of GUTS parameters? Estimating GUTS parameters with LCx values from public databases for QSAR development

Florian Schunck¹, Sophia Mescieri², Nadia Iovine², Anna Lombardo², Emilio Benfenati² and Andreas Focks³, (1)Institute of Mathematics, University of Osnabrueck, Germany, (2)Mario Negri Institute for Pharmacological Research, Italy, (3)Osnabrueck University, Germany

The application of GUTS models in environmental risk assessment is limited by the lack of raw survival data required for parameter calibration, blocking their use in mechanism-based QSAR development and routine effect assessment. This study proposes generating a-priori GUTS model parameter estimates using existing LCx, LDx, and NOEC values from public databases.

The methodology involves extracting effect levels (e.g., LC50, NOEC) and associated concentration/exposure duration data from entries in public databases such as the US EPA ECOTOX. The process begins by standardizing the data to a common unit (mg/kg) and creating exposure profiles for each chemical based on collected metadata. Associated effect levels are interpreted as time-anchored survival probabilities. All resulting data for the same chemical and life stage are then combined into a pseudo-experiment and fed as observations to the GUTS-SD model. Using Bayesian MCMC sampling, the posterior parameter distributions of the GUTS-SD model are estimated. The approach was validated using artificial survival data and derived LCx values for a theoretical chemical under controlled conditions.

The validation results demonstrate that GUTS parameters can be successfully estimated from reconstructed survival time-series derived from LCx values, provided there are sufficient endpoints and effect levels. As data availability diminishes, the uncertainty in parameter estimation increases.

In an application example, the study analyzed LCx and LDx values for adult and larval honeybees (*Apis mellifera*) from the US EPA ECOTOX database, estimating GUTS parameters for 154 datasets. Correlations between GUTS parameters (kd, m, b) and physico-chemical descriptors (water solubility, LogP) were explored, indicating potential value in incorporating GUTS parameters into QSAR development.

This study establishes the feasibility of inferring GUTS parameters from publicly available survival endpoints, offering a pathway to reduce animal testing in chemical effect assessments. The consistent compilation of GUTS parameter estimates for various species and chemicals can benefit both experimentalists and modelers. Further research should investigate the relationships between GUTS parameters and chemical descriptors to support mechanism-based QSAR models, potentially simplifying the development and application of toxicokinetic/toxicodynamic (TKTD) approaches in pesticide risk assessment.

4.09.T-05 Combining individual-based laboratory, semi-field, and field data with mechanistic models for enhanced certainty in environmental risk assessment

Vanessa Roeben¹ and Thomas G. Preuss², (1)Bayer CropScience AG, Germany, (2)Bayer Research & Development Services LLC, Germany

Environmental risk assessment of pesticides can be significantly improved by integrating individual-based laboratory, semi-field, and field data through mechanistic effect models. This holistic approach leverages the strengths of each dataset type—combining the control and mechanistic insight of lab studies with the ecological realism of field data—to provide a more robust and comprehensive evaluation of risks to non-target organisms such as bees and earthworms. By calibrating models with laboratory data and validating them against semi-field and field observations, inconsistencies can be identified and addressed, increasing confidence in regulatory decisions. Case studies demonstrate that this integrative modeling framework enhances the ecological relevance and certainty of risk assessments, supporting next-generation regulatory frameworks and paving the way for the inclusion of non-animal data and more meaningful endpoints in environmental regulation. 4.09.P From Outliers to Insights: Transforming Environmental Risk Assessment through Effect Modelling

4.09.P-Mo288 Mechanistic Refinement of Tier 1 Ecotoxicity: A DEB-TKTD Framework for Robust Algal Toxicity Endpoints to Support EU Regulations.

Erik B Muller¹, Marie Trijau² and Carlo Romoli¹, (1)ibacon GmbH, Germany, (2)IBACON GmbH, Germany

The current standard analysis of Tier 1 algal growth inhibition tests (e.g., OECD 201) relies on simplifying assumptions, such as instantaneous toxic impact and constant exposure concentration, which often lead to suboptimal data analysis and assessment. These analytical shortcomings result in high uncertainty, ECx estimations with unduly wide confidence intervals, and potential over-protectiveness in NOEC/LOEC determination, especially when results lack a "perfect" dose-response pattern. To meet the demand for more robust and reliable environmental risk assessment (ERA) data under EU REACH and future Pharmaceuticals in

the Environment regulations, we developed and validated a mechanistic Dynamic Energy Budget-Toxicokinetic/Toxicodynamic (DEB-TKTD) modeling framework. This framework successfully implements an algal DEB model with a reduced GUTS framework for damage accumulation, allowing for the explicit consideration of time-dependent effects and toxicokinetics (TK). By analyzing the totality of the time-series data from standard tests, including experiments with challenging or "troublesome" compounds, this approach delivers significantly tighter confidence intervals for No-Effect Concentrations (NECs) and ECx values. Furthermore, it provides a transparent and robust method to interpret results even when chemical degradation or speciation is substantial over the course of the test. This advancement delivers the necessary mechanistic, high-precision tool for deriving accurate Predicted No-Effect Concentrations (PNECs), critical for enhancing the efficiency and defensibility of regulatory ERA in the European Union.

4.09.P-Mo289 Evaluation of Potential EDC effects on Fathead Minnow Populations with DEB-IBM models

Erik B Muller¹, Marie Trijau², Carlo Romoli¹, Marina Lauck³, John Marton³, Valentin Mingo⁴ and James Robert Wheeler⁵, (1)ibacon GmbH, Germany, (2)IBACON GmbH, Germany, (3)Corteva Agriscience, (4)Corteva Agriscience, Germany, (5)Corteva Agriscience, Netherlands

We used a Dynamic Energy Budget-Individual-Based Model (DEB-IBM) to assess the population-level hazard of a plant protection product on Fathead Minnow (FHM). The study aimed to evaluate results from an Extended One Generation Reproduction Test (FEOGRT). The DEB-IBM approach tracks individual fish performance (growth, reproduction, survival) over time. The DEB model was calibrated with FEOGRT data. The experimental results indicated that, relatively to the control, FHM exposed to PPP X reproduced less (but not statistically significantly) and had an elevated gonadosomatic index, whereas growth appeared unaffected. These observations can be mechanistically explained by a single physiological mode of action (pMoA) in the model. Six-year population simulations confirmed that the median long-term population growth rate and the abundance of adult males were only marginally affected, if at all. Total and juvenile abundance showed slight reductions (8%), but the median exposed populations remained stable, staying within the 95–105% confidence interval of the control. The study concludes that the substance is unlikely to affect FHM populations under the tested conditions. This mechanistic modeling approach provides a streamlined, validated tool to extrapolate individual-level pMoAs to population-level risk without requiring a calibrated TKTD module, and is applicable to any fish species in the AmP collection.

4.09.P-Mo290 Mechanistic Modeling of the Antidepressant Bupropion's Impact on Daphnia magna populations: Meeting Future EU Pharmaceutical ERA Requirements

Erik B Muller¹, Safa Chaabani², Carlo Romoli¹, Marie Trijau³, Veerle L. B. Jaspers² and sigurd einum⁴, (1)ibacon GmbH, Germany, (2)Norwegian University of Science & Technology, Germany, (3)IBACON GmbH, Germany, (4)NTNU, Germany

The forthcoming EU pharmaceutical legislation and its strengthened Environmental Risk Assessment (ERA) requirements mandate robust, ecologically relevant data for human medicinal products, with the potential for refusal of marketing authorization based on inadequate assessment. This study provides a necessary mechanistic approach by using Dynamic Energy Budget (DEB) theory to model the effects of the antidepressant Bupropion on the keystone aquatic invertebrate, *Daphnia magna*. A Toxicokinetic-Toxicodynamic (TKTD) analysis identified the Physiological Mode of Action (PMoA) as a direct increase in costs for reproduction, which ultimately reduced individual survival and reproductive output. We employed a DEB-Individual Based Model (DEB-IBM) to extrapolate these effects to long-term population dynamics, using simulations with dynamic food, mimicking the feeding regime in OECD *Daphnia* reproduction studies. This mechanistic approach offers the high-tier, process-based evidence required to meet the stricter environmental sustainability criteria embedded in the new EU ERA framework.

4.09.P-Mo291 Beyond Single Stressors: Combined Effects of Polyethylene Terephthalate (PET) Microplastics and Food Limitation on Daphnia magna Population Dynamics and Implications for REACH Regulation

Erik B Muller¹, Safa Chaabani², Carlo Romoli¹, Marie Trijau³, Gabriel Olthof⁴, Martin Wagner⁵, Veerle L. B. Jaspers⁶ and sigurd einum², (1)ibacon GmbH, Germany, (2)Norwegian University of Science & Technology, Norway, (3)IBACON GmbH, Germany, (4)NTNU, Norway, (5)Department of Biology, Norwegian University of Science & Technology, Norway, (6)Biology, Norwegian University of Science & Technology, Norway

Polyethylene terephthalate (PET) is an extensively used thermoplastic polymer, but a detailed understanding of its population-level adverse effects remains limited. This knowledge gap is critical, particularly as PET is being evaluated as a potential 'Polymer of Concern' under future EU REACH regulations, where multi-stressor data are essential for robust risk assessment. The goal of this study was to investigate the combined effects of PET microplastics and food availability on the population dynamics of a keystone aquatic organism, the water flea *Daphnia magna*.

We collected abundance data from *Daphnia magna* populations exposed to two concentrations of PET microplastics (125 and 250 mg/L, irregular particles <63 µm) and two food levels (high: 5 mg C/individual/d; low: 2.5 mg C/individual/d) for 60 days. A Dynamic Energy Budget Individual-Based Model (DEB-IBM) was validated using these experimental observations and subsequently employed to predict population responses to lower, more realistic doses of PET microplastics (1, 5, and 20 mg/L) under low food conditions.

Experimental results demonstrated that MP exposure caused a significant decline in population density and induced substantial changes to population dynamics. Model predictions confirmed that exposure to PET microplastics negatively impacts daphnid growth and reproduction, translating directly into decreases in population abundance. Crucially, both the experimental data and model simulations consistently suggest that food limitation significantly exacerbates the adverse effects of PET microplastics.

Our findings highlight the ecological complexity of plastic pollution and the necessity of integrating multiple environmental stressors into the ecological risk assessment of MPs. This integrated experimental and modeling approach provides essential population-level data, which is paramount for informing proactive risk mitigation strategies and the potential classification and restriction of PET as a Polymer of Concern under future REACH regulatory frameworks.

4.09.P-Mo292 Effect of Background Mortality Modelling Strategy on Environmental Risk Assessment of Chemicals Using GUTS Models

Carlo Romoli¹, Roman Ashauer² and Erik B Muller¹, (1)ibacon GmbH, Germany, (2)Syngenta Crop Protection AG, Germany

Toxicokinetic–toxicodynamic (TKTD) models, such as the General Unified Threshold model of Survival (GUTS), are increasingly used in environmental risk assessment (ERA) for aquatic organisms. A key modeling decision concerns the treatment of background mortality (hb). Two strategies are commonly applied: (O1) fitting hb together with all other parameters, or (O2) estimating hb from control data and fixing it during subsequent fitting. While previous work (Plantade et al., 2023) showed little difference between these approaches for LC50 under constant exposure, their implications for ERA endpoints under realistic exposure scenarios remain unclear. We reanalyzed 38 survival datasets using a Python implementation of GUTS-RED (open source at <https://github.com/ibacon-GmbH-Modelling/pyGUTSred>) and computed LC50 and LP50 values. The LP50 represents the multiplication factor applied to time-variable exposure profiles (FOCUSsw scenarios) to cause 50% mortality at the end of the profile, as recommended by EFSA for higher-tier ERA. In total, 152 model fits (SD and IT variants) were combined with 10 FOCUS profiles, yielding 1520 LP50 estimates. Our results confirm that fitting hb to control data and then fixing it (O2) generally leads to more conservative endpoints: >60% of LC50 and LP50 values were lower with O2 than with O1. For the LP50, differences were sometimes amplified by the interaction between parameter values and exposure dynamics, with ratios exceeding 100 in extreme cases. These occurred in datasets with non-monotonic dose–response or poorly identifiable parameters, highlighting the need for biological plausibility checks and, in some cases, additional experimental data. Goodness-of-fit comparisons (AIC) showed no systematic advantage for either strategy. In conclusion, fitting hb to control data and then fixing it tends to produce more precautionary ERA outcomes, aligning with regulatory principles. However, parameter identifiability and exposure variability can strongly influence LP50 predictions, suggesting that guidance should consider both statistical fit and biological realism.

4.09.P-Mo293 SETAC working group on TKTD models for aquatic primary producers – status update

Cecilie Rendal¹, Udo Hommen², Johannes Witt³, Amund N. Løvik⁴, Stefan Reichenberger⁵, Elena Alonso⁶ and Annika Mangold-Döring⁷, (1)Syngenta Ltd, Denmark, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Bayer Research & Development Services LLC, Germany, (4)Syngenta Ltd, Switzerland, (5)knoell France SAS, France, (6)knoell Iberia S.L., Spain, (7)Environmental Risk Assessment team, Wageningen University and Research (WUR), Netherlands

The use of toxicokinetic-toxicodynamic (TKTD) models to assess the effects of time-variable exposure of organisms to plant protection products is now considered as an acceptable approach in most of the EFSA guidance in force. Since the publication of the Scientific Opinion of the EFSA PPR panel (2018) on the state of the art of TKTD models for regulatory risk assessment of pesticides for aquatic organisms, regulatory

submission of these models have increased, especially of the GUTS model for lethal effects. Some models are also available for assessing effects on the growth of primary producers (algae or macrophytes), but a harmonized framework for calibration, validation and extrapolation of primary producer models does not exist yet. A TKTD and growth model for the standard macrophyte test species *Lemna* sp. was developed by Schmitt et al. (2013) and subsequently refined and harmonized by the SETAC *Lemna* working group. As a follow-up activity, a new working group was established in 2024 with the aim to identify suitable workflows and measures for algae and macrophyte TKTD modelling in Tier 2C (refined exposure experiments and modelling). In particular, the following objectives should be achieved:

1) Development of a unified strategy for calibration, validation and extrapolation of TKTD models for primary producers

2) Create and test user-friendly, open-source software to support practical application

The working group has over 20 members and has been meeting regularly since autumn 2024. The poster will present the current state of work. The group has notably worked on the following tasks:

1) Review the checklist for primary producer models from the EFSA opinion for its practicability

2) Investigate the impact of the growth rate of the species on effects (conclusion: the high growth rate of *Lemna* is not a sufficient reason to question its representativeness for other, slower growing macrophytes under time-variable exposure)

3) Design of the mandatory sensitivity analysis for Tier 2C modelling studies (recommendation: perform combined uncertainty/sensitivity analysis with TKTD input parameter distributions reflecting their actual uncertainty from the calibration)

4) Model calibration: test different implementations and different calibration methods of the *Lemna* model (preliminary results: the three tested calibration methods yielded very similar parameter estimates and confidence intervals)

5) Calculation of statistically correct prediction intervals

4.09.P-Mo294 From individual to population modelling: A tiered ecological risk assessment of insecticide effects in *Chironomus riparius*.

Tido Strauss¹, Natalie Albrecht¹, Jana Gerhard¹, Josef Koch¹, Maxime Vaugeois² and Nika Galic³, (1)gaiac eco assessment GmbH, Germany, (2)Syngenta Ltd, United States, (3)Syngenta Crop Protection AG, Switzerland

Mechanistic effect models (MEMs) are applied to refine risk at several tiers of the ecological risk assessment of chemicals. They should be designed as realistically as possible for a specific risk assessment question and, in the case of aquatic invertebrates, address population properties quantitatively as this is the relevant specific protection goal.

Density-dependent mechanisms are crucial for the regulation of stable, persistent animal populations, and their functional understanding is essential for the prediction and management of populations and must therefore be implemented in population models to describe their dynamics in the field. However, the greatest challenge in extrapolating to the field population is the lack of field data for the most relevant and sensitive environmental parameters (e.g., background mortality of larvae, loss of emerged adults, food availability).

We present a tiered modelling approach for the multivoltine, r-strategist taxon *Chironomus riparius* (Diptera), exposed to a hypothetical insecticide. The model framework integrates individual-based population models (IBMs) including a Dynamic Energy Budget (DEB) model, and toxicokinetic-toxicodynamic (TKTD) modules to connect exposure and effects and extrapolate laboratory data to real-world field scenarios.

To evaluate multi-peak exposures under various temperature profiles, we employed both the DEB-TKTD model with moving time window (MTW) for individual-level assessment and the more complex model for population-level field scenarios.

The population-level simulations offered additional insights beyond simple comparisons of maximum larval effects. It enables tracking of both larval density dynamics and cumulative adult emergence patterns over time. Furthermore, the model allows us to examine density-dependent population effects, which can potentially compensate for losses at high insecticide concentrations.

By incorporating temperature and size-dependent biological and toxicological processes, we analysed effects from exposure to the insecticide across multiple variables: exposure concentration, environmental temperature, and seasonal timing. This integrated modeling approach, combining individual and population-level responses under realistic conditions, delivers more thorough risk assessments for aquatic invertebrates - from worst-case individual life cycles to realistic field population scenarios - thereby reducing uncertainty in risk characterization.

4.09.P-Mo295 The SETAC MAPPED Workshop: Seeking How to Assess Population Relevance of Endocrine Disrupting Effects Using Models

Charles Hazlerigg¹, **Thomas G. Preuss²**, Andreas Focks³, Valery Forbes⁴, Udo Hommen⁵, Oliver Jakoby⁶,

Joachim Ulrich Kleinmann⁷, Laurent L.-M. Lagadic⁸, Kate Mintram⁹, Erik B Muller¹⁰, Melissa Reed¹¹, Pernille Thorbek¹², Charles Tyler¹³ and Lennart Weltje¹⁴, (1)Enviresearch Ltd., United Kingdom, (2)Bayer Research & Development Services LLC, Germany, (3)FB06/Institute of Mathematics, University of Osnabrueck, Germany, (4)Florida Atlantic University (FAU), (5)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (6)RIFCON GmbH, Germany, (7)BASF, Germany, (8)Bayer AG, Germany, (9)Brunel University, United Kingdom, (10)ibacon GmbH, Germany, (11)Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom, (12)BASF, United Kingdom, (13)University of Exeter, United Kingdom, (14)Agricultural Solutions - Ecotoxicology, BASF, Germany

ECHA/EFSA (2018) states that models are one option for assessing the relevance of effects from Endocrine Disrupting Chemicals on vertebrate wildlife populations. An important step in such an assessment is defining what response in a population may be considered relevant. A creditable attempt at defining assessment criteria for use in risk assessment was presented in the EFSA (2023) Birds and Mammals guidance. This stated two criteria for concluding a low population-level risk using models: (i) the exposed population mean should not fall below the lower 95th percentile of the control and (ii) the lower 95th percentile of the exposed population should not be consistently below the lower 95th percentile of the control population (...on a limited number of points...). However, one encounters issues with these criteria when implemented in practice. For example, a population relevant effect can be identified using criterion 2, even when comparing two sets of control simulations without any chemical involvement at all (Tagliati et al. 2025).

As part of the SETAC MAPPED workshops (2024-2025), further options on how to assess population relevance in models have been explored for fish and will be presented. Some options explored revisions to the EFSA (2023) criterion 2, considering the use of alternative lower percentiles, as well as different frequencies and the consecutive nature of failing timepoints. These could be in isolation or in combination. Alternative approaches investigated population trends using census data over time, whilst others considered equivalence testing as opposed to more traditional hypothesis testing. Results from simulations with three fish population models (three-spined stickleback, brown trout and zebrafish) were used to inform the options explored and how they would address some of the ongoing challenges with defining appropriate criteria. The options presented may be used to inform risk assessors when making their decision on which approach may be taken in regulatory chemical assessment.

4.09.P-Mo296 Applying the Normal Operating Range Concept to Stochastic Models: A Robust Method for Detecting Population-Level Effects

Oliver Jakoby¹, Torben Wittwer¹, Alexander Singer¹, Felix von Blanckenhagen², Tina Grimm¹ and Lara Ibrahim¹, (1)RIFCON GmbH, Germany, (2)Rifcon GmbH, Germany

Mechanistic effect modelling is a valuable tool in higher tier Environmental Risk Assessments (ERA) of pesticides. Stochastic population models enable evaluation of potential population-level effects across diverse environmental scenarios and exposure patterns.

Currently, no explicit guideline exists for identifying pesticide effects from simulated population dynamics. The EFSA Bird & Mammal Guidance (2023) proposes two criteria for assessing low population-level risk: (i) the treatment mean abundance remains above the control's lower 95% confidence limit, and (ii) the treatment's lower 95% confidence limit is not consistently below the control's. Yet, no standardized method exists for applying these criteria to stochastic models.

We present a method specifically designed to detect the occurrence and duration of population-level effects in stochastic simulations, aiming to implicitly account for the above-mentioned EFSA criteria. Our approach constructs a model Normal Operating Range (mNOR) for the control mean abundance by bootstrapping the usual number of simulation replicates from a large number of control simulations. For each bootstrapping set, daily mean control abundances are calculated. The minimum and maximum values across these sets define the daily mNOR. Next, a daily mean treatment abundance is calculated based on one set of treatment replicates. The number of treatment replicates is kept comparable to that used for the bootstrap control sets to ensure consistency. Low population-level risk can be expected if daily mean treatment abundance remains within the mNOR for a relevant period.

We illustrate the proposed method using the stochastic, individual-based and spatially explicit simulation model eVole, which is frequently applied for higher tier ERA of small herbivorous mammals. We explore different scenarios and demonstrate how thresholds for acceptable effects can be integrated. We further derive daily confidence limits for both treatment and control, to explore how our approach relates to the proposed EFSA criteria.

Our approach supports recent efforts to improve ERA robustness by applying the NOR concept. Sensitivity to stochastic fluctuations is reduced by basing mNOR on mean values rather than extreme percentiles, while still

accounting for inherent variability in model outputs. This ensures robust detection of treatment effects and aligns with ideas posed in EFSA Bird & Mammal guidance.

4.09.P-Mo297 Acceptability of Mechanistic Effect Models in the Regulatory Environmental Risk Assessment of Pesticides: Considerations and Conditions from the SETAC MAD working group

Andreas Focks¹, *Jeremias Martin Becker², Alpar Barsi³, Thomas G. Preuss⁴, Udo Hommen⁵, Oliver Jakoby⁶, Benoit Goussen⁷, Stefan Reichenberger⁸, Melissa Reed⁹, Johan Axelman¹⁰ and Sabine Duquesne¹¹*, (1)FB06/Institute of Mathematics, University of Osnabrueck, Germany, (2)IV 1.3, German Environment Agency (UBA), Germany, (3)Dutch Board for the Authorisation of Plant Protection Products and Biocides (Ctgb), Netherlands, (4)Bayer Research & Development Services LLC, Germany, (5)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (6)RIFCON GmbH, Germany, (7)ibacon GmbH, Germany, (8)knoell France SAS, France, (9)Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom, (10)Swedish Chemicals Agency, Sweden, (11)German Environment Agency (UBA), Germany

Mechanistic effect models (MEMs) dynamically simulate essential processes in ecological systems and how these processes are affected by chemicals (Grimm & Martin, 2013). The modeled systems can range from (sub)organisms, to populations, communities, or ecosystems. Recently, MEMs have been increasingly proposed for use in the regulatory environmental risk assessment (ERA) of pesticides. The work in the SETAC working group on 'Model Acceptability criteria and scenario Development (MAD)' has been focussed on the use of MEMs for the regulation of plant protection products in the European Union. So far, MEMs for regulatory purposes have been proposed mainly as refinement options, e.g., for assessing the effects of time-variable exposure on organisms or assessing effects on populations (EFSA PPR, 2013). However, MEMs can be useful exploratory tools to address various questions; this includes ranking the effectiveness of alternative risk mitigation measures or supporting the interpretation of ecotoxicological studies. In retrospective risk assessments, such models can be used to analyze mechanisms behind effects observed in (semi-) field studies and to support the establishment of appropriate assessment factors in ERA with an improved mechanistic understanding.

This contribution summarises considerations and background on the development and evaluation of mechanistic effect models, compiled by a multi-partite consortium with stakeholders from industry, contract research organizations (CRO), academic research institutions, and a number of European regulatory authorities. Such a multi-stakeholder group cannot define binding acceptability criteria for MEMs in the ERA of pesticides. However, it can provide input for further regulatory development that may be used to promote the development of such criteria and to identify critical research questions for the further assessment of MEMs and their use in the ERA of pesticides. The full extend of results is published in the MAD book (Focks et al., 2026). The proposed concept provides means to properly assess mechanistic effect models for their use in the environmental risk assessment of chemicals, here specifically of pesticides, because, if they are properly tested and applied, MEMs can improve ERA and make it safer and more relevant.

4.09.P-Mo298 From Outliers to Solutions: Evaluating Insecticide Efficacy for Whitefly Control in Cotton

Andre Gergs¹, *Angelika Weinhold¹, Elena Hettmann¹, Mariana Durigan², Lokeshkumar Kadu³, Jocelyn Kratchmer¹ and Christian Marienhagen¹*, (1)Bayer AG, Germany, (2)Bayer SA, Brazil, (3)Bayer CropScience Limited, India

The safe and efficient use of pesticides is critical for their registration, necessitating comprehensive field trials to evaluate the efficacy of formulated products across various cropping systems. In our presentation, we focus on the development of agronomic advice for managing whitefly infestations using the insecticide spidoxamat in cotton. The whitefly, *Bemisia tabaci*, poses a significant threat to agricultural productivity through direct crop damage and indirectly via the transmission of viral diseases. Although spidoxamat and other ketoenols generally demonstrate high efficacy against treated whitefly populations, some outliers observed in field trials suggest inconsistent performance influenced by environmental conditions and pest pressures.

To systematically address these outliers, we employed an individual-based modeling (IBM) approach integrated with a Dynamic Energy Budget (DEB) theory-based toxicokinetic-toxicodynamic (TK-TD) model. This integrated modeling framework allowed us to assess mortality rates of immature whitefly stages and the effects of spidoxamat exposure on the fecundity and fertility of adults as quantified in the greenhouse. We validated the

model using field trial data from diverse locations in India, Pakistan, and Brazil, enabling us to predict population dynamics and the efficacy of spidoxamat under varying field conditions. Our modeling efforts identified environmental scenarios that may lead to reduced performance of the insecticide and proposed optimal application strategies tailored to different pest pressures and temperature regimes. Notably, our results indicated that a second application of spidoxamat could significantly enhance population control, especially when administered between 7 and 14 days post-initial treatment. This timing is linked to the insecticide's efficacy half-life and the developmental duration of immature stages, reinforcing the necessity for precise application strategies in effective management of *B. tabaci* populations. Ultimately, our findings illustrate the critical importance of integrating empirical data with mechanistic modeling to turn outliers into actionable insights, thereby enhancing pest management strategies through effect modeling approaches.

4.09.P-Mo299 Quantifying Intraspecies Variability in Sensitivity to Toxic Effects to Improve Chemical Risk Assessment

Poornima Nagesh, Selwyn Hoeks, Aafke Schipper and Mark Huijbregts, Department of Environmental Science, Radboud Institute for Biological and Environmental Sciences, Radboud University, Netherlands

Chemical pollution poses a persistent threat to freshwater ecosystems, and assessing the effects of chemical substances on species and aquatic communities is central to chemical risk assessment. Species sensitivity distributions (SSDs) are commonly used to evaluate the ecological risks of chemical exposure, accounting for interspecies variation in sensitivity to toxic impacts. However, SSDs do not reflect the effects of chemical exposure on species abundance, considered an important endpoint in biological conservation. As a promising alternative, the change in mean species abundance (MSA) as a function of chemical exposure can be quantified by combining species-specific exposure–response relationships and population growth theory. Information on intraspecies variability in responses to toxicity tests is, however, not commonly reported. Here, we used regression models to predict intraspecies variability in responses to chemical exposure of ~3017 chemical-species combinations that have not been tested before. We first derived the ratio of the EC50 and EC10/EC20 Values of species-chemical combinations, based on existing toxicity databases, as a measure of intraspecies variability. After that, we explained differences in intraspecies variability via various regression models using species type (algae, invertebrates, and vertebrates), mode of action (e.g. (non)polar narcosis), and exposure duration (chronic vs acute) as predictor variables. As our model can be directly used to predict intraspecies variability, it provides great opportunities to integrate intraspecies variability into chemical risk assessment.

4.09.P-Mo300 Roles of Allometry, Trophic Guilds, and Phylogeny in Cross-species Sensitivity Extrapolation

Andrew Beckerman¹, Xiaoxiao Li², Amy Rose Ockenden¹ and Lorraine Maltby¹, (1)School of Biosciences, University of Sheffield, United Kingdom, (2)University of Sheffield, United Kingdom

Most chemicals and species have never been tested, leaving both chemical potency and species sensitivities largely unknown. This knowledge gap poses a major challenge for modern ecological risk assessment's emerging focus on multiple species and multiple chemicals: How can we incorporate diverse species and their variation in sensitivity into community-level assessments when empirical data are sparse? Addressing this question is essential for linking species-level endpoints to community-level responses such as biodiversity and ecosystem functioning. To identify general principles governing cross-species variation in chemical sensitivity across the tree of life, we compiled an integrated dataset of 906 species (algae, invertebrates, vertebrates) and their sensitivities to 999 chemicals among six categories of chemicals, combined with information on species phylogeny, body mass, and trophic guild. We first used a machine-learning model to predict sensitivity for all species-chemical combinations. We then fitted Bayesian hierarchical models incorporating phylogenetic structure, allometry, and trophic guilds to evaluate their relative contributions in explaining species sensitivity. We found that species sensitivity to chemicals is strongly phylogenetically conserved, and models that include phylogenetic structure greatly outperform those that exclude it. All chemical categories exhibited a high phylogenetic signal, indicating that species with shared evolutionary history tend to respond similarly to chemical stress. In contrast, both global and taxonomic group-specific body size (allometric) effects were close to zero, suggesting that neither body mass nor trophic feeding guild systematically predicts sensitivity at this

broad scale. Our findings advance cross-species extrapolation and provide the bridge for linking species-level sensitivity to community-level responses, ultimately improving predictions of biodiversity loss and ecosystem functioning under chemical stress.

4.09.P-Mo301 Population model for chemical and radiological hazards in marine biota: application to Atlantic cod in the Oslofjord

Jordi Vives i Batlle¹, Catherine Barnett², Eric Blanchardon³, Jacqueline Calabria⁴, Trine Celiu⁵, David Copplestone⁶, Alicia Escribano⁷, Lamia Fathi⁸, Esther Folorunso⁶, Hallvard Haanes⁵, Susana Petisco⁹, Maria Psaltaki¹⁰, Almudena Real⁷, Hans-Christian Teien¹¹ and Allison Villarreal¹², (1)Belgian Nuclear Research Center (SCK CEN), Belgium, (2)UK Centre for Ecology & Hydrology, United Kingdom, (3)Nuclear Safety and Radiation Protection Authority (ASNR), France, (4)International Atomic Energy Agency (IAEA), Austria, (5)Norwegian Radiation and Nuclear Safety Authority (DSA), Norway, (6)University of Stirling, United Kingdom, (7)Research Center on Energy, Environment and Technology (CIEMAT), Spain, (8)Moroccan Agency for Nuclear and Radiological Safety and Security, Morocco, (9)University of the Basque Country (UPV/EHU), Spain, (10)National Technical University of Athens (NTUA), Greece, (11)Norwegian University of Life Sciences, Norway, (12)University of Stirling, United Kingdom

Many radioactively contaminated sites are affected by both radiological and chemical pollutants, highlighting the need for consistent chemical and radiological impact assessment. Models to assess ionising radiation and chemical effects on wildlife are being developed. The challenge is to make these approaches practical for use in regulatory assessments.

In this study, carried-out as part of the activities of IAEA MEREIA Working Group 5 on mixed stressors in the Oslofjord, we evaluate a candidate approach to model dynamically in a practical scenario the effect of mixed chemical and radiological contamination in non-human biota. Building on work for IAEA and EC project RadoNorm, we extended our approach to a full toxicokinetic – toxicodynamic model by incorporating biokinetic transfer processes for waterborne radionuclides to fish and sediment, coupled to an ordinary differential equation (ODE)-driven logistic population model that can evaluate population-level impacts on mortality, morbidity and fecundity in a population of healthy and sick animals, with a common repair system for radioactive and chemical pollutants.

The model was set-up for cod (*Gadus morhua*) in the Oslofjord, considering Iodine-131 as the radionuclide and mercury (Hg) as the contaminant. The model inputs are the concentrations of the radionuclide (Bq/kg) and the chemical (mg/kg) in biota, along with biokinetic and ecotoxicological data. We also demonstrate how to include in the model multiple radionuclides and chemicals (e.g. heavy metals and organics), and how to consider not only additivity but antagonism/synergism in the mixture.

The focus of this study was on determining the key uncertainties and data gaps, and how the approach can be made useful for regulators in a multi-contaminant situation. Initial results indicate that increasing Hg concentrations beyond EU Environmental Quality Standards are the driving force affecting the population in the ecosystem of the Oslofjord. Current levels could potentially lead to tipping points with severe population decline. Parameter sensitivity analyses reveal significant data gaps (particularly in EC50 values), introducing uncertainty in predictions. Despite these limitations, findings suggest that toxic metals - especially Hg - pose an ecological risk, potentially amplified by radionuclide mixtures. The study calls for better ecotoxicological data and improved assessment models to support regulatory decisions and pollution control measures.

4.09.P-Mo302 toxdr: An R Package to Automate Dose-Response Curve Analysis

Jack Salole and Joanna Wilson, McMaster University, Canada

As test methods become more sophisticated, the complexity of toxicity test data becomes complex, and can consist of multiple endpoints across many technical and/or biological replicates. Currently, these values are used to determine effect measures (i.e. LC50, IC25) through dose-response modelling. While this process is well understood and can be completed with various programs, consistently applying it over many tests or experimental subsets is a tedious process. The ‘toxdr’ package is being developed to address this limitation of current programs. This package provides a set of modular functions that can intake raw data, perform quality

checks, apply user-specified transformations, fit and select the best fitting dose-response model, and determine the specified point estimates across multiple experimental subsets. Importantly, these modular functions are combined into a pipeline function that allows an automated process to analyze large datasets. This package is designed to support both quantal and quantitative endpoints, making it adaptable to diverse test measurements. This package is particularly well-suited for researchers working with large-scale toxicity studies that require efficient, consistent, and transparent data processing across large datasets. Publicly available versions of this package are currently being applied in research contexts to estimate effect measures. Here, we present an overview of the package and a case study using this package to rapidly analyze toxicity data from a dataset with 300 unique experimental subsets in under 5 minutes.

4.10 Navigating and Harnessing Complexity in Ecological Risk Assessment of Chemicals

4.10.T-01 Navigating species diversity and data gaps: the role for trait-based approaches and modelling

Nika Galic¹, Valery Forbes², Volker Grimm³, Amelie Schmolke⁴, Maxime Vaugeois⁵, Charlotte Elston⁶ and Richard Brain⁵, (1)Syngenta Crop Protection AG, Switzerland, (2)Florida Atlantic University (FAU), (3)UFZ-Helmholtz Centre for Environmental Research, Germany, (4)RIFCON GmbH, Germany, (5)Syngenta Crop Protection LLC, United States, (6)Syngenta Ltd, United Kingdom

We present a trait-based framework combining systematic trait analyses for species selection and mechanistic modeling of field-relevant species in ecological risk assessments. Traditional focal species selection in pesticide risk assessments has been limited by its focus on presumed vulnerability traits and practical considerations, often missing potentially vulnerable species and lacking consistency. To address these limitations and data gaps, particularly for protected species where information is scarce, we propose a structured framework that supports the identification of representative species through trait-based analyses. We focus on two approaches: a supervised top-down method identifying traits associated with vulnerability, and an unsupervised bottom-up approach that groups species based on shared traits. The former assumes that protecting the most vulnerable species will safeguard less vulnerable ones and has been applied to pollinators, aquatic invertebrates, and wildlife species. The latter incorporates relevant traits through classification and categorization methods, such as discriminant analysis, non-metric dimensional scaling, and cluster analyses.

We demonstrate how these approaches can be applied to identify representative non-target arthropod species in European agricultural landscapes, where an estimated 3,000 species are present. The framework builds upon existing analyses of species traits and crop presence conducted by EFSA and industry groups.

A key extension of the approach is the incorporation of trait-based mechanistic modeling, allowing a single model to be applied across multiple species within the same trait group. These models can evaluate multiple scenarios and examine trait-stressor interactions, while maintaining consistent underlying model structure and processes. This approach enables standardized comparison across species without requiring separate model frameworks, as demonstrated in applications to solitary bees and cyprinid fish. The framework's adaptability makes it valuable for comparing risk assessments and management strategies across multiple species, especially for species with limited data. This flexibility extends across different ecosystems and geographical regions, informing and supporting ecological risk assessments of non-target arthropods - one of the most diverse taxonomic groups providing essential ecosystem services in agricultural landscapes.

4.10.T-02 APODEMUS, a Population Model for the Wood Mouse: implementation and model analysis

Alexander Singer¹, Amelie Schmolke¹, Matthias Becher¹, Lara Ibrahim¹, Silke Laucht², Thomas Martin³, Oliver Jakoby¹, Amund N. Løvik⁴ and Nika Galic⁵, (1)RIFCON GmbH, Germany, (2)Rifcon GmbH, Germany, (3)Effect Modelling, Rifcon GmbH, Germany, (4)Syngenta Ltd, Switzerland, (5)Syngenta Crop Protection AG, Switzerland

The wood mouse, *Apodemus sylvaticus*, is a small mammal species that occurs across large parts of Europe. The species uses various habitats, has an omnivorous diet and can use pesticide treated agricultural fields for foraging. Thus, it is one of the focal species in risk assessments of plant protection products (PPPs) in the European Union. However, exposures and effects of PPPs on populations in the field are challenging to assess across different regions and landscapes. Population modeling has emerged as a valuable tool in higher-tier risk

assessments, complementing and extending data obtained from field studies. These models can simulate individual-level exposure and effects through modeled life-cycle processes, enabling predictions of population-level impacts. In this context, we introduce APODEMUS (A POpulation Dynamical spatially Explicit Model of the wood moUse). The model development was conducted using best practices, based on a comprehensive literature review and involved feedback from multiple stakeholders. The individual-based model represents the life cycle of the species using a Dynamic Energy Budget (DEB) model. The spatially explicit model considers the varying attractiveness of different habitats to the wood mouse. Density dependence can emerge from competition for space (represented by home ranges) by the mice. We applied the simulation model using an agricultural landscape whereby the habitat attractiveness was defined by expert opinion. We conducted a sensitivity analysis with the model, assessing the interaction of ecological parameters and the landscape scenario with model outputs including population abundance, structure and distribution across the landscape. These model outputs will ultimately be important to address scenarios including exposure to a pesticide in different agricultural landscapes and the comparison of model outputs to available wood mouse field study data conducted under different conditions. We present APODEMUS as a transparent and tested tool specifically designed for higher-tier mammal risk assessments. This model serves as a valuable complement to field studies by enabling the assessment of diverse environmental conditions, encompassing various landscape configurations and exposure scenarios.

4.10.T-03 Chemical Co-Exposure and Risk Estimation for European Watersheds: A Combined Approach Using Models and Monitoring

Sophie Mentzel¹, Jos van Gils², Merete Grung¹, Samantha Eslava Martins¹, Frederik Verdonck³, Karel Viaene³, Karel Vlaeminck³, Anders L. Madsen⁴, Luka Snoj⁵, Gašper Šubelj⁵ and Jannicke Moe¹, (1)Norwegian Institute for Water Research, Norway, (2)Deltares, Netherlands, (3)ARCHE Consulting, Belgium, (4)HUGIN EXPERT, Denmark, (5)TC Vode, Slovenia

The EU Chemicals Strategy for Sustainability seeks to integrate environmental risks from “combined exposure” to unintentional chemical mixtures into regulatory assessments. ENCORE (ENvironmental CO-exposure and Risk Estimation, 2025–2027) is developing a probabilistic framework to assess mixture risks to aquatic ecosystems at the watershed scale across Europe. This approach synthesizes diverse information—chemical use, transport, degradation, fate, and hazard—while explicitly accounting for uncertainty in both exposure and hazard data. Building on the SOLUTIONS project’s large-scale exposure model, ENCORE applies object-oriented Bayesian Network (OBN) methodology to update prior probabilities from process-based simulations with monitoring evidence, improving prediction accuracy. Key data sources include pan-European datasets from the European Environment Agency: Waterbase Emissions (WISE-1) and Waterbase Water Quality (WISE-6). A pilot study using a subset of pesticides in Belgium demonstrates the implementation of this probabilistic approach, enabling exploration of alternative emission scenarios and mixture risk characterization methods. This proof-of-concept will inform scaling to larger European regions. Ultimately, ENCORE aims to identify chemicals that contribute most to mixture risk by incorporating spatial and seasonal exposure patterns across watersheds, supporting next-generation environmental risk assessment and management.

Disclaimer/Disclosure:

The ENCORE project is sponsored by the European Chemical Industry Council (CEFIC) as part of the Long Range Initiative (LRI) under project ECO-66 “Next generation risk assessment methods supporting the identification of environmental co-exposures of potential concern”.

4.10.T-04 ECOMIX: Understanding and Managing the Impacts of Mixtures of Chemicals and Co-Stressors on Mixtures of Species in English Rivers

Alistair Boxall¹, Lorraine Maltby², Sim Reaney³, Andrew Beckerman², Amy Rose Ockenden², Jun Li⁴, Martha Villamizar¹, Ivo Pink³, Alejandra Bouzas Monroy¹, Angelica Pardo Islas¹, Anthony Turner², Xiaoxiao Li⁵ and Leuan Roberts¹, (1)University of York, United Kingdom, (2)School of Biosciences, University of Sheffield, United Kingdom, (3)Durham University, United Kingdom, (4)University of York, United States, (5)University of Sheffield, United Kingdom

Rivers in England are in an unhealthy state. Only 16% of rivers meet the European Water Framework Directive for Good Ecological Status. While it is recognised that chemical pollution from wastewater emissions,

agriculture, highways and legacy mining activities is contributing to the problem, we still have a poor understanding of the real risks of chemicals and co-stressors in England's rivers. For example, current regulatory monitoring only focuses on a small number of chemicals in use, ecotoxicity testing focuses on only a small number of species that may not reflect sensitivity of the actual species that occur in English rivers, and chemicals assessment takes a single compound approach ignoring the fact that rivers are exposed to chemical mixtures and other co-stressors. The ECOMIX project is therefore developing a new catchment-based approach to chemical assessment and management that addresses these challenges. This approach: 1) assesses impacts of mixtures of chemicals and co-stressors on the structure and functioning of UK-relevant species assemblages at high spatial resolution; 2) considers the current situation and also looks to the future to account for the effects of global megatrends on chemical sources, fate processes, exposure and effects; and 3) allows us to target interventions where they are going to have maximum impact allowing us to benefit from the use of chemicals while protecting biodiversity. Focusing on the Yorkshire region in the North of England, the study, which has been running for over 3 years, is using a combination of continuous environmental monitoring, exposure modelling at high temporal and spatial resolutions, ecotoxicity testing on multiple algal and invertebrate species and hierarchical species sensitivity distribution and food web modelling to characterise the current and future risks of mixtures of over 40 high priority chemicals and co-stressors arising from different sources. This presentation will: provide an overview of the project approach; illustrate the results obtained to date on the occurrence, effects and risks of the case study chemicals in Yorkshire's rivers; and describe our plans for a catchment dashboard to support management efforts to improve the chemical quality of rivers in the region and to protect them into the future.

4.10.P Navigating and Harnessing Complexity in Ecological Risk Assessment of Chemicals

4.10.P-Tu380 Airborne particules and urban agriculture : optimization of health risk assessment

Sarah Boitelle, Ludivine Canivet and Annabelle Deram, Université de Lille, IMT Lille Douai, Université d'Artois, Laboratoire de Génie Civil et géo-Environnement (LGCgE), France

Urban agriculture presents health challenges linked to soil contamination and air pollution. While most studies have focused on soil pollutants, the contribution of particulate deposits from urban traffic to contamination of edible vegetables remains insufficiently assessed. This research aims to characterize the toxicity of these particles in relation to their physicochemical composition and better integrate their ingestion into human health risk assessments.

To achieve this goal, juvenile snails (*Helix aspersa*), well-established ecotoxicological models, were used due to their sensitivity to pollutants and ability to bioaccumulate contaminants. A total of 450 snails, sourced from a local farm, were randomly distributed into standardized experimental boxes after a three-week acclimation period in a vegetated environment (plantain, grasses, herbaceous plants).

Two exposure modalities were implemented:

- Dietary ingestion: incorporation of particles into a specific snail feed, allowing for chronic and homogeneous exposure;
- Ingestion via plant material: lettuce leaf fragments impregnated with particles, provided intermittently to ensure complete consumption.

Three types of particles were tested at five different concentrations, each with three replicates of four snails, resulting in a total exposure period of 28 days with biweekly feeding. Snail growth was monitored throughout the experiment. At the end of the exposure period, the snails were frozen and dissected for biochemical analyses.

The biochemical assays will focus on Major biological macromolecules (proteins, lipids, and carbohydrates), Oxidative stress markers (glutathione peroxidase (GPx), glutathione S-transferase (GST), and catalase (CAT)), Overall antioxidant potential (2,2-diphenyl-1-picrylhydrazyl (DPPH) method)

This experiment aims to highlight the differences in oxidative stress induced by the various types of dust particles. Ultimately, this may allow the different characteristics of the particles to be linked to the variations observed in the measured responses. The expected results will contribute to highlight a critical point of vigilance regarding the need to fully account for the ingestion of atmospheric particles deposited on vegetables —an exposure route that has so far been largely overlooked in environmental health studies—in health risk assessment protocols, in order to better reflect real exposure conditions in urban agriculture.

4.10.P-Tu381 PECsw refinement approaches in Environmental Risk Assessment for collyria medicinal products

Giulia Baldone¹, Giada De Angelis¹, Marco Domenico Rodda², Lara Brunasso Cattarello¹, Virginia Carlucci¹, Marta Lettieri¹ and Antonio Conto², (1)Chemsafe Srl, Italy, (2)Chemsafe USA Corp, Italy

The Environmental Risk Assessment (ERA) evaluates the environmental impact of Human Medicinal Products (HMPs) based on their release into the environment via wastewater by excretion of drugs following their therapeutic use by patients. ERA is mandatory for all new Marketing Authorization (MA) applications for medicinal products. The guideline describes a step-by-step process based on the analysis of environmental exposure to the medicinal products, considering the worst-case dose regimen scenario. Phase I of the ERA includes the calculation of the Predicted Environmental Concentration in Surface Water (PECSW) of the medicinal products, taking into account the maximum daily dose (MDD), standard values of wastewater per inhabitant per day and of portion of treated population. If the calculated PECSW exceeds 0.01 µg/L, Phase II is necessary. In Phase II, PECSW may be refined by modifying the fraction of market penetration (FPEN), the proportion of the population being treated daily with a specific drug substance, based on actual prevalence data of the target disease/s and area, and on the worst-case treatment regimen specific for each disease addressed by the product. In the case of a collyrium, not all the product enters the body, but most of it drains out of the eye, onto the patient's cheeks during the administration. Therefore, the quantity of the drug that is actually absorbed by the patient during the treatment does not correspond to the MDD, but it is lower. Consequently, for the purposes of the ERA it would be relevant to consider some additional factors, such as the volume of a drop, the conjunctival sac capacity (often exceeding the average drop volume), the frequency of administration of the drops and the actual absorption rate of the eye, which is limited by the fact that only a small fraction of each drop is retained during ocular administration. These types of risk assessments need to be adapted based on approaches that, although consistent with the scopes of the ERA, are not addressed in the current reference guideline. In conclusion, it would be desirable for the competent authorities evaluating ERA submissions to remain open to accepting well-justified alternative approaches.

4.10.P-Tu383 Regional Variability of Pesticide Residues in Cottonseed and Fiber Across Türkiye's Major Agro-Ecological Zones

Volkan Mehmet ÇINAR¹ and Cafer Turgut², (1)Anadolu University, Türkiye, (2)Istanbul University, Türkiye

This study examines pesticide residues in cottonseed and fiber collected during the 2024 and 2025 seasons from Türkiye's major cotton-growing regions, highlighting geographical differences across areas. The sampling sites represent various ecological zones: the Aegean Region (Aydın and İzmir), the Mediterranean Region (Adana and Hatay), and the Southeastern Anatolia Region (Van and Diyarbakır). A total of 31 pesticides were detected in 2024, with 12 residues in cottonseed and 19 in fiber, indicating that fiber contains a broader range of pesticides. Acetamiprid, Chlorantraniliprole, Chloromequat, and Diuron were consistently found across all three regions, establishing the common residue baseline. However, residue diversity varied significantly by region. The Aegean provinces, especially Aydın, had the highest variety of pesticides, reflecting intensive farming systems and a long growing season that encourages repeated chemical use. The Mediterranean provinces exhibited a moderate but varied profile, with Adana showing a broader presence of pesticides in fiber, likely influenced by its warm climate and multi-cycle pest pressure. In contrast, the Southeastern Anatolia provinces—particularly Diyarbakır—had fewer seed detections, while Van showed notable fiber diversity, suggesting region-specific agronomic practices. Insecticides led in all three regions, followed by growth regulators, herbicides, and acaricides. Compounds like cypermethrin, lambda-cyhalothrin, malathion, and pyriproxyfen appeared more often in fiber, indicating different deposition patterns under varying climate conditions. Overall, the findings indicate that pesticide contamination in cotton is influenced not only by crop management but also by the ecological characteristics of Türkiye's different regions. These spatial variations highlight the importance of region-specific monitoring methods and localized pesticide-reduction strategies to improve environmental safety and protect consumers.

Disclaimer/Disclosure:

This study is supported by The Scientific and Technological Research Council of Türkiye (TÜBİTAK), with project number 123C296, within the scope of the "2218-National Postdoctoral Research Fellowship Program". Volkan Mehmet ÇINAR would like to thank TÜBİTAK.

4.10.P-Tu384 (Re)Establish the use of the Geometric Mean as Refinement Option for Chronic Aquatic Risk Assessments

Hanna Samantha Schuster¹, Maike Habekost², Eric Bruns³, Helena Crosland¹, Akshaya Lekha¹ and Nadine S Taylor¹, (1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)BASF, Germany, (3)Bayer Research & Development Services LLC, Germany

In the European Union, the risks of pesticides to aquatic organisms are assessed using a tiered system, whereby data on the acute and chronic effects of a substance on standard species (i.e. algae, macrophyte, aquatic invertebrate and fish) forms the basis of risk assessment (RA). The use of a geometric mean (geomean) was outlined as an acceptable refinement option for both acute and chronic RA in the EFSA Aquatic Guidance Document (2013). In recent years, this refinement option has been restricted especially for chronic tests (currently not accepted for chronic fish and aquatic invertebrates, Recurring Issues EFSA, 2018). Furthermore, its use as a refinement option for primary producers has also now been questioned by regulators and consequently could result in critical issues for the aquatic risk assessment. The main concerns over the use of the geomean approach from regulatory authorities are 1) the lack of comparability between tests regarding duration, endpoint and life stage; and 2) the missing verification of the protectiveness of the geomeans approach using results of the surrogate reference tiers. Conversely, a robust geomean approach could be more prominent in the future as there are also challenges on the use of Species Sensitivity Distributions (SSD). These challenges can lead to defaulting to Tier I risk characterisation due to the absence of alternatives for risk assessment.

To address the concerns from regulatory authorities chronic geomeans are calculated from existing regulatory data (across the 4 species groups). The data is used to assess comparability of different type of endpoints (e.g. length and reproduction endpoints in chronic aquatic invertebrate tests) as well as protectiveness in comparison to higher tiers as reference data (e.g. SSDs or mesocosm studies). To ensure the robustness of the geomean, reliability of endpoints used for the calculations will be investigated and any exclusion criteria determined and documented.

The outcomes of this analysis will inform the use of chronic geomeans and support transparent, protective aquatic risk assessments in regulatory practice.

4.10.P-Tu385 The challenge of deriving population model parameters from multiple data sets: the example of mortality rates in the wood mouse

Silke Laucht¹, Lara Ibrahim², Amelie Schmolke², Alexander Singer², Amund N. Løvik³ and Nika Galic⁴, (1)Rifcon GmbH, Germany, (2)RIFCON GmbH, Germany, (3)Syngenta Ltd, Switzerland, (4)Syngenta Crop Protection AG, Switzerland

As indicated in multiple EFSA guidance documents, mechanistic effect models can be applied to provide scenario-specific temporal predictions of pesticide effects. In population models, reliable and adequate predictions require the representation of physiological and ecological processes of the species. However, even for well-researched species, knowledge is not complete, leading to simplifications of the model. For instance, models might not consider all covariables that likely influence a process in nature and are reflected in empirical measurements. Nevertheless, a reliable parametrisation can be achieved if data are compiled from available ecological studies which increases statistical power as well as coverage of the environmental context (concerning, e.g., different populations, climate, landscape, diversity or anthropogenic influence). However, empirical studies often employ different methods, describe different time scales, record different covariates, present data from different times and in different formats, and apply different statistical analyses. Thus, field data available must be harmonised, summarised and interpreted in the model context before they can be used for model parametrisation.

Here, we present an example for model parameterisation using the wood mouse (*Apodemus sylvaticus*). The population model APODEMUS developed for the species summarises the daily mortality rate of individual mice into a single parameter ('daily natural mortality'). This seemingly simple parameter is used in many population models. However, mortalities are reported in different ways in published studies. We demonstrate how the parameter can be consolidated from multiple sources. More specifically, we focus on field methodological differences (e.g. how is mortality/survival determined in the field?), differences in statistical evaluation (e.g. capture-mark-recapture models vs. minimum number alive approaches), and differences in the definition of important co-variables such as age or reproductive status that may impact mortality and other parameters. Using a single parameter from the wood mouse population model, we demonstrate the intricate process of model parameterisation that integrates data from multiple published sources. This example serves to illustrate a systematic approach for parameterising ecological models, highlighting both the challenges and methodological solutions in this complex process.

4.10.P-Tu386 Predicting Wood Mouse Densities in European Agroecosystems: Insights from an Explainable Machine Learning Study

Jochen Zubrod¹, Steven Kragten² and Nika Galic³, (1)Zubrod Environmental Data Science, Germany, (2)Syngenta Agro GmbH, Germany, (3)Syngenta Crop Protection AG, Switzerland

Normal Operating Ranges (NOR) describe the natural variability of system properties such as population density or abundance and are increasingly recognized in ecological risk assessment as critical for interpreting population-level effects and improving model design. Recently, mechanistic effect models have been used to determine NORs, but it is not yet clear under which conditions they are suitable for this purpose. A complementary approach is to derive NORs based on available data to better understand this variability in the field. Here we present the results of an analysis focusing on a species important for mammal risk assessment – the wood mouse, *Apodemus sylvaticus*.

We compiled an extensive dataset on wood mouse population densities from peer-reviewed literature and industry field studies, resulting in 806 samples from 54 crop fields across the species' western European range. Data encompassed both agricultural and semi-natural habitats and included 84 explanatory variables describing crop characteristics, habitat structure, climatic factors, and experimental design parameters. Machine learning models predicting wood mouse densities achieved high predictive power (test $R^2 = 0.804$; restricted to predictions within the applicability domain: test $R^2 = 0.834$) and, using explainable machine learning techniques, key ecological, methodological, and agricultural drivers of wood mouse population estimates were identified.

Population density ranges were estimated as NOR surrogates in two ways: 1) via prediction intervals for context-specific model predictions (e.g., density range in a specific crop field on a given day of the year), accounting for both model uncertainty and inherent data variability, and 2) via aggregating predictions *inter alia* spatio-temporally (e.g., density range in cereal in southern Germany during summer). Both methods highlight substantial natural variability in wood mouse densities.

Our study delivers the first comprehensive synthesis of wood mouse population data in agroecosystems and contributes – also via the identified data gaps and methodological challenges – to developing more robust, evidence-based approaches for assessing and managing pesticide risks to small mammals.

4.10.P-Tu387 Optimal Complexity in Ecological Modelling: Application of a Novel Framework to Evaluate Biological Realism of Earthworm and Wild Pollinator Population Models

Harriet Gold¹, Claire Brittain², Alice Johnston¹, Nika Galic³, Jacqueline Hannam⁴ and Simon Potts⁵, (1)Cranfield University, United Kingdom, (2)Syngenta Ltd, United Kingdom, (3)Syngenta Ltd, Switzerland, (4)University of Greenwich, United Kingdom, (5)University of Reading, United Kingdom

Ecological models can support land management decisions and ecological risk assessments that need to account for invertebrate population responses at the field to landscape level. Models that incorporate greater biological and environmental detail (i.e. individual-level physiology and behaviour, fine-resolution environmental heterogeneity) have a greater capacity to represent emergent population dynamics, especially under novel conditions. However, more complex models risk high uncertainty, loss of interpretability and excessive computational demand, particularly at larger spatial extents. This trade-off between realism and tractability poses a long-standing challenge in ecological modelling and motivates the goal of determining optimal model complexity. In practice, models tend to be developed on an ad hoc basis, with structures optimised for specific species, scenarios and spatial scales, hindering generalisable insights needed to advance predictive ecological models. We developed and applied a novel approach to quantify the biological realism of models for two non-target invertebrate groups. Mechanistic and process-based population models for earthworms ($n = 23$) and wild pollinators ($n = 24$) were identified through a structured review. We find that earthworm models are predominantly non-spatial or micro-scale (<10 m extent) and often incorporate physiological mechanisms, whereas pollinator models are typically implemented across landscape to regional extents and focus on individual-level or aggregated movement behaviour. Our results highlight structural trade-offs that reflect differing priorities in model development for these taxa. Greater integration of physiological and behavioural mechanisms across broader spatial extents would, however, enable models to better represent phenotypic plasticity in spatiotemporally heterogeneous environments, supporting more informed predictions of population responses in agricultural landscapes. Systematic model testing is a crucial next step to quantify relationships between model structure, system behaviour, computational demand and predictive performance across spatial scales, providing evidence for where higher biological realism is important and where efficiencies can be gained.

4.10.P-Tu388 Risky Buzz-ness: Navigating ECHA's Bee Guidance for Biocidal Product Risk Assessments *Helen Sneath, Don Bealing and Samantha Walker, Sagentia Regulatory, United Kingdom*

ECHAs Guidance on the assessment of risks to bees from the use of biocides entered into force for both active substance and product applications on 1st February 2026. Aligned with the EFSA guidance for plant protection products, the new ECHA guidance represents a significant change in approach for biocidal risk assessments. We document our first experience of applying the guidance to biocidal products, highlighting practical considerations, data requirements, and interpretation issues. Lessons learned provide valuable perspectives for stakeholders preparing to navigate bee risk assessments for biocidal product authorisations.

4.10.P-Tu389 Evaluating Changes in PT18 (Insecticide) Emission Calculations: Comparison of the 2008 and 2024 Emission Scenario Documents *Mathew Jackson, Sagentia Regulatory, United Kingdom*

Environmental risk assessment (ERA) of insecticides under the Biocidal Products Regulation (BPR) requires calculation of local emissions into the environment, allowing subsequent Predicted Environmental Concentration (PEC) derivation and risk characterisation. Such calculations are performed in accordance with assumptions and equations presented within the Product-Type 18 (PT18) (insecticides) Emission Scenario Document (ESD). Since the publication of the original PT18 ESD in 2008, there have been substantial developments in data availability and modelling approaches. The updated (December 2024) PT18 ESD introduces significant methodological revisions aimed at improving realism, transparency and regulatory harmonisation of insecticide ERA across Europe. Consequently, differences in the equations and resulting outputs of emission calculations exist between the original and updated ESD. This study investigated such differences in emission calculations between the 2008 and 2024 versions of the PT18 ESD, using prallethrin as a representative active substance. Indoor and outdoor 2008 emission scenarios were directly compared against their equivalent 2024 scenario, using identical insecticide product specific inputs and default inputs for all other fields as appropriate (as relevant for the original and updated ESDs, accordingly). Results of these direct comparisons showed that in numerous instances, when comparing like-for-like, calculated emissions are considerably higher for indoor scenarios when based on the updated ESD. In contrast, like-for-like comparison of outdoor scenarios show lower indirect (via wastewater for urban product uses) and direct soil (for rural product uses) emissions based on the updated ESD. However, it is noted that the updated ESD now also considers direct emissions to surface water (via rainwater discharge) for outdoor scenarios, which may potentially complicate risk assessments. Equation parameters which have undergone notable changes within the updated ESD include 'simultaneity factor' derivation and default 'line/area/volume treated with the product'. Understanding these differences is essential for ensuring consistency across future PT18 insecticide environmental exposure and risk assessments.

4.10.P-Tu390 Risk-based Approach for Regulation of Marine Pollution *Kirit Wadhia, National Oilwell Varco (NOV), United Kingdom*

Introduction

It is apparent that regulations worldwide exist for management of marine pollution dealing with different industry sectors. There is disparity between the different frameworks employed and even within. Criteria for different sectors require particular and specific considerations.

Concern of marine pollution impinges on the change pertaining to physical, chemical, and biological state of the water bodies and coastal areas. The 1982 UN Convention on the Law of the Sea defined marine pollution as: "the introduction by man, directly or indirectly, of substances or energy into the marine environment ... which results or is likely to result in such deleterious effects as harm to living resources and marine life." (UNCLOS, 1982). The most significant threat is the potential impact on marine wildlife and ecosystems.

Chemical pollution in general can emanate from a range of sources including crude oil and other petroleum products, antifoulants, pesticides, pharmaceuticals and personal care products.

In context of the petroleum sector industrial discharge (i.e. produced water) containing chemicals from anthropogenic and natural sources is of primary concern.

The offshore oil and gas industry thematic strategy (Offshore Strategy) sets the objective of preventing and eliminating pollution and taking the necessary measures to protect the OSPAR maritime area against the adverse effects of offshore activities so as to safeguard human health, conserve marine ecosystems and, when

practicable, restore marine areas which have been adversely affected.

Risk assessment involves evaluation taking into consideration the potential direct and indirect consequences. It involves comparison of the exposure of the ecosystem to chemicals of pertinence & concern with the sensitivity of the ecosystem for these chemical through the specific exposure-route.

Perspective pertaining to the regulatory framework with insight of developments, considerations and progress concerning risk-based approach for the management of produced water discharges is the focus of this conveyance.

4.11 Navigating Marine Pollution in a Changing Climate: Emerging Contaminants, Ecosystem Impacts, and Integrated Solutions

4.11.T-01 Advancing Ecotoxicology With Sea Stars And Brittle Stars: Current Evidence, Research Gaps And Future Directions

Camilla Mossotto¹, Antonia Concetta Elia², Monia Renzi³, Damià Barceló⁴, Marino Prearo¹ and Paolo Pastorino¹, (1)The Veterinary Medical Research Institute for Piedmont, Liguria and the Aosta Valley, Italy, (2)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (3)Department of Life Sciences, Via Giorgieri 10, Trieste, 34127, Italy, Italy, (4)Department of Chemistry and Physics, University of Almería, Spain

Sea stars (Asteroidea) and brittle stars (Ophiuroidea) play key ecological roles but they remain underrepresented in ecotoxicological research compared with other marine invertebrates. This review examines how these taxa have been used in ecotoxicology over the past two decades, the contaminants and biological endpoints investigated and their suitability as bioindicators for environmental assessment.

A structured literature search of peer-reviewed studies published between 2000 and 2025 identified 76 relevant publications focused on exposure to anthropogenic contaminants, including metals, pharmaceuticals, microplastics, hydrocarbons, persistent organic pollutants and pesticides. Research trends, contaminant categories and biological endpoints were synthesised to evaluate current knowledge and taxonomic representation.

The most common approach was environmental monitoring, followed by laboratory exposure studies.

Combined field/laboratory designs remained scarce. Research output was uneven across different regions and focused heavily on Asteroidea, with limited attention given to Ophiuroidea despite their global distribution and suitability for toxicity testing. A wide range of endpoints were investigated, including bioaccumulation, survival, development, immune and cellular responses, behaviour, histopathology and DNA damage. Heavy metals and persistent organic pollutants were the contaminants most frequently studied, and most investigations evaluated only one endpoint under controlled laboratory conditions. Behavioural and reproductive endpoints, as well as multi-contaminant and multi-stressor designs, were underrepresented.

Overall, sea stars and brittle stars are ecologically important species that are underrepresented in marine ecotoxicology research. The development of ethical, standardised methodologies for using these organisms in toxicity assessments could enhance the ecological relevance of marine pollution research.

4.11.T-02 Presence of contaminants of emerging concern in remote areas: Arctic Ocean as a case of study

Marta Llorca-Casamayor¹, Eloy Torres-Arévalo¹, Albert Pina Benages¹, David Alcaide Benavides¹, Xianyu Kong², Boris Koch² and Marinella Farre¹, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (2)Helmholtz-Zentrum für Polar- und Meeresforschung, Alfred Wegener Institute (AWI), Germany

In recent years, the presence of anthropogenic substances in remote areas has become a major concern.

Moreover, due to changes in marine patterns driven by climate change (CC), it is increasingly important to evaluate contaminants of emerging concern (CECs) in order to understand their long-range transport and persistence.

This study focuses on assessing the presence of different families of CECs in the Arctic region. Owing to Arctic amplification, climate change is more pronounced in this area, with temperatures rising three times faster than the global average. As a result, marine ecosystems in the High North are under considerable pressure. Within this context, we focused on CECs such as plastic additives, pharmaceuticals, marine toxins, and perfluoroalkyl substances (PFASs)—including legacy compounds like PFOA and PFOS, as well as persistent and mobile (PMOC) PFASs such as trifluoroacetic acid (TFA) among others.

Samples were collected during the ONE-BLUE Arctic case study sampling campaign onboard the R.V. Polarstern. Water samples were obtained throughout the entire water column using the vessel's CTD rosette sampler and a solid-phase extraction was performed onboard for CEC analysis.

The suspect screening revealed the tentative identification (confidence level 2) of several siloxanes and pharmaceuticals as well as some plastic additives and short chain PFASs. Conversely, the results from the suspect screening of marine toxins did not show the presence of these natural substances in Arctic waters. Regarding plastic additives, the compounds that have been quantified included 4-methylbenzotriazole, benzyl butyl phthalate, bis(2-ethylhexyl)phthalate, caprolactam, Citroflex 4, dibutyl phthalate, diethyl phthalate, dipropylene glycol dimethyl ether, laurilactam, tributyl phosphate, triphenyl phosphate, and tris(2-butoxyethyl)phosphate, ranging from 0.1 to 50 ng/L. In the specific case of PMOCs related to short-chain PFASs, the results showed the presence of TFA in almost all samples, at concentrations below 20 ng/L, highlighting the occurrence of this highly mobile compound in the area. Finally, the most ubiquitous compounds were the plastic additives diethyl phthalate and triethyl phosphate, as well as the short-chain TFA. These results demonstrate the presence of CECs, including PMOCs, in Arctic environments. This knowledge is highly important for elucidating the new transport patterns expected in the near future under ongoing climate change scenarios.

4.11.T-03 Integrative Growth Inhibition and Metabolomic Alterations on Marine Microalgae *Tetraselmis suecica* Exposed to CECs

Edoardo Barbieri¹, Albert Pina Benages², Xavier Borrell Diaz¹, Marinella Farre¹, Victoria Osorio¹ and Marta Llorca-Casamayor¹, (1)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Spain, (2)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain

The increasing presence of Contaminants of Emerging Concern (CECs) in marine environments poses potential risks to aquatic organisms, but their consequences on marine water bodies remain poorly understood. In this context, microalgae are key indicators of marine health, but traditional growth inhibition tests often fail to detect sublethal responses in resistant marine species.

To overcome this challenge, we evaluated *Tetraselmis suecica* as a model organism by combining growth inhibition assays with metabolomic profiling. Growth tests were optimised using OECD reference compounds (potassium dichromate and 3,5-dichlorophenol), then applied to a synthetic mixture of 14 CECs at concentrations up to 32× environmental levels. Additionally, the developed growth inhibition test was applied to 23 real marine samples collected along the Catalan Coast in the frame of the ONE-BLUE project, in parallel with suspect screening to identify chemicals potentially linked to the toxicity observed in the growth inhibition tests. Cultures were monitored spectrophotometrically for 72 h, and samples without significant growth differences were analysed for targeted and suspect metabolomics using LC-HRMS.

Results showed no growth inhibition for the CEC mixture, but metabolomic analysis revealed distinct biochemical shifts. Potassium dichromate induced overall increased levels of amino acids, including histidine, lysine, phenylalanine, and tryptophan, while CEC exposure caused marked underexpression of them. Real sample analysis revealed growth inhibition in areas near harbours and WWTP emissaries, with suspect screening detecting plastic additives and pesticides as possible contributors to toxicity.

These patterns suggest sublethal physiological effects, including oxidative stress, impaired respiration, and membrane remodelling, which may precede photosynthetic dysfunction.

Our findings confirm that metabolomic profiling provides early indicators of contaminant stress, complementing conventional lethal endpoints. This integrative approach advances marine ecotoxicology by enabling the detection of sublethal biochemical disruptions before growth effects occur, supporting improved environmental risk assessment and monitoring strategies for emerging pollutants even in real marine conditions.

4.11.T-04 Interactive Effects of Emerging Contaminants and Climate Change Stressors: Chronic Impacts of Amitriptyline and Tributyl Phosphate on the Physiology and Behaviour of Marine Medaka (*Oryzias melastigma*)

David Nos, Marie-Laure Begout and Xavier Cousin, French Institute for Ocean Science (IFREMER), France

The increasing presence of Contaminants of Emerging Concern (CECs) in coastal ecosystems, combined with ocean warming and acidification, poses growing risks for marine organisms, yet long-term effects data remain limited. We investigated the chronic effects of two widely detected CECs on the marine medaka *Oryzias melastigma*, a robust ecotoxicological model. The individual and combined effects of chemical exposure, increased temperature (29 °C), and reduced pH (7.6) were evaluated over a 4-month exposure. Fish were exposed to amitriptyline (AMI) or tributyl phosphate (TBP) through spiked food (100 ng/g), mimicking environmentally realistic trophic transfer. The evaluation of interactive impacts of climate stress and CECs was made possible through the establishment of twelve experimental conditions combining two chemical treatments, two temperatures, two pH levels, and their interactions. Growth, metabolism, reproduction, behaviour, transcriptomics, and microbiome responses were assessed across different tissues.

Preliminary findings highlight temperature as a key driver of biological responses. Males exhibited significant growth increases at warmer temperatures, whereas females showed no clear effect. Reproductive outputs revealed an increase in egg production in females under acidic conditions, particularly with AMI exposure, suggesting a synergistic interaction between the chemical and lowered pH. However, warming consistently reduced fecundity across treatments, even when pH was lowered, indicating its role as a dominant stressor. Full interpretation will rely on ongoing analyses of F1 hatching success, parental and offspring behaviour, and transcriptomics to evaluate potential multigenerational effects and the pathways disrupted by both contaminants in combination with climate-change stressors.

Overall, the experimental framework provides a powerful approach to disentangle chemical-climate interactions and their chronic impacts on fish. By integrating behavioural, physiological, transcriptomic, and microbiome endpoints, this work will advance understanding of how marine organisms respond and adapt to co-occurring environmental stressors. The results will support improved assessment of ecological risks in future ocean scenarios shaped by pollution and climate change.

4.11.T-05 Uncoating the Problem: Leachates From Coatings Affect Estuarine Copepods Under Climate Change Scenarios

Juliette Grandjean¹, Maria Kazour², Jana Asselman³ and Ana Isabel Catarino¹, (1)Flanders Marine Institute (VLIZ), Belgium, (2)Flanders Marine Institute (VLIZ), Netherlands, (3)Blue Growth Research Lab (BGRL), Ghent University, Belgium

Antifouling coatings have been used to prevent the growth of fouling organisms on submerged vessels and structures. However, coatings undergo physical and chemical degradation, leaching the toxic biocides from their coating matrix. These leachates have been found to have hazardous effects on aquatic organisms, such as copepods, cockles, and ragworms. In parallel, climate change, particularly rising seawater temperature, exacerbates existing environmental stressors and introduces further ecological challenges. Yet, the combined effects of leachates from coatings and climate change-related stressors remain largely unexplored. The goal of this study was to investigate the combined effects of leachates from coatings and increased temperatures in the harpacticoid copepod *Nitokra spinipes*, a species with a relevant role in estuarine food webs. Paint items were produced by applying thin layers of a commercial coating onto silicone molds. Leachates were generated by immersing the paint items in a filtered 7 PSU aquatic medium for seven days, at room temperature (21 °C), in the dark. The toxicity was then assessed by exposing *N. spinipes* adults and nauplii to the leachates at 22 °C and 25 °C (+3 °C; RCP 8.5 scenario, IPCC 2021). To ensure that the organisms were responsive to the toxicants, a positive control was included using copper sulphate in acute toxicity tests on both the adults and nauplii at 22 °C. Our results showed a synergistic effect in adults resulting from combined exposure to coating leachates and higher temperature, expressed by a lower median lethal dose (LC50) at 25 °C (after 72-h, LC50_22°C = 48.8 ± 2.92% and LC50_25°C = 14.2 ± 10.00%). In contrast, the nauplii showed no significant temperature-related differences in mortality (LC50_22°C = 22.3 ± 13.08%, and LC50_25°C = 16.9 ± 1.57%), or larval development.

Therefore, the tested leachates induced significant toxicity in both life stages. Interestingly, a significant hormesis effect was observed for the larval development ratio at both temperatures, showing a positive effect from the leachates at a low dose. Our findings suggest that the predicted increase in temperature may have additional effects on the leachate's toxicity in adult copepods, and could lead to cascading effects (e.g., at the population level). These results advance our understanding of the combined effects of coating leachates and climate change on aquatic organisms.

4.11.P Navigating Marine Pollution in a Changing Climate: Emerging Contaminants, Ecosystem Impacts, and Integrated Solutions

4.11.P-We343 Warming Increases the Toxicity of Plastic Additives in the Marine Copepod *Centropages typicus*: Towards Climate-Aware Marine Pollution Risk Assessment

Paula Aguilera, Sergi Omedes, Montserrat Solé and Enric Saiz, Institut de Ciències del Mar - CSIC, Spain

Plastic additives are emerging contaminants in marine ecosystems, yet their combined effects with climate-related stressors remain poorly understood. Copepods, as key zooplankton components of marine food webs, are highly sensitive to environmental changes, and their vulnerability to pollution under warming conditions may have far-reaching ecological consequences.

This study investigated the individual and combined effects of five plastic additives: bisphenol A; dibutyl phthalate; 3,3',5,5'-tetrabromobisphenol A; triphenyl phosphate; and 2-ethylhexyl diphenyl phosphate, on the marine copepod *Centropages typicus* under two temperature regimes representing ambient (16°C) and heatwave (22°C) conditions. The goals were: 1) to determine acute toxicity thresholds (LC50 values), 2) evaluate how elevated temperature modifies toxicity, and 3) assess effects of chemical mixtures and biomarker responses to investigate sublethal stress responses.

Adult copepods were exposed in multi-well plates to the five plastic additives. Additionally, different mixtures were tested: two mixtures containing an equitoxic concentration corresponding to the total LC50 (LC10 of each additive), 2) a sublethal LC15 mixture (LC3 of each compound), and 3) a mixture at an environmentally relevant concentration. Biomarker response was analysed in the LC15 mixture to investigate sublethal physiological effects.

Results showed that increased temperature consistently enhanced the toxicity of organophosphorus compounds and dibutyl phthalate, lowering their LC50 value and revealing that thermal stress can worsen the effects of plastic-associated chemicals. The exposure to the chemical mix caused higher mortality than predicted from single-compound exposures. This may indicate synergistic interactions, with its effects amplified under heatwave conditions. Moreover, the environmental concentrations under heatwave condition caused significantly higher mortality. Exposure to the LC15 mixture induced significant biomarker responses.

These findings show that rising ocean temperatures may exacerbate the risks posed by environmental chemical mixtures associated with plastics. By considering multiple stressors and biological endpoints, this work contributes to a better understanding of contaminant effects in a changing ocean. It also contributes to realistic, temperature-inclusive approaches for environmental risk assessment and management which are essential to safeguard marine ecosystems.

4.11.P-We344 Microplastic Contamination In Deep-Sea Invertebrates From The Central Mediterranean Sea

Camilla Mossotto¹, Paolo Pastorino¹, Alice Gabetti¹, Alessandra Maganza¹, Monia Renzi², Tecla Bentivoglio³, Serena Anselmi³, Antonia Concetta Elia⁴, Damia Barceló⁵, Matteo Riccardo Di Nicola¹, Caterina Faggio⁶, Marino Prearo¹ and Giuseppe Esposito¹, (1)The Veterinary Medical Research Institute for Piedmont, Liguria and the Aosta Valley, Italy, (2)Department of Life Sciences, Via Giorgieri 10, Trieste, 34127, Italy, Italy, (3)Bioscience Research Center srl, Italy, (4)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, (5)Department of Chemistry and Physics, University of Almería, Spain, (6)Chemical, Biological, Pharmaceutical and Environmental Sciences, University of Messina, Italy

Microplastics are recognised as an emerging contaminant in marine ecosystems, but information on their presence in deep-sea habitats remains limited. This study addresses this knowledge gap by examining microplastic occurrence in 35 specimens representing nine species of deep-sea invertebrate collected from the Gulf of Orosei on the east coast of Sardinia, Italy. The aim was to assess the extent of contamination and to explore whether ecological traits influence microplastic accumulation patterns.

Organisms belonging to three major invertebrate groups (i.e., Arthropoda, Echinodermata and Mollusca) were sampled at depths between 250 and 450 metres. After laboratory processing to isolate and characterise microplastic particles, the polymer types and particle shapes were identified using Fourier Transform Infrared

(FTIR) spectroscopy. Statistical analyses were employed to evaluate similarities and differences among species. Microplastics were found in nearly all specimens, with a total of 105 particles recorded across the species sampled. Filaments and fragments were the most common shapes, and particles were primarily composed of polyethylene, polypropylene and polyethylene terephthalate. Regression analyses revealed a significant positive correlation between organism weight and microplastic abundance in Echinodermata, suggesting that larger individuals accumulate more particles. Cluster analysis revealed that contamination patterns were more closely aligned with ecological behaviours, such as feeding strategy, than with taxonomic relationships. These findings provide the first evidence of microplastic contamination in multiple deep-sea invertebrate species from the Gulf of Orosei. The results emphasise the importance of species-specific ecological characteristics in shaping microplastic exposure and accumulation in deep-sea environments.

4.11.P-We345 Plastic Meets Climate: Nitokra spinipes in the Face of Dual Challenge

Juliette Grandjean¹, Jana Asselman² and Ana Isabel Catarino¹, (1)*Flanders Marine Institute (VLIZ), Belgium*, (2)*Blue Growth Research Lab (BGRL), Ghent University, Belgium*

In estuarine waters, organisms are subject to multiple stressors in the environment, including contaminants of emerging concern, such as microplastics, and fluctuating physicochemical parameters due to tidal and freshwater inputs. However, due to global change, physicochemical parameters are predicted to be shifted towards new extremes in estuaries. Additionally, estuaries are considered reservoirs of increasing plastic pollution, but the assessment of the combined effects of these stressors on primary benthic consumers is lacking. Therefore, the goal of this work is to assess the combined effects of multiple stressors (temperature, salinity, microplastics) on benthic primary consumers, on both the larval and adult stages. First, the stressors (salinity, temperature, microplastics) will be tested alone through acute toxicity tests on both stages, following standard protocols, to estimate the median lethal dose (LD50). The microplastic experiments will focus on the particle's effects. Effects of the leaching chemicals from the polymer matrix will be excluded by using a dialysis test with adult animals. Based on effect data for each stressor, three carefully selected combinations (from a fractional factorial experiment) will represent a best-case, an intermediate, and a worst-case scenario, with overall toxicity levels approaching half of the LD50. These combinations will be tested over single life stages but also across multiple generations (three generations) to obtain information not only on their toxicity but also on their sub-lethal effects (e.g., oxygen consumption rate, reproduction rate and success). Overall, this study will provide a comprehensive assessment of how multiple stressors interact to affect benthic primary consumers throughout their life cycle, thereby contributing to a better understanding of their vulnerability and resilience.

4.11.P-We346 Assessing Marine Ecotoxicity of Hazardous Constituents in Oilfield Produced Water

Sarah Daflon, Alyne Moraes Costa, Marllon Robert dos Santos Valentim and Juacyara Carbonelli Campos, *School of Chemistry - UFRJ, Brazil*

Produced water (PW) is the primary wastewater generated during oil and gas exploration, and many of its constituents can damage the aquatic environment. This study evaluated various substances found in PW by assessing acute toxicity using *Vibrio fischeri* and chronic toxicity with two species of sea urchins collected in Brazil, *Arbacia lixula* and *Echinometra lucunter*. The inorganic substances assessed included nitrogen, ammonia, and several metals, such as zinc, cadmium, copper, lead, iron, and manganese. The organic substances evaluated were ethylbenzene, o-xylene, phenol, o-cresol, p-cresol, and some carboxylic acids, including cyclohexane carboxylic acid, methyl pentanoic acid, cyclohexane pentanoic acid, cyclohexane acetic acid, and pentane carboxylic acid. The acute and chronic toxicity assessments were conducted in accordance with Brazilian standards, specifically ABNT 15411:2021 and ABNT 15350:2020, respectively. Ammonia nitrogen exhibited high chronic toxicity, particularly to *E. lucunter*, with a no-observed-effect concentration (NOEC) of 0.08 mg NH₃/L. This substance is a significant contributor to PW toxicity due to its generally high concentrations. The most toxic metals evaluated for all organisms tested (with NOEC values equal to or less than 1 mg/L) were iron and zinc, which are commonly found at elevated levels in produced water compared to seawater. Copper was also highly toxic to marine organisms despite its low PW concentration (<0.005 mg/L). All organic substances tested were highly toxic to the evaluated organisms; however, chronic toxicity assessments with sea urchins indicated greater sensitivity for most organic compounds than acute toxicity evaluations. Among the carboxylic acids, methyl pentanoic acid was the least toxic to *V. fischeri* (EC20 of 783.5 mg/L), but it was one of the most toxic to both sea urchin species, with a NOEC of 0.05 mg/L. Conversely, cyclohexane pentanoic acid was found to be more toxic to *V. fischeri* (EC20 of 0.787 mg/L) than to *A. lixula* (NOEC of 25 mg/L) and *E. lucunter* (NOEC of 3.12 mg/L). Naphthenic acids are considered one of the most toxic components of PW, and their hazardous presence, along with other components such as nitrogen,

ammonia, metals, and other toxic organic substances, needs attention and monitoring to prevent their release into the environment.

4.11.P-We347 Comparing Acute Freshwater and Marine Toxicity Data to Inform the Potential Use of REACH Freshwater Data in the Harmonised Mandatory Control System (HMCS) for Offshore Oil and Gas Production Chemicals

Olivia Lin Tran¹, Lucy Kennelly¹, Dean Leverett¹, Adam Peters¹, Charlotte Linley¹, Kirit Wadhia², Nik Robinson³, Mathijs Smit⁴ and Ian Casson⁵, (1)wca environment Ltd., United Kingdom, (2)National Oilwell Varco (NOV), United Kingdom, (3)NIKAM Consulting Ltd., United Kingdom, (4)Shell Global Solutions International BV, Netherlands, (5)Arxada, United Kingdom

Over the past decade, various aspects of the Harmonised Mandatory Control Scheme (HMCS) under the Oslo-Paris Commission (OSPAR) have been updated to align with EU chemicals legislation. These updates include substance restrictions, authorisations and exemptions under the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) Regulation and Biocidal Products Regulation (BPR). Currently, harmonisation with assessment factors (AFs) under REACH for the derivation of Predicted No Effect Concentrations (PNECs) is under consideration, which would allow greater use of freshwater data in the HMCS. This would be beneficial in reducing new testing and improving animal welfare if freshwater data are already available through REACH. However, the derivation of marine PNECs under REACH guidance use relatively high assessment factors (generally 10x those applied in the freshwater assessment), which may result in considerably lower PNECs than would be derived under the HMCS.

To assess whether freshwater and marine data for offshore chemicals can be used interchangeably, we have compared freshwater and marine sensitivities for fish, invertebrates and algae based on a literature review, covering various types of chemicals, and a de novo analysis of freshwater and marine acute toxicity data for offshore oil and gas production chemicals. The ratio of freshwater to saltwater (FW:SW) toxicity is frequently reported in literature as a parameter to compare sensitivities, with a ratio within a factor of 10 proposed by some papers to indicate equivalent sensitivity between freshwater and marine species. Therefore, this parameter was applied throughout this assessment to provide a consistent comparison of freshwater and marine sensitivities in both the literature review and de novo analysis. Statistical analyses of freshwater and marine datasets were also conducted.

This poster will present the findings of this analysis and discuss the suitability of harmonisation with REACH assessment factors for PNEC derivation under the HMCS. Consideration will be given to the applicability of freshwater toxicity data for marine environmental risk assessment.

4.11.P-We348 Offshore Chemical Regulatory System & Risk Assessment

Kirit Wadhia, National Oilwell Varco (NOV), United Kingdom

Introduction

Protection of the marine environment from the discharge of chemicals used offshore is of global importance. Sustainable operations in the oil and gas sector requires a regulatory framework ensuring protection of the ecosystem and prevention of deleterious environmental impact.

Chemicals' use and discharge for petroleum exploration activities in the OSPAR region require chemicals to be registered via the OSPAR's Harmonised Mandatory Control System (HMCS). The objective of the HMCS is to protect the marine environment by identifying those chemicals used in offshore oil and gas operations with the potential for causing an adverse environmental impact and restricting their use and discharge to the sea. Thus, for the chemical supply industry there is pressure to develop products that comply and fulfil technical performance and environmental risk criteria, Operators' (oil companies) requirements are more linked to ensure optimum operational performance.

On the environmental regulatory front Recommendation 2012/5 requires Contracting Parties to implement a risk-based approach (RBA) for the management of produced water discharges from offshore installations. RBA utilises a stepwise screening tiered approach involving either whole effluent toxicity and/or substance -based approach with use of dispersion modelling to establish if chemical discharges are likely to result in adverse effects to the marine environment.

Does this approach regarding methodology and regulatory framework criteria address the evaluation of potential combined effects of chemicals? Does the regulatory implementation require field monitoring to assess the impact on the ecosystem?

Reference

OSPAR (2012), Guidelines in support of Recommendation 2012/5 for a Risk-based Approach to the Management of Produced Water Discharges from Offshore Installations. Oslo-Paris Convention for the Protection of the Marine Environment of the North-East Atlantic. Agreement: 2012-7. London, UK.

4.11.P-We349 PEARL Project: Integrated Assessment of Environmental Fate and Ecotoxicological Risk of Chemical Emissions from Offshore Wind Farms

Matthieu Dussauze¹, Jean-Luc Boudenne², Christelle Caplat³, Bruno Coulomb², Nolwenn Quillien¹, Pierre-Yves Le Gac⁴, Maelenn Le Gall⁴ and Nicolas Michelet¹, (1)France Energies Marines, France, (2)Laboratoire Chimie de l'Environnement, Aix-Marseille Université, France, (3)Marine Ecosystems and oRganisms reSEArch Lab, Université de Caen-Normandie, France, (4)Laboratoire Structures, Matériaux Avancés et Sollicitations Hyperbares, Ifremer, Plouzané, France, France

The deployment of offshore wind energy raises environmental concerns, particularly regarding chronic chemical emissions that may affect ecological quality within and around Offshore Wind Farm (OWF) areas. Among these emissions, those related to cathodic protection systems using galvanic anodes (GACP) and impressed current (ICCP) are of particular concern. Additionally, emerging floating technologies may introduce new environmental concerns, such as the potential chemical pressure from synthetic mooring lines, which should be anticipated prior to large-scale deployment.

The PEARL project adopts an integrative and multidisciplinary approach to define the chemical risks associated with chronic releases from GACP and ICCP systems across all environmental compartments (water, sediments, and biota) potentially impacted by the development of offshore wind projects in the English Channel and North Sea, as well as along the Atlantic and Mediterranean coasts.

The project combines laboratory experiments, in situ monitoring, and hydro-sedimentary modelling to investigate the behaviour, fate, and local accumulation of metallic elements released by GACP. Modelling will integrate current and future OWFs up to 2050 with other anthropogenic activities and potential natural sources. In parallel, the project will assess environmental pressures generated by ICCP by determining chlorine production rates under different configurations and developing analytical methods to detect chlorination by-products in marine environments.

Ecotoxicological investigations will combine laboratory and in situ ecotoxicological approaches, evaluating model species responses to GACP and ICCP exposure, together with biomonitoring in OWF. Additionally, modelling work will build on these results to assess concentrations of elements originating from GACP within the trophic web around a case study area in Fécamp OWF.

Finally, PEARL will also address chemical pressures from the ageing and degradation of synthetic mooring lines (polyester, polyamide), implementing laboratory ageing protocols to characterize element releases and assess potential environmental impacts.

By integrating experimental, field, and modelling approaches, PEARL will provide a scientific basis for OWF risk assessment, supporting sustainable marine energy and informing regulations.

4.11.P-We350 The risks of multiple human activities to benthic biodiversity disturbance in the Belgian Part of the North Sea: quantitative assessment using an adapted InVEST model

Dries Fredericus Elisa Louis Lorré, Sara Vandamme, Colin Janssen and Jana Asselman, Blue Growth Research Lab (BGRL), Ghent University, Belgium

Marine ecosystems increasingly face cumulative pressures from multiple human activities that act as interacting stressors on biodiversity and the ecosystem services it underpins. In the Belgian Part of the North Sea (BPNS), physical disturbance from bottom-contact fishing, sediment extraction, dredging, disposal of dredged material, and the rapid expansion of offshore wind energy contribute to shifting seafloor conditions and altered benthic community structure. Despite extensive monitoring, current cumulative risk assessments often rely on qualitative scoring and lack empirical grounding, limiting their relevance for evidence-based marine spatial planning. Here, we present a data-driven adaptation of the InVEST Habitat Risk Assessment (HaRA) model that integrates high-resolution macrobenthos monitoring with spatially explicit activity-intensity layers to quantify biodiversity disturbance risk under realistic multi-stressor exposure. Generic categorical scoring criteria are replaced by continuous, empirically derived exposure–consequence relationships based on five biodiversity indicators, enabling intercomparable, decision-ready risk estimates. Applied to the BPNS, the model identifies

bottom-contact fishing as the dominant driver of benthic biodiversity disturbance, while extraction and dredging produce strong but localized effects. Scenario analysis indicates that planned offshore-wind expansion will increase local biodiversity-disturbance risk within new concession zones but is expected to cause only minor basin-wide changes, reflecting prior spatial planning was successful in selecting locations where human development and ecological risks are well balanced. By empirically grounding risk estimates and capturing interactions among multiple marine stressors, this adapted HaRA framework provides an integrated, transparent tool to support marine spatial planning, conservation prioritization, and transparent trade-off analysis among competing uses.

4.11.P-We351 The origin of sediment organic carbon influences hydrophobic organic pollutant dynamics in Arctic shelf sediments

Xiaodi Shi¹, Laurent Oziel², Jonathan P. Benskin¹, Örjan Gustafsson¹ and Anna Sobek³, (1)Stockholm University, Sweden, (2)Alfred Wegener Institute for Polar and Marine Research, Germany, (3)Environmental Science, Stockholm University, Sweden

The fate of hydrophobic organic pollutants in the marine environment is largely controlled by organic carbon (OC) cycling processes. The Arctic is warming three times as fast as the global average and climate change is profoundly altering OC fluxes due to e.g. intensified permafrost thaw, enhanced river runoff and shifting primary production dynamics. As a consequence, remote Arctic shelf sediments serve as an ideal receptor for quantitative and empirical assessments of the impact of OC quantity and quality on pollutant fate. Here, we compiled a database of congener-specific polychlorinated biphenyl (PCB) concentrations (514 entries, 85 sites) in surface sediment of four Eurasian Arctic shelves via integration of new measurements and literature data. Total organic carbon content and isotopic data were retrieved or predicted from CASCADE (The Circum-Arctic Sediment CARbon DatabasE) to assess the relative contribution of terrestrial and marine OC in the sediment. In order to reduce variability in water-phase concentrations, influences from longitude and depositional year were corrected. And samples were grouped into the Barents Sea and the Laptev and East Siberian Seas, due to differences in congener profiles. The resulting variability in concentration was used to infer sediment absorption propensity of PCBs. In the Barents Sea, we found that marine OC resulted in 5-15 times (mean: 11 times) higher concentrations (in ng-PCB/g-OC), compared to terrestrial OC. In the Laptev and East Siberian Seas, the positive effect of marine OC on PCB sequestration was the most pronounced for higher chlorinated PCB congeners. No statistical differences were found between terrestrial and marine OC for tri- and tetra-PCBs, but absorption propensities of marine OC were 6-7 times higher for penta-PCB and 16-22 times for hexa-PCB. Based on these results, PCB sequestration in Arctic shelf sediments was predicted under three future scenarios for climate change using an observational dataset of terrestrial inputs and marine OC fluxes derived from the global 'state-of-the-art' ocean and sea ice biogeochemistry model FESOM2.1-REcoM3.

4.11.P-We352 Cleaning Sediments and Restoring Ecosystems – Evolving Towards an Adaptive Risk Assessment and Management Framework

Robert K Johnston, Applied Ecological Solutions

Cleanup at many large contaminated sediment sites can be very costly, time consuming, and ineffective if larger scale pressures and ecological processes are not adequately addressed by the remedial design. A holistic approach is ideal—one that integrates remediation with restoration to maximize synergies, reduce costs and environmental impacts, and promote long-term sustainability. Sustainable remediation strategies should be informed not only by considerations of regulatory compliance but also by stakeholder goals, values and expectations. Traditionally, remediation efforts have focused on mass removal or reducing exposure to sediment-associated contaminants to address human health and ecological risks. However, evaluating the success of such remedies has proven challenging due to the complexity of ecosystem interactions, the lack of comprehensive monitoring data, and the need to align cleanup objectives with ecosystem recovery.

Additionally, sediments are linked to processes occurring within the watershed making them susceptible to, and potential drivers of, chemical, physical, and biological stressors from larger scale social and economic pressures, climate change, and other disturbances associated with the Anthropocene. Drawing on the results of case studies, key concepts and lessons learned to better integrate sediment cleanup and ecosystem recovery goals are discussed. By integrating risk assessment and adaptive management into a unified Adaptive Risk Assessment and Management framework—incorporating the Plan-Do-Act-Check-Learn adaptive management cycle alongside an iterative risk assessment process—organizations can enhance risk management decisions, foster continuous stakeholder engagement, and ultimately improve both cleanup and restoration outcomes. This approach ensures flexibility, promotes ongoing learning, and aligns remediation strategies with evolving ecological and sustainability goals.

4.11.P-We353 *Ostreopsis cf. ovata* and benthic invertebrates in the Mediterranean Sea: an ecotoxicological study

Guillaume Barnouin¹, Monica Campas², María García-Altare³, Gilbers Romero Suarez¹, Lucile Le Fresne⁴, Francesca Rossi⁵, Chiara Incani³, Jorge Diogène⁶, Rachel Clausing⁷, Luisa Mangialajo⁴, Marie-Yasmine Dechraoui Bottein¹, Mélissa Richard⁴ and Mohamed Mehiri⁸, (1)Université Côte d'Azur, CNRS, ECOSEAS, UMR 7035, France, (2)IRTA, Marine and Continental Waters, La Ràpita, Spain, (3)IRTA, Marine and Continental Waters, Spain, (4)Université Côte d'Azur, CNRS, ECOSEAS, France, (5)Stazione Zoologica Anton Dohrn, Genoa Marine Center, Italy, (6)IRTA, Spain, (7)Fondation Prince Albert II de Monaco, Monaco, (8)Université Côte d'Azur, CNRS, ICN, France

Harmful algal blooms (HABs) are proliferations of microalgae affecting environmental, animal, or human health. Benthic toxin-producing microalgae present emerging risks in Europe, notably the dinoflagellate *Ostreopsis cf. ovata*, which produces toxins of the ovatoxin (OVTX) group. Blooms of this species pose potential health risks to humans through direct exposure and seafood contamination, while also being linked to mass mortalities of sea urchins. However, the broader ecological consequences of these blooms and the pathways of toxin transfer through food webs remain poorly understood.

This study investigates the impact of *Ostreopsis cf. ovata* and its associated toxins on benthic invertebrate communities and evaluates the potential role of these organisms as vectors of biotoxin transfer through coastal food webs. To address this, we conducted a field study along the French Riviera during summer 2024, including sampling of both *O. cf. ovata* and benthic macrofauna. In total, 12,596 invertebrates from 100 genera were collected and identified for ecological and toxin analysis.

Invertebrate species identification and enumeration indicated changes in benthic invertebrate community composition correlated with the abundance of *Ostreopsis cf. ovata*, with certain taxa exhibiting declines while other increased in abundance. Toxin analysis using neuroblastoma cell-based assay combined with LC-MS/MS quantification of OVTX analogues (OVTX-a to -e) indicated that some of the most abundant taxa exhibited the highest OVTX concentrations, reaching up to 50 ng total OVTX/g in some amphipods. This suggests that certain invertebrate taxa may be resistant to *Ostreopsis* toxins, allowing OVTX to accumulate within their tissues at high concentrations.

By integrating ecological, toxicological, and public health perspectives, this study demonstrates that *Ostreopsis* blooms alter benthic community composition, which may promote toxin transfer through trophic chains and thereby pose a threat to seafood safety. These findings underscore the need for reinforced monitoring and adaptive management strategies to address the One Health consequences of HABs in the context of climate change and increasing anthropogenic pressures on Mediterranean coastal ecosystems.

4.11.P-We354 Effects of Rising Temperatures on Oxidative Stress Biomarkers in the Mussel *Mytilus galloprovincialis*

Alessandra Maganza¹, Camilla Mossotto¹, Alice Gabetti¹, Alessia Merialdi¹, Antonia Concetta Elia², Barbara Caldaroni², Rebecca Gentile², Sara Glorio Patrucco¹, Giuseppe Esposito¹, Marino Prearo¹, Alessandra Favole¹ and Paolo Pastorino¹, (1)The Veterinary Medical Research Institute for Piedmont, Liguria and the Aosta Valley, Italy, (2)Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy

The Mediterranean coastline is widely recognized as a highly vulnerable environment, showing strong sensitivity to the effects of climate change. Rising sea temperatures are expected to have a significant impact on the physiological and metabolic responses of many marine organisms. Among them, mussels, particularly *Mytilus galloprovincialis*, represent a valuable model species for both aquaculture and ecological or ecotoxicological research. They are widely used as sentinel organisms for monitoring marine pollution and have proven to be highly reliable bioindicators under controlled laboratory conditions.

To obtain a more comprehensive understanding of the effects of temperature on *M. galloprovincialis*, we tested five different thermal conditions. A total of 500 mussels were used in the experiment, with 100 individuals assigned to each temperature. For every thermal condition, the 100 mussels were distributed into four replicate aquaria, each containing 25 individuals. Each aquarium held 20 L of water and was equipped with continuous aeration. The water temperatures were set to 17 °C (control), 22 °C, 24 °C, 26 °C, and 30 °C. Mussels were exposed to these conditions for 30 days. At each temperature, 10 individuals were randomly sampled at 12 and

24 hours, and at 3, 5, 10, 15, 20, and 30 days. Water parameters remained constant throughout the experiment. At each sampling time, mussels were sampled and the tissues were stored at -80°C for subsequent biochemical analyses. The tissues were analysed using a suite of enzymatic oxidative stress biomarkers to assess the physiological stress experienced by the organisms under simulated climate-change conditions. The results highlight the influence of temperature on the enzymatic stress of mussels, with distinct trends observed across the analysed tissues. These findings are particularly relevant in the context of climate change, as organisms already experiencing stress may exhibit a heightened sensitivity to additional stressors, such as pollutants or bacterial and parasitic diseases. It is noteworthy that some of these stressors may be intensified by rising temperatures.

4.11.P-We355 Power Under Pressure: Cellular Energy Allocation and Glutathione S-Transferase Reveal Bivalve Stress from Exposure to Natural Radioactivity

Chris Martin¹, Daisy Hunt², Terri Davis¹, Lara Pearson³, Neil Willey², Franck Dal Molin¹ and Marta G.L. Assuncao¹, (1)Centre for Environment, Fisheries and Aquaculture Science (Cefas), United Kingdom, (2)University of the West of England, United Kingdom, (3)No Affiliation, United Kingdom

Although the discharge of industrially derived Naturally Occurring Radioactive Materials (NORM) is a major source of radiological and chemical contaminants in the marine environment, their ecotoxicological effects on marine organisms remain poorly understood. We conducted Cellular Energy Allocation (CEA) and glutathione S-transferase (GST) assays as indicators of physiological stress in three edible bivalve species, *Cresstoderma edule*, *Mytilus edulis* and *Magallana gigas*, after laboratory-controlled exposures to polonium-210 (210Po) and lead-210 (210Pb), two of the most radiotoxic naturally occurring elements, via seawater and spiked algae mix. Total CEA was calculated as the ratio of energy budget (in the form of lipid, carbohydrate and protein) to energy consumption (Electron Transport System) to determine the overall impact on tissue or organisms' energy expenditure. GST activity was quantified in tissue samples as a key biomarker of detoxification. At the end of the 14-day exposure, *C.edule*, had the highest mean 210Po activity concentration followed by *M. edulis* and *M. gigas* (wet weight concentrations). Significant deviations from control group values in total CEA were observed in some exposure groups, namely *M. gigas* digestive and gill tissue samples with decreased values, and *C.edule* (whole body) with an increase in total CEA. Analysis of individual energy budget components revealed no consistent trends across species or tissue types. Conversely, GST levels significantly decreased in *C. edule* after exposure, and in *M. Edulis* and *M. gigas* were significantly higher, particularly in the digestive gland. Exposure to 210Po and 210Pb was shown to elicit a discernible stress response in the physiological energy budgets of two of the three selected bivalve species and induced measurable changes in detoxification biomarkers across all species examined. The radiological hazard and ecological risk from chronic exposure to legacy NORM discharges in the marine environment are measured using specific metrics and traditionally considered in isolation from other health hazards and risks. Ecotoxicological endpoints can help bridge this knowledge gap and present an innovative opportunity for evaluating such risks. The need for such approaches is heightened by the potential change in uptake, speciation and mobilisation that current environmental stressors (climate change and acidification) might pose to industrially derived NORM.

4.11.P-We356 Cellular Responses in Haemocytes Induced by Exposure to Chemicals of Emerging Concern

Lygia Nogueira, Maria T. Hultman, You Song, **Steven Brooks** and Tania Gomes, Norwegian Institute for Water Research, Norway

The increasing use and production of chemicals has led to a rise in the number of contaminants of emerging concern (CECs) in the marine environment. Assessing and prioritizing compounds with insufficiently characterized adverse effects is crucial to ensure environmental and ecological protection. In this study, cytotoxic and early-warning effects in haemocyte responses of *Mytilus edulis* after single- and mixture exposure of 12 CECs plus one transformation product using flow cytometry. The results demonstrated that CECs modulated several cellular parameters, including cell metabolism, reactive oxygen species (ROS) production, intracellular calcium levels, mitochondrial membrane potential (MMP) and multi-xenobiotic resistance (MXR) activity. However, cytotoxicity was predominantly observed in granulocytes exposed to highest concentration of 6-PPD, 6-PPD-quinone, 2-ethylhexyl diphenyl phosphate, triclocarban, citalopram, and octocrylene. Based on these findings, NOEC, EC10, and EC25 values were extrapolated for the respective compounds and applied to

design a mixture experiment (6 CECs × 3 levels; Definitive Screening Design model). The results identified 6-PPD as the primary driver of cellular alterations, affecting 4 of the 6 parameters in granulocytes and 3 of the 6 in hyalinocytes. In granulocytes, MMP was exclusively affected by citalopram, which also contributed to 4 of the 6 altered endpoints in granulocytes and 2 of the 6 in hyalinocytes. Moreover, 6-PPD-quinone was identified as the sole driver of intracellular calcium disruption in hyalinocytes, while triclocarban contributed to both cytotoxicity and ROS production in granulocytes. Octocrylene was associated with increased ROS generation in both haemocyte subpopulations. Finally, EDHPHP, which did not significantly affect early-warning biomarkers when tested individually, was shown to drive ROS production and MXR activity in the mixture experiment. Compounds of emerging concern (CECs) were found to modulate a wide range of cellular parameters in *Mytilus edulis* haemocytes. The cellular responses were strongly influenced by intrinsic differences between haemocyte subpopulations. Mixture exposures demonstrated that chemical interactions can substantially modify the toxicity profiles of CECs. Overall, the study highlights the complexity of CEC-induced cellular stress and reinforces the value of haemocyte-based biomarkers for detecting early ecotoxicological effects.

4.11.P-We357 Interactive effects of citalopram and climate stressors on sea urchin embryo development

Alexandre Schönemann¹, Juan Ignacio Bertucci² and Juan Bellas¹, (1)Spanish Institute of Oceanography (IEO-CSIC), Spain, (2)Spanish institute of oceanography (IEO-CSIC), Spain

Marine ecosystems are increasingly exposed to combined pressures from chemical pollutants, plastic debris, and climate change, with the presence of the pharmaceutical Citalopram (CIT) in coastal waters coinciding with projected ocean warming (OW) and acidification (OA). Using the sea urchin *Paracentrotus lividus* as a robust model, this study assessed how CIT toxicity is modulated under factorial combinations of these climate stressors during early embryo development (Control: 20 °C, pH 8.0; OW: +4°C; OA: pH 7.6; OW+OA). CIT alone significantly decreased growth, while acidification alone caused no effect but revealed a synergistic toxicity with CIT, resulting in stronger growth inhibition. Conversely, ocean warming, whether alone or combined with OA, masked the inhibitory effect of CIT on growth, leading to a slight increase. However, morphometric analysis demonstrated a consistent detrimental effect of warming, as embryo width significantly decreased across all treatments involving elevated temperature, while width remained stable under OA, CIT, or their combination without warming. These findings highlight that acidification is the main driver of synergistic toxicity concerning growth, whereas warming acts as a secondary stressor specifically compromising embryo width, underscoring the necessity of integrating multi-stressor interactions into ecological risk assessments for future ocean scenarios.

Disclaimer/Disclosure:

4.11.P-We358 Establishment of Baseline Total Hemocyte Count (THC) in the Marine Amphipod *Parhyale hawaiiensis*

Natália de Farias, Ana Julia Gotto, Andrey Majarowsky, Jéssica Cardoso and Gisela Umbuzeiro, Universidade Estadual de Campinas, Brazil

Parhyale hawaiiensis is a marine, epibenthic, circumtropical organism that has been increasingly used across different research fields, ranging from toxicity studies to evolutionary developmental biology. Among these areas, immunotoxicology has gained particular prominence due to growing concerns about the immune health of aquatic organisms continuously exposed to many environmental contaminants. There is an urgent need to better understand how the immune system of these organisms, especially marine invertebrates, responds to contaminant exposure. Hemocytes play a central role in the immune response of these organisms, being responsible for key defense functions such as phagocytosis, encapsulation, coagulation, and the production of reactive oxygen species and antimicrobial peptides. The Total Hemocyte Count (THC) represents one of the most accessible and informative biomarkers for assessing immunological status. Although *P. hawaiiensis* has already been established as a model species in ecotoxicology, its application in immunotoxicological studies still requires methodological refinement. The aim of this study was to establish reference hemocyte values for male and female *P. hawaiiensis*, providing basis for developing THC assay protocol. Two age groups, 5 and 8 months old were used, each comprising 100 organisms (50 males and 50 females). Hemolymph was collected from the dorsal region between the 1st and 2nd segments, transferred to a 4% paraformaldehyde solution, and

subsequently placed in a Neubauer chamber for counting under an inverted microscope. For 5-month-old organisms, females exhibited a mean ($\pm$ SD) hemocyte count of $10,029 \pm 10,727$ hemocytes per individual, while males showed $12,389 \pm 9,890$ hemocytes per individual. In 8-month-old organisms, females exhibited $14,395 \pm 12,790$ hemocytes per individual, and males $14,240 \pm 11,705$ hemocytes per individual. Both males and females at 8 months showed a slight increase in hemocyte abundance compared to those at 5 months. No statistically significant differences in THC were detected between males and females at either age. This study establishes reliable baseline THC values for male and female *P. hawaiiensis* at two developmental stages. Further research is required to determine whether THC can serve as a robust endpoint in ecotoxicological studies when *P. hawaiiensis* are exposed to compounds with known immunomodulatory activity.

4.11.P-We359 Acute Toxicity Testing in the Marine Medaka (*Oryzias melastigma*): Protocol Adaptation and Refinement

David Nos¹, Melissa Font¹, Sarah Johann², Jakob Pfefferle³, Marie-Laure Begout¹ and Xavier Cousin¹,
(1)MARBEC Université de Montpellier, France, (2)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (3)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany

Accurate assessment of chemical toxicity in marine environments is essential for effective ecosystem protection. Current regulatory tests are predominantly designed for freshwater species, which can lead to inaccurate extrapolations when applied to marine organisms. To address this gap, we developed a high-throughput fish embryo acute toxicity protocol using the marine medaka (*Oryzias melastigma*), a species well-suited for laboratory testing due to its small size, short lifecycle, non-seasonal reproduction, transparent chorion, and sexual dimorphism.

Embryos up to 12 days post fertilization were assessed for key endpoints indicative of acute toxicity, including hatching, mortality, malformations, heart rate, and larval photo-motor response. Experiments explored combinations of intrinsic factors (age, developmental stage) and extrinsic factors (incubation temperature, exposure vessel, measurement day) to optimize protocol reproducibility and endpoint sensitivity. Larval development and behavioural performance were most consistent at 28°C, enabling the evaluation of all endpoints within the experimental period and providing robust detection of acute toxic effects.

The optimized protocol is currently being validated using triclosan as a positive control to generate reproducible data on method responsiveness and support inter-laboratory standardization. This work provides an experimentally grounded framework for acute toxicity testing in marine fish embryos, offering a reliable, ethical, and high-throughput approach that enhances the relevance and accuracy of marine ecotoxicological assessments.

4.11.P-We360 Abidjan Convention and the Chemical Management Strategy

Kirit Wadhia, National Oilwell Varco (NOV), United Kingdom

Protection of the marine environment from the discharge of chemicals used offshore is of global importance. Sustainable operations in the oil and gas sector requires a regulatory framework ensuring protection of the ecosystem and prevention of deleterious environmental impact.

The Convention on Cooperation for the Protection, Management and Development of the Marine Environment and Coastal Areas of the West, Central and South Africa Region (Abidjan Convention) has been instigated with the rationale of integrating a concerted management of regional ecosystems. Pertaining to the Convention, the Malabo Protocol provides Contracting Parties of the region with a common framework to better supervise the development of these activities and ensure their compatibility with the protection of the marine environment. This development came in response to the accelerated development of offshore oil and gas activities in the region. The implementation plan fundamentally requires a clear understanding of a viable strategy, taking into account the elements and aspects that currently exist.

The objective of this conveyance is to examine the pertinent considerations of adaptation of chemical management strategy from a global perspective. The goals and plan to align with existing international standards will be assessed. Implications of capacity and infrastructure to achieve defined standards and the need for scientific and technical co-operation to facilitate progress will be analysed. Challenges and concerns focused on categorisation of chemicals and ecotoxicological testing will be addressed, as well as monitoring programmes and implementation procedures and overall objectives.

In essence the existing challenges of the Malabo Protocol will be highlighted, and potential scope for prudent course of action to advance the mission of the Abidjan Convention will be portrayed. This fulfils the aim to “Protect, Conserve and Develop the Abidjan Convention Area and its Resources for the Benefit and Well-being of its People.”

4.12.P Next Generation Environmental Risk Assessment: Incorporating NAMs, AI, and Big Data for Real World Decisions

4.12.P-Th171 Next-Generation Risk Assessment for Reproductive and Developmental Health Implications of Agrochemicals

Yankai Xia¹, Quanquan Guan¹, Xuan Ma² and Yujie Liu¹, (1)State Key Laboratory of Reproductive Medicine, Center for Global Health, School of Public Health, Nanjing Medical University, Nanjing, China; Key Laboratory of Modern Toxicology of Ministry of Education, School of Public Health, Nanjing Medical University, China (Mainland), (2)The Affiliated Wuxi Center for Disease Control and Prevention of Nanjing Medical University, Wuxi Center for Disease Control and Prevention, Wuxi Medical Center, Nanjing Medical University, Nanjing, China, China (Mainland)

The expanding use of agrochemicals has raised concern over their reproductive and developmental health implications. However, the diversity of compounds and complexity of real-world exposure patterns limit the capability of traditional toxicology to generate reliable human health risk assessments. Next-Generation Risk Assessment (NGRA) addresses these limitations by integrating exposure science, mechanistic understanding, and NAMs within an evidence-based, decision-oriented framework. In line with this paradigm, we developed an integrated exposomics platform to characterize exposure profiles of agrochemicals in human populations and to continuously identify emerging contaminants in environmental and biological samples along with their potential health implications. By combining exposomic data with deep-learning models, we simulate complex real-world exposure patterns and identify potential health impacts, enabling predictive prioritization of high-exposure-risk chemicals. Furthermore, advanced high-throughput systems, including organoids and organ-on-chip technologies, allow us to sensitively detect biological responses induced by agrochemicals during critical reproductive and developmental windows, and to elucidate their mechanisms of action on reproductive function, early developmental processes, and key regulatory pathways. Finally, we established the Targeted Risk Assessment of Environmental Chemicals (TRAEC) strategy, which emphasizes multi-source evidence integration as core principles of NGRA. Using this framework, atrazine demonstrated a higher composite neurodevelopmental toxicity score (8.70) compared with pyridaben (7.64), indicating differential levels of concern. This framework provides an operational approach for hazard identification, prioritization, and regulatory decision-making for agrochemicals, and establishes a systematic foundation for future research on chemical exposure and public health.

4.12.P-Th172 Extending the Health Impact Pathway Approach to Environmental Risk Assessment. Challenges and Opportunities

Jose V. Tarazona, Ana Fernandez Agudo, Noelia Dominguez-Morueco, Maria Fuentes-Andion and Maria del Carmen Gonzalez-Caballero, Institute of Health Carlos III (ISCIII), Spain

Next Generation Risk Assessment (NGRA) frameworks, based on NAMs and Adverse Outcome Pathways (AOP) are emerging. However, in most cases the approach is to accommodate the new, usually mechanistic based, information, to the current risk assessment paradigm, proposing NAM-based Points of Departure (PoD). Setting a PoD based on no effects at initial Key Events is a protective approach, the difficulty appears when trying to quantify the progression towards adversity. Risk assessment is by definition an identification of likelihoods, not certainties, and this aspect is frequently missed in PoD-based approaches. Quantitative AOP focuses on direct toxic effects. Indirect consequences, including stress adaptation are not covered, despite the evidence that in many cases indirect effects are leading the main environmental impacts.

For Human Health, we have proposed a new concept, Health Impact Pathways (HIP), using AOP networks for supporting the identification of intermediate events linked to physiological consequences with health relevance. Here we are exploring the applicability of this approach to environmental NGRA. HIPs consider that the

induction of a KE already represent a chemical stress, the individual may avoid progression towards adversity through physiological and/or structural adaptations. The conceptual change vs. AOP frameworks is the consideration that these changes, even not progressing towards the specific adverse outcome, increase the susceptibility and, as a consequence, the probability of the individual to suffer direct or indirect health effects. The proposed extrapolation to population level consequences is based on the consideration of the potential effects of the chemical stress associated to intermediate KE on key population dynamic drivers; that should be adapted to the biological and ecological characteristics of the different species and traits. A main advantage of this approach is the consideration of morbidity associated changes for modelling the expected impact of chemical exposure on the population dynamics, including behavioural effects associated to neurotoxicity drivers, increased susceptibility to infection diseases linked to immunotoxicity drivers, among others. The implementation is probabilistic should be adapted to the characteristics of the focal species. AI is proposed for facilitation the data extraction and analysis of interactions.

4.12.P-Th173 The Source To Outcome Pathway (STOP) – Next Generation Risk Assessment (NGRA) put into practice

Knut Erik Tollefsen, Kim Leirvik, Sam Welch, Walter Zobl, Li Xie and Viviane Girardin, Norwegian Institute for Water Research, Norway

Advancing environmental risk assessment requires a paradigm shift from traditional single-chemical evaluations to more holistic approaches capable of addressing complex, real-world chemical exposures. Next Generation Risk Assessment (NGRA) promotes this transition by integrating diverse data sources and mechanistic understanding to inform both single and cumulative chemical risk assessments. Central to this evolution is the Source-To-Outcome Pathway (STOP) framework, which combines the Aggregated Exposure Pathway (AEP) and Adverse Outcome Pathway (AOP) concepts. AEP structures information on chemical use, fate, and exposure, while AOPs link molecular initiating events to adverse biological outcomes. Together, they support a more transparent and mechanistically informed weight-of-evidence approach.

As bioassay data spanning different levels of biological organisation proliferate, frameworks like STOP will become essential to manage and contextualize disparate data. This work illustrates the use of STOP in NGRA through a case study involving priority pollutants and emerging contaminants, demonstrating how qualitative descriptions and quantitative assessments can be combined for more wholistic assessment. It will also introduce a Graphical User Interface, the Source-to-Outcome Predictor (STOPredictor; <https://www.niva.no/source-to-outcome-predictor>) that aligns exposure information with effects thresholds to predict risk of ecologically relevant mixtures of pollutants.

4.12.P-Th174 Integrated Risk Assessment of Bisphenol Compounds on Obesity Using the TRAEC Strategy and Large Language Model-Assisted Evidence Synthesis

Quanquan Guan, Lu Zhou, Yujie Liu and Yankai Xia, Key Laboratory of Modern Toxicology of Ministry of Education, School of Public Health, Nanjing Medical University, China (Mainland)

Bisphenol compounds are widely used environmental chemicals with increasing concern regarding their contribution to obesity, yet the strength and consistency of evidence across exposure contexts and chemical analogues remain insufficiently clarified. To address this gap, we performed a comprehensive risk assessment based on the Targeted Risk Assessment of Environmental Chemicals (TRAEC) strategy, synthesizing evidence from 39 epidemiological studies, 93 in vivo studies, and 103 in vitro studies retrieved from major scientific databases. This assessment aimed to systematically evaluate the obesogenic potential of bisphenol analogues and to integrate epidemiological findings with mechanistic data streams. Using the TRAEC scoring framework, including reliability, correlation, risk intensity, and evidence integrity scores, we found that adult exposure to bisphenol compounds confers a moderate strength of obesogenic risk overall. Among the five major analogues assessed (BPA, BPS, TBBPA, BPAF, and BPF), tetrabromobisphenol A (TBBPA) demonstrated the highest integrated obesogenic risk score (8.69), whereas bisphenol F (BPF) showed the lowest score (5.32), with epidemiological evidence for BPF exhibiting notable inconsistency at environmentally relevant exposure levels. These differentiated risk profiles reflect both structural diversity and heterogeneous biological activity across bisphenol subclasses. To support transparent and scalable evidence synthesis, we further established a large-

language-model assisted systematic review framework, incorporating ChatGPT-5.1, DeepSeek-v3.2, Claude-4, Gemini-2.5 Pro, and Kimi (K2 Thinking). This framework enabled automated long-text extraction, mechanistic mapping, and cross-study scoring, demonstrating the feasibility and added value of LLMs in handling complex multi-stream evidence during environmental chemical risk assessment. Overall, our findings demonstrate that bisphenol compounds, particularly TBBPA, pose measurable obesogenic risks, while some analogues such as BPF show weaker or inconsistent associations under real-world exposure conditions. This multi-stream assessment underscores the importance of integrating epidemiological and mechanistic evidence using structured frameworks such as TRAEC, and highlights the promise of AI-assisted methodologies in advancing chemical risk assessment.

4.12.P-Th175 The MAGIC Effect Graph – An Ecotoxicological Knowledge Base

Lara Petschick¹, Sascha Bub¹, Jakob Wolfram¹, Larissa Zoë Herrmann¹, Dino Bussen² and Ralf Schulz², (1)iES Landau, Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, Fortstrasse 7, Landau, Germany, Germany, (2)iES Landau, Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, Fortstrasse 7, Landau, Germany; Eusserthal Ecosystem Research Station (EERES), Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, Fortstrasse 7, Landau, Germany, Germany

Laboratory effect data are needed to assess environmental risks of chemicals. Databases (db), such as the US EPA ECOTOX Knowledgebase and the EFSA OpenFoodTox, collect and provide these data to the public. Modern approaches like machine learning (ML) can unlock these data to assess the potential environmental impact of the large, increasing number of manufactured chemicals, but they rely on a high data quality for robust results. For the MAGIC effect graph, we compiled six large effect dbs with different scopes (including standardized and non-standardized tests) into a single graph db (668k endpoints, 10k chemicals, 10k biological taxa) by harmonizing terminologies and deriving quality indicators based on study parameters and curation status. Data is enriched by connecting it to additional sources (e.g., the GBIF Backbone Taxonomy) and by applying ML to predict missing labels (i.e., acute, chronic). As a result, the MAGIC effect graph provides the following solutions:

1. It offers a harmonized view over six of the most important dbs for laboratory effect data. With the MAGIC effect graph, all these dbs can be queried simultaneously.
2. Additional curation of the underlying data allows for consolidation of the ecotoxicological knowledge in the source dbs. By synchronizing the terminologies of the source db, it is for the first time possible to get an overview over the available effect data without overlaps that may bias the results.
3. A normalized score (0-1) aggregates essential quality indicators to help interpret and select reported effect endpoints, e.g., in situation where different effect concentrations are reported.

We demonstrate the usefulness of the score by benchmarking four hypothetical endpoint selection scenarios (S1-4) with original, curated study results from two large-scale studies in Germany and the US, respectively. In S1 the minimum effect concentration of all available was selected, in S2 the effect concentration with the highest score, in S3 a randomly selected effect concentration, and in S4 the median effect concentration among those above a fixed score. Applying S1-4, the analysis of the two case studies was recreated and checked whether the original interpretations still hold true. Our results show that scenarios using the score generally outperform others in reenacting original results, indicating the score is a valuable indicator for informed effect data selection. The MAGIC effect graph will be made available to the public.

4.12.P-Th176 High-Throughput Transcriptomics for Prioritization of Per- and Polyfluoroalkyl Substances in Drinking Water

Yi Chuang¹, Shu-Yu Wu², Yu-Jung Shih², Yunjia Yao³, Yue-Liang Guo¹ and Yi-Jun Lin², (1)National Taiwan University, Taiwan (Greater China), (2)National Yang Ming Chiao Tung University (NYCU), Taiwan (Greater China), (3)No Affiliation, Taiwan (Greater China)

Per- and polyfluoroalkyl substances (PFAS) comprise a large class of persistent synthetic chemicals with potential adverse health effects. The increasing detection of PFAS in drinking water has raised widespread concern and motivated regulatory actions. However, toxicological data remains unavailable for most PFAS,

limiting their inclusion in large-scale hazard evaluation. High-throughput transcriptomics (HTTr), which measures genome-wide expression changes in human-relevant cell models, offers a promising tool for rapid chemical prioritization. In this study, we integrated transcriptomic points of departure (tPODs) derived from HTTr assays with drinking water occurrence data to prioritize PFAS based on their combined toxicity potentials and exposure levels. HTTr data for multiple PFAS across several human-derived cell lines were retrieved from the U.S. EPA CompTox Dashboard. Multiple quantitative approaches were used to derive tPODs for each cell line, and the resulting values were compared across methods. The Toxicological Priority Index (ToxPi) was then applied to integrate these multi-method results into a composite toxicity potential score for each PFAS. A systematic literature search and screening process was conducted to compile PFAS drinking water occurrence data across different countries and regions. A risk index approach was used to integrate the ToxPi score with the exposure concentrations to rank PFAS across geographic areas. This study proposes a conceptual framework that applies HTTr information to rank PFAS detected in drinking water, supporting monitoring and regulatory decision-making for PFAS.

4.12.P-Th178 Next-Generation Environmental Risk Assessment for Chemicals Regulated under Water Quality Standards in Korea and the European Union

Sangha Ahn¹, Chaein Chong¹, Donghyeon Kim² and Jinhee Choi¹, (1)University of Seoul, Korea, Republic of, (2)Department of Applied Biosciences, University of Seoul, Korea, Republic of

Despite continuous monitoring of water quality standard chemicals, frequent detection of emerging contaminants and limited ecotoxicological data availability have created persistent regulatory gaps in aquatic ecosystem protection. This study developed a Next-Generation Environmental Risk Assessment (NGeRA) framework to screen and prioritize water quality standard chemicals in Korea and the European Union (EU). The study focused on drinking water and national standard monitoring substances in Korea and the EU. A total of 279 chemicals from the Seoul Water Institute in Korea were included (91 regulated monitoring substances, 136 unregulated emerging contaminants, and 52 substances with insufficient toxicity data), along with 72 national water quality standard chemicals. From the EU, 73 drinking water monitoring substances and 88 water environment monitoring substances were assessed. Among these, 48 chemicals were identified as common to both Korea and the EU. These substances were evaluated across multiple toxicity endpoints using high-throughput in vitro data from ToxCast and in vivo ecotoxicological data from the ECOTOX database. To address data gaps, in-house developed machine learning models and QSAR prediction tools validated against OECD ecotoxicological test guidelines were employed.

Toxicological evidence was integrated using a Weight-of-Evidence (WoE) approach incorporating Adverse Outcome Pathway (AOP) network. Chemicals were prioritized based on data availability and predicted ecological hazard potency. Of the substances commonly regulated in both Korea and the EU, 21 were determined to have sufficient information and low ecological concern, requiring no further assessment. Conversely, 27 substances exhibited potential hazards across multiple endpoints—including acute toxicity, chronic toxicity, and endocrine disruption—and were identified as priority candidates. For these priority substances, Species Sensitivity Distribution (SSD) modeling and cross-species extrapolation were applied according to data availability and hazard profiles.

This study presents an NGeRA-based framework for assessing water substances without animal testing. By integrating multiple levels of New approach methodologies (NAMs), it supports evidence-based identification of priority chemicals and informs policies for regulatory refinement, prioritization, and environmental standard updates to protect aquatic ecosystems.

4.12.P-Th179 Assessment of Air Pollution-Related Health Risks from Stratospheric Aerosol Injection

Yuko Mochida¹, Tatsuya Nagashima² and Norihiro Itsubo Dr¹, (1)Waseda University, Japan, (2)National Institute for Environmental Studies (NIES), Japan

Global mean temperature has increased by approximately 1.5°C since the pre-industrial era. Under current climate mitigation efforts, achieving the 1.5°C and 2°C temperature goals set by the Paris Agreement is considered challenging. One of the mitigation strategies gaining attention is Stratospheric Aerosol Injection (SAI). SAI aims to lower the Earth's surface temperature by injecting aerosols into the stratosphere at an altitude

of approximately 20 km to enhance the reflection of incoming solar radiation. However, numerous uncertainties remain, including potential health impacts from aerosol particles and the risk of stratospheric ozone depletion, resulting in significant hesitation toward large-scale implementation.

The objective of this study is to quantitatively assess the health risks associated with SAI by estimating country-level increases in PM_{2.5} concentrations and the resulting health losses. The amount and locations of SO₂ injection are determined based on the SAI injection model. Increases in tropospheric PM_{2.5} from stratospheric aerosol injections are calculated using a chemical transport model. Changes in health risks associated with PM_{2.5} increases are estimated using concentration–response functions for air pollution. The additional health burden due to SAI is calculated by subtracting baseline health losses under no-SAI conditions from those under SAI-induced PM_{2.5} increases, enabling country-level analysis of health impacts.

The results indicate that SAI implementation increases PM_{2.5} concentrations, thereby increasing health losses. Moreover, because aerosol injection locations are determined based on latitude, the magnitude of additional health risks varies regionally.

Future work will incorporate all related impacts, including aircraft manufacturing and jet fuel production and consumption to provide a comprehensive assessment of SAI implementation. Comparing these impacts with the expected temperature reduction from SAI will allow for a trade-off analysis between climate mitigation benefits and associated health risks.

4.12.P-Th180 Concentration Profiling and New Approach Methodology-Based Mixture Risk Assessment of Bisphenol A and Its Analogs in Foods

Yi-Jun Lin¹, Yun-Jia Yao¹, Chun-Hui Chiur², Shih-Han Sun¹ and Yu-Tsung Lee², (1)Institute of Food Safety and Health Risk Assessment, College of Pharmaceutical Sciences, National Yang Ming Chiao Tung University, Taipei 112, Taiwan, Taiwan (Greater China), (2)Research Center for Food and Cosmetic Safety, Chang Gung University of Science and Technology, Taiwan (Greater China)

The substitution of bisphenol A with structurally similar analogs has raised concerns due to their comparable endocrine-disrupting activities. Diet is considered the primary route of bisphenol (BP) exposure for the general population; however, limited data on exposure levels and toxicological information for BP analogs hinder comprehensive risk assessments. This study investigated 16 BPs in commonly consumed foods (n = 336) and assessed the mixture risk of endocrine activity resulting from co-exposure to multiple BPs in the Taiwanese population using new approach methodologies (NAMs). A representative food sampling list was designed using the core food method, and a UPLC–MS/MS analytical method coupled with QuEChERS extraction was developed and validated for determining BP concentrations in food samples. High-throughput toxicokinetic modeling was applied to convert in vitro ToxCast high-throughput screening endocrine bioactivity concentrations to human equivalent doses (HEDs), which were subsequently used to assess mixture risks through the margin of exposure (MOE) approach. The analytical method met regulatory validation criteria, with correlation coefficients of calibration curves > 0.99, recoveries within 60–125%, and relative percent differences < 30%. Eleven BPs were detected, with BPA showing the highest detection frequency (61.0%), followed by BPS (25.3%) and 4,4-BPF (20.8%). The mean concentrations of the sum of the 11 detected BPs (Σ11BPs) in foods ranged from 0.06 to 33.09 ng/g. The risk assessment indicated a low concern for endocrine activation from dietary co-exposure to BPs, though a moderate concern was identified from a more conservative perspective. This study enhances understanding of the dietary risks from BP mixtures and demonstrates the utility of NAMs in assessing human health risks posed by environmental contaminants.

4.13 Plastics in Terrestrial Environments: Connecting Uses, Fate, Exposure, Impacts and Innovations on Soil Health

4.13.T-01 Field Relevant Microplastic Concentrations Affect Soil Ecosystem Functioning in Mesocosms

Bayreuth, Germany, (9)Korea Institute of Toxicology, Korea, Republic of, (10)University of Ljubljana, Slovenia, (11)Free University Berlin, Germany, (12)Finnish Environment Institute (SYKE), Finland

The increasing use of plastics in agriculture, for instance mulching film, contributes to plastic residues in soils. Soil microplastic (MP) concentrations are expected to keep rising due to growing use of agricultural plastics, the application of plastic-contaminated biosolids and aerial deposition of MPs. Experiments to date revealed initial effects of MPs on soil physicochemical properties, invertebrates, microorganisms and plants, but rarely studied complex interactions between organisms in the soil. Therefore, this study evaluated the effects of MPs on soil ecosystem functioning using a more holistic approach that reflects these complex ecological interactions using environmentally realistic mesocosm systems. A simulated agricultural ecosystem was made using Lufa 2.2. natural soil in which we introduced two species of earthworms (*Aporrectodea caliginosa* and *Dendrobaena veneta*), three species of springtails (*Heteromurus nitidus*, *Ceratophysella denticulata* and *Protaphorura fimata*) and lettuce (*Lactuca sativa*) as crop. MP types tested were conventional low-density polyethylene (LDPE) and biodegradable starch-polybutadiene adipate terephthalate (PBAT) blend, both sourced from agricultural mulching films. The aim was to investigate the interactions and impacts on physical, (bio)chemical and biomolecular responses within the system after 13 weeks of exposure. Soil physicochemical properties were affected by both MP types. Springtail community composition was not affected, nor was earthworm survival and reproduction, although molecular biomarkers show affected Electron Transfer System and Glutathione S-transferase activity in the earthworms, indicating oxidative stress. Plants exhibited adverse effects, showing strong activation of defense mechanisms and lowered chlorophyll content. Microbial community composition changed due to MP exposure and microbial activity was significantly enhanced. By combining all non-correlating and non-redundant response variables into a single multivariate analysis, we show that the overall profile of soil properties and biological functioning of the soil system significantly shifted in a treatment-specific manner, already at environmentally relevant concentrations of 0.05% LDPE (w/w dry soil). By linking MP-induced effects on soil properties, fauna and flora, this study demonstrates that mulching film-derived MPs, even at levels currently observed in the environment, may pose a risk to agricultural soil health and functioning.

4.13.T-02 Biodegradable Microplastics in a Realistic Soil–Plant–Earthworms Set Up

Mathilde Henrion¹, Lluís Martin-Closas¹, Van Xuan Nguyen², Mohammad Wazne³, Laurent Simon³, Camille Larue⁴, Iseult Lynch⁵ and Ana M. Pelacho⁶, (1)Dpt. Agricultural and Forest Science and Engineering, University of Lleida, Spain, (2)Centre de Recherche sur la Biodiversité et l'Environnement (CRBE), University of Toulouse, France, (3)Université Claude Bernard Lyon 1, France, (4)French National Centre for Scientific Research (CNRS), France, (5)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom, (6)University of Lleida, Spain

From the 1950s, plastics began to be widely used in agriculture with low-density polyethylene (LDPE) mulching. These films have revolutionized cropping by improving the soil microclimate and creating better growing conditions. However, once in contact with the soil, they gradually deteriorate and break down into microplastics. To reduce LDPE accumulation, biodegradable mulches were introduced in the 1980s as a sustainable alternative. They aim to be incorporated directly into the soil after use, where they micronise through weathering and biodegrade by soil organisms. Since both biodegradable mulches and LDPE mulches are a source of microplastics into agricultural soils, to gain understanding of their corresponding impacts in real cultivated crops, the present study assessed the effects of their microplastics on spinach plants and earthworms. Microplastics were produced from a commercial biodegradable mulch and LDPE pellets, and incorporated into pots filled with a substrate at 0.25% and 1% (w/w) and incubated for 5 weeks in a greenhouse. After incubation, earthworms (*A. caliginosa* and *A. chlorotica*) and/or spinach plantlets were added to the corresponding treatments resulting in 20 experimental conditions, including controls. At harvest, substrate samples were analysed for total organic carbon, total nitrogen, and weights. Spinach plants were assessed for weights, photosynthetic pigments, tannins, phenolics, and malondialdehyde. Earthworms were evaluated for fresh weight and malondialdehyde.

Microplastics from biodegradable mulch or LDPE pellets did not affect the substrate parameters. Spinach plant

weight was not affected by the presence of microplastics nor earthworms, though low biodegradable mulch microplastics concentration tended to increase chlorophyll a and b while high doses tended to decrease them. Carotenoids were enhanced by the high dose of LDPE. Lipid peroxidation was inhibited by the presence of microplastics and earthworms. Overall, the presence of earthworms buffered the effects of microplastics on spinach. Malondialdehyde remained mainly unchanged for the two earthworm species for all treatments. These results may indicate the activation of antioxidants defence systems, preventing strong lipid peroxidation. Microplastics contamination had limited effects on the substrate, or on spinach and earthworms physiology. These results highlight the key role of earthworms in buffering the biological effects of microplastics in soil-plant systems.

4.13.T-03 Polymer- and Size-Specific Effects of Microplastics on Soil Respiration and Implications for Phytoremediation

Lucas Kurzweg¹, Pauline Seidel², Oliver Kretschmar², Tilmann Priebe², Maurice Hauße², Christian Siewert² and Kathrin Harre³, (1)Chemical Engineering, University of Applied Sciences Dresden (HTW Dresden), Germany, (2)University of Applied Sciences Dresden (HTW Dresden), Germany, (3)Agriculture/Environment/Chemistry, University of Applied Sciences Dresden (HTW Dresden), Germany

Soils are major sinks for microplastics (MPs), where synthetic polymers can persist for decades and alter soil structure, biogeochemical parameters and microbial activity. Soil respiration (SR), the combined CO₂ efflux from microbial decomposition and root respiration, is a key integrative indicator of soil functioning and carbon cycling, and thus a useful indicator to assess MP impacts. Phytoremediation (PR) nature-based option with fast-growing woody species such as *Salix caprea* could be used to restore soil functioning and health. Links between MP properties, SR responses and potential of PR to restore negative MP impacts remain poorly investigated. Here, we investigated how MP polymer type and particle size affect SR in two different soil types, and whether *S. caprea* can contribute to MP mitigation. MPs of polypropylene (PP) and polyamide 6 (PA) were produced in three size classes (1–3, 63–100, 100–200 µm) and added (1 wt%) to a sandy forest soil and a silty loam agricultural soil. SR was monitored over 28 days in an automated incubation system. In parallel, pot experiments with *S. caprea* were conducted in sand spiked with MPs of low-density polyethylene (LDPE) and PA in small (1–30 µm) and larger (2400–1200 µm) size fractions. Plant growth, root-MP interactions and MP recovery were assessed. MPs affected SR within 28 days in a size-, polymer- and soil-dependent manner. Larger particles generally increased SR, whereas the smallest size classes tended to reduce SR, particularly for PP in the loamy agricultural soil. We attribute these trends to structural effects on pore space and oxygen transport combined with polymer-specific bioavailability. More polar, water-absorbing PA consistently stimulated SR more than PP. In the PR experiment, *S. caprea* tolerated high MP loads without growth impairment and immobilised larger MPs on roots via fine root hairs, but overall MP removal from the substrate was low and very small particles remained in the pots. Our findings show that MP size and chemical properties modulate SR and thus soil carbon cycling. PR with *S. caprea* was mainly effective via root immobilisation of larger MPs. This work highlights SR could be a useful parameter to monitor the effect of MP remediation technologies on soil health and carbon cycling. Nature-based mitigation measures show a high potential but a better understanding of fate and root uptake of small MPs and effects on plants is needed in future work.

4.13.T-04 Freeze-thaw cycles can accelerate the vertical migration of pesticides and microplastics in soil.

Siqi Wu¹, Alexander Böhme¹, Andreas Schaeffer², Zhongli Chen³ and Annika Jahnke¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Institute Environmental Research, RWTH Aachen University, Germany, (3)Chongqing University, China (Mainland)

Keywords: Microplastic, Pesticide, Freeze-thaw, Vertical migration, soil column

Microplastics (MPs) are pervasive soil contaminants that can modify soil structure, influence water flow, and alter the fate of co-occurring agrochemicals through their hydrophobic surfaces and strong sorption interactions. Freeze-thaw (FT) cycles, common in temperate agricultural regions, further fragment plastics, increase soil porosity, and accelerate chemical release, collectively influencing pollutant transport. Here, we systematically evaluated how polyethylene (PE) MPs, FT cycles/room temperature, and soil type (sandy reference soil and clay field soil) regulate the vertical migration of twenty pesticides with diverse physicochemical properties using controlled soil-column experiments. Breakthrough curves, 5% and 50% breakthrough volumes (BVs), and

microplastic migration were quantified. FT cycles consistently enhanced pesticide leaching, with sandy reference soil groups exhibiting the highest leaching rate, whereas room-temperature field soils retained pesticides most effectively. Correlation analysis identified log KOC as a dominant predictor of migration behavior, while water solubility influenced leaching only in organic-rich soils. FT cycles also increased the downward transport of PE MPs. This study highlights how soil texture, climatic stressors, and compound properties jointly control pesticide mobility and microplastic redistribution, with implications for groundwater contamination risk.

4.13.T-05 Microplastic Risks in Soils Are Fragmentation Kinetics– and thus Time-Dependent

Thuy-Dung Nguyen, Jan E. Groenenberg and Albert Koelmans, Wageningen University and Research (WUR), Netherlands

Ongoing plastic emission and plastic fragmentation that increase particles' bioaccessibility over time call for a prospective ecological risk assessment framework. Thus, we developed a framework that incorporates a temporal dimension to fragmenting microplastics in soils, capturing their time-dependent behaviour and ecological risks. Two types of polymer coated fertilizers (PCF), an agriculture product with growing demands, were used as a case study.

The fragmentation model with the fragmentation rate optimized to fit measured PCF concentration data of a long term field experiment with yearly PCF application (sampled after seven years) was well able to describe the data. Fragmentation rate, particle's number, size and volume over time were calculated using the calibrated model. Food-dilution and physical- blocking-based effect thresholds, both of which are dependent on particle volume and size, were used to construct species sensitivity distributions (SSDs) and to estimate hazardous concentrations affecting 5% of species (HC5). Exposure and effects data were aligned for consistent risk characterization. Simulations were run to predict the particles' fragmentation and risks for the two PCFs for the time period of 30 years for both single and multiple application of PCF. The fragmentation model fitted well to both measured PCF concentration data and resulted in different fragmentation rates. As fragmentation progresses, SSDs, HC5 values, and corresponding risk characterization ratios shift, reflecting the increasing bioavailability and potential risk of smaller PCF-derived particles. Repeated PCF applications are predicted to elevate ecological risk, with the magnitude of risk significantly influenced by both the fragmentation rates and reapplication frequency. Besides community ecological risk, species- specific risks were also calculated to detect potentially endangered species over the investigated time period. Calculation was performed probabilistically to capture uncertainty in fragmentation kinetics and data alignments.

The proposed framework provides a dynamic, time-dependent ecological risk assessment for fragmenting microplastics. Its application may advance current risk assessment practices for microplastics through explicitly linking and aligning microplastic fragmentation kinetics to exposure and effects, supporting regulatory evaluation of PCFs, as well as other fragmenting microplastics products.

4.13.P Plastics in Terrestrial Environments: Connecting Uses, Fate, Exposure, Impacts and Innovations on Soil Health

4.13.P-Mo303 Biodegradation of 14C-radiolabelled Natural Polymers in Soil in the Presence of Active Coal

Julia Marie Peters¹, Dieter Hennecke², Andreas Schaeffer³, Annika Jahnke⁴ and Michael Hüben², (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Institute Environmental Research, RWTH Aachen University, Germany, (4)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany

The biodegradability of polymers is determined according to OECD test guidelines (TG), for example TG 301 and TG 307. As synthetic polymers are restricted due to the EU Regulation (2023/2055) producers strive to shift to natural polymers, which are considered biodegradable by default, and synthetic polymers which show proof of fast biodegradation (i.e. >60% mineralisation measured in TG 301). The degradation rate and formed degradation products of respective polymers are often unknown. Even though natural polymers are considered

biodegradable this does not mean that they would pass those degradation tests. In our project an OECD TG 301 test showed that combining different natural polymers in a seed coating resulted in less than 60% mineralisation in 28 d. Furthermore, the presence of active coal in the seed coating has shown a decreasing effect on the biodegradability. Therefore, a simulation test (OECD TG 307) was chosen to learn more about the degradation behaviour of this seed coating material. For this purpose, the seed coating was produced with ¹⁴C-radiolabelled cellulose, sodium alginate and active coal as well as without active coal. The ¹⁴C-radiolabel allows to follow degradation processes in the complex soil matrix and to determine mineralisation (CO₂ formation) even at environmentally relevant polymer concentrations.

In the two tested soil types the difference between the mineralisation of the seed coating with and without active coal can be observed. Overall, it shows higher ¹⁴CO₂ formation in a loamy soil than a sandy soil. A water extraction of mono- and oligosaccharides is followed by an EDTA extraction of soil samples taken at different time intervals. The extraction was developed to quantify the degradation of the alginate (pyrolysis-gas chromatography and mass spectrometry (GC/MS)) as well as measure a shift in the molar mass (field-flow fractionation coupled to a multi-angle light scattering detector (FFF-MALS)). The amount of mono- or oligosaccharides extracted with water did not change substantially between 0 d and 28 d for both soil types, which could be due to mono- and oligosaccharides being degraded to ¹⁴CO₂ while the polymer chains are also degraded to mono- and oligosaccharides. The EDTA extraction has shown a recovery of the alginate from the seed coating of 70% with FFF-MALS-RI. The incubation time of the OECD TG 307 is finished in December 2025 and will be presented with the finalized extraction results at SETAC 2026.

4.13.P-Mo304 The Fate of Composted Compostable Plastics

Julia Naima Möller, Wageningen University and Research (WUR), Netherlands

Compostable plastic products are commonly perceived as an environmentally friendly alternative to conventional plastics. However, European standard tests to certify a material as “compostable” do not reflect realistic conditions in municipal composting facilities. Studies have shown that high numbers of microplastics derived from compostable plastic products remain in the compost and may have a higher resistance to enzymatic degradation than previously assumed. The compost containing the residual biodegradable plastic fragments is then distributed to agricultural fields. It has also been shown that compostable plastic products can contain additives and non-intentionally added substances (so-called NIAS) - which can leach from the product over time. Negative effects of these leachates have been reported for aquatic organisms, but studies concerning the effects on soil systems are lacking.

In this project we aim to determine if residual microplastics derived from already composted compostable plastic bags will degrade under field conditions within two years. For this we characterized and quantified the biodegradable plastic fragments in the compost from a Dutch municipal composting plant. The characterized compost was placed in mesocosms on a Dutch field and sampled at the beginning of the experiment and after 3, 6 and 12 months (18 and 24 months are yet to be sampled). These samples are analyzed via NMR (Nuclear Magnetic Resonance) spectroscopy for a mass-based monitoring, allowing comparisons of mass and particle reduction.

Further we will try to assess the chemical composition of compostable biowaste collection bags and how the chemical leachate from compostable plastic products affect earthworm fitness, reproduction and development.

As the use of compostable plastic products is expected to increase significantly in the coming years, we consider it essential to close the knowledge gap on the fate and effects of compostable plastic bags after they have undergone the conventional composting process and end up in agricultural fields. This study would then be one step towards determining if compostable plastics are indeed environmentally friendly and in compliance with the European Green Deal, the Zero Pollution Action Plan and the European Soil Strategy.

4.13.P-Mo305 The soil legacy of biodegradable and conventional plastic mulching films: impacts on plant performance and soil invertebrate

Anita Jemec Kokalj¹, Taja Korpar¹, Teja Pelko¹, Ajda Kokalj², Katarina Vogel-Mikuš¹, Gabriela Kalcikova¹, Sabrina Carola Caroccio³, Giusy Curcuruto³, Valentina Giglio³, Giuliano Vox⁴, Fabiana Convertino⁴ and

Evelia Schettini⁴, (1)University of Ljubljana, Slovenia, (2)Gimnazija Poljane, Slovenia, (3)Institute of Polymers, Composites and Biomaterials (IPCB), National Research Council, Italy, (4)University of Bari Ado Moro, Italy

There is limited knowledge on the terrestrial hazards of mulching films and their potential microplastic release after field exposure. To address this gap, a research was carried out to investigate the legacy effects of mulching film application on soil. Two mulching films, one polyethylene (PE) and one poly(butylene adipate-co-terephthalate) (PBAT), were tested. The films were buried 10 cm deep below the soil under a Mediterranean climate. Soil samples containing microplastics released from PE and PBAT (coded as PE-soil and PBAT-soil, respectively) were collected after 32 and 276 days. After the exposure, we tested the effects of soils on terrestrial crustacean woodlouse *Porcellio scaber* (2 weeks) and two crops: the sunflower *Helianthus annuus* and maize *Zea mays* (8 weeks). Soil properties (pH, water holding capacity), woodlouse immune and detoxification responses, and plant physiological traits were assessed. Microplastics released from mulching films did not alter soil water holding capacity, but PBAT-soil collected after 276 days had a lower pH. *P. scaber* showed no significant changes in enzyme activities or immune parameters. Also, most plant physiological traits (transpiration rates, potential photochemical efficiency (Fv/Fm), actual photochemical efficiency (Y) and chlorophyll a/b ratio remained unaffected in sunflower and corn. However, some changes were observed in plants. Sunflower shoots grew better in PE-soil collected after 32 days (higher shoot fresh weight), but not in the case of soil collected after 276 days. After this latter period, PBAT-soil increased sunflower root water content, but reduced root dry weight and PE-soil induced oxidative stress in sunflower roots. In corn, elevated root proline at both time points and lower root water content was found when cultured in PBAT-soil collected after 276 days. We conclude that mulching films in general did not induce severe effects on soil, but some changes were induced by both mulching films irrespective of their biodegradability potential.

4.13.P-Mo306 From Soil Contaminant to Drought-Like Stress Inducer: Physiological and Biochemical Responses of Sunflower to Microplastics from Biodegradable Bags

Teja Pelko¹, Maša Andlovic¹, Jure Mravlje², Gabriela Kalcikova³, Anita Jemec Kokalj¹ and Katarina Vogel-Mikuš², (1)University of Ljubljana, Biotechnical Faculty, Department of Biology, Ljubljana, Slovenia, (2)University of Ljubljana, Biotechnical Faculty, Department of Biology, Ljubljana AND Jozef Stefan Institute, Ljubljana, Slovenia, (3)University of Ljubljana, Faculty of Chemistry and Chemical Technology, Ljubljana, Slovenia

Biodegradable plastics are promoted as sustainable alternatives to conventional polymers, yet fragmentation into microplastics (MPs) introduces new stressors to terrestrial systems. MPs can alter soil physicochemical properties and plant physiology, but whether they induce drought-like stress compared with conventional polymers remains unclear. We tested if pristine MPs from two poly(butylene adipate-co-terephthalate) bags suitable for home (PBAT_HOME) and industrial (PBAT_IND) composting trigger drought-like responses in sunflower (*Helianthus annuus* L.), compared with MPs from conventional polyethylene (PE) bags. Seedlings were grown in soil spiked with MPs at 0, 0.05%, 0.5% and 1% w/w. Polyethylene glycol (PEG) at the same concentrations was included as a positive control treatment for drought-like responses, because it is a well-established early biomarker of drought and osmotic stress. We quantified growth (fresh and dry weight of shoots and roots), photosynthetic pigments (chlorophylls, carotenoids), actual and potential photosynthetic efficiency, biochemical markers (H₂O₂, proline, total soluble sugars), as well as soil water holding capacity and pH.

PE had minimal effects on plant growth at all endpoints. In contrast, PBAT MPs caused dose-dependent stress responses, strongest at 1%: shoot and root biomass decreased, total chlorophyll content declined with a relative increase in carotenoids. Proline increased in shoots, while H₂O₂ and total soluble sugars increased in both roots and shoots, consistent with oxidative stress. Two-way clustering analysis of physiological and biochemical variables grouped both 1% PBAT treatments with all three PEG treatments, indicating a classical water-deficit signature rather than a nonspecific toxicity pattern. Soil responses were polymer-specific: WHC increased by 1% for all three types of MP, while pH increased only for 1% PBAT_IND compared to the control samples, indicating that different chemical properties of polymers can alter soil properties in different ways, affecting the plant water status.

Overall, our results show that pristine PBAT MPs—despite being labelled "biodegradable"—can cause drought-like stress in one of the major crops, while PE MPs have minimal impact. These findings challenge the

assumption that compostable plastics are agronomically harmless and highlight the need for polymer-specific risk assessment frameworks that integrate plant physiology with soil property changes.

4.13.P-Mo307 Impacts of Low-Density Polyethylene (LDPE) microplastics (MPs) on soil organism growth and functioning: influence of additive dose

Adrien Blanchard¹, Juliette Faburé², Agnès Richaume³, Veronika Khodyrieva⁴, Patrick Navard⁵, Manon Marret⁶ and Amélie Cantarel⁷, (1)National Research Institute for Agriculture, Food and Environment (INRAE), France, (2)AgroParisTech, France, (3)Univ de Lyon, Ecologie Microbienne, CNRS and INRAE, Villeurbanne (France), France, (4)Institut de Chimie de Nice, UMR CNRS 7275 Université Côte d'Azur, France, (5)MINES PARIS – PSL, France, (6)Univ de Lyon, Ecologie Microbienne, CNRS and INRAE, Villeurbanne, France, (7)Univ de Lyon, Ecologie Microbienne, CNRS and INRAE, Villeurbanne, France

Plastics, such as the most widely produced and used plastic, low-density polyethylene (LDPE), are made up of a main polymer and a large group of substances known as 'additives'. MPs additives are most likely to enter the soil environment. Additives are then suspected to play a role in the toxic effects generated by MPs, but the effects of these leachates have not yet been thoroughly assessed and all current scientific data focus on additive characterisation in soil or on additive effects on a single organism.

The aim of the work presented was to answer the following question: what are the effects of MPs and what is the influence of the additive dose on the growth of soil organisms and soil functions at relevant environmental exposures?

The answer to this question was based on three hypotheses:

- 1) MPs have negative effects on the growth of organisms
- 2) The concentration of additives is involved in the toxicity of MPs to soil organisms.
- 3) MPs and additives interfere with soil functioning.

To answer these questions, we worked with three biological models: two endogeic annelids (*Aporrectodea caliginosa* and *Enchytraeus albidus*) and a monocotyledonous forage plant: *Lolium perenne* L. These organisms were exposed according to three biological modalities, without interaction (one species), with one interaction (two species) and with two interactions (three species). To assess the effects of MPs and additive doses, we compared the growth of the organisms between three treatments: control (non-contaminated) - conventional MP exposure and "over-concentrated in additive" MPs exposure.

Regarding organism growth, no effect of MPs or additive dose was observed, neither in enchytraeids, earthworms nor in plants. Regarding microbial activities, the Denitrification Enzyme Activity is the only activity that responded to MPs exposure without interaction. In fact, no effects were observed on Substrate Induced Respiration and Nitrification Enzyme Activity.

We also observed that MPs and additives had adverse effects on the growth of all organisms when exposed in interaction with other organisms. Based on our results, it is likely that the toxicity of MPs is related to the leaching of additives into the soil, which may affect soil functioning. This work also shows that working with environmentally relevant organisms in interaction can help to understand the effects of a contamination on soil ecosystem functioning.

4.13.P-Mo308 Indirect trophic transfer of nanoplastics in soil ecosystems: A three-level exposure model with lettuce, snails, and springtails

Dokyung Kim and Youn-Joo An, Konkuk University, Korea, Republic of

Micro- and nanoplastics present in soil environments can be absorbed by plants and may reach higher trophic levels via animals that consume these plants. Therefore, studies on trophic transfer of micro- and nanoplastics within soil ecosystems are necessary. To this end, we aimed to observe the indirect transfer of nanoplastics within a three-tiered trophic system in soil ecosystem using lettuce, snails, and springtails. Fluorescent

nanoplastics were absorbed from the soil into lettuce, and plastic fluorescence was detected on the snail feces and the surface of springtails ingesting the snail feces. The transferred plastics were found to affect oxidative stress indicators such as microorganisms within snail feces. Furthermore, it was found that springtails disperse nanoplastics throughout the medium as they move after ingesting the feces. These findings suggest that micro- and nanoplastics in soil can be transferred and cycled throughout the entire soil ecosystem as well as higher trophic levels, emphasizing the need for plastic pollution management in food resources.

4.13.P-Mo309 Terrestrial Ecotoxicity Studies for Microplastic Particles – Influence of particle size, shape, polymer type and UV aging

Karsten Schlich¹, Cecilia Diaz¹, Markus Simon¹, Simon Gutierrez² and Kate Schofield², (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ricardo-AEA Ltd, United Kingdom

Growing interest in the effects of microplastic particles (MPs) on ecosystems has led to a surge in related research. While early studies focused on marine systems, attention has recently shifted towards terrestrial environments. Concerns about the reliability and relevance of MP ecotoxicological studies often stem from inconsistent reporting of particle properties and limited environmental representativeness (de Ruijter et al., 2020; Mehinto et al., 2022).

This work aimed to improve the hazard and risk assessment of MPs in terrestrial systems by identifying testing and reporting challenges and proposing solutions. Within the Holistic Environmental Risk Assessment for Microplastics in the Terrestrial Environment project (ECO 61), a review of terrestrial effect studies on engineered nanoparticles and micro- and nanoplastics (MNP) was completed. A comparative analysis was conducted using a strengths, weaknesses, opportunities, and threats (SWOT) framework.

A tiered testing approach was applied: pristine particles were studied in Tier 1 and UV-aged particles in Tier 2. In Tier 1, long-term effects of six MPs differing in shape, size, and polymer type were tested on soil microorganisms (OECD TG 216), plants (ISO 22030), and earthworms (OECD TG 222). Glass particles served as a negative control. Test systems were designed to minimize contamination and ensure compliance with quality assurance (QA) and quality control (QC) guidelines. Concentrations ranged from 0.1 to 1000 mg/kg dry weight soil to encompass environmentally relevant and worst-case exposures. In Tier 2, three of the particles were UV-aged following OECD TG 316 recommendations and retested.

QA/QC criteria were met across systems, with only minor deviations. Results suggest current regulatory test systems are sufficiently conservative to assess potential effects. Significant effects generally appeared at 100 and 1000 mg/kg soil. There was no clear indication that one of the organisms was most sensitive or that polymer type, size or shape are the main drivers for effects. However, UV aging appeared to enhance toxicity in some materials, particularly towards soil microorganisms. In plant tests, glass beads indicated a possible 20% background effect from particle presence alone.

These findings will be used to develop a holistic environmental risk assessment framework for MPs in terrestrial ecosystems now.

4.13.P-Mo310 Assessing the ecotoxicity of polypropylene fragments on earthworm with soil covering and mixing exposure scenarios

Jin Il Kwak¹, Youn-Joo An² and Patricia Holden³, (1)Pukyong National University (PKNU), Korea, Republic of, (2)Konkuk University, Korea, Republic of, (3)University of California, Santa Barbara, United States

Even though microplastics would initially emit to surface of environmental media in the realistic soil environment, there are limited research on considering different exposure scenarios of microplastics to earthworms. The purpose of the present study is to evaluate the ecotoxicity of microplastic fragments on earthworms which an important ecological indicator for soil pollution. Polypropylene (PP) fragments from products and earthworm *Eisenia fetida* were selected as model microplastics and test species. To compare the different exposure scenarios, column soil test and whole mixed soil test were conducted. In the column soil test,

amended soil with PP fragments were placed on the topsoil. After 3 weeks, earthworms avoided amended soil with PP fragments and then mortality, reproduction inhibition, *in vivo* cytotoxicity were not observed in the column test. On the other hand, inhibitions in lysosomal stability of earthworm cells, male and female reproductive tissues were significantly observed when earthworms were exposed by PP fragments thoroughly during whole exposure period (3 weeks). These results may be associated with the reduction of exposure level (concentration and period) due to the avoidance behavioural reactions of earthworms to pollutants in the column test.

4.13.P-Mo311 (Eco)toxicological effects on humans and on biota from micro/nanoplastics in relation with agrochemical applications - combined exposure of nano-pesticides and plastics

Evgenia Chaideftou¹, Willie Peijnenburg² and Hedwig Sutterlüty¹, (1)Medical University of Vienna, Austria, (2)Leiden University, Netherlands

Nano- and microplastic occurrence is widely evidenced across several environments, marine, freshwater, and soil. This includes agricultural soils, and various studies investigate the occurrence of plastics in agricultural soils. An increasing number of scientific articles report for example the enhanced efficacy of nanoplastics when combined with chemicals like pesticides, and this co-exposure may have synergistic effects. The data of such studies with pesticide are of high importance as this evidence can serve in resolving several issues in risk assessments, like combined effects (with other pollutants) that occur under realistic conditions. However, we still know very little on the (eco) toxicological effects on humans and on biota from micro/nanoplastics in relation with agrochemical applications, and it is also not clear how this information could be utilized in the field of regulatory risk assessments. A systematic literature review was therefore conducted to investigate: (i) the (eco)toxicological effects from combined exposure to nano- pesticide and plastic, and if we need to focus on specific toxicological impacts; (ii) if and which of the impacts on the organisms of the environment (humans and biota) from these combined exposures to (nano) pesticide and plastic, are assessed or sufficiently investigated to serve for regulatory risk or effect assessment schemes; (iii) which are the advances in nanomaterials in relation to ecotoxicological effects from pesticide and (micro/nano)plastic - combined exposure? This search aimed to shed light on how to utilize this information in novel or alternative regulatory risk assessments, and thus to facilitate minimization of adverse effects on environmental and human health.

4.13.P-Mo312 Towards a Holistic Hazard Assessment Framework for Microplastics in Terrestrial Environments

Kate Schofield¹, Simon Gutierrez², Megan Griffiths¹, Markus Simon³ and Karsten Schlich⁴, (1)Ricardo-AEA Ltd, United Kingdom, (2)Ricardo-AEA Ltd, Spain, (3)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

Microplastics (MPs) are increasingly recognised as pollutants of concern in terrestrial environments, yet current risk assessment approaches struggle to capture their particulate behaviour and environmental complexity. In this work, we outline a new hazard assessment framework for MPs in soil, developed as part of a wider research programme (ECO61, CEFIC-LRI). The framework takes inspiration from established chemical regulatory systems and adapts them to address the practical and conceptual gaps surrounding microplastic testing and evaluation.

We propose a tiered testing approach that brings together OECD and ISO methods to assess biological responses at multiple levels, from microbes and invertebrates to plants. Central to this framework is a call for more consistent particle characterisation, covering aspects such as shape, size, polymer type, surface charge, and ageing. Building on lessons learned from evaluating engineered nanomaterials (ENMs), the framework also stresses the need for test materials that better reflect environmental conditions, particularly fibrous and aged MPs, which are common in real soils but rarely included in standard laboratory tests.

Different methods for deriving Predicted No-Effect Concentrations (PNECs) are discussed, including traditional assessment factors, species sensitivity distributions (SSDs), and weight-of-evidence approaches. We also highlight ongoing challenges with data quality, reproducibility, and the lack of harmonised test standards. Furthermore, the framework makes recommendations for improving consistency, developing reference materials, and linking MP hazard assessment more closely with soil health indicators.

Overall, this work aims to help researchers and regulators move toward more realistic, evidence-based evaluations of microplastic hazards in terrestrial ecosystems.

4.13.P-Mo313 UV-Induced Microplastic Formation and Pollutant Release from Cigarette Butts: Insights from Soil Column Migration and TED-GC/MS Analysis

Siqi Wu¹, Alexander Böhme¹, Andreas Schaeffer² and Annika Jahnke¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Institute Environmental Research, RWTH Aachen University, Germany

Keywords: Microplastic, Cigarette butts, Soil column, Ultraviolet aging, Vertical migration

Cigarette butts (CBs) represent one of the most pervasive anthropogenic litter items worldwide, yet their transformation into microplastics and their role as sources of emerging pollutants in the terrestrial environment remains poorly understood. This study investigates the UV-induced aging of cigarette butts on soil cores, focusing on the formation of microplastics and the release of associated chemicals, as well as their subsequent migration behavior in soil. Controlled UV-aging experiments were conducted to simulate environmental weathering, followed by soil-column studies to evaluate the vertical transport of CB-derived microplastics and pollutants under real-world infiltration conditions. A microplastic detection strategy was established using Thermal Extraction-Desorption Gas Chromatography-Mass Spectrometry (TED-GC/MS), enabling high-resolution quantification of polymer residues along soil profiles. Complementarily, non-targeted analytical approaches were employed to identify and characterize aged-CB-derived organic chemicals released into soils. The findings address the rates and mechanisms of microplastic generation from cigarette butts, identify key pollutant species mobilized during UV aging, and elucidate their migration pathways in soil. This work provides crucial insight into CB-related environmental risks and supports the development of targeted strategies for pollution mitigation in terrestrial ecosystems.

4.13.P-Mo314 Azoles and other pesticides/biocides sorbed to plastic could pose a threat

Marit Almvik¹, Anan Zhao², Sven Roar Odenmarck¹, Ida Skaar² and Christopher Miles², (1)Norwegian Institute of Bioeconomy Research, Norway, (2)Norwegian Veterinary Institute, Norway

Azoles are a class of antifungal agents widely used in medicine, agriculture, and various industries. They play a critical role in treating fungal infections, which cause over two million deaths globally each year. However, their extensive use in agriculture, cosmetics, medicine, including veterinary medicine, wood protection, and even golf course maintenance has contributed to increasing fungal resistance, threatening both human and plant health. Recent research under the “Jekyll and Hyde” project, led by the Norwegian Veterinary Institute in collaboration with NIBIO and others, investigates whether plastic waste in nature can act as a carrier for harmful fungi and azoles. Volunteers across Norway collected plastic samples from diverse environments, including forests, fields, and mountains. From these, 120 representative samples were analyzed for microbial presence, azoles, and chemical composition.

Surprisingly, NIBIO detected pesticides and other pollutants in 25 plastic litter samples and azoles in 14 of the samples. These azoles included active substances from plant protection products, antiparasitic agents, and biocides commonly used in Norway. Industrial chemicals such as methylbenzotriazole and benzisothiazolinone were also found, though their role in resistance remains unclear.

The findings suggest azoles bind more strongly to plastic than previously assumed, allowing contaminants to persist and spread beyond agricultural areas into natural habitats. This raises concerns about environmental transport of antifungal agents and the potential acceleration of resistance development, posing risks to health and ecosystems.

Disclaimer/Disclosure:

The work has been financed through funding from the Norwegian Research Council, project 336251-KPSSAMARBEID22 "Could fungi be Jekyll and Mr. Hyde in the plastic litter problem"

4.13.P-Mo315 Aging of Microplastics in Soils: Effects on Surface Chemistry and Interactions with Organic Contaminants

Yuval Shahar¹, Raz Lev¹, Vered Mordehay¹, Evyatar Ben Mordehay² and Benny Chefetz³, (1)The Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Israel, (2)The Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Israel. Agriculture Research Organization - Volcani Institute; Rishon LeZion, Israel, Israel, (3)The Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Israel. Agriculture Research Organization - Volcani Institute; Rishon LeZion, Israel, Israel

Microplastics are frequently accumulated in agricultural lands, with concentrations ranging from few to tens of thousands of particles per kg of soil. Despite their extensive occurrence, little is known about their long-term fate and physicochemical transformations in soil, processes that subsequently influence their behavior as sorbents for organic contaminants. Thus, this study investigated the fate of Linear Low-Density Polyethylene

(LLDPE) microplastics during soil incubation and how these transformations affect the surface properties of LLDPE and interactions with organic contaminants. To that end, LLDPE mulch film that had undergone one year of environmental weathering was ground to 0.7-1 mm particles and incubated for 20 months in three loess soils. Particles were extracted after 6, 11, 15, and 20 months and used as sorbent for organic contaminants. ATR-FTIR analyses were performed to characterize surface chemical changes.

Across soils, LLDPE aging resulted in a pronounced increase in polar functional groups (particularly C-O bonds) during the first six months, likely due to eco-corona formation, while polymer backbone alterations remained minimal. Sorption affinity (K_d values) ranged from <0.1 to 1721 mL/g, with diphenhydramine, venlafaxine, 6PPD-quinone, aspartame, and oxcarbazepine exhibiting the highest affinities. Nearly half of the compounds (42%) exhibited relatively low K_d values (<5 mL/g), with only minor effects of soil type. Soil aging of the LLDPE particles had a limited influence on the sorption affinities, with 90% of contaminants exhibiting minor changes, with only five compounds displaying a K_d increase of >10 , mainly within the first six months. Desorption was largely reversible, with hysteresis observed only for four contaminants.

Our data show that the sorption affinities varied widely across contaminants; nevertheless, K_d values measured for LLDPE microplastics were often of the same order of magnitude as those of the same contaminants in the soils or lower. Consequently, under environmentally realistic conditions, the contribution of LLDPE microplastics to overall contaminants retention and soil affinities is expected to be limited, while compound-microplastic specific interactions cannot be fully excluded.

4.13.P-Mo316 Microplastic contamination in agricultural soils: uFTIR method assessment and European survey of 220 fields.

Nicolas Beriot¹, Adrian Grunder², Moritz Bigalke³ and Joelle Herforth-Rahmé⁴, (1)Wageningen University and Research (WUR), Netherlands, (2)University of Bern, Switzerland, (3)Technical University of Darmstadt, Germany, (4)FIBL, Switzerland

Plastic use in agriculture has tremendously increased in the past decades resulting in plastic contamination in soils. Few studies evaluated the contamination in different agricultural systems but each studies used a different protocols making them difficult to compare, especially when considering the smaller sizes of plastic debris. One method that is generally use to quantify microplastic contamination is density separation followed by imaging with FTIR spectroscopy. Within the MINAGRIS project, we worked with two laboratories (from the University of Bern and University of Wageningen) to establish and evaluate a microplastic quantification method with density separation and FTIR spectroscopy. Here we present first, the results from our quality controls from which we propose guidelines for microplastic assessment in soils, covering:

- Sample contamination using blank chemicals and blank soils
- Measurement variability across different operators, extractions and laboratories.
- Recoveries for three polymers in different spiked soils : Polyethylene (PE), Polylactic Acid (PLA) and Polyvinyl chloride (PVC)

Then we present the results for more than 220 agricultural fields across different pedoclimatic regions and agricultural systems in Europe. The soil was collected by teams in 11 different study sites, from 10 different countries. Our goal is to provide a snapshot of the microplastic contamination in Europe in 2022 and relate it to the different land managements.

4.13.P-Mo317 Searching for Microplastics in Complex Matrices: Insights from an Interlaboratory Comparison

Dean Velikov¹, Frank Von der Kammer¹, Patrizia Marie Schmidt² and Thilo Hofmann¹, (1)University of Vienna, Austria, (2)BASF, Germany

Global plastic production continues to rise due to its versatility, durability, and use in modern society, leading to an increasing amount of macro- and micro- plastic materials entering the environment. These materials have a wide range of physicochemical properties, and the lack of harmonized procedures for sampling, matrix removal, and analysis has made cross-study comparisons difficult. Standardized methodologies are urgently needed to improve the reliability and comparability of microplastic measurements across environmental matrices.

In this work, we address the current absence of an agreed-upon extraction protocol for microplastics by

developing a standardized method for extraction of microplastics from compost, with a targeted publication as an ISO standard by February 2027. The method comprises deagglomeration, organic matter removal, and density separation, with each procedural step optimized through multiple iterations of method refinement.

We present the results of an interlaboratory comparison conducted to evaluate the performance of the proposed protocol. Nine laboratories participated, applying different analytical techniques, including micro-Raman, micro-FTIR, and Py-GC/MS, to quantify microplastics in shared test materials. All laboratories successfully reproduced the extraction process within their replicates, although interlaboratory variability was observed. The results and the feedback received enabled the identification of steps requiring further optimization. The comparison confirmed that LDPE and PBAT can be repeatedly and reproducibly extracted, and it is reasonable to assume that other low-density microplastics ($<1.4 \text{ g/cm}^3$) could be recovered using the same approach, provided they remain stable under Fenton treatment.

This emerging standard is intended to provide a robust foundation for generating more comparable microplastic data across laboratories and for advancing our understanding of microplastic occurrence in compost and similarly complex environmental matrices.

4.13.P-Mo318 Modelling the Transport of Microplastics Across Reactive Barriers in Aquifer Recharge System: A Case Study in Palamós

Albert Contreras Llin¹, Jesús Carrera² and Silvia Diaz Cruz¹, (1)Institute of Environmental Assessment and Water Research (IDAEA), CSIC, Spain, (2)GHS (UPC-CSIC), Geosciences Department, IDAEA-CSIC, Spain

Managed aquifer recharge (MAR) with reactive barriers (RBs) is a promising strategy to limit microplastic (MP) transfer from wastewater effluents to groundwater, but field-scale transport processes and retention mechanisms remain poorly constrained. We investigated MP behaviour in a pilot MAR system in Palamós (Spain) fed by secondary effluent from a municipal wastewater treatment plant. We focused on three infiltration lines: a sand reference (T2) and two organic-rich RBs, T4 (sand–compost–clay) and T5 (sand–woodchips–clay). MPs were quantified in water at the MAR inlet (INF), immediately below the barrier (OB) and at the aquifer outlet (C), and in barrier material sampled at two depths (L1, L3) after system dismantling. MPs were extracted by oxidative digestion and density separation, classified by morphology and size by stereomicroscopy, and identified by FTIR imaging.

We developed a one-dimensional advection–dispersion model including two solid-phase compartments for reversible and irreversible retention, with first-order attachment/detachment kinetics and a blocking/straining function. RB and aquifer segments were represented explicitly, using field-based hydraulic parameters and residence times. Model calibration targeted water-phase MPs/L at INF, OB and C and retained MPs/kg in barrier material.

MP concentrations decreased along the MAR system with strong contrasts among lines: total removal (INF?C) reached 33% (T2), 88% (T4) and 100% (T5). Organic RBs accumulated substantially more MPs, with higher loads near the barrier surface, indicating efficient near-inlet interception. Size distributions narrowed along the flow path and polymer diversity decreased, showing strong size- and polymer-selective filtration. The dual-site model successfully reproduced both water and solid-phase data, yielding higher attachment rates and greater irreversible retention in organic RBs than in the aquifer.

Our results demonstrate that organic-rich RBs embedded in MAR can significantly reduce MP fluxes to groundwater and that field-calibrated dual-site models provide a powerful tool to support design and upscaling of MP-mitigating MAR systems.

4.13.P-Mo319 Effects of Microplastic Polymer Types on Soil Hydraulic Response and Microplastic Transport During Rainfall Events

Qi Liu, Loes van Schaik and Jantien Baartman, Wageningen University and Research (WUR), Netherlands

Microplastics (MPs, diameter $< 5\text{mm}$) are widely detected in terrestrial environments, yet their fate in soil and their mobility during precipitation events remain insufficiently understood. In particular, it is unclear how different MP polymers influence soil structure and soil hydrological properties and, consequently, runoff patterns and MP transport. This study aims to determine how pristine LDPE, weathered LDPE, and weathered PBAT affect soil hydraulic properties, runoff characteristics, and sediment and plastic transport.

Loess soil flumes ($1 \text{ m} \times 0.5 \text{ m} \times 0.3 \text{ m}$) were individually spiked with 0.1% w/w MPs (pristine LDPE,

weathered LDPE, or weathered PBAT) and incubated under repeated wet–dry cycles for six months to promote soil aggregation. Following this incubation, the flumes were subjected to simulated rainfall at an intensity of 70–73 mm h⁻¹ for 30 minutes. Runoff was collected every three minutes until flow ceased. Ongoing analyses include soil properties such as water retention curves, saturated hydraulic conductivity, measured before and after the rainfall event, as well as MP partitioning across soil aggregate size fractions.

We hypothesize that soils containing LDPE will behave differently from those containing PBAT because LDPE's hydrophobicity and low density are expected to reduce water retention and decrease K_{sat}, which will subsequently lower soil infiltration, and accelerate runoff initiation, thereby enhancing the transport of LDPE particles due to their buoyancy. Furthermore, we expect pristine LDPE to exert a stronger influence than weathered LDPE, as its smoother surface and higher hydrophobicity. In contrast, weathered PBAT—being more hydrophilic—is expected to increase soil water-holding capacity, delay surface saturation, and produce later runoff initiation with lower sediment concentrations and reduced sediment/runoff ratios, while also resulting in comparatively lower PBAT transport due to its higher density and affinity for soil particles. Currently, soil property analysis and MP quantification are ongoing; at SETAC we expect to be able to present the results. This research advances understanding of MP–soil interactions under realistic rainfall conditions and provides new insight into the mechanisms controlling runoff and sediment transport as well as MP mobility in agricultural landscapes. The findings will help clarify whether soil will act as a sink or a source of MPs in the future.

4.14.P Soil Monitoring and Resilience - Which Chemicals, What Effects and How to Protect Ecosystem Functioning?

1. Introduction

The European Soil Monitoring Law (SML) introduces a need for systematic prioritization of contaminants for soil monitoring to address diffuse pollution. With thousands of chemicals regulated by different frameworks, prioritization must balance scientific robustness, regulatory coherence, data availability, and practical feasibility. This paper contributes to developing prioritization for the SML by comparing methodologies applied to soil contaminants from various frameworks, focusing on conceptual design, parameter selection, and handling data gaps. The work results from collaboration across EU Soil Mission and Horizon Europe projects in the Soil Pollution and Remediation cluster.

2. Materials and Methods

Several prioritization methods have emerged, addressing the environment and human health or single compartments like water. We analyse four approaches for soil pollutants:

- (i) risk-based scoring integrating persistence, mobility, bioaccumulation, ecotoxicology, and toxicity
- (ii) tiered frameworks combining emission models with measured soil data
- (iii) multi-criteria decision analysis (MCDA) aggregating hazard, exposure, and socio-economic indicators
- (iv) category-based schemes classifying substances into “action categories” before ranking.

A common dataset of 20 substances was tested with these approaches developed in Soil Mission projects (ARAGORN, ISLANDR), the Norman Network, and the German Environment Agency (UBA) on pesticides (data-rich), PFAS (data-poor), metals, and emerging substances to illustrate how methodological choices influence outcomes.

3. Results and Discussion

Key differences include reliance on occurrence versus proxy data, treatment of uncertainty, and capacity to integrate mixture effects or climate stressors. Simple scoring offers transparency and ease but may oversimplify risks. Risk-based, tiered, and MCDA approaches provide flexibility and accommodate diverse data contexts yet require harmonized input, which may not be publicly available. Category-based approaches help manage knowledge gaps and guide research priorities but depend on expert judgment.

4. Conclusions

Hybrid strategies combining risk-based logic with uncertainty indicators and adaptive mechanisms best address monitoring needs. Recommendations include harmonizing parameter definitions, improving data interoperability, and embedding prioritization tools into EU-wide and national programs to strengthen comparability and policy relevance.

4.14.P-Th182 PFAS Contamination in Swiss Soils – an Overview

Elvira Rudin¹, Juliane Glüge², Basilius Thalmann³ and Martin Scheringer⁴, (1)ETH Zurich, Zurich University of Applied Sciences, Switzerland, (2)ETH Zurich, present address Swiss Federal Office for the Environment, Switzerland, (3)Zurich University of Applied Sciences, Switzerland, (4)ETH Zurich, Switzerland

Due to their persistence, toxicity, and their widespread use, per- and polyfluoroalkyl substances (PFASs) are a reason for concern for the environment and human health. Therefore, threshold values for chemical soil protection are needed. In order to set these values and prioritize measures, knowledge on PFAS concentrations in Swiss soils is crucial.

Information on background concentrations of PFASs in Swiss soil was published by Thalmann et al. in 2022. However, further knowledge on soil contamination is limited. To improve this, a data collection of measurements of PFASs in Swiss soils was initiated. Measurement results from over 1000 samples were gathered with most of the data originating from cantonal measurement campaigns. The objectives of these campaigns varied, some assessed background concentrations of PFASs in soil, while others screened for potentially contaminated sites or assessed known contaminated sites further.

This study summarizes the current knowledge on PFAS soil levels in Switzerland. It sheds light on which PFASs are found at the highest concentrations and which PFASs have the highest detection frequencies. Furthermore, it identifies relevant PFAS sources and concentration differences between land-uses. Particular attention was paid to understand substance patterns associated with different PFAS applications or land-uses. We were able to show that the application of sewage sludge, the use of firefighting foam as well as diffuse pollution are associated with specific substance-patterns. An in-depth cluster-analysis was performed to determine whether other parameters (such as location, suspected PFAS-sources or soil characteristics) can explain differences in the frequency of substance detection and measured concentrations.

These results improve our understanding of the concentration of PFASs in soil and contribute to the derivation of soil threshold values in Switzerland.

4.14.P-Th183 Normal operating ranges in soil ecotoxicology: the development of effect-based thresholds to assess the impact of chemicals on soils

Mathieu Renaud¹, Sophie Campiche², Laura Centeno², Benoît J.D. FERRARI¹ and Louveline Lépeule³, (1)Ecotox Centre, Switzerland, (2)Envibiosoil, Switzerland, (3)Swiss Centre for Applied Ecotoxicology, Switzerland

In ecotoxicology, the biological response of organisms in reference conditions is necessary to interpret responses obtained in contaminated conditions. In the case of retrospective assessments of diffuse pollution in soils, it is not always possible to obtain a representative uncontaminated natural reference soil. Furthermore, artificial soils used in standardized bioassays (e.g. OECD soil) are not always representative of the soil properties in the study site. As soil organisms are sensitive to soil properties, when comparing different soils it can sometimes be difficult to determine how much of the response observed is due to contamination or to differences in soil properties.

One way to address this issue is to characterize the natural variability of the biological responses (e.g. survival,

growth, reproduction) obtained on different natural reference soils with different geochemical properties. Defining a Normal Operating Range (NOR) for several soil bioindicators would provide a reference based on the effect of soil properties on the variation of the biological response. The normal response thresholds can then allow evaluating if the effects of suspected contaminated sites fall outside the natural variability, in cases where establishing reference sites is challenging.

To demonstrate this concept, a pilot study was conducted with agricultural soils (temporary prairies or organically managed) from the Jura region of Switzerland. The biological responses on these soils were assessed using 4 species: *Folsomia candida* (ISO 11267), *Enchytraeus crypticus* (ISO 15387), *Allium cepa* and *Brassica napus* (ISO 18763). To establish these NOR, two statistical approaches were compared: one assuming a normal distribution and calculating percentiles (2.5 and 97.5) as thresholds. The second based on the Minimum Detectable Difference (MDD) expressing the inherent variability, and the Maximum Detectable Difference (MTI) representing the variability between the reference soils in comparison to a control soil (e.g. LUFA).

In general, it was possible to develop normal operating ranges for all bioassays. However, the approach based on MDD/MTI which is dependent on a control response (LUFA 2.2) is less adequate if the control soil is not representative of the region. The current study is an initial pilot and must now be extended to other biogeographic regions of Switzerland, but these tools are a promising approach to be used in monitoring contexts.

4.14.P-Th184 A novel Mixture Risk Assessment Approach for Agricultural Soils put to the Test: Which Trophic Levels are at Risk in Soil Field Samples?

Fabian G. P. Balk¹, Beatrice Mah², Eva Lauber¹, Mathieu Renaud¹, Benoît J.D. FERRARI¹ and Marion Junghans¹, (1)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Switzerland, (2)Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, Germany

Plant protection products (PPP) are applied in agricultural fields for crop protection and may accumulate in the soil. As a result from serial applications or slow degradations of PPP, the soil and organisms therein may be exposed to a mixture of PPP residues. However, single substance environmental risk assessment in soil does not consider the added risk, which may arise due to co-exposure with other substances. We here present a novel mixture risk assessment approach for soils, termed RQtaxa, which assesses four trophic levels in soils for their potential risk due to exposure to multiple PPP residues. The RQtaxa approach has the advantage that it does not exceed the conventional method of summing up all risk quotients of detected PPP residues in a given mixture but differentiates by organism groups. The RQtaxa concept was applied to soil field samples from the Swiss national soil monitoring network, which also contained information on the crop type of the soil samples. This exercise provides insights into which soil organism groups are at risk in the various crop types and reveals data gaps on missing soil organism toxicity data, which helps to steer further ecotoxicity testing. In addition, it also highlights how many PPP residues drive the mixture risk in which crop types. With the recently endorsed EU soil monitoring law, the RQtaxa concept would be an interesting option to consider mixture risk assessment on an international scale.

4.14.P-Th185 Soil Risk Assessment of Pesticides: Issues with Using Regulatory and Research Data in the Retrospective Risk Assessment

Eva Lauber, Fabian G. P. Balk and Marion Junghans, Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Switzerland

In order to maintain health and function, agricultural soils need to be regularly evaluated: pesticide residues are monitored and used in conjunction with soil ecotoxicity data in a retrospective risk assessment. For this purpose,

we evaluated regulatory and research studies on pesticides using the modified, soil-specific Criteria for Reporting and Evaluating Ecotoxicity Data (CRED) with some amendments (e.g. exposure must be through soil, no recovery accepted). We faced two major groups of issues: the quality of the studies and their reporting. Regarding the study quality, common issues are lacking analytical verification, unknown test organism sensitivity (positive control), missing solvent control and incomplete statistical evaluation. Regulatory study reports are still rarely available publicly, usually only the study summaries in regulatory dossiers. These summaries often omit important details, such as soil properties or specifics of the test item application. In research articles the test item is often not properly identified, pesticide use history of the sampled/test field is lacking or field collected test animals are used. General issues in presenting the outcome include not reporting the data for the effect results (at least mean value $\pm$ SD per treatment for all measured effects), for the statistical results (e.g. statistical significance, fitted curve, goodness of fit, confidence intervals) or for the validity criteria as defined by standard test guidelines.

These issues resulted in a large number of refusals of potentially relevant studies. As a consequence, the derived risk-based hazard values are less robust and in case of resulting data gaps higher assessment factors need to be selected.

In addition, we observed that the results of the seedling emergence test on terrestrial plants following the standard test method are difficult to compare with the results on other soil organisms (application rate instead of concentration in soil is used), while the test with predatory mite seems to be superfluous based on its apparent relative insensitivity to pesticide exposure.

Regarding the regulatory studies, some points identified above might be addressed in the ongoing revision of the SANCO guidance document on terrestrial ecotoxicology. The here applied soil-specific CRED guideline is highly recommended to be used in order to minimise the gap between research and regulatory frameworks.

4.14.P-Th186 Effects Of Reduced Application of Pesticides On Soil Residue Concentrations And Soil Invertebrates

Gilda Federica Dell'Ambrogio¹, Philippe Jeanneret¹, Florian Walder¹, Benoît J.D. FERRARI², Marcel van der Heijden³, Thomas D. Bucheli⁴, Mathieu Renaud² and Stefanie Lutz⁵, (1)Agroscope, Switzerland, (2)Ecotox Centre, Switzerland, (3)University of Zurich / Agroscope, Switzerland, (4)Environmental Analytics, Agroscope, Switzerland, (5)University of Zurich, Switzerland

Pesticides are widely used in conventional agriculture to protect crops and to support yields, but once applied, they can reach the soil where many persist for years, resulting in the chronic exposure of soil organisms. Soil biota play several functions that are crucial for maintaining soil health. There is increasing evidence that pesticides have an adverse effect on the fitness of soil organisms, which can result in shifts in communities and ultimately in changes in soil functions. A more sustainable approach to agriculture to minimize the impact on soil organisms is needed. The PestiRed project aims to reduce the pesticide use by 75% applying alternative measures for weed, pest and disease control, based mostly on agroecological principles. A maximum yield loss of 10% is allowed. Such innovative measures are tested on several farms across three Swiss regions. On each farm, one plot is managed conventionally while innovative measures and pesticides reduction are applied to a second plot.

To investigate the consequences of pesticide reduction on soil contamination, concentrations of 146 residues are measured in both plot types of the PestiRed farms. Measured environmental concentrations are then compared with application data, as well as with ecotoxicological data to assess potential risk to soil biota. In a second step, the same samples are used to evaluate the fitness of two model invertebrates after exposure to the real soil residue concentrations.

Preliminary results suggest that residue concentrations decreased with time and management change, but this reduction remained modest and did not fully reflect the 75% reduction in the application. Site-specific characteristics and substance properties likely contribute to this discrepancy. Similarly, ecotoxicological assays showed large variability in the reproduction response, suggesting that additional factors, beyond management alone influence the results. More in-depth analysis will be used to further explore the contribution of the different drivers.

Combining complementary indicators of soil health (chemical, ecotoxicological, ecological) provides a more comprehensive approach to addressing the problematic from different lines of evidence, enabling an integrated assessment of the management effect on soil health.

4.14.P-Th187 Effects of Fluroxypyr on Soil Mesofauna Assessed by Non-Parametric Indicators in Field Mesocosms

Iwona Gruss¹, Irimina Ćwieląg-Piasecka², Larysa Jazienicka² and Isha Shakoor², (1)Wroclaw University of Science and Technology, Poland, (2)Wroclaw University of Environmental and Life Sciences, Poland

Fluroxypyr is a widely used auxinic herbicide, yet its potential to disturb soil mesofauna remains poorly understood, despite recent laboratory evidence indicating toxicity to non-target invertebrates. This knowledge gap is especially relevant for belowground ecosystems, where pesticide impacts are often inferred rather than measured under realistic conditions. The present study aimed to assess the sensitivity of soil mesofauna to fluroxypyr using non-parametric indicators in a controlled field mesocosm experiment.

Fluroxypyr, applied as a commercial plant protection product, was tested in a field mesocosm experiment using intact soil cores exposed to five agriculturally relevant application rates (0–400 g a.i. ha⁻¹) and incubated under natural conditions for 20 days. Soil fauna were extracted and identified at the family level. Soil biological quality was assessed using a modified, abundance-weighted QBS-Ar index, while community-level responses were evaluated based on selected microarthropod taxa and soil microbial functioning was quantified by measuring soil respiration.

Fluroxypyr application significantly affected selected soil organisms and functional indicators. Among Collembola, only family Isotomidae showed a significant response to treatment, with abundance reduced relative to the control. Gamasida (Acari) abundance declined significantly with increasing herbicide dose. Soil biological quality, expressed as the multiplied QBS-Ar index, was significantly reduced at the highest application rate. Soil respiration exhibited the strongest response, declining markedly with increasing fluroxypyr dose and reaching the lowest values at 400 g ha⁻¹.

These results demonstrate that fluroxypyr, at commonly applied agricultural doses, can impair both soil microbial functioning and key decomposer groups. The findings highlight the importance of incorporating non-parametric, community-level and functional indicators—particularly total Collembola abundance and respiration—into herbicide risk assessment. They challenge the assumption that auxinic herbicides pose negligible risks to belowground biodiversity and support the need for more inclusive evaluation frameworks for soil organisms.

Disclaimer/Disclosure:

This research was funded in whole by National Science Centre, Poland [Grant number: 2025/57/B/ST10/01727] “Influence of secondary plant metabolites on degradation of pesticides in agricultural soils” carried out under the OPUS 29 call.

4.14.P-Th188 A Microcosm on Tires? – Investigating the Presence of Microorganisms on Tire Wear Particles in Soil under Different Environmental Conditions.

Katharina Wiessner¹, Vanessa Bartl², Vita Kucmaite², Emilie Morineau³, Ambra Muca², Katharina Keiblinger⁴ and Elisabeth Simboeck³, (1)University of Natural Resources and Life Sciences, University of Applied Sciences Technikum Wien, Austria, (2)University of Applied Sciences Technikum Wien, Austria, (3)University of Applied Sciences Vienna (UAS Technikum), Austria, (4)University of Natural Resources and Life Sciences, Austria

It is well established, that tire wear particles (TWP) pose a risk to the environment. Not only are they persistent, but they also contain a complex mixture of substances, such as zinc and other heavy metals, as well as polycyclic aromatic hydrocarbons (PAHs), that can be released into the surrounding environment through leaching. Especially terrestrial organisms are at risk to be exposed to TWPs and their leachables, as soil is the major sink for TWPs. Upon this potential risk for the environment emanating from TWPs, the question arises, if soil microorganisms are still able to grow in such a seemingly hostile environment.

To investigate the growth of soil microorganisms on the surface of tire wear particles, different amounts of TWPs in the size range of 0.8 – 1 mm were mixed with soil samples of varying water content and incubated at room temperature in the dark for several weeks. The TWPs were then viewed in the SEM to examine them for microbial presence at different time points. To enable reliable identification of microorganisms in the SEM, several TWPs that were not mixed with soil were viewed in the SEM and compared with TWP samples that were incubated in soil and subsequently freeze-dried to preserve any attached microorganisms. Additionally, a

leachate of soil samples was prepared in a 0.85% saline solution and filtered through a 10 µm filter to retain microorganisms from the soil. The filter was then viewed in the SEM as well. To determine potential changes in soil microbial growth in the presence of TWPs, DNA was extracted from soil samples exposed to TWPs and from control samples without added TWPs, and DNA concentrations were measured.

Preliminary results indicate that microorganisms are able to grow on the surface of tire wear particles, contrary to our initial hypothesis. However, the identification of microorganisms on TWPs is challenging, as the particles exhibit highly irregular surfaces with agglomeration-like structures and short protruding fibers resulting from the milling process. Furthermore, TWPs can only be used once for SEM analysis, limiting the comparability. As a next step, the experiment could be repeated using environmental SEM (eSEM), which would allow the same TWP to be examined at multiple time points and enable direct tracking of microbial growth. The soil microbiome is an important indicator for soil health, making its monitoring essential for soil research looking to preserve one of earth's most valuable resources.

4.14.P-Th189 Urban Unconventional Water Infiltration and Soil Resilience: Hydrodynamic and Bio-Physico-Chemical Impacts

Alexandra CERONE¹, Claire VILLETTE², Dimitri HEINTZ³, Adrien WANKO NGNIEN¹ and Loïc Maurer¹, (1)University of Strasbourg, CNRS, ENGEEES, ICube UMR 7357, France, (2)University of Strasbourg, CNRS, IPHC UMR7178, France, (3)University of Strasbourg, CNRS, IPHC UMR7179, France

Freshwater resources are facing increasing scarcity, which could affect one in four people by 2050 (United Nations, 2015). To deal with these issues, in 2023, France adopted the « Water Plan », which promotes the use of unconventional water (treated wastewater and stormwater) for urban cleaning and green space irrigation.

The study investigates the impacts of unconventional water infiltration on urban soil quality. Soils and unconventional water were characterized for physical (grain size, porosity, density), hydrodynamic (permeability, water retention), geochemical (pH, conductivity, ionic interactions) and biological properties. Non-targeted high-resolution mass spectrometry (HRMS) was used to detect heavy metals, PAHs, pesticides, pharmaceuticals residues and microplastics.

An experimental setup based on soil columns evaluated different soil occupation (vegetated and non-vegetated), soil types and water saturation levels simulating piezometric fluctuations. Hydrodynamic, physico-chemical and microbiological parameters were monitored to follow infiltration impacts, pollutant retention and to better understand the soil – subsoil – groundwater continuum.

Preliminary results reveal strong contrasts: the first soil type exhibits an much higher porosity at depth ($\phi = 70.4 \pm 0.6 \%$), which promotes infiltration, whereas the second soil type is denser ($\phi = 49 \pm 1 \%$). HRMS analyses show over 250 potential features in unconventional water, including aromatics, PAHs, PCBs, pesticides and polar pollutants.

These results highlight the complexity of urban soils and unconventional waters. Integrating hydrodynamic, physico-chemical and “-omics” approaches provides a robust framework to assess soil health and micropollutant retention. This work supports sustainable urban water management and enhances urban soil resilience under increasing environmental pressures.

4.14.P-Th190 Climate-Induced Remobilization of Nonextractable Organohalogens in Permafrost Soils *Xiaojing Zhu, Helmholtz Center for Environmental Research (UFZ), Germany*

Nonextractable residues (NER) represent a major yet under-recognized portion of organic pollutants in soils. This gap is particularly striking in permafrost environments, where halogenated organic compounds were found to be dominated by NER, frequently exceeding extractable fractions (EF) by two to three orders of magnitude. Such distributions suggest that frozen soils act as large, long-term reservoirs of bound pollutants that conventional EF-based monitoring does not capture.

In this study, NER-to-EF ratios were evaluated across permafrost soils spanning a natural temperature gradient, revealing a consistent decrease in NER relative to EF with increasing temperature. To experimentally

investigate the potential for climate-driven remobilization, controlled incubations were performed on three permafrost soils with contrasting organic matter contents, along with a sterilized control, under a warming–cooling cycle. Across all active soils, temperature shifts led to measurable increases in EF up to 50-fold, indicating mobilization of previously bound organohalogenes. Synthetic-like organohalogenes showed faster release than natural ones, suggesting that NER binding history governs remobilization potential. The magnitude of release varied among soils: higher organic matter contents were associated with slower remobilization, while soils with lower organic matter exhibited more pronounced increases. Microbial activity proved essential, as distinct phyla were associated with enhanced release in each soil, whereas the sterilized control exhibited strongly suppressed remobilization.

Overall, the results indicate that climate warming can promote the remobilization of legacy organohalogen contaminants stored as NER in permafrost. These findings underscore the need to incorporate NER into soil monitoring and resilience frameworks, especially in northern regions undergoing rapid environmental change.

4.15.P Statistics for Setting Endpoints – from Tried and Tested to New and Exciting Methods

4.15.P-Th191 Statistical Analysis of Ecotoxicology Data for Regulatory Purposes: an IEAM Special Series
Raoul Wolf¹, David Fox² and Jannicke Moe³, (1)Norwegian Geotechnical Institute (NGI), Norway, (2)Environmetrics Australia, Australia, (3)Norwegian Institute for Water Research, Norway

Statistical methodologies and tools applicable to ecotoxicology have developed and improved over recent decades. Nevertheless, regulatory risk assessments are still largely based on statistical principles and approaches that are no longer state-of-the-art. SETAC meeting sessions dedicated to statistical methods have witnessed a high level of interest and discussion regarding the progress and applications of statistical methodologies. Many ecotoxicologists have expressed interest in the revision of the 2006 OECD document no. 54 ("Current approaches in the statistical analysis of ecotoxicity data: a guidance to application"). This guidance is no longer considered reflective of contemporary statistical methods or computational platforms used in ecotoxicology, and its revision process is ongoing.

Against this background, a call for papers for a Special Series in Integrated Environmental Assessment and Management (IEAM) was launched in autumn 2024 with manuscript submissions until summer 2025.

The purpose of this Special Series was to provide an overview of the statistical ecotoxicology landscape and reflect on recent developments, processes and opinions. Relevant topics include (but are not limited to): similarities and differences of toxicity metrics (NOEC, BMD, NEC, ECX, NSEC, and more); developments and tools for dose-response modelling; developments and tools in SSD modelling (model averaging, mixture models); Bayesian vs. frequentist approaches; and case studies of novel statistical methodologies highlighting their benefits. We welcomed and encouraged contributions and viewpoints from members of all sectors, including academia, industry and government.

By the time of writing (November 2025), five papers have been accepted for the series, with several more manuscripts under evaluation. In this poster we give an overview of the final series of papers, focusing on the variety of approaches, scientific novelties, and implications for regulatory ecotoxicology and risk assessment.

4.15.P-Th192 The Benefits of Bayesian Statistics: Examples from the Revised OECD Document 54 Annexes

Raoul Wolf¹, Jannicke Moe² and David Fox³, (1)Norwegian Geotechnical Institute (NGI), Norway, (2)Norwegian Institute for Water Research, Norway, (3)Environmetrics Australia, Australia

OECD Document 54 ("Current Approaches in the Statistical Analysis of Ecotoxicity Data: A Guidance to Application"), first released in 2006, is being revised to include Bayesian methods alongside traditional frequentist approaches. The OECD document 54 annexes provide example datasets from OECD test guidelines 201 (algal growth inhibition), 202 (Daphnia acute immobilisation), 211 (Daphnia reproduction), and 215 (fish juvenile growth). Additionally, a new dataset for 236 (fish embryo acute toxicity) was considered.

The revision reflects a broader shift in life sciences toward Bayesian statistics, valued for handling hierarchical, nonlinear, and data-limited scenarios, while offering transparent assumptions, improved uncertainty quantification, and reproducible workflows. Criticisms of Bayesian methods—higher data demand, greater uncertainty, and subjectivity due to priors—will be addressed through intuitive workflows, checklists, and comparisons with frequentist results.

For concentration-response analysis, log-normal, log-logistic, and Weibull type I models were applied, with model choice guided by Bayesian cross-validation. ECX values and credible intervals were derived from posterior distributions. Hypothesis testing used Bayesian hierarchical regression (analogous to ANOVA), with partial pooling to reduce false positives/negatives and significance assessed via posterior draws and the ROPE

principle, yielding NOEC/LOEC values.

Validation included prior-posterior and posterior-predictive checks, plus sensitivity analyses to detect prior-likelihood conflicts. Results showed Bayesian methods robustly produced EC/LCx and NOEC/LOEC values across datasets, with credible intervals automatically capturing uncertainty from data variability, sample size, and priors. While strong priors influenced some parameters, final endpoints remained unaffected.

Overall, Bayesian analysis matched frequentist outcomes in most cases and offered advantages in challenging contexts (e.g., zero-inflation, small samples). The methodology meets regulatory requirements in principle, demonstrating that Bayesian approaches are not more data-demanding, uncertain, or subjective than frequentist ones—and can even reduce uncertainty in some cases. The study encourages scientists and regulators to adopt Bayesian methods for standard ecotoxicity data analysis, highlighting their robustness, transparency, and potential to improve regulatory statistics.

Disclaimer/Disclosure:

This work is part of the project "ZeroPM: Zero pollution of persistent, mobile substances" which has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 101036756.

4.15.P-Th193 FXMATE: Open-Access Statistics for Ecotoxicity Effects MAde Totally Easy

Jochen Zubrod, Eric Bollinger, Dominic Englert and Felix König, Paliner GmbH, Germany

Chemical registration and environmental risk assessment depend on robust statistical evaluation of ecotoxicity test data. Despite the guidance provided, for example by the OECD, inconsistencies in statistical practice persist, often arising from custom code or opaque workflows. These limitations can bias toxicity estimates and complicate the statistical justification of regulatory decisions.

FXMATE is designed to address these issues as an open-access software framework for reproducible, transparent, and standardized ecotoxicological data analysis. The framework implements automated workflows aligned with OECD test guidelines (e.g., 201 and 211), covering data validation, guideline-specific preprocessing, dose-response modelling, and hypothesis testing. While experienced users retain full control over analytical choices, optional constraints and decision guidance are provided to reduce common statistical errors. The framework combines established state-of-the-art modelling approaches, such as bootstrapping and model averaging, with a modular architecture that allows integration of emerging statistical methods as they gain regulatory relevance, including recently proposed hypothesis tests for count data (e.g., CPCAT and Dunnett GLM). For continuous, quantal, and count data, decision trees derived from and extending OECD guidance formalize the selection of appropriate statistical analyses.

By combining guideline-conform statistical methodology with transparent implementations, FXMATE contributes to more consistent and defensible statistical evaluations of ecotoxicity data. This work contributes to ongoing efforts within the ecotoxicological community to modernize statistical practice and ensure that environmental risk assessments remain both reliable and reproducible. As an open-access scientific infrastructure provided entirely free of charge to the scientific community, FXMATE is expected to lower technical barriers, reduce analytical errors, and improve the quality and transparency of ecotoxicological assessments, goals aligning closely with SETAC's mission and good scientific practice.

4.15.P-Th194 Rethinking NOEC Determination for Quantal Data with Cliff Responses: A Critique of the Cochran–Armitage Test and a Proposed Workflow

Zhenglei Gao¹ and Andreas Solga², (1)Data Science, Bayer CropScience AG, Germany, (2)Bayer AG, Germany

For quantal endpoints, the step-down Cochran–Armitage (CA) trend test is a common route to derive NOECs once monotonicity is confirmed. In cliff-edge response patterns, where no or minimal effects at lower doses followed by a sharp increase, the CA test's linear-trend assumption and default asymptotic p-values can yield false-positive LOECs, particularly when replicate structure is mis-specified. Using a *Daphnia magna* acute immobilization dataset (OECD 202) with 0% immobility up to 20 mg/L, a small effect at 40 mg/L (6.7%), and a large effect at 80 mg/L (63.3%), the standard CA procedure selected a NOEC of 20 mg/L (asymptotic $p=0.006$ at 40 mg/L). In contrast, bias-reduced logistic regression, Williams' test, Fisher's exact tests with Holm–Bonferroni adjustment, and an exact CA computed at the replicate level all support a NOEC of 40 mg/L. We investigate two parallel CA adjustments for replicated cliff patterns, trend-consistent overdispersion assessment with Rao–Scott correction and exact CA with replicate-based sample sizes and evaluate their performance alongside logistic regression in an extensive beta-binomial simulation framework using flexible probit-type dose–response curves. Preliminary results generalize the case study, indicating that both CA adjustments

mitigate cliff-driven false positives and align with biologically grounded inference. The proposed workflow improves reliability of regulatory endpoints by reducing artifacts from trend leverage and sample-size misspecification, maintaining power near the smallest effect size considered biologically meaningful (e.g., EC5–EC10), and transparently handling replicated designs.

4.15.P-Th195 Pool or Not to Pool Controls: An Industry Perspective

Marysia Agnieszka Tobor-Kaplon¹ and Emily Scorgie², (1)Syngenta Crop Protection B.V., Netherlands, (2)Global Science Delivery, Syngenta Seeds B.V., Netherlands

Regulatory ecotoxicology needs a consistent answer to a simple question: which control should we compare to treated groups? Right now, the answer varies by guideline, and so do the endpoints.

Alongside negative control, regulatory ecotoxicity tests require a solvent control when a solvent is used to dissolve the test item. OECD guidance, however, is inconsistent on whether to compare test groups to the negative control or the pool of both controls : some test guidelines recommend pooling when no statistical significance between the two is found (e.g., OECD 210, 211, 220, 222, 239), others do not and to use the solvent control for comparison (e.g., OECD 201, 208, 221). Unlike all other guidelines, OECD 231 prescribes negative control when a significant difference is found. OECD TG 54 adds further ambiguity; its flow charts advise pooling when there are no significant differences, while its text warns that small sample sizes (common in ecotoxicology testing (n of 4–8)) may mask true differences and that pooling combines two sources of variability.

We are not arguing with the statistical appropriateness of this procedure but want to highlight a major implication it brings to regulatory science: pooling can increase test power, which may be desirable in some disciplines, but in regulatory science it can cause lower endpoints, which in turn might lack biological relevance. For example, two labs testing the same substance could report different endpoints solely because one used solvent control (doubling control n). This penalizes low solubility substances.

This is especially impactful in aquatic ecotoxicology which still often relies on statistical significance alone, sometimes meaning LOECs are related to effects as small as 1%.

We propose a harmonized approach: use a single control group for comparisons in regulatory studies. This would align statistical practice with regulatory intent, improve cross-study comparability, and avoid penalizing substances based on test design rather than true effect.

4.15.P-Th196 Are lack-of-fit tests fit for purpose?

Pernille Thorbek¹, Lijuan Yan² and Yahya Ghalayini², (1)Apd/EE, BASF, United Kingdom, (2)BASF, Germany

Lack-of-Fit testing is used as a criterion for selecting the best dose-response models in many Test Guidelines and statistical decision schemes. While most people might understand it as a method that determines whether a model adequately describes the relationship between the model and the data, in fact it tests whether the unexplained variation can be explained purely by random variability. Thus, the lack-of-fit test is a rather theoretical approach that may have limited practical value for real-world decision-making. Even if a dose-response model is not perfect (i.e. some discrepancies beyond random stochasticity), it can still be useful for predicting effects reliably. When a lack-of-fit test is used as a cut-off criteria, sometimes it leads to rejection of very well-fitting dose-response models and instead less reliable interpolation methods are used, or it even prevents endpoint derivation altogether. Indeed, other statistical guidelines advocate that lack-of-fit test should not be used in isolation. We recommend that lack-of-fit should not be used as a hard cut-off criterion, but instead be used in conjunction with visual inspection and other assessment criteria such as AIC and significant model parameters.

4.15.P-Th197 Statistics for visual injury: data types and options for dose-response modelling and species sensitivity distributions

Pernille Thorbek¹, Lijuan Yan², Thomas Sinclair², Christoph Mayer² and Ruth Albuquerque³, (1)Apd/EE, BASF, United Kingdom, (2)BASF, Germany, (3)BASF, United Kingdom

There has recently been an increasing demand for statistics for visual injury generally in the form of EC50 or ER50 and Species Sensitivity Distributions (SSDs). To estimate reliable EC50s and subsequently SSDs, the data have to be suitable for dose response modelling. This would typically mean numerical quantitative data. While visual injury scores may appear quantitative, because they are expressed in percent damage, they are in fact closer to an ordinal scale. In line with this, the OCPPTS 850.4000 series generally considers visual ratings as qualitative data, rather than quantitative. Moreover, a previously published survey shows there are large differences in scoring methods, as well as how these are interpreted both between and within labs. Consequently, while the visual injury data can be ranked, they are not on a continuous scale, e.g. 60 % is not necessarily the same as twice 30%. This represents a violation of the assumptions for most dose-response models typically used in ecotoxicology. Here, we outline different options for dose-response modelling of visual injury data and discuss to what extent each violates the statistical assumptions. Nevertheless, before work is undertaken to change test guidelines and scoring methods for visual injury, it would be prudent to first check whether other endpoints, such as biomass SSDs, are protective of also visual injury.

4.15.P-Th198 Biological relevance and statistical significance in Collembola soil field studies

*Agnes Schimera¹, Michael Thomas Marx², Melanie Bottoms³, Gregor Ernst⁴, Zhenglei Gao⁵, Jörg Hanisch⁶, Oliver Jakoby⁷, Stefan Kimmel⁸, Amanda Sharples⁹, Frank Staab¹⁰, **Pernille Thorbek¹¹**, Torben Wittwer⁷ and Lijuan Yan¹⁰, (1)ADAMA, Germany, (2)Bayer Research & Development Services LLC, Germany, (3)Syngenta Ltd, United Kingdom, (4)Bayer CropScience AG, Germany, (5)Data Science, Bayer AG, Germany, (6)Rifcon GmbH, Germany, (7)RIFCON GmbH, Germany, (8)Corteva Agriscience, Germany, (9)FMC Corporation, United States, (10)BASF, Germany, (11)BASF, United Kingdom*

Soil mesofauna field studies conducted for ecological risk assessments of plant protection products (PPPs) often require expert knowledge. In an ongoing debate about alternative statistical methods, the Closure Principle Computational Approach Test (CPCAT; introduced for Poisson-distributed count data) is presented. However, the biological relevance of potential effects in field studies remains undiscussed.

The primary aim was to investigate how to implement biological relevance in data evaluation. Biological Control Ranges (BCR) were established for each taxon and sampling time point within individual studies. Quantified as a percentile of the respective control abundance data to exclude extreme values, the BCR was considered as indicator for biological relevance of potential PPP effects by comparing whether the average abundance of a treatment group is in- or outside of the BCR. High variability in control abundance of Collembola resulted in largely varying BCR values between studies.

The secondary aim was to investigate performance of different statistical methods and their impact on the biological relevance conclusion. Abundance data exhibited over-dispersion in the majority of cases, violating the Poisson-distribution assumption. Consequently, CPCAT showed significant differences in more than 50% of the comparisons between control and treatment plots even before test item application happened in the field (at pre-treatment sampling). Post-application, most statistical significances determined by CPCAT occurred despite the absence of a dose-response relationship and the arithmetic mean abundance values in the assigned treatment plots being within the BCR; thus, they should be considered as false positive results. In contrast, the Dunnett's test and Ranked Dunnett's test which are either considering normally distributed data or independent from the data distribution barely detected a significant difference at pre-application when the abundance average values of assigned treatment plots were within the BCR. Similar treatment-independent observations can be made at post-application samplings. Our investigation shows that the pre-requisites for CPCAT (Poisson distribution, no over-, or under-dispersion of data) were not met in the majority of the field data cases examined.

This poster highlights the importance of a holistic interpretation combining ecological context via BCR with fit-for-data/appropriate statisticals to ensure meaningful conclusions.

4.15.P-Th199 Methods for Assessing Dispersion to Guide CPCAT Use for NOEC Determination

*Lijuan Yan¹, Frank Staab¹ and **Pernille Thorbek²**, (1)BASF, Germany, (2)Apd/EE, BASF, United Kingdom*

CPCAT has been proposed for analyzing field data or soil and other organisms. However, it has also been shown that when data does not follow a Poisson distribution, the results are less reliable as overdispersed data leads to increased rates of false positives and underdispersed leads to increased rates of false negatives.

Therefore, it is important to reliably assess the underlying distribution of the data to be analysed before using CPCAT. The Hampel identifier recommended by Lehmann et al. (2018) does not always give reliable results.

Moreover, a practical challenge to assessing the underlying distribution is the typical limited replication in field studies, which reduces the power of single study dispersion tests. In order to achieve more reliable determination of the underlying distribution, we propose aggregating control group observations across multiple soil mesofauna field studies and assessing dispersion at different taxonomic resolutions. An added advantage of such an approach is that ecological information about how these organisms are distributed in space (and time) can help inform appropriate statistical methods. This poster will (1) summarize limitations of existing dispersion diagnostics for small sample ecotoxicological studies, (2) report empirical dispersion patterns by taxon using pooled control data, and (3) give practical pre screening guidance for CPCAT application. We welcome collaboration and funding to extend this work; preliminary results and a proposed study protocol will be presented.

4.15.P-Th200 When Counts Deviate: Robust Overdispersion Diagnostics for Ecotoxicity Data

Benjamin Daniels, Pia Kotschik, Susanne Walter-Rohde and Thomas Gräff, German Environment Agency (UBA), Germany

Count-based endpoints such as reproduction or abundance measurements are central to many laboratory and field ecotoxicity studies. Although several statistical procedures for analyzing such data have been proposed, their regulatory use is only sparsely standardized in key guidance documents such as ISO 20281 (2006) or OECD 54 (2006). Robust tools exist, most notably GLM-based Dunnett tests using Poisson, quasi-Poisson or negative-binomial error structures. These approaches combine generalized linear models (GLM) with Dunnett-type multiple comparisons to detect treatment-related decreases or increases relative to a control. An additional Poisson-based alternative is the CPCAT, which similarly depends on the Poisson distribution but incorporates the closure principle as a rigorous framework to control α -inflation.

Yet a key unresolved question is how to evaluate whether Poisson-based assumptions are appropriate for a given dataset. While Poisson models imply equality of mean and variance, real ecotoxicological datasets often deviate from this, especially field reproduction data, which frequently show overdispersion driven by environmental and biological variability.

This raises a practical issue: at what point does deviation from mean-variance equality invalidate Poisson-based test methods for deriving NOECs? Mild departures are expected due to sampling variability and are typically tolerated by established procedures, yet clear guidance on acceptable deviations is lacking. Several diagnostics exist to quantify such departures. The regression-based overdispersion test of Cameron & Trivedi (1990) and the Pearson dispersion statistic are widely used but require fitting a Poisson GLM in advance, thereby inheriting potential model-specification issues and limiting their suitability for early exploratory checks.

In this contribution, we compare the strengths and limitations of these model-based diagnostics using a meta-analysis of existing and simulated data. We further introduce a distribution-agnostic alternative that assesses mean-variance differences directly within treatment groups, allowing both over- and underdispersion to be detected. This method provides an accessible and interpretable tool for standardized preprocessing of count data and supports transparent decision-making when selecting appropriate statistical procedures for NOEC derivation. Our aim is to contribute to a more harmonized framework for analyzing count data in ecotoxicology.

4.15.P-Th201 Old-fashioned data for a contemporary approach: Optimising toxicological studies design for Benchmark Dose modelling.

Michail Gioutlakis¹, Jens Schabacker², **Martin Vallon**¹ and Torben Wittwer¹, (1)RIFCON GmbH, Germany, (2)Rifcon GmbH, Germany

Benchmark Dose (BMD) modelling is an approach for deriving an appropriate endpoint from dose-response data that can be used in environmental wildlife risk assessment. The use of BMD was introduced into the EU regulatory framework in 2005 and since then one scientific opinion and two guidance documents specifically on BMD have been published by the European Food Safety Authority (EFSA). The Guidance document on risk assessment for birds and mammals (EFSA 2023) requires the use of BMD modelling to determine endpoints from toxicity studies data instead of using the No Observed Adverse Effect Level (NOAEL).

The currently used guidelines for toxicological studies have been developed to generate data suitable for NOAEL determination but not for BMD modelling. Although BMD modelling makes a better use of dose-response data, data generated by the current study designs might be unsuitable for BMD modelling or they

might lead to unreliable results that cannot be used in wildlife risk assessments. Even if BMD modelling is required by EFSA 2023, new toxicological studies are avoided for animal welfare reasons.

Optimising number of tested doses, spacing between doses and the number of animals per dose within the framework of current OECD and EPA guidelines (OECD 206, 416, 443, 414 and USEPA 850.2300) could improve data suitability for BMD modelling and consequently the reliability of the results in cases where testing is permitted.

A review of the available guidance documents, scientific opinion and the relevant scientific literature was performed, and specific recommendations can be given for optimising the study design of birds and mammals toxicological studies in favor of BMD modelling. Furthermore, characteristics of a design that can lead to unsuitable data will be presented.

The resulting recommendations can be considered for planning toxicological studies, that are intended to be used for BMD modelling. With our study, we contribute to the discussion about revision of study designs within guidance documents to generate data suitable for BMD modelling.

4.15.P-Th202 Challenges of Scientific Rigor and Practical Implementation of EFSA Scientific Opinion on The Use and Reporting of Historical Control Data

Zhenglei Gao¹, Stefan Kimmel², Felix Kluxen³ and Emily Scorgie⁴, (1)Bayer AG, Germany, (2)Corteva, Germany, (3)BASF, Germany, (4)Syngenta, Netherlands

Historical control data (HCD) are an important element in toxicological evaluations with emerging importance in ecotoxicology. Currently, researchers typically consider HCD only after conducting the study analysis, using them to contextualise results via expert judgement. A recent EFSA scientific opinion introduces a novel approach of incorporating HCD into the statistical analysis itself. Put simply, the idea is to combine concurrent control (CC) data with a curated subset of HCD to create a combined control group for use in the (likely more complex) statistical analysis. This approach promises a less subjective use of HCD, but raises methodological and operational challenges. The key issues include defining exchangeability between CC and HCD, pre-specifying HCD inclusion criteria, and choosing modelling frameworks that borrow information from HCD adaptively while controlling error rates. We explore the soundness of the proposed novel approach along with anticipated challenges regarding practical implementation, if the Scientific Opinion were to be developed into guidance for regulatory processes.

4.15.P-Th203 Assessing LD50/10 as a Proxy for Avian Reproductive Risk in Wildlife

Jens Schabacker¹, Martin Vallon² and Michail Gioutlakis², (1)Rifcon GmbH, Germany, (2)RIFCON GmbH, Germany

According to the 2023 EFSA guidance document on risk assessment for birds and mammals, the acute toxicological endpoint tested, divided by ten, should be used as a surrogate toxicological endpoint for reproductive risk assessment when it falls below the reproductive endpoint. This idea originates from a 2008 EFSA publication, specifically Appendix 11 (Callahan & Mineau 2000), in which sublethal clinical signs (such as hypo-reactivity, asthenia, anorexia, ataxia, emaciation and piloerection) were analysed in 166 acute avian pesticide studies. The aim of the study was to identify humane test designs that could predict LD₅₀ values.

The LD50/10 concept involves extrapolating acute lethality data to potential reproductive impairments, such as disrupted pair formation or parental care. However, it should be noted that the assumption that acute toxicity reliably predicts long-term, population-relevant effects on reproduction has not yet been proven.

In the Avian Acute Oral Toxicity Test (OECD TG 223), a single high dose being administered by gavage to fasted birds, producing rapid peak plasma concentrations and immediate toxic effects. Although these tests are useful for identifying hazards, they do not represent realistic environmental exposures, which are typically lower and continuous.

In contrast, the Avian Reproduction Test (OECD TG 206) involves monitoring the entire reproductive cycle to determine endpoints such as fertility, hatchability, and offspring survival following dietary exposure. These endpoints are considered to be more ecologically relevant. According to the 2023 EFSA guidance document, the biologically relevant effects should be chosen for the endpoint setting of wild birds: e.g. direct reproductive and developmental effects; body weight changes of at least 10% (BMDL10); and behavioural or neurological effects

affecting survival or mating. Other effects, such as organ-level, minor, or transient effects, are generally considered to be less relevant.

Although the sublethal signs identified by Callahan and Mineau are useful for their intended purpose, they do not correlate with population-level reproductive effects, which limits their ecological relevance. Consequently, while the use of LD₅₀/10 as a surrogate endpoint in ecological reproductive risk assessments is possible, it is not always appropriate, as it can overestimate, underestimate or misrepresent the true reproductive endpoint. Unfortunately, this is not stated in EFSA (2023).

4.16 Towards a Fit-For-Purpose Risk Assessment of Non-Conventional Plant Protection Products

4.16.T-01 Formulation-Dependent Cellular Bioavailability of dsRNA in Non-Target Organisms: Implications for Environmental Risk Assessment of RNA Interference Based Pesticides

Hannah-Philine Dey¹, Susanne Bär¹, Esther van der Zalm¹, Kristin Hirte¹, Urwa Bergs¹, Elke Eilebrecht², Eileen Knorr³, Christoph Hellmann³, Fabian Weichert⁴, Henner Hollert⁴ and Sebastian Eilebrecht⁵, (1)German Environment Agency (UBA), Germany, (2)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Pest and Vector Insect Control, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (5)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

RNA interference (RNAi)-based pesticides are a novel approach for crop protection, offering a species-specific mode of action distinct from conventional chemical and biological pesticides. These products use double-stranded RNA (dsRNA) molecules designed to match to essential mRNA sequences in target organisms. Upon uptake, the dsRNA activates the organism's RNAi pathway, leading to degradation of the target mRNA, which can result in impaired growth, reproduction, or survival.

Due to their sequence specificity, RNAi-based pesticides are expected to pose minimal risks to non-target organisms (NTOs), which potentially contributes to developing more sustainable plant protection products. Nevertheless, there are still key uncertainties regarding environmental risks, especially in relation to exposure, off-target effects and cellular bioavailability, which is influenced by the formulation of the dsRNA. Many pests still cannot be targeted through RNAi due to biological barriers and the low persistence of naked dsRNA. Consequently, substantial research is focused on formulations that increase the persistence and bioavailability of dsRNA. Although prolonged persistence and cellular bioavailability improves pest control, it also increases environmental risks and may affect the susceptibility of NTOs. Therefore, the changed properties of formulated dsRNA must be urgently addressed in environmental risk assessment.

The aim of the first phase of our research project is to establish a test system to evaluate the cellular bioavailability of formulated dsRNAs in standard NTO models, focusing on the zebrafish embryo model first. To achieve this, zebrafish embryo tests were conducted in accordance to OECD guideline 236 using sublethal concentrations of the formulated dsRNA to enable downstream analysis. To establish a standardised positive control protocol, embryos of the transgenic zebrafish line Tg(fli1:EGFP) were exposed to a nano-lipid formulated dsRNA targeting the enhanced green fluorescence protein (EGFP) messenger RNA. EGFP downregulation was assessed both at the protein level by quantifying the fluorescence signal as well as at the mRNA level using quantitative polymerase chain reaction (qPCR) and transcriptome analysis. Together, these complementary approaches are expected to provide a comprehensive basis for demonstrating the suitability of using EGFP transgenic NTOs to test the cellular bioavailability of RNAi-based pesticide formulations

4.16.T-02 A meta-analysis of peptides used in plant protection: Sources, modes of action, and structure-derived properties of regulatory importance

Nina Cedergreen and Kitzia Molina-Zamudio, No Affiliation, Denmark

Many chemical plant protection products (PPPs) pose risks to human health, non-target organisms, and the environment, prompting a shift toward natural alternatives. Peptides have gained attention as promising candidates due to their low environmental persistence, target specificity, and diverse mechanisms, acting as antimicrobials, insecticides, antivirals, anthelmintics, and herbicides. Despite increasing recognition, peptides are not yet fully integrated into the PPP landscape, with a lack of systematic classification and risk assessment frameworks.

This meta-analysis compiles current knowledge on peptide-based PPPs, including those that are

commercialized, patented, or under development, and proposes a clear categorization based on structural and physicochemical features. We compile our dataset by extracting peptides from references in Web of Science, antimicrobial peptide databases, and superfamily classifications, ultimately yielding 4,492 unique peptides after deduplication and filtering for only plant protection.

Based on our database, the most common use of peptides is antibacterial, followed by antifungal, insecticidal, and antiviral. However, the intended uses commonly overlap, with 61% of peptides claiming broad-spectrum activity, raising concerns about non-target effects. Therefore, instead of classifying them by use, we analysed their structural architecture and physicochemical properties and correlated them with the reported modes of action. Generating peptide clusters with specific structural and physicochemical properties facilitates the formulation of hypotheses on environmental effects and their impacts on beneficial organisms.

This peptide database will form the foundation for our work in ENSAFE (ENSAFE.dk), where our aim is to provide data and models to predict the environmental fate and effects on non-target organisms of exemplary peptides.

4.16.T-03 A Fit-for-purpose Approach for the Assessment of Active Substance of Low-Concern

Aude Kienzler¹, *Gertie Arts², Domenica Auteri¹, Athanasios Dalakouras³, Franco Ferilli¹, Georgios Fragkoulis⁴, Belen Guijarro⁵, Emmanouil Karazafeiris⁴, Dimitrios Karpouzas⁶, Roberto Lava¹, Christopher Lythgo¹, Urania Menkissoglu-Spiroudi⁴, Emmanouil Nikolaos Papadakis⁴, Kalliope Papadopoulou⁶, María José Patino-Ropero⁵, Bastian H. Polst⁷, Jose-Luis Alonso-Prados⁵, Rachel Sharp¹, Anne Steenbergh⁸, Sofia Tsaloumi³, Aggeliki Tsampoula⁴ and Zisis Vryzas⁹*, (1)European Food Safety Authority (EFSA), Italy, (2)Wageningen Environmental Research, Italy, (3)ELGO, Greece, (4)Aristotle University of Thessaloniki (AUTH), Greece, (5)CSIC - INIA, Spain, (6)University of Thessaly, Greece, (7)Wageningen Environmental Research, Netherlands, (8)Dutch Board for the Authorisation of Plant Protection Products and Biocides (Ctgb), Netherlands, (9)School of Agriculture, Aristotle University of Thessaloniki (AUTH), Greece

The EU regulatory framework for pesticide risk assessment was primarily conceived for conventional synthetic pesticides and does not consider the specificities of Low-Concern Active Substances (LCASs), such as botanicals, semiochemicals, microbial metabolites, inorganics, peptides, and dsRNA. In addition, some of the current data requirements may not be needed for these types of substances, if adequately justified. However, without agreed guidance on how to identify the relevant data to be submitted and how to perform the environmental risk assessment (ERA) for these types of substances, dossiers for LCASs end up with many data gaps. Furthermore, concerns have been raised as to whether alternative modes of action are appropriately addressed with the standard data requirements and ERA.

To address these challenges, a more flexible and fit for purpose ERA approach was needed, that would allow both a better justification of data waiving and to take into account the particular properties of the active substance.

This approach was developed by a consortium in response to a call launched by EFSA in 2024. Based on problem formulation, the proposed approach makes use of pathways to harm (PtH), where harm is defined as not meeting the protection goal. A PtH is defined as a sequence of events through which a hazard can lead to adverse effects. In this context, the aim of the PtH is to assess the likelihood of breaching the protection goal, based on the likelihood of each individual event to take place. The PtH are in this way used as a method to combine all lines of evidence given by the data available for an overall weight-of-evidence assessment. Detailed, generic PtH for each relevant hazard (toxicity, suffocation, desiccation, hypoxia, RNA interference, mating disruption, leaching potential) and non-target organisms' (birds and mammals, aquatic organisms, bees, non-target arthropods, soil macro-organisms, soil microorganisms, non-target terrestrial plants) combination have been developed. In addition, analysis plans providing information on which analyses may be used to assess the likelihood of the individual events were built. Further, guidance on the likelihood assessment, including the uncertainty analysis related to this assessment, is given.

This presentation will present the approach developed, its added value and how we believe it will allow to address (part of) the challenges encountered when assessing such actives substances.

4.16.T-04 Advancing Ecotoxicological Risk Assessment for Microbial Plant Protection Products: Insights from RATION WP2.2

Bruno Guimarães¹, Judith Epping², Stephan Jänsch³, Spyridon Vlogiannitis⁴, Gunter Brader⁵, Jose-Luis Alonso-Prados⁶, Belén Guijarro⁶, Dimitrios Karpouzas⁷, Michael Werner⁸ and Stefania Loutseti⁹, (1)Syngenta Crop Protection AG, Portugal, (2)Wageningen University and Research (WUR), Wageningen, Netherlands, (3)ECT Oekotoxikologie GmbH, Germany, (4)IMBB-FORTH, Greece, (5)Austrian Institute of Technology, Austria, (6)National Institute of Agricultural and Food Research and Technology - Spanish National Research Council (INIA-CSIC), Spain, (7)University of Thessaly, Department of Biochemistry and Biotechnology, Greece, (8)Syngenta, Switzerland, (9)Syngenta Ltd, Greece

The increasing use of microbial plant protection products requires robust ecotoxicological risk assessment frameworks tailored to their unique biological characteristics. EU regulations mandate comprehensive environmental safety evaluations, yet standard testing protocols designed for chemical pesticides may not adequately address microbial-specific traits such as viability, colonization potential, and biological mode of action. RATION WP2, Task 2.2 developed a tiered ecotoxicity testing strategy and problem formulation (PF) tailored for microbial pesticides.

A systematic 4-step approach was implemented using 3 model microbial active substances (SeMNPV BV-0004, *B. velezensis* FZB42, *P. lilacinum* PL11): PF through literature and regulatory assessment; adaptation of OECD guidelines; proof-of-concept testing; and integration into risk assessment development. Standard protocols were modified to address microbial characteristics, including natural soil with native communities, repeated applications mimicking GAP practices, extended pollinator exposure periods, and sensitive life stage assessment. A harmonized analytical strategy combining DNA detection via qPCR with viability assessment was applied across environmental compartments.

Problem formulation identified specific hazard and exposure considerations including viability under field conditions, colonization potential, sensitive life stages, and realistic exposure routes. Adapted protocols enabled microbial-appropriate risk characterization. Experimental results provided empirical data across terrestrial, pollinator, and aquatic compartments. In soil, PL11 and FZB42 showed no significant effects on earthworms, Collembola, or nematodes. For pollinators, acute and chronic tests showed no adverse effects at field rates, though PL11 caused larval mortality at 10× maximum field rates, identifying honey bee larvae as a sensitive life stage. Aquatic microcosm studies with FZB42 showed no significant effects on invertebrates or algae. The qPCR-viability strategy is proving robust for differentiating living from non-living microbes.

Integration into RATION WP2, Task 2.4 framework is creating a feedback loop where experimental data update problem formulation and inform scenario selection and waiver criteria. This work is providing methodological tools and scientific evidence to inform EU regulatory frameworks, ensuring microbial PPPs are assessed with ecological relevance while minimizing unnecessary testing.

4.16.P Towards a Fit-For-Purpose Risk Assessment of Non-Conventional Plant Protection Products

4.16.P-Mo320 Bio-pesticides: A Risk Assessor's Nightmare or an Opportunity to Re-Wire the Risk Assessment?

John Kandris, **Sofia Mirmigkou** and Katerina Kyriakopoulou, Benaki Phytopathological Institute (BPI), Greece

It is apparent in recent years that non-conventional active substances have become popular in plant protection. Substances such as plant extracts enter the market with the hope of taking their share in the market against "traditional" active substances. However, these non-conventional substances (e.g. of botanical origin, substances of Unknown or Variable Composition, Complex Reaction Products, or Biological Materials; UVCBs) fall under the same data requirements as the conventional chemicals used in plant protection (Reg.1107/2009) which

implicates the environmental risk assessment.

Issues challenged with their identity, difficulties with deciding the appropriate substance to be considered relevant for the environmental risk assessment, are only some faced by risk assessors and can potentially impact the exposure assessment when dealing with such dossiers. In addition, issues concerning the fulfillment of the data requirements according to Reg. 1107/2009, 283/2013 and 284/2013 are also apparent as they picture a conventional and strict assessment with the provisions of specific tests concerning a synthetic active substance compound.

Examples of such substances are capric, caprylic and pelargonic acid, paraffin oils, fatty acids from hydrolyzed vegetable oils. In these cases, alternative approaches were followed for the exposure assessment and testing, with the most apparent being the read-across between dossiers based on chemical similarity, the work around which needed to be decided as the characterization of their composition is not possible, and, the use of QSAR estimates for environmental properties, although they are not recommended for risk assessment, since are not reported in any EU guidance document or communication list. In addition, data requirements have been waived based on lead components' natural occurrence in the environmental matrices, indicating the non-feasibility of testing.

These different approaches might be a potential and effective way forward to the environmental risk assessment under Plant Protection Product regulatory framework. Using available information from open literature, such as natural occurrence in the environment, DT50 values for PEC calculations a more pragmatic approach is introduced. In combination with a read across approach through similar dossiers and a well-studied ecotoxicological profile, safe use for specific bio-pesticides might be demonstrated even without a quantitative risk assessment.

4.16.P-Mo321 Science-based data waivers for low-concern pesticides: A Pathways-to-harm Problem-formulation Toolbox

Zisis Vryzas¹, Gertie Arts², Athanasios Dalakouras³, Georgios Fragkoulis⁴, Belén Guijarro⁵, Emmanouil Karazafeiris⁴, Dimitrios Karpouzas⁶, Urania Menkissoglu-Spiroudi⁴, Emmanouil Nikolaos Papadakis⁴, Kalliope K. Papadopoulou⁶, María José Patino-Ropero⁷, Bastian H. Polst⁸, Jose-Luis Alonso-Prados⁹, Anne Steenbergh¹⁰, Sofia Tsaloumi⁶ and Aggeliki Tsampoula⁴, (1)School of Agriculture, Aristotle University of Thessaloniki (AUTH), Greece, (2)Environmental Risk Assessment, Wageningen University and Research (WUR), Netherlands, (3)Hellenic Agricultural Organization – Demeter, Greece, (4)Aristotle University of Thessaloniki (AUTH), Greece, (5)National Centre National Institute for Agricultural and Food Research and Technology, Greece, (6)University of Thessaly, Greece, (7)National Centre National Institute for Agricultural and Food Research and Technology, Spain, (8)Wageningen University and Research (WUR), Netherlands, (9)National Institute of Agricultural and Food Research and Technology - Spanish National Research Council (INIA-CSIC), Spain, (10)Dutch Board for the Authorisation of Plant Protection Products and Biocides (Ctgb), Netherlands

Low-concern pesticides such as microorganisms, botanicals, semiochemicals, inorganic substances and biomolecules are increasingly promoted to reduce dependence on synthetic pesticides. Their diverse physicochemical properties, modes of action (e.g., suffocation, mating disruption, RNA interference) and application patterns challenge current EU risk-assessment schemes, which were mainly designed for conventional toxicants applied by foliar spraying. To address this gap, we developed a fit-for-purpose problem-formulation (PF) approach using generic Pathways to Harm (PH) and linked analysis plans, with a specific focus on science-based data waiver criteria. Waiver criteria were systematically collected from EFSA peer-review conclusions and Rapporteur Member State reports, relevant European Commission and OECD guidance, read-across from non-EU frameworks (EPA, Canada, Australia), and targeted case studies for botanicals, straight-chain lepidopteran pheromones, dsRNA, peptides, microbial metabolites and inorganics.

The criteria were grouped by LCAS type. Typical justifications include exposure comparable to natural background levels, rapid breakdown to non-toxic products, high volatility and low persistence, food-grade or naturally ubiquitous substances with a history of safe use, and inert, insoluble inorganic minerals.

These grouped criteria were then integrated into a spreadsheet-based Analysis Plan tool consisting of seven hazard-specific sheets (toxicity, hypoxia, suffocation, desiccation, mating disruption, RNA interference and leaching), each aligned with generic PH events and providing structured options for evidence generation, including NAMs.

The resulting toolbox supports transparent, harmonised and efficient regulatory assessments for existing and emerging low-concern pesticides while maintaining EU environmental protection goals.

4.16.P-Mo322 Streamlining risk assessments using Decision Trees for biocontrol products

Milena Stephan¹, Rüdiger Hauschild² and Emmanuelle Bonneris³, (1)IBMA, Knoell Germany GmbH, Germany, (2)IBMA, APIS Applied Insect Science GmbH, Germany, (3)IBMA, Bayer SAS, France

The growing global demand for sustainable agricultural practices has led to a growing interest in biocontrol products as viable alternatives to conventional chemical pesticides. To effectively regulate these biological products, experts from member companies of the International Biocontrol Manufacturers Association (IBMA) have developed decisions trees which support identification of potential risk areas for natural substances and microorganisms when used as plant protection products.

The first data decision tree categorizes natural substances into three groups based on their identification and characterization and their known or suspected risk profiles. The data decision tree on natural substances, introduces a tiered approach to identify and assess potential risks in four key areas: effects on human health, residues, environmental fate and behaviour, and effects on non-target organisms. For each group, the use of the decision tree for natural substances allows to reflect on the needed data to assess human and environmental safety.

The second decision tree addresses the challenges associated with the evaluation of microorganisms as biocontrol agents. Starting with the identity of the microorganism, its biology and ecology can be described and used to assign it to one of six ecological groups. For these groups, proposals are made which information is needed to determine the risk to humans through direct exposure or residues, to non-target organisms or the environment. The potential production of microbial compounds is included in the decision tree, and a proposal is made which compounds need special attention.

A third decision tree about semiochemicals has been submitted for publication in a peer-review journal.

All decision trees are designed to support a more efficient and science-based regulatory process, facilitating the market access of biocontrol products while ensuring human and environmental safety. They align with current ongoing EU initiatives such as “pathway to harm” and the “problem formulation approach” endorsed last year. These tools are intended for use by regulatory authorities, researchers, and industry stakeholders to accelerate the adoption of sustainable pest management solutions.

This presentation will provide an overview of the decision trees, highlighting their structure, key considerations, practical applications in regulatory submissions and their role in advancing sustainable agriculture globally.

4.16.P-Mo323 Towards a Fit-For-Purpose Risk Assessment of Non-Conventional Plant Protection Products in the TRIBIOME Project

Javier Alcodori¹, Arantxa Ballesteros Rianza², Enrique Cubas³ and Rosa Doménech³, (1)Processes and Products Safety Unit, ITENE Research Centre, Valencia, Spain, (2)Processes and Products Safety Unit, ITENE research centre, Valencia, Spain, (3)ITENE Research Centre, Spain

Non-conventional plant protection products (NCPPs), such as microbial formulations and plant extracts, are promising sustainable alternatives to synthetic pesticides. However, regulatory frameworks and risk assessment methods, designed for conventional chemicals, are often ill-suited for these novel substances. The TRIBIOME

project addresses this gap by developing fit-for-purpose risk assessment strategies for NCPPs, particularly those designed to modulate the plant-soil microbiome.

The project's methodology involved a comprehensive safety evaluation of specific microbial strains and plant-derived extracts (cane and onion). This included assessing their efficacy in enhancing plant resilience and nutrient uptake. A core component was an extensive toxicological testing regime using in vitro cell viability assays on human lung (A549), skin (HaCaT), and intestinal (CaCo-2) cell lines, and ecotoxicity evaluations on freshwater biota (algae and *Daphnia magna*). The project also advocates for an adapted risk assessment framework that incorporates New Approach Methods (NAMs) and predictive modeling to reflect the unique, often lower-risk properties of NCPPs.

The results demonstrated a strong safety profile. Neither the plant extracts (0–100 ppm) nor the microbial strains (10^3 – 10^7 CFU/mL) induced cytotoxicity in any human cell models. In aquatic tests, all microbial agents and both plant extracts showed no adverse effects on algal growth. However, *Daphnia magna* exhibited differential sensitivity, with cane extract showing higher toxicity (LC50 of 1.24 ppm) than onion extract (LC50 of 24.6 ppm), indicating that certain plant extracts require concentration-dependent risk management for aquatic invertebrates.

In conclusion, the TRIBIOME project confirms that the assessed NCPPs, especially microbial strains, present minimal risks to human health and primary producers. While some plant extracts require careful consideration for aquatic invertebrates, the overall findings underscore the necessity of developing tailored regulatory frameworks that facilitate the safe integration of these sustainable products into agriculture, moving beyond one-size-fits-all chemical pesticide models.

4.16.P-Mo324 Regulatory Strategies for E-Fate and Ecotox Assessment of Natural Substances in Plant Protection

Aleksandra Zakryś-Zalewska¹, Maria Borja² and Kari Moshenberg³, (1)SynTech Regulatory Europe GmbH, Poland, (2)SynTech Research Group, Spain, (3)SynTech Research Group, Germany

Natural substances and semiochemicals are increasingly used in plant protection and integrated pest management due to their favorable environmental profiles. This trend reflects a reduction in chemical pest management and a growing emphasis on alternative, innovative pest control solutions. In the EU, a key challenge is meeting the requirement for standardized testing for environmental fate (e-fate) and ecotoxicology (ecotox) for these substances.

For naturally occurring compounds that are readily biodegradable, e-fate and chronic ecotox studies are unnecessary. When biodegradability is uncertain or limited, testing may be required. This poses challenges during study design due to characteristics including mixture complexity, variable components, inorganic nature, insufficient radiolabelling possibilities, high volatility, low solubility, or hydrophobic properties. These features often cause technical difficulties in dosing, measurement, and create significant obstacles to interpretation.

A tiered approach is proposed to determine testing needs:

First tier: A weight-of-evidence strategy, as for microorganisms, integrating existing data from EU frameworks (e.g., PPP Regulation, REACH), biodegradation testing, QSAR, and read-across from similar substances.

Expanded guidance on read-across for environmental risk assessment would enable harmonized workflows based on structural similarity and toxicity profile alignment, consistent with OECD and EFSA principles.

Second tier: Focus on identifying compartments of concern and relevant non-target organisms. For substances with limited chronic bioavailability, acute exposure should be prioritized. Pragmatic PEC modelling can be used to identify compartments that require further assessment.

Third tier: Fit-for-purpose testing involves adapted designs, such as closed systems for volatile compounds, passive dosing for low-solubility substances, or tailored analytical methods. The focus should be on compartment-specific testing and assessment of relevant non-target organisms.

Aligned regulatory flexibility to accept robust waivers or non-standard methods is essential for registering substances with unique properties. The tiered approach ensures environmental safety with strong protection goals, supports innovation and EU policy, while avoiding unjustified testing burdens which may restrict market access for innovative compounds.

4.16.P-Mo325 Using problem formulation for an efficient, fit-for-purpose risk assessment of microbial plant protection products

Anne Steenbergh¹, Gertie Arts², Peter Bakker³, Wietse de Boer⁴, Deborah C.M. Glandorf⁵, Mechteld ter Horst⁶, Rob de Jonge⁷, Willem Jan de Kogel⁶ and Jurgen Kohl⁶, (1)Dutch Board for the Authorisation of Plant Protection Products and Biocides (Ctgb), Netherlands, (2)Environmental Risk Assessment, Wageningen University and Research (WUR), Netherlands, (3)University of Utrecht, Netherlands, (4)NIOO, Netherlands, (5)Independent scientist, Netherlands, (6)Wageningen University and Research (WUR), Netherlands, (7)National Health Institute, Netherlands

Biological plant protection products (PPP) are important building blocks for integrated pest management and can contribute to a more sustainable agriculture. In Commission Regulation (EU) No 283/2013 microbial PPP are referred to as PPP containing an active substance that is a microorganism. Before these products can be placed on the market, the environmental and public health safety of their use need to be assessed. In other regulatory frameworks, such as for GMOs, also the release of microorganisms is assessed. Similarly to this regulatory framework we propose to use the problem formulation approach based on pathways to harm to arrive at a fit-for-purpose environmental and public health risk assessment of microbial PPP (i.e., both the active substance and the product in the context of the European PPP regulation), by tailoring the risk assessment to the individual microbial PPP and harmonizing this approach when possible. Pathways to harm are being developed for different hazards, among others antimicrobial resistance, invasiveness, toxicity, pathogenicity and infectivity. Each pathway to harm consists of several events, starting with the use of the PPP and ending with the protection goal. Testable hypotheses are formulated for each of the events in the causal pathway to harm. For each testable hypothesis, the information is identified which is needed to test it. Each of the events in the pathway has to take place for harm to occur, therefore it is efficient to start with the event in the pathway which is easiest to assess. This approach is flexible, efficient and can be adapted to the microorganism in question or the use which is being assessed. In case none of the events can be excluded to occur, the pathway to harm approach helps to combine all available information in a weight-of-evidence approach to assess the likelihood of not meeting the protection goal. By providing generic pathways to harm, the approach also helps to harmonize assessments while allowing for flexibility. Problem formulation also leads to a more transparent assessment and helps to communicate about risks. Hence, risk managers are better informed and the resulting risk management decision can be better substantiated.

4.16.P-Mo326 Ecotoxicological Data Gaps in EFSA Reviews of Microbial Plant Protection Products: A Focus on Secondary Metabolites and Infectivity/Pathogenicity

Bruno Guimarães¹, Judith Epping², Tobias Pamminer³, Gunter Brader⁴, Dimitrios Karpouzas⁵, Michael Werner⁶ and Stefania Loutseti⁷, (1)Syngenta, Portugal, (2)Wageningen University and Research (WUR), Portugal, (3)Bayer CropScience AG, Portugal, (4)Austrian Institute of Technology, Austria, (5)University of Thessaly, Department of Biochemistry and Biotechnology, Portugal, (6)Syngenta, Switzerland, (7)Syngenta Ltd, Portugal

Microbial active substances provide environmentally friendly alternatives or complements to chemical pesticides for sustainable agriculture. However, their regulatory assessment presents distinct challenges: once released, microbial agents may produce secondary metabolites, multiply, spread, and potentially transfer antimicrobial resistance genes, necessitating tailored risk assessment approaches fundamentally different from those for chemical pesticides. Regulatory approval faces recurring ecotoxicological data gaps that prolong evaluation periods. Understanding predominant concerns and common deficiencies is essential for streamlining dossier preparation and ensuring robust risk assessments.

We systematically analysed publicly available European Food Safety Authority (EFSA) peer review documents for microbial active substances in the EU Pesticides Database, focusing exclusively on ecotoxicological issues. The dataset captured 126 microbial active substances (fungi, bacteria, viruses), yielding 1,078 observations categorized by EFSA classification (data gap, not finalized, critical concern, no issues), area of concern (pollinators, soil organisms, aquatic organisms, birds and mammals, non-target arthropods), and keywords (secondary metabolites/toxins, infectivity/pathogenicity, data missing). We quantified frequencies and identified patterns by microbial type and environmental compartment.

The majority of issues were data gaps (52%) or not finalized risk assessments (48%). Pollinators represented 24% of concerns, followed by soil organisms (21%), aquatic organisms (19%), non-target arthropods (17%), and birds and mammals (15%). Two dominant themes emerged: secondary metabolites/toxins (45% of issues) – including uncertainty regarding production levels, environmental fate, and toxicity to non-target organisms; and infectivity/pathogenicity (24%) – requiring data on potential infection across life stages and clearance assessments. Notably, 55 of 86 substances were classified as not low risk.

Recurring ecotoxicological data gaps, particularly concerning secondary metabolites and

infectivity/pathogenicity, significantly challenge regulatory approval across all non-target organism groups. These findings provide actionable insights for industry stakeholders to anticipate regulatory requirements, prioritize data generation, and accelerate market authorization while ensuring environmental safety.

4.16.P-Mo327 Improving Aquatic Toxicity Tests with MPCA's – How, When, and at What Levels to Test **Henry O Krueger¹ and Sarah McCoy², (1)Senior Advisor Eurofins Agrosciences Services (US), United States,** **(2)Eurofins Agroscience Services US, United States**

An environmental risk assessment is a function of hazard and exposure. There is currently a lack of modeling and studies to characterize an aquatic exposure via MPCAs, which are vastly different than conventional chemicals. Preliminary work for exposure assessments would be useful and informative when setting test levels. Current guidelines set upper limits of test concentrations in water at unrealistically high levels. These concentrations may be relevant for products that are directly sprayed to water for mosquito control or invasive aquatic plants, but are not realistic for products directly sprayed to fields, soil incorporated, in-furrow applications, or seed treatments. Testing such high concentrations in water can result in opaque test solutions and excessive particles suspended in water that can interfere in the feeding of invertebrates and clog gills in fish. Aquatic testing of conventional chemicals has well defined upper limits for testing; 100ppm or the limit of water solubility. Alternatively, MPCA's are often particles suspended in water and solubility limits are not applicable. Assessing particle distribution in water is more relevant; are they floating, sinking, or in suspension in the water column. Consideration of cell viability, dormancy and metabolite expression in water is also important. We suggest several shorter and less expensive trials to address some of these questions. Preliminary testing more appropriate for MPCA's would be; distribution of particles in the water column, cell viability and expression, as well as effects of light, temperature, pH and salinity. These types of preliminary trials can be useful tools for better understanding exposure that then can be used to design better aquatic tests. The information is also useful in providing data that can be used to support waiver requests.

4.16.P-Mo328 The Effects of a Microorganism-based Plant Protection Product on Zooplankton Community Composition

Judith Epping¹ and Paul van den Brink², (1)Wageningen University and Research (WUR), Wageningen, Netherlands, (2)Wageningen University and Research (WUR), Netherlands

Microorganism-based plant protection products are a promising alternative to synthetic pesticides. Because of the natural occurrence of many microbial strains in the environment and their attributed species specificity, their direct toxicity to aquatic non-target organisms is expected to be low. Yet, information on their fate in water and sediment, including viability, as well as indirect effects on aquatic environments, including zooplankton community composition, is still very limited. For example, it was reported that microbial pesticides may increase turbidity, which could affect primary production or filter feeding, both of which influencing zooplankton fitness. We conducted an indoor microcosm experiment over 28 days with three different treatment concentrations of the microbial pesticide RhizoVital42 (*Bacillus velezensis* FZB 42). Treatment concentrations were 1x application of the max. recommended dose (Day 0), 4x application of the max. recommended dose (Day 0, 7, 14, 21) and 1x application of 10x of the max. recommended dose (Day 0). The set-up consisted of 4 replicates per treatment and 6 control replicates. Microcosm systems included 12L unfiltered pondwater, macrophytes, freshwater shrimp and snails, natural sediment and a natural zooplankton community (collected on Wageningen University campus). Zooplankton samples were collected weekly and identified to lowest taxonomic level possible. Preliminary results indicate that zooplankton community composition in the treatments differed significantly from the controls on day 14, 21 and 28. Further analysis will focus on treatment and species differences and relate the outcomes to results of the currently ongoing quantification of *B. velezensis* in water and sediment over the experiment duration. The results of this microcosm experiment will provide new insights into the effects of microorganism-based plant protection products on aquatic ecosystems and zooplankton communities in particular.

4.16.P-Mo329 Identification of Common Pain Points in the EU Botanical Biopesticide Approval Process: Causes, Consequences and Potential Solutions

Judith Epping¹ and **Tobias Pamminer²**, (1)Wageningen University and Research (WUR), Wageningen, Netherlands, (2)Early Environmental Safety, Bayer AG, Monheim am Rhein, Germany

Biopesticides are considered a promising tool in the ongoing search for sustainable plant protection alternatives. Compared to other industrial countries, the number of approved biopesticides in the EU is relatively low, especially for botanical (plant-based) biopesticides. Botanical biopesticides currently fall into the same regulatory category as well characterized, pure synthetic pesticides, while frequently containing multiple natural compounds of varying concentrations. This poses a challenge to risk assessors and leads to a lengthy and costly registration process, hindering market access of these more environmentally friendly solutions. To address this challenge and improve the requirements for botanical biopesticide registration, it is crucial to know where mismatches with the current scheme occur. We have conducted a structured, semi-quantitative analysis of EFSA peer-reviewed reports on botanical biopesticides to identify frequently flagged issues. Using network-analysis, we determined common connections between unresolved issues and sections in the evaluation dossier with the goal of formulating concrete interventions that could advance the regulatory process for these substances without diminishing safety assessment. We collected information from data gaps that were flagged by EFSA in the review process for 14 botanical biopesticides and assigned keywords to each flagged issue to characterize reoccurring pain points. We also paired keywords to help uncover patterns where issues may propagate throughout the review process. Finally, we ran a co-occurrence network analysis on the top 15% most frequently occurring terms and determined how frequently each keyword occurs as well as which pairs of keywords commonly occur together within each evaluation. Data gaps categorized under the keywords “analytical method” and “technical properties” were most frequently (co-)occurring and are central to the network, meaning they are likely to trigger an issue in a following dossier section. Most flagged data gaps stem from the identity section of the dossier, highlighting the mismatch between the risk assessment requirements and the inherent characteristics of botanical biopesticides. Based on our findings we will provide practical recommendations to start addressing identified issues. We hope this semi-quantitative approach can serve as a blueprint to improve data driven policy analysis in a wide range of highly regulated products beyond plant protection.

4.16.P-Mo330 Study for the Control of Leaf-Cutter Ants, Aiming to Improve Agriculture, Aid Human Health, and Contribute to Ecotoxicology.

João Batista Fernandes¹, **Lulliana Franco¹**, **Eduarda Oliveira dos Santos¹**, **Artur da Silva Cruz¹**, **Anderson do Rego Pires¹**, **Sean dos Santos Araujo¹**, **Moacir Rossi Forim¹**, **Maria Fátima das Graças Fernandes da Silva¹**, **Marisa Narciso Fernandes¹** and **Odair Correa Bueno²**, (1)Federal University of São Carlos (UFSCar), Brazil, (2)Center for the Study of Social Insects, UNESP Rio Claro, Brazil

Omics data, TK-TD (TKTD) models, GUTS, PBK, NAMs, and ADME, studies involving natural products, ants, symbiotic fungi, acetylcholinesterase, environment, toxicology have received great attention contributing to ecotoxicology and to improving the health of the population.

The aim of this study was controlling the leaf-cutter ants (*Atta sexdens*) and their symbiotic fungus, *Leucoagaricus gongylophorus*, to improve agricultural production by evaluating the interaction among natural products from Brazilian plants.

The plants studied were collected in various locations in Brazil, their extracts were obtained using organic solvents and fractionated using different types of chromatography. The identification of the compounds was carried out using modern spectrometry methods, mainly UHPLC-QTOF/MS-MS and NMR. The extracts and isolated compounds were tested as insecticides against ants, for inhibition of fungus growth and the acetylcholinesterase enzyme of *Atta sexdens*.

In this study, the plants *Himatanthus articulatus* (Apocynaceae), *Parahancornia amapa* (Apocynaceae), *Vismia guianensis* (Hypericaceae), *Nectandra rigida* (Lauraceae), *Pouteria torta* (Sapotaceae), and *Clibadium surinamense* (Asteraceae) were used. The prepared extracts of these plants and several isolated compounds showed high insecticidal activity and inhibition of the fungus and in microelectrode of acetylcholinesterase enzyme from *Atta sexdens*.

The identified (28) or noted (36) compounds belong to the following classes: flavonoids, coumarins, chromones, terpenes, pterocarpanes, aryl-naphthalene lactones, iridoid lactones, triterpenes, benzophenones, anthranols, and anthraquinones, such as justicidin B, catechin, pumieride, isoplumieride, plumericin, beta-sitosterol, stigmaterol, citrate of lupeol, beta-amyrin cinnamate, ursolic acid and several inedited compounds. The panel to be presented during the meeting, SETAC EUROPE 36th ANNUAL MEETING, will include the identified compounds, their spectroscopic identification, and the results of the bioassays.

In conclusion, the results obtained contributed to the control of leaf-cutter ants and, consequently, to the improvement of agriculture, assisting in human health and ecotoxicology.

4.16.P-Mo331 RNAi-based pesticides - A novel class of pesticides with a huge potential for sustainability requires a novel approach for environmental risk assessment

Hannah-Philine Dey¹, Esther van der Zalm¹, Susanne Bär¹, Kristin Hirte¹, Urwa Bergs¹, Elke Eilebrecht² and Sebastian Eilebrecht², (1)German Environment Agency (UBA), Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

RNAi-based pesticides could provide a far more sustainable solution compared to classical chemical pesticides. They are very specific, rapidly degraded in the environment and their active ingredients are naturally occurring substances.

As their mode of action differs significantly from those of chemical synthetic pesticides, they require a different kind of risk assessment.

Current guidelines for risk assessment are designed for the assessment of chemical pesticides. As two RNAi-based plant protection products and one biocide already have entered the EU review procedure for authorization, we are developing approaches for an appropriate risk assessment guideline parallel to this procedure, comprising a tiered alignment analysis using all possible combinations of in-silico-cut siRNAs from the precursor dsRNA against genomes or transcriptomes of non-target species of increasing evolutionary distance from the target organism, and a bioavailability assay. With these approaches the aim is to adapt risk assessment to and possibly reduce data requirements for RNAi-based pesticides in the future, as specific ecotoxicology tests may be waived.

This talk shows why RNAi-based pesticides can be an excellent sustainable alternative compared to chemical pesticides, why they require a different kind of risk assessment, and presents approaches how this assessment can be implemented.

4.16.P-Mo332 Considerations for nucleic acid measurements in soil and sediment systems to meet environmental fate testing guidelines

Hannah Stewart¹, Sarah McCoy¹ and Joshua R. Arnie², (1)Eurofins Agrosience Services US, United States, (2)Plants and Invertebrates, Eurofins Agrosience Services US

With the growing landscape of biostimulants and biopesticides, there is an industry need for the robust quantitation of nucleic acids in environmental fate studies. Environmental fate testing guidelines OECD 307 and OECD 308 are routine tests for the registration of test substances. These guidelines were built on the principles of conventional organic chemistry, where radio-labeled test substances are frequently utilized for ease of analysis. The amount of a substance in soil, sediment, or water can be easily tracked so that the transformation rate, and the distribution of the chemical in water vs. sediment can be calculated over time. However, it is not always practical to use radio-labeling methods when dealing with nucleic acid test substances. Instead, quantitative Polymerase Chain Reaction (qPCR) can be used as an alternative method to measure the change in the concentration of nucleic acids over time. It is important to consider the limitations of this methodology and how it may affect the data being considered for risk assessment. The following are some of the areas for consideration when designing a method validation to support environmental fate studies: extraction method and limits, distribution of test substance in matrices based upon the determined limits, interactions between the test substance and matrix, qPCR primer design and optimization and standard curve creation. Overall, qPCR is a valuable tool to determine the amount of nucleic acids in a test system over time; and, with appropriate measures, it can be considered fit-for-purpose to quantify nucleic acids in environmental fate studies.

4.16.P-Mo333 Risk assessment innovation for double-strand RNA (dsRNA) pesticides with *Caenorhabditis elegans* and *Drosophila melanogaster* as ecotoxicological model

Xupeng Yu and Nico van den Brink, Wageningen University and Research (WUR), Netherlands

Current pesticide risk assessment protocols in the EU are primarily designed for chemical pesticides, with limited standardized approaches for low-risk pesticides. To potentially increase the toolbox for low-risk pesticide Environmental Risk Assessment (ERA), the potential of two in vitro whole organism models, *Caenorhabditis elegans* and *Drosophila melanogaster*, was assessed. Activity and development of *C. elegans* were measured using WMicrotracker ONE, and mortality and development of *D. melanogaster* were assessed with a dsRNA feeding assay. Our results showed that clear, concentration-dependent responses to dsRNA were detected in *C. elegans*. Furthermore, *D. melanogaster* showed no detectable effects in the feeding assay under the tested conditions. These findings demonstrate the potential of *C. elegans* as a suitable species for dsRNA pesticide risk assessment, while *D. melanogaster* may still be a potential model for other types of low-risk pesticides, but not dsRNA pesticides.

Track 5: Life Cycle Assessment and Footprinting

5.01 Addressing Sustainability Aspects of Circular Technologies Using New Approaches in LCA

5.01.T-01 Holistic Sustainability Assessment: Developing a Circularity Indicator Tool for Packaging

Stuart Robert John Walker¹, Rachael Rothman² and Justine Gloz³, (1)University of Sheffield, United Kingdom, (2)Chemical and Biological Engineering, University of Sheffield, United Kingdom, (3)Industrial Technical Center for Plastics and Composites (IPC), France

Life Cycle Assessment methods present complex results in a digestible format. Circularity indicators aim to represent circularity in a system through quantitative metrics such as break-even points, reuse numbers, or circularity scores or rankings.

However, whilst these measures are useful for the assessment of circularity, they do not give detail on the environmental sustainability of a product or system and are often somewhat simplistic.

Creating a combined method appears to be a good solution. The challenge lies in ensuring simplicity: A combined indicator which requires both LCA and circularity indicators to be calculated separately and presented together serves only to increase the practitioner's workload and overload the user with complex information.

Through the EU Buddiepack project, a Circularity Indicator tool was developed with the aim of assessing the circularity of packaging. The tool aimed to include environmental sustainability, social impact, economic factors, and circularity ratings.

Three overarching categories were developed: Circular flow of resources, value or economy, and sustainable development. Indicators were included within each of the three categories developed. The Circular flow of resources category was ultimately defined by a modified version of the Product Circularity Indicator. The value category was defined by three sub-categories: Overpackaging, Product waste and Material safety. The Sustainable development category was defined by four categories: Environmental Impact, Economic Impact, Social Impact, and a qualitative category on Total litter.

In each subcategory in the value category, either an existing metric was used or modified, or a specific scoring category was developed. For the three quantitative categories in the Sustainable development category, simplified versions of environmental LCA, economic assessment and social impact assessment were used. All subcategory indicators are calculated in the Circularity Indicator tool, which requires minimal user input and shares data between categories. Standard values for unknown data are offered to the user where necessary, and a large number of packaging materials and formats are built into the tool.

The tool aimed to balance detailed and trustworthy results for both circularity and environmental impact. Though opportunities for improvement exist, testing suggests that it has been successful.

Innovative solutions to over-packaging and single-use plastics, and related microplastic pollution (IA)

5.01.T-02 Opportunities and limits of new LCA approaches in the circular design of chemical and pharmaceutical manufacturing

Christopher Oberschelp¹, **Stephan Pfister²**, **Jing Huo¹** and **Stefanie Hellweg¹**, (1)ETH Zurich; NCCR Catalysis, Switzerland, (2)ETH Zurich, Switzerland

Chemicals and pharmaceuticals deliver essential societal functions but drive substantial environmental burdens across global value chains. Life cycle assessment (LCA) is central to greener and more circular design, yet its use is hampered by scarce primary data, confidentiality, and poor coverage of emerging substances. In this work, we explore how new LCA approaches (parametric inventory models, large-scale and LLM-assisted data mining, and regionalized emission data) can both improve and bias decision-making for circular strategies in chemical and pharmaceutical manufacturing. We combine background data from established databases with foreground models built from primary industrial information, process handbooks, and parametric LCIs embedded in supply chains for selected specialty chemicals. Three industrial case studies are analyzed in “conventional” vs “enhanced” LCA variants: solvent recovery in ethylene glycol production for pharmaceutical manufacturing, regionalized raw material sourcing, and historical steam cracker feedstock switches with implications for future biogenic feedstocks. Results show that scaling solvent recycling and reuse delivers far larger climate benefits than incremental process optimizations (e.g. catalyst choice) in mature technologies, and that regionalized LCIs materially change results where local energy mixes and emission controls differ. LLM-assisted data collection accelerates the construction of regionalized LCIs at moderate coverage, but maintaining data quality at higher coverage levels requires hybrid workflows and robust QA, limiting net effort savings. The feedstock case demonstrates that focusing on ethylene alone can hide higher system-wide emissions from on-purpose propylene (PDH), highlighting the risk of burden shifting when evaluating “circular” feedstock changes. Overall, our findings clarify both the opportunities and limits of emerging LCA tools and data, and provide practical guidance for their use in circular design and supplier engagement in the chemical and pharmaceutical sectors.

5.01.P Addressing Sustainability Aspects of Circular Technologies Using New Approaches in LCA

5.01.P-Tu391 Comparative life-cycle and cultural assessment of anaerobic digestion with and without thermal-hydrolysis pretreatment (THP-AD)

Paniz Pouryaghoubi¹, **Raf Dewil¹**, **Lise Appels¹** and **Barbara Rossi²**, (1)KU Leuven, Belgium, (2)University of Oxford, Department of Engineering Science, United Kingdom

Sludge treatment technologies deliver environmental, economic, and social benefits by reducing sludge volumes, mitigating hazards, and enabling resource recovery. A comprehensive life cycle assessment (LCA) is essential to identify the most suitable option under real-world constraints.

Existing LCAs of anaerobic digestion (AD) and thermal hydrolysis pretreated anaerobic digestion (THP-AD) are limited by inconsistent inventories and sparse comparative evidence across impact categories, especially when linking biochemical performance to environmental outcomes. Moreover, results are rarely stress-tested across the three ReCiPe perspectives (individualist, hierarchist, egalitarian), and only a few studies explore this dimension alongside environmental results, reducing decision-usefulness.

This study presents a comparative LCA of AD versus THP-AD using ReCiPe. The functional unit is 1 ton dry solids of wastewater treatment sludge treated, with a cradle-to-end-of-life boundary including energy recovery and digestate/end-of-life (EoL) handling. Inventories combine peer-reviewed literature and LCI databases; results are complemented by sensitivity and scenario analyses (e.g., energy mixes, recovery efficiencies).

Environmental results are reported under all ReCiPe perspectives; an exploratory assessment screens cultural perspectives for key stakeholder groups.

Results show that THP-AD improves biodegradability and biogas yields, which offset added pretreatment burdens and reduce global warming potential versus AD. Contribution analysis (CA) highlights the decisive role

of EoL routes and energy recovery. Scenario analysis shows strong sensitivity to the electricity mix, with lower impacts under low-carbon grids, exemplified by a ‘greener’ electricity mix in France (lower CO₂ emissions due to the high share of nuclear power) compared to Belgium. The study will report how results vary across ReCiPe perspectives and summarize these insights.

The study identifies conditions under which THP-AD is preferable and parameters that govern that choice (EoL route, energy mix, recovery efficiencies). The findings provide an evidence-based basis for utilities and policymakers and underscore the role of LCA (with perspective/sensitivity analysis) in evaluating sludge treatment options.

5.01.P-Tu392 Excellence in Excrements: Circular Management System of Manure

Kathrin Weiland¹, Theresa Kern², Andreas Mautner³, Iris Kral⁴, Alexander Bauer² and Alexander Bismarck⁵, (1)University of Applied Sciences Vienna (UAS Technikum), Austria, (2)Institute of Agricultural Engineering, University of Natural Resources and Life Sciences, Austria, (3)Institute of Environmental Biotechnology, University of Natural Resources and Life Sciences, Austria, (4)Ernst & Young denkstatt GmbH, Austria, (5)Institute of Materials Chemistry and Research, Polymer and Composite Engineering (PaCE) Group, Faculty of Chemistry, University of Vienna, Austria

Livestock manure is one of the main sources of greenhouse gas emissions in the agricultural sector and contributes to land pollution and eutrophication of surface waters. To minimise the environmental impact, a sustainable manure management solution is needed that address environmental challenges while enabling manure to be a valuable raw material in a circular system.

We present a holistic approach for upcycling of low-grade biomass by taking advantage of herbivore digestion system and the resulting manure to create high-value products such as biogas, pulp fibres and a fertilizer precursor. This approach generated high biogas yields (399 LN kg⁻¹ VS) while preserving substantial amounts of lignocellulosic fibres. These fibres were then used to produce high-performance nanocellulosic materials, achieving excellent mechanical properties such as tensile strengths of up to 200 MPa. The environmental impact of this manure-valorisation system was evaluated by lifecycle assessment in a cradle-to-gate approach and compared with two already established processes; Kraft pulp production from hardwood chips and biogas production from agricultural waste. A proxy approach was used to upscale the scenario in which manure was used as raw material from laboratory to an industrial scale. In all impact categories using manure showed to have lower environmental impact than using hardwood as raw material. The results demonstrate that a circular manure management system offers a sustainable alternative to traditional manure treatment giving a valorisation possibility to a condemned raw material.

5.01.P-Tu393 Sustainability Life Cycle Assessment of Modular Swappable Battery Systems for Electric Mobility: A PRISMA-Based Analysis

Amrutha Rajamani, **Nidhiben Patel** and Francesco Romagnoli, Institute of Energy Systems and Environment, Faculty of Electrical and Environmental Engineering, Riga Technical University, 12/1 Azenes iela, Riga, LV1048, Latvia, Latvia

The rapid expansion of electric mobility has increased the demand for battery systems that are sustainable, adaptable, and resource efficient. Traditional fixed lithium-ion batteries used in electric vehicles face challenges related to long charging times, material intensity, and limited flexibility, prompting growing interest in modular and swappable battery systems. These systems can reduce charging downtime, extend service life through controlled charging, and improve circularity by enabling repair, replacement, and reuse. However, their overall sustainability performance remains insufficiently assessed.

This study aims to examine the environmental, economic, and circularity implications of modular swappable battery systems through a systematic literature review. Using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) approach, a structured search was conducted in major scientific databases, followed by multi-stage screening and thematic classification. The review was organized into three focus areas: sustainability and life cycle impacts of batteries in micromobility, eco-design strategies for light electric mobility, and circularity and end-of-life management.

The final selection included studies covering life cycle assessment, cost analysis, and end-of-life strategies. Findings show that environmental impacts are dominated by the manufacturing phase, while operational practices such as charging patterns and maintenance influence overall performance. Modular designs show potential to reduce full-pack replacements and support more efficient repair and reuse pathways. Circular strategies, including recycling and second-life applications, demonstrate additional benefits, although research specifically addressing swappable configurations remains limited.

Overall, modular swappable battery systems offer promising opportunities to enhance sustainability in light electric mobility, yet current assessments lack harmonized methods and integrated environmental, economic, and social perspectives. The results highlight the need for standardized evaluation frameworks and real-world data to better quantify the benefits and guide future development of next-generation battery technologies.

5.01.P-Tu394 A Systematic Constraint-Based Life Cycle Assessment Framework for Circular Agriculture: Case Study of Agricultural Plastic Waste Management in Taiwan

Shaolin Peng¹, Zih-Ee LIN², Yasuhiro FUKUSHIMA³, Wei-Ju HUANG⁴ and Ying-Liang CHEN²,
(1)Department of Resources Engineering, National Cheng Kung University, Japan, (2)Department of Resource Engineering, National Cheng Kung University, Japan, (3)Department of Frontier Sciences for Advanced Environment, Graduate School of Environmental Studies, Tohoku University, Japan, (4)Department of Urban Planning, National Cheng Kung University, Japan

Circular agriculture systems are characterized by high variability, context dependence, and operational uncertainty. In Taiwan, fragmented small-scale farming structures further complicate implementation, creating gaps between theoretical environmental benefits and practical feasibility. However, conventional Life Cycle Assessment (LCA) primarily focuses on environmental performance by aligning functional units. This limits its capacity to capture the real-world constraints that shape circular agriculture. Consequently, the assessment outcomes often fail to provide implementable and contextually grounded guidance.

The emerging Constraint-based LCA concept shifts the analytical focus from functional units to the explicit integration of real-world constraints, including physical, policy, operational, and socio-economic limitations. Yet, empirical case studies are needed to establish the feasibility of this approach across diverse contexts. This study aims to develop a systematic Constraint-based LCA framework to address this gap.

The operational framework is validated using a case study of agricultural plastic waste management in Meinong District, Kaohsiung City, Taiwan. It comprises four steps aligned with, and extending, the ISO 14040 structure: (1) goal and scope definition with constraint identification, informed by stakeholder interviews, policy review, and decision-context analysis; (2) life cycle and constraint inventory, combining conventional LCI with the identification and quantification of constraints across six categories (environmental, economic, social, technical, policy, spatial); (3) system boundary reconfiguration, dynamically adjusting boundaries to reflect processes that remain feasible under the identified constraints; and (4) feasibility evaluation, using context-specific indicators through scenario and sensitivity analyses.

The framework reveals constraint interactions often overlooked by conventional LCA. By explicitly quantifying multiple constraints informed by stakeholder insights, it facilitates the identification of currently viable pathways and the boundary conditions (e.g., subsidies, policy support) required to expand feasibility. The assessment results therefore support pragmatic, context-sensitive decision-making in the Meinong case. The study offers the first set of operational guidelines for applying Constraint-based LCA, supporting the development of more actionable and deployable circular agriculture strategies.

5.01.P-Tu395 Nitrogen Footprint Focusing on Industrial Sector in Japan Based on Inventory Database in IDEA

Yuki Ichisugi¹, Kenichiro Tsukahara² and Kiyotaka Tahara², (1)National Institute of Advanced Industrial Science and Technology (AIST), Tokyo, Japan, (2)National Institute of Advanced Industrial Science and Technology, Japan

In the concept of “Planetary Boundaries”, excessive atmospheric nitrogen consumption caused by population increase and economic growth has received widespread attention during recent years.

This is due to the use of atmospheric nitrogen, which is released back into the atmosphere and water as reactive nitrogen (ex, NO_x, total nitrogen) after it has been used in various processes. Therefore, it is important to analyze the nitrogen flow to reduce the burden on the environment. In previous LCA research, reactive nitrogen has been targeted as elementary flow regarding as environmental burden substance. On the other hand, input data including atmospheric nitrogen, NH₃ and so on have not been targeted as elementary flow regarding as resource or environmental burden substance.

Additionally, technologies which aim to recycle reactive nitrogen into atmospheric nitrogen for reducing environmental burden have been developed in recent years. In this case, we need to analyze environmental burden in total. Hence, we need not only amount of reactive nitrogen as output data, but also amount of nitrogen as input data. At the same time, we need to confirm the nitrogen balance between input and output to verify the validity of the entire mass balance process because it is significant to reduce the environmental burden in entirety.

In this presentation, we will show the results of nitrogen footprint focusing on industrial sector in Japan using inventory database of IDEA. We developed the nitrogen input and output amount for each process data adjusted each functional unit (ex. kg, m³, and so on). We collected product amount of each industrial product in a year and connected to process data. Finally, we analyzed total nitrogen amount of target year, 2015. We estimated nitrogen footprint of industrial sector in Japan.

5.01.P-Tu396 Life Cycle Assessment of a new Acrylonitrile-Butadiene-Styrene Dissolution Recycling Technology

Meis Uijtewaald¹, Martijn Broeren¹, Milad Golkaram² and Lucie Prins², (1)CE Delft, Netherlands, (2)TNO, Netherlands

Acrylonitrile-butadiene-styrene (ABS) is widely used in consumer electronics housings, automotive interior components, and small appliances. Mechanical recycling of ABS at end-of-life results in ABS with a lower quality than virgin ABS, due to degradation of the butadiene rubber. A new technology is being developed for dissolution recycling of ABS, recovering virgin-quality SAN polymer. The environmental impact of the ABS dissolution recycling process was studied in a prospective Life Cycle Assessment (LCA) following the Product Environmental Footprint (PEF) method. The data for dissolution recycling is for a full scale dissolution plant (20 kta) and is derived from a model based on lab scale processes. A cradle-to-gate analysis of the dissolution process shows a 65% carbon footprint reduction of recycled SAN compared to virgin SAN and even higher reductions on all other environmental impact indicators. A cradle-to-grave analysis of the application of recycled ABS in car panels using the Circular Footprint Formula from the PEF method shows carbon footprint reductions of 19% compared to virgin ABS when assuming disposal at end-of-life to up 39% when assuming dissolution recycling at end-of-life. Hence, dissolution recycling of ABS can result in a considerable reduction of the environmental impact of ABS, while maintaining a virgin-like quality, making it possible to apply the recycled ABS in a wide variety of products. In combination with the possibility to process difficult-to-recycle waste streams, this technology is could be a valuable addition to mechanical recycling of ABS.

5.01.P-Tu397 Implementing Circular Value Chains in the Oil & Gas Industry: A Sustainability Assessment of Crankshaft Remanufacturing

Rocio Pena and Ana Fuentes Moldes, AIMEN, Spain

R3-MYDAS is a Horizon Europe project that aims to accelerate the manufacturing industry's transition toward sustainable and circular value chains. A key aspect of this effort is the implementation of Sustainability by Design (SbD) principles to ensure that innovative circular processes generate environmental, economic, and social benefits. In this context, the project encompasses three industrial demo cases, with a focus here on the oil & gas sector's crankshaft component.

Traditional linear value chains in the oil & gas industry often lead to component disposal when failures occur, generating significant environmental and economic costs. The R3-MYDAS project proposes a remanufacturing approach for crankshafts, enabling repair and reintegration during maintenance and end-of-life. To achieve this, worn areas of the crankshaft are scanned to create a 3D model, guiding the design of the required clad layer,

which is then applied using laser cladding. While this innovative process restores components to near-original specifications, improving precision, cost-efficiency, and environmental performance, understanding its broader impact requires a structured evaluation.

To this end, an SbD assessment has been conducted for the crankshaft demo case, focusing on environmental and socio-economic dimensions to ensure that the remanufacturing strategy is both sustainable and socially responsible:

- **Environmental dimension:** A Life Cycle Assessment (LCA) evaluates the environmental impacts of the remanufacturing process, including carbon footprint and resource efficiency, following ISO 14040 guidelines. The assessment highlights both the potential benefits of shifting from a linear to a circular value chain and the environmental hotspots where further improvements could enhance sustainability.
- **Socio-economic dimension:** Life cycle cost analyses are conducted to ensure that the remanufacturing approach is economically viable and competitive with conventional production and maintenance methods. In addition, the assessment also considers potential social implications across the value chain, such as workforce adaptation and occupational safety.

The proposed remanufacturing strategy is designed to be sustainable, with potential for further optimization to improve process efficiency and support wider industry adoption. The crankshaft demo case illustrates how circular strategies can be implemented in industrial contexts, showing how SbD can guide circular strategies.

The authors thank R3-Mydas project. This project has received funding from the European Union's Horizon 2023 research and innovation programme under grant agreement No. 101138738.

5.01.P-Tu398 Eco-Design and Carbon Footprint Minimization in 3D-Printed Drug Products through Integrated Production Efficiency and Sustainable Logistics

Dimitrios Aristotelis Koumpakis¹, Konstantinos Tsirkinidis², Dimitrios Christoforidis², Christos Vlachokostas², Alexandra Michailidou², Panagiotis Barmpalexis³, Afroditi Kapourani³, Naoum Tsolakis⁴, Harisios Achilles⁴ and Dimitrios Aidonis⁴, (1)Dept Mechanical Engineering Aristotle University of Thessaloniki, Greece, (2)Dept. Mechanical Engineering Aristotle University of Thessaloniki, Greece, (3)Dept. Pharmacy, Aristotle University of Thessaloniki, Greece, (4)Dept. Supply Chain Management, International Hellenic University, Greece

The rapid expansion of three-dimensional (3D) printing in pharmaceutical manufacturing offers a transformative pathway toward personalized medicine, on-demand production, and improved therapeutic precision. However, the environmental implications of 3D-printed drug products remain insufficiently explored, particularly with respect to material use, energy demand, and distribution-related emissions. This project addresses these challenges by investigating how eco-design principles and carbon footprint minimization strategies can be integrated across the full value chain of 3D-printed pharmaceuticals.

The study focuses on the development of a sustainability-oriented framework that combines product eco-design, production efficiency, and sustainable logistics to reduce the environmental burden of drug manufacturing. At the product level, eco-design approaches are applied to optimize formulation composition, minimize excipient and packaging waste, and improve printability while maintaining drug quality, dosage accuracy, and patient-specific functionality. At the process level, the project evaluates critical manufacturing parameters affecting energy consumption, material efficiency, and production yield, aiming to identify operating conditions that lower emissions without compromising performance or regulatory compliance.

Beyond production, the project examines the logistics dimension of decentralized and on-demand pharmaceutical manufacturing. By comparing centralized and distributed supply models, it assesses the potential of localized 3D printing to reduce transportation distances, storage requirements, and associated greenhouse gas emissions. Life Cycle Assessment (LCA) and carbon footprint analysis are used as core tools to quantify environmental impacts and identify hotspots throughout raw material sourcing, printing, post-processing, packaging, and delivery stages.

The expected outcome is a set of practical design and operational guidelines for more sustainable 3D-printed drug products, supporting the transition toward greener pharmaceutical systems. By linking engineering optimization with environmental assessment and supply chain innovation, the project contributes to the broader goals of circular economy, low-carbon healthcare, and resilient medicine production. Ultimately, it demonstrates how 3D printing can evolve from a technological innovation into a sustainability-enabling solution for the future of pharmaceuticals.

The work is funded within the framework of the “SUB1.1: Clusters of Research Excellence (CREs)” Programme of the National Recovery and Resilience Plan ‘Greece 2.0’, and co-financed by the Greek State and the European Union (project code: YII3TA-0560854)

5.01.P-Tu399 Do Rental and Sharing Models Deliver? Life Cycle Assessment-Based Lessons on Logistics, Use Intensity and Circular Design

Astrid Stalmans, Anse Smeets, Karolien Peeters and Jeroen Gillabel, Flemish Institute for Technological Research (VITO), Belgium

Rental and sharing systems are increasingly promoted as circular business models with the potential to reduce environmental burdens by replacing individual ownership with collective use and preventing underutilization of products. However, their actual sustainability performance depends strongly on logistics, use patterns, and system design. Within a local Green Deal project on Rental and Sharing in Flanders (Belgium), a streamlined Life Cycle Assessment (LCA) focusing on climate change and resource use was performed on 7 case studies. The case studies were selected to reflect variation in product types, target customers (B2C vs B2B), organizational scale, seasonality in use, use cycle duration, and geographical coverage of the service. The objective was to identify the conditions under which renting and/or sharing delivers net environmental benefits compared to traditional purchase models, and to derive general recommendations for implementing rental and sharing systems. Each rental or sharing model was compared with its corresponding reference scenario, typically a traditional purchase scenario. The evaluation followed LCA principles, accounting for environmental impacts across the full life cycle of a product: production, distribution, use, repair activities, and end-of-life processing. All transportation steps associated with use and repair activities are considered. This encompasses transport to the consumer and back to the store, as well as transport to and from repair facilities, where applicable. Results indicate that products with relatively high production impacts and low use rates are particularly suitable for shared use, and repairable product designs and logistics emerged as critical drivers of environmental performance. Rental and sharing models can offer substantial benefits in terms of resource efficiency, as fewer products are required to meet the total user demand. However, the implications for climate change are more complex. When products are rented or shared at high frequency and for short usage periods, customer transport to and from the pick-up location - particularly when conducted by car - can offset or even exceed the climate benefits achieved through reduced production volumes. To ensure that environmental gains are effectively realized, it is therefore crucial to optimize transport logistics, for example by promoting alternative, low-carbon modes of mobility or by organizing the rental or sharing service as locally as possible.

5.01.P-Tu400 Waste Footprint Analysis in Japan Using Waste Input-Output Model for Advancing Waste Circularity

Atsushi Fukada¹, Yasushi Kondo¹, Yuki Ichisugi² and Norihiro Itsubo Dr¹, (1)Waseda University, Japan, (2)National Institute of Advanced Industrial Science and Technology (AIST), Tokyo, Japan

The transition to a circular economy requires robust methods to quantify waste flows induced by consumption across complex supply chains. This study quantifies Japan's consumption-based waste footprint in 2020 using an extended Waste Input-Output (WIO) model. The WIO framework integrates waste generation, treatment, and recycling flows into conventional input-output analysis, enabling systematic tracking of waste directly and indirectly induced by final consumption both domestically and abroad.

Traditional waste accounting often overlooks indirect waste embedded in supply chains, limiting policy insights. To address this, we constructed a 2020 WIO table by harmonizing Japan's official Input-Output Tables and industrial waste statistics. The resulting model integrates production sectors and waste management sectors—such as recycling, landfill, and incineration—within a unified matrix framework.

Using this model, we estimate Japan's total waste footprint as approximately 635 million tons, with 334 million tons generated domestically and 301 million tons abroad. Major waste generation occurs in food manufacturing, construction, and service sectors, underscoring the importance of supply chain perspectives. Domestic waste treatment relies heavily on incineration, raising concerns about greenhouse gas emissions, while recycling predominantly serves the cement and agricultural industries, indicating sector-specific circular flows.

The study's single-country scope limits detailed tracing of foreign waste destinations, highlighting the need for future multi-regional extensions to better capture global waste flows. Nonetheless, the WIO model offers a powerful tool for comprehensive waste flow assessment and supports evidence-based policies for circular economy transitions.

This work provides critical insights into consumption-induced waste dynamics and treatment pathways in Japan, contributing to sustainable waste management strategies and advancing methodologies for global applications.

5.01.P-Tu401 The potential of calcium and magnesium silicate as a circular input for correcting soil acidity and decarbonizing maize production in Brazil.

Janaine F. Gaelzer Timm¹, Marília Folegatti¹, Cristiano A. de Andrade¹, Anna Leticia Montenegro Turtelli Pighinelli¹, Thaisa Lana Pilz Savioli¹, Rosângela Stralio², Eliane P. Clemente Almeida³ and Nilza Patrícia Ramos¹, (1)Embrapa Meio Ambiente, Brazil, (2)Embrapa Solos, Brazil, (3)Embrapa Milho e Sorgo, Brazil

The reuse of inputs from one production chain in another supports the circular economy and contributes to decarbonization. Calcium magnesium silicate (CMS), obtained from stainless steel slag, can act as a soil acidity corrective, partially or fully replacing calcitic or dolomitic limestone. Although technically equivalent, it is necessary to assess whether metals present in CMS (e.g., chromium, lead, cadmium) may generate adverse effects on human health and ecosystems. This study evaluates the effects of metal bioaccumulation from CMS applied in maize cultivation in Mato Grosso, Brazil. The environmental profile of CMS was analyzed using life cycle assessment (LCA), considering its application in soil for the production of 1 ton of maize grains at 13% moisture. System boundaries cover stages from planting to harvest, including fertilizers, pesticides, and machinery fuel. We defined 3 scenarios: S1 (100% limestone), S2 (50% limestone and 50% CMS), and S3 (100% CMS). Impact categories include climate change (IPCC 2021 - GWP 100y), acidification, and freshwater ecotoxicity and eutrophication (Environmental Footprint 3.1), and human toxicity - cancer and non-cancer (USEtox 2). Calculations were performed in SimaPro v.9.6 with ecoinvent v.3.10. Climate change impacts decrease from 260.63 kg CO₂ eq in S1 to 241.07 kg CO₂ eq in S2 and 221.52 kg CO₂ eq in S3 (15% reduction). Acidification remains nearly constant (7.68 mol H⁺ eq), varying only 0.19%. Terrestrial eutrophication changes from 33.98 to 33.95 mol N eq (-0.09%). Freshwater ecotoxicity rises from 6452.67 to 7293.21 CTUe (13%). Freshwater eutrophication falls from 0.0288 to 0.0278 kg P eq (3.5%). Human toxicity-cancer decreases from 2.06E-07 to 2.03E-07 (1.08%), while human toxicity-non-cancer increases from 2.88E-07 to 2.90E-07 (0.70%). CMS, even within regulatory limits, can increase human toxicity and freshwater ecotoxicity if applied excessively or repeatedly. Results also indicate significant differences in CO₂ between CMS and limestone, as CMS does not undergo carbonation in soil. Differences in other impacts are minor and may reflect LCA uncertainties. Overall, CMS shows environmental performance equivalent to limestone. Moreover, its reuse replaces conventional inputs without performance losses and mitigates impacts associated with the underutilization of this metallurgical by-product, contributing to more sustainable material management and a circular economy.

5.01.P-Tu402 Synergizing Life Cycle Assessment and Logistics to Improve Supply Chain Management

Maryam Hoseini and Stuart Robert John Walker, University of Sheffield, United Kingdom

Reusable packaging is increasingly promoted as a strategy to reduce waste and environmental impacts, yet its actual performance depends on complex interactions between product design and supply-chain logistics. This study demonstrates how combining Life Cycle Assessment (LCA) with logistics analysis strengthens supply-chain decision-making, drawing on insights from the BUDDIE-PACK project across four use cases: takeaway food containers, refillable detergent bottles, semi-rigid catering trays, and on-the-spot consumption containers. Using cradle-to-grave LCA aligned with Product Environmental Footprint (PEF) principles, the analysis quantifies impacts across production, transportation, washing, use, and end-of-life stages. Key environmental hotspots are identified in material production, washing operations, transport distances, and disposal pathways. Break-even analyses and sensitivity tests further examine how factors such as washing efficiency, consumer transport, and packaging mass influence the environmental viability of reuse.

The results show that reusable solutions only outperform single-use options when supported by efficient and well-designed logistics loops. High-efficiency washing, minimized transport burdens, lightweight yet durable designs, and credible recycling routes meaningfully reduce environmental impacts.

Overall, integrating LCA with logistics provides a realistic and actionable roadmap for scaling reusable packaging systems. The synergy provides a robust foundation for designing supply chains that are both environmentally resilient and operationally viable.

5.01.P-Tu403 Exploring the Use on Land Phase in Nutrient Recovery: Nuancing the Fertilizer Substitution Principle in Life Cycle Modelling with tier 3 model Daisy

Lilla Simon¹, Panagiotis Papazoglou Karachontzitis², Ivona Sigurnjak³, Sander Bruun², Benyamin Khoshnevisan⁴ and Morten Birkved¹, (1)University of Southern Denmark, Department of Green Technology, Denmark, (2)University of Copenhagen, Denmark, (3)University of Ghent, Belgium, (4)University of Southern Denmark (SDU), Denmark

Nutrient recovery (NR) technologies in wastewater treatment (WWT) are increasingly promoted as circularity solutions, yet life cycle assessment (LCA) studies often use simplified fertilizer substitution and use on land (UoL) approaches that overlook site-specific agronomic dynamics. While previous research shows that methodological choices around fertilizer substitution strongly influence LCA results, detailed UoL modelling remains rare. This study evaluates how integrating the tier 3 agro-ecosystem model Daisy within a consequential LCA framework can refine assessments of bio-based fertilizers (BBFs) from NR systems.

The UoL stage of an ammonium-rich BBF produced at a pilot scale ion exchange/adsorption unit integrated into municipal WWT was modelled using Daisy. Simulations were parameterized with site-specific soil, weather, crop rotation, and management data from a three-year field trial, supplemented with BBF mineralization data from pot experiments and all scaled to the same yield/area standard. Three BBF application scenarios were modelled: (1) BBF with a measured N content of 4 kg N/ton BBF, and alternative optimized scenarios using (2) natural zeolite with a higher adsorption capacity and (3) polymeric resin. A reference scenario with only mineral NPK fertilizer application was also modelled. Results were translated into consequential LCA models and compared to scenarios where tier 1 IPCC emission factors were used with the same 3 BBF scenarios modelled in Daisy.

Results between the 6 modelled scenarios varied only slightly. In the climate change category, an impact reduction of 7.05 and 2.2% was observed in Daisy modelling compared to IPCC UoL results in scenarios using zeolite with an adsorption capacity of 4 kg N/ton and resin with 100 kg N/ton, respectively. The small change in impacts is explained by similar properties of the BBF and synthetic fertilizer. To support LCA practitioners in tool selection in the UoL phase, a decision aid was developed based on key factors such as decision context, UoL impact share, BBF type and mineralisation behavior, novelty and type of BBF. Model calibration with measured data is recommended to ensure robustness.

Overall, integrating Daisy into NR LCAs enhances representativeness and provides a stronger basis for evaluating BBFs and NR technologies within circular nutrient management. The proposed decision aid contributes towards more consistent and transparent UoL modelling practices.

5.01.P-Tu404 Advancing Circular Life Cycle Assessment Through Time-Explicit Modelling and System Expansion. A Case Study for Wind Turbine Systems

Roel Degens¹, Giuseppe Cardellini², Gustavo Martinez², Amelie Müller³ and Tom van Schaijk², (1)Flemish Institute for Technological Research (VITO), Netherlands, (2)Flemish Institute for Technological Research (VITO), Belgium, (3)Leiden University, Netherlands

Transitioning to a renewable energy system is rapidly increasing the demand for Critical Raw Materials. Recovering these critical materials through circular practices can be a great opportunity for the European Union. Traditional LCA is well suited for evaluating linear product systems. However, the application of conventional LCA to circular systems raises several methodological challenges, most notably those related to multifunctionality and to the allocation of burdens and credits associated with end-of-life recycling processes. Combining system expansion to model multiple lifecycles of a given product system with time-explicit LCA could solve these issues.

In this study we model and compare two different wind turbine product systems in Belgium with 1 kWh of electricity as functional unit. Both product systems have two lifetimes of wind turbines. In the first product system, referred to as the linear system, both the initial wind turbine and the second wind turbine is manufactured from virgin materials. It has standard, non circular end-of-life strategies at its end of life. In the second product system, referred to as the circular system, the initial wind turbine is likewise manufactured from virgin material. The second life of the wind turbine is modelled from recycled materials recovered from the first wind turbine.

The initial results show that applying circular practices can significantly lower global warming impacts. The extra environmental burdens added from the recycling processes are smaller compared to the environmental impacts of manufacturing a second wind turbine from virgin materials. In essence, recycling results in lower environmental impacts than extracting and processing the raw materials from their ores.

Integrating a temporal dimensions into the model is still a work in progress. We aim to achieve this by conducting a time explicit LCA. It is expected that both the linear as the circular product system will have lower environmental impacts in their second life due to the decarbonization of the economy. How this temporal dynamic will eventually influence the final results is yet to be determined at the time of writing. The goal of this work is to further develop methodologies related to circular LCAs by combining time explicit LCA with system expansion. This could potentially solve certain issues conducting LCAs of circular product systems and improve the level of detail of these LCA studies in general.

Disclaimer/Disclosure:

This work was supported by the CIREC project, which is an energy transition fund project (E2-ETF-2022-000795), sponsored by the Belgian Federal Public Service Economy.

5.01.P-Tu405 Assessing the risk of Pharmaceuticals in the Environment (PiE) as a result of recycling primary packaging

Rachel Moreby¹, James Nieman¹, Kathryn Hill¹, Irene Bramke² and Samuel K Maynard³, (1)AstraZeneca, United Kingdom, (2)AstraZeneca, Netherlands, (3)Environmental Protection, Global Sustainability and SHE, Operations, AstraZeneca, United Kingdom

Pharmaceutical packaging take-back and kerbside recycling schemes are increasing due to industry commitment to circular economy principles. In the UK, some high street pharmacies offer medicine blister recycling, while Swedish patients can recycle empty pharmaceutical packages in household bins. There is however a lack of published research on the environmental risk posed by the release of active pharmaceutical ingredients (APIs) during recycling or on the typical levels of API residue on packaging materials after use. API residues left on packaging may enter rinse water at recycling centres and, depending on wastewater treatment, could be discharged into the environment, presenting a potential localised pollution risk.

This case study uses AstraZeneca's Safe API Discharge Programme to assess Pharmaceuticals in the Environment (PiE) risks from recycling blister packs. The programme calculates a Risk Quotient (RQ) by comparing theoretical discharge quantities to a Predicted No Effect Concentration (PNEC), usually used to assess manufacturing emissions. In this study, residue values documented for coated tablets stored in HDPE bottles were utilized as conservative estimates due to the lack of blister-specific data. Three hypothetical APIs with varying ecotoxicity were assessed across different recycling volumes, assuming full compliance and daily processing at a single facility, with standard effluent discharge and dilution factors. Results indicate that for APIs with medium and high PNECs, PiE risk from blister pack recycling is negligible. However, recycling moderate to high volumes of blisters containing highly ecotoxic APIs may result in a risk ($RQ > 1$) under certain circumstances. This underscores that a universal risk assessment is not feasible, as API ecotoxicity and recycling volume both influence PiE risk. Scheme type also matters as takeback schemes typically process smaller volumes at a single site, while kerbside recycling may result in larger, decentralised volumes. We explore other contributing factors to recycling volumes and also consider the impact of dose form (blister, inhaler or injection pen) on the outcome of the assessment. The assessment demonstrates the importance of tailoring risk evaluations – to the API, packaging type, local conditions, and scheme methodology – and refining assessments as recycling programmes expand. Further work may include analysis to verify API residues on blisters to support the desktop assessment.

5.02 Advancing Methods for Prospective Life Cycle Assessment to Support Radical Approaches to Sustainable Research and Innovation

5.02.T-01 Dynamic Counterfactual LCA: Prospective Consequences via Socio-ecological Modeling

Pierre Jouannais¹ and Thomas Elliot², (1)ITAP, INRAE, France, (2)Department of Sustainability and Planning, Aalborg University, Denmark

Beyond its standard description as a life-cycle modeling approach, LCA actually consists of two distinct logics: attributional LCA, which assigns average environmental burdens to products themselves, and consequential LCA (CLCA), which propagates effects of decisions through production systems and markets. In practice, CLCA relies on simplified heuristics that capture only short-term or proximate effects, whereas real-world decisions can trigger delayed, amplifying, or nonlinear consequences.

This work introduces Dynamic Counterfactual LCA (DC-LCA), an extended form of CLCA designed to capture

such long-term, system-level propagation effects. Rather than setting the studied product system in the future as in traditional Prospective LCA, DC-LCA models a present-day system while projecting consequences dynamically into the future. It integrates System Dynamics (SD) modeling to explicitly represent delays, feedbacks, and the evolution of social and environmental variables over time. By simulating a counterfactual world evolving without the studied intervention associated with the functional unit, impacts can be derived from the dynamic integration of differences between “with” and “without” scenarios at each point in time.

We demonstrate the approach using a socio-ecological SD model representing the spread of vegan diets within a population. A single individual switching diet for one year is introduced as a perturbation to the model associated with a functional unit, creating small but time-dependent deviations in vegan and omnivore population trajectories. These delayed deviations are translated into temporally resolved demand changes, enabling total environmental consequences to be computed using a dynamic and prospective LCA framework.

Results show that delayed, system-mediated effects dominate the immediate impact of the dietary change. Impacts are nonlinear and non-symmetric: reversing the dietary change or scaling its magnitude does not simply invert or proportionally adjust total emissions.

DC-LCA thus departs from the linear assumptions of classical CLCA by embedding decisions within evolving social and environmental systems. It offers a more realistic representation of causality, the sole necessity for the canonical definition of CLCA, highlighting that the consequences of actions depend not only on current supply chains but also on the social dynamic context in which they unfold.

5.02.T-02 Prospective Life Cycle Assessment in Mineral Value Chains: an Extend SIMPL Approach (SIMPL-Minerals)

Jonas Klimt¹, Ioan-Robert Istrate¹, Valerio Barbarossa¹, Antoine Beylot², Frederic Lai³ and Bernhard Steubing¹, (1)Leiden University, Netherlands, (2)French Geological Survey (BRGM), France, (3)Bureau of Geological and Mining Research (BRGM), France

As the energy transition accelerates, the need for minerals is expected to rise sharply, bringing increased attention to the environmental consequences of expanding their supply. Prospective Life Cycle Assessment (pLCA) offers a way to estimate these future impacts. Yet many pLCA studies in the mineral sector rely on different assumptions and parameters, making their results difficult to compare. To support more consistent prospective life cycle inventory (LCI) modelling in this context, this study introduces a structured approach. Our approach builds on the existing SIMPL framework for scenario-based pLCA modelling and extends it with elements tailored specifically to mineral value chains, forming the SIMPL-Minerals (SIMPL-M) approach. These additions include defining the key stages and processes of mineral supply chains, identifying the parameters linked to those stages, and connecting these parameters to broader macro-level drivers that shape future developments. The resulting parameter set was reviewed and refined through semi-structured expert interviews. We then applied the SIMPL-M approach in an exemplary case study assessing future global nickel sulfate production for batteries.

Using SIMPL-M, we identify 18 central parameters that should be considered when conducting pLCA of mineral supply chains. These parameters reflect variations in deposit characteristics, technologies, and geographic conditions, and span both primary and secondary production, from ore extraction or waste collection to refined materials. Each parameter is positioned within a generic inventory model blueprint to show where it becomes relevant along the value chain. By linking these parameters to macro-level factors, the approach supports coherent scenario construction and consistent assumptions about how parameters evolve over time. When applied to the nickel sulfate case study, SIMPL-M demonstrates that incorporating parameters beyond conventional background LCI data can meaningfully alter impact assessment outcomes.

By adapting the SIMPL framework to the specific needs of mineral value chains, we develop the SIMPL-M approach. SIMPL-M supports practitioners in applying parameters systematically within inventory modelling and constructing scenarios grounded in macro-level drivers influencing parameter change. In doing so, it improves comparability across pLCA studies and reduces modelling effort for users.

Disclaimer/Disclosure:

This work received funding from the project RAWCLIC under the HORIZON-CL5-2024-D1-06 scheme and from the EIT RawMaterials and the European Union under the project HiQ-LCA (project agreement 22039).

5.02.T-03 Climate change impacts with prospective characterization factors: sensitivity of background inventories

Marcos Djun Barbosa Watanabe and **Francesco Cherubini**, Norwegian University of Science & Technology, Norway

Prospective life cycle assessment (pLCA) is increasingly used to evaluate future environmental impacts as technologies, socio-economics, and policy contexts evolve. While methodological advances have strengthened prospective life cycle inventory modelling, progress in prospective life cycle impact assessment has remained limited. Recent work addressed this gap by developing prospective characterization factors (pCFs) for climate change, consistent with IPCC methods and derived from Integrated Assessment Model (IAMs) scenarios under different Representative Concentration Pathways (RCP) and Shared Socioeconomic Pathways (SSPs). These pCFs capture shifts in radiative efficiencies and impulse response functions for CO₂, CH₄, and N₂O, revealing substantial variation in future climate metric values and enabling their integration into LCA tools. Building on this foundation, the present study applies the new pCFs in a comprehensive sensitivity analysis of all activities inecoinvent. Using Brightway2 and IAM-RCP-SSP specific GWP100 and GTP100 values for 2030, 2040, and 2050, we examine how emission timing, scenario choice, and climate metric selection influence future climate impacts. Results show that activities dominated by non-CO₂ gases are most sensitive to pCFs, with methane- and nitrous-oxide-intensive systems exhibiting distinct response patterns, while fossil-CO₂-dominated activities remain comparatively stable. These findings highlight where prospective modelling most affects outcomes, support better interpretation of long-term uncertainty, and strengthen the coherence and decision relevance of prospective life cycle impact assessment.

5.02.T-04 Is Time-Explicit Life-Cycle Assessment Useful? A Vehicle Eco-design Case Study

Thomas Arblaster¹, **Jeroen Guinée**¹, **Carlos Felipe Blanco Rocha**¹, **Ivana Burzic**², **Claudia Pretschuh**² and **Nils Thonemann**¹, (1)Leiden University, Netherlands, (2)Wood K plus - Kompetenzzentrum Holz GmbH, Austria

Life-cycle assessment (LCA) is increasingly used for eco-design. Time-explicit LCA is emerging as a framework for the coherent inclusion of temporal dynamics. However, for the additional efforts of this approach to be justified, it should improve the value of the assessment to its application. The question is therefore whether time-explicit LCA can yield insights beyond those obtained with conventional (temporally static, near-present) LCA or prospective (temporally static, future) LCA. To answer this question, we consider a case study in automotive eco-design: the development of a polypropylene (PP) composite with a softwood filler, which could substitute talcum-PP in the production of interior trims. Both alternatives are assessed from cradle to grave, considering components produced from 2030 to 2055.

Moving from a system based on primary material, using considerable fossil resources (near-present static), to a circular system using more renewable energy (prospective static) consistently leads to impact reduction. Following life-cycle stage contribution analysis, the temporal perspective influences which activities are identified for potential impact mitigation. Softwood-PP enables lightweighting and has a lower polypropylene volume, generally making it the preferred alternative in temporally static perspectives. However, with the assumption that increased circularity is primarily driven by the mechanical recycling of secondary compound, talcum-PP is at a distinct advantage, as a future feedstock of secondary softwood-PP relies on this novel compound being introduced in the first place. Consequently, a time-explicit perspective indicates a preference for talcum-PP.

Based on these results, it becomes a priority to investigate whether a softwood filler could be combined with secondary talcum-PP – either through chemical recycling or by creating a hybrid composite – which could bring the preference of a time-explicit perspective in line with the temporally static results. The relevance of these questions is not apparent from either temporally static perspective. Considering the system as temporally differentiated leads to a more holistic assessment, which can indeed yield novel insights. This case study highlights the value of time-explicit LCA, especially concerning design for a circular economy. While the practical application of time-explicit LCA still faces many challenges, our results indicate that these challenges are worth addressing.

5.02.P Advancing Methods for Prospective Life Cycle Assessment to Support Radical Approaches to Sustainable Research and Innovation

5.02.P-Tu406 Structuring the Application of Life Cycle Assessment to Emerging Technologies: A Multi-Perspective Approach

Kamal Kamali¹, Guido Sonnemann¹, Nils Thonemann², Bertrand Laratte³ and Roland Hirschier⁴, (1)University of Bordeaux, France, (2)Leiden University, Netherlands, (3)Laval University, Canada, (4)Technology & Society Laboratory, Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland

Modelling decisions made during the goal and scope definition stage can substantially influence LCA outcomes and might result in model-dependent conclusions. This issue becomes even more pronounced when assessing emerging technologies, characterised by high design freedom. In such situations, LCA faces additional challenges, including limited comparability, data scarcity, and/or high uncertainty. In this context, we propose a novel, structured approach to applying LCA that models emerging technologies from multiple perspectives depending on the technology readiness levels.

Based on the inductive reasoning of 20+ publications of the first and second author on LCAs of emerging technologies, a set of research questions were formulated that aligns with the technologies maturity level. Additionally, the reasoning was challenged, criticed and scrutinized by three invited experts from the LCA community who joined the work for this purpose and have proposed revisions to increase rigor.

The resulting multi-perspective approach structures the application of LCA to emerging technologies by aligning goal and scope definitions with the technology's maturity, from conceptual development to full-scale implementation. The six perspectives are: theoretical assessment (TRL 1–2), laboratory scale (TRL 3–5), industrial scale-up (TRL 4–6), lifecycle integration (TRL 6–9), market consequences (TRL 6–9), and future estimations and target benchmarking (TRL 3–9). Recommendations are given for each perspective concerning the LCA goal, system boundary, functional unit, temporal and geographical scope, and applicability of conclusions.

Starting point for the present work is the hypothesis that LCA conclusions are inherently model-dependent, substantially shaped by modelling decisions made during the goal and scope definition stage, an issue that becomes particularly significant when assessing emerging technologies. As a possible way to overcome this, a multi-perspective approach that privileges explorative LCA modes is proposed and aligned with the TRL levels, providing structure to the application of LCA during technological development.

5.02.P-Tu407 Future Analysis of Environmental Impacts by Combining Japan's Energy System Model With LCA

Ryuta Hamaguchi¹, Etsushi Kato², Atsushi Kurosawa² and Norihiro Itsubo Dr¹, (1)Waseda University, Japan, (2)The Institute of Applied Energy, Japan

Since the adoption of the Paris Agreement, ambitious greenhouse gas emission targets have been set in many countries. In Japan, increasing attention has been directed toward more stringent future environmental roadmaps, such as the Carbon Neutral 2050 target. Furthermore, interest in environmental impact categories beyond climate change is growing, leading to an increase in studies incorporating multi-criteria analysis, including biodiversity, resource consumption etc.

Along with the growing awareness of environmental issues, diverse methodologies for assessing environmental impacts have been developed. Energy system models (ESMs) are computer programs that organize the components of an energy system, depicting the flow from energy production, transport, and conversion to consumption. The TIMES-Japan, developed by the Institute of Applied Energy (IAE), is an ESM used to determine Japan's future electricity generation mix and technology deployment, and is employed in environmental policy making and evaluation. Life Cycle Assessment (LCA) is a widely used methodology for quantifying diverse environmental impacts of products and services.

While both systems assess environmental impacts, each has its own challenges and constraints. ESMs tend to focus on CO₂ emissions and cannot evaluate environmental impacts other than climate change. On the other

hand, in LCA, the validity of the results depends on the degree of data availability, and a key challenge is the lack of background data when evaluating future technologies.

In previous studies that attempted to integrate ESMs and LCA, challenges such as database consistency and model-induced uncertainties have been identified. This study aims to quantify Japan's future environmental impacts while addressing these challenges.

In this study, the Premise framework is employed to couple the Ecoinvent with TIMES-Japan, thereby creating an inventory database that reflects a future energy system structured in accordance with Japan's environmental roadmap. The resulting database will be validated by comparison with other regional and global-scale case studies, and a framework will be developed to incorporate diverse social and technological scenarios.

The application of the developed framework contributes to the creation of background data for Prospective LCA, as well as to the incorporation of multifaceted environmental impacts into ESMs that have traditionally relied solely on CO₂ emissions as constraints.

5.02.P-Tu408 Sea vs Land Mining for Manganese Products: Comparative Prospective Life Cycle Assessment

Sonja Henriksson¹, Rickard Arvidsson² and Linus Hammar Perry³, (1)Chalmers University of Technology, Sweden, (2)Environmental Systems Analysis, Chalmers University of Technology, Sweden, (3)University of Gothenburg, Sweden

The transition to renewable energy will entail an increased demand for materials, but the future supply of many of the required materials is sensitive to geopolitical and trade factors. This is especially true for Europe, as many of these materials, including manganese, are principally mined overseas. One emerging technology that could provide an alternative source of materials is sea mining of polymetallic nodules, either from the deep sea or shallower waters (~100 m). However, little is known about its environmental impact. This has sparked a global debate, and several countries have called for a moratorium on sea mining until more is known about its environmental impact. To date, few studies have quantified the environmental impacts of sea mining in direct comparison with land-based mining, and no studies focus specifically on sea mining in European waters.

In this initiated study, we provide insight into the environmental impacts of sea mining in European waters by performing a prospective life cycle assessment of sea mining in an area of manganese-rich polymetallic nodules located in the shallow waters of the Bothnian Bay (~80 m). These impacts are also compared to those of “conventional”, land-based mining of manganese. To perform the assessment, data is provided by a collaborating sea mining company called Scandinavian Ocean Minerals. The aim of this study is to investigate which of the following options has the lowest environmental impact from a life cycle perspective: (1) manganese materials from nodules mined in the Bothnian Bay, or (2) manganese materials from ore mined on land.

The environmental impacts will be quantified for two manganese reference products important to the green transition and the current industry: 1 kg manganese sulfate used in battery production (e.g., in nickel-manganese-cobalt [NMC] lithium-ion batteries), and 1 kg ferromanganese used as an alloy in steel production. Main results will be presented for the impact categories global warming and mineral resources. We will also address biodiversity impacts using various biodiversity indicators. Considering the immature state of sea mining, a prospective inventory modeling is performed for the years 2030-2050. Background system data are adjusted over time according to different future scenarios.

With the results of this study, we hope to contribute with quantitative data and comparative perspectives to the growing global debate on the environmental impacts of sea mining.

5.02.P-Tu409 Coupling LCA and Stock / Flow Model for the Assessment of Concrete Waste Management Future Scenarios

Hiam Dahanni¹, Ziyang He², Eva Queheille¹, Yiwen Zhang³ and Myriam Saadé⁴, (1)Université Gustave Eiffel, France, (2)National Institute for Environmental Studies (NIES), Japan, (3)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (4)UTOPII, France

With about 6 billion cubic meter per year, concrete is the most widely used construction material at global scale. Because of its cement content, concrete manufacturing is responsible for a major part of the embodied greenhouse gases (GHG) of buildings and civil engineering infrastructure. Concrete manufacturing also leads to the extraction and use of primary resources, such as sand and aggregates, and to the generation of large flows of construction and demolition concrete waste. This study aims at assessing future concrete end-of-life strategies at

national level through the combination of MFA and LCA. Based on a functional unit defined as “1 management of the concrete waste volume generated in France during a 10 year period starting from 2025”, it explores scenarios incorporating sub-scenarios of waste outflow generation (business as usual BAU, less concrete, low demand, longer lifetime, recycling), as well as sub-scenarios of concrete end-of-life management (landfilling, backfilling, reuse, recycling in road and concrete, recycling in concrete with accelerated carbonation). The considered time horizon is 2025 to 2100 with a 10 year time step. The methodological approach consists in coupling Material Flow Analysis (MFA) with Life Cycle Assessment (LCA) through the integration of two MFA sub-models (inflow-based + stock-based) in the Flexibe Open Dynamic Material Systems Model (flodym), linked with supply chain graph-based LCA model developed in Brightway 2.5. Results show that scenarios maximizing the recycling and accelerated carbonation of recycled concrete aggregates might lead to a reduction of impacts on climate change due to CO₂ carbon capture. This environmental improvement is however counterbalanced by an increase in other environmental impact categories due to increase consumption in electricity for accelerated carbonation processes.

5.02.P-Tu410 Life Cycle Environmental Impacts of Digital Services: Mitigation Strategies for Video Streaming

Thomas Hennequin, Seunghye Lee, Alireza Soltani Nezhad, Martijn Kamps and Felipe Blanco rocha, Department of Circularity & Sustainability Impact, Energy and Material Transition, TNO, Utrecht, The Netherlands, Netherlands

The information and communication technologies (ICT) sector is responsible for large shares of energy and material consumption, contrary to common and misleading perceptions of digital ‘dematerialization’ or of the largely invisible ‘cloud’. End-user devices, networks, and data centers are very material parts of digital services supply chains. With an increasing share of global digitalization, the consequences of ICT are expected to grow in the future. Indeed, ICT is the cause of 5 to 7% of global electricity consumption, a share that is forecasted to double by 2030. ICT is also increasingly dependent on key minerals and metals, and is a primary driver of critical raw materials such as indium, gallium, and germanium. Robust models to quantify the environmental impacts of digital services’ supply chains are urgently needed.

This study presents a prospective life cycle assessment (LCA) of ICT focused on the digital service of video streaming and its supply chain. We modelled the life cycle environmental impacts of one hour of video-on-demand streaming to an LCD TV in the EU, including interventions such as substituting components in TVs, and alternative hardware in data centers. Results provide insights into the contribution of the main stages of the supply chain as well as into the mitigation potential of the interventions considered.

This work illustrates the ability of prospective LCA to provide insights into digital services and associated explorative mitigation strategies. It highlights the need for models that (1) account for the entire life cycle of digital services, and (2) include impacts beyond climate change. Insights gained following this approach lead to recommendations that support individuals, technological innovators, and policymakers; three actors who all have a role to play in advancing a resilient and sustainable ICT sector.

5.02.P-Tu411 Towards robust and consistent, yet technology-specific prospective life cycle assessment

Rosalie van Zelm¹, Mark Huijbregts² and Mitchell van der Hulst¹, (1)Radboud University, Netherlands, (2)No Affiliation, Netherlands

As a technology develops from idea to production, we gather information and thereby reduce the uncertainty when estimating the industrial-scale environmental footprint. We have a growing knowledge of our new technology, but at the expense of influence. At the time that we know a lot, we have little influence left, so it becomes difficult to decrease the footprints. At an early stage, we have more influence, but little information. Prospective Life Cycle Assessment (pLCA) allows an emerging technology, still in early development, to be modeled at a future, more-developed phase. The goal of our work is to practically demonstrate a comprehensive and generalizable approach to perform technology-specific pLCA, which can lead to realistic environmental impact predictions on industrial scale.

For this, we applied a three-phase pLCA framework to case studies on varying technologies. Each technology had a current TRL between 5 and 7 and was upscaled to TRL 9, including scale-up changes, and sometimes

industrial learning and/or external developments. Further, methods were developed to estimate industrial scale footprints for pharmaceutical synthesis from industrial scale data. And a method was developed to assess process-specific learning and include external developments.

We showed that the relative importance of each technological development to the future environmental footprint of a new technology can differ between product systems. Further, including a range of impact categories is important to prevent burden shifting and to focus on minimizing overall environmental impact. Finally, technology preference can change in the future due to developments in the background systems, leading to quantitative changes in the impacts of the foreground system, but also to an altered avoided burden. Our new methods to quantify impacts of upscaling technologies showed that Process-specific learning curves in prospective LCA provide practical solutions for integration of learning in foreground and background processes of new technologies produced at industrial scale. Moreover, they enable contribution analyses and the separate assessment of developments in the foreground and background system. More process-specific learning curves need to be developed to ensure robust upscaling. Our developed framework and methods contribute to more certain predictions, ensuring early-phase influence to minimize environmental impacts of new technologies.

5.02.P-Tu412 Prospective Macro-Level Life Cycle Assessment: A Systematic Review

Aaron Paris, Jeroen Guinée and Nils Thonemann, *Institute of Environmental Sciences (CML), Leiden University, Netherlands*

Transitions to sustainable societies require assessments of future environmental impacts at the macro-level. We examined how prospective process-based Life Cycle Assessment (LCA) is used to model environmental impacts at national to global scales. Our research objectives were to (i) provide an overview of modelling approaches in prospective macro-level LCA; (ii) identify common pitfalls and best practices; and (iii) highlight key challenges and suggest priorities for future research.

We reviewed 86 peer-reviewed studies, selected from an initial set of 925 articles, with a primary focus on how system scaling, temporal evolution, and temporal distribution were addressed in the inventory analysis phase. In addition, we assessed elements from the other three LCA phases, including research objectives, temporal scope, system boundaries, and the treatment of sensitivity and uncertainty. We also examined terminology use and transparency.

We classified the reviewed approaches by how system scaling is treated in the foreground system: (i) coupling with Dynamic Stock Models, which captures stock dynamics but overlooks socio-economic aspects; (ii) coupling with Energy System Models, which provides detailed insights but is limited to the energy sector; (iii) coupling with Integrated Assessment Models, which offers broader socio-economic coverage but operates at coarse resolution and typically requires collaboration with model developers; and (iv) uncoupled approaches, which allow flexibility but risk oversimplification. We identified twelve key pitfalls, including simplified treatments of system scaling, temporal dynamics, and distribution; a narrow climate focus; limited scenario diversity; and weak internal consistency. We also highlight best practices for avoiding these pitfalls.

Our review reveals a diverse field with inconsistent terminology, assumptions, and modelling practices. To strengthen the field, we recommend improving transparency and adopting consistent terminology; improving the representation of the complexity of sustainability transitions; strengthening policy relevance; and developing methodological guidance. Addressing these priorities will improve the robustness of prospective macro-level LCA and advance our understanding of sustainability transitions.

5.02.P-Tu413 Toward a Generalized Scale-Up Framework in Prospective Life Cycle Assessment

Marc Majó¹, Jacopo Sorani¹, Bernd Nowack¹ and Roland Hirschier², *(1)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (2)Technology & Society Laboratory, Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland*

Prospective Life Cycle Assessment (pLCA) plays a crucial role in evaluating emerging technologies from the early stages of development. A major challenge is the absence of generalized approaches for translating laboratory-scale information into industrial-scale inventories. Existing scaling methods, engineering approximations, simulations, and empirical relations, have been applied in isolated studies but lack a unified, generally applicable structure. Laboratory data typically shows inflated electricity demand, excess solvent use, limited separation performance, and batch-related losses, producing non-linear deviations when extrapolated to

industrial conditions.

This study develops a systematic framework for scaling production steps within pLCA. We combine a structured review of upscaling approaches with an assessment of the physical and operational mechanisms driving scale-dependent changes. A critical-point analysis identifies the flows most affected by scale, including energy use, solvent and reagent consumption, waste generation, and infrastructure effects, clarifying which parameters require adjustment.

A general upscaling strategy is introduced based on dominant unit operations such as heating, cooling, drying, and solvent recovery, supported by a calculation tool that derives energy and fuel demand from low-TRL data and enables scenario building. Minimum data requirements (stoichiometry, yields, solvent and reagent flows, thermal loads, waste streams) provide a consistent basis for extrapolation.

Sector-specific mechanisms in petrochemical, biochemical and pharmaceutical systems are incorporated, accounting for thermodynamic integration, mass-transfer limitations, bioreactor behavior, high-purity separation and utility-intensive operations.

The resulting framework offers a transparent and reproducible pathway to construct industrial-scale inventories when only early-stage information is available, improving robustness, comparability and interpretability in pLCA.

5.02.P-Tu414 Toward the ecodesign of emerging technologies: a collaborative bibliographic tool for technology upscaling modelling in LCA

Lucas Riondet¹, *Véronique Perrot Bernardet¹, Maud Rio² and Peggy Zwolinski², (1)Arts et Metiers Institute of Technology, CNRS, Bordeaux INP, I2M, UMR 5295, France, (2)Univ. Grenoble Alpes, CEA LITEN DTNM, France*

The upscaling of emerging technologies is a multifaceted socio-technical phenomenon covering technological development and deployment in society to meet societal imperatives (e.g. sustainability). It has been characterized in previous research by five archetypes: upsizing from laboratory to industrial scale (archetype 1), mass producing related to industrial engineering (archetype 2), reaching a level of cumulated service (archetype 3), integrating a complex system (archetype 4) and down-limiting related to planetary boundaries (archetype 5). Each upscaling archetype encompasses a specific industrial system vision, referring to a great variety of lifecycle inventory modelling. To help LCA practitioners and designers collaborate on the upscaling modelling, this research paper presents a methodology supported by a literature management tool: the upscaling archetype (UA) by Engineering Field (EF) matrix. A case study on the photovoltaic sector is presented to show the diversity of available models. The use of the UA-EF by LCA practitioners and technical engineers could induce the design team to take ownership of the upscaling archetypes and help generate shared representations and LCA practices. This tool is intended for distribution to research institutes and companies to be regularly updated and strengthen interdisciplinarity between engineering fields and LCA.

5.02.P-Tu415 A Joint Conceptual and Computational Structure for Dynamic and Prospective LCA

Fabio Sporchia¹, **Thomas Schaubroeck²** and **Massimo Pizzol³**, *(1)Aalborg University, Denmark, (2)Luxembourg Institute of Science and Technology, Luxembourg, (3)Planning, Aalborg University, Denmark*

As sustainability challenges intensify and decision-makers increasingly seek to anticipate future consequences, a growing number of studies are extending LCA to account for temporal aspects. However, the terminology utilized to describe this kind of studies remains inconsistent. In particular, the distinction between “prospective LCA” and “dynamic LCA” is often unclear, and the underlying computational approaches are not always clearly defined. This lack of clarity limits effective communication, comparison of studies, and the development of standardized and consistent tools.

We set this work specifically to clarify the differences between “prospective” and “dynamic” LCA studies and focus on representing this through a matrix-based computational structure in parallel with the discourse on semantics. First, we mapped the most commonly utilized definitions of prospective and dynamic LCA, particularly focusing on the standard inventory and impact assessment phases. Second, we expand the classic matrix notation to reflect all temporal dimensions that can potentially be captured in LCA. Third, we map the relations between the existing tools that allow prospective and/or dynamic LCA and the classification we

propose.

We summarize a set of definitions and a classification of dynamic and prospective LCA studies that prioritize the computational distinctions. We discuss the potential and limitations in the context of existing approaches and tools, and the associated practices. We highlight that trade-offs can arise between comprehensiveness, computational effort, and data requirement. We discuss the implications of accounting for the temporal aspects in all the elements of the classic matrix-based calculation approach to provide clear distinctions. We believe that this pragmatic approach should be used in parallel with the discourse on semantics. The focus is therefore on classifying a model based on its structure rather than based on its name here. The classification can facilitate modelling choices to match the data availability and the needs of decision-makers.

5.02.P-Tu416 Building a prospective, scenario-based environmental assessment of future European battery recycling by coupling Material Flow Analysis and Life Cycle Assessment

Harmjan de Vries¹, José Mogollón¹, Ioan-Robert Istrate¹, Valerio Barbarossa¹, Max Tippner² and Franziska Maisel², (1)Leiden University, Netherlands, (2)Fraunhofer-Gesellschaft, Germany

Driven by the increase in electric vehicles, portable electronics, light electric mobility, and stationary energy storage, battery waste in Europe is increasing rapidly and becoming more complex due to differences in chemistries, applications, and recovery pathways. Projecting the environmental impacts attributed to this waste stream and identifying potential environmental trade-offs is needed to shape policy, but these impacts are highly sensitive to several key parameters that are not typically included in traditional Life Cycle Assessments. Changes in battery demand, development of new battery chemistries and recycling technologies, alternative second-life pathways such as refurbishment and reuse, as well as decarbonisation of the energy grid, all have major implications for the environmental performance of future recycling systems.

This study aims to cover these dynamic conditions by combining a scenario-based material flow analysis model with prospective Life Cycle Assessment. We cover the main battery types used in Europe across all applications: lead-acid, lithium-ion, nickel-cadmium, nickel-metal hydride, and alkaline batteries. A hierarchical material flow model tracks the end-of-life flows of products, components, materials, and elements across three scenarios - Business As Usual, Increased Recovery, and Circularity. These flows are integrated into a prospective LCA using dynamic background inventories generated with PREMISE, which applies energy- and industry-system transformations from integrated assessment models to reflect future electricity mixes, fuel use, and material production. Integrating both dynamic foreground flows and background conditions in this way allows for consistent comparison between system parameters and makes it possible to isolate the drivers most responsible for future variability in environmental impacts.

Preliminary results show that the greenhouse gas impacts of recycling lithium-ion batteries are projected to exceed the impacts of all other battery types combined by 2040 in all three scenarios. Sensitivity analysis will identify the most influential system parameters, with a particular focus on how shifts in lithium-ion chemistries affect recoverability and environmental impacts.

5.02.P-Tu417 Uncertainty and Sensitivity of Scenario Choices in Prospective LCA

Jóhanna Sofía Guldbrandso Nolsøe¹, Súsanna Rakul Foldbo Hjallnaðfoss¹ and Massimo Pizzol², (1)Aalborg University, Denmark, (2)Planning, Aalborg University, Denmark

Uncertainty is recognised as inevitable in prospective Life Cycle Assessments (LCAs), and scenarios are a widely suggested approach to address uncertainties about future developments. Recent methodological advancements have been made to systematise the generation of prospective background systems. However, it is unclear how the use of such future scenarios affects the comparison between technologies. This study investigates the influence of scenario-related uncertainty on the results of prospective LCAs.

Using a novel LCA tool, we assess the same set of technologies under different future scenarios generated in Premise. The modelling spanned across 19 future scenarios for the scenario years 2030, 2040, and 2050. Four technologies from different sectors were chosen as case studies to enable analysis of potential sector-related differences: electricity, transport, steel and agriculture. Each technology was modelled for two countries to analyse potential geographical differences. For continuity and comparability, the technologies were modelled for one European and one Asian country. The scenario results were analysed to identify which conditions lead to ranking one alternative as better than the other, and how consistent the evaluation was across future scenarios.

The results indicate a sector-specific sensitivity for the climate change impact category, depending on which scenarios are included in the analysis. This sensitivity is highlighted by the example of electricity, where the choice of scenario can shift the ranking of the regional impact scores. This effect was not observed for the transport, steel and agricultural sectors. Consequently, the choice of scenarios introduces an additional source of uncertainty, as the ranking of alternatives becomes dependent on the selection of scenarios. In a decision-making context, this means that scenario choices could lead to different conclusions.

This study highlights and analyses the existing gaps in knowledge about the implications of scenario choices for prospective LCIA results. This work further emphasises the importance of using multiple scenarios to explore a range of possible futures, and to be aware that outcomes may vary substantially depending on scenario choices. Decisions supported by prospective LCA should consider the scenario-dependency of results as a critical dimension of uncertainty that can influence the robustness and relevance of conclusions.

5.02.P-Tu418 Prospective Life Cycle Assessment of Novel Nanofiltration Membrane Manufacturing Methods for Sustainable Scale-Up

Pablo Almendras Flores and Rob Lammertink, University of Twente, Netherlands

As water scarcity becomes more severe, membranes have emerged as a major technology for water treatment and purification, acting as a selective barrier that allows water to pass while retaining contaminants. Among them, nanofiltration (NF) membranes specifically remove small organic molecules and multivalent ions. However, their manufacturing relies on fossil-based raw materials and solvents. Novel fabrication techniques have shown potential as sustainable alternatives to conventional processes, yet they are still in early development stages. In this work, a prospective Life Cycle Assessment was combined with process modelling to evaluate the environmental performance of novel fabrication methods, ranging from laboratory scale to state-of-the-art techniques, and study their scalability potential. The manufacturing process of a hollow fiber nanofiltration membrane module consists of four steps: fiber support fabrication, nano coating, drying, and module assembly. Since the last two steps are always required for membrane conditioning and module preparation, the comparison was focused on the first two steps. Three technologies were evaluated for the first step and two for the second. The results were quantified per 1000 m², and the methods with lowest environmental burden for each step were identified. Implementing emerging technologies, compared to the conventional process, led to a CO₂ reduction of up to 75% in the fiber support fabrication and up to 46% in the coating step. Considering all four steps of the process, the total CO₂ emissions were reduced by up to 37%. Hotspots of the process were identified, and a sensitivity analysis assessed their influence on the overall environmental impacts. The parameters studied included electricity source, water use, glycerine use, pH conditions and solvent recycling. These insights will help membrane researchers and industry manufacturers identify critical improvement areas and move toward more sustainable membrane production.

5.02.P-Tu419 Precision in Prediction: Mitigating Material-Related Uncertainty in Prospective Product Carbon Footprinting

Hummen Torsten¹, Christoph Helbig² and Alexandra Belyaeva¹, (1)Robert Bosch GmbH, Germany, (2)University of Bayreuth, Germany

Early-stage prospective life cycle assessment is valuable for supporting product development decisions before design choices become fixed and costly to modify. Because material production often dominantly contributes to cradle-to-gate product carbon footprint (PCF), early uncertainty in provisional material type, supplier choice and recycled content can strongly influence prospective PCF estimates. At the same time, the growing integration of automated assessment tools into digital design workflows requires PCF calculations to rely on minimal early design information. The approach developed here is demonstrated using mechanically engineered products as a case study.

This study addresses the challenge of quantifying and transparently representing early-stage PCF uncertainty when only limited information is available. It investigates how uncertainty evolves as additional inventory data becomes accessible and whether automated introduction of new information layers can reduce it.

A multi-layer automated framework is developed that sequentially incorporates: (1) proxy material information and estimated net mass; (2) manufacturing processes predicted from historical data; (3) statistically derived scrap-rate distributions for the predicted process; and (4) geometry-based scrap estimation. At each layer, uncertainty in material properties, scrap behavior and process characteristics is represented through probability distributions and propagated to the PCF via Monte Carlo simulation, enabling a structured evaluation of how uncertainty evolves as the LCI becomes more detailed.

It is hypothesized that uncertainty reduction in automated early-stage PCF estimation depends not only on adding new information but on how each layer interacts with and propagates assumptions from earlier stages. Geometry-based scrap estimation is expected to refine uncertainty ranges more reliably where applicable, as it introduces part-specific geometric constraints that depend less on upstream predictions.

This research contributes a transparent approach for automated early-stage PCF estimation that incorporates automated uncertainty quantification and evaluates how uncertainty evolves across sequential data layers, supporting prospective LCA in increasingly digital engineering environments where design decisions must be made with incomplete early-stage information.

5.02.P-Tu420 Dynamic-prospective or time-explicit life cycle assessment: unite two novel approaches

Ladislav Lang-Hogrefe, JOANNEUM RESEARCH, Austria

Dynamic and prospective methods are one of the largest growing research areas in life cycle assessment (LCA). Time differentiating approaches promise to fill gaps in the lacking accuracy of static average and data collected in the past. While previous methods had either dealt with the temporal evolution of transition dynamics or with the temporal distribution of process dynamics, recently two developments have arisen that cover both aspects.

Time-explicit LCA with *bw_timex* includes arbitrary temporal distributions of process flows in front of the evolution of prospectively modified background databases. Dynamic-prospective LCA with *Prosperdyn* develops transition paths for industry systems transforming towards climate neutrality. Although both developments consider absolute and relative temporal information as well as dynamic impact assessment, significant differences occur, which concede both their individual field of application.

The current work attempts ascertaining which of the two software packages suites better for different applications. Areas of interest are biomass growth, energy and industry transformation activities or delayed emissions of carbon capture. The flexibility in relative time information is a great advantage of *bw_timex*. *Prosperdyn* considers the timing of infrastructure deployment separately and avoids depreciation of construction emissions.

In conclusion, the parallel development bears witness of the relevance of a combined dynamic prospective method. Two methods try to fill quite similar research gaps. At this point, there are two possible solutions for continuing methodological research: either allocating distinct use cases to the respective software or finding a sufficient way to integrate the advantages of one method into the other for providing one joint method.

5.03 Chemicals, Dyes and Textiles: Advancing Toxicological Assessments and Life Cycle Analysis for a Safe and Sustainable Future

5.03.T-01 Benchmarking Environmental Impacts in the Safe and Sustainable Design of Chemicals

Elisabetta Abbate¹, Grazia Maria Cappucci², Leo Posthuma³, Ad M. J. Ragas⁴, Mark Huijbregts⁴ and Serenella Sala⁵, (1)Department of Environmental Science, Radboud University, Nijmegen ; European Commission, Joint Research Centre, Ispra (VA), Netherlands, (2)Seidor, Milan, Italy, (3)Department of Environmental Science, Radboud University, Nijmegen; Centre for Sustainability, Environment and Health (DMG), National Institute for Public Health and the Environment, Netherlands, (4)Department of Environmental Science, Radboud University, Nijmegen, Netherlands, (5)European Commission - Joint Research Centre (JRC), Italy

The introduction of the Safe and Sustainable by Design (SSbD) framework has emphasized the importance of conducting early-stage environmental sustainability assessment – through Life Cycle Assessment (LCA) – to anticipate environmental burdens of chemicals and materials before they enter the market. This has led to efforts to overcome the limited availability of data for constructing robust early-stage Life Cycle Inventories (LCIs), for example by estimating energy and mass balances, or developing streamlined tools for preliminary assessments of emerging technologies.

Nevertheless, meaningful early-stage assessments depend on the definition of an appropriate benchmark, which is a reference level of environmental performance against which the impacts of a novel chemical or technology are compared. While defining a benchmark is relatively straightforward for LCAs of existing products, the definition of the benchmark for chemicals that assist early-stage assessments is much more challenging.

The goal of this study is to explore how impact values vary across chemicals to establish a benchmark that can serve as a basis for applying the SSbD framework to early-stage design of chemicals. First, we selected 71 organic base chemicals from the related BAT Reference Documents for Large Volume Organic Chemicals (BREF). We calculated the impacts of such selected chemicals, in terms of 1 kg of chemical considering a cradle-to-gate system boundary using EF3.1 method. Third, for each impact category, we compiled the impact values of all the 71 organic base chemicals, identified the full range, ranked the results and split them into quartiles.

This benchmark can ultimately help to – among other - (1) evaluate for which impact categories the cumulative distribution is flat (no impact differences) or vary diverse (steep), (2) understand the (molecular, process, factory) "features" driving the differences, and (3) optimise the innovation towards areas that matter most, benchmarked against the context of the worst-performing alternatives.

This study highlights the need for further discussion on the information needed to establish robust benchmark, including choices of system boundaries and functional unit considerations. Future works will be dedicated in testing and adapting such classes of performances and proxy references, and explore the possibility to create classes of performances for the safety component of the SSbD framework.

5.03.T-02 Potential of Cyanobacterial Pigments for Sustainable Applications in Textile Dyeing

Mariana Reimão¹, Liliana Almeida¹, Nádia Eusébio², Vitor Vasconcelos¹ and Marisa Freitas³, (1)CIIMAR, CIMAR-LA, University of Porto, Portugal, (2)NGC, KOD-Bio, Portugal, (3)E2S, Polytechnic of Porto (E2S|P.Porto), Portugal

Growing awareness of the environmental and health hazards posed by synthetic colourants has renewed interest in natural substitutes across various industries, such as cosmetics, food, and textiles. Cyanobacteria are a group of photosynthetic microorganisms known to produce colourful natural pigments as chlorophylls, carotenoids and phycobiliproteins, which have demonstrated potential for large-scale industrial applications [1,2,3], leading to a more sustainable future. This study evaluates the feasibility of using pigments from cyanobacteria as sustainable colourants for the textile industry.

Cyanobacteria strains were obtained from LEGE-Culture Collection and cultivated in Z8/ Z8-TM 25 medium, supplemented with Vitamin B12. Textile dyeing experiments were conducted on both synthetic and natural fibres, considering the pigment content in the aqueous extracts of each strain. Dyeing was performed with a 1:10 bath ratio, using NaCl as an exhausting agent, under a 120-minute cycle at 40°C. A post-dyeing fixation process was applied to enhance colour retention. The dyed fabrics underwent quality control assessments for colour reproduction and fastness to rubbing, washing, water, and perspiration, following European Standards (UNE-EN ISO) for textiles.

In general, the results suggest a better dyeing performance of the studied pigments in the semi-synthetic fibre than in the natural fibre, indicating a higher affinity for the semi-synthetic fibre. According to the classification assigned to these pigments, the results are in line with what is expected for direct dyes. More promising colours were obtained with marine strains, for both viscose and cotton. Regarding colour change assessment, industrial

laundering had the worst results in colour fastness, for both marine and freshwater strains. In general, good results were obtained in the staining assessment for the fibres tested, with values comprised between 3 (fair) and 5 (excellent).

In summary, cyanobacterial pigments show considerable promise as sustainable substitutes for synthetic dyes in the textile industry, provided certain conditions are met. The method currently employed already constitutes a more environmentally friendly approach to textile dyeing. However, additional optimisation, especially through the incorporation of alternative dyeing auxiliaries, may further improve the efficiency and overall performance of this technique.

5.03.T-03 Toxicity of the Anthraquinone Dye Alizarin to Early Life Stage Zebrafish

Steve Wiseman¹, **Justin Dubiel¹**, Luis Terrazas Salgado¹, Natalia Oliveira de Farias², Lauren Zink³, Rayen Morales Urrutia¹, Cameron Hunter Collins⁴, Lauren Eagon⁴, Laura Pizarro¹, Manos Vogiatzakis¹, Carter Langevin¹, Jon Doering⁴ and Gisela Umbuzeiro², (1)University of Lethbridge, Canada, (2)State University of Campinas (UNICAMP), Brazil, (3)University of British Columbia, Canada, (4)Louisiana State University, United States

Natural and anthropogenic chemicals are an essential part of modern society, but there are growing concerns about environmental contamination and its effects on organisms. As a result, production and use of more sustainable materials has become a focal point in many industries. This is especially true in the textile industry where there is increasing focus on use of natural dyes as ‘safer’ alternatives to synthetic dyes. One of the oldest natural dyes, alizarin, has emerged as a potential candidate for use in waterless dyeing processes. A small number of studies have shown that alizarin might not be a safe alternative to synthetic dyes, but additional research is needed to assess its toxicity. In this study, zebrafish (*Danio rerio*) embryos were exposed to alizarin by microinjection, and developmental toxicity and associated molecular mechanisms were investigated. Exposure to alizarin resulted in non-monotonic increases in mortality. Additionally, the proportion of embryos exhibiting one or more developmental malformations (i.e. spinal curvature, yolk sac and pericardial edema) followed the same non-monotonic trend. Dose-dependent reductions in body length, eye area, head area, yolk area, and cranial melanophore count were also observed. In a behavioural assay, exposure to alizarin caused dose-dependent increases in average swimming velocity that persisted through post-stimulus recovery periods. Mechanistically, mRNA abundance of *cyp1a* was increased in embryos exposed to alizarin. Alizarin also activated the zebrafish AhR2, in vitro. Exposure to alizarin also increased mRNA abundance of the oxidative stress response genes *gpx1a*, *sod1*, *gst*, and *cat*. These results suggest that embryotoxicity of alizarin is at least in part mediated by the AhR, with contribution from oxidative stress. Additional work is ongoing to assess the toxicity of other anthraquinone dyes to early life-stage zebrafish.

5.03.T-04 Safe-by-design: Searching for Non-toxic and Non-mutagenic emodin derived dyes

Natália de Farias¹, Giovanna Rodrigues¹, Gabrielly Groto¹, Otto Seppänen², Petri Heimonen², Riikka Räisänen² and Gisela Umbuzeiro¹, (1)Universidade Estadual de Campinas, Brazil, (2)University of Helsinki, Finland

Dyes play an important role across various industrial sectors. Although many synthetic dyes are available, there is increasing interest in replacing them with natural alternatives. Emodin, a natural dye extracted from the fungus *Cortinarius sanguineus*, shows high technological potential for waterless dyeing methods such as supercritical CO₂ (sc-CO₂). However, emodin is highly toxic to aquatic organisms and mutagenic due to DNA intercalation. Chemical modification of emodin (derivatization) is a promising strategy to reduce or eliminate these negative effects. This study evaluated the aquatic toxicity and mutagenicity of eight emodin-derived dyes to identify promising natural-based alternatives. Emodin derivatives (purity >98%) were provided by the Colour4CRAFTS project. Acute toxicity was assessed through concentration–response tests with *Daphnia similis* (48 h, OECD 202) and zebrafish embryos *Danio rerio* (96 h, FET, OECD 236). Tests included solvent and negative controls and were approved by the UNICAMP Ethics Committee. Mutagenicity was evaluated at each compound's maximum solubility using the Microplate Agar (MPA) version of the Salmonella/microsome assay with TA1537, TA100, YG1041 and TA98 strains, with and without metabolic activation (S9). TA1537 strain was included due to its known sensitivity to anthraquinones. All derivatives were less toxic to *Daphnia* than emodin. For zebrafish embryos, five derivatives tested also showed reduced toxicity. Emodin was mutagenic only in TA1537 (+S9) and negative in the other strains. Among the derivatives, EMD1, EMD4 and EMD8 exhibited a mutagenic response similar to emodin in TA1537 (+S9). EMD4 additionally showed

mutagenicity in TA100 ($\pm$ S9) and TA98 (?S9), while EMD8 was mutagenic in TA100 and TA98 (?S9), indicating the derivatization led to other forms of interaction with DNA. EMD2, EMD3, EMD5, EMD6 and EMD7 were non-mutagenic in all strains. Derivatization successfully reduced acute toxicity for all compounds except EMD8, and five derivatives lost the ability to induce mutations. EMD3 and EMD7 were the most promising dyes, showing no acute toxicity to *Daphnia* and no mutagenicity. Ongoing fish embryo tests are being done and then we will be able to verify if it is possible to obtain an emodin derivative that is not toxic to both, organisms and not mutagenic. This work illustrates the safe-by-design concept and reinforces the importance of toxicological evaluation in the development of new dye products.

5.03.T-05 In Silico Approaches for the Prediction of Climate Indicators for Life Cycle Impact Assessment *Arianna Sgariboldi, Nicola Chirico and Ester Papa, DiSTA, University of Insubria, Italy*

Life cycle assessment (LCA) is a valuable tool for analysing and managing the environmental impact of substances throughout their life cycle. One of the four stages that define LCA is life cycle impact assessment (LCIA), during which various climate change-related indicators are analysed and quantified, such as global warming potential (GWP) and ozone depletion potential (ODP). The Safe and Sustainable by Design (SSbD) framework suggests the use of in silico models based on machine learning techniques, such as quantitative structure–activity relationships (QSAR), to address potential data gaps relating to the activities and/or properties of existing and new chemicals and chemical alternatives. In this study, QSAR models were developed to estimate the most used indicators and properties in climate assessments, thereby helping to overcome the lack of experimental data for existing and new chemicals. QSAR models were developed using multiple linear regression by means of ordinary least squares (MLR-OLS) and variable subset selection (VSS) to predict GWP, ODP and removal efficiency for a large dataset of around 700 chemicals, divided into 20 different structural classes (mostly halogenated), compiled from the latest Scientific Assessment of Ozone Depletion report published by the World Meteorological Organization (WMO) in 2022. The best QSAR models were selected based on multiple metrics of goodness of fit, robustness, and predictive ability, as well as an evaluation of the applicability domain. These models have R^2 values ranging from 0.75 to 0.84 and Q^2_{ext} values ranging from 0.70 to 0.88 and have proven to be reliable tools for predicting climate indicators. The molecular descriptors selected in the best models mainly encoded electronic and geometric properties, as well as the presence of specific atoms and fingerprints. These new QSAR models are available in the free software QSAR-ME Profiler 2025 and can be easily applied to predict the properties of new chemicals, thereby reducing data gaps in environmental assessments. Furthermore, they can be incorporated into sustainability evaluation processes to support the selection of environmentally preferable alternatives and to provide valuable input for the LCIA stage of the LCA, as well as for the SSbD framework.

This research is funded by the Italian Ministry of Education, University and Research, PhD grant n° 39-034-C7-DOT13C7288-10505 to Arianna Sgariboldi (CUP: J13C23000210001)

5.03.P Chemicals, Dyes and Textiles: Advancing Toxicological Assessments and Life Cycle Analysis for a Safe and Sustainable Future

5.03.P-Mo334 C.I. Direct Blue 218 induces micronuclei in somatic cells and DNA damage in sperm of a model invertebrate in in vivo experiments

Gabriely Fernanda Groto Militão, Amanda Rocha Rodrigues, Marina Tenório Botelho and Gisela Umbuzeiro, State University of Campinas (UNICAMP), Brazil

C.I. Direct Blue 218 (DB218) is a copper-chelated dimethoxybenzidine-based azo dye used in textile and paper industries. It was classified by IARC as class 2B as there are few and conflicting data available. Also no data on its aquatic toxicity was found in the literature. The invertebrate *Parhyale hawaiiensis* has been recognized as a new model in ecotoxicology, is easily cultured in the lab and can provide insights on different endpoints including mortality, reproduction inhibition and genotoxicity in somatic and germ cells. Its ability to digest cotton fibers can also be used as an alternative route of exposure. This study evaluated the effects of DB218 (purity >95%) in *P. hawaiiensis* observing mortality (via water) and reproduction (via dyed cotton ingestion). Its genotoxicity was evaluated by the micronuclei test in somatic cells (hemocytes) and in sperm cells (DNA damage). To complement the bacterial mutagenicity data a test with an alternative strain of *Salmonella* (YG1041) that is very sensitive to azo dyes was conducted. Acute toxicity (96 h) with neonates of *P. hawaiiensis* followed a standardized protocol. A chronic test was conducted with 60 organisms aged 80 days to assess the reproductive

effects of the ingestion of dyed cotton fibers. After 40 days the number of neonates per female was recorded and compared to the historical control. For bacterial mutagenicity, DB218 was tested in the miniaturized version of the Salmonella/microsome assay (Microplate Agar, MPA) with the YG1041, without and with S9 (5, 10, and 30%). Micronuclei frequency was assessed in hemocytes of 30 adults of *P. hawaiiensis* after 96 h exposure. Slides were stained with 10% Giemsa, and 500 cells per organism were counted. For DNA damage, the comet assay in sperm cells was performed after 96 h exposure of 16 adult males. One hundred comets per gel were analyzed (%DNA in tail) using Comet Score 2.0. No acute toxicity was observed in *P. hawaiiensis* and ingestion of DB218 dyed cotton did not affect reproduction. DB218 showed no mutagenicity in YG1041 without and with metabolic activation (S9). However, DB218 significantly increased micronuclei frequency in hemocytes and caused sperm DNA damage. This work provides evidence that DB218 is a possible germ cell mutagen. Experiments are being conducted using enzyme biomarkers to help elucidate its mode of action. *P. hawaiiensis* model seems to be a promising tool in eco/genotoxicology.

5.03.P-Mo335 Integrating Cyanobacterial Pigments into Cellulosic Textiles To Enhance Circularity and Sustainable End-of-Life

Marisa Freitas¹, Mariana Reimão², Liliana Almeida² and Vitor Vasconcelos², (1)E2S, Polytechnic of Porto (E2S|P.Porto), Portugal, (2)CIIMAR, CIMAR-LA, University of Porto, Portugal

The end-of-life management of textiles is a critical environmental challenge, particularly for cellulosic fibers, which can be designed to enhance biodegradability. Using biobased colorants and coatings from cyanobacteria offers dual benefits: sustainable pigmentation and facilitation of fiber breakdown in composting or soil. These bio-based approaches also reduce the ecotoxicity risks associated with conventional synthetic dyes, which are often persistent, bioaccumulative, and harmful to soil and aquatic organisms. Furthermore, fiber configurations, including yarn structure and fabric density, can influence microbial accessibility and enzymatic depolymerization, linking material design directly to environmental safety and sustainable end-of-life outcomes. This review synthesizes recent advances in applying cyanobacterial pigments and biomass in textile production, highlighting their use as natural colorants and functional coatings with low ecotoxicological impact. It examines how textile configurations influence biodegradation and environmental safety, considering the interplay between fiber type, structure, microbial susceptibility, and potential contaminant release. Particular attention is given to phycobiliproteins and whole biomass applications, focusing on their binding efficiency to cellulosic substrates and compatibility with biological degradation.

Cyanobacterial pigments have been reported to provide effective and relatively stable coloration of cellulosic fibers, while potentially minimizing ecotoxicological concerns. Coatings incorporating pigment extracts or whole biomass appear promising in enhancing microbial degradation, although further empirical validation is needed. Overall, the reviewed literature indicates that the combination of natural bio-based pigmentation with intentionally designed fiber configurations may facilitate accelerated biodegradation and reduce environmental risks, without substantially compromising material performance during use, though these effects remain context-dependent and warrant additional investigation.

Integrating cyanobacterial pigments and biomass with fiber configurations offers a promising pathway toward sustainable, circular textile lifecycles. By linking pigmentation, fiber design, and ecotoxicological considerations, these bioinspired approaches support environmentally responsible end-of-life scenarios and a transition toward a safer, more circular textile industry.

This work was carried out within the scope of the project “TextileWaVE” (COMPETE2030-FEDER-00900800), funded by the European Regional Development Fund (FEDER) through the Thematic Programme Innovation and Digital Transition (COMPETE 2030), and by the Fundação para a Ciência e a Tecnologia (FCT), I.P.

5.03.P-Mo336 Microbial Decolourisation of Commercial Textile Dyes

Liliana Almeida¹, Diogo Alexandrino¹, Rui S. Oliveira², Maria de Fátima Carvalho¹ and Marisa Freitas³, (1)CIIMAR, CIMAR-LA, University of Porto, Portugal, (2)Centre for Functional Ecology, Associate Laboratory TERRA, Department of Life Sciences, University of Coimbra, Portugal, (3)ESS, Polytechnic of Porto, Portugal

Synthetic dyes used in textile processing are increasingly recognised as environmental contaminants of concern due to their aromatic complexity, persistence and potential ecotoxicity. Current EU regulatory developments are placing growing pressure on the textile industry to mitigate dye pollution. In this context, biological decolourisation strategies offer promising low-impact alternatives for treating dye-containing effluents. This study assessed the ability of bacterial and fungal isolates obtained from composting environments to decolourise four commercial textile dyes. Bacterial and fungal isolates previously recovered through a cellulolytic culturomics workflow were tested against four industrial dyes. Assays were performed at two dye concentrations (0.03 and 0.06 g/L) in Nutrient Broth, using incubations at 28 °C (bacteria) and 25 °C (fungi). Decolourisation was quantified spectrophotometrically at dye-specific wavelengths over seven days. For fungal assays, both live and autoclaved fungal biomass were evaluated to distinguish the contributions of active biological processes and non-active mechanisms to colour removal. All assays included triplicates and uninoculated controls. Bacterial isolates exhibited significant variation in decolourisation efficiency across dye types ($p < 0.05$). Several strains exceeded 80% decolourisation for Red, Yellow, and Navy dyes. Fungal isolate *Mucor circinelloides* F-CL4 demonstrated similar efficiencies between live and autoclaved biomass for certain combinations. Decolourisation of the Black dye was limited under all tested conditions. These findings indicate that multiple mechanisms contribute to colour removal. Environmental microbial isolates, including fungal strains such as *Mucor circinelloides* and bacterial strains from genera such as *Bacillus*, *Glutamicibacter*, and *Glycomyces*, demonstrated measurable decolourisation capacity across a range of commercially relevant textile dyes. Although removal efficiencies varied markedly by dye structure, several isolates achieved high levels of colour reduction. This indicates that dye removal proceeds through multiple mechanisms, with biosorption likely dominating for several dye classes. Collectively, these findings highlight the potential of environmental microorganisms as low-impact biological tools for the treatment of dye-containing textile effluents and support the advancement of more sustainable, biologically based strategies for mitigating dye pollution.

5.03.P-Mo337 PFAS as the “knot in the yarn” of textile circularity

Diogo Alexandrino¹ and **Maria de Fátima Carvalho²**, (1)No Affiliation, Portugal, (2)CIIMAR, CIMAR-LA, University of Porto, Portugal

Per- and polyfluoroalkyl substances (PFAS) are a category of chemical commodities with orthogonal application across many industrial and economic sectors. The textile industry is not an exception to this, as PFAS have a ubiquitous presence across the textile value-chain and the life-cycle of textile products. Despite recent pushes towards PFAS-free textiles (either voluntary or regulatory-driven), PFAS impregnation (e.g., polytetrafluoroethylene, side-chain fluorinated polymers) remains the main strategy for the manufacturing of functional and occupational textiles with water-repelling or fire-retardant properties. However, even if the removal of PFAS as textile components is achieved, per- and polyfluorinated chemicals are still expected to be a common occurrence across the life-cycle of textiles, either as contaminants of raw materials (e.g., per and polyfluorinated pesticides in natural fibers), chemical finishing or coating of garments or via cross-contamination from different sources during manufacturing and transport.

Textile waste is a massive global challenge on its own, but current waste management practices of PFAS-containing textile waste (i.e., landfilling and incineration) have the potential to aggravate this environmental problem by serving as sources of PFAS dissemination into the ecosystems via soil percolation, leaching and volatilization. European sustainability policies and the textile waste management sector have been pushing for the reuse, recycling and valorization of textile waste through greener and bio-based processes (e.g., biological/chemical recycling, biorefineries, biodegradation), but the biological recalcitrance of PFAS turns them non-compatible with the typical circularity of these processes.

In this platform presentation, we will showcase our ongoing research on the microbial defluorination (i.e., the cleavage of the highly stable carbon-fluorine bond) of persistent fluorinated pollutants, including PFAS, and reflect how defluorinating microbes and their enzymes can be critical assets in the design of avant-garde bioprocesses for textile waste mitigation, recycling and valorization.

5.03.P-Mo338 Hybrid Flow Chemistry Designs Reduce the Environmental Impacts of Pharmaceutical Production

Kristie Tjokro¹, Valerio Barbarossa², Martina G. Vijver¹, Tommaso Iacoangeli³, Giuliano Caracciolo Torchiarolo³, Riccardo Cari³, William Herbert Gazzo³ and Stefano Cucurachi¹, (1)Leiden University, Netherlands, (2)PBL, Netherlands, (3)Angelini Pharma, Italy

The pharmaceutical sector urgently needs to decarbonize. In 2015, its emission intensity was ~55% higher than the automotive industry's. One proposed strategy is the use of flow chemistry. Typically, pharmaceuticals are produced using batch chemistry, in which production occurs over discrete batches and steps. This is a slow, costly, and waste-generating process that drives up emissions. In flow chemistry, production occurs in one continuous stream. Where feasible, flow chemistry has several advantages over batch, including an improved safety profile, faster throughput, smaller physical footprint, reduced waste, and a lower demand for solvents and reactants. While the advantages of flow chemistry are evident for single-step reactions, the implications of transitioning from batch to flow are less clear for multi-step syntheses. Using life cycle assessment, we evaluate the environmental impacts of producing an active pharmaceutical ingredient (API) under batch, flow, and hybrid configurations to determine whether flow consistently reduces environmental impacts in pharmaceutical production. To this end, we assessed trazodone hydrochloride, an antidepressant medication, which is produced over three phases. Using primary data from the manufacturer Angelini Pharma, we assessed four configurations: Batch, Flow, Batch–Batch Optimized, and Flow–Batch Optimized. These vary in Phase 1 (batch or flow) and Phase 2 (batch, flow, or optimized batch with improved solvent use/recovery), while Phase 3 (finishing) remained the same. Flow, Batch–Batch Optimized, and Flow–Batch Optimized all show considerable emissions reductions across every impact category, except freshwater ecotoxicity. The hybrid alternative Flow–Batch Optimized has the best environmental performance overall, with reductions around 18% for the climate change impact category compared to the baseline. This shows that, contrary to expectations, a fully continuous system is not always optimal; a hybrid system of flow and optimized batch might yield better environmental outcomes. Across all alternatives, the main contributing factors to climate impacts include supply-chain factors such as the production of precursor chemicals, followed by hazardous waste incineration, solvent recovery, and solvent use. Our results show no universal advantage for flow over batch; only thorough assessment of different configurations can reveal the best option. A hybrid configuration might be the way forward for API production.

5.03.P-Mo339 Fast-screening tool for early-stage environmental assessment of pharmaceutical synthesis route design

Yiyi Cao¹, Ad M. J. Ragas² and Rosalie van Zelm¹, (1)Radboud University, Netherlands, (2)Environmental Science, Radboud University, Netherlands

With more innovative active pharmaceutical ingredients (APIs) developed and applied, synthesis processes become more complicated, increasing the environmental burdens of the pharmaceutical production. As the key element of the drug design, synthesis route design is very crucial for integrating the environmental sustainability at the earliest stage. Early-stage API development often involves low technology readiness, with limited synthesis data and numerous assumptions in scaling, resulting in high uncertainty in environmental impact assessments. While some screening tools exist to conduct a simplified assessment, the specific capability of these tools on route screening is not clear, and pharmaceutical companies each choose a tool including different features. The aim of this research is to decide an optimal tool that consolidates key methodological elements from both literature and practice to facilitate the early-stage sustainability assessment of API synthesis routes in both academic and industrial contexts.

This study first identified the existing assessment tools by conducting a literature review. Considering

prospective assessment is also an important aspect of synthesis route screening, we conducted two rounds of literature searching on screening tools and prospective assessment tools respectively. Second, we distributed online surveys to pharmaceutical companies to collect information on screening tools used, environmental considerations, and expectations for an optimal tool. Third, a set of criteria was determined from both literature and surveys to assess and compare the functionality and characteristics of each identified assessment tool. Results show that the performance of assessment tools under different criteria differs a lot. In terms of impact coverage and life cycle phase coverage, tools such as LiSET and FineChem extend their system boundaries, allowing for a more comprehensive evaluation. Meanwhile, CHEM21 and GCIPR focus only on the reaction stage, providing process-level insights without full life cycle interpretation. FLASC and iGAL provide route-level hotspots while able to compare different processes or routes. In this case, a combination of tools is more suitable than a single tool for synthesis route design. The study will finally decide which tools to combine together to frame a suitable screening tool. During the presentation, a case study will be presented to show the applicability of this final early-stage screening tool.

5.03.P-Mo340 A Critical Review on Environmental Sustainability Assessment of Decontamination Processes in the Supply of Medical Devices and Pharmaceuticals

Jens Forré, Lieselot Boone and Jo Dewulf, Ghent University, Belgium

Decontamination processes are vital across sectors such as food, biotechnology and in particular the supply of medical devices (MDs) and pharmaceuticals to ensure sterility and safety. Their application minimizes the risk of contamination, thereby safeguarding product quality and public health.

However, these processes are often energy- and resource-intensive, generating diverse waste streams, resulting in notable environmental impacts. Life Cycle Assessment (LCA) provides a standardized framework to quantify such impacts. Existing LCA studies on decontamination show that the contribution of decontamination to the overall environmental impact often varies due to e.g., the choice of decontamination process and differences in LCA methodology. It is therefore vital to provide a thorough overview of the current state of LCA studies on decontamination and to identify key differences among them.

This study presents a comprehensive review of the extant literature on environmental sustainability assessments of decontamination processes, focusing on the supply of MDs and pharmaceuticals. The food sector is also included due to strong technological parallels. The primary objective of this study is to provide insights into the available LCA studies to highlight methodological differences within the four-step framework defined in ISO14040. To this end, 2349 studies were screened, of which 70 fulfilled the inclusion criteria for detailed analysis. These were categorized by the type of decontaminated product: products, production equipment, production environment and waste. For each category, technology maps were developed to classify the various decontamination techniques (e.g., chemical, thermal), providing an overview of documented techniques. Studies will be compared regarding goal and scope, data inventory and impact assessment methodology. The impact assessment analysis will ascertain the contribution of the decontamination to the total life cycle impacts per considered product category. Furthermore, innovative technologies will be benchmarked against conventional ones. One preliminary result shows that foam flow cleaning can reduce the carbon footprint by up to 95% compared to traditional Cleaning-In-Place. The outcomes of this review will facilitate the provision of guidance for future LCA studies addressing decontamination processes and establish a fundamental basis for subsequent research endeavors regarding the environmental sustainability of these processes.

Saxe⁶, Pascal Seel⁷, Laura Tasso¹ and Jad Zoghaib⁴, (1)Quantis, France, (2)EcoBeautyScore Association, Belgium, (3)LVMH Recherche Parfums & Cosmétiques, France, (4)L'Oréal, France, (5)Henkel AG & Co. KGaA, Germany, (6)Kenvue, United States, (7)Beiersdorf AG, Germany

The EcoBeautyScore (EBS) Association has developed a harmonized environmental footprinting and scoring system for cosmetic products, aligned with the EU Product Environmental Footprint (PEF). Since 2025, this

scoring system has been deployed across Europe to enhance transparency for consumers.

One of the main methodological challenges concerns freshwater ecotoxicity, especially during the end-of-life stage of cosmetic formulas. The EF 3.1 database covers only a limited share of cosmetic ingredients and often lacks robust characterization factors.

To address these data gaps, EBS developed two methodological innovations.

The first is the MSS-HC5 method for deriving effect factors (EF). Unlike the PEF approach, which relies on statistical Species Sensitivity Distributions (SSD-HC20), MSS-HC5 uses a streamlined but highly reliable dataset of chronic ecotoxicity values (EC10 or NOEC) across the three standard trophic levels. The lowest chronic value—the Most Sensitive Species (MSS)—is selected and adjusted using a Coverage Factor that accounts for data completeness. When chronic data are missing, acute EC50 values are converted using acute-to-chronic ratios. This approach reduces variability, maintains conservative protection goals, enables a efficient scaling and long-term database maintenance.

The second innovation concerns the estimation of fate and exposure factors ($FF \times XF$). Since full calculation requires many physicochemical parameters, EBS developed a clustering-based read-across method. From a dataset of over 1,100 substances, biodegradability and bioaccumulation were identified as the dominant drivers of variation in log (CF). Four clusters were defined using thresholds for biodegradability and bioaccumulation. Each cluster was assigned a semi-specific $FF \times XF$ value.

The integration of MSS-HC5 with the clustering approach increased coverage of freshwater ecotoxicity characterization factors from about 30% to roughly 60% for the EBS priority ingredients. The updated database also improves applicability for REACH-exempt substances, such as polymers or low-volume ingredients.

In conclusion, the combined MSS-HC5 and $FF \times XF$ clustering methods provide a pragmatic, scalable, and scientifically robust framework for generating freshwater ecotoxicity characterization factors tailored to cosmetic ingredients. This approach strengthens reliability, addresses data scarcity, and supports the operational rollout of the PEF-aligned EcoBeautyScore systems.

5.03.P-Mo342 Differences in the Sensitivity of Freshwater and Marine Organisms in the Acute Toxicity Evaluation of Deep Eutectic Solvents

Amanda dos Santos¹, Lucas da Silva Domiciano², Beatriz Mirabili Santana¹, Gisela Umbuzeiro³ and Valéria de Carvalho Santos-Ebinuma¹, (1)Faculdade de Ciências Farmacêuticas, Universidade Estadual Paulista (UNESP), Brazil, (2)Faculdade de Tecnologia, Universidade Estadual de Campinas (UNICAMP), Brazil, (3)State University of Campinas (UNICAMP), Brazil

Environmentally friendly solvents such as Deep Eutectic Solvents (DES) have attracted growing interest. DES are formed by combining safe, inexpensive components that, through hydrogen bonding, create mixtures with melting points lower than those of the individual substances. Although considered green alternatives, their wide range of formulations requires evaluation of their potential environmental impacts. This study aimed to evaluate the acute toxicity of five DES produced using 1:1 L-menthol (LM) with acetic, propionic, hexanoic, octanoic, and decanoic acids, using the freshwater microcrustacean *Daphnia similis* and the marine amphipod *Parhyale hawaiiensis*. DES were dissolved in culture water under agitation, and five concentrations were tested for each formulation. *Daphnia* tests were conducted using neonates (?24h), with 4 replicates per concentration (10mL of solution and 5 organisms per tube) at 20±2 °C under a 16:8h light: dark photoperiod for 48h. *Parhyale* tests were conducted using neonates (?7d) in 96-well microplates, with 24 replicates per concentration (200µL of solution and 1 organism per well) at 26±2 °C under a 12:12h light: dark photoperiod for 96h. Tests were valid when control immobility/mortality was ?10%. The 50% effective/lethal concentrations (EC50/LC50) were estimated using the drc package in R. For *D. similis*, the DES ranked from most to least toxic based on their EC50 values as follows: LM: Octanoic Acid (0.0002%) > LM: Decanoic Acid (0.0007%) > LM: Hexanoic Acid (0.002%) > LM: Propionic Acid (0.003%) > LM: Acetic Acid (0.005%). For *P. hawaiiensis*, the LC50 values ranked: LM: Hexanoic Acid (0.00004%) > LM: Propionic Acid (0.0003%) > LM: Acetic Acid (0.002%) > LM: Octanoic Acid (0.003%) > LM: Decanoic Acid (0.02%). For the acetic acid formulation, *D. similis* and *P. hawaiiensis* responded in the same range of sensitivity. For the propionic and hexanoic acid formulations, *P. hawaiiensis* was more sensitive, and the opposite was observed for the octanoic and decanoic acid formulations. These findings indicate that DES can be highly toxic (up to LC50 0.00004%) and should be evaluated using both marine and freshwater organisms to avoid underestimating their hazard. Additional tests with fish and algae are underway to complement the toxicity assessment. Overall, although these formulations are considered green alternatives, their toxicity should be determined and incorporated into life cycle assessment of the processes in which they are applied.

5.04 Complementing and Combining LCA with Other Methodologies for Better Decision Making

5.04.T-01 Including Ecosystems in LCA: the BES Footprint

Andreas Gess¹, Sharon Stauffert¹, Marina Isasa² and Rafael Horn Mr³, (1)University of Stuttgart, Germany, (2)Tecnalia Research Foundation, Spain, (3)Fraunhofer Institute for Building Physics (IBP), Germany

Answering the need for harmonized assessment of nature from a life cycle perspective, we present a Biodiversity and Ecosystem Services (BES) footprint to assess products and organisation within a consistent and integrative framework. Building on Life Cycle Assessment (LCA) and the System of Environmental Economic Accounting – Ecosystem Accounting (SEEA EA), it brings together established methods from environmental assessment and Natural Capital Accounting (NCA) to create a unified basis for nature-related evaluation and disclosure. The BES Footprint is structured around two core components: the Biodiversity Footprint, which captures biodiversity risk, and the Ecosystem Service Footprint, which quantifies changes in key ecosystem services. The framework outlines methods for embedding ecosystem-service quantification and biodiversity impact modelling within existing LCA structures such as EF 3.1, LANCA, and BioMAPS, while maintaining alignment with SEEA EA and natural-capital principles. It supports assessments under evolving disclosure and regulatory expectations and provides a basis for consistent nature-related risk and opportunity assessment, stronger governance, and improved investor confidence. It covers essential regulating and provisioning services with the option to include additional services or incorporate improved metrics as they become available. The BES Footprint supports multiple levels of assessment depending on user needs: Level 1 (screening; country-averages and no Foreground data), Level 2 (partial assessment; regionalized data with foreground inputs), and Level 3 (full BES Footprint; combination of global and regionalized data). This tiered structure enables its application across diverse decision contexts, from strategic planning and risk screening to detailed site-specific evaluations. To operationalise these applications, further guidance is foreseen. A systematic comparison of LCA and NCA underpins the BES Footprint, highlighting their complementary strengths and the need for integrated approaches. It addresses key challenges—including spatial and temporal resolution, assumptions and simplifications, and value-chain coverage—and proposes modelling principles that support consistent, scalable assessment of biodiversity and ecosystem services. The application of the BES Footprint follows the LCA phases—goal and scope definition, inventory, impact assessment, and interpretation. These developments form part of the broader A-Track project

5.04.T-02 Integrating Criticality Indicators into the Life Cycle Assessment Framework: Hydrogen Production as a Case Study

YI LI¹, Anish Koyampambath¹, Benjamin McLellan², Emmanuel Mignard¹ and Guido Sonnemann¹, (1)University of Bordeaux, France, (2)Kyoto University, Japan

Environmental Life Cycle Assessment (LCA) traditionally characterizes resource-related damage primarily through the concept of resource depletion. However, this concept does not fully capture broader concerns such as geopolitical, economic, and social constraints that affect resource availability. To address this limitation, it is essential to integrate criticality assessment of raw materials into the LCA framework. This integration allows for evaluating not only physical scarcity but also risks related to accessibility, geopolitical concentration, and market volatility.

In the context of the energy transition, hydrogen is emerging as a key energy carrier, particularly through water electrolysis. Yet, several electrolysis technologies rely on critical raw materials (CRMs), such as platinum group metals in proton exchange membrane (PEM) electrolyzers and rare earth elements in solid oxide electrolysis cells (SOECs). Although these technologies offer strong environmental performance, they also raise concerns about supply risks and long-term resource security. Current environmental LCA methodologies have limited capability to capture such trade-offs.

This study applies an integrated LCA framework that incorporates raw material criticality indicators, especially supply risk metrics, into conventional environmental LCA. The approach links geopolitical supply risk as a midpoint characterization factor with material mass flows within the LCA, aiming to provide results that reflect both environmental impacts and potential supply chain vulnerabilities.

A case study on hydrogen production via these electrolysis technologies is used to illustrate the method. The analysis highlights trade-offs between environmental performance and raw material criticality, offering insights into how decisions favoring environmental benefits may introduce new material dependencies. Integrating criticality indicators into the LCA framework supports more holistic decision-making in energy technology development and resource planning, offering a dual-perspective contribution to sustainable development.

5.04.T-03 Behaviour Operationalization in Life Cycle Assessments for Decision Making – an Interdisciplinary Framework

Mareike Tippe¹, Henning Wigger¹, Thomas Vogt¹ and Ines Weller², (1)German Aerospace Center (DLR) - Institute of Networked Energy Systems, Germany, (2)Universität Bremen, Germany

Life cycle assessments (LCAs) are investigating environmental effects of products, technologies and services over their whole lifecycle and are an essential tool when it comes to decision-making in various contexts. Even though many studies – especially of technological devices – attribute large shares of the environmental impacts to the use phase of products, effects and impacts of user behaviour are often neglected or only considered in simplified manners. As there is a lack of standardization in norms and guidelines on the operationalization of behavioural effects, our study develops a framework to integrate user behaviour into LCAs, supporting informed decision-making.

Based on expert interviews with social scientists and LCA practitioners followed by a consecutive deductive content analysis, we identify challenges and opportunities for operationalizing user behaviour in LCAs for the framework development. The proposed framework combines qualitative methods (e.g., interviews, ethnographic methods) with quantitative social scientific data to contextualize LCA results. Clustering approaches (e.g., k-means or agglomerative clustering) are applied to represent different technology adoption and usage behaviours. The integration of user behaviour into LCAs can provide a more comprehensive understanding of the environmental consequences of technology design, enabling decision-makers to make more informed choices about investments, policies, and technological setups. Our study addresses the current lack of standardization and guidance on operationalizing user behaviour in LCAs. By developing a framework that is applicable to various technologies, we aim to support the development of more sustainable products, services, and technological infrastructures. The proposed framework can be used to evaluate the environmental impacts of different technologies with a focus on energy using devices that strongly rely on human-technology interactions (like smart technologies, digital applications etc.)

The framework enhances the accuracy and reliability of LCA results by combining the LCA methodology with social scientific approaches, ultimately supporting decision-making practices. Furthermore, our study highlights the importance of considering user behaviour in LCA studies, as it can significantly influence the environmental performance of products and services, being therefore relevant in strategic decision-making for sustainability.

5.04.T-04 Integrating planetary boundaries into energy system optimisation models for absolute environmental sustainability assessment: a methodological framework

Nicolas Ghuyts¹, Anne van den Oever², Diederik Coppiters³, Francesco Contino³ and Hervé Jeanmart³, (1)iMMC, UCLouvain, Belgium, (2)Free University Brussels (VUB), Belgium, (3)UCLouvain, Belgium

Transforming energy systems to address climate change must avoid shifting burdens to other planetary boundaries. Yet most energy models still focus primarily on greenhouse gas reduction, often neglecting broader life-cycle impacts on critical Earth-system processes. This narrow scope can unintentionally shift environmental pressures from climate to land, materials, or ecosystems, even in scenarios deemed sustainable.

To address this gap, we present a modeling framework that integrates prospective life cycle assessment and planetary boundary metrics into a national energy optimization model. The framework first incorporates life-cycle and planetary-boundary metrics into a multi-objective optimization model, then uses goal programming to characterize the different trade-offs in environmental impacts, and finally applies interpretable machine learning to streamline the overwhelming set of trade-offs into system archetypes.

Applied to a 2045 low-carbon scenario for Belgium as a case study, the approach reveals that all near-optimal pathways meet the climate target but exceed planetary boundaries for land use and ecotoxicity under the most permissive downscaling principle, indicating that decarbonization alone is insufficient for absolute sustainability. From the near-optimum space exploration and interpretable machine learning, four distinct system configurations emerge—dominated respectively by electrification, hydrogen, renewable power capacity, or mixed strategies—each achieving similar costs yet distinct environmental trade-offs.

Future extensions of this work should incorporate dynamic demand changes and behavioral adaptations to further align energy systems with absolute sustainability targets.

5.04.T-05 Integrating Life Cycle Assessment with Complementary Methods for Low-carbon Hydrogen

Anthi Chatzopoulou¹, Francois-Xavier Dezert², Baptistine Gourdon³, Guillaume Batot⁴, Sofiane Cherkaoui Malki⁵, Ambroise Lachat⁶, Emmanuel Mignard⁷, Julie Cren⁸, Pierre Rigault⁸, Louison Collin⁹, Lucie Deneux⁹, Diego Larrahondo⁸, Alessandro Poles¹⁰, Yoann Jovet⁸, Catherine Azzaro-Pantel¹⁰, Fadzaï Mundembe⁷, Franck Castagna¹ and Nicolas Rogy¹, (1)IFP Energies nouvelles, France, (2)IFP Energies nouvelles & LAMSADE – Laboratoire d'Analyse et Modélisation de Systèmes pour l'Aide à la Décision, CNRS, Université Paris Dauphine-PSL, France, (3)LAMSADE – Laboratoire d'Analyse et Modélisation de Systèmes pour l'Aide à la Décision, CNRS, Université Paris Dauphine-PSL, Paris, France & Université Paris Dauphine-PSL, France, (4)IFP Energies Nouvelles, ., France, (5)EXPLAIN Consultancy, France, (6)BRGM, Geosciences and Environmental Division, France, (7)Université de Bordeaux, CNRS, Bordeaux INP, ISM, France, (8)University Grenoble Alpes, CEA, LITEN, DTCH, France, (9)CETIM, Senlis Cedex, France, (10)Laboratoire de Génie Chimique, Université Toulouse, France

To reduce greenhouse gas (GHG) emissions according to Paris Agreement, Europe has to become climate neutral up to 2050 and one of the key solutions seems to be energy transition towards low-carbon hydrogen. However, the energy transition presents significant challenges, as it entails diverse impacts, such as social or environmental impacts, that vary across projects and require assessment through suitable methodologies. A commonly used methodology is Life Cycle Assessment (LCA), however not all sustainability aspects are covered through it. This study focuses on the complementary methods used along LCA to identify how the dimensions of sustainability are assessed so far in the low-carbon hydrogen projects in European Union (EU). A systematic review was conducted across Web of Science for studies published between 2015 and 2024. The review comprised of several phases, each of which addressed various limitations. Moreover, whilst the study was initially conceived with a global scope, the area of interest was subsequently limited to the EU to ensure the accuracy of our derivative insights. A comprehensive analysis of the articles revealed significant findings into the coupled methodologies employed in LCA, and the conditions under which they are applied.

Findings of the study prompted a review of 90 methodologies with the aim of assessing the sustainability aspects of low-carbon hydrogen in the EU. A significant proportion of the reviewed articles were concerned with LCA performance, either as a standalone method or in conjunction with other approaches. As the LCA is mostly focused on the environmental dimension, alternative methodologies such as the Technoeconomic Assessment or Life Cycle Cost were utilized complementarily to address the technical and financial evaluation of the projects. Furthermore, Multicriteria Decision-making Methods were employed, incorporating multiple aspects, along with other relevant assessment approaches.

The present study constitutes an exhaustive analysis of the methodologies employed in conjunction with LCA to address the sustainability of low-carbon hydrogen projects. LCA is a frequently used approach for the evaluation of low-carbon hydrogen with a focus on its environmental dimension. Nevertheless, in order to perform a comprehensive assessment of low-hydrogen initiatives, it is imperative to integrate LCA with alternative approaches.

5.04.P Complementing and Combining LCA with Other Methodologies for Better Decision Making

5.04.P-We361 Recommend Economic, Environmental and Social Consideration for Cereal Production socio-eco-efficiency evaluation and predictive optimisation

Hamza Taoumi¹ and Khadija Lahrech², (1)Sidi Mohamed Ben Abdellah University, Fez, Morocco, (2)Sidi Mohamed Ben Abdellah University, Morocco

Sustainable development has been the interest of multiple researchers and scholars worldwide for centuries. A modelling approach to orient the world for evaluation from the socio-eco-efficiency perspective is vital to empower the collaborative efforts and innovative approaches aiming to build a resilient and inclusive agricultural system meeting current demands, preserving ecosystems and supporting future generations. The conducted study aims to develop, particularly in the era of European cereal production, a holistic optimising model, which considers various dimensions and factors to catalyse positive change and pave the way for a prosperous and sustainable future in light of industrial ecology and circular economy methodology, tools, and principals. Results of this study have shown that all investigated countries were able to achieve a high value of the “Sustainability index” indicator in the last years. However, an analysis carried out comparing all the input variables has concluded the necessity to act on the main variables related to Climate Change, Ozone, Photochemical Oxidation, Abiotic Depletion, and Toxicity to attain the ideal scores equal to 1,00. Accordingly, the developed model could help users, policymakers, scientists, scholars, governments, and communities not only in Europe, but also worldwide to frame their knowledge for achieving the sustainability goals and to orient them per aspect, per family, and per category for better categorisation and multi-dimensional speciality to find a suitable strategy and to establish the right rule in the micro, and macro environment, from the operational level to the strategic one.

5.04.P-We362 Challenges of Social Life Cycle Assessment in Agri-food systems

Melanie Douziech, Nadja El Benni, Stefan Mann, Melf-Hinrich Ehlers and Andreas Roesch, Agroscope, Switzerland

Environmental Life Cycle Assessment (eLCA) is the reference method to evaluate the environmental impacts of products throughout their life cycle. Yet there is a growing need for methods integrating more sustainability dimensions into decision making. Social Life Cycle Assessment (S-LCA) has emerged in this context for the assessment of social impacts across the value chain of products. Despite its potential, the application of S-LCA in agri-food systems remains underdeveloped, particularly in the context of accounting for the background through databases.

This study aimed to identify key challenges specific to the application of S-LCA to the agri-food sector and how database integration can enhance the robustness of such social impact evaluations. We first conducted a scoping review to identify challenges in S-LCA applications and then applied S-LCA to conventional apple and tomato production in Switzerland. The case studies followed the S-LCA guidelines and used the PSILCA v3 database to account for background processes, allowing a direct comparison with eLCA.

We classified the challenges into the ones related to (1) boundary conditions, (2) S-LCA steps, and (3) the integration of S-LCA with other sustainability assessment frameworks. Specific challenges for agri-food systems include the underrepresentation of animals in S-LCA and the lack of a stakeholder category and indicators accounting for the specificities of farmers. Additionally, the granularity of data in existing S-LCA databases does not align well with that of eLCA, limiting the comparability of both approaches.

The case studies revealed that high-value input processes—such as worker wages and trade union density— influence the social risks the most. However, the use of non-specific processes for Switzerland questioned the representativeness of the results. Still, the social hotspots identified stayed robust to the modelling assumptions.

To advance the applicability of S-LCA in agri-food systems and increase its usefulness in decision-making processes in combination with eLCA, future research should focus on integrating agricultural-specific flows in existing databases, improving the representation of farmers and animals, and enhancing the alignment of social and environmental LCA naming. This research contributes to integrating life cycle thinking with innovative frameworks to address the complex interactions between the environmental, economic, and societal dimensions of sustainability.

5.04.P-We363 Forecast and Prevent: A dynamic LCA-integrated Decision Framework for Reducing Food Waste in the Visitor Economy

sara zanni¹, Gerald Reiner², Alexandra Thomik² and Florian Cramer³, (1)University of Bologna, Italy, (2)Vienna University of Economics and Business, Austria, (3)IÉSEG School of Management, France

Background: In the tourism and hospitality sector, procurement logistics related to food acquisition patterns contribute significantly to greenhouse gas emissions and resource consumption, primarily driven by the need to maintain high service levels. Yet, decisions on ordering, redistribution and menu design are rarely guided by integrated environmental and operations modelling.

Purpose: The project develops a decision framework that couples supply chain modelling, demand and surplus forecasting, and life cycle assessment (LCA) for perishable food chains in a coastal tourism region. Rather than focusing only on model performance, the project is explicitly oriented towards providing actionable information to retailers, hospitality operators, and public authorities.

Approach: The analysis examines two supply chain networks, including dairy products and beverages, focusing on order and return policies, ingredient reallocation, and waste reduction strategies. System dynamics models are created to demonstrate food flows in the tourism and hospitality sectors from production to consumption or recovery, along with key influencing variables. Additional data layers, such as inventory and booking information, offer critical context for product streams, with booking patterns significantly affecting order values. LCA models are integrated into these flows to dynamically assess the climate, water, and land use impacts of various logistics and reverse logistics policies. By continuously combining these models with managerial decisions, the framework captures an evolving LCA perspective rather than a static snapshot.

Relevance: The framework helps the industry identify strategies that reduce waste and emissions while keeping service levels and margins intact. It illustrates trade-offs between prevention and end-of-pipe solutions. For policymakers, it offers a way to measure the environmental gains of prevention-focused approaches, aids in designing incentives and reporting standards, and provides a transparent tool to align food waste reduction, climate goals, and social objectives at the destination level. The presentation will demonstrate, through an initial pilot, how this integrated framework can inform decisions at both corporate and regional levels.

5.04.P-We364 Can You Keep (Your) Score? How Methodological Choices Affect the Sustainability Score of Your Food

Yanne Goossens, Thünen Institute, Germany

Literature has highlighted the need for a harmonised methodology for assessing the sustainability of food products. In this context, we developed a concept for scoring the sustainability of food products, combining both LCA and non-LCA elements across all dimensions of sustainability (environment, economy, society, animal welfare, and possibly even health).

A wide range of methodological decisions defines the resulting calculation and assessment tool. An in-house expert consultation has led to a first set of methodological choices, which need to be validated through extensive stakeholder processes and sensitivity analyses. While the LCA part is currently based on the PEF single score of a food product, the non-LCA elements incorporate information such as the presence of certification labels (such as those referring to organic farming or a higher animal welfare standard) or the implementation of biodiversity-enhancing measures at the farm. The LCA and non-LCA-elements are combined using distinct weighting factors. The resulting sustainability score then rates food products on a [0,100] scale and can be applied to both single as well as composite products.

This poster sheds light on how methodological decisions affect the score obtained for a selection of products. Focus hereby lies on: weighting assigned to the LCA score; weighting assigned to the non-LCA elements; indicators representing the non-LCA elements; choice options for each non-LCA indicator and values assigned to them; and finally, rating approach in terms of number of classes and setting of thresholds. All of these decisions need to be finalised in co-creation with food system actors. The examples shown on the poster highlight the importance of harmonisation and transparency to avoid cherry picking by those applying an assessment scheme and avoid confusion by consumers who might want to base their purchasing decisions on such scores.

Disclaimer/Disclosure:

The research is performed within the project “CO2 footprints in the food chain” (<https://www.thuenen.de/en/cross-institutional-projects/co2-footprints-in-the-food-chain>). The project is

5.04.P-We365 A Combined Sustainability Approach to Guide Infrastructure Design for Poly(hydroxyalkanoate) Production from Food Waste

Floriana Coppola¹, Virginia Carvalho², Neda Tozija³, Nada Tozija³, Jorge Santos² and Serena Righi⁴, (1)University of Bologna, Italy, (2)AquaInSilico Lda, Portugal, (3)TransfoLAB BCN, Spain, (4)Department of Physics and Astronomy "Augusto Righi", University of Bologna, Italy

The shift from fossil-based polymers and the growing focus on circular bioeconomy strategies have increased the need for bioprocesses capable of synthesizing sustainable biopolymers. Poly(hydroxyalkanoate)s (PHAs) are promising microbial polyesters, yet its production from virgin substrates raises costs and pressure the food supply chain. Using carbon-rich organic residues as alternative feedstocks can lower environmental and economic burdens while addressing waste-disposal challenges. However, the sustainability of this route depends heavily on the design and operation of the supporting biorefinery system. The BioLaMer project investigates a black soldier fly larvae (BSFL) biorefinery converting food waste (FW) into high-value biopolymers, requiring strategic decisions on process configuration before scaling up.

This study addresses the challenge of evaluating the potential environmental impacts of alternative production strategies for cultivating BSFL fed with FW to produce 1 ton of PHA per year. The study shows how early-stage Life Cycle Assessment (LCA) can provide valuable insights for defining the business model of an innovative production system, by highlighting environmental trade-offs between two alternative configurations: (i) a decentralised network of BSFL cultivation plants, located near FW sources within the urban area; and (ii) a centralised setup. While decentralisation may help reduce FW transport, it may also introduce challenges such as more frequent maintenance, distributed energy consumption, and additional logistics for larvae collection. This analysis uses the scale-up data estimated for Life Cycle Costing (LCC) based on the productivities achieved at laboratory scale so far (~10 kg of wet larval biomass per each larvae farm with 35-d cycle growth). Such upscaled data are translated into material and energy flows for a gate-to-gate LCA using the Environmental Footprint 3.1 method, focusing on environmental hotspots and key contributors across both scenarios.

Preliminary sustainability assessment has already been guiding the biorefinery design, with an energy consumption analysis to find solutions to accommodate lower temperatures during winter season. In conclusion, the study assesses whether combining LCC-based upscaling with early-stage LCA can show how sustainability assessment supports system design before scale-up.

5.04.P-We367 Visualizing multi-way relationship of environmental burdens and economic benefits in global supply chains of nations

Keitaro Maeno, Kamrul Islam and Masaharu Motoshita, National Institute of Advanced Industrial Science and Technology, Japan

This study develops an analytical framework to visualize the multi-way relationships among environmental burden footprints and socio-economic benefits while capturing their propagation structures along global supply chains (GSCs) of industries of nations. Specifically, using the multi-regional input-output model, we estimated GHG emissions and freshwater consumption footprints and aggregated embodied intensities (AEIs), defined as burden footprints per unit of PPP-based value added, at each propagation tier of the relevant GSCs, which implicate the eco-efficiency of the GSCs. Results showed the structures of the relevant burden footprints along the propagation tiers of the GSCs with their eco-efficiency. For example, in the case of manufacturing GSCs in the USA, the freshwater footprint is concentrated at tiers close to final production, and the corresponding AEIs exceed the global average at almost all tiers, while those of GHG emissions were below the average, indicating relatively high urgency of efforts to reduce the freshwater footprint especially at closer tiers of the relevant GSCs in terms of enhancing the eco-efficiency of the GSCs. We applied the proposed framework to GSCs of all

industries of nations and identified the key features for footprint reduction and eco-efficiency enhancement in the relevant GSCs.

5.04.P-We368 A Framework for Evaluating Nutrients Recovery Alternatives

Dewan Sabbir Ahammed Rayhan and Sara Toniolo, *Department of Management, University of Verona, via Cantarane 24, 37129 Verona, Italy, Italy*

Nutrients recovery from source-separated organic fraction of municipal solid waste (SS-OFMSW) is a waste valorization process, and it is becoming an integral part of a waste management system, since it not only reduces the loss of natural resources but also upsurges the production of value-added bio-products. There are a number of treatment alternatives for nutrients recovery from organic waste, characterized by different social, economic, environmental, and technical performances. However, the identification of the most suitable alternative from multiple alternatives becomes difficult for a decision-maker due to the complexity of life cycle-based methodologies and data requirements. Under this light, the objective of this study is to show how to select the most suitable nutrients recovery treatment alternatives among multiple alternatives where data availability is limited.

To meet the objective, this research is developed through two steps. First, this study analyzes 31 different studies on LCA of waste management and treatment alternatives for nutrients recovery from municipal solid waste (MSW) and explores the most impacting phases based on types of input wastes and recovered nutrients, functional unit, processes included within the system boundaries, allocation procedures, and applied life cycle impact assessment (LCIA) method. Secondly, to assess the social, economic, environmental, and technical performance of treatment alternatives by a single effort, the integration of multi-criteria decision analysis (MCDA) with LCA is examined.

This research summarizes the most impactful phases of environmental impact for different nutrients recovery alternatives, facilitating the identification of the most suitable nutrients recovery alternatives. Finally, this study proposes an integrated framework of LCA and MCDA for evaluating the sustainability performance of nutrients recovery treatment alternatives.

Disclaimer/Disclosure:

This study is a part of a research project titled “Circular processes associated with the treatment of organic waste from a life cycle perspective,” carried out at the University of Verona, in the Department of Management. The project is supported by “Innovative systems for the sustainable production of biomethane from OFMSW and other organic matrices [Grant No: INNOVATION AGREEMENTS DM 31/12/2021 (MISE)].”

5.04.P-We369 Material Flow Analysis and Life Cycle Assessment of Aluminium: Challenges and Steps Toward Circularity

Serenella Sala¹, **Andrea Amadei**¹ and **Sara Venturelli**², *(1)European Commission - Joint Research Centre (JRC), Italy, (2)KU Leuven University, Italy*

Aluminium is a crucial material in the EU's industrial system, particularly in the transportation, construction, and packaging sectors. As a Critical Raw Material (CRM) and Strategic Raw Material (SRM), aluminium poses risks to the EU's resilience and competitiveness. Among all SRMs, aluminium consumption has the most significant environmental impact in the EU, due to its high demand in various industries. To mitigate these risks, unlocking the full potential of aluminium recycling and closed-loop production is essential. This study will present the state-of-the-art of combining dynamic Material Flow Analysis (MFA) and Life Cycle Assessment (LCA) to the aluminium value chain. By integrating dynamic MFA with LCA, the study provides a framework for assessing the environmental impacts of the aluminium value chain and promote sustainable practices. The findings will reveal substantial environmental impacts caused by the EU's resource and trade dependency on third countries, and will underscore the importance of considering global dynamics in assessing environmental impacts. This study will leverage insights on key areas: environmental impacts, secondary material, stock dynamics, end-of-life management, and alloy complexity. Handling the complexity of the aluminium value chain could pave the way forward for substantial advancements in sustainable aluminium production and lifecycle management. The importance of advanced sorting processes for optimizing aluminium scrap treatment and understanding distinct types of aluminium process losses will be highlighted. As well as the need to address alloy differentiation and the potential for downcycling during recycling, which can affect the environmental benefits of secondary production. Overall, these advancements are crucial for strengthening the EU's resilience

and competitiveness while reducing the material's criticality and environmental footprint associated with the aluminium value chain, thereby supporting a more circular and sustainable economy.

5.04.P-We370 Life Cycle Assessment of Buildings Based on Forest Carbon Sequestration Using Satellite Data

Miyu Yamaguchi¹, Bailing Zhang¹, Satoshi Kita² and Norihiro Itsubo Dr¹, (1)Waseda University, Japan, (2)Sumitomo Forestry Co., Ltd, Japan

In order to achieve a carbon-neutral society by 2050, the building sector—which accounts for roughly 30% of total energy consumption—must urgently accelerate decarbonization through the use of wood and other low-impact materials. Wood has recently attracted attention as a key means of reducing the carbon footprint of buildings, not only because it requires less energy during production than steel or concrete, but also because trees absorb CO₂ during their growth and store it as carbon within their biomass, which can then remain fixed in buildings over long periods. Through this carbon-sequestration effect, the long-term and widespread use of wood enables a continuous and sustainable carbon cycle from forests to buildings, thereby increasing carbon stocks across society and contributing to broader climate-change mitigation efforts.

Against this background, Japan is scheduled to enact the Building Environmental Performance Assessment Act (“Building LCA Act”) in 2028, which will mandate comprehensive environmental impact assessments for buildings. Under this legislation, environmental burdens must be quantified across the entire life cycle of buildings, making the treatment of carbon stored in wood a critical and often debated issue. Carbon sequestration varies significantly depending on factors such as tree species, age, forest management practices, soil conditions, and climate, meaning that precise evaluation based on the wood's procurement region is essential for credible and scientifically sound assessments.

This study focuses on differences in the harvesting regions that supply wood and seeks to capture spatiotemporal variations in forest carbon sequestration by considering carbon stored in trees and soils, as well as carbon dynamics associated with land-cover change, using satellite-derived data and geospatial analysis. The resulting forest information is then integrated into building LCA to quantitatively assess the environmental impact-reduction effects of wood use in buildings under different sourcing scenarios. Through this approach, the study aims to clarify how regional differences—including species composition, forest management, and land-use modifications—are reflected in the life-cycle environmental impacts of buildings, thereby providing insights that may support more sustainable material procurement and informed policy-making.

5.04.P-We371 Where to install the next direct air capture and storage plant? Optimal Technology Deployment via Integrated Lifecycle Assessments and Techno-Economic Optimization

Vittoria Bolongaro¹, Tom Terlouw², Gian Kaufmann³ and André Bardow⁴, (1)ETH Zurich, Switzerland, (2)Paul Scherrer Institute, Switzerland, (3)MyClimate, Switzerland, (4)Energy and Process Systems Engineering, Department of Mechanical and Process Engineering, ETH Zurich, Switzerland

Carbon Dioxide Removal (CDR) solutions are indispensable for achieving global net-zero climate goals. A promising CDR technology is Direct Air Carbon Capture, Transport and Storage (DACCTS). As DACCTS moves toward commercialization, the need for integrated assessment methodologies is critical to provide ex-ante assessments of CDR efficiency, life-cycle environmental performance, and costs. Due to the anticipated gigaton-scale deployment, we must ensure climate benefits across varying regional and temporal conditions. Here, we develop a holistic and integrated framework to optimize DACCTS system performance and costs across regions and time. The bottom-up assessment combines geospatial modeling, energy-system analysis, spatially- and temporally-explicit techno-economic optimization of solid sorbent DACCTS configurations, CO₂ transport-routing analysis, and life-cycle assessment (LCA). The framework captures regional and temporal climate variability impacting the specific energy demand, as well as renewable and grid electricity availability, land constraints, CO₂ transport and storage logistics, and technology-specific learning rates. We examine grid-connected, off-grid, and hybrid configurations for 2025 and 2050 across multiple climate pathways.

Two main methodological innovations distinguish this work: First, future climate conditions and weather extremes are incorporated through different climate scenarios to identify regions where DACCTS deployment remains resilient to evolving climatic stresses. Second, LCA is applied to the region- and time-specific DACCTS supply chain, with optimal CO₂ transport routes determined based on locally available multimodal transport infrastructure and storage sites. Together, these elements identify favorable climate, energy, and economic conditions that justify siting DAC plants farther from storage sites, and where the development of new storage hubs would most substantially reduce system-wide costs and impacts.

By coupling LCA with spatial-temporal techno-economic optimization, the study identifies optimal regions for

DACCTS deployment, i.e., cost-effective, low-impact locations where CDR can be achieved at scale. The results demonstrate the benefits of integrating LCA into a multi-method decision framework by providing actionable insights for policymakers, investors, and industry that pinpoint resilient, cost-effective, and environmentally robust regions for DACCTS development.

5.04.P-We372 Circularity and Life Cycle Assessment of climbing holds made from recycled polyamide climbing ropes

Ruud Bongers¹, Anna Schwarz², Casper De Schrevel³, Paul Kwant⁴ and Yvonne van der Meer¹, (1)Maastricht University, Netherlands, (2)LCA Department, Netherlands, (3)CHILL B.V., Brightlands Chemelot Campus, Netherlands, (4)Zuyd University of Applied Sciences, Netherlands

With growing demand for sustainable, circular practices, the sports industry is under pressure to adopt circular economy principles and reduce its environmental impact. However, little is known about how circular design strategies affect environmental and circularity performance in sports equipment. Climbing holds are commonly manufactured from non-recyclable thermoset resins, generating significant environmental burdens and limited circularity. This study addresses the environmental impact and circularity of redesigned climbing holds through Design from Recycling, Design for Recycling, and Design for Durability.

Replacing thermosets with mechanically recycled polyamide 6 (PA6) reduced environmental impacts by 90% across key categories, including climate change, marine ecotoxicity, fossil resource depletion, and human toxicity. Short-loop recycling from climbing ropes showed lower environmental impact compared with long-loop recycling from automotive waste. Circularity scores align with environmental performance, with virgin thermosets below 0.1 and recycled PA6 scenarios above 0.9. Lifetime extension for recycled PA6 holds further reduced inflow energy demand, although these benefits were only partially captured by Material Circularity Indicator (MCI) values. Including mould use increases the impact of thermosets, as silicone casting moulds have a short lifetime. For rPA6, durable aluminium injection moulds reduced the impact per hold.

These results demonstrate that short-loop recycling of climbing ropes into climbing holds is a viable and scalable circular strategy. Next, combining Design from Recycling, Design for Recycling, and Design for Durability significantly reduces environmental burden. Additionally, combining Life Cycle Assessment (LCA) with circularity indicators provides a complementary perspective. LCA captures the scale of environmental benefits, whereas circularity metrics highlight structural improvements. These results show that circular strategies can support a more sustainable product design in the sports equipment sector.

5.04.P-We373 Integrating Life Cycle and Circularity Assessment to Guide Eco-design of Functional Electronics

Jana Deckers, Stefanie De Smet, Karolien Peeters and Pieter Willot, Flemish Institute for Technological Research (VITO), Belgium

The transition to sustainable and circular electronics requires decision-making that extends beyond traditional product performance indicators. Within the UNICORN project, Life Cycle Assessment (LCA) and Circularity Assessment (CA) were combined to identify, evaluate, and prioritise eco-design measures for functional electronics integrated into smart systems.

Four use cases, a smart battery casing, a dashboard module, a sensing system with integrated electronics and a tire sensor, were analysed from a cradle-to-gate perspective, using inventory data from industrial partners and theecoinvent database. Environmental impacts were assessed using the European Commission's Environmental

Footprint (EF) method, covering 16 midpoint indicators such as climate change, acidification, eutrophication, and resource use. Circularity performance was evaluated using a set of indicators adopted from ISO 59020 that include, among others, renewable, recycled, and reusable material inflows and outflows. This integrated approach enabled the identification of design improvements that simultaneously reduce environmental impacts and enhance circularity.

Results show that targeted material optimization, such as the use of recycled metals, can substantially improve environmental and circularity performance when implemented early in the design stage. However, trade-offs must be carefully assessed, as environmental gains in terms of climate change may be offset by increases in other impact categories, such as land or water use, or by heightened reliance on critical raw materials, or reduced recyclability due to altered material chemistry. For example, the use of alternative metals like copper in conductive inks in the dashboard module lowered the contribution to ecotoxicity, but at the same time the use of critical materials increased.

The integrated use of LCA and CA provides a structured, evidence-based approach to support decision-making in product development. By identifying the most promising design levers, such as the application of more environmentally friendly conductive inks, and exposing potential trade-offs early in the innovation process, this combined methodology enables more balanced, system-level optimisation.

5.04.P-We374 Refined Methodology for Assessing Corporate Water Footprint Across the Entire Value Chain

Magda CARRASCO¹, Celine GODARD¹, Guillermo Güemes Ferrer², Victor Frontere², Maelle Esteve¹, Jad Zoghaib¹, Jacques L'Haridon¹, Quentin Vincent¹, Hugo Berard², Julie Christiaen², Delphine Bouvier¹, Hans Buchholz¹, Alain Vidal² and Jehanne Fabre¹, (1)L'Oréal, France, (2)Quantis, France

Water is an indispensable resource, contributing significantly to global economic value. For businesses, understanding how water is utilized across their value chain is crucial for managing operational risks, minimizing potential profit losses, and ensuring the sustainable use of this resource.

The cosmetics industry relies on water as a key component in the production of its raw materials, manufacturing, and usage of its products. Water footprint assessments have focused primarily on blue water (surface and ground water) and grey water (wastewater), frequently overlooking the role of green water (rainwater) and the interconnection of hydrological cycles.

The primary objective of the methodology is to provide a detailed and data-driven analysis of the impacts and dependencies on water across L'Oréal's value chain, using the latest available data and enabling a more precise modeling of its impact on both water quantity and quality. The updated approach refines the previously followed water footprint methodology by incorporating green water volumes, thereby achieving a more comprehensive understanding of water dependencies. The methodology also distinguishes between direct and indirect impacts, offering clearer insights into where levers can most effectively be activated. The assessment covers the full value chain, from raw material production to finished product end-of-life, and utilizes indicators such as water withdrawals, freshwater eutrophication, and freshwater ecotoxicity.

This assessment provides enhanced insights into the water impacts of purchased goods, distinguishing their influence on withdrawals and freshwater eutrophication. It also features refined crop water needs modeling, incorporating regional requirements and green water contributions to understand primary water sources. Furthermore, it details impacts from finished product use and end-of-life on freshwater ecotoxicity and rinsing-related water withdrawals.

Just like a refined carbon footprint, this analysis becomes an internal decision-making tool for managing water-related risks and guiding action plans.

5.04.P-We375 From lab to rail: A Combined Mechanical LCA Matrix for Fiber Reinforced Polymers

Sabrina Sigourney Judie Diniz, Marcel Andres, Jens Bachmann and Steffen Opitz, German Aerospace Center (DLR), Germany

The design of next generation vehicle structures increasingly demands novel material systems that combine high mechanical performance with environmental sustainability. While mechanical criteria traditionally dominate material selection, developments in sustainability requirements have exposed a gap in current multi criteria decision making (MCDM) tools. In this regard most frameworks focus only on climate related life cycle impacts, neglecting other significant environmental impact categories. This study presents a selection matrix tailored for fiber reinforced polymer (FRP) systems that explicitly integrates all impact categories of the environmental footprint method at the early design stage.

Initially, prevailing MCDM approaches are screened and consolidated to identify common decision criteria, weighting schemes, and data sources. Based on these results, a set of application specific FRP constituents are chosen, encompassing various polymer matrices and reinforcing fibers. Mechanical descriptors can be collated from literature and mechanical testing, while ecological characteristics were derived from life cycle inventories (LCI) customized for each polymer/fiber pair. Additional LCIs were assembled using the structure of established databases but modified to capture the heterogeneity of polymer systems.

The resulting framework was validated first on individual materials and subsequently on material combinations. Each combination is classified within the matrix reflecting the mechanical and environmental performance. Comparative analyses highlight possibilities, revealing that materials that perform better from a mechanical standpoint can suffer substantial impacts in categories such as ecotoxicity or resource use. Conversely, polymers with lower mechanical properties can achieve better results regarding potential environmental impacts when coupled with appropriate fibers. It is therefore essential to consider both sides simultaneously.

The simplified matrix offers practitioners an intuitive, data driven tool that can be applied early in the design process, thereby enabling concurrent assessment of performance and sustainability. By bridging the methodological divide between mechanical engineers and LCA experts, the matrix facilitates interdisciplinary collaboration and supports evidence based material decision making for future structural elements.

5.04.P-We376 Thermal-Comfort Impacts of Residential Heat Pumps

Agnese Fuortes¹, Carlos Felipe Blanco Rocha², Merla Kubli³, Joris T.K. Quik¹ and Willie Peijnenburg¹, (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Leiden University, Netherlands, (3)TUDelft, Netherlands

Ensuring efficient and sustainable heating and cooling is essential for the energy transition, yet thermal comfort depends on the interplay among building insulation, heating technologies, occupant behavior, and policy and infrastructure conditions. Heat pumps are particularly relevant due to their dual heating and cooling functionality, compatibility with renewable electricity, and technological maturity. However, despite their promise, important questions remain regarding the most sustainable pathways forward, as previous life cycle assessment (LCA) studies often simplify behavioral influences and ignore system-level feedbacks.

This work presents a system dynamics (SD)-guided parametric LCA framework combined with global sensitivity screening to investigate the causal factors shaping the environmental impacts of heat-pump-based thermal comfort. The SD model represents interactions among building characteristics, climate, comfort preferences, and policy-driven changes in electricity carbon intensity. Because electricity consumption during operation is consistently identified as the dominant environmental hotspot, the SD model focuses on the adoption and use phases of residential heat pumps. This structure enables a high-dimensional, feedback-aware exploration of how uncertainties and nonlinear relationships propagate through environmental impacts. The integrated SD-LCA approach investigates which technological, behavioral, and policy factors most strongly influence the sustainability of heat-pump heating and cooling, helping to identify interventions with the highest leverage. The study establishes a foundation for future work that further advances dynamic, system-oriented methods in sustainability assessment.

5.04.P-We377 Comparing Simplified Environmental Indicators with LCA: A Case Study on Noble Metals Recovery from E-Waste

Alessandro Francini¹, Antonella Cornelio², Elza Bontempi², Angela Serpe³, Anna Maria Ferrari⁴, Paolo Neri¹ and Roberto Rosa¹, (1)Department of Sciences and Methods for Engineering, University of Modena and Reggio Emilia, Italy, (2)INSTM and Chemistry for Technologies Laboratory, Department of Mechanical and Industrial Engineering, University of Brescia, Italy, (3)Department of Civil and Environmental Engineering and Architecture, and Research Unit of INSTM, University of Cagliari, Italy, (4)Interdepartmental Center for

The application of simplified sustainability assessment tools during process design can be particularly helpful for the comparison of alternatives and the early adoption of more environmentally efficient solutions. This is especially relevant for processes aimed at recovering critical raw materials from waste. The ESCAPE approach (Evaluation of Sustainability of material substitution using CARbon footPrint by a simplifiEd approach) was developed to provide a simplified sustainability index based on carbon footprint and embodied energy, allowing rapid comparisons between recovered or substitute materials and their primary counterparts. In this study, we applied both the ESCAPE approach and the Life Cycle Assessment (LCA) methodology to a hydrometallurgical method designed to recover copper, silver, and gold from waste Random Access Memory (RAM) modules. The process relies on benign, selective, and recyclable reagents under mild conditions, and is designed to offer a more sustainable alternative to conventional hydrometallurgical recovery routes. This study aimed to assess the consistency between ESCAPE and LCA in identifying main environmental impact contributions. Additionally, results were used to perform a preliminary benchmark of the sustainability of the recovery method against conventional primary extraction processes for noble metals, based on available industrial data. Overall, the ESCAPE approach effectively identified a significant portion of the system's potential environmental impacts, closely aligning with LCA findings. However, discrepancies emerged in specific impact categories and when applying economic allocation within the LCA. Different LCA end-of-life modeling approaches were also examined to better understand how they affected the results. Based on these findings, we highlight strengths and limitations of the two approaches to define the most appropriate application boundaries for their effective use. We also propose a dual-assessment framework integrating ESCAPE and LCA to promote the adoption of sustainable practices particularly during the early-stage experimental design.

This work was carried out in the framework of the “SMART PCBs - Sustainable Materials Recycling Technology for Printed Circuit Boards” project co-funded by the Italian Ministry of Environment and Energy Security (MASE), Call RAEE 2020, CUP F57G20000050001.

5.04.P-We378 Integrating persistent mobile toxic chemicals into life cycle assessment: a cradle-to-grave evaluation of a low-carbon, nature-based wastewater treatment technology

Nooshin Barzegar Marvasti¹, Iestyn Stead², Chris Betteridge³, Ben Herbert⁴, Peter Fantke⁵, William A. Stubbings Dr¹, Mohamed Abou-Elwafa Abdallah Dr¹ and **Luisa Orsini¹**, (1)University of Birmingham, United Kingdom, (2)United Kingdom, (3)Environmental Consultant at Stopford, United Kingdom, (4)Director of Technology and Innovation at Stopford Ltd, United Kingdom, (5)Substitute ApS, Goethe University Frankfurt, Denmark

Persistent, mobile, and toxic chemicals (PMTs) are widespread in aquatic environments, with wastewater as their primary source. As freshwater scarcity intensifies, wastewater reuse is critical for sustainable water management. However, traditional wastewater treatment processes are largely ineffective at removing PMTs. Advanced oxidation and chemical treatments, also known as tertiary treatments, can be effective, but are energy-intensive and may generate secondary pollution products. With their higher sustainability, nature-based solutions offer a promising alternative to mechano-chemical tertiary treatments, but they typically have a large land-use footprint and slow treatment rates limiting their scalability and economic viability. A recently developed nature-based solution leverages the filter-feeding capabilities of *Daphnia* (waterfleas) to capture and bioaccumulate a broad spectrum of PMTs, along with excess nutrients and suspended solids. As an emerging technology, its life cycle environmental impacts remain unassessed. This study presents the first cradle-to-grave life cycle assessment (LCA) of this emerging technology. Unlike conventional LCAs, our study bridges the gap between chemical water quality assessment and life cycle thinking, integrating contaminants typically overlooked in standard LCA frameworks. Results show that the technology achieves a low overall environmental footprint, while reducing ecotoxicity and eutrophication potential. Scenario-based analysis indicates that recycling of infrastructure materials can reduce resource depletion, further reducing the carbon footprint of the technology. This LCA sets a new benchmark for evaluating wastewater treatment technologies and highlights the strong potential of the *Daphnia*-based technology as a sustainable, scalable option for tertiary water treatment and reuse.

5.04.P-We379 Integrating the Impacts of Wildfire into Life Cycle Assessment: An Approach Applied to an Extensive Livestock System

*Renata Martins Pacheco¹, Miquel Andón¹, Sara Mollà Borredà², **Tamara Schmidt³** and Montserrat Nunez¹, (1)IRTA, Sustainability in Biosystems, Torre Marimon, 08140 Caldes de Montbui, Catalonia, Spain, Spain, (2)Forest Sciences and Technology Centre of Catalonia (CTFC), Spain, (3)IRTA, Spain*

Global change is amplifying challenges in landscape management, particularly through the increasing frequency and severity of wildfires, which cause substantial losses in lives, biodiversity, and ecosystem services (ES). Climate change is expected to exacerbate this trend, while socioeconomic drivers such as rural depopulation and land abandonment further heighten wildfire risk by altering land use and increasing fuel loads. In Europe, abandoned rural areas are recognized as wildfire hotspots, making fuel management a key priority. Wildfire protection itself is an ES that can be compromised by human activities, yet current Life Cycle Assessment (LCA) approaches do not account for wildfire protection. This study addresses this gap by proposing a novel method to integrate wildfire impacts into LCA. Specifically, we (1) identify impact pathways linking environmental interventions in the Life Cycle Inventory (LCI) related to fuel-load management with a new wildfire protection impact category and existing indicators, and (2) test the approach in a case study comparing wildfire-related impacts with and without fuel management through grazing. A literature review was conducted to establish relevant causality chains, operationalized using fire behavior modeling (FlamMap) and characterization factors (CFs) for impact categories. First, changes in biomass load are quantified and translated into fire intensity, efficiency, and emission factors (e.g., CO₂, PM₁₀, SO₂), which vary with fuel type and moisture content. These emissions are then multiplied by CFs to generate category-specific impact scores. The method is applied to an extensive, multifunctional small ruminant herd in the Spanish Pyrenees, comparing scenarios with and without livestock presence. Results link wildfire impacts to existing LCA categories such as climate change, particulate matter, and acidification, while highlighting data gaps for others (e.g., eutrophication, ecotoxicity). Unlike conventional LCA, this approach addresses an environmental hazard typically assessed through risk-based methods, revealing the potential benefits of extensive livestock systems often deemed less eco-efficient than intensive ones. By incorporating wildfire impacts, this framework supports more holistic sustainability assessments and informs land management, food security, and climate adaptation policies in vulnerable regions.

5.04.P-We380 Variability of Logistics Services: Insights for Life Cycle Assessment

***Sara Toniolo¹** and Ivan Russo², (1)University of Verona, Italy, (2)Department of Business Administration, University of Verona, Italy*

Logistics decarbonization has emerged as a new stream for extended sustainable operations, reducing the impacts by designing logistics solutions with lower CO₂ emissions. However, capturing the logistics emissions across supply chains still represents a challenge fed by the difficulty in knowing the practices along the supply chain and how to measure them.

In light of this, this research aims to reveal how to capture the dimensions of logistics service variability to improve life cycle inventory modelling. Our research focuses on developing a life cycle inventory (LCI) capable of reflecting the inherent complexity and high variability of logistics services. To achieve this, we adopted a mixed data collection approach combining both qualitative and quantitative data. Specifically, we engaged multiple logistics service providers (LSPs) and requested detailed information regarding their operations performed for the same company. The inquiry was structured around two main operational domains: warehouse management and transportation activities. By comparing how different LSPs manage storage, energy use, vehicle operations, and transport planning for an identical customer, we captured the heterogeneity of service provision and identified representative parameters for inventory modeling.

One set of variations concerns warehouse management, including energy consumption, the use of other energy carriers, water usage, space utilization, and stock management. Another set of variations relates to transportation practices. In addition to the fuel types and vehicle categories already commonly considered in LCA studies, further variability was identified in route management, driving habits, driver-assistance measures in traffic conditions, vehicle load factors, loading/unloading cycles, and the co-functionality of services provided to different customers.

The analysis highlights the significant variability that characterizes logistics services, both in warehouse operations and transportation practices. Understanding these differences is essential for designing more accurate life cycle inventories and supporting the development of more efficient decarbonization solutions for logistics.

5.04.P-We381 Modeling Ecolabel Certification Credibility under Climate Uncertainty: Toward Integrated Sustainability Assessment

Sandra Ceballos-Santos¹, Ana Espinola-Arredondo², Pere Fullana-i-Palmer¹ and Alba Bala¹, (1)ESCI-UPF (Unesco Chair in Life Cycle and Climate Change), Spain, (2)Washington State University, United States

Ecolabels play a key role in promoting sustainable resource management, yet their reliability under climate uncertainty remains insufficiently understood. This study addresses the challenge of how environmental variability affects the credibility and monitoring needs of fishery certification schemes.

A game-theoretic signaling framework is developed to analyze the strategic interaction between fishermen seeking certification and a monitoring authority operating under incomplete information. The model identifies the conditions under which certification credibly conveys environmental performance (separating equilibrium), and the conditions under which it fails to do so (pooling equilibrium). The model incorporates certification costs, expected profit gains, and the probability of unfavorable environmental conditions.

The results show that moderate certification costs, asymmetric economic gains, and higher environmental risk promote informative certification, thereby reducing the need for direct monitoring. Conversely, low certification costs or generous subsidies can erode its credibility, increasing oversight requirements.

These findings offer quantitative insights for integrated assessment and sustainability governance, demonstrating how institutional and behavioral uncertainty can complement traditional Life Cycle Assessment (LCA) approaches. This framework supports the design of adaptive, risk-informed certification systems, advancing life cycle thinking in policy and natural resource management.

5.05.P Embracing Outliers Within the Emerging Nexus of Agriculture, Food Systems, and the Bioeconomy

5.05.P-Tu421 Bio-based Fertilisers from Fisheries Wastes: An Environmentally Friendly Alternative to Mineral Fertilisers?

Jan Landert¹, Nicolas Wittmann², Jean-François Fabre³, Claire Vialle³, Caroline Sablayrolles³, Diogo A. Teixeira⁴, Helena I. Monteiro⁴, Bruna Moura⁴, Carlos Bald⁵, Bruno Iñarra⁵ and Laura de Baan¹, (1)Research Institute of Organic Agriculture FiBL, Frick, Switzerland, (2)Research Institute of Organic Agriculture FiBL, Frick, Switzerland, Germany, (3)Univ Toulouse, Toulouse INP, INRAE, LCA (Laboratoire de Chimie Agro-industrielle), Toulouse, France, (4)Low carbon & Resource Efficiency, R&Di, Instituto de Soldadura e Qualidade, Portugal, (5)AZTI, Food Research, Basque Research and Technology Alliance (BRTA), Spain

The production of mineral fertilisers poses several sustainability issues, including high energy use (nitrogen fertiliser) or resource depletion (phosphorous fertiliser). To address these challenges and related geopolitical dependencies, the nutrient recovery from biowaste streams in the form of bio-based fertilisers (BBFs) is increasingly promoted. There is a growing number of life cycle assessment (LCA) studies on BBF production from common biowaste streams such as sewage sludge or animal manure. Despite fisheries waste being another abundant and nutrient-rich side stream, information on the environmental impacts of its transformation to BBFs and their application is limited. This study aims to address this lack of information by assessing environmental impacts of three BBFs produced from fisheries waste and their application in comparison to mineral fertilisers.

The system boundary included the transport of raw wastes, their transformation to BBFs, the transport to the farm and their application in broccoli cultivation. The functional unit considered was 1 kg of broccoli.

Foreground data on three BBFs was collected from two pilot-scale and one industrial-scale production plants in Europe. Information on the application of these BBFs was based on a field trial with broccoli in Estonia. The assessment was conducted with the FarmLCA tool and Brightway 2.5 and included five midpoint indicators: Climate change (GWP100), Terrestrial acidification, Marine eutrophication, Freshwater eutrophication and Mineral resources use.

Regarding Global warming and Mineral resources use, two of the BBFs had similar or lower impacts compared to mineral fertiliser (1-13% lower). For Terrestrial acidification, Marine eutrophication, and Freshwater eutrophication, the mineral fertiliser showed the lowest impacts. While the production of BBFs contributed up to 49% and 54% to the impacts of Global warming and Mineral resources use, respectively, field emissions dominated the other three impact categories. Yet, sensitivity analyses also revealed uncertainties, e.g. for the modelling of NH₃ emissions.

The analysis has shown that the production of BBFs and their agronomic performance should be further optimised to serve as environmentally friendly alternative to mineral fertilisers. This study provides guidance for such an optimisation process by identifying relevant contributions and levers during production and application of BBFs.

5.05.P-Tu422 Quantification of the Relevance of Time-Dynamic Carbon Accounting for Different Feedstock and End-of-Life Emission Scenarios of PLA

Nadja Vierzigmann¹, Nil Güreli¹, Ali Ghannadzadeh² and Grit Walther¹, (1)Chair of Operations Management, School of Business and Economics, RWTH Aachen University, Germany, (2)Faculty of Science and Engineering, Aachen-Maastricht Institute for Biobased Materials (AMIBM), Netherlands

As a biobased polymer with the possibility to degrade in a reasonable period of time, Polylactic Acid (PLA) is often regarded as a sustainable alternative to fossil-derived plastics and a leading polymer in the bioplastics sector. Recent studies show that the impact of biogenic carbon on the global warming potential is subject to the temporal dynamics of biomass growth rates and end-of-life (EoL) processes. However, current LCAs often apply a static approach when assessing biogenic carbon. Thus, such a static assessment overlooks the impact of temporary carbon storage and neglects that carbon neutrality does not equal climate neutrality. Consequently, the climate impact of PLA is not yet well depicted in current assessments.

The present study addresses this challenge by quantifying temporal carbon dynamics through the application of a Biobased Materials Life Cycle Assessment (BBM-LCA) framework and comparing the impacts of different feedstocks and EoL treatments on the climate impact of PLA. Our approach integrates time-dependent life cycle inventories, net ecosystem exchange (to represent carbon uptake and release during feedstock cultivation), and dynamic characterization factors. We evaluate how different feedstocks (corn, sugarcane, and sugar beet) and EoL pathways (mechanical recycling, chemical recycling, composting, and incineration) shape the timing and magnitude of emissions, and how temporal dynamics alter conclusions on the overall impact compared to a conventional static assessment.

Preliminary results show that the static approach overestimates the global warming potential compared to dynamic accounting by up to 56%. Although EoL emissions represent only a small share of total emissions, accounting for the timing of biogenic carbon release leads to significant differences: the dynamic LCA indicates a lower GWP100 by 45% for delayed emissions for the composting scenario of PLA and a 56% reduction for chemical recycling.

Our findings underline that a dynamic perspective on biogenic carbon cycles materially shifts the environmental profile of biobased plastics and thus must not be neglected for a comprehensive sustainability assessment of PLA.

5.05.P-Tu423 Decoupling Biodiversity Footprints of Food Consumption from Economic Growth Varies with the Wealth of a Country

Hanzhong Zheng¹, Koen Kuipers², Selwyn Hoeks¹, Sarah Sim³ and Mark Huijbregts¹, (1)Radboud University, Netherlands, (2)Environmental Science, Radboud University, Netherlands, (3)Unilever, United Kingdom

Food systems pose a critical threat to global biodiversity, yet it remains unclear whether and under what circumstances biodiversity footprints can be decoupled from economic growth, which is essential for sustainable development. Here we quantify changes in land use-based biodiversity footprints of food consumption in 158 countries (1995 - 2020) to evaluate whether country-specific changes in the biodiversity footprints of food consumption are (de)coupled from economic growth. We used the Food and Agriculture Biomass Input-Output

(FABIO) multi-regional input-output (MRIO) model to derive these land use-based biodiversity footprints. We adopt a consumption-based biodiversity footprint approach, which accounts for both domestic and transboundary impacts to explore decoupling. We consider two commonly used and complementary biodiversity indicators to quantify biodiversity losses associated with food consumption: the potentially disappeared fraction of species, i.e., the relative loss in global species richness (RSR-loss); and the decline in local ecosystem intactness, i.e., the loss of mean species abundance (MSA-loss). RSR-loss measures the loss in species richness relative to a natural reference condition. MSA-loss reflects the average loss in species abundance relative to a natural reference condition (while not considering increase in species abundance). We find a strong decoupling in 8-9%, weak decoupling in 62-70%, and coupling in 22-29% of the countries. Decoupling is more likely at higher GDP per capita levels and more evident for plant-based food consumption compared to animal-based food consumption. However, total biodiversity footprints remain dominated by animal-based food consumption, constraining the potential for global decoupling. These results show current levels of decoupling are not yet sufficient to achieve global net reductions in biodiversity footprints.

5.05.P-Tu424 Mapping Biomass Flows for Material Use in Switzerland: Towards a Systemic Framework for Biomass Valorisation

Nadia Ilaria Malinverno¹, Esther Thürig² and Claudia Som¹, (1)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (2)Swiss Federal Institute for Forest Snow and Landscape Research (WSL), Switzerland

A systemic understanding of how biomass is produced, processed, and utilised within the technosphere and society is necessary to understand the sustainable biobased transition of materials. Biomass plays a crucial role in achieving net-zero goals by substituting fossil-based materials and storing biogenic carbon in long-lasting material applications. However, identifying sustainable cascading pathways remains challenging due to inconsistent data, sector-specific models, and limited cross-sector integration.

The newly launched Swiss research project ACHIEVE develops an integrated framework for the valorisation of biomass in the technosphere, focusing on cascading use pathways, material substitution, and carbon storage. The project brings together leading Swiss research institutions and industry partners to establish a coherent national picture of biomass production, transformation, and use across sectors such as forestry, agriculture, industry, construction, and bioeconomy.

A first objective is to build a comprehensive overview of existing models and datasets used for biomass flow quantification in Switzerland and Europe. These include statistical inventories, material flow analyses (MFA), dynamic stock models, and life cycle-based approaches. By systematically mapping and comparing these models, ACHIEVE aims to identify synergies, inconsistencies, and data gaps, thereby supporting harmonisation across spatial, temporal, and sectoral boundaries. This model synthesis should provide the foundation for a consistent national assessment of biomass flows.

Building on earlier work, including the static MFA of woody biomass developed in the Joint Initiative SCENE, ACHIEVE extends the analysis to encompass major agricultural and industrial biomass resources within the technosphere. The integration of multiple modelling approaches will enable the transition from static representations to dynamic MFA, capturing regional changes in biomass stocks and flows.

By combining data integration, systems modelling, and stakeholder input, ACHIEVE seeks to identify promising cascading use pathways that maximise material valorisation and minimise emissions, while recognising that diverting biomass for material use may affect existing uses in other sectors and create trade-offs. ACHIEVE aims to assess these tensions transparently and engage the research community to refine methods, address gaps, and advance circular bioeconomy and net-zero strategies in Switzerland.

5.05.P-Tu425 Effects of Allocation on Nutrient Sharing Between Crops: A Comparative LCA of the Soybean–Cotton System in Brazil

Thaís Lana Pilz Savioli¹, José Paulo Pereira das Dores Pilz Savioli¹, Alexandre Cunha de Barcellos Ferreira¹, Adriana Marlene Moreno Pires¹, Roberto Torres², Marília Folegatti¹ and Nilza Patrícia Ramos¹, (1)Brazilian Agricultural Research Corporation (Embrapa), Brazil, (2)Bayer SA, Brazil

The allocation of nutrients from mineral fertilization remains a challenge in the Life Cycle Assessment (LCA) of agricultural systems. Agricultural studies commonly allocate all impacts and benefits of nitrogen (N),

phosphorus (P), and potassium (K) to the crop planted at the moment of application. This allocation approach is suitable for systems with a single annual crop, but it does not reflect contexts like Brazil, where two crops may be grown within the same agricultural year. Consequently, this practice is simplistic and overlooks soil-plant dynamics, characterized by the residual effect of phosphorus, the high mobility and leaching potential of potassium, and the low persistence of nitrogen in the system. As a result, this simplification may change LCA outcomes, influencing management decisions and conclusions regarding key environmental hotspots. In this context, the current study assesses the effect of various nutrient allocation approaches for N, P, and K in a soybean-cotton system with established soil fertility in Mato Grosso, Brazil. The analysis compares three scenarios: (i) full allocation of fertilization to soybean; (ii) equal distribution between soybean and cotton; and (iii) a proportional approach based on nutrient export and crop yield. In the latter scenario, the model fully allocates N to the receiving crop, allocates P according to nutrient export, and distributes K by crop in sandy soils or proportionally to export in clay soils, reflecting the differences in soil retention and mobility. The study models the inventory using the ICVCalc tool and calculates impacts in SimaPro software using the ecoinvent 3.11 database and the ReCiPe 2016 method. This research focuses on assessing the effects of eutrophication, acidification, climate change, and other categories directly linked to N, P, and K dynamics, as well as the differences in the results of each allocation approach. By demonstrating how allocation alternatives can change agricultural LCA results, the study highlights the need for allocation criteria that more consistently represent the biogeophysical processes of tropical systems, improving completeness and representativeness of fertilizer-related effects in LCA cases. The findings aim to support recommendations for allocating mineral fertilizers in life cycle assessments of Brazilian agriculture.

5.05.P-Tu426 Towards a Transparent and Sustainable Atlantic Fisheries Sector: The SMART4SEA Approach

Eva Martínez-Ibáñez¹, Jara Laso¹, Ana Cláudia Dias², Paula Quinteiro³, Md Salauddin⁴, John O'Sullivan⁵, Eoghan Clifford⁶, Alex Wan⁶, Pedro Manuel⁷, Cheila Almeida⁸, David Baptista de Sousa⁹, Martín Rodríguez⁹, Sara Cunha¹⁰, José O. Fernandes¹⁰, Mémona Dalichampt¹¹, Tanguy Busnel¹¹, Juan Pablo Pérez¹², Jorge Romón¹², María Margallo¹ and Carla Pires¹³, (1)Department of Chemical and Biomolecular Engineering, University of Cantabria, Spain, (2)University of Aveiro, Portugal, (3)Environment and Planning, University of Aveiro, Portugal, (4)University College Dublin, Ireland, (5)University College Dublin (UCD), Ireland, (6)School of Engineering, University of Galway, Ireland, (7)Bitcliq Technologies S.A., Portugal, (8)Divisão de Aquacultura, Instituto Português do Mar e da Atmosfera (IPMA), Portugal, (9)ANFACO-CYTMA, Spain, (10)University of Porto, Portugal, (11)Valorial, France, (12)ARVI Innovapesca, Spain, (13)Instituto Português do Mar e da Atmosfera (IPMA), Portugal

The Atlantic fisheries sector, a cornerstone of the region's economy, culture, and food security, faces growing pressure to ensure environmental sustainability, traceability, and transparency across its value chains. Despite recent advances, the sector still struggles with fragmented data systems, limited interoperability, and the absence of integrated digital infrastructures and harmonized data protocols. These deficiencies restrict the flow of reliable information to authorities and consumers, hindering effective environmental management, enabling food fraud, and undermining public trust in seafood products. Addressing these shortcomings is therefore essential to enhance transparency and traceability, strengthen governance mechanisms, and ultimately secure the long-term resilience of Atlantic fisheries in a rapidly changing socio-environmental context.

In this context, the European project SMART4SEA proposes an innovative environmental traceability framework designed to enhance transparency and communication with consumers throughout the Atlantic fisheries sector. The project focuses on key priorities such as detecting fraud in fishery products, reducing the ecological footprint of extractive activities, mitigating marine litter, and improving resource efficiency. To achieve these goals, SMART4SEA integrates advanced digital technologies, circular-economy principles, and transnational cooperation among ten partners from four Atlantic-region countries, promoting knowledge exchange, the uptake of best practices, and ensuring the scalability and replicability of the developed solutions. As a preliminary outcome, a digital infrastructure is expected to be established in the coming months to integrate real-time data from the fisheries under analysis.

The expected outcomes of SMART4SEA will reinforce data-driven traceability and environmental responsibility in value chains that are strategic for both food security and regional economic growth. The project will deliver innovative tools for producers and processors, while empowering consumers with clear, trustworthy

environmental information supporting more responsible choices and contributing to a resilient, sustainable blue economy.

5.05.P-Tu427 From Waste to Fuel: Life Cycle Insights into Biogas from Winery By-products

Vitor Barroso¹, José Pereira², Ana Faria¹ and Mara Caldeira Silva³, (1)Fraunhofer Portugal AWAM - Research Center for Advanced Water, Energy and Resource Management, Portugal, (2)Departamento de Química e Bioquímica, Universidade de Évora, Colégio Luís António Verney, Évora, Portugal, (3)Fraunhofer Center for Advanced Water, Energy, and Resource Management (AWAM), Portugal

Wineries generate large volumes of organic residues whose management represents both an environmental challenge and a resource recovery opportunity. Anaerobic digestion (AD) offers a circular solution for these streams; however, little is known about how different winery residues compare environmentally under harmonized assessment conditions. This study performs a comparative gate-to-gate Life Cycle Assessment (LCA) of two AD pathways: (A) biogas production from 1 m³ of winery wastewater, and (B) biogas production from 1 tonne of grape pomace. Inventory data were compiled from recent experimental and literature sources and modelled in OpenLCA using ecoinvent 3.10. Environmental impacts were evaluated using the ReCiPe Midpoint (H) method.

To enable comparability, results were expressed using both substrate-based functional units and an energy-based functional unit (MJ of useful energy, derived from methane yield and lower heating value, or LHV). Preliminary results indicate that grape pomace can produce higher biogas yields; however, the upstream energy need, due to the digestion time and pre-treatment requirements, result in higher impacts per unit of substrate. Conversely, winery wastewater offers a lower methane potential but contributes to net environmental benefits through reduced organic load, such as eutrophication and aquatic toxicity. Sensitivity analyses demonstrate that methane content, digester heating demand and biogas utilisation route strongly influence the ranking of scenarios.

This work provides a comparative LCA for bioenergy production using solid and liquid winery residues. The findings support evidence-based decisions for sustainable waste-to-energy strategies in the wine sector and emphasise the importance of functional unit selection in comparative LCA studies.

Keywords: anaerobic digestion; biogas; grape pomace; winery wastewater; LCA; circular bioeconomy

5.05.P-Tu428 Enhancing Environmental Accounting: An Exploratory Approach to Soil Stocks in Agricultural Life Cycle Assessment

José Paulo Pereira das Dores Pilz Savioli, Thaisa Lana Pilz Savioli, Adriana Marlene Moreno Pires, Nilza Patrícia Ramos, Cristiano A. de Andrade and Marília Folegatti, Brazilian Agricultural Research Corporation (Embrapa), Brazil

Agricultural Life Cycle Assessment (LCA) is not a closed system. Modeling agricultural processes requires dealing with edaphoclimatic variability. A key variability aspect is the presence of soil stocks (such as phosphorus, heavy metals and water), which form part of the biophysical context in which agricultural activities occur. These stocks influence how processes should be modeled and interpreted within LCA. Yet current LCA databases and modelling approaches often treat these stocks implicitly or as background conditions. As a result, agricultural datasets become highly dependent on the initial context in which they were generated. Based on this premise, this work aims to examine LCA database models to understand how soil stocks are currently modeled. Consider phosphorus (P), for example, a critical contributor to freshwater eutrophication. Many tropical soils have more adsorption of P, which prevent their leaching. Soils with high levels of available P require less or even no phosphate fertilization, respecting the crop's needs, while soils poor in available P demand higher doses of fertilizer. However, applying little or no phosphate fertilizer now does not necessarily mean a more sustainable practice, because past over-fertilization has already raised soil P levels to very high values. Thus, agriculture should work with target values for soil nutrient stocks, since a good practice requires preventing both shortages and accumulation. Moreover, erosion-driven P losses depend on the current stock level (whether past or newly applied), meaning emissions may appear higher simply due to geographic or pedological conditions rather than actual fertilization practices. As stocks approach environmental thresholds, high level P may also

trigger higher P exports. Similar complexities arise for other soil stocks such as water and heavy metals. Thus, without explicitly accounting for soil stocks, LCA results may ambiguously represent environmental performance, merging management impacts with geographic or pedological characteristics. This also weakens comparability across datasets, since differences in stock dynamics are not adequately reflected in flow values. The findings obtained from this review can support the development of modelling approaches that reduce the context-dependency of agricultural LCA datasets and improve comparability between datasets, yielding more robust environmental assessments while remaining consistent with core LCA principles.

5.05.P-Tu429 Exploring Outliers in Large-Scale Life Cycle Assessments of Experimental Farms

Juliet Amy Telfer¹, Joseph Poore¹, Valentina Caldart¹, Florian Payen¹ and Guillaume Royer², (1)HESTIA Project, Department of Biology / Oxford Martin School, University of Oxford, United Kingdom, (2)HESTIA Project, Department of Biology / Oxford Martin School, University of Oxford, France

Experimental farms are able to test a large range of management practices. Even if trials are not conducted with the aim of improving sustainability, focusing instead on yield improvement or climate adaptation, for example, they can still reveal potential methods of reducing environmental impacts. Life cycle assessment (LCA) is a key tool for assessing the sustainability of farming practices. The covariance between the resulting environmental impacts and cultivation variables, e.g., the quantity of fertiliser applied, can reveal potential mitigation options. However, focusing on covariance alone means that outliers may not be fully considered (e.g., if their weight in the correlation is low) or may be excluded from some analyses. This research focuses on these outliers, to see what lessons can be learned from them and how they can be included in the search for impact-reducing practices. To show how this can be done, we are using the Sustainable Corn CAP (Cropping Systems Coordinated Agricultural Project) Research Data. The data was collected between 2011 and 2015, covering eight states in the US, and containing over 3,000 production cycles of maize, soybean, and wheat. Treatments used in the experimental trials include varying practices such as cover crops, fertiliser applications, crop rotations, drainage systems, and tillage regimes. The data also contains measured soil information (e.g., carbon and nitrogen contents), allowing for a more accurate calculation of a cycle's soil-related emissions, such as carbon dioxide emissions from soil carbon stock changes. This dataset has been uploaded onto HESTIA to conduct the LCAs, a platform that makes food production and impact data available in a standardised format. HESTIA contains over 1000 models which calculate emissions and resource uses, producing multi-indicator impact assessments for each cycle in the dataset. We analyse the contributions of emissions to each indicator for the outlier farms; assess what drives these impacts; and pinpoint the reasons behind each outlier. The multi-indicator assessment also allows us to analyse trade-offs between indicators and understand why they exist. Our work ensures that we can capture the benefits of novel practices and alternative technologies when designing farm advice by focusing on outliers and not simply excluding them.

5.06.P Energy Systems in Transition Present New Challenges for LCA Practitioners and Researchers

5.06.P-Mo343 Environmental Evaluation of Solid-State Battery Manufacturing Using a Cradle-to-Gate LCA Approach

Debashri PAUL¹, Viera Pechancová², Thaiskang Jamatia², Haojie Fei² and Petr Saha², (1)Tomas Bata University in Zlín, Zlín, Czech Republic, (2)Tomas Bata University in Zlín, Czech Republic

The development of next-generation battery technologies is driven by the need for higher energy density, improved safety, and more sustainable production routes. Solid-state batteries that combine lithium metal anodes with high-nickel cathodes have emerged as promising candidates, yet the environmental impacts of their manufacturing processes are not fully assessed. This study addresses this gap by evaluating the environmental performance of an experimental solid-state battery based on an NMC811 cathode and solid polymer electrolyte, and comparing it with a state-of-the-art NMC622 lithium-ion battery using a liquid electrolyte.

In the solid-state configuration, the graphitic anode is replaced with lithium metal to increase energy density. Since lithium metal is unstable in liquid electrolytes due to dendrite formation, solid polymer electrolytes are selected to improve interfacial stability and enable safe cycling. The primary objective of the study is to quantify

material and energy demands associated with producing key solid-state battery components and to identify the dominant contributors to environmental burden.

The methodology combines laboratory-scale fabrication of dry-processed composite cathodes, thin lithium metal anodes, and polymer electrolytes with a cradle-to-gate life cycle assessment. Standard LCA frameworks are used to evaluate material flows, energy consumption, and environmental impacts across all relevant processing steps. Questionnaires have been distributed for inventory buildup to obtain process-level data for solid electrolyte synthesis, polymer formulation, and lithium metal handling in order to ensure representative inventory inputs.

Preliminary insights already indicate environmental hotspots associated with raw materials such as cobalt, solid electrolyte production, and energy-intensive lithium metal processing, including coating steps. Detailed quantification of these impacts will be carried out in the subsequent stages. Identifying these hotspots will support strategies to reduce the environmental footprint of solid-state batteries.

Understanding the implications of transitioning from conventional lithium-ion to solid-state architectures is essential for guiding sustainable battery development. The outcomes of this work will inform process optimization and design decisions that advance solid-state battery technologies while maintaining environmental responsibility.

5.06.P-Mo344 From Charging to Sustainability: Assessing Use-Phase in Battery Life Cycle Assessment

Maria Soares, Rafaela Gonçalves and Emanuel Lourenço, INEGI - Institute of Science and Innovation in Mechanical and Industrial Engineering, Portugal

Life Cycle Assessment, LCA, is a robust methodology for evaluating the environmental impacts of products across all life stages, from raw material extraction to end-of-life. In the context of battery systems, the use phase is particularly significant, as it directly influences the overall energy demand and associated emissions.

Accurately representing this phase requires a detailed understanding of battery performance throughout its lifetime, including charging energy requirements, which are affected by degradation and efficiency losses.

This work proposes a structured approach to quantify the energy input during the operational life of a battery module, enabling a realistic estimation of its environmental footprint. Key parameters, such as initial and aged capacity (Ah), average voltage (V), charging efficiency at the beginning and end of life (%), and number of cycles, are obtained through experimental testing. These parameters allow the calculation of energy per cycle and total energy delivered over the battery's lifetime, considering both initial and aged conditions.

The methodology involves computing the initial and aged energy per cycle, multiplying by the respective number of cycles, and adjusting for charging efficiency to determine total energy delivered. Summing these values provides the lifetime energy input, which, when combined with the regional electricity mix, enables the assessment of environmental impacts such as CO₂ emissions per kWh.

By integrating this use-phase evaluation into the broader LCA framework, the approach ensures a comprehensive representation of operational impacts, supporting informed decisions in battery design and sustainability strategies.

This work will be further developed and will therefore contribute to a complete life cycle analysis of battery systems and their role in reducing environmental burdens in electric mobility.

5.06.P-Mo345 Life Cycle Assessment of Hybrid Energy Storage Systems for Maritime Electrification: Environmental Trade-offs and Benefits

Maria Leonor Carvalho¹, Maria Anna Cusenza¹, Gianmarco Gottardo², Giovanni Dotelli² and Pierpaolo Girardi¹, (1)RSE SpA - Research on Energy System, Italy, (2)PoliMi, Italy

Maritime transport is a major and growing source of greenhouse gas emissions, projected to increase by up to 130% over 2008 levels by 2050. Electrification is a key strategy for reducing emissions, enabling high-efficiency propulsion systems powered by renewable energy. However, the adoption of Battery Energy Storage Systems (BESS) in maritime applications is limited by mission profiles with high dynamic loads and long durations, requiring significant oversizing of storage systems, which increases mass, volume, and costs. Hybrid Storage Systems (HSS), combining batteries with supercapacitors (SC) or Superconducting Magnetic Energy Storage (SMES), offer an effective solution to manage power transients and reduce thermal and electrical stress on batteries, improving efficiency, lifetime, and reliability. This approach was investigated in the European project Vessel Advanced Clustered and Coordinated Energy Storage Systems (V-ACCESS), which included a dedicated task applying the Life Cycle Assessment (LCA) methodology (ISO 14040/14044) to estimate the potential environmental benefits of hybrid systems compared to battery-only configurations.

Three representative marine applications were analysed: a fully electric ferry, an Offshore Supply Vessel with Active Heave Compensation and a trawler. For each, several configurations were assessed considering different size of the BESS, SC and/or SMES. The functional unit for the LCA was one hour of mission over a 30-year of vessels lifetime. The scope covered storage systems, including replacements, energy losses during charge/discharge (considering efficiency degradation over 30-years), and cooling-related losses. System boundaries followed a cradle-to-grave approach, from raw material extraction to end-of-life treatment. Environmental impacts were assessed using the EF 3.1 method. Life cycle inventory was built based on both primary/simulated data and secondary data. Specifically, foreground processes were modelled based on data provided by V-ACCESS industrial partners; background processes were modelled based on Ecoinvent 3.9.1 database.

The LCA quantified life cycle impacts of hybrid storage adoption and potential benefits over battery-only systems. Analysis of different configurations identified the most suitable solution for each application. A key contribution to eco-design came from the analysis of individual process contributions to overall impacts.

5.06.P-Mo346 How to Build State-of-the-Art Life Cycle Inventory Models for Renewable Energy Systems

Nour El Imane Hamda¹, Nicolas Rogy², Joanna SCHLESINGER³ and Mathilde MARCHAND-LASSERRE³, (1)IFP Energies nouvelles (IFPEN), France, (2)IFP Energies nouvelles, 1 et 4 avenue de Bois Préau, 92852 Rueil-Malmaison, France, France, (3)MINES PARIS – PSL, France

The growing deployment of renewable energy technologies such as wind and solar power as well as public criticism about their potential environmental impacts; has increased the need for reliable tools to evaluate their environmental performance. Life Cycle Assessment (LCA) is widely used, but its accuracy depends on access to detailed technical data that feed the Life Cycle Inventory (LCI). The potential environmental impacts of renewables vary depending on the system manufacturer and model. However, exhaustive technical data allowing to build full LCI of different renewables systems is often confidential or unavailable, making representative LCAs difficult to compute.

Manufacturer and model-specific technical data can be available in databases, scientific literature or reports of companies, making it possible to build some mathematical models to predict missing LCI data. Several models have been proposed in the literature, although useful, these models are not always statistically justified and do not consistently quantify the uncertainty in their predictions, raising questions about their reliability.

This work presents a clear and structured methodology for building state of the art models for energy systems LCI prediction when technical data are scarce. The approach includes screening LCA, to identify key contributors, correlation analysis to select the most relevant parameters, regression models to estimate key dimensions and masses, and explicit integration of uncertainties. Uncertainties from both model parameters and prediction errors are then propagated through the LCI using Latin Hypercube Sampling, providing confidence intervals for all outputs.

The methodology is applied to a cradle-to-grave LCA of a fictitious 6 MW onshore wind turbine installed in Île-de-France, Franch region, assuming only its nominal power is known. After uncertainty propagation, the climate change impact is estimated at a median of 14.9 g CO₂-eq/kWh, with a 90% confidence interval of [9.8; 22.2].

This demonstrates how limited technical information can significantly increase uncertainty in LCA results.

Overall, this framework improves the robustness and transparency of LCAs for renewable energy systems under data scarcity. It can support large-scale impact assessments and early-stage evaluations of future installations.

5.06.P-Mo347 A Life Cycle Assessment of Sustainable Aviation Fuel (SAF) Produced from Indonesian Coconuts

Yikai Liu¹, Masahiro Nakamura² and Norihiro Itsubo Dr³, (1)Waseda University, China (Mainland), (2)LEXER RESEARCH Inc., Japan, (3)Waseda University, Japan

Following the Paris Agreement and the commitment of many countries to achieve carbon neutrality by 2050, it has become clear that emission-reduction technologies alone are not sufficient to meet long-term climate goals. A deeper transformation of the energy system is required, and the aviation sector faces particularly complex challenges.

Sustainable aviation fuel (SAF) has emerged as a promising option for reducing aviation emissions. However, its environmental performance varies widely depending on the feedstock, land-use conditions, and production requirements. In this case, Indonesia with its abundant coconut resources, has recently attracted attention as a potential supplier of coconut-oil-based SAF via the Hydroprocessed Esters and Fatty Acids (HEFA) pathway. Yet, comprehensive and transparent life cycle assessments of coconut-derived SAF remain limited.

This study evaluates the emissions of SAF produced from Indonesian coconut oil and examines how land-use assumptions, agricultural practices, and HEFA processing conditions influence overall results. The assessment integrates primary data collected from Indonesian coconut-oil producers with process data obtained from research institutions in Japan, allowing for a more realistic representation of the production system. Multiple land-use change (LUC) scenarios are modeled to reflect plausible development pathways.

The analysis adopts a cradle-to-gate system boundary, covering coconut cultivation, crude coconut-oil extraction, hydrogen and electricity use in the HEFA process, and allocation of co-products. Sensitivity analyses further investigate the effects of hydrogen sourcing, electricity mixes, and LUC assumptions on total emissions. Preliminary results indicate that coconut-based SAF can reduce emissions substantially compared with conventional jet fuel in several scenarios. However, the magnitude of these reductions depends strongly on land-use dynamics and the energy mix used during HEFA processing.

Overall, this study highlights the importance of integrating region-specific primary data and robust land-use modeling when assessing emerging bio-based fuels. As one of the first systematic evaluations of Indonesian coconut-derived SAF, the findings offer insights that may support sustainable feedstock selection, aviation decarbonization strategies, and broader international energy-transition efforts.

This study was conducted as an academic research project. Industrial data were provided through research collaboration, without any financial support from the involved companies. The authors declare no conflict of interest.

5.06.P-Mo348 Clean Fuel, Dirty Build-Out? Quantifying Infrastructure Erosion of Hydrogen's Climate Benefit in Short-Haul Aviation

Alex James Kenneth Newman¹, Stuart Robert John Walker¹ and Rachael Rothman², (1)University of Sheffield, United Kingdom, (2)Chemical and Biological Engineering, University of Sheffield, United Kingdom

Hydrogen continues to attract attention as a potential low carbon aviation fuel, yet the conditions under which it truly delivers climate benefit are often assumed rather than tested. The fundamental barrier is volumetric storage. Conventional airframes place fuel within the wings, achieving large capacity with minimal intrusion into the cabin or hold. Liquid hydrogen cannot be stored this way due to its cryogenic nature and the surface area constraints required to limit boil off. Most proposed airframes therefore relocate fuel into cylindrical or toroidal tanks within the fuselage. This architecture imposes a direct penalty on either payload or range. As the energy requirement increases the tank volume expands, progressively displacing revenue generating space. Hydrogen aircraft are therefore likely to be viable only for short range missions where fuel demand is modest and fuselage intrusion remains tolerable.

That physical feasibility interacts problematically with infrastructure. Long haul flights are concentrated at major hubs. In contrast, short haul operations form dense, decentralised networks spanning many regional airports. If hydrogen is adopted for these segments the supporting fuel infrastructure must proliferate across

orders of magnitude more locations than would be required for long-haul hub centred deployment. The environmental cost of producing, distributing and storing hydrogen at this scale is poorly understood and may offset aircraft level emissions savings.

This work applies a cradle to grave life cycle assessment with system expansion to estimate the net climate outcome of hydrogen based short haul aviation in Europe. The model includes centralised production and mixed pipeline and tanker distribution, followed by airport storage, handling, refuelling and use phase substitution of fossil kerosene. Results are reported as net GWP for one year of European short haul flights and as a seat kilometre intensity metric. The study interrogates whether infrastructure demand materially erodes climate benefit and determines the conditions under which hydrogen powered aviation remains environmentally defensible at continental scale.

5.06.P-Mo349 Assessing the Environmental Impacts of a 10 kWel Coupled System Based on Metal Hydride Storage

Nicol Jaramillo Rodriguez¹, Julián Puszkiel², Gabriele Scarpati³, Yuanyuan Shang³, Julian Jepsen², Thomas Klassen⁴ and Claudio Pistidda³, (1)Institute of Hydrogen Technology, Helmholtz-Zentrum Hereon GmbH, Helmut Schmidt Universität, University of the Federal Armed Forces Hamburg, Institute of Materials Science,, Germany, (2)Institute of Hydrogen Technology, Helmholtz-Zentrum Hereon GmbH, Helmut Schmidt Universität, University of the Federal Armed Forces Hamburg, Institute of Materials Science, Germany, (3)Institute of Hydrogen Technology, Helmholtz-Zentrum Hereon GmbH, Germany, (4)Institute of Hydrogen Technology, Helmholtz-Zentrum Hereon GmbH, Helmut Schmidt Universität, University of the Federal Armed Forces Hamburg, Institute of Materials Science., Germany

The need to reduce greenhouse gas emissions is driving the development of renewable electricity systems and increasing the demand for effective large-scale energy storage solutions. Hydrogen is recognized as a key energy carrier for enabling long-duration energy storage, but challenges remain for large-scale solid-state hydrogen storage technologies. Helmholtz-Zentrum Hereon addresses these challenges via the Digi-HyPro project, developing integrated medium- and large-scale hydrogen systems based on commercially available AB₂-type hydride alloys. This study presents a cradle-to-grave attributional life cycle assessment (LCA) of an integrated hydrogen production, storage, and use system currently under construction. The system includes a 9.6-kW net-power anion-exchange membrane electrolyzer, a 1-kg H₂ metal-hydride storage module, and a 5-kW net-power proton-exchange membrane fuel cell. While most existing LCAs of hydrogen storage technologies focus primarily on CO₂-equivalent emissions and compressed-gas systems, this work provides a more comprehensive evaluation of a solid-state storage approach across a broader set of environmental impact categories.

Life cycle modeling is performed in Umberto using ecoinvent 3.11. The system boundary covers the materials and manufacturing of the metal-hydride tank, electrolyzer, and fuel-cell stack; balance-of-plant components; operational electricity demand; and thermal energy requirements for hydrogen absorption and desorption. Environmental impacts are assessed using ReCiPe 2016, examining global warming potential, mineral and metal resource use, and selected human-health and ecotoxicity indicators. To contextualize metal-hydride performance, the system is compared with a modeled 300-bar pressure tank as a conventional compressed-hydrogen baseline. Scenario analyses are conducted for a range of electricity supply conditions, from the current grid mix to highly renewable and fully renewable electricity scenarios. The study aims to identify the most relevant contributors to environmental impacts across the assessed categories and to clarify trade-offs between system efficiency, material requirements, and environmental performance. By assessing solid-state hydrogen storage within an integrated system and considering impacts beyond climate change, this work fills an important gap in the LCA literature and supports informed decision-making for future hydrogen storage technologies aligned with sustainability goals.

5.06.P-Mo350 Climate-optimal deployment of green hydrogen

Kiane de Kleijne¹, Anne Ottenbros² and Steef Hanssen², (1)Technical University Eindhoven, Netherlands, (2)Radboud University, Netherlands

Green hydrogen is projected to play a key role in achieving net-zero emissions, with applications across various sectors. While hydrogen applications have been assessed on costs, competitiveness and feasibility, it is unclear which applications are most favourable for the climate. Here, we use prospective life cycle assessment to compare the greenhouse gas emissions of green hydrogen use in various applications with: i) their fossil counterparts, and ii) low-emission alternatives for these applications, which are other mitigation technologies that provide the same service. Specifically, we look at methanol, ammonia, steel, aviation fuel, passenger cars, long-term grid balancing, and domestic and industrial heat production for the year 2030. We demonstrate that

green hydrogen production, transport and application leads to emissions savings compared to their fossil counterparts, but emissions are similar or higher than those of the low-emission alternatives. Only with very low hydrogen production emissions and without transport do the green hydrogen-based applications result in net emissions savings compared to the low-emission alternatives for: ammonia, steel, long-term grid balancing, and industrial and domestic heat. We conclude that for green hydrogen to fulfil its anticipated role in the net-zero transition, emission reductions are needed across the supply chain, as well as a prioritisation of hydrogen use in different applications that accounts for and optimises climate benefits.

5.06.P-Mo351 Quantifying Life-Cycle Stage Burden-Shifting Intensity in Global Warming Potential Induced by Post-Combustion Carbon Capture and Storage for Decarbonizing Energy-Intensive Industries

Yipeng Yao, Marie-Eve DUPREZ and Guy DE WEIRELD, University of Mons, Belgium

Energy-intensive industries (EIIs), together with the emissions arising from their energy supply, account for around 60% of global greenhouse gas releases, making their decarbonisation critically important. Post-combustion carbon capture and storage (PCCCS) is widely considered a key mitigation option due to its broad applicability, modest retrofit requirements, and diverse technological choices. However, from a life-cycle perspective, PCCCS is itself energy- and material-intensive, potentially generating additional CO₂-equivalent emissions that offset part of its CO₂ mitigation benefits.

To elucidate the systemic challenge of hidden yet critical life-cycle burden shifting induced by PCCCS, this study introduces the parasitic Global Warming Potential (GWP) penalty rate, a metric designed to quantify the intensity of life-cycle stage burden shifting in GWP induced by PCCCS—that is, the extent to which climate burdens move from the capture stage to other life-cycle stages. Using 80 meta-data points from 43 studies published between 2015 and 2025, we systematically quantified this indicator.

For PCCCS in EIIs, the parasitic GWP penalty rate exhibits an interquartile range (IQR) of 9%–27%, with the mean value at 19%; Specifically, adsorption (IQR 21%–37%, mean 31%) > absorption (8%–26%, 18%) > calcium looping (8%–27%, 15%) > membrane (8%–20%, 15%). These findings show that parasitic burdens represent a non-negligible component of the overall GWP results of PCCCS, highlighting the need for their explicit consideration in life-cycle assessments and for further work to identify mitigation priorities.

5.06.P-Mo352 Time-explicit Life Cycle Optimization for Transition Pathways: An Open-Source Python Implementation

Timo Diepers¹, Jan Tautorius¹, Jan Marcus Hartmann¹ and Niklas von der Assen², (1)RWTH Aachen University, Germany, (2)Institute of Technical Thermodynamics (LTT), RWTH Aachen University, Germany

Achieving environmental sustainability requires transforming existing anthropogenic systems over time. Transition pathway optimization supports this transformation by identifying the optimal scale and timing of technological choices based on defined objectives such as minimizing environmental impacts. To quantify environmental impacts of technologies, these optimization problems are often linked with Life Cycle Assessment (LCA) in so-called Life Cycle Optimization (LCO). However, in conventional LCA, life cycle stages of technologies, and their elementary flows, intermediate flows and environmental impacts, are aggregated over time. This overlooks the temporal distribution of life cycle stages, the temporal evolution of processes within life cycle stages and the temporal accumulation of emissions environmental impacts over time.

To overcome these limitations, we combine transition pathway optimization with time-explicit LCA, which introduces time as an additional dimension in life cycle modeling. To this end, we expand the conventional two-dimensional LCA matrices into three-dimensional tensors. Thereby, we enable the consideration of temporally dynamic scaling of processes, the processes' elementary and intermediate flows, as well as characterization factors. With this new tensor structure, the temporal distribution of life cycle stages, the temporal evolution of processes within life cycle stages and the temporal accumulation of environmental impacts can be considered. By further implementing the new tensor structure in LCO, we enable the determination of the optimal scale and timing of technology deployment to achieve minimal cumulative environmental impact.

We present an open-source implementation of this method in the Python package Optimesx, which extends the Brightway LCA framework, integrating Pyomo for mathematical optimization. Optimesx provides a unified structure for time-explicit life cycle modeling and LCA-based transition pathway optimization, enabling users to define optimization problems that consider time-resolved life cycle inventories and time-resolved life cycle impact assessment. We demonstrate the functionalities of Optimesx through a transition pathway optimization of

an industrial energy system, showcasing how time-explicit modeling enables more representative, forward-looking sustainability assessments.

5.06.P-Mo353 Digitalising Environmental Transparency for Renewable Energy: Sensitivity and Hotspot Analysis of Blockchain-Enabled Traceability of Solar Photovoltaic Panels Life Cycle

Anete Kalnina¹, Maksims Feofilovs² and Francesco Romagnoli², (1)Riga Technical University, Latvia, (2)Institute of Energy Systems and Environment, Riga Technical University, Latvia

Europe's pathway toward climate neutrality by 2050 increasingly relies on robust, high-quality environmental information capable of supporting sustainable product design, transparent supply chains, and verifiable environmental claims. Upcoming regulatory frameworks, including the Ecodesign for Sustainable Products Regulation, the Corporate Sustainability Reporting Directive with disclosure obligations requiring the introduction of Digital Product Passports and even sector-specific traceability requirements such as the EU Battery Passport, pave the way for a transition toward digitally enabled lifecycle data systems. The frameworks aim to improve the reliability, auditability, and granularity of environmental information while reducing risks of greenwashing and strengthening trust across value chain actors. As Europe moves toward digital environmental data ecosystems, there is growing interest in digital traceability architectures capable of capturing product-specific lifecycle information. The present study adopts the Life Cycle Assessment methodology in line with ISO 14040 to investigate how the environmental performance of a blockchain-enabled digital traceability system is influenced by variations in system parameters across its lifecycle. The case of Solar Photovoltaic Panels Life Cycle is selected as object of the study. By combining sensitivity analysis with threshold identification, the study highlights the trade-offs between increased data transparency and the material/energy intensity of the digital infrastructure required to achieve it. Findings provide insights into the design of environmentally responsible digital transparency systems and inform policy discussions on how to ensure that the digitalization needed to document Europe's progress toward climate neutrality itself does not create disproportionate environmental burdens.

5.06.P-Mo354 Circularity Assessment of the Electricity Sector: Development of an LCA-Based Metric

Maria Anna Cusenza and Pierpaolo Girardi, Ricerca sul Sistema Energetico RSE SpA, Italy

In the context of the European Union energy transition, circular economy models play a central role in strategies for competitiveness and decarbonisation. Circular business models, such as extending product lifespans and resource recovery, help mitigate risks related to energy security and the supply of critical minerals essential for green technologies. Effective action requires metrics to assess the current state and monitor progress towards a more circular energy sector.

Within this framework, the research focused on developing an improved version of a circularity metric for the electricity sector at macro-scale. Building on a previous tool, it was redesigned to comply with RACER criteria (Relevance, Acceptance, Credibility, Ease, Robustness) defined by the Bellagio Charter, the European reference for circularity indicators. Particular attention was given to ensuring that all indicators are based on reliable and verifiable data, mainly official statistics, and to improving data availability and temporal consistency. These enhancements guarantee continuity and annual accessibility of statistical series, essential for multi-year monitoring.

The metric is structured into three areas: enabling factors (policies, innovation), sector structure and operations (technology configuration, material and energy flows), and environmental effects, assessed through the Life Cycle Assessment methodology (ISO 14040/14044). The circularity score classifies electricity systems as "beginner", "started", "concerned" or "circular". Applied to the Italian electricity system for 2023, with reference to 1 kWh of gross domestic consumption (excluding transmission), the metric shows a "consolidated" status in the circular transition. Annual monitoring, retroactive to 2021, highlights stability, confirming sector maturity.

The metric, among the few tools available in the literature for assessing electricity system circularity, can be updated annually using official and scientific data, enabling rapid assessment of the system's evolution and supporting targeted actions to enhance circularity. It can also be integrated as an additional parameter within broader sustainability assessment frameworks. Future developments include extending system boundaries to

cover transmission and evaluating applicability to other European Union Countries. However, the need for a continuously updated digital system is emphasised, capable of quickly collecting data across all dimensions of circularity.

Disclaimer/Disclosure:

This work has been financed by the Research Fund for the Italian Electrical System under the Three-Year Research Plan 2025-2027 (MASE, Decree n.388 of November 6th, 2024), in compliance with the Decree of April 12th, 2024”.

5.07 How Low Should You Go? Recent Developments in Absolute Environmental Sustainability Assessment

5.07.T-01 Absolute Environmental Sustainability Assessment of Global Economy via Environmentally Extended Input Output Analysis

Andrea Paulillo¹ and Qiang Yang², (1)Chemical Engineering, University College London (UCL), United Kingdom, (2)University College London (UCL), United Kingdom

Industrialisation and rising consumption have pushed seven of nine Planetary Boundaries (PBs) beyond safe ecological limits. Absolute Environmental Sustainability Assessment (AESA) is a novel approach to evaluate whether systems operate within these limits. However, the evolution of overshoot across different economies over time, and the role of global supply chains in driving this overshoot, remain poorly understood. Here, we perform an AESA across 37 high-income and 12 middle/low-income economies over 1995-2020 using Exiobase v3.9.6 and a newly developed PBs-based impact assessment method (PB-IA), evaluating 9 Earth-system indicators across 7 PBs under 4 equity-based allocation approaches.

Results show that environmental decoupling from economic growth is uneven and insufficient across economies and PBs, with no economy achieving absolute environmental sustainability. Decoupling is observed mainly in high-income economies—particularly for climate change, land-use, and biodiversity-related PBs, but these economies account for only ~20%-35% of global impacts. In contrast, middle/low-income economies—responsible for ~65-80% of global impacts, remain strongly coupled to major environmental pressures. Global supply chains increasingly redistribute environmental pressures through trade, but domestically produced impacts remain dominant, accounting for ~68%-78% of impacts across PBs. Over time, impact reductions in high-income economies are largely driven by foreign impact intensities reduction (efficiency and technology improvements abroad). Conversely, rising impacts in middle/low-income economies are mainly driven by growing domestic consumption.

While global supply chains have redistributed environmental impacts across economies and enabled relative decoupling in high-income economies, they have not delivered absolute environmental sustainability. Demand-side shifts in high-income economies with technology, finance, and capacity-building for middle/low-income economies is essential for pushing the world towards absolute environmental sustainability while ensuring equitable development.

5.07.T-02 Evaluating Global Hydrogen Supply Pathways under Resource Limits through Cost and Planetary Boundaries Minimisation

Jesmyl Elisa Córdova Córdova and Carlos Pozo Fernández, Departament Enginyeria Química, Universitat Rovira i Virgili, Spain

Hydrogen is seen as an energy carrier for the transition to a low-carbon future. While today's hydrogen production is predominantly fossil-based and centralised, future production and demand are likely to decouple. Regions with abundant renewable energy can supply low-cost green hydrogen, while others face high demand but limited local potential. This mismatch introduces significant challenges across the supply chain, including resource constraints, transport logistics, and environmental thresholds defined by the Planetary Boundaries (PBs) framework.

To address these gaps, we developed a scenario-based, multi-objective Mixed-Integer Linear Programming (MILP) model to optimise global hydrogen supply chains under projected 2050 conditions. The model includes 46 production technologies, ranging from conventional methods to emerging approaches using waste and biomass as feedstock. We included 25 transport options combining different hydrogen carriers and transportation means. Hydrogen trade is allowed across 12 world regions, with region-specific resource limits. Furthermore, our analysis spans hydrogen demand scenarios from 138 to 614 Mt/year and considers resource

allocations from 10 to 100%.

The system is optimised under two objectives: cost minimisation and minimisation of the Planetary Boundary Footprint (PBF), an aggregated indicator reflecting boundary transgressions across ten Earth-system processes. To distinguish between solutions achieving the same PBF, we fix its value and maximise the Planetary Boundary Budget (PBB), a novel metric that reflects the remaining safe operating space across all boundaries. In both cases, environmental impacts were calculated using a prospective life cycle assessment aligned with the Planetary Boundaries-Life Cycle Impact Assessment framework.

Results show that under a 10% resource allocation, only 326 Mt H₂ can be supplied. This quantity remains below IEA and IRENA estimates. Cost-optimal solutions tend to rely mostly on fossil feedstocks and some biomass, increasing pressure on PBs such as Nitrogen flow and CO₂-based control variables. In contrast, PBF-optimised pathways favour nuclear-powered water electrolysis, reducing key environmental impacts, yet at higher costs.

Despite all the options considered, a fully green hydrogen system by 2050 is infeasible due to resource constraints, which highlights the need for region-specific strategies that balance costs, technologies, and Earth-system limits.

5.07.T-03 Defining Sustainability Targets for Mobility and Batteries

Sophia Roy¹, Abdur-Rahman Ali², Jean-Philippe Harvey¹, Christoph Herrmann² and Louis Fradette¹, (1)Montreal Polytechnic, Canada, (2)Technical University Braunschweig, Germany

Delivering mobility services within the safe operating space (SOS) will be complex as passenger mobility demand is expected to triple to 183 trillion passenger-kilometres in 2050. Therefore, assessing safety limits during the design phase of mobility services is imperative. We propose a methodology to downscale the SOS to mobility sub-sectors and ultimately product component, demonstrated with electric vehicle batteries. We compute targets for 2030, 2035 and 2050, and perform an uncertainty analysis based on a multiplicity of allocation factors and study parameters, including location, driving intensity, battery capacity and lifetime. We conduct our case study in Germany and Canada to assess how travel intensity and reduced car dependency affect target distributions. We find similar targets for both countries due to comparable mobility requirements and anticipated decarbonization of grid mix. Opting for a mini versus a mid-size car permits ~40-50% higher mean targets per kWh. For a 72-kWh battery pack, mean targets (and 5th to 95th percentiles) for the year 2030 stand at 10 (1-27) kg CO₂-eq/kWh and 1 (0.2-2) m³ water/kWh. Unless the yearly travel distance in both Germany and Canada is significantly decreased, increasing the share of public and active mobility is necessary in order to meet calculated sustainable mobility targets. Our target distributions facilitate their operationalization by moving beyond a yes/no assessment of SOS compliance, providing valuable insights for policymaking.

5.07.T-04 Remote-Sensing-Supported Planetary-Boundary-Based Absolute Environmental Sustainability Assessment. A case study for Iron Ore Regions

Alexander Griebler and Michael Tost, Montanuniversität Leoben, Austria

Absolute Environmental Sustainability Assessment (AESA) asks whether activities are compatible with a fair share of the Earth's carrying capacity. While the planetary boundaries (PB) framework provides a science-based reference, its operationalisation at regional and sector levels and its integration with life cycle assessment (LCA) remain limited, particularly where data are scarce.

We develop a PB (planetary boundaries)-based AESA framework for iron ore regions that directly evaluates PB control variables and systematically combines remote sensing and complementary datasets with conventional LCA data. First, we implement a prototype assessment for Kiruna (Sweden), using globally consistent gridded data to characterise regional pressures on selected PBs and to downscale the global safe operating space. This first case, now completed, focuses on regional environmental status rather than a full product LCA and serves to identify methodological gaps, including sensitivity to spatial boundaries and the interpretation of highly impacted urban areas (focus on remote sensing and global available datasets). Results for Kiruna indicate local transgressions for several PB indicators and reveal spatial hotspots, but also show that concentrated urban/industrial impacts may coincide with comparatively intact surrounding ecosystems. This questions simple per-area or per-capita downscaling and highlights risks of selective boundary setting if regional units are not defined transparently.

In a second step, we extend the framework in a full AESA of cradle-to-gate iron ore production in Eisenerz

(Styria, Austria). Here, site-specific life cycle inventory data are combined with spatially explicit PB indicators, an improved allocation scheme, and additional remote sensing and statistical datasets where LCA databases lack coverage. This enables a more comprehensive assessment of PBs and links regional conditions to production-related pressures.

Together, the two case studies provide a coherent storyline from framework setup and first testing to a more comprehensive AESA implementation. We conclude that PB-based AESA supported by remote sensing and extended data sources is feasible and yields useful insights, while requiring thoughtful interpretation of spatial heterogeneity and functional land use. The proposed approach reduces dependence on indirect LCIA-to-PB conversions and offers a template for spatially explicit absolute environmental sustainability assessments.

5.07.P How Low Should You Go? Recent Developments in Absolute Environmental Sustainability Assessment

5.07.P-Th204 A framework for combining prospective life cycle assessment and Absolute Environmental Sustainability Assessment (pAESA) through integrated assessment models

Janis Gerhardt-Mörsdorf¹, Anders Bjørn² and Christine Minke³, (1)Institute of Mineral and Waste Processing, Recycling and Circular Economy Systems, Technical University Clausthal, Germany, (2)Technical University of Denmark (DTU), Denmark, (3)Technical University Clausthal, Germany

Emerging technologies are essential to reduce human pressures on Earth's ecosystems. A key challenge is ensuring these technologies operate within planetary carrying capacities. Prospective life cycle assessment (pLCA) estimates future eco-efficiency under socioeconomic transition pathways but lacks explicit context relative to planetary limits. Absolute environmental sustainability assessment (AESA) evaluates impacts within these limits to make absolute sustainability claims but has mainly focused on current technologies with limited use of future scenarios. This study bridges that gap by integrating pLCA and AESA using harmonized scenarios from integrated assessment models (IAMs) to evaluate whether novel technologies—e.g. green hydrogen production—can operate within allocated carrying capacities in the future.

Future-oriented scenarios are central to pLCA. Temporal alignment of foreground and background systems through IAM integration using tools like premise is standard practice. This provides a strong foundation to unify pLCA and AESA by consistently applying IAM outputs across all AESA steps, drawing on the AR6 scenario database.

A key feature is dynamic, time-explicit implementation that aligns emission trajectories with prospective pathways. The dynamic functional unit drives a matching life cycle inventory. IAM data defines the climate change carrying capacity using the SSP1-1.9 CO₂ gross emission trajectory as baseline; other carrying capacities are treated as static.

Allocations of carrying capacities are based on regional GDP, population, energy demand, and emissions from AR6 data. This supports various allocation principles i.e. grandfathering, equal per capita, historical responsibility, capability to reduce, economic value, needs fulfillment, cost optimization and sufficiency lifestyles. Results are interpreted at multiple time points to capture temporal evolution.

The framework is idealized and reveals limitations due to the current state of the research. IAMs' climate focus may bias AESA; mismatches between carrying capacity scenarios and those used in pLCA and sharing principles need resolution. IAMs' neoclassical economic assumptions challenge equitable sharing. Static impact factors limit capturing ecosystem dynamics; inter-boundary interactions lack comprehensive integration for holistic sustainability. Case studies like green hydrogen production are needed to test and refine this framework's real-world applicability and effectiveness.

5.07.P-Th205 Additivity of Impacts Matters: Integrating Responsibility Principles in AESA of Economic Sectors

Gabin Guillemaud¹, Anthony Benoist² and Éléonore Loiseau¹, (1)ITAP, Univ Montpellier, INRAE, Institut Agro, Montpellier, France, France, (2)CIRAD, UPR BioWoEB, France

Absolute Environmental Sustainability Assessment (AESA) aims to operationalise the planetary boundaries framework at decision-relevant scales, such as economic sectors. The downscaling step in AESA requires strict additivity: All allocated SOS (aSOS) must equal the global SOS. Just as the downscaling step has to ensure aSOS additivity, the environmental impact assessment must preserve the additivity of impacts to comply with the defined aSOS. However, from a life cycle perspective, this additivity is not guaranteed, particularly if the

study focuses on an intermediate sector in a value chain.

This work proposes a consistent methodology to ensure additivity in both the downscaling and environmental assessment steps of AESA for economic sectors. It relies on three complementary accounting approaches based on different principles of responsibility, i.e. production-based (PBA), consumption-based (CBA), and income-based (IBA).

PBA assigns responsibility for direct impacts of a sector. This approach is geographically intuitive, but does not account for emissions embodied in international trade.

CBA assigns responsibility to final consumers by attributing upstream embodied impacts. This approach is widely used in AESA and captures global supply-chain interdependencies, but it limits the ability to assess the responsibility of intermediate sectors.

IBA assigns responsibility to primary suppliers by attributing downstream induced impacts. This allows to study the environmental responsibility of sectors not directly linked to final demand. This approach is therefore complementary to CBA.

Sharing principles adopted follow the responsibility principle associated with each approach: sales turnover for PBA, final consumption expenditure for CBA, and value added for IBA. The methodology is applied to the country-level economic sectors of EXIOBASE, a multi-regional environmentally extended input-output table, for the climate change as a proof of concept.

Results highlight that IBA can be incorporated into AESA alongside PBA and CBA. This allows for a more complete assessment that does not focus only on final consumers.

The proposed methodology contributes to improving the consistence and completeness of AESA applied to economic sectors. By ensuring additivity of two main steps of AESA, it advocates for the standardisation of the definition of system boundaries. Finally, it feeds future work on reducing methodological biases and implicit assumptions in AESA.

5.07.P-Th206 Multi-dimensional allocation model within the AESA framework with Uncertainty

Propagation: a case study on the EU-27 automotive sector

Leonardo Ferhati¹, Alexis Laurent², Mattia Marinelli¹ and Francesco Pastorelli¹, (1)DTU Wind and Energy Systems, Denmark, (2)Technical University of Denmark (DTU), Denmark

Absolute Environmental Sustainability Assessment (AESA) offers a science-based framework to evaluate whether human activities remain within the planetary boundaries (PBs).

This is done by downscaling the Safe Operating Space (SOS) -the space human activities can operate within to keep the environment similar to the Holocene conditions, which have allowed humankind to thrive- to a country/sector level by using predefined allocation principles. Yet, most AESA studies adopt a single, uniform sharing principle, typically population, to downscale global boundaries, neglecting both the heterogeneous nature of environmental mechanisms and the uncertainty embedded in sharing assumptions.

Here we developed a multi-dimensional (Multi-D) allocation model tailored to the biophysical and socioeconomic relevance of specific impact categories from the "EFv3.1" impact assessment method (PB-EF).

The developed approach aims at a more robust, transparent, and context-sensitive allocation approach for mitigating the limitations inherent in applying a single, uniform sharing principle across all categories, which can lead to biased outcomes (favoring some entities while negatively disadvantaging others).

We demonstrate this by applying this novel framework to the EU-27 automotive sector, focusing on passenger light-duty mobility to analyze how varying sharing principles and uncertainties influence absolute sustainability outcomes.

This work represents a crucial first step toward a unified methodology designed for the equitable distribution of global carrying capacities among countries, sectors, and companies.

5.07.P-Th207 PyUNCASE - Towards A Python Package for Systematically Allocating Carrying

Capacities Under Uncertainty in AESA

Thibault Pirson¹, Erwan Ike de Bantel², Gonzalo Puig-Samper³, Jan Marcus Hartmann⁴, Niklas von der Assen⁴, Mikolaj Owsianiak⁵, Julie Clavreul⁶, Ghada Bouillass², Bernard Yannou², Marija Jankovic² and David Bol¹, (1)ICTEAM Institute, Université catholique de Louvain, Place du Levant 3, 1348 Louvain-la-Neuve, Belgique, Belgium, (2)Université Paris-Saclay, CentraleSupélec, Laboratoire Genie Industriel, 91190 Gif-sur-Yvette, France, France, (3)MINES Saint-Etienne, France, (4)Institute of Technical Thermodynamics, RWTH Aachen University, Schinkelstraße 8, Aachen 52062, Germany, Germany, (5)Section for Quantitative Sustainability Assessment, Department of Environmental and Resource Engineering, Technical University of Denmark, Denmark, (6)ENGIE Lab CRIGEN, France

The transformation of human activities to comply with carrying capacities must be supported by absolute environmental sustainability assessment (AESA) methods that allow stakeholders to compare their environmental impacts to their fair share of carrying capacities. The allocation phase has been identified in the literature as a major source of uncertainty in AESA results, as it can be grounded in various distributive justice theories and implementation options. Existing guidelines and frameworks for allocating carrying capacities (UNCASE) already constitute a robust scientific ground to systematically allocate carrying capacities in AESA, but they require specific knowledge, data, and time resources for practical implementation. In fact, UNCASE proposes probability-based AESA indicators by considering all available allocation methods together with other sources of uncertainty, such as uncertainty in life-cycle inventory data. Without a dedicated toolkit, the broad application of this framework remains limited, thereby relying on heterogeneous practitioner choices and implementations (with potential implementation errors, transparency and reproducibility issues). This leads to (i) arbitrary and limited choice of allocation methods in AESA studies, (ii) difficulty to properly interpret results, and finally (iii) difficulty to compare AESA outcomes across studies. This work hence presents the first python package (named PyUNCASE) for systematically allocating the carrying capacities in AESA. The open-source toolkit automatizes the assignment of carrying capacities down to the country and sector levels, considering available allocation methods. This allows practitioners to apply it systematically across countries and economic sectors. By considering available allocation methods in AESA, the proposed package supports ongoing discussions regarding the application of sharing principles. In addition, this offers a common starting point to promote harmonization in their implementation. The package also enriches current AESA guidelines by offering a flexible tool that can adapt to future consensus on carrying capacity allocation and new allocation methods. Its functionalities can be extended in the future (including the prospective allocation of carrying capacities and the calculation of probability-based AESA indicators by combination with LCA impact scores) to strengthen the robustness of AESA outcomes by supporting widespread uncertainty assessment.

5.07.P-Th208 Assessing the Absolute Environmental Sustainability of Diets on a Spatialized Scale: A Case Study on Danish Tomato Consumption and Marine Eutrophication

Robin Raupach¹, Olivier Jolliet², Eldbjørg Vea¹ and Matilda Nordman¹, (1)Technical University of Denmark, Denmark, (2)Technical University of Denmark (DTU), Denmark

Global food production exerts significant pressure on the Earth system, contributing to the transgression of multiple planetary boundaries, particularly those related to biosphere integrity, land use, freshwater, and biogeochemical flows. Marine eutrophication is a highly localized impact category, yet current assessments rarely account for spatial differentiation or consumption-based perspectives. This study proposes a methodological framework for spatialized Absolute Environmental Sustainability Assessment (AESA) of food products, linking dietary consumption to local environmental boundaries. We apply the framework to quantify marine eutrophication impacts from tomato consumption in Denmark and compare these impacts to regional safe operating spaces (SOS) for oxygen depletion across coastal large marine ecosystem subsegments (cLMEss). Using national consumption data, origin-country trade models, spatial crop production allocation, life cycle inventories, and local characterization factors, we estimate impacts at a 5 arcmin resolution. Results reveal that production location strongly influences eutrophication impacts: although most tomatoes consumed in Denmark originate from Italy and Spain, the highest pressures occur in the North and Baltic Seas, where SOS transgressions reach up to 155%. In total, Danish tomato consumption affects ten cLMEss, including both transgressed and non-transgressed regions. These findings underscore the importance of regionalized assessments for localized impact categories and demonstrate the potential of spatialized AESA to identify impact hotspots. Extending this approach to full diets and additional impact categories can inform strategies for reducing environmental pressures through dietary shifts and procurement choices.

5.08 Increasing Access to Life Cycle Data: Bridging Transparent, Inclusive, and Reproducible Sustainability Knowledge

5.08.T-01 Toward Transparent and Inclusive Applications of Artificial Intelligence in Life Cycle Assessment

Laure Patouillard¹, Han De Wachter¹, Nicolas Hübner², Manish Kumar³, Artur Donaldson⁴, Simone Cornago⁵, Pietro Bartocci⁶ and Tu Qingshi⁷, (1)CIRAIG, Polytechnique Montreal, Canada, (2)Institute of Environmental Technology, Technische Universität Berlin, Germany, Germany, (3)Helmholtz Institute HIU, Karlsruhe Institute of Technology (KIT), Germany, (4)PRé Sustainability, the Netherlands, Netherlands, (5)SC Sustainability Consulting Pte. Ltd., Singapore, Singapore, (6)RISE Processum AB, Sweden, Sweden, (7)Sustainable Bioeconomy Research Group, The University of British Columbia, Canada, Canada

Artificial Intelligence (AI), encompassing both machine learning and generative approaches, is increasingly explored in Life Cycle Assessment (LCA) to automate repetitive and data-intensive tasks such as mapping background processes. These capabilities could significantly improve access to life cycle data and foster reproducibility of LCAs. However, efficiency gains should not come at the expense of quality. AI introduces ethical and organisational challenges that may hinder transparency, fairness, and inclusivity among others, but existing reviews have largely focused on technical aspects, leaving these implications poorly explored.

This study critically analyses 150 AI-LCA applications (methods or tools employing AI to perform specific LCA tasks) identified through academic and grey literature. Applications were classified according to their origin and the LCA workflow steps they address. Each was evaluated using semi-quantitative scoring approach against 14 criteria grouped into four categories: technical maturity, potential to enhance LCA practice, operational feasibility, and ethical risks. Operational feasibility captures inclusivity by assessing ease of use, accessibility, and current adoption, while ethical risk criteria address fairness and transparency among others.

Results indicate that most applications focus on predicting impact score (50%), estimating missing data (30%), and mapping background processes (8%), with only a small fraction employing generative AI. While automation potential is high, most tools remain at proof-of-concept stage and lack full integration into LCA workflows. Operational feasibility is a major barrier: applications often require coding skills, lack open access, and provide limited documentation, resulting in low adoption. Ethical risks are significant, with low scores for fairness, transparency and accountability due to black-box models, insufficient documentation, AI divide, and representation bias in training data.

Although AI offers transformative opportunities for LCA, current practices fall short of the transparency and inclusivity required for responsible integration. Open-source tools with multilingual comprehensive documentation and intuitive interfaces, combined with guidelines to mitigate fairness, transparency, and accountability risks, should be developed for an inclusive, responsible and wide adoption of AI by the LCA community.

5.08.T-02 Interoperability Requirements for Digital Product Passports in the Circular Economy

Niklas Hoffmann, Maximilian Blum and **Kay Lorenz Langhammer**, Wuppertal Institute for Climate, Environment and Energy, Germany

The transition to a Circular Economy (CE) requires digital solutions that support industrial processes and increase transparency across the product lifecycle. The Digital Product Passport (DPP) is expected to play a central role, but its success depends on interoperability — the ability of systems and actors to reliably exchange and use data. This research, conducted within the EU-funded ENCIRCLE project, offers a structured analysis to guide the technical design of interoperable digital CE solutions.

A multi-stage methodological approach was applied. First, desktop research mapped the current regulatory and standardisation landscape, including the Ecodesign for Sustainable Products Regulation (ESPR), findings from the CIRPASS project and specifications of the Asset Administration Shell (AAS). Second, interviews with seven experts from industry, academia and standardisation bodies validated initial insights and highlighted

emerging trends. Third, an expert workshop with specialists in standardisation and AAS consolidated the requirements for CE use cases. The analysis followed the four dimensions of the New European Interoperability Framework: technical, syntactic, semantic and organisational interoperability.

The results show that the standardisation landscape for DPP interoperability remains fragmented, with existing standards covering only basic elements such as identifiers and secure data exchange. The work of CEN/CENELEC JTC 24 on core DPP standards and the ongoing standardisation of the AAS were identified as the most influential developments.

Across the four dimensions, clear requirements were derived. Technically, structured and openly documented REST-APIs are needed. Semantically, standardised data models, shared terminologies and globally resolvable identifiers are essential. Syntactically, machine-readable formats and mechanisms for data authenticity and integrity are required. Organisationally, governance structures and defined responsibilities for data quality are crucial. While blockchain was assessed as having low practical relevance, the role of AI for semantic mapping remains an open but promising topic.

This research provides a consolidated overview of the evolving interoperability landscape for the CE and supports developers, policymakers and industry stakeholders working towards data-driven circularity.

5.08.T-03 Addressing the Reproducibility Problem in Life Cycle Assessment Studies: A Critical Scientific Challenge

Kamal Kamali¹, Anish Koyamparambath¹, Bertrand Laratte² and Guido Sonnemann¹, (1)University of Bordeaux, France, (2)Laval University, Canada

A growing reproducibility crisis is affecting many scientific disciplines, and environmental sciences, particularly Life Cycle Assessment (LCA), are no exception. Reproducibility has multiple and sometimes conflicting definitions. Here, we follow the US National Science Foundation's definition: "obtaining consistent results using the same input data; computational steps, methods, and code; and conditions of analysis." As reproducibility is a core scientific criterion; results that cannot be reproduced are unreliable claims. Despite recognition of this problem by LCA researchers and guidance documents offering recommendations, the reproducibility challenge persists in LCA. Reproducibility in LCA is hindered by inadequate reporting. Key modelling elements such as system boundaries, functional units, LCIA methods, and assumptions are often poorly communicated or omitted, while most inventories are reported in incomplete or non-standard formats. Reviews of hundreds of studies show that over 60% lack transparent inventory data.

ISO 14044 defines reproducibility as "a qualitative assessment of the extent to which information about the methodology and data values would allow an independent practitioner to reproduce the results reported in the study." This definition presents reproducibility as a spectrum, the closer the reproduced results are to the original, the higher the degree of reproducibility. Thus, it can be concluded that the list of information required to be reported by ISO is not sufficient nor meant to achieve bitwise reproducibility. This gap shows the need for clear, detailed guidance and accessible tools that enable practitioners with varying levels of experience to perform reproducible LCAs.

In this work, we conduct three complementary reviews to identify the gaps underlying the reproducibility challenge in LCA and to develop adoptable solutions. The first examines the LCA guidance documents, the second reviews LCA research, and the third reviews meta-LCAs. We then develop a documentation framework for achieving reproducible LCAs that relies on structured, systematic, and standardized reporting of all relevant methodological choices, inventory data, and LCIA results. We operationalize the framework with an intuitive spreadsheet-based tool. This framework renders environmental impact results scientifically testable despite confidentiality constraints and facilitates meaningful meta-analyses by making the spreadsheet template machine readable.

5.08.T-04 PROXYLCA : A Standardised Framework for Estimating Missing Food Life Cycle Inventory Data

Clara Payró¹, Justine Brun², Maria Bystricky², Oliver Taherzadeh³, Paul Behrens⁴ and Melanie Douziech², (1)Agroscope, Switzerland & Institute of Environmental Sciences, Leiden University, Switzerland, (2)Agroscope, Switzerland, (3)Institute of Environmental Sciences, Leiden University, Leiden, Netherlands, Netherlands, (4)Institute of Environmental Sciences, Leiden University, Leiden, Netherlands; Oxford Martin School, University of Oxford, Oxford, UK, United Kingdom

Global food systems account for roughly one-quarter to one-third of anthropogenic greenhouse gas emissions, occupy about half of the world's habitable land, and consume over 70% of global freshwater, with most of these impacts occurring at the production stage. As countries increasingly depend on food imports, trade patterns have become a key driver of these pressures. However, the limited geographical coverage of existing life cycle inventory (LCI) databases—heavily focused on Europe and North America—makes it challenging to assess the sustainability of global food trade patterns, particularly from Latin America, Africa, and Asia which are acutely affected by agri-food resource extraction. Current extrapolation methods to fill these gaps often require extensive data and fail to accurately transpose detailed field-level emission modeling embedded in the original inventory, limiting their reproducibility and scalability.

To address this gap, we developed PROXYLCA, a standardised, globally applicable framework that uses multivariate similarity analysis of large agricultural databases (FAOSTAT) to identify suitable proxies in LCI databases. The framework constructs composite proxies of existing LCIs without altering original emission models, regionalises the proxy LCIs to reflect local conditions, assesses data quality using a matrix-based approach, and provides recommendations on using principal component analysis to interpret results. Applied to 230 product–country combinations across 59 countries, PROXYLCA enables comparisons of environmental performance between imported and domestically produced foods. For approximately half of these combinations, existing LCIs allowed validation of the framework and results. Initial findings highlight regional differences in impact categories such as water scarcity and biodiversity, underscoring the importance of regionalisation.

PROXYLCA offers a practical and scalable solution to fill food LCI data gaps, supporting transparent and reproducible life cycle assessments which can help guide sustainable trade policies on the basis of robust, geographically relevant impact assessment.

5.08.P Increasing Access to Life Cycle Data: Bridging Transparent, Inclusive, and Reproducible Sustainability Knowledge

5.08.P-Tu430 Scaling Industrial Life Cycle Sustainability Assessments through Automation and Standardization: An Assessment of Barriers and Technical Solutions

Leonie Reif and Jana Backes, RWTH Aachen University, Germany

Integrating sustainability metrics into routine industrial decision-making remains challenging because current Life Cycle Assessment (LCA) practices are often too complex and inconsistent to allow for standardized industry adoption. These challenges are becoming more urgent as CO₂ pricing mechanisms (e.g., EU ETS, CBAM) create direct financial consequences for industrial sectors. Comprehensive sustainability assessments that integrate social and economic dimensions of sustainability, such as Life Cycle Sustainability Assessments (LCSA), introduce yet additional challenges. This motivates the following research questions:

1. What are the current barriers that limit the wider adoption of LCA for industrial applications?
2. What additional challenges does integrating economic and social assessments, as part of the LCSA methodology, present – especially for industry application?
3. Most important: Which opportunities exist for targeted standardization and computational automation to enable scalable, reproducible, and comparable sustainability assessments for industrial sectors?

Drawing on a structured review of existing challenges, we develop a research framework that organizes barriers into categories, such as data scarcity, methodological inconsistency, and low applicability of results, and identifies opportunities where advanced computational tools could provide substantive improvements. The framework highlights technical solutions such as Machine-Learning-supported data mapping, automated process decomposition using Large Language Models (LLMs), integrated uncertainty modeling, and multi-criteria trade-off analysis. For each opportunity, we assess its potential impact, such as expected cost and time savings, its limitations, and its implementation feasibility.

Our analysis suggests that combining targeted methodological standardization with computational automation

can significantly reduce assessment uncertainty, improve reproducibility, and enable a shift from retrospective compliance toward proactive decision support. This study contributes a comprehensive synthesis of current obstacles and provides a framework that defines strategic opportunities to accelerate the industrial adoption of LCSA practices.

5.08.P-Tu431 Data Based Buildings Archetypes for Probabilistic LCA

Thibault Chevilliet¹, Florence Jacquinod², Charlotte Roux³ and Adélaïde Feraille¹, (1)Navier, ENPC, Institut Polytechnique de Paris, Univ Gustave Eiffel, France, (2)Univ Gustave Eiffel, ENSG, IGN, EIVP, LASTIG, France, (3)MINES PARIS – PSL, France

Context - To reduce the environmental impact of urban development, planners must assess proposed construction at the earliest design stage. At this stage, urban projects are defined only by programmatic areas, and planners typically lack information about building geometry or material composition. Archetypes thus provide a solution for urban scale Life Cycle Assessment (LCA). However, current studies often use a single archetype for all buildings uses and most of them omit uncertainty and sensitivity analyses, even though the main goal of such early assessments is to determine both a mean value and the variability—the range of the projected construction impacts. In this work, focusing on materials, we investigate different methods for constructing program-specific archetypes (Individual housing, Collective housing, Offices, etc.), enabling comprehensive LCA (uncertainty, sensitivity and contribution analyses) of urban projects thanks to a French buildings database.

Methods – Common construction products processes are created to link the archetypes to a background database (ecoinvent). Two methods are then applied to the French Buildings Regulation ('RE2020') Observatory database to create program-specific archetypes. The first, direct strategy defines each archetype as a weighted linear combination of all buildings belonging to a given use category. A second approach use pre-calculated materials intensities to link the archetypes to the created products-processes. Along the way, we introduce a strategy to deal with lognormal fitting and lists of values that contain many zeros.

Results and Discussion – Results for both kind of archetypes are discussed. The first approach appears to be time-consuming but reliable, whereas the second is faster but introduces unrealistic products combinations, creating outliers that greatly increase standard deviations. This preliminary study shows that program-specific archetypes can be created from built projects database and employed in a probabilistic LCA. It also highlights that a more transparent buildings database with accurately identified construction products could reduce the uncertainties on LCA results. Future work will improve these initial results : computational efficiency of buildings-based archetypes will be increased through reused Monte-Carlo runs on products, and the physical relevance of materials intensities based archetypes will improved by introducing dependant sampling.

This research was conducted as part of a thesis funded by the ANR (ECOCIM ANR-22-CE04-0019).

5.08.P-Tu432 From Parametric LCA to Digital Twin: a Model and Data Framework for LCA

Automation

Jóhanna Sofia Guldbrandso Nolsøe¹, Till Tschiltshcke², Sebastian Wehking² and Massimo Pizzol¹, (1)Aalborg University, Department of Sustainability and Planning, Denmark, (2)Fraunhofer Institute for Production Systems and Design Technology, Germany

LCA is essential for evaluating environmental performance, yet traditional approaches are often static and labor-intensive, limiting their use in dynamic systems where variations in operating conditions demands models that are flexible and automated. At the same time, industry is embracing digitalization through real-time data, automation, and digital twins—virtual representations of physical systems. Integrating LCA into these frameworks enables dynamic, data-driven sustainability assessments. This study outlines the development of a parameterized LCA model designed to incorporate both data variability and process variability within the assessment framework, while enabling automation of calculations. The application context is microalgal production, a process characterized by high variability due to factors such as meteorological conditions, geographical location, and operational capacity.

Given this variability in operations, it is essential to adapt the LCA model not only in terms of the input values used for modeling but also in terms of its structural configuration—specifically, the types of activities included under different operational scenarios. To address this challenge, we developed data collection guideline tailored

for the development of a parametrized and digitalized LCA model. This guideline is tailored to accounts for variability effects, prioritizes components already utilized in production, and identifies specific sources of variability within the system, that are then turned into model parameters. Next, interviews with technology developers clarified the current level of digitalization and data integration, so that the LCA model can build on top of existing capacity and seamlessly integrate with that. The parameterized model is then integrated with a digital twin representation of the production facility, thereby enhancing dynamic assessment and decision-making capabilities. A semantic schema then maps primary process information to the provided secondary data and elements of the LCA model and allows for automated reasoning and model reconfiguration. The implementation of the data mapping and the interface to an LCA software (brightway) is described through a functional and logical system architecture. Overall, this system allows an automated LCA to be implemented via a software-based microservice that can be integrated into existing industrial IT environments through appropriate communication endpoints.

5.08.P-Tu433 An Innovative Method for Retriving Inventory from Product Definition: LCA of Magnesia-carbon Refractory Ceramics

Md Jubayed¹, Angélique Leonard² and Rinus Siebring³, (1)University of Liège, Belgium, (2)University of Liege, Belgium, (3)Tata Steel Netherlands, Netherlands

Refractory materials are essential for sustaining high-temperature industrial processes, with the steel industry being the largest consumer. Collecting inventory for refractory production is challenging due to confidentiality concerns and suppliers' reluctance to share data. To overcome this, an innovative method has been developed to retrieve essential inventory data from the refractory's product definition. The method is demonstrated through a case study comparing two magnesia-carbon refractory bricks used for steel ladle slag lining: one produced in China and the other in the Netherlands. Inventories for brick production are derived from the respective product definitions and compared actual industrial data. Life cycle assessment results reveal that the Netherlands brick performs better in climate change and acidification, while the Chinese brick shows lower impacts in other categories considered in this study. Electricity consumption during magnesia production and thermal energy demand for ladle heating are identified as the major environmental hotspots. Energy transition scenarios demonstrate the potential for significant improvements. Replacing national grid electricity and natural gas with renewable electricity and green hydrogen leads to more than 30% reductions in most impact categories. Climate change impacts, for instance, decrease from 1.89 to 0.97 kg CO₂ eq for the Chinese brick and from 1.67 to 0.77 kg CO₂ eq for the Netherlands brick. Sensitivity analysis shows that magnesia production strongly influences environmental performance, while uncertainty associated with product-definition-derived data is generally minor for most impact categories.

5.08.P-Tu434 Multi-regional Chemical Emission Inventory for Freshwater Ecological Risk based on PRTR and GLORIA

Marika Muramoto¹, Wataru Naito², Masaharu Motoshita³, Keitaro Maeno³ and Norihiro Itsubo Dr¹, (1)Waseda University, Japan, (2)Riss, National Institute of Advanced Industrial Science and Technology, Japan, (3)National Institute of Advanced Industrial Science and Technology, Japan

Freshwater ecosystems face a biodiversity crisis: roughly one quarter of species are at risk of extinction, largely due to chemical pollution and agricultural activities. The Global Framework on Chemicals (GFC) calls for evidence-based management of chemicals across their life cycle. In LCA study, impact assessment methods such as the USEtox model and the use of hazard concentrations for 20% of species (HC20) have advanced. On the inventory side, Leclerc et al. (2023) estimated a global toxic footprint by combining multiple emission

databases with an environmentally extended multi-regional input–output model, but their assessment relies strongly on extrapolation using proxy indicators (e.g., economic output) where Pollutant Release and Transfer Register (PRTR) data are lacking, leaving room for more detailed analysis of country- and sector-specific emission patterns.

This study aims to develop a multi-regional chemical emission inventory by integrating national PRTR data with the Global Resource Input–Output Assessment (GLORIA) database and to link this inventory to freshwater ecological risk assessment.

We first selected approximately 200 chemicals of concern for freshwater ecosystems, including metals, from PRTR in regions such as Japan, Europe, North America, and so on. Facility-level annual releases were then compiled by compartment (air, water, soil) and industrial activity, and each emitting facility was mapped to the corresponding GLORIA sector to calculate emissions by country, substance, and sector. For countries and substances without PRTR coverage, we completed the inventory by combining sectoral production data from GLORIA with emissions derived from PRTR countries. For ecological risk assessment, we applied a nonlinear model for algae, invertebrates, and fish, used species sensitivity distribution curves to describe log-normal concentration–effect relationships for each substance, and derived characterization factors by accounting for mixture toxicity across multiple substances and species.

This presentation reports initial analyses of emission patterns and examines how key inventory assumptions influence ecological risk indicators. The integrated PRTR–GLORIA inventory provides a promising approach to explicitly represent regional and sectoral differences in chemical emissions within LCA and can support the identification of chemical pollution hot spots, priority substances, and options for improving national chemicals management policies.

5.08.P-Tu435 Towards Reproducible, Transparent, and Interoperable LCI: the Role of Collaborative Digital Tools

Gabrielle Tihon, Martin Besnier, Paul Grédigui, Alice Marchal, Yohan Lanier, Mathis Girard, Eulalie Bonnot and Antoine Bouvart, Holis, France

Context

As sustainability assessments become central to regulatory and corporate decision-making, the demand for comprehensive and specific Life Cycle Inventory (LCI) data is rapidly increasing. Yet, LCI data collection remains fragmented and largely confined to conventional LCA-oriented sources, overlooking complementary sustainability data such as Material Flow Analysis, logistics data, or risk and compliance information. This lack of integration limits data completeness, traceability, and reproducibility, especially across global supply chains.

Research Question

How can a digital, collaborative data collection system improve the completeness, reproducibility and interoperability of LCI data by integrating heterogeneous sustainability data sources, while engaging supply chain stakeholders in continuous improvement?

Methods

We propose a collaborative data collection tool - Holis Workshop - aiming to simplify seamless data exchange between brands and suppliers, while adding value for both parties. Holis Workshop works together with Holis Studio - LCA & eco-design platform - but can virtually be paired with any LCA software.

The tool allows standardized and flexible data requests at process, product, and portfolio levels, while connecting with LCA software and enterprise systems (ERP, PLM). Its architecture is designed to integrate non-traditional LCI data sources (e.g. logistics datasets, material flow data) through common data structures and mapping protocols to ensure data reproducibility.

Advanced features under development include automated anomaly detection, consistency checks, and impact-driven prioritization of data gaps, improving data robustness and uncertainty management.

For suppliers, the tool reduces data sharing burden through existing systems integration (ERP, PLM) and efficient batching. In future versions, the tool will allow suppliers to value all transmitted data and offer cost-saving insights and eco-design recommendations on their own processes. We are actively gathering industry feedback to ensure this feature meets real-world needs and expectations.

Conclusion

Holis Workshop demonstrates how collaborative digital infrastructures can bridge fragmented sustainability data ecosystems and move beyond conventional LCA data boundaries. By integrating diverse data sources and enabling transparent, reproducible, and scalable LCI data collection, the approach contributes to more robust inventory modeling, improved regulatory alignment.

5.08.P-Tu436 A Data Structure for Life Cycle Inventory and Life Cycle Assessment Data in the Digital Product Passport

Berend A Mintjes¹ and **Francesco Barilli²**, (1)Leiden University, Netherlands, (2)No Affiliation, Switzerland

Digital Product Passports (DPPs) are a tool for digitally transferring information along value chains. DPPs can support Life Cycle Assessments (LCAs) by improving data availability and reducing the burden of data collection along supply chains. Particularly, embedding life cycle inventory (LCI) data within DPPs has the potential to enhance the transparency and standardisation of product sustainability reporting. However, the practical integration of LCI and LCA data into DPPs raises methodological and structural questions regarding how environmental information should be collected, organised, and communicated in this context.

In this paper, we investigate potential pitfalls and their solutions in the incorporation of environmental footprints in DPPs. We outline data requirements for PEF-compliant LCA studies, both for output data (PEF results) and input data (unit process LCIs and product system parameters), and translate these to a DPP system. From this, we derive a comprehensive data structure for unit process LCI data (inputs) and LCA results (outputs) in DPPs that enables standardisable, PEF-compliant environmental impact calculation.

We demonstrate the relevance of this data structure using two case studies: printer cartridges and heat pumps. By comparing and contrasting applications across these different product categories, we aim to show the general applicability of our data structure. We conclude with recommendations for the implementation of sustainability indicators in DPP regulations and infrastructure.

5.08.P-Tu437 Integrating Life Cycle Data into Digital Product Passports: Open-Source vs Licensed Inventories

Alice Mondello¹, **Franco Donati¹**, **Jeroen Guinée¹** and **Marco Cinelli²**, (1)Leiden University, Netherlands, (2)Decision Engineering for Sustainability and Resilience Laboratory, Leiden University College, Faculty Governance and Global Affairs, Leiden University, Netherlands

Digital Product Passport (DPP) is an emerging instrument that may enable greater access, transparency, and traceability of product sustainability and life cycle data across supply chains. According to current European Commission proposals, DPPs will include Life Cycle Assessment (LCA) inventory data and impact assessment results, making the availability of accessible and high-quality datasets a critical prerequisite. However, widely used LCA databases may be subject to restrictive licenses, limiting their future integration into DPPs.

To address this data-access challenge, the study explores whether open-source LCA inventory datasets can support DPP implementation without compromising methodological robustness. To answer this research question, an exploratory case study focused on laser welding processes is used as a test bed. Because laser welding represents an intermediate manufacturing step used across multiple value chains, its inventory data can directly support the DPPs of diverse final products, including pharmaceutical devices, automotive components, and battery systems. Specifically, the study compares the modelling of this process using licensed ecoinvent data and other open-source alternative databases.

The study aims to map differences by evaluating inventory flows, system modelling consistency, and data completeness under harmonised LCA assumptions. Expected results include the identification of key structural and methodological differences between databases. These may relate to the sector-process hybrid versus the process-based structures, as well as to the emphasis on carbon footprint information compared with broader product footprint data.

Beyond the specific laser welding case, the study emphasizes the broader relevance of improving access to life cycle data as a foundation for effective DPP implementation. In this context, achieving an appropriate balance between the openness of publicly available inventories and the methodological robustness and the granularity of licensed datasets such as ecoinvent emerges as a key challenge across all product sectors. The insights generated aim to support policymakers, database developers, and industry stakeholders in facilitating the reliable integration of LCA data into future DPPs, ultimately contributing to more transparent and interoperable digital product information systems.

5.08.P-Tu438 Reusables, Disposables and Systems In-between – A Comparison of the Environmental Impacts of Trocar Systems Using Life Cycle Assessment and Material Characterization

Rebekka Maria Brandwijk¹, Pranav Nakhate¹, Yvonne van der Meer¹, Tim Stoberneck² and Hugo Touw²,
(1)Maastricht University, Netherlands, (2)Radboudumc, Netherlands

While healthcare is important, it is also responsible for approximately 7% of national greenhouse gas emissions and 4.2% of all waste in the Netherlands. One component that contributes to this issue is the usage of a lot of disposable instruments, such as the trocar. This instrument that is used in all laparoscopic surgeries to create an opening into the body is available as a disposable, reusable and hybrid system. These different systems all have their own perceived advantages, one of which is that the reusable system is often assumed to have the lowest environmental impact. However, the environmental impact of a trocar system depends on several factors, such as the specific type and the hospital. This research therefore not only determines which trocar has the lowest impact, but also what other variables involved at the hospital lead to more sustainable practices. This is done by analyzing different types of trocars in different settings. The environmental impacts were calculated through life cycle assessment using Activity Browser and Ecoinvent (cut-off). The scope for all different systems was cradle to grave and excluded hospital infrastructure and any potential repairs of the trocar systems. To consider all different variables, data was gathered directly through material analysis (more specifically, Fourier-Transform Infrared Spectroscopy), interviews and surveys where possible. Preliminary results reveal that the reusable trocar system used in the academic hospital with external sterilization had the lowest carbon footprint (0.32 CO₂eq) whereas usage of the disposable system at the same hospital led to the highest impact (1.74 CO₂eq). The impact of the former mainly originated from the sterilization process (91%), whereas the latter was mostly caused by the manufacturing phase (81%). These results can subsequently be used to define other points of improvement to reduce environmental impacts. The findings can help to make all laparoscopic surgeries more sustainable. Furthermore, the research provides a workflow that can also be applied to other medical instruments to continue decreasing the impact of the healthcare sector.

5.08.P-Tu439 Life Cycle Insights of Regional Natural Gas Liquids (NGLs) Supply and Use as Steam-Cracker Feedstock

Sangram Ashok Savant, ecoinvent Association, Switzerland

The steam cracking process supplies essential building blocks used in the chemical and plastic industries, namely light olefins and aromatics. Heavy hydrocarbons remain a dominant global feedstock for steam cracking. On average, such feedstock mixture consists mainly of naphtha and atmospheric gas oil accounting for about 51% and 6%, respectively. At the same time, natural gas liquids (NGLs), whether as mixed streams or separated fractions (e.g., such as ethane, propane, and butane), are gaining importance as feedstock for steam crackers worldwide.

Notably, supply chain models used in life-cycle databases often treat NGL feedstocks and downstream steam cracking systems as regionally homogeneous. This approach, however, neglects substantial regional differences in upstream extraction, fractionation, transportation, and steam cracking feedstocks and facility configurations, which can significantly influence energy demand, greenhouse gas emissions, and other environmental burdens.

Versions 3.11 and 3.12 of the ecoinvent database provide enhanced geographic coverage of oil and gas extraction for 40 countries, natural gas supply mixes for 57 countries, refined regional transport and pipeline/LNG shipping distances. Building on this geographical representation, we present how regional NGL production and fractionation affect the life-cycle impact assessment (LCIA) results of key feedstocks and how these effects carry through regional steam cracking operations.

Developed within ecoinvent, we present a comprehensive LCI modelling framework that enables capturing the regional variability of NGLs production/fractionation in key producing countries. By applying region-specific parameterization instead of a one-size-fits-all assumption, we reveal substantial variation in LCIA results. For instance, regional carbon-intensity scores for ethane from NGL fractionation range from 50% below to 11% above the global average representation.

This analysis underlines the importance of adequate supply chain resolution: from NGL extraction via fractionation and transport to steam cracking operation regions, for more credible LCIA results for key

hydrocarbon feedstocks and petrochemicals. Looking ahead, the ecoinvent team will expand the modelling beyond steam cracking to enable geographically explicit supply chains from oil and gas extraction to NGL production. On this basis, further regionalizing downstream petrochemicals and plastics production remain a key objective.

5.08.P-Tu440 Beyond Standard Distances: Modeling Transport Routes in the ecoinvent Database

Mattia Clementi¹, Enkeled Hoxha¹, Avraam Symeonidis² and Thomas Sonderegger², (1)ecoinvent Association, Switzerland, (2)ecoinvent, Switzerland

Transport accounts for 23% of global energy-related CO₂ emissions, yet LCA databases like ecoinvent generally rely on simplified distance assumptions. Current methodologies often lack the integration of world trade flows, distance-calculation algorithms, and transparent uncertainty characterization; these gaps become critical as regulatory frameworks demand greater data specificity.

With the aim of improving the accuracy and transparency of transport distances in ecoinvent's inventories, we present a novel methodology that incorporates global trade and transport data into the ecoinvent database. The approach identifies production and consumption centers within countries, then computes origin and destination hubs through clustering and optimization algorithms, ultimately connecting these hubs into a network.

UNCTAD trade statistics provide empirical modal splits for the different segments, supported by mode-specific solutions that are used for routing and distance calculation: OpenRouteService for road and rail, the Python searoute package for maritime, and great circle distance for aviation. Benchmark validation against real-world data confirms the accuracy of the methodology: results fall within a 0.5-5% interval across different modes of transport.

The results provide distance calculations for different product categories differentiated by fleet composition, emission standards, and regional characteristics. This improves the distances and the related emissions used in the ecoinvent database while providing transparency on underlying data and modeling. The framework demonstrates how data integration, transparent validation, and AI-supported automation can transform static estimates into dynamically calculated and realistic transport distances. Overall, this new approach gives a more accurate representation of the impact of transport in supply chains.

5.08.P-Tu441 Describing the development of harmonised life-cycle inventories for Brazilian pasture systems supporting beef production.

Rafael Zortea¹, Sophia Chamilete², José Savioli², Alexandre Berndt³, Roberto Giolo de Almeida⁴ and Marília Folegatti², (1)IFSul - Câmpus Sapiranga, Brazil, (2)Embrapa Meio Ambiente, Brazil, (3)Embrapa Pecuária Sudeste, Brazil, (4)Embrapa Gado de Corte, Brazil

This study describes the development of harmonised life-cycle inventories for Brazilian pasture systems supporting beef and dairy production. A stepwise process was implemented combining literature review, inventory construction in ICV Calc Software, export and refinement in LCA software, and expert validation through workshops. Three pasture management systems (extensive, semi-intensive and intensive) were characterised, with explicit documentation of inputs, operations, and system boundaries both for beef and dairy cattle, totaling 25 inventories combining distinct pastures and management systems. Scenarios with and without land use change (LUC) were generated using the BRLUC methodology. A comprehensive screening of scientific studies enabled benchmarking and ensured methodological transparency. This iterative workflow produced a set of traceable and replicable pasture datasets, laying a qualitative foundation for future quantitative analyses, literature comparisons, and low-carbon beef certification programmes.

5.08.P-Tu442 New modelling approach for multi-nutrient inorganic fertilizers in the ecoinvent database: solving the double-counting issue.

Andreas Giakoumatos¹, Francesco Cirone² and Simone Fazio¹, (1)ecoinvent, Switzerland, (2)Agriculture, ecoinvent, Switzerland

In ecoinvent database, multi-nutrient inorganic fertilizers (MNIFs) can be modeled either as a composition of single inorganic nutrients (SIN) (as N, P₂O₅, K₂O) or as complete fertilizer products (such as NPK (15-15-15)). The supply chain starts from: i) The chemical production activity of MNIFs linked to their market; ii) Markets are connected with nutrient activities supplying the SIN of MNIFs; iii) The nutrient supply activity is an intermediary between the chemical production and the market mix of SIN; iv) The market mix providing SIN from the MNIFs to the agricultural production systems.

When MNIFs are applied in crop production datasets, the amounts of SIN are partially double-counted or, in some cases, underestimated due to the supply chain. The new modelling addresses this issue by estimating the

residual nutrient contribution dose (RNCD) from MNIFs and applying correction flows at the crop inventory level. The RNCD of each SIN from the MNIFs is calculated based on the nutrient composition of MNIFs per the exchange amount in the crop dataset. As a result, the inorganic fertilizer is now linked to the MNIF for each specific SIN (e.g., “inorganic nitrogen fertilizer, as N, from NPK (15-15-15)”). Finally, market datasets for MNIF fertilizers are recalculated to rebalance nutrient shares, ensuring that the quantities reflect the compositional ratios of each MNIF. The new modeling affects approximately 400 datasets. The results show a reduction (or slight increase) in LCIA scores in most cases, since inorganic fertilizers are among the most impactful inputs in agricultural inventories.

5.08.P-Tu443 Data Extrapolation in Life Cycle Inventories for the Agri-food Sector: Challenges and Approaches

Sara M. Pinto¹, **Carolina C. Fraga¹**, **Daniela Correia²** and **Emanuel Lourenço¹**, (1)INEGI - Institute of Science and Innovation in Mechanical and Industrial Engineering, Portugal, (2)MC Sonae – Mc Shared Services, S.A., Portugal

Life Cycle Assessment (LCA) has become an essential tool for evaluating the environmental impacts of the agri-food sector, yet researchers often encounter data gaps in life cycle inventories (LCI), especially when analysing region-specific practices, emerging food products, processing technologies, or situations where primary data collection is not feasible. Inventory data extrapolation becomes a crucial methodological necessity, but it also introduces significant uncertainties that can compromise the robustness and reliability of LCA results. Accurate and representative inventory data are crucial for reliable LCA studies, as the quality of LCI directly affects the robustness of impact assessment results and, consequently, the credibility of sustainability conclusions. When primary data are incomplete, missing, or inconsistent, extrapolation allows practitioners to estimate, adapt, or extend available information to develop more comprehensive inventories. However, the range of extrapolation approaches and the lack of harmonised guidance present challenges for methodological transparency and comparability, especially in agri-food systems where processes vary significantly across regions and production conditions.

This work conducts a structured literature review to examine the role of data extrapolation in LCI development for the agri-food sector. The review aims to identify and discuss the main types of data gaps reported in agri-food LCAs, exploring challenges and sources of uncertainty within the sector, list common extrapolation practices used in the context of LCIs, and identify strategies to improve the reliability and transparency of extrapolated data. Approaches such as proxy datasets, scaling methods, and contextual adjustments are examined regarding their potential advantages, limitations, data requirements, and suitability for different gap scenarios. It also investigates how these practices influence uncertainty and how their applicability varies with technological, geographical, and temporal characteristics of the agri-food sector systems.

This work advances LCA methodology by critically analysing extrapolation practices in agri-food contexts and suggesting ways to improve transparency, reproducibility, and reliability when data gaps require extrapolation in LCA development.

This work was supported by Agenda VIIAFOOD - Plataforma de Valorização, Industrialização e Inovação comercial para o AgroAlimentar (Aviso nº 02/C05-i01/2022; agenda nº C644929456-00000040), funded by the Portuguese Recovery and Resilience Plan (PRR) and European funds NextGeneration EU.

5.09.A Life Cycle Assessment for Sustainability Decisions: Methodological Challenges and Future Directions

5.09.A.T-01 People in the ISO Life Cycle

Tomas Ekvall¹ and **Sofia Poulidikou²**, (1)Tomas Ekvall Research, Review & Assessment, Sweden, (2)Höganäs AB, Sweden

When the generic standards for life cycle assessment (LCA; ISO 14040 and 14044) are due for systematic review next time, the arguments for revising the standards are strong. Both clarifications and updates are needed. However, increasing the clarity of the standards will be a major challenge, because long-standing conflicts over the LCA methodology remain – for example on allocation and the choice of input data. Resolving these conflicts probably requires constructive discussions based on a deeper understanding of the opposing positions. The aim of this presentation is to contribute to such understanding. We explore how different mental models of the life cycle can relate to different ideas of the purpose of LCA and, hence, to different opinions on

the appropriate methodological choices. We do so by describing two archetypical examples of LCA experts.

“The chemical engineer” considers the life cycle as a system of physical flows – an extension of the flow charts used in process industry. The task of an LCA practitioner is then to quantify these flows as precisely as possible. Input data on activities in the supply chain should ideally be primary data from the contracted suppliers. Marginal, credit-based mass-balance and book-and-claim approaches are problematic because they result in models that deviate from the physical reality. Substitution can be problematic because it increases uncertainty and, hence, reduces precision in the results. Economic allocation is avoided because it is not robust over time. When an allocation problem occurs, it is instead reasonable to look for the best physical basis for the allocation.

“The systems scientist” observes that the purpose of LCA to assist in the transition to a sustainable society and defines the life cycle as a large sociotechnical system. Human decision-makers, market mechanisms, etc. are important aspects of this system. Relevance for decision-making and incentives for change are more important than precision. Consequential LCA is relevant because it takes market mechanisms into account in the use of marginal data and substitution. People can be accounted for also in attributional LCA through economic allocation. Chain-of-custody approaches should be assessed case by case depending on whether they drive change or merely allow for greenwashing.

Constructive debates on the mental models and on the purpose of LCA can lead to better understanding of opposing positions on the methodology.

5.09.A.T-02 Measuring Sustainability and Circularity of Products: Development of a Harmonized Digital Material Passport for Chemicals Enabling the Transfer of LCIA, Circularity and Safety Data Along Supply Chains

Alessandro Pistillo¹, Peter Saling², Dominik Auer³ and Achim Ilzhöfer⁴, (1)BASF, Germany, (2)CDS/S, BASF, Germany, (3)WACKER Chemie, Germany, (4)COVESTRO AG, Germany

The transition toward a circular economy and the implementation of sustainability principles in product design require transparent, interoperable, and verifiable data exchange across complex supply chains. Upcoming regulatory frameworks in the European Union and other jurisdictions mandate Digital Product Passports (DPPs) for diverse product categories, including textiles, tyres, construction materials, and detergents. These developments will significantly impact chemical manufacturers, who must provide cradle-to-gate life cycle impact assessment (LCIA) data, circularity metrics, and product safety information (e.g., substances of concern) to downstream sectors in a standardized and scalable manner.

This contribution outlines an approach for developing a harmonized Digital Material Passport (DMP) for chemicals, designed to enable the efficient transfer of sustainability and circularity information along value chains. The work includes sectoral specific guidelines for environmental sustainability, circularity, and material declaration grounded on ISO/EN standards and landmark regulations and frameworks, complemented by an emerging information model that defines a comprehensive set of attributes for LCIA and circularity metrics, as well as material declaration. These elements form the foundation for a horizontally harmonized vocabulary and determination methodology, ensuring consistency across sectors and alignment with regulatory requirements. The proposed framework addresses three critical challenges:

1. Data interoperability through standardized vocabularies and machine-readable formats;
2. Methodological harmonization for calculating LCIA and circularity indicators at the chemical product level;
3. Integration into digital ecosystems to support secure, scalable data exchange between upstream and downstream actors.

Preliminary results demonstrate how harmonized guidelines and attribute models can reduce complexity and foster transparency, enabling chemicals to serve as enablers of sustainability in downstream applications. The presentation will discuss the developed LCIA and circularity framework, as well as the conceptual architecture of the DMP, key design principles for interoperability, and lessons learned from initial implementation efforts. This work contributes to accelerating compliance with DPP regulations and advancing the circular economy in the chemical sector downstream applications.

5.09.A.T-03 The EcoBeautyScore: A Science-Based and Harmonized Environmental Scoring Scheme for Cosmetics

Sophie Achigar¹, Alessio Aufoujal¹, Tasnim Balgobin¹, Eric Bone², Andrea M Carrao³, Iguatemi Costa⁴, Laurent Gilbert⁵, Stéphanie Johann¹, Mathilde Kolenda¹, Sacha Laruelle⁶, Rebekah Lees⁵, Jacques L'Haridon², Camille Martin², Olena Onyshchenko⁷, Anke Pilzner⁸, Jennifer K. Saxe⁹, Pascal Seel⁸, Laura Tasso¹ and Jad Zoghaib², (1)Quantis, France, (2)L'Oréal, France, (3)Kao USA Inc., Cincinnati, OH, France, (4)Natura Cosméticos, Brazil, (5)EcoBeautyScore Association, Belgium, (6)LVMH Recherche Parfums & Cosmétiques, France, (7)Henkel AG & Co. KGaA, Germany, (8)Beiersdorf AG, Germany, (9)Kenvue, United States

The EcoBeautyScore (EBS) Association has created a harmonized, science-based framework to measure and communicate the environmental performance of cosmetic products. Built on Life Cycle Assessment (LCA) and aligned with the European Commission's Product Environmental Footprint (PEF) guidelines, the methodology adapts PEF principles to the specific characteristics of cosmetics, considering their diverse functions and usage patterns. Since mid-2025, the system has been progressively deployed in Europe to support transparent consumer communication.

The footprinting approach evaluates 16 environmental impact categories across the full product life cycle, using PEF-consistent normalization and weighting to obtain a single aggregated footprint. To ensure comparability, products are grouped into 30 coherent segments defined by their primary function, each with standardized functional units and default usage doses.

A major pillar of EBS is the construction of harmonized ingredient databases covering production and end-of-life impacts. Due to the large diversity of cosmetic ingredients, a prioritization strategy was applied to identify the most impactful and frequently used substances. Data were sourced from public datasets and industry contributions; when needed, scientifically robust default values were used. Significant advances were made in ecotoxicity modelling, especially to address limitations in USEtox 2.1. The Most Sensitive Species–HC5 approach was adopted to improve the robustness and coverage of effect factors.

To support consumer understanding, the aggregated footprint is translated into an A–E score. This scoring relies on segment-specific statistical calibration based on a representative sample of at least 100 marketed products per segment, ensuring realistic and meaningful thresholds.

Testing on over 1,900 products revealed strong differences between product types. For rinsed-off products, the use phase dominates impacts but offers little differentiation; ingredient production and end-of-life phases are more discriminating. For leave-on products, packaging and ingredient end-of-life are the main contributors. These findings highlight the importance of refined ecotoxicity modelling and segment-specific assessment. Overall, the EBS framework provides a robust, scalable, and transparent system to assess and compare the environmental impacts of cosmetic products, supporting both consumer information and eco-design strategies.

5.09.A.T-04 Advancing Consumption-Based Decision Support: Modelling Carbon and Biodiversity Border Taxes for EU Food Systems

Livia Cabernard¹, Nadine vom Hofe¹, Veronika Schlosser² and Jutta Roosen¹, (1)Technical University Munich, Germany, (2)Technical University of Munich, Germany

The European Union's food system exerts disproportionate pressure on global climate and biodiversity, largely through imports from high-impact regions. To support evidence-based decision-making on sustainable food systems, we evaluate how trade-based policy measures can reduce the environmental footprint of EU food consumption. We integrate a high-resolution, multi-regional input–output framework, spatially explicit land-use-change emissions, ecoregion-level biodiversity risks, and EU-specific demand elasticities to assess the effects of carbon and biodiversity Border Adjustment Taxes (BATs) on the EU's international food supply chains. We model carbon, biodiversity, and combined BATs across ten tax levels, and assume that high-impact imports are replaced with domestic EU production. Results show that a combined BAT of 100 €/tCO₂-eq and 100 × 10¹² €/PSL_{glo} reduces EU food-related impacts by 9% (climate) and 15% (biodiversity), with even greater reductions for beef (–12% climate, –35% biodiversity). Reductions are concentrated in Latin America, Africa, and Asia–Pacific, and are accompanied by job losses and value-added shifts in exporting regions. A small number of trade flows drive much of the effect: the Netherlands' and Italy's reduced beef imports from Brazil, Australia, Namibia, and Botswana account for half of the environmental impact reduction of beef, while France's reduced imports of vegetables, fruits, and nuts from Morocco and Côte d'Ivoire account for a quarter of total job losses. While BATs alone cannot align EU food consumption with planetary boundaries, they provide strong leverage for targeting high-impact flows. Integrating carbon and biodiversity pricing into EU trade policy would fill a critical gap and advance the Green Deal and Farm-to-Fork objectives. This study supports policymakers by identifying leverage points in international supply chains and quantifying the global consequences of sustainability-oriented trade measures.

5.09.B Life Cycle Assessment for Sustainability Decisions: Methodological Challenges and Future Directions

5.09.B.T-01 Applying Life Cycle Assessment at Different Levels: Deriving Insights for the Potential of Bio-based Solutions

Giulia Listorti¹, Taija Sinkko², Annarita Valenzano³, **Andrea Amadei¹** and Serenella Sala¹, (1)European Commission - Joint Research Centre (JRC), Italy, (2)Piksel S.r.l., Italy, (3)Unisystems S.r.l., Italy

The scarcity of natural resources and increasing environmental pressures due to current production and consumption patterns demand policies to ensure the EU's competitiveness and sustainability. The bioeconomy offers a pathway to transition towards greener systems. Life Cycle Assessment, a method for evaluating environmental impacts across the whole value chain and life cycle stages, enables analysis of multiple environmental impacts, unveiling burdens, benefits and trade-offs, but at the same time facing challenges in comparability between studies due to varying system boundaries and assumptions. LCA can be used to assess and compare the environmental performance of products, as well as to allow analysis at a more aggregate level. The aim of the study is to assess environmental impacts using illustrative case studies at the material (e.g., plastic packaging or fuel), and product level (e.g., packaged product or vehicle), up to enlarging the analysis to selected insights at the EU aggregate consumption level, both as a total consumption of selected materials and when considering the average EU citizen. By analyzing impacts at these scales, the study reveals insights into material choices, product performance, and broader consumption trends, supporting informed decision-making for sustainable development.

The magnitude of environmental impact differences diminishes as the assessment shifts from the material to the product level, and further to the EU citizen level. This variation depends on modeling assumptions, the type and relevance of the conventional material, and the feedstock of bio-based alternatives. Nevertheless, the results provide valuable insights on the expected environmental impacts, trade-offs, and key leverage points in consumption that support the transition to sustainability. At the material level, the choice of bio-based materials is relevant for specific environmental impacts. Instead, product level analysis highlights leverage points and potential benefits across the entire value chain. The benefits obtained at the EU level depend on the rate and share materials can substitute their conventional counterparts. Results also show the importance of conducting analysis at various levels while transparently reporting all modelling choices and assumptions behind, to make sure correct and consistent messages are conveyed to support the research and policy debate in finding solutions for sustainability transitions.

5.09.B.T-02 Enhancing Comparative Life Cycle Assessment Decision-Making Through Objective Reduction of Impact Categories Under Uncertainty

Tejas Dilipsing Patil¹ and Sibylle Duval--Dachary², (1)IFP Energies Nouvelles (IFPEN), France, (2)IFP Energies nouvelles (IFPEN), Rueil-Malmaison, France

Comparative Life Cycle Assessments (LCAs) often include many midpoint impact categories, which can make results harder to interpret and decisions more complicated. Existing methods for choosing relevant categories were developed for single systems and are not well suited to comparative studies that involve uncertainty. This research aims to develop an objective and transparent way to reduce the number of impact categories while keeping results meaningful and reliable. The main hypothesis is that if the difference between systems is neither statistically nor practically significant, that category may not be considered for decision-making.

The proposed framework focuses on the Life Cycle Impact Assessment (LCIA) step and integrates uncertainties in characterization factors, which are often simplified or ignored in current studies. These uncertainties are represented through probability distributions and analyzed using statistical tests. A combination of significance testing and effect size analysis helps identify which categories show real and meaningful differences. Depending on the comparison, paired t-tests or one-way repeated-measures ANOVA are used, with corrections applied to avoid false positives and prevent type-1 errors. Only categories showing statistically and practically significant differences are selected for decision making.

The approach was tested by comparing the production of one kilogram of three lithium-ion battery chemistries, LFP, NCA, and NMC111 using data from ecoinvent 3.11 and the EF 3.1 method. Uncertainties of twelve impact categories were analyzed using 1,000 samples of characterization factors generated through Latin Hypercube Sampling. The results showed that six categories had both statistical and practical significance, confirming the method's ability to simplify comparisons by objectively reducing the number of impact categories.

This framework provides a clear, data-driven approach to support decision-making in comparative LCAs. It can be applied to any LCIA method, depending on the availability of uncertainty data, and remains flexible to meet user-specific needs. Future work will extend the framework to a territorial context, connecting results to

planetary boundaries to evaluate how close each impact is to critical environmental thresholds and to further refine the selection of impact categories.

Disclaimer/Disclosure:

This research was conducted within the LCA SPLEEN project, part of the PEPR SPLEEN program for industrial decarbonization and benefited from French State aid managed by the Agence Nationale de la Recherche under the France 2030 plan bearing the reference code ANR-22-PESP-0003.

5.09.B.T-03 More Robust Results through Normalisation using the Central Values from the Inventory Database

Arnaud Helias¹, Michèle Gaillard¹ and Karine Dufossé², (1)National Research Institute for Agriculture, Food and Environment (INRAE), France, (2)Montpellier Agro Institute, France

Normalisation in LCA allows comparing impacts relative to each other by making results dimensionless, enabling aggregation through weighting and consistency checks against a reference. LCA relies on external normalisation for meaningful references. Previous studies highlighted the importance of aligning normalisation references with inventory data and proposed values linked to LCI databases. This work improves the approach by replacing the geometric mean with the median to enhance robustness, illustrated using the Ecoinvent database and the Environmental Footprint (EF) 3.1 method. LCA impacts and flows are often log-normally distributed, making geometric mean a relevant option. However, some flows are negative, rendering geometric mean calculation impossible and previous estimation algorithms partially unsatisfactory. For log-normal distributions, the geometric mean and median are theoretically equivalent, motivating the use of the median as the reference. Calculations were performed using Ecoinvent 3.11 for APOS, Cut-off, and Consequential system models with Brightway 2.5, and results were compared with EF 3.1 literature values. Strong log-log correlations were observed between geometric mean and median for all models ($r > 0.999$). Comparisons with EF 3.1 show high correlation ($r > 0.98$) but discrepancies regarding certain impacts are being discussed. Using the median of inventory databases as the normalisation value produces more robust and consistent results, minimizing biases. In absolute sustainability assessments, impacts are normalised according to the safe operating space, raising issues of consistency in metrics and system boundaries. Data-consistent normalisation mitigates these issues, while still requiring alignment with planetary boundary considerations, offering a practical alternative to reconciling all units and system differences.

5.09.B.T-04 Damage-Based Weighting Factor for Human Health-Related Impacts

Michèle Gaillard and Arnaud Helias, INRAE Montpellier, France

Aggregating information to simplify multicriteria decision-making is a common but complex problem. Life Cycle Assessment addresses it in two ways: (1) through modelling up to the damage level and grouping impacts by area of protection, and (2) through less advanced (midpoint) modelling in which aggregation is obtained through weighting.

After normalisation, weighting methods imply choices and face criticism because they depend on value judgments and/or political decisions. For instance, for the Environmental Footprint 3.1 single score, weighting factors are built from a panel approach, meaning that the selection of the panellists can greatly influence the results. However, weighting factors derived directly from damage instead are preferable. Impact categories are then weighted according to their severity. From this, an interesting assumption is that midpoint impacts weighted according to damage should converge towards the contributions of final impacts in the protection areas, and to study possible divergences.

To develop weighting factors based on damage, giving the example of Human-Health-related impacts, epidemiological data from the Lancet Commission on Pollution and Health were used. The most recent updates provide quantified estimates of pollution-related mortality and of climate-change-related mortality. These data were compared, using correlation analysis, with the individualist ReCiPe 2016 endpoint results.

This analysis reveals a significant correlation between the data, showed by the $R=0.84$ and $p\text{-value}<0.05$. Particulate matter shows the highest impact and conversely, Human toxicity cancer and Photochemical ozone show the lowest impact on Human Health damage. The Climate change indicator deviates the most from the

regression line.

These initial results have demonstrated a promising and significant relation between epidemiological data and endpoint results on Human Health damage for the ReCiPe Individualist perspective. The same data collection strategy will be applied for the Ecosystem Quality and Resources areas of protection to complete the weighting factors based on damage.

This exploration could strengthen the robustness of the methodology used and better reflecting weightings associated with actual damage on Earth.

5.09.P Life Cycle Assessment for Sustainability Decisions: Methodological Challenges and Future Directions

5.09.P-We382 Qualitative And Quantitative Comparison Between Emerging Guidelines for Automotive Life Cycle Assessment in Europe: A Case Study of a Battery Electric Vehicle

Hazem Eltohamy¹, Katharina Gompf², Ioan-Robert Istrate¹, Bernhard Steubing¹ and Jeroen Guinée¹, (1)Leiden University, Netherlands, (2)Bayerische Motoren Werke (BMW Group), Germany

Life cycle assessment (LCA) has become a key tool in the automotive sector for shaping environmental strategies and ensuring policy compliance, highlighting the critical role of methodological decisions. This study analyzes three major recent LCA guidelines developed through prominent European harmonization efforts: TranSensus LCA, Catena-X, and the United Nations Economic Commission for Europe (UNECE) Automotive LCA Guidelines. A qualitative comparison reveals substantial alignment among the guidelines, with notable differences primarily in the modeling of electricity and the treatment of multifunctionality, where methodological flexibility still exists. When applied to a battery electric vehicle, a quantitative comparison reflecting expected practical applications indicates less than a 10% variation in most impact categories. However, certain intra-guideline methodological choices produce larger discrepancies, such as 27% for the Circular Footprint Formula and 11% for static electricity modeling in climate change impacts. Overall, the results suggest that horizontal harmonization across guidelines is largely achieved, whereas vertical harmonization within individual guidelines and their consistent practical implementation remain areas for further development. The findings of this study provide important insights into the current state of harmonization, the consequences of applying different approaches. They also draw attention to the areas where further alignment should be prioritized to make the efforts towards harmonization more effective in terms of fostering consistency and reliability in automotive LCA practice.

Disclaimer/Disclosure:

The presented work was conducted within the TranSensus LCA project which was granted from the European Union's Horizon Europe research and innovation program under Grant Agreement Nr. 101056715. Views and opinions expressed are, however, those of the author(s) only and do not necessarily reflect those of the European Union or CINEA. 5.09.P-We383 Assessing Individual Carbon Footprints in Higher Education in Taiwan: A Behavior-Linked Emission Model

Szu-Chieh Chen¹, Mei-Fang Su¹, Si-Yu Chen², Tien-Hsuan Lu³ and Chung-Min Liao², (1)Chung Shan Medical University, Taiwan (Greater China), (2)National Taiwan University, Taiwan (Greater China), (3)National Taichung University of Education, Taiwan (Greater China)

Higher education institutions contribute to sustainable development through education, research, and community engagement. This study examined the relationship between carbon emissions and knowledge, attitude, and practice (KAP) regarding carbon emission-related issues among university students. A cross-sectional online survey was conducted in the period September-December 2024 across eight universities in central Taiwan, yielding 293 valid responses. Daily per-capita carbon emissions were estimated based on activity categories and emission factor.

Results showed that daily living accounted for the largest share of emissions (88%), followed by transportation

(20%) and academic activities (10%), with an average daily emission of ~12 kg CO₂e per person. Significant differences in emissions were observed across living arrangements and household sizes ($p < 0.05$). In the KAP analysis, attitude and practice demonstrated a strong positive correlation ($r = 0.59$, $p < 0.01$), while practice and total carbon emissions were negatively correlated ($r = -0.12$, $p < 0.01$).

This study quantifies student-level carbon emissions in Taiwanese higher education and addresses a research gap by linking individual-level KAP variables with carbon emission estimates. The findings provide a basis for understanding the distribution of emissions and for informing sustainability-related policies in higher education institutions. Future initiatives may focus on campus infrastructure and education to support sustainability and net-zero carbon goals.

5.09.P-We384 Decision Making Towards the Hydrogen Economy: Product Environmental Footprint Category Rules for Fuel Cells for Electricity Production – Proposal and Results of the HyPEF Project
Till M. Bachmann¹, Ahmed F. Cakir¹, Khaoula Ben Hnich², Simone Maranghi³, Stavros Katsiaounis⁴ and Diego Iribarren², (1)EIFER, Germany, (2)IMDEA Energy, Spain, (3)Ecoinnovazione, Italy, (4)ADVENT, Greece

The energy transition requires low-carbon solutions. Hydrogen systems are high on the political agendas. To prioritise solutions, their environmental performance needs to be evaluated in a comparable, consistent and transparent way. While Life Cycle Assessment (LCA) is a prominent approach for evaluating environmental performance of products, so-called Product Category Rules (PCRs) can be drafted to achieve comparability and consistency. When using the Product Environmental Footprint (PEF) methodology, as outlined in the European Commission Recommendation 2021/2279, such rules are referred to as PEFCRs. In the frame of the European HyPEF project (<http://hypef.eu>), initial versions of PEFCRs have been drafted for three hydrogen-related product categories (i.e. “Devices for hydrogen production”, “Tanks for hydrogen storage”, and “Hydrogen fuel cells intended for electricity production”). They are “shadow PEFCRs” because they have been developed without direct involvement of the European Commission. After having also integrated feedback from an external review panel, they have been applied to fuel cells. This work covers how hydrogen systems are categorized into eleven product types. Furthermore, it explains the specific rules for fuel cells, including how representative products are chosen, how the functional unit and system boundaries are defined, which environmental impacts are most relevant, and which additional technical or environmental information is proposed to be provided. Results are shown for one representative product and three types of fuel cells: low-temperature proton-exchange membrane (PEM) fuel cells, high-temperature PEM fuel cells, and solid oxide fuel cells. Key challenges, such as limited data and defining the functional unit and the representative product, are also discussed.

Disclaimer/Disclosure:

The HyPEF project is supported by the Clean Hydrogen Partnership and its members. It receives funding from the European Commission (Grant Agreement No 101137575).

5.09.P-We385 Integrated Tool for Quantification and Communication of Carbon Footprint in Brazilian Livestock Production

Sophia Chamilete¹, Rafael Zortea², Roberto Giolo de Almeida³, Alexandre Berndt⁴ and Marília Folegatti¹, (1)Embrapa Meio Ambiente, Brazil, (2)IFSul - Câmpus Sapiranga, Brazil, (3)Embrapa Gado de Corte, Brazil, (4)Embrapa Pecuária Sudeste, Brazil

Population growth and increasing purchasing power, especially in developing countries, are expected to drive a global rise in the demand for animal proteins such as meat and milk by 2050. In this context, the livestock sector faces the challenge of increasing productivity in a sustainable manner, reducing environmental impacts without compromising animal welfare or food security. To address this challenge, Brazil has developed the “Low-Carbon Milk” and “Low-Carbon Beef” programs, which establish guidelines for production systems with lower greenhouse gas (GHG) emissions. As technical support for these initiatives, the Low-Carbon Livestock

Calculator (LCLC) was developed to estimate the carbon footprint of livestock products such as meat and milk produced under tropical conditions. This calculator was built by combining equations proposed by the Intergovernmental Panel on Climate Change (IPCC) with the Life Cycle Assessment (LCA) methodology. Emission factors associated with animal feeding, energy use, and transportation are included as input data in the LCLC, complementing the results generated by the IPCC equations. For beef production systems, the LCLC adopts a cradle-to-slaughterhouse gate system boundary, whereas for milk production systems, it applies a cradle-to-farm gate boundary. The LCLC provides estimates of the carbon footprint of beef and milk, defined as the balance of GHG emissions and removals occurring throughout the product life cycle. The functional unit for beef systems is 1 kg of processed meat, comprising forequarter, hindquarter, and short plate cuts, each representing a reference flow. For milk production systems, the functional unit is 1 kg of fat- and protein-corrected milk (FPCM). The results generated by the LCLC are intended to support decision-making by producers and industries, although they can also be disseminated in an aggregated form for regional or national analyses. These results can also serve as instruments for communication and strategic planning, contributing to the development of mitigation strategies and the enhancement of GHG removals toward more efficient and sustainable livestock systems. Furthermore, the LCLC can provide technical input for the formulation of public policies and certification schemes aimed at promoting and valuing low-carbon livestock products.

5.09.P-We386 Developing a Scalable Carbon Budgeting Framework for Decarbonising UK Highway Maintenance: Evidence from a Cornwall Case Study

Xiaocheng Hu, Nurullah Yildiz and Xiaoyu Yan, University of Exeter, United Kingdom

Highway maintenance contributes significantly to the indirect carbon impacts of the transport sector, yet no established method exists for translating national Net Zero targets into operational carbon budgets for routine road maintenance. This study develops a scalable, evidence-based carbon budgeting framework for UK local authorities, demonstrated through a corridor case study in Cornwall.

The work begins by identifying the challenge of aligning local maintenance practices with the UK's legally binding carbon budgets. Through a systematic review of global and sectoral carbon budgeting approaches and decarbonisation pathways, we assess the strengths and limitations of existing methods and their relevance to the material- and energy-intensive nature of highway maintenance.

To address this challenge, we design a mixed-methods framework that integrates baseline life-cycle emissions, sector-specific decarbonisation pathways, scenario modelling, and stakeholder insights. The methodology uses a grandfathering-based budgeting approach with 2022 emissions as the reference year, combined with material- and activity-specific reduction trajectories drawn from national and European guidance. The A30 Hook Corridor test case illustrates the framework using detailed emissions data for asphalt, concrete, plastics, steel and iron, transport, plant operations, waste, chemicals, and ancillary materials.

Results indicate that maintenance-related emissions could fall to roughly 10% of 2022 levels by 2050 when sectoral pathways are applied. Asphalt remains the dominant source of embodied carbon, while transport and plant emissions decline sharply as electrification and hydrogen technologies mature. Scenario modelling reveals substantial variation in reduction potential across activities, underscoring the need for targeted interventions and activity-level planning.

The findings show that corridor-level carbon budgeting offers a practical link between national climate commitments and on-the-ground maintenance planning. The framework enables authorities to allocate, track, and adjust carbon budgets in line with Net Zero objectives and can be scaled across different operational contexts. Future work will expand the framework to support broader adoption and guide long-term decarbonisation strategies in the UK highway maintenance sector.

5.09.P-We387 Ecotoxicity Impacts of Chemical Pesticides Applied to Vegetable Crops in Finland During 2003–2019

Kati Räsänen¹, Irene Vänninen², Sirpa Kurppa², Jussi V.K. Kukkonen³ and Peter Fantke⁴, (1)Bioeconomy and environment / Sustainability science and indicators, Natural Resources Institute Finland (Luke), Finland, (2)Natural resources / Plant health, Natural Resources Institute Finland (Luke), Finland, (3)University of Eastern Finland, Finland, (4)substitute ApS; Goethe University Frankfurt; University of South Africa, Denmark

On a global basis information on the use of chemical pesticides on different crops and their related environmental impacts over time is currently lacking (Mark et al., 2024). Mapping the use of pesticides is the

basis for the analysis of ecotoxicological impacts for any crop production system and agricultural area. To address this gap, we conducted a multi-year study to understand dynamics in impacts and possible shifts in main contributing pesticides.

We showed impacts of chemical pesticide use in carrot, potato, swede, and fresh pea production in southwestern Finland over 17 years. The data cover chemical pesticide usage on more than 100 field vegetable farms in southwestern Finland in 2003–2019. We used widely used life cycle impact assessment models to estimate related emissions into the environment and assess potential freshwater ecotoxicity impacts of 57 pesticides applied on the studied crops.

Pesticide usage and related ecotoxicity impacts varied across crops, years and pesticide target classes. The usage and impacts of pesticides used on carrots and fresh peas increased over time. In contrast, usage and impacts decreased over time for swede. For potatoes, the usage of pesticides increased, while the impacts decreased over time, although the differences were not statistically significant. Overall, the amounts of pesticides used were not directly related to their environmental impacts, mainly due to differences in ecotoxicity potency across pesticides. In our study, the impacts were dominated by a limited set of substances. The most hazardous substances were the herbicides acifluorfen and linuron, the fungicide mancozeb and the insecticides lambda-cyhalothrin, cypermethrin, dimethoate and alpha-cypermethrin.

Our results provide extensive information of impacts of pesticides on selected field vegetables in southwestern Finland. We were able to rank chemical pesticides in terms of their impacts under real-world applications, and derived recommendations for replacing the most hazardous chemicals identified with less harmful alternatives. This can inform pesticide substitution and other impact reduction measures in Finland and has the potential to be applied to other pesticides, crops, and regions.

5.09.P-We388 Normalization And Weighting As Tools For Product Development – A Case Study Of An Electrode

Lotta Hepo-oja, Technical Research Centre of Finland Ltd. (VTT), Finland

Individual indicator results are often the go-to when talking about life cycle assessment (LCA) and comparing different options. This poses a problem, when speaking about total environmental impacts as it is not easy to compare specific units and make decisions about the relevance of each result. Normalization and weighting help unify results and together with a single score result they help decision making especially in situations where materials are replaced by new and innovative ones.

This is relevant for printed electronics where materials are evolving at a rapid rate but may struggle with things like higher energy demand and subsequent climate or resource impacts while other environmental impacts may be lower than their traditional counterparts. Normalization and weighting give better insights to technology developers on what should be the focus of research and development actions. It might be that the envisioned change in one material is not that relevant after all when looking beyond a single impact category result, like climate change.

This study is part of the three-year EU SUSTRONICS project which promotes sustainable electronics. The study focuses on electrodes for wearable health monitoring devices. LCA is used to evaluate the sustainability of different material combinations, focusing on the environmental impacts of substrates, conductive inks, and adhesive biomaterials but also including other components and life cycle stages.

The assessment has been carried out throughout the project, for three generations of the product. Results for the final 3rd generation are expected by the end of the project in May 2026. The assessment has progressed from only climate change impacts of substrates and inks in generation 1 to full LCA of the whole life cycle using PEF3.1 method with all its 16 impact categories and recommended normalization and weighting factors.

Electrode life cycle is divided into manufacturing, use and end-of-life stages where manufacturing is further divided between all the materials used to see their individual contributions. Results will be presented as normalized and weighted impacts and comparison will potentially be done using the PEF single score.

Findings of the study are used to guide product development and further understanding whether switching to greener conductive materials and bio-based substrates is worth the potential loss in performance.

5.09.P-We389 Harmonizing Life Cycle Inventories for Agricultural Products: A Swiss Case Study on Environmental Benchmarking and Reporting

Melanie Douziech, Eric Mehner, Jens Lansche and Thomas Nemecek, Agroscope, Switzerland

The use of Life Cycle Assessment (LCA) to quantify the environmental impacts of products is central to sustainable decision-making as well as reporting and informing consumers. However, in the agri-food sector, the methodological diversity inherent in LCA—due to varying assumptions, data sources, and regional contexts—presents significant challenges in creating consistent, comparable environmental benchmarks. Benchmarks are hereby understood as average impacts of typical production systems.

This study presents a strategy for generating parameterized Life Cycle Inventories (LCIs) of reference systems from farm-level to product-level, specifically addressing gaps in country- and production-specific environmental impact data. By applying this approach to eight commonly produced and consumed Swiss food products—apples, tomatoes, potatoes, carrots, winter wheat, sunflower oil, milk, and pork—we aim to provide robust environmental benchmarks that can support decision-making in industry, policy and the public.

Key methodological challenges addressed include harmonizing LCIs across agricultural practices and food processing stages thus contributing to a better comparability across LCIs, as well as parametrizing LCIs to increase the flexibility in the calculation of environmental impact results. Results indicate that agricultural production consistently drives environmental impacts across all product categories, although processing stages—such as oil extraction or cereal drying—can amplify impacts. Notably, post-harvest storage can increase global warming potential by up to 35% for each additional two months of storage.

In addition to developing a practical methodology, this research also focuses on effective communication strategies for disseminating these benchmarks to diverse audiences. Environmental impact data will be communicated through consumer-facing platforms, including a web-page and a consumer newspaper, alongside more technical publications targeted at industry and scientific stakeholders.

This research underscores the importance of harmonizing approaches and overcoming methodological challenges to ensure consistent, transparent, and meaningful environmental benchmarks. It therefore contributes to ongoing efforts to standardize LCA practices and improve the reliability of environmental reporting across sectors.

5.09.P-We390 Life Cycle Assessment in Regulatory Science: the should, could and shouldn't

Rachael Rothman¹, Stuart Robert John Walker² and Benjamin Lowe², (1)Chemical and Biological Engineering, University of Sheffield, United Kingdom, (2)University of Sheffield, United Kingdom

Life Cycle approaches are used in many aspects of policy and regulation, including emissions reporting, however a full life cycle assessment is often not carried out, or even necessary. In some cases this simplifies methodology and enables faster reporting, however it can also lead to unintended consequences. The UK Life Cycle Assessment Regulatory Science and Innovation Network was set up in 2024 to help support the UK government move towards its net zero goals by providing evidence, and developing robust, harmonised methodologies.

Guidance on where LCA should, could and shouldn't be used in regulatory science have been developed. For example, digital product passports are a positive step forward in the transfer of reliable primary data and should be used to improve product assessments; LCA should be used in the development of biomass policy; results of LCA on low TRL processes should only be presented with caveats so as not to be misleading; individual product LCAs over a wide range of products would be too time consuming.

In addition, working groups have explored the use and availability of data, including where proxy data is not satisfactory, and the harmonisation needed to enable transparent, reliable comparison of products.

Examination of how data issues interact with methodological choices across real regulatory use cases including EPDs, CBAM, ecolabelling, investment decisions, and sector specific rules have been explored, identifying the research and infrastructure priorities needed to strengthen the robustness and consistency of LCA in regulatory and policy contexts.

Evidence generated through the network fed into a UK government consultation on low carbon product emissions reporting.

Disclaimer/Disclosure:

This work was supported by Innovate UK through the Life Cycle Assessment Regulatory Science and Innovation Network (LCA-RSIN) and by the Grantham Centre for Sustainable Futures at the University of Sheffield.

5.09.P-We391 Integrating LCA and Energy Modelling in Buildings with Green Roofs: Methodological Challenges

Débora Pons Fiorentin¹, Gabriel Perez², Sandra Rafael³ and Paula Quinteiro⁴, (1)University of Aveiro, Portugal, (2)Universidad de Lleida, Spain, (3)IDAD, Portugal, (4)CESAM, University of Aveiro, Portugal

Buildings are a major contributor to greenhouse gas emissions, mainly due to energy consumption for heating, cooling and electrical devices. In the European Union, approximately 75% of the building stock is energy inefficient, underscoring the urgent need for energy-efficiency measures. This challenge is addressed through directives such as the European Green Deal and the Energy Performance of Buildings Directive, which promote the integration of passive energy-efficiency strategies to enhance building and urban sustainability. Among these strategies, green roofs - vegetated structures above buildings - have emerged as a promising mechanism to improve the building's thermal performance. The integration of LCA and energy modelling provides a robust methodological foundation for evaluating the influence of green roofs as a passive energy-efficiency strategy, which is essential for outlining a framework to incentivise their use and reduce the building's energy consumption and potential environmental impacts. Previous studies have assessed the influence of green roofs on a building's thermal performance, quantifying heating and cooling energy consumption relative to a conventional flat-roofed building, often combining Life Cycle Assessment (LCA) and energy modelling. It has been common to define the functional unit (FU) based on the green roof's area, while accounting for its lifespan. However, the definition of FU remains an ongoing debate among experts, as it currently does not comprehensively capture the integration of green roofs and buildings and their functionality. In this sense, this work proposes expanding the system boundary to include both the green roof and the building, given that the study aims to assess the environmental effects of green roofs on the thermal efficiency of a residential building. The FU could consider the volume of the residential building, specifying the number and typology of floors, the roof area and its lifespan, and the amount of energy required to guarantee a comfortable temperature for the coldest and warmest conditions.

5.09.P-We392 Evaluating Urban Greening as an Urban Heat Island Mitigation Strategy in Tokyo Through Life Cycle Assessment.

Ylva Karin Perynea Wallmark¹, Tomohiko Ihara² and Norihiro Itsubo Dr¹, (1)Waseda University, Japan, (2)Tokyo University, Japan

Global temperatures have risen by more than 1.5°C above pre-industrial levels, and cities are experiencing more intensifying heat due to the Urban Heat Island (UHI) effect. In Tokyo, UHI has increased local temperatures by up to 3.2°C, driven by heat-retaining materials, dense built structures, and declining tree canopy coverage.

Urban greening is widely recognized as an effective cooling strategy, as trees provide shade and enhance evapotranspiration. However, urban trees also generate emissions across their life cycle through planting, maintenance, and eventual removal. This raises the question of whether their long-term cooling and CO₂ sequestration benefits outweigh the environmental costs. This study addresses this question using a Life Cycle Assessment (LCA) approach.

The research examines four common Japanese tree species to determine how many trees of each species are required to reduce temperatures within a target Area of Interest (AOI) by 1°C. Because canopy size, growth characteristics, and CO₂ absorption vary by species, understanding these differences is essential for selecting the most efficient cooling strategy.

In addition, to further compare, solar-reflective building coatings, as an alternative UHI mitigation method are also evaluated for their cooling effectiveness and greenhouse gas emissions.

Microclimate simulations are conducted using ENVI-met, while SimaPro is used to quantify life-cycle emissions. Together, these tools allow for a comparison of biological and non-biological strategies in terms of both cooling performance and environmental impact.

The anticipated outcomes will clarify which tree species offer the best balance of cooling and low emissions, and how they compare to reflective surface technologies. The findings aim to support urban planners and policymakers in designing effective, low-carbon strategies for reducing UHI in Tokyo and similar high-density cities.

5.09.P-We393 Scope 3 Environmental Impacts of Workplace IT: Finding the Balance Between Insights and Actions

Alireza Soltani Nezhad¹, Thomas Hennequin², Hans Stokking³, Hettie Boonman⁴, Bernard van Gastel⁵, Marie-anne Degier³, Kas Jansen² and Mark Huijbregts⁶, (1)Department of Circularity & Sustainability Impact, Energy and Material Transition, TNO, Utrecht, The Netherlands & Department of Environmental Science, Institute for Biological and Environmental Sciences, Radboud University, Nijmegen, The Netherlands, Netherlands, (2)Department of Circularity & Sustainability Impact, Energy and Material Transition, TNO, Utrecht, The Netherlands, Netherlands, (3)Department of Technical Sciences – Networks, TNO, Den Haag, The Netherlands, Netherlands, (4)Department of Economics & Innovation Policy, TNO, Den Haag, The Netherlands, Netherlands, (5)Department of Software Science, Radboud University, Nijmegen, The Netherlands, Netherlands, (6)Department of Environmental Science, Institute for Biological and Environmental Sciences, Radboud University, Nijmegen, The Netherlands, Netherlands

Scope 3 emissions, defined as all indirect greenhouse gas (GHG) emissions (excluding Scope 2) that occur in an organisation's upstream and downstream value chain, represent an important part of its total greenhouse gas footprint. Information and communication technology (ICT) is a relevant source of Scope 3 emissions, and the this sector is estimated to contribute 2–4% of global GHG emissions. Workplace ICT can form a relevant share of organisational Scope 3 impacts. In many cases, workplace ICT is not reported in detail in corporate social responsibility (CSR) reporting. Connections between hardware and software, software-as-a-service (SaaS), hardware replacement policies, and user behaviour are not always tracked consistently, and the translation of CSR goals into concrete ICT interventions is unclear. Life cycle inventories (LCIs) for hardware are also limited. This makes it difficult for organizations to gather reliable Scope 3 data and identify improvement options.

This study presents a Scope 3 accounting framework for workplace ICT to support CSR reporting and guide decisions. Workplace ICT includes end-user devices, workplace software, and the associated cloud-based services that support routine organisational activities. The analysis does not cover the deployment of ICT solutions such as back-end business applications or large-scale data-processing systems that are not directly linked to these workplace services. The framework is demonstrated with real-life organisational use cases, using primary asset and usage data from Dutch organizations. We combine these data with background inventories and apply a consequential life cycle assessment (LCA) to estimate the Scope 3 impacts of workplace ICT. Then, we focus on mitigation interventions along two main organisational levers: procurement decisions and employee behaviour.

The study evaluates the mitigation potential of selected interventions. For procurement, this includes extending device replacement cycles and choosing lower-impact devices or cloud options. For employee behaviour, we consider interventions like reducing video-conferencing resolution. An effect–effort matrix, informed by ICT procurement staff, prioritizes interventions by environmental benefit and feasibility. Organisations can use the framework to develop tailored workplace ICT impact profiles and prioritise interventions. Overall, our contribution is to link Scope 3 impact insights for workplace ICT with concrete mitigation actions.

5.09.P-We394 On The Relevance of Lab-scale Life Cycle Assessments

Rickard Arvidsson, Environmental Systems Analysis, Chalmers University of Technology, Sweden

In recent years, life cycle assessment (LCA) has been increasingly applied to emerging technologies that currently exist only at the laboratory scale. These lab-scale LCAs are typically conducted using the available experimental data from early-stage processes without considering technological upscaling or maturity. Consequently, such studies often raise concerns regarding their representativeness and relevance, particularly the extent to which the environmental hotspots identified at laboratory scale correspond to those observed at industrial scale.

This study reviewed and analyzed over 30 published LCAs that reported both laboratory- and industrial-scale results across diverse technological domains, including chemical synthesis, wastewater treatment, food processing, carbon capture, and emerging batteries, to systematically evaluate how absolute environmental impacts and hotspots change with scale. The results show that absolute environmental impacts typically decrease by up to 99% during upscaling, primarily due to improvements in energy and material efficiency, process integration, and waste reduction. The findings also indicate that lab-scale LCAs often capture environmental hotspots that may diminish or disappear when the system is scaled up to industrial production. The study further discusses which types of research questions lab-scale LCAs can appropriately address and for which stakeholder groups they offer meaningful insights. Additionally, it highlights that incorporating sensitivity analyses or discussing how environmental hotspots may change with upscaling can make lab-scale LCA results more relevant and informative for a broader audience.

5.09.P-We395 Evaluation of Net-Zero Strategies for Construction Products Using Life Cycle Assessment
Ewa Katarzyna Lagodzka¹, Agneta Ghose² and Massimo Pizzol², (1)Aalborg University, Denmark, (2)Planning, Aalborg University, Denmark

The concept of net-zero has gained a lot of attention following the Paris Agreement and EU regulations, yet its definition and calculation methodology have been interpreted in many ways. In the building sector, terms such as Net-Zero Energy Buildings focus on minimizing operational energy rather than the impact of construction materials. Recently, the Net-Zero Carbon Buildings Standard has emerged, addressing both operational and embodied emissions. The net-zero concept is also widely used in business. Many companies have pledged to achieve net-zero by 2050, but these commitments often lack clarity on whether they rely on major emission reductions or offsets. To address this, the Science-Based Targets initiative (SBTi) introduced the Corporate Net-Zero Standard, which requires companies to reduce at least 90% of emissions before offsetting the rest. Beyond buildings and business, it remains unclear how the concept of net-zero can be generally applied at the product level.

This study investigates whether specific products can be considered to have net-zero emissions in a life cycle perspective, taking construction products as a case study. The methodology combines a literature review of strategies across main construction products, with Life Cycle Assessment (LCA) modelling. Strategies are considered at two levels: material and product, which can demonstrate that achieving net-zero emissions requires different types of strategies- on the production and on the design side. To illustrate the approach, a window is used as an example. At the material level, general strategies identified for glass include waste heat recovery, carbon capture and storage, use of fossil-free energy, and increased recycled content, together with specific innovations like hybrid melting furnaces. At the product level (window in this context), strategies include substituting aluminium frames with wood-aluminium composites, integrating solar control films, and replacing metallic spacers with warm-edge alternatives.

The expected outcome is to quantify the effectiveness of each of the strategies and to evaluate whether their combination can achieve the net-zero emission material or product. While the window serves as an example, the approach is expected to be applied to several construction materials and products. This work will contribute to clarifying the concept of net-zero in products and provide insight into reducing the environmental impacts of materials in the construction sector.

Disclaimer/Disclosure:

The study is carried out within the ASCCENT project funded by the European Union grant no. 101159895.

5.09.P-We396 Grounding future regulations into common standard for pharmaceuticals LCA: hands-on comparison of UK standard and French guideline

Veronica Di Battista¹, Chrystelle Verhoest² and Kranti Navare², (1)Arcadis, Germany, (2)Arcadis, Belgium

Regulatory developments across Europe are fundamentally reshaping the life cycle assessment (LCA) landscape for pharmaceutical products – transforming it from a voluntary exercise to a prerequisite for market access. As these direct regulations come into force, the ability to deliver robust and consistent LCA results is becoming essential for pharmaceutical companies seeking to comply with evolving legislative requirements and remain competitive in the European market. The only standard dedicated to the LCA of pharmaceuticals – PAS 2090 – has been published in December 2025 by the British Standards Institution (BSI).

Meanwhile, the French government has already introduced a methodological guidance for pharmaceutical products LCA with a specific focus on Product Carbon Footprint (PCF). This guidance does not fully align with the PAS 2090 standard.

Although it is a well-intentioned effort to support the industry in disclosing PCFs, this development highlights the risk of regulatory fragmentation and the importance of harmonizing standards at the European level, and eventually globally, to ensure consistent, efficient and comparable environmental assessments within the pharmaceutical sector. In this study, we aim to provide a comparative analysis of the PAS 2090 standard and the French PCF methodological guideline. We identify key differences with respect to methodological approaches and data requirements, which strongly influence the final impact assessment results. We focus on climate change impact category, as this is the only one in scope of the French PCF methodology. The comparison is based on practical case study applications on synthetically derived medicines and biologics. The findings of this study underscore the importance of adopting a common, industry-specific standard for pharmaceuticals' LCA when implementing new country-specific regulations. Divergent methodologies risk generating non-comparable results across countries and may significantly increase both the costs and complexity associated with conducting LCAs for medicines. Furthermore, such fragmentation presents substantial challenges for future harmonization

of results at the European level, ultimately hindering regulatory alignment and the effective assessment of environmental impacts within the pharmaceutical sector.

5.09.P-We397 Cradle-to-grave LCA of Ethinyl Estradiol: Production hotspots and End-of-Life Burdens

Muhammed Ayaj Ansar¹, Carlos Alvarez Largo¹, Ad M. J. Ragas² and Rosalie van Zelm¹, (1)Radboud University, Netherlands, (2)Environmental Science, Radboud University, Netherlands

While pharmaceuticals are introduced to improve quality of life, production and disposal cause environmental impacts leading to loss of life years and loss of biodiversity. Life cycle assessment (LCA) can guide sustainability decisions, but it remains constrained by scarce primary data for active pharmaceutical ingredient (API) synthesis, and limited integration of end-of-life impacts. A cradle-to-grave LCA of ethinyl estradiol is conducted, a widely used synthetic estrogen with documented aquatic ecotoxic effects at low concentrations. The objective of this study is to quantify environmental hotspots across multiple impact categories from ethinyl estradiol synthesis at an EU-based API manufacturer to final disposal, and to assess improvement options through sensitivity analyses. The functional unit is 1 kg of ethinyl estradiol and the system includes synthesis, formulation, packaging, distribution, patient use, wastewater treatment, and environmental fate. Industrial primary data for ethinyl estradiol synthesis are combined with background data from ecoinvent. Upstream chemicals missing in databases are modelled using an upscaling-based estimation method. For the use and end-of-life stages, substance-specific pharmacokinetics are combined with the ePiE model (wastewater removal and fate estimation) and linked to freshwater ecotoxicity. ReCiPe 2016 was used for the impact assessment with a systematic stepwise procedure. Preliminary contribution analysis indicates that upstream starting-material production contributes more than 40% across selected midpoint categories (e.g., climate change, human toxicity, and ecotoxicity), whereas ethinyl estradiol synthesis at the European plant contributes less than 29%. A solvent reuse scenario reduces selected midpoint indicators by 19–46% relative to the base scenario reflecting current practice. This study is the first to present a cradle-to-grave LCA of ethinyl estradiol that combines industrial primary data for API synthesis with explicit modelling of end-of-life ecotoxicity. The framework of this study can be used consistently and transparently to compare a range of impact categories to identify improvement options from a life cycle perspective. The study provides a transparent basis for decision makers (e.g., manufacturers and regulators) to prioritise improvement action and implement policy measures such as stakeholder responsibilities for waste treatment within the value chain.

5.09.P-We398 Miscanthus to Xylo-oligosaccharides and Biocarbon: Innovating Feed, Food and Steel Industries with the MAXFEED System

Ariane Silveira Sbrice Pinto, Patricia Thorney and Scott Banks, Aston University, United Kingdom

The perennial grass *Miscanthus* holds substantial promise as a lignocellulosic feedstock for a biorefinery approach that delivers both climate mitigation and high-value bioproducts. Xylo-oligosaccharides (XOS), for instance, are valuable prebiotic ingredients used in food, feed, and health applications. XOS in an animal's diet can reduce CH₄ emissions for cattle, specifically. Alongside, Biochar offers a renewable and lower-carbon alternative to replace part of metallurgical coal in blast furnaces, enhancing sustainability. To highlight the environmental opportunities, challenges, and uncertainties of producing biochar and xylo-oligosaccharides (XOS) with *Miscanthus*, a life cycle assessment (LCA) was conducted. The impact of XOS as an animal feed supplement was forecasted considering raw beef production in the UK's market³ since the prebiotic effect of XOS showed potential to reduce CH₄ emissions^[2], while biochar was used as an alternative feedstock to coal in the steel-making industry. The MAXFEED system operated alone and combined with the food and steel systems. The system boundary was cradle-to-gate, including the following systems: *Miscanthus*'s farm, MAXFEED factory (biochar and XOS), steel-making (pig iron production), and cattle's farm (raw meat). For 1 kg of products as functional unit (pig iron and meat (97.2%)), significant reduction of global warming (GWP100a) and land use (LUP) potential was observed. Negative GWP100a during the biomass production mitigated environmental burdens allocated to products in comparison to their benchmarks - pig iron, beef, and coal. A significant step towards carbon-neutral bioproducts due to a 89% reduction in GWP100a was observed when compared to the conventional pig iron production—the carbon footprint falls to 0.20 kg CO₂ eq. per kg of pig iron produced with biochar, mitigating approximately 50% of the steel footprint. Alongside, the combined benefits of carbon sequestration during biomass production and the reduction in CH₄ emissions resulting from the prebiotic property of XOS can reduce the overall LUP of meat production from cattle fattened with XOS supplementation. LUP decreased by about 93%, with the index dropping to ~489 [dimensionless] per kg of meat produced, compared to animal feed production without XOS supplementation. Scalability challenges for the UK's landscape were identified, suggesting opportunities to explore different markets and applications for the bio-products.

5.09.P-We399 A Call for Revising ISO 14040 and 14044

Tomas Ekvall, Tomas Ekvall Research, Review & Assessment, Sweden

Standards within ISO are subject to systematic review every five years. In these reviews, a decision is taken whether to revise the standards. Since most of the text in the generic standards for life cycle assessment (LCA; ISO 14040 and 14044) will be nearly 30 years old at the upcoming review, the arguments for revising the standards are strong. Clarification of the existing terminology in the standards is needed, because other standards and guidelines that are based on ISO 14040+44 diverge in the interpretation of terms such as “system expansion” and “underlying physical relationships”. Even the basic terms “life cycle” and “product system” need clearer definitions. The current standards are not sufficient to know if the life cycle is a system of physical flows or a sociotechnical system – or even if it is the system modelled in an attributional LCA or in a consequential LCA.

Since the methodology has developed, we would also benefit from clear definitions of new terms such as attributional, consequential, prospective, and dynamic LCA, foreground and background systems, primary and secondary data, etc.

The understanding of how the appropriate methods depend on the context of the study have developed. Revised LCA standards can account for this through explicit flexibility in methods or through a structure of methods designed for different contexts.

Updates in the standard texts are needed because LCA practice has developed. As an example, the current requirement to qualitatively and quantitatively describe all unit processes is outdated, because commercial databases have changed the conditions for data collection and reporting.

5.09.P-We400 Enhancing Supply Chain Transparency in Electric Arc Furnace Stainless Steel Production: A Decision Support Tool Based on Life Cycle Assessment

Luca Testini¹, Alessandro Misul², Vincenzo Morreale², Philippe Brocard², Livia Persico², Davide Mombelli¹ and Giovanni Dotelli³, (1)Politecnico di Milano, Italy, (2)Cogne Acciai Speciali S.p.A, Italy, (3)Department of Chemistry, Materials and Chemical Engineering "Giulio Natta", Politecnico di Milano, Italy

Stainless steel production via Electric Arc Furnace (EAF) is characterized by a high share of indirect environmental impacts due to the intensive use of alloying elements. Despite this, the contribution of raw materials procurement to the overall impact of different stainless-steel grades remains insufficiently quantified, limiting the accuracy of corporate sustainability reporting, the identification of effective mitigation strategies and transparent communication to stakeholders.

This study develops a cradle-to-gate Life Cycle Assessment (LCA) model that integrates direct process emissions with upstream impacts associated with raw materials, energy supply, transport and auxiliary operations. The model covers a broad portfolio of stainless-steel grades and enables a grade-specific environmental characterization. Primary data on raw material inputs, electricity consumption, process emissions, waste and water flows were collected at facility level, while upstream processes were modelled using ecoinvent 3.11. LCA calculations were performed with Brightway 2.5 and impact assessment was performed with the Environmental Footprint 3.1 method, including normalization and weighting to derive single-score indicators.

Results demonstrate that raw materials systematically account for more than 90% of total impacts across all stainless-steel categories. Duplex and austenitic grades show the highest single scores, followed by precipitation-hardening, ferritic and martensitic steels. The dominant contributions originate from nickel, chromium and molybdenum related raw materials, mainly ferroalloys, whereas the influence of direct emissions and in-house energy use is comparatively limited.

By providing steel grade-level granularity, this work offers an effective approach for corporate reporting and stakeholder communication. The developed model serves as a dynamic decision-support tool, enabling steelmakers to optimize strategic sourcing, for instance, by mitigating financial risks associated with the EU Carbon Border Adjustment Mechanism (CBAM) on extra-EU ferroalloy imports. Furthermore, it allows customers to accurately calculate their indirect (Scope 3) emissions based on the specific steel grade purchased, ensuring compliance with current regulations. Finally for policymakers, these findings offer the evidence needed to refine steel production environmental benchmarks, ensuring that regulations include data about the most critical production mix in the industry.

5.09.P-We401 Environmental sustainability benchmarking in the construction sector

Alexandra Weniger¹, Marzia Traverso¹, Isabela de Paula Salgado², Tobias Hatzfeld² and Edeltraud Günther², (1)RWTH Aachen University, Germany, (2)UNU-FLORES, Germany

An important contribution to drive an environmentally sustainable construction sector is the definition of benchmarks for environmental impacts, enabling measurement and comparison of environmental performance against established standards and targets. The approach has reached increasing attention over the past years. However, there is still no consensus on sector- or product-specific benchmark values, nor on the methodologies for calculating them. This study aims to evaluate existing environmental sustainability benchmarking approaches for the construction industry.

For that, the PRISMA approach was applied for three different types of sustainability benchmarking in construction: 1) limit values, i.e. the upper or lower acceptable performance level; (2) reference values, representing state of the art or best practice performance; and (3) target values, defining desired performance to be achieved. The databases Scopus and Web of Science were used for the time period until 2025 (August). Studies were included in the systematic literature review if they developed either a benchmarking method or benchmark values in construction. They were analysed with regard to their underlying data foundation, methodologies, and existing benchmark values for construction products.

To evaluate existing values, GWP benchmarks for the life cycle stages A1-A3 of the product category buildings were aligned to the same functional unit and then mapped to determine benchmark ranges. It became evident that while environmental sustainability benchmarks appear to have great potential to drive sustainable development in construction, differences in methodological choices result in large variations, questioning their reliability and effectiveness. Main challenges could be identified in heterogeneity in scope, unit, terminology, and allocation rules, as well as a lack of comprehensive data foundations. An overview will be provided of current benchmarking practices along with their associated opportunities and challenges. These insights into benchmarking methodologies do not only benefit stakeholders within the construction sector but will also offer valuable perspectives applicable across various fields of study concerning effective integration of sustainability assessment results into policy- and decision making.

Disclaimer/Disclosure:

This research was funded by the German Research Foundation (DFG), as part of the Collaborative Research Centre/Transregio 280 (CRC/TRR 280) ‘Design Strategies for Material-Minimized Carbon Reinforced Concrete Structures’ (Project E01, project number 417002380). The financial support by the German Research Foundation (DFG) is gratefully acknowledged.

5.09.P-We402 Beyond the Cell: Unlocking Sustainability in Battery Pack Design for Electric Mobility

Rafaela Gonçalves, Maria Soares and Emanuel Lourenço, INEGI - Institute of Science and Innovation in Mechanical and Industrial Engineering, Portugal

The transition to electrified mobility and renewable energy storage has increased the demand for sustainable battery technologies. While most research focuses on cell-level solutions, pack-level components—representing 30–40% of system weight and involving complex manufacturing—remain underexplored despite their significant environmental, economic, and social impacts. This study addresses this gap by performing a life cycle sustainability assessment of a battery pack designed for semi-solid-state cells, focusing exclusively on pack-level components and processes to ensure applicability across different chemistries.

Using a cradle-to-gate approach, environmental impacts were evaluated with ReCiPe 2016 Midpoint, economic performance through cost modeling, and social risks via the Social Hotspots Database. Results reveal three critical hotspots: the mechanical structure, which drives 56% of environmental impacts due to aluminum-intensive designs; the Battery Management System (BMS), responsible for 57% of costs and major social risks linked to electronics supply chains; and thermal management, contributing 9% of environmental burden but

influencing safety and lifetime.

Mitigation strategies include modularity and recyclability for structural components, design-for-recycling for BMS electronics, and advanced thermal solutions such as phase-change materials. These approaches can reduce emissions, extend lifetime, and support circular economy principles. Findings provide actionable guidance for eco-design, enabling stakeholders to anticipate trade-offs and prioritize interventions early in development, advancing sustainability in next-generation battery systems.

5.09.P-We403 Smart design for a dual-purpose farm level calculation tool for beef cattle – reconciling advising and reporting

Veerle Van linden, Anne-Sophie Sacré and Reindert Heuts, Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Belgium

What's the dual purpose?

The beef cattle sector is facing a substantial emission reduction target by 2030. Production conditions for own feed supplies are becoming more difficult and the context less predictable, so farmers need targeted advice. At the same time, individual farmers are increasingly being asked by their customers for climate figures in connection with their reporting obligations (such as CSRD).

What's the challenge?

Farmers often must fill in multiple tools: tailored advice requires detailed and farm specific data, while reporting agencies prefer simplified models with minimal data demand. In both cases, the administrative burden is borne by the farmer. Upfront smart design of the calculation tool can reconcile both purposes, is the lesson learnt in Klimrek dairy.

How does smart design work?

The basis for the calculation tool is the same but the parametrization and added features are tailored to the specific needs. The two goals place different demands on the scan, e.g. completeness, suitability for scenario analyses, time spent, data quality assurance, etc. Two distinct calculation models are built on the same underlying architecture and can be converted into one another depending on the goal. In order to be successful, we use co-creation for both calculation models, each with their unique set of stakeholders.

Expected results

The result will be a practically oriented scan for reporting and a premium scan for advice. Both scans will give insights in the environmental performance of the sector but only the premium scan will allow for in depth data analysis in support of policies.

Why it is relevant?

The concept of a dual-purpose convertible calculation tool is a big step forward in supporting farmers, who are confronted with the obligation to report their footprint and who want to benefit from the insights provided by environmental footprinting for their business, without double work.

Disclaimer/Disclosure:

The tool will be developed starting in Jan 2026 with the financial support of VLAIO (90%) and an additional 10% funding from the dairy beef sector.

5.09.P-We404 Review of using Multi-Criteria Decision Analysis in Life Cycle Sustainability Assessment studies

Christina Wulf¹, Breno Barros Telles do Carmo² and Marco Cinelli³, (1)Research Center Jülich GmbH, Germany, (2)Universidade Federal do Ceará, Brazil, (3)Decision Engineering for Sustainability and Resilience Laboratory, Leiden University College, Faculty Governance and Global Affairs, Leiden University, Netherlands

Use of Multi-Criteria Decision Analysis (MCDA) methods becomes more and more prominent in Life Cycle Sustainability Assessment (LCSA) studies. From the field of MCDA many different methods available for weighting and aggregating impacts. However, there is little exchange between LCSA practitioners and MCDA specialists. Previous publications show that sustainability assessment practitioners make accidental mistakes when applying MCDA. Thus we took a closer look at the use of MCDA in LCSA studies specifically and want to identify improvement potential for LCSA practitioners.

We performed a literature search in Scopus for the terms 'Life Cycle Sustainability Assessment' and 'Multi-Criteria Decision Analysis' in Title, Abstract and Keywords. The search was performed in February 2025 and we did not regalement the time period. The first article was published in 2011 that fit our search terms. In total we found 120 articles, from which 55 were eligible for the assessment.

The bibliometric analysis showed that on average there is an increasing number of publications over the years. The case studies discuss typical topics in LCA with focus on energy and mobility technologies as well as the construction and the food sector. The publications were published in classic LCA journals, e.g. Journal of Cleaner Production, and topic is pursued by authors all over the world.

We were looking for specific aspects that are crucial for the application of MCDA:

Who is the decision maker for the case study, what type of typology is applied for the decision making problem, what methods are used for weighting and aggregating are used, and who was the topic of uncertainty assessment addressed in the different studies.

We found that MCDA is mostly performed by LCSA practitioners who learned about MCDA while they are doing it. That leads to several problems with the studies from an MCDA perspective. On the one hand, there is most often no clear definition of the problem statement. And on the other hand, there is a mismatch of chosen aggregation methods with applied indicators and weighting methods. Thus, it is of utmost importance that LCSA practitioners who want to perform MCDA become better educated. In contrast, it also means that MCDA experts need to communicate better when certain approaches are valid. A first step would be better aid for selecting MCDA methods.

Disclaimer/Disclosure:

This topic is based on a book chapter that should be published next year in the LCSA Contribution of the Springer LCA Compendium.

5.10.A Life Cycle Impact Assessment Modelling and Application

5.10.A.T-01 GLAM 1.1 - The full midpoint-endpoint Global Life Cycle Impact Assessment Method

Olivier Jolliet¹, Peter Fantke², Francesca Veronesi³, Martin Dorber³, Solène Boivent¹, Eleonore Kaplan¹, Masaharu Motoshita⁴, Timothy Grant⁵, Alexis Laurent¹, Marco Cinelli⁶, Cecilia Askham⁷, Llorenç Milà I Canals⁸ and Archana Datta⁸, (1)Technical University of Denmark (DTU), Denmark, (2)substitute ApS, Denmark, (3)Norwegian University of Science & Technology, Norway, (4)National Institute of Advanced Industrial Science and Technology, Japan, (5)Lifecycles, Australia, (6)Decision Engineering for Sustainability and Resilience Laboratory, Leiden University College, Faculty Governance and Global Affairs, Leiden University, Netherlands, (7)Norwegian Institute for Sustainability Research (NORSUS), Norway, (8)United Nations Environmental Programme (UNEP), France

The Life Cycle Initiative, hosted at UNEP, has developed a Global LCIA Method (GLAM) through a science-based consensus process. GLAM 1.0 focused on endpoint/damage level, but missed multiple midpoint indicators. This work aims to presents GLAM 1.1 as a full consistent midpoint-endpoint LCIA method. GLAM 1.1 covers classification, midpoint & damage characterisation, normalisation and weighting. It assesses the life cycle impacts of products on human health (HH), ecosystem quality (EQ) and socio-economic assets (SEA). Three principles were applied to derive the the GLAM midpoint indicators: 1) Use GLAM already defined and commonly used midpoints, selected at the earliest "point of convergence", 2) differentiate between types of effect for HH (e.g. cancer, cardiovascular disease), and 3) Otherwise, divide endpoint damages by the damage of a reference substance.

GLAM provides 1.1 million characterization factors covering 14000 category-flows combinations for more than 17 impact categories. Novelties include the inclusion of the use phase HH impacts of chemicals in products, nutrition & physical activity as well as impacts on workers. EQ impacts considers new factors for marine microplastics, land use fragmentation, terrestrial ecotoxicity and accounts for species richness and vulnerability through spatialized Global Extinction Probability (GEP). For SEA, land use impacts on 5 ecosystem services are considered and a dissipation-based framework is set up for mineral resources.

These damage scores can then be normalized by the average total impact per person worldwide for the corresponding AoP. Normalized global damages are presented for HH, EQ and SEA, showing in particular substantial impacts for climate change, PMs, nutrition and physical activity benefits and dominant impacts of land use on terrestrial ecosystems, of ecotoxicity on freshwater ecosystems and of eutrophication and marine plastics on the marine environment. We will finally present consistent sets of impact category specific midpoint weights and AoP specific weighting factors to respectively apply to normalized midpoint or endpoint damages.

GLAM has benefited from the collaboration of more than 200 scientists from across the world and constitutes a quantified "one Earth" dataset for impacts on both ecosystem and human health. Once implemented in LCA software it will offer valid CFs worldwide, for application to global supply chains, and provide increased ability to avoid burden shifting.

Disclaimer/Disclosure:

GLAM development was supported by the Life Cycle Initiative in particular thanks to the continuous financial support of the Swiss government. A major part of the work was also provided via free work contribution of the more than 200 scientists worldwide supported by their own institution and projects.

5.10.A.T-02 The Environmental Footprint Life Cycle Impact Assessment method: updates for the EF 4.0 version

Esther Sanye-Mengual¹, Nicola Ferrara¹, Giulio Bracalente¹, Grazia Maria Cappucci², Cecilia Casonato³, Valeria De Laurentiis¹, Laura Garcia Herrero¹, Sara Venturelli⁴, Giulia Listorti¹, Serenella Sala¹ and Fulvio Ardente⁵, (1)European Commission, Joint Research Centre, Directorate D – Sustainable Resources, Italy, (2)Seidor, Italy, (3)Department of Agricultural and Food Sciences, University of Bologna, Italy, (4)KU Leuven, Belgium, (5)European Commission - Joint Research Centre (JRC), Italy

The Environmental Footprint (EF) methods, developed by the European Commission, offer standardized frameworks for assessing environmental impacts of products and organizations across their life cycles. Introduced in 2013, these methods (including Product Environmental Footprint (PEF) and Organization Environmental Footprint (OEF)) support policy-making, corporate accountability, and sustainable consumption. The Joint Research Centre (JRC) periodically updates the EF Life Cycle Impact Assessment (LCIA) method to incorporate advancements in impact assessment modeling. The upcoming EF4 LCIA (expected Q2 2026) aims to address two new environmental aspects: biodiversity loss due to land use (using the BIOMAPS model) and environmental impacts due to microplastics emissions (based on MarILCA). Existing categories are revised to reflect improved models, updated characterization factors, including subregional impacts (e.g., water use). Normalization and weighting factors are adjusted to align with new data and address limitations. The EF4 LCIA will expand to 18 categories, enabling more accurate trade-off analyses and comparative assessments. This contribution presents the EF4 methodology, compares it quantitatively to the EF3.1 version, and outlines limitations to guide future research and long-term developments in EF-based sustainability assessments.

5.10.A.T-03 Bringing Pathogens into Life Cycle Assessment: A Spatially Explicit Framework for Health Impact Assessment

Vanessa Schenker¹, Yao Zhou² and Stephan Pfister², (1)Institute of Environmental Engineering, ETH Zurich, Switzerland, (2)ETH Zurich, Switzerland

Pathogens originating from wastewater remain a relevant human health concern, yet their impacts cannot be assessed within life cycle assessment (LCA). This gap limits the ability of LCA to evaluate wastewater management, even though treated effluents introduce microbial contamination into surface waters, and overflow events or reduced treatment can amplify pathogen loads. Quantitative microbial risk assessment (QMRA) provides estimates of infection risks, with recreational water use identified as a major exposure pathway. However, QMRA does not capture system-wide trade-offs or allow comparison of wastewater technologies. Bridging QMRA with LCA enables quantification of pathogen-related health impacts from a life cycle perspective.

We present a spatially explicit framework that quantifies human health risks in four steps: fate and transport modelling, exposure assessment, dose-response modelling, and conversion of illness cases to disability-adjusted life years (DALYs). Hydrological and wastewater infrastructure datasets are combined with performance data from Swiss treatment plants to predict pathogen concentrations at recreational sites. Age-specific exposure

doses are derived from population density and behavioral data, and pathogen-specific dose–response relationships estimate illness risks and DALYs. The approach is demonstrated for Switzerland over one year and six pathogens. Concentrations are modelled at designated recreational sites where exposure through swimming is most relevant. We evaluate a baseline scenario reflecting current treatment performance and a degraded scenario with tenfold higher effluent concentrations representing overflows or reduced removal efficiency. Under current conditions, median *Escherichia coli* concentrations at recreational sites are 124 colony-forming unit (CFU)/L in rivers and 54 CFU/L in lakes, illustrating low pathogen levels. When integrating all six pathogens, national health impacts amount to 7 DALYs/year. In the overflow scenario, median concentrations increase (1227 CFU/L in rivers; 540 CFU/L in lakes), and combined pathogen-related impacts rise to 70 DALYs/year. The results show the low current burden and the high sensitivity of pathogen-related health impacts to effluent quality. The framework produces pathogen-specific characterization factors, offers a transparent, scalable approach for integrating pathogen risks into LCA, and supports more comprehensive evaluation of wastewater management options.

5.10.A.T-04 Assessing Global Biodiversity Impacts from Agricultural Intensification (2000–2019)

Veronika Schlosser¹, Laura Scherer² and Livia Cabernard³, (1)Technical University of Munich, Germany, (2)University Leiden, Netherlands, (3)Technical University Munich, Germany

Agricultural intensification has raised crop yields but puts increasing pressure on global biodiversity. Despite advances in mapping land-use change and biodiversity indicators, the combined effects of temporally and spatially explicit intensification and crop-specific pressures remain poorly quantified.

This study integrates 20 years of high-resolution land-use intensity data across cropland, plantations, and pastures to quantify biodiversity impacts and attribute them to intensity levels, land-use types, and 143 crop types. We examine how intensification has affected biodiversity since 2000, identifying the land-use types, intensities, regions and crops driving these trends. Compiling a global dataset with three intensity levels (high, medium, low) for crops, pasture, and plantations at 0.25° resolution from 2000 to 2019, we calculated potential species loss (PSL_{glo}) using global characterization factors that consider different intensification levels and linked impacts to the spatio-temporal distribution of crops.

From 2000 to 2019, global biodiversity impacts from agriculture increased by 1.3% PSL_{glo}, but 83% of the increase were concentrated on just 10% of the global agricultural land. Hotspots primarily occurred in the tropics, where high ecological sensitivity coincided with rapid agricultural changes. Increases from high-intensity land use in Southeast Asia, East Africa, and Brazil matched major oil palm, maize, and rice production. Pasture impacts declined globally due to abandonment, though local hotspots persisted. Decreases in low-intensity agriculture in Australia reflected rangeland contraction, while low-intensity expansion appeared in western Brazil and central Africa. Declining impacts in Ecuador, Peru, and Colombia suggest effective conservation measures.

At the crop level, oil palm, maize, and rice accounted for ~50% of the increases in cropland and plantation impacts. Oil palm impacts were concentrated in Indonesia, maize impacts were widespread, and rice impacts grew most in Sub-Saharan Africa. Medium-intensity banana plantations in the DRC made a notable contribution to global impact growth, illustrating how crop type, management intensity, and location interact.

Mitigating biodiversity loss requires managing both expansion and intensification. Crop-specific sustainability standards, improved monitoring of inputs, and integrating restoration into land-use planning are crucial for balancing production with biodiversity conservation.

5.10.B Life Cycle Impact Assessment Modelling and Application

5.10.B.T-01 Characterizing Chemical Toxicity for Life Cycle Assessment Using Machine Learning Models Based on Environmental Footprint – A textile case study

Tianran Ding, Gustavo Larrea Sr, Federico Busio, Antonino Marvuglia and Thomas Schaubroeck, Luxembourg Institute of Science and Technology, Luxembourg

The transition toward safer and more sustainable chemicals requires reliable tools to identify toxicity at early design stages. However, Life Cycle Assessment (LCA) is often limited by missing toxicity characterization factors (CFs), particularly for novel or emerging substances such as alternative surfactants and bio-based solvents. This study, that was conducted as part of two EU-funded projects (CALIMERO and DESIDERATA), addresses this challenge by developing a machine learning (ML) workflow that predicts both human and ecotoxicity CFs directly from molecular structures, enabling more comprehensive environmental assessments. The framework integrates molecular descriptor generation, feature curation, Gaussian Mixture Model (GMM)-based clustering, and three ML algorithms—Extreme Gradient Boosting, Gaussian Process regression, and Deep

Neural Networks—to model CFs across 16 environmental compartments. Model performance was assessed using data from the Environmental Footprint v3.0 database, achieving coefficients of determination (R^2) up to 0.65 for ecotoxicity and 0.61 for human toxicity. The approach was demonstrated through a textile case study comparing denim washing processes using pumice and synthetic stones. Incorporating predicted CFs revealed that missing toxicity data can substantially underestimate human toxicity impacts by 4 orders of magnitude, altering the perceived environmental ranking of alternatives.

Ongoing work focuses on strengthening prediction reliability to support high-technology-readiness-level applications within the DESIDERATA project. Planned enhancements include integration of Graph Neural Networks, improved applicability domain assessment, and expanded chemical coverage to ensure robust, transparent, and scientifically sound predictions. This work demonstrates the potential of ML to fill critical toxicity data gaps, supporting safer chemical design and more reliable sustainability assessments across industries.

Disclaimer/Disclosure:

This study is part of the projects CALIMERO (grant number: 101060546) and DESIDERATA (grant number: 101178011) funded by the European Union and SERI.

5.10.B.T-02 Effect Factors for Terrestrial Plastic Pollution for Application in Life Cycle Assessment

Christina Galafon¹, Laura Zantis², Nils Thonemann³ and Martina G. Vijver³, (1)*Fraunhofer Institute for Environmental, Safety and Energy Technology UMSICHT, Germany,* (2)*RPTU University of Kaiserslautern-Landau, Germany,* (3)*Leiden University, Netherlands*

Soils are known to be plastic pollution sinks, receiving up to 4-23 times the amount of microplastics discharged into the ocean per year. Although the uptake of plastics by plants and soil biota has been demonstrated and resulting effects have been summarized, this information is currently not usable for life cycle assessment (LCA), a common tool to assess potential environmental impacts of products and processes. The aim of our research is to develop effect factors (EFs) for the uptake of plastics by terrestrial organisms that can be integrated into LCA, and to determine influencing factors.

We derived EFs from species sensitivity distribution (SSD) curves based on effect concentrations obtained from existing experiments. We extrapolated acute values and values that correspond to different dose descriptors by using uncertainty factors and applied statistical testing to determine influencing factors. The SSD curves are based on 3-7 animal species and 14-15 plant species, depending on the inclusion criteria for existing literature. The resulting EFs vary between 0.23 – 0.31 PAF.m³.kg⁻¹, which is in the range of previously published EFs for the terrestrial environment but significantly lower than for the aquatic environment and sediments.

The extrapolation from acute to chronic effect concentrations contributes less to the overall uncertainty factor than the extrapolation from other dose descriptors. The inclusion of values from experiments that measured no statistically significant effect even at the highest tested concentration increases the uncertainty of the data but also the number of species that meet the threshold of $n \geq 5$ for a species to be included in the SSD curve. The Kruskal–Wallis ANOVA and subsequent Dunn’s post-hoc tests indicated no significant overall effect ($p > 0.05$) of the size and shape of the plastics nor of the soil type used for the experiments on the effect concentrations of the three species with the highest number of data points: *E. fetida* ($n=29$), *Z. mays* ($n=28$), and *L. sativa* ($n=23$). This finding is in line with previously developed EFs for other environmental compartments and reduces the complexity of characterization factors for plastic emissions.

Our EFs increase the robustness of previous research regarding the terrestrial environment and allow for an integration with existing fate factors to form characterization factors for plastic emissions for all relevant environmental compartments.

5.10.B.T-03 Development of LCA Characterization Factors for TRWP Physical Effects and Leachate Ecotoxicity

Louisa Ainara Nina Ospital¹, Manuele Margni² and Anne-Marie Boulay¹, (1)*CIRAIG Polytechnique Montreal, Canada,* (2)*Institute of Energy and Environment, School of Engineering, HES-SO Valais-Wallis, Sion, Switzerland*

Tire and Road Wear Particles (TRWP), composed of weathered rubber polymers, chemical additives, and road minerals, are an important source of microplastics in the environment. Detected in all environmental compartments, multiple adverse effects on the biota were reported in the literature, both from the particles themselves and from leached additives. Current LCIA methods for microplastics address only the physical particle effects and do not reflect the combined chemical and physical impact pathways of TRWP, creating a

methodological gap in the impact assessment of these pollutants.

This study develops TRWP-specific characterization factors (CFs) that differentiate and integrate physical and chemical toxicity pathways. A multimedia fate model adapted from SimpleBox4Plastics is used to derive fate factors (FFs), considering TRWP transport, settling, removal, and degradation processes. The model enables the assessment of the redistribution of TRWPs initially emitted into air or onto road surface, towards roadside soil, natural soil, agricultural soil, marine and freshwater, and associated sediments.

To characterize the chemical toxicity of TRWP leachates, species sensitivity distributions (SSDs) were developed and compared to SSDs of key additives frequently found in the leachates, namely 6PPD, 6PPD-q, DPG, Zn. Because TRWP leachate EC10 values express toxicity per mg TRWP/L, the expected aqueous concentration of each additive in a 100 mg TRWP/L leachate was computed, and the associated potentially affected fraction (PAF) was obtained from additive SSDs. The summed additive PAFs were consistently lower than the PAF of the TRWP leachate mixture, suggesting that other additives not accounted for (e.g., MBT, BT derivatives, PAHs) and mixture interactions may also contribute to ecotoxicity.

The resulting freshwater EEF for TRWP leachates is 1985.5 (89.8–43904.4) PAF·m³/kg, about twice as high as available EEFs for the physical effects of generic microplastics. When combined with the FFs determined for each environmental compartment, physical and chemical CFs are formulated to characterize both impact pathways, with preliminary values at 1.52E+05 PAF m³·d/kg of TRWP emitted in freshwater. Additional work is needed to expand terrestrial datasets and harmonize leaching protocols to refine the ecotoxicity CFs and reduce uncertainty.

5.10.B.T-04 Microplastics, Tire Particles, and Cellulosic Fibers in LCA: MarILCA Regionalized Multimedia Characterization Factors

Nadim Saadi¹, Carla Hajjar¹, Louisa Ainara Nina Ospital¹, Joris T.K. Quik², Elena Corella-Puertas³, Anne Hids², Marion Naia Lebrun⁴, Juliette Louvet⁵, Yibo Tang¹, Nils Thonemann⁶ and Anne-Marie Boulay¹, (1)CIRAIG Polytechnique Montreal, Canada, (2)National Institute for Public Health and the Environment (RIVM), Netherlands, (3)Quantitative Sustainability Assessment, Technical Univ. of Denmark, Denmark, (4)Norwegian University of Science & Technology, Norway, (5)Laboratoire des Sciences du Climat et de l'Environnement, Univ. Paris-Saclay, France, (6)Leiden University, Netherlands

It is estimated that worldwide, 10 to 40 million tons of microplastics (MPs) are emitted annually into the environment. Once released, MPs redistribute across environmental compartments, affecting organisms in each of them. However, current Life Cycle Impact Assessment (LCIA) methods only partially account for their impacts on ecosystem quality (EQ) by considering a limited number of compartments and particles. This study advances the work of the MarILCA group by integrating the physical effects of MPs, tire and road wear particles (TRWPs), and cellulosic fibers across all environmental compartments into life cycle assessment (LCA).

Characterization factors (CFs) are developed for 20 polymers, 6 cellulosic materials, and TRWPs, for multiple shapes and sizes commonly emitted over the lifecycle of products and services. To this end, particle fate is modelled using the new SimpleBox object-oriented (SBoo) fate model for microparticles, which computes fate factors (FFs) in air; terrestrial (roadside, agricultural, and natural); freshwater (water and sediments); and marine (water and sediments) environments at continental and global scales, following USEtox regionalization across eight regions. SBoo was improved to account for (i) size and shape effects, (ii) degradation using the PlasticFADE model, and (iii) regional marine currents and biofouling through the use of the TrackMPD ocean circulation model.

FFs are combined with exposure and effect factors (EEF), based on hazardous concentration for 20% of species (HC20) in water, sediments, and terrestrial environments separately, to obtain updated CFs and their uncertainties. Impacts across compartments are aggregated using the volume and number of species living in each compartment. For IMPACT World+ (IW+) and ReCiPe, CFs representing regional species loss are derived, while for GLAM and LC-IMPACT, the Global Extinction Probability is applied to combine impacts at different scales and derive CFs representing global species loss. 21 600 CFs are produced, ranging from 2.6E-19 to 1.5E-7 PDF·yr/kg (preliminary). Their application is demonstrated through LCA case studies in agriculture, textiles, and food packaging, highlighting the importance of including these impacts in LCA. Overall, the resulting CFs support environmental decision-making, are provided in different units compatible with multiple LCIA methods, and are proposed to contribute to the upcoming update of the Environmental Footprint method (EF4.0).

5.10.P Life Cycle Impact Assessment Modelling and Application

5.10.P-Mo355 Performing life cycle impact assessment with the mid- and endpoint method ReCiPe

Rosalie van Zelm¹, Thomas Hennequin² and Mark Huijbregts¹, (1)Radboud University, Netherlands, (2)TNO, Netherlands

While general guidelines to perform LCAs are available, specific recommendations on performing and reporting the life cycle impact assessment (LCIA) step in a standardized way are lacking. Previous LCAs have shown that this lack can lead to incomplete results, followed by misinterpretation. In the LCIA step, the magnitude and significance of the potential environmental impacts are quantified and evaluated. Here, we show how to systematically perform and report the LCIA step, to identify the most meaningful LCA results, and check their robustness. To develop the procedure, we used the widely applied LCIA methodology ReCiPe, which includes so-called characterisation factors (CFs) that express the environmental impact per unit of emission or extraction for 18 midpoint categories, such as global warming and acidification, and three endpoint categories (human health damage, ecosystem damage, and resource scarcity). The CFs are developed for three perspectives, addressing inherent value choices in the calculation models. The procedure was specifically developed to demonstrate the full use of a comprehensive multi-indicator method, making use of its full range of possibilities. We applied our method to a passenger car tire case study. Although according to the LCA guidelines, impact categories can be chosen in the goal & scope definition, we recommend to include all ReCiPe impact categories on endpoint level and all three perspectives in the initial assessment, and only decide after the contribution analyses which impact categories or areas of protection to focus on, to prevent unintended burden shifting. The most relevant impact categories could then be presented for one perspective, when all perspectives point into the same conclusion. If not, these differences should be discussed.

We argue that it is important to use the latest impact assessment methodology in LCA case studies, thus including new insights. For the future, improvements are for example expected regarding the inclusion of more toxicants, including nanoparticles and microplastics. Uncertainty in the CFs, caused by model input parameters, should also be included in a next version of the ReCiPe method, next to the scenario uncertainty embedded in the perspectives.

Being comprehensive on the LCIA results will lead to a clear, distilled message to stakeholders to decrease environmental impacts, without unintended burden shifting across the supply chain, or between different environmental impacts.

5.10.P-Mo356 How a methodology developed to identify volatile ingredients improves the reliability of impact assessment of cosmetic products in life cycle assessment

Delphine Moulin-de-Vincenzi, Swati Kaushik, Gérard Provot, Lea Albayeh, Jad Zoghaib, Eléonore Sicourmat, Séverine Brinster and Jacques L'Haridon, L'Oréal, France

L'Oréal has been conducting Life Cycle Assessments (LCA) to measure the environmental impacts of its cosmetic products for many years. All this knowledge has been used to create an environmental design method aiming at improving the environmental profile of products under development, while maintaining or enhancing the consumer's benefits. This method was integrated within SPOT (Sustainable Product Optimization Tool), the product evaluation tool used by product development teams to assess the environmental performance of all new Group's cosmetics. Based on a full life cycle approach, this tool is currently using the planetary boundaries concept to weight and aggregate in a single environmental footprint 14 impacts of a finished product, including formula, packaging, manufacturing and distribution to consumers.

Product portfolio analysis with SPOT showed that the formula end-of-life (i.e. after consumer use) is one of the major life cycle stages responsible for the environmental footprint of cosmetic products. However, the contribution of formula end-of life to the product footprint highly depends on the environmental compartments where formula ingredients are emitted during the product use phase. For the sake of simplification, while remaining representative of reality, most formula ingredients in SPOT are supposed to be discharged into sewers when the product is used by consumers. However, few highly volatile ingredients are released to air such as propellants and some liquid ingredients with high vapor pressure. The distinction between ingredients considered volatile and non-volatile in SPOT required the development of a specific method, as there is no harmonized and agreed-upon technical definition of a volatile chemical substance, despite the existence of several international regulations on volatile organic compounds.

The methodology developed to identify volatile ingredients for application in our product environmental design

tool SPOT will be described and its influence on the environmental footprint of ingredients, formulas and finished products will be shown through case studies. More broadly, the advantages of this methodology for the cosmetics sector and potentially other sectors wishing to improve the robustness of end-of-life assessment of chemical products in LCA will be highlighted.

5.10.P-Mo357 Evaluating the Social Impacts in the Emerging Second-Life Battery Sector: A Comprehensive Framework

Rui Couto Alves Dos Reis and Emanuel Lourenço, INEGI - Institute of Science and Innovation in Mechanical and Industrial Engineering, Portugal

The battery sector has grown substantially over the past decade, producing an unprecedented volume of batteries to meet rising demand for sustainable energy and mobility. However, this raises concerns about battery disposal, as higher production will result in a corresponding increase in retired battery waste streams.

Second-life applications of batteries present a compelling opportunity to address this challenge. Retired batteries can be repurposed for less demanding uses like energy storage and grid balancing. This extends battery lifespan, reduces waste, decreases demand for raw materials, and promotes environmental and economic sustainability.

While the environmental and economic implications of battery reuse have been widely studied, the social dimension remains underexplored. To address this gap, this paper proposes a framework for systematically assessing the social impacts of the emerging second-life battery sector. This framework adopts a methodology aligned with the guidelines established by UNEP/SETAC and ISO 14075. The initial step involves defining the goal and scope of the assessment, with particular emphasis on establishing system boundaries and delineating which elements are included in or excluded from the analysis.

Subsequently, primary data are collected on material quantities, origins, costs, and associated processes and energy inputs to identify key social impacts. These data are complemented by databases such as PSILCA and SHDB, which allow for an evaluation of potential social impacts. Through this analysis, we can identify the main social hotspots, prioritise subcategories and indicators for further examination.

Building on the second phase of the framework, it engages directly with stakeholders through customised questionnaires and interviews with partners and sector experts. This step offers a more grounded and realistic perspective on the sector's challenges and best practices. This approach is particularly valuable for highlighting areas where early interventions can foster positive change or identifying practices that are already contributing to improved social conditions across different categories of impact.

The integrated framework contributes to a more comprehensive understanding of social sustainability within the second-life battery sector, supporting the development of strategies that enhance social value, promote responsible innovation, and strengthen overall system resilience.

Disclaimer/Disclosure:

This work has been developed in the framework of the BIG LEAP project, co-funded by the European Union under grant agreement N°101137815.

5.10.P-Mo358 Modelling electricity consumption for zero emissions vehicles and fleet LCAs: guidelines from the TranSensus LCA European research project

Anne Grau¹, Marie Pinochet², Hazem Eltohamy³, Bernhard Steubing³, Marco Rauget⁴, Kadam Lokesh⁴, Nikolas Hill⁴, David Algsten⁵, Erik Nellström-Montemartillo⁵, Diana Bartaune⁶, Katharina Gompf⁶, Davis Jose⁷, Mara Neef⁸, Till Uhlmann⁸ and Ketan Vaidya⁹, (1)EDF Group, France, (2)CEA, France, (3)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (4)Ricardo-AEA Ltd, United Kingdom, (5)Scania, Sweden, (6)BMW Group, Germany, (7)Institute of Sustainability in Civil Engineering, RWTH Aachen University, Germany, (8)Volkswagen AG, Germany, (9)Northvolt AB, Sweden

Electricity consumption modelling is a highly debated topic in the LCA community, since the two main options that can be used: the location-based approach and the market-based approach, have both their pros and cons, and cannot be used simultaneously within the same LCA, if one wants to avoid double counting. Therefore, one of the tasks assigned to the TranSensus LCA European project, which was to reach a consensus among its consortium for a harmonised, commonly accepted and applied LCA approach for electricity consumption modelling for zero-emission vehicles and fleet, was not an easy one.

Nevertheless, due to a clear 30-month consensus building process, based on discussions, aimed at a common understanding of the location-based and market-based pros and cons, 3 consecutive voting sessions, aimed at selecting requirements and recommendations, completed by recommendations from the project Advisory Board, the following guidance was agreed upon:

- The location-based approach shall be used for the vehicles production phase. However, if desired, a 100% market-based approach can be used (in which residual mixes are used, to avoid double counting issues). Lastly, when needed, a mixed-method approach may be used. The last 2 options come with several safeguards related to the physical reality of the consumed electricity delivery.
- A “dynamic” modelling approach shall be used for the use phase, based on a reputable energy future scenario, to assess the most realistic context occurring over the full-service life of the vehicles. However, because of legal obligations, one may opt to use a more conservative “static” modelling approach, where the electricity mix at date of the vehicles production is used.

The TranSensus LCA European project lasted 30 months and included 20 beneficiaries (11 industries plus 10 academics), 24 associated partners and 4 wider consultation groups. The TranSensus guidelines, published in 2025, establish 56 methodological requirements and 81 recommendations, covering environmental and social LCAs for zero-emission vehicles, fleet and prospective scenarios analyses. It is important to note that TranSensus guidelines is a living document to be updated as necessary.

The electricity modelling guidelines may be later updated based on better electricity traceability and the availability of databases with residual mixes background processes and of new future electricity production processes (for instance from the PREMISE project).

Disclaimer/Disclosure:

The presented work was conducted within the TranSensus LCA project which was granted from the European Union’s Horizon Europe research and innovation program under Grant Agreement Nr.101056715. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or CINEA. 5.10.P-Mo359 Land-Use Biodiversity Characterization Factors for Wetland Agriculture in Europe **Bonivasius Pradipta Retmana, Quint van Giersbergen, Birka Wicke and Rosalie van Zelm, Radboud University, Netherlands**

Wetlands contain a large portion of the world’s soil carbon and are home to many specialized species. In Europe, however, many wetlands have been drained for agriculture, leading to high greenhouse gas emissions and biodiversity loss. Wetland agriculture, known as paludiculture has been proposed to produce biomass while maintaining ecosystem functions by keeping water tables high. However, its environmental benefits remain debated. Biodiversity in paludiculture systems is poorly documented. While biodiversity impacts due to land use are addressed in Life Cycle Assessment (LCA), paludiculture in LCA remains challenging because its species composition and land-use dynamics differ from typical agricultural systems. Popular Life Cycle Impact Assessment (LCIA) methods like ReCiPe2016 and LC-Impact, do not specifically address wetland agriculture. This research therefore aims to develop paludiculture-specific biodiversity Characterization Factors (CFs), expressing potential species loss due to paludiculture land conversion for different European countries, and compare them to CFs for drained peatland agriculture to provide impacts of paludiculture. CFs are expressed as Potentially Disappeared Fraction (PDF) of species per unit of land area. To determine CFs, species loss from land transformation and occupation were determined. Land-use areas for paludiculture, drained peatland agriculture, and natural peatlands were drawn from “Building the European Peatlands Initiative” map. Species lists and occurrence coordinates were obtained from the IUCN Red List database and the Global Biodiversity Information Facility (GBIF). All species occurrences were spatially matched to corresponding pixels in the map for each country. These inputs were used in the Species-Area Relationship (SAR) model to derive CFs for all European countries. Preliminary results for the Netherlands show that paludiculture leads to lower potential biodiversity loss compared to drained peatland used for agriculture. CFs for drained agriculture also fall within the same order of magnitude as conventional agriculture in LC-Impact, suggesting good comparability. Still, several uncertainties remain to be addressed, such as missing species in paludiculture areas due to limited spatial information and the use of a 500-year default regeneration time. As next step, we plan to expand the CF calculation to all European countries to create a spatially explicit characterization heatmap.

5.10.P-Mo360 Modelling organic agriculture in land use impact categories: a proposal for the Environmental Footprint methods

Cecilia Casonato¹, Claudia Daniel Escorza², Laura Garcia Herrero³, Vasco Orza⁴, Taija Sinkko⁴, Giulia Listorti³, Serenella Sala³ and Esther Sanye-Mengual³, (1)Department of Agricultural and Food Sciences, University of Bologna, Italy, (2)Departamento Biología vegetal e ciencias do solo, Universidad de Vigo, Vigo, Spain, Spain, (3)European Commission - Joint Research Centre (JRC), Italy, (4)Piksel S.r.l., Italy

Currently, no consensus has emerged on methodologies to incorporate different agricultural practices (APs) into Life Cycle Assessment (LCA). This represents a major scientific challenge, whose relevance is unanimously agreed to correctly identify, assess, and thus promote, more sustainable production methods. In the context of the Environmental Footprint (EF) methods, the Joint Research Centre (JRC) has explored possible solutions to bridge this gap focusing on AP variability, in particular organic farming systems, in land use impact categories. A short-term solution has been proposed, introducing "scaling coefficients" derived from the meta-analyses available in the JRC Farming Practice Evidence Library to adjust characterisation factors (CFs), thus reflecting the effects of organic farming in the soil and biodiversity impact categories. The approach has been tested in organic datasets, showing a reduction in the impact of organic systems with limited effect at single weighted score level. The testing also unveils challenges associated to the modelling of organic farming systems, such as crop yields differences and inventory modelling, as well as co-products allocation in relation to green manure use. This proposed approach aims to enable LCA to differentiate agricultural systems while outlining future research directions. Further knowledge on the effects of organic farming on environmental indicators might enable the definition of CFs for the variety of APs, including a higher level of granularity at elementary flow level and geographical regionalisation. Better modelling of different APs might involve the revision of other impact categories, such as toxicity-related categories, or the weighting set, as well as the further development of land use impact assessment modelling to better consider local conditions (e.g. soil characteristics).

Disclaimer/Disclosure:

The present study has been developed in the context of the Administrative Arrangement "Technical support for the Environmental Footprint and the Life Cycle Data Network (EF5)" (JRC N° 36372 – ENV N° 09.0202/2022/879207/AA/ENV.B.1) between the Joint Research Centre and the Directorate General for the Environment (DG ENV) of the European Commission.

5.10.P-Mo361 Environmental Impacts of Livestock Systems - Insights from Recent LCA Studies

Eva Martínez-Ibáñez¹, Jara Laso², Ana Fernández Ríos¹, María Margallo¹ and Ruben Aldaco¹, (1)University of Cantabria, Spain, (2)Department of Chemical and Biomolecular Engineering, University of Cantabria, Spain

Food production, especially livestock farming, is widely recognized as a significant driver of environmental impacts worldwide. Life cycle assessment (LCA) has become a crucial approach for evaluating these systems, as it enables the quantification of environmental burdens throughout a product's entire life cycle. This work provides a systematic analysis of 54 peer-reviewed studies applying LCA to livestock production, focusing on beef, pork, chicken, lamb, and milk. The primary aim is to evaluate the consistency and comparability of methodologies across studies, as well as to identify emerging challenges and research gaps that warrant further investigation.

Results show considerable variation in reported environmental impacts, largely influenced by factors such as animal species, production practices, allocation approaches, and system boundaries. Ruminant systems, particularly beef and lamb, generally demonstrate higher global warming potential due to methane emissions and lower feed efficiency. However, these findings must be interpreted in the context of the substantial methodological differences observed among studies. Choices such as the definition of system boundaries and the selection of impact categories were found to significantly affect outcomes, limiting cross-study comparability.

Although current LCA studies provide valuable insights, they remain limited by uncertainties associated with data quality, representativeness, and the absence of standardized methods that integrate environmental, social, and economic dimensions. Future research should emphasize methodological harmonization, the development of region-specific and dynamic LCA models, and the inclusion of broader sustainability indicators. Enhancing data transparency and consistency is critical to improve the reliability and policy relevance of livestock sustainability assessments, ultimately supporting the design of more effective, context-specific mitigation strategies.

5.10.P-Mo362 Rethinking water use impact assessment: a novel multimedia fate model covering the full water balance

(1)Autonomous University of Barcelona (UAB), Spain, (2)Texas A&M AgriLife Blackland Research & Extension Center, United States, (3)Institute of Agrifood Research and Technology (IRTA), Spain, (4)Institute of Agrifood Research and Technology (IRTA), Caldes de Montbui, Spain

Green water—soil-stored rainwater consumed by plants through evapotranspiration—accounts for the majority of agricultural water use, yet it remains largely overlooked in Life Cycle Assessment (LCA), which traditionally focuses on blue water withdrawals. This omission limits the ability of LCA to represent the full environmental implications of water use in agriculture. This study advances water-related LCA by integrating green water consumption into both life cycle inventory (LCI) and life cycle impact assessment (LCIA), while maintaining compatibility with existing blue water assessment methods. Building upon a mechanistic framework for water use impact modeling, we generate new inventory data and hydrologically consistent fate factors (FFs) that capture water stocks and flows among interconnected environmental compartments at a watershed scale.

The methodology is demonstrated for the Fluvia watershed in Catalonia, Spain, where the SWAT+ ecohydrological model was applied to simulate the spatial and temporal distribution of water resources. High-resolution outputs such as evapotranspiration, runoff, and percolation were translated into green and blue water consumption flows for major crops and agricultural practices. These data improve current LCI databases by incorporating seasonal variability, differences in irrigation strategies, and management-specific water demand. To quantify downstream impacts, we used a multimedia fate factor model representing six hydrological compartments: air, soil, vegetation, surface water, groundwater, and fossil water. Monthly transfer rate matrices (k-matrices) derived from SWAT+ outputs were inverted to compute fate factor matrices, resulting in 120 sets of FFs over a 10-year period. The inclusion of soil as an explicit compartment allows for the first time the linkage of green water consumption to its environmental consequences within LCA.

This proof-of-concept confirms the feasibility and necessity of fully accounting for water balance dynamics in LCA, enabling differentiation of water sources and their impacts at the watershed level. Future work will extend the model to broader geographic regions, allowing the identification of agricultural practices that reduce water consumption and associated impacts.

5.10.P-Mo363 Towards an Impact Assessment of Land Use on Soil Biodiversity

Adrien Burg, Arnaud Helias and Amandine Pastor, National Research Institute for Agriculture, Food and Environment (INRAE), France

Life cycle impact assessment (LCIA) indicators assessing land-use impacts on community composition are currently limited to a few well-studied groups, overlooking soil organisms despite their major contribution to global biodiversity and ecosystem functioning. Advances in environmental DNA (eDNA) metabarcoding and large-scale monitoring now provide the data needed to incorporate soil organisms into these models and improve the taxonomic coverage of biodiversity impact assessment. Relative change of species richness (PDF) is commonly used in LCA to estimate damage to biodiversity. For microbes, richness can increase with land use intensity, leading to counterintuitive results in LCA, such as a beneficial effect of land conversion for local soil biodiversity. A more detailed analysis of lower taxa affinities (phyla, class) with land use is then required to transcribe insights from soil ecology into LCA. Methodological adaptations are also required to derive community composition indicators from environmental DNA data rather than species inventories. Two major eDNA data collection programs are now available to test our methodology: RMQS, in France, focusing on bacteria, and LUCAS Soil, across Europe, focusing on bacteria, fungi, protists and eukaryotes. Processing robust soil biodiversity characterization factors requires addressing key methodological consideration. Taxonomic richness for microorganisms is estimated via OTU richness, with definitions of OTUs (e.g., 95% similarity, zero-radius) influencing richness estimates. The choice of the taxonomic rank affects land-use affinities, as bacterial and fungal richness patterns vary across phyla and classes, making averaged subtaxa characterization factors different from kingdom level ones. Spatial aggregation shows that ecoregions, commonly used for plants and vertebrates, may mask fine-scale variation in bacterial richness, which is strongly influenced by soil properties such as acidity, texture, and C:N ratio. Finally, reference situations need to be defined to compute PDF, but samples from natural sites are scarce, especially considering the needed representativeness for all pedoclimatic regions. Reclassification of sites under human land use could be performed following conventional approaches. Used on large scale datasets (RMQS, LUCAS), this methodology will be used as a LCIA model to assess the impacts of land use on below-ground biodiversity, complimentary to models for above-ground biodiversity.

5.10.P-Mo364 Framework development for characterization factors of marine biodiversity assessment under future climate change.

Runya Liu and Norihiro Itsubo, Waseda University, Japan

The ocean covers more than 70% of the Earth's surface and supports a very large amount of biodiversity, estimated to be over 80% of all global species. Recent studies have shown that climate change is creating serious challenges not only for life on land but also for marine ecosystems. Changes such as increasing sea temperature, ocean acidification, and deoxygenation are disrupting the stability of marine environments and may lead to strong reductions in fisheries and habitat quality. However, in the LCIA field, research on marine biodiversity is still very limited, especially regarding the development of characterization factors (CFs) for marine species.

In this study, we propose a practical framework to develop spatial characterization factors for marine biodiversity under future climate change, mainly focusing on sea temperature rise. We follow the LIME3 approach and combine it with species distribution models (SDMs) to estimate changes in species habitat suitability under future scenarios. Environmental data for both current conditions and the 2100s (SSP1–RCP2.6) were taken from Bio-ORACLE, including variables such as ocean temperature, salinity, and nutrients. Occurrence records of marine species were collected from GBIF and OBIS.

The resulting CFs are shown on maps with a 0.05° resolution and expressed as the marginal effect of greenhouse gas emissions on species extinction rate, following the indicator recommended in the Planetary Boundaries framework. These CFs help identify which species are more vulnerable to future climate change. They also provide a way to check whether different climate mitigation policies or emission reduction scenarios are strong enough to protect marine ecosystems. For LCA users, this framework makes it possible to quantify life-cycle impacts on marine species and also compare these results with existing terrestrial assessments. Overall, this research helps connect ecological information with LCIA and contributes to filling the current gap in marine biodiversity characterization factors.

5.10.P-Mo365 Integrating Soil Biodiversity Impacts of Open Trenching into Life Cycle Impact Assessment

Monu George Varghese, INaB, RWTH Aachen, Germany

Soil biodiversity plays a central role in maintaining ecosystem functions, yet disturbance from open trenching remains poorly represented in Life Cycle Impact Assessment (LCIA). Existing practice relies primarily on the Potentially Disappeared Fraction (PDF) of species as an indicator of biodiversity loss, which captures direct habitat disruption but does not reflect fragmentation effects or post-disturbance recovery. This limits the ability of LCIA to characterize the full ecological consequences of excavation activities.

This work addresses the challenge by developing a demonstrative framework that retains PDF as the main indicator while testing how fragmentation metrics and recovery dynamics can be integrated to improve the assessment of soil biodiversity impacts from open trenching. The purpose is to explore methodological options, evaluate their feasibility, and identify where existing LCIA models can be strengthened.

The approach uses literature-derived characterization factors, soil and habitat data, and spatial fragmentation indicators such as edge density and connectivity. Biodiversity loss is quantified using standard PDF calculations and then adjusted through fragmentation effects and recovery scenarios based on soil return after excavation.

This allows the comparison of baseline PDF-only assessments with extended versions that incorporate ecological structure and temporal recovery. Intermediate results focus on the extent to which fragmentation amplifies impacts and how soil restoration influences recovery potential.

Preliminary findings suggest that including fragmentation and recovery dynamics alters both the magnitude and distribution of biodiversity impacts, revealing where recovery pathways can mitigate disturbance and where fragmentation leads to persistent ecological degradation. These outcomes highlight methodological opportunities for improving the representation of soil biodiversity in LCIA and offer a basis for future development of more ecologically realistic indicators.

The study contributes to ongoing efforts to strengthen biodiversity modelling within LCIA and supports more informed decision-making in infrastructure and environmental planning.

5.10.P-Mo366 Assessing Biodiversity with LCA: How far can we go?

Anne Asselin¹, Aurore Wermeille¹, Pablo Tirado-Seco², Cécile Sophie Marie Bulle³, Joséphine Gatin⁴, Ivan Viveros-Santos², François Saunier², Marion DEVIENNE⁵ and Philippe Osset⁵, (1)Sayari, France, (2)CIRAIG, France, (3)Montreal Polytechnic, France, (4)SAYARI, France, (5)SCORE LCA, France

Biodiversity loss is one of today's major environmental challenges. In this context, Life Cycle Assessment (LCA) has long sought to quantify impacts on biodiversity through the "ecosystem quality" area of protection. To help industrial stakeholders better understand the capabilities and limitations of these approaches, SCORE LCA has launched a study on the relationship between LCA and biodiversity, aiming to provide both state-of-the-art and practical recommendations.

Two case studies serve as illustrative threads: electricity generation from photovoltaic systems in France, and the ecological restoration of an industrial site after solar farm decommissioning. These examples help examine how existing LCA impact assessment methods cover biodiversity pathways, how their metrics should be interpreted, and where their blind spots lie. The study compares major LCIA methods by analyzing their coverage of biodiversity loss drivers, the meaning and relevance of their metrics, their geographical resolution, and their alignment with global biodiversity monitoring concepts and frameworks.

Current LCIA approaches only partially capture the five key biodiversity loss drivers. They also rely on metrics with differing meanings, making interpretation challenging. Moreover, they struggle to reflect local ecological conditions, land-use practices, or pressures such as invasive species. The case studies aim to clarify how these issues affect real-world assessments, including the difficulty of addressing restoration and compensation through LCA, and the limited integration of biodiversity variables.

Beyond reviewing methods, the study will deliver practical recommendations. It will help practitioners understand when LCIA is appropriate for biodiversity evaluation, when complementary tools are necessary, and how LCA fits within emerging corporate sustainability frameworks. Completion is expected in March 2026 and will provide guidance on combining LCA with other biodiversity indicators to support robust decision-making.

The authors thank Score LCA members for funding the study and providing feedback.

5.10.P-Mo367 Assessment of the impact of nitrogen deposition on terrestrial ecosystems

Ayana Matsunaga¹, Kentaro Hayashi Dr², Tang Longlong³, Tatsuya Nagashima⁴ and Norihiro Itsubo Dr¹, (1)Waseda University, Japan, (2)Research Institute for Humanity and Nature, Japan, (3)National Agriculture and Food Research Organization, Japan, (4)National Institute for Environmental Studies (NIES), Japan

Global biodiversity is declining at an unprecedented rate. According to IPBES, at least 680 vertebrate species have gone extinct since 1500, and the current extinction rate is tens to hundreds of times higher than the long-term average over the past 10 million years. Approximately 25% of assessed taxa, including plants, are listed as threatened on the International Union for Conservation of Nature and Natural Resources (IUCN) Red List. The planetary boundaries framework further indicates that biogeochemical flows have substantially transgressed safe limits, with nitrogen identified as a major contributor. Although nitrogen is an essential nutrient for plants, increased anthropogenic nitrogen emissions enhance nitrogen deposition, altering plant nitrogen use, productivity, and community composition. However, the quantitative relationship between nitrogen deposition and plant biodiversity loss remains insufficiently resolved.

The objective of this study is to quantitatively evaluate the effects of nitrogen deposition on terrestrial plant biodiversity. We estimated the Mean Species Abundance (MSA), a biodiversity indicator representing species richness and relative abundance compared to undisturbed natural conditions, using global nitrogen deposition data for 2010 at a spatial resolution of $1.125^\circ \times 1.125^\circ$. The deposition dataset includes dry and wet deposition of both ammonium and nitrate ions. MSA values were calculated following the methodology of Hans van Grinsven et al., focusing on vascular (higher) plants at the global scale.

Visualization and country-level comparison of nitrogen deposition using QGIS reveal that China, the United States, India, and Russia exhibit the highest nitrogen deposition impacts. This pattern is reflected in the MSA estimates, suggesting substantial risks to plant biodiversity in these countries. By partitioning the globe into 32 source regions and using scenario data for additional NH_3 and NO_x emissions from each region, it is possible to identify which emitting regions contribute to deposition in which receptor regions.

This study provides a quantitative basis for relating nitrogen deposition to plant biodiversity decline and for comparing impacts among countries and regions. In future work, we will extend the approach to assess how changes in plant biodiversity propagate to broader biodiversity and ecosystem service impacts.

5.10.P-Mo368 How to Integrate Marine Environmental Impacts of Marine Technologies into Life Cycle Assessment

Mona Delval¹, Patrik Henriksson¹, Paul Behrens¹, Laura Scherer¹, Pablo Trucco-Pignata², Patricia Grasse³, Phil Renforth⁴ and Nils Thonemann¹, (1)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (2)National Oceanography Centre, United Kingdom, (3)German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Germany, (4)Research Centre for Carbon Solutions, Heriot-Watt University, United Kingdom

Human activities are increasingly expanding into marine environments. While Life Cycle Assessment (LCA) is used to evaluate marine technologies environmentally, it faces challenges in accounting for marine-specific impacts. Advancing LCA for marine technologies requires a clear understanding of their interaction with the marine environment, which is essential for developing (sub-compartmentalised and regionalised) characterisation factors (CFs). In our study, we first present a methodological approach for identifying pathways for marine environmental impacts, which includes qualitatively determining the marine environmental flows and the fate, exposure, and effect processes of the marine technology, as an initial step toward CF development. We then demonstrate its application using ocean alkalinity enhancement (OAE) as a case. OAE is a marine carbon dioxide removal technology that is attracting growing interest due to its potential contribution to climate mitigation targets. Our approach draws on oceanography and geochemistry literature relevant to the technology, and is complemented by expert input from the fields of life cycle impact assessment (LCIA), oceanography, and OAE. We analyse which components of the marine environmental impact pathways are currently modelled in LCIA and identify missing elements, key knowledge gaps, and research needs to improve OAE impact assessment within LCA. From our analysis, three main impact categories emerge for OAE marine environmental impacts: marine ecotoxicity, marine eutrophication, and ocean acidification. Current LCIA models do not capture these pathways entirely and necessitate significant adaptation for OAE evaluation. Present models lack relevant environmental flows, represent the ocean in a simplistic manner that neglects its spatial variability, and often assume emissions entering the marine environment via freshwater or atmospheric systems rather than direct ocean release. Future research must develop OAE-specific fate models, expand experimental data on ecotoxicological and eutrophic responses to OAE deployment, and assess the effect of enhanced alkalinity on a wider range of calcifying species. Models incorporating marine sub-compartments must also be developed for spatially accurate impact assessment. Overall, our methodology provides a structured approach to identifying marine environmental impact pathways of marine technologies and can also be more broadly applied to other emerging technologies.

5.10.P-Mo369 Life Cycle Impact Assessment of dynamic fisheries: Characterization factor temporal series for Peruvian stocks

Ruben Manrique-Muñante, Alejandro Deville, Ian Vázquez-Rowe and Ramzy Kahhat, Peruvian Life Cycle Assessment Network (PELCAN), Peru

Recently developed Life Cycle Impact Assessment (LCIA) models offer a promising framework for quantifying the environmental footprint related to the exploitation of biotic resources. The Fisheries Impact Pathway proves to be a reliable LCIA model for quantifying these impacts; however, we have identified certain methodological aspects relevant to impact assessment in dynamic fisheries, particularly temporality, that require enhancement to better capture biodiversity impacts. This study aims to develop a characterization factor (CF) temporal series for 10 representative Peruvian fishing stocks. The methodology framework comprises 1) improving model performance using extensive statistical criteria to obtain reliable estimates for CF calculation; 2) implementing an exclusive economic zone (EEZ) approach to address the efficiency of national policy interventions; and, 3) integrating time variability in stock abundance, which is relevant for stocks affected by El Niño Southern Oscillation (ENSO).

According to our statistical analysis, improved model estimates result when abundance indices are included within a narrower modelling timeframe. The refined CFs calculated using these estimates deviate up to 4 orders

of magnitude from previously reported values, usually showing lower values, reduced uncertainty and pronounced sensitivity to annual biomass fluctuations. In addition, weak to moderate statistical correlations were observed between the CFs and typical ENSO indices, suggesting sensitivity to climatic events driving stock landings and biomass variability. Furthermore, the case studies revealed differences in biodiversity impacts across stocks destined for direct human consumption, as well as additional impacts, up to 61% in fishmeal and fish oil production among plants operated by a major local producer. These findings indicate that the temporal dimension of fishery-related CFs is critical, especially when fluctuating parameters are intrinsic to the modeled system. We recommend applying these dynamic CFs rather than the static CFs to quantify marine biotic resource depletion impacts for Peruvian seafood and aquaculture.

5.10.P-Mo370 Which Area of Protection for Fish?

Arnaud Helias¹ and Karine Dufossé², (1)National Research Institute for Agriculture, Food and Environment (INRAE), France, (2)Montpellier Agro Institute, France

Fishery impacts remain insufficiently covered in current LCA studies. To address this gap, the European Commission tasked experts with integrating fisheries into the Environmental Footprint method. Comparing the available approaches helps clarify the distinction between impact and characterisation factor (CF), and between protecting ecosystems (Ecosystem Quality area of protection (AoP)) and preserving ecosystem services (Socio-economic assets). Two main approaches were examined. The fisheries science approach developed by the Scientific, Technical and Economic Committee (STECF) evaluates stock status using two indicators: abundance (current biomass relative to a reference) and fishing pressure (mortality relative to a reference). These feed a decision tree, with impacts increasing as pressure rises and abundance decreases. The LCA approach derives CFs from a dynamic population model. It integrates abundance, pressure, resilience (replenishment rate) and stock size. High pressure increases impacts, while low abundance, resilience or stock size decreases them. Missing values can be replaced by modelled ones. Both approaches depend on abundance and pressure, but differ in important ways. STECF assumes no impact before optimum exploitation is exceeded, whereas LCA considers impacts from the start of fishing. LCA also adds a temporal dimension through resilience. Most importantly, STECF describes the state of the stock, while LCA quantifies the responsibility of a specific fishing activity for that state, which explains the inclusion of stock size in LCA. As a result, the two frameworks may diverge significantly. These differences raise a central question: should assessments focus on the intrinsic ecological value of fish populations or on their instrumental value as resources? For the Ecosystem Quality AoP, LCA is more suitable because it treats all species as equally important and evaluates impacts proportionally. For the Socio-economic assets AoP, the STECF approach is more aligned, since larger stocks provide greater resource value. Both approaches can also be adapted to either perspective simply by adding or removing stock size in CF calculations. The author concludes that the LCA approach offers stronger methodological consistency, while STECF benefits from acceptance within fisheries science. Ultimately, both perspectives are needed for integrating fisheries into the Environmental Footprint method.

5.10.P-Mo371 Incorporating Black Soldier Fly oil in Aquafeeds: Environmental Implications from a Life Cycle Perspective

Sara Silva¹, Maria J Mota² and Paula Quinteiro³, (1)University of Aveiro, Portugal, (2)SORGAL, Sociedade de Óleos, Portugal, (3)CESAM, University of Aveiro, Portugal

Fishmeal (FM) and fish oil (FO) are the primary protein and lipid sources in aquafeeds, widely used for their high nutritional quality and essential nutrients for optimal fish growth. However, their production is linked to the overexploitation of marine resources and related environmental impacts. Alternative ingredients, such as those derived from black soldier fly (BSF), offer a sustainability opportunity by converting agri-food by-products into BSF protein meal and oil. BSF oil, due to its rich nutrient profile (particularly fatty acids), can support fish health and performance.

Using life cycle assessment (LCA) methodology, this study assesses and compares, from a cradle-to-gate perspective, the environmental performance of a conventional aquafeed and an innovative one that partially

replaces FO, both used for seabass production. The functional unit is 1 tonne of aquafeed. Primary data was collected from a representative Portuguese aquafeed producer, and the impact assessment was conducted using the Product Environmental Footprint.

Preliminary results reveal that aquafeed containing BSF oil performed worse in climate change (CC) and freshwater eutrophication (FE) but delivered improvements in marine eutrophication (ME) due to reduced sunflower meal impacts, with minor gains observed for acidification (AC) and fossil resource use (FRU). The farming and diet of BSF larvae influenced CC and FE outcomes, highlighting the need for production optimisation. Feed ingredient production was the hotspot, accounting for over 90% of CC, FRU, and FE impacts in innovative aquafeed, compared to 84% of CC and 96% of ME in conventional aquafeed. Cereals and by-products were the main contributors, with wheat, maize, and pea production driving AC and EU. In contrast, energy use and fuel (mainly steam from natural gas and diesel for agricultural machinery) dominated CC and FRU impacts. Transportation of feed materials also contributed substantially, higher than 10% to the impact for CC, AC, and FRU.

Overall, partially replacing FO with BSF oil does not appear to yield significant improvements in aquafeed sustainability, underscoring the importance of locally sourced feed ingredients. Further research, by expanding system boundaries to include farm-gate performance and economic and social dimensions, will support a more holistic sustainability assessment and evidence-based decision-making for sustainable aquaculture.

5.10.P-Mo372 An updated characterization model for freshwater consumption impacts on riverine fish species in LCA

Slim Mtibaa¹, Kamrul Islam¹, Eleonore Pierrat², Stephan Pfister³, Francesca Veronesi⁴ and Masaharu Motoshita¹, (1)National Institute of Advanced Industrial Science and Technology, Japan, (2)No Affiliation, Denmark, (3)ETH Zurich, Switzerland, (4)Norwegian University of Science & Technology, Norway

Consuming freshwater beyond the regional carrying capacity—the maximum volume of water that can be sustainably used by human activities—poses a critical threat to aquatic biodiversity and ecosystem integrity. Therefore, quantifying the potential impacts of such overconsumption is essential for guiding responsible and sustainable water use and for assessing the environmental impacts of global value chains. In Life Cycle Assessment (LCA), these impacts have typically been assessed through Life Cycle Impact Assessment (LCIA) frameworks, which develop spatially explicit characterization factors to quantify the potential damage to freshwater ecosystems caused by human water use. However, existing approaches generally treat water use as an undifferentiated pressure, without distinguishing between sustainable consumption and overconsumption beyond regional carrying capacity. In this study, we quantified the regional carrying capacity of freshwater consumption as the difference between available freshwater resources and the environmental water requirements needed to sustain aquatic ecosystems across approximately 11,000 watersheds worldwide, based on WaterGAP model. We then identified freshwater overconsumption by human activities and applied a global model relating freshwater fish species richness to river discharge and other covariates (elevation, basin area, and climate zone) to derive two species–discharge relationships (SDRs), distinguishing watersheds experiencing overconsumption from others. These SDRs were subsequently used to develop characterization factors measuring the effects of human freshwater consumption on freshwater fish biodiversity. Our analysis revealed higher characterization factors in watersheds where human water consumption exceeded regional carrying capacity, indicating stronger biodiversity impacts under overconsumption conditions. These findings highlight the importance of explicitly accounting for overconsumption in LCIA water-impact assessment models. Incorporating this distinction can improve the accuracy of global characterization factors and support more responsible and targeted freshwater management strategies aligned with biodiversity conservation goals. The model integrates LCIA consensus methods from the UNEP Life Cycle Initiative to enhance the assessment and make the biodiversity impacts more consistent with the midpoint impact assessment method “AWARE”.

5.10.P-Mo373 Do antibiotics have a major impact on aquatic wildlife? A freshwater ecotoxicity impact assessment of antibiotic mixtures including binary interactions

Jordy Motte¹, Jo Dewulf¹, Lieselot Boone¹, Qiyun Zhang, Ph.D. candidate¹, Ad M. J. Ragas² and Karel De Schamphelaere³, (1)Ghent University, Belgium, (2)Environmental Science, Radboud University, Netherlands, (3)Society for Environmental Toxicology and Chemistry (SETAC), Belgium

Every year, significant amounts of antibiotics enter the environment through human consumption in households and hospitals or use in the veterinary sector. These substances cannot be fully removed via wastewater treatment. Consequently, antibiotics end up in surface waters where they can affect freshwater ecosystems. The European Commission recently launched a revised version of the Urban Wastewater Treatment Directive to reduce environmental damage from pharmaceutical emissions. A good understanding of the freshwater

ecotoxicity impact caused by these chemical mixtures is needed to encourage the protection of aquatic wildlife.

Life cycle assessment (LCA) places ecotoxicity in a broader perspective by looking at the environmental impact over the entire life cycle. Traditionally, the USEtox model is utilized within LCA to calculate the ecotoxicity impact of chemical substances. To quantify the impact of a chemical mixture, the impact of all individual substances is simply summed up. However, interactions between substances in the mixture are not taken into account. In the TransPharm project, a novel methodology was developed to determine the ecotoxicity impact of chemical mixtures on freshwater ecosystems.

In the new methodology, concentration addition was applied at species level to create a model that is consistent with the original concentration addition concept derived from environmental risk assessment. Next, binary interactions are taken into account using the cumulative risk assessment framework from the Environmental Protection Agency in the United States. This new method was demonstrated based on a Swiss hospital that discharges antibiotics.

The results from this assessment show that the new model mostly leads to a lower freshwater ecotoxicity impact of an antibiotic mixture compared to the traditional model. For example, the ecotoxicity impact of a norfloxacin-erythromycin mixture is overestimated by 23% when using the traditional model. By including binary interactions, the ecotoxicity impact slightly increases (4% for norfloxacin-erythromycin mixture) or decreases (4% for norfloxacin-ciprofloxacin mixture) depending on the considered mixture. A sensitivity analysis illustrates that the impact on freshwater ecosystems is highly dependent on the included interaction parameters. This impact can vary by up to 400%. Nevertheless, this work concludes that including interactions may unnecessarily increase the complexity of these calculations.

5.10.P-Mo374 New and robust freshwater ecotoxicity characterization factors for pharmaceuticals toward a more complete end-of-life evaluation

Tolga Ayeril¹, Rosalie van Zelm² and Ad M. J. Ragas³, (1)Radboud University Nijmegen, Nijmegen, Netherlands, (2)Radboud University, Netherlands, (3)Environmental Science, Radboud University, Netherlands

Pharmaceuticals are biologically active and diverse compounds that are not fully removed in wastewater treatment and can reach surface waters. Their specific mode of action may affect non-target species, yet assessing their environmental relevance remains challenging due to limited ecotoxicity data.

Life cycle assessment (LCA) quantifies the environmental impacts of products and services. In the Life Cycle Impact Assessment (LCIA), the magnitude of the potential environmental impacts of a product system are quantified. For this, characterization Factors (CFs) are used to transform emissions and resource extractions into environmental impact scores on impact categories. The USEtox model, the consensus LCIA model, contains 3104 substances, but only 67 are pharmaceuticals. Thus, many pharmaceuticals are treated as having no ecotoxicity impact in LCIA calculations, leading to underestimation in LCIA results. This study aimed to increase the number of pharmaceuticals included in ecotoxicity assessment by deriving CFs for freshwater ecotoxicity. We derived CFs for 292 pharmaceuticals, 21 of which were compared with the existing CFs in USEtox. For 60 pharmaceuticals, we compared EFs derived from EC10 values extrapolated from acute EC50s versus chronic NOECs. A case study was conducted to demonstrate the applicability of the new CFs in LCA. Input data for fate and exposure factors were compiled from multiple databases. Effect factors (EFs) were derived from chronic EC10s collected from different databases for at least three trophic levels using HC20 as a benchmark. The new CFs were applied in a case study quantifying freshwater ecotoxicity from pharmaceuticals discharged with treated municipal wastewater. UBA emission data were combined with both new and existing USEtox CFs to calculate impact scores.

The largest CFs were obtained for pharmaceuticals with a highly specific mode of action, such as ethinyl estradiol. For such pharmaceuticals, EFs based on chronic EC10s extrapolated from chronic NOECs can be several orders of magnitude higher than those based on chronic EC10s extrapolated from acute EC50s, showing that acute-to-chronic extrapolation factors for crustaceans and fish may underestimate chronic effects. In the case study, impact scores were about seven times higher with the new CFs than with USEtox CFs. By

substantially expanding ecotoxicity coverage, this study enables a more complete evaluation of pharmaceutical emissions in healthcare LCA studies.

5.10.P-Mo375 Integrating Ecotoxicity Testing and Life Cycle Assessment (LCA) for Holistic Evaluation of Advanced Wastewater Treatment

Rita Ewela Ojo, Isabel Lopes and Ana Cláudia Dias, University of Aveiro, Portugal

A comprehensive evaluation of wastewater treatment processes requires analytical frameworks capable of capturing both the ecotoxicological effect of treated effluent and the system-wide environmental footprint of the treatment systems. Ecotoxicological assays, with untreated and treated effluents, provide critical insights by measuring biological responses to complex mixtures, revealing additive, synergistic, and antagonistic effects. On the other hand, Life Cycle Assessment (LCA) offers a structured approach to quantify environmental impacts across all operational stages, including emissions to air, water, and soil. Integrating these tools can provide a more holistic approach to assessing the environmental impacts of advanced wastewater treatment technologies designed to remove contaminants of emerging concern, for which chemical analyses alone may be insufficient.

This review critically examines methodological pathways for combining standardized ecotoxicity testing with LCA to characterize the environmental impacts of conventional and advanced wastewater treatment processes. Case studies involving activated sludge, moving bed bioreactors (MBBRs), ozonation, and granular activated carbon treatment processes are included to illustrate how the integration of ecotoxicological assays with LCA can provide a comprehensive evaluation of the benefits of advanced wastewater treatment processes. The use of a multi-species test battery to assess toxicity and provide insights into the potential risks of transformation products formed during treatment is also explored. These practical examples also highlight persistent challenges, including variable sensitivity among test organisms, limited data for chronic and sublethal effects, and a lack of holistic evaluations across diverse micropollutants.

In conclusion, this integrated approach strengthens the scientific basis for evaluating and optimizing advanced wastewater treatment technologies and enhances the capacity to support more environmentally protective decision-making.

5.10.P-Mo376 Exploring Ecotoxicity Impacts of Plastic Additives in Fishing Gear and Implications for LCIA

Nora Løvdal Gamnes¹, Ahmed Marhoon² and Cecilia Askham³, (1)NORSUS - Norwegian Institute for Sustainability Research, Norway, (2)Norwegian University of Science & Technology, Norway, (3)Norwegian Institute for Sustainability Research (NORSUS), Norway

Plastic waste in marine environments is a growing concern, with approximately 20% of ocean plastic pollution originating from the fishing and aquaculture sectors. This research addresses a critical gap in life cycle impact assessments (LCIA) by investigating the ecotoxicity of plastic additives found in lost fishing gear, which are often overlooked despite their potential harmful effects on marine ecosystems. The purpose of this study is to elucidate the ecological impacts of these additives and to improve existing LCIA methodologies.

To tackle this challenge, we conducted a comprehensive assessment using the Norwegian fishing sector as a case study. We adopted the ISO 14040:2006 standard and employed the USEtox method to systematically evaluate the impacts of various fishing gear types, including trawl nets, gillnets, autoline, demersal seine nets, and traps and pots. Our methodology involved calculating the emissions of plastic additives into marine environments based on their concentrations and the loss rates associated with gear components. We developed

two scenarios: a baseline scenario including only confirmed gear components, and a secondary scenario that included potential undocumented additives, leveraging Monte Carlo simulations to account for uncertainties.

Preliminary results indicate that incorporating additional components substantially increases ecotoxicity impacts across all gear types. Specifically, traps and pots exhibited the highest baseline impacts, primarily due to their low capture rates. Sensitivity analyses highlighted the critical role of additive leakage and bioavailability in determining overall environmental impacts.

Our findings underscore the urgent need for more comprehensive data on plastic additives in life cycle inventories, which currently capture less than 10% of relevant information. By advancing the understanding of the ecotoxicological effects of plastic fishing gear and enhancing LCIA methodologies, this study highlights the pressing need for better regulatory frameworks and mitigation strategies within the fishing industry, ultimately promoting sustainable practices and reducing marine pollution.

5.10.P-Mo377 Integrating The Cocktail Effect In Life Cycle Assessment

Anouar Mejait¹, Arnaud Chaumot², Olivier Geffard^{Pr2}, Eric Latrille², Dominique Patureau², Arnaud Helias² and Remi Servien², (1)No Affiliation, France, (2)National Research Institute for Agriculture, Food and Environment (INRAE), France

Life Cycle Assessment (LCA) currently evaluates toxicity impacts using characterization factors that assume additive effects between substances. This simplification overlooks potential interactions within chemical mixtures, creating uncertainty about whether impacts are under- or overestimated. Recent advances in mixture risk assessment underline the need to integrate combined effects into environmental models. In this study, we test the LCA additivity assumption and develop a proof of concept that explicitly incorporates chemical mixture (“cocktail”) effects into effect-factor calculations.

We investigated contaminants frequently detected in French urban wastewater, including pesticides, metals, pharmaceuticals, and other compounds using *Gammarus* spp. as a model organism. Each substance was tested individually across a concentration gradient reflecting environmental levels up to 50× their maximum effluent concentration. Binary and multi-substance mixtures were then assessed at different concentration combinations. Monosubstance data were used to generate Independent Action (IA) and Concentration Addition (CA) predictions for mixture toxicity.

Observed mixture effects were compared to IA expectations to determine whether responses were additive, synergistic, or antagonistic. For mixtures showing deviations, alternative modelling strategies were applied. We then fitted the mixture toxicity data using a Generalized Additive Model (GAM), incorporating nonlinear dose-response functions and an interaction term capturing the nature of mixture effects. From the GAM-derived response surfaces, we extracted mixture EC10 values of one substance at fixed proportions of the other and compared them to monosubstance EC10 values to compute an allocation factor (α). Assuming similar patterns across species, we extrapolated these results to ecosystem-level sensitivity and recalculated hazardous concentrations (HC20) for mixtures. This allowed us to define a cocktail effect factor that adjusts the LCA Effect Factor, producing more realistic thresholds that reflect exposure to multiple co-occurring contaminants. This work introduces a new modelling framework integrating mixture effects into LCA toxicity characterisation. The approach will be applied to case studies of water bodies impacted by urban and industrial effluents and may support improved prioritisation of substances for wastewater treatment based on both concentrations and mixture toxicity potential.

5.10.P-Mo378 The Updated and Consolidated ProScale-E - Ecotoxicity Potential Scoring Method for Chemical Footprint, LCA and SSbD assessment

Tomas Vilhelm Rydberg¹, Athanasios Gkrillas², Pernilla Andersson³, Maja Halling¹, Martin Klatt⁴, Therese Kärnman¹, Pearl Nemeth⁵, Peter Saling⁶, Triranta Sircar³ and Rosella Telaretti Leggieri¹, (1)Swedish Environmental Research Institute (IVL), Sweden, (2)Merck KGaA, Belgium, (3)IVL Swedish Environmental Research Institute, Sweden, (4)BASF, Germany, (5)Anthesis, United Kingdom, (6)CDS/S, BASF, Germany

This abstract presents the updated ProScale-E version (2.0). The ProScale-E method has now been revised in order to align the ProScale and ECETOC Task Force approaches. Novel results from the update are shown in this presentation. The ambition for the current ProScale-E model was to a) obtain a model aligned with REACH,

straightforward to use, easy to understand, require little to moderate substance data and still provide meaningful results for substances classified according to ecotoxicity (hazard classes in the H400 family) thereby accounting for the severity of impacts, b) accounting for potency of substances, and c) facilitating inclusion of fate and degradation of substances.

A detailed analysis was carried out of the criteria for hazard classification of ecotoxicity.

The consolidated scoring system for eco-toxicity hazards based on a grouping of hazard statements from CLP is aligned with REACH classification. Assigning significance to the M-factor is a key aspect of ProScale-E, as the M-factor is based on EC50 values, and therefore introduces the potency of a substance into the scoring.

Substances having more than one H4XX-phrase (e.g. classified as both acute and chronic) will be assigned to the highest ProScale-E hazard class among the ones relevant to the classification for that substance. ProScale-E accounts for degradation in three levels, each separated by a factor of 10: 1) readily degradable, 2) rapidly (but not readily) degradable/inherently degradable, 3) not degradable/persistent/very persistent.

Comparing ProScale-E 2.0 with its predecessor, it is evident that the update is relevant, due to the span of ratios (Table 1) for even this small sample of substances. As an example, Bisphenol-A (CAS: 1980-05-07) comes out with the same characterization factor (CF) for ProScale-E 1.0 and 2.0, whereas TDI (CAS: 584-84-9) has a factor 1000 lower CF in version 2.0 compared to version 1.0.

ProScale-E appears to be an easy-to-use approach for screening level ranking/prioritization of ecotoxicity impact potentials. Development of characterization factors and validation is in progress, as is application in actual assessments.

5.10.P-Mo379 Local-Scale Toxicity Impacts in USEtox: Assessing Variability Across Selected Emission Scenarios

Alessandro Francini¹, Paolo Neri¹, Antonella Sola¹, Roberto Rosa², Anna Maria Ferrari¹ and Peter Fantke³, (1)Department of Sciences and Methods for Engineering, University of Modena and Reggio Emilia, Italy, (2)Interdepartmental Center En&Tech, University of Modena and Reggio Emilia, Italy, (3)substitute ApS, Denmark

Life Cycle Impact Assessment (LCIA) models often rely on site-generic approaches and average assumptions when quantifying characterization factors (CFs), reflecting the holistic scope of LCA and limited availability of spatially resolved inventory data. Numerous studies have explored ways to incorporate region-specific conditions to enhance model accuracy and reduce CF uncertainty. For human toxicity and freshwater ecotoxicity, the UNEP/SETAC reference model USEtox already enables partial spatialization through sub-continental archetypes and an urban air compartment for densely populated areas. More recently, the inclusion of a nested, multi-compartment local scale in the USEtox model was proposed, quantifying the potential over- or underestimation of CFs when emissions occur locally rather than at continental scale. In our study, we apply the USEtox model with the proposed local-scale extension to investigate the variability of human toxicity and freshwater ecotoxicity CFs for a broad range of site-specific urban emission scenarios. We model emissions of multiple toxic chemicals across 10 European urbanized areas with different meteorological and exposure conditions. Temperature, wind speed, rainfall rate, and air mixing height were sourced from Copernicus ERA5 reanalysis dataset, while exposure conditions reflect partially urbanized environments including freshwater, natural soil, and agricultural soil compartments. The resulting CFs are used to (i) evaluate and discuss the modifications introduced to incorporate the local scale in LCIA toxicity and ecotoxicity characterization for conditions where local-scale emission data are available, (ii) quantify the influence of local meteorological and exposure parameters on CF variability, and (iii) compare local-scale CF variability with that derived for different sub-continental regions. For both human toxicity and freshwater ecotoxicity, CF variability for emissions to local air, freshwater, and soil remains within one order of magnitude. The largest variability occurs for emissions to natural and agricultural soils, particularly for substances such as benzene and toluene, for which the highest local CFs are associated with scenarios characterized by relatively high annual rainfall. Overall, these findings support a more accurate representation of impacts of toxic chemical emissions in sub-regional contexts, while balancing the search for spatial resolution with data availability and practical application.

5.10.P-Mo380 Early-Stage Life Cycle Assessment to Support the Ecodesign of Laboratory-Scale Poly(hydroxyalkanoate) Production Strategies

Florian Coppola¹, Riccardo Morsiani¹, Bruno Serafim², Diana Araújo², Maria A. M. Reis², Filomena Freitas², Sibu C. Padmanabhan³ and Serena Righi⁴, (1)University of Bologna, Italy, (2)NOVA University Lisbon, Portugal, (3)Trinity College Dublin, Ireland, (4)Department of Physics and Astronomy "Augusto Righi", University of Bologna, Italy

Fossil-based plastic pollution and the growing burden of food waste management highlight the need for more sustainable material systems. Among emerging solutions, bioplastics such as poly(hydroxyalkanoate) (PHA) offer potential advantages, but their environmental performance depends strongly on feedstock origin and bioprocess configurations.

The BioLaMer project, funded by the European Innovation Council, investigates a proof-of-principle fly larvae biorefinery in which black soldier fly (BSF) larvae feed on food waste, from which lipid-rich fractions are recovered and used for PHA. The challenge addressed in this study is to evaluate whether early-stage Life Cycle Assessment (LCA) can support ecodesign by distinguishing environmental trade-offs between alternative laboratory-scale strategies.

To address this question, PHAs were produced by cultivation of the bacterium *Cupriavidus necator* on BSF larvae lipid-rich fraction as the sole carbon source. A gate-to-gate LCA is being performed to compare two cultivation scenarios in 3-L bioreactors operated for 36 h or 60 h. The system included inoculum preparation, microbial growth under varying nitrogen and lipid concentrations, PHA accumulation, and finally enzymatic extraction of the biopolymer. Foreground data were obtained from laboratory experiments, while background data were sourced from Sphera and Ecoinvent databases. Environmental impacts will be assessed using the Environmental Footprint 3.1 method.

With the experimental inventory now complete, LCA modelling is underway. The assessment will therefore test how early-stage LCA can identify meaningful environmental hotspots and operational trade-offs at a stage where process modifications remain feasible and cost-effective.

The findings of this study, integrating LCA into low-TRL (Technology Readiness Level) bioprocess development, aim to inform the ecodesign of PHA production pathways within BioLaMer project and to demonstrate whether early environmental assessment can guide more sustainable decision-making before scale-up.

5.11 Modelling of Environmental Footprints of Critical And/Or Strategic Raw Materials

5.11.T-01 The Critical Raw Materials act: exploring criteria to prioritise critical and strategic raw materials

Andrea Amadei¹, Sara Venturelli², Michael John Bennett¹ and David Pennington¹, (1)European Commission, Joint Research Centre, Directorate D – Sustainable Resources, Italy, (2)European Commission, Joint Research Centre, Directorate D – Sustainable Resources / KU Leuven University, Department of Materials Engineering, Leuven, Belgium, Italy

Several industries in the European Union (EU) heavily rely on critical raw materials (CRMs), being indispensable inputs for a wide set of technologies and applications. However, the EU's demand for CRMs is mostly met by imports, exposing the EU's strategic dependencies to potential geopolitical shifts and crises. The Joint Research Centre (JRC) is supporting the implementation of Article 31 of the EU Critical Raw Materials Act (CRMA) by performing an analysis to assess the necessity and proportionality for introducing an Environmental Footprint Obligation (EFO) of CRMs. To assess which CRMs should be prioritised for EFOs, the present study focused on the analysis of the type and scale of environmental impacts of CRM consumption in the EU27 for 2022. Numerical findings associated with the life cycle environmental impacts of the CRMs (calculated for 16 impact categories of the EU Product Environmental Footprint) were combined with data on consumed masses (both domestically produced and imported) leveraging Material System Analysis studies. Stakeholders and experts were actively involved during the whole development of the project and contributed by providing key data. The results of this study underlined the key role of aluminium, copper and manganese as

dominant drivers of environmental impacts across various impact categories. Overall, aluminium occupied the first position out of the SRMs analysed in 13 scrutinised impact categories. Aluminium and copper, together with manganese, occupied the three top positions in the rankings in more than 66% of the impact categories tested. On top of the magnitude of the environmental footprints of the CRMs and SRMs, the exploration of additional criteria (such as co-product dependency, criticality and strategic relevance) showed that a holistic approach to prioritising raw materials is advisable. For instance, Platinum Group Metals (PGMs) exhibit a higher economic importance than aluminium, despite having lower total environmental impacts. Even if the analysis of the environmental footprint associated with each SRM represents an important means to assess the achievement of CRMA Article 31 objectives, the findings related to the prioritisation criteria analysis suggest that the identification of a ranking of SRMs should not only examine closely their environmental impacts, but should also include other relevant criteria that may coincide with, or differ from, the assessment of environmental sustainability impacts.

5.11.T-02 Prospective Life Cycle Assessment to Support Decarbonization of Critical Raw Material Supply Chains

Ioan-Robert Istrate¹, Vanessa Schenker², Antoine Beylot³, Jonas Klimt¹, Stephan Pfister⁴ and Bernhard Steubing¹, (1)Leiden University, Netherlands, (2)Institute of Environmental Engineering, ETH Zurich, Switzerland, (3)French Geological Survey (BRGM), France, (4)ETH Zurich, Switzerland

The mining and metals sector faces the dual challenge of scaling up production to meet growing demand while simultaneously reducing greenhouse gas (GHG) emissions and other environmental impacts. Critical raw materials (CRMs) underpinning clean energy technologies are under increasing scrutiny to avoid unintended burden shifting toward resource extraction and refining. Life cycle assessment (LCA) has been widely applied to assess CRM supply chains, yet its potential to guide decarbonization strategies remains underexplored. Prospective LCA extends the capabilities of LCA by integrating future scenarios to anticipate environmental implications of technological innovations, policy developments, and market shifts. Here, we showcase scenario analysis and prospective LCA to inform decarbonization strategies for CRM supply chains through two complementary approaches: i) evaluating the technical mitigation potential and trade-offs of decarbonization options and ii) assessing future scenarios aligned with climate policies and industry roadmaps. For the first approach, we focused on four CRMs used in lithium-ion batteries: lithium hydroxide, cobalt sulfate, nickel sulfate, and graphite. An attributional LCA identified GHG hotspots, based on which we quantified the mitigation potential of a scenario involving renewable electricity and electrified heat for on-site operations, energy efficiency, renewable electricity and electrified heat in the chemical industry, and renewable electricity elsewhere in the global economy. Combined, these options could reduce GHG intensity by 53–86%, leaving a mitigation gap of 14–47% even under such optimistic scenario. The second approach accounts for plausible future developments in technology and policy, providing a more plausible perspective on the achievable mitigation potential. Here, we focused on 24 operating and announced projects producing battery-grade lithium carbonate from brines, modelling future changes in the energy and chemical reagent sectors and technology optimization. Results reveal wide variation in mitigation potential across projects and highlight trade-offs, notably increased water scarcity impacts (up to 50%) linked to low-carbon heat adoption via heat pumps. Operationalizing scenario-based assessments is key to enabling the practical application of prospective LCA in both academia and industry and driving progress toward decarbonized supply chains.

5.11.T-03 Material Footprint Method: Beyond Bill of Material to Operationalize Criticality Assessment Methods

Mael Mouhoub¹, Titouan Greffe², Cécile Sophie Marie Bulle² and Manuele Margni¹, (1)HES-SO Valais Wallis, Switzerland, (2)University of Quebec in Montreal (UQAM), Canada

Introduction :

Assessing the criticality of mineral resources has emerged as a pivotal challenge in the European Union, driven by the increasing demand for critical raw materials (CRMs) for electrification and geopolitical uncertainty

regarding their supply. While some traditional approaches to assess how product systems are exposed to criticality focus on the bill of materials (i.e. the quantity of CRM in the final product), this simplification proves inadequate for technologies where consumables, services, or upstream losses play a significant role as they also involve the use of CRMs beyond the final product content. Although the literature identifies the characterization of intermediate flows (IFs) as a potential solution, no CRM-specific framework has yet been operationalized.

The study proposes a first step toward operationalizing a mineral resources use impact assessment method characterizing intermediate flows to assess the life cycle dependency of the product system on CRMs. This framework is illustrated through the case study of the production of 1 kg of hydrogen with an anion exchange membrane electrolyzer stack focusing on the nickel material footprint.

Methods :

1. A matrix Q^* was developed, equivalent to the characterization factor matrix, but tailored for IFs. Q^* is populated with pure CRM values based on stoichiometry and upstream supply chain of each IF characterized. For instance, Q^* (nickel, nickel class 1) contains the amount of nickel per kilogram of nickel class 1 IF.
2. The supply vector is calculated by multiplying the inverse of the technology matrix by the vector of final demand.
3. The material footprint is calculated by multiplying the new matrix Q^* by the supply vector.

Results:

Results obtained using this new framework indicate that producing 1 kg of hydrogen requires 1.62×10^{-3} kg of nickel, with approximately half of this nickel embedded in the energy inputs for electrolysis. Compared to the bill of materials approach, the novel approach yields twice the amount of nickel needed along the value chains, an additional 15% from manufacturing, and a 100% increase from the use-phase electricity.

Conclusion:

This analysis underscores the importance of adopting a life cycle perspective in evaluating the use of critical raw material in product systems. In the context of hydrogen production, the study reveals novel trade-offs between CRMs embedded in electrolyzer stacks and those associated with energy inputs.

5.11.T-04 Development of a Methodology to Include Instrumental Value Loss in Indicators for Abiotic Resources Dissipation in Life Cycle Assessment

Manon Lisiecki¹, Sébastien ARTOUS² and Jair Santillán-Saldivar³, (1)Univ. Grenoble Alpes, CEA LITEN DTNM, France, (2)Atomic Energy Commission (CEA), France, (3)Bureau of Geological and Mining Research (BRGM), France

In complement to the concept of depletion, which describes the impact of resource extraction from the biosphere, dissipation focuses on the inaccessibility to abiotic resources once they entered the technosphere. Resources are considered dissipated when they cannot be recovered. The inaccessibility of these resources can be due to economic (not worth recycling) or technological (no technology available) constraints. The risk of supply scarcity, especially for critical raw material, highlights the need to implement strategies towards a circular economy to promote resource efficiency. The economic value dissipation potential (EVDP) method, introduced by Santillán-Saldivar et al., assesses the potential economic value loss due to abiotic resources dissipation by developing a characterization factor for life cycle assessment (LCA). It considers the price and the economic importance at the EU level as a weight factor for the recoverability function specific to the compartment of dissipation. In this work, the recoverability function is modified to incorporate the role of technology maturity, thereby capturing potential recoverability based on technical constraints. Moreover, the resource should only be useful to human activity if it can fulfill certain technical characteristics. A new iteration of the method is proposed, incorporating functionality value loss by using entropy as a proxy for resource purity.

This additional parameter aims to assess the effort required to recover the resource while preserving its purity—and thus its functionality. The effort to recover the resource is calculated, compared to post-primary extraction values, and the result is integrated into the initial EVDP indicator equation. Three metals used in electrical and electronic equipment: gold, copper and germanium, were selected based on their strategic importance and the increasing demand driven by technological advancements to demonstrate the calculations. The results show that recovery efforts are driven by both economic constraints and technological maturity. For critical metals even at a low maturity, its high recovery value can incentivize the optimization of recovery processes. The presentation will explore the potential mitigation of dissipation for strategic metals in printed circuit boards within the French market, with the aim of generalizing this indicator to prospectively assess the benefits of developing new recovery technologies.

5.11.P Modelling of Environmental Footprints of Critical And/Or Strategic Raw Materials

5.11.P-Th209 Parametric life cycle assessment (LCA) models for metallurgical-grade silicon production using novel processes

David Clousier¹, Thomas Gibon¹, Peter Hinderink², Gustavo Quillo², Mari Voldsund³ and Enrico Benetto¹, (1)Luxembourg Institute of Science and Technology, Luxembourg, (2)Process Design Center, Netherlands, (3)Elkem, Norway

The EU's dependence on critical raw materials (CRMs) is rising as it accelerates the deployment of decarbonization technologies to achieve climate neutrality by 2050. However, the production of these materials often relies on carbon compounds as reductants, especially when hydrogen lacks sufficient potency.

The MECALO (MEtal CARbon LOoping) project aims to develop a groundbreaking concept for producing decarbonized silicon. This approach replaces fossil carbon inputs with carbon black produced from captured and recycled carbon off-gases which is then reused in the reduction of SiO₂. While this concept is still under development, it must be benchmarked against competing reference processes. These reference processes, including conventional processes (with and without carbon capture) and novel modified processes for metallurgical-grade silicon production, have been modelled parametrically using brightway and lca_algebraic. These flexible surrogate models capture the relationships between material and energy flows, enabling their use in the process design phase.

Operationalizing life cycle assessment (LCA) for industrial process design is essential to make sustainability assessments more relevant. By embedding quantitative environmental indicators directly into the design phase. Rather than treating them as post-hoc evaluation, we here enhance the practicality of sustainability methods. To streamline this integration, we developed code that automatically converts parameter, array, and formula dictionaries into lca_algebraic-compatible data. This simplifies the addition and transformation of life cycle inventories without requiring their complete recreation. Our results demonstrate that environmental impacts can be estimated in real time for any configuration of metallurgical-grade silicon production. Variables such as yield, carbon capture rate, carbon input sources, operational region, and reactor setup can be directly translated into a range of life cycle impact assessment outcomes.

Early analyses of carbothermic reactors reveal that the global warming potential is significantly influenced by the national electricity mix across all processes. Prospective LCA indicates that the reference configuration will fall short of the EU's emission reduction targets. In contrast, novel processes, designed for CO₂-neutral silicon production, show potential for achieving lower emissions.

Disclaimer/Disclosure:

The work has been funded through the MECALO project. This project has received funding from the European Union's Horizon Europe research and innovation programme under grant agreement n. 101177480.

5.11.P-Th210 Reducing Ecotoxic Impacts in Offshore Operations: Modeling Produced Water CRM Extraction and APG Utilization

Maksim Kurbasov and Karen Feilberg, DTU Offshore (Technical University of Denmark), Denmark

Offshore oil and gas operations in the North Sea generate substantial volumes of produced water and associated petroleum gas (APG), which are traditionally managed through direct discharge and flaring, respectively, contributing to marine pollution and greenhouse gas emissions. This study addresses the challenge of quantifying and mitigating the ecotoxicological impacts of these waste streams on marine ecosystems, including bioaccumulation of contaminants, ocean acidification, and biodiversity loss, while exploring economically viable alternatives that transform liabilities into assets.

We propose an integrated modeling framework to evaluate ecotoxicity before and after implementing two innovative technologies: chemical precipitation for critical raw material (CRM) extraction from produced water and APG redirection to cryptocurrency mining with carbon capture.

The approach couples thermodynamic simulations for optimizing CRM precipitation in high-salinity brines with environmental dispersion models for APG emissions, incorporating metrics such as predicted no-effect concentrations for key contaminants (e.g., lithium, magnesium, boron) and global warming potential equivalents, alongside assessments of pH shifts and plume dispersion under offshore conditions.

Modeling results indicate baseline practices yield high ecotoxicity risks, with produced water discharges exceeding toxicity thresholds for marine biota and APG flaring emitting approximately 4,360 tons of carbon dioxide-equivalent per site annually; post-implementation, CRM extraction reduces contaminant loads by up to 90% and APG mining cuts emissions by over 80%, generating annual revenues of 0.4-0.8 million euros per installation.

These findings demonstrate that the technologies significantly lower ecotoxic burdens without financial strain on operators, achieving net-positive socioeconomic outcomes.

This work advances integrated ecotoxicity assessment in offshore operations by linking waste utilization to sustainability goals, offering scalable applications for regulatory compliance and green energy transitions in the European Union.

5.11.P-Th211 Can mineral production be sustainable? A global ecological footprint assessment of environmental trade-offs

Kamrul Islam, Keitaro Maeno and Masaharu Motoshita, National Institute of Advanced Industrial Science and Technology, Japan

Minerals and metals are fundamental to global economic development and the transition towards low-carbon technologies. Demand for minerals continues to rise due to population growth, infrastructure expansion, and the rapid deployment of renewable energy systems, batteries, and electric vehicles. However, the environmental pressures associated with mineral production are substantial and increasingly visible. Mining contributes to land transformation, CO₂ emissions, and intensifying competition for freshwater resources—particularly in regions already facing scarcity. These impacts occur simultaneously and often interact, yet most sustainability assessments focus on a single environmental indicator, limiting the ability to understand trade-offs or unintended consequences across impact categories. A more integrated framework is needed to evaluate the environmental sustainability of mineral production holistically. The ecological footprint (EF) provides such a framework by translating diverse environmental pressures into a common unit of biologically productive land area. Although widely used in sustainability research, its application to mining remains limited, with previous studies examining only land use, carbon emissions, or water consumption in isolation. Building on recent advances in quantifying water and land constraints at global scales, this study applies an expanded EF framework that simultaneously accounts for built-up land, carbon absorption land, and water consumption. By integrating these dimensions, we provide a comprehensive global assessment of the environmental burden of mineral production and reveal inherent trade-offs that shape its sustainability.

5.11.P-Th212 Advancing green metal supply-chain decisions with Canadian site-specific LCIs

Marin Pellan¹, Anne de Bortoli¹, Cécile Sophie Marie Bulle² and Guillaume Majeau-Bettez³, (1)Polytechnique Montreal, Canada, (2)UQAM, Canada, (3)Chemical Engineering, Polytechnique Montreal, Canada

The transition toward a net-zero economy requires a rapid expansion in the production of minerals essential for low-carbon technologies. Yet the quality of existing life-cycle inventory (LCI) data remains limited by outdated, incomplete, and non-representative datasets, constraining the ability of Life Cycle Assessment (LCA) to guide sustainable metal supply-chain decisions. This work proposes a methodological framework to generate high-resolution, site-specific LCIs and national market-weighted LCIs, applied to the case of Canada.

The approach builds upon MetalliCan, an open-access, site-level database of Canadian metal production, integrating detailed information on greenhouse gases, pollutants, water use, land occupation, material use, and waste streams. These data are used to construct 50+ site-specific cradle-to-gate LCIs for gold, silver, copper, nickel, and other key metals, which are directly implemented in Brightway. A modular LCI modeling framework enables dynamic assembly of mining, beneficiation, and refining stages, while parameterizing variability in ore type, ore grade, deposit type, and mining method. Data gaps are addressed using parametric relationships and the lca-algebraic tool, enabling transparent quantification of the influence of critical parameters on environmental performance.

LCAs are performed using Impact World+ 2.1, a globally regionalized LCIA method. The resulting site-specific LCIs are aggregated into market-weighted Canadian LCIs, representing average metal consumption in Canada. In a second step, these LCIs are used to compare Canada's environmental performance against production in other world regions using literature-based inventories. Several scenarios are assessed, including: (i) mining and beneficiation in Canada with refining abroad; (ii) full Canadian supply-chain control (mining, beneficiation, and refining in Canada); and (iii) scaling impacts under existing and potential future production capacities. The framework also evaluates sustainability implications of future metal demand required to achieve carbon neutrality.

Overall, this work demonstrates the value of high-quality, site-specific and parametric LCIs for characterizing the environmental performance of metal supply chains, identifying opportunities for strategic relocalization, and informing evidence-based mineral policy in Canada.

5.11.P-Th213 Material Footprint of Japan based on the 2020 Input-Output Analysis and Development of Circularity Indicators

Naoki Ichizawa, Atsushi Fukada and Norihiro Itsubo, Waseda University, Japan

Policies promoting the circular economy have advanced rapidly worldwide. In the European Union, the proposed Circular Economy Act aims to strengthen markets for secondary raw materials and integrate circularity into industrial competitiveness and clean-technology strategies. In Japan, the Fifth Fundamental Plan for a Sound Material-Cycle Society, adopted in August 2024, positions resource circulation as a national priority with concrete directions for the next five years.

Despite this policy momentum, academic and practical discussions still lack a unified framework for assessing circularity. Major challenges include (i) substantial variation in how circularity is defined and measured across studies and (ii) insufficient alignment between proliferating indicator sets and the needs of circular business models or resource-circulation policies. Although international standardization is progressing, with ISO 59020 providing a framework for circularity assessment and clarifying principles for boundary setting and indicator selection, it remains limited to a measurement framework and does not prescribe harmonized indicators for quantifying national resource use. Consequently, complementary and empirically grounded quantitative indicators are still needed for policy evaluation.

To address this gap, this study focuses on the Material Footprint (MF) as a comprehensive indicator of national-level resource use. MF, the official SDG 12.2.1 indicator, attributes global primary material extractions to a country's domestic final demand across four resource categories—biomass, fossil fuels, metal ores, and non-metallic minerals—capturing upstream extraction embodied in trade and enabling international comparability.

We integrated the 2020 Input–Output Table with raw material equivalent (RME) coefficients to estimate the material extractions induced by Japan's domestic consumption of a wide range of products and services. This enabled quantification of upstream resource use and derivation of sector-level resource intensity indicators. We also examined the consistency between MF and key components of circularity indicators referenced in ISO 59020, evaluating MF's potential as a foundational indicator for circularity assessment.

The results provide a quantitative basis for evaluating resource use at both product and sector levels, contributing to the development of more robust indicators for advancing the circular economy.

5.11.P-Th214 Environmental Case for Formalising Artisanal Cobalt Mining in the Democratic Republic of the Congo: Life Cycle Assessment for Europe's Green Transition

Xintong Cao¹, Rosa Cuellar Franca² and Maria Sharmina¹, (1)Tyndall Centre for Climate Change Research, School of Engineering, University of Manchester, United Kingdom, (2)Department of Chemical Engineering, University of Manchester, United Kingdom

Cobalt is indispensable for the EU's green and digital transition, yet its dominant supply from the Democratic Republic of the Congo (DRC) poses severe sustainability challenges. While the social risks of artisanal and small-scale mining (ASM) (such as child labour) have spurred calls for formalisation, the environmental trade-offs between different mining methods remain poorly quantified. A critical barrier is the lack of region-specific inventory data for DRC that includes ASM, undermining robust environmental footprints and hindering evidence-based policy for securing critical raw materials.

To bridge this gap, we conducted a life cycle assessment (LCA) of three cobalt mining systems: 1) Large-scale mining (LSM), 2) LSM with integrated formal ASM, and 3) LSM with informal ASM. The LCA models were built on life cycle inventories (LCI) that accurately reflects DRC-specific conditions, including formal and informal ASM. We compared the environmental performance of these systems under a baseline and alternative scenarios, analysing variables such as tailings management, transport logistics, and the national electricity mix. Our analysis demonstrates that formalising and integrating ASM with LSM can significantly mitigate the adverse environmental impacts of informal ASM, bringing its performance close to that of regulated industrial mining. Contribution analysis identifies explosive blasting, milling machinery-driven steel depletion, mine construction, and diesel-based transport as main hotspot processes. The environmental impacts across 18 categories of ReCiPe 2016 midpoint (H) are primarily driven by energy production for material manufacturing and transport operations, as well as contaminants from operational supply chains of the hotspot processes. This study provides the first quantifiable environmental rationale that formalising ASM cobalt in the DRC not only addresses pressing social concerns but also offers environmental benefits. We advance the field by introducing a critically needed LCI dataset that includes ASM and DRC-specific parameters, directly addressing methodological gaps in critical raw materials assessments. Our transparent, scenario-based approach offers actionable insights for EU policymakers and industries, supporting the development of secure, responsible, and scientifically informed raw material strategies.

5.11.P-Th215 Methodological Barriers in Life Cycle Assessment of Advanced Materials: Insights from the MACRAMÉ Project

Blanca Suarez Merino¹, Rayen Chantal Mentler², Veronique Adam DR¹, Jorge Lago², Devendra Joshi², Matteo Vezzali³, Letizia Bocchi³, Lucie Chupin⁴, Martin Heise⁵, Nazende Günday-Türeli⁶ and Ailing Qiao⁶, (1)TEMAS Solutions, Switzerland, (2)TEMAS Solutions GmbH, Switzerland, (3)Medica SPA, Italy, (4)Carbon Waters, France, (5)Filk Freiberg Institute, Germany, (6)MyBiotech, Germany

The increasing use of advanced materials such as graphene oxide, few-layer graphene, carbon nanotubes and polymer-based nanostructures raises important questions about their environmental sustainability. Life Cycle Assessment (LCA) offers a well-established framework for evaluating impacts, yet current LCA methodologies are not fully adapted to the specific behaviours, release mechanisms and toxicity of nanomaterials.

A central challenge is the lack of nanoform-specific data, emission factors and toxicity characterisation factors in widely used databases and Life Cycle Impact Assessment Analysis (LCIA) methods. This hinders robust impact quantification and limits the implementation of Safe and Sustainable by Design (SSbD) for emerging materials.

To address these limitations, the MACRAMÉ project has developed detailed Life Cycle Inventory datasets for four representative nanomaterials across varying Technology Readiness Levels. Missing datasets in ecoinvent v3.11 were reconstructed using literature and patent-based synthesis routes, proxy substances adjusted for molecular weight, and expert-derived assumptions. Material Flow Analysis data were integrated to approximate releases in the absence of empirical nanoform measurements.

The results highlight persistent methodological barriers: dependence on proxies, insufficient release quantification, and the lack of characterisation factors for human toxicity and ecotoxicity. These limitations lead to considerable uncertainties in impact assessment.

The MACRAMÉ approach provides a structured pathway towards improving LCA methodologies for nanomaterials and contributes essential foundations for future SSbD-oriented evaluation frameworks.

5.11.P-Th216 Modelling Environmental Footprint of Neodymium and Dysprosium in Nd-Fe-B Magnets and Benefits of Reducing Dy Content

Stellina Samuel, Ioan-Robert Istrate and René Kleijn, Leiden University, Netherlands

Neodymium (Nd) and Dysprosium (Dy) are critical raw materials essential for the production of high-performance Nd-Fe-B (Neodymium-Iron-Boron) permanent magnets used in green technologies, such as electric vehicles and wind turbines. However, they are associated with geopolitical supply risks due to their concentrated production in China; their extraction also causes considerable environmental damage and social risks, particularly in the unregulated mining regions of Myanmar. As the global demand for these magnets increases, several studies have examined the technical feasibility of reducing their Dy content, while maintaining magnet performance, through material-efficiency techniques, but none have specifically assessed the environmental implications of such a reduction.

This study evaluates the environmental impacts of varying Dy content (1 to 8 wt.% Dy) in sintered Nd-Fe-B magnets using life cycle assessment. We modelled all processes, from raw material extraction – including Nd from the Bayan Obo mine in China and Dy from ion adsorption clay deposits in Myanmar – to the production of a shaped magnet. Six magnet compositions were assessed using the 16 impact categories of the Environmental Footprint method. Contribution analyses were performed to quantify the relative role of Nd and Dy in the overall magnet impacts and to identify hotspot processes.

Results show that, despite representing only a small fraction of the magnet composition, Dy has a disproportionate contribution to environmental impacts, particularly freshwater ecotoxicity, terrestrial and marine eutrophication and land use. Reducing its content, systematically reduces impacts in all categories, even despite increased Nd content. Each 1 wt.% reduction in Dy content prevents the leaching of 220 kg of ore and avoids 4.7 kg of CO₂-eq emissions per kilogram of Nd-Fe-B magnet. For low-Dy content magnets (1 wt.%), Nd oxide production is the most significant contributor to all impact categories, including over 80% of ozone depletion and human carcinogenic toxicity.

By modelling the entire supply chain, the results demonstrate that reducing Dy content through material efficiency is an effective strategy that limits depletion of critical raw materials and significantly reduces environmental footprint of Nd-Fe-B magnets.

5.11.P-Th217 How Data and Modeling Choices in Critical Raw Material Supply Chains Shape the Environmental Footprint of Electric Vehicles

Brenda Miranda Xicotencatl¹, Ioan-Robert Istrate¹, Aina Mas Fons², Sónia Martins da Cunha¹, René Kleijn¹ and Arnold Tukker¹, (1)Leiden University, Netherlands, (2)Bureau of Geological and Mining Research (BRGM), France

The transition to global net-zero greenhouse gas emissions relies on electric vehicles (EVs), whose environmental performance is strongly influenced by the supply chain of critical raw materials such as lithium, cobalt, graphite, and neodymium. Lithium-ion batteries and Nd-Fe-B permanent magnets rely on these critical raw materials. Life Cycle Assessment (LCA) is central to evaluating the potential environmental impacts of these components; however, further methodological harmonisation is required to achieve comparability and compliance with emerging European regulations (e.g., the Battery Regulation, the Critical Raw Materials Act, and the Corporate Sustainability Reporting Directive). This study applies regulation-aware LCA guidelines developed within the MaDiTraCe project to assess a product system comprising an NMC811 battery pack and Nd-Fe-B magnets.

The analysis adopts a cradle-to-gate-plus-grave perspective, with a basket functional unit, encompassing the functions provided by the battery and rotor magnets. Datasets for Li, Co, Nd, graphite, magnets and battery were sourced from peer-reviewed literature and adapted for guideline compliance, compatibility with ecoinvent v3.10.1 and reproducibility in open-source software. The impact assessment followed the Environmental Footprint LCIA method v3.1. We explored alternative modelling decisions, including recycling allocation and sourcing scenarios, and their effects on the environmental profile of the EV components.

The battery supply chain accounts for most of the environmental burden of the product system, while the magnets contribute less than 7% in every impact category. Anode and cathode manufacture and cell assembly dominate impacts in 13 of 16 categories (28%-87%), while cathode raw material acquisition drives Ionising

radiation (56%), Particulate matter (34%) and Water use (68%). Modelling decisions significantly affect results. Allocation by substitution in recycling scenarios offsets burdens, leading to apparent benefits in acidification. Commodity sourcing (e.g., Li from brine vs. spodumene) alters climate change impacts by up to 20%. Harmonised LCA practices improve comparability and transparency in assessing EV components, supporting compliance with EU regulations and informed decision-making. Results inform hotspot-based data collection efforts and demonstrate the influence of modelling choices on outcomes.

5.11.P-Th218 New Life Cycle Inventories of Rare Earth production from Brazilian ion-adsorption clays and Australian heavy mineral sands based on mining project Feasibility Studies

Olivier Karl Anton Heldwein¹, Johann Fellner² and Fridolin Krausmann³, (1)BOKU University, VIRWa GmbH, Austria, (2)VIRWa GmbH, Austria, (3)BOKU University, Austria

Rare earth (RE) elements are considered critical raw materials and their demand is projected to increase significantly over the next decades, especially in the applications for the energy transition, digitization and defence. In response to the increased global demand and the high reliance on China in RE mining and refining, many new mining projects are pursued outside China. Two types of deposits are gaining importance for their ease of mining and reduced complexity compared to hard-rock carbonatite mining; ion-adsorption clay (IAC) and heavy mineral sand deposits. However, there are no LCA studies for the production of RE from heavy mineral sands, while for IACs life cycle inventories (LCIs) are only available for the in-situ leaching method, but not for open pit mining with a central leaching plant like proposed for 2 largescale projects in Brazil. To close this gap, 2 new LCIs for RE production from IACs via open pit mining and leaching at a central processing facility, and from heavy mineral sand deposits are developed. These LCIs will be based on a review of existing LCIs for RE production as well as publicly available data from feasibility studies. For the IACs feasibility studies of the Colossus and Caldeira project in Brazil will be used, and for the heavy mineral sands studies of the Donald, Wimmera, and Goschen projects in Victoria, Australia. To also make the LCI results applicable to similar mining projects, a special emphasis will be placed on the relationship between ore characteristics and the magnitude of flows. This will help to better understand the environmental impacts of the global RE industry in the future and identify advantages and drawbacks of different RE production routes.

5.11.P-Th219 Evaluating End-of-Life Recycling Pathways of Battery Electric Vehicles: A Life Cycle Assessment Approach

Davis Jose¹ and Marzia Traverso², (1)Institute of Sustainability in Civil Engineering, RWTH Aachen University, Germany, (2)RWTH Aachen University, Germany

The rapid rise of battery electric vehicles (BEVs) has introduced new environmental and resource-related challenges, particularly as these vehicles approach end-of-life (EoL). Unlike conventional internal combustion engine vehicles, BEVs contain complex components enriched with critical raw materials, making their end-of-life treatment both an opportunity and a challenge for recycling systems. As Europe accelerates its transition toward electrified mobility and also on the release of the European directive for End of life of vehicles, understanding how current recycling processes perform becomes increasingly important for ensuring material circularity and minimizing environmental impacts. This study addresses the central question of whether existing EoL recycling strategies for key BEV components are environmentally efficient and capable of supporting future circular economy goals. To investigate this, the research focuses on four major subsystems traction batteries, electric motors, copper wiring harnesses, and automotive shredder residue (ASR) chosen for their high concentrations of valuable and critical materials. The challenge is approached through a Life Cycle Assessment (LCA) framework, which evaluates the environmental burdens associated with current recycling processes. Using established LCA methodology, the study aims to identify hotspots within recycling chains, and compares the relative impacts of the selected components.

The results show that EoL of traction batteries exhibit the highest GWP, driven by energy-intensive processing steps and the presence of lithium, cobalt, nickel, and other critical materials. The remaining components demonstrate lower GWP values; however, the remaining components presents significant uncertainty due to its heterogeneous composition and inconsistent recovery routes, despite its comparatively low modeled GWP in SimaPro.

The study concludes that improvements in material separation, targeted recycling technologies, and more comprehensive datasets are essential to enhance the environmental performance of BEV recycling. These insights are highly relevant for policymakers, industry stakeholders, and researchers, as they support the development of more efficient EoL systems and contribute to advancing circularity and sustainability within the rapidly evolving automotive sector.

5.11.P-Th220 LCA Analysis of Forged Steel Production: Product Assessment and Optimization Strategies for Improved Environmental Performance

Martino Oliboni¹, Pere Barriobero Vila², Ester Basagaña³, Jose Maria Cabrera², Irene Calliari¹, Juan Emilio Rey Castañeda², Roberto Elvira⁴, Towhid Faraji⁵, Mirko Pigato⁶, Ulrich Prahl⁷, Mathias Zapf⁷, Anna Vilalta³ and Anna Mazzi¹, (1)University of Padova, Department of Industrial Engineering, Via Marzolo, 9, 35131 Padova, Italy, Italy, (2)Technical University of Catalonia (UPC), Spain, (3)COMFORSA, Camí de la Creu, Spain, (4)SIDENOR I+D, S.A., Spain, (5)Institute of Metal Forming, TU Bergakademie Freiberg, Germany, (6)University of Padova, Department of Industrial Engineering, Italy, (7)Institute of Metal Forming, TU Bergakademie Freiberg, Bernhard-von-Cotta Straße 4, 09599 Freiberg, Germany, Germany

The European Green Deal and the Fit for 55 legislative package aim to reduce greenhouse gas emissions across the European Union and achieve climate neutrality by 2050. In this context, the LIGHTFORGE project aims to develop low-density Fe-Mn-Al-C steels suitable for industrial forging to reduce the weight of vehicles. This study assesses the environmental impacts associated with the production of a forged component (drop arm) manufactured from conventional 42CrMo4 steel, using the life cycle assessment methodology. A cradle-to-gate system boundary was used, with a functional unit of 1 ton of finished product. The data used in the study includes primary information provided by the companies involved in the project and secondary data sets from database such as Ecoinvent. The assessment was carried out using SimaPro software and the ReCiPe impact assessment method.

The results show that over 60% of the impacts in the categories analyzed come from billet production processes. For this first part of the process, the steelmaking phase is the most critical due to the use of raw materials such as ferromanganese, ferromolybdenum, ferrochromium, and silicon. Hot rolling has been identified as the main critical phase for the categories of water consumption, fossil resource scarcity, and ionizing radiation. The environmental impacts associated with forging the drop arm are principally caused by the consumption of electricity.

A sensitivity analysis examined two scenarios: replacement of the Spanish electricity mix with photovoltaic energy and changing from road to rail transport for billets. Increasing the share of renewable electricity leads to significant reductions in several impact categories, while shifting transport modes produces relatively minor benefits.

The study identifies billet production, particularly the steelmaking phase, as the main critical point and suggests optimizing the use and sourcing of materials and the use of renewable electricity to reduce environmental impact. Future work will compare these results with drop arm manufactured from low-density Fe-Mn-Al-C steels and extend the assessment to include the use and end of life phases.

5.11.P-Th221 Can we Save Materials by Adding Materials? Exploring the Advanced BMS Paradox

Anne van den Oever, Maeva Lavigne Philippot and MAARTEN MESSAGIE, Free University Brussels (VUB), Belgium

Batteries are a cornerstone technology for the energy transition, and substantial resources are being mobilized to rapidly expand the battery production capacity in Europe. However, this expected growth is linked to a critical challenge. Batteries depend on several critical raw materials, including natural graphite, cobalt, silicon metal, lithium and manganese, and the availability of these materials is limited. A key question for the coming years is how Europe can expand battery capacity while remaining within material supply boundaries. Extending battery lifetime offers one promising pathway to limit the raw-material demand associated with increased battery capacity. However, this introduces a fundamental tension, because lifetime extension typically relies on additional sensors, electronic components and energy use, all of which also require critical raw materials. This work evaluates this trade-off by assessing the environmental impacts of an advanced battery management system (BMS) developed in the NEMO project. Through improved temperature, voltage, current and cell-

impedance sensing, as well as advanced modelling, machine learning and cloud-based data analysis, the project aims to extend battery lifetime and increase safety. By performing a comparative life cycle assessment and life cycle costing of an NMC523 battery with a benchmark BMS and two advanced BMS concepts, this study examines whether the combined benefits of added lifetime and safety outweigh the environmental burdens related to the additional hardware. A central methodological challenge that will be explored is how to explicitly include the added function of increased safety relative to a benchmark BMS in the functional unit, for example by estimating changes in failure probabilities and ageing. Additionally, detailed life cycle inventories (LCIs) are created for a benchmark system based on the open source foxBMS 2 platform and for two advanced systems that incorporate data from the NEMO project. These inventories represent a significant improvement in the quality of available BMS data compared with the LCIs currently provided in ecoinvent. The work also develops two prospective scenarios to explore how different future conditions related to raw material availability may influence the comparative results. At the conference, an overview of the methodological approach and the main challenges encountered will be presented, together with preliminary results if they are available.

5.11.P-Th222 Operationalizing the Characterization of Potential Impacts of Dissipation: an Exploration through the Ecoinvent Database

Titouan Greffe¹, Mael Mouhoub², Maxime Agez³, Manuele Margni² and Cécile Sophie Marie Bulle⁴, (1)University of Quebec in Montreal (UQAM), Canada, (2)CIRAIG, University of Applied Sciences (HES-SO), Switzerland, (3)CIRAIG, Department of Chemical Engineering, Polytechnique of Montreal, Canada, (4)CIRAIG, University of Quebec in Montreal (UQAM), Canada

International recommendations from UNEP-SETAC Life Cycle Initiative points towards the characterization of mineral and fossil resource loss, the so-called dissipative flows. However, life cycle inventory (LCI) databases do not include resource dissipative flows but only extraction flows. Many life cycle impact assessment (LCIA) methods characterizing dissipation have been proposed but are still not operationalized due to missing dissipative flows in LCI databases. The objective is to propose a series of proxy allowing to operationalize those LCIA methods despite the discrepancy between inventory flows and characterized flows. This operationalization is illustrated with the ACP and RESEDA methods. To reach that general objective, three subobjectives are defined: develop an operational proxy classification method, apply it to characterize the entire ecoinvent database with ACP and RESEDA methods and explore the contribution of the foreground and background of processes to the resources services loss and discuss the limits of the proxy classification proposed. To address the first subobjective, we classify emissions of metals to the environment as dissipative flows, either as pure element or embedded in chemicals (aluminum in Aluminium hydroxide). Metal flows inputs to tailings and landfills are dissipative, however are intermediate flows in LCI databases. The proxy chosen for those intermediate flows is the output long-term emission to the environment. Regarding fossil resources, we identify two dissipation pathways: combustion and emissions of embedded fossil carbon in chemicals and plastics to the environment. To address the second subobjective, we implemented the newly developed characterization model into brightway2 with ecoinvent 3.11 cutoff version. The potential ACP impact score is mostly coming from background processes, revealing the importance of operationalization at the LCI database level. We address the third subobjective by adding missing dissipative flows to some ecoinvent processes, identified through study of mass imbalance between inputs and outputs and experts' knowledge, to then study ecoinvent processes potential impact change relatively to the original ecoinvent database, using the ACP indicator. The limits of proposed proxies are explored in depth to provide a full picture of impact results uncertainties. We demonstrate the operationalization of both ACP and RESEDA methods of metallic and fossil resources dissipative flows.

5.11.P-Th223 Future Welfare Loss Method

Bernard De Caemel¹, Tom Huppertz¹, Simon Standaert¹, Elisabeth van Overbeke¹ and Bo Weidema², (1)RDC Environment, Belgium, (2)Danish Centre for Environmental Assessment, Aalborg University, Denmark

Sub-soil resources such as minerals and fossil fuels are exhaustible, and their accelerated use raises concerns about the burden imposed on future generations. Existing approaches either assume that market prices already internalise all social costs, as is common in Cost–Benefit Analysis (CBA) or rely on long-term and highly uncertain physical forecasts of ore grades, technologies and extraction costs, as in Life Cycle Assessment (LCA).

We performed a study which addresses the challenge of valuing the social cost of depleting sub-soil resources in a way that is theoretically sound, empirically feasible and directly usable in CBA and LCA. We propose a market-price-based valuation method that exploits the information embedded in current resource prices while correcting for the divergence between private and social discount rates. Using Hotelling's rule, we model the time path of the net resource price (market price - extraction cost) and show how a higher market discount rate, compared to a lower social discount rate, leads to underpricing of resource depletion.

Empirically, we use five-year trend prices for a wide range of mineral and fossil resources, extraction costs (mainly from Eurostat data), and assumptions on market and social discount rates, with alternative scenarios for time to depletion and declining rates. For each resource, we compute a price correction factor from the ratio of integrals of market and social discount factors, which, multiplied by the scarcity rent, yields the externality cost of depletion. Results indicate substantial positive social costs, often amounting to several tenths of the current price and reaching or exceeding the market price for high-rent, relatively scarce resources such as crude petroleum and copper.

The proposed factors provide a practical set of social cost values for sub-soil resources that are consistent with economic theory yet avoid speculative long-term scenario modelling. These factors can serve as monetary characterisation factors for abiotic resource depletion in LCA and as correction terms in CBA, thereby improving the treatment of resource use in environmental decision-making, supporting more sustainable choices on extraction, recycling and technology development.

We are proud to add that our method is being recommended by GLAM (United Nations Environmental program).

An Early Warning System (EWS) for chemicals is being developed within the Horizon Europe Partnership for the Assessment of Risks from Chemicals (PARC) to address the growing number of substances and their potential risks. As previous consultations with stakeholders on EWS in general have been limited, this study focused on investigating expectations and familiarity of European stakeholders, as a basis to improve the PARC EWS. A stakeholder survey was developed, validated and disseminated across European and national organisations. The categorical answers were evaluated using Fisher's exact test to examine potential differences among types of organisation (e.g. governmental agencies and academia). In addition, a Stakeholder Interaction Forum (SIF) was organised to discuss survey results, stakeholder expectations, as well as EWS communication strategies and data needs.

In total, 61 individuals responded to the survey, mainly from government agencies (n=25), research institutes (n=16) and academia (n=11). Most participants considered an EWS "very" or "somehow" important, with significant variation among organisation types ($p < 0.05$). Awareness and understanding of existing EWS differed widely, indicating a need for clear terminology. 41 % reported having previously considered outputs from EWS or similar systems. The number of respondents choosing "conducting further research" as one of the reactions to an early warning signal varied significantly among the organisation types. Answers also varied regarding preferences for EWS communication channels and the EWS inputs that were considered valuable for signal evaluation. Most respondents (79 %) reported a willingness to receive potentially uncertain alerts. The desired EWS update frequency was scattered in the survey, while yearly updates with the option for rapid alerts in urgent cases was judged most feasible during the SIF.

The combined survey and SIF outcomes provide direct guidance for further development of the EWS. The investigation indicates that an EWS architecture shall become flexible to accommodate differing needs, that moderate uncertainty in signals is deemed acceptable, and that annual EWS updates, as well as an event-driven fast-track option, are desired. We anticipate a continuously strong stakeholder engagement in future planned activities, which will further inform the development of EWS on EU and European national level.

The authors thank the participants of the survey and the Stakeholder Interaction Forum. This work was funded by the European Union's Horizon Europe research and innovation programme under Grant Agreement No 101057014 and was partly co-funded by the authors' organizations and national authorities.

6.01.P-Th225 Archived Suspended Particulate Matter as an Early-Warning Tool: 18-Year of Non-Target Screening Identifies Emerging Contaminants and Regulatory Success

Javad Mottaghishah¹, Erica Selin², Anna Kärrman³, Maria Larsson⁴, Fredric Södergren Seilitz³, Jan Koschorreck⁵, Bernd Göckener⁶ and Lutz Ahrens¹, (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Orebro University, Sweden, (3)Man-Technology-Environment Research Center, Sweden, (4)MTM Research Centre, Orebro University, Sweden, (5)German Environment Agency (UBA), Sweden, (6)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Sweden

Early detection of chemical trends is critical for proactive environmental protection. This study demonstrates the potential of archived suspended particulate matter (SPM) as an early-warning tool for contaminants of emerging concern (CECs). SPM collected between 2005 and 2022 from two Rhine River sites (Weil am Rhein and Koblenz) within the German Environmental Specimen Bank was analysed using liquid chromatography–high-resolution mass spectrometry (LC-HRMS) with suspect and non-target screening. Structural annotation, supported by retention-time indices and multiple MS/MS evidence sources (mzCloud, FISh, CFM-ID), yielded 332 compounds across confidence levels (Level 2.1: 3%, 2.2: 6%, 3.1: 53%, 3.2: 38%). Trend analysis showed that 25% of detected chemicals increased significantly over time, with stronger increases at Koblenz (29%) than at Weil (18%). Increasing compounds included pharmaceuticals, industrial chemicals, surfactants and biocides, whereas 13–14% of features declined, reflecting regulatory measures and improved wastewater treatment.

Notable decreases included PFOS, diazinon, carbamazepine and climbazole. ECOSAR-based hazard prediction indicated that nearly half of annotated structures (47%) pose high acute toxicity ($LC_{50}/EC_{50} > 1 \text{ mg/L}$) to aquatic organisms. By exploiting archived SPM for retrospective and trend-based analysis, this approach enables early identification of emerging contamination, supports evaluation of regulatory success and provides actionable watch lists for targeted monitoring and risk management. Complementary effect-based analysis (EBA) and GC-HRMS investigations were conducted separately to further broaden the chemical and toxicological scope of this early-warning framework.

6.01.P-Th226 Early detection of potential human and ecological risks of Critical or Strategic Raw Materials in water

*Elvio D Amato¹, Sanah Majid², Thomas L. ter Laak¹, Anne Jans³ and **Stefan Kools¹**, (1)KWR Water Research Institute, Netherlands, (2)KWR Water Research Institute, Belgium, (3)Ministry of Infrastructure and Water Management (RWS), Netherlands*

This presentation will show work that started as a the outcome of a national early warning approach for chemicals that potentially pose risks in waters in the near future. Here, we assessed Critical or Strategic Raw Materials (CRM, SRM) as a sharp increase is expected in the use of these compounds in the next 20 years, which could ultimately lead to increased concentrations in surface water and drinking water. As a start, we identified that seven critical materials that warrant extra attention due to their environmental hazards and limited policy focus: cerium, dysprosium, gadolinium, germanium, neodymium, palladium and platinum. Monitoring of these substances is still limited, making it difficult to determine their origin and trends. In this study, we compiled available monitoring and (eco)toxicological data to conduct a preliminary assessment of the occurrence of these metals in Dutch surface waters and their associated risks. Monitoring data for surface water, wastewater and drinking water were retrieved from national databases, and the collected (eco)toxicological data include data relevant to organisms in surface water and to human exposure via drinking water. Surface water monitoring databases contained data for a subset of these five of seven metals (cerium, dysprosium, gadolinium, neodymium and platinum). All seven metals were all investigated in wastewater, but the concentrations were often below the detection limits exceeding than those used for surface water. Overall, concentrations in wastewater and surface water were generally comparable. Ecotoxicological data for freshwater organisms are available for all seven metals. We compared the average concentrations in surface water and wastewater to the available ecotoxicological standards to assess whether exceedances occur. Some of the compounds, including cerium, gadolinium and neodymium, have been measured in drinking water sources (before treatment), yet human toxicological data were only available for cerium and gadolinium. These findings show important gaps in both monitoring and toxicity data. Our assessment provides water authorities and utilities with early insight into emerging CRM/SRM pressures and supports future environmental and human health risk evaluations.

This work was funded by Rijkswaterstaat in context of the National "Approach to Emerging Substances", initiated by the Ministry of Infrastructure and Water Management.

6.01.P-Th227 Chemicals In Energy-Transition Technologies: Cross-Sector Inventory And Development Of A New Risk Indicator

Soumaya NOUIGUES¹, Adèle BRESSY¹, Jean-marc BRIGNON², Cécile DUMAS³ and Johnny GASPERI⁴, (1)Leesu (ENPC), France, (2)INERIS, France, (3)IFPEN, France, (4)LEE (Université Gustave Eiffel), France

The rapid deployment of low-carbon technologies is increasing the variety of chemicals used in energy systems. However, many of these substances have not yet been adequately characterised in terms of their environmental behaviour and hazards. Anticipating these risks is essential to support strategic decisions in energy decarbonisation pathways.

This work aims to develop a harmonised, cross-technology inventory covering batteries, hydrogen systems, photovoltaics, nuclear applications, wind power and CO₂ capture processes. The chemicals and materials were identified through expert workshops, technical documentation, safety data sheets and scientific literature. A multi-source approach combining industrial reports, quantitative calculations and expert judgement was applied to estimate quantities used. The substances were classified into key hazard groups, including carcinogenic, mutagenic and reprotoxic compounds; heavy metals; persistent and mobile chemicals; fluorinated polymers; solvents; and engineered nanomaterials.

More than 430 chemicals were identified across the studied technologies. The highest prevalence of priority substances was found in batteries, hydrogen systems and photovoltaic technologies, including persistent

fluorinated salts and polymers, toxic metals and nanomaterials.

A set of qualitative and quantitative risk indicators was developed to conduct cross-sector and cross-technology risk comparisons, combining hazard information with exposure parameters. This approach ensures the integration of both well-characterised substances and those for which data are limited.

Overall, this study is one of the first to provide an integrated assessment of chemical use across energy-transition systems. It offers a scalable tool for identifying priority substances to support future environmental policy and risk-management decisions.

6.01.P-Th228 A Network and Cheminformatics Approach to Reveal Human Protein Targets of Endocrine-Disrupting Chemicals

Mélanie Gou, Florence Jornod, Théo Jamay and Karine Audouze, Université Paris Cité, Inserm UMR S-1124, HealthFex, SysTox team, 75006 Paris, France, France

Endocrine-disrupting chemicals pose a persistent challenge for chemical risk assessment, as their effects often emerge from diverse and sometimes unexpected interactions with human biological systems. Anticipating such risks requires tools capable of detecting early signals before adverse effects become evident. To contribute to this need, we developed ED-Net, a network-based framework designed to identify potential human molecular targets relevant to endocrine disruption.

To develop ED-Net, we adapted an established approach that builds networks of proteins responding to similar chemical influences. In simple terms, when several endocrine disruptors affect the same proteins, these proteins are grouped together because they likely share related biological roles. Each affected protein becomes a node in the network, and we connect two proteins only when several endocrine disruptors act on both of them, indicating a meaningful shared response. This produces a clear and reliable map of protein relationships in the context of endocrine disruption.

Complementing these associations, ED-Net integrates structural fingerprint analysis to reveal molecular similarities between chemicals and support the identification of plausible protein targets. The model allows users to explore known proteins, examine putative targets, and access descriptive information for each protein or chemical, including their classification and links to external resources such as UniProt or PubChem. ED-Net will be available as a web platform.

Initial results indicate that ED-Net can uncover biologically relevant targets for chemicals with limited toxicological data and highlight new associations consistent with endocrine-related pathways. By combining network science and cheminformatics, ED-Net provides a powerful tool to enhance early warning systems for endocrine disruptors and support prioritisation efforts in regulatory toxicology.

6.01.P-Th229 Embedding Health in Climate Adaptation: Research Directions for Drinking Water Systems

Sanah Majid¹, Martin Korevaar¹, Dirk Vries¹, Caro Mooren², Peter van Thienen¹ and Milou M. L. Dingemans³, (1)KWR Water Research Institute, Netherlands, (2)KWR Water Research Institute, Nieuwegein, The Netherlands; Copernicus Institute of Sustainable Development, Utrecht University, Utrecht, The Netherlands, Netherlands, (3)KWR Water Research Institute, Utrecht University, Netherlands

Climate change is reshaping water systems globally. In specific cases, it has a profound consequences for human health. Rising temperatures, changing precipitation patterns, and more frequent extreme weather events are disrupting both the quality and availability of drinking water. The Netherlands, known for its advanced water management, is also vulnerable to climate change induced extreme events, such as, flooding, drought, and salinization. These events pose immediate challenges to public health and the resilience of water infrastructure. Our study examines the climate–water–health nexus with a focus on the Dutch water system. We assessed key health risks, policy integration, knowledge gaps and research priorities. Through a comprehensive literature review, policy analysis, and interview with the experts in the field of water management, public health, climate change, and governance, we identified direct health risks, including increased microbial and chemical contamination, as well as, broader impacts, such as food insecurity and mental health concerns. While water

governance in the Netherlands aligns closely with EU climate objectives, gaps persist in policy implementation and the integration of health considerations. Critical research needs include (near) real-time monitoring, improved understanding of microbial and chemical dynamics under climate stress, and stronger integration between science, governance, and public engagement. To address these challenges, we propose a research roadmap that prioritizes the development of health risk indicators, innovation in monitoring and data systems, designing and testing of climate-resilient (drinking) water infrastructure, and embedding research into policy frameworks. Our findings emphasise the need for integrated, evidence-based adaptation strategies to safeguard public health and strengthen the resilience of Dutch drinking water systems in the face of accelerating climate change.

6.02 Bringing “Design” back to SSbD: Designing Molecular Structures for Safety and Sustainability

6.02.T-01 Designing What to Assess in SSbD: A Pathway Builder Integrating Governance Mapping and Morphological Analysis

Che Xiao¹, Marco Cinelli² and Stefano Cucurachi¹, (1)Leiden University, Netherlands, (2)Decision Engineering for Sustainability and Resilience Laboratory, Leiden University College, Faculty Governance and Global Affairs, Leiden University, Netherlands

The European Commission’s Safe-and-Sustainable-by-Design (SSbD) framework distinguishes a (re)design phase from the assessment. In practice, however, SSbD efforts – including those emerging in healthcare – mostly start from a short list of options and focus on evaluating them, rather than structuring how options are generated and governed. This can lead to narrowly framed choices and “forever chemical” lock-ins, as seen for per- and polyfluoroalkyl substances (PFAS).

This work addresses two related challenges: (i) the lack of an explicit meso-level pathway builder that links macro-level problem framing to micro-level design options across the life cycle, and (ii) the absence of clear responsibility mapping for who can change which options. A governance-aware, morphological pathway builder is presented, integrating (i) a macro–meso–micro framing of the design problem, (ii) Responsibility-Accountable-Consulted-Informed (RACI) governance mapping of stakeholder roles along the value chain, and (iii) General Morphological Analysis (GMA) with Cross-Consistency Assessment (CCA) to explore and systematically prune a constrained morphological design space.

The methodology is implemented as a spreadsheet-based prototype and illustrated for single-use injection devices and associated packaging, shaped within the EU Innovative Health Initiative (IHI) ENKORE project. Even conservative parameterisation yields many “device-packaging-logistics-use-EoL” combinations. Applying consistency checks will further remove infeasible and non-compliant configurations, delivering a manageable portfolio of governed, assessment-ready pathways that respect sterility, regulatory and logistical constraints while making explicit which stakeholders must be involved in what implementation.

Rather than selecting “best” designs, the proposed pathway builder structures transparent design pathways that can subsequently be evaluated with life cycle, risk or other assessment workflows. It offers a concrete way to “bring back the design” into SSbD practice and to support safer, more circular, and better-governed innovation pathways for healthcare devices, reducing the risk of future PFAS-like crises.

6.02.T-02 Interactive Generative Modelling for Inverse Design of Safe and Sustainable Antioxidants

Franziska Weissbach¹, Christina Humer¹, Kathrin Fenner² and Kjell Jorner¹, (1)ETH Zurich, Switzerland, (2)Environmental Chemistry, University of Zürich, Switzerland

Ensuring the safety of novel chemicals requires proactive strategies that consider environmental and health hazards already at the molecular design stage. Phenolic antioxidants are widely used and increasingly considered contaminants of emerging concern, exemplifying the need for molecular (re)design that maintains function while reducing risk. This work addresses this challenge by developing an interactive generative modelling framework for the de novo design of safer phenolic antioxidants aligned with Safe and Sustainable by Design (SSbD) principles.

We employ a genetic algorithm to generate and evolve molecular structures while optimizing four key criteria: synthesizability, antioxidant activity, biodegradability, and (eco)toxicity. Synthesizability is assessed with heuristics; antioxidant activity is approximated via O–H bond dissociation energies and ionization potentials; ready biodegradability is predicted using a machine-learning model developed by Körner et al. (Environ Sci:

Proc Imp 2024); and baseline (eco)toxicity is estimated through log Kow. A human-in-the-loop interface enables domain experts to provide real-time feedback guiding the optimization. The user can dynamically adjust objective weights, remove undesirable structural motifs or add promising structures, integrating intuition that is otherwise difficult to capture.

The genetic algorithm efficiently identifies a diverse set of promising phenolic structures with improved predicted profiles for performance and safety. Molecular similarity analysis confirms high structural diversity among the generated molecules, which supports a broad exploration of independent structural strategies. Comparison with a curated set of ~500 antioxidants in current use shows that early generations of molecules generated by the genetic algorithm rediscover known molecules, while later generations explore increasingly novel chemical space.

This work demonstrates how generative modelling, expert interaction, and predictive hazard assessment can be integrated into a practical SSbD-oriented design workflow. It is embedded in an interdisciplinary project in which our project partners are developing experimental high-throughput methods for assessing persistence, toxicity, and degradation-product hazards. The project lays the foundation for a closed-loop design approach coupling high-throughput experimentation and generative modelling via active learning to accelerate the development of safer functional chemicals.

6.02.T-03 An Integrated Early-Stage SSbD Workflow Using AI/AOP-Based NGRA and Streamlined LCA for Chemical Substitution

Jaeseong Jeong, Hyeonwoo Kim and Jinhee Choi, University of Seoul, Korea, Republic of

Early-stage Safe and Sustainable by Design (SSbD) decision-making requires simultaneous consideration of chemical safety and environmental sustainability. While AI-driven predictive toxicology and Adverse Outcome Pathway (AOP)-based Next-Generation Risk Assessment (NGRA) have advanced mechanistic hazard evaluation, they are rarely integrated with life-cycle sustainability metrics. This separation can lead to unbalanced or misleading substitution choices, particularly in consumer product applications. In this study, we propose a practical early-stage SSbD workflow that combines (1) AI/AOP-based NGRA for rapid identification of mechanistic hazard hotspots, and (2) a streamlined cradle-to-gate Life Cycle Assessment (LCA) to assess environmental performance with minimal data requirements. The two assessment streams are qualitatively linked through a simple risk assessment (RA)–LCA matrix to highlight alignment, conflicts, and potential trade-offs. To illustrate feasibility, the workflow is applied to a representative set of alternative chemicals commonly used in consumer products (e.g., plasticizer or bisphenol analogues). The results demonstrate that integrating AI-based hazard prediction with simplified LCA provides balanced and actionable early SSbD insights, enabling prioritization of safer and more sustainable alternatives before detailed testing or full LCA is conducted. This framework offers a lightweight, scalable approach that can support rapid design iterations and early innovation in chemical substitution.

Disclaimer/Disclosure:

This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through ‘Technology Development Project for Safety Management of Household Chemical Products’ (RS-2023–00215309), funded by Korea Ministry of Environment.

6.02.T-04 Integrated Methodology and Decision Support System for Safe and Sustainable Substitution

Susan Dekkers¹, Neeraj Shandilya¹, Thomas Hennequin¹, Stéphanie Desrousseaux², Loélia Fohet³, Laura Magnasco⁴, Poornima Nagesh⁵, Martin Himly⁶, Joséphine STECK² and Eugene van Someren¹, (1)TNO, Netherlands, (2)Atomic Energy Commission (CEA), France, (3)Industrial Technical Center for Plastics and Composites (CT-IPC), France, (4)RINA Consulting S.p.A., Italy, (5)Radboud University, Netherlands, (6)Paris Lodron University of Salzburg, Austria

To enable the practical implementation of the Safe and Sustainable by Design (SSbD) approach in developing safer and more sustainable alternatives to replace substances of concern, the HORIZON project PLANETS is developing an integrated methodology and a Decision Support System (DSS). The integrated methodology enables assessments across all relevant SSbD dimensions: human and environmental safety, environmental, economic, and social sustainability and functional performance. It supports decision-making and the identification of optimal and robust design choices. Unlike fixed aggregation methods, the approach is flexible and tailored to data availability, quality, and stakeholder needs.

The DSS builds on the JRC SSbD framework and extends into a digitally operational tool incorporating diverse assessment methods, including in silico modelling, experimental assays, life cycle assessment, life cycle costing,

performance testing and social impact assessment. The DSS provides an interactive environment for selecting relevant SSbD aspects, integrating assessment results, applying optimization and multiple-criteria decision analysis, and visualizing trade-offs using tools like spider charts, Pareto fronts, and heatmaps. Three industrial real-life cases—surfactants, flame retardants, and plasticizers—are employed to test and optimise the integrated methodology and DSS. Initial results show successful integration of heterogeneous data, improved transparency in decision making, and support for exploring safety-sustainability trade-offs. Ultimately, the DSS aims to guide innovators from early development to market launch, fostering safer and more sustainable chemical design across Europe.

Disclaimer/Disclosure:

This project received funding from the European Union's Horizon Europe research and innovation programme under grant agreement n° 101177608.

6.02.P Bringing “Design” back to SSbD: Designing Molecular Structures for Safety and Sustainability

6.02.P-We405 Rational Nano-Engineering of Thyme Polyphenols Encapsulated in β -Cyclodextrin–Chitosan Carriers Mitigates Cisplatin Neurotoxicity: A Molecular-to-Organism Toxicological Assessment
Mohammad Yahya Alfaifi¹, Nuha Elamin², Ali Nasr³, Ali A Shati¹, Nashwa Elwahab⁴, Waleed Serag⁵, Reda Elshaarawy⁵, Serag Elbehairi¹ and Ebtesam Kotb⁵, (1)King Khalid University, Saudi Arabia, (2)Imam Mohammad Ibn Saud Islamic University, Saudi Arabia, (3)Port Said University, Egypt, (4)Sinai University, Egypt, (5)Suez University, Egypt

Cisplatin-induced neurotoxicity remains a major challenge in oncology, illustrating how therapeutic efficacy can be undermined by toxic consequences across molecular, cellular, and organismal levels. Aligned with the conference theme of environmental and human toxicology—from molecular mechanisms to in vivo outcomes—and the subtheme of designing safer molecular structures, this study employs a nano-engineering strategy to develop a sustainable neuroprotective formulation capable of mitigating cisplatin's damaging effects. Thyme polyphenols, known for potent antioxidant and anti-inflammatory actions yet limited by instability and low bioavailability, were incorporated into β -cyclodextrin–chitosan (CDCS) nanocarriers to enhance molecular stability, biological performance, and safety. The engineered TP#CDCS system represents a shift beyond simple substitution, focusing on structural redesign to generate a safer therapeutic adjunct.

Using an in vivo rat model with molecular toxicology assessments, we examined the ability of TP#CDCS to counteract cisplatin-induced oxidative stress, inflammatory signaling, and apoptosis. Biochemical endpoints including oxidative markers (MDA, GSH, TAC), neuronal injury indicators (CK-BB, NSE), and regulators of apoptosis and inflammation (p53, caspase-3, PGE2) were quantified to map the multi-level toxicodynamic response. Histopathological and immunohistochemical evaluations, particularly GFAP expression and neuronal architecture, provided organism-level confirmation. Cisplatin caused marked molecular and cellular disruption, whereas TP#CDCS significantly restored redox balance, suppressed apoptotic pathways, reduced astrocytic activation, and improved neuronal viability to near-control levels.

Overall, the results show that nano-engineered β -cyclodextrin–chitosan carriers enhance the functional properties of thyme polyphenols, creating a safer molecular profile and offering an effective, sustainable strategy to reduce the neurotoxic burden of a widely used chemotherapeutic agent. This work highlights the potential of combining natural polyphenols with rationally designed nanostructures to advance safer-by-design approaches that achieve therapeutic benefit while minimizing human and environmental harm.

6.02.P-We406 Redesigning Organophosphate Flame Retardants for Safety and Sustainability
Hannah Flerlage¹, Steven Beijer¹, Jelle Hofman¹, Bianca Stadelmann², Tiago J Martins¹, Emeline Delcros¹, Ge Xie³, Michiel Kraak², Ingrida Bagdonaitė³, Antonia Praetorius² and Chris Slootweg¹, (1)Van 't Hoff Institute for Molecular Sciences, University of Amsterdam, Netherlands, (2)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (3)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands

Polyurethane foams (PUF) are a ubiquitous material used in furniture, vehicles, and insulation. The flammability of PUF necessitates the use of flame retardants. After the phase-out of tris(2-chloroethyl) phosphate (TCEP) in 2015 due to reproductive toxicity and carcinogenicity, the homologue tris(chloropropyl) phosphate (TCPP) became the most used flame retardant for PUF. While sometimes assumed less toxic, a screening report from 2018 grouped TCPP with TCEP, indicating risks to children. Both chemicals are frequently found in

environmental monitoring studies.

To avoid repetition of this apparent regrettable substitution, we set out to explore molecular structure alterations to systematically improve the hazard profile and aim to design a safe and sustainable flame retardant using versatile organophosphorus chemistry. This contribution highlights the redesign process and gives an overview of the subsequent assessment.

For the molecular redesign, we employed learnings from our previous study on computer-aided redesign of organophosphates, rules of thumb, chemists' intuition and predictive models to test our hypothetical alternative structures. The design aims to decrease toxicity and increase biodegradability to prevent environmental pollution. We also explore sustainable production, linking to ongoing research in our labs to synthesize organophosphates from wastewater-recovered phosphates. The selected structure moreover contains functional groups that could allow permanent linking to matrices.

We compare our newly designed flame retardant to TCEP and TCPP, and the structurally intermediate alkyl phosphates triethyl phosphate and tripropyl phosphate, used as polymer additives. After developing a synthetic route to access our redesigned chemical, we performed a series of experiments, including (i) an investigation of the chemical stability with ³¹P-NMR, (ii) an explorative biodegradability study with sewage sludge monitoring CO₂ evolution, (iii) acute and chronic ecotoxicity studies with the algae *Raphidocelis subcapitata* and the crustacean *Daphnia magna*, (iv) ongoing evaluation of the flame retardancy of the new chemical in PUF. Results indicate that the toxicity was successfully decreased, and the degradability much increased, potentially necessitating a further design iteration to improve the balance between environmental degradability and stability during the use phase.

6.02.P-We407 Integrating Early-Stage Aquatic Toxicity Testing to Guide the Development of Recyclable, Flame-Retardant Epoxy Vitrimers

Rafael Reis¹, Arvinth Sekar², Cédric Hervieu², Sabyasachi Gaan² and Ksenia J Groh³, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Swiss Federal Laboratories for Materials Science and Technology (Empa), Switzerland, (3)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Epoxy thermosets are widely used in electronics, construction, and transportation due to their mechanical strength, durability, and thermal stability. However, their permanent crosslinked structure limit recyclability and end-of-life options. Moreover, their flame retardancy typically relies on additive, non-reactive compounds, often halogenated, that may be persistent, bioaccumulative, and toxic. Advancing towards safer and more sustainable materials requires polymer systems that couple high performance with enhanced circularity and reduced hazard potential. Early integration of toxicological considerations is therefore a key component of the Safe and Sustainable by Design (SSbD) framework.

This study applies an SSbD-guided workflow to support the development of recyclable epoxy-based vitrimers incorporating polyphosphite and related phosphorus-containing structures. These multifunctional building blocks enable covalent adaptable networks that deliver intrinsic flame retardancy and allow thermomechanical reprocessability. However, because such structures may also contribute to environmental risks, early-stage ecotoxicological screening is critical for identifying potential concerns to enable material optimization before advancing toward upscaling.

We implemented a fish cell-based acute toxicity assay (OECD Test Guideline 249) in a 96-well plate format to increase throughput and confirmed transferability between formats using 3,4-dichloroaniline. The assay was used to evaluate the toxicity of individual monomers and cross-linkers, including diethyl phosphite (DEP) tethered to diethylene glycol (DEG), triethylene glycol (TEG), 1,5-pentanediol (PDO), and polyethylene glycol 200 (PEG-200), as well as leachates from materials under different curing and reprocessing conditions. This approach enabled systematic study of formulation, curing, and reprocessing effects, providing insights into structure–activity relationships for designing safer epoxy vitrimers.

By combining material performance data with rapid aquatic toxicity screening, the presented workflow supports iterative refinement of vitrimer formulations toward reduced hazard while maintaining essential functionalities such as flame retardancy and recyclability. Overall, this case study highlights the value of early ecotoxicological input in guiding materials innovation and demonstrates a practical approach for implementing SSbD principles in the development of next-generation flame-retardant vitrimers.

6.02.P-We408 Age-dependent ecotoxicity of biocomposites leachates towards freshwater species

Cátia Venâncio¹, Sara Costa², Rafaela Maria Tavares Reis², Susanne Kate Lang³, Hans Knudsen³, Aratz Genua⁴ and Isabel Lopes¹, (1)University of Aveiro, Portugal, (2)CESAM, University of Aveiro, Portugal, (3)Comfil ApS, Denmark, (4)Unidad de Polímeros y Composites, Spain

The development of biocomposites across sectors in response to environmental concerns from synthetic polymers has increased. Although promising, conventional risk assessments often overlook adverse effects.

Biocomposites may release toxic leachates with age, yet current 24-hour tests may underestimate long-term impacts. Accordingly, this work assessed the ecotoxicity of 32- and 64-day leachates from nine biocomposites [PA5%W; PA5%C; BUP04; BUP05; HTPLA-PLA-50216; HTPLA-PLA-PLA1-PLA2 (1 mm); HTPLA-PLA-PLA1-PLA2 (5 mm); HTPLA-PLA-PLA3-PLA4 (3 mm); HTPLA-PLA-PLA1-PLA4 (5 mm)] in five freshwater species: the microalgae *Raphidocelis subcapitata* (OECD 201), the macrophyte *Lemna minor* (OECD 221), the rotifer *Brachionus calyciflorus*, the cladoceran *Daphnia magna* (OECD 202), and the fish *Danio rerio* (OECD 236). Leachates were produced in distilled water following CEN/TS15863 at 8 cm³/cm² and supplemented with salts according to species requirements.

The 32-day leachates caused marked biological effects, especially at intermediate/lower dilutions for *R. subcapitata*, with sharp declines in yield and growth (e.g., 12.5–25% of HTPLA-based, PA5%C, and PA5%W composites), while minor effects were observed in *L. minor*. *Brachionus calyciflorus* showed high mortality for certain HTPLA-based and PA5%C composites, whereas *D. magna* showed no mortality. No *D. rerio* embryo mortality was observed, but larvae exposed to 100% leachates from PA5%C and HTPLA-50216 were significantly smaller than controls.

Phytotoxicity increased with ageing (64-day leachates) in *R. subcapitata*, with most composites suppressing growth at ≥25% and all causing near-zero growth at 100%, while *L. minor* effects remained minor (e.g., BUP05). *Brachionus calyciflorus* responses ranged from no toxicity to strong, dose-dependent mortality, whereas *D. magna* remained unaffected. *Danio rerio* embryos showed no mortality, but significant larval length reductions were observed for several HTPLA-based, PA5%C, and BUP04 composites, especially at 100% leachate. These findings highlight the need for ecotoxicological assessments to anticipate environmental impacts and guide biocomposite manufacturing.

6.02.P-We409 CCPD: A Promising Safer Alternative to 6PPD – Comparative Aquatic Toxicity, Environmental Fate, and Environmental Risk Assessment

*Damien Carson*¹, *Pauline Remuzat*², *Michael Essers*³, *M. Wiedemeier-Jarad*³ and *Audrey Batoon*⁴, (1)*Blue Frog Scientific Limited, United Kingdom*, (2)*Blue Frog Scientific SAS, France*, (3)*LANXESS Deutschland GmbH, Germany*, (4)*LANXESS Corporation, United States*

6PPD and its ozonation transformation product 6PPD-quinone (6PPD-Q) are significant aquatic toxicants, with 6PPD-Q causing acute mortality in coho salmon (*Oncorhynchus kisutch*) via stormwater runoff. In response to these findings, we evaluated N,N'-dicyclohexyl-p-phenylene-1,4-diamine (CCPD, CAS 4175-38-6) as a potential safer alternative.

This study presents environmental fate and aquatic toxicity data for CCPD and its ozonation product CCPD-Q (CAS 1653-85-6), and incorporates risk characterisation principles.

CCPD exhibits a log K_{ow} of 4.8 and QSAR-BCF value of 771. The substance demonstrated significant environmental degradation (61% biodegradation in 28 days, OECD 301D), and hydrolytic instability (DT₅₀ of 18-19 h (pH7) and 2.3 h (pH9) at 12 °C, OECD 111).

Acute toxicity to coho salmon was assessed under flow-through conditions (OECD 203). CCPD is less toxic to coho salmon than 6PPD (96h LC₅₀ of 32 µg/L for CCPD versus 14 µg/L for 6PPD). In contrast to 6PPD-Q on coho salmon, which has a 24h LC₅₀ of 95 ng/L, CCPD-Q shows no acute toxicity at the solubility limit (149 µg/L).

Compared to coho salmon, CCPD exhibited comparable toxicity to *Daphnia magna* with a 48h EC₅₀ of 58.5 µg/L (OECD 202). Acute toxicity to the common guideline fish test species, rainbow trout (*Oncorhynchus mykiss*), under flow-through conditions indicates lower sensitivity with a 96h LC₅₀ >57 µg/L (OECD 203). Additionally, recognising the relevance of pulsed stormwater exposures, a static test on rainbow trout was conducted to simulate transient exposure scenarios. The instability of CCPD and co-exposure to transformation products was apparent with a 48h LC₅₀ of 44 µg/L (EPA OCSPP 850.1075). Due to hydrolytic instability precluding standard algal tests, a flow-through *Lemna* sp. growth inhibition test (OECD 221) is also in progress. Whilst the CCPD parent compound remains toxic to aquatic organisms, it presents high potential for rapid biodegradation and exhibits elevated primary degradation rates and as such is not considered persistent.

A preliminary environmental risk assessment conducted in accordance with EU REACH indicates safe use of CCPD during manufacture and tire use, when applying the existing operational conditions and risk management measures applied for 6PPD.

These studies complete the short-term dataset for classification and hazard assessment. Future long-term studies will further define CCPD's suitability as a safer, functional alternative to 6PPD in tire and rubber goods.

6.02.P-We410 Safe-by-Design Metal-Phenolic Networks for Environmental and Biomedical Applications: A Systematic Review

*Ilona Juvonen*¹, *Alla Kroshovyan*², *Danylo Merzhyievskiy*², *Anne Kahru*² and *Monika Mortimer*², (1)*Tallinn University of Technology, Estonia*, (2)*National Institute of Chemical Physics and Biophysics, Estonia*

Metal–phenolic networks (MPNs), composed of plant-derived polyphenols that coordinate metal ions, are an emerging class of materials developed for applications in environmental and biomedical fields. Here, a meta-analysis of ecotoxicity data for MPNs and their constituent metal ions and phenolic ligands was conducted to support safe-by-design approaches for these materials. A systematic literature search identified 767 publications on MPNs, of which 85 contained toxicity tests without additives toxic to test organism. Most studies assessed in vitro endpoints in human or murine cells (n=75); in vivo acute or subacute tests used rodents or zebrafish (n=19). We found no environmental toxicity studies of MPNs on non-vertebrate species. Twenty-one metal ions, ten bimetallic complexes, and 29 polyphenols, plant extracts, polymers, or conjugates were reported as MPN components. MPN development for various applications has primarily focused on Fe³⁺–tannic acid systems. Fe³⁺–polyphenol complexes were generally biocompatible, whereas Cu²⁺–polyphenol complexes, which were the second most studied MPN, showed cytotoxicity. Hemolysis was examined for 23 MPNs of which three were hemolytic. No acute toxicity was observed in in vivo assays. We used harmonized hazard classifications and acceptable daily intake values of metals and ligands to assess the potential toxicity of MPNs. For environmental hazard evaluation, we collected EC₅₀ values for metal ions and phenolic ligands from 340 studies, involving algae, cyanobacteria, protozoa, crustaceans, earthworms, midges, *Aliivibrio fischeri*, and several fish species. Cu²⁺ and Cd²⁺ were consistently the most toxic ions; the toxicity of Ni²⁺, Zn²⁺, and V³⁺ varied; Ce³⁺, Gd³⁺, Al³⁺, and Eu²⁺ generally showed lower toxicity. Data on phenolic ligands were scarce, though epigallocatechin gallate has been self-classified as potentially chronically toxic to aquatic environments, while tannic acid has been classified as a GRAS (generally recognized as safe) substance. The meta-analysis aids in making informed decisions when selecting starting materials for novel MPN synthesis, upscaling, and production. The results support risk evaluation of MPNs and enable preliminary hazard ranking based on their metallic and phenolic components when empirical data on MPNs are unavailable.

Disclaimer/Disclosure:

This work was supported by Estonian Research Council grants (PRG2188 and PRG2595). Ilona Juvonen is supported by the SETAC Europe Students Attendance Grant.

6.02.P-We411 Developing an Approach to Examine Hazards of Ingredients in Consumer Products: Application to Cleaning Products With and Without Green Labelling

Kiana Porter¹, Ba Reum Kwon¹, Louis Tremblay² and Bryan W. Brooks¹, (1)Baylor University, United States, (2)Mannaki-Whenua Landcare Research, New Zealand

Consumers use a variety of products daily and are exposed to various chemicals contained in consumer products, for which the risks are poorly understood. While global regulatory efforts to manage chemical risks are increasing, the empirical data on persistence, bioaccumulation, and toxicity are not available for most chemicals in commerce. In this study, we selected three categories of cleaning products, i.e., all-purpose surface cleaners, laundry detergents, and dish care products. Within each category, we selected three representative products marketed as “original,” “greener,” and certified as “safer choice” by the U.S. Environmental Protection Agency (US EPA), as well as “EcoStore” from New Zealand. We focused on organic compounds in products and examined whether “greener” marketed, “safer choice”, and/or “EcoStore” products show less persistence, bioaccumulation, and/or toxicity. Data were collected using EPI Suite (US EPA) for predicted ‘P’, ‘B’, and ‘T’ values, e.g., persistence, bioaccumulation factors (BCF), and acute fish toxicity (LC50). Probabilistic distributions were developed for each P, B, and T and compared to established cut-off criteria (BCF of 500, 2000, 5000 L/kg, and LC50 of 0.1, 1, 10, 100 mg/L) to calculate exceedance probabilities. Notably, 38.8 % of the organic ingredients in “greener” labeled laundry care products exceeded the level of concern (< 0.1-1.0 mg/L), demonstrating “highly toxic” and “very highly toxic”, followed by 34.9 %, 31.2 %, and 30.4 % of “original,” “EcoStore,” and “safer choice” products, respectively. Moreover, 40.8% of the “greener” labeled laundry detergents showed the longest persistence (1/2t ? 40 days) compared to other products, which warrants potential hazards. However, more than 90 % of these ingredients were considered “low bioaccumulative (< 500 L/kg)”. Although organic ingredients in dish care products showed less toxic potential compared to all-purpose or laundry care products, 49.2 % of ingredients from the “original” labeled dish care products showed “very highly bioaccumulative (? 5000 L/kg)”. We subsequently propose a probability-based framework for comparing chemical hazards within and across specific consumer product. This approach supports data-driven substitution, encourages safer product innovation, and can be extended to broader classes of consumer products.

6.02.P-We412 Mapping the SSbD-Thinking and (lack of) Knowledge Exchange of Actors along a Product’s Life Cycle

Nina van Dulmen¹, Maaike Weber², Carlos Felipe Blanco¹ and Jeroen Guinée¹, (1)Leiden University, Netherlands, (2)TU Delft, Netherlands

Safe and Sustainable by Design (SSbD) is a pre-market approach for developing chemicals that fulfill their intended functions while minimizing hazardous properties and reducing quantities that could threaten human or environmental health. The safety dimension focuses primarily on the design of the chemical or material itself, whereas the sustainability dimension considers its entire life cycle. Ultimately, these aspects and potential systemic trade-offs converge only at product-level analysis, covering the chemical's journey from its ingredient production to end-of-life treatment of the product, and potential subsequent cycles.

Various actors engage along a chemical- and product's life cycle, each with distinct interests and views on SSbD. For example, a chemist may emphasize hazard assessment, whereas a product developer focuses more on the composition of the product, material inputs, and views safety from the user perspective, and relies the chemists' assessment. This reveals a gap in understanding what SSbD entails beyond its formal definition, and how it can be operationalized. To address this, we take the product life cycle as our scope, and examine what SSbD means for different actors involved, as chemists, material developers, process designers, or product developers.

Using actor network theory, we take a socio-material approach to a case study of a care mattress. Through life cycle and actor mapping with an SSbD focus, to understand how SSbD is perceived from different perspectives. This helps illustrate how SSbD may need to be framed differently at different moments, and how it could be operationalized across a product's life cycle. We visualize scenarios with- and without SSbD thinking to clarify what SSbD entails, and what this means for the definition of SSbD. Hereby, we gain insights into actor networks and SSbD's positioning herein: where do the responsibility lie on who is doing what and when, and how does knowledge transfer through the system.

By taking this lens, we identify the different meanings of SSbD to different actors, the moments where knowledge transfer breaks down, and how to prevent the latter. We propose how SSbD can be directed to become operational (e.g., a chemist could be responsible for a thorough hazard assessment, where the product developer is responsible for consumer safety). This provides clarity to practitioners to what SSbD means for them, what information they must pass on, and where their responsibilities lie.

Disclaimer/Disclosure:

This work is part of the project Safe-by-Design Circular Products (with project number NWA.1437.20.106 of the research programme 'Towards a practical Safe-by-Design approach for chemical products and processes') which is (partly) financed by the Dutch Research Council (NWO).

6.02.P-We413 From Regulation to Data: Building an SSbD Requirements Tool Using Ontologies and Knowledge Graphs for the Pharmaceutical Sector

Jacopo Sorani¹, Roland Hischier² and Bernd Nowack¹, (1)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (2)Technology & Society Laboratory, Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland

Pharmaceutical innovation has greatly expanded human life expectancy, yet the life cycle of medicinal products continues to generate significant environmental and occupational challenges. Active pharmaceutical ingredients (APIs), designed to remain biologically potent at low concentrations, contribute to ecological effects and antimicrobial resistance once released into the environment. In parallel, small-molecule manufacturing is highly resource-intensive, as confirmed by LCA studies showing elevated energy demand, solvent use and waste generation, while exposing workers to potent intermediates and high-hazard solvents.

The European Commission's Safe and Sustainable by Design (SSbD) framework aims to embed safety, sustainability and environmental performance early in chemical and pharmaceutical design. However, when operationalising SSbD in the pharmaceutical sector, two major obstacles emerge: (i) SSbD requires extremely heterogeneous data, spanning toxicology, environmental fate, process safety, exposure, LCA and regulatory compliance, produced by different teams, in different formats, and at different stages; (ii) these data are governed by multiple regulatory frameworks (EU, US, OECD, ISO) that express similar requirements using inconsistent terminology, thresholds and metadata conventions. FAIR data principles are therefore essential, yet industry surveys show that data silos, non-interoperable formats and inconsistent ontologies remain pervasive barriers.

To address this, we conducted a structured policy analysis of key regulations driving SSbD-relevant evidence needs and translated deontic clauses (“shall”, “should”, “may”) into machine-readable Data Requirements. These were encoded into a cross-regulatory pharmaceutical Knowledge Graph linking regulations, requirements, datasets, lifecycle stages, ontologies and LCA-relevant parameters. Preliminary results show strong redundancy in required datasets, substantial terminology misalignment, and limited recognition of datasets shared across frameworks (e.g., biodegradation half-lives, solvent hazards, worker exposure bands). Building on this mapping, we propose the development of a data-completeness tool that prioritises high-value datasets, identifies gaps and visualises how individual data points propagate across SSbD, safety and sustainability assessments, supporting more coherent and efficient implementation of SSbD in pharmaceuticals.

6.02.P-We414 Avoiding Tomorrow’s Chemical Mistakes Today

Jeroen Guinée and Martina G. Vijver, Leiden University, Netherlands

The Safe and Sustainable by Design (SSbD) framework is gaining momentum within the European Union, with scholars, industry, and policymakers actively exploring its implementation. This presentation highlights key challenges that remain, particularly regarding methods, the interpretation of “life cycle” within SSbD, and data. The current methodological pillars of SSbD - Hazard Assessment (HA), Risk Assessment (RA), and Life Cycle Assessment (LCA) - offer a strong foundation for evaluating chemical safety and sustainability and for identifying potential trade-offs. However, their integration with design processes, innovation pathways, and broader ethical and social considerations remains limited. In addition, the concept of “life cycle” is not yet clearly defined in the SSbD context.

Beyond these methodological issues, the most significant barrier to SSbD is the availability and quality of data. Although notable progress has been made in advancing safety and sustainability assessment methods, improvements in data generation, accessibility, and reliability have not kept pace. Because both safety and sustainability assessments depend fundamentally on data, this imbalance weakens the effectiveness of the SSbD framework.

To address these challenges, we propose a three-step data strategy, starting with safety data. Advancing SSbD in a meaningful way requires a robust, regulatory-driven approach to enhance data availability and quality for both safety assessments and LCA. Without such a strategy, further methodological innovation risks becoming an empty exercise, one that obscures rather than enables real progress.

6.02.P-We415 Towards Safe and Sustainable Chemical Substitution

Hedwig Braakhuis, Bernice Scholten, Pavel Kostadinov, Neeraj Shandilya, Jack Vogels, Susan Dekkers, Xavier Pinho and Wouter Fransman, TNO, Netherlands

Chemical substitution is a critical pillar in the European Union’s Chemicals Strategy for Sustainability, aiming to mitigate human and environmental harm by replacing hazardous substances with safer alternatives. Chemicals that are persistent or induce carcinogenic, mutagenic, reprotoxic or endocrine disrupting effects are being restricted. Category-wide restrictions – such as for several PFAS - are being introduced to avoid regrettable substitution. Identifying suitable safer alternatives for restricted chemicals is challenging since an alternative should provide equal performance while being less hazardous. Information on chemical performance is specific for each application, and this information is scattered across several sources. Hazard information on chemicals is often incomplete or lacking.

We present a data-driven methodology that links desired chemical performance to physicochemical (PC) properties rather than relying solely on structural similarity, thereby reducing the risk of regrettable substitution. Target performance profiles are translated into PC property ranges, derived from benchmark substances and literature, and used to filter large candidate pools. Data gaps in PC properties and hazard are addressed using

TNO's Substance Information System (SIS), which aggregates information on >4 million chemical substances, combined with predictive in silico (QSAR/AI) models for key PC and toxicological endpoints where experimental data are lacking. This enables systematic identification and ranking of candidate substances on both performance fit and hazard indicators. Interactive visualizations (e.g. performance–hazard maps, radar plots and ranked shortlists with filters) support transparent discussions of trade-offs and selection of the most balanced options.

Case studies, including surfactant and solvent replacement, demonstrate how TNO's substitution tooling facilitates the design of products that meet both regulatory and functional requirements. This integrated approach empowers industry to advance chemical substitution, reduce hazard profiles, and deliver safe, sustainable products for global supply chains.

6.03.P Cap-and-Trade Systems for Hazardous Chemicals: Defining Caps, Allocation Weights, and Implementation Pathways

6.03.P-Mo381 A Proposal for an EU Cap-and-Trade System for Hazardous Chemicals: Design Options for SVHCs and PFAS

Matti Vainio¹ and Daniel Slunge², (1)University of Helsinki, Finland, (2)Environment for Development/FRAM, University of Gothenburg, Sweden

The current risk management approaches under the EU's REACH regulation – restrictions and authorisation – have not been as effective in reducing chemicals-related risks as was hoped for in 2007 when the regulation entered into effect. Although the current approaches can be improved, they are likely to continue facing many of the same challenges observed today.

This paper proposes a new, complementary approach to reducing the prevalence of hazardous substances in the EU. It examines how a cap-and-trade system for hazardous substances could facilitate a significant reduction or phase-out of such substances. A cap-and-trade system – also referred to as tradeable quotas – would allow the continued manufacture, placing on the market or use of hazardous substances in cases where an outright ban would have disproportionate socio-economic impacts. By setting an ambitious reduction target for selected hazardous substances and allowing market operators to exchange allowances from one year to another or between the operators, the system would promote substitution and find cost-effective ways to reach the target.

Drawing on practical elements from existing quota and trading systems, such as the EU's Fluorinated Greenhouse Gas Regulation, the American Innovation and Manufacturing Act (of HFCs) as well as the EU Emissions Trading (ETS) of CO₂, the paper outlines how a cap-and-trade approach could be designed for hazardous chemicals. It then discusses how this system would function alongside targeted restrictions where specific risks require separate action.

The key features of any cap-and-trade system – allocation mechanisms (grandfathering or auctioning), transferability, and monitoring and verification of the quota – are discussed as well as the potential to build on the EU's existing "F-gas portal". The types of hazardous chemicals that could be regulated through a transferable quota system are also briefly examined.

A cap-and-trade system in hazardous chemicals would enable the EU to set ambitious reduction targets for the substances that are of most concern as the system would also give industry the flexibility to meet those targets in the least-cost manner. The relevance of this approach is also considered in the context of EU decision making, where adoption would follow the qualified majority procedure.

6.03.P-Mo382 Regulating Hydrofluorocarbons (HFCs) in the EU – A Review of the Quota System

Sylvie Ludig, Wolfram Jörß and Victoria Brebeck, Öko-Institut, Germany

Fluorinated greenhouse gases (F-gases) make up ~2% of total EU greenhouse gas emissions and have been regulated in the EU since 2006. Hydrofluorocarbons (HFCs) contribute ~ 90% to F-gases emissions. Next to specific bans, the 2014 revision of the F-gas Regulation (FGR) introduced an EU-wide phase-down until 2030 for HFCs placed on the market. The 2024 revision of the FGR features a steeper reduction of HFC amounts until 2030 as well as a phase-out of HFCs by 2050, accompanied by additional bans. To implement the HFC reduction, a system of HFC quotas was introduced.

HFC quota is needed by producers and importers that place HFCs on the EU market. It is allocated for a specific year based on reference values reflecting activities in previous years and on declarations of anticipated demand. Quota is valid for a specific transaction year. Quota authorisations are required when importing equipment pre-filled with HFCs into the EU. Such authorisations can be obtained from quota holders and can be banked for use in future years.

Additional flexibility mechanisms of the FGR include the possibility to transfer allocated quota and to delegate quota authorisations to other companies. However, the rules for quota transfers, quota authorisations and delegations of quota authorisation under the quota system are not designed to support free trade. Traded quota amounts are tracked in the European Commission's HFC registry, but not publicly available. Prices linked to such quota-related transactions are agreed bilaterally between involved companies and are not subject to obligatory reporting in the HFC registry. However, price monitoring data based on market research reveals significant market values of quotas and quota authorisation.

Until 2025, quota allocation was free of charge, allowing for windfall profits of quota recipients. However, the 2024 revision of the FGR introduced a fixed price of 3€ / t CO₂e, to be paid to the European Commission for the allocation of HFC quota starting 2026.

Yearly reports on reporting data by companies have shown that compliance to the system is good, with only a limited number of companies exceeding their available quota or quota authorisation. While it is not possible to quantitatively assess illegal imports of HFCs into the EU, we conclude that the FGR featuring both bans and the HFC quota system has been successful in supporting a shift in the industry away from high-GWP HFCs as well as in reducing HFC emissions in the EU.

6.03.P-Mo383 A Market for Change: Can Cap and Trade plastics systems support a more sustainable plastics future?

Hadeel AL-Zawaidah¹, Marlene Kammerer², Denise Mitrano³ and Kryss Waldschläger¹, (1)Wageningen University and Research (WUR), Netherlands, (2)Oeschger Centre for Climate Change Research, Institute for Political Science, University of Bern, Switzerland, (3)Nestlé S.A., Netherlands

In response to escalating global plastics pollution, a wide range of policy tools have been introduced across the plastics life cycle. However, as negotiations toward a global treaty progress, more integrative and flexible approaches are needed. One less explored market-based instrument that could contribute to this policy mix is a cap and trade (CAT) system. While CAT has been used in a variety of environmental contexts, its application to plastics remains unexplored. Here, we assess whether CAT can be tailored to the specific characteristics of plastics. We structure our analysis around three key design elements derived from past cap-and-trade experience: (1) defining plastic materials and target groups, (2) establishing the cap and allocating permits, and (3) creating a competitive market environment. Building on this, we explore a three-tier structure (i.e., global, national, and sectoral caps) that reflects the spatial and temporal scale of plastics across their full life cycle. Our results present viable reasons to support the potential of a plastics CAT system. It could reduce primary plastics production while also supporting recycling and fostering more circular practices by integrating economic incentives across the entire life cycle. Yet, substantial limitations persist, including the diversity of plastic materials and additives, complex transboundary supply chains, and uneven national monitoring and reporting capacities. Social and political realities, from waste-sector working conditions to the difficulty of negotiating ambitious global caps, further challenge feasibility.

Overall, our intention is not to present a CAT system as the ultimate solution for plastics, but rather to highlight that it may serve as a valuable component of a broader policy mix. By outlining opportunities and limitations, we aim to support ongoing discussions on how such a system could be designed and where it may complement future international plastics governance.

6.03.P-Mo384 Weighting Approaches for Chemicals to Develop Economic Incentives that Efficiently Reduce Hazardous Emissions

Anna Lunde Hermansson¹, Mikael Gustavsson² and Thomas Backhaus¹, (1)RWTH Aachen University, Germany, (2)University of Gothenburg, Sweden

Economic incentives are proposed as an efficient tool to motivate reduction of emissions of hazardous chemicals. If the indicators for implementing such a market-based system are science-based, with weighting approaches to compare chemicals, the data can also support decision-makers opting for less hazardous alternatives. Weighting of chemical properties and/or hazard classifications, that are often associated with large knowledge gaps, is not without complication. Therefore, it is important to critically assess previous work to learn from those examples. Here, different economic instruments to reduce the use of hazardous chemicals, and the underlying weighting approaches, have been reviewed and assessed with respect to feasibility and extendibility beyond the sectors and chemical domains to which they currently apply. The pros and cons of using different weighting-approaches have been analysed to develop scenarios for possible implementation of science-based economic instruments, targeting different environmental compartments and chemical groups. The weighting-approaches were categorised in five different groups: (1) flat rate-based, (2) hazard-based, (3) impact-based, (4) risk-based, (5) allocation-based approaches. A diverse number of methods, fitting into the weight-approach categories, were identified at different spatial and temporal resolution. The different approaches have differing requirements on chemical data (physicochemical properties, (eco)toxicological profile, and environmental fate properties) and current approaches rarely consider the real-world complexity of chemical exposures but rather assessing chemicals and their effects in isolation. The data availability and assessment will partly determine the optimum choice of economic instrument, where a flat-base rate can be assigned as a measure of per-kg chemical emitted/produced while a quota system would also require scientific assessments of the carrying capacity of the exposed environmental compartment (or human). Due to the heterogeneity and uncertainty of chemical impact, the boundaries of the system need to be clearly defined and the procedure of weighting of chemicals must be transparent. Effective economic instruments can complement the current regulatory framework and increase incentives for reducing the emissions of hazardous chemicals.

6.03.P-Mo385 Using Relative Risk Indicators to Inform Allocation Weights in Chemical Cap-and-Trade Systems

Thea Marcelia Sletten¹, David Spurgeon², Sarah Roberts² and Ece Özdemiroglu³, (1)Economics for the Environment Consultancy (EFTEC), London, United Kingdom, (2)United Kingdom Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Economics for the Environment Consultancy (EFTEC), United Kingdom

Cap-and-trade systems for hazardous chemicals can complement existing regulations by creating market incentives for earlier and more efficient substitution. A central requirement is the development of allocation weights that reflect differences in the potential to cause harm across substances. This work examines how Relative Risk Indicators (RRIs) from the Environmental Risks and Impacts of Chemicals (ENRICH) framework can inform such weights.

ENRICH assigns substances to eco-potency groups using species sensitivity distribution data for more than 12 000 chemicals and to exposure groups using national and international monitoring distributions. These groupings form a 7×7 matrix of RRIs that represent substance-specific levels of concern based on combined eco-potency and exposure. Because RRIs are ordinal, they indicate which substances are likely to pose greater concern relative to others, but they do not define the absolute magnitude of risks or impacts.

To explore how RRIs can be translated into numerical allocation weights, three illustrative weighting rules are developed: (i) a community-impact rule based on predicted percentages of species affected within the ENRICH framework, (ii) a multiplicative rule using the product of eco-potency and exposure groups, and (iii) an additive rule using their sum. Each rule is normalised to allow comparison of the degree of separation they create between levels of concern, i.e., how strongly it differentiates quota requirements across substances with different RRIs.

The three approaches generate distinct patterns of regulatory pressure. Community-impact weighting creates steep differences between substances with high RRIs and all others, concentrating compliance costs on those of greatest concern. Multiplicative weighting spreads cost differences across the full range of RRIs, strengthening substitution incentives for both mid- and high-concern substances. Additive weighting offers only limited separation, simplifying implementation, but provides weaker substitution signals for the higher RRIs than the

other two approaches.

This analysis illustrates how RRI grouping can be operationalised into alternative allocation weighting rules and provides a basis for further methodological development of cap-and-trade mechanisms for chemicals.

6.03.P-Mo386 The possible role of financial incentives in the substitution of very hazardous substances

Elke Van Asbroeck, Apeiron-Team NV, Belgium

Regulatory authorities at both the Belgian national level and the European level have concluded that the current pace of chemical substitution is insufficient. Apeiron-Team supported two studies commissioned by these authorities and investigated barriers and incentives for substitution. These studies were informed by real-world substitution cases and interviews with stakeholders included manufactures and users of the incumbent, alternative suppliers, investors and NGO's next to the regulators. One key measure identified was the introduction of financial incentives. This concept was further developed to promote safer and more sustainable chemical use while safeguarding the competitiveness of European industry.

This presentation outlines the development of such financial instruments and highlights areas for further refinement. The concept, grounded in the polluter-pays principle, primarily targets industrial applications, focusing initially on downstream users and manufacturers. In practice, the greatest leverage for substitution is expected among downstream users, for whom the concept has been most extensively developed.

A central consideration is that the financial mechanism should not hinder innovation. To address this, partial fee waivers could be granted based on the implementation of efficient innovation programs. Efficiency may be demonstrated through collaborative efforts to eliminate hazardous substances while emissions and exposure are reduced beyond legal requirements.

The fee is calculated using reported emission and exposure data combined with monetized impact assessments, similar to those used in authorization dossiers. A key area for further exploration is the integration of life-cycle impacts, as current authorization assessments focus primarily on direct emissions and exposure. Tools such as ProScale, evaluated within Safe and Sustainable by Design (SSbD) projects, are being considered for this purpose.

The concept could also incorporate the availability of alternatives, significantly increasing the financial fee where substitution is feasible. The proposed "avoidable use fee" aims to reduce the impact of highly hazardous substances by imposing a proportional financial burden on continued use when safer alternatives or impact-reduction measures are achievable through innovation.

6.03.P-Mo387 Cap-and-Trade Systems for Hazardous Chemicals – What Can We Learn from F-Gas Regulations in the EU and the US?

Daniel Slunge¹ and Matti Vainio², (1)Environment for Development/FRAM, University of Gothenburg, Sweden, (2)Helsinki University, Finland

Cap-and-trade systems have been widely used in climate policy but remain largely unexplored for regulating hazardous chemicals. Two existing systems, the EU Fluorinated Greenhouse Gas (F-gas) Regulation and the US American Innovation and Manufacturing (AIM) Act, govern industrial chemicals through transferable quotas and therefore provide relevant experience for considering similar approaches for hazardous substances. This paper reviews how these systems function and identifies design features that may be applicable when regulating groups of hazardous chemicals.

Both systems establish legally binding, declining caps on the placing on the market or consumption of hydrofluorocarbons (HFCs). The 2024 revision of the EU F-gas Regulation introduced a much steeper reduction trajectory than the earlier 2014 regulation, reflecting rapid technological progress, strengthened EU climate targets, and the need for improved market surveillance. Verified data exist for quota allocations and placing-on-the-market quantities, while emissions trends rely on inventory estimates rather than direct compliance monitoring.

Transferability of allowances is permitted in both jurisdictions. In the United States, the Environmental Protection Agency publishes annual notices confirming that allowance transfers occur. In the European Union, transfers are recorded in the F-gas Portal, but aggregated trading volumes are not publicly available. Evidence suggests that such transfers facilitate compliance but do not constitute a large, liquid market.

Several elements of these systems appear relevant for potential cap-and-trade approaches to hazardous chemicals: robust inventories before setting the cap; multi-year allocation windows; clear long-term reduction

schedules; centralised and audited reporting; and transferability to allow substitution to start where costs are low. While hazardous chemicals present additional challenges due to diverse hazard profiles and use patterns, the experience from HFC quota systems demonstrates that quota-based approaches can provide predictability, flexibility, and cost-effective pathways for reducing harmful substances.

6.04 Endocrine Disruption: Scientific and Regulatory Challenges

6.04.T-01 Characterisation of molting disruptors in arthropods using an AOP-informed multi-species screening approach

Knut Erik Tollefsen¹, Selim Ait-Aissa², Carlos Barata Dr³, François Brion⁴, Laure Chabot², John K. Colbourne⁵, Alex R O Cousins⁶, Elena Gorokhova⁷, Henrik Holbech⁸, Taisen Iguchi⁹, Ioanna Katsiadaki⁶, E. Katsavou¹⁰, Sunghwan Kim¹¹, Youngjun Kim¹², Youngsam Kim¹², Katerina Kyriakopoulou¹⁰, Hitoshi Miyakawa¹³, Chang-Beom Park¹⁴, Pascal Pandard², Changseon Ryo¹², Jose V. Tarazona¹⁵, Monica Torres-Ruiz¹⁵, Marta vannoni¹⁶, Hajime Watanabe¹⁷, Haruna Watanabe¹⁸, Pu Xia⁵ and Li Xie¹⁹, (1)Norwegian Institute for Water Research, France, (2)National Institute for Industrial Environment and Risks (INERIS), France, (3)Chemistry, Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain, (4)INERIS, France, (5)University of Birmingham, United Kingdom, (6)Centre for Environment, Fisheries and Aquaculture Science (Cefas), United Kingdom, (7)Stockholm University, Sweden, (8)University of Southern Denmark (SDU), Denmark, (9)Yokohama City University, Japan, (10)Benaki Phytopathological Institute (BPI), Greece, (11)Kyungpook National University, Korea, Republic of, (12)Korea Institute of Science and Technology Europe (KIST-Europe), Germany, (13)Utsunomiya University, Japan, Japan, (14)Korea Institute of Toxicology, Korea, Republic of, (15)Institute of Health Carlos III (ISCIII), Spain, (16)University of East Anglia (UEA), United Kingdom, (17)Osaka University, Japan, (18)National Institute for Environmental Studies (NIES), Japan, (19)Norwegian Institute for Water Research, Norway

Molting is a central developmental process in arthropods, governed by coordinated endocrine, neuroendocrine, metabolic, behavioral, and structural pathways. These pathways are susceptible to disruption by chemicals that interfere with hormonal signaling, cuticle turnover, chitin synthesis, neuropeptide activity, or gene regulatory networks. Because molting disruption can arise through diverse and often poorly resolved mechanisms, new mechanistically anchored tools are needed to identify key events underlying toxicity and to detect molting disruptors across a broad range of arthropod species and chemicals.

This project, co-financed by the Partnership for the Assessment of Risk from Chemicals (PARC), aims to establish an integrated, AOP-informed scientific framework to characterise molting disruption using model organisms and wildlife species. The work involves sequential steps starting with a systematic review, refinement, and expansion of existing molting-relevant Adverse Outcome Pathways (AOPs). Conserved molecular initiating events, key events, and pathway linkages will be mapped and evaluated across taxa, while also identifying knowledge gaps for targeted experimental investigation.

Building on this mechanistic foundation, a suite of bioassays has been developed and will be harmonised across laboratories to quantify molecular, cellular, phenotypic, behavioral, and organism-level responses to stressors. Approaches include transcriptomics, targeted gene expression analyses, metabolomics, hormone quantification, behavioral profiling, and advanced in vitro and in vivo NAMs. Computational x-species comparisons will support identification of conserved responses and improve extrapolation across species groups.

The resulting toolbox will be applied to environmentally relevant chemicals to identify compounds capable of perturbing molting physiology and related biological pathways. Multi-endpoint and multi-species datasets will be integrated to construct quantitative AOPs (qAOPs), enabling the development of predictive models and quantitative key event relationships describing how early molecular perturbations propagate to organism-level adversity for use in Next Generation Risk Assessment (NGRA).

This presentation will summarise the scientific foundation, introduce the methodological approaches, and present results from initial steps of the work (i.e. AOP-definition, bioassay development, reference chemical testing).

Disclaimer/Disclosure:

This work was supported by the Research Council of Norway project EXPECT (RCN-315969), EU-HEU project PARC (#101057014), and NIVA's Computational Toxicology Program, NCTP (RCN-342628).

6.04.T-02 RetiNAM: Identification of Biomarkers for the Disruption of the Retinoic Acid Signaling Pathway Using a Zebrafish Embryo Model

Vanessa Fee Saalmann¹, Eva Fetter², Jürgen Arning², Gerd Maack², Susanne Walter-Rohde², Tamara Tal¹ and Stefan Scholz¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)German Environment Agency (UBA), Germany

Endocrine-disrupting chemicals are a major concern in ecotoxicology due to their ability to interfere with hormone signaling across species. Therefore, current regulations for chemicals such as REACH, have a particular focus on the identification of endocrine disruptors (ED). Standardized test methods for endocrine disruption focus on EATS (estrogen, androgen, thyroid, steroidogenesis) modalities. The retinoic acid (RA) pathway is another highly conserved endocrine signaling pathway, essential for physiological and cellular processes including neurodevelopment and morphogenesis. As RA pathway disruption can affect organisms at population-relevant levels, regulatory interest in the retinoid system has grown, with OECD efforts in 2012 and 2021 to review and harmonize regulations, focusing on key organ systems and highlighting the need for validated assays. However, there is a lack of validated methods to detect disruption of the RA signaling pathway. In line with the EU "Roadmap to phase out animal testing", new approach methods (NAMs) are needed to fill ED-related testing gaps. One strategy to identify RA disrupting chemicals is the identification of biomarkers for key events leading to apical adverse outcomes. The RetiNAM project aims to identify and quantify sensitive and specific biomarkers for RA pathway disruption in zebrafish embryos with a focus on chemicals that act via binding to the retinoid X receptor (RXR) or retinoic acid receptors (RAR), and elicit transcriptional changes leading to morphological and behavioral outcomes. We demonstrated that exposure to RAR and RXR agonists and antagonists induced specific effects, including craniofacial, fin and tail malformations. Acute neuroactivity testing indicated diverse neuroactive effects across multiple endpoints. Developmental neurotoxicity testing resulted in altered visual and acoustic startle responses. Additionally, widespread hyper- or hypoactivity were observed, respectively. These results suggest that the zebrafish embryo model can be used to diagnose RA pathway perturbations. Ongoing transcriptomic analyses will identify key RA pathway target genes, anchoring the phenotypic effects to the underlying molecular mechanisms. By integrating morphological assessment, behavioral profiling and transcriptomic analysis, this study will address current regulatory gaps in the evaluation of RAR or RXR-mediated endocrine disruption and supports the use of NAMs in environmental risk assessment.

6.04.T-03 Which Fish? Considering Inter-Species Differences in the Design of a Fish Full-Life Cycle Study with an Estrogen Receptor Degradar

Alison Nimrod Perkins¹, Suzanne Zvalaren Schneider² and Michael Lee¹, (1)Eli Lilly and Company, United States, (2)Eurofins Agrosience Services US, United States

Imlunestrant is a potent, selective estrogen receptor alpha (ER α) degrader approved for breast cancer. To evaluate environmental risk from patient use, a fish full-life cycle study (FFLC) was essential. Draft and validated FFLC guidelines vary in recommended fish species but do not consider underlying biology. Since physiological roles of ER and pharmacological specificity vary between fish species, we investigated imlunestrant's species-specific ER antagonist activity and developmental/reproductive effects across three small fish models to determine if one species was substantially more sensitive and establish appropriate test levels. Initial ER antagonist assays revealed marked interspecies variability in response to imlunestrant. Zebrafish showed IC₅₀ values of 128.3 nM (ESR1), 14.05 nM (ESR2a), 3.85 nM (ESR2b). Medaka demonstrated IC₅₀ values of 17.52 nM (ESR1), 20.42 nM (ESR2a), 34.61 nM (ESR2b). Fathead minnow exhibited IC₅₀ values of 25.37 nM (ESR1) and 0.553 nM (ESR2b), 100-fold lower than other species; ESR2a was not identified in fathead minnow at the time of this work. The paucity of data for ER knockout in fathead minnow hindered interpretation, so in vivo studies were conducted.

In vivo species sensitivity screening (21-day adult reproductive assays plus embryo-larval assessment) at nominal concentrations of 1.5, 15, and 150 μ g/L imlunestrant correlated with receptor sensitivity. Fathead minnow showed pronounced reproductive effects (31% and 79% reduction at 15 and 150 μ g/L, respectively) and concentration-dependent reductions in larval growth (13 to 32% weight reduction). Zebrafish and medaka showed minimal reproductive impacts in adults and no differences in larvae.

Based on sensitivity results, a FFLC (OECD 240) was conducted with fathead minnow. Fish were exposed continuously across three generations to five measured concentrations ranging from 0.015 to 8.1 μ g/L (F0), 0.019 to 7.1 μ g/L (F1), and 0.022 to 6.9 μ g/L (F2). At sexual maturity, the F1 generation showed significant

effects at 7.1 µg/L including reduced hatching (14%), increased male vitellogenin (80-fold), and increased length/weight in females. Males from F1 reproductive groups showed increased weight at 1.8 µg/L, the most sensitive endpoint. Gonadosomatic index and interstitial cell proliferation increased significantly at 7.1 µg/L, confirming endocrine modulation. Overall NOEC and LOEC were 0.43 and 1.8 µg/L.

6.04.T-04 Assessment of thyroid disruption using an alternative fish model, the three-spined stickleback

Ioanna Katsiadaki, Ellen Blaker, Irene Cano Cejas, Alex R O Cousins, Ben Maskrey, Megan Parker and Marion Sebire, Centre for Environment, Fisheries and Aquaculture Science (Cefas), United Kingdom

Regulatory assessment of chemicals with endocrine-disrupting properties covering oestrogen, androgen and steroidogenic pathways, are conducted traditionally using three model fish species, zebrafish, medaka and fathead minnow. However, investigations for chemicals that disrupt the Thyroid Hormone System (THS) employ amphibians.

A detailed review paper (DRP) prepared for the OECD proposed a series of biochemical, histological, and morphological endpoints for assessing THS-disrupting chemicals in fish, originally developed for zebrafish under an EU funded project, ERGO. The authors joined the OECD validation work for these endpoints and PARC, where they were tasked on strengthening the AOPs for thyroid disruption in fish, focusing on TR antagonism, a less developed molecular initiating event (MIE).

The studies presented evaluated the responses of the three-spined stickleback (*Gasterosteus aculeatus*) to two prototypic stressors, in view of expanding the taxonomic domain of applicability of fish thyroid AOPs. Exposures involved the natural thyroid receptor (TR) agonist, thyroxine (T4) and the TR antagonist, 1-850 whilst endpoints were assessed at TG236 (Fish Embryo Toxicity Test) and TG210 (Fish early life toxicity test) stages (12dpf and 40dpf respectively for this model species).

In addition to the proposed endpoints under OECD validation, we assessed behaviour and spatial gene expression, both at eleuthero-embryo level. The results are presented along with apical and thyroid specific endpoints from juvenile fish (TG210), discussing the value of these endpoints for regulatory testing and AOP development.

This work was supported by the Department of Food and Rural Affairs (Defra) and UKRI via membership of the Partnership for the Assessment of Risks from Chemicals (PARC).

6.04.P Endocrine Disruption: Scientific and Regulatory Challenges

6.04.P-Mo388 A Desk-Based Approach to Determine the New CLP Endocrine Disruption Hazard Classes

Marianne Matzke¹, Pauline Remuzat², Damien Carson³, Jamie Marshall³, John Miller³, Kai Benjamin Paul³ and Bryony Ross³, (1)Blue Frog Scientific SAS, United Kingdom, (2)Blue Frog Scientific SAS, France, (3)Blue Frog Scientific Limited, United Kingdom

With the implementation of new endocrine disruption (ED) hazard classes in the CLP regulation (Regulation (EC) No 1272/2008) and increasing regulatory scrutiny under REACH (EU & UK), the Biocidal Products Regulation (BPR) and the Plant Protection Products Regulation (PPPR), ED assessment of substances/actives must be proactively addressed to ensure compliance and market access.

Based on expert judgement through developed knowledge and experience as well as key guidance documents, we developed a flow scheme for the stepwise approach of assessing ED properties based on available and alternative information. This tiered approach, from Phase I initial screening, to Phase II full ED assessment, aids in the fulfilment of the requirements under the new CLP hazard classes, avoids additional animal testing, and aligns with state of the art of regulatory science.

In short, Phase I includes a literature search to identify possibly relevant data from open literature, an evaluation of the literature to retrieve relevant and reliable information, database searches and in silico profiling. These lines of evidence are collected in a structured excel file, which allows for the generation of Conceptual Framework (CF) Level 1 information in accordance with the ECHA/EFSA Guidance (2018). The next step is then to screen for adverse effects to human health and environmental species that may be plausibly linked to an endocrine mode of action and thus contribute evidence for the substance to be classified as an endocrine disruptor. Phase I is concluded with a screening report summarising the available data, its interpretation and any conclusions. The process either stops if no effects of relevance are identified or moves to a Phase II full ED assessment if required. Specifically, our long-standing expertise in in silico profiling underpins this regulatory compliance focused screening and assessment procedure by aiding robust conclusions on ED modalities and negating the need for additional animal testing. Here we show the flow scheme and a case study of how the lines

of evidence go toward a robust and coherent conclusion on ED.

The presented approach ensures compliance with the new CLP requirements for hazard communication on endocrine disruption based on all available data, proactively identifying potential requirements asked for by authorities, extending the longevity of submissions.

6.04.P-Mo389 Beyond EATS: How to Handle Non-EATS Data in an Endocrine Disruption Weight of Evidence Assessment

Chloe Eastabrook and Gareth Le Page, Enviresearch, United Kingdom

The recent update to ECHA's Classification, Labelling and Packaging (CLP) guidance introduced two hazard categories for endocrine disruptors (ED). As CLP does not require additional testing for hazard classification there is an emphasis on the importance of weight-of-evidence (WoE) approaches. Thus, assessments rely on existing data, often from the open literature where reliability and relevance can vary significantly.

Current regulatory focus has largely centred on EATS-mediated pathways (estrogen, androgen, thyroid, and steroidogenesis). However, the updated CLP guidance also acknowledges non-EATS mechanisms despite providing no guidance on how to define these or how they should be evaluated. Non-EATS data will likely originate from studies without standardised test guidelines and might include non-standard species, adding further complexity to interpretation. While non-EATS modalities were mentioned in the ECHA EFSA 2018 guidance for pesticides and biocides, the CLP update has brought renewed attention to these often less-characterised modalities.

Integrating non-EATS data into regulatory assessments presents challenges, including the lack of standardised testing frameworks, limited adverse outcome pathway (AOP) development beyond EATS, and the need for robust criteria to assess relevance and reliability. This poster will discuss these additional challenges to an already highly complex assessment process. Alongside this, practical approaches for scoping and incorporating non-EATS data and modalities into ED assessments will be explored, ensuring current EU regulatory requirements are met.

6.04.P-Mo390 Endocrine Disruption Assessments – Where Yesterday's Submissions Meet Today's Expectations

Eva Eschenbach and Florian Zindler, Exponent, Germany

The evaluation of substances for potential endocrine disrupting (ED) properties in non-target organisms is a key component of chemical risk assessment. However, only in 2018 these assessments became mandatory and around the same time, EFSA and ECHA published a joint guidance document designed to support the selection of appropriate testing strategies and the evaluation of conducted studies. Since then, both applicants and regulators have gained substantial experience in the evaluation of ED studies and accompanying assessments, and the overall knowledge base has expanded significantly.

Given that many submissions were originally prepared at a time when regulatory expectations and experience were still limited, while the evaluation of active substance renewals can extend over several years, a common challenge arises: Studies and accompanying assessments were often submitted when experience was still developing, yet they are reviewed later against a much broader and more mature body of case examples. As a result, discrepancies frequently occur between the applicant's conduct and interpretation of the data at the time of submission and the regulators' evaluation at the time of review. Furthermore, the scientific literature continues to expand rapidly, and applicants often receive requests from stakeholders to assess the relevance of newly published peer reviewed studies for ongoing renewal processes.

Due to the procedural constraints of the renewal process, opportunities to address comments from the regulators and other stakeholders after submission are limited, particularly when additional information, new studies or extensive literature evaluations are required to resolve outstanding concerns.

It is therefore crucial to review existing ED assessments and studies for completeness and relevance against the current state of the (regulatory) science. To this end, we propose strategic approaches for proactively managing potential uncertainties within submitted ED studies and assessments and provide recommendations for the systematic evaluation of relevance and reliability of scientific literature. The aim is to better anticipate regulatory requests, strengthen the scientific robustness of submissions, and minimise the need for additional testing. Insightful examples are provided to highlight the untapped potential of study raw data, the importance of historical controls, and the practical application of recent scientific and regulatory recommendations.

6.04.P-Mo391 Assessment of Endocrine Effects of Construction Products in the Environment

Elena Perabo¹ and Peter Behnisch², (1)Hydrotox GmbH, Germany, (2)BioDetection Systems BV, Netherlands

Endocrine disruptors are substances that interfere with the hormonal systems of humans and animals and can cause harmful effects even at extremely low concentrations. They influence vital processes such as reproduction, development, growth, and behavior. These endocrine-disrupting chemicals (EDCs) are present in many synthetic products – including construction materials, whose hormonal effects are often insufficiently understood because no comprehensive testing is required before they are placed on the market.

Considering this background, there's an urgent need to systematically investigate EDC-related risks and to identify alternative construction products that are safe for human health. This serves consumer protection and supports the EU's goals within the framework of the circular economy and the zero-pollution strategy. The contamination of groundwater and especially of drinking water as a potential consequence with EDCs released by construction products should be prevented in future.

The aim of the research project is to evaluate construction products regarding potential endocrine effects in environmentally exposed applications. The basis for this is the European testing standard DIN CEN/TS 17459:2023-02, which provides guidance for the assessment of the release of hazardous substances via eluates. However, this standard currently does not include any tests for detecting endocrine effects.

The project therefore examines the suitability of commercially available, particularly standardized endocrine test methods (such as ISO 19040-3 for estrogenic activity, ER CALUX) for the investigation of construction-product eluates. The objective is to develop scientifically sound recommendations for expanding the testing methodology to include appropriate endocrine assays.

In addition, proposals will be developed on how endocrine effects can be integrated into the certification criteria of Blue Angel ecolabel to make safe products identifiable to consumers.

Work Package 1 involves a literature review on suitable endocrine tests for aqueous samples and on hormonally active substances in construction products intended for outdoor use. This review forms the basis for a testing program in Work Package 2, which includes 20 construction products and four laboratory tests for detecting endocrine effects. Product selection is based on environmental relevance, while the tests consider both acute and chronic effects as well as scientific, practical, and economic aspects.

6.04.P-Mo392 From Literature Search to Regulatory Assessment: Addressing Endocrine Disruption with Non-Standardized Data

Imke Van Dingenen¹, Finn Thomson¹, Nele Deleebeeck², Michiel Claessens¹ and Bart Kerré¹, (1)Arcadis, Belgium, (2)ArcelorMittal, Belgium

In 2023, new hazard classes for endocrine disruption (ED) were introduced under the European Classification, Labelling and Packaging (CLP) Regulation (Regulation (EC) No 1272/2008). All substances and mixtures products placed on the EU market must be classified according to these new hazard classes by the applicable deadline. As CLP does not require the generation of new test data, companies and regulators should rely exclusively on existing data.

In the current project, a comprehensive literature search was conducted to determine the current knowledge on potential ED activity and adverse effects for a series of rare earth elements (REEs). One of the main challenges for these types of literature searches is the lack of harmonized guidance for assessing the reliability and regulatory adequacy of data derived from non-standardized studies. Therefore, available guidance documents (e.g. OECD guidance document 150 on the testing and assessment of endocrine disruption, ECHA/EFSA guidance, CLP and REACH endpoints specific guidance) were used to extract relevant criteria to develop a tailored strategy and template for systematically assessing the reliability of literature data on endocrine disruption properties. Key aspects addressed include the evaluation of study design (e.g., test species, endpoints measured), limitations in the study design, relevance to ED mechanisms (such as estrogenic, androgenic, thyroid, and steroidogenic pathways). The proposed template and strategy represent a step forward in bridging this regulatory gap and may serve as a foundation for future harmonized approaches in the evaluation of non-standardized ED studies.

This project highlights the need for further regulatory and scientific guidance on the assessment of non-standardized ED data to facilitate the effective use of available evidence for regulatory decision-making under

the revised CLP Regulation. Improved guidance will be essential to ensure both the protection of human health and the environment and the efficient management of substances lacking standardized data, such as REEs.

6.04.P-Mo393 Weighing the Real Evidence and Avoiding the ED Trap

Nicola Dennis and Stephen Ruckman, Sagentia Regulatory, United Kingdom

Since 2018, it has been a requirement for active substance renewal and new active substance registration to provide an assessment on the endocrine disrupting properties of a pesticide in accordance with EFSA / ECHA Guidance for the identification of endocrine disruptors in the context of Regulations (EU) No 528/2012 and (EC) No 1107 / 2009. In a bid to harmonise assessments for endocrine disruption, an expert meeting was held in November 2024, a report on the outcome of this meeting was published in October 2025 (Recurring issues in mammalian toxicology and ecotoxicology related to endocrine disruptors. EFSA Supporting publication 2025:EN9743). Common challenges in the interpretation of non-target organism data were identified and include:

- High variability and poor reporting of vitellogenin (VTG) a biomarker used to identify EAS (estrogen, androgen and steroidogenesis) activity in fish.
- Quality of reporting for histopathological evaluations.
- Data limitations leading to a limited weight of evidence and uncertainty.
- Limited experience in performing and interpreting Conceptual Framework Level 5 data.

We present supportive evidence to open up the discussion on the challenges of interpreting endocrine disruptor data, particularly when faced with identifying a plausible link between adversity and endocrine activity when an alternative non-endocrine mode of action may be the driver. Focussing primarily on the EAS modality, we will discuss how variability in VTG data can lead to uncertainty. Particularly when looking at the influence and relevance of possible outliers. Should effects only be considered at the replicate level even if this seems improbable at the individual level. Can histopathologists reliably opine on the potential for endocrine disruption without sight of the whole dataset. How is uncertainty balanced when looking at the weight of evidence particularly when considering a non-endocrine mode of action. Is there sufficient knowledge within Industry and Regulatory Authorities to critically assess alternative pathways that may be based on years of targeted academic research. How easy is it to move away from the tiered approach of testing under the Conceptual Framework to generate data to answer specific questions.

6.04.P-Mo394 Is it time to revisit threshold levels for endocrine disruptors?

Rebecca Jayne Brown and Grace Panter, wca environment Ltd., United Kingdom

The European Union (EU) approach for assessment of most chemicals with an endocrine disrupting (ED) mode of action is to assume there is no safe level of exposure. ED hazard assessment has been adopted based on legitimate concerns regarding the potential for low concentration responses (LCR) and non-monotonic concentration responses (NMCR) following exposure to some endocrine active substances. Although hazard-based regulation has improved understanding of ED modes of action there are concerns that it relies on intensive animal testing, focuses on effects at high concentrations, can be time consuming to reach a conclusion and can lead to unfortunate substitutions. In addition, it limits potential for exposure-based waivers for low volume or readily biodegradable substances which will never be present in the environment at meaningful concentrations and is a barrier to adoption of exposure based next generation risk assessment approaches. Standardisation of fish endocrine toxicity tests (increased replication, advice on concentration setting, minimising solvent use, etc.) has improved confidence in their outcomes and the routine inclusion of biomarker endpoints means that there is supporting information regarding mechanistic effects and concentration response relationships. Case studies with estrogenic substances, azole fungicides and pharmaceuticals are used to demonstrate that NMCR and LCR are not the rule and that it is possible to derive threshold levels for many ED substances. This provides a basis for rethinking regulation of ED substances to allow a more pragmatic approach in scenarios where exposure is negligible.

6.04.P-Mo395 Assessment gaps and opportunities in regulatory endocrine disruptor testing of fish – a scientific perspective

Lisa Annie Baumann¹, Henrik Holbech², Dries Knapen³ and Lucia Vergauwen³, (1)VU University Amsterdam (VU), Amsterdam, Netherlands, (2)University of Southern Denmark, Denmark, (3)University of Antwerp, Belgium

Regulatory assessment of endocrine disruptors (EDs) in fish relies largely on established OECD test guidelines (TGs), yet these protocols make limited use of the biological information that could be obtained from exposed

animals. While EU chemical regulation increasingly requires animal testing for ED identification, the upcoming EU roadmap for phasing out animal experiments aims to achieve the opposite. This is problematic, as for the identification of EDs an adverse effect, an endocrine activity, and a biologically plausible link between the two has to be demonstrated. However, demonstrating endocrine adversity currently still requires data from animal experiments and cannot (yet) be generated through new approach methodologies (NAMs) alone. Improving existing fish tests is therefore essential as the currently established OECD in vivo TGs often fail to exploit the full potential of animal experiments.

We summarized endpoints included in validated OECD TGs using fish and compared them with additional endpoints that could technically be assessed but are not currently required. Across 91 possible endpoints, only 31% are mandatory in present TGs, leaving 69% of available biological information unused. The gaps span molecular, physiological, morphological, and behavioural levels. Despite their routine use in research and diagnostic laboratories, transcriptomic analyses, hormone measurements, expanded histopathology of organs beyond the gonads, and systematic behavioural assessments are still not included in fish regulatory tests. Their integration would substantially strengthen mechanistic interpretation, support identification of adversity, and increase the scientific robustness of ED evaluations without increasing animal use.

This simple but insightful analysis demonstrates that there is a strong potential to improve regulatory decision-making and ensure more ethical, scientifically sound use of animals in ED assessment by including multiple relevant endpoints assessed with existing routine methodologies.

6.04.P-Mo396 Best Practices on the Conduct of The Fish Sexual Development Test (FSDT) – OECD TG 234 – Part 1

Francesca Pellizzato, Conor Clenaghan, Helene Serra-Niemininen, Pamela Campbell, Marta Sobanska and Vincent Bonnomet, European Chemicals Agency (ECHA), Finland

The Fish Sexual Development Test (FSDT) according to the OECD TG 234 is a validated test guideline targeting early life stages of development to assess effects on vitellogenin (VTG) and sex ratio. It provides information on both the endocrine activity and adversity of potential endocrine disruptors (ED). It is the main test requested under REACH in the substance evaluation process to clarify endocrine disrupting properties related to estrogenic, androgenic and steroidogenic modalities in fish. The test can also be requested under REACH during the compliance check process instead of the fish early life stage test (OECD TG 210) if there are triggers that the substance is potentially an ED. The information obtained from an OECD TG 234 study may provide conclusive evidence on the ED properties of a substance leading to its identification as a Substance of Very High Concern under REACH and/or its classification as an ED under the classification, labelling and packaging (CLP) Regulation. Since its adoption in 2011, the test has been requested by Member States or ECHA in more than 20 decisions under REACH. Because it requires testing on vertebrate animals, it is important to ensure that the test is performed as requested and provides reliable information. Using the accumulated experience on FSDT studies, an ad-hoc working group was established in 2025 by Member States and ECHA to review the test performance and address the main challenges identified. The analysis focused on 15 studies received under REACH and conducted by 8 different laboratories: 13 performed with zebrafish and 2 performed with Japanese medaka. Based on that analysis and following the discussions in the ad-hoc working group, a technical note has been prepared outlining key requirements and recommendations for the conduct and reporting of FSDT studies according to OECD TG 234.

This poster presents Part 1/2 of the technical note, which provides clarifications on specific requirements of the test guideline - including duration of the test, redistribution of the fish, sex ratio and exposure concentrations for difficult-to-test substances - to improve the performance of the studies. A separate abstract has been submitted (Part 2), which covers practical recommendations to support the performance and reporting of the test.

6.04.P-Mo397 Best Practices on the Reporting of the Fish Sexual Development Test (FSDT) – OECD TG 234 - part 2

Francesca Pellizzato, Conor Clenaghan, Vincent Bonnomet, Marta Sobanska, Pamela Campbell and Helene Serra-Niemininen, European Chemicals Agency (ECHA), Finland

The Fish Sexual Development Test (FSDT) according to the OECD TG 234 is a validated test guideline targeting early life stages of development to assess effects on vitellogenin (VTG) and sex ratio. It provides information on both the endocrine activity and adversity of potential endocrine disruptors (ED). It is the main test requested under REACH in the substance evaluation process to clarify endocrine disrupting properties related to estrogenic, androgenic and steroidogenic modalities in fish. The test can also be requested under REACH during the compliance check process instead of the fish early life stage test (OECD TG 210) if there are

triggers that the substance is potentially an ED. The information obtained from an OECD TG 234 study may provide conclusive evidence on the ED properties of a substance leading to its identification as a Substance of Very High Concern under REACH and/or its classification as an ED under the classification, labelling and packaging (CLP) Regulation. Since its adoption in 2011, the test has been requested by Member States or ECHA in more than 20 decisions under REACH. Because the test requires testing on vertebrate animals, it is important to ensure that it is performed as requested and provides reliable information. Therefore, with this accumulated experience, an ad-hoc working group was established by Member States and ECHA to review the test performance and address common challenges. The analysis focused on 15 studies received under REACH, 13 using zebrafish and 2 using Japanese medaka, performed by 8 different laboratories. Based on that analysis and the discussions in the ad hoc working group, a technical note has been developed outlining key requirements and recommendations for the conduct and reporting of FSDT studies according to OECD TG 234.

This poster presents Part 2/2 of the technical note, focusing on practical recommendations for study performance and reporting. This part of the note supplements the requirements in the OECD TG 234 by including further guidance on the selection of test concentrations, evaluation and documentation of histopathological endpoints, and assessment of vitellogenin levels. A separate abstract has been submitted (Part 1), which addresses specific requirements of the test guideline.

6.04.P-Mo398 Does age matter?: An Investigation of the Variation in Vitellogenin Production Compared to Fathead Minnow (*Pimephales promelas*) Age Using Historical Control Data

Amy Snow, Smithers, United States

Vitellogenin (VTG) is the egg yolk precursor protein produced by the liver in fish, a process thought to be mediated by estrogen, androgen and steroidogenic (EAS) modalities. Test guidelines for potential endocrine disruptors have integrated this biomarker (in combination with other weight of evidence) as a method of detecting interference with the endocrine system. The highly variable data produced from this indicator has been shown to be a challenge in endocrine screening assays as decreased statistical sensitivity is prevalent. The variability of VTG concentration among fish of the same sex has been attributed to several different factors (e.g. naturally occurring variability, spawning cycle timing, etc.). This investigation utilized historical control data to compare the plasma VTG concentrations from both male and female fathead minnow (*Pimephales promelas*) in order to evaluate the variability in comparison to the age of the fish. Data from Fish Short-Term Reproductive Assays, Fish Sexual Development Tests and Fish Full Life Cycle Tests (modified to include endocrine endpoints) were analyzed in order to determine a potential correlation between VTG concentration and age. In addition, potential correlations between other variables (e.g. wet body weight and fecundity) were explored. This analysis aims to understand a potential cause for the variability in VTG concentrations of sexually dimorphic Fathead Minnow to potentially inspire changes in guidance for future testing.

6.04.P-Mo399 Body weight change in Fish Short Term Reproduction Assays

James Robert Wheeler¹, Valentin Mingo² and Davood Poursina³, (1)Corteva Agriscience, Netherlands, (2)Corteva Agriscience, Germany, (3)Corteva Agriscience

The Fish Short Term Reproduction Assay (FSTRA) is a screening assay for the Estrogen, Androgen and Steroidogenesis modalities in fish. Sexually mature spawning male and female fish are held together and exposed to a chemical for 21 days. Symptoms of toxicity, fecundity and fertility are assessed daily. At termination vitellogenin, secondary sexual characters (species dependent) and gonad histopathology are analysed. Measurements of wet weight and length are taken before the exposure to ensure the fish are within a suitable size and variability range. The OSCPP test guideline also requires measuring body and gonad weights at termination to calculate the Gonadal Somatic Index. It has been demonstrated that many of the mechanistic endpoints may be affected by generalised toxicity or are correlated to body size. Therefore, it is of high interest to understand how body weight change can be assessed in range finding and FSTRA studies to improve test designs and interpretation of results. In analogy to how such assessments are used in mammalian toxicology studies. Here, we analyse the results of a historical dataset of FSTRA studies to explore what range of weight changes have been observed and if there is any relationship with effects on the FSTRA endpoints. We then use a recently performed FSTRA dietary restriction study to explore the power of assessing body weight change. Recommendations for implementing body weight change in FSTRA studies are made. We hope these analyses will support further use of body weight data in the performance and interpretation of FSTRAs conducted for regulatory and research purposes.

6.04.P-Mo400 Why not Medaka?: An Overview for the use of Japanese Medaka (*Oryzias latipes*) as a Model Species for Endocrine Disruption Investigation Using Historical Control Data

Tracey Jayne Goodband, Smithers, United Kingdom

Over the last decade, more emphasis has been placed on the investigation of potential endocrine activity of chemicals on fish with new requirements under EFSA/ECHA and US FDA/EPA. Standard OECD in vivo guidelines for investigating potential endocrine activity in fish include the Fish Short Term Reproduction test (OECD 229), Fish Sexual Development Test (OECD 234) and the Medaka Extended One Generation Reproduction Test (OECD 240). The Japanese Medaka (*Oryzias latipes*) is recommended as a test species in these guidelines and is specific to the OECD 240 (MEOGRT), which is the only Tier 5 test for aquatic organisms.

The small size, relatively short life cycle, easily identifiable phenotypic secondary sex characteristics and genetic sex determination makes *O. latipes* an excellent species for laboratory testing. However, it is not a species that has been traditionally used in Europe or America with most CROs preferring fathead minnow and/or zebrafish. As such, there is a lack of experience with the species and historical control data (HCD) is limited. This presentation will discuss HCD data collected at Smithers ERS over the last 7 years from studies conducted with medaka with specific emphasis on the MEOGRT.

6.04.P-Mo401 Medaka and Zebrafish Display Contrasting Responses to Chronic Exposure to Ethinyl Estradiol

Audrey Phan¹, Larissa Kern², Helmut Segner², Lisa Annie Baumann³, Gregory F. Lemkine⁴ and Andrew Tindall⁴, (1)Masaryk University, France, (2)Centre for Fish and Wildlife Health, University of Bern, France, (3)VU University Amsterdam (VU), Amsterdam, Netherlands, (4)Laboratoire Watchfrog, France

Medaka and zebrafish have become standard models to study the impacts of endocrine disruptors on fish. Although these two species of fish share many similarities and advantages, there are important differences in terms of sex differentiation which could influence the results of studies relating to the reproductive axes. To determine the sensitivity of physiological responses of the two species to estrogenic chemicals, we conducted two parallel chronic exposures of both medaka and zebrafish with ethinyl estradiol (EE2). The fish were exposed from fertilisation to 60 days post hatch in an OECD test guideline 234-like exposure. Fish were then reared in clean water for 3-4 months. Endpoints were measured at both the end of the exposure phase and the end of the depuration phase and included physical condition, mortality, gene expression, gonadal sex, reproductive competence and F1 larval survival.

In response to EE2, medaka exhibited an increase in the expression of genes regulated by estrogenic signalling such as vtg and ER α , increased incidence of intersex in genetically male fish, a female biased sex ratio and reduced F1 survival. Expression of vtg and ER α was also increased in zebrafish exposed to EE2. However, after the exposure period, there appeared to be a delay in sex differentiation in zebrafish in response to EE2 and following the depuration period, adult zebrafish exposed to 10 or 30 ng/L EE2 were all phenotypically male. As it was impossible to determine genetic sex with this strain of zebrafish, it is unclear whether the male skewed sex ratio was due to EE2 provoking stress-induced masculinisation of fish that would have developed as female and/or selective mortality of female fish. Histopathological analyses of juvenile zebrafish (30 ng/L) revealed very high amounts of proteinaceous fluid (presumably VTG) in kidney tubuli. Excessive hepatic VTG production can reach levels that exceed renal filtration capacities, leading to death. These effects may have caused female-specific mortality.

Metabolomic studies may also give insights into whether increased mortality and delayed sexual differentiation are linked to increased energy expenditure due to over stimulation of the production of glycoproteins required for oocyte production following exposure to exogenous estrogens. It remains to determine to what degree these effects on sex differentiation are due directly to endocrine signalling and whether they are representative of wild-type ZZ/ZW zebrafish.

6.04.P-Mo403 Assessment of Thyroid Hormone System Disrupting Effects of the Insecticides Diflubenzuron and Pyriproxyfen During Early Zebrafish Development

Rafaela da Silva Brito¹, Elise Pesce², Nathalie Hendriks³, Bruno Fiorelini Pereira¹ and Lisa Annie Baumann³, (1)Universidade Federal de São Paulo, Brazil, (2)Vrije Universiteit, France, (3)Vrije Universiteit, Netherlands

Mosquito larval control in the Global South relies on insect growth regulators such as diflubenzuron (DFB) and pyriproxyfen (PPF), which the World Health Organization recommends as a vector control strategy. Although these larvicides exhibit low acute toxicity, they may still affect non-target aquatic organisms at sublethal concentrations, possibly acting as endocrine disruptors. This study employs a recently developed Adverse Outcome Pathway (AOP) framework-based experimental approach to assess whether DFB and PPF act as potential thyroid hormone-disrupting chemicals (THDCs) in fish. Using Tg(tg:mCherry) zebrafish (*Danio rerio*) embryos, we measured swimming behavior and thyroid follicle development after 96 h of exposure to DFB and PPF (nominal concentrations of 1, 2, and 4 mg/L). Both compounds led to a significant increase in thyroid follicle fluorescence intensity, indicating changes in thyroid development and activity. Light–dark behavioral testing revealed increased swimming during the light phase and decreased swimming during the dark phase, suggesting neurodevelopmental effects and/or altered visual processing. These results are consistent with the AOP proposed by Götz and colleagues (2022), in which thyroid peroxidase (TPO) inhibition leads to retinal layer changes that can affect visual function and swimming performance in fish. Ongoing histopathological analyses of retinal structure aim to determine whether DFB and PPF exposure had direct impact on eye development, the key event of the AOP which would support their classification as THDCs. Additional assessments will examine potential neurotoxic effects of DFB and PPF in the Tg(eno2:Cerulean, gfap:mCherry, mbp:citrine) triple-transgenic line and estrogenic effects in the Tg(vtg1:mCherry) line. These findings will provide detailed insight into the effects of DFB and PPF on non-target organisms and thereby provide critical evidence to guide the development of future environmental regulations on larvicide use in the Global South.

6.04.P-Mo404 Identification of Histopathological Reference Points in the Brain of Zebrafish Embryos to detect Morphological Changes induced by Endocrine Disruptors

Nathalie Hendriks¹, Elise Pesce² and Lisa Annie Baumann³, (1)VU University Amsterdam (VU), Netherlands, (2)VU University Amsterdam (VU), France, (3)VU University Amsterdam (VU), Amsterdam, Netherlands

Thyroid hormone system-disrupting chemicals (THSDCs) can interfere at different level of the Hypothalamic-pituitary-Thyroid (HPT) axis, and exposure during early life stages can lead to different adverse effects, such as impaired neurodevelopment. As the HPT axis is highly conserved among vertebrates, zebrafish embryos provide a powerful model for studying thyroid disrupting effects. The Thyroid-Fish Embryo toxicity (tFET), was developed in the ERGO project and is currently under OECD validation. This assay covers multiple endpoints related to THSD (TH levels, swim bladder inflation, eye development, and thyroid follicle morphology using a transgenic line).

Data from tFET experiments performed in the ERGO project show that exposure to different model THSDCs during early life stages (from 0 to 120 hpf) impaired normal eye development. To assess this adverse effect, histopathology was used to measure the thickness of retinal layers and to assess morphological changes in eye development (see AOP#365). During those analyses it was observed that the THSDC exposure also had an effect on brain development of exposed zebrafish embryos, an effect that is well established in mammals. Consequently, as a follow-up to the work conducted in ERGO, the present study aims to investigate potential morphological alterations in the developing brain using the same histological sections.

The first step to establish such an assessment is to identify reliable histopathological reference points in different regions of the brain of zebrafish embryos to subsequently detect and measure morphological changes that are comparable between individuals.

To investigate brain development across multiple regions, specific histological sections were selected based on the presence of distinct morphological structures that could serve as reliable reference points. These reference points were chosen from different region of the brain to allow detection and comparison of morphological changes across regions.

By identifying consistent reference points within the embryonic brain, additional quantitative information can be extracted, including the grey-to-white matter ratio in different brain regions and total brain area relative to overall embryo area. This approach could provide valuable evidence of neurodevelopmental impairment caused by THSDC exposure and may additionally help to determine whether it exerts region-specific effects on brain development.

6.04.P-Mo405 Endocrine Disruption of Zebrafish Brain and Sensory Organ Development

Clara Kempkens Palacios¹, Elise Pesce², Nathalie Hendriks¹ and Lisa Annie Baumann³, (1)VU University

Amsterdam (VU), Netherlands, (2)VU University Amsterdam (VU), France, (3)VU University Amsterdam (VU), Amsterdam, Netherlands

Thyroid hormones (THs) are crucial for neurodevelopmental processes of vertebrates, making them potential targets of endocrine disruptors. Accordingly, impaired neurodevelopment is the primary adverse health effect of THSDs in humans, while it has not been sufficiently addressed from that perspective in fish. A recently established adverse outcome pathway (AOP) shows the link between lowered TH levels and impaired eye development resulting in impaired vision and lowered survival of fish (AOP #365). However, the impact of TH system disruptors (THSDs) on other neurodevelopmental processes, such as brain and sensory organ formation have not sufficiently been studied in fish. Consequently, the present project aims to fill knowledge gaps on TH-regulated development of the fish brain and sensory organs, such as the olfactory epithelium and the lateral line. The findings will be set into an environmental context by investigating the impact of THSDs on development and function of these important parts of the nervous system in developing fish embryos. This will be done according to the AOP concept to identify critical neuro-related endpoints for THSD in fish that are also relevant for risk assessment of other vertebrates and humans. Different transgenic zebrafish lines with fluorescently labelled nervous and sensory cells will be exposed to different model THSDCs to study the impact on specific neurodevelopmental processes from molecular up to behavioural level.

Disclaimer/Disclosure:

The PhD project will start in December 2025. First results will be presented at the 36th SETAC Europe annual meeting in May 2026.

This PhD project is part of the EU project “NeXED”, which is funded by the European Union’s Horizon Europe Research and Innovation programme, under the Marie Skłodowska-Curie Action (Grant Agreement number 101168892).

6.04.P-Mo406 Brain Morphology Impairment in Zebrafish Embryos as an Endpoint of Thyroid-related Developmental Neurotoxicity

Elise Pesce¹, Nathalie Hendriks², Peter Cenijn² and Lisa Annie Baumann³, (1)VU University Amsterdam (VU), France, (2)VU University Amsterdam (VU), Netherlands, (3)VU University Amsterdam (VU), Amsterdam, Netherlands

Thyroid Hormone System Disrupting Chemicals (THSDCs) are known to affect the development of the nervous system in vertebrates by interfering with the thyroid hormone system (THS) during early-life development. THs play a crucial role in brain development, including the differentiation of various brain cell types, such as oligodendrocytes. As a result, assessing THS disruption effects on brain development is a significant concern for environmental and human health safety.

We are currently investigating the effects of THS disruption using a triple-transgenic zebrafish (*Danio rerio*) line which allows for the quantification of three different brain cell types and thereby the detection of developmental neurotoxicity (DNT). In this line, neurons, astrocytes and oligodendrocytes express three distinct fluorescent proteins, driven by the regulatory sequences of enolase 2, glial fibrillary acidic protein, and myelin basic protein, respectively. In this study we focus on the oligodendrocyte differentiation as a potential DNT endpoint. Previous studies have shown alterations in oligodendrocytes differentiation following exposure to several DNT compounds and THSDCs. Consequently, we are investigating exposure to different THS disruption mechanisms of action, that likely result in structural alterations of oligodendrocytes.

After 5-days of exposure to model compounds, T3 and Propylthiouracil (TH synthesis inhibitor), we firstly investigated oligodendrocytes structural alterations in zebrafish embryos by confocal imaging. Results show that the volume of oligodendrocytes in the brain decreased in PTU-exposed fish and increased in T3-exposed fish. Secondly, to confirm dysregulation in key genes expression involved in neurodevelopmental processes, we are investigating thyroid- and brain-related gene expression and DNT biomarkers. After validation of the methods using the model compounds, two environmental relevant pollutants, known for their THS disrupting properties, triclosan and benzophenone-2, will be tested in this model. These new brain-specific approaches will be combined with specific TH-related endpoints as TH levels and thyroid follicle morphology to assess sensitivity and specificity of oligodendrocytes imaging.

In summary, our data suggest that new endpoints focusing on DNT could be a great addition for THS disruption assessment in zebrafish embryos, as the recently developed tFET (thyroid Fish Embryo Toxicity test) currently under OECD validation.

6.04.P-Mo407 Screening ANSES priority substances for thyroid activity using two Eleuthero-embryonic Bioassays

Sara Cvetkovics¹, Barbara Robin-Duchesne¹, Laurent Sachs², Gregory F. Lemkine¹ and David Du Pasquier¹, (1)Laboratoire Watchfrog, France, (2)Laboratoire Physiologie Moléculaire et adaptation- Muséum National d'Histoire Naturelle, France

Chemical disruption of thyroid function can occur through multiple modes of action (MoA), and there is a growing need for whole-organism assays capable of detecting diverse mechanisms while remaining aligned with the principles of animal welfare. Two complementary eleuthero-embryonic tests have been developed for this purpose: the *Xenopus* Eleuthero-embryonic Thyroid Assay (XETA), OECD test guideline n°248, based on a transgenic *Xenopus laevis* line expressing GFP under a thyroid-responsive promoter, and the Transgenic Eleuthero-embryo Thyroid Specific test (TETHYS), based on a transgenic medaka line expressing GFP in thyroid follicles under the thyroglobulin promoter. Both assays operate over 72 hours and make use of non-protected developmental stages, offering an ethical and rapid screening strategy.

As part of the French national effort to strengthen the evaluation of endocrine disruptors, ANSES established a priority list of 16 chemicals requiring targeted testing because of suspected endocrine-related effects, environmental occurrence, or human exposure potential. This list includes industrial chemicals, pesticides, metabolites, and transformation products for which in vivo endocrine data are limited or insufficient for regulatory decision-making. In this study, these priority substances were screened for thyroid activity using both the XETA and TETHYS assays.

XETA primarily detects MoA affecting thyroid hormone signaling, while TETHYS provides complementary sensitivity to mechanisms involved in thyroid hormone synthesis, including iodine-uptake inhibition. Among the substances tested, four demonstrated clear thyroid activity: two were positive in XETA and two in TETHYS. These findings highlight the mechanistic complementarity of the two assays and the value of applying them in parallel to improve the detection of thyroid-active substances. For each active chemical, preliminary MoA hypotheses were generated by comparing the profiles obtained with those of previously characterized reference compounds.

Overall, this study demonstrates that combining XETA and TETHYS provides a robust and ethically improved approach for identifying thyroid-active chemicals. This dual-assay strategy enhances MoA coverage and supports more reliable prioritization.

6.04.P-Mo408 Bridging In Vivo and In Vitro Evidence from New Approach Methodologies (NAMs): Comparing XETA and ToxCast Data to Identify Thyroid-Active Substances

David Du Pasquier¹, Barbara Robin-Duchesne¹, James Robert Wheeler², Paula Garcia³, Laurent L.-M. Lagadic⁴ and Gregory F. Lemkine¹, (1)Laboratoire Watchfrog, France, (2)Corteva Agriscience, Netherlands, (3)Corteva Agriscience, United Kingdom, (4)Bayer AG, Crop Science Division, Environmental Safety, Germany

The identification of thyroid-active chemicals remains a major challenge for hazard assessment. The thyroid system can be affected through various mechanisms, including hormone synthesis, metabolism, and receptor-mediated pathways. To improve mechanistic understanding, it is essential to establish the coherence between in vivo and in vitro New Approach Methodologies (NAMs) targeting the thyroid axis.

The *Xenopus* Eleutheroembryonic Thyroid Assay (XETA) is an OECD test guideline (OECD TG 248) for identifying thyroid active chemicals. The XETA uses fluorescent *Xenopus laevis* transgenic eleutheroembryos to identify activity of the thyroid axis and how it can be altered by chemicals. As it uses non-protected embryonic life-stages, according to the current EU legislation on the protection of experimental laboratory animals, the XETA is considered a NAM.

In the present work, we conducted XETAs with reference chemicals selected with existing knowledge on their specific mechanism of action in mammals to expand the dataset of reference chemicals that were used in the OECD validation of the test guideline. In total, 60 reference chemicals have now been tested in the XETA. These substances were selected to represent a broad range of mechanisms, including thyroid peroxidase inhibition, thyroid hormone synthesis disruption, altered deiodinase activity, and competitive binding to thyroid hormone transport proteins.

To further explore the mechanistic concordance between in vivo and in vitro NAMs, we have interrogated the CompTox Chemicals Dashboard containing relevant high- throughput bioactivity data (ToxCast and Tox21 databases) to retrieve assay data for the same set of chemicals. We have then performed a comparative analysis to evaluate the level of agreement between the responses in the XETA and the high- throughput in vitro

mechanistic signatures.

This combined analysis aims to (i) assess the reliability of the XETA in capturing thyroid-related mechanisms of action; (ii) identify consistencies and discrepancies with in vitro assay outcomes; and (iii) contribute to the integration of mechanistic data in a weight-of-evidence approach for endocrine disruptor identification. Ultimately, this work will help clarify how amphibian-based embryo assays and large-scale in vitro screening platforms can be used to support the implementation of NAMs and provide confidence in the assessment of thyroid-active substances within regulatory contexts.

6.04.P-Mo409 Impact of a Mixture of Organic Pollutants on the Thyroid Axis

Manon Bonnelle¹, Sébastien Le Mével¹, Clémence Soulier¹, Chloé Wu², Clara Han³, Stéphane Reynaud⁴ and Jean-Baptiste Fini¹, (1)CNRS/MNHN, France, (2)Student, France, (3)Laboratoire d'Ecologie Alpine, France, (4)Laboratoire d'Ecologie Alpine, France

Endocrine disruptors are widely recognized for their adverse effects on human and environmental health. Studies suggest that their ubiquitous presence impact amphibian metabolism, contributing to their decline over several decades. In this context, a mixture of six obesogenic EDs (TBT [organotin compound], TCS [chlorophenol / antimicrobial agent], DDE [organochlorine pesticide metabolite of DDT], PBDE [brominated flame retardant], BaP [polycyclic aromatic hydrocarbon – PAH], and DEHP [phthalate plasticizer]) was assessed at concentrations corresponding to environmental quality standards (EQS) during short- and long-term exposure in *Xenopus tropicalis* at three developmental stages (NF47, 62, and 65). We hypothesized that metabolic dysregulation observed on liver by our collaborators could find some origins in brain and thyroid gland, given that the thyroid system plays a key role in metabolic regulation.

Regarding the F0 generation, short-term exposure (4 days post fertilization; NF47) induced an increased cell proliferation and reduced cell mortality in the brains of exposed tadpoles. We assessed mobility of animals with light/ dark stimulus. *X. tropicalis* eleutheroembryos were naturally more active in darkness, and exposure significantly intensified this mobility. At the molecular level, using RNAseq, exposure to the mixture led to deregulation of several genes involved in metabolism and thyroid function. In the long term (3 weeks), histological analyses on premetamorphic (NF62) and metamorphic (NF65) tadpoles revealed pronounced alterations in the thyroid glands, including increased colloid content, clusters of thyrocytes, and follicular disorganization, which were observed significantly in both sexes.

To investigate potential transgenerational impacts of this obesogenic mixture, the F1 generation which was not directly exposed was also examined. Long-term exposure (3 weeks) resulted in a significant decrease in thyroid colloid in both male and female tadpoles (NF65), and the observed pattern suggests a possible maternal transmission of this impairment.

Overall, these results demonstrate that this obesogenic mixture is biologically active even at EQS concentrations, highlighting the need to assess chemical mixtures rather than isolated compounds in environmental risk evaluation. Notably, thyroid impairments were observed in non-exposed offspring, revealing a transgenerational impact that may have important implications for long-term population health.

6.04.P-Mo410 Optimising the First Phase of OECD Guideline 241: the Larval Amphibian Growth and Development Assay to meet Validity Criteria and Analyse Plasma Thyroid Hormone Levels.

Severine Brigitte Larroze¹, Kathryn Gerry² and Helen Garcia¹, (1)Scymaris Ltd., United Kingdom, (2)Analytical Chemistry, Scymaris Ltd., United Kingdom

The Larval Amphibian Growth and Development Assay (LAGDA) is a level 4 in vivo assay of the OECD Conceptual Framework on Endocrine Disruptors Testing and Assessment and provides data on adverse effects on the hypothalamus pituitary thyroid and gonadal axes using the model *Xenopus laevis*. The assay was adopted in 2015 with few chemicals tested during the validation process and little data on inter-laboratory reproducibility. So far, only a few studies have been conducted and very few laboratories are able to perform this test.

Starting at Nieuwkoop and Faber (NF) stage 8 to 10 for approximately 110 days depending on control animals' developmental rate, the study is divided in two phases, larval and juvenile, with a period of transition with duplicated replicates. A previous full scale trial performed in our laboratories highlighted difficulties with

maintaining adequate water quality, especially during the larval phase of the study, due to the feeding regime proposed in the guideline. Also, regulatory authorities often request additional endpoints such as thyroid hormones plasma analysis which needs developing.

The aim of this study was to perform a feeding trial focused on the first phase of LAGDA following the OECD 241 guideline up to NF stage 62 by trying different feeding regimes with different flow rates to investigate the feasibility of passing strict study validity criteria. The study was initiated with four sets of two replicate dilution water control vessels with 20 *X. laevis* eggs. An adapted diet of sera® Micron following 50% of recommended feeding guidelines in test guideline OECD 231 as well as an enhanced sera® Micron diet supplemented with *Artemia* spp. nauplii and spirulina was used. A flow-through design with 35 ml/min and 50 ml/min flow rates were also tried. Blood samples were collected at NF stage 62 and analysed for Thyroid Stimulating Hormone (TSH), free and total T3 (triiodothyronine) and T4 (thyroxine) using analytical method developed and validated in-house. Data was used to determine typical control levels, required minimum sample volumes and level of dilution. Crucial information regarding the quantity of blood drawn from NF stage 62 animals was gathered to determine if successful analysis of all hormones in a single individual was possible.

6.04.P-Mo411 When Tadpoles Grow Faster Than Expected, Statistics Get Tricky

Marysia Agnieszka Tobor-Kaplon¹, Jacqueline Augusiak¹ and Emily Scorgie², (1)Syngenta Crop Protection B.V., Netherlands, (2)Global Science Delivery, Syngenta Seeds B.V., Netherlands

When tadpoles develop very fast, standard statistics can fail. We show how to rescue OECD TG 231 analyses with a practical, reproducible nested ANOVA strategy.

The Amphibian Metamorphosis Assay (OECD TG 231), occupying Level 3 in the OECD Conceptual Framework for endocrine disruption testing, tracks developmental changes over 21 days, from (Nieuwkoop–Faber) NF stage 51 to ~NF 60. Endocrine diagnostic endpoints include developmental stage (NF) and normalized hind limb length (nHLL) at days 7 and 21, while wet weight (WW) and snout to vent length (SVL) are also recorded and analyzed.

Under typical conditions, ~80% of tadpoles per group remain at NF <60 and endpoint means are analyzed using standard methods. But when >20% surpass NF 60 in one or more groups, the guideline's Annex 3 prescribes a two factor ANOVA with nested variance. This framework uses all tadpoles, groups them by LateStage (NO: NF <60; YES: NF >60), and “slices” the analysis into separate ANOVA F tests for each LateStage group. Annex 3 significantly increases the complexity of the required analysis. To perform this analysis correctly and thoroughly, we see a need for a more thorough explanation. We've also identified and corrected inconsistencies and inaccuracies in the methodology.

Key statistical insights include:

1. Correction of the appropriate error structure to avoid pseudo replication.
2. What is slicing?
3. Considering monotonicity assumptions in concentration–response trends.

We also address common obstacles:

- Lack of mixed model capability in available software.
- Software limitations for slicing.
- Absence of LateStage = YES tadpoles in controls.
- Missing LateStage categories in certain treatment groups.

6.04.P-Mo412 Thyroid Hormone Disruption by Model Chemicals and Indoor Dust: A Multi-Country Assessment

Jiri Novak, Marie Smutná, Zuzana Tousova, Lisa Melymuk and Klára Hilscherová, RECETOX, Faculty of Science, Masaryk University, Czech Republic

Endocrine-disrupting chemicals (EDCs) pose significant risks to human health. In addition to dietary sources, environmental exposure contributes substantially, particularly indoors, where limited ventilation and multiple pollutant sources create complex chemical mixtures. The indoor environment is therefore a critical exposure setting, especially for young children, who are more vulnerable due to ongoing development and behaviors such as floor contact and hand-to-mouth activity. Disruption of the system of thyroid hormones (TH) is of particular concern since it can affect crucial processes such as metabolism regulation, neurodevelopment, reproduction, and carcinogenesis.

This study applied a battery of new approach methodologies (NAMs) using in vitro bioassays to evaluate TH-related endocrine-disrupting potential in a diverse set of model chemicals relevant to human exposure. These chemicals represented multiple categories, including pharmaceuticals, pesticides, industrial compounds, environmental pollutants, and constituents of personal care and consumer products. Additionally, complex mixtures extracted from 21 indoor settled dust samples collected from households with young children in four European countries were assessed.

The assay battery targeted key TH-related endpoints: synthesis (thyroperoxidase [TPO] inhibition), transport (thyroxine–transthyretin [T4–TTR] displacement), receptor agonism (ThR), and metabolism (deiodinase inhibition [DIO1, DIO3], and aryl hydrocarbon receptor [AhR]-mediated activity). Endocrine-disrupting potential was detected in most tested chemicals and dust sample extracts. Notably, settled dust extracts exhibited diverse effect patterns across countries, with frequent detection of T4–TTR displacement and AhR-mediated activity.

These findings underscore the pervasive endocrine-disrupting potential of indoor environments and the complexity of identifying causative pollutants, highlighting the need for improved risk assessment strategies for indoor exposure.

6.04.P-Mo413 Inhibition of the Thyroid Hormone Receptor Alpha (TR α) by Mycotoxins and Their Mixtures

*David Ocampo, Ana Valdehita, David Hernandez-Moreno and **Maria Luisa Fernandez-Cruz**, Department of Environment and Agronomy, National Institute for Agriculture and Food Research and Technology (INIA), CSIC, Carretera de la Coruña km 7, 28040 Madrid, Spain, Spain*

The effect of mycotoxins on thyroid hormone receptor alpha (TR α) has been poorly studied. Only beauvericin (BEA), ochratoxin A (OTA), and deoxynivalenol (DON) have been evaluated showing antagonistic effects. Furthermore, mycotoxins frequently co-occur in aquafeeds, which may lead to synergistic or antagonistic interactions.

This study aimed to evaluate the effect of mycotoxins commonly found in aquafeeds on TR α . First, twelve substances were individually tested, including the acetylated derivatives 15-O-acetyl-DON and 3-acetyl-DON, aflatoxins (AFB1, AFB2), enniatins (ENNA, ENNA1, ENNB, ENNB1), fumonisins (FB1, FB2), nivalenol (NIV) and zearalenone (ZEN). In addition, the combined exposure of BEA, ENNB and FB1 was evaluated. For this study, the PC-DR-LUC cell line was exposed 24 hours to the mycotoxins, both in the absence and in presence of triiodothyronine (T3), to determine whether they induce or inhibit TR α activity. The mycotoxins were tested at a range of non-cytotoxic concentrations. For the co-exposure assays, cells were treated with two fixed concentrations of ENNB or BEA (0.1 μ g/mL and 1 μ g/mL, non-effective and effective, respectively) combined with FB1 (0.019-10 μ g/mL). The co-exposure effect of ENNB and BEA was assayed in a range of ENNB concentrations (0.0049-1.25 μ g/mL) with the two fixed concentrations of BEA.

None of the tested mycotoxins showed agonistic activity on TR α . No antagonist effects were recorded for 3-acetyl-DON, 15-acetyl-DON, AFB2, ENNA, FB1, FB2 and ZEN. However, NIV presented a strong antagonistic activity, followed by ENNB1, ENNA1, ENNB and finally AFB1. Co-exposure assays revealed that all concentrations of FB1 reverse the inhibitory effect produced by ENNB at 1 μ g/mL. FB1 and BEA generate a double response following a U-shaped hormetic response. FB1 increased the inhibition of the receptor produced by BEA (0.1 μ g/mL) at low concentrations (0.078-2.5 μ g/mL) and reverse the antagonistic effect produced by BEA (1 μ g/mL) at high concentrations (1.25-10 μ g/mL). The inhibitory effect induced by BEA at 0.1 μ g/mL was enhanced by ENNB at concentrations of 0.62 and 1.25 μ g/mL. Also, the effect of BEA at 1 μ g/mL was increased by ENNB at the highest non-toxic concentration assayed (1.25 μ g/mL).

These results highlight the need to evaluate the mixture effects due to the coexistence of multiple mycotoxins in aquafeeds. Understanding how they interact is essential to protect fish health and aquaculture production.

6.04.P-Mo414 A Tiered Strategy for the Integration of Complementary Lines of In Silico Toxicological Evidence Permitting Evaluation of Endocrine Disrupting Potential

James Firman¹, Franklin Bauer², Gaspard Levet², Paul Thomas² and Mark Cronin³, (1)School of Pharmacy and Biomolecular Sciences, Liverpool John Moores University, United Kingdom, (2)KREATiS SAS, France, (3)Liverpool John Moores University, United Kingdom

A variety of computational modelling tools, including quantitative structure-activity relationships (QSAR), structural alert-based profilers and molecular docking simulations, are available for the purposes of providing evidence in relation to toxic potential. Confidence in the appropriateness of their conclusions may be enhanced by means of considering the weight-of-evidence drawn from an assortment of approaches – particularly where these should align in description of a credible adverse outcome pathway (AOP) linking molecular initiating event (MIE) to apical effect.

Within this study, a tiered testing strategy, allowing for the rational integration of outputs emerging from a collection of complementary *in silico* techniques, is described. The context explored is that of endocrine disruption (ED) – a complex collection of outcomes, holding significance within both human and environmental toxicology. Although challenging to characterise with sufficient reliability by means of individual tools, existing mechanistic knowledge may be harnessed in order to provide a basis for the compilation of evidence.

The preliminary phase of the strategy concerns evaluation of the suitability of existing experimental data, with respect to the substance and endpoint of interest (for example, oestrogenic, androgenic, thyroid-mediated effects). Should available data be insufficient, or absent, then *in silico* screening is enacted. Relevant profiling tools are initially applied, with the intention of identifying compounds bearing structural features liable to be associated with the given effect. Absence of such alerts would see that, as a secondary means of examination, appropriate QSAR were utilised. If likewise negative, then a conclusion of lower ED concern may be drawn. Hits at either the profiler or QSAR stages shall precede the application of molecular docking approaches, relatable specifically to MIE. Evidence of strong interaction with the protein target may be interpreted as indicative of putative ED potential – itself further examinable by means of more expansive quantitative AOPs (qAOPs) based upon suitable *in vitro* data.

Presented case studies demonstrate the applicability of the tier-based assessment strategy. Furthermore, they allow for identification of challenges associated with such integrated approaches – most notable amongst which are the need for validation procedures, alongside a capacity to appraise the levels of certainty required to make a decision.

6.04.P-Mo415 Quantitative Structure–Activity Relationship Models for Assessing Thyroid Hormone System Disruption: A Review

Marco Evangelista and **Ester Papa**, DiSTA, University of Insubria, Italy

Thyroid hormone (TH) system disruption is a significant health concern, due to the critical role THs play in metabolism, growth, and brain development. Traditional reliance on animal-based testing for hazard assessment is no longer feasible, driving the need for new approach methodologies (NAMs), such as *in silico* methods based on quantitative structure–activity relationship (QSAR) approaches. This review, covering scientific literature from 2010 to 2024, maps the state-of-the-art in QSAR model development for predicting TH system disruption. A specific focus is placed on QSAR models that address molecular initiating events (MIEs) within the adverse outcome pathway (AOP) framework for TH system disruption to place the review at the science-policy interface.

A total of 30 papers presenting 86 QSAR models are analyzed, examining their data sources, modeled endpoints, algorithms, molecular descriptors selected, validation strategies, and the definitions of their applicability domains (ADs).

Modelled datasets fall into two categories: those including structurally heterogeneous chemicals (67% of the QSARs), and class-specific datasets mainly focused on halogenated and/or hydroxylated structures that resemble THs (e.g., PCBs, PBDEs), limiting the number and variety of local QSARs. QSARs primarily target TH receptors (TRs) and transthyretin (TTR), which together account for 57% of all models reviewed. A major gap remains, as many critical MIEs among the over 20 identified in the literature are either significantly under-addressed or entirely unmodeled. Despite the consistent application of validation procedures, a crucial finding is the frequent lack of a clearly defined AD for approximately 37% of the QSAR models, which severely limits their utility. Furthermore, while key structural features driving TTR and TR binding are consistently identified, there is limited emphasis placed on mechanistic interpretation of models, which can undermine their reliability. This review serves as a "state-of-the-art" resource, identifying both existing QSARs and critical research gaps. The findings underscore the immediate need for increased data generation for poorly addressed MIEs, broadening chemical space coverage beyond TH-like structures, and prioritizing models with clearly defined

ADs and enhanced mechanistic interpretability. Advancing these areas will promote wider confidence in and regulatory acceptance of QSARs as effective NAMs for assessing TH system disruption

This research was funded by the PhD programme in Chemical and Environmental Sciences (DiSCA) at the University of Insubria (Italy). PhD scholarship awarded to Marco Evangelista

6.04.P-Mo416 A Clustering Approach for Profiling Potential Estrogen Receptor-Mediated Endocrine-Disrupting Chemicals

Yoce Aprianto¹, Dominique Patureau², Laure Mamy¹, Jérôme Mao², Eric Latrille², Virginie Rossard², Remi Servien², Fabienne Bessac³, Sophie Hoyau⁴ and Pierre Benoit¹, (1)Paris-Saclay University, France, (2)INRAE, Université Montpellier, France, (3)Université de Toulouse, LCPQ (UMR 5626) & Ecole d'Ingénieurs de Purpan, France, (4)Université de Toulouse, LCPQ (UMR 5626), France

Endocrine-disrupting (ED) chemicals influence the normal function of the endocrine system through diverse mechanisms, including binding to, activating (agonism), or blocking (antagonism) nuclear hormone receptors (NRs). Estrogen Receptor (ER), which belongs to NRs, is among the primary known targets of endocrine disruption.

Although ED chemicals have been widely reported over decades, the identification and detection of substances with ED properties (e.g., estrogenic activity) remain a challenging task. They represent a highly heterogeneous group of chemicals, each characterized by distinct chemical properties and biological activities (bioactivity). Considering this diversity, endocrine disruptions do not have a single endpoint. It requires multiple assessment methods to evaluate the interaction between chemicals and NRs. However, testing all compounds with standard biological-based tests is not feasible.

The present study aims at proposing an *in silico* clustering approach to categorize the ED potency of compounds by linking their chemical structures and bioactivity. Targeting the estrogen pathway, we tested the hypothesis that structurally similar compounds, which would be assigned to the same cluster, might have similar estrogenic ED potency. TyPol (Typology of Pollutants), an in-house web platform, was used to perform clustering based on Partial Least Squares (PLS) regression and a hierarchical clustering algorithm. A total of 81 molecules constituted the ER agonist data set. The model was built using 42 molecular descriptors (e.g., molecular weight...) and *in vitro* ER bioactivity (i.e., relative binding affinity (RBA), 10% of maximum effect (EC10)). To assess the specificity of endocrine-mediated activity, we calculated the specificity ratio (SR_{baseline}). Then, we computed the Bemis-Murcko scaffolds for each compound to analyze chemical similarity within the cluster. Our initial findings suggest that the TyPol tool can discriminate between organic compounds having higher ED potency and those having lower potency. Clusters with higher estrogenic ED potency contain molecules that share flavones (e.g., quercetin, genistein) and steroidal scaffolds (e.g., mestranol, estriol). They are characterized by moderate to high RBA, a lower EC10, and a higher SR_{baseline} compared to other groups. The four-component PLS model indicates good statistical performance. This research could support improved decision-making on screening and prioritization of ED chemicals.

The work was financially supported by the French Office for Biodiversity (OFB) within the framework of the TyPol-PE project and by INRAE AgroEcoSystem Division. The authors wish to thank the CALMIP supercomputing center for providing access to HPC resources under allocation 2016-[P1222].

6.04.P-Mo417 Mixture Effects of Bisphenol A and Analogues on the Regeneration of Freshwater Planarians

Patrícia Veríssimo Silva¹, Beatriz Brites², Renan Castellano Gebara³ and Susana Loureiro², (1)Department of Biology, University of Aveiro, Campus Universitário de Santiago, University of Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)Center for the Development of Functional Materials (CDMF), Federal University of São Carlos (UFSCar), Brazil

Bisphenols are synthetic compounds widely used in the production of polycarbonate and epoxy resin polymers, with Bisphenol A (BPA) being the most common. Due to its endocrine-disrupting properties, BPA has been increasingly replaced in consumer products by structural analogues. However, many of these alternatives exhibit comparable or even greater toxicity than BPA and have been detected in various environmental matrices.

Because environmental exposures occur as complex mixtures, evaluating their combined effects is crucial for realistic hazard and risk assessment. The growing use of BPA alternatives, coupled with significant data gaps regarding their single and mixture toxicity, makes this an urgent regulatory concern. Freshwater planarians, recognised for their remarkable regenerative capacity, provide a sensitive model for assessing the effects of chemicals that may interfere with tissue regeneration, such as endocrine disruptors. Therefore, this study aimed to investigate the effects of bisphenol mixtures on the regeneration of the freshwater planarian *Girardia tigrina*. Adult planarians were decapitated immediately before exposure to BPA, BPAF, BPS-MAE and BPZ, and their binary mixtures for eight days. Mixtures were prepared following a fixed-ratio ray design. Regeneration of the blastema was measured at 48 hours, and photoreceptor and auricle regeneration were monitored every 24 hours. Data were analysed using the MixTox tool, applying the Concentration Addition (CA) and Independent Action (IA) models, with tests for deviations indicating synergism, antagonism, or dose-dependent effects. Among the individual compounds, BPAF was the most toxic ($EC_{50} = 0.40$ mg/L), followed by BPZ ($EC_{50} = 0.83$ mg/L), BPA ($EC_{50} = 3.54$ mg/L) and BPS-MAE ($EC_{50} > 5$ mg/L). The BPA + BPAF mixture was best described by the CA model, suggesting additive effects and a similar mode of action. In contrast, the BPS-MAE + BPZ mixture was best fitted by the IA mode, indicating distinct modes of action and limited interaction. The results enhance our understanding of the single and mixture effects of BPA analogues, which are crucial for addressing key gaps in hazard assessment and preventing regrettable substitutions. Moreover, *G. tigrina* proved to be a sensitive model for evaluating regenerative disruption by endocrine-active compounds.

G. Masaryk Water Research Institute (VUV TGM)- Hydrobiology lab, Czech Republic, (6)Finnish Environment Institute (SYKE), Finland, (7)INERIS, France, (8)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (9)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (10)German Federal Institute of Hydrology (BfG), Germany, (11)University of Brescia, Italy, (12)Swedish University of Agricultural Sciences, Sweden, (13)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Switzerland, (14)Southern California Coastal Water Research Project (SCCWRP), United States, (15)University of Florida, United States, (16)ARPA Lazio, the Regional Environmental Protection Agency-Lazio Region, Italy, (17)Spanish National Research Council (CSIC), Spain, (18)European Commission - Joint Research Centre (JRC), Italy, (19)Environment and Health, Italian National Institute of Health, Italy

Effect-based methods have been included in the Water Framework Directive to evaluate estrogenic substances. The European Commission's Joint Research Centre performed an interlaboratory study to assess and evaluate estrogenic effect-based methods and effect-based-trigger values to figure out if they would be compliant with chemical analysis. To do so, the effect-based-trigger values were derived based on three options: linking the effect-based trigger value to environmental quality standards (option 1), correlating in vitro and in vivo data (option 2), and averaging bioassay-specific effect-based-trigger values (option 3).

In this study, surface water samples from eight Northern Italian sites with known estrogenic hormone and endocrine-disrupting chemical contamination were analysed by fourteen laboratories using effect-based methods, and four performed chemical analysis.

Chemical analysis suggested a cumulative risk of estrogenic hormones and endocrine-disrupting chemicals in several samples with estrone and bisphenol A as main drivers. Effect-based methods detected estrogenic activity, though specificity varied: some bioassays responded selectively to hormones, while others also detected other endocrine-disrupting chemicals. Notably, effect-based methods identified estrogenic risk in a sample

where chemical analysis showed no individual exceedances of environmental quality standards. The highest compliance with chemical analysis across water samples was achieved when effect-based trigger value option 1 was applied.

The study also highlighted the need to harmonise the effect-based methods – including data evaluation – for addressing chemical mixtures, with recommendations to the Member States for their application in the Water Framework Directive.

In conclusion, effect-based methods demonstrate high sensitivity in detecting estrogenic effects and their integration with chemical data ensures protection against cumulative estrogenic risks from both hormones and endocrine-disrupting chemicals. However, the coverage of mode of action remains limited for other pollutants, and in vitro assays capable to detect multiple modes of action – such as those critical for assessing per- and polyfluoroalkyl substances - are often lacking. Biotechnology-based innovations demonstrate significant potential to advance this field by accelerating efforts to close the existing gap.

6.04.P-Mo419 Development of a Highly Sensitive Reporter Gene Cell Line for Detecting Estrogenic Activity (the ER Isjaki Assay)

Aline Colonnello Montero, Geeta Mandava, Agneta Oskarsson and Johan Lundqvist, Swedish University of Agricultural Sciences, Sweden

In recent years, the European Union has proposed changes to the regulation for environmental protection of water bodies by including the environmental quality standards (EQSs) for 17 β -estradiol (E2), estrone (E1) and 17 α -ethinyl estradiol (EE2) in inland and other surface waters, which are below the chemical limit of detection. Although bioassays based on mammalian cells have generally lower detection limits than chemical analysis for estrogens, the suggested EQSs are also challenging the analytical capacity of the current bioassays. These changes highlight the need to develop more sensitive assays capable of detecting estrogens at regulatory relevant concentrations. As a result, this study aims to develop and establish the optimal experimental conditions for a novel and highly sensitive reporter-gene assay designed to detect estrogenic activity.

To this end, optimization of transfection plasmid concentration, exposure time and basement membrane matrix effect, assay reproducibility and quality as well as relative effect potency (REP) of natural estrogens and estrogenic compounds were carried out. The optimal conditions for the newly developed assay based on transiently transfected MCF-7 cells were set as 5 ng of plasmid per well in 96-well uncoated plates and exposure to treatments for 24 hours. As a result, the assay displayed an average effect level 20%, also expressed as sensitivity, for E2, E1 and EE2 of 0.29, 1.36 and 0.02 pM.

In this study, we established the conditions for an assay detecting estrogenic activity that is approximately 10 to 100 times more sensitive compared to other bioassays. In addition, our assay does not require cell lysis to measure bioactivity, thus allowing assessment without sample pre-concentration. The high sensitivity shows that the cells can be used to detect E2, EE2 and E1 activities at low levels, which are required to meet regulatory standards. Also, activity measurement without cell lysis opens the possibility of developing an effect-based-biosensor that would allow for automatized analysis. Importantly, the developed assay has an in vivo-relevant REP for EE2 of 23 compared to E2, something that the current in vitro assays for estrogenicity have failed to demonstrate. This is an advantage over other bioassays and adds to the benefits of this assay as a potential solution to meet the suggested regulatory changes for estrogens monitoring in inland waters.

6.05.P From Pollution Hotspots to Pro-Environmental Behaviour Change: The Role of Citizen Science in Observing and Addressing Emerging Contaminants

6.05.P-Th230 Ocean Literacy and Art: How Raising Awareness through Art promotes Behaviour Change
Joao Frias¹, Nóirín Burke² and Roisin Nash¹, (1)Atlantic Technological University, Ireland, (2)Galway Atlantaquaria, Ireland

The Ocean sustains life on Earth through essential ecosystem services, including carbon and nutrient cycles, production of oxygen, provision of food, mineral extraction, and supply of biomolecules used in cosmetics and pharmaceutical products. Although scientists understand environmental processes and interactions, the general public often lacks awareness of fundamental Ocean dynamics, mostly due to limited engagement rather than lack of information.

To improve Ocean engagement within local communities, the Ocean Literacy (OL) education framework was applied and contextually adapted. This framework, which explores the “understanding of the Ocean's influence on us, and our influence on the Ocean”, is built on seven fundamental principles that connect Ocean knowledge with diverse disciplines, such as biology, chemistry, geology, physics, economics, and visual arts.

In this work, the OL framework was used to empower artists to become local Ocean ambassadors. A call for artists was launched within the Waves of Change project, where six artists were selected to participate in a residency designed to deepen Ocean knowledge, in a unique experience. The residence included a one-day sea expedition aboard the R/V Tom Crean, a month-long residence in Galway, a visit to the local aquarium, and four masterclasses with scientists and artists on sustainable aquaculture, parasites, noise and microplastic pollution, biodiversity, and music. These activities provided opportunities for artists to collect audio-visual materials and to interact with researchers, PhD students, vessel crew and aquarium staff.

During the residence, artists translated complex scientific concepts into artworks using diverse media such as sculpture, photography, art installation, videoart, animation, illustration, and sound. Their pieces addressed biodiversity, climate change, underwater noise, ocean acidification, and plastic pollution, were displayed in the Ripples art showcase, in March 2025. This co-designed immersive exhibition engaged 150 visitors, promoting dialogues on Ocean challenges and solutions.

This work highlights the importance of empowering artists as local Ocean ambassadors, capable of translating complex scientific concepts into art pieces that promote community dialogue, reflections and even behaviour change. Such initiatives build communities of practice and encourage dialogue and shared responsibilities over the Ocean and its resources, in a sustainable and harmonious way.

6.05.P-Th231 A Decadal Assessment of Korea's Comprehensive Nation-Wide Marine Ecosystem Survey: Integrating Stressor Diagnostics and Ecological Health Risk Evaluation

Gyung Soo Park, Marine Biotechnology, Anyang University, Korea, Republic of

The National Marine Ecosystem Survey (NMES) of the Republic of Korea has been operating for a decade under a biennial cycle, covering coastal, tidal flat, rocky shore, and seabird ecosystems, and integrating physical, chemical, and biological indicators to assess ecosystem structure and function across multiple spatial and temporal scales.

Using ten years of NMES data, we developed a diagnostic framework for ecosystem health evaluation and dominant stressor identification. Indicators such as salinity, nutrients, chlorophyll a, zooplankton biomass, sediment grain size, organic carbon, and benthic macrofaunal density were analyzed through reference-condition approaches, outlier detection, and artificial-intelligence-assisted anomaly recognition. The results demonstrate distinct ecological typologies across the four Korean seas (West, South, East and Jeju)—reflecting differential patterns of nutrient enrichment, sediment stress and biological community responses.

The computed Ecosystem Health Index (EHI), based on an Ecosystem Outliers Index (EOI) framework, revealed clear spatial gradients and temporal shifts correlated with eutrophication and organic loadings. Moreover, ecosystem stress was found to be driven not only by the intensity of human activities but also by structural vulnerabilities inherent to natural systems, such as tidal effects including current velocity, direction, and tidal ranges, which amplify stress responses in specific habitats. The framework enables identification of anomalous conditions and supports assessment of cumulative multi-stressor risks.

This work contributes to ecological risk assessment by bridging large-scale monitoring and management applications. It highlights a shift from pollutant-centric monitoring to an ecosystem-based, risk-informed diagnostic system. The proposed approach strengthens the scientific basis for marine ecosystem protection, prioritized restoration and sustainable policy development.

Keywords:

marine ecosystem monitoring, ecosystem outliers index, ecosystem health index, stressor diagnostics, ecological risk assessment, long-term monitoring, Korea

6.05.P-Th232 Whats in our water? Water testing design to engage different audiences

Katie Reilly¹ and Iseult Lynch², (1)University of Birmingham, United Kingdom, (2)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom

Water quality is of increasing concern globally, within increasing risk of water scarcity due to changes climates and extreme weather in addition to an increasing quantity and diversity of water pollution. There is a lot of public interest in this topic, from a range of different communities who are keen to explore and advocate for their local spaces. Making water testing accessible, and understandable is an important element of engaging people and empowering them to advocate for their spaces. Through a citizen science project working with young people we designed a method of water testing that could be done without any external researcher input enabling them to monitor their local environments for varying water quality and key pollutants such as nitrates and phosphates. We also tested for turbidity using a Secchi disk, water temperature, pH and conductivity using a probes and looked for potential indicators of varying water quality too (such as plastic pollution). Following on from the successful in-field work, we designed a water testing activity that can be done, really easily, in a classroom/open day/science festival where we explore the importance of building broader environmental questions into the materials to increase the confidence (and enjoyment) of the people taking part. These questions can range from how the scientific process works, through to the importance of including evidences and having a baseline of data when campaigning to the best ways to visualise results. The project was hugely enjoyable and successful, and the table top activity has been piloted at science festivals, in school and at drop in events aimed at young people. The citizen science community involved in the project have been essential to shaping this work, and we highlight through this the importance of working with communities to create the best resources and study designs for the specific groups to be able to monitor their environments effectively, and showcase their results in due course!

6.05.P-Th233 Sunscreen User Habits and Public Perceptions of Sunscreen Pollution: A Case Study from a British Coastal City

Anneliese Ananya Hodge¹, Elizabeth Gabe-Thomas², Frances Hopkins², Mahasweta Saha³ and Awadhesh Jha⁴, (1)University of Plymouth & Plymouth Marine Laboratory, United Kingdom, (2)Plymouth Marine Laboratory, United Kingdom, (3)United Kingdom, (4)University of Plymouth, United Kingdom

Sunscreens are topical personal care products (PCPs) that contain ultraviolet (UV) filters to protect against UV radiation. These filters are considered chemicals of emerging concern (CECs), due to their widespread use and global distribution. Understanding public perceptions of marine pollution is essential for assessing consumer awareness and behaviour. However, existing studies largely focus on public health perspective and application rates, with limited attention to public awareness of sunscreens as marine pollutants.

This study aimed to review the current knowledge base on public perceptions of sunscreen pollution, provide insights into marine policy and regulation of sunscreen ingredients, and explore public awareness and attitudes in the UK. A literature review and critical evaluation of global regulatory developments were conducted alongside a series of public outreach events. A total of 281 participants voluntarily responded to a set of questions covering sunscreen habits, emotional responses and environmental awareness. 89% of respondents reported using sunscreen, and 81% were unfamiliar with the term 'reef-safe'. 55% had never considered sunscreens as harmful to the marine environment.

Qualitative thematic analysis revealed key public concerns, including environmental impact, demand for clearer product labelling, and calls for further research. These findings suggest a significant gap in public understanding of sunscreen-related marine pollution and underscore the importance of improved education, transparent marketing, and stronger regulatory frameworks. This study provides a foundation for future research and policy development aimed at aligning consumer behaviour with marine conservation goals. It also reflects an integrated approach to bridging science, policy and public engagement in addressing emerging environmental challenges.

6.05.P-Th235 Collecting microfibres and behavioural insights through a citizen study on microfibre emission from household clothes washing

Antonia Praetorius, Allison Moll, Anna Bosshard, Cameron Brick and Lies Jacobs, University of Amsterdam, Netherlands

Citizen science can serve the dual purpose of contributing to scientific data collection as well as to assess citizen's perceptions and behaviours with respect to a topic of interest. Here, we present the outcomes of an innovative citizen science project on synthetic microfibre release during home washing, designed in collaboration between environmental scientists and psychologists.

The release of microfibers during washing of synthetic textiles (e.g. polyester) is a major contributor to the emissions of microplastics to the environment. However, mechanisms driving microfibre emissions are poorly understood and little is known about the willingness of individuals to adopt pollution-reducing measures. Existing studies on the impact of textile properties or of washing conditions on microfibre release are limited by non-realistic laboratory set-ups or case-by-case assessments and do not include behavioral dimensions. In this citizen science project washing practices and related microfibre release were studied in two different home-washing campaigns in the Netherlands (involving 50-80 citizens each), allowing for a fine-grained data collection in real-life settings. Citizens were equipped with either washing bags or external washing machine filters (both commercially available) to collect microfibres released from their everyday clothes during typical home washing conditions over the course of several months. In addition to collecting the microfibres, participants reported data on textile characteristics and washing conditions. Alongside this data collection, psychological surveys, before and after participation, were completed by the citizen scientists to assess (changes in) perception, behaviours and pro-environmental attitudes.

This study yielded insights into total amounts and characteristics of microfibres released under different washing conditions and for different clothing items; and also revealed that participation in such a data collection impacted problem awareness and perceived responsibility, but did not significantly change personal norms, social norms about sustainability or perceived behavioural control.

6.05.P-Th236 Empowering Citizens to Monitor Beach Macro Litter: A Mediterranean Case Study Using the REMEDIES App

Vesna Kuralt¹, Tamara Bizjak¹, Andreja Palatinus¹, Annamaria Vujanovic², Jan Puhar², Andrea Camedda³, Sylvain Petit⁴, Antonios Eleftheriou⁵, Alae-eddine Barkaoui⁶, Kledisa Cela⁶, Milica Velimirovic⁷, Marko Petelin⁸, Davide Poletto⁹ and Gherardo Toso⁹, (1)National Institute of Chemistry, Slovenia, (2)University of Maribor, Slovenia, (3)IAS-CNR, Italy, (4)SMILO, France, (5)Marine Conservation Greece, Greece, (6)Environmental and Territorial Management Institute, Albania, (7)Flemish Institute for Technological Research (VITO), Belgium, (8)Infodata, Italy, (9)Venice Lagoon Plastic Free, Italy

Plastic pollution continues to threaten the ecological integrity of Mediterranean shorelines, where dense populations, heavy tourism, and infrastructural gaps drive ongoing litter buildup. Detecting and addressing these pollution hotspots calls for scalable monitoring methods that are both scientifically sound and socially participatory. Citizen science provides an effective route to broaden data collection while fostering awareness and pro-environmental behavior.

Within the Horizon Europe REMEDIES project, a multinational citizen-science program was launched to monitor beach macro litter (>2.5 cm) across six Mediterranean countries including Italy, Slovenia, Albania, Greece, Morocco, and France in 2024 and 2025. Volunteers participated in seasonal surveys using the REMEDIES mobile app, which offers harmonized instructions for recording the quantity, typology, material composition, and spatial distribution of litter items in accordance with the Marine Strategy Framework Directive (MSFD) guidelines.

This collaborative approach delivers high-resolution and comparable datasets across varied coastal contexts as well as strengthens public engagement with environmental issues. Early findings indicate that involvement in monitoring activities improves understanding of pollution sources and pathways among volunteers and inspires broader community participation in environmental stewardship.

6.05.P-Th237 Citizen Science Monitoring of Riverine Microplastics

Guðrun Obersteiner¹, Sabine Lenz¹, Reinhold Ottner¹, Christian Zafiu² and Anna Noichl¹, (1)University of Natural Resources and Life Sciences (BOKU), Austria, (2)BOKU University, Austria

Rivers play a key role in transporting macro and micro plastics from terrestrial sources to marine environments, but monitoring their occurrence is difficult. Macro plastic pollution varies strongly by location and is influenced by many parameters like littering, hydrological and shore conditions etc. which are not sufficiently investigated to date. Even less information is available for microplastics in rivers.

While volunteers have been cleaning up macroplastics from rivers for some time now— but mostly without collecting important data—there is even less awareness about microplastics in rivers. Also, scientific studies dealing with riverine microplastics mainly focus on specific large rivers in Austria and cannot provide a comprehensive picture of the pollution situation.

Plastic Pirates – Go Europe! <https://www.plastic-pirates.eu/en> is a citizen science initiative launched in Germany in 2016 and expanded across Europe in 2022 with support from the European Commission. School classes and youth groups (ages 10–16) collect and document riverine litter as well as microplastic following standardized procedures. Activities in Austria began in 2021, and first microplastic results are presented in this paper.

However, the reliability of data collected by citizen science is sometimes questioned, and particularly in the field of microplastics, where the collection methods themselves are not yet fully developed, it is unclear how useful such results can be. The aim of this study was therefore to compare the results from citizen science research with purely scientific surveys, but also to show the extent to which participation in the citizen science project Plastic Pirates influences the environmental knowledge and perception of the participants.

6.05.P-Th238 A Multi-Scale Citizen Science Framework Using Artificial Intelligence to Monitor Plastic Litter in Rivers and Streams

Arne Van Overloop¹, Stefan Livens¹, Liesbeth De Keukelaere¹, Ils Reusen¹, Els Knaeps¹, Marian-Daniel Iordache¹, John Seghers², Thomas de Groote³ and Kenneth Lowyck³, (1)Flemish Institute for Technological Research (VITO), Belgium, (2)European Commission - Joint Research Centre (JRC), Belgium, (3)RiverCleanup, Belgium

Plastic pollution in and around freshwater systems remains insufficiently monitored across size classes, limiting our ability to assess environmental status and design effective mitigation measures. This work presents a flexible, citizen-science-based monitoring framework that uses smartphone imagery and Artificial Intelligence (AI) object detection to generate dense, georeferenced records of litter. Volunteers photograph debris encountered along waterways, and the images are processed through an AI model that counts and classifies items into up to 32 categories. This can enable the identification of hotspots, spatial and temporal trends, and uncommon occurrences that typically remain undocumented.

The technique serves as a natural follow-up to drone-based monitoring, extending observations to ground level and increasing resolution at minimal cost. Although applied here across Belgian rivers and streams, the approach is designed to be scalable and adaptable for use in other freshwater contexts.

To broaden detection across plastic size ranges, complementary processing flows are being developed, including approaches for identifying mesolitter, pellets, and microplastics retained on filters (approximately 300–1000 µm in this work). This multi-scale strategy supports future integration of field sampling, laboratory analysis, and automated recognition workflows.

The citizen-science model reduces logistical and financial barriers by providing a low-threshold, largely automated workflow requiring minimal expert training. While the AI system supports detailed categorisation, operational focus is placed on five prevalent litter types: cans, plastic bottles, plastic bags, cigarette butts, and cigarette packages. The resulting high-density spatial information assists partners in designing targeted interventions and informs broader environmental management strategies. Potentials, challenges, and limitations for wider implementation will be addressed.

6.05.P-Th239 Development of a tool for remote detection of plastic pellets based on relationships between eco-geomorphological characteristics and pellet concentrations along the Scheldt riverbanks, Belgium

Hanne Diels¹, Arne Van Overloop², Raewyn M. Town¹ and Ronny Blust¹, (1)ECOSPHERE, University of Antwerp, Belgium, (2)VITO, Belgium

Since the 1970s the widespread presence of industrial plastic pellets has been observed in surface waters and beaches all over the world. Pellets are being unintentionally released into the environment along the manufacturing and logistics chain and transported far from pellet related activities. International citizen science groups are active in documenting global pellet pollution. Nevertheless, data are mainly obtained by time consuming, target-based strategies with different sampling methods, which makes it difficult to critically evaluate the results.

We present a study in the Scheldt estuary encompassing the port of Antwerp (Belgium), one of Europe's largest polymer hubs. To elucidate the relationship between the riverbanks' ecological and geomorphological characteristics and pellet concentrations, field measurements were conducted on 28 locations along the riverbanks between May 2023 and February 2025. A standardized methodology applicable in an heterogeneous landscape was developed. At each location 9 quadrats (50 by 50 cm) were placed in 3 lines, based on the deposited tidal materials. The materials within the quadrats were collected, air dried, sieved and pellets were counted. On 6 hotspots seasonal sampling took place targeting pellets, macroplastics (> 25 mm) and mesoplastics (5 – 25 mm). Drone images were obtained by using a high-resolution optical camera and a multispectral (12 band) camera on 1 location.

The results show that plastic accumulation hotspots are located close to urban (macro/meso) or industrial areas (pellets) in the river's outer bend or close to a man-made construction. Surface roughness due to the riverbanks' morphology or vegetation increases the ability to act as a plastic trap. The ratios between macro-, mesoplastics and pellets showed that the occurrence of 1 macroplastic is associated with 5 mesoplastics (median 2.0) and 31 plastic pellets (median 2.3). First drone results were promising: riverbank morphology and superficial plastics are observable. Most plastics are found within tidal deposited materials, which makes it difficult to have a realistic idea of the degree of pollution if you only look at the superficial materials.

This research is ongoing. We aim to use this knowledge and new field data to develop AI driven plastic detection tools to detect pellets by smartphone imaging or identify potential plastic pellet accumulation zones by drone imaging of the riverbanks' characteristics linked to plastic hotspots.

6.06 Impact of Armed Conflict in Terrestrial and Aquatic Environments

6.06.T-01 Framework For War-Related Marine Damage Assessment Of Ukraine's Black And Azov Sea Territorial Waters

Hans Sanderson¹, Richard J Wenning², Andriy Grafov³, Theodore Tomasi⁴, Viktor Komorin⁵ and Oksana Abdulaieva⁶, (1)Aarhus University, Denmark, (2)Wenning Environmental LLC, United States, (3)HELCOM, Finland, (4)Integral-Corp, United States, (5)Ukrainian Scientific Centre of Ecology of the Sea, Ukraine, (6)Ministry of Environmental Protection and Natural Resources, Ukraine

Russia's war of aggression against Ukraine has caused a significant yet largely unmeasured environmental crisis in the Black Sea and Azov Sea. Conflict-related debris—including unexploded ordnance (UXO), naval mines, munitions fragments, sunken ships, and explosive residues—has introduced persistent pollutants into already vulnerable marine ecosystems within Ukraine's territorial waters. The corrosion of munitions, repeated attacks on coastal and port infrastructure, and major hydrological disruptions such as the destruction of the Kakhovka Dam have collectively released fuels, metals, explosives, and toxic combustion byproducts into coastal and offshore waters. To address this threat, a marine environmental damage assessment framework has been developed that integrates two environmental liability models—the U.S. Natural Resource Damage Assessment (NRDA) and the European Union Environmental Liability Directive (ELD)—both adapted for wartime conditions and guided by the principles of International Humanitarian Law (IHL). The framework is based on an evidence-driven approach to quantify injuries and damages, aligning with US NRDA and EU ELD methodologies. We present an assessment framework for evaluating the severity and extent of environmental impacts on Ukraine's coastal and marine resources in Black Sea and Azov Sea territorial waters. The framework is a five-step approach that begins with a desktop preliminary screening analysis, comparing the pre-conflict baseline (defined as conditions before the annexation of the Crimean Peninsula) and current environmental conditions to ascertain the types and extent of service losses using available data (step 1). It then proceeds to fill critical data gaps and verify current environmental conditions (step 2), followed by a detailed damage assessment using classical economic methods (step 3). The results inform a restoration strategy (step 4) and the monitoring and adaptive management strategies needed to support long-term recovery and restoration of marine resources (step 5). It offers the foundation for a long-term marine recovery strategy that aligns Ukraine's post-war reconstruction with EU environmental standards and regional cooperation mechanisms.

6.06.T-02 Toxic Traces of Tirpitz: Using Microbial Communities to Identify Shipwreck Pollution

Wyona Schütte¹, Lillian Bünning², Jennifer Strehse², Sven Van Haelst¹, Bryan Lintott³, Matthias Brenner⁴, Nico

Boon⁵, Edmund Maser² and Maarten De Rijcke¹, (1)Flanders Marine Institute (VLIZ), Belgium, (2)Institute of Toxicology and Pharmacology for Natural Scientists, University Medical School Schleswig-Holstein, Germany, Germany, (3)Technology and Safety Institute, UiT - The Arctic University of Norway, Norway, Norway, (4)Alfred Wegener Institute for Polar and Marine Research, Germany, (5)Center for Microbial Ecology and Technology (CMET), Belgium

Shipwrecks have a considerable impact on their surrounding environment. In the case of warships, corrosion causes the release of contaminants from both fuel and explosives, which contaminate sediments, water and marine biota. Due to their toxic and carcinogenic properties, explosives like 2,4,6-trinitrotoluene (TNT) represent a significant environmental concern. Marine organisms exhibit cellular stress responses even at low exposure levels and can bioaccumulate TNT and its metabolites, posing a potential risk to the human seafood consumer.

Despite ongoing corrosion processes and an expected increase in leakage of harmful substances, no comprehensive monitoring of wrecks is in place. Microbial communities, which are sensitive indicators of environmental changes, offer a promising and accessible solution, addressing challenges such as the complexity and diversity of pollutants. Initial studies have shown that bacterial community changes around shipwrecks can be linked to hydrocarbons or steel, however, no research explored microbial responses to explosives.

This study investigates microbial changes around the remains of the World War II battleship Tirpitz, which sank 1944 close to the city of Tromsø, Norway. Sediment and water samples were collected by divers, partly next to remaining munitions. Explosives (TNT and its main metabolites) were measured using gas-chromatography combined with mass spectrometry (GC-MS/MS). Next, microbial communities will be analyzed using 16S rRNA nanopore sequencing and related to concentrations of explosives in sediments and water.

Our results revealed TNT in sediments in all collected samples, with the highest concentrations next to a depth charge, indicating leakage into the surrounding environment. Based on our previous investigations on a marine sediment microbiome heavily influenced by explosives in a munition dumping area, we expect a sensitive shift in microbial communities exposed to higher concentrations of TNT. This work highlights the influence and potential risks of shipwrecks for their surrounding environment, and microbial community changes related to leaking explosives will help to identify taxa potentially serving as indicators for shipwreck pollution.

6.06.T-03 Warship wrecks and their munitions cargo as a threat to the marine environment and humans: the V 1302 "JOHN MAHN" from World War II

Edmund Maser¹, Lillian Bünnig¹, Matthias Brenner², Sven Van Haelst³, Maarten De Rijcke³, Patrick Müller⁴, Uwe Wichert⁵ and Jennifer Strehse¹, (1)Christian-Albrechts-University of Kiel (CAU), Germany, (2)Alfred Wegener Institute for Polar and Marine Research, Germany, (3)Flanders Marine Institute (VLIZ), Belgium, (4)3D Artist Freelancer, Germany, (5)Consultant BLANO, MELUND and HELCOM SUBMERGED, Germany

Beside several million metric tonnes of all kinds of munitions dumped into the seas during and after the two World Wars several thousand ships containing munitions and fuels were lost at sea. The munition casings are now corroding and releasing their toxic chemicals into the environment thereby posing a risk to the marine ecosphere and the human seafood consumer.

In the course of the European Interreg research project North Sea Wrecks the "Vorpostenboot V 1302" (civilian name John Mahn) at the Belgian coast was selected as a case study to focus on munitions onboard the wreck and their impact on the marine environment.

The wreck site of the V 1302 and surrounding areas were mapped by scientific divers and a multibeam echosounder. Water and sediment samples were taken in a cross-shaped pattern around the wreck. To assess a possible entry into the marine food chain, caged blue mussels were exposed at the wreck, and fish that stays locally at the wreck were caught. All samples were analyzed for the presence of TNT and metabolites thereof by GC-MS/MS analysis.

TNT was the most abundant energetic compound (EC) in water and sediment samples, while the TNT metabolites 1,3-dinitrobenzene, 2-amino-4,6-dinitrotoluene and 4-amino-2,6-dinitrotoluene were less abundant. Caged mussels revealed the presence of explosive chemicals in mussels at the V 1302 wreck, with an average total concentration of 2 to 4 ng/g mussel dry weight, while passive samplers showed a mean total concentration of approximately 10 to 40 ng per sampler for all the energetic compounds.

Finally, energetic compounds were detected in fish (*Trisopterus luscus*) caught at the V 1302 wreck. In fish filets TNT was the most prominent EC, while TNT metabolites were less abundant. Surprisingly, fish bile (which serves as a major excretion route in an organism from the liver to the intestine) contained only low concentrations of TNT metabolites, while TNT itself was absent. These findings hint at an alternative route for

the entry of EC into fish.

Evidence was provided in this study that sunken warship wrecks emerge as a point source of contamination with nitroaromatic energetic compounds leaking from corroding munitions cargo still on board. Fortunately, so far, the concentrations found in mussel flesh and fish filet were only in the one-digit ng per gram range thus indicating no current concern for the human seafood consumer. However, in the future the situation may worsen as the corrosion continues.

6.06.T-04 Revisiting Deposition of Ammunition in Swiss Lakes: from Monitoring Organic Munition Constituents to Assessing their Release and Fate

Chloé Udressy¹, Jakov Bolotin¹, Juliane Hollender², Ralf Kaegi³ and Thomas Hofstetter¹, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Process Engineering, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland

Chemical pollution of aquatic and terrestrial environments with munition constituents (MCs) such as explosives from the legacy of military activities poses a potential risk to ecosystems and human health. The exposure assessment of the diffuse pollution originating from several hundred thousand tons of ammunition dumped worldwide into aquatic environments during the 20th century was, however, impeded by the sampling resolutions, instrumental sensitivities, and/or the scope of quantified MCs of past monitoring studies. Moreover, the ongoing deterioration of ammunition casings, which is closely tied to environmental conditions, might alter the likelihood of MC emissions and is understood only scarcely. This is especially the case for landlocked countries such as Switzerland, where freshwater lakes hold not less than 14 thousand tons of ammunition.

In our study, we are therefore designing sampling procedures and analytical methods to investigate the emission and fate processes of MCs from ammunition deposited in freshwater lakes. Specifically, we are developing methods for the quantification of 26 MCs and selected transformation products in water and sediments in the low to sub- ng/L and µg/kg concentration range with liquid chromatography-high resolution tandem mass-spectrometry (LC-HRMS/MS). Current limits of quantification for water analysis, which range from 0.01 to 1 µg/L, are being improved by implementing an enrichment step using solid-phase extraction (SPE). Using an accelerated solvent extraction (ASE) method for sediment analysis, very good absolute recoveries of 80-120 % are obtained for approximately half of our analytes. To support the evaluation of MCs distribution and ammunition casings deterioration, we will perform complementary analyses including (1) Pb-210 dating, (2) X-ray fluorescence (XRF) scanning with a focus on heavy metals, and (3) clay and total organic carbon (TOC) content estimation as indicators for MC sorption to sediment constituents. These analytical procedures will be applied to samples collected over selected open-water ammunition deposition sites in Switzerland. To increase sampling resolution, we successfully tested the deployment of a multicorer which allowed to simultaneously retrieve 6 cores of 60-80 cm at fixed relative horizontal distances at 215 m underwater in 20 min. This study will provide valuable information for the potential needs and risks of recovering ammunition lying at the bottom of Swiss lakes.

Disclaimer/Disclosure:

This project is funded by the Swiss Federal Office for Defense Procurement (armasuisse) through contract no. AR-F04-008.

6.06.P Impact of Armed Conflict in Terrestrial and Aquatic Environments

6.06.P-We416 Biological Assessment of Military Contamination in the Oceans

Guido Gonsior, Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany

After World War II, enormous quantities of weapons were sunk in the oceans. Chemical weapons are not expected to have any long-term effects on the environment, as they react extremely quickly under water with all biological materials. The extent to which this is scientifically sound has yet to be clarified. However, it is also clear that no access is granted to the chemical weapons that are still at the bottom of the sea. In addition, most public research on other weapons such as bombs and ammunition is excluded for security reasons. Public interest is currently focused on the recovery of old ammunition. Large sums of money have been made available for this purpose. However, the question arises as to what happens during recovery. Contaminated sediments in particular could be further distributed and damage ecosystems. However, it is clear that recovery seems unavoidable given the enormous pollution. In any case, we have attempted to further assess the environmental risks in this difficult field by examining ammunition and testing fireworks for their toxicity to

marine organisms.

We thus present an approximation of the risks to be expected from military contamination in the oceans. However, a biological assessment and accompanying biological monitoring during the salvage operations are essential.

6.06.P-We417 Dissolution Experiments on Solid Explosive Material Recovered From Sea-Dumped Munitions

Maria Khon, Aaron Beck, Eric P. Achterberg and Jens Greinert, GEOMAR Helmholtz Centre for Ocean Research Kiel, Germany

Military activities and post-war dumping have introduced large quantities of high explosives such as TNT, RDX, and HMX into terrestrial and marine environments. Residues from these explosives can persist in surface soils and dissolve into groundwater, posing long-term environmental risks. Millions of tons of munitions were historically dumped at sea, and breaching by corrosion allows dissolution and spread of explosive chemicals into the surrounding environment. Upon release, toxic explosive chemicals pose risks to marine ecosystems, seafood safety, and human health. Understanding dissolution and transport processes is therefore essential for understanding the potential exposure of munition chemicals to marine ecosystems. However, little is known about the primary controls on dissolution of solid explosives or their rates in marine systems.

The current study tested the effect of water current speeds on dissolution of explosive chemicals from fragments recovered from WWII-era munitions in the Baltic Sea. Experiments were conducted using deionised water at room temperature, simulating shaking, stirring, and flume conditions. Dissolution kinetics were assessed after solid-phase extraction and HPLC-APCI-MS analysis. Contrary to expectations, results showed limited dependency of water current speed on dissolution rate. However, during the simulated shaking conditions, the highest flow velocity (120 rpm) led to a clear increase in dissolved TNT after 24 hours. Overall, TNT levels were between 115 % and 185 % higher than at 30 rpm, approximately twice as high, indicating that stronger water movement substantially enhances dissolution. In addition, some fragments contained the explosive tetryl, enabling assessment of its dissolution behaviour alongside the more commonly detected TNT and RDX. Tetryl was detected in solution after 24 hours of exposure, indicating that it actively dissolves under the tested experimental conditions.

These results provide new insights into the dissolution behaviour of sea-dumped explosive material and provide quantitative information on the environmental release of explosive chemicals.

6.06.P-We418 Effects of Clearance Operations on the Temporal and Spatial Dynamics of Munition Compounds in Lübeck Bay, Baltic Sea.

Jana-Sophie Appelt, Aaron Beck, Jens Greinert and Eric P. Achterberg, GEOMAR Helmholtz Centre for Ocean Research Kiel, Germany

An estimated 1.6 million tons of munitions rest on the seafloor in the German territories of North and Baltic Sea due to dumping of bombs, torpedoes, and other munitions after World War I and II, as well as unexploded ordnance (UXO). These munitions and their associated munition compounds (MC) pose potential risks to marine ecosystems, blue economy and human health globally. Advanced degradation and corrosion of munition shells allow release of toxic explosive chemicals into the surrounding environment. In the Baltic Sea, where water exchange is limited, such contaminants can accumulate more rapidly than in open marine systems. As corrosion progresses, munition shells also become increasingly fragile, underscoring the need for clearance operations before corroded munitions become unsafe to handle.

To address these challenges, the German government has launched a pilot project for the removal of sea-dumped munitions in Lübeck Bay. The project aims to gain knowledge on clearance of various munition types, and to demonstrate that systematic clearance is feasible. The results of these clearance tests will be used further to develop a mobile platform for the large-scale, on-site destruction of recovered munitions.

Here, marine clearance operations were monitored for the first time to evaluate environmental effects. Water samples were collected during research cruises before, during and after clearance activities at four known dumping sites in Lübeck Bay. Dissolved explosives (TNT, 2-Amino-4,6-Dinitrotoluene (ADNT), RDX, HMX and Dinitrobenzene (DNB)) were preconcentrated by solid phase extraction and analysed using HPLC-APCI-MS. Before clearance, total MC concentrations ranged from 4 to 344 ng/L. Preliminary results show a reduction after clearance at only one of the sites. Where munition piles were only partially cleared, the decrease in concentrations was insignificant. Furthermore, the clearance changed the munition compound composition, with DNB, RDX, and TNT dominating before, and ADNT and TNT afterwards, suggesting ongoing degradation processes. RDX showed the highest pre-clearance concentration on average (18 ng/L), but was below the detection limit post-clearance, indicating a successful removal. Samples collected every eight hours during clearance showed strong fluctuations, but no increase in overall concentrations. These findings provide important insights into the immediate effects of marine munitions clearance operations and their efficiency.

6.06.P-We419 Environmental Impact of WWII Warship Wrecks and Munitions in the English Channel: Evidence of Long-Term Contaminant Release

Benjamin Orban¹, Yann Aminot², Karine Moisan², Laurence Poirier¹ and Gaëlle Dieulefet¹, (1)*Nantes University, France*, (2)*French Institute for Ocean Science (IFREMER), France*

Historic shipwrecks are increasingly acknowledged as significant sources of marine pollution. Many carried substantial amounts of fuel, paint, electrical systems, and munitions that can release toxic substances as they corrode. However, the data needed for a reliable and accurate large-scale assessment of their environmental impact remain scarce. The CONTEPAV project investigates the environmental impact of such wrecks, focusing on contaminant release processes and spatial patterns in the eastern English Channel, a highly dynamic environment with strong hydrodynamics and high wreck density.

Four representative warship wrecks were studied, including the British minesweeper HMS Magic and the German vessels Greif and Gauss. Surface, inside the wrecks, and core sediments were collected at varying distances, complemented by passive samplers (SPMD, DGT, POCIS) deployed on the wrecks to detect ongoing pollutant releases. Sediment cores were divided to 3 sections of about 14-15cm, corresponding to bottom, medium and top core sections. Analyses focused on hydrocarbons (PAHs, alkanes), metals, PCBs, and explosive compounds (TNT and breakdown products).

Results reveal decreasing vertical metal concentrations toward the top core section, consistent with a slowing in metal releases from the shipwrecks. Copper and zinc show significant enrichment near wreck structures, exceeding both ERL ecotoxicological thresholds. Correlation between distribution patterns suggest that manganese and vanadium concentration are not influenced by the structure. Many samples contain high PCB concentration above and EAC thresholds for several congeners (PCB 118 dominates the PCB profile). Highest PCB concentrations are found in sediment collected inside the wrecks, confirming a direct link with onboard PCB containing materials. Although TNT concentrations in sediments were below detection limits, passive samplers detected nanogram-per-liter releases, confirming ongoing but low-level leakage from corroded munitions.

These findings demonstrate that WWII wrecks continue to act as localized and persistent sources of contamination, decades after sinking. The results highlight the need for long-term environmental monitoring and integrated risk assessment frameworks to address underwater cultural heritage and war remnants as potential pollution sources.

6.06.P-We420 Hotspots of Environmental Contamination from Explosive Chemicals Released from Sea-Dumped Munitions

Aaron Beck¹, Mareike Keller¹, Mario Esposito¹, Gabriel Nolte¹, Tim Weiss¹, Matthias Brenner², Jens Greinert¹ and Eric P. Achterberg¹, (1)*GEOMAR Helmholtz Centre for Ocean Research Kiel, Germany*, (2)*Alfred Wegener Institute for Polar and Marine Research, Germany*

The German Baltic Sea is widely contaminated with low levels of dissolved explosive chemicals (or munition compounds, MC), including 2,4,6-trinitrotoluene (TNT), 1,3,5-trinitro-1,3,5-triazinane (RDX), and 1,3-dinitrobenzene (DNB). Chemical mapping in the water column has shown clear spatial differences among different explosive compounds, with TNT concentrations especially high in Kiel Bay, and RDX and DNB concentrations relatively elevated in Lübeck Bay. The reason for these spatial trends is not known, but has been hypothesized to result from varying explosive mixtures in different munitions types dumped in the two regions. In the current study, water samples were collected throughout the study region with a Niskin rosette, and close to munition objects using a small ROV and a towed video platform. Additional water samples were collected at the seafloor with a lander that performed automated solid-phase preconcentration. Dissolved MC were analyzed immediately after sample collection by shipboard automated solid-phase extraction and analysis by HPLC-APCI-MS. Deep water samples showed the typical pattern of high TNT concentrations in Kiel Bay (up to 10 ng/L), and elevated RDX and DNB in Lübeck Bay (up to 203 and 137 ng/L, respectively). Targeted water samples close to munition objects showed sources of TNT, RDX, and DNB were present at all munition sites and chemical release occurred only from objects with breached housings. However, a diverse array of munitions targeted in Lübeck Bay revealed clear differences among objects, with sources emitting either 1) all three MCs but predominantly TNT, 2) moderate TNT and high RDX and DNB, or 3) high DNB and low TNT and RDX. The toxicity of these MCs to aquatic organisms follows the order DNB > TNT > RDX. Thus, the environmental risk posed by different munition types would follow the same order (all else being equal), with objects containing the Type 2 (high DNB/RDX, moderate TNT) or Type 3 (high DNB, low TNT/RDX) explosives posing the greatest environmental health threat. For environmental protection, the highest priority for remediating munition objects should focus on breached objects with DNB-containing explosive fill. The current study shows that regional mapping can identify high-risk regions. A combination of geophysical target mapping,

visual object inspection, and targeted water sample analysis then provide data for definitive prioritization of munition objects for remediation.

6.07.A Innovative Strategies in Implementing Safe and Sustainable by Design (SSbD) Approaches

6.07.A.T-01 Developing a Safe and Sustainable by Design (SSbD) Bio-based Chemical Platform within the NEXT-STEP Project: Focus on Hazard and Worker Exposure Assessment (SSbD Steps 1 & 2)

Laurent Bilteryst, Certech, Belgium

The European NEXT-STEP project (1 June 2024 – 31 May 2028), funded by the Circular Bio-based Europe Joint Undertaking (CBE-JU), aims to demonstrate a sustainable, safe, and economically viable production process for the bio-based chemical platform 3MdVL and its derivative 3MPD. These monomers are designed to replace fossil-based polyols and monomers, with applications in PLA co-polymers and recyclable NIPU foams. Ensuring safety during development, NEXT-STEP implements a Safe and Sustainable by Design (SSbD) framework aligned with the European Commission's Joint Research Centre methodology.

This study focuses on Steps 1 and 2 of SSbD: hazard assessment and human health and safety in production. Step 1 identifies intrinsic hazards to human health, the environment, and physical safety, using bibliographic data, MSDS, and CLP criteria. Step 2 evaluates worker exposure across laboratory to demonstration scales, using modeling tools (Stoffenmanager®, IHMod®) and, where necessary, analytical verification following international standards (EN482:2021, ISO16017-1/2:2020, EN689:2018). The Risk Characterisation Ratio (RCR) provides a quantitative measure to flag potentially unacceptable exposures, guiding mitigation or substitution strategies.

Preliminary results indicate that most chemical building blocks pose low risk, while a few NIPU production substances were identified as higher risk for human health. These findings are communicated to partners to identify safer alternatives or implement mitigation measures to ensure controlled worker exposure. The iterative assessment throughout the project timeline allows integration of evolving process conditions and scientific developments.

By embedding safety considerations into early molecular and process design, NEXT-STEP demonstrates how SSbD can reduce chemical hazards, optimize production processes, and ensure inherent safety for workers. This approach enables the development of 3MdVL and 3MPD monomers that meet functional performance targets while minimizing environmental and human health risks, illustrating a practical pathway for sustainable bio-based chemical innovation.

Keywords: Safe and Sustainable by Design, bio-based chemicals, worker exposure, hazard assessment, 3MdVL, 3MPD

6.07.A.T-02 A Tiered Ecotoxicity and Biodegradability Testing Approach of Novel SURFsUP Biosurfactants for Home and Personal Care Products and Agrochemicals

Rubén Francisco Martínez López¹, Sofie Lodens², Hernan Rico¹, PATRICIA SOLORZANO³, Virginia Cazzagon¹ and Socorro Vázquez-Campos¹, (1)Leitat Technological Center, Spain, (2)Bio Base Europe Pilot Plant, Belgium, (3)Hehs, Leitat Technological Center, Spain

The SURFsUP project aims to develop next-generation biosurfactants that are safe, sustainable, and biodegradable for applications in home care, personal care, and agrochemicals. To ensure the implementation of the Safe and Sustainable by Design (SSbD) Framework established by the European Commission-Joint Research Centre, a comprehensive experimental testing approach was implemented to evaluate environmental safety and biodegradability of the biosurfactant formulations.

A stepwise approach was adopted, starting with acute ecotoxicity tests on aquatic and soil organisms from different trophic levels including OECD 201 (algal growth inhibition -R. subcapitata), OECD 202 (Daphnia magna immobilization), and ISO 16072 (soil respiration -bacteria). Additional tests included OPPTS 850.420 (seed germination/root elongation -L. sativa-) to broaden species coverage. The second step comprises chronic tests such as OECD 208 (seedling emergence and growth -C. sativus-), OECD 211 (Daphnia magna reproduction) and OECD 220 (earthworm reproduction -Enchytraeide crypticus-). Biodegradability was assessed using OECD 301F standard test (manometric respirometry) and a rapid MTT screening assay to confirm microbial viability and degradation potential.

Preliminary results show low (or none) acute toxicity of the biosurfactants across the tested species, with EC50 values higher than 100 mg/L in all cases, confirming their suitability to be tested in chronic tests.

Biodegradation in soil and water compartments will be tested to investigate their potential persistency in environment once the biosurfactants formulations are released in wastewater treatment plants during use and end of life stages.

The integration of ecotoxicological investigations and biodegradation assays through a tiered approach helped to reduce experimental testing and prioritize the most promising biosurfactant formulations to support the SSbD implementation for home and personal care products and agrochemicals.

6.07.A.T-03 DECISION T-REEX: A Decision Tree for Environmental Exposure Assessment for (Advanced) Materials

Vicenç Pomar Portillo and Bernd Nowack, Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland

Estimating environmental exposure during early product development stages is often limited by a lack of detailed input data and accessible methods. Existing exposure assessment tools, while well established, are often too complex for early-stage decision-making for (advanced) materials and offer limited flexibility under uncertainty.

To address this gap, Decision T-REEX was developed as a modular tool that estimates emissions to air, water, and soil across the life cycle of (advanced) materials. The tool guides users through structured questions covering production, manufacturing, use and end-of-life stages. The use phase are further divided into service life, application before use and maintenance, allowing the tool to capture diverse release pathways. Based on the provided information, Decision T-REEX assigns release scenarios using Environmental Release Categories (ERC) defined by the European Chemicals Agency (ECHA) and, where applicable, Specific Environmental Release Categories (SPERC) developed by recognised industrial sector organisations. On top of that, it includes a feature to flag scenarios of potential concern and suggests mitigation actions.

The tool was tested on three industrial case studies: a sunscreen with nanosized titanium dioxide, a post-harvest fruit coating, and an anti-corrosion coating. For each case, life-cycle specific emission estimates to environmental compartments were produced. For the sunscreen and fruit coating, the tool identified complete release to water during use. The anti-corrosion coating, while applied indoors with minimal release, was flagged for potential environmental exposure due to moderate degradation in outdoor settings.

Decision T-REEX showed promising performance in clarifying where releases may occur across the life cycle and how design or use-phase conditions could influence them. Even when only limited information is available, it supports early-stage decision-making by offering a transparent and structured basis for exposure assessment. The tool will be integrated into the digital platform of the European-funded SUNRISE project, which aims to advance the practical implementation of Safe and Sustainable by Design (SSbD) methodologies for advanced materials.

Disclaimer/Disclosure:

Funding for this research was received from the European Union (EU) Horizon Europe project SUNRISE (Grant agreement number – 101137324 and the Swiss State Secretariat for Education, Research and Innovation (SERI) no 23.00563).

6.07.A.T-04 A Multilevel Qualitative Assessment Tool for Safety Screen-ing of Advanced Materials

Elena Badetti¹, Sara Trabucco¹, Andrea Brunelli¹, Elisa Giubilato², Vanessa Canaletti¹, Chiara Missaglia¹, Alberto Katsumiti³, Itziar Polanco³, Vicenç PomarPortillo⁴, Bernd Nowack⁵, Carlos A Rumbo⁶, María Rivero García⁷, Morgan Lofty⁸, Janeck Scott-Fordsmand⁹, Hubert Rauscher¹⁰, Irantzu Garmendia Aguirre¹⁰, Lisa

Pizzol¹¹, Alex Zabeo¹¹, Stefano Manfredini¹², Filippo Marchetti¹², Danail Hristozov¹¹ and Antonio Marcomini¹³, (1)Ca' Foscari University of Venice, Italy, (2)Green Decision, Italy, (3)GAIKER Technology Centre, Spain, (4)Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (5)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (6)UBU, Spain, (7)ITENE Research Centre, Valencia, Spain, (8)IOM, United Kingdom, (9)Aarhus University, Denmark, (10)JRC, Italy, (11)Greendecision (GD), Italy, (12)Università di Ferrara, Italy, (13)University Ca' Foscari Venice, Italy

The JRC Safe and Sustainable by Design (SSbD) framework for chemicals and materials promotes the development of safe and sustainable chemicals/materials from the early design phase. In this context, the Horizon Europe SUNRISE project has developed a questionnaire-based tool—building upon a previous version from the H2020 SUNSHINE project—to support the early-stage safety assessment of advanced materials (AdMa) synthesized for innovative applications. The tool helps companies to identify potential human health and environmental risks along the AdMa life cycle, already in the first stages of material development. The questionnaire follows a multilevel structure, where top-level questions address the most critical safety aspects across the AdMa lifecycle and guide users to specific sub-questions only when needed. Another advancement is the integration of suggestions for suitable tools and analytical methods that can be used to address data gaps identified during the assessment. To evaluate its applicability, the tool was tested on an industrial case study within the SUN-RISE project. The case study involved TiO₂-based AdMa, obtained through different synthetic processes, intended for use as UV filters for sunscreen formulations. The process enabled the identification of key life cycle stages (synthesis and use phase) and exposure routes to be considered in the assessment. Thus, it supports the identification of data needs and knowledge gaps that must be addressed to align with evolving regulatory requirements and to facilitate the design of safe and sustainable AdMa.

6.07.A.T-05 Retrospective SSbD case study of a small-molecule antibiotic: cross-domain evaluation of safety and sustainability in pharmaceutical development

Jacopo Sorani¹, **Francesco Barilli¹**, Bernd Nowack¹ and Roland Hischer², (1)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (2)Technology & Society Laboratory, Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland

The pharmaceutical sector is essential for human health and wellbeing but is associated with high environmental and occupational burdens, especially for small-molecule medicines with long, solvent-intensive syntheses. Applying Safe and Sustainable by Design (SSbD) principles to pharmaceuticals is challenging because development can last 10–15 years, and the information needed for safety and sustainability assessment is often fragmented and unavailable when key design decisions are taken.

We conducted a retrospective SSbD analysis of a recently developed antibiotic, in collaboration with a F. Hoffman-La Roche AG. The aim was to understand how safety and sustainability considerations could have been integrated earlier in the research and development pipeline. We first reconstructed the “data landscape” of the molecule: for each development phase, from early discovery to late-stage development, we identified which data are generated, by whom, in which format (qualitative, quantitative, predicted or experimental), and whether they are usable for safety and sustainability assessment.

We then performed an ex-ante life cycle assessment (LCA) of the manufacturing route, guided by the forthcoming PAS 2090 standard on life cycle assessment of pharmaceutical products. Because existing LCA databases contain very few pharmaceutical intermediates, reagents and specialised solvents, we developed a structured proxy approach. Proxy chemicals were selected using structural and functional similarity and information from the reaction database Reaxys, so that key energy and material hotspots could still be screened while keeping assumptions transparent.

In parallel, we explored how early molecular and process information can support environmental risk assessment (ERA) and worker protection. Using simple descriptors derived from chemical structure and minimal route knowledge (for example partition coefficients, acid dissociation constants, functional groups, structural alerts, etc.), combined with tools from the Partnership for the Assessment of Risks from Chemicals (PARC) Toolbox, we tested how early signals of persistence, mobility and occupational hazard could have been identified.

Our work proposes concrete insertion points for SSbD in pharmaceutical innovation and outlines minimal data

packages and proxy rules that can enable simplified, cost-effective safety and sustainability assessment at early stages, supporting more sustainable antibiotic development.

6.07.B Innovative Strategies in Implementing Safe and Sustainable by Design (SSbD) Approaches

6.07.B.T-01 ProScale Service Life: Assessing Direct Use-Phase Exposure in Early Innovation

Amanda Lundberg¹, Therese Kärnman², Efstathios Reppas Chrysovitsinos², Rosella Telaretti Leggieri², Erwan Guy Saouter³ and Pernilla Andersson⁴, (1)IVL, Sweden, (2)Swedish Environmental Research Institute (IVL), Sweden, (3)No Affiliation, France, (4)IVL Swedish Environmental Institute, Sweden

Introduction

Applying the Safe and Sustainable by Design (SSbD) framework requires tools that capture toxicological impacts of chemicals from a life cycle perspective to guide innovation [1]. Due to the lack of tools, direct impacts on consumers during the service life of products has been hard to capture. ProScale is a risk-based, life cycle-oriented approach for chemical footprinting that was developed to address this gap by estimating toxicity potentials across the life cycle of products [2]. Therefore, the ProScale method is applicable in the context of the SSbD as a bridge between risk assessment and life cycle assessment (LCA). Herein, we present the recently developed ProScale for Service Life (ProScale-SL) module for assessment of consumer impacts during the service life of products.

Methods

The ProScale-SL module assesses toxicological impacts on consumers in various types of indoor environments. The SL module is, as seen Eq. 1, based on five factors, of which the first four correspond to the characterization factor (CF):

- $PS_{i,r}$ (mg): route-specific process score for substance i ,
- m_{ref} (kg): reference-flow mass for one product unit,
- $PPDD_{i,r}$ (mg/person/day): per-person daily systemic dose for exposure to substance i and via route r ,
- $PHFH$ (person-days): person-time factor over the functional unit horizon, aggregating exposure across all users within this time horizon in an archetypal indoor environment (AIE),
- HFi,r : hazard factor, primarily based on hazard phrases from the Globally Harmonised System,
- MF (kg): inventory mass flow of products in the modelled system.

$$ProScale = \sum_{Substances} ((HF \times PPDD \times PHF) / m_{ref}) \times MF \quad (Eq.1)$$

Results and Conclusions

Here we revisit a fictive case study where e.g. Bisphenol A based polycarbonate was assessed with the ProScale for Workers methodology. We apply the SL module to the bottles in a household AIE. Preliminary results indicate that the module can capture the impacts of hazardous substances.

In summary, we see that the ProScale-SL module can cover the impacts of concerning substances which may be harmful to humans in the service life phase. With this module, integrated alongside already existing ProScale modules, and new developments, we foresee that the ProScale methodology will become a tool suitable for LCA practitioners, risk assessors, and others concerned with the impacts of chemicals across the life cycle of products.

Presentation preference: Platform presentation

6.07.B.T-02 How to consider benefits related to functionality in SSbD? An overview of early phase benefit assessments and an application to selected case studies

Merve Tunali¹, Nihal Engin Vrana², Xavier Wurtz², Bernd Nowack³ and Simone Schulte⁴, (1)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (2)SPARTHA Medical, France, (3)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (4)Evonik Operations GmbH, Germany

Even though the Safe and Sustainable by Design (SSbD) framework considers many safety and sustainability aspects from the innovation and design phase to the fully developed materials and products, there is still a gap in the consideration of functionality-related benefits of chemicals or materials. To address this gap, we propose the implementation of an early-phase benefit assessment that considers functionality-related benefits alongside societal impacts; accounting for both positive and negative aspects and applied it to two cases: a wound care solutions used in healthcare and antimicrobial coatings based on upconverting particles used in public spaces. First, specific indicators for both positive and negative aspects were defined, and a qualitative scoring system was assigned. Negative indicators include the development of antimicrobial and cross-resistance, as well as animal testing for both cases. Positive indicators include reduced infections for both cases; additionally, for wound dressings, improvements in wound healing and shorter hospital stays were considered, while for antimicrobial coatings, increased public health due to reduced chemical usage and improved quality of life were included. A balance factor was calculated by dividing the sum of points from positive indicators by the sum of points from negative indicators. The balance factor was found to be 2 for wound dressings, and between 1-2 for upconverting particles, indicating that potential benefits are likely based on the functionality. In addition, guidance is provided on extending the assessment from qualitative to semi-quantitative and quantitative methods as the TRL level develops.

6.07.B.T-03 Implementing SSbD in battery recycling processes of RESTORE and potential applications of SSbD data for the EU Battery Product Passport

Camilla Delpivo, Socorro Vázquez-Campos and Christophe Aucher, Leitat Technological Center, Spain

The project RESTORE aims at developing innovative, safe, cost effective and scalable solution for the separation, recovery, purification, upcycling, and validation of materials and metals, to be directly transformed into new battery precursor and functional materials. In this context, the SSbD framework developed by the EU Joint Research Centre is implemented to ensure the integration of the SSbD principles and assessment, that will result in safer technologies with improved recovery yield and increased quality of the recycled/recovered materials. Finally, it will provide a demonstration on how data and information collected for the SSbD assessment can be embedded in the EU battery product passport, to actively support decision-making at all stages of the battery recycling step, from material valorisation to recycling-process safety and second-life applications.

The SSbD assessment is being performed by collecting data and information in specific templates and by using predictive models or experiments/ measurements. The SSbD assessment results obtained are shown and discussed with interested partners (actors in the recycling steps/ processes) to make them aware of possible hazards coming from materials generated during pre-treatment processes, or in relation to release and exposure issues specific to the pre-process assessed. This allows defining corrective measures or to re-design specific steps of battery pre-processing steps. Finally, we will demonstrate how the data and information retrieved along the SSbD assessment can be included in the battery product passport, to provide to the different actors in the battery value chain key information on safety and sustainability of materials and processes.

SSbD principles will be applied and monitored to improve different aspects of safety and sustainability of battery pre-treatment processes simultaneously, with the aim to ensure resource-efficient production, addressing adverse effects on humans and ecosystems.

In a SSbD perspective, including key SSbD data to the battery product passport will empower end-users of battery materials/parts facilitating their decision-making (e.g. to decide on safer materials or processes or providing safer working conditions to protect workers health). Furthermore, the SSbD data will add value to the information reported in the battery product passport, allowing to anticipate safety and sustainability issues as well as anticipating future legal requirements.

6.07.B.T-04 Operationalising Safe and Sustainable by Design for Industry: Mapping, Coordinating, and Structuring Chemical and Material Innovation with the PLANETS Workflow

Joséphine STECK¹, Thomas Hennequin², Ayse Ay³, Anita Sosnowska⁴, Matiss Reinfelds⁵, Martin Himly⁶, Neeraj Shandilya², Loélia Fohet⁷, Sabine Hofer⁸, Nobert Hostätter⁸, Cécile Philippot⁹ and Stéphanie Desrousseaux⁹, (1)Atomic Energy Commission (CEA), France, (2)TNO, Netherlands, (3)BASF, Germany, (4)University of Gdańsk, Poland, (5)BioNanoNet Forschungsgesellschaft mbH, Austria, (6)Paris Lodron University of Salzburg, Austria, (7)Industrial Technical Center for Plastics and Composites, CT-IPC, Biopôle Clermont-Limagne, 63360 Saint-Beauzire FRANCE, France, (8)Department of Biosciences & Medical Biology, Division of Allergy & Immunology, University of Salzburg, Austria, (9)Univ. Grenoble Alpes, CEA LITEN DTNM, France

The Joint Research Centre has accelerated the transition towards safer and more sustainable innovation in the EU through the introduction of the Safe and Sustainable by Design (SSbD) framework. To support its operationalisation, several tools and initiatives have emerged, including CEFIC's SSbD approach, the PARC toolbox, and IRISS project. Among these efforts, EU PLANETS project addresses 11 key challenges to SSbD operationalisation—such as integration of safety and sustainability considerations, embedding SSbD within innovation processes, and improving data management. By developing a tiered, multi-criteria workflow grounded in SSbD principles, PLANETS aims to promote the design for safer alternatives for plasticizers, flame retardants, and surfactants. This contribution presents the PLANETS workflow and early insights from three case studies (CS).

The workflow was co-developed by a multidisciplinary team through iterative cycles, tackling key issues. Drawing on insights from the literature, the resulting structure includes two main phases—scoping and assessment—supported by an educational kit. The assessment phase is further subdivided into simplified, intermediate, and full tiers, enabling a progressive and adaptable evaluation process.

The scoping phase covers the motivation for (re)design, value chain definition, regulatory landscape analysis and SSbD specification. These steps help clarifying objectives, system boundaries, and resource needs at an early stage. In the assessment phase, defining core product functions remains essential. The overall process requires adapting to varying numbers of alternatives, potentially clustering similar options for feasibility. SSbD ambassadors to each CS supported coordination, stakeholder engagement facilitation, and integration of safety and sustainability from the start. Training and onboarding workshops fostered a shared understanding and reinforced collaboration, while the framework enabled multidisciplinary engagement and transparent trade-off analysis.

Overall, the workflow offers a structured and practical guide for SSbD framework implementation. Its initial application within PLANETS project demonstrates its potential value, with future refinements planned based on user feedback, expanded datasets, and broader validation across industrial contexts.

6.07.B.T-05 Policy Gaps for Advanced Materials: Insights from EU Regulatory Mapping and Industrial Case Studies

James Baker¹, Blanca Suarez Merino², Oona Freudenthal³, Ghaya Rziga³, Lasse Steffens⁴ and Danail Hristozov⁵, (1)TEMAS Solutions, Netherlands, (2)TEMAS Solutions GmbH, Switzerland, (3)Luxembourg Institute of Science and Technology, Luxembourg, (4)Institute of Safety and Risk Sciences (ISR) University of Natural Resources and Life Sciences, Austria, (5)East European Research and Innovation Enterprise (EMERGE), Bulgaria

Advanced Materials (AdMa) support EU sustainability goals, yet their complex behaviours and life-cycle transformations challenge regulatory frameworks designed for conventional chemicals. The SUNRISE project combined a top-down mapping of EU strategies and regulations with bottom-up insights from three industrial case studies to identify gaps affecting the safe and sustainable development of AdMa and to provide evidence for future SSbD-oriented approaches.

Mapping covered 18 strategies, directives and policy instruments linked to the European Green Deal, the Chemical Strategy for Sustainability and sectoral and environmental legislation. Each instrument was reviewed for nanoform-specific data requirements, transformation and degradation considerations, release assessment provisions and coverage of life-cycle stages. In parallel, interviews with industrial partners captured challenges related to characterisation, regulatory compliance, testing needs, monitoring requirements and end-of-life handling. Findings were integrated using a harmonised framework that compared policy expectations with industrial realities.

Four cross-cutting gaps emerged. First, harmonised consumer-use labelling for nanomaterials lacks across EU product legislation. Second, nanoform-specific occupational exposure limits are absent. Third, guidance for assessing transformation, degradation and release under realistic operational conditions is insufficient. Fourth, most regulations do not explicitly address aged or weathered forms of AdMa, despite their relevance for environmental fate and hazard. These gaps were observed across different instruments revealing that many policies still assume static material behaviour.

Industrial case studies confirmed these issues. Companies reported difficulties assessing release and ageing of nano-enabled coatings under offshore stressors, limited guidance for mixture toxicity and end-of-life considerations for biocidal systems, and uncertainties when registering hybrid nano-composites under REACH. They also highlighted missing protocols for monitoring nanoparticle emissions into wastewater and the fragmentation of regulatory pathways.

Overall, the analysis shows that the EU regulatory landscape is only partially equipped to address the dynamic properties of AdMa. Addressing these gaps will require coordinated policy development, improved test methods, strengthened monitoring capabilities and harmonised frameworks aligned with SSbD principles.

6.07.P Innovative Strategies in Implementing Safe and Sustainable by Design (SSbD) Approaches

6.07.P-Th240 Safe and Sustainable by Design: Driving Innovation Toward Safer and More Sustainable Chemicals, Materials, Processes and Products

Irantzu Garmendia Aguirre¹, Rasmussen Kirsten² and Hubert Rauscher¹, (1)European Commission - Joint Research Centre (JRC), Italy, (2)Retired, Italy

The Safe and Sustainable by Design (SSbD) framework, developed by the European Commission's Joint Research Centre, is described here. It is applicable to chemicals and materials, and the European Commission recommends its use in research and innovation activities. This framework is one means to facilitate achieving the goals of the European Union's Chemicals Strategy for Sustainability. The implementation of the SSbD framework calls for a new way of thinking and a shift in current innovation practices. It thus requires safety and sustainability to be considered in an integrative manner from the early stages of innovation, and with a life cycle perspective.

This work describes the policy context in which SSbD was developed, outlines the concepts underpinning SSbD, and its assessment steps. Furthermore, it presents some early implementation lessons learned, gives an overview of ongoing work to implement and advance its development, and provides an outlook for future developments. The transition to SSbD requires deeper integration of several disciplines, until now often independently practiced, that address chemical risk and sustainability. In addition, the implementation of these disciplines, from the early design phase of new chemicals, materials, processes, and products onward, makes the engagement of communities in the research and innovation fields paramount

6.07.P-Th241 Unveiling the 2025 SSbD framework

Serenella Sala¹, Irantzu Garmendia Aguirre², Elisabetta Abbate³ and Giulio Bracalente¹, (1)European Commission, Joint Research Centre, Directorate D – Sustainable Resources, Italy, (2)European Commission, Joint Research Centre, Directorate F – Health and Food, Italy, (3)Department of Environmental Science, Radboud University, Nijmegen, The Netherlands, Netherlands

The 2025 Safe and Sustainable by Design (SSbD) framework, developed by the European Commission Joint Research Centre (EC-JRC), builds on the foundation set in 2022 to enhance safety and sustainability across the life cycle of chemicals and materials. This revision emerged from extensive testing and stakeholder collaboration, focusing on refining the framework to better assist the innovation process. The SSbD framework integrates a co-creation process illustrated through various testing phases and workshops, aimed at gathering input for its refinement.

Central to the framework is its set of principles, designed to clarify and guide its application. The scoping analysis contextualizes key issues related to innovation, engaging actors throughout the lifecycle and proposing methodological criteria for adherence to SSbD principles. The framework introduces a comprehensive assessment structure: safety, environmental sustainability, and socio-economic sustainability. The safety assessment incorporates intrinsic chemical/material properties alongside exposure evaluations providing a holistic safety approach. Environmental sustainability employs Life Cycle Assessment to cover the chemical/material life cycle from raw materials to end of life, offering screening level assessments for less mature innovations. Socio-economic sustainability expands its focus on social fairness, competitiveness, and supply chain vulnerabilities, considering risk governance and financial stability.

The framework provides sub-chapters to evaluate safety and sustainability of processes. Additionally, the evaluation segment identifies trade-offs and uncertainties inherent in the implementation of SSbD, using dashboards for visual representation to highlight hotspots and guide innovation. A dedicated documentation chapter ensures transparent and systematic recording of the framework's implementation, fostering accountability and clarity in its application. Overall, the 2025 SSbD framework strives to guide and support innovation by addressing safety and sustainability comprehensively, supported by stakeholder feedback and robust methodological guidance.

6.07.P-Th242 A Common Language for Safe and Sustainable by Design: One Wordbook to Understand Them All

Joséphine STECK¹, Cécile Philippot¹, Stéphanie Desrousseaux¹, Thomas Hennequin², Neeraj Shandilya³, Loélia Fohet⁴, Raphaël Croibier⁴, Laura Magnasco⁵, Martina Riccio⁵, Sabine Hofer⁶, Norbert Hostätter⁶, Martin Himly⁶, Poornima Nagesh⁷, Anita Sosnowska⁸, Szymon Zdybel⁹ and Matiss Reinfelds¹⁰, (1)Univ. Grenoble Alpes, CEA LITEN DTNM, France, (2)Department of Circularity & Sustainability Impacts, TNO, Utrecht, The Netherlands., Netherlands, (3)Department of Risk Analysis for Prevention, Innovation & Development, TNO, Utrecht, The Netherlands, Netherlands, (4)Industrial Technical Center for Plastics and Composites, CT-IPC, Biopôle Clermont-Limagne, 63360 Saint-Beauzire, France, France, (5)RINA Consulting S.p.A., Italy, (6)Department of Biosciences & Medical Biology, Division of Allergy & Immunology, University of Salzburg, Austria, (7)Radboud University, Netherlands, (8)University of Gdańsk, Poland, (9)QSAR Lab, Poland, (10)BioNanoNet Forschungsgesellschaft mbH, Austria

Creating a common and shared understanding of key concepts is a critical step toward the successful operationalisation of the Safe and Sustainable by Design (SSbD) approach. As highlighted in several publications, terminology consistency remains a major challenge for the SSbD community. To address this need, a dedicated Wordbook has been developed within the PLANETs project to compile, harmonise and clarify essential terms used across SSbD-related disciplines.

This Wordbook is a carefully curated collection of more than eighty key terms and their definitions, covering domains such as safety (hazard and exposure), sustainability (environmental, economic and social aspects) including methodological tools, indicators, and frameworks relevant to the SSbD approach. The distribution of terms is well balanced between the two foundational pillars of SSbD, with 36 terms related to sustainability and 33 to safety, while generic and regulatory aspects are represented by more than 15 additional terms. Each term is classified by theme, topic, and name, providing a user-friendly structure that supports both expert and non-expert understanding.

The main objective of this resource is to foster a shared vocabulary among SSbD experts and broader innovation community. By ensuring conceptual clarity and coherence, it strengthens communication, facilitates interdisciplinary collaboration, and supports the integration of SSbD principles across research and innovation processes.

The Wordbook is made available internally as a project deliverable and publicly through the open-access platform ZENODO (and will be updated every six months), ensuring transparency and broad accessibility, as well as on the project website. It also forms part of a wider educational kit designed to build capacity, promote

training, and support the adoption of the SSbD approach across scientific, industrial, and policy communities. Ultimately, this initiative contributes to the development of a consistent and operational language that underpins the implementation of the SSbD approach across these diverse contexts.

6.07.P-Th244 Methods and Tools for the Safety Assessment of Advanced Materials

Vicenç Pomar Portillo¹, Blanca Suarez Merino², Santiago Aparicio³, Elena Badetti⁴, Matthew Boyles⁵, Andrea Brunelli⁶, Carlos Fito⁷, Irantzu Garmendia Aguirre⁸, Elisa Giubilato⁴, Alberto Katsumiti⁹, Erik Laurini¹⁰, Morgan Lofty¹¹, Domenico Marson¹⁰, Lisa Pizzol¹², Isabel Rodríguez-Llopis⁹, Carlos A Rumbo³, Janeck J Scott-Fordsmand¹³, Vicki Stone¹⁴, Sara Trabucco⁴, Danail Hristozov¹⁵ and Bernd Nowack¹⁶, (1)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Spain, (2)TEMAS Solutions, Switzerland, (3)International Research Center in Critical Raw Materials for Advanced Industrial Technologies-ICCRAM, Universidad de Burgos, Spain, (4)Department of Environmental Sciences, Informatics and Statistics, Ca' Foscari University of Venice, Italy, (5)Centre for Biomedicine and Global Health, School of Applied Sciences, Edinburgh Napier University, United Kingdom, (6)Ca' Foscari University of Venice, Italy, (7)ITENE Research Centre, Spain, (8)European Commission - Joint Research Centre (JRC), Italy, (9)GAIKER Technology Centre, Spain, (10)Molecular Biology and Nanotechnology Laboratory, DEA, University of Trieste, Italy, (11)Institute of Occupational Medicine (IOM), United Kingdom, (12)GreenDecision Srl, Italy, (13)Aarhus University, Denmark, (14)Heriot Watt University, United Kingdom, (15)East European Research and Innovation Enterprise (EMERGE), Bulgaria, (16)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland

Advanced materials raise significant challenges for environmental and human safety assessment due to their specific physicochemical properties and behaviour across biological and environmental systems. These characteristics can limit the applicability of testing strategies originally developed for conventional chemicals, and they create a need for approaches that capture material specific mechanisms, transformations and interactions under realistic conditions.

To support this need, an extensive landscape of relevant methodologies and tools was examined and structured. Hazard identification approaches were analysed across in silico, in vitro and in vivo methods, with particular attention to techniques that address nanomaterial specific modes of action in freshwater, seawater and soil systems. In addition, computational tools for exposure, fate and risk assessment were classified into three tiers according to their data requirements, mechanistic resolution and suitability for different innovation stages. Their accessibility was also evaluated, including technology readiness level, maintenance status, cost and ease of use, providing insight into their practical applicability in both research and industrial contexts. Moreover, databases and digital tools repositories containing physicochemical information, hazard data, exposure indicators and environmental fate information were mapped to improve their usability for assessing advanced materials.

This work aligns with the Safe and Sustainable by Design framework of the European Commission by offering a structured basis for integrating safety considerations from the earliest phases of advanced materials development. Through the identification of methodological strengths, current gaps and future opportunities, the assessment landscape is clarified and strengthened, supporting responsible and sustainable innovation in advanced materials.

6.07.P-Th245 New approach methodologies for the safety assessment of Advanced Materials

Itziar Polanco¹, Amaia Garcia-Bilbao¹, Ana Rodríguez Bernaldo de Quirós², Letricia Barbosa-Pereira², Antia

Lestido-Cardama², Raquel Sendón², Perfecto Paseiro Losada³, Danail Hristozov⁴, Felipe Goñi de Cerio¹ and Alberto Katsumiti¹, (1)GAIKER Technology Centre, Spain, (2)Instituto de Materiales (iMATUS), Spain, (3)Department of Analytical Chemistry, Nutrition and Food Science, Faculty of Pharmacy, University of Santiago de Compostela, Spain, (4)EMERGE Ltd, Bulgaria

New Approach Methodologies (NAMs) are crucial for tiers 1/2/3 Safe and Sustainable by Design (SSbD) assessment by providing a tiered, data-driven approach to evaluate chemical and material safety and sustainability. In later tiers (2 and 3), which involve more complex and data-intensive assessments, NAMs move beyond early-stage qualitative analysis towards semi-quantitative and quantitative data based integrate in vitro methods, in silico tools, and other advanced techniques. In this work, we show examples of the implementation of Tier 2/3 models for two routes of exposure (ingestion and inhalation) and methods to evaluate endocrine disruption and neurotoxicity of Advanced Materials (AdMa). Models for ingestion and inhalation (gastrointestinal triculture models and MucilAir, respectively) are used for both acute (24 hours) and subacute exposures (up to 28 days). These advanced in vitro models retain physiologically relevant exposure scenarios particularly appropriate for ingestion and inhalation, which have the potential to improve the in vivo predictability and lead to reliable outcomes. The neurotoxicity model offers a very versatile and sensitive tool for screening of neurotoxicant AdMas. For endocrine disruption, the OECD TG 455 was adapted and used to evaluate the toxicity mixtures. All exposure protocols were adapted for AdMa exposure and showed good sensitivity and great robustness in comparison to traditional monoculture models used for the same purpose. This work was supported by the EU Horizon Projects “Safe and Sustainable by Design Advanced Materials” (SUNRISE) under Grant Agreement no. 101137324, “Integrated assessment and Advanced Characterisation of Neuro-Nanotoxicity” (iCare), under Grant Agreement no. 101092971 and the Ministerio de Ciencia e Innovación, Agencia Estatal de Investigación and by Fondo Europeo de Desarrollo Regional (FEDER). Ref.No. PID2021-124729NB-I00 “MIGRABIOQUANT” (MCIN/AEI/10.13039/501100011033/FEDER, UE).

6.07.P-Th246 In vitro Ecotoxicity Models for Hazard Screening of Advanced Materials in support of SSbD Assessment

Mikel Isasi-Vicente, Vanesa Benito, Paula Valiente Gómez, Alberto Katsumiti and Felipe Goñi de Cerio, GAIKER Technology Centre, Spain

Advanced Materials (AdMas) are increasingly being used in a wide range technological applications thanks to their unique physico-chemical properties. However, as a result of their novelty, their effect over the environment remains unknown and ecotoxicity models for hazard screening of AdMas are currently scarce. In this study, we applied two in vitro fish-based ecotoxicological models to support SSbD assessment of AdMas: a monotypic culture model using tilapia OmB brain cells and a monotypic culture model using rainbow trout RTgill-W1 gill cells. A dispersion protocol was developed using natural organic matter (NOM) to simulate environmental conditions and ensure that AdMas remained suspended during exposure. Once established, the in vitro models were exposed for 24 hours to different concentrations of AdMa suspensions (from environmentally relevant to high concentrations) and cell viability, ROS production and inflammation were assessed. Results showed that both models represent sensitive New Alternative Methodologies (NAMs) to evaluate acute effects of AdMas in this study. In both models, most of the AdMas caused effects at the highest concentrations tested over the three cell viability parameters (plasma membrane integrity, metabolic activity and lysosomal membrane integrity), but overall, ROS production was observed to increase in RTgill-W1 cells in a dose-dependent manner. In contrast, no significant ROS production was detected in OmB brain cells after 24h of exposure. These findings suggest that the tested AdMas can exert mild cytotoxic effects on fish cells, particularly at higher concentrations. However, the absence of ROS production in brain cells and the relatively low levels of toxicity observed suggest that the neurotoxic effects of these materials may be limited under the tested conditions. This work showed that in vitro tests based on fish cells represent a useful tool for ecotoxicological hazard screening of AdMas. These approaches are essential for improving our understanding of the environmental risks associated with emerging materials and for informing regulatory frameworks that ensure the development of safe(r) and more sustainable AdMas. This work was supported by the iCare project (Grant Agreement ID: 1010929071) and the SUNRISE project (Grant Agreement ID: 101137324), both funded by the European Commission.

6.07.P-Th247 Tier 2/3 in vitro methods for early stage-hazard assessment of Safe and Sustainable by Design (SSbD) biocides

Itziar Polanco¹, Isabel Rodríguez-Llopis¹, Alberto Lopera-López², María José Lopez Tendero², Pau Camilleri³, Carlos Fito³, Danail Hristovoz⁴, Felipe Goñi de Cerio¹ and Alberto Katsumiti¹, (1)GAIKER Technology Centre, Spain, (2)Laurentia Technologies, Spain, (3)ITENE Research Centre, Spain, (4)EMERGE Ltd, Bulgaria

Safe and Sustainable by Design (SSbD) is a design approach for developing and evaluating new chemicals and materials, as well as assessing existing ones, with an emphasis on maintaining functionality while minimizing adverse impacts on human health and the environment. For it, new approach methodologies (NAMs), based on in vitro methods, offer valuable tools for early-stage hazard assessment of SSbD chemicals and materials. In this study, simple (monoculture of enterocytes, Caco-2 cells) and more robust (gastrointestinal epithelial tri-culture model, Caco-2 + HT29-MTX + M Cells) in vitro models were employed to assess the hazards of innovative and conventional biocide alternatives. Both models were exposed for 24 hours to the final product formulations (ranging from 0.03-30%, concentrations used during production and application phases of the products) and to individual compounds (at the corresponding concentrations present in the product formulations), and effects on cell viability (resazurin), inflammatory response (IL-8, sublethal concentrations), and barrier integrity (TEER) and permeability (LY assay) were evaluated. Results showed that both products were significantly cytotoxic starting at 0.03% for Caco-2 cells (innovative was slightly more cytotoxic than reference). In addition, a slight increase of IL-8 release was observed at 0.03% of the innovative product. On the other hand, cytotoxic effects on tri-culture model started at 0.3% (only reference). Inflammatory response showed a significant increase of IL-8 at 0.3% (only reference). Results obtained from barrier integrity of the tri-culture model showed significant decrease in TEER values starting at 0.3% (only reference) and from 3% in both products. In accordance to these results, barrier permeability significantly increased starting at 3% (both products). Overall, results indicated that the toxicity of the innovative product was generally lower than the reference product. In addition, both models showed high sensitivity, however, the tri-culture model was more sensitive and robust than Caco-2 model, indicating that the epithelial tri-culture model could be more suitable for toxicity assessment of the human GIT. This work was supported by the EU Horizon Project “Safe and Sustainable by Design Advanced Materials” (SUNRISE) under Grant Agreement no. 101137324.

6.07.P-Th248 Integrating Predictive Ecotoxicology into the Sustainable Design of Paper-Based Electronic Materials

Dominika Kowalska¹, Anita Sosnowska¹, Szymon Zdybel¹, Sara Carniello², Elisabeth Schwarz-Funder² and Tomasz Puzyn¹, (1)QSAR Lab, Poland, (2)JOANNEUM RESEARCH Forschungsgesellschaft mbH, Graz, Austria, Austria

The growing demand for environmentally responsible electronics has accelerated the development of paper-based, printed components that offer a sustainable alternative to conventional plastic- and metal-based devices. A key challenge is selecting functional chemicals-such as flame retardants, conductive inks and binders, that provide adequate performance while remaining low in ecotoxicity and compatible with biodegradation. In line with the Safe and Sustainable by Design (SSbD) framework, this study incorporates predictive environmental toxicology into the early formulation stages of new material systems. Initially, we employed a data-driven computational workflow to assess the ecotoxicity of 29 chemical constituents (and their precursors) of the paper based Printed Circuit Boards (PCBs). Experimental data for fish, invertebrates, and algae were compiled, and when data gaps existed, available quantitative structure-activity relationship (QSAR) models and read-across approach were used to generate reliable toxicity predictions. Then, all compounds were classified according to U.S. EPA environmental toxicity categories to enable comparative hazard assessment and support the identification of safer substitutes. Most substances evaluated had sufficient experimental or predicted data to support classification. The resulting hazard profiles ranged from practically non-toxic to moderately or highly toxic, highlighting a subset of chemicals of potential environmental concern. Finally, we assessed the environmental impact of the final product, which is mainly consisted of polymers. It has been demonstrated that components in polymerised form should not exhibit toxicity. Consequently, it is important to evaluate the toxicity of monomers and their precursors because, if polymerisation or recycling is insufficient, they may be released into the environment. Overall, the study underscores the potential of in silico tools to guide the selection of low-toxicity, recyclable components for sustainable electronic materials. Remaining challenges include limited high-quality ecotoxicity data, restricted model applicability for novel chemicals, and the difficulty of evaluating polymers-barriers that must be addressed to fully integrate computational methods into sustainable materials development and regulatory practices.

6.07.P-Th249 Occupational and consumer exposure to VOCs during the production and use phase of renewable Wood Plastic Composites for car interior trims

Wouter Gebbink¹, Hariprasad Alwe², Mansoor Ahmad Bhat³, Ivana Burzic⁴, Martin Lindemann⁴, Nacho Martin-Fabiani-Carrato³, Maria Molnar⁴, Yentl Pareja Rodriguez¹, Andrea Pipino⁵, Claudia Pretschuh⁴, Tanja Radu³ and Hilda Witters¹, (1)Flemish Institute for Technological Research (VITO), Belgium, (2)TOFWERK AG, Switzerland, (3)Loughborough University, United Kingdom, (4)Wood K plus - Kompetenzzentrum Holz GmbH, Austria, (5)Centro Ricerche Fiat, Italy

Major vehicle manufacturers have adopted the use of bioplastics and bio-based plastics, including natural-fiber composites and engineering plastics fortified with natural fibers, but their application is still limited. Until now, car interior trims are usually made of virgin plastics like Polypropylene (PP) filled with mineral powder like talc, and when introducing new materials, the development is recommended to be done according to the SSbD Framework. The SSbD4Chem project aims to develop Renewable Wood Plastic Composites (WPCs) for car interior trims with the target to reduce Total Volatile Organic Compounds (TVOCs) emissions compared to PP interior trims and assure no risk to human health. WPC based on renewable/recycled PP reinforced with cellulose and wood-based fillers are investigated, focusing on VOC emissions and potential occupational and consumer exposure (Step 2 and 3 of SSbD Framework) ensuring safe use from the early R&D phase. To estimate human exposure to TVOCs from interior trims, testing was done to determine emission factors from the various WPCs (standardized method VDA 278). These WPC included soft wood fibers, fibrous cellulose powder and hemp with content ranging between 15% and 30%. Emission factors from these WPC were compared to commercial PP formulation containing talc (benchmark). ECETOC-TRA Consumer model was parameterized for a car-scenario and interior air concentrations were estimated in different scenarios using the emission factors. Air change rates were varied based on literature data simulating parked/driving, open/closed window and ventilation/no ventilation scenarios. Emission factors from pristine WPC and weathered WPC (UV, humidity and temperature changes) were also used as input to the model. The model predicted TVOC interior air concentrations resulting from WPC emissions to be reduced by a factor of 3-6 compared to the benchmark. Increased air change rates (through open windows, turning on fan and/or no circulation) further decreased the air concentrations by a factor of up to 35 when driving with open windows compared to a parked car with closed windows. Weathering the WPC during a period of 10 days resulted in reduced emissions of TVOC which led to reduced air concentrations by a factor of 2-40 (depending on the WPC) compared to predicted air concentrations based on emissions from pristine WPC. Scenarios covering worker exposure during compounding of the WPCs are currently under development within the project.

6.07.P-Th250 The ProScale Suite

Therese Kärnman, Pernilla Andersson, Maja Halling, Amanda Lundberg, Efsthios Reppas Chrysoitsinos, Rosella Telaretti Leggieri and Tomas Vilhelm Rydberg, Swedish Environmental Research Institute (IVL), Sweden

The ProScale consortium, formed in 2015, identified ambitions to reduce chemical exposures along the life cycle of products beyond regulatory requirements. Several tools are available for assessing human and ecotoxicological ((eco)toxicity) indicators in LCA, but few focus on near-field exposure. Hence, ProScale was developed and launched in 2017 to fill that gap. Recent studies have shown that there is a need for tools that are easy-to-use and cover all impact pathways. Triggered by that need and the inclusion in the Safe and Sustainable by Design (SSbD) framework led to recent advancements of ProScale.

The purpose of this abstract is to introduce the new advancements of ProScale, including the development of several new modules and their coherence.

The recent advancements and development of new modules allow for full (eco)toxicity assessments in LCA, from cradle-to-grave, taking into consideration both near-field and far-field exposure. The foundation of all modules is that hazard- and exposure information is combined to derive ProScale scores for a product, unit process and/or system. The hazard information originates from GHS while the exposure information is based on exposure modelling recommendations by ECHA in several guidance documents for exposure assessments under REACH (EU Regulation No. 1907/2006).

The original module, ProScale-W was mainly developed for assessing near-field exposure of chemicals for Workers. Recently, recommended default exposure settings for products' end-of-life have been added. Also, the hazard factor scoring has now been developed to include the newest hazard categories under CLP (EU Regulation No. 1272/2008). Further, a separate module for the Service Life was developed, ProScale-SL, to ensure coverage of all life cycle stages. Two more modules have been developed where needed to complete the

desired applicability domains, also to: direct exposure to the environment and indirect exposure to humans. These modules are referred to as ProScale-E and ProScale-IE respectively. The ProScale-IE module advances ProScale from being a tool only focusing on near-field exposure to also account for indirect exposures, i.e., exposure of chemicals to humans via food/water/air intake.

In summary, these modules will allow for a coherent toxicity potential assessment for ecotoxicity as well as human toxicity for both direct and indirect exposure routes in chemical footprint contexts, such as LCAs of products along the whole lifecycle.

6.07.P-Th251 Extending ProScale to Far-Field Human Exposure: The Indirect Exposure (IE) Module *Efstathios Reppas Chrysositsinos, Pernilla Andersson, Amanda Lundberg, Maja Halling, Rosella Telaretti Leggieri, Therese Kärnman, Ioannis Liagkouridis and Tomas Vilhelm Rydberg, Swedish Environmental Research Institute (IVL), Sweden*

ProScale is a screening-level life-cycle tool for chemical impact assessment that operates on regulatory data, ensuring compatibility with risk-assessment practice. While other ProScale modules target direct human exposure and ecotoxicity potentials, indirect (far-field) human exposure remains insufficiently captured in early-stage SSbD assessments. We introduce the ProScale Indirect Exposure (IE) module, designed to quantify systemic human exposure arising from chemical releases into environmental media across the life cycle.

IE adapts the ProScale-E architecture by combining hazard factors (HF), substance-specific mass flows (MF), and a persistence–exposure relevance factor (PFI,r) for key routes: inhalation via air, ingestion via drinking water, and dietary exposure through food. MF is calculated by coupling product composition with environmental release fractions derived from REACH/ERC scenarios. PFI,r integrates a persistence multiplier (Pdeg), based on standard REACH biodegradation tiers, and a route-specific environmental relevance multiplier (EI,r), determined by physico-chemical triggers for volatility, mobility, solubility, sorption, and bioaccumulation. The combined ProScale-IE score thus maps intrinsic hazard onto conservative, regulatory-consistent estimates of far-field exposure potential.

We apply IE to a retrospective polycarbonate-bottle case study previously evaluated with other ProScale modules, focusing on additives and detergent residues released during use and end-of-life. Environmental release fractions, persistence categories, and EI,r tiers were assigned using only SDS/REACH-level data to mirror realistic SSbD data availability. Preliminary results show that a small number of substances dominate far-field impacts due to high persistence and mobility; while others are associated with volatility-driven inhalation.

We view the IE module as a screening-level chemical-footprinting extension of ProScale with high SSbD relevance. ProScale-IE complements existing ProScale modules, forming a unified screening framework for life-cycle chemical assessment.

6.07.P-Th252 Does Chain Length Matter? Influence of Molecular Properties on the Ecotoxicity of Alkyl Phosphate Flame Retardants

Milo Leon de Baat¹ and Michiel Kraak², (1)Chemical Water Quality & Health, University of Amsterdam (UVA), Netherlands, (2)Sciencepark 904, University of Amsterdam (UVA), Amsterdam, Netherlands

Flame retardants are chemicals used in consumer and industrial products to reduce the flammability of e.g. plastics, paints, textiles and fuel. They may, however, also cause cancer, behavioural changes and allergic reactions in test organisms. Alternatives have been designed, but it is yet unclear if these are less toxic to marine biota than the original flame retardants. It has been shown that compounds with shorter carbon chain lengths tend to be less toxic than their longer analogues, but it remains unknown if this also applies to alkyl phosphate FRs. Since this knowledge may aid the design of safer alternatives, the present study aimed to investigate the relationship between molecular properties of alkyl phosphate flame retardants and their ecotoxicity. To this end, the acute (48h) toxicity of five alkyl phosphate FRs to *Artemia salina* nauplii (<24h) was determined, following OECD guideline 202 with slight modifications. The selected compounds included Trimethylphosphate (TMP) Triethylphosphate (TEP) Tripropylphosphate (TPP) Tributylphosphate (TBP) and Tris(2-chloroethyl)phosphate (TCEP). The tests were performed in 24-well plates with 6 concentrations per compound in artificial seawater, including a negative control, and with four replicates per treatment. Log-logistic concentration-effect models were fitted to the 48h mobility data to derive effect concentrations. In decreasing order, the EC50 values were 22416 ug/L for TMP, 8067 ug/L for TEP, 489 ug/L for TPP, 409 TCEP, and 45 ug/L for TBP. All EC50 values differed significantly except for TMP and TEP, and for TPP and TCEP. These results showed that the longer the carbon chain, the lower the EC50 value, hence the more toxic the compound. Yet, TCEP was more toxic than TEP, although they have the same carbon chain length. This can be explained by the chlorine atoms in TEP, which may have increased its ecotoxicity.

TMP was the least toxic compound, thus the most promising alternative, but the flame-retardant efficiency should be considered before application. It is concluded that flame retardants that are chlorine-free and have shorter carbon chains are less toxic to *A. salina*. These findings can facilitate the design of safer alternative flame retardants.

This poster was developed by students as the final product of a BSc-level course on Ecotoxicology, and won the best poster prize in the assessment of the course.

6.07.P-Th254 Implementing Safe and Sustainable-by-Design Strategies in the Development of TiO₂@Surfactin for Cosmetic Application

Sara Trabucco¹, Andrea Brunelli¹, Elisa Giubilato¹, Chiara Missaglia¹, Stefano Manfredini², Filippo Marchetti², Paola Ziosi³, Ilenia Gugel², Alberto Katsumiti⁴, Lisa Pizzol⁵, Danail Hristozov⁶ and Elena Badetti¹,
(1)Department of Environmental Sciences, Informatics and Statistics, Ca' Foscari University of Venice, Italy, (2)Faculty of Medicine, Pharmacy and Prevention, Department of Life Sciences and Biotechnology, University of Ferrara, Italy - CompLife srl, Milan, Italy, Italy, (3)CompLife srl, Milan, Italy, Italy, (4)GAIKER Technology Centre, Basque Research and Technology Alliance (BRTA), Spain, (5)GreenDecision Srl, Italy, (6)EMERGE Ltd, Bulgaria

Advanced Materials (AdMa), including engineered nanomaterials, offer novel functionalities but require early-stage risk assessment if an SSbD approach is followed, to ensure their safe and sustainable development. The European Commission's Safe and Sustainable by Design (SSbD) framework supports this goal by integrating hazard, occupational exposure, and application-related exposure considerations from the design phase onward. Within the SUNRISE project, representative AdMa were selected to demonstrate the implementation of the safety part of SSbD. The case study focused on three TiO₂-based AdMa functionalized with surfactin (P25@SS, TiO₂@SS-1, and TiO₂@SS-2), developed as UV filters for sunscreen formulations. A qualitative questionnaire was first administered to the company in order to identify safety-relevant data gaps, which guided subsequent physicochemical characterization using techniques such as TEM, ATR-FTIR, TGA-DSC, BET, DLS, ELS and CSA. The characterization highlighted relevant differences among the AdMa. P25@SS showed larger particle size and lower surfactin coverage compared to the TiO₂@SS-1, and TiO₂@SS-2 alternatives. Despite similar coating percentages for TiO₂@SS-1 and TiO₂@SS-2, DSC data suggested different SS arrangements, consistent with BET results showing a higher surface area for TiO₂@SS-1. FTIR confirmed effective surfactin coating across all samples.

After optimizing stock dispersions in ultrapure water, the colloidal behaviour of the AdMa was evaluated in media relevant for human (sweat, saliva) and environmental (freshwater, marine water) exposure, as well as in cell-culture media supporting (eco)toxicological testing. All SS-functionalized materials showed stable dispersions and negative surface charge, with zeta potential values decreasing in complex media but without marked effects on sedimentation behaviour, indicating the stabilizing role of the coating. These data supported the interpretation of the preliminary ecotoxicity tests on zebrafish embryo assays and algae growth inhibition, which showed no acute toxicity in freshwater organisms.

Overall, the case study demonstrates how a structured, questionnaire-driven workflow can guide targeted testing and support the early application of the SSbD framework to AdMa design.

6.07.P-Th255 Implementing the Joint Research Centre's (JRC) Safe and Sustainable by Design (SSbD) Framework to Guide the Development of Novel Bio-Based Flame Retardants Within the BIOSAFIRE Project.

Judith Llanes-Escalada¹, Paloma Gómez-Fernández¹, Amaia Garcia-Bilbao¹, Elise Morel², James Baker², María García-García³, Lisa Pizzol⁴, Sarah Devecchi⁴, Danail Hristozov⁴, Petri Widsten⁵, Lauri Tuominen⁵, Susana Carregal-Romero⁶, Felipe Goñi de Cerio¹ and Patricia Ares-Elejoste¹, (1)GAIKER Technology Centre, Basque Research and Technology Alliance (BRTA), Spain, (2)TEMAS Solutions GmbH, Hausen (Switzerland), Switzerland, (3)Centro Nacional de Verificación de Maquinaria (CNVM). Instituto Nacional de Seguridad y Salud en el Trabajo, O.A., M.P (INSST). Camino de La Dinamita s/n, 48903 Barakaldo, Bizkaia (Spain), Spain, (4)Green Decisions SRL., Italy, (5)Teknologian tutkimuskeskus VTT Oy (VTT), Kemistintie 3, 02150 Espoo (Finland), Finland, (6)CICbiomaGUNE (BRTA), Spain

Flame retardants play a key role in reducing fire damage. However, despite their intended benefits, growing evidence shows that many of these substances pose significant risks to human health and the environment. Numerous flame retardants are known to be problematic due to their persistence, bioaccumulation, and adverse effects such as neurotoxicity and endocrine disruption. Their widespread detection in air, dust, drinking water, food and recycled materials further underscores the need for urgent action.

Given their structural features and potential as fire-resistant materials, lignins and tannins have attracted rising attention. Building on this, the EU-funded BIOSAFIRE project aims to create new high-performance bio-based flame retardants capable of replacing current hazardous options. A central element of the project is the continuous integration of the Safe and Sustainable by Design (SSbD) approach throughout the innovation process, from material selection to end-of-life considerations. Applying the SSbD framework will clarify how early hazard screening, life-cycle perspectives and sustainability requirements guide design and development decisions.

To demonstrate improved safety and sustainability, project outcomes will be benchmarked against existing alternatives. Five case studies across four major industrial sectors —naval, rail, household appliances and construction— will later be used to validate and refine the framework. At this initial stage, work has concentrated on identifying and characterizing candidate materials while preparing appropriate testing strategies in accordance with SSbD principles. Efforts have been focused on the definition of the intended function, preliminary safety and sustainability assessments, and the planning of early design and testing. Some preliminary safety-related assays have already begun in parallel, although still at an exploratory level. This structured approach ensures that considerations of safety, performance and sustainability are embedded from the very beginning.

BIOSAFIRE is thus poised to advance safer fire-protection solutions in Europe, supporting not only the development of innovative flame retardants but also the broader adoption of an innovation framework applicable to other chemical sectors

6.07.P-Th256 Innovative Furniture Design Solutions for Eliminating Chemical Flame Retardants

Joanna Cloy¹, Jamie Clarkson² and Rowan Stanforth¹, (1)Fidra, United Kingdom, (2)FIDRA, United Kingdom

The UK's current prescriptive furniture fire safety requirements contribute to the UK's public, wildlife and environment having some of the highest flame retardant levels in the world. The commonly used brominated flame retardants and organophosphate flame retardants are of major concern and under careful scrutiny by the European Chemicals Agency. The legal requirement for flaming ignition source testing is met by the use of chemical flame retardants in upholstered furniture. This exposes people and the environment to potentially harmful chemicals and hinders product circularity, without any clear evidence of a fire safety benefit.

Innovative design solutions offer opportunities to reduce or ideally eliminate the use of harmful chemical flame retardants in furniture products but the UK's furniture fire safety regulations do not account for modern furniture construction methods, such as the use of fire barriers materials. Other solutions include the use of safer alternatives to toxic chemicals. For example, use of naturally flame resistant wool or treatment of upholstered furniture fabrics with low toxicity expanded graphite instead of persistent brominated flame retardant chemicals to achieve product flame retardancy. In addition to effective policy changes and intelligent design solutions,

Fidra believe that we can reduce or eliminate the use of harmful chemicals through enforced product chemical labelling to disclose chemical flame retardants present in materials throughout supply chains and through implementing extended producer responsibility schemes.

In summary, this presentation will outline the growing research evidencing the environmental impacts of chemical flame retardants used in furniture products, the current regulatory barriers to reducing flame retardant use in the UK, sustainable design solutions being developed by progressive industries as well as the challenges associated with managing furniture waste containing persistent chemical flame retardants. Findings presented will help inform policy, research and furniture supply chain industry innovation developments needed in the future to support sustainable by design solutions and public and environmental protection from harmful chemicals.

6.07.P-Th257 Implementing Safe-and-Sustainable-by-Design for Perovskite-Silicon Tandem Solar Cells
Katharina Lang-Hogrefe¹, Matiss Reinfelds¹, Thomas Rath², Stefan Moscher², Johanna K. Scheper¹ and Andreas Falk¹, (1)BioNanoNet Forschungsgesellschaft mbH, Austria, (2)Technical University Graz, Austria

The SSbD (safe and sustainable by design) framework recommended by the European Commission aims to minimize risks of safety and sustainability in new materials by a multi-perspective approach. To date its practical application in solar cell development is emerging but still in early stages with many open questions regarding precise assessment strategies or how to consider all steps along the life cycle. Perovskite solar cells have great potential for versatile applications and due to their high-power conversion efficiency; however, most perovskites are lead-based materials posing substantial safety and sustainability concerns. By applying a tailored scoping strategy aligned with the revised SSbD framework we aim to identify and reveal the environmental and safety hotspots along all process steps of the tandem solar cell module. Thereby the study will deliver a solar cell with reduced lead-content, more sustainable chemicals and reduced risk for workers and users without trade-offs in the performance. Regarding the safety and environmental assessment, the full production processes will be scanned regarding potential risks in the relevant categories, predefined in the scoping. Preliminary analyses identified lead-content and oxidizing solvents as hotspot in the material use, so alternatives will be identified and evaluated. Regarding process safety a detailed investigation will check the safety concerns and risks of all required steps, e.g. the spraying process and the plasma crystallization step. Mitigation strategies for identified risks will be designed and implemented in close collaboration with the technology developers to ensure fast and lasting effectiveness. In addition, the potential to reduce environmental impact of the final product will be attempted by considering measures to maximize resource efficiency for different fabrication techniques, and designing the solar cell module with best fit for recycling and circularity. By uniting the different assessment dimensions of SSbD we help to guarantee environmental compatibility and safety for the whole production process, as well as to include considerations regarding the end-of-life and the recyclability right from the start. The applied scoping and assessment strategy will be adaptable to similar technology and material development processes and help to advance the field of solar cell technology, the implementation of SSbD and associated strategies for safety and sustainability assessments.

6.07.P-Th258 Towards Ideal Safe and Sustainable Home Batteries: Criteria and Application
Samia Ouhammi¹, Niels van Veen¹, Lya G. Soeteman-Hernandez¹, Floris Teunissen¹, Jannie Coenen¹ and Johannes Lijzen², (1)RIVM, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands

Societal background

Batteries are key to achieve the Green transition. Last year in particular the development and use of home batteries is booming within the field of the energy transition. The ideal home battery is safe, sustainable and circular, without the use of hazardous or critical materials. However, a clear description of parameters that constitute the ideal battery is lacking, despite many developments in battery technology. This hampers policy makers as well as innovators in decision-making, as it lacks focus and clarity on weighing pros and cons of decisions.

Envisioned result and impact

In general, regulators formulate their criticisms well, but describing products in terms of what would be ideal seems to be more challenging. In this project we apply an innovative approach to translate parameters set by an ideal product into a set of concrete criteria. We have tested this approach on home batteries. These types of batteries are currently heavily promoted, but are still surrounded by high uncertainties about their composition, their risks, safe use and environmental impact. On one hand we defined properties for an ideal battery in terms of functionality, safety, sustainability, circularity (including critical materials) and cybersecurity, based on criteria in Safe-and-Sustainable-by-Design approaches like the JRC SSbD framework (2025). These criteria are specified in more detail based on literature and important characteristics of home batteries. On the other hand battery types were selected that are currently used and are expected in the near future. This was done based on input by suppliers, producers, knowledge organisations and literature. Five type of batteries were selected: lithium-iron phosphate (LFP), lead-gel, Nickel Manganese Cobalt (NMC), salt and solid-state batteries. The definition of an ideal home battery in combination with an assessment of the selected type of batteries, will give direction for further efficient and effective home battery technology development. This approach might form a basis for application for other energy transition technologies, for SSbD for batteries, and to develop knowledge to support current safety and sustainability regulatory frameworks. The result of the project is a draft practical approach including criteria how to address functionality aspects, safety, sustainability, circularity and cybersecurity and a comparison of the selected home batteries based on these parameters.

6.07.P-Th259 From Lignin to BPA-Free Epoxy Resins: Implementing Safe and Sustainable by Design in Polymer Innovation

Yentl Pareja Rodriguez¹, Wouter Gebbink², Marc Comí Bonachi¹, Karolien Peeters¹, Lise Asscherickx¹, Astrid Stalmans¹, Karolien Vanbroekhoven¹, Hilda Witters¹, Kelly Servaes¹ and Seppe Van der Heyden¹, (1)VITO, Belgium, (2)PFA Brussels, Belgium

Bisphenol A is widely used in epoxy resin production, yet its endocrine-disrupting properties and potential human and environmental contact throughout product life have prompted the search for safer, sustainable alternatives. This need is particularly relevant in construction and infrastructure applications, where coatings undergo prolonged mechanical and environmental stress that may lead to material degradation and release of chemical constituents. The LEGACY project addresses this challenge by developing fully biobased, bisphenol A-free epoxy systems derived from lignin and evaluating their safety within the integrated Safe and Sustainable by Design (SSbD) framework.

The project aims to determine whether lignin-based epoxy intermediates can replace bisphenol A while reducing intrinsic hazards and limiting exposure across the material life cycle. Early-stage material development is integrated with systematic safety evaluation. Hazard assessment combines physicochemical characterization, computational modelling, read-across analyses, and non-animal in vitro assays targeting key human health and ecological endpoints, including endocrine activity, irritation, skin sensitization, developmental effects, and aquatic toxicity. Exposure assessment examines potential release and contact during coating application, occupational handling, use-phase wear, and end-of-life scenarios through scenario analysis, controlled emission studies, and environmental distribution modelling.

Sustainability aspects are considered to ensure hazard and exposure reduction aligns with broader environmental objectives. This integrated approach supports the identification of promising biobased structures and formulation strategies that achieve functional performance while minimising risk.

By integrating hazard, exposure, and life cycle considerations into early material design, the project contributes to advancing SSbD practices in polymer development. This work offers a pathway to reduce reliance on bisphenol A in epoxy resin applications and provides a framework for evaluating emerging biobased materials in a manner that supports regulatory alignment, industrial feasibility, and long-term environmental protection.

6.07.P-Th260 Implementing the SSbD framework to support the development of bio-based sustainable surfactants

Elena Badetti¹, Marco Picone¹, Petr Humpolíček², Věra Kašpárková², Andrea Porcari³, Martina Menegaldo¹, Pier Paolo Guolo¹, Alessandro Bonetto¹, Elena Destro⁴ and Elena Semenzin¹, (1)Ca' Foscari University of Venice, Italy, (2)Tomas Bata University in Zlin, Czech Republic, (3)Italian Association for Industrial Research (AIRI), Italy, (4)Italian Association for Industrial Research (AIRI), Rome, Italy

SurfToGreen is an innovation action aiming to develop a new portfolio of fully bio-based surfactants for key applications. By using renewable biomass-derived building blocks sourced from EU agricultural and forest side

streams, the project seeks to create surfactants with up to 95% bio-based content, overcoming the current performance and production throughput constraints. Thus, SurfToGreen seeks to provide environmentally friendly alternatives to conventional, petroleum-based products, thereby contributing to a more sustainable future.

Safety and sustainability of innovative solutions are assessed following the EC Safe and Sustainable by Design (SSbD) framework. More specifically, hazard assessment, occupational, environmental and public health risk assessments, and Life Cycle Assessment are performed throughout the entire value chain of SurfToGreen biosurfactants in specific applications, through the creation of specific thresholds and criteria. Techno-economic and social acceptance assessments are also foreseen, to support the decision making process in SSbD. The assessment will be validated engaging partners and their networks covering all the surfactant value chain, including feedstock producers, chemical manufacturers, and end-users (large, medium and small enterprises). The project will validate the effectiveness, sustainability and safety of its bio-based formulations in industrial demonstrators for home and personal care, textile enhancement, and agriculture.

Disclaimer/Disclosure:

SurfToGreen is a Circular Bio-based Europe Joint Undertaking funded project (2024-2029, GA 101157688).

6.07.P-Th261 From Control Banding to Integrated Assessment: A Dual Risk and Environmental Approach Applied to Proton Exchange Membrane Electrode Fabrication

Joséphine STECK¹, Konstantina-Roxani Chatzipanagiotou², Foteini Petrakli² and Aliona Nicolenco³, (1)Univ. Grenoble Alpes, CEA LITEN DTNM, France, (2)Innovation in Research and Engineering Solutions SNC (IRES), Brussels, Belgium, Greece, (3)CIDETEC, Basque Research and Technology Alliance (BRTA), Spain

The move toward Safe and Sustainable by Design (SSbD) requires methodological frameworks that can address safety, environmental performance and functionality at early stages of material and process innovation. In this work, we focus on the application of a control-banding-based Chemical Risk Assessment (CRA) as a practical tool to evaluate safety aspects during development and scale-up, and on its complementarity with Life Cycle Assessment (LCA). Rather than treating LCA and CRA as isolated assessments, the study explores how both types of indicators can be jointly mobilized to support SSbD decision-making.

The approach is tested through two electrochemical manufacturing case studies: porous electrode fabrication for Proton Exchange Membrane systems and catalyst-coated electrodes for Proton Exchange Membrane Fuel Cells, including end-of-life recycling. These systems traditionally rely on platinum-group metals; the substitution of Pt with Ni-based or emerging catalyst formulations is assessed through a dual lens: (i) worker and process safety through control banding, and (ii) potential environmental impacts through LCA.

The control banding methodology is applied at successive development stages, enabling rapid identification of chemical hazards, exposure determinants and mitigation priorities, even when full toxicological or exposure datasets are not available. LCA is performed in parallel to capture environmental trade-offs across the life cycle, and the combined outputs are positioned within the Joint Research Centre's SSbD framework to map points of convergence and divergence between safety-oriented and environment-oriented criteria.

Results highlight that integrating CRA control banding and LCA from the earliest phases of innovation supports more robust substitution decisions, avoids late-stage lock-ins, and contributes to a more concrete operationalization of SSbD in industrial settings. The work demonstrates how control banding can act as an entry point for safety assessment within SSbD, while maintaining methodological complementarity with LCA.

6.07.P-Th262 Data quality, data gaps and functionality: Development of a transparent safety assessment framework within the BIORING project

Joanke van Dijk¹, Jovita Moreno Vozmediano², Jorge Blanco-Cejas², Cyrille Durand¹, Vince Hop³, Blanca Suarez Merino¹, Andrea Porcari⁴, Elena Destro⁵ and Jose Maria Cuevas⁶, (1)TEMAS Solutions GmbH,

Switzerland, (2)Rey Juan Carlos University, Spain, (3)Process Design Center, Netherlands, (4)Italian Association for Industrial Research (AIRI), Italy, (5)Italian Association for Industrial Research (AIRI), Rome, Italy, (6)GAIKER, Spain

The EU project BIORING aims to develop a novel portfolio of renewable formulations for UV curable polyurethane biocoatings with optimal biodegradable and/or recyclable features for the construction, furniture, automotive sectors and beyond.

Implementing Safe and Sustainable by Design (SSbD) in the BIORING project involves key challenges, particularly in meeting data and criteria requirements during early innovation phases. A major limitation is the lack of data on biomass conversion processes into bio-based chemicals. Here, we develop and apply a strategy to include data quality and data gaps in the chemicals hazard evaluation to support SSbD integration and support decision-making for more safe and sustainable chemistries in a transparent manner.

The safety assessment focuses on components used in the production of biobased products, and includes catalysts, by-products, and other process-related substances. The assessment draws on existing knowledge such as review papers, databases, and regulatory sources, and uses in silico tools to address data gaps as far as possible. The goal is to support project partners in identifying and transitioning to safer alternatives, in line with the SSbD Framework. Experimental and in silico data are integrated into a harmonized safety score, while remaining data gaps are clearly communicated to guide further decision-making with regards to selecting appropriate management options. Final decision-making also considers the intended functionality and use context of each chemical or material, alongside broader criteria such as Green Chemistry principles.

Disclaimer/Disclosure:

BIORING is a Circular Bio-based Europe Joint Undertaking funded project (2023-2026, GA 101112379)

6.07.P-Th263 Data Requirements for the Redesign of Mineral Carbonation Process with the ‘Safe and Sustainable-by-Design’ Principles

Ponnapat Watjanatepin¹, Laura Steinwider², Nina Miladinović¹, Luka Ceyssens¹, Tom Van Duyse¹, Sara Vicca², Tom Van Gerven¹ and Karel Van Acker¹, (1)KU Leuven, Belgium, (2)University of Antwerp, Belgium

In 2024, the European Commission Joint Research Centre introduced methodological guidance for implementing Safe and Sustainable-by-Design (SSbD) principles, aiming to integrate safety, environmental, economic, and societal considerations into the development of chemicals, materials, and processes. This framework represents an evolution of Life Cycle Sustainability Assessment (LCSA) by explicitly incorporating safety dimensions. However, practical applications remain scarce, and case studies demonstrating SSbD integration are limited. This study addresses this gap by identifying essential data requirements for conducting Life Cycle Assessment (LCA) aligned with SSbD principles and proposes a process-flow approach to integrate environmental impact calculations with SSbD assessments. The methodology is applied to a case study on mineral carbonation of steel slags as a carbon capture, utilization, and storage (CCUS) technology. Beyond assessment, the study explores redesign strategies for the current mineral carbonation process to enhance alignment with SSbD principles, focusing on reducing energy intensity, optimizing material flows, and minimizing occupational hazards. The outcomes provide a practical roadmap for generating and structuring data to meet SSbD criteria while informing process improvements for safer and more sustainable CCUS technologies. Future work will extend to economic and social dimensions for comprehensive sustainability evaluation and apply the proposed approach in real-world projects to advance safe and sustainable manufacturing value chains.

6.07.P-Th264 SSbD4SME: A Digital Tool Assisting SMEs in the Development of Safe and Sustainable Products

Wouter Gebbink, Lise Asscherickx, Frederik Byl, Bart Daniels, Michiel Jacobs, Karolien Peeters, Yentl Pareja Rodriguez, Astrid Stalmans, Karel Styns, Richard Vendamme, Sven Vercauteren and Hilda Witters, Flemish Institute for Technological Research (VITO), Belgium

Developing or re-designing products according to the Safe and Sustainable by Design (SSbD) Framework requires multi-disciplinary expertise. Small and Medium Enterprises (SMEs) often lack in-house expertise in one or several disciplines (i.e., hazard, risk and life cycle assessments) needed to perform a full SSbD assessment. Therefore, the aim of the SSbD4SME project is to develop a digital screening tool that will assist

SMEs in selecting suitable alternative chemicals to replace problematic ones (reference) in existing products or to ensure safe and sustainable chemicals are used when developing new products.

The SSbD4SME tool contains several modules covering the first 4 steps of the SSbD Framework: 1) hazard characterization, 2&3) human and environmental exposure and risk assessment during the production and use phase and 4) life cycle assessment (LCA). In order to make the SSbD4SME tool user-friendly for SMEs, information from existing databases will be used when available to minimize data input by SMEs and default scenarios allow for easy use of the tool. The current version of the tool contains pre-set human and environmental exposure scenarios for chemicals used in textiles and LCA scenarios for textile products. By entering a chemical CAS number, hazard information on the existing (reference) and alternative chemicals will be collected from online databases and the resulting SSbD-score will be calculated by the tool. An exposure and risk assessment is performed using CHESAR with the required chemical input obtained from existing database (obtained again via CAS number), and pre-set exposure scenarios for chemicals used for finishings and coatings in textiles. SSbD-scores are generated for reference and alternative chemicals based on the risk characterization ratios (RCR). The LCA module focuses on textile products and can be applied for a 'cradle to gate' (impact of the manufactured textile product) or 'cradle to grave' (impact of the manufactured textile product including its use phase and disposal) LCA, depending on the product development stage. SSbD-scores will be generated for different environmental impact categories. The SSbD4SME tool also contains a database of alternative chemicals that can assist SMEs in selecting chemicals to substitute problematic ones. The SSbD4SME project will provide SMEs with a screening tool that can assist them during the (re)development stage of (new) products in selecting safe and sustainable chemicals.

Disclaimer/Disclosure:

This project is funded by FOD Economie – “Belgium builds back circular” project (BE-C[C53]-I[I-515]- (ID BOSA). Project reference BBBC3 call – proposal SSbD4SME.

6.07.P-Th265 Bridging Science and Industrial Innovation: Implementation of the Safe and Sustainable by Design (SSbD) Framework in the Development of Alternatives to Substances of Concern in the DESIDERATA project

Panagiotis Isigonis¹ and DESIDERATA Consortium², (1)Luxembourg Institute of Science and Technology, Luxembourg, (2)DESIDERATA consortium, Luxembourg

The operationalisation and testing of the Safe and Sustainable by Design (SSbD) framework is taking place in full scale since the adoption of the Recommendation by the European Commission in 2022. The DESIDERATA project inherently incorporates the SSbD framework as the core of the industrial innovations for the development of alternatives to Substances of Concern (SoC) with plasticising, flame retardant and surfactant properties.

We demonstrate how the SSbD framework is implemented and operationalised in five Use Cases for the development of alternatives in the lubricants, polymers, electronics, additive manufacturing and construction sectors. Targeted Substances of Concern include medium-chain chlorinated paraffins, halogenated flame retardants, antimony trioxide, polytetrafluoroethylene (PTFE) and aluminium powders. Preliminary results on the safety and sustainability assessment of the SSbD alternatives are discussed, which are based on the application of OECD validated methodologies, New Approach Methodologies (in silico/in vitro), standardised Life-Cycle Assessment methodologies and more. Tiered approaches are employed where possible, to support the application of targeted techniques that allow the identification of hotspots and employment of alternative development routes/corrective measures along the value chain and the lifecycle stages of the DESIDERATA products.

Proof of Concept for the implementation of the SSbD framework is under development, which aims to integrate safety and sustainability (environmental and socio-economic) with functionality and technical performance, without compromising investment and R&D practices in industrial settings. We discuss how critical decision points should be incorporated in the implementation of the framework and how the SSbD practitioners may align the work with technical developers within interdisciplinary environments. Overall, the integrated approach developed in the DESIDERATA project aspires to ensure regulatory alignment, enhance practical applicability, and support systemic transitions towards safer and more sustainable chemicals and materials.

Disclaimer/Disclosure:

Funded by the European Union, under GA 101178011, and SERI.

6.07.P-Th266 Critical evaluation of the SSbD framework to support early stage innovation
hiram Moerman, apeiron-team NV, Belgium

The SSbD framework is conceived to support innovation towards a safer and more sustainable society. While the framework contains guidance on the evaluation of innovations on the basis of hazard, risk and impact, it fails to provide specific handles how to support the innovator in the innovation project.

On the basis of two concrete innovation projects, one TRL1-3 (FONT project) and a follow-on project (RADAR project) at TRL 4-6, the SSbD framework and the proposed updated framework are evaluated. In these projects four innovations are developed in collaboration with industry partners.

Specific tools and approaches were developed to allow interaction with the innovator along the innovation project, tools for data structure over the lifecycle and tools to handle the multi stakeholder aspect of the SSbD support of an innovation project.

In the specific projects innovators, scientists and industry were represented.

Overall, within the two projects, the concept of the SSbD integrator has been developed. This innovative role assures the translation of the SSbD framework in a workable project approach.

6.07.P-Th267 Tailoring, Tiering and Archetypal Scenarios: Outcome of two Workshops on SSbD Scenarios in the Network for Safe and Sustainable Chemicals & Materials (NSC)

Wendel Wohlleben¹, Carla Caldeira², Martin Himly³, Danail Hristozov⁴ and Lya G. Soeteman-Hernandez⁵, (1)No Affiliation, Germany, (2)SYENSQO, Italy, (3)Paris Lodron University of Salzburg, Austria, (4)GreenDecision Srl, Italy, (5)National Institute for Public Health and the Environment (RIVM), Netherlands

The term “SSbD scenario” was integrated into the revised SSbD Framework, where it serves as bridge between the SSbD scoping and a tailored safety and sustainability assessment. A first NSC workshop (NSC: Network for Safe and Sustainable Chemicals & Materials) in June 2005 explored the description of the SSbD scenario, comprising aspects of the SSbD scoping and aspects of the business case and project plan. The ideal SSbD approach proceeds from simplified to intermediate to full SSbD, if the project passes the respective gates into lab phase, pilot phase, launch phase. But not all projects operate in a context allowing that tiered SSbD approach in full swing. A second NSC workshop in December 2025, using well-established economic metrics of R&D pipelines, explored the tailoring of SSbD approaches to selected case studies, and derived also archetypal scenarios that can serve as template for innovators to adapt their SSbD approaches. Scenarios are tailored based on the novelty (disruptive or incremental), the sector of use, and the objective (or value proposition: safer, more sustainable, cheaper, more performant, system-integrated, etc), the R&D budget and the immediacy (TRL, time to market). One scenario showed the full potential of SSbD: a relatively big project (budget of 1mn€/y) with disruptive technology in a sensitive lifecycle value chain and big market potential. Even here, tiering and prioritization is essential, and then allow several rounds of re-design with both safety and sustainability assessment of increasing maturity. For all other scenarios, with more typical market potential (net present value of e.g. 5mn€) and more modest budget (e.g. 250k€/y), the scope of the SSbD WP has to be strongly prioritized according to the specific SSbD pull, to the novelty, and to specific objectives. The essential requirement to a positive Return on Investment of implementing SSbD work packages is a strong SSbD pull by the downstream lifecycle actors. It can compensate for all other impacts. This goes as far that for innovation cases in cosmetics and pharma, the probability of commercial success is 0% without SSbD, and safety screenings are done by all competitors. The proposed and tested methodology suggests that SSbD practices will first permeate industries in end-consumer markets, and those with a high environmental footprint, because SSbD pull is high there. However, incremental innovations will remain very selective in their SSbD tailoring.

Disclaimer/Disclosure:

We acknowledge funding from the European Union's Horizon Europe research and innovation program under grant agreement no 101058245 and 101177608.

6.07.P-Th268 A certification Scheme for Safe and Sustainable by Design: Fulfilling the Needs of Industry

James Baker¹, Oona Freudenthal², Ghaya Rzig², Lasse Steffens³, Wendel Wohlleben⁴, Lisa Pizzol⁵, Danail Hristozov⁵, Hubert Rauscher⁶ and Blanca Suarez Merino⁷, (1)TEMAS Solutions, Netherlands, (2)Luxembourg Institute of Science and Technology, Luxembourg, (3)Institute of Safety and Risk Sciences (ISR) University of Natural Resources and Life Sciences, Austria, (4)Dept. of Chemical, Material & Regulatory Sciences BASF, Germany, (5)GreenDecision Srl, Italy, (6)Joint Research Centre JRC, Italy, (7)TEMAS Solutions GmbH, Switzerland

Safe and Sustainable by Design (SSbD) applied to chemicals and materials is becoming increasingly recognised as an essential element underpinning the full value chain from blueprint through sourcing of raw materials to development and testing, to market readiness of a product, while supporting regulatory preparedness for industry. The Joint Research Centre's SSbD framework and guidelines promote a tiered approach considering various innovation options or the Technology Readiness Level (TRL) level of the chemical/material, which is in part mirrored by the Integrated Impact Assessment Framework being developed as a practical support tool in the Horizon Europe HE project SUNRISE. The public consultation results on the implementation of SSbD, available in 2025, show high stakeholder interest, revealing the need for further guidance, better access to tools and an increasingly unified approach to safety and sustainability assessments.

SSbD is not enshrined in any regulation. SSbD implementation does not equate to regulatory compliance, but clearly industry would benefit from a certification scheme demonstrating SSbD adoption. An innovative scheme is under development as part of the SUNRISE project, comprising a first step of self-assessment based on a questionnaire following the structure of the JRC SSbD framework and covering all stages of the product life cycle. Industry must justify whether their solution improves, worsens, or does not change key factors compared to mainstream alternatives e.g., including critical raw material use, human exposure, recyclability, material efficiency, durability, and overall environmental performance. Industry should provide justification (improvement, deterioration or neither of both, in comparison to the main stream alternative) for a range of factors including phase out the use of Carcinogenic, Mutagenic and Reprotoxic (CMR) substances, reduce human exposure as well as enhance recycling, material efficiency, durability and environmental performance. Evaluation and certification will be carried out by an independent and recognised authority, enabling the industry to claim SSbD compliance for a specific product.

Disclaimer/Disclosure:

The SUNRISE project received funding from Horizon Europe GA No. 101137324 and from the Swiss State Secretariat for Education, Research and Innovation (SERI)

6.07.P-Th269 A Matrix-based Scoring System for Selecting Safe and Sustainable by Design Solutions in a Bio-based Coatings Development

Cyrille Durand and Joanne van Dijk, TEMAS SOLUTIONS, Switzerland

There are very few polymer solutions available on the market that combine energy effective UV curing manufacturing, high biogenic content, and performances in line with demanding industrial sectors, such as automotive, furniture and construction.

The BIORING project addresses this challenge by using the safe and sustainable by design JRC framework to rethink the chemistry of UV curable polyurethane systems and develop a novel portfolio of monomers, oligomers, and biobased coatings.

We apply an iterative approach to data gathering, increasing the level of knowledge, and addressing data gaps, along the development phases of the chemical materials.

The final goal is to compare several alternatives to identify the most SSbD-compliant solutions. We develop a matrix-based scoring system that integrates multiple dimensions, including safety, sustainability, circularity, performance and economic aspects. Each dimension is represented by a set of indicators selected from SSbD strategies, such as hazard assessment (e.g., harmful substance criteria), occupational safety (e.g., exposure levels), consumer safety (e.g., chemical release), life cycle analysis (e.g., climate impact, land use, resource efficiency), life cycle costing, and measures of circularity (e.g., CTI, recyclability).

For each BIORING alternative, indicators are assigned a score (s?) and a weight (w?). The overall SSbD score is calculated as $SSbD\ Score = (w \times s)$ and then converted into a readiness label, enabling comparison across alternatives.

The matrix is applied to the BIORING demonstrator, a biobased coating for automotive interiors, using the data (both quantitative and qualitative) generated from the BIORING SSbD assessment, allowing alternatives to be compared through a consolidated score. As BIORING is a low-TRL project (TRL 3–5), there is still substantial room for improvement and further development of our solutions. For this reason, intermediate scores are kept visible within the system to pinpoint hotspots and provide actionable guidance for improving overall performance.

One key outcome of the BIORING process will be a White Paper giving learning and recommendations to apply

the SSbD framework to biobased coatings

The Bioring is a Circular Bio-based Europe Joint Undertaking funded project (2023-2026, GA 101112379).

6.09.P Risk Perceptions, Risk Communication, and Public Trust in Environmental and Risk Assessment

6.09.P-Th270 Parameter Influence on Environmental Impact Targets in Battery Production: A Systematic Sensitivity Approach

Abdur-Rahman Ali¹, Sophia Roy², Steffen Blömeke¹ and Christoph Herrmann¹, (1)Institute of Machine Tools and Production Technology (IWF), Chair of Sustainable Manufacturing and Life Cycle Engineering, Technische Universität Braunschweig, Germany, (2)Montreal Polytechnic, Canada

Reducing the environmental impacts of products like electric vehicle batteries to stay within humanity's safe operating space necessitates target-based approaches and an understanding of parameter influences on target variability. This study conducts a systematic sensitivity analysis to identify key parameters influencing climate change impact targets for battery production, using Sobol first-order indices to decompose target variability. The parameters considered include national climate change impact budgets, allocation factors at various levels (sector: mobility and product: battery), vehicle lifetime (modeled via a Weibull distribution with varying shape and scale parameters), battery capacity, and number of vehicles. The analysis spans temporal (2030, 2035, 2050), spatial (Germany, Canada), and technical (34–122 kWh capacities) scenarios. Considering the parameter ranges and distributions, the results show that vehicle lifetime is the dominant driver of variability, followed by national budgets and mobility sector allocation factors. These insights enable battery producers in strategic planning by focusing on parameters affecting environmental impact targets such as lifetime but also focus on taking action to harmonising industry wide applicable budgets and allocation factors.

6.09.P-Th271 What Level of Protection Does the Public Prefer in Setting Environmental Water Quality Benchmarks for Aquatic Life? A Nationwide Web Survey in Japan

Yuichi Iwasaki¹, Yukie Shibata² and Masashi Soga³, (1)National Institute of Advanced Industrial Science and Technology, Japan, (2)Yokohama National University, Japan, (3)The University of Tokyo, Japan

Understanding what levels of biological protection the public prefers is essential for effective environmental management, for example when setting water quality benchmarks for aquatic life. However, it remains unclear which biological levels of organization people believe should be protected. To address this gap, we conducted a nationwide online survey in Japan (n = 1211) and asked participants to choose their preferred level of biological protection, ranging from sub-individual responses such as DNA or cellular damage to higher-level effects such as the extinction of multiple species. Surprisingly, more than half of the respondents selected the sub-individual level of protection, suggesting a preference for a stricter protection level than those commonly accepted in actual management (i.e., the population level or higher). The results also suggest that individuals with stronger conservation attitudes, a greater perceived risk of chemicals, a stronger connection to nature, a greater ability to identify species, and older age were more likely to prefer stricter protection. Despite the possibility that the preference for stricter protection stems from misunderstandings of sub-individual level effects, our findings suggest that regulators and environmental managers should recognize and address the gap between public preferences for biological protection levels and the protection goals commonly adopted in environmental management, particularly in stakeholder engagement settings.

6.09.P-Th272 A Review of Default Assumptions Used in Bird and Mammal Risk Assessments for Seed Treatments and Potential Mitigation Options for the UK

Helena Crosland¹, Sarah Priestly², Nadine S Taylor¹, Alan Lawrence³, Michael Fryer⁴ and Melissa Reed⁵, (1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)RSK Adas Ltd., United Kingdom, (3)Alan Lawrence Ltd., United Kingdom, (4)Ecotoxicology, Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom, (5)Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom

Under retained EU legislation, the UK Health and Safety Executive's Chemicals Regulation Division (HSE CRD) requires assessment of potential impacts from pesticide active substances and plant protection products (PPPs) on wild birds and mammals.

Pesticide seed treatments offer a targeted crop protection approach with multiple advantages: reduced reliance on foliar applications, protection during vulnerable early growth stages, and potentially lower overall environmental exposure. However, these products frequently fail authorization due to unacceptable acute and chronic risks identified during risk assessment (RA). This stems from conservative default assumptions - particularly that availability of treated seeds on the soil surface is high and that treated seeds and emerging seedlings contain high pesticide concentrations while representing attractive food sources for wildlife. Consequently, an increasing number of PPPs are being withdrawn during re-registration processes, raising concerns about UK food production resilience. At the same time there is an increasing public awareness of chemical exposure as a risk to wildlife.

This HSE CRD project investigated the potential for evidence-based refinements to the RA, which could maintain robust environmental protection whilst maintaining availability of safe and effective products supporting UK crop production and yield.

The project examined the following data sources: publicly available research routinely cited in seed treatment RAs; contemporary research obtained from the updated EFSA bird and mammal guidance (2023) and provided by key stakeholders; and peer-reviewed publications identified through data mining. All relevant citations underwent reliability and relevance assessment, followed by focused discussions on critical aspects of seed treatment RA methodology.

The project report will be publicly released, with ongoing discussions planned regarding future data generation needs. These efforts aim to enhance transparency and stakeholder confidence in the UK RA framework, ensuring decisions are grounded in current scientific evidence while balancing agricultural productivity requirements with environmental protection imperatives.

6.09.P-Th273 Pesticide Fates and Effects on Environments in the Northern Zone

Kati Räsänen¹, Marleena Hagner², Irene Vänninen³, Terho Hyvönen², Katri Siimes⁴, Ian C.W. Hardy⁵, Marit Almvik⁶, Roger Holten⁶, Kathinka Lang⁶, Alina Koch⁷, Nora Badawi⁸, Ελένη Καρασαλή⁹, Viktorija Zagorska¹⁰, Daiva Šileikienė¹¹, Bodil Lindstrom¹² and Laima Česonienė¹¹, (1)Bioeconomy and environment / Sustainability science and indicators, Natural Resources Institute Finland (Luke), Finland, (2)Natural Resources Institute Finland (Luke), Finland, (3)Natural resources / Plant health, Natural Resources Institute Finland (Luke), Finland, (4)Finnish Environment Institute (SYKE), Finland, (5)University of Helsinki, Finland, (6)Norwegian Institute of Bioeconomy Research, Norway, (7)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (8)Geological Survey of Denmark & Greenland (GEUS), Denmark, (9)Benaki Phytopathological Institute (BPI), Greece, (10)LLU Institute of plant protection technologies, Latvia, (11)Vytautas Magnus University, Lithuania, (12)Department of aquatic sciences and assessment, Swedish University of Agricultural Sciences, Sweden

Plant protection products (PPPs) are used to protect crops from pests in agriculture, forestry and horticulture. Concerns regarding the environmental impacts of pesticide residues occurs. We want to address these concerns, considering the unique climatic conditions in the Northern zone of European Union (EU) which together with agricultural practices used influence pesticide behaviour and persistence, but also risks and risk mitigation methods for approved PPPs. Information exchange between authorities within the Northern European zone is important because of similar climatic, agricultural conditions and practices, which are different from those in Central and Southern parts of Europe. As the data on use, residues and risks of pesticides are currently dispersed across different databases of various authorities and researchers, and are published mostly in national publications, there is a great need to collect, analyze and publish this information as one compact resource.

The aim of this project is to assemble and analyze existing data on pesticide use, their residues and risks of pesticides, but also risk mitigation strategies for approved PPPs, in the Nordic and Baltic countries. Using this consolidated information, we will evaluate potential strategies to reduce pesticide risks to the environment. We identify data gaps and future research steps needs and make recommendations on how to reduce pesticide related risks. The outputs of this project will close knowledge gaps, enhance the development of risk assessment processes and reduce the risks of pesticides in the Nordic and Baltic countries and in the EU.

Results will be disseminated in a scientific publication, which will be communicated to scientific audiences and to the public in constituent countries in 2026-2027.

Disclaimer/Disclosure:

The project will be funded by Nordic Chemicals Program.

6.09.P-Th274 Enabling regulatory validation and innovation: Precaution, risk, “Toxic Ignorance Cycles”, and New Approach Methodologies

Paris Jeffcoat¹, Gordon Hickey¹, Niladri Basu¹ and Steven Maguire², (1)McGill University, Canada, (2)University of Sydney, Australia

Regulators in chemicals management across jurisdictions face significant challenges as they move away from vertebrate animal testing and realise the transformational potential of New Approach Methodologies (NAMs). While NAMs offer a promising new means of (eco)toxicological knowledge production for decision-makers, uncertainties remain, slowing adoption. However, regulatory scientists have long faced an uphill battle against uncertainty in decision-making contexts, and it is noted that in some regulatory contexts what is referred to as uncertainty can hide the distinction between uncertainty, risk, and ignorance. In this presentation we consider innovation in regulatory science broadly and offer some overarching observations from social science and policy perspectives that relate to the impact of risk perceptions in regulatory environments. We provide high-level insights from three related mixed methodology studies (involving interviews, policy analysis, and participant observation) that offer insight into NAM validation processes and implementation barriers for actors across regulatory, academic, and industry environments. Specifically, we report on: 1) how uncertainty and ignorance impact regulatory (non)decisions and (in)action in risk assessment; 2) how certain types of precautionary mindsets may present institutional barriers to NAM acceptance and adoption in risk assessment; and 3) how actors involved in NAM validation act as Institutional Entrepreneurs to navigate change. Together, the observations and recommendations from these mixed method studies utilise the NAMs case to offer insight into how risk perceptions impact regulatory innovation more broadly. We illustrate how greater consideration of risk perceptions, risk complexity, interpretations of risk and precaution, and an awareness of toxic ignorance cycles, can enable stronger alignment between regulatory objectives and policy implementation.

6.10 Translating Complexity – The Role Science Communication Plays in Generating Lasting Societal Impact

6.10.T-01 Clear, Concise, and Complete: Finding the Sweet Spot for Detail and Simplification in Science Communication

Katharina Lang-Hogrefe, Beatriz Alfaro Serrano, Evgenya Zeevi, Matiss Reinfelds, Johanna K. Scheper and Andreas Falk, BioNanoNet Forschungsgesellschaft mbH, Austria

Scientific communication is an important tool to ensure that innovation hits the ground and reaches the relevant audience. Next to scientists this also includes regulators, policy makers, but also the broad community, especially for topics with wide outreach like safety and sustainability. For advanced materials their complexity requires clear and specialised yet accurate communication that balances necessary simplification with the preservation of essential scientific information. Often the communicated outcomes of research are not clear for “outsiders”, do not deliver actionable information and therefore miss trust and impact in the population. This study will compare different communication tools and methods (videos, interviews, visual aids, articles etc.) and analyse their success for various media and communication strategies. A special emphasis will be placed on ‘infographics’, static visuals providing ‘easy-to-grasp’ information for a broad audience. We will illustrate the working principles of different classes of chemicals like flame retardants and surfactants. In this format different familiar symbols (flames, helmets, emojis etc.) are used to illustrate aspects like danger and safety and allow for an intuitive and quick understanding of complex issues. Preliminary results show that infographics are an effective tool to communicate matters of safety of chemicals and materials. The impact of infographics on LinkedIn will be compared with other shared content like video materials and text-based postings. Additionally, also an investigation is attempted on whether individuals reacting to posts including infographics are directly involved in the projects, affiliated with partner institutions, or originate from external audiences, to quantify the outreach of the content and the diversity of the audience as a first indicator for social acceptance. Further on, the use of infographics for other purposes like websites or a printed materials will be evaluated. In addition, we will share lessons learned from several research projects in the field of chemicals and advanced materials. To conclude, breaking-down complexity requires the minds of different stakeholders to extract the essential information. Simplification needs to be handled with delicacy, because generic content will not gather attention or interest. Finally, every means of communication needs to be tailored to the respective audience and balanced with regard to length, detail and precision.

Disclaimer/Disclosure:

This work has received funding from the European Union's Horizon Europe research and innovation programme under grant agreement 101177608 (PLANETS), 101138475 (SSbD4Chem), 953183 (HARMLESS), and 953152 (DIAGONAL).

6.10.T-02 Science communication to the general public through younger generations

Rozarka Jilkova, Faculty of Science, Masaryk University, Czech Republic

Scientific thinking fundamentally differs from general public perception, particularly in considerations of probability and interdisciplinarity. It is essential to understand the complete chain of events: from the sources and concentration of a substance in an environmental matrix, through exposure routes, to its potential harmful effect on health. How can we effectively communicate this complex, data-driven, and probabilistic perspective to a general audience?

One possibility is to educate young people, specifically high school students, and give them an opportunity to experience being a scientist. To accomplish this, we created a highly practical summer school to transform students into active scientists, allowing them to gain a deep, experiential understanding of the complexity of scientific work and its societal relevance.

This work describes an innovative outreach initiative, the "Environment and Health Summer School" (EHSS), organised by RECETOX at Masaryk University, Czech Republic, in cooperation with the science learning center Bioskop, Masaryk University, Czech Republic. The primary objective is to engage high school students (age 16-20) by providing a hands-on, authentic scientific research experience. The programme simulates the full scientific method, from learning fundamental information through conducting a small case study (defining hypotheses, sampling, lab work, analysing data) to presenting findings in a conference-style format. This approach develops both technical skills and critical thinking, while demonstrating the connection between academic research and real-world societal impact.

The EHSS serves as a successful model for science outreach that moves beyond passive learning to active thinking. We anticipate that these motivated high school students will become effective ambassadors, discussing the environmental issues and probabilistic concepts learned with their friends, schoolmates, and family; thereby supporting our objective of communicating science to the wider community. A core achievement of the summer school was training participants to take a comprehensive and systematic approach to problems. This ability to communicate systematic thinking—not just facts—is a valuable perspective they can pass on in their discussions, helping to raise public awareness and promote more informed societal dialogue, not only about environmental challenges.

Disclaimer/Disclosure:

The activities were carried out with the support of a project which has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 857560, and funding from the support of the RECETOX Research Infrastructure (No LM2023069) and project 0053/7/NAD/2025 financed by the Ministry of Education, Youth and Sports, Czech Republic.

6.10.T-03 Interactive Web-based Applications as Effective Data Exploration and Risk Communication Tools

John Gondek¹, Shaun A. Roark¹ and Christopher J McCarthy², (1)Jacobs, United States, (2)Jacobs

Environmental datasets are often complex mixtures of physical, geochemical, and biological data. Understanding the relationship among these groups and how they feed into risk estimates and risk assessments can be an opaque process. Challenges arise in trying to thoroughly communicate the risk assumptions and results to stakeholders that are not risk practitioners. One solution to this problem has been to present our risk assessment data using an interactive web-based platform. These applications can include data summary tables, data and risk visualizations, and geospatial analyses. This has proven to be a powerful risk communication tool for stakeholders, as the assumptions used in risk assessment (such as receptor or toxicity benchmark) can be modified and the user can instantly view how the magnitude and spatial extent of risks may change. This provides transparency to stakeholders as different exposure scenarios can be evaluated in real-time and can be used to quickly identify areas of the site or receptors that are most at-risk.

Furthermore, these applications can be built to perform and automate complex statistical and multivariate analyses, making them effective data exploration resources. This allows risk practitioners to assess and analyse the complex relationships among variables within an easy-to-understand visual interface, and is far more efficient than individually running statistical tests and data visualizations for each possible interaction.

This presentation will cover three examples where web-based tools were developed to convey complex risk assessment results to both technical and non-technical audiences. The example tools were built for a PFAS risk assessment for wildlife in a coastal system, a metals risk assessment with emphasis on bioavailability modifying factors, and a calculator for deriving media-based ecological screening values for site-specific receptors.

Web-based tools open the world of data exploration and risk communication to a broader stakeholder audience. These tools have allowed us to engage with risk assessment specialists, technologists from other disciplines, risk managers, and non-technical groups to interactively walk through complex datasets and risk assessment results. The platforms used in our examples, R and Shiny, can also be considered for incorporation into existing larger data/project communication dashboards.

6.10.T-04 Co-created Zero-pollution Solution Strategies for Micropollutant Management: Approached from a Systems Perspective

Floris Naus¹, Kaitlyn Carter², Millaray Sierra Olea³, Carme Bosch⁴, Massimiliano Sgroi⁵, Thomas Oudega⁶, Matthias Zessner⁶ and Dominique Narain-Ford¹, (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Society for Chemical Engineering and Biotechnology e.V. (DECHEMA), Netherlands, (3)Society for Chemical Engineering and Biotechnology e.V. (DECHEMA), Germany, (4)Eurecat, Technology Centre of Catalonia, Spain, (5)Polytechnic University of Marche (UNIVPM), Italy, (6)TU Wien, Institute of Water Quality and Resource Management, Austria

Persistent, mobile, and potentially toxic (PM(T)) substances in the soil-sediment-water system pose a significant barrier to the reuse of natural resources and the realization of a safe circular economy in Europe. According to the European Commission, pollution by PM(T) substances is often a systemic issue, closely linked to how these chemicals are produced, used, and released into the environment. The problem is further exacerbated by inadequate technical solutions for substitution, monitoring, risk assessment and treatment within the soil-sediment-water system. Furthermore, the effective implementation of such technical solutions for managing PM(T) substances in a circular economy also depends on the surrounding social, economic, and governance conditions, referred to in this paper as boundary conditions. These conditions, as well as the associated solutions they are meant to support, vary across Europe.

This presentation presents key insights needed for collaboratively developing solution strategies to manage PM(T) substances within a circular economy. In total, four co-creation workshops focusing on three diverse circular economy routes at the local level were conducted. Our results reinforce that technical solutions alone are insufficient to achieve zero pollution without accompanying boundary conditions. Co-creation processes can help reveal these critical sticking points and bridge the gap between local needs and top-down policy design. This presentation will dive into the importance of integrating technical solutions with local governance, regulatory, and social conditions and how several of the priority actions were developed into specific policy recommendations.

6.10.P Translating Complexity – The Role Science Communication Plays in Generating Lasting Societal Impact

6.10.P-Mo420 Implications of Post-Modern, Post-Truth Philosophies and the Dunning-Kruger Effect to Micro-Nano-Plastic Environmental Risk Communication

Scott D Dyer, LeTourneau University, United States

Science is at risk. Public trust in science has been decreasing over time and has been exacerbated by an increased rate of journal retractions over the past decade. Opinions outweigh facts, illustrating a post-modern philosophy. Confidence in decisions may be greatest by people with a little education on a topic, exceeding that of experts, evidence of the Dunning-Kruger Effect.

Scientists involved in studying the relationships between polymer chemistry and plastics understand the difficulty in educating fellow scientists and the public. Communicating the differences between various monomers, oligomers, polymers and plastics requires a deep knowledge of chemical structure and how it relates to environmental fate and potential risk. For example, there are terms used in scientific literature and social media that use the term “liquid plastics”. This term could refer to the pre-mold state of thermoset or thermoplastics. However, the term is most often used for polymers that can be dissolved in water, a violation of the definition of plastic. Polyethylene glycol is soluble, yet polyethylene (PE) plastic is not. The overlap in terminology confuses the public and decision-makers. Another example is “polyvinyl”, where polyvinyl chloride (PVC) is a well-known insoluble plastic, yet polyvinyl alcohol’s (PVA) properties are based on the degree of hydrolyzation of the polyvinyl acetate and cross linking. Properties of PVA range from soluble gels,

films and textile coatings and adhesives. The reception of such nuances by experts is often put aside by decision-makers to an “end justifies the means” perspective, i.e., post-modern, Dunning-Kruger model, potentially leading to inappropriate actions and judgements. Communications regarding plastics and similar sounding materials need to consider the broad array of properties and educational diversity. If ignored, polymers and plastics will continue to be confused and the credibility of good science dissolved.

6.10.P-Mo421 Anatomy of a Decision: The REACH Board of Appeal 2009–2025

Kevin Bonnot¹, Marie Collard², Elizabeth Dufourcq Sekatcheff³ and Jesus Arroyo⁴, (1)*dsm-firmenich, Belgium*, (2)*DSM-Firmenich SA, Belgium*, (3)*School of Environmental Engineering, French Agency for Food, Environmental and Occupational Health & Safety (ANSES), Maisons-Alfort, France*, (4)*European Chemical Industry Council (CEFIC), Belgium*

Since 2006, Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) has reoriented chemicals governance in the European Union (EU). Within the European Chemicals Agency (ECHA), the Board of Appeal (BoA) provides an internal judicial remedy against ECHA decisions. Yet, despite more than fifteen years of decisions, no comprehensive synthesis has assessed the BoA’s overall influence or drawn lessons for the next generation of regulatory challenges. This review is therefore timely to take stock of past jurisprudence and identify improvements in anticipation of new criteria such as endocrine disruptors (ED) and persistent, mobile and toxic (PMT) substances that are expected to generate an increasing number of appeals.

We compiled and analysed all BoA decisions from 2009-2025, categorizing them by topic, outcome and stakeholder type to identify temporal trends and interpretative shifts in key REACH provisions. Descriptive statistics (annual trends, topic distribution, success rates) are combined with doctrinal analysis of pivotal rulings to trace the interpretation of key REACH provisions (information requirements, adaptations, access to studies). A thematic lens examines scientific and regulatory dimensions, including vertebrate testing as a “last resort” (article 25 of REACH regulation), weight-of-evidence assessments, read across approaches, QSAR models, and determinations of persistent, bioaccumulative, toxic (PBT) and very persistent and very bioaccumulative (vPvB) substances.

The BoA has delivered a triple contribution: (i) legal by consolidating predictability in the REACH regime; (ii) scientific by encouraging robust use of new approach methodologies and evidence integration; and (iii) regulatory by providing guidance that shapes ECHA practice and industry compliance. In addition, this review distils actionable good-practice guidance for future decision-making. By offering the first comprehensive, quantitative and qualitative synthesis of BoA jurisprudence, this work fills a notable gap and proposes a framework for measuring downstream impacts on testing practices and for tracking evolution alongside forthcoming REACH changes. The review will interest regulators, practitioners, and scientists seeking evidence-based insights at the law-science interface of chemicals policy.

6.10.P-Mo422 Daphnia Detectives

Katie Reilly¹ and Iseult Lynch², (1)*University of Birmingham, United Kingdom*, (2)*School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom*

Daphnia are a fantastic model organism, and widely used in ecotoxicology and environmental monitoring. Their historic use has led to a range of endpoints such as changes to life history, number of offspring, growth, movement, and molecular markers. Daphnia Detectives, is an ongoing project championing Daphnia and their ability to detect environmental issues and tell the story of these problems in an engaging way. The project is made of several strands including an introduction to Daphnia, their lifecycle, biology and use in research through microscopy. The importance of Daphnia and their ability to detect pollution, often using microplastics and fluorescent markers to engage audiences in how Daphnia can be used to detect and explore the impact of a well-known pollutant that has increasing public awareness and concern. In addition to the hands on element, Dearbhla the Daphnia (the larger than life Daphnia mascot) is a key player in the story telling and the anthropomorphising of environmental issues to share alternative perspective of environmental issues with the public.

The panel of activities and materials has been developed for showcasing at the Royal Society Summer Science exhibition in 2025 and includes highlights about generating key messages, developing hands on materials and exploring evaluation strategies to ensure that public engagement and science communication is a two-way approach. In addition, some of these materials have been further adapted to create interactive content for schools, that is freely available online and ties into the school curriculum in the UK to support STEM education and exploratory learning.

Within Daphnia Detectives we explore ethical engagement, pedagogical problem sets and strategic storytelling to demonstrate and celebrate the environmental research underway in an engaging and creative way. This work highlights ways in which researchers can adapt their research content, experimental designs and results in exciting ways to both showcase their research but also to involve different communities into the research process too to create lasting impact and legacy of engagement in STEM research and environmental impacts.

6.10.P-Mo423 From Community Collection to Data-Driven Insights: Mapping Riverine Plastic Litter with Plastic Pirates Belgium

Nelle Siele Meyer¹, Line Debaveye², Charlotte Dhondt², Therese Nitschke², Gert Everaert³, Jan Seys² and Ana Isabel Catarino², (1)Ocean and Human Health, Flanders Marine Institute (VLIZ), Belgium, (2)Flanders Marine Institute (VLIZ), Belgium, (3)Ocean & human health, Flanders Marine Institute (VLIZ), Belgium

Plastic pollution is an issue of high priority for policymakers, since plastic litter accumulated in aquatic and land systems. Plastic litter is a source of contaminants of emerging concern (CECs), such as micro- and nanoplastics, and leached associated chemicals (e.g., additives, plasticizers, etc). Current local citizen science initiatives for litter collection and monitoring are popular and represent an opportunity to strengthen collaboration with the scientific community. Monitoring strategies have to rely on a multitude of surveying methodologies, since (plastic) litter is highly variable, and heterogeneously distributed in the environment, including in riverine and inland water systems. Citizen science initiatives can assist in monitoring, overcoming resource constraints (e.g., funding and personnel), facilitating sampling across extensive geographical areas, and increase awareness and environmental stewardship on plastic pollution in the local community. The goal of this work is to present the scientific and community engagement process of the project Plastic Pirates, using the Belgian use case as an example. This European project has been established in the Flemish region since 2022, and has engaged nearly 1500 school children, with many schools having a long-term involvement and monitoring the same geographical area over time. The resulting open access and FAIR data, which is validated by experts and data managers, is crucial for quantifying stranded litter and microplastics in riverine environments, assessing the origin and fate of plastic items, and resolving spatial-temporal litter accumulation trends in Belgium. In Flanders, the project contributes to other scientific projects such as TREASURE (Interreg North Sea) and INSPIRE (Horizon Europe), demonstrating the reach and utility of citizen science data in feeding into larger international research initiatives. Furthermore, the project includes supporting open access materials for schools and educators, available in multiple languages, and has synergies with local NGOs, actively contributing to scientific literacy and inclusion initiatives. By mobilizing the public in the scientific research process, Plastic Pirates supports research outcomes and community engagement in Belgium. All inputs from this initiative contribute to informing regulators and developing effective mitigation strategies related to plastic pollution.

This work has been funded by the Department of Economy, Science and Innovation (EWI Department) of the Flemish Government, Belgium

6.10.P-Mo424 Hazards in Risk Communication

Watzke de Wolf, Finland

Science communication has changed dramatically. It used to be something scientists shared mainly with other scientists—through conference talks and articles in specialist journals. Today, the goal is broader: making research understandable for the public, policymakers, and other stakeholders. Done well, it builds trust, informs decisions, counters misinformation, encourages engagement, and supports funding. Clear goals, simple language, and adapting to the audience are key. But there's another side to the story. While most discussions highlight the benefits, the downsides are often overlooked, and these can erode trust in scientists. This presentation explores the hazards associated with cultural misunderstandings and misuse of science communication. We will present findings from a survey of EU REACH regulators on national views of hazards and risks, analyzed using the Risk Perception Attitude (RPA) framework. We'll also show examples of risk communication used for economic gain—by companies for commercial purposes or by scientists and research groups to increase the chances of their proposals being funded. The speed of online communication makes the challenge to avoid miscommunication and misuse even greater. Scientists need to work with social scientists and professional communicators to craft messages that are clear, honest about uncertainties, and sensitive to cultural differences in today's digital world.

6.11.P Translating Laboratory-Based Ecotoxicological Assessments to Population-Level Effects of Chemicals

6.11.P-Th275 What('s in) the shell! Is shell deposition an acute endpoint?

Sven Ritschar¹, Alan J. Jones², Maike Habekost¹ and Lennart Weltje³, (1)BASF, Germany, (2)BASF, United States, (3)Agricultural Solutions - Ecotoxicology, BASF, Germany

Regulatory ecotoxicology increasingly uses endpoints beyond survival to capture species-specific sensitivities. The oyster shell deposition test (OCSPP 850.1025) measures shell growth inhibition as an acute toxicity indicator, yet it is often treated as a survival endpoint in European risk assessments. This misclassification overlooks that shell deposition reflects metabolic processes rather than lethality, leading to overly conservative risk characterizations and disproportionate refinement steps without improving ecological relevance. In contrast, U.S. regulatory frameworks explicitly recognize this endpoint as an acute growth measure, underscoring a more proportionate approach compared to the conservative EU.

Further, there is evidence that oysters are less, or similarly, sensitive compared to standard aquatic species when exposed to pesticides. Therefore, a comparison of growth and survival endpoints of the eastern oyster was conducted and compared to survival endpoints for *Daphnia magna*. Results indicate that the use of the growth endpoint in environmental risk assessment is not appropriate, particularly for acute risk assessment where survival-based endpoints are more biologically meaningful. While mollusc endpoints add value by broadening species coverage, their interpretation must align with biological meaning to avoid disproportionate outcomes. Clear distinction between growth-based and survival endpoints will ensure scientifically sound decisions and maintain proportionality in risk management.

6.11.P-Th276 Progressing Short-Term Methods to Estimate Chronic Marine Toxicity for Regulatory Use in the North-East Atlantic Region

Kirit Wadhia¹ and Mathijs Smit², (1)National Oilwell Varco (NOV), United Kingdom, (2)Shell Global Solutions International BV, Netherlands

1. Introduction

Within the North-East Atlantic region, reliable risk- and hazard- assessments are crucial for the management and permitting of offshore chemicals, produced water and other wastewater discharges. Assessments mostly rely on regulatory required acute Whole Effluent Toxicity (WET) and chemical toxicity tests, performed with a limited number of species, potentially leading to overly precautionary risk estimates due to the application of conservative assessment factors.

Chronic toxicity data potentially reduce this uncertainty, but application of such data in regulatory context is limited, e.g. not regulatory required, practical limitations, availability and associated costs.

Risk-based approaches increase demand for chronic marine toxicity data to reliably assess chemicals and wastewater discharges both offshore and from land-based sites to coastal environments.

There is a need to further develop and deploy short-term tests to assess chronic marine toxicity for regulatory use for both WET and chemical testing.

2. Objective

Identify suitable methods for estimating chronic marine toxicity based on existing protocols and global practices that would be applicable to the management of both offshore and coastal chemical use and discharges.

3. Deliverables

A set of well validated protocols that estimate chronic toxicity, selected based on their availability, regulatory acceptability and efficiency in terms of costs and executability.

4. Implementation Plan

- Review and analysis of existing protocols
- Protocol selection and testing plan design
- Pilot testing
- Dissemination

6.11.P-Th277 Integrating Behavioural Endpoints and Community-Level Effects to Understand Ecosystem-Level Impacts of Psychopharmaceuticals

Elieen Versteegen, Edwin Peeters, Ivo Roessink and Paul van den Brink, Wageningen University and Research (WUR), Netherlands

Aquatic environments are increasingly contaminated with psychopharmaceuticals, raising concerns about their impacts on non-target organisms. Compounds such as carbamazepine (CBZ) and citalopram (CIT) may interact

with organisms' neuroendocrine systems, altering their behaviour. Yet, the ecological relevance of behavioural changes under realistic exposure conditions remains uncertain. To investigate this, we combined behaviour-oriented 48h laboratory experiments with 13-week outdoor mesocosm studies to assess behavioural, population-, and ecosystem-level effects of CBZ and CIT.

In laboratory assays, movement-based behavioural endpoints in *Gammarus pulex* were more sensitive to CBZ and CIT than mortality, showcasing their potential as sensitive indicators of pharmaceutical exposure. However, behavioural effects of CBZ and CIT occurred only at concentrations far above those found in the environment, suggesting that short-term exposure is unlikely to trigger responses in the environment.

Because environmental exposure is typically chronic, we conducted two mesocosm studies to examine the long-term effects of CBZ and CIT on the behaviour of *G. pulex* and *Lymnaea stagnalis*, as well as on the broader aquatic community. The exposures had little effect on *G. pulex* movement but caused noticeable changes in *L. stagnalis* locomotion. These behavioural alterations did not translate into measurable population-level effects. After 13 weeks of exposure, no significant effects were detected on water quality, bacterial composition, zooplankton, macroinvertebrates, or community structure, indicating that environmentally relevant concentrations up to 100 µg/L are unlikely to produce population- or ecosystem-level impacts under these conditions. These results highlight the complexity of linking behavioural responses to ecological outcomes. Although behavioural endpoints show promise as early indicators of pharmaceutical exposure, their ecological relevance and suitability for regulatory risk assessment remain uncertain. Future research should focus on long-term studies which include effects on reproduction, as short-term behavioural changes may not translate into population-level effects, and organisms may adapt over time. Mesocosm studies offer a valuable addition to single-species tests by capturing species interactions, community dynamics, and indirect effects, providing a more realistic foundation for assessing the ecological risks of psychopharmaceuticals.

6.11.P-Th278 The SETAC MAPPED workshop: a proposed list of fish species to assess for the population relevance of endocrine disruption

Thomas G. Preuss¹, Udo Hommen², Lisa Annie Baumann³, Alice Baynes⁴, Zhenglei Gao⁵, Charles Hazlerigg⁶, Markus Hecker⁷, Ioanna Katsiadaki⁸, Emily A. McVey⁹, Kate Mintram¹⁰, Tiphaine Monsinjon¹¹, Erik B Muller¹², Patricia IS Pinto¹³, Melissa Reed¹⁴, Charles Tyler¹⁵, James Robert Wheeler¹⁶ and Henrik Holbech¹⁷, (1)Bayer AG, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)VU University Amsterdam (VU), Amsterdam, Netherlands, (4)Department of Life Sciences, Brunel University, United Kingdom, (5)Data Science, Bayer AG, Germany, (6)Enviresearch Ltd., United Kingdom, (7)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (8)Centre for Environment, Fisheries and Aquaculture Science (Cefas), United Kingdom, (9)RIVM, Netherlands, (10)Brunel University, United Kingdom, (11)Le Havre Normandy University, France, (12)ibacon GmbH, Germany, (13)CCMAR - Center for Marine Sciences, Portugal, (14)Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom, (15)Exeter University, United Kingdom, (16)Corteva Agriscience, Netherlands, (17)University of Southern Denmark (SDU), Denmark

Agrochemicals and biocides require an assessment on whether they have endocrine disrupting properties. A substance is considered to have endocrine disrupting properties that may cause adverse effects on non-target organisms when it meets specific criteria. However, according to the definition in Commission Regulation (EU) No 2018/605, this classification applies "unless there is evidence demonstrating that the adverse effects identified are not relevant at the (sub)population level for non-target organisms," which aligns with the protection goals of ecotoxicological risk assessments. Currently methods to consider population relevance of endocrine disruptors have not been available, so a SETAC workshop on the use of 'Models to Assess the PoPulation relevance of effects of Endocrine Disruptors (EDs)' (MAPPED) was formed to explore the issues for fish and amphibians.

To assess whether the effects of ED are relevant at population level, a key pre-requisite is to understand the population biology of the affected fish species. To ensure protection for all fish species in Europe, the population relevance assessment should focus on the most vulnerable species. Here a vulnerable species is defined as a species that is innately sensitive, likely exposed to the chemical(s), and has a life strategy or behaviour that may make it less resilient. Hazard assessment for ED assumes that all species are exposed and sensitive. Therefore, our approach to species selection has focused on life-strategy and behaviour. In this presentation, we identify key traits for life-history and behaviours most relevant for assessment of effects from

EDs. All freshwater fish species in Europe with sufficient information on relevant traits were clustered based on their trait combinations, and representative species for each cluster were then chosen. To perform a fully comprehensive assessment of the potential hazard to all European fish populations from ED under the current regulatory regime would require an assessment for all species relevant for the effect selected from all clusters. As such, this first proposal was to identify a set of focal fish species to assess population relevance of ED to help guide efforts in developing suitable population models.

The presented work was conducted at the SETAC MAPPED workshop

6.11.P-Th279 The SETAC MAPPED workshop: Application of effect modelling to assess population relevance of endocrine disruption mediated effects on freshwater fish

Melissa Reed¹, Udo Hommen², Charles Hazlerigg³, Kate Mintram⁴, Erik B Muller⁵, Charles Tyler⁶ and Thomas G. Preuss⁷, (1)Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Enviresearch Ltd., United Kingdom, (4)Brunel University, United Kingdom, (5)ibacon GmbH, Germany, (6)University of Exeter, United Kingdom, (7)Bayer Research & Development Services LLC, Germany

Plant protection products and biocides require an assessment of whether they have endocrine disrupting properties. In EU Regulation 2018/605, however, there is a caveat to the definition of endocrine disrupting properties, whereby it states - “unless there is evidence demonstrating that the adverse effects identified are not relevant at the (sub)population level for non-target organisms”. Currently methods to consider population relevance have not been available, so a SETAC workshop on the use of ‘Models to Assess the PoPulation relevance of effects of Endocrine Disruptors (ED)’ (MAPPED) was formed to explore the issues for fish and amphibians.

The working group on fish populations has explored the selection of species to be modelled, processes they believe should be included in a model that assesses consequences of endocrine disruption on populations, what is needed for an environmental scenario, how to assess population relevance from the model output and the validation process for the models. For all these topics, the focus is on how they differ when addressing the hazard of endocrine disruption rather than using a population model for risk assessment.

A case study is presented that shows how a population model may be used for this assessment. For this some issues specific to a hazard assessment (e.g. how do you set up a model when the level and pattern of exposure are not be taken into account) and some issues are related to population level assessment in general (e.g. how to account for variability and uncertainty when deciding if a difference to control runs indicates an adverse effect on the population).

The case study uses an individual based three-spined stickleback model to explore these issues. Two example endocrine disrupting chemicals are used to illustrate how effects can be extrapolated from typical regulatory studies to population level effects. The chemicals selected have been chosen because they are known EDs with different effects at the organism level and can be used to explore how these effects may, or may not, translate to population level effects.

Track 7: Moving Beyond - Cross Cutting Themes, Emerging and Transdisciplinary Topics

7.01 Advances in Predictive and Regulatory Toxicology and Ecotoxicology: Issues, Challenges and Opportunities

7.01.T-01 Building nano-QSARs and the importance of assessing their limitations

Surendra Balraadsing¹, Willie Peijnenburg² and Martina G. Vijver¹, (1)Leiden University, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands

The toxicity of engineered nanomaterials (ENMs) can be altered depending on their physico-chemical properties or environmental conditions, which makes toxicity testing time-consuming and costly. NanoQSARs can be effective here to aid in the risk assessment of ENMs. Quantitative structure activity relationships (QSARs) are built under the assumption that structurally similar substances will result in similar biological effects.

Nano-QSARs can be built using various different machine learning algorithms that can rapidly learn from large quantities of complex data. While machine learning algorithms have powerful predictive capabilities, it is important that the limitations and biases of nano-QSARs are properly evaluated to ensure robust and accurate predictions. This study investigates model limitations and prediction uncertainties of nano-QSARs in depth and discusses the importance of proper model assessment.

7.01.T-02 Mechanistic Model for Predicting Acute Oral Toxicity: Data Uncertainty and Model Predictability

Stela Kutsarova¹, Daniela Nedelcheva¹, Ayce Mehmed¹, Stoyanka Stoeva¹, Marin Georgiev¹, Todor Petkov¹, Atanas Chapkanov¹, Terry W Schultz² and Ovanes Mekenyan¹, (1)Laboratory of Mathematical Chemistry (LMC) Prof. Assen Zlatarov Burgas State University, Bulgaria, (2)The University of Tennessee, College of Veterinary Medicine, United States

Everyday exposure to various chemical compounds with potential adverse effects on human health, combined with the regulatory ban on using animals in acute oral toxicity (AOT) testing for cosmetic ingredients and products, are prerequisites for developing reliable in silico models. A read-across (RA) workflow based on mechanistic considerations for predicting AOT has been built in the QSAR Toolbox using a training set of 10,069 chemicals. The model automatically provides a numerical rat oral LD50 value for AOT and a categorical prediction in the form of a GHS classification distribution. The training set is initially divided into groups (scenarios) of chemicals that share the same protein binding reactivity and/or specific mechanisms related to acute oral toxicity (e.g., mitochondrial uncoupling). The model also accounts for in vivo metabolic activation and the neutralization of parent chemicals. When an untested chemical is submitted for prediction, the model automatically identifies its reactivity mechanism and assigns it to the relevant scenario associated with that mechanism. This process forms a primary group of mechanistically similar analogues. The primary group is then refined to include the most structurally similar compounds by applying rule-based structural profiling in the QSAR Toolbox. The LD50 prediction for the target chemical is based on a RA with analogues that are both mechanistically and structurally similar. The model's numerical performance achieved an R2 of 0.89. The reliability of the predictions is evaluated through a three-layered applicability domain. The accuracy of both numerical and categorical predictions is assessed, considering the uncertainty in experimental data and the limitations of the modeling approach. Experimental uncertainty defines the probability distribution of the numerical prediction, i.e., the confidence interval, which takes the form of a Gaussian distribution. This Gaussian distribution also informs the GHS classification prediction. Two extremes are possible: an unambiguous GHS classification, where the distribution is sharp and the probability of falling into a single category is high; and an ambiguous classification, where the distribution is broad and no definitive GHS category can be assigned. The model's GHS categorical performance was found to be an R2 of 0.91.

7.01.T-03 Performance of models predicting ready biodegradability

Romanas Cesnaitis¹, Panagiotis Karamertzanis², Heidi Ekholm² and Kostas Andreou², (1)Telakkakatu 6, European Chemicals Agency (ECHA), Finland, (2)European Chemicals Agency (ECHA), Finland

ECHA's guidance states that (Q)SAR models for predicting ready biodegradation are generally not yet accurate enough to reliably predict rapid degradation. (Q)SAR predictions can, on the other hand, be used as supporting evidence to indicate that the substance is not readily biodegradable. In this presentation, the results of curation of REACH experimental data on ready biodegradation and use of this curated dataset for the unbiased external validation of various (Q)SAR models, including Biowin, Opera, Vega, Catalogic, and by Körner et al.(2024), will be presented.

The extracted REACH data were curated to remove non-experimental data, unreliable experimental studies, studies with test material other than discrete organics, studies failing guideline validity criteria and substances with conflicting results. The curated dataset of experimental data, including 2684 structures (691 labelled as readily biodegradable and 1993 as non-readily biodegradable), not present in the training and validation sets of the targeted models allowed for their unbiased external validation. The models were compared based on how well their training sets span the industrial chemical space, their predictive performance and applicability domain coverage.

The balanced accuracy ranged from 0.600 to 0.771, while the sensitivity for identifying non-readily biodegradable substances varied between 0.217 and 0.848. The applicability domain coverage ranged from 28.5% to nearly the entire chemical space, yet the predictive performance remained relatively unaffected even for structures outside this domain. Further analysis in regard of precision and negative predicted value indicating the proportion of predicted readily biodegradables which have been also experimentally tested as readily biodegradable, indicated that "readily biodegradable" predictions may still not be accurate enough to reliably

predict rapid degradation while the chances of a correct non-readily biodegradable prediction are much higher. Based on the global performance results, consensus modelling offers limited advantages for general use compared to using Biowin 6 alone. However, it can be valuable when the goal is to identify a small number of highly certain positives or negatives, or to increase confidence in the predicted biodegradability of a single substance. This could make consensus modelling a promising approach for replacing an experimental test, but it comes at the detriment of a reduced applicability domain.

7.01.T-04 From Literature to Mechanistic Insight: A Retrieval-Augmented Generation-Driven Framework for Nanomaterial Adverse Outcome Pathways

Yunchi Zhou¹, Ying Wang¹, Xiaomin Li¹, Xiaoli Zhao² and Wenhong Fan¹, (1)School of Materials Science and Engineering, Beihang University, China (Mainland), (2)State Key Laboratory of Environmental Criteria and Risk Assessment, Chinese Research Academy of Environmental Sciences, China (Mainland)

Authors: Yunchi Zhou (Presenter), Ying Wang, Xiaomin Li, Xiaoli Zhao, Wenhong Fan

The extensive use of nanomaterials (NMs) has led to increasing releases into aquatic environments, raising growing concern about their potential ecotoxicity. Due to their unique physicochemical properties, NMs can interact with aquatic organisms in complex ways and induce various hazardous effects. Traditional experimental approaches are time-consuming, costly, and unable to cover diverse species, highlighting the need for an efficient and economical ecological risk assessment framework to elucidate the toxicity mechanisms of nanomaterials. The Adverse Outcome Pathway (AOP) framework provides a structured approach to toxicity evaluation by linking molecular initiating events (MIEs) triggered by NMs to subsequent key events (KEs) across biological levels and ultimately to adverse outcomes (AOs) relevant to risk assessment. However, the highly complex bio-environmental interactions of NMs and the requirement to integrate scattered literature, multidisciplinary knowledge, and multi-level evidence make manual AOP construction labor-intensive and prone to missing critical information. Large Language Models (LLMs) offer new opportunities for advancing NMs AOP development. With strong abilities in extracting information from vast literature, integrating cross-domain knowledge, and identifying complex biological relationships, LLMs can substantially reduce the time required for data synthesis and help overcome gaps in expert knowledge, thereby improving the depth, coherence, and accuracy of AOP construction. However, the knowledge depth of the general large model in the field of AOP in nanomaterials is not yet sufficient to assist us in AOP development. In this study, we focused on nanoparticles and developed an AOP knowledge base through a systematic review of nanotoxicology literature. By incorporating Retrieval-Augmented Generation (RAG), we equipped an LLM with expert-level knowledge in nanoparticle AOPs and built a specialized question-answering system for nanomaterial AOP analysis. Our results show that the RAG-enhanced LLM significantly outperforms a general LLM in answering NMs AOP-related queries. It not only improves understanding of nanoparticle toxicity mechanisms but also demonstrates strong potential to support the development of comprehensive AOP networks for NMs.

7.01.T-05 From Machine Learning to Fundamental AI Models in QSAR: How to Improve the Regulatory Acceptance?

Tomasz Puzyn¹, Michał Kałapus¹, Kamil Antoszewski¹, Karol Topka-Kłóńczyński¹ and Maciej Gromelski², (1)University of Gdańsk, Poland, (2)QSAR Lab, Poland

Quantitative structure-activity relationship (QSAR) models remain one of the most prominent *in silico* New Approach Methods (NAMs). The OECD QSAR Assessment Framework (QAF) can be viewed as a comprehensive procedure for evaluating both existing and newly developed QSAR models. However, an open question is to what extent this framework reflects the most recent advances in the field — particularly the emergence and application of fundamental AI models. Furthermore, does a positive QAF evaluation necessarily ensure regulatory acceptance? And what is the role of human judgment in this process, and how can its impact be minimized?

In this contribution, we discuss several additional factors that, in our view, should be considered when evaluating the regulatory acceptability of QSAR models: (i) the toxicological relevance of the model, (ii) regulatory relevance of the model, and (ii) its user-friendliness and intuitiveness. We then present a case study comparing the outcomes of applying QAF – together with these two supplementary criteria – to predictions of

the same 3 endpoints generated by a classical machine-learning QSAR model and by a QSAR model based on a fine-tuned FM4M fundamental AI model recently developed by IBM. We hope that our analysis will contribute meaningfully to the ongoing discussion and offer valuable guidance for developers of AI-driven QSAR tools seeking to maximize their potential for regulatory acceptance.

7.01.P Advances in Predictive and Regulatory Toxicology and Ecotoxicology: Issues, Challenges and Opportunities

7.01.P-We422 Ensuring Regulatory Compliance with the (Q)SAR Assessment Framework: Best Practices and Case Examples of Reporting (Q)SAR Predictions for REACH

Doris Hirmann, Salvador Moncho Escriba, Ulla Simanainen and Eszter Harsanyi, European Chemicals Agency (ECHA), Finland

QSAR models are an efficient, cost-effective alternative to assess the hazards of chemicals for regulatory purposes. By promoting the application of QSARs, ECHA aligns with the ethical concerns associated with animal testing (the principles of the 3Rs: Replacement, Reduction, and Refinement) and aims at enhancing the scientific robustness of chemical assessment. On the other hand, ECHA's efforts in protecting health and the environment require the careful assessment of how computational models are used to ensure an adequate level of protection.

The (Q)SAR Assessment Framework (QAF), developed by ECHA in collaboration with the Italian National Institute of Health (ISS) and the Organisation for Economic Cooperation and Development (OECD), represents a significant advancement in the field. It provides a consistent and transparent methodology for regulators, users and developers to evaluate the reliability and relevance of (Q)SAR models and predictions. The QAF includes a series of assessment elements and detailed checklists for assessing models, predictions, and results from multiple predictions, ensuring clarity, consistency, and transparency in the evaluation process. Hence, (Q)SAR users are informed of the requirements and can enhance their application and documentation, increasing the probability of regulatory acceptance. Furthermore, the framework encourages (Q)SAR model developers to create models that are fit for regulatory applications, thereby increasing confidence in the use of these models for hazard assessment.

The QAF is meant to be broadly applicable irrespective of the modelling technique, the predicted endpoint, and the intended regulatory purpose, and therefore does not provide exhaustive instructions on all possible aspects. There is a need to adapt it to specific regulatory applications, and it provides certain flexibility with regards to interpretation. In this presentation, we will provide case examples and recommendations about the best practices to report (Q)SAR predictions for facilitate REACH compliance on basis to the QAF.

7.01.P-We423 Strengthening Regulatory QSAR Evaluation: Application of the QSAR Assessment Framework to a Bioaccumulation Case Study

Darina Yordanova, Irina Dermen, Nadezhda Dimitrova and Ovanes Mekenyan, Laboratory of Mathematical Chemistry (LMC) Prof. Assen Zlatarov Burgas State University, Bulgaria

The growing use of in silico Quantitative Structure-Activity Relationship (QSAR) methods offers significant opportunities to strengthen regulatory chemical assessments while reducing animal testing. However, the consistent and transparent evaluation of QSAR predictions remains a key challenge for regulatory acceptance. The QSAR Assessment Framework (QAF) was developed to provide practical, harmonized guidance for evaluating QSAR models and predictions across different regulatory contexts. Building on internationally recognized principles, such as the OECD QSAR validation criteria, the framework supports assessors and registrants in judging model reliability, assessing applicability domains, and integrating predictions within a weight-of-evidence approach.

This work outlines the core elements of the QAF and demonstrates its application in the context of REACH registration from the user point of view. It was selected a case study that focuses on fulfilling a specific REACH information requirement for bioaccumulation and illustrates how the framework supports evaluation of QSAR predictions. It shows how all requirements defined in the QAF are addressed to justify a QSAR prediction, with particular emphasis on evaluating prediction reliability and uncertainty. This includes the selection of appropriate analogue chemicals to support endpoint predictions, the use of metabolism simulation, and the analysis of applicability-domain outcomes. The results are structured using the (Q)SAR Model Reporting Format (QMRF) and (Q)SAR Prediction Reporting Format (QPRF), in full alignment with the requirements

outlined in the QAF document. The automated population of the QPRF file with information required for the QAF assessment elements as well as the possibility further direct transferring to IUCLID is an essential part of reporting process that will benefit both – facilitation of the users in report preparation and consistent evaluation by the regulators.

7.01.P-We424 Performance Of the iSafeRat® Model in the Recent ECHA Evaluation of Chronic Fish Toxicity Predictions

Maxime Edelblout¹, Floriane Larras¹ and Paul Thomas², (1)KREATiS, France, (2)KREATiS, ., France

In the context of regulatory ecotoxicological assessment under REACH and the need to limit animal use in experimental testing, ready access to reliable QSAR predictions for chronic fish toxicity has become increasingly important. Recently, ECHA published a comprehensive analysis entitled “Replacing Fish Early Life Stage Toxicity Test: Performance of Three QSAR Tools for Recently Submitted REACH Data”, evaluating the predictive performance of three models—ECOSAR, VEGA and iSafeRat®—against newly submitted experimental datasets. This poster focuses on the results obtained for the iSafeRat® chronic fish toxicity model and discusses the specific issues associated with our predictions and lessons learned for future model refinement at KREATiS. The ECHA evaluation was conducted on a dataset of 49 substances for which iSafeRat produced predictions for 18 compounds falling within its applicability domain, consistent with its principle of refusing to extrapolate beyond domain boundaries. Out of these 18 predictions, 17 were classified by ECHA as well-predicted, while one was considered an outlier. Overall, we are satisfied with these results, especially considering that the ECHA evaluation method corresponds to a worst-case scenario as toxicity predictions were generated directly from SMILES with no refinement or correction of intermediate parameters. The standard KREATiS regulatory workflow relies on a three-step QSAR cascade: prediction of log KOW from structure, prediction of water solubility from log KOW, and prediction of chronic fish toxicity from solubility. For QPRFs prepared by KREATiS, each intermediate value is systematically checked against reliable available experimental data to ensure coherence and to correct upstream parameters when necessary. Our analysis of the ECHA evaluation shows that the single poorly predicted substance exhibited an inaccurately predicted water solubility value. When replacing the predicted water solubility with the corresponding experimental value, the resulting chronic fish prediction becomes consistent with the experimental toxicity. This observation highlights not only the importance of scrutinizing and validating intermediate properties, but also how model users can optimize predictive accuracy through informed parameter correction. With ongoing refinements, we anticipate enhanced performance in forthcoming evaluations, exceeding what was observed under the stringent conditions of the recent ECHA publication.

7.01.P-We425 How to: Integration of Quantitative Structure Activity Relationships into the Safe and Sustainable by Design Framework

Arianna Sgariboldi¹, Nicola Chirico¹, Simone Marzeddu², Giuseppe Granato² and Ester Papa¹, (1)DiSTA, University of Insubria, Italy, (2)Hazardous Substances Section, Service for environmental education and training and for the technical coordination of Directorate activities (DG-TEC), Italian Institute for Environmental Protection and Research (ISPRA), Italy

The Safe and Sustainable by Design (SSbD) framework was introduced in the European Commission (EC) within the Chemicals Strategy for Sustainability (CSS) which promoted innovation for safe and sustainable chemicals toward an environment free of toxic substances. This framework is currently a voluntary approach to guide the innovation process for chemicals and materials. SSbD integrates an assessment of the environmental sustainability with safety considerations to provide a comprehensive evaluation. The general structure of the SSbD framework is composed of two phases, a first one for the innovation (redesign) of a chemical/material, and a second one for safety and sustainability assessment. The EC's SSbD framework supports and promotes, especially in the early stages of innovation, the use of new approaches to test and evaluate chemicals and materials, including predictive tools, which sometimes may involve a higher degree of uncertainty. This work explores the integration of in silico approaches within SSbD and how strategies based on quantitative structure–activity relationships (QSARs) can estimate missing data for properties considered in different steps of the framework, for existing and new chemicals, in line with Regulation (EU) 2024/1781 on Ecodesign for Sustainable Products (ESPR). The proposed workflow addresses parameters listed in Annex I of the ESPR Regulation—such as substances of concern, product environmental (PEF) and carbon footprint (PCF), and durability—and outlines how QSAR-derived data can be incorporated into the Digital Product Passport for traceability and compliance.

The workflow tackles key challenges: identifying stages where QSARs add value; integrating data while ensuring reproducibility according to OECD principles; assessing and communicating uncertainty transparently;

and harmonising outputs from multiple QSAR tools to meet regulatory requirements for verifiability and standardisation. It also considers how computational methods can reduce testing costs and administrative burden, supporting Small and Medium-sized Enterprises (SMEs) and accelerating innovation. In conclusion, this work proposes a systematic approach to select and integrate QSAR models within SSbD, ensuring alignment with EU sustainability and ecodesign requirements, facilitating digital information management, and promoting harmonisation for future regulatory frameworks.

7.01.P-We426 Potentials and challenges for mobility assessment of UVCB substances using in silico tools *Antje Gerloff-Elias and Claudia Ileana Cappelli, knoell Germany GmbH, Germany*

The assessment of substance mobility in soil has become increasingly important with the introduction of “new” hazard classes under Regulation (EC) No 1272/2008 (Classification, Labelling and Packaging of substances and mixtures; CLP) for persistent substances.

Results from OECD 106 and 121 studies can provide crucial data for assessing the potential mobility of a substance. However, experimental normalised organic carbon to water partition coefficient (KOC) data (the primary parameter for mobility assessment) is available for only approximately 20% of EU REACH-registered substances, creating significant data gaps. Furthermore, adsorption testing is often time-consuming, expensive, and difficult to scale for broad assessments, particularly for complex scenarios or many substances. Specifically for difficult to test substances such as instable substances or substances of unknown and variable composition (UVCBs) or ionisable substances, the experimental design is challenging.

In silico predictions offer an alternative to assess the mobility of substances, when no experimental data is available. Opportunities include high-throughput analysis of complex chemical mixtures and facilitation of prioritisation of substances/constituents for further testing. Limitations stem from the variable composition of UVCBs making accurate modelling difficult, the uncertainty of model predictions, and the need to bridge gaps between in silico output and real-world experimental validation, particularly for regulatory compliance. Here we describe the challenges for mobility assessment of complex UVCB substances and present a workflow how in silico-generated predictions can support mobility assessment under CLP and EU REACH.

7.01.P-We427 Simulating Kinetics of Metabolism. QSAR Application

Atanas Chapkanov¹, Hristiana Stoyanova (Ivanova)¹, Gergana Dimitrova¹, Yoanna Todorova¹, Terry W Schultz² and Ovanes Mekenyan¹, (1)Laboratory of Mathematical Chemistry (LMC) Prof. Assen Zlatarov Burgas State University, Bulgaria, (2)The University of Tennessee, College of Veterinary Medicine, United States

The importance of toxicokinetics in predicting toxicological endpoints has increased markedly over the years. It has evolved from being completely disregarded in early models to being modelled qualitatively and later quantitatively. The Laboratory of Mathematical Chemistry (LMC) has extensive experience leveraging toxicokinetics to model various effects. Initially, a large set of tissue-specific metabolic simulators was developed and continuously improved by incorporating additional documented metabolism data and expert knowledge. These simulators enable the generation of potential metabolites for any target and the subsequent application of hazard alerts responsible for the ultimate prediction. Later, an attempt was made to quantify hazard potential by calculating the amounts of active metabolites (i.e., those causing effects such as protein adducts). In recent developments, we focus on modelling the kinetics of metabolism, aiming to explicitly express the quantities of parent chemicals and their metabolites as functions of time. Practically, this task is achieved by developing a novel model to predict reaction rates. Due to data deficiencies and insufficient metabolic information, the present work considers in vitro (rat) half-lives of parent structures to indirectly estimate reaction rates. To reduce misclassification caused by various possible transformations, here we focus on two reaction types: hydrolysis and hydroxylation. We examined various chemical parameters (2D, 3D, local) as potential descriptors. The reliability of the predictions is evaluated through internal cross-validation and has proven valuable. However, the results should be considered preliminary due to the limited scope of modelled transformations and the small size of the training dataset. Future model developments are planned and will

involve expanding the training set with additional transformation types, as well as other species (e.g., humans) and tissues (e.g., in vivo half-lives).

7.01.P-We428 Validation of machine learning-based QSAR models using reference chemicals for regulatory applications

Donghyeon Kim¹, Siyeol Ahn², Jiyong Jeong² and Jinhee Choi², (1)University of Seoul, Paris-Cité University, Korea, Republic of, (2)School of Environmental Engineering, University of Seoul, Korea, Republic of

Machine learning-based QSAR models were developed to predict regulatory-relevant toxicological endpoints, including acute and chronic toxicity, carcinogenicity/mutagenicity/reproductive toxicity (CMR), and neurotoxicity, by integrating large-scale in vitro assay data with curated in vivo toxicity information. The models were constructed to capture mechanistic signals associated with adverse outcomes, enabling transparent linkage between assay-derived biological activity patterns and apical toxicity endpoints of regulatory interest. To evaluate their robustness, applicability, and regulatory readiness, the models were validated using well-established reference chemicals provided by international bodies involved in NAMs evaluation, including ECVAM and other validation-oriented agencies. These reference chemicals span diverse chemical classes and toxicity modes of action, providing a rigorous basis for assessing model performance across different domains of applicability. Comparative analysis demonstrated that the models achieved consistent predictive accuracy across endpoints, and mechanistic concordance analyses indicated that predictions were supported by biologically plausible assay profiles. The results collectively highlight that ML-based QSAR models, when anchored to empirical in vitro and in vivo data and evaluated with internationally recognized reference chemicals, can offer reliable support for regulatory decision-making. This study underscores the potential of NAMs-driven computational approaches to enhance hazard assessment frameworks and contribute to the broader acceptance of AI-enabled predictive tools in regulatory toxicology.

7.01.P-We429 Improving the predictive performance of toxicity prediction machine-learning models using state-of-the-art deep learning approaches

Donghyeon Kim¹ and Jinhee Choi², (1)University of Seoul, Paris-Cité University, Korea, Republic of, (2)School of Environmental Engineering, University of Seoul, Korea, Republic of

In our previous study, machine learning models were developed to predict regulatory-relevant toxicological endpoints using curated in vitro and in vivo datasets; however, for several key endpoints, predictive performance remained limited due to small dataset sizes and highly imbalanced class distributions. These constraints hindered the ability of conventional machine learning algorithms to learn meaningful decision boundaries and capture mechanistic signals associated with adverse outcomes. To address these challenges, we explored the applicability of state-of-the-art deep learning approaches increasingly adopted in the computer science field, including advanced data augmentation strategies, representation learning, and architectures optimized for learning from sparse and imbalanced data. By integrating these methods into the existing toxicity prediction workflow, we systematically evaluated whether modern deep learning techniques could enhance model robustness, improve classification performance, and expand the domain of applicability for endpoints historically constrained by data limitations. Preliminary results demonstrate notable performance gains for selected regulatory endpoints, suggesting that next-generation deep learning methods can complement traditional machine learning models and offer a viable pathway for improving toxicity prediction when empirical data are scarce or unevenly distributed. This study highlights the potential of leveraging cutting-edge computational techniques to advance predictive toxicology and strengthen model readiness for regulatory applications.

7.01.P-We430 Comparison of OECD 236 Guideline with the Toxicity Profile of Zebrafish Cell Lines
vicente aranda¹, Eugenia Valsami-Jones², Manpreet Kaur², Tajudeen Oyehan², Rafael Garcia¹ and Rafael Gozalbes¹, (1)ProtoQSAR SL, Spain, (2)University of Birmingham, United Kingdom

The OECD 236 guideline provides an alternative to animal testing for acute fish toxicity, as required by REACH, BPR, and PPP in Europe. Although this assay reduces the use of animals, it involves zebrafish embryos, which are not regarded as fish under regulatory definitions because they are not considered independently feeding larval forms; however, they are still whole living organisms. To further reduce animal use, OECD 249 was developed as a fully in vitro method using rainbow trout gill cells (RTgill-W1) as a substitute for OECD 236 and 203; however, its regulatory acceptance remains limited.

In this study, we aim to determine whether essays conducted under OECD 236 produce toxicological data comparable to those from an adaptation of OECD 249 using zebrafish cell lines instead of rainbow trout gill cells. To achieve this, we have developed a Quantitative Structure-Activity Relationship (QSAR) model trained on curated acute toxicity data from OECD 236 studies and compared its predictions with experimental results obtained from acute toxicity assays using zebrafish embryo cell lines. These findings may help advance regulatory adoption of zebrafish-based in vitro assays aligned with OECD 249 principles, thereby reducing reliance on animal experimentation and promoting next-generation risk assessment strategies.

7.01.P-We431 The role of chemical specificity in modelling approaches

Surendra Balraadjsing¹, Pim Wassenaar², Martina G. Vijver¹ and Willie Peijnenburg², (1)Leiden University, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands

At present, over 350,000 chemicals are registered for production and use worldwide. These registered substances enable a wide range of industrial and societal applications, but also pose risks to human health and the environment. To manage chemical safety, regulatory frameworks rely on hazard and risk assessments. However, these assessments face significant challenges, including i) a lack of reliable and comprehensive data, and ii) a relatively slow and inefficient evaluation and regulation process.

Innovation of chemicals evolves rapidly, with estimates of over 2,000 new chemicals introduced to the global market yearly. These innovations are increasingly driven by chemical specificity, particularly in the context of mode of action (MoA). Yet most predictive models in toxicology and risk assessment are grounded in data-driven patterns. This creates a fundamental friction: the more specific a MoA is, the less detectible these data-driven patterns become during modeling, as they are overshadowed by patterns of the larger data mass.

Quantitative Structure Activity Relationships (QSARs) are created based on the structural information of chemicals with the aim of applying them to novel (untested) substances. However, from (Balraadjsing et al., 2024) and Minnema et al. (submitted) we learned that QSARs do not always generalize well when applied to novel materials or chemicals with specific MoA. Here we build upon this idea to describe a framework that investigates how chemical specificity can be better acknowledged in modelling approaches.

7.02 Advancing Pollution Control in Wastewater: Monitoring, Risks, and Regulatory Transitions

7.02.T-01 Get to know the European HORIZON Project URBAN M20 “Effective Monitoring and Modelling solutions for data-driven holistic management of urban water quality”

Miriam Langer¹, Isolde Wackernagel², Cornelia Kienle³, Heinz Singer², Silwan Daouk⁴, Luca Vezzaro⁵ and Lena Mutzner², (1)FHNW, Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Swiss Centre for Applied Ecotoxicology, Switzerland, (4)VSA, Plattform Water quality, Switzerland, (5)DTU, Denmark

The European Union’s Zero Pollution Action Plan sets ambitious targets for cleaner urban water environments, aiming to reduce health risks and environmental impacts caused by stressors such as chemical and microplastic emissions. Achieving these goals requires, first, extensive high-quality data; and second, robust support for pollution control strategies throughout the entire urban water cycle. However, the current Best Available Monitoring Methods (BAMMs) face critical limitations. Laboratory analyses and sensor technologies often target only a small range of contaminants. They also involve high operational costs and require complex maintenance. Furthermore, they provide data with limited spatial and temporal resolution, which poses challenges for their broad application by water utilities. Although digital twins and modelling tools can help to bridge these gaps, they rarely integrate real-time data and are subject to significant uncertainties. Furthermore,

fragmented data storage across institutions restricts accessibility for decision makers.

The HORIZON Europe and SERI funded URBAN M2O project, launched in June 2025, addresses these challenges by developing integrated solutions, such as:

- a. combining validated, AI-enhanced monitoring sensors with fit-for-purpose modelling tools tailored to the needs of regulators and water utilities and benchmarked against BAMMs (organic chemicals, metals, microplastics, pathogens, and effect-based tools);
- b. establishing a multistakeholder Data Management System (DMS) to deliver 'whole system' and open access information, enabling a harmonised approach to urban water quality management;
- c. creating a flexible Digital Urban Water Twin (DUWT) to simulate pollutant pathways and evaluate reduction strategies in different climate scenarios. These will be demonstrated in three EU case studies, which will showcase varying data availability and climate challenges.

The URBAN M2O project involves end users, industrial partners, and academic institutions to ensure co-production of knowledge from design to implementation. The project invites sensor developers and interested urban communities to join as external partners, offering them the opportunity to test their sensors against comprehensive BAMB measurements or explore the digital urban water twin for their own water cycles.

7.02.T-02 Chemical Target Screening and Mixture Risk Assessment of Wastewater: A Pan-European Study

Angela Maria Castro Velazco¹, Iker Alvarez-Mora², Werner Brack¹, Charlotte Henkel¹, Martin Krauss¹ and Saskia Finckh¹, (1)Helmholtz Centre for Environmental Research GmbH (UFZ), Germany, (2)Research Centre for Experimental Marine Biology and Biotechnology (PiE-EHU/UV), University of the Basque Country, Spain

Complex mixtures of chemicals from domestic and industrial activities reach the aquatic environment via Wastewater Treatment Plant (WWTP) effluents. These micropollutants are often only partially removed by conventional treatment processes, contributing to toxic pressure on aquatic organisms. The revised Urban Wastewater Treatment Directive (UWWTD) emphasises priority substances and improved monitoring, yet harmonised large-scale mixture assessment remains limited. Thus, in this study, influent and effluent samples from 30 WWTPs across 15 European countries were investigated to: (1) better understand chemical occurrence, (2) evaluate removal efficiencies, (3) assess the risks posed by complex chemical mixtures on key biological quality elements, and (4) examine how well the UWWTD benchmark substances represent broader mixture behaviour. Chemical target screening resulted in 402 compounds reliably detected and quantified, with human pharmaceuticals representing the largest group of detected compounds. Concentrations ranged from <1 ng/L to >200 µg/L, and only 44% of compounds were well removed (>80 removal) by conventional treatments, while most exhibited limited removal. Mixture risk assessment revealed widespread exceedance of chronic toxicity thresholds across Europe, particularly for algae and daphnia. Based on compounds with available measured effect data, the main risk drivers for algae were ketoprofen and N,N-Dimethyldodecylamine, while for daphnia, risks were dominated by fipronil and diazinon. Under a no-dilution scenario of the effluent, chronic risk thresholds were exceeded at 60% of the sites for algae and in all sites for daphnia. UWWTD benchmark substances were detected in over 94% of effluents, confirming their limited treatability under conventional treatments. Based on average ozonation removal rates from the literature, predicted quaternary treatment scenarios indicated substantial reductions of effluent concentrations and risks. Overall, micropollutants were widespread and often poorly removed by conventional treatment. Mixture risks were largely driven by non-benchmark substances, and although predicted quaternary treatments reduced the concentrations and toxic pressure, their effectiveness is not uniform across chemical mixtures and biological quality elements. This highlights the need for widespread mixture-based monitoring and expanded benchmarks to ensure protection of aquatic ecosystems.

7.02.T-03 Effect-Based Monitoring Identifies Macrolide Antibiotics as Main Toxicity Drivers in Flemish Wastewater Treatment Plant Effluents, Belgium

Warich Leekitratanapisan¹, Marie Pardon², Peter de Witte², Annelii Ny², Soraya Chapel², Deirdre Cabooter² and Karel De Schampelaere¹, (1)Ghent University, Belgium, (2)KU Leuven, Belgium

The revised EU Urban Wastewater Treatment Directive (UWWTD) incorporates new obligations for advanced treatment and enhanced monitoring of micropollutants in urban wastewater systems, supporting more robust strategies for protecting surface-water quality. However, chemical monitoring alone often fails to capture mixture effects relevant to ecological health. This study evaluated the ecological risks of organic micropollutants (OMPs) mixtures in effluents from 16 wastewater treatment plants (WWTPs) across Flanders, Belgium, by integrating effect-based monitoring (EBM) with targeted chemical analysis. Bioactivity of solid-phase extraction (SPE) effluent extracts was assessed using a *Microcystis aeruginosa* growth inhibition assay. Among 130 identified compounds, 26 OMPs were quantified across major classes. The bioassay showed high sensitivity, with EC10 and EC50 values corresponding to relative enrichment factors of 1.1–4.7 and 4.1–38, respectively. Iceberg modeling indicated that macrolide antibiotics, particularly azithromycin and clarithromycin, accounted for most of the observed inhibitory effects, while remaining bioactivity likely reflects contributions from other, unquantified mixture components. Risk characterization in receiving waters using chemical risk quotients, effect-based trigger values, and margin-of-safety metrics consistently identified potential ecological concern ($RQ > 1$) at most sites, with smaller WWTPs and low-dilution catchments exhibiting the highest risk. This work demonstrates the added value of combining EBM with chemical monitoring to improve mixture risk assessment, identify key toxicity drivers, and support regulatory transitions toward more holistic effluent evaluation under the UWWTD.

Disclaimer/Disclosure:

The study was supported by the Research Foundation Flanders (FWO) in the SBO research project “SmartDetox” (S002121N) and KU Leuven, IOFm/16/003. The authors would also like to thank Birte Raes from Aquafin NV for supporting with the WWTP effluent sample collection and provided useful information of the wastewater treatment plant sites.

7.02.T-04 Volatile organic compounds as early indicators of bleach and antibiotic stress in anaerobic microbial communities

Baptiste Poursat¹, Tania Gomez-Borraz², Bill Sloan² and Caroline Gauchotte-Lindsay³, (1)No Affiliation, United Kingdom, (2)University of Glasgow, United Kingdom, (3)James Watt School of Engineering, University of Glasgow, United Kingdom

Anaerobic digesters and septic tanks depend on stable microbial communities, yet early detection of disturbance remains difficult because routine indicators such as pH, methane or VFAs only change once inhibition is already advanced. Household inputs containing bleach, antibiotics and pharmaceuticals can disrupt anaerobic metabolism even at low concentrations, but current monitoring approaches cannot detect these effects early enough to prevent loss of performance. Volatile organic compounds (VOCs) offer a rapid, non-invasive readout of microbial activity and can shift within minutes to hours following stress.

We evaluated whether VOC fingerprints can reveal early metabolic responses to chemical stress using batch assays exposed to hypochlorite and sulfamethoxazole, complemented by a three-month monitoring campaign of septic tanks connected to a local community. VOCs were collected using SPME and thermal desorption and analysed by TD-GC-MS, with non-target data processed and diversity metrics.

Bleach caused an immediate 50% drop in methane production without affecting pH, highlighting functional inhibition despite stable routine parameters. VOC richness and Shannon diversity remained unchanged, but individual VOC features shifted significantly after chlorination, including transient compounds likely linked to oxidative stress. In the septic tanks, VOC community profiles showed substantial temporal variability driven by influent changes, yet specific VOCs consistently responded to chlorination and may serve as stress biomarkers.

This work provides proof of concept that non-target VOC profiling can detect metabolic disturbances before major performance losses occur. While community-level VOC patterns remained relatively stable, shifts in individual VOCs revealed chemical stress responses not captured by conventional monitoring. VOC analysis therefore offers a non-destructive, complementary tool for early warning in anaerobic systems. Future work will develop concentration–response relationships and identify metabolic pathways associated with stress-responsive VOCs to enable operational deployment.

7.02.P Advancing Pollution Control in Wastewater: Monitoring, Risks, and Regulatory Transitions

7.02.P-Th280 City-Scale Shotgun Metagenomic Surveillance of Antimicrobial Resistance across a sewage network that includes Urban, Hospital, and Airport Wastewater in Larnaca, Cyprus

Despo Fatta-Kassinou¹, Andrea Naziri¹, Popi Karaolia¹ and Sotirios Vasileiadis², (1)University of Cyprus, Cyprus, (2)University of Thessaly, Greece

Wastewater surveillance is emerging as a key pillar of One Health monitoring of antimicrobial resistance. Building on studies from individual sites, this work provides a city-scale view by exploring how different human activity zones; urban, touristic, hospital, and airport, contribute to distinct microbiome and resistance profiles within the sewage network of Larnaca, Cyprus.

A two-year sampling campaign was conducted across ten geographical points within the sewage system: six urban pumping stations, the city General Hospital, the International Airport and the influent and effluent of the wastewater treatment plant (WWTP). This WWTP serves Larnaca's population equivalent of 72,000, a number that doubles during periods of high tourism. Composite 24-hour wastewater samples were collected every fourteen days. Shotgun metagenomic sequencing was carried out for diversity analyses, multivariate ordination, while a random-forest feature selection approach was used to characterize spatial and temporal patterns. Microbial source tracking was applied to evaluate the contribution of upstream locations to key sinks in the network.

Location was the dominant factor shaping microbial community, functional and antimicrobial resistance profiles. Hospital, airport and treated effluent samples exhibited distinct and reproducible signatures, while urban pumping stations showed similar characteristics, reflecting a shared urban input. Seasonal and temporal differences were minimal, possibly reflecting the minimal corresponding environmental condition differences. Urban pumping stations represented the primary contributors to the influent of the treatment plant due to their high wastewater flow. Despite representing a minor volumetric input, hospital wastewater accounted for ~15% of the resistome at the downstream urban pumping station that receives it, demonstrating its disproportionate impact.

This study shows that antimicrobial resistance patterns at the city scale are governed mainly by spatial structures and source-specific inputs rather than seasonal variation. The findings highlight the value of integrating metagenomics with source-tracking approaches to identify key contributors within urban wastewater systems and to support targeted surveillance and management under a One Health framework.

7.02.P-Th281 Sampling Approaches for Wastewater-Based Epidemiology: Influences of Time-Weighted Composite and Grab Sampling through Time

MD ALAMIN¹, Adam R. Wronski¹, Fallon Bain¹, Kacie A. Kaneshiro¹, Janelle Oldfather¹, Christine C. Snow¹, Olivia Sagvold¹, Charlotte Nwagwu¹, HyeonYoung Choi¹, Audrey Robertson², Layla Lustri², Victoria Salinas², Laura M Langan³, Heidi K Bojes² and Bryan W. Brooks⁴, (1)Baylor University, United States, (2)Environmental Epidemiology and Disease Registries Section, Texas Department of State Health Services, United States, (3)Department of Environmental Health Sciences, University of South Carolina, United States, (4)Department of Environmental Science, Environmental Health Science Program, Baylor University, United States

Wastewater-based epidemiology (WBE) has been crucial for tracking viruses and chemical usage and subsequently informing public health decisions. How and when to sample remains an important consideration because grab sampling during weekdays is common. We tested the hypothesis that viral RNA from four infectious diseases (using RT-qPCR) and chemical markers (pharmaceuticals using isotope dilution LC-MS/MS) would not vary between paired grab and composite sewage samples collected during Fall and Spring seasons in Texas, USA. We did not observe any significant ($p > 0.05$) differences for any viral targets between weekend and weekday sampling. However, SARS-CoV-2 concentrations in Spring were significantly higher ($p < 0.05$) than during the Fall season. We also observed significantly ($p < 0.05$) higher levels of N2 and C28311T in composite samples compared to grab samples.

Most chemical markers were significantly elevated ($p < 0.05$) during the Spring. Similarly, significant differences ($p < 0.05$) by sample type were observed for most compounds; most chemical markers were significantly

elevated ($p < 0.05$) in composite samples compared to grab samples. Atenolol, benzoylecgonine, sildenafil, and triamcinolone acetonide were significantly ($p < 0.05$) higher on the weekend, while concentrations of methylphenidate and amitriptyline were significantly ($p < 0.05$) higher in weekday samples. Though composite sampling is not consistently used in WBE, we observed significantly ($p > 0.05$) higher levels of virus targets and chemical markers in time-weighted composite samples.

7.02.P-Th282 Treatment of microplastics in wastewater treatment plants (WWTPs) case studies in Wallonia, Belgium: methods and results

Audrey Joris, Aymeric Nagant and Laurence Haouche, ISSeP, Belgium

The occurrence of microplastics (MPs) in the environment has become a global environmental issue. According to a rough estimate 70-80% of marine plastics originate from land and are carried by rivers to the oceans. Currently, there is a rising concern about the role of wastewater treatment plants (WWTPs) in the release of MPs in the environment. Recent studies have shown that the presence of MP in wastewater is partly due to plastic microbeads contained in personal care products and plastic fibres released by the washing of synthetic fabrics. During treatment process in WWTP, around 99% of MP pass mainly into sludge.

In 2020, 69% of all WWTP sludge produced in Wallonia was recycled in agriculture. It is therefore important to evaluate the efficiency of Walloon WWTPs for the treatment of MPs. This study aims to assess the balance sheet. First, a sample preparation protocol has been developed to remove organic matter and separate MP by density difference. Then, a representative selection of WWTPs in Wallonia has been characterized in terms of MPs load in wastewater (inlet), in effluent (after treatment) and in sludge. Two analytical techniques were used to evaluate the number of MPs according to their size: Nile Red Microscopy for particles from 100 μm to 1 mm, and microFTIR spectroscopy from 20 μm to 200 μm . In addition, microFTIR spectroscopy gives the nature of MPs (PE, PP, PS...).

Next, a WWTP abatement rate was calculated from the data obtained. This is the percentage reduction in the number of MPs in the effluent (OUT) compared to the number of MPs observed in the raw water (IN). The abatement rate obtained between wastewater and effluent is 53-89%. This rate is close to that stated on publications on this subject. Regarding sludge, it is the receptacle for MPs, with a wide variety of particle shapes and discoloration observed. MicroFTIR data showed the presence of PET and PA in all three sample types. The sludge contains also PE, PP and PS. These are the most common MPs found in the environment.

7.02.P-Th283 Practical Experiences with Controlling Ozonation in Full-Scale Quaternary Treatment for Micropollutant Removal from Municipal Wastewater

Birte Raes, Aquafin, Belgium

The revised Urban Wastewater Treatment Directive (2024/3019) requires advanced treatment for micropollutant removal at selected urban wastewater treatment plants (UWWTP's). In April 2025, the first full-scale quaternary treatment in Flanders was taken into operation at the Aartselaar UWWTP, combining ozonation and granular activated carbon (GAC). While literature recommends controlling ozonation via online dissolved organic carbon (DOC) or ΔUV measurements, practical implementation revealed several challenges.

Three CARBOVIS 705 sensors (WTW) were installed before ozonation, between ozonation and GAC, and after ozonation to measure UV absorption at 254 nm. These sensors allow measurement of other parameters such as dissolved organic carbon (DOC) based on site-specific calibration. The sensors feature ultrasonic and pressurized air cleaning, supplemented by weekly manual acid cleaning. Despite these measures, stable calibration of UV sensors against DOC proved difficult. Moreover, variability in laboratory DOC results across analytical methods makes it difficult to use this parameter. Use UV signal for operational control and insights will therefore be more robust than DOC-based interpretations.

Operational experience highlighted fouling as a major issue. The sensor positioned after ozonation was most prone to fouling, and weekly acid cleaning was insufficient to maintain stability. Rain events caused signal drift in all sensors hampering their use for process control. These findings underline the importance of sensor maintenance and the need for more advanced control strategies that take into account the limitations of the on-site sensors. While online UV monitoring offers a practical approach for ozonation control, its reliability depends on rigorous cleaning protocols and consideration of site-specific conditions.

This work provides insights to bridge the gap between theoretical recommendations and operational realities in full-scale wastewater ozonation systems. Lessons learned will inform best practices for implementing advanced treatment.

7.02.P-Th284 Enhancing Pharmaceutical Removal via Photoelectrochemical Oxidation in Wastewater Effluent

Sanjeeb Mohapatra¹, Luuk Rietveld², Jan Peter van der Hoek² and Henri Spanjer², (1)Delft University of Technology, Delft, Netherlands, (2)Delft University of Technology, Netherlands

Organic micropollutants such as pharmaceuticals pose significant environmental and public health risks. These contaminants not only contribute to the spread of antibiotic resistance but also disrupt aquatic ecosystems. Advanced oxidation processes are known to effectively degrade pharmaceuticals, and among these, photoelectrocatalysis (PEC) offers a promising method for removing contaminants present at trace levels ($\mu\text{g/L}$ to ng/L). The focus of the presented study was to assess the influence of five quaternary ammonium compounds (QACs) on BiVO_4 photoanodes, modifying the structural properties and enhancing photoelectrocatalytic performance. The QAC-modified BiVO_4 photoanode variants were characterized using X-ray diffraction, scanning electron microscopy, energy-dispersive X-ray spectroscopy, X-ray photoelectron spectroscopy, UV-Vis spectroscopy, and linear sweep voltammetry. PEC degradation experiments were conducted using effluent, collected after secondary treatment at a wastewater treatment plant, spiked with 10 selected pharmaceuticals at an initial concentration of $10 \mu\text{g/L}$. The removal efficacy of the modified BiVO_4 photoanodes was evaluated under simulated solar irradiation. Among the tested variants, the photoanode modified with the alkyl trimethyl ammonium compound ATMAC C18 showed the most rapid degradation, with several pharmaceuticals being removed within the first 15 minutes. However, dialkyl dimethyl ammonium compound DADMAC C18 modified photoanode was identified as the best-performing variant, with diclofenac degraded rapidly.

Keywords: Pharmaceuticals; Advanced Oxidation; Wastewater treatment; Photodegradation

7.02.P-Th285 Exploring Biological Activity in Granular Activated Carbon during Full-Scale Quaternary Treatment at a Municipal Wastewater Treatment Plant

Birte Raes¹, Daniel Modrall Sperling², Jan Dries² and Lennert Dockx¹, (1)AquaFin, Belgium, (2)Antwerp University, Belgium

The revised Urban Wastewater Treatment Directive (2024/3019) requires large wastewater treatment plants and those in sensitive areas to implement quaternary treatment for micropollutant removal. In April 2025, the first full-scale quaternary treatment system in Flanders was commissioned at the Aartselaar wastewater treatment plant. This advanced treatment combines ozonation and granular activated carbon (GAC), two complementary technologies that remove residual micropollutants and associated ecotoxicological effects.

It is theorized that the combination of ozone and GAC will result in a synergistic effect. Ozonation increases dissolved oxygen and converts residual non-biodegradable organic material into biodegradable organic matter in the water entering the GAC stage. Prolonged contact time between organic material adsorbed onto GAC, high oxygen content and biofilm growing on the carbon granules result in conditions that may promote adapted biofilms capable of degrading persistent dissolved organic carbon. Such biofilm activity could support self-regeneration of activated carbon, potentially extending its operational lifetime and improving micropollutant removal efficiency.

To explore this hypothesis, biological activity in the full-scale GAC is monitored through multiple approaches. Sampling ports allow collection of GAC from three levels of the carbon bed (top, middle, bottom). Oxygen concentrations are measured at inflow and outflow to assess redox conditions and oxygen uptake. Manganese uptake is monitored at the same points as an indicator of microbial activity, and manganese accumulation on the carbon bed is quantified to evaluate fixation as manganese oxide by aerobic biofilms. Micropollutant removal behavior is assessed at the full-scale GAC filters in an attempt to distinguish adsorption from potential biodegradation. Antwerp University characterizes biofilm activity through GAC ATP concentration and performs microbial community profiling via 16s RNA sequencing.

This research complements the bench scale research of Antwerp University within the same project and

provides new insights into the synergy between ozonation and GAC and the potential role of biofilms in enhancing micropollutant removal and operational sustainability in advanced wastewater treatment systems.

7.02.P-Th286 Biodegradation of Imidacloprid in a Microbial Fuel Cell and Its Residual Toxicity to *Daphnia similis*

Gabriela Barreiro¹, Rodrigo Correia², Gilmar Silva³, Eliane Pedrozo⁴, Flávio Teixeira da Silva⁴ and Teresa Paiva⁴, (1)University of São Paulo, Lorena Engineering School, Brazil, (2)Fluminense Federal University-UFF, Brazil, (3)Universidade Federal Fluminense, Brazil, (4)Universidade de São Paulo, Escola de Engenharia de Lorena, Brazil

The treatment of wastewater containing imidacloprid (IMI), a systemic insecticide, is challenging due to its lack of efficient removal through conventional processes. Several methods have been employed to treat IMI-containing wastewater, such as adsorption and advanced oxidation processes; however, tertiary treatment could enhance IMI removal in these wastewaters. In this work, was studied the biodegradation of commercial formulation of IMI (Galeão®) in a double-chamber microbial fuel cell (MFC), inoculated with the electroactive bacteria *Shewanella oneidensis* and *Clostridium butyricum*, respectively. The anode of the MFC received 2.3 mL of the freshly grown bacterial suspension (or sterile nutrient broth for the controls), 1 mL of insecticide solution and 96.7 mL of sterile distilled water, reaching a final working volume of 100 mL, while the cathode was filled with a 0.5 M potassium ferricyanide ($K_3[Fe(CN)_6]$) solution prepared in phosphate-buffered saline (PBS, pH 7.0). The analysis of possible intermediate metabolites was performed by gas chromatography coupled to mass spectrometry (GC-MS) and revealed the hydrolysis of the nitro group. The toxicological assay was conducted to determine whether the transformation of IMI in the MFC reduced its adverse effects on the organism *Daphnia similis*. The toxic effects were evaluated by comparing mortality and observable stress responses after exposure to untreated IMI solutions, which showed an LC50 of 19.84 mg/L, confirming the pronounced sensitivity of the species. For the samples treated in the MFC, a 1:10 dilution resulted in 100% mortality, while 1:100 dilutions produced approximately 85% mortality, and 1:1000 caused no mortality. These results place the EC50 between 1:100 and 1:1000 and indicate limited effectiveness of the treatment in reducing IMI toxicity. Similar patterns of high toxicity observed in controls without inoculum reinforce the conclusion that the MFC process did not significantly remove IMI nor reduce its harmful effects on aquatic organisms.

7.02.P-Th287 Wastewater treatment plants in Wallonia (Belgium): their impact on endocrine disruption in aquatic environments and their treatment efficiency (STEP-PE project)

Carole Chalon¹, Yves Marneffe¹, Cecile Kech¹, Eva Minocci², Jeanne Braat³ and Marcie Radoux¹, (1)ISSeP, Belgium, (2)Aquaconseil, Belgium, (3)CNRS, France

Wastewater treatment plants (WWTPs) are recognized as sources of endocrine-disrupting (ED) compounds and micropollutants that may affect aquatic ecosystems. This study assessed whether discharges from 28 Walloon WWTPs influence chemical quality of receiving waters and fish health. Three complementary approaches were applied: (i) evaluation of ED activities with YES/YAS tests and (ii) chemical analyses of influent and effluent, and (iii) biological analyses of fish upstream and downstream of selected sites. Estrogenic activity, the predominant activity at both the entry and the exit, was markedly reduced after the epuration process, while anti-estrogenic activity increased. Androgenic activity was quantified in nearly 60% of influents but is almost absent in effluents, except at one site. Anti-androgenic activity appeared in effluents of seven WWTPs, often coinciding with loss of agonist activity. Overall, discharges from about one third of WWTPs impacted ED activity in the receiving waterbody downstream. Chemical analyses revealed phthalates as the prevalent contaminant family. Across all sites, the sum of concentrations for the 6 families studied decreased overall by 93%, except per- and polyfluoroalkyl substances (PFAS), which increased by 25%. Four substances—nonylphenol metabolite, DEHP, octocrylene, and DEET—exceeded 100 ng/L in effluents. Eleven compounds, including bisphenol A, several PFAS, and personal care products (PCP) such as triclosan and cashmeran, were

detected in more than half of effluents. Exploratory removal efficiency calculations indicated high elimination of chlorophenols, moderate removal of alkylphenols, phthalates, and PCP, while PFAS showed negative efficiency. Fish analyses revealed significant differences (increase) in estrogenic activity in bile downstream of one WWTP and in vitellogenin of male fish downstream of another, suggesting localized biological impacts. However, histological examination of male gonads showed minimal or no feminization effects across sites. In conclusion, WWTPs achieve substantial removal of many contaminant families, yet endocrine-disrupting activities and persistent substances such as PFAS remain of concern. These findings highlight the need for improved treatment strategies and monitoring to mitigate ecological risks and safeguard aquatic life in receiving waters.

7.02.P-Th288 Assessing Wastewater and Sewage Sludge Treatment Efficiency by Combining Physicochemical Characterization and in vivo Endocrine Disruption Bioassays

Sara Cvetkovics¹, Erika Sinisgalli², Anne-Sophie Permal³, Rania Krimou³, Sabrina Guérin³, Gregory F. Lemkine⁴, Dominique Patureau² and David Du Pasquier⁴, (1)University of Montpellier, France, (2)INRAE, Univ Montpellier, LBE, 102 Av. des Etangs, 11100, Narbonne, France, France, (3)Syndicat Interdépartemental pour l'Assainissement de l'Agglomération Parisienne (SIAAP), France, (4)Watchfrog S.A., France

Treated wastewater sludge contains nutrients valuable for agricultural soils but also carry contaminants, including endocrine-disrupting compounds. This study aims to assess the endocrine-disrupting activity of wastewater and sludge while evaluating their agronomic potential, addressing the need to balance environmental safety and nutrient recovery. Samples were analyzed using in vivo endocrine bioassays, phytotoxicity tests, and physicochemical analyses of nutrients, metals, and organic contaminants to provide an integrated assessment of risks and benefits. This abstract focuses on the results of endocrine bioassays, which capture complex biological responses to mixtures of contaminants found in sludge and wastewater.

Wastewater, sludge, and sludge liquor were sampled from a Parisian wastewater treatment plant (WWTP) at different stages of the treatment process during two seasonal campaigns, winter and summer, allowing evaluation of both solid and liquid phases, and seasonal variability. Samples were tested using two in vivo fish eleutheroembryo assays: the Rapid Estrogen ACTivity In Vivo (REACTIV) assay (OECD TG 252) and the Transgenic Eleutheroembryonic THYroid-Specific (TETHYS) assay.

A preliminary lethality test established the Maximum Tolerated Concentration for each sample. Results showed that wastewater toxicity markedly decreased after denitrification, indicating effective removal of toxic components. In contrast, sludge toxicity increased after the thickening stage that follows anaerobic digestion, suggesting enrichment of persistent compounds during dewatering.

Thyroid assays from the winter campaign revealed that thyroid activity in wastewater decreased throughout treatment and was no longer detectable in the effluent. However, variability was observed in thyroid activity of sludge samples between sampling weeks, possibly due to differing amounts of rainwater the WWTP has received. Estrogen activity was detected mainly in influent and raw sludge, implying that estrogenic compounds are effectively removed in later stages.

The results of the summer campaign are pending and expected by April 2026, providing insight into seasonal trends. Overall, while wastewater treatment effectively removes endocrine and toxic activity from the liquid phase, sludge fractions remain potential sources of endocrine-disrupting substances. Continued monitoring and optimization of sludge treatment are crucial to ensure safe agricultural reuse.

7.02.P-Th290 Deployment and Performance Evaluation of a Biofilm-Based Passive Sampler for Urban Wastewater Monitoring

Azziz Assoumani, Bénédicte Lepot, Anna Voiland, Louise Durand, Claudine Châtellier, Hervé Adrien, Abd El Rahman El Mais, Selim Ait-Aissa and Nina Huynh, INERIS, France

The use of passive samplers (PS) for monitoring aquatic environments under the Water Framework Directive was recently made possible in France with the publication of the ministerial decree of April 26, 2022. However, the use of PS for monitoring wastewater is more complex due to matrices loaded with organic carbon, suspended solids, and debris. Specific PS adapted to this type of water have been developed and tested to address this issue. The Prebio cell, developed and commercialized by AdScientifique, is a PS based on in situ biofilm development, specially designed for deployments in wastewater. Within the program of the French

national laboratory for the monitoring of the aquatic environment (AQUAREF), the Prebio cell was tested during two deployment campaigns in the influent and effluent waters of a wastewater treatment plant in Oise region (France).

The first campaign aimed at verifying the applicability of the Prebio cell for wastewater monitoring and defining the optimal duration of deployment, with a view to issuing recommendations for their implementation. Twelve Prebio cells were deployed for 4 months in the influent and for 6 months in the effluent. They were retrieved at different times to follow the biofilm growth and the accumulation of alkylphenols and bisphenol A, analyzed by GC-MS. Grab samples were collected at the same time as the Prebio cells. Suspect screening was performed by a LC-QTOF to compare the range of the substances identified in the of biofilm samples and the grab water samples. The second campaign was conducted to compare the results of target chemical analyses of biofilm samples and water samples collected using automatic samplers averaged over 24 hours. Target analyses were performed by GC-MS and LC-MS, and focused on alkylphenols, bisphenol A, and per- and polyfluoroalkyl substances (PFAS).

The first campaign revealed that the Prebio cell was easy to use, as no power supply nor metrological checks were required. Optimal exposure times were defined for collecting sufficient biofilm and accumulating contaminants in sufficient quantities to conduct targeted analyses and suspect screening. During the second campaign, a comparison of the 24-hour averaged sampling method with the Prebio cell showed that biofilm can be used to determine the presence of the targeted contaminants in wastewater. The Prebio cell appears to be a promising tool that complements 24-hour average sampling for regulatory monitoring of wastewater.

Disclaimer/Disclosure:

This work was done within the AQUAREF programme, partly funded by the French Agency for Biodiversity.

7.02.P-Th291 Lab-controlled evaluation of different passive samplers to monitor pulsed micropollutant levels

Anna Huang¹, Steven Droge², Milo Leon de Baat³ and Sanne van den Berg¹, (1)Wageningen University and Research (WUR), Netherlands, (2)Environmental Risk Assessment, Wageningen University and Research (WUR), Netherlands, (3)Chemical Water Quality & Health, University of Amsterdam (UVA), Netherlands

Aquatic micropollutants often occur at incidental peaks, for example, during run-off from agricultural land after heavy rain, sewage overflow in urban areas, or periodic release of waste effluents from industrial processes. Such incidental peaks may be missed by occasional grab sampling, and the pollution concentration peak has often passed once effects are noticed. Therefore, field samplers that can integrate exposure over time and capture such pulsed events are needed. Ideally, the sampler facilitates extraction for chemical analysis and provides a time-weighted quantitative indication of the micropollutant levels. There are various types of samplers for aquatic systems in use, with different characteristics that determine their applicability.

Micropollutants have different chemical properties that influence the suitability of the applied sorbent material. In addition, micropollutants may be released from the sorbent into cleaner water in the period after a peak concentration. We evaluated POCIS discs, SPME fibers, and CLAM pump cartridges in aquaria spiked with a mixture of 10 pesticides at environmentally relevant concentrations (0.5 to 45 µg/L). Aquaria were either stirred or still, using 3 scenarios: 7 days of constant concentrations, a single 1-day pulse followed by 6 days of clean water, and a repeated 1-day pulse with 2-3 days of clean water before and after. Polyacrylate SPME fibers did not accumulate detectable levels of weakly hydrophobic pesticides, and rapidly lost most medium hydrophobic chemicals after each pulse. POCIS discs (HLB sorbent encased in teflon membranes) accumulated all pesticides, except the most hydrophobic one (afoxolaner, logP 6), retained them after the pulse, but were strongly influenced by water flow rate. CLAM cartridges (HLB) captured all tested chemicals, and although breakthrough to a second cartridge did occur, recovery rates (based on pump volume and spiked concentrations) were 50-130%.

7.02.P-Th292 Automated Passive Sampler Exposure Device (PASED) for Monitoring of Organic Contaminants in Water

Kai Wilschnack¹, Xiangning Zeng², Adrian Nightingale², Gregory Slavik², Roman Grabic³ and Gary Fones⁴, (1)University of Portsmouth, United Kingdom, (2)University of Southampton, United Kingdom, (3)University of South Bohemia Ceske Budejovice, Czech Republic, (4)University of Portsmouth, United Kingdom

Anthropogenic organic contaminants in water are typically monitored using spot sampling, allowing the determination of concentrations at one point in time. Alternatively, time-weighted average (TWA) concentrations can be determined by passive samplers, such as Chemcatcher. However, temporal variation

within the deployment period cannot be assessed, making it difficult to identify pathways and point source events. Hence, an automated passive sampler exposure device (PASED) was developed, allowing the measurement of organic contaminants at increased time resolution (days instead of weeks) for the same operational costs by autonomously exposing passive sampler discs.

PASED was tested in the laboratory and in the field to ensure reproducibility, effective seal and linear uptake. Field tests were performed at a wastewater outlet pipe in the River Test, Southeast England. For the first 2-week deployment, one disc was kept sealed and three discs were exposed after one week. Chemcatcher cages were deployed alongside PASED, as well as up- and downstream of the outlet pipe. Samples were analysed using a targeted UHPLC-MS/MS method for 212 pharmaceuticals, plant protection products and their transformation products. TWA concentrations were calculated using three literature uptake rates.

In total, 121 (57%) contaminants were detected at least once during the first deployment at TWA concentrations from 0.00085 – 0.0014 ng/L (cilazapril) to 201 – 561 ng/L (fexofenadine). Hazards were generally low (HQ < 0.1 for 99% of observations), but high for diclofenac and imidacloprid at the outlet (HQ > 1). Only few contaminants (n = 11 to 37) were detected in the two field blanks and the sealed PASED disc at generally small concentrations < 0.1 ng/L. The deployment field blank and PASED blanked had fewer contaminant detections (n = 11 and 14) at lower concentrations than the retrieval field blank (n = 37), indicating that PASED seals effectively. There were no significant differences (p = 0.749) between the standard deviations of replicates deployed in PASED and Chemcatcher cages, suggesting a similar performance. However, TWA concentrations were lower in PASED, indicating a slower uptake, most likely driven by the higher flow rate in front of the Chemcatcher cage, 0.25 m/s compared to 0.11 m/s in front of PASED. Overall, initial results showed an effective seal, no blank contamination, and a similar performance to established Chemcatcher cages.

7.02.P-Th293 Integrated Ecotoxicological Approach with Advanced Chemical Analyses to Study Natural Toxic Mixtures from WWTP Affected River Waters

Maria Teresa Palumbo¹, Stefano Polesello¹, Jacopo Grisotto², Giacomo Bonacina¹, Claudio Roscioli¹, Camilla Mariani³, Marianna Rusconi¹, Giovanna Paolone², Marco Parolini⁴, Laura Marziali⁵, Lucia Valsecchi¹ and Sara Valsecchi¹, (1)Italian National Research Council (CNR), Italy, (2)University of Verona, Italy, (3)State University of Milan, Italy, (4)University of Milan, Italy, (5)Water Research Institute (IRSA-CNR), Italy

Complex mixtures originating from wastewater treatment plants (WWTPs) often contain thousands of pollutants which enter the aquatic environment and may exert combined toxic effects on ecosystems and human populations. To address this complexity and to assess the overall hazard posed by environmental mixtures, an integrated approach combining chemical analyses with ecotoxicology is essential.

In this work we studied the toxic mixture from two WWTP-impacted river-waters by combining the exposure assessment, obtained from wide chemical target analysis of pharmaceuticals and trace metals, and the ecotoxicological assessment including both experimental methods and modelling approach.

The samples were collected from Lambro and Molgora rivers, both downstream from two WWTPs in the province of Monza-Brianza in Northern Italy.

Water sample has been extracted on SPE and the methanolic eluates were analysed by a high-resolution mass spectrometry based on Orbitrap principle. The overall toxicity of the samples was measured with the 72h algal growth inhibition test, the 48h *Daphnia* spp. immobilization test, the 96h zebrafish behavioral test. The algal and *Daphnia* tests were also conducted on SPE-organic extracts to calculate the median effective concentration (EC50) expressed as Relative Enrichment Factor (REF).

The exposure and the effect data were integrated following the iceberg modeling approach, which quantitatively compares toxic equivalent concentrations from bioassays (TEQbio) with chemical-analysis-derived toxic equivalent (TEQchem) to assess which amount of the observed toxic effects could be explained by the detected organic chemicals.

Preliminary results showed the presence of dozens of pharmaceuticals, while slight - moderate toxicity was measured with the three bioassays in the natural waters from both rivers. However, marked toxic effects on algae and on *Daphnia magna* were found in the adsorbable organic fraction with 72h-EC50 values of 8.8 and 13.3 REF in Lambro and Molgora samples, and 48h-IC50 of 31.06 REF in Molgora, respectively.

The integrated approach highlighted the main drivers of toxicities in both samples, however the comparison between TEQchem and TEQbio showed that the effects explained by the detected chemicals overestimate the observed one, suggesting the presence of antagonistic effects or chemical measurement uncertainties.

7.02.P-Th294 Integrated study of the water quality of the San Pedro River, Aguascalientes, Mexico: determination of physicochemical, toxicological and microbiological risk

Ana Laura Carbajal-Hernández¹, Roberto Rico-Martínez¹, Mario Alberto Arzate-Cárdenas¹, Jorge Hernández-López² and Roberto Carlos Valerio-García¹, (1)Universidad Autónoma de Aguascalientes, Mexico, (2)Centro de Investigaciones Biológicas del Noroeste, Mexico

The San Pedro River in the state of Aguascalientes, Mexico, is the state's main surface water river. Over the last two decades, many pollutants have been dumped into the river, becoming a public health problem. Therefore, the objective of this research was to evaluate the physicochemical, toxicological, and microbiological characteristics of the state's main river. Eight collection sites were established along the river, and certain physicochemical parameters were determined for each sample. Three groups of aquatic organisms of different trophic levels (*Danio rerio*, *Daphnia pulex*, and *Raphidocelis subcapitata*) were used for toxicological analysis and were exposed to various fractions of the water samples (20, 40, 60, 80, 100%). Median lethal and inhibitory concentrations (LC50 and IC50) were determined, followed by acute toxicity units (aTU). Pathogen detection and typing were determined by endpoint polymerase chain reaction (PCR) and real-time PCR. The presence of resistance genes for the antibiotics oxytetracycline, florfenicol, and enrofloxacin was determined by multiplex real-time PCR. The physicochemical parameters showed dissolved oxygen values ranging from 2.17 to 5.8 mg/L, electrical conductivity values ranging from 508 to 3236 $\mu\text{S}/\text{cm}$, and total dissolved solids ranging from 358 to 1618 mg/L. Ammonium registered values greater than 0.5 mg/L in all sampling areas, nitrates ranged from 0.75 to 71.08 mg/L, nitrites from 0.30 to 73.60 mg/L, phosphates from 0.45 to 9.02 mg/L, and sulphates from 0.60 to 3.82 mg/L. The toxicological evaluation with *D. pulex* showed aTU values >2 in only two sampling areas; with *R. subcapitata*, five areas recorded aTU >2 , and with *D. rerio*, all collection areas showed aTU >2 . Among the pathogenic organisms identified in the water samples were *Campylobacter jejuni*, *Escherichia coli* O157:H7, *Salmonella invadens*, and *Vibrio cholerae*. Molecular analysis revealed the presence of resistance genes to all three antibiotics in all sampled areas. Anthropogenic activities in the region have undoubtedly had a negative impact on river water quality, and even though water supply sources in Mexico have been recognized as a vital priority, the state of health of its water resources is discouraging.

7.02.P-Th295 Effects of metal-salt phosphate precipitation on riverine ion loads and biological endpoints: Insights from a two-year monitoring

Theresa Piana¹, Ralf Bernhard Schaefer² and Elisabeth Berger³, (1)Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, Landau, Germany, Germany, (2)Research Center One Health Ruhr, University Duisburg-Essen, Germany, (3)Department of Electrical and Industrial Engineering, University of Applied Sciences Landshut, Landshut, Germany, Germany

To meet increasingly strict regulatory thresholds for phosphorus, European wastewater treatment plants (WWTPs) are required to intensify chemical phosphate elimination. Metal salts are commonly used as precipitants, forming insoluble metal–phosphate complexes that are removed during treatment. However, accompanying anions (e.g., chloride, sulphate) and excess salts can enter receiving waters, increasing downstream salinity. Except for chloride, no binding environmental standards exist for salinity in Europe, so these inputs may go unnoticed, potentially altering chemical and ecological conditions.

To examine whether intensified phosphorus elimination affects downstream ion loads and biota depending on the type of precipitant, we conducted a two-year field study at a WWTP in Germany, during changes from aluminium-sulphate to iron(II)sulphate, and later to a mixed iron(II)chloride/polyaluminium-hydroxychloride formulation with variable dosing. Water samples were collected biweekly upstream, at the WWTP inlet and outlet, and at three downstream sites to capture spatial gradients. Standard cuvette tests were used to analyse nutrient loads, TOC, water hardness. Major and metal ions ($\text{Fe}^{2+}/\text{Fe}^{3+}$, $\text{Al}^{3+}/\text{Al}^{2+}$, SO_4^{2-} , PO_4^{3-}) were quantified using ICP-OES/MS and ion chromatography. To capture high-frequency dynamics, eleven conductivity loggers were installed along the river gradient and at the WWTP inlet and outlet, recording at 10-minute intervals. To assess ecological impacts, annual diatom and macroinvertebrate sampling was carried out before and after precipitant changes following standard protocols.

Preliminary conductivity data revealed pronounced seasonal variation, with lowest values in winter (224–492 $\mu\text{S cm}^{-1}$), despite occasional peaks associated with road-deicing, and highest values in summer (348–663 $\mu\text{S cm}^{-1}$), consistent with seasonal hydrology and temperature-dependent ion mobility. Maximum conductivities were consistently observed at the WWTP sites. Conductivity increased downstream of the WWTP but returned to upstream levels within 3–5 km, with a secondary peak 1.25–2.5 km downstream attributable to road runoff. Periods of aluminium-sulphate dosing were associated with elevated downstream salinity, whereas conductivity decreased following the precipitant change; upstream values remained stable, indicating that WWTP treatment was the driver. These preliminary trends will be further interpreted in conjunction with ongoing chemical and biological analyses.

7.02.P-Th296 Bridging Wastewater and Potable Water: Challenges and Recommendations

Dominique Narain-Ford, Harold van den Berg and Frank Swartjes, RIVM, Netherlands

Global freshwater scarcity for potable water production is intensifying due to population growth, deteriorating water quality, salinization, and rising demand. While arid regions are most affected, recent evidence shows that European countries with temperate climates also face increasing shortages, driven by extreme weather events and decreased river flow capacities. Despite ongoing efforts to enhance water use efficiency, alternative sources for drinking water are urgently required. Among unconventional options, direct and indirect potable wastewater reuse could offer a stable, cost-effective solution with established infrastructure and lower energy demands compared to desalination. Although EU policy promotes wastewater reuse, adoption for large-scale potable water reuse in the EU Member States remains limited, hindered by insufficient public awareness and a lack of supportive regulatory frameworks. Potable water production via wastewater reuse is particularly sensitive to the presence of pharmaceuticals, metabolites, and antimicrobial-resistant organisms—often referred to as contaminants of emerging concern—for which the health risks are unknown or no limit values have been established. Whether potable reuse is direct or indirect, it necessitates advanced treatment, comprehensive monitoring, sustainable management, public acceptance, and uniform governance. This presentation synthesizes the current state of the art and identifies knowledge gaps and key requirements for robust and safe potable water reuse. In addition to the research gaps identified from the literature, we consulted the opinions of international experts regarding knowledge gaps. Consequently, we propose strategic directions to enhance the reliable and sustainable use of reclaimed wastewater for drinking water production, thereby supporting EU climate adaptation and water security ambitions.

7.02.P-Th297 Prioritization of Relevant Micropollutants in Reclaimed Water use in Agriculture

Lucas Leonel Alonso¹, Sofia Semitsoglou¹, Sara Rodriguez-Mozaz¹ and Gianluigi Buttiglieri², (1)*Catalan Institute for Water Research (ICRA), Spain*, (2)*Quality Area, Catalan Institute for Water Research (ICRA), Spain*

The reuse of reclaimed water for agricultural irrigation is increasingly promoted in water-scarce regions, particularly across the Mediterranean, but the presence of micropollutants in treated wastewater remains a concern for environmental and human health. Within this context, the NEWater project (Natural based and low Energy consumption unconventional solutions for the management of WATER sources) aims to develop energy- and cost-efficient hybrid biological, physical and nature-based treatment systems, validated across four large-scale demonstration sites representing wastewater effluents, agricultural drainage and household greywater. To harmonize monitoring efforts across partners, this study establishes a prioritized list of pharmaceutical compounds for reclaimed water irrigation scenarios, complemented by a specific list for greywater applications. An extensive literature review covering more than 60 studies and four participating countries identified over 150 pharmaceuticals and transformation products. A multi-criteria decision framework was applied, integrating occurrence, persistence, bioaccumulation and toxicity (OPBT), together with crop uptake potential, previous experimental evidence and alignment with EU policies, including Directive 2024/3019 and the EU Watch Lists. Catalonia was selected as a reference region due to its comprehensive dataset and pronounced water stress.

Based on the scoring criteria, eight pharmaceutical compounds were selected for the general list, including venlafaxine and diclofenac (scores of 6 and 5, respectively), followed by azithromycin, clindamycin, carbamazepine, fluoxetine, sertraline and O-desmethylenlafaxine (score 4). For greywater, where fewer studies and regulatory references exist, 10 additional compounds were prioritized. Triphenyl phosphate and benzophenone-3 ranked highest, followed by trimethoprim, bisphenol A, triclosan and caffeine. Due to limited information on greywater contamination, further substances with a total score of 4—such as 1H-benzotriazole, TCEP, acetaminophen and ibuprofen—were also included.

Overall, the general and greywater-specific lists provide a harmonized, adaptable framework that supports the evaluation of contaminant behavior in reclaimed water systems and their potential accumulation in soils and crops. The knowledge generated throughout the project will also enable refinement of the prioritized lists and guide future monitoring strategies.

7.02.P-Th298 How to Find Persistent Chemicals in Discharges – Persistence-Directed Testing Combined With Target, Suspect and Nontarget Analysis

Pia Marie Kronsbein¹, Mette Møller², Heidi Birch², Martin Hansen¹ and Philipp Mayer¹, (1)Technical University of Denmark (DTU), Denmark, (2)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark

Persistence is one of the most problematic properties of a contaminant entering aquatic environments. However, data on persistence from standardized simulation biodegradation tests is very scarce for chemicals in use. There are many pathways for chemicals to enter surface waters and one of the most significant is discharges from domestic and industrial wastewater treatment plants (WWTPs). Discharges from WWTPs are complex mixtures, containing non-monitored chemicals, unidentified transformation products, low-tonnage production chemicals, and UVCBs, that might include persistent compounds. Hence, the total number and type of persistent compounds in effluents is generally unknown and methods to assess these are needed. A novel persistence-directed testing approach is here presented where biodegradation simulation tests are conducted by diluting a whole effluent sample in an environmental water sample containing degrading microorganisms (biotic test systems). Test systems are incubated for 40 – 60 days and then analyzed by chromatographic methods. By comparing the peak area ratios between the biotic test system and the abiotic control, persistent features can be singled out. In this way, even unidentified chromatographic features (chemicals) occurring in an effluent can be categorized as persistent. Chemical analysis performed by high resolution mass spectrometry, allows a combination of target-, suspect-, and non-target screening. Environmentally highly relevant persistent features can then be prioritized during structure elucidation efforts. This approach has successfully been applied to evaluate persistence of chemicals in discharges from offshore oil platforms, where a much higher number and fraction of persistent chemicals were found by LC-HRMS compared to GC-MS analysis. Persistence-directed testing can now be applied to find persistent chemicals in WWTP discharges, which however requires method adaptation. The poster will address (1) the need for sample preparation and conservation prior to analysis, (2) the optimal combination of analytical methods for covering the chemical space of organic pollutants in WWTP discharges, (3) how the approach can inform regulation of persistent chemicals in case of high-confidence identification and (4) how the approach can enhance mechanistic understanding of structural characteristics that drive persistence. The poster will present the current state of development and invites for discussions.

7.02.P-Th299 The “rapidly biodegradable” criterion in the recast Urban Waste Water Treatment Directive: regulatory uncertainty and methodological implications for micropollutant exemption

Floriane Demailly, Mylène Leger and Cyril Durou, CEHTRA, France

The recast Urban Waste Water Treatment Directive (UWWTD, 2024/3019) introduces an extended producer responsibility (EPR) for micropollutants based on polluter pay principle. In its current form only manufacturers of cosmetics and pharmaceutical products will be required to contribute to the financing of expenses related to the implementation of quaternary treatment to remove micropollutant. This EPR system shall be applicable by 31 dec 2028.

From an environmental standpoint, an exemption may be granted for certain micropollutants that are deemed rapidly biodegradable in wastewater or that do not generate micropollutants at end of life. Rapidly biodegradable in water is a new term in the regulatory world. However, for the moment, the directive provides neither an operational definition of “rapidly biodegradable” nor a list of accepted test methods, leaving a room for interpretation on the assessment of “rapidly biodegradable” criterion of micropollutant and preparing relevant information for exemption dossiers.

This work critically examines, among others, this criterion in the context of existing European Chemical legislation frameworks (REACH, CLP) and OECD guidelines for ready and inherent biodegradability. We analyze the extent to which these screening tests, conducted under standardized laboratory conditions, are transferable to urban wastewater systems, which are characterized by short hydraulic retention times, complex and variable biomass, fluctuating physico-chemical conditions and the presence of multi-component mixtures. A key question is whether “rapidly biodegradable” should be equated with ready biodegradability criteria, with maximum environmental half-lives (DT_{50} / DT_{90}) in matrices representative of sewer networks and treatment plants, or with an integrated weight-of-evidence approach combining experimental data, transformation product profiling and fate modelling.

We show that the absence of a precise definition and harmonized methodological framework increases the risk of heterogeneous data requirements for producers and inconsistent exemption decisions for micropollutants. Finally, we discuss options to operationalize the criterion (combinations of OECD tests, studies on activated sludge and real effluents, scenario-based modelling) and propose elements for scientifically robust criteria that could inform future implementing acts under the UWWTD and support a consistent application of the “rapidly biodegradable” concept across Europe.

7.03.P Advancing the Chemical Safety of Plastics: Bridging Science, Policy, and Innovation

7.03.P-Mo425 Enhancing the PlastChem Inventory for Chemical Prioritization in Plastics

Laura Monclus¹, Raoul Wolf¹, Hans Peter H. Arp¹, Ksenia J Groh², Jane Muncke³, Zhanyun Wang⁴ and Martin Wagner⁵, (1)Norwegian Geotechnical Institute (NGI), Norway, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Food Packaging Forum Foundation (FPF), Switzerland, (4)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (5)Department of Biology, Norwegian University of Science & Technology, Norway

Plastics are a significant source of chemical exposure throughout their entire life cycle, posing risks to human health and the environment, and the achievement of a safe circular economy. The PlastChem inventory, launched in 2023, consolidated fragmented public data on 16,325 unique plastic chemicals, that is, substances that can potentially be present in plastics, and provided a framework for identifying and prioritizing chemicals of concern in plastics. We now present PlastChem v1.1, an upgraded version featuring a more robust database architecture with improved usability and reproducibility, refined curation processes, and expanded hazard and exposure information. Key updates include integration of the recent releases from FCCmigex, LitChemPlast, and ECHA food-contact material data, alongside rigorous CAS Registry Number verification. Hazard information has been refined using seven updated regulatory sources and offers greater granularity across harmonized classifications, self-classifications, and authoritative lists, including substances under evaluation in the EU. A major advancement is the incorporation of human exposure data from the FCChumon database, covering over 3,000 plastic chemicals detected in humans. In addition, backend refinements streamline the data consolidation, formalize manual curation steps, and enable the efficient extension and updating of the database, readying the platform for future dynamic integration with user interfaces. PlastChem v1.1 includes an overall higher number of unique chemicals in plastic, including those of concern. In addition, its improved identifier traceability makes it easier to prioritize plastic chemicals for regulation and prepare the database for future updates and expansions. The updated inventory presents an important support for global policy processes, such as the negotiations of the Global Plastic Treaty. It also offers a solid basis for monitoring plastic chemicals of concern, helping to design safer plastics, and assess environmental and human exposure. Periodic updates will keep the inventory relevant as chemical use and regulatory landscape evolve.

7.03.P-Mo426 Mapping the regulatory landscape of plastic additives across their lifecycle

Olwenn Viviane Martin and **Jonah Vairon**, Plastic Waste Innovation Hub, UCL Arts and Science, University College London, United Kingdom

Background: A wide variety of additives are added to plastics during production to enhance the performance or appearance of plastic, rubber materials, and other polymers. As most additives are not covalently bound to the polymeric matrix, they can readily migrate from materials or micro- and nanoplastic particles (MNPs) during and after the often very short useful life of the product. Due to the ubiquity and multitude of uses of plastic materials, releases of plastic additives to their surrounding environment across their lifecycle are regulated across regulatory silos in multiple pieces of legislation with clauses related to chemical safety.

Aims: This study mapped common plastic additives, their function(s) in specific polymers to regulatory requirements for various uses of these chemicals and materials at different lifecycle stages. The aim was to identify and analyse commonalities and differences between regulatory processes for specific intended uses of plastics and/or associated additives.

Methods: Through a bottom-up approach, the 417 individual additives listed under ECHA's plastic additive initiative (PlasI), their function and the type of polymer in which they are typically used against the regulations listed in the ECHA's chemical legislation database (EUCLEF). EUCLEF is articulated around 90 lists of substances that typically correspond to annexes of 52 specific pieces of legislation. The text of all legislations was reviewed and was complemented by an analysis of relevant guidance documents, where appropriate.

Results and discussion: There are notable differences in the risk assessment and management of plastic additives across their lifecycle, and risk management can be driven by considerations other than toxicity (beyond hazard classification). The coverage of chemicals at different lifecycle stages also differs. A total of 181 PlasI substances are not regulated under any of the reviewed legislations, while 16 fall within the scope of most of these. Transport and environmental emissions apply to a small number of plastic additives. General product safety is currently opaque, whilst there are some notable differences in approaches between product-specific legislation. We highlight opportunities for improving the overall coherence and consistency of the regulation of plastic chemicals.

Disclaimer/Disclosure:

7.03.P-Mo427 Prioritizing plastic food contact chemicals and identifying structurally-similar chemicals

Helene Wiesinger¹, Lindsey Parkinson², Birgit Geueke¹, Albert Anguera Sempere¹, Justin Michael Boucher¹, Etienne Cabane¹, Martin Scheringer³ and Jane Muncke¹, (1)Food Packaging Forum, Switzerland, (2)Independent consultant, Czech Republic, (3)ETH Zurich, Switzerland

The chemical safety of plastic food contact materials (FCMs) is critically important, due to the high likelihood for human exposure. Over 7'629 food contact chemicals (FCCs) are potentially used in, present in, or migrating from plastic FCMs, complicating hazard and risk management. To identify potentially hazardous plastic FCCs, we prioritized them using high-quality hazard and exposure data and identified structurally similar chemicals by grouping them. Overall, 807 plastic FCCs are known to be hazardous using GHS-aligned regulatory data. We ranked these hazardous plastic FCCs into four tiers: 88 are known to migrate from FCMs and are detected in human biomonitoring (Tier 1); 238 migrate but lack biomonitoring evidence (Tier 2); 161 are detected in FCMs but lack migration evidence (Tier 3); and 320 are listed for use but lack experimental evidence (Tier 4). However, at least 6'391 (84%) plastic FCCs lack hazard data, hindering hazard and risk assessment, and potentially leading to regrettable substitutions. Grouping structurally similar chemicals can help avoid replacing one hazardous substance with an equally hazardous, but untested chemical. To facilitate this, we developed a semi-automatic, modular, and quality-checked methodology for grouping chemicals into human-readable and structure-based groups, using SMARTS-pattern matching, curated list comparisons, and keyword searches. Of 7'629 known plastic food FCCs, 2'265 were assigned to priority groups with particularly many hazardous chemicals, including primary aromatic amines (38 known to be hazardous of 69 total), organotins (27 of 47), PFASs (26 of 94), metals (26 of 85), ortho-phthalates (20 of 63), hindered phenol derivatives (16 of 132), organophosphates (15 of 95), and siloxanes (6 of 44). Of 2'265 chemicals in priority groups, 345 are known to be hazardous, 235 pose other hazards (i.e., lower hazard categories or environmental), and 1'685 lack sufficient hazard data, highlighting the potential for regrettable substitution and key targets for future research. Note, not all known hazardous FCCs are assigned to a priority group. Our prioritization and grouping methods provide a practical, science-based, freely available, and scalable solution for better chemicals management in materials. It supports prioritization for regulation and targeted data gap filling, highlights chemical groups with the potential for regrettable substitution, and enables group-based regulatory approaches.

Disclaimer/Disclosure:

The authors thank the PlastChem team, FPF's Scientific Advisory Board, the Minderoo team, and FPF's funders for their valuable support and contributions.

7.03.P-Mo428 Suspect Screening of Plastic Chemicals in Plastics and Tissues from Arctic Marine Wildlife

Linyan Zhu¹, Laura Monclus², Jens Søndergaard³, Jakob Strand¹, Martin Wagner⁴ and Katrin Vorkamp⁵, (1)Aarhus University, Denmark, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Department of Bioscience, Aarhus University, Denmark, (4)Department of Biology, Norwegian University of Science & Technology, Norway, (5)Department of Environmental Science, Aarhus University, Denmark

Plastic pollution introduces not only particulate debris but also thousands of plastic chemicals into the environment. Many of these compounds are potentially persistent, bioaccumulative, mobile, and toxic, yet their leaching from the plastic material and exposure to wildlife remains poorly understood. The Arctic, a sink for long-range pollutants, faces additional risks from plastic pollution, including plastic ingestion by seabirds and marine mammals and potential resulting chemical exposure.

In this study, we used gas chromatography- (GC-) and liquid chromatography- (LC-) coupled with a high-resolution mass spectrometer (HRMS) for suspect screening of plastic chemicals in Northern fulmars (*Fulmaris glacialis*) and ringed seals (*Pusa hispida*) from Greenland. Paired samples of bird muscle, liver, and plastic particles retrieved from their stomachs and liver samples from ringed seals were prepared using optimized extraction and cleanup protocols and analyzed on GC- and LC- HRMS. A suspect list of plastic chemicals was built upon the PlastChem database. A comprehensive suspect list and spectral libraries matching were applied on HRMS data. Statistical analyses included principal component analysis (PCA) to visualize chemical profiles and correlation analysis to assess chemical associations among paired samples.

We identified 79 and 55 chemicals via GC- and LC-HRMS, respectively. Among these 135 plastic chemicals, 111 were identified in ringed seal livers, 91 in fulmar livers, 94 in fulmar muscles and 101 in plastics recovered

from the fulmar stomachs. Plastics recovered from fulmar stomachs included three types: polyethylene, polypropylene, and polystyrene. The PCA revealed distinct profiles for the different samples analyzed with GC-HRMS, while LC-HRMS results indicated strong overlap of fulmar tissues and plastics, with ringed seal livers forming a separate cluster. Correlation analysis showed 42 plastic chemicals with positive associations across paired samples; 18 of them showed a strong correlation between plastics and tissue, suggesting plastic as the source of exposure to plastic chemicals. Of the 18 chemicals, eight are known to be present in or leachate from the three polymer types detected. Our findings demonstrate that Arctic wildlife species are exposed to plastic chemicals. The ingestion of plastic particles can be an exposure pathway; however, exposure from the food chain and the surrounding environment cannot currently be ruled out.

7.03.P-Mo429 Quantifying Impacts of Packaging Choices in Consumer Baskets: Material Use, Environmental Impacts, and Chemical Releases

Ricarda Fieber¹ and **Catharina Bening²**, (1)No Affiliation, Switzerland, (2)ETH Zurich, Switzerland

The presence and release of hazardous chemicals and microplastics originating from food packaging has become an increasing concern for environmental and human health. While packaging policies, retailer initiatives, and consumer interest in sustainable options are growing, there remains a lack of integrated information linking packaging quantities, environmental impacts, circularity potentials, and chemical and microplastic release risks across real-world consumption patterns. This information gap limits the ability of policymakers, industry actors, and consumers to make informed decisions that reduce packaging-related burdens.

This study takes a first step toward closing this knowledge gap by combining detailed packaging data with representative food consumption patterns. We build on a comprehensive packaging database covering 3,750 retail food products and construct archetypical consumer shopping baskets, each reflecting distinct purchasing behaviors. For these baskets, we systematically quantify and compare packaging material types, packaging quantities, associated life cycle environmental impacts, material circularity potential, and the potential release of hazardous chemicals and microplastics throughout the use phase. This multidimensional assessment enables a comparison of packaging designs across products, consumer groups, and impact categories. By integrating multiple assessment dimensions, the study aims to advance a more holistic understanding of how packaging design choices and consumption patterns interact to shape environmental sustainability and human health outcomes. The approach is intended to enhance the evidence base for packaging-related policy development, support retailers in portfolio management and design decisions, and improve transparency for consumers seeking to reduce the environmental and health impacts associated with food packaging.

7.03.P-Mo430 Mapping Additive Flows Using a Functionality-Based Material Flow Analysis Model

Yiwen Zhang¹, **Zhanyun Wang¹**, **Masahiro Oguchi²** and **Bernd Nowack¹**, (1)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (2)National Institute for Environmental Studies (NIES), Japan

Plastics are used in a wide range industrial and consumer products, and their performance relies heavily on chemical additives. More than 10,000 chemicals have been identified to have been used in plastics, providing more than 20 functionalities (e.g. plasticity, flame retardancy, etc.). Due to their hazardous properties, the presence of plastic additives in primary and recycled materials raises concerns on the safety of plastic products and the quality of secondary materials. Despite these implications, there is no comprehensive overview of the mass flows of the major categories of plastic additives, including their levels in products. The objective of this study is therefore to explore a new way of mapping the flows of plastic additives over the entire lifecycle of plastics using dynamic probabilistic material flow analysis. Typical concentrations of additives for individual polymer-product category-functionality combinations were compiled from handbooks, product datasheets and other sources. These concentrations were analyzed to derive typical use patterns of additives by functionality (e.g., flame retardants) within individual product categories, which are then integrated into a material flow analysis model with a high resolution in the end-of-life flows to quantify the corresponding additive flows. Preliminary material flow analysis results show that higher amounts of additives are found in container and packaging flows due to high plastic consumption volumes and PVC flows due to the overall high additive content. Thus, this study reveals the general use patterns of different functionality categories of plastic additives and indicates the hotspots of additive flows during the use phase. Modelling additive flows can help to

understand the source of chemicals in products and waste flows, and assess the feasibility of mechanical recycling of individual waste flows in terms of the content and types of chemical additives therein.

7.03.P-Mo431 A Generic Approach for Estimating Environmental Release of Synthetic Polymer Microparticles (SPM)

Thorsten Wind¹, Torsten Funk², Frederic Fournier³, Martin Gloeckner⁴, Tim Gieshoff⁵, Axel Hessland⁶ and Martin Klatt⁷, (1)Henkel, Germany, (2)ChemServ EU-CH Funk Consultant, Switzerland, (3)Bostik SA, France, (4)IVK-Industrieverband Klebstoffe e.V., Germany, (5)Deutsche Bauchemie e.V., Germany, (6)Industrieverband Klebstoffe e.V., Germany, (7)BASF, Germany

In 2023, the European Commission introduced a restriction on Synthetic Polymer Microparticles (SPM) under entry 78 of Annex XVII of the REACH Regulation, as laid down in Commission Regulation (EU) 2023/2055. This restriction prohibits placing on the market of polymers that meet the SPM definition—solid, synthetic, limited solubility in water, non-biodegradable, and <5mm (<15mm for fibres with a length to diameter ratio >3)—unless their use is specifically derogated. Derogations apply where releases can be prevented or minimized, or to avoid overregulation of certain uses and sectors. For derogated uses, suppliers must provide Instructions for Use and Disposal (IFUD) and report on estimated environmental releases of SPM to ECHA on a yearly basis (per legal entity) to monitor the effectiveness of IFUD and the restriction overall.

This poster presents a generic approach, E-calc_SPM, developed by the European Adhesive and Sealants Industry Association (FEICA), to support suppliers of SPM and SPM-containing mixtures in estimating environmental releases. The concept builds on emission estimation principles from Specific Environmental Release Categories (SPERCs), developed by downstream user associations for relevant lifecycle steps of chemical substances. E-calc_SPM applies conservative (Tier 1.5) assumptions to ensure broad applicability, which may lead to overestimations of environmental release. In addition, pathways to air, water, and soil are assessed using statistical evaluations (Eurostat data) of sewage treatment connectivity and sludge disposal practices across Europe.

It is acknowledged that due to the generic nature of the approach, there may be cases where a more detailed, site-specific or product-specific assessment increases accuracy. However, applying this concept enables companies to meet reporting obligations efficiently while maintaining flexibility for diverse operational contexts. It may also offer a practical solution for harmonizing environmental emission reporting of SPMs across organizations based on the widely accepted SPERCs.

7.03.P-Mo432 Regrettable Substitutions? Comparative Toxicology of Bisphenol Analogues in Marine and Mammalian Reproductive Systems

Fábio Yu Chen¹, Bárbara S. Mendes², Paloma Tolda², Ana Sofia Melo², Daniela Lopes², Inês Galante², Joana Santiago², Roberto Martins³, Margarida Fardilha² and **Susana Loureiro²**, (1)CESAM & Department of Biology, University of Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)CESAM - Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal

Bisphenol A (BPA), a well-known plasticiser and endocrine disruptor, has been shown to have harmful effects and is restricted within the European Union. The 2024 regulation banning BPA in food contact materials has led to increased use of its analogues (e.g., BPS, BPAF). These substitutes may be “regrettable”, with toxicity levels similar to BPA both for human health and for the environment. To contribute to the development of New Approach Methodologies (NAMs) in reproductive toxicology, and having the One Health approach in mind, the toxicological potential of BPA, BPS, and BPAF was evaluated using different reproductive but related metrics: the development of embryos of marine invertebrates (e.g., sea urchin) and the viability and motility of bull sperm, using standardised or well developed protocols. Sea urchin *Paracentrotus lividus* embryo tests were performed after artificial fertilisation and development abnormalities emerged at concentrations of 0.049 mg/L for BPA and at 0.470 mg/L for BPS and BPAF, with the calculated EC50 values of 1.57 mg/L, 2.19 mg/L and 0.100 mg/L, respectively. At 5 mg/L (BPA) and 0.47 mg/L (BPAF), the development of embryos stopped at the morula stage. Bovine spermatozoa were treated with bisphenols (2–200 mg/L) for the analysis of cell viability (1h) and motility (0h and 1h). Viability was not affected by any of the compounds. BPAF significantly inhibited the progressive motility, whereas BPA and BPS produced no significant effect. The immobilisation of spermatozoa was significantly increased by BPA and BPAF (200 mg/L), whereas BPS produced no effect. Overall, the toxicity level followed the trend BPAF > BPA > BPS, with BPAF significantly affecting marine embryos and mammalian sperm motility, thus establishing a regrettable substitution for BPA. BPS showed relatively lower effect levels, although further studies are still needed. The results confirm the growing concern over the safety of the potential substitute BPAF and emphasise the importance of conducting additional mechanistic studies to assess the proper safety of new BPA substitutes.

7.03.P-Mo433 Developing a Risk-Based Grading Framework for Recycled Plastics: Addressing Plastic Additives to Promote Recycling

Kyoko ONO, Masashi GAMO, Naoya KOJIMA, Naohide SHINOHARA and Isamu OGURA, National Institute of Advanced Industrial Science and Technology, Japan

Promoting plastic recycling is an increasingly important issue from the perspectives of resource recycling and preventing plastic pollution. Determining the risk of the chemicals, such as plastic additives, contaminants, and by-products contained (hereinafter referred to as plastic chemicals) in recycled plastics is difficult because recycled plastics are made from a variety of plastic wastes, such as used plastic products and leftovers from the production of plastic products. However, unless such risks are assessed and managed, resource-efficient recycling of plastics will come to a standstill or remain limited.

This study aims to develop a grading concept based on a risk assessment framework for chemicals contained in plastics for waste plastics and recycled plastics, and to conduct a trial grading of recycled plastics.

The grade of recycled plastic was determined according to the risk of the chemical substances contained in the plastic. This risk corresponds to the hazard ratio of plastic chemicals for a specific recycled plastic in a specific use case. The hazard ratio is expressed as follows:

$$C \times L \times M \times E / T$$

where C is the concentration of the plastic chemical(s) in the recycled plastic; L is the leaching characteristic of the plastic chemical(s); M is the degree of potential to be transferred from the media, which depends on the type of plastic resin or medium (air, liquid, or solid) that contacts the chemical in plastic; E is the exposure factor of the use scenario; and T is a parameter representing toxicity of the plastic chemicals, such as the upper exposure limit. The grade range is set based on parameters dependent on product use (M and E). We are currently gathering M and E to define grade ranges applicable to variable use cases and exposure scenarios for plastic products. Examples of the items which each grade will suit for are 1) food packaging, 2) skin care packaging, 3) daily goods such as stationery, and 4) item with minimal human contact such as flowerpots.

This study establishes risk-based grading framework for recycled plastics as a practical indicator. This enables businesses to apply appropriate recycled plastic use without specialized risk assessment knowledge and supports smooth distribution of recycled plastics.

7.03.P-Mo434 Effect of Plastic Recycling on Polymer Characterisation

C. Moscoso-Pérez, V. Fernández-González, E. Concha-Graña, Purificación López-Mahía and **Soledad Muniategui-Lorenzo**, Grupo Química Analítica Aplicada (QANAP), IUMA – CITEEC. Universidade da Coruña, Spain

This work focuses on studying the effect of the mechanical recycling processes on polymers. Polymer recycling can be classified into primary recycling (re-extrusion), mechanical recycling, chemical recycling and energy recovery. Mechanical recycling is a cost-effective and eco-friendly option for thermoplastic polymers.

Mechanical recycling involves several physical steps and is the most common polymer recycling method after energy recovery. This study applied mechanical recycling, comprising washing, drying, extrusion, and shredding to three recycled polymers: polypropylene (rPP), polyethylene terephthalate (rPET), and high-density polyethylene (rHDPE)). As all of these processes are physical, they can cause some structural and physical-chemical changes to the polymer. Three consecutive cycles were performed, and the initial and final samples (after three cycles) were analysed using FT-IR, SEM, and Py-GC-MS, to detect any structural and chemical changes.

FT-IR analysis revealed an increase in the crosslinking bands of the polymers, potentially due to the temperature

employed during the recycling process, resulting in an elevated polymer density. A decrease in the crystallinity bands was also observed. SEM analysis revealed smoother polymer surfaces with each recycling cycle. Few changes to the pyrolysis profiles were observed, and these changes did not affect the identification of the polymers or plastic additives. The effect of the mechanical recycling process was consistent across all three polymers studied.

7.03.P-Mo435 Formulating And Recycling Of Conductive Polymer Composites For Sustainable 3D-Printed Printed Circuit Boards (PCBs)

Theophile Heliot¹, Severine Jeulin², Xavier Schultze², ambre brizon², Karim Inal³ and Vincent Semetey¹,
(1)Chimie Paris PSL, France, (2)L'Oréal, France, (3)MINES PARIS – PSL, France

Electronic devices have been evolving towards better performances and new applications, but their production remains wasteful and ? is too great a challenge because of their small size and complexity. We focus our work on a versatile building block found in nearly all of them: Printed Circuit Board (PCB). Their architecture has evolved for reasons of functionality and safety into the layered copper/FR4 structure (fire-resistant epoxy resin reinforced with glass fibers) that is standard today. However, while this structure is well suited for versatility and high-volume manufacturing, it raises two major sustainability concerns. First, fabrication—particularly the etching step—requires an excess of copper and the use of solvents. Second, the thin, intertwined layers of different materials make efficient recycling difficult and lead to poor recovery yields.

To address these challenges, we investigated conductive materials compatible with additive manufacturing of PCBs by fused deposition modeling (FDM) as well as chemical recycling approaches such as selective dissolution and depolymerization, in order to delaminate and separate materials at the molecular scale.

We have formulated materials from different types of conductive charge (metallic, carbon-based and polymer) in a biobased plastics. While optimizing for good processability, namely extrusion and FDM, and checking for conductivity, we want additionally to develop a chemical recycling process through selective dissolution using Hansen Solubility Parameters.

Sustainability is improved both at the production phase —by using a non-wasteful additive method with less metal— and at the end-of-life phase.

7.03.P-Mo436 Towards a One Health Understanding of Artificial Materials: Research Infrastructure

Ondrej Adamovsky¹, Jana Klanova¹, Antonio Rosato² and Francesca Morelli³, (1)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (2)Interuniversity Consortium for Magnetic Resonance of Metal Proteins (CIRMMP), University of Florence, Italy, (3)Consorzio Interuniversitario di Risonanze Magnetiche di Metalloproteine, Italy

The increasing release of micro- and nanoscale particles from anthropogenic activities represents a significant and growing concern due to their unique physicochemical properties, environmental persistence, and potential impacts on ecosystems, food systems, and human health. To address this challenge, the FHERITALE project (Food, Health and Environment Research Infrastructures to Tackle Emerging Priorities, an EU-funded initiative) aims to establish an entry point for the European scientific community to investigate artificial materials at the micro- and nanoscale within a comprehensive One Health framework. The presented poster will present current project outcomes, including a broad survey conducted among European Research Infrastructures (RIs) to map existing services relevant to micro- and nanoparticle research across environmental, food, and health domains. Participating RIs provided detailed information on physical, chemical, in vitro, in vivo, and computational methodologies currently available for studying the behavior, uptake, and biological effects of artificial materials. The resulting service catalogue highlights the available analytical capabilities, including advanced microscopy, spectroscopy, mass spectrometry, NMR, and EPR techniques, molecular modeling, multi-omics platforms, and a

wide range of biological testing systems that span organoids, model ecosystems, and whole-organism assays. Early achievement includes mapping service availability across multiple RIs, as well as identifying technological gaps and outlining strategic priorities for strengthening interdisciplinary research capacity. The poster will also summarize other current FHERITALE achievements that integrate environmental, food safety, and human health research on artificial materials. In summary, the FHERITALE-related poster will promote cooperation across significant European risks, enabling harmonization of methodologies, increasing analytical capability, and enhancing the understanding of risks associated with micro- and nanoscale materials.

7.04 Bridging the Data-to-Regulation Gap: How to Align NAMs with Regulatory Decision-Making

7.04.T-01 A Regulatory Window for Animal-Free Environmental Risk Assessment: Integrating New Approach Methodologies for Legacy Pharmaceuticals

Samuel K Maynard¹, Rachel Moreby¹, Natalie Burden², Anja Coors³, Luigi Margiotta-Casaluci⁴, Helmut Segner⁵, Charles Tyler⁶ and Stewart Owen¹, (1)AstraZeneca, United Kingdom, (2)NC3Rs, United Kingdom, (3)ECT Oekotoxikologie GmbH, Germany, (4)King's College London, United Kingdom, (5)University of Bern, Switzerland, (6)University of Exeter, United Kingdom

Upcoming revisions to the European pharmaceutical legislation present a timely window of opportunity to reduce vertebrate testing for legacy Active Pharmaceutical Ingredients (APIs). Under the proposed updates, the generation of environmental data will be required not only for new APIs but also for those approved prior to the introduction of the current environmental risk assessment framework. With over 1,200 legacy APIs lacking sufficient environmental data, compliance with these new requirements is likely to trigger extensive vertebrate testing. However, by integrating New Approach Methodologies (NAMs), such as in vitro and in silico techniques, into the revised legislation, there is significant potential to reduce reliance on animal use. Here, we propose a tiered decision-making framework that prioritises the replacement, reduction or refinement (3Rs) of animal testing through use of in vitro techniques and predictive computational models, with vertebrate in vivo testing for legacy pharmaceuticals reserved only when scientifically justified. This approach could prevent testing on more than 300,000 fish, reduce costs significantly, and support the EU's commitment to animal welfare. In light of the European Commission's ongoing development of a roadmap to phase out animal testing in chemical safety assessment, our proposal offers a practical opportunity to demonstrate the applicability of NAMs in regulatory decision making. It also provides a path towards the goal of vertebrate animal-free assessments without compromising environmental protection or patient access to medicines.

This presentation will outline a combination of factors which have aligned to provide an opportunity which, if taken, can enhance progress towards the understanding of how NAMs could be used in regulatory decision making. Critically, this opportunity on a selection of pharmaceuticals presents itself whilst also minimising the impact of the usual hurdles and blockers to the implementation of non-animal data

7.04.T-02 AMiCl-BD: a QSAR Assessment Framework Compliant Machine Learning Model

Floriane Larras¹, Emel Ay-Albrecht¹ and Paul Thomas², (1)KREATiS, France, (2)KREATiS, France

In silico approaches are relevant alternative methods to produce data for regulatory purposes. The release of the OECD principles for model and prediction validation forced the scientific community to develop and use only models considered as robust with a significant level of available information to meet authorities expectations. For KREATiS, the robustness of a model strongly relies on the quality of the data present in a model and this requires in-depth curation of the studies that cannot be simply automated. Following this philosophy, we developed a first model predicting the ready-biodegradability of organic chemicals with the aim to be acceptable for regulatory purposes. The AMiCl-BD (Aerobic Microbial Classification model for Ready-Biodegradability)

model is based on OECD 301/310 studies selected according to a stringent 3 step curation workflow resulting in a final dataset of 2183 substances split into a training, an internal validation and an external set. Finally, a random forest and a support vector machine model were developed according to the five OECD principles using optimized MACCS Keys fingerprints as model descriptors. First, the deep curation was a crucial step that required most of the time of model development and revealed numerous inconsistencies in experimental results. Second, the model exhibited very good goodness-of-fit, robustness and predictivity with a trend for conservative predictions. Importantly, this model demonstrates a well-balanced performance between precision and sensitivity (or specificity), particularly for compounds within its applicability domain. Third, the model provides as output a binary class along with a probability providing a level of confidence in the prediction. In addition, an automatic applicability domain assessment is implemented and a dynamic in-house reliability index is computed to support the trust of the users and authorities into the prediction. It is clear that machine learning approaches clearly suffer of a reputation of black box that may prevent their use for regulatory purposes. However, the AMICI-BD model tackles this drawback as possible by providing clear and accessible insight regarding the elements critical for the QSAR Assessment Framework.

7.04.T-03 Modernizing persistence and toxicity assessment through coupling biodegradation with an in vitro bioassay

Yohan Seol¹, Luise Henneberger¹, Eunhye Bae¹, Cleo Amelia Maria Soldini², Carolin Seller², Johannes Tolls Dir³, Kathrin Fenner² and Beate Escher¹, (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag) & University of Zurich, Switzerland, (3)Henkel AG & Co KGaA, Germany

The conventional method of assessing the persistence (P), bioaccumulation (B), and toxicity (T) of chemicals is time-consuming, expensive and relies heavily on animal testing. This method cannot keep up with the drastic increase in global chemical production, resulting in a data gap in hazard profiles under the CLP and REACH regulations. To accelerate PBT assessment, novel hazard indicators, namely Cumulative Toxicity Equivalents (CTE) and Persistent Toxicity Equivalents (PTE), for the high-throughput screening of hazardous substances have been proposed. CTE represents the measured toxic effects of a substance using in vitro bioassays and PTE represents the toxic effects remaining after its simulated environmental degradation. Since the bioaccumulation reflects the internal concentration of a substance in relation to its toxic effect, bioaccumulation can be considered a part of toxicity assessment and therefore integrated into CTE and PTE. Six benzalkonium chloride surfactants (BACs) were selected to demonstrate the applicability of the CTE/PTE hazard indicators. CTE was determined using the MitoOxTox assay, which detects cytotoxicity, oxidative stress response and mitochondrial toxicity. MitoOxTox captures the three key events central to the adverse outcome pathways shared across major clusters of human disease but in the future a broader test battery will be applied. With increasing alkyl chain length, the cytotoxicity increased and effects in all endpoints were consistent with predicted baseline toxicity. We then applied a high bacterial density biodegradation test using sewage sludge, which had previously been demonstrated to mimic environmental degradation. BACs were nearly completely degraded (> 90%) within 72 hours. After biodegradation, the slurry was extracted by solvent extraction and the supernatant by solid-phase extraction. Subsequent bioassay testing revealed that effects decreased over time and correlated with the decrease of the BAC concentration. If transformation products (TPs) had been formed at all, their contribution to bioactivity was negligible. Therefore, we can conclude that BACs are not PBT chemicals, which is consistent with the results according to the PBT assessment in REACH (but now includes consideration of transformation products). This study demonstrates a workflow for fast screening of the toxicity and persistence but it remains to be expanded to more persistent substances and those that form problematic TPs.

Disclaimer/Disclosure:

We acknowledge funding by the Initiative and Network Fund of the Helmholtz Association, project “Co-Creation process for the modernization of chemical hazard indicators – CoModHaz” KA-TCP-20 and by the Swiss National Science Foundation (SNF) in the context of a Sinergia project (CRSII_222712).. All experiments were run on the CITEPro (Chemicals in the Environment Profiler) (bio)analytical platform funded by the Helmholtz Association.

7.04.T-04 Practical Implementation of NAMs into Toxicological Assessment of Pesticide Residues

Darina Yordanova¹, Stela Kutsarova², Ksenia Tankova¹, Marin Georgiev¹, Juan Manuel Parra Morte³, Martina Panzarea³, Andrea Gissi³, Salvador Moncho Escrivá⁴, Tomasz Sobanski⁵ and Ovanes Mekenyan¹, (1)Laboratory of Mathematical Chemistry (LMC) Prof. Assen Zlatarov Burgas State University, Bulgaria,

(2)No Affiliation, Bulgaria, (3)European Food Safety Authority (EFSA), Italy, (4)No Affiliation, Finland, (5)European Chemicals Agency (ECHA), Finland

The plant protection products may undergo various (a)biotic degradation processes that alter the original chemical structure of the pesticide after their application to crops and the subsequent entrance to the common food chain. As a result, a mixture of compounds can be formed, comprising the unchanged active substance (the parent compound), along with its metabolites and degradation products, all of them collectively known as pesticide residues. This variety of structures that could be formed, hurdles the toxicological assessment of pesticide residues by requiring significant efforts and resources.

The implementation of New Approach Methodologies (NAMs) offers new opportunities to improve the scientific and ethical basis of pesticide residues assessments. As highlighted by the European Food and Safety Authority (EFSA) and the European Chemical Agency (ECHA), the in silico approaches such as (Quantitative) Structure-Activity Relationship ((Q)SAR) modelling and read-across, can be practically applied to support the toxicological evaluation of structures, including metabolites, especially when experimental data are limited. In this respect, EFSA, in collaboration with ECHA, is currently running a project with the aim to develop a semi-automated workflow for bacterial gene mutation assessment of pesticide residues using the freely available QSAR Toolbox software and its interoperability with MetaPath (storing metabolism data) and IUCLID (storing toxicological data).

The workflow will consist of several key steps of analysis of the residues including: categorization based on their quantity, identification of major rat metabolites, gathering experimental data, searching for analogues for read-across purposes and (Q)SAR model predictions. Finally, the workflow will provide an overall conclusion on the bacterial mutagenicity for each structure. The user interaction is minimized to facilitate and streamline the work with the system and to ensure efficiency, reproducibility, and consistency in the assessment process. The logic implemented for each of the workflow steps aligns with the main principles of residue definition as recommended by EFSA and the forthcoming OECD guidance.

A pilot version of the semi-automated workflow has been already developed and tested on real case studies provided by EFSA pesticide applicants. Encouraging results are obtained, indicating the workflow as a practical tool to support the integration of NAMs in regulatory toxicology.

7.04.P Bridging the Data-to-Regulation Gap: How to Align NAMs with Regulatory Decision-Making

7.04.P-Tu444 Optimizing In vitro Battery for Genotoxicity Testing Using a Probabilistic Network To Support Decision Making

Zheng Zhou and Ullrika Sahlin, Lund University, Sweden

Current strategies for genotoxicity testing use multiple in vitro and in vivo assays to evaluate three key endpoints: gene mutation, clastogenicity, and aneuploidy. Optimizing in vitro test batteries has become a priority for next-generation risk assessment (NGRA). Recent efforts introduced quantitative evaluation of the battery but may fail to adequately address uncertainties in assay accuracy and endpoint relationships. We developed a probabilistic Bayesian network that explicitly models such uncertainties and applies decision analysis to recommend stepwise testing protocols.

We constructed a probabilistic network based on the description of assay objectives in OECD guidelines. We adopted the data from Luijten et al. (2024) including 2,239 chemicals tested across ten assays. Due to missing values, we supplemented with TRAID project reporting assay sensitivity/specificity against rodent carcinogenicity. with 237 chemicals overlapping between datasets. Endpoint values, though unobserved, are essential for conditional probability estimation. We applied Bayesian latent class analysis, which enabled endpoint simulation from in vivo assay results. The conditional probabilities were estimated on the data of Luijten et al. (2024), TRAID and simulated endpoint values.

We evaluated the model's sensitivity to prior probabilities of carcinogenicity (0.1, 0.5, 0.9), reflecting potential in silico predictions in NGRA workflows. Genotoxicity was defined as positive if any endpoint was positive. Using the framework of Integrated Approach to Testing and Assessment, decision analysis assessed posterior probabilities under stepwise assay addition to identify minimal assay combinations for conclusive results and optimal sequential strategies.

The probabilistic network showed strong predictive performance, with 91% sensitivity and 85% specificity. Decision analysis revealed that a conclusive positive genotoxicity result required two positive outcomes from the HPRT and in vitro micronucleus (MN) assays. In contrast, a conclusive negative required three negative

results from HPRT, in vitro chromosomal aberration (CA), and in vitro MN assays. The bacterial reverse mutation (Ames) test provided limited information when combined with other in vitro assays.

Our probabilistic approach characterizes assay accuracy and relationships while providing a practical, stepwise testing protocol. We recommend initiating test batteries with HPRT and in vitro MN assays.

7.04.P-Tu445 NAMs-based Assessment of Endocrine Disrupting Chemicals under K-BPR : Case Study on Preservatives

Ji-Yeon Roh¹, Donghyeon Kim², Siyeol Ahn³ and Jinhee Choi⁴, (1)Knoell Korea, Korea, Republic of, (2)Department of Applied Biosciences, University of Seoul, Korea, Republic of, (3)School of Environmental Engineering, University of Seoul, Korea, Republic of, (4)University of Seoul, Korea, Republic of

As of 2025, a total of 368 preservative-type biocidal active substances—including product preservatives, film preservatives, and fiber/leather preservatives—have been notified as existing substances under the Korean Consumer Chemical Products and Biocides Safety Control Act (K-BPR). These notified substances face an approval deadline in December 2027, and preparations for their AS approval applications are currently underway.

Preservative-type substances are widely used across a broad range of consumer products, primarily to prevent product degradation and extend shelf life. Because these substances are designed to ensure long-term stability and preservation, they may also pose potential long-term hazards to human health and the environment. Additionally, concerns have been raised regarding the possibility of tolerance or resistance developing through repeated exposure. For these reasons, evaluating the potential endocrine-disrupting effects (EDCs) of preservative substances under chronic or repeated exposure conditions represents a critical hazard domain. Under the K-BPR, a substance is recognized as having endocrine-disrupting potential only when it is listed in the EU ED Lists I or II.

In this study, we aimed to screen preservative-type biocidal substances belonging to three product types that are currently undergoing the approval process under the K-BPR. Using TOXBAL, a DART model-based predictive tool, we identified substances with potential endocrine-disrupting activity, even if they are not included in EU ED Lists I or II. QAC benzyl-C12-16 (CAS 68424-85-1) and triclocarban (CAS 101-20-2) were selected for additional evaluation regarding their potential endocrine-disrupting effects. For these substances, we integrated NAMs-derived information with exposure pathways relevant to the Korean regulatory context and conducted a next-generation risk assessment case study to support regulatory decision-making related to endocrine disruption.

This study not only provides AOP-based foundational ED-related toxicological information for preservative substances undergoing approval, but also demonstrates the feasibility of conducting NGRA using NAMs. Such a framework is particularly useful for evaluating EDCs, where toxicological data are often limited, as it helps identify priority substances through mechanistic signals. For substances requiring further evaluation, the use of NAMs can support risk determination without relying on animal testing.

7.04.P-Tu446 Advancing Confidence in NAMs for Fish Acute Toxicity Assessment: Outcomes from the 2025 Innovate EcoSafety Summit

Julie Krzykwa¹, Natalie Burden², Michelle Rau Embry³, Amy Marriott² and Amelie Ott⁴, (1)HESI Global, Washington, United States, (2)NC3Rs, United Kingdom, (3)HESI Global, (4)International Collaboration on Cosmetics Safety (ICCS), United States

The inaugural Innovate Ecosafety Summit brought together 57 experts from academia, government, industry, and non-profit sectors across 10 countries to accelerate the adoption of new approach methodologies (NAMs) in chemical safety assessment. The three-day event focused on two critical topics: replacing acute in vivo fish testing and applying NAMs in endocrine disruptor assessment for fish and amphibians.

The acute fish toxicity discussion session provided an opportunity for breakout groups to evaluate example datasets under three regulatory contexts: Deriving a Predicted No Effect Concentration (PNEC), deriving a Fish-

Specific Risk Quotient (RQ), and Classification & Labelling (CLP). Confidence in NAMs was highest when data were corroborated by QSARs and the mechanisms of action were well understood. Conversely, confidence dropped when evaluating reactive compounds, scenarios where there were dataset discrepancies, or where there was a lack exposure data (relevant to the risk-based contexts).

Discussions indicated that confidence in using NAMs is shaped not only by data quality but also by the clarity of frameworks and through collaborative interpretation. Participants emphasized the need for consistent terminology, mechanistic understanding, and better integration with exposure models. The use of data-driven case studies highlighted where NAMs add value, and where gaps remain.

Next steps include developing further case studies and establishing criteria for data applicability in specific contexts. The Summit underscored the importance of cross-sector collaboration and regulatory evolution to reduce vertebrate testing while maintaining robust environmental protection.

7.04.P-Tu447 Towards NAM-based Frameworks for Assessing Endocrine Activity in Aquatic Vertebrates: Outcomes from the 2025 Innovate EcoSafety Summit

Natalie Burden¹, Michelle Rau Embry², Julie Krzykwa³, Amy Marriott¹ and Amelie Ott⁴, (1)NC3Rs, United Kingdom, (2)HESI Global, (3)HESI Global, Washington, United States, (4)International Collaboration on Cosmetics Safety (ICCS), United States

The 2025 Innovate EcoSafety Summit convened a global, cross-sector community to advance predictive, non-animal approaches for chemical safety assessment. A central focus was the development of prototype frameworks for evaluating endocrine activity (specifically for the estrogenic, androgenic, thyroid, and steroidogenic (EATS) modalities) in aquatic vertebrates without reliance on traditional in vivo assays. Breakout group discussions, balanced across academia, industry, and government organisations, explored the essential components of such frameworks under hazard- and risk-based decision-making paradigms.

The discussions revealed strong convergence on a tiered, mechanistic framework that begins with existing data and escalates when uncertainty persists. Core elements included integration of in silico, in vitro, and cross-species endocrine activity data, with an emphasis on the need to demonstrate transparency, reproducibility, and weight-of-evidence approaches. Risk-based groups highlighted the critical role of exposure data and in vitro to in vivo extrapolation tools in reducing uncertainty, while hazard-based groups emphasised precautionary principles (i.e. the need for generation of higher-tier hazard data to address uncertainty), and the use of qualitative thresholds.

Key outcomes included the need for shared terminology, context-specific confidence criteria, and structured validation of novel approaches. Next steps identified include mapping assay coverage for thyroid and steroidogenesis pathways, piloting integration tools, and developing user-friendly guidance for regulators and data submitters.

This session lays the groundwork for a follow-up activity in 2026 to stress-test such prototype frameworks, which will have an initial focus on estrogenic activity, using real-world data. This activity will identify what further work is needed to ensure sufficient confidence to enable the regulatory acceptance of NAMs and reduce reliance on in vivo testing in aquatic vertebrate endocrine disruptor assessment.

7.04.P-Tu448 Establishing Molecular Size and Log P as Reliable Indicators for Worldwide Bioaccumulation Assessment: A New Decision Tree Screening Approach

Kevin Bonnot¹, Marie Collard², sylvia gimen³ and Neil Wang⁴, (1)dsm-firmenich, Belgium, (2)DSM-Firmenich SA, Belgium, (3)Firmenich, Belgium, (4)Syensqo, France

Since the implementation of REACH, various parameters have been used to screen and prioritize chemicals, with log Kow as the primary criterion for bioaccumulation. ECHA guidance also recommends parameters such as maximum molecular diameter to support conclusions on a substance's lack of bioaccumulative potential. To our knowledge, these criteria have not been systematically re-evaluated using the wealth of new data now available.

In this study, we compiled a dataset of 655 compounds with publicly available experimental fish BCF values. For each compound, 4,179 molecular descriptors were calculated using AlvaDesc. Feature selection employed sparse Partial Least Squares (sPLS) to identify the 20 descriptors most strongly correlated with bioaccumulation

(log BCF ? 3.3). Decision trees were trained to generate transparent classification rules using empirical class priors and an asymmetric cost matrix heavily penalizing false negatives. The probability threshold (τ) was optimized via repeated, stratified five-fold cross-validation (ten repetitions), first minimizing false negatives, then reducing false positives. Rule stability was assessed through extensive bootstrapping, retaining only trees with zero false negatives and aggregating recurrent rules and split variables.

Our results indicate that an ultra-conservative threshold ($\tau ? 0$) is required to achieve zero false negatives, which increases false positives at the screening stage. The most recurrent decision rules combine hydrophobicity, molecular size, and topological descriptors (log Kow, Size3, BLTD48), refined by polarity (e.g.TPSA.Tot.). These patterns are chemically plausible and align with bioaccumulation mechanisms and main regulatory cut-off values. The main discriminating descriptor was log Kow (threshold ?4.5), followed by Size3 derived from average molecular diameter, consistent with ECHA Guidance R.11.

This data-driven analysis confirms that the log Kow and size thresholds currently applied under REACH are appropriate, robust, and enable a highly protective approach (no false negatives). We propose a decision-tree workflow integrating multiple descriptors into a science-driven, transparent, and highly sensitive tool, ensuring protection through a conservative, zero-false-negative strategy.

7.04.P-Tu449 Science without borders: State of the art of the regulations on the use of NAMs under EU REACH and K REACH

Donghyeon Kim¹, Elizabeth Dufourcq Sekatcheff², Ji-Yeon Roh³, Dawoon Jung⁴ and Jinhee Choi⁵,
(1)University of Seoul, Paris-Cité University, Korea, Republic of, (2)French Agency for Food, Environmental and Occupational Health & Safety (ANSES), France, (3)University of Seoul, Korea, Republic of, (4)Korea Environment Institute, Korea, Republic of, (5)School of Environmental Engineering, University of Seoul, Korea, Republic of

New Approach Methodologies are defined as “any technology, methodology, approach, or combination that can provide information on chemical hazard and risk assessment to avoid the use of animal testing”. The European Commission is set to publish a roadmap in early 2026 to phase out animal testing in chemical safety assessments, accelerating research initiatives and the development of NAMs as alternatives to animal testing. However, regulatory practices and acceptance of NAMs tend to evolve at a slower pace. Indeed, there are several hurdles to the integration of NAMs in a regulatory framework: ranging from the need to gain confidence (via standardization and formal validation by the OECD), to the current regulatory framework that cannot yet accommodate this new type of data. In Korea, the regulatory landscape shows a similar yet distinct trajectory. Under the Act on the Registration and Evaluation of Chemical Substances (K-REACH), a major amendment in 2018 mandated the prioritization of vertebrate animal alternative testing and prohibited duplicate animal tests for the same chemical, establishing a clear legal basis for encouraging NAMs. Korea has also strengthened institutional capacity through KoCVAM, which participates in international validation efforts and supports the development and evaluation of alternative test methods. While these legal and organizational steps signal strong policy intent, the practical regulatory uptake of NAMs remains gradual. In this review, we sought to establish a comparison of the regulation on the use of NAMs under REACH regulation in Europe vs Korea. We conducted a comprehensive analysis ranging from the legal basis for the use of NAMs to policy roadmaps and several concrete case examples. In addition, we investigated whether our own NAM portfolio matched the criteria for regulatory acceptance and how it could be improved for a better fit for purpose approach for NGRA. This study aims to provide insights for researchers wishing to develop NAMs fit for regulatory purposes, and to strengthen international harmonization of regulatory practices and favor the use of existing data across borders to reduce animal testing.

7.04.P-Tu450 In-Depth Comparison of Predictivity Performances of Regulatory Compliant Ready-Biodegradability Models

Floriane Larras¹, Emel Ay-Albrecht¹ and Paul Thomas², (1)KREATiS, France, (2)KREATiS, ., France

Ready biodegradability is a key endpoint for the environmental hazard assessment of chemicals in the framework of different regulations. Many freeware models are known to predict the ready biodegradability of

organic chemicals and several of them are regularly used for the completion of regulatory dossiers like Biowin, VEGA SARpy and OPERA R-Biodeg models. Recently, KREATiS released a new model following as possible its philosophy of model development: a deep and manual curation of the dataset to reject as possible the non-reliable studies, a mechanistic understanding of the predicted endpoint and total compliance with the QSAR Assessment Framework set by the OECD in 2023. This new model, called Aerobic Microbial Classification of Ready-Biodegradability (AMiCl-BD), contains two modules: a Random Forest and a Support Vector Machine (SVM)-based ones. The aim of this poster is to present predictivity performances of these five models tested along a same dataset, discuss the impact of the applicability domain as defined by the model developers and discuss these results in the light of the characteristics of the models (e.g. training set, descriptors, model choice). To be fair, the applicability domain of each model was defined automatically with no in-depth check of the data (e.g. analogues selected for applicability domain indices for AMiCl, VEGA, OPERA) meaning that the statistical values can be considered as worst-case. This analysis is based on 1135 substances that are not present in any of the training set of these models. The predictivity statistics were computed two times for each model: for all the predicted compounds and only for those falling inside model applicability domains, as detailed by the model developers. A first observation is that strong differences of accuracy and precision were observed between the models before and after the applicability domain assessment. Applying a strict applicability domain enhanced the performance of most models. In other words, these models predict less but with more confidence. If VEGA displayed satisfying statistics for the negative predictivity, the AMiCl ones presented the best balance while predicting ca. 1.6 times more substances falling inside applicability domain. Also, the fact to set a strict applicability domain by default led to the rejection of numerous predictions correctly predicted with AMiCl, especially for the non-readily biodegradable compounds.

7.04.P-Tu451 Innovate EcoSafety Summit: A Collaborative Model for Advancing Environmental Risk Assessment

Julie Krzykwa¹, Natalie Burden², Michelle Rau Embry³, Amy Marriot² and Amelie Ott⁴, (1)HESI Global, Washington, United States, (2)UK National Centre for the 3Rs, United Kingdom, (3)HESI Global, (4)International Collaboration on Cosmetics Safety (ICCS), United States

The Innovate EcoSafety Summit was established to provide a dedicated forum for cross-sector discussions on advancing environmental risk assessment. The inaugural meeting focused on the use of new approach methodologies (NAMs) for estimating acute fish toxicity and screening for endocrine activity in fish and amphibians. Although method development is progressing in both areas, regulatory use has been limited by a lack of clarity on expectations for method performance, confidence in the methods, and guidance on interpretation.

To address these challenges, the summit combined plenary presentations with breakout discussions. Mixed-sector groups were tasked with evaluating case studies under defined scenarios and identifying where NAM data were sufficient and where key gaps remained. For acute fish toxicity, groups evaluated datasets inspired by real chemicals across different regulatory contexts (e.g., classification and labeling, derivation of predicted no-effect concentration (PNEC), and fish-specific risk quotient calculation). For endocrine activity, groups were asked to outline components of a framework for assessing estrogenic, androgenic, thyroidal, and steroidogenic activity using NAMs.

For acute fish toxicity, participants identified clear conditions under which NAMs can be used with confidence (for example, when the mode of action is well-characterized and within the known applicability domain of the methods, there is concordance across different lines of evidence, and decision contexts are less sensitive to quantitative uncertainty). Factors that reduced confidence included metabolic uncertainty and discordant datasets. Discussion on endocrine activity revealed general agreement on the need for a tiered testing strategy, but also a varying level of confidence in negative results. Across both themes, the discussions emphasized the need for clearer terminology, defined applicability domains, and increased familiarity with NAM datasets. Participants identified short-term actions to advance implementation, including training through scientific and regulatory forums, developing case studies, clarifying decision criteria, and providing guidance to support consistent submission and evaluation of NAM data. These discussions underscored that continued progress depends on shared interpretation, coordinated development, and cross-sector collaboration.

7.04.P-Tu452 Responding to Regulatory Concerns on Air-Breather Bioaccumulation with NAMs: Extending Existing In vitro Rat Liver Assays - Developing and Validating a New Test Guideline

Gordon Sanders¹, Michelle Rau Embry², Verena Kosfeld³, Heike Laue⁴ and Christian Schlechtriem⁵, (1)Givaudan International SA, Switzerland, (2)Health and Environmental Institute (HESI), United States, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Givaudan, Switzerland, (5)Bioaccumulation & Animal Metabolism, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany

In June 2017 ECHA revised its Chapter R11: PBT/vPvB Assessment document to include new screening threshold criteria for bioaccumulation in air-breathing organisms linked to Kow and Koa (log Kow >2 in conjunction with log Koa >5). For substances screening as potentially bioaccumulative in air-breathing organisms, generation of further information, such as toxicokinetic (TK) data (e.g. OECD 417), may be necessary, which would be both animal and resource intensive. A significant percentage of REACH registered substances fulfill the proposed cut-off thresholds, and would thus, necessitate further assessment. No test guidelines nor tiered framework for generation of lower-tier screening data exists. This inspired the 4-year CEFIC LRi programme of ECO 41, Enhanced Screening Methods to Determine Bioaccumulation Potential of Chemicals in Air-Breathing Species, which consisted of 3 work packages: 1) Propose and evaluate a screening test to establish Koa; 2) Review and compilation of existing data on bioaccumulation and TK for air-breathing species; 3) Develop an In vitro NAM (new approach methodology) for assessing bioaccumulation. The In vitro Rat liver S9 assay developed offers a Tier 2 NAM approach and can be used to de-prioritise chemicals from eventual Tier 3 In vivo studies. The predictive capacity of this testing protocol was demonstrated to be fit-for-purpose and is ready for validation.

Several other national and international initiatives have followed-on from this, including: i) the European Chemicals Agency (ECHA) work group on Toxicokinetics and Bioaccumulation Assessment of Air-Breathing Mammals, who reported their findings in November 2022; ii) the Umweltbundesamt project Integrated Strategy for the Assessment of Aquatic and Terrestrial Bioaccumulation which considered in vitro rat hepatocyte and liver S9 data, and iii) the US-EPA led SPSF (Standard Project Submission Form) to develop an OECD Test Guideline for determining human intrinsic clearance rates and protein binding capacities, methods that are closely related to the rat depletion assay.

This presentation will review and assimilate the work performed through the various projects in the domain of air-breather B, consider commonalities and differences between findings, and, propose a pathway forward to consolidate the existing information, identify remaining gaps while suggesting solutions to elevate suitable NAMs to a status of regulatory acceptability to fill the air-breather B end-point.

7.04.P-Tu453 AI in chemical regulation: Current approaches and future potential for integrating AI within chemical hazard and risk assessments

Helena Crosland¹, Hanna Samantha Schuster¹, Olha Khomenko² and Bashir Mohammad Surfraz³,
(1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)Cambridge Environmental Assessments (CEA), Helsby, United Kingdom, (3)Environmental Fate and Behaviour, RSK ADAS Ltd, United Kingdom

Chemical regulation procedures are becoming increasingly complex within the European Union (EU) coinciding with the continued drive towards reduction of animal testing (e.g. New Approach Methodologies NAMs). Thus, there is an urgent need to make the most of existing information and alternative (new) methodologies.

Meanwhile, machine learning (ML) and artificial intelligence (AI) have been rapidly developing and could provide very powerful tools in addressing these opposing regulatory requirements.

The European Food Safety Authority (EFSA) has recently published an outline of their vision of the use of AI for regulatory risk assessment for pesticides. However, no harmonized regulatory AI tools or official guidance for their use in risk assessment, are available. Consequently, the use of these tools is often limited to tasks such as supporting with literature searches and reviews, summarising large regulatory documents and writing code for computer models and big data.

AI has the potential to be beneficial in the development of data-intensive and expert driven NAMs (e.g. in vitro assays, in silico models, omics technologies) by making them more accessible and democratic for regulators and other stakeholders. For example, AI could assist a regulator with reviewing the validity of code for a novel model submitted by an applicant. This improved potential to develop NAMs, while concurrently ensuring the ability of regulators to review these methods, could be of particular use in avoiding animal testing for low-toxicity substances which may only require a screening assessment for toxicity.

While advanced ML tools offer these promising capabilities, they often lack transparency required to be accepted as standalone decision-making tools. Key limitations and concerns with current ML approaches are hallucinations and bias of generative AI; environmental impacts of a large scale deployment; and the link of cutting-edge technologies with extant regulations. Therefore, although AI should have a significant impact on the in bridging the gap between NAMs and regulatory decision making, the development of AI tools and guidance will need to involve stakeholders from all parties (regulators, academia and industry) for its success. This poster will discuss how AI is currently being used in a regulatory environment (by risk assessors as well as regulators); what are the major concerns and the current limitations of these technologies how such tools may develop in the future.

7.04.P-Tu454 Are We Under the Illusion of Control? Looking Beyond Quantification to Uncover “Real” Environmental Concentration Distributions of Chemicals

Larissa Zoë Herrmann¹, Sascha Bub¹, Jakob Wolfram¹, **Lara Petschick¹**, Johan Axelman², Gustaf Boström³ and Ralf Schulz¹, (1)Rhineland-Palatinate Technical University Kaiserslautern-Landau, Germany, (2)Swedish Chemicals Agency, Sweden, (3)SLU Centre for Pesticides in the Environment, Swedish University of Agricultural Sciences, Sweden

Understanding data limitations is vital in an effort to benchmark the reality of exposure models against monitoring data and transition to a systems-based, more effective, and resource-efficient regulatory environmental risk assessment. The “real” distribution of pesticide concentrations in surface waters is only partly represented by monitoring. Measured environmental concentrations below their limit of quantification offer partial info that can help reconstruct the “real” environmental concentrations.

This study compared multiple statistical approaches to: (1) determine appropriate methodology for handling censored MEC distributions, (2) apply optimal methodology combinations to approximate REC distributions, (3) contextualize RECs with substance-specific and environmental parameters, and (4) analyze environmental risks for aquatic non-target organisms based on assumed REC-derived exposure.

Monitoring data (n=39 mil.) from 43,202 sites across 34 countries (2001–2023) were collected, containing 1,958 substances (11% pesticides). After curation and outlier removal, we developed a tiered hybrid modelling strategy: MEC normalization with median LOQs combined with multiple-censored maximum likelihood estimation for moderate censoring (<70%), Helsel's regression on order statistics for high censoring (70–90%) or multiple detection limits, and quantile random forest as fallback.

Censoring proportions ranged 1–100% (median=36%) across substance classes. Sampling frequencies varied substantially between organic (median monthly=1), pesticidal (2), and inorganic chemicals (2.5); maximum frequencies vary from organic 4–5, inorganic 5–18, pesticides 6.5–250 samples monthly. Organic non-pesticides are quantified more frequently than organic pesticides. Spatial analysis revealed higher concentrations for inorganic chemicals across Europe; pesticides exhibited higher median concentrations than non-pesticide organics but lowest detection rates above LOQ.

By combining measurement normalization with tiered hybrid modelling, this study addresses a critical methodological gap in handling censored water quality data at a continental scale. Emerging spatial-temporal patterns, particularly pronounced pesticide contamination relative to organic non-pesticides, provide foundation for threshold integration and risk prioritization. Ongoing work includes risk characterization, model validation, and integration of supplementary explanatory data (e.g., pesticide application rates).

7.05.P Enhancing Chemical Safety using NGRA: Bridging Human Toxicology and Ecotoxicology

7.05.P-We432 Biomarker Signatures for Detecting Chemical-Induced Developmental Delays in Zebrafish Embryo Model

Gloria Chidiebere Ajugwo, Emmanuel Ogwu Chukwu, Vanessa Fee Saalmann, Bingxu Chen and Stefan Scholz, Helmholtz Centre for Environmental Research GmbH (UFZ), Department Ecotoxicology, Germany

Chemicals can disrupt normal embryonic development, resulting in embryo toxicity, developmental delay or abnormal development. Detecting developmental toxicity is critical for both humans and the environment. Zebrafish embryos are widely used in developmental toxicology, supported by advances in automated image-based assessment of structural features. To improve chemical comparison and link effects to mechanisms of toxicity, identifying biomarkers for developmental delay is crucial. To establish morphological markers for developmental delay in zebrafish embryos at the 96 hours post fertilisation (hpf) reference stage, we quantitatively characterised the morphological progression from 72 to 96 hpf using the Automated Imaging Robot (AIR). Features were quantified using FishInspector software and analysed with KNIME workflows and R scripts. For validation, embryos were incubated at different temperatures (24.5–27.7°C) and compared with structural features at 96 hpf. Using regression analysis, structural features with stage and temperature dependency were identified. An existing dataset of ~200 chemicals (PrecisionTox project) with quantitative morphological effect data was used to identify compounds primarily causing developmental delay. The stage

and temperature dependency of 48 structural features were evaluated with heatmaps and principal component analysis. Seventeen of these features strongly correlated ($r^2 > 0.8$) with developmental progression. Of these, nine also showed strong temperature dependency and were selected as robust biomarkers of delayed development. Using the PrecisionTox chemicals, 56 chemicals showed effects on one or more of the nine biomarkers. One compound, 4-methylimidazole, had effects on all nine biomarkers and showed greater sensitivity for these biomarkers (median EC50=6,206 μ M) than for other morphological features (median EC50=12,849 μ M), indicating that developmental delay was the primary effect. At higher concentrations, other structural features unrelated to developmental delay, like notochord curvature were identified. Our study established and validated nine developmental delay biomarkers in zebrafish. These biomarkers provide mechanistic links to modes of action, distinguishing compounds that primarily slow development from those causing other developmental effects. They can aid in prioritising chemicals with potential developmental toxicity relevant to environmental and human health.

7.05.P-We433 Harmonizing NAMs Across Species: Molecular Docking and *Caenorhabditis elegans* for Endocrine Disruptor Screening

Chaein Chong¹, Donghyeon Kim², Keon Kang³ and Jinhee Choi¹, (1)University of Seoul, Korea, Republic of, (2)Department of Applied Biosciences, University of Seoul, Korea, Republic of, (3)School of Environmental Engineering, University of Seoul, Korea, Republic of

The increasing global production of plastics has raised concerns about additive chemicals—including plasticizers, stabilizers, antioxidants, and other functional agents—that can leach from polymer matrices and lead to widespread human and environmental exposure. While regulatory attention to endocrine-disrupting chemicals (EDCs) and their association with plastic additives has increased in recent years, hazard information for numerous plastic additives remains limited.

Here, we applied an integrated new approach methodologies (NAMs)-based framework combining in silico molecular docking and in vivo *Caenorhabditis elegans* assays to efficiently screen the endocrine-disrupting potential of plastic additives. Molecular docking of 417 EU REACH-registered additives was performed against human estrogen and androgen receptors (ER α and AR), followed by cross-species docking using AlphaFold-predicted structures of the *C. elegans* nuclear receptors NHR-14 and NHR-69, which are putative orthologs of human ER α and AR, respectively. Chemicals showing strong binding interactions across species were further examined through a systematic literature review focused on ER- and AR-mediated effects. By integrating evidence, 2-(2H-benzotriazol-2-yl)-4-methylphenol (UV-P) and 1,3-dimethyl-2-benzylimidazolium bromide (DBM) were identified as potential ER and AR disruptors and were subsequently validated through reproductive toxicity assays using *C. elegans* wild-type N2 and loss-of-function mutant strains (nhr-14 and nhr-69). This NAMs-based framework directly aligns with Next Generation Risk Assessment (NGRA) principles by linking molecular initiating events (MIEs) to adverse outcomes (AOs) through mechanistic understanding. By connecting in silico predictions (Level 1) with non-vertebrate whole-organism models (Level 3-4) within the OECD EDC assessment framework, this approach demonstrates how cross-species MIE conservation assessment can expand the utility and predictive power of alternative animal models while adhering to the 3Rs principles. The cross-species docking strategy exemplifies how NAMs can harmonize mechanistic data across species, supporting unified chemical risk assessment aligned with the One Health framework.

7.05.P-We434 Estimation of Intra-Specific Ranges of Genetic Susceptibility to Toxicity Using Genetically Diverse Populations of Human Lymphoblastoid Cell Lines

Vesa Hongisto¹, Konrad Patyra¹, Maria Adonay², Robert Anholt², Trudy Mackay², Pekka Kohonen³, John K. Colbourne⁴, Juha Rantala¹ and Roland Grafström⁵, (1)Misvik Biology Oy, Finland, (2)Department of Genetics and Biochemistry, Clemson University, Clemson, SC, USA, United States, (3)Misvik Biology Oy, Sweden, (4)University of Birmingham, United Kingdom, (5)Karolinska Institute, Sweden

Aim of the study is to provide a greater understanding of the genetic sources of variation that underlie individual susceptibility to toxicity. Consequently, we have carried out high throughput screening of thirteen chemicals (Cadmium chloride, Sodium (meta)arsenite, Acrylamide, 4-Methyl imidazole, Dexamethasone, Cyclosporin A, Tamoxifen, Genistein, Rotenone, Tetraethylthiuram disulfide, Valproic acid, 5-fluorouracil and DMSO) in 261

lymphoblastoid male and female cell lines from 18 populations to discover genetic variability and sex-dependent changes in toxic responses in humans.

Clear response differences to all toxicants were found and ANOVA analysis of the cell line dose-response toxicity data from the populations revealed significant intra-population sex differences and population specific responses to the toxicants studied.

Further aim is to evaluate the degree of certainty in causal links between molecular key events and chemical risks to human health. Thus, the role of single nucleotide polymorphisms in the toxic responses will be studied using a genome wide association analysis and expression quantitative trait locus mapping is carried out to reveal phenotypic variation in the cell lines.

It is commonly considered that pathways predictive of human toxicity are restricted to closely related species (i.e. mammals). By measuring variability in gene expression among non-sentient organisms (NSOs), we will demonstrate that toxicity responses are shared in distantly related organisms. Omics experiments are planned to confirm that the genetic regions controlling variation in molecular key events observed in humans also control variation in the fruit fly. With these findings we hope to promote the use of NSOs to predict human toxicity in regulatory risk assessment.

Disclaimer/Disclosure:

The study is conducted within the H2020 funded PrecisionTox project (Grant agreement ID: 965406).

7.05.P-We435 From Human NAMs to Ecosystem Protection: A Key-Event–Driven Strategy for Cross-Species Toxicity Translation

Jaeseong Jeong, Chaein Chong and Jinhee Choi, University of Seoul, Korea, Republic of

Protecting human and ecological health under a One Health paradigm requires approaches that move beyond siloed toxicological assessments. While human new approach methodologies (NAMs) generate rich mechanistic information, their relevance for ecological species remains unclear without a transparent biological bridge. Here, we present a key event (KE)–centric cross-species integration framework that operationalizes mechanistic conservation to translate human in vitro response data into ecologically meaningful evidence. Using two widely used consumer-product chemicals as case studies, we identified evolutionarily conserved KEs across endocrine signaling and cellular stress pathways. Human NAM assays were mapped to ecotoxicological endpoints based on mechanistic relevance, orthologous protein similarity, and Gene Ontology–based functional conservation. This enabled the generation of KE-aligned datasets spanning molecular, cellular, and organismal outcomes. Rather than constructing full quantitative species sensitivity distributions, we used KE-wise comparisons to evaluate how human-derived mechanistic thresholds complement or diverge from ecotoxicological sensitivity patterns. The results reveal that cross-species alignment is strongly KE-dependent rather than chemical-dependent. Nuclear receptor–mediated pathways showed consistent correspondence between human NAMs and ecological endpoints, supporting their use for filling data gaps. In contrast, stress-response KEs exhibited more divergent sensitivity patterns across taxa, highlighting the value of ecological assays in capturing species-specific vulnerabilities not reflected in human models. This KE-based strategy provides a transparent and scalable path toward mechanistic cross-species interpretation, enabling human NAMs to inform environmental protection while preserving ecological relevance. The framework demonstrates how conserved biology can anchor One Health–oriented risk assessment and illustrates the potential for mechanistic data streams to converge into integrated, interpretable evidence for chemical safety decision-making.

7.05.P-We436 Case Study-Led Evaluation of an Integrated Human Health–Environmental Next Generation Risk Assessment Framework

Claudia Rivetti¹, Maria Baltazar² and Bruno Campos², (1)Safety, Environmental and Regulatory Sciences (SERS), Unilever, United Kingdom, (2)Unilever, United Kingdom

While human health and environmental risk assessment have traditionally been related but separate disciplines, there is growing recognition of the benefits of increased integration to enhance scientific robustness, efficiency,

and decision-making transparency. The evolution of chemical safety assessment is increasingly shaped by the adoption of Next Generation Risk Assessment (NGRA) principles, which prioritise non-animal New Approach Methodologies (NAMs) which are applied alongside robust and refined exposure data and models. These advances have the potential to support a more holistic approach to risk assessment.

Here, we present a novel, tiered NGRA framework designed to integrate human health and environmental safety evaluations. The framework enables cross-domain alignment during exposure and hazard characterisation, supporting unified safety decisions. Early tiers leverage in silico tools and existing data to predict properties and toxicity mechanisms relevant to both human and environmental species. Tiers 1 and 2 incorporate a battery of NAMs spanning diverse biological and taxonomic domains, generating protective points of departure (PoDs) for species of interest.

The framework's utility is demonstrated using Benzophenone-3 (BP-3), a UV filter used in personal care products. In silico predictions indicated generic toxicity mechanisms, while in vitro bioactivity data from human- and fish-derived models were assessed alongside non-vertebrate in vivo data to define safe exposure levels. Human and environmental exposures were estimated using country-specific scenarios and physiologically based kinetic (PBK) models. Molecular homology tools are employed to evaluate the evolutionary conservation of biological targets and toxicological processes to support cross-species interpretation of bioactivity data.

While the framework aims to harmonise assessment strategies, differences in exposure assessment, protection goals, and species biology necessitate domain-specific considerations. This case study-led evaluation underscores the feasibility and value of an integrated NGRA framework, supporting more comprehensive, ethical, and scientifically robust chemical safety assessments aligned with 21st-century toxicology principles.

7.05.P-We437 A new Approach Methodology Integrating Human and Ecotoxicity Data to Assess Safer Chemical Alternatives in Consumer Products

Ajaya Kumar Sahoo and Jinhee Choi, School of Environmental Engineering, University of Seoul, Korea, Republic of

Consumer markets are increasingly globalized, driving a rapid increase in both the quantity and diversity of chemicals used in products. As a result, human exposure to chemicals from consumer products has become widespread and is often underestimated. Moreover, inadequate post-use management and the absence of ecosystem-centric policies contribute significantly to environmental pollution; for instance, chemicals from packaging materials and plastics are now pervasive across ecosystems. Therefore, it is essential to evaluate the risks posed by marketed products using new approach methodologies (NAMs), which can integrate human toxicity and ecotoxicity data to enable the identification and recommendation of safer chemical alternatives for consumer applications. In this study, we curated the chemicals present in the consumer products marketed in Korea. We then integrated human toxicity and ecotoxicity data for these chemicals from publicly available platforms such as ToxCast, eChemPortal, EnviroTox, and other resources to understand their potential hazards to human health and the ecosystem. A cheminformatics-based approach was employed to group these chemicals according to their structural features, scaffolds, and physicochemical properties, combined with NAM based toxicity endpoints. Additionally, we employed cross species sensitivity distribution (SSD) modelling to assess associated risks across different species and species groups. To further classify products, we integrated toxicity data with the United Nation's Globally Harmonized System for classification and labeling (GHS) enabling differentiation between data-informed safer and non-safer products. Thereafter, we performed life cycle assessment (LCA) for the identified non-safer products to evaluate their impacts throughout their life cycle. Finally, we proposed safer chemical alternatives by comparing our findings with the US EPA safer chemical ingredients list and other safer chemical initiatives across the globe. In sum, our findings highlight the value of integrating human and ecotoxicity data within the NAM frameworks to identify safer chemical alternatives, contributing to global initiatives for chemical safety and sustainability.

7.05.P-We439 Theoretical equations and statistical regressions for the median lethal and hazardous aqueous concentrations (LC50, HC50) and oral doses (LD50, HD50) as a function of octanol-water partitioning *K_{ow}*

Jan A.J. Hendriks¹, Venja Sandrine Anna Margit Schoenke¹ and Yen Le², (1)Radboud University, Netherlands,

(2)Department of Environmental Science and Technology, School of Chemistry and Life Sciences, Hanoi University of Science and Technology, Hanoi, Vietnam

Setting: Over the last decades, anthropogenic pressures on the environment have dramatically intensified and diversified. Nowadays, we have to deal with 100,000+ pollutants, sites and species.

Relevance: While models are available, application to thousands of cases is severely limited by data gaps due to financial, ethical, disciplinary and other constraints. In particular, exchange of data between ecotoxicology and human toxicology is restricted to a comparison of a couple of QSARs for LC50 in fish and LD50 in rodents.

Objectives: The aim of the present study is obtain theoretical and empirical relationships for common assessment endpoints, viz. single-species median lethal (LC50) and multi-species median hazardous (HC50) aqueous concentrations for aquatic species as well as oral doses (LD50, HD50) for rodents as a function of chemical properties (esp. Kow, m) that allow for a quantitative mechanistic interpretation. more from linear to non-linear relationships, from minimum to excess toxicity, from single- to multispecies endpoints and from concentrations to doses.

Methods: As we aim to cover many substances and species, we rely on generic rather than specific properties for our theoretical analysis, in particular molecular mass and octanol-water partition ratios. To reduce variability due to different conditions we used curated toxicity data. We assigned one mode to each chemical based on the information provided by models and databases based on the following procedure. We calculated intercepts, slopes, explained variance and significance for 11 common modes of action.

Results: Empirical single-species (LC50) and multi-species (HC50) concentrations were mostly within the theoretical envelope. With some exceptions, median lethal water concentrations for single- LC50 and multiple-species HC50 decreased statistically significantly as a function of the octanol-water concentration Kow. Slopes were steep and intercepts were high for some compared to other modes of action. Lethal doses LD50 and HD50 were (near-)independent of octanol-water partition ratios Kow.

Discussion: The theoretical and statistical relationships allow comparison of data for aqueous exposure of cold-blooded aquatic species and oral administration of rodents in a consistent and mechanistic way, rather than ad hoc correlations reported in the past. These relationships provide a framework to further integrate ecotoxicology and human toxicology in an empirical and theoretical sound way.

7.05.P-We440 Next-Generation Risk Assessment Application for Potential Endocrine Disruptor Evaluation in Consumer Chemical Products

Ji-Yeon Roh¹, Gaeul Yang² and Jinhee Choi², (1)Knoell Korea, Korea, Republic of, (2)University of Seoul, Korea, Republic of

Under the Korean Consumer Chemical Products and Biocides Safety Control Act (K-BPR), which began in 2019, the household chemical products subject to safety confirmation have been reduced from the existing 43 items to 30 items, as of December 2025. This change reflects the regulatory transition in which several categories—such as disinfectants, algacides, and repellents—will be shifted to the biocides approval regulations. Among the remaining 30 product categories, several household chemical products—such as laundry detergents and fabric softeners, cleaners, and deodorizing agents—continue to be included, and these products are used frequently in everyday life. In this study, we identified potential endocrine-disrupting chemicals (EDCs) based on household chemical products with verifiable ingredient information. We then examined the functions and roles of these substances within the products and categorized the level of concern according to their potential for exposure. The substances were initially prioritized using machine learning models designed to screen chemicals for their developmental and reproductive toxicity (DART) potential, through which candidates with possible endocrine-disrupting (EDCs) activity were identified. The results were categorized into two major groups: preservative biocidal active substances and other ingredient chemicals. For each classified substance, endocrine-disrupting potential was further evaluated using NAMs-based evidence obtained from the Tox21 database. In addition, exposure pathway information was collected and grouped according to product use patterns within the relevant regulatory context, enabling a systematic classification of substances that require further assessment. This study not only provides foundational information for identifying substances with potential endocrine-disrupting (ED) effects in household chemical products regulated as safety-confirmation items under the Korean biocides framework, but also demonstrates the applicability of next-generation risk assessment (NGRA). By presenting a case study that applies NAMs-based screening approaches in situations where available ED-related information is limited, the findings suggest the potential regulatory utility of NGRA methodologies.

7.05.P-We441 Estimating Combined Risk of Tetramethylammonium hydroxide (TMAH) and Co-Solutes in River Water

India is rapidly expanding in semiconductor chip manufacturing to push for the country's robust and sustainable technological infrastructure. However, this expansion also comes with environmental issues, which need proper mitigation and management to ensure long and sustained growth. This study focuses on the major pollutants of this industry sector, investigating the human risk assessment of these pollutants, interaction between them, and treatment strategies.

Semiconductor manufacturing releases toxic tetramethylammonium hydroxide (TMAH) and SiO₂ nanoparticles along with other heavy metals used for doping and other specific properties and PFAS coming out as byproducts. CMP processes generate high-stability nano-colloids. Environmental and human health risks remain insufficiently characterized. TMAH is a major pollutant; being a quaternary ammonium compound, its TMA⁺ cation is responsible for neurotoxicity, has a low LD50, and causes acute neurotoxicity. SiO₂-NPs exhibit contradictory toxicity data and have high environmental persistence. Combined presence of these pollutants in wastewater complicates treatment, raising the need for toxicology-based treatment optimization. Treated water from the treatment plants of these industries is being released into nearby water bodies, and the residual concentration of these pollutants should be monitored.

The plan is to first quantify acute human toxicity for TMAH using interspecies scaling and effluent concentrations. Multiple exposure pathways are to be considered for the interaction of humans with the pollutants in the water bodies. Risk estimation for TMAH and other co-solutes will be calculated for all the different exposure pathways to achieve a holistic approach to monitoring the risk for these pollutants. TMAH and its interaction with the ecological conditions of the region are to be considered to create ecologically sensitive zones. Then the toxicity indices of SiO₂-NP and major heavy metals coexisting with TMAH are to be compiled and analyzed. Data models for both acute and chronic toxicity studies will be prepared. Based on these combined risk assessment studies, a risk-treatment selection model is to be developed.

These model studies will help us make better assessments of environmental and ecotoxicological implications and identify regulatory inconsistencies. Based on the studies, if the risk is considerably higher, then specific targeted treatment methods will be developed and explored.

7.06.P Exploring Planetary Boundaries and Transformation Pathways for Novel Entities

7.06.P-Th300 Environmentally Safe and Just Pharmacy: A Framework and Action Plan for Operating Within the Earth System Boundary for Novel Entities

Alistair Boxall¹, Priyanie Amerasinghe², Michael Grant Bertram³, Sally Gaw⁴, Austin D. Gray⁵, Karen A. Kidd⁶, Laura M Langan⁷, Kenneth M.Y. Leung⁸, Jack Lewis Manera⁹, Karina Maglioranza¹⁰, Rik Oldenkamp¹¹ and Bryan W. Brooks¹², (1)University of York, United Kingdom, (2)IWMI, Sri Lanka, (3)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (4)University of Canterbury, New Zealand, (5)Virginia Tech, (6)McMaster University, Canada, (7)University of South Carolina, (8)City University Hong Kong, Hong Kong (Greater China), (9)Swedish University of Agricultural Sciences, Sweden, (10)Mar del Plata University, Argentina, (11)VU University Amsterdam (VU), Netherlands, (12)Baylor University, United States

Pharmaceuticals are vital for human and animal health, yet their widespread release into the environment contributes to the transgression of the "Novel Entities Planetary Boundary" and poses a significant threat to global ecosystems. This study introduces the concept of an "Environmentally Safe and Just Pharmacy," which integrates environmental protection and social equity, aligning with the "Safe and Just Earth System Boundaries" framework. We propose six overarching criteria and fifteen subcriteria that, if met, would ensure that pharmaceutical design, production and use do not contribute to exceeding the Novel Entities boundary. Based on a comprehensive review of existing data and knowledge, we conclude that current global practices for pharmaceuticals fail to meet many of our proposed criteria. The key findings are that environmental considerations are not systematically integrated into pharmaceutical design, manufacturing practices cause disproportionate pollution in vulnerable regions, and the continuous input of pharmaceuticals leads to widespread and persistent environmental contamination. We also confirm the significant contribution of pharmaceutical pollution to the global antimicrobial resistance crisis. To address this critical issue, we present a ten-point roadmap detailing necessary actions for a just transition to a sustainable future. The roadmap calls for global cooperation and includes strategic investments in sustainable molecular design, strengthening environmental risk assessment, improving wastewater treatment infrastructure, promoting responsible disposal and circular economy principles, and ensuring equitable access to pharmaceuticals for all societies. This

framework provides a qualitative foundation for future efforts to bring pharmaceuticals into an Environmentally Safe and Just operating space.

7.06.P-Th301 Methods to Assess Planetary Boundaries for Chemical Pollution - Interim and Future Approaches

Kristina Flexman¹, Caspar Corden², Rob Whiting², Karina Reynolds-Young², Miriam L. Diamond³ and Zhanyun Wang⁴, (1)Environmental Policy and Economics, WSP, United Kingdom, (2)WSP, United Kingdom, (3)School of the Environment, University of Toronto, Canada, (4)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The scientific literature indicates that chemical pollution may be threatening the global environmental conditions that have supported life throughout the Holocene. This threat could push Earth out its safe operating space, thereby breaching planetary boundaries. At the same time, there are large data and methodological gaps that inhibit our understanding of the full scale and nature of the environmental risks and impacts from chemicals and chemical pollution. The hazards and exposure for the 350,000+ chemicals used globally have only been assessed for a small fraction. The toxic effects of many chemicals on plants, animals, and humans are unknown.

Previous assessments of planetary boundaries for chemical pollution (e.g. Persson et al., 2022) conclude that planetary boundaries are exceeded because the rate of chemical safety assessment and monitoring cannot keep up with the rate of production and environmental releases. To date, no fully quantitative methods to assess planetary boundaries for chemical pollution have been applied at a global scale. Moreover, previous work generally looks at the uncertainties surrounding chemical risks and impacts, rather than evidence of disruption to Earth system functioning.

WSP is currently leading a study for the European Commission with three key components:

1. Reviewing existing methods for assessing planetary boundaries for chemical pollution.
2. Developing options to quantitatively define and assess planetary boundaries for chemicals, including methods which are not currently feasible based on available data and maturity of methods, but could be feasible in the future.
3. Developing and applying interim methods for an assessment of planetary boundaries for chemicals. These methods are based on existing data, without the need for new complex models.

The review of existing methods has been completed and draft options for methods have been developed. These options will be further refined through collaboration across the project team and with a scientific roundtable of experts. The study is due to complete in May 2026, and therefore the results are expected to be available to present at the SETAC meeting.

The output of the study is intended to further the concept of planetary boundaries for chemical pollution and influence future research and policy communication.

Disclaimer/Disclosure:

This study is commissioned by the European Commission (EC-ENV/2024/OP/0024).

7.06.P-Th302 Equity and Sustainability: Broader Implications of Downscaling Planetary Boundaries

Rodrigo Salvador¹ and Murillo Vetroni Barros², (1)Department of Engineering Technology and Didactics, Technical University of Denmark (DTU), Ballerup, Denmark, Denmark, (2)Universidade Estadual do Paraná, Brazil

As planetary boundaries (PB) gain traction as a framework for guiding global absolute sustainability, the challenge of translating these boundaries to actionable targets at national, sectoral, or company levels, known as downscaling, has become increasingly urgent. Therefore, this research aims to examine broader sustainability implications of applying different downscaling overarching principles, including equal per capita, sovereignty-based, capability-based, needs-based, historical responsibility, and ecological capacity-based approaches. Through synthesis and analysis of these overarching principles, we identify the broader sustainability implications of using these principles for downscaling PBs. While each overarching principle offers distinct ethical and operational advantages, their application raises complex trade-offs related to equity, governance, and systemic coherence. They may reinforce or undermine broader sustainability goals, such as intergenerational justice, global cooperation, and resilience across socio-ecological systems. We argue that uncritical application

of any single overarching principle risks fragmenting responsibility, exacerbating inequalities, or overlooking local contexts and systemic interdependencies. Our findings highlight the value of considering hybrid, context-sensitive approaches that balance fairness with feasibility, and global ambition with local relevance. Our research also draws on aspects that are not considered by these principles when downscaling PBs, including resource exchange (e.g., flows of physical resources and money), global flows, and cross-boundary effects, different local and regional biophysical limits, and intergenerational equity. This contribution aims to inform the development of integrated sustainability strategies that are both scientifically grounded and socially legitimate, supporting the pursuit of sustainable product and system innovation within planetary limits.

7.06.P-Th304 Getting to the Boundary: Collecting and Mapping Chemical Concentrations Globally

Anna Shalin¹, Lixi Wang², Matthis Schäfer³, Lin Boynton¹, Andrew Hicks¹, Derek C.G. Muir⁴, Zhanyun Wang⁵ and Miriam L. Diamond⁶, (1)University of Toronto, Canada, (2)Peking University, China (Mainland), (3)ETH Zurich, Switzerland, (4)University of Guelph, Canada, (5)Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland, (6)School of the Environment, University of Toronto, Canada

Novel entities are increasingly recognized as significant drivers of the triple planetary crisis of climate change, biodiversity loss, and chemical pollution. One way to address this has been through the planetary boundaries framework, first introduced by Rockström and colleagues in 2009, which has been an effective means of communicating the urgent need to maintain the biophysical stability and resilience of the Earth system on which society depends. Among these boundaries, chemical pollution, renamed “novel entities” by Steffen et al. (2015), remains a boundary that has yet to be quantitatively defined.

Building on Rockström et al.’s (2023) refined framework of “safe” and “just” boundaries, this poster presents recent efforts towards defining the “safe” (biophysical) boundary for novel entities, focusing on chemical pollutants.

To capture the ecotoxicological impact of chemicals at a global scale, as a proxy for Earth system disruption, we compiled a harmonized, global database of measured chemical concentrations across multiple environmental media (including air, surface water, groundwater, soil, biota, and sediment) from public databases and scientific literature, building off Isaacs et al.’s (2022) multimedia monitoring database. To support long-term, large-scale analyses, our open-access database was built in PostgreSQL, which enables efficient management of relational data, easy integration of new data, as well as extraction of chemical identities, environmental media, and geospatial attributes across millions of records.

We compared these concentrations against vetted ecotoxicological benchmarks collected from 37 countries to calculate unsafe exceedances expressed as risk quotients. Aggregating these data from regional to global scales enables identification of priority pollutants and geographic hotspots, which we visualize through spatial maps. This assessment provides the foundation for a meta-analysis aimed at informing the status of chemical pollution relative to a “safe” planetary boundary.

Disclaimer/Disclosure:

This research is part of the Earth Commission’s effort to define safe and just boundaries for the Earth system. The work of the Earth Commission, a program of Future Earth, is made possible through the support of Oak Foundation and the Global Commons Alliance, a sponsored project of Rockefeller Philanthropy Advisors.

7.06.P-Th305 Mapping Global Burdens of Novel Entities in People

Matthis Schäfer¹, Lin Boynton², Anna Shalin³, Lixi Wang⁴, Andrew Hicks³, Derek C.G. Muir⁵, Miriam L. Diamond⁶ and Zhanyun Wang¹, (1)ETH Zurich, Switzerland, (2)University of Toronto, Switzerland, (3)University of Toronto, Canada, (4)Peking University, China (Mainland), (5)No Affiliation, Canada, (6)School of the Environment, University of Toronto, Canada

Chemical pollution has been recognized as one of the major drivers of the triple planetary crisis of climate change, biodiversity loss, and pollution. The planetary boundaries framework introduced by Rockström et al. (2009) identified chemical pollution as one of nine boundaries that determine Earth’s stability and resilience, delineating a safe operating space for humanity. In 2015, Steffen et al. renamed and expanded the boundary of “chemical pollution” to encompass “novel entities.” While a qualitative argument made by Persson et al. (2022) suggests that global society is exceeding the boundary for novel entities, the boundary has not yet been formally quantified.

In 2022, the planetary boundaries framework was further refined by the introduction of “safe” and “just” boundaries. Safe boundaries describe the biophysical resilience and stability of the Earth system, while just boundaries refer to the maximum pressure that can be exerted on a system to minimize significant harm to humans. This poster presents a collation and analysis of human biomonitoring data aimed at advancing the development of a just boundary for novel entities.

We assembled a database of chemical biomarkers measured in human populations across different matrices (e.g., blood, human milk) from national and international human biomonitoring initiatives such as US NHANES and HBM4EU, complemented by additional data sourced from the scientific literature with a specific focus on low-income countries and vulnerable populations. All data are maintained in a PostgreSQL database, allowing integration of new data over time.

We identified unjust exceedances by calculating risk quotients from measured concentrations in our database and vetted health-based guidance values. Aggregating these data from regional to global scales allowed us to identify priority pollutants and geographic hotspots, which we visualized through spatial mapping. The findings further highlight significant data gaps. Our assessment establishes the basis for a meta-analysis toward defining a just boundary for novel entities.

7.06.P-Th306 Global Emissions of Selected Engineered Nanomaterials: Towards Defining Planetary Boundaries for Novel Entities

*Anna Lia S. Tromer Dragsdahl¹, Kerstin von Borries¹, Steffen Hansen¹, **Stig Olsen¹** and Arturo Keller², (1)Technical University of Denmark (DTU), Denmark, (2)University of California, Santa Barbara, United States*

Novel entities—including engineered nanomaterials (ENMs)—pose emerging challenges to Earth system resilience due to their potential persistence, toxicity, and global dispersion. While the planetary boundary framework has been proposed to define safe operating spaces for such substances, quantifying the boundary for ENMs remains elusive due to data gaps and methodological limitations. This study advances the absolute environmental sustainability assessment of ENMs by integrating global emission estimates with a removal rate model for nanomaterials in wastewater treatment systems.

Building on AquaQuant, a globally differentiated wastewater emission model developed in previous work, we estimate emissions for nano-silver, nano-titanium dioxide, and carbon nanotubes based on production volumes, uses, and regional wastewater infrastructure characteristics. Removal efficiencies are derived from literature, coupled with treatment technology distributions, and finally applied at a global scale, enabling an approximation of ENM discharge from wastewater to aquatic and soil environments.

The results are contextualised within the planetary boundary framework for novel entities and will aim to provide preliminary insights into whether current ENM emissions may exceed estimated safe thresholds. We discuss the implications for regulatory science, the need for harmonised monitoring approaches, and the importance of integrating diverse knowledge systems to advance boundary-setting for novel entities.

This work supports the development of an emission inventory by providing a scalable modelling approach that can link global emissions to human and ecosystem impact. It also highlights the importance of including vulnerable regions in global assessments, where data gaps may mask disproportionate exposure and risk.

7.06.P-Th307 Effect of anthropogenic nanoparticles on the fate of natural suspended particulate matter

Alice Pradel¹, Benoit Gaire¹, Hiba Lamguirisse¹, Véronique Lachaize², Arthur Gaveau², Brivaela Moriceau³ and Jerome Labille¹, (1)CEREGE, CNRS, Aix Marseille University, IRD, INRAE, France, (2)A5 Science, Technopole de l’environnement de l’Arbois Méditerranée, France, (3)Laboratoire des Sciences de L’Environnement Marin (LEMAR), France

Anthropogenic nanoparticles (ANPs), whether engineered or incidentally produced, are increasingly released into marine systems, yet their influence on Earth system processes remains poorly understood. Because suspended particulate matter (SPM) plays a central role in nutrient and carbon cycling, it is essential to know whether ANPs can modify the settling rate of SPM. This knowledge is key to defining a safe planetary boundary for ANPs.

This study examines whether, and how, ANPs can alter the settling rate of natural marine SPM. To do so, three model ANPs were selected for their abundance in the natural environment : nanoplastics, nano-black carbon, and titanium dioxide nanoparticles. First, their impact on SPM settling rate was measured using freshly collected SPM from Arctic waters, during shipboard experiments. Second, complementary laboratory studies assessed interactions between ANPs and components of SPM (polar microalgae and resuspended sediments) through measurements of adhesion forces, aggregation behavior, and changes in particle size.

Results show that nanoplastics accelerated settling of SPM by nearly 30 percent, while titanium dioxide nanoparticles produced a more moderate impact. However, nano-black carbon had minimal effect. Early mechanistic results suggest that enhanced settling is not primarily driven by the bridging of particulate matter by nanoparticles but may instead relate to the formation of large nanoparticle aggregates or the presence of residual micrometric particles in the ANP suspensions.

These findings indicate that certain novel entities can modify physical processes that regulate carbon and nutrient transport, highlighting a pathway of impact that extends beyond toxicity. Understanding such mechanisms is essential for assessing global-scale risks, informing the development of planetary boundaries for novel entities.

7.07.P Health and Well-Being Effects of Blue Spaces: The Ocean-Human Health Nexus in an Ocean Under Stress

7.07.P-Th308 The Nasal Microbiome as Exposome Biomarker in Belgian Coastal and Inland Inhabitants

Silke Lambert¹, Jan G. Bourgois², Greet Cardon², Colin Janssen² and Jana Asselman³, (1)Blue Growth Research Lab, Ghent University, Belgium, (2)Ghent University, Belgium, (3)Blue Growth Research Lab (BGRL), Ghent University, Belgium

Sea spray aerosols (SSAs), generated by bursting bubbles from breaking waves, contain a complex mixture of inorganic salts, marine microbiota and bioactive molecules. According to the “old friends” hypothesis, exposure to diverse microbiota at low concentrations may support immune system regulation rather than cause disease. At the same time, during Harmful Algal Blooms, SSAs have been shown to contain high concentrations of marine toxins leading to harmful respiratory health effects. Therefore, this study aims to identify which marine microbiota are present in inhaled SSAs, and to determine how SSA exposure shapes the human nasal microbiome. We seek to evaluate their potential as exposome biomarkers of coastal environmental exposure within a One Health framework.

We recruited 62 healthy adults (18–50 years) in Belgium divided into two groups: individuals living at the coast (>1 year) and inland (>1 year). Nasal swabs of the participants were collected at four time points over eight weeks, alongside weekly sea air samples. DNA was extracted from the nasal swabs as well as the sea air samples and Illumina sequencing was performed. Climate and GPS data were integrated to explore associations with nasal microbiome composition.

Results reveal distinct 16S nasal microbiome profiles between coastal and inland groups, with shared genera typical of human nasal microbiota (24%) and unique genera specific to each group (17% for the coastal and 11% for the inland group). Importantly, genera overlapping between sea air samples and coastal nasal swabs (13%) suggest that marine microbiota are present in the nasal cavity of coastal residents.

These findings suggest that living near the coast may lead to inhalation of marine microbiota, potentially influencing human health. Functional analysis of these genera is ongoing to assess their potential impact on human health. The temporal design allows investigation of microbiome stability, weather-driven fluctuations, and the role of individual behavior (e.g., time spent outdoors, physical activity) in shaping the nasal exposome.

This study supports the nasal microbiome as a non-invasive exposome biomarker to assess environmental exposure to natural ecosystems. In line with One Health, this work highlights how environmental microbial dynamics at the ocean-atmosphere interface can shape human health outcomes—underscoring the need to protect both ecosystem and respiratory health in an era of rapid environmental change.

7.07.P-Th309 Immunological responses to marine aerosols: the influence of bacterial abundance and endotoxin levels

Yunmeng Li¹, Wyona Schütte¹, Wannes Van Beeck², Max Dekeukeleire², Colin Janssen³, Nico Boon³, Jana Asselman⁴, Sarah Lebeer², Irina Spacova² and Maarten De Rijcke¹, (1)Flanders Marine Institute (VLIZ), Belgium, (2)University of Antwerp, Belgium, (3)Ghent University, Belgium, (4)Blue Growth Research Lab (BGRL), Ghent University, Belgium

It is increasingly recognised that “blue spaces” promote human health and well-being through psychological, physiological, and social benefits. Beyond these effects, sea spray aerosol (SSA) exposure may provide an additional pathway linking the ocean to human health. These aerosols contain diverse microorganisms and biogenic molecules that are presumed to interact with the human immune system, yet direct evidence of such interactions is lacking.

This study investigates whether human immune cells recognise and respond to marine bacteria present in SSA and whether that exposure may confer regulatory effects. Natural SSA were collected along the Belgian coast and complemented by laboratory-generated SSA. Bacterial and endotoxin concentrations were quantified, and human reporter cell lines were used to assess the activation of key immune receptors and transcription factors, including toll-like receptors (TLR4, TLR2/6) and the transcription factors NF- κ B and IRF. Concentration–response relationships were established, and assays combining a challenge test with SSA pre-exposure were used to examine potential immune priming effects.

SSA exposure induced dose-dependent activation of all immune pathways, with receptor activity correlating with bacterial and endotoxin levels. Pre-exposure experiments revealed non-linear effects: low-level SSA exposure tended to dampen responses to subsequent pathogen challenge, while higher exposures enhanced activation. This pattern suggests a complex balance between immune regulation and potential pro-inflammatory stimulation.

Our findings provide the first evidence that human innate immune cells detect and respond to marine aerosol microorganisms. These results suggest that low-level exposure to SSA may contribute to the health benefits associated with coastal environments, while high exposure levels could carry inflammatory risks. This work advances understanding of the biological dimension of ocean–human interactions and highlights the need to consider marine microbial aerosols in assessing coastal health effects.

7.07.P-Th310 Emotional Responses to Coastal and Urban Environments: an Immersive Video Experiment

Elias De Craene¹, Julia Kinet², Filip Raes³, Ann Buysse⁴ and Gert Everaert⁵, (1)Flanders Marine Institute (VLIZ), Division of Ocean & Human Health; Ghent University, Department of Experimental Clinical and Health Psychology; KU Leuven, Research Unit Behaviour, Health and Psychopathology, Belgium, (2)Ghent University, Blue Growth Research Lab (BGRL); Flanders Marine Institute (VLIZ), Division of Ocean & Human Health, Belgium, (3)KU Leuven, Belgium, (4)Ghent University, Department of Experimental Clinical and Health Psychology, Belgium, (5)Flanders Marine Institute (VLIZ), Division of Ocean & Human Health, Belgium

Although evidence for the health and well-being benefits of coastal environments is growing, the impact of these settings on affect and emotions remains unclear. Moreover, coastal areas are highly diverse and include distinct sub-environments that may evoke different emotional experiences. Understanding how the coast and its various sub-environments shape emotional responses is crucial for uncovering their therapeutic potential and informing evidence-based coastal planning. In this study, we conducted a randomized crossover experiment in which 60 participants watched eight sub-environmental videos within an immersive setting under two conditions: four coastal videos and, as a control condition, four urban videos. The coastal videos depicted a breakwater, the beach, the dunes, and the dike, while the urban videos consisted of two church scenes and two videos of aesthetically pleasing façades. For each video, participants provided four emotional state reports—two during the video and two post-exposure. During viewing, participants continuously reported their real-time valence and arousal level using a joystick, reflecting two core dimensions of affect. Following each video, they rated the degree to which they experienced two complex emotions: awe and connectedness to the environment. The experiments have been completed, and all data have been collected. In line with our expectations, preliminary results indicate that videos in the coastal condition yielded higher scores for valence, awe and connectedness to the environment, but also for arousal, where we initially expected lower scores compared to videos in the urban condition. The combination of more positive valence and higher arousal when watching the coastal videos suggests that participants felt more elated and happy compared to the urban videos. When

examining specific sub-environments, the dike video consistently produced lower scores across all outcome measures relative to some or all other coastal videos. A possible explanation for this is that the dike video was perceived as a less natural environment compared to the others, as it was the only coastal video that included built elements and the only one in which people were clearly passing by. These findings highlight the importance of distinguishing between coastal sub-environments when assessing their emotional impact, and they provide insights that may guide policy makers in the design of coastal spaces.

7.07.P-Th311 Marine Mammals Stranded In The Basque Coast Under The One Health Approach:

Anisakis Sp. And Avian Influenza

Manuel Soto¹, Denis Benito¹, Xabier Lekube¹, Xeiider Gerrikagoitia², Marta Barral², Iruñe Valenciano¹, Andrea Estarrona¹ and Urzi Izagirre¹, (1)Research Centre for Experimental Marine Biology and Biotechnology (PiE-EHU/UV), University of the Basque Country, Spain, (2)NEIKER – Basque Institute for Agricultural Research and Development, Basque Research and Technology Alliance (BRTA), Spain

When discussing the importance of marine mammals within the One Health perspective, among the main factors of interest are the zoonotic diseases and the presence of parasitic agents that could impact human activities and/or health. In the case of the zoonotic diseases the infection by influenza A virus has been frequently detected in marine mammals causing different grade mortality events. In the last years, the highly pathogenic avian influenza H5N1 virus has been rapidly expanding and infecting a new variety of avian and mammal species, including marine mammals, resulting in high mortality rates among pinnipeds and cetaceans. Among the most studied parasitic agents affecting marine mammals are the worms belonging to the *Anisakis* genus, as they infect intermediate hosts of commercial and gastronomic interest. These ubiquitous nematodes, well known gastrointestinal parasites, which use marine mammals as final hosts in their life-cycle, infest these when fish and cephalopods with their larvae are consumed. The aim of this work was to investigate the presence and impact of the mentioned parasites and virus in marine mammals stranded in the Basque Coast. For that purpose the stomach content of 21 specimen of 3 species of odontocetes (*D. delphis*, *S. coeruleoalba*, *P. phocoena*) stranded in the Basque Coast (2023-2025) were analysed to determine the prevalence and mean abundance of *Anisakis* sp. Other samples including hyssop collection (oral cavity, blowhole, anus) and frozen tissues (brain, lung, muscle, intestine) from 39 marine mammals were studied to evaluate the influenza A virus infection in the Basque coast from 2012-2024. Samples were collected by the Stranded Cetacean Network of the Basque Country (SAREUS) and were archived in the Biscay Bay Environmental Biospecimen Bank of the Plentzia Marine Station. Present results indicate that all species were infested with *Anisakis* sp. (prevalence ranging from 50-100%), massive loads being recorded mainly in *S. coeruleoalba*. In conclusion, these mammals can be considered as indicators of *anisakis* loads affecting fisheries and hence, human health. On the contrary, all samples were negative for influenza. Despite the negative results obtained, the continuation of the monitoring of the presence of *Anisakis* sp. and influenza virus in marine mammals, together with possible health affection due to the presence of environmental stressors (i.e. pollutants, global warming, interaction with human activities).

Disclaimer/Disclosure:

SAREUS project is funded by Fundación Biodiversidad (MITECO, PRTR, NextGenerationEU), and Basque Government. CBET+: IT1743-22 consolidated research group of the Basque Government).

7.07.P-Th312 Strategies for Healthy Ageing: Physiological, Psychological and Cognitive Responses to Coastal vs. Urban Exposure in Older Adults

Julia Kinet¹, Elías De Craene², Mazarine Six³, Sara Vandamme³, Mirko Petrovic⁴, Greet Cardon⁵, Jan G. Bourgois⁵, Colin Janssen³, Gert Everaert⁶ and Jana Asselman³, (1)Blue Growth Research Lab (BGRL) Ghent University, Flanders Marine Institute (VLIZ), Belgium, (2)Division of Ocean & Human Health, Flanders Marine Institute (VLIZ); Department of Experimental Clinical and Health Psychology, Ghent University; Research Unit Behaviour, Health and Psychopathology, Catholic University of Leuven, Belgium, (3)Blue Growth Research Lab (BGRL), Ghent University, Belgium, (4)Section of Geriatrics, Department of Internal Medicine and Paediatrics, Ghent University, Belgium, (5)Department of Movement and Sports Sciences, Ghent University, Belgium, (6)Division of Ocean & Human Health, Flanders Marine Institute (VLIZ), Belgium

With population ageing accelerating worldwide, maintaining functional ability through preventive health strategies is becoming increasingly important. In this context, exposure to natural environments has emerged as a promising contributor to physical and mental well-being. Although observational studies suggest multiple health benefits of coastal environments, experimental evidence remains limited. Research is particularly scarce on physiological and cognitive effects in older adults, as well as on distinctions between passive and active

exposure. To address these gaps, this field study examined how coastal versus urban exposure affects physiological, psychological and cognitive outcomes in older adults, comparing seated and walking conditions. In a within-subject cross-over design, 48 older adults (60–86 years, 54% male) completed both a coastal and urban exposure session, each consisting of a 15-min seated phase, followed by a 30-min walk. Physiological measures (salivary cortisol, heart rate and heart rate variability) were collected before, during, and after exposure. Self-reported stress and mood, as well as cognitive performance (visual attention and processing speed) were assessed before and after exposure. During recovery (20 min after the walk), sustained reductions in cortisol were observed only after coastal walking (–15%, $p = .008$), and parasympathetic activity remained elevated after coastal walking but decreased after urban walking (–13%, $p = .043$). Coastal walking was also associated with an overall reduction in perceived stress (post-pre contrast: –6.66, $p = .039$), improved visual attention (+38.91 test score points, $p < .001$) and larger gains in processing speed (+7.48 test score points, $p < .001$). Mood did not change significantly (all $p > .05$), as baseline positive mood was already high and negative mood was low, limiting the potential for further change. These findings indicate that coastal environments may provide added restorative value beyond physical activity alone, since coastal walking was associated with stronger physiological, psychological, and cognitive benefits than urban walking in older adults. Coastal walking may therefore represent an accessible, low-cost, and scalable strategy to support healthy ageing. Future research should clarify dose-response relationships, including the optimal duration and frequency of coastal exposure needed to achieve these health benefits.

7.07.P-Th313 A transdisciplinary framework to accelerate research on ocean-human health connections

Gert Everaert¹, Raf Aerts², Jan G. Bourgois³, Ann Buysse⁴, Adrian Covaci⁵, Maarten De Rijcke⁶, Eveline Diopere⁷, Alexander Hooyberg⁸, Carl Lachat⁹, Lies Lahousse¹⁰, Jan Mees⁶, Nathalie Michels¹¹, Michelle Plusquin¹², Filip Raes¹³, Karen Rappé⁶, Henk Roose¹⁴, Marine Severin¹³, Karen Van Campenhout¹⁵, Lynn Vanhaecke¹⁶, Colin Janssen⁷ and Jana Asselman¹⁷, (1)Ocean & human health, Flanders Marine Institute (VLIZ), Belgium, (2)Belgian Institute of Health, Belgium, (3)Ghent University, Department of Movement and Sports Sciences, Belgium, (4)Ghent University, Department of Experimental Clinical and Health Psychology, Belgium, (5)University of Antwerp, Belgium, (6)Flanders Marine Institute (VLIZ), Belgium, (7)Ghent University, Blue Growth Research Lab, Belgium, (8)Ghent University, Belgium, (9)Ghent University, Department of Food Technology, Safety and Health, Belgium, (10)Ghent University, Department of Bioanalysis, Belgium, (11)Ghent University, Department of Developmental Personality and Social Psychology, Belgium, (12)Hasselt University, Department Biology – Geology, Belgium, (13)KU Leuven, Belgium, (14)Ghent University, Department of Sociology, Belgium, (15)Government of Flanders, Department for Spatial Development, Environment, Belgium, (16)Ghent University, Department of Translational Physiology, Infectiology and Public Health, Belgium, (17)Blue Growth Research Lab (BGRL), Ghent University, Belgium

The ocean has long been associated with human health benefits and a general sense of wellbeing. Despite multiple historical and cultural remnants, such as sea sanatoria and thalassotherapeutic centra that proclaim an intrinsic positive connection between the ocean and human health and the ocean, we still lack comprehensive, evidence-based mechanistic and epidemiological data for these health effects.

The Ostend Working Group on Ocean-Human Health (OHH) presents an OHH framework to assess how ocean health relates to human health. The OHH framework is built around four key components: (a) ocean stimuli; (b) interaction with ocean stimuli; (c) individual sensing and processing; and (d) individual and collective health outcomes.

The OHH framework allows a holistic view on OHH research and integrates findings and perspectives from biological sciences, psychological sciences and social sciences into a transdisciplinary approach. Moreover, the OHH framework offers researchers a global OHH context and a systematic research approach that facilitates the harmonization of ad hoc research questions and associated hypotheses towards the shared objective of understanding the pivotal role of the ocean on human health.

The OHH framework is designed to support scientists, policymakers, and the public in investigating the intrinsic connection between ocean and human health. By promoting a holistic approach that prioritizes respect and care for the oceanic spheres, such as through integrated policies, it ultimately contributes to healthier ecosystems and communities.

7.07.P-Th314 One Health case study at the bay of Plentzia (Basque Country)

Oihane Diaz de Cerio¹, Nestor Etxebarria¹, Ionan Marigomez¹, Olga Hernández-Manrique², Andrea Albert², Aline Chiabai² and Marc Neumann², (1)Research Centre for Experimental Marine Biology and Biotechnology (PiE-EHU/UV), University of the Basque Country, Spain, (2)Basque Centre for Climate Change (BC3), Spain

This study explores the application of the One Health paradigm in the Plentzia estuary, aiming to integrate environmental, human, and ecosystem health through a Living Lab approach. The project was co-designed by researchers from PiE-UPV/EHU and BC3 to address complex socio-ecological challenges in coastal systems. Its main objectives were: (i) to investigate the dynamics of environmental pathogens and their relationship with climate change drivers and pollutants; (ii) to develop an extended One Health conceptual framework that captures interconnections between coastal pathogen changes and human, animal, and plant health; and (iii) to establish a One Health Living Lab (OHLL) as an open, participatory space for innovation and governance.

A comprehensive monitoring program was implemented in 2023–2024, including monthly and seasonal sampling in the estuary and bay. Water column profiles, chemical analyses, eDNA sequencing, and biological sampling (zooplankton, phytoplankton, phytobenthos, and sentinel species) were conducted alongside socio-economic assessments and wastewater effluent monitoring. Results revealed significant seasonal patterns: zooplankton abundance peaked in spring and summer, while phytoplankton composition varied more between bay and estuary than by depth. Notably, blooms of *Ostreopsis cf. siamensis* exceeded alert thresholds for the first time, coinciding with water temperatures above 20.5°C. *Vibrio* diversity and pathogenicity were highest in summer. Antibiotic resistance was prevalent below the halocline, with 52% of isolates being native marine bacteria, 24% potentially pathogenic. Biomarker analysis in oysters established reference levels for stress indicators, showing seasonal variability linked to salinity, temperature and contamination. Chemical monitoring revealed pharmacological compounds and pesticides in WWTP effluents, with seasonal trends aligned with rainfall. Socio-economic studies highlighted demographic patterns and beach usage peaks during summer.

The extended One Health framework integrated the DPSEEA model with participatory cognitive mapping, enabling visualization of interdependencies among environmental, biological, and social health determinants. Monitoring results fostered engagement with hospitals, public health agencies, water authorities, NGOs, and citizens, strengthening governance and knowledge transfer, and positioning the OHLL as a collaborative platform for sustainable innovation.

7.07.P-Th315 Microbial Hydrocarbon Degradation Potential of the Baltic Sea Ecosystem

Joesele Serrana¹, Benoit Dessirier², Francisco J. A. Nascimento³, Elias Broman⁴ and Malte Posselt⁵, (1)Department of Environmental Science, Stockholm University, Stockholm, Sweden, (2)Baltic Sea Centre, Stockholm University, Sweden, (3)Stockholm University, Sweden, (4)Department of Ecology, Environment, and Plant Sciences, Stockholm University, Sweden, (5)Department of Environmental Science, Stockholm University, Sweden

The Baltic Sea receives petroleum hydrocarbons from various point sources. The degradation of these contaminants in the environment is typically facilitated by a variety of microorganisms that possess a range of genes and metabolic functions related to the degradation of various hydrocarbon substrates. However, our understanding of natural attenuation and the microbial capacity to degrade these contaminants within the Baltic Sea ecosystem remains limited. In this study, we compiled metagenomes from the benthic and pelagic ecosystems across the Baltic Sea to identify microorganisms and characterize their genes and metabolic functions involved in the degradation of hydrocarbon compounds. Known hydrocarbon-degrading phyla, i.e., Pseudomonadota, Myxococcota A, Actinomycetota, and Desulfobacterota, were identified within the Baltic Sea metagenome-assembled genomes (MAGs). Notably, 80% of the MAGs exhibited multiple hydrocarbon degradation gene annotations (>10 reads per kilobase million). Aerobic degradation was the predominant pathway for hydrocarbon degradation across environmental samples. Hydrocarbon degradation gene abundances varied among samples and Baltic Sea subbasins, with long-chain alkanes and dibenzothiophene compounds being the preferred substrates. Species richness and diversity of both benthic and pelagic microorganisms positively correlated with hydrocarbon degradation gene diversity, with the pelagic ecosystem exhibiting significantly higher richness and diversity compared to the benthic ecosystem. Additionally, the composition of

the hydrocarbon degradation genes across the Baltic Sea subbasins was influenced by oil spill history, with areas that experienced higher spill volumes showing lower microbial diversity, suggesting potential enrichment of specific hydrocarbon degraders. Among the environmental factors assessed, depth played a significant role in shaping the composition of genes involved in hydrocarbon degradation within the Baltic Sea. This knowledge will aid in understanding the natural capacities of microbial communities, potentially linked to the natural attenuation of hydrocarbon pollutants in the area. Insights into microbial degradation potential can enhance predictions of petroleum pollutant persistence and accumulation, support mitigation strategies for marine pollution, and reveal the ecological resilience of native microbial communities in marine ecosystems.

7.08.P Holistic Sustainability Assessment: Innovative Approaches for Integrating Environmental, Societal, Health, and Economic Analysis for Decision-Making

7.08.P-Th316 A First-of-Its-Kind Ontology Supporting Safe and Sustainable by Design Decision-Making in the Plastic Value Chain

Arturo Hernandez Morales¹, Pedro Pablo García Pozo², Ángel Fuentes Almoguera², Francisco Manuel Pérez Morcillo² and Francisco López Guirao², (1)IDENER.AI, Mexico, (2)IDENER.AI, Spain

1. Background

Implementing Safe and Sustainable by Design (SSbD) principles in the plastic value chain demands coherent integration of heterogeneous information covering safety, environmental, economic, and social dimensions. However, the data underpinning these evaluations remain fragmented across databases, processes, stakeholders, and life cycle stages.

2. Objective

This work presents one of the first ontology-based frameworks specifically engineered to formalise the complex life cycle and assessment knowledge required to operationalise SSbD principles in the plastic value chain. The ontology provides a semantic architecture that structures domain information, integrates diverse type of data, and enables coherent evaluation across the four dimensions.

3. Methods

The ontology was developed using a modular approach aligned with the European SSbD Framework, combining a top-down translation of SSbD principles with bottom-up input from sustainability experts. It structures the plastic value chain into core domains: Component System, Life Cycle Phases, Processes, Subsystems, and an SSbD Assessment Framework, each formalising entities and relationships to represent material flows, process logic, and evaluation needs. Implemented using the Web Ontology Language (OWL), the model defines relevant classes, properties, and constraints, while a dedicated assessment module encodes indicators, system boundaries, and Technology Readiness Level (TRL) rules to adjust evaluation scope based on technological maturity.

4. Results

This ontology provides a harmonised representation of the plastic value chain, linking material flows, processes, and SSbD indicators in a coherent structure. Its TRL-based assessment logic enables evaluation depth to adapt to technology maturity, supporting both early-stage screening and comprehensive analysis. This structure improves data interoperability and supports integration into decision-support tools for SSbD implementation.

5. Conclusions

This first-of-its-kind ontology addresses the fragmentation of SSbD-relevant data in the plastic value chain by unifying life cycle and assessment information into a coherent semantic framework. By providing a structured backbone for data interoperability, the ontology supports the development of decision-support systems that can automate SSbD evaluations, guide material and process selection, and improve transparency in sustainability-driven design.

7.08.P-Th317 Material Bottlenecks in the Green Transition: The Case of Resource Criticality and Circular Design in PEM Electrolyzers

Gero Walter¹, Jana Gerta Backes², Achim Kampker¹, Heiner Hans Heimes¹, Julius Hausmann¹ and Sebastian Biegler¹, (1)Chair of Production Engineering of E-Mobility Components, RWTH Aachen University, Germany, (2)RWTH Aachen University, Germany

Green hydrogen will play a key role in the energy transition. In this regard, Proton Exchange Membrane Electrolyzers (PEMEL) are an important solution for its production, as they can track intermittent load profiles from renewable energy sources such as wind and solar. Despite their advantages, they depend on critical and strategic raw materials with a highly concentrated supply. The platinum group metals used as catalysts have the potential to act as a bottleneck during market scale-up. Alongside the imperative of sustainability, it is therefore essential for the assurance of a secure supply chain to implement R-strategies throughout the entire life cycle of PEMEL. The early market stage of PEMEL results in substantial variations in the composition of raw materials utilized, the design, and the implementation of condition monitoring of current systems on the market, which hinders the standardized implementation of R-strategies.

This work presents a comprehensive multi-criteria decision-analysis approach for identifying optimal circular strategies for PEMEL systems at various life cycle stages. Building upon the Resource States Framework, we systematically decompose PEMELs into product, part, and particle levels to map relevant R-strategies across each stage of use and end-of-life management. We propose a methodological approach combining life cycle sustainability assessment (LCSA), technological feasibility and criticality aspects, with dedicated supply chain analyses to capture the named parameters overlooked in conventional sustainability assessments.

The proposed holistic framework enables early identification of potential trade-offs among environmental integrity, economic and technological feasibility, and resource security and scarcity, thus informing policy development and industrial practice toward resilient PEMEL value chains. This facilitates the implementation of identified requirements for future economic systems, such as the implementation of a digital product passport or the targeted implementation of circular design.

7.08.P-Th318 Integration of Risk Assessment Results into a Holistic Evaluation of Remediation Solutions for Contaminated Sites – a Case Illustration at Tier 1 and Tier 2 Levels of Risk Assessment

Gabrielle Dublet-Adli¹, Michel Hubert², Elvia Rufo³, Silke Gabbert³, Emma Knight¹, Angelina Herzog¹, Marco Uzielli⁴, Erlend Sørmo¹, Gerard Cornelissen¹ and Hans Peter H. Arp¹, (1)Norwegian Geotechnical Institute (NGI), Norway, (2)Norwegian University of Science & Technology, Norway, (3)National Institute for Public Health and the Environment (RIVM), Netherlands, (4)University of Florence, Italy

Europe faces many contaminated sites, with an estimated 60–70% of soils considered unhealthy. These sites often require remediation to reduce risks to human health and the environment. Yet actions targeting one contamination problem may have variable efficiencies and unintended consequences on other contaminants, soil health, ecosystem services, land use, or the local economy. Tools are needed to help decision-makers distinguish between restorative and regrettable remediation. Existing frameworks assess risks to health and environment through tiered, stepwise approaches, progressively adding detail as contamination is characterized. A key challenge is integrating risk assessment results into transdisciplinary discussions with stakeholders at all stages, including early phases when scenarios are not yet chosen and contamination is poorly known. Flexibility of the framework is essential to incorporate risk aspects from the start, update information as it is collected, and adapt to diverse national regulations across Europe. In ARAGORN, risk assessment tools are developed to provide early risk metrics that can be integrated into holistic sustainability assessments. They enable Tier 1 evaluations based on soil concentrations, with straightforward upgrading to Tier 2 using site-specific data such as soil properties or concentrations in porewater, groundwater, or plants. Tier 1 results can support stakeholder discussions to identify and prioritize parameters requiring further investigation. A remediation add-on allows parametrizing theoretical effects of remediation scenarios, enabling early screening of options and prioritization of resources for site-specific tests. Results from these tests can then refine evaluation of remediation impacts on risk indicators. The presentation will describe the methodological approach for risk assessment and indicate how outcomes are integrated into a socio-economic decision-making framework. A case study will illustrate the methodology, conditions of applicability, and limitations. These aspects will be discussed in relation to other existing tools. Finally, the potential for ARAGORN tools to be further developed and applied will be outlined, along with future work to integrate them into co-creation and transdisciplinary efforts in soil remediation,

7.08.P-Th319 Economic Sustainability Assessment of Sea Bass Feed with Black Soldier Fly Meal: Integrating ESM, TEA, and I-O Models”

Marta Ferreira Dias¹, Jefferson Souza², Fernando Reis¹ and Paula Quinteiro³, (1)GOVCOPP, DEGEIT,

University of Aveiro, Portugal, (2)DEGEIT, University of Aveiro, Portugal, (3)CESAM, University of Aveiro, Portugal

Recent environmental policies have placed greater emphasis on the use of more sustainable products and technologies, thereby increasing the need for integrated assessments capable of guiding these decisions. In this context, insect-derived products are a sustainable alternative, but require analysis of economic, social, and environmental impacts throughout their life cycle. This study assesses the economic sustainability of sea bass feed produced with Black Soldier Fly (BSF) meal, integrating methods that complement Life Cycle Assessment to support more robust decisions.

The challenge is to understand and to analyse how an innovative product compares with a conventional alternative in terms of direct, indirect, and economic welfare effects. The work combines three approaches: the Economic Surplus Model (ESM), which estimates gains for producers and consumers; Technical-Economic Analysis (TEA), to assess financial viability; and the Input–Output (I-O) model, which calculates impacts on production, wages, and imports in the Portuguese economy. The data refer to 2025 and have been normalized to 1 ton of product.

The results show that conventional aquafeed has an economic impact of €1.73 per €1 invested, whereas BSF aquafeed has an impact of €1.58, reflecting a lower impact on the Portuguese economy in this food chain. Despite this, BSF aquafeed has a lower cost of approximately 8.85% per ton (€882.18) compared to conventional aquafeed (€967.86). Import dependency is similar: 30.16% for conventional aquafeed and 32.85% for BSF aquafeed. The impact on remuneration is also very similar, with values of around 33.64% (BSF) and 33.38% (conventional). In the ESM, aquafeed (BSF) shows greater welfare gains per ton (

7.08.P-Th320 Comparing and Prioritizing Measures for Remediating Polluted Soils: A Holistic and Integrated Framework for Socio-economic Analysis

Silke Gabbert¹, Elvia Rufo², Gabrielle Dublet-Adli³, Ali Kanso⁴, Marco Uzielli⁵, Dorina Podar⁶, Alexandre Perleir⁴, Gaylord Machiner⁴, Michel Hubert³, Carmen Roba⁶, Cristina Lorena Vacar⁶, Nicoleta Brisan⁶ and Yasmine Zaki Abdelaziz⁷, (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)RIVM, Netherlands, (3)NGI, Norway, (4)Microhumus, France, (5)University of Florence, Italy, (6)Babeş-Bolyai University, Romania, (7)ICONS, Italy

Soil contamination caused by single contaminants or mixtures affects both ecosystem organisms and humans. Negative impacts on ecosystems and human health can spread from local to regional, continental, or even global scales, and can last for decades or even centuries. Furthermore, soil contamination can cause high welfare losses to society, e.g. a decline in the healthy living environment for terrestrial and water organisms; reduced availability of healthy food and drinking water along with corresponding clean-up costs; increased treatment costs for certain diseases; and costs resulting from the loss of ecosystem services. Addressing soil contamination, therefore, is a multi-dimensional social challenge. Soil remediation denotes all management actions that aim to remove degradation (e.g., detoxify areas with contaminants or excess nutrients from soil and water) to achieve safe and stable environments. Remediation is then followed by restoration actions to suitably achieve the target 'reference model' of the site according to its desired long-term use. A number of technologies for soil remediation and ecological restoration have been developed. Decision-makers such as land-owners, local municipalities or stakeholders have to compare technically available remediation options and restoration scenarios, and identify the scenarios which are most appropriate.

This study introduces a holistic framework for socio-economic analysis (SEA) to compare and prioritize soil remediation and restoration scenarios. The framework provides guidance on how information about hazards and environmental and human health risks of soil pollution can be transformed into comprehensive outcomes such as positive and negative impacts, the change of ecosystem resilience, and corresponding social costs and benefits of remediation measures. This transformation process is facilitated by input from experts, local stakeholders and citizens, making SEA a co-creative process instead of a purely one-directional analysis. Furthermore, it is shown how positive impacts are to be balanced against negative impacts, and against the costs of soil remediation and restoration scenarios. SEA results in transparent decision rules in order to identify the remediation and restoration scenario which is socially (most) beneficial. Finally, the framework describes how the assessed positive and negative impacts, benefits and costs of soil remediation can be transformed into spatially explicit information.

7.08.P-Th321 The ARAGORN Decision tree - guidance for remediating and restoring contaminated soils through co-creation and integrated risk, socioeconomic and resilience assessment

Mari Engvig Løseth¹, Gabrielle Dublet-Adli², Michel Hubert², Elvia Rufo³, Silke Gabbert³, Emma Knight², Marco Uzielli⁴, Erlend Sørmo⁵, Gerard Cornelissen⁶, Xenia Trier⁷ and Hans Peter H. Arp⁶, (1)Norwegian Geotechnical Institute (NGI), Oslo, Norway, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)National Institute for Public Health and the Environment (RIVM), Netherlands, (4)Università di Firenze, Italy, (5)NMBU, Norway, (6)NGI, Norway, (7)University of Copenhagen, Denmark

Managing contaminated land is a complex challenge, as the best remediation or management approach is not always evident. A holistic evaluation must go beyond assessing current contamination risks to include the potential impacts of remediation strategies, life cycle considerations, socio-economic implications, and resilience to future changes such as climate variability or evolving land use. Addressing these dimensions is critical to avoid regrettable remediation and ensure long-term ecological and economic value. The ARAGORN project introduces the ARAGORN Decision Tree, a structured tool designed to guide landowners and stakeholders through this process. The decision tree integrates regulatory requirements, risk assessment, and sustainability principles into a practical framework for informed decision-making. It consists of three main phases:

- Phase 1: Pre-Assessment

- o Step 1a: Determine when to investigate soil contamination based on national regulations and practices.
- o Step 1b: Analyze boundary conditions, including intended land use, timeframes, economic constraints, and stakeholder interests.
- o Step 1c: Assess contamination status using standardized risk analysis guidelines

- Phase 2: Defining Needs and Goals

Evaluate the necessity for remediation and restoration by coordinating risk assessments with socio-economic and resilience analyses to identify benefits and objectives.

- Phase 3: Monitoring Progress

Track key indicators and socio-economic goals to ensure remediation and restoration actions remain on course.

Throughout all phases, the decision tree emphasizes alignment with EU and national regulatory contexts, stakeholder co-creation, and the use of dashboards for spatial planning and indicator tracking. By combining technical, environmental, and socio-economic perspectives, ARAGORN provides a robust decision-support system that bridges science, policy, and practice, contributing to sustainable land management and resilience.

7.08.P-Th322 Towards Healthy Soils: A Decision Support Tool for Sustainable Remediation Practice

Michel Hubert¹, Gerard Cornelissen¹, Emma Knight¹, Gabrielle Dublet-Adli¹, Erlend Sørmo², Hans Peter H. Arp¹ and Angelina Herzog¹, (1)Norwegian Geotechnical Institute (NGI), Norway, (2)Norwegian Institute of Life Science (NMBU), Norway

Persistent and bioactive pollutants pose a major challenge to soil health in Europe, where an estimated 60–70% of soils are considered unhealthy. Despite ongoing EU initiatives aiming for healthy soils by 2050, remediation remains complex and interdisciplinary, involving stakeholders, problem owners, and regulators. Different technologies modify key parameters in distinct ways—for example, soil washing reduces total contaminant concentrations, sorbent amendments lower bioavailable fractions, and top cover systems decrease infiltration rates. Selecting an appropriate method is further complicated by site-specific constraints such as soil texture, contamination extent, and the diverse behaviours of persistent contaminant groups. So far, helpful decision-support systems for selecting adequate remediation options are missing.

In this study, we developed an Excel-based remediation tool that serves as a user-friendly, cross-disciplinary decision-support system. The tool quantifies changes in risk-related parameters, which can be manually integrated into existing human health and environmental risk assessment frameworks to estimate risks after remediation. Its database is built on a structured literature review and expert input from ARAGORN project partners. The tool covers eight remediation methods—excavation and containment, capping, monitored and enhanced natural attenuation, phytoremediation, emerging bioremediation using nanomaterials, biochar and Fe-

based sorbents, chemical reduction, and soil washing—and evaluates their effects on four contaminant groups: Per- and Polyfluorinated substances (PFAS), organochlorinated and brominated substances (OCBs), petroleum and coal substances (PETCO), and metals.

Based on site- and contamination-specific inputs, the tool identifies feasible remediation options and provides quantitative estimates of how each method influences parameters relevant for risk assessment. Users can compare how strategies affect bioavailability, emissions, or mobility for different contaminant groups before and after remediation.

This remediation add-on is designed to complement existing risk assessment tools and represents a step toward a holistic framework for soil restoration that integrates human and environmental perspectives. It supports evidence-based decision-making for sustainable soil management across disciplines.

7.09.P Implications of Climate Change for Agriculture Ecosystems: What Does It Mean for Plant Protection Product Risk Assessments and Agricultural Practices?

7.09.P-Th324 Mitigating Climate Stress in Tea Cultivation: Monitoring Conventional vs. Eco-friendly Strategies for Environmental Risk Assessment and Crop Resilience

Jehn-Yih Juang, National Taiwan University, Taiwan (Greater China)

Climate change poses significant threats to established agricultural systems, particularly for sensitive high-value crops like tea (*Camellia sinensis*) in Taiwan. Rising temperatures and increasing extreme weather events are shifting agroecological boundaries, challenging farming practices, and altering environmental risk landscapes regarding pest dynamics. To develop actionable knowledge, it is critical to quantify how agricultural practices, specifically conventional versus eco-friendly approaches, modify the crop microenvironment and influence environmental risks.

This study uses long-term in-situ eddy-covariance (EC) monitoring to investigate the impact of management strategies on the microclimate and energy fluxes of tea fields in Northern Taiwan. We compared a conventional operation field with an eco-friendly (organic-certified) field to assess impacts on "field-level" climate resilience. Observations reveal a stark contrast in energy partitioning: the eco-friendly field exhibited 10% lower sensible heat flux and 25% higher latent heat flux (evapotranspiration) than the conventional field. Crucially, the eco-friendly practice demonstrated superior buffering of environmental extremes; the diurnal range of canopy temperature in the conventional field was 1.6°C higher than in the eco-friendly field, indicating higher susceptibility to heat stress.

While the eco-friendly practice resulted in a higher daily soil water loss rate (0.97% d⁻¹ vs. 0.45% d⁻¹), it successfully reduced vapor pressure deficit (VPD) and temperature variation within the canopy. These differences are pivotal for risk assessment. The hotter, more variable microenvironment in conventional fields may exacerbate pest outbreaks and alter the degradation and environmental fate of plant protection products (PPPs), potentially increasing spatiotemporal heterogeneity and uncertainty in exposure and risk. Conversely, the cooler, more humid microclimate in eco-friendly fields suggests a stabilizing effect. These findings provide a scientific basis for farmers to adopt eco-friendly strategies that conserve the ecosystem and manipulate the microclimate to reduce vulnerability under changing climatic conditions.

7.10.P Innovative and Transdisciplinary Approaches to Eliminate Hazardous Chemicals and Develop More Sustainable Chemicals and Materials

7.10.P-Th325 Towards a Safe, Sustainable and Sufficient Chemistry

Romain Figuière¹, Kerstin von Borries² and Joanne van Dijk³, (1)Department of Environmental science, Stockholm University, Sweden, (2)Technical University of Denmark (DTU), Denmark, (3)TEMAS Solutions, Switzerland

In October 2020, the European Commission published a Chemical Strategy for Sustainability (CSS) to better protect citizens and the environment while ensuring the competitiveness of the European chemical industry

where they proposed, among others, to phase-out uses of the most harmful substances, unless proven essential and to encourage the development of chemicals and materials which are safe and sustainable by-design (SSbD). Together with alternatives assessment processes, the essential-use concept and the SSbD frameworks are tools which could be applied to help limit the uses of harmful chemical substances and encourage the implementation of alternatives with limited impacts on the environment and human health. The main goal of this study is to systematically compare these concepts to clarify their respective scopes, methodologies, and decision-making functions to determine how they could complement each other to support a coherent, science-based decision-making process for reducing chemical risks and promoting sustainable chemical innovation within planetary boundaries by analyzing their respective guidance documents to identify potential similarities and differences between the frameworks.

Based on our findings, we believe that the different frameworks could be implemented sequentially to limit development and uses of harmful chemical substances. The effort for substitution could be focus only on functions which are necessary to the final products and society by applying the essential-use concept first. Such evaluation can be followed by an assessment of alternatives to determine whether potential safer and suitable alternatives delivering similar functions are already available. The SSbD framework can then be applied to design new chemicals or materials only if it is not the case.

We believe that such approach could be implemented in a regulatory context when restricting uses of a substance of concern. We also believe that this approach could be applied on a voluntary basis by companies seeking to (re)design their products and minimize impacts to the lowest level necessary to achieve the intended product function.

7.10.P-Th326 Enhancing Hazard Assessment in Safe and Sustainable by Design: The Case of Mistra SafeChem

Ziye Zheng¹, Swapnil Chavan², Ioannis Liagkouridis¹, Ioana Chelcea² and Maja Halling¹, (1)Swedish Environmental Research Institute (IVL), Sweden, (2)Research Institutes of Sweden, Sweden

Safe and Sustainable by Design (SSbD) is an emerging European approach aimed at guiding the development of chemicals and materials that are safe throughout their life cycle while supporting broader sustainability goals. A central pillar of SSbD is early-stage hazard assessment, yet this step is frequently limited by incomplete data and slow or resource-intensive testing. In silico tools therefore play a critical role in enabling proactive chemical design and informed decision-making.

Within the Swedish research programme Mistra SafeChem, we have developed a comprehensive in silico hazard prediction toolbox that provides calibrated and validated predictions for 35 human health and environmental endpoints using large, up-to-date datasets and uncertainty estimation supported by conformal prediction. The toolbox includes multiple machine-learning and deep-learning models and offers consensus predictions with quantified uncertainty through a user-friendly interface. Alongside model development, Mistra SafeChem has designed several SSbD case studies with industrial partners that apply these tools to real-world chemical and material innovation challenges, demonstrating practical integration of in silico hazard assessment into SSbD workflows.

To support broader SSbD implementation, we also apply established tools such as VEGA, the OECD QSAR Toolbox and other widely recognised predictive systems. These tools complement the Mistra SafeChem in silico Toolbox by enabling read-across, mechanistic exploration, applicability-domain analysis and integration of additional regulatory-relevant endpoints. Together, this suite of models enables more robust and transparent hazard evaluations.

Across both Mistra SafeChem and several EU SSbD-focused research projects—including PARC, TORNADO, BioSusTex and CheMatSustain—we investigate how in silico modelling can fill key data gaps, prioritise safer chemical alternatives and guide targeted experimental follow-up. Results show that consensus modelling strategies can improve predictive accuracy, while applicability-domain assessments reveal limitations: some case-study chemicals fall outside the coverage of current ecotoxicity models, highlighting the need for expanded training datasets and refined modelling approaches.

Overall, the combined use of complementary in silico tools provides an efficient and scalable foundation for SSbD hazard assessment, supporting reduced testing needs and accelerating sustainable chemical design.

7.10.P-Th327 Predicting Hazard Statements Under the Classification, Labelling and Packaging Regulation Using Conformal Prediction and Molecular Representations

Ulf Norinder¹, Ziye Zheng² and Ian Cotgreave³, (1)Orebro University, Sweden, (2)Swedish Environmental Research Institute (IVL), Sweden, (3)Research Institutes of Sweden, Sweden

Effective communication of chemical hazards is essential for protecting human health and the environment, yet many substances lack sufficient experimental data to support reliable hazard classification under the European Union Classification, Labelling and Packaging (CLP) regulation. This study addresses the challenge of predicting hazard statements (H-statements) for human health and environmental endpoints by developing non-animal computational models trained on regulatory-compliant data extracted from the European Chemicals Agency Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) registration dossiers. We constructed machine-learning models using Random Forest classifiers combined with Mondrian conformal prediction to provide calibrated confidence estimates for each prediction. Multiple molecular featurization strategies were investigated, including N-grams, molecular fingerprints, and extended connectivity descriptors, and were further combined using consensus modelling approaches based on class votes or median conformal prediction p-values. The models were trained and evaluated across ten hazard-statement groups comprising thousands of classified and non-classified substances with standardized SMILES structures. Results show that most featurization strategies produced valid conformal predictors, but ensemble consensus models consistently achieved the highest performance. At a typical significance level of 0.2, many models provided efficiencies near or above 80%, indicating a high proportion of informative single-label predictions. Balanced accuracy, sensitivity and specificity were robust across endpoints, and N-gram-based descriptors proved particularly advantageous for representing diverse chemical structures, including those containing metals and salts.

These findings demonstrate that combining conformal prediction with complementary molecular representations enables reliable and transparent prediction of H-statements under the CLP regulation. The resulting models support chemical hazard assessment, read-across applications and risk management, offering a practical in silico tool to reduce the need for new animal testing while improving accessibility to hazard information.

The European Commission's Safe and Sustainable by Design (SSbD) framework aims to integrate safety and sustainability considerations early in chemical innovation. Bisphenol A (BPA) and two alternatives, Bisphenol AP (BPAP) and Isosorbide, were selected as substances in this fictitious case study to evaluate the framework's applicability in polycarbonate and epoxy resin applications.

The challenge was to determine whether existing tools could support decision-making under conditions typical of early innovation, where data availability is limited. To address this, 22 tools included in the PARC SSbD toolbox developed in the PARC project were tested across the following parts of the assessment: hazard identification, worker and environmental risk, consumer risk, environmental sustainability, and socio-economic impact. Tools were mapped to innovation stages to identify their suitability for early versus late development phases.

Methods included predictive modeling for hazard endpoints, exposure estimation for production and use phases, life cycle assessment for environmental impacts, and social life cycle assessment and lifecycle costing for socio-economic risks, emphasizing the importance of supply-chain considerations. The approach emphasized minimal data requirements and integration of multiple tools into model pipelines.

Results show that hazard assessment tools can provide early screening with limited input, while exposure models for production and application phases vary in complexity and conservatism. Environmental sustainability assessments highlight significant differences in life-cycle impacts among substances, and socio-economic analysis reveals strong regional influence on social risk outcomes. Across the full assessment, the case study demonstrates that tool applicability and reliability depend on data availability and integration strategies.

In conclusion, the findings confirm that the EC SSbD framework can guide early-stage innovation and provide actionable insights for chemical substitution. Importantly, the results inform improvements to the PARC SSbD Toolbox, enhancing its usability and relevance for innovators and regulators seeking safer and more sustainable solutions.

7.10.P-Th329 Using Machine Learning Approaches to Understand Microbial Metabolism of Pharmaceuticals within the Environment to Facilitate Design for Degradation in Medicinal Chemistry
Roisin Murphy¹, Helen Sneddon¹, Alistair Boxall¹ and Irene Bramke², (1)University of York, United Kingdom, (2)AstraZeneca, Netherlands

Within Green Chemistry, the concept of 'benign by design' is of particular interest, with the 10th principle of Green Chemistry, 'design for degradation' suggesting that there should be effort put into designing chemicals and products to degrade at end-of-life. Pharmaceuticals in the environment (PiE) are considered a global threat, both to ecological and human health, and therefore require an environmental risk assessment (ERA) at the point of EU marketing approval. However, the degradability of pharmaceuticals in the environment is not currently considered in R&D.

In this poster, machine learning techniques and models are presented that could be utilised to assess environmental degradability of a molecule before synthesis has even begun. The aim of this modelling is to produce a useful tool for medicinal chemists that can guide design choices, alongside the other computational tools utilised during the initial multiparameter optimisation processes in early stages of drug development.

By using publicly available biodegradation data obtained from the Organisation for Economic Co-operation and Development (OECD) Ready Biodegradability, Inherent Biodegradability and simulation tests, machine learning models were built in order to successfully classify the biodegradation potential of small molecules. The models achieved high balanced accuracy across both binary and multi-class classification tasks. From these models, structural insights could be extracted through the use of SHapley Additive exPlanations (SHAP) to suggest moieties that would enhance the biodegradability of a chemical. The applicability domains of these models were discussed, with exploration of chemical fingerprint similarity, nearest neighbors analysis and model confidence suggestion. Furthermore, counterfactuals were generated from the model to suggest structural modifications on the individual case, which may inform design. Although, due to the limitations of the training data available, the modifications generated may lack biological relevance, which is why this research is best utilised with the insight of an experienced medicinal chemist.

The proposed thinking could enable the collaboration between environmental risk assessors and medicinal design chemists in order to design non-persistent pharmaceuticals during the early stages of drug development, extending beyond current "rules of thumb" for degradation potential.

7.10.P-Th330 Optimized Throughput in Aquatic Ecotoxicology: A Platform for Early-Phase Assessment of Agrochemicals

Hannes Armin Reinwald, Marc-Sven Roell and Thorsten Leicher, Bayer Research & Development, Germany

To support the “Safety by Design” paradigm, the development of next-generation crop protection products relies on robust, high-quality ecotoxicological data generated during early phases of compound development. This comes with two challenges: the need to evaluate hundreds of molecules and their metabolites within a single chemical class, and the often very limited quantities of compounds available due to the time- and cost-intensive nature of de novo synthesis. While computational models offer scalable approaches for chemical hazard assessment, their reliability is fundamentally dependent on the quality and breadth of experimental data particularly for novel chemical classes outside established applicability domains. These constraints highlight the critical need to scale up ecotoxicological hazard assessments without compromising data quality or regulatory relevance.

To address these challenges, BAYER’s Early-Environmental Safety (eEnSa) Department has developed a high-throughput aquatic ecotoxicology screening platform that enables parallelized acute toxicity testing in miniaturized well-plate formats. The platform supports simultaneous testing of six regulatory-relevant aquatic species (*D. magna*, *C. riparius*, *Desmodesmus* sp., *Raphidocelis* sp., *L. gibba*, and *W. arrhiza*). Through parallelization and miniaturization, the amount of compound required for all six assays is reduced to as little as 1 mg or less, making comprehensive screening feasible with limited material within a short period of time. Automated liquid handling, dilution series preparation, and compound application ensure high reproducibility and standardization, while integrated image analysis algorithms enable objective and efficient endpoint quantification. Preliminary validation with sets of reference compounds demonstrated strong concordance with endpoints reported in the PPDB or the EPA’s ECOTOX Knowledgebase, confirming the reliability of the approaches.

This platform generates high-quality, comparable data to serve as a foundation for future predictive modeling and supports early identification and prioritization of safer crop protection candidates. Advancements in automated video tracking, image analysis, and data processing will further increase throughput and sensitivity, enabling earlier detection of sublethal and behavioral endpoints. This approach advances efficient, data-driven hazard assessment within the safety-by-design framework for plant protection product development.

7.10.P-Th331 Image processing and acquisition for the automated assessment of ecotoxicological effects

Rainer Kathan and Hannes Armin Reinwald, Bayer AG, CropScience, Germany

For the development of new crop protection active ingredients, we at Bayer Crop Science pursue the "Safety by Design" approach. This requires conducting ecotoxicological environmental hazard assessments for hundreds of molecules at an early stage of research.

Classical evaluation methods cannot guarantee this throughput without significant personnel resources and also introduce subjective interpretation possibilities. Therefore, we strive for a high degree of automation in biological assays to optimize data acquisition and apply modern algorithms.

Our system automates data acquisition and processing, thus ensuring the necessary throughput. The frame rate can reach up to 70 frames per second (FPS), and with a 96-well multititer plate, we achieve a resolution close to full HD per well. These technical features enable precise analysis of various organisms using image and video recordings.

The developed software allows for standardized and repeatable analysis of the recordings. Multiple organisms in a single well can be segmented, counted, and tracked. The current state of development makes it possible to determine movement patterns, distance, speed, and length, for example, of *Daphnia* sp. as well as determining the size or pigmentation of *Wolffia* sp. Automated image recognition and tracking enable the reproducible detection of sublethal effects, increasing the throughput of biological assays. Furthermore, the archived image data allows for the continuous improvement of evaluation metrics using new algorithms, eliminating the need to

repeat experiments. In the long term, our approach aims to detect sublethal effects and develop models for predicting chronic ecotoxicological studies.

I declare no conflict of interest.

The research and development was sponsored by Bayer AG Division Crop Science.

7.10.P-Th332 Safety aspects of novel fluorine-free coatings under the SSbD framework

Ioannis Liagkouridis, Rosella Telaretti Leggieri, Ziye Zheng, Ottavia Ring, Sara El Ghamri, Gunnar Thorsén and Håkan Stripple, Swedish Environmental Research Institute (IVL), Sweden

Concerns over the impacts of per- and polyfluoroalkyl substances (PFAS) on human health and the environment and resulting regulatory restrictions have created a pressing demand for benign alternatives within coating applications where PFAS are commonly used. Aligning with the EU Green Deal and Chemicals Strategy for Sustainability strategies towards a circular economy and a toxic-free environment the TORNADO project aims to develop innovative PFAS-free coatings that are safer and more sustainable than current PFAS-based water- and oil-repellent coatings for use in the packaging, textile, and kitchenware sectors. To ensure that the novel coatings meet safety and sustainability criteria, TORNADO aligns with the European Union's Safe and Sustainable by Design (SSbD) framework. The innovation thus proceeds in parallel with an SSbD assessment. The safety assessment in line with the SSbD framework is addressed by the authors. As a first step, a comprehensive hazard assessment of the intrinsic properties of the chemical and materials involved in the synthesis of TORNADO coatings has been performed using a combination of scientific literature and in silico QSAR-based prediction tools. The assessment is continuously updated with new substances added to align with developments in coating synthesis. As a second step, a human health and environmental risk assessment of the manufacturing and processing steps within TORNADO was conducted. The assessment employed the Chemical Agency's Chemical Safety Assessment and Reporting (CHESAR) tool and its integrated models for human exposure and environmental fate, including the ECETOC Targeted Risk Assessment (TRA) and the European Union System for the Evaluation of Substances (EUSES). Since several chemicals involved in the processes are new or uncommon, leading to challenges in the collection of input data for risk assessment tools, a workflow for data collection was set up involving the use of both literature data and in silico predictions. Finally, the risk assessment of the use phase of TORNADO coatings is currently ongoing, in parallel with an evaluation of their chemical footprints throughout their life cycle using USEtox. At the same time, the broader environmental, social, and economic impacts are assessed by partners in the project, and a full SSbD assessment in line with the framework will be produced through a joint effort in early 2026.

Disclaimer/Disclosure:

The TORNADO project received funding from the European Union's Horizon Europe research and innovation programme under grant agreement No. 101091944.

7.11.P Regulatory Implications of Digital (Precision) Agriculture: Environmental Risk Assessment in Time and Space

7.11.P-Mo437 Precision application of pesticides in agriculture: update of the European Precision Application Task Force (EUPAF) for field crops

Anne Alix¹, Jonas Schartner², Anne Steenbergh³, Bernhard Gottesbüren⁴, Peter Lhoben⁵, Patrick Pagani⁶ and Corné Kempenaar⁷, (1)Corteva Agriscience, United Kingdom, (2)Federal Office of Consumer Protection and Food Safety, Department of Plant Protection Products, Unit Environment, Germany, (3)Dutch Board for the Authorisation of Plant Protection Products and Biocides (Ctgb), Netherlands, (4)Make-Sense Consulting, Germany, (5)CEMA, Belgium, (6)Copa Cogeca, Belgium, (7)BO Akkerbouw, Netherlands

An update of the work of the European Precision Application Task Force (EUPAF) on precision pesticide applications in European field crops is proposed. This update outlines the task force's structure, approach, findings, and implications for regulatory risk assessment and sustainable agriculture. Established in June 2023, EUPAF comprises 127 experts from 60 organizations across 19 countries, aiming to integrate precision application technologies with regulatory frameworks for plant protection products. It is organized into five task groups addressing inventory, use descriptions, risk assessment, and case studies. The task force compiled a

detailed inventory of precision application techniques used in two-dimensional field crops, categorizing them into band, patch, and spot applications, with variable rates possible within each category. This inventory includes traditional and new technology sprayers and reports usage reduction percentages. TG2 developed standardized descriptions and dedicated language for Good Agricultural Practice (GAP) tables used in regulatory dossiers, based on existing EPPO and ISO definitions, and prepared a supporting handbook and glossary. Precision applications generally reduce exposure risks by lowering application volumes and targeting treatments, though factors like application location, resolution, and timing also influence exposure to crops and non-target organisms. Current risk assessments use realistic worst-case scenarios, but EUPAF proposes tailored assessments reflecting precision use benefits. The task force is working on refining exposure assessment methods by incorporating treated area and developing more complex models that integrate real-time parameters such as weather and geolocation to enable situation-specific risk assessments. Finally, data are collected to create case study documents illustrating precision use categories, serving as practical templates for regulatory contexts. Precision application technologies can contribute to reducing the environmental footprint of plant protection products and support sustainable agriculture, but they require evolving regulatory assessment models to quantify benefits and support decision-making. EUPAF aims to provide foundational scientific elements for this evolution.

7.11.P-Mo438 Ecotoxicological Implications of Precision Spray Technologies: Challenges and Opportunities

Alice Tagliati, Gareth Le Page, Chloe Eastabrook and Emma Tilston, Enviresearch Ltd., United Kingdom

As part of the UK Health and Safety Executive's initiative to develop a robust independent pesticides regulatory system for Great Britain, a report was commissioned to explore how precision spray methods might impact the ecotoxicological risk assessment of non-target organisms (NTOs) under the GB regulatory framework.

The aim of this report was to evaluate the implications of applying the current ecotoxicological risk assessment framework to precision spraying practices, specifically spatially variable rate applications, band, and spot spraying, and to identify knowledge gaps. Our analysis focused on key organism groups: birds and mammals, bees, non-target arthropods, soil organisms, and non-target plants.

Precision application techniques introduce spatial heterogeneity in pesticide distribution within fields and off-field habitats, creating opportunities for risk refinement, but also new challenges. For some birds and mammals, chronic risk can be refined if accounting for foraging patterns and habitat overlap, while acute risk cannot be refined. Although bee colonies may benefit from lower overall pesticide use, their high mobility limits the reduction of exposure for individuals, and spray drift remains a concern. Non-target arthropods (NTAs) and soil organisms show potential for recovery from untreated refugia, but population-level effects depend on species ecology and recolonisation dynamics. For non-target plants, untreated areas and buffer zones may provide meaningful mitigation, though drift-driven impacts persist.

Overall, precision spraying can reduce overall pesticide input and offers a pathway to align crop protection with biodiversity goals. However, current ecotoxicological frameworks assume uniform exposure and do not capture spatial variability or recovery potential. Integrating precision technologies into risk assessment will require new ecological data, refined exposure factors, and standardised approaches to account for species-specific traits and landscape-level effects. This work highlights the need for a paradigm shift in ecotoxicology, moving from uniform exposure assumptions toward dynamic, spatially explicit assessments that reflect modern agricultural practices.

7.11.P-Mo439 Recent Developments in Spray Drift Modelling for Precision Applications

Jenny Deng¹, Henk Jan Holterman² and Koen van Boheemen¹, (1) Wageningen University and Research (WUR), Netherlands, (2) Agrosystems Research, Wageningen University and Research (WUR), Netherlands

Precision application of plant protection products (PPPs) is a promising way forward in pesticide application, since it has the potential to reduce the amount of PPPs applied and to reduce the exposure of different off-field areas and non-target organisms to PPPs. Precision application for crop protection could play a role in the exposure assessment of PPPs in the authorisation process. Basically, variable-rate and spot-spraying

applications can be distinguished. In a variable-rate application the whole field is treated while the dose is varied to meet the conditions of each location in the field. In a spot-spraying application for each in-field location the decision is made whether or not a (full dose) spray application is required. This study deals with the modelling of the downwind deposits of spray drift after a PPP precision application. With precision applications, the downwind deposits not only depend on the environmental conditions but also on the application technique, including the geometry and layout of the treated spots in the field. Recent model developments focused on establishing a spray drift metamodel that can account for varying environmental conditions and spray application conditions, including drift mitigating techniques. The model can be used for both variable-rate and spot-spraying applications. Downwind deposits of spray drift are evaluated at off-field evaluation strips, such as adjacent watercourses or non-target terrestrial areas. Downwind spray drift deposits depend on the location and distribution of the treated in-field areas and the dose rates applied. Wind direction is the major environmental parameter involved. Example computations indicate that drift reductions with precision applications can be higher or lower than the reduction based on reduced amount of PPP. The spray drift model can be used on a single-field scale but it also has potential to be used in exposure assessment on a regional or national scale. In this way, the model can help to assess exposure to spray drift in a regulatory context.

7.11.P-Mo440 SPOTMOD: Simulation of run-off exposure from precision application by mechanistic modelling with VFSSMOD

Robin Sur¹, *Jorge Olivares-Rivas², Stefan Reichenberger³, Tyler J. Schultz⁴ and Rafael Muñoz-Carpena⁵, (1)Bayer AG, Germany, (2)knoell Germany GmbH, Germany, (3)knoell France SAS, France, (4)University of Florida, United States, (5)Agricultural and Biological Engineering, University of Florida, United States*

Field “spot treatments” of agrochemicals, e.g. by automated weed detection in combination with precision application technology, can significantly reduce chemical input on the field. Localized, high-resolution chemical application reduces off-field drift and surface runoff to adjacent water bodies and terrestrial habitats compared to broadcast application. While quantification of drift reduction is advancing, very limited work exists for the quantification of potential pesticide runoff reduction from spot application practice in the scientific and regulatory context.

The untreated field area can act as a sink for dissolved and adsorbed pesticides before the surface runoff exits the field, thus leading to a reduction of pesticide runoff and erosion losses additional to the effect of reduced applied mass. A new 2D mechanistic modeling framework, SPOTMOD, has been developed that considers i) sources: pesticide runoff generation from treated spots in the field, ii) sinks: infiltration, sedimentation and pesticide trapping on downslope segments of the field, iii) variable vegetation conditions during the cropping period and their effects on infiltration and sedimentation, iv) variable spot size and treated area fraction, v) variable spatial application patterns ((quasi)-random and observed), vi) long-term exposure calculations (PEC_{sw}). In a first step, an application pattern on the field is generated based on spot size and treated area fraction (or a real infestation pattern is imported). The field is then divided into strips in slope direction with the same width as the treated spots. These strips are subsequently simulated with a coupled PRZM-VFSSMOD modelling system, which can deal with complex sequences of treated spots (sources) and untreated areas (sinks) along the flow path. For each runoff event, the edge-of-field runoff hydrographs and associated sediment and pesticide loads are summed up and fed into a TOXSWA metamodel. Different realizations of the application pattern allow to construct a probability distribution of PEC_{sw} for each event and thus identify realistic worst-case application patterns. Parallel optimization of SPOTMOD on a High-Performance Computer allows for systematic exploration of key settings. An end-user solution around a metamodel is also developed using machine learning. The SPOTMOD metamodel is expected to make a significant contribution to the establishment of field-specific risk assessment/management approaches.

7.11.P-Mo441 Digital Farming - opportunity for landscape-specific risk management

Balthasar Smith¹, *Burkhard Golla², Jörn Strassmeyer³, Jens Wegener⁴ and Jonas Schartner¹, (1)Federal Office of Consumer Protection and Food Safety (BVL), Germany, (2)Julius Kühn Institute (JKI), The Institute for Strategies and Technology Assessment, Kleinmachnow, Germany, (3)Julius Kuehn-Institute - Federal Research Centre for Cultivated Plants, Germany, (4)Julius Kühn Institute (JKI), Application Techniques in Plant Protection, Braunschweig, Germany*

The authorisation of plant protection products (PPPs) in the European Union ensures a high level of protection for humans and the environment in accordance with legal requirements (Regulation (EC) 1107/2009). PPPs may only be authorised if it can be ruled out that they have unacceptable effects on the environment.

PPPs may only be authorised if it can be ruled out that they have unacceptable effects on the environment. In accordance with the uniform principles (Regulation (EU) 546/2011) it must be observed whether this protection

target can be achieved by directions of use if risks have been identified in the risk assessment. These conditions of use include the risk mitigation measures specified in the authorisation of a plant protection product (see also Regulation (EU) 1107/2009 – 36 (3) 3. (...) appropriate conditions may be imposed with respect to the requirements referred to in Article 31(3) and (4) and other risk mitigation measures deriving from specific conditions of use.

The presentation will explore two key questions:

- What requirements must risk mitigation measures meet in order to be implemented?
- What opportunities does "digital farming" offer for further developing area-specific risk management?

For the drift entry path, an established model is used to determine entries into non-target areas, which is based on the drift values according to Ganzelmeier and Rautmann 1995 et al.. Depending on the spraying technique used, this model shows a fixed relationship between distance and expected concentration.

This makes it very well suited for area-specific risk management in a landscape context. The opportunities offered by digital farming, taking into account GIS data and a pesticide application manager (see also projects such as PAM, OPAL), are highlighted. Consideration is given to which of the aforementioned requirements can be positively influenced here.

Finally, the question is raised as to what development opportunities digital farming offers for establishing more advanced risk mitigation measures with a greater reduction effect, such as greater distances of 30 m to surface water bodies with the simultaneous use of drift-reducing technology.

This should contribute to the discussions on digital tools and models to include site-specific information into risk management and assessment, ensuring that current procedures are prepared for future challenges.

7.11.P-Mo442 Field specific risk management for plant protection products: a “digitalized” way forward

Gunnar Kahl¹, Andrew C. Chapple², Frank Scherr², Robin Sur² and Thomas G. Preuss², (1)knoell Germany GmbH, Germany, (2)Bayer Research & Development Services LLC, Germany

Smart farming technologies and usage of farm management information systems implementing detailed geospatial data are used more and more commonly in agriculture. The authorization approach of plant protection products in Europe does not currently make use of these advances. A 90th percentile protection goal is currently often established based on a few realistic worst-case scenarios. Within this process the products receive authorization and mitigation requirements on the product label, which usually cover all fields, no matter if the field is very vulnerable or not. This is a pragmatic approach that may lead to sufficient protection of most fields while at the same time other fields are accepted as being underprotected.

To overcome the limitations of the currently implemented generalized approach, a transformation of the current risk assessment scheme towards a digital driven field specific risk management is proposed in three phases, which would be introduced step by step. The risk assessment procedure on EU and member state level would remain in large parts as it is. All three phases make use of the availability of farm management information systems to distribute field specific restrictions and mitigation requirements. In phase 1 the mitigation requirements, based on standard regulatory scenarios (e.g. FOCUS), are transferred to the specific fields which present the closest similarities to the given scenario with respect to soil and climate conditions. In phase 2, field specific modelling is performed where the standard parameterization can be adapted to local conditions. In phase 3, geospatial data are used to derive field specific parameterizations for the exposure and effect models. In all phases, each field receives application restrictions and mitigation requirements depending on the local situation which the farmers can fulfil by combining different mitigation options from a mitigation toolbox. With a field specific risk management, the protection goal is respected, and the protection level can be increased by imposing additional mitigation or application restrictions to vulnerable fields. These vulnerable fields could now be identified and receive specific protection rather than being treated like all other fields. The proposed system would decrease both overprotection of non-vulnerable areas (allowing optimised pest control and resistance management) and underprotection of vulnerable areas (by inducing field specific risk management options).

7.11.P-Mo443 Innovating Environmental Risk Assessment for Precision Agriculture and Drone Application Technologies: Emerging UK Regulatory Considerations

Melissa Reed¹, Claire Glennie², Pamela Johnson², Amy Stewart² and Grant Stark², (1)Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom, (2)Health and Safety Executive (HSE), United Kingdom

Approaches to authorising plant protection products (PPPs) need adapting to more accurately characterise the risks associated with the application of PPPs using new technologies. The UK is currently exploring how we can adapt existing approaches for precision agriculture and applications by drones.

Precision applications have the potential to minimise the amount of PPP needed to provide effective control giving environmental benefits. Minimising use has the potential to reduce environmental exposure to non-target organisms which could be considered in the risk assessment, but the level of this reduction is uncertain and will depend the ecology of the species of concern. This poster covers some of our experience with different types of precision applications and explores the extent to which the risk assessment can be refined based on current knowledge and where new data and / or tools will be required.

Application via drone has different advantages and risks. They can be beneficial when the area to be treated is inaccessible for example in railway cuttings and bridges providing a safer working environment for operators. However more information is needed on exposures from spray drift as this will differ from conventional equipment. It is also not known if there is potential for increased soil exposure as a result of rotor down draft pushing the PPP through the vegetation layer, or removing PPP deposited on leaf surface from previous spray passes. HSE is working with industry to ensure suitable data are generated to support the regulatory process.

7.11.P-Mo444 Precision Pesticide Application and the Risk to Soil Organisms

Emma Tilston, Alice Tagliati and James Garratt, Enviresearch Ltd., United Kingdom

As part of the HSE's work to develop a robust independent pesticides regulatory regime for Great Britain this desk study investigated the change in risk profile of soil-dwelling organisms, under conditions of precision application, compared with whole-field application. Precision application practices will result in heterogeneous exposure where exposure frequency, duration and intensity will vary in ways that will alter the actual exposure to which different individuals of a population may be exposed. This differs from the current approach which assumes uniform application across the whole field and where spatial and temporal variability are largely ignored, as are chemical and organismal traits that enable recolonisation.

The current EU risk assessment framework was evaluated for three scenarios: 1) variable rate application based on a pre-defined map, on a spatial scale of >10 m, 2) pre-defined band spraying over crop rows, on a spatial scale of ~1 m and 3) spot or patch spraying, on a spatial scale of <1 m.

Knowledge of four aspects of organism ecology were identified as being required for the evaluation of risk:

- 1) the extrapolation of laboratory toxicity endpoints to field conditions
- 2) the spatial distribution of soil organisms
- 3) the mechanisms and rates of dispersal (and hence recolonisation potential) of soil organisms
- 4) the impact of agricultural practices on the spatial distribution and dispersal of soil organisms

It was concluded that the continued use of the current approach to risk assessment would be conservative. Calculations based simply on reduced average application rates would not provide an adequate level of protection. For earthworms and micro-arthropods, recolonisation is a plausible refinement option for band and spot applications, but an unaffected population in the untreated area(s) would need to be demonstrated. For microorganisms, in the absence of soil disturbance (tillage) natural recolonisation is unlikely to be fast enough to lead to recovery within regulatory acceptable timescales, thus refinement based on recolonisation would not be appropriate.

Ideally, an expert working group should be formed to (re)define protection goals and to specify acceptable recolonisation endpoints for target taxa. New, bespoke studies on the spatial variation of soil physico-chemical properties, soil organism distributions and recolonisation timescales as appropriate endpoints for risk assessment are required to address knowledge gaps.

7.12.A Solutions from Source to Sink: Preventing, Removing, and Managing Pollution Across the Plastic Continuum

7.12.A.T-01 Household Micro- and Nanoplastics: Sources, Determinants, and Opportunities for Intervention

Amanda A Durkin¹, Barbara M. Scholz-Boettcher², Lisa Charlotte Balding², Virissa Lenters³, Bente Santbrink¹, Runyu Zou¹, Ulrike Gehring⁴ and Roel Vermeulen⁴, (1)University Medical Center Utrecht, Netherlands, (2)Carl von Ossietzky University of Oldenburg, Germany, (3)Vrije Universiteit, Netherlands, (4)Utrecht University, Netherlands

Human exposure to micro- and nanoplastics (MNPs) remains poorly characterized, particularly regarding factors that influence inhalation exposure indoors. We focused on women of reproductive age, as pregnancy and early life are critical windows of heightened vulnerability to environmental contaminants. We conducted an observational study among 105 women in the Netherlands. Passive indoor dust samples were collected in glass petri dishes at baseline and after 3 months. Pyrolysis–gas chromatography–mass spectrometry quantified MNP composition and mass. Questionnaires captured sociodemographic and household factors, and environmental data were linked to home addresses. Determinants of MNP deposition were examined with multivariable mixed-effects linear regression. We detected MNPs in all samples, reported as clusters related to the respective quantifiable base polymers and accordingly include copolymers on a proportional basis. Polyethylene terephthalate (C-PET), polystyrene (C-PS), and polypropylene (C-PP) were most commonly detected with deposition rates up to 27.69 µg/m²/day. C-PET accounted for 80% of total deposition, while the next most abundant polymers, C-PP and C-PE, contributed 6.4% and 6.3%, respectively. Repeated samples collected three months apart showed fair reliability (ICC = 0.44). Higher deposition was observed in multi-person vs single-person households, and during fall and winter vs summer, whereas more living space per person was associated with lower deposition. Determinants explained up to 46% of the variance in MNP deposition. This study is one of the first in-depth assessments of determinants of indoor MNP deposition. We identified several consistent factors influencing exposure, explaining a substantial proportion of variability, although specific indoor sources remain largely uncharacterized. We hypothesize that C-PET and C-PP originate from textile fibers, which were visually evident in the processed sample but not fully captured in the questionnaire. Evidence-based strategies for exposure mitigation remain limited. While deposited dust samples provide a reliable measure of household exposure, source identification requires more targeted approaches and questionnaires offer only limited information. These findings lay the groundwork for future studies to refine exposure assessment and develop actionable interventions, including design improvements, behavioral modifications, and household strategies to reduce exposure to indoor MNPs.

7.12.A.T-02 Reducing Microplastics Emissions from Clothing and Footwear – A Dynamic Probabilistic Material Flow Analysis Study

Anne Hids¹, Joris T.K. Quik¹, Yvette Agnes Maria Mellink² and Anne van Bruggen¹, (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Wageningen University and Research (WUR), Netherlands

Microplastics from clothing and footwear contribute to the growing plastics pollution problem. Actions from consumers, industry and policy makers can reduce the emissions of microplastic. Information on effectiveness of specific mitigation measures should facilitate this. In this study, thirteen mitigation measures aimed towards reducing the microplastic emissions from clothing to the environment were analysed for their emission reduction potential. This was done using an existing modelling approach using material flow analysis (RIVM report 2024-0106), which for the first time included footwear.

Consumption of clothing is estimated to have released 290 ton (250 – 340 ton) microplastics and Footwear 140 ton (120 – 160 ton) of microplastics to the environment in the Netherlands for 2022. In Europe consumption and manufacturing of clothing is estimated to release 8100 ton (7100-9200 ton) and footwear 3100 ton (2600 – 3700 ton) of microplastics to the environment. This excludes emissions outside of Europe, e.g. due to manufacturing or end of life textile exports. Most clothing emissions enter the environment through outdoor air, mostly due to wear and tear of clothing. The second largest sink for clothing is surface water, which is caused by microplastic loss during washing or drying. For footwear, the largest environmental sink are soils because of shoe sole wear. Four of the thirteen mitigation measures aimed at microplastics loss had a reduction potential higher than 10% compared to the baseline in 2050, assuming a stringent degree of implementation. The mitigation measure with the highest reduction potential were (i) replacing synthetic materials with natural materials (ii) improving fabric quality to reduce microfiber release during wearing, washing and drying of garments; (iii) increasing the

lifetime of garments, combatting fast fashion and (iv) using more delicate washing regimes. A second scenario aimed at less stringent implementation, e.g. voluntary, showed largely the same effectivity of measures, but at a much lower reduction.

It is up to stakeholders in the textile value chain (e.g. policy makers, industry and consumers) to implement mitigation measures. Their cooperation is needed to this and realize the highest potential emission reduction. It is recommended to extend this analysis to include other environmental impacts and assess cost-effectivity of selected measures.

7.12.A.T-03 Advancing Plastic Release Modeling: Quantifying Macro- and Microplastic Emissions Across 30 European Countries and Incorporating Microplastic Size Distributions

Danyang Jiang and **Bernd Nowack**, *Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland*

The global presence of plastics is a major environmental challenge of the 21st century. Addressing this issue requires detailed knowledge of environmental emissions. Material flow analysis (MFA) combined with release assessments enables quantification of plastic releases across the entire product life cycle. In this study, we developed a plastic release model based on MFA for the EU27, Switzerland, Norway, and the United Kingdom, comprehensively quantifying macro- and microplastic emissions of LDPE, HDPE, PP, PS, EPS, PVC, and PET for 2020. The model consists of ten aggregated product sectors, 45 product categories, 12 waste collection systems, and six recycling systems, accounting for 456 emission flows across all life stages. Geographical differences in emission factors, linked to consumer behaviors and waste management practices, were observed across countries.

For Europe as a whole, the emission factor was $0.187 \pm 0.018\%$ for macroplastics and $0.0404 \pm 0.0030\%$ for microplastics. The emission factors vary widely between countries. Microplastic emissions to soils range from $0.047 \pm 0.010\%$ in Latvia to $0.019 \pm 0.003\%$ in Belgium. Subsurface soil receives microplastics mainly from sewage leakage and construction pipe use, with Romania showing the highest emission factor ($0.008 \pm 0.003\%$). Macroplastic emission factors are higher than microplastic overall, with soil as the main receiving compartment, ranging from $0.52 \pm 0.18\%$ in Greece to $0.04 \pm 0.01\%$ in Lithuania.

We further incorporated microplastic size distributions into the model, including pellets, microbeads, fiber shedding, fiber production, weathering, and abrasion. We found that microplastic emissions in Europe primarily consists of particles in the 2–5 mm size range in terms of mass, largely resulting from agricultural plastic use and recycling. Peaks between 0.1 and 2 mm were also observed, resulting from various MP emission pathways. Varied size patterns for different polymers were observed, reflecting their different uses. This study provides a solid basis for identifying key plastic emission sources and guiding policies to mitigate plastic pollution in Europe. The size-specific results can be integrated into fate modeling and used to support risk assessment studies.

7.12.A.T-04 Removal of microplastic from sedimentation tanks by use of in-situ microflotation (ISM)

Stefan Grass, **Mareike Löffler**, **Sophie Rischmüller**, **Marina Huber-Gedert**, **Christina Marx** and **Mike Wenzel**, *MicroBubbles GmbH, Germany*

The progressive sealing of urban areas has led to an increased surface runoff that transports pollutants, including microplastics (MP), to connected aquatic ecosystems. In this context, tire wear particles (TWP) and tire road wear particles (TRWP) are considered as the most abundant MP class. Due to the growing awareness of the toxicity of microplastics and associated pollutants of TRWP, the upstream treatment of surface runoff in sedimentation tanks prior to discharge into water bodies is becoming particularly important. In detail, the fine particulate fraction of total suspended solids $< 63 \mu\text{m}$ (TSS63) is contaminated with micropollutants, including MP. However, previous studies have shown that existing stormwater tanks frequently lack efficiencies for TSS63 (Sandoval et al., 2023). In general, the sedimentation efficiency of small particles is expected to be lower due to their high mobility.

In response to these issues, a monitoring with a pilot built using in situ-microflotation (ISM) has been developed and successfully transferred from the laboratory to the targeted use case. The results show that we were able to observe a greatly increased elimination of TSS63 and TWP for the ISM compared to the used sedimentation tank without ISM technology. The microflotation retrofit resulted in a substantial enhancement in performance, achieving TSS63 efficiencies ranging from 55 % to 80 % across a range of hydraulic loadings from 0.5 to 10 m/h, highlighting the independence from hydraulic loading. Regarding the removal of tire wear particles, microflotation achieved an average removal rate between 63 % and 81 % was achieved over a period of nine month. ISM is a scalable and modular solution for enhancing the removal of fine suspended solids and microplastics from urban stormwater. The capacity to be retrofitted into existing infrastructure or integrated into

new designs provides a considerable degree of flexibility for municipalities and utilities. In view of increasing anthropogenic pollution from urban surface runoff to water bodies, this is an important step forward for more sustainable water management and less environmental pollution.

7.12.B Solutions from Source to Sink: Preventing, Removing, and Managing Pollution Across the Plastic Continuum

7.12.B.T-01 Towards Safer Food Packaging: Tackling Microplastics, Chemicals and Protecting Human Health

Lisa Zimmermann¹, Birgit Geueke¹, Christoph Schuer², Etienne Cabane¹, Justin Michael Boucher¹, Martin Wagner³ and Jane Muncke¹, (1)Food Packaging Forum, Switzerland, (2)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Department of Biology, Norwegian University of Science & Technology, Norway

Micro- and nanoplastics (MNPs) have been detected in various foods and beverages, leading to widespread human exposure. To prevent MNPs from entering foodstuffs, their sources must be identified. While current research focuses mainly on environmental contamination, the role of plastic food packaging and other food contact articles (FCAs), such as processing and transport equipment, as direct sources of MNPs in food remains largely overlooked, despite the extensive use of plastics in FCAs.

To address this gap, we systematically mapped the scientific evidence of MNPs in foodstuffs originating from the normal and intended use of FCAs, such as bottle opening, and published the FCMiNo dashboard. A limited subset of studies indicates that plastic FCAs can release MNPs into foodstuffs under intended or foreseeable conditions of use. In this first mapping, we included literature published before 2023. Currently, we update the systematic evidence map with studies published between 2024 and the end of 2025, and here we share first results.

Beyond MNPs, chemicals used in FCAs also pose safety challenges, as they include known hazardous and unknown substances that migrate into foodstuffs. Current regulatory requirements are insufficient to protect public health because they do not address mixture toxicity nor microplastics. We therefore propose a novel approach to establishing the safety of chemicals in finished FCAs. This approach places material inertness at the centre, as inert materials are also most suitable for implementing a circular economy.

To minimize the impacts of (plastic) food packaging and FCAs on humans and the environment, sustainability aspects beyond safety need consideration. The Understanding Packaging (UP) Scorecard is a science-based, freely available tool that implements the concept of inertness and can be used to select the safest and most sustainable foodware. It evaluates chemicals of concern and material inertness to score product safety. On top of that, the UP Scorecard considers climate change, water use, plastic pollution, sustainable sourcing, and recoverability to rate a product's overall sustainability. It demonstrates that reuse systems based on inert materials have the lowest safety and sustainability impacts.

7.12.B.T-02 Does environmental policy support the circularity and sustainability of fishing gear?

Mona Arnold¹, Paule España², Asier Asueta³, Noora Harju¹ and Katri Behm¹, (1)VTT Technical Research Centre of Finland Ltd, Finland, (2)GAIKER Technical Research Centre, Spain, (3)Gaiker Technical Research Centre, Spain

Abandoned, lost, or discarded fishing gear (ALDFG) is a major source of marine plastic pollution, contributing to ecological, economic, and societal challenges across aquatic environments. Recent EU regulations, including the Single-Use Plastics (SUP) Directive with the Extended Producer Responsibility (EPR) schemes require new, circular approaches for managing fishing gear waste. A sustainable value chain for circular end-of-life (EoL) fishing-gear management faces numerous challenges. This work is a part of an EU-project SEARCULAR and it aims to develop and evaluate a port-based circular solution ("Blue Point") that enables efficient collection, sorting, and subsequent recycling of EoL fishing gear, while assessing its overall sustainability.

The work includes the identification, characterization and quantification of fishing gear waste along the Basque coast. Based on the data obtained, material simulation of future Blue Point operations was done, covering all stages: material reception, characterization, sorting, conditioning, and validation. Environmental impacts are quantified using LCA and they are combined with cost benefit analysis (CBA) to support the overall

sustainability assessment of the solution.

The study found that although the ecological impact of fishing-gear waste is widely recognised as a major issue in the marine environment, the actual waste volumes are relatively low. Integrating fishing-gear waste with other local waste streams can further improve economic sustainability. LCA results are still to be finalised, but they aim to verify the benefits of circular solutions compared to linear value chains.

The study provides a blueprint for port-based, circular management of fishing gear end-of-life (EoL) that is both feasible and environmentally preferable, offering a replicable model for sustainable EoL fishing-gear management. The integration of LCA, CBA and stakeholder perspectives ensures robust, actionable recommendations for policy and practice.

7.12.B.T-03 Essentiality, Safety, and Sustainability: A Novel Policy Framework for Effective Plastics Production Reduction

Romain Figuière¹, Trisia Farrelly², Bethanie Carney Almroth³ and Richard C. Thompson⁴, (1)Department of Environmental science, Stockholm University, Sweden, (2)Cawthron Institute, New Zealand, (3)University of Gothenburg, Sweden, (4)School of Biological and Marine Sciences, University of Plymouth, United Kingdom

Plastic production is responsible for many impacts on the environment across the whole life cycle of the products, from the raw material extraction to the technologies used for remediation. Scientists, international organizations and policy makers agreed that the key to address the global plastics crisis is to reduce the production of plastic items. The aim of this study is to present a novel and objective policy framework to phase-out “non-essential”, “avoidable” or “unnecessary” plastics products drawing from the definitions of the Nordic Council and building on the essential-use concept proposed by the European Commission for implementation in the REACH Regulation, while expanding its application as a means of restricting the plastic production to only products that are safe, sustainable, and that have a use that is necessary for health and safety, or critical for the functioning of society.

Given the complexity and number of plastics materials, we propose that the framework should be applied to the whole plastic product or plastic component instead of single chemical substances contained in the material. The assessment would result in three potential outcomes: (1) the plastic product does not raise specific concern, its production and trade is allowed; (2) the plastic product is identified as non-essential, hence its production and trade would be phased-out without delay; (3) Plastics products which are identified as essential but unsafe or unsustainable are given a time-limited exemptions to develop a safer and more sustainable product, or system to ensure that essential needs are met.

In our view this framework offers an objective approach to facilitate consensus in negotiations while supporting the production and trade of essential, safer and more sustainable plastic products. We believe that this approach is material agnostic and should also be applied to plastic alternatives and non-plastic substitutes to prevent regrettable substitutions and outcomes.

7.12.B.T-04 Designing Circular Plastics with Bauhaus Chemistry

Hans Peter H. Arp, Norwegian Geotechnical Institute (NGI), Norway

Less than 10% of global plastic is recycled, hindered by material complexity, economic constraints, exports, and informal waste streams. Plastic waste is projected to nearly triple to 1,014 million tons by 2060, dominated by short-lived applications such as packaging and textiles, while long-lived uses will create “locked-in” waste for decades. These trends underscore how far we are from achieving a circular economy for plastics.

A major barrier is the chemical diversity within plastics. Thousands of substances serve overlapping or non-essential functions, creating complexity that obstructs governance and recycling. Chemical simplification offers a pathway forward by reducing unnecessary diversity and prioritizing safer alternatives. Policies promoting

fewer, safer chemicals, combined with essential-use and safe-by-design principles, can guide innovation toward circularity.

We introduce the concept of Bauhaus Chemistry, inspired by Bauhaus design principles of simplicity and “truth to materials.” Bauhaus design (1919–1933) emphasized minimalism and functional use of materials, driving innovation and mass production with few industrial commodities such as steel and glass. Applying similar thinking to plastics means designing with fewer, high-quality materials for multiple functions, improving recyclability and reducing chemical complexity.

Commodity plastics—high-volume polymers like PET and LDPE—should be standardized for reuse and mechanical recycling within pure waste streams, supported by clear labeling and strict chemical controls. Examples include PET bottle schemes analogous to glass recycling systems. Non-commodity plastics, such as those in electronics, should be recognized as outside the circular economy, with a focus on safer chemistry rather than recyclability.

To accelerate this transition, we propose four principles of Bauhaus Chemistry:

Design more with less – minimize material and chemical diversity.

Inspiration through simplification – streamline complexity through design.

No waste, no waste exports – enable local recycling and reuse.

Localized production and material cycles – strengthen regional circularity.

Implementing these principles can reduce hazardous substances, enhance recyclability, and align plastics with circular economy objectives.

7.12.P Solutions from Source to Sink: Preventing, Removing, and Managing Pollution Across the Plastic Continuum

7.12.P-Th333 The Drain is a Reactor: Assessing Interactions in the Wastewater System

Stuart Robert John Walker¹ and Rachael Rothman², (1)University of Sheffield, United Kingdom, (2)Chemical and Biological Engineering, University of Sheffield, United Kingdom

Polymers in Liquid Formulation (PLFs) are found in millions of everyday products, from soap to paint.

Wastewater treatment systems already receive an unprecedented mixture of products, and despite regulation, many inappropriate products enter wastewater directly or indirectly. When mixed with PLFs, these products can remain in wastewater systems, travel further, and interact with other products.

As global water stress increases, drives to reduce water use are rightly encouraged, reducing the volume of water entering wastewater systems and increasing product concentrations.

This combination of increasing concentration, PLF use and more products leads to increased potential for product mixing and a practically infinite array of end-of-life fates for any product. This makes assessment using conventional Life Cycle Assessment (LCA) impossible.

Our work aims to address this by developing product risk profiles based on interaction potential and impact. Work to date has understood the wastewater system, identified PLF-containing products, and considered those product family interactions which may cause most risk.

Understanding the wastewater system began with expert interviews. The second stage involved data collection on products entering the system, undertaken through workshops with individuals who identified themselves as engaged in climate change and environmental issues. Individuals were asked to consider a range of PLF-containing products, and to highlight whether they personally would dispose of them through the wastewater system, and whether they thought others would do so.

The final initial stage was the engagement of PLF experts from academia and industry. This group were shown a matrix of products and asked to rate potential interactions between product groups from benign to high risk. Results of this first phase highlight eleven product categories of note, including fertilisers and pharmaceutical products.

Work is now underway on modelling interactions between products. The goal of the work is to produce risk profiles for products, indicating the likelihood of environmentally damaging interactions in the wastewater

system. As a likely enabler of transport and interaction, PLFs will be the initial focus. Ultimately, the project will produce a model able to identify the highest risk interactions of a product in the wastewater system, and a series of a "must avoid" interactions which have the potential for high environmental impact if allowed to occur.

7.12.P-Th334 Looking forward to the EU Urban Wastewater Treatment Directive (UWWTD): Development of a novel sampling and sample preparation approach for microplastic analysis

Mike Wenzel, Stefan Grass and Marina Huber-Gedert, MicroBubbles GmbH, Germany

The implementation of mandatory microplastic monitoring at wastewater treatment plants (WWTP) through the EU UWWTD represents a significant step towards tackling microplastic pollution. However, the implementation of the UWWTD is hindered by several microplastic monitoring frameworks are still not fully standardized with regard to sample preparation and sampling approaches. Looking into the future, it is reasonable to assume that the UWWTD will be linked to regulatory thresholds for microplastic concentrations. Therefore, uncertainties for assessing microplastic concentrations must be eliminated. Our study addressing these issues and demonstrate the effectiveness of a novel device called the MIPS (MicroPlastic Separation, patent pending) device, which can efficiently separate microplastics from wastewater matrices via microflotation. The separation mechanism is based on the hydrophobic interactions between finely dispersed air microbubbles (30-60 µm) and microplastics in an aqueous medium.

Regarding sample preparation approaches the presented method has advantages over others (e.g. density separation), as these are often combined with the use of highly concentrated, expensive, and environmentally harmful chemicals. Moreover, using the MIPS for sample preparation is fast (approx. 1 h), whereas settling times during density separation often exceed 24 h, preventing a timely assessment of microplastic concentrations during monitoring campaigns. The MIPS is also being tested as a sampling system capable of collecting high sample volumes and, hence, increasing the representativeness of collected samples. The system is capable for being scaled up far beyond a sampling volume of 1000 L. Our overall goal is to establish a tool that combines sampling and sample preparation in one step minimizing the need for further preparation steps. The newly developed MicroPlastic Separation device (MIPS, patent pending) clearly demonstrated its suitability to reduce some main components of WWTP efficiently while providing high and robust recoveries for microplastics of 68?10% for polystyrene particles. For the matrix removal, a quantitative reduction is obtained for model compounds (96,7% for cellulose and 99,9% for sand). This can improve time efficiency of monitoring campaigns and also adding strong sustainability features, as only water and air is used.

7.12.P-Th335 Longitudinal and Vertical Distribution of Tire & Road Wear Particles and Microplastics in Contrasting Urban Bioswales

Sampriti Roy¹, Tiago De Oliveira², Sophie Ricordel¹, Rachid Dris³, Elodie Passeport⁴ and Johnny GASPERI⁵, (1)Université Gustave Eiffel, France, (2)Gers-Lee, Gustave Eiffel University, France, (3)Université Paris-Est Créteil, France, (4)Rutgers University, United States, (5)Université Gustave Eiffel, France

Microplastics (MPs) and Tire and Road Wear Particles (TRWPs) are classified as emerging contaminants in urban stormwater, yet their distribution patterns within green infrastructures like Sustainable Urban Drainage Systems (SUDS) remains inadequately understood. A major knowledge gap persists regarding how the design, stormwater inflow dynamics, and hydraulic connectivity of SUDS, like bioswales, govern the retention and distribution patterns of MPs and TRWPs in soils. To address this, the study compares two structurally and hydrologically contrasting bioswales: in Nantes, France, located beside a very low traffic density road and functioning as the final unit in a multi-bioswale treatment chain, and one in New Jersey, USA, situated along a high traffic density roadway and receiving untreated first-flush stormwater through a concentrated inlet. Surface soils (0-5 cm) and cores (up to 45 cm) were collected across cross-sectional and longitudinal transects in both

bioswales and analyzed using pyrolysis-gas chromatography-mass spectrometry (Py-GC/MS) for TRWPs and polymeric MPs - polypropylene (PP), polystyrene (PS), and poly (methyl methacrylate) (PMMA). In the French bioswale, a decreasing contamination profile was observed from the inlet (4.7 mg/g) along the 11 m runoff flow path to the outlet (1.36 mg/g) of the bioswale. TRWP concentrations also decreased from road-adjacent soils toward the opposite slope. The USA bioswale showed sharp TRWP enrichment at the inlet (13 mg/g) and attenuation along the 48 m flow path to the outlet (1.76 mg/g), consistent with high traffic loading and direct first-flush inputs. TRWP in the transect from the road-adjacent points to the opposite side of the bioswale showed similar decreasing patterns as the French bioswale. PP, PS, and PMMA exhibited similar distribution and attenuation patterns in both sites as TRWPs but with lower concentration ranges. In core layers of both sites, decreasing concentrations were found with increasing soil depths. Through the distribution patterns obtained in the study, we highlight the efficiencies of the studied bioswales for TRWP and MP (PP, PS, PMMA) retention and that the structural configuration, inflow regime, and hydrologic pathways are significant controls on contaminant fate in bioswales. The study provides new field-based evidence for better understanding and optimizing SUDS design to enhance contaminant retention and reduce their downstream transport.

7.12.P-Th336 Polymer Identification and Plastic Additive Screening from Multiple Trap Fisheries

Catherine Wardinski, Donna Bilkovic, Kirk Havens, Andrew Scheld, David Stanhope, Kory Angstadt, Noah Tait and Meredith Evans Seeley, Virginia Institute of Marine Science

Abandoned, lost and discarded fishing gear (ALDFG) is an abundant form of plastic pollution in water bodies worldwide. Previous research has focused on polymer composition of floating ALDFG such as nets, typically with end-of-life upcycling in mind. While 25 million pots and traps are lost internationally each year, there is little understanding about the plastic make up of traps and how they differ across fishery types. Moreover, fishing traps have relatively unique plastic components, such as vinyl coatings and rubber components, which are relatively understudied in the marine environment compared to buoyant plastics (polyethylene, polypropylene). In conjunction with a large-scale, multi-country derelict trap removal and data collection program (National TRAP program at the Virginia Institute of Marine Science), we have received samples of lost fishing traps for chemical characterization. These include American lobster, blue crab, spiny lobster, stone crab, and mangrove crab fisheries. Primary polymer analysis was completed with Attenuated Total Reflectance Fourier Transform Infrared Spectroscopy (ATR-FTIR). Pyrolysis - Gas Chromatography/Mass Spectrometry (Py-GC/MS) was used to confirm polymer identification and a non-targeted analysis of plastic associated chemicals (e.g., plastic additives such as UV-stabilizers) for a subset of derelict trap components. Our results show a variety of polymers within each trap type and significant differences between fisheries. We also identify a number of plastic constituents with potential toxicological concerns, and the most pragmatic options for end-of-life upcycling options. This research provides novel insight into the environmental ramifications of one of the most abundant but often forgotten forms of fishing debris.

7.12.P-Th337 Nanoplastic filtration using native wood membranes: A nature-based solution to water purification

Alice Pradel¹, Maximilian Ritter², Wenqing Yan³ and Denise Mitrano¹, (1)Environmental Systems Science Department, ETH Zurich, Switzerland, (2)Institute for Building Materials, ETH Zurich, Switzerland, (3)Cellulose and Wood Materials, Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Nanoplastic (NP) contamination in water bodies is widespread. Removing NPs from water sources intended for human consumption requires efficient, environmentally friendly, and cost-effective methods. This study evaluates the use of native wood membranes to filter NPs from freshwater using a pressure-driven process. The performance of the filter was assessed for different tree species, membrane thicknesses and filtration cycles, by measuring NP concentration in the filtrate and NP deposition in the wood membranes. Retention efficiency varied widely between species. After a single filtration cycle, spruce, a common softwood species, reduced NP concentrations by approximately 90%, while poplar, a hardwood, only reduced NP concentrations by ~20%. These differences in retention efficiency are linked to microstructural differences between soft- and hardwood tissues. Increased membrane thickness and repeated filtration further enhanced NP retention in all conditions. This work demonstrates that native (i.e. without chemical modification) softwood membranes can be used in low-pressure filtration systems to remove NPs.

7.12.P-Th338 Exploring Dutch Rivers: Scaling of Dimensions and Concentrations of Plastics

Jasmijn Polinder¹, Frank Collas², Félix Leiva¹, Stephanie Oswald¹, Aafke Schipper¹, Margriet M Schoor², Wilco Verberk¹ and Jan A.J. Hendriks¹, (1)Radboud University, Netherlands, (2)Rijkswaterstaat, Netherlands

Plastic pollution is an environmental concern due to its widespread presence. While particle size and abundance are crucial for modelling ecological impacts, like ingestion, these factors are not yet well understood in rivers. Moreover, many studies focus on one size class of plastic particles. This study examined the relationships among size dimensions, size-concentration, and size-cumulative surface area of a wide size range of plastic particles collected with trawl nets from upstream and downstream sites in two Dutch rivers during 2023 and 2024. Measurements included the longest length, surface area, circumference, and particle count. Geometric means of particle concentrations and cumulative surface area concentrations were calculated for equally sized bins. Reduced major axis and ordinary least squares regressions were used to determine the slopes of bivariate relationships between size dimensions (length–surface area slopes: 1.46 – 1.83; length–circumference slopes: 1.02 – 1.07; circumference–surface area slopes: 1.30 – 1.76), size-particle concentration (slopes: 0.19 – 1.44), and size-cumulative surface area (slopes: 5.15 – 7.71). Significant positive relationships were found among size dimensions. A significant increase in particle concentration with increasing length was observed only at the length threshold, which was applied because microplastics were accidentally sampled. Overall, particle length was not a reliable predictor of particle concentration. However, cumulative surface area concentration increased significantly with length. This study is the first to explore the relationship between size dimensions and concentrations of plastic particles across a broad size range (micro to macro) in Dutch rivers, providing urgent baseline information for monitoring and impact assessment.

7.12.P-Th339 From Source to Sea: Identifying Macrolitter Sources for Sustainable Litter Management at the Yser River Mouth

Therese Nitschke¹, Camille Lacroix², Gita Maas³, Perrine Guillemenot², Marine Paul², Lisa Inès Devriese¹ and Ana Isabel Catarino¹, (1)*Flanders Marine Institute (VLIZ), Belgium*, (2)*CEDRE Centre de Documentation, de Recherche et d'Expérimentations sur les Pollutions Accidentelles des Eaux, France*, (3)*Stichting De Noordzee, Netherlands*

Aquatic litter pollution is a complex challenge and the sources of most items found in the environment remain poorly understood. Identifying these sources is essential for targeted decision-making, effective mitigation, and evaluating policy impact. In this study, we combined year-round riverine and coastal litter observations at the Yser River mouth in Nieuwpoort, Belgium, with the Matrix Scoring Technique based on Tudor & Williams (2004) for litter source identification, a method that links litter items to the human activities (i.e. fishing, agriculture) that release them. Our aims were to determine the major contributing sectors, compare riverine and beach litter composition, and assess seasonal differences across a riverbank, harbour, and beach location. Eight litter samples were collected at the Yser River mouth from autumn 2024 to autumn 2025, including all anthropogenic items > 2.5 cm. The samples were sorted into the EU standardized Joint List of Litter Categories (J-list), and the Matrix Scoring Technique was applied to assign different likelihood levels for each litter category to 54 pre-defined and standardized sources. Regional conditions were taken into account by using thematic maps and expert knowledge. Source contributions were calculated from item counts to produce the final likelihood matrix. The dominant sources of macrolitter along the Yser River mouth vary spatially, with tourism and households contributing across all sites but sewage outlets appearing only at the riverbank, harbour and boating activities only downstream, and marine inputs such as fishing most prominent at the beach. These patterns indicate a transition from mainly land-based recreational and residential sources upstream to a mix of urban-industrial, maritime, and tourism-related inputs toward the coast. This study shows that integrating standardized litter categorization with the Matrix Scoring Technique provides a robust, transparent, and scalable way to identify the human activities that generate macrolitter across aquatic environments. These insights can inform coastal management, targeted mitigation measures, user education, enforcement, and funding allocation. Our findings also highlight the need to develop practical interventions, including awareness campaigns addressing intentional littering. This work advances source-identification methods and contributes essential evidence for designing more effective, regionally tailored aquatic litter reduction strategies.

7.12.P-Th340 Microplastic Pollution and Ecotoxicological Impact of the surface waters and sediments of rivers collected in Japan

Go Suzuki¹, Atsuko Amano², Natsuyo Uchida³, Kosuke Tanaka¹, Seiichi Uno⁴, Takuya Itaki² and Kei Nakayama⁵, (1)*National Institute for Environmental Studies (NIES), Japan*, (2)*National Institute of Advanced Industrial Science and Technology, Japan*, (3)*Material Cycles Division, National Institute for Environmental Studies (NIES), Japan*, (4)*Kagoshima University, Japan*, (5)*Ehime University, Japan*

Microplastic (MP) pollution is a major global concern increasingly recognized as a threat to human and planetary health. MPs enter the ocean through multiple pathways—including urban dust, textile washing, and fragmentation of marine plastic litter—but few studies have quantitatively assessed the ecological risks associated with different MP sources. Here, we conducted a preliminary ecological risk assessment of MPs in Japanese river surface waters and estuarine sediments, using measured concentrations and predicted no-effect

concentration (PNEC) ratios to inform mitigation strategies. For MPs in surface waters from 28 rivers, Q2 particle concentrations for the 1–5 mm, 0.3–1 mm, 0.1–0.3 mm, and 0.02–0.1 mm fractions were 2.3, 2.1, 1,300, and 4,400 MP/m³, respectively. Mass-based Q2 values were 0.087, 0.014, 0.015, and 0.010 mg/m³, indicating that particles 0.3–5 mm accounted for ~80% of total mass. Polyolefins (PP, PE) dominated all size classes (>60%), followed by PET (~20%), and fragments and fibers composed >90% of particles in the 1–5 mm and 0.3–1 mm fractions. For estuarine sediments collected from eight rivers, Q2 particle densities were 180, 98, 1,800, and 14,000 MP/kg dw, and mass concentrations were 2.4, 0.55, 0.011, and 0.022 mg/kg dw, with 0.3–5 mm particles contributing ~98% of total mass. Polyolefins accounted for ~30–80%, PET for <10–30%, and other polymers (e.g., PAN, PA) for 20–50%, with substantial variation across size classes. As in surface waters, fragments and fibers dominated the 1–5 mm and 0.3–1 mm fractions (~90%). Of particular note, even buoyant polyolefins (PP and PE) exhibited markedly higher composition ratios in sediments when particle sizes were <0.1 mm, demonstrating clear settling behavior. This suggests that miniaturization of particles may reduce their inherent buoyancy—potentially through biofilm formation—and thereby promote their transfer to bottom sediments. Such behavior implies the presence of high-concentration hotspots in coastal benthic environments. Under a worst-case scenario, concentrations of 0.02–0.1 mm MPs in estuarine sediments exceeded the PNEC at several sites. Given that polyolefins comprise 40–60% of domestic production and waste in Japan and continue to be released, settle, and accumulate in sediments, our findings indicate that polyolefin fragment MPs should be prioritized for detailed evaluation and development of release-reduction measures among MPs transported to the ocean via rivers.

7.13 The FAIR Principles in Environmental Toxicology and Chemistry: Enabling Data-Driven Insights

7.13.T-01 FAIR and CREED: Partners in Better Risk Assessment?

Iain Wilson¹, Graham Merrington¹, Adam Peters¹, Elizabeth Middleton², Christopher Cooper³, David Boyle⁴ and Tara Miller⁵, (1)wca environment Ltd., United Kingdom, (2)NiPERA Inc., United States, (3)International Zinc Association (IZA), Belgium, (4)Cobalt Institute, United Kingdom, (5)International Copper Association (ICA), United Kingdom

The FAIR Guiding Principles (FGP) for scientific data management and stewardship set out to improve the Findability, Accessibility, Interoperability, and Reuse of digital assets. To have scientifically robust risk assessments data needs to be findable, accessible and also should be reliable and relevant for its given purpose. The CREED approach (Criteria for Reporting and Evaluating Exposure Datasets) was developed to provide a systematic approach the consistent and transparent evaluation of the reliability and relevance of exposure data used in risk assessments. By combining the FGP and CREED it allows for scientifically robust, repeatable environmental risk assessments to be performed.

To perform environmental risk assessment for a substance, environmental exposure data, either modelled or measured, need to be available. Regulatory monitoring data can be obtained from many sources, including, online portals and direct requests to the data owners. However, the data use requirements vary significantly between jurisdictions, and data availability can vary from request-to-request from the same jurisdiction as well as between jurisdictions. The application of FAIR principles to methodological information related to the analysis of samples, for example method used and accreditation of the analysis, would also allow for more datasets to be fully assessed using CREED and provide a definitive conclusion following a published approach on the reliability and relevance of the data used in the risk assessment. When data is available, and it has been shown to be reliable and relevant for your given purposes, it is important that it is included in the risk assessment. By not using all of the data available, especially where the amount of high quality exposure data are a consideration, this can undermine the conclusions drawn and may require further expenditure of limited resources.

This presentation will show using recent experiences obtaining, using and reviewing European surface water monitoring data for regulatory sources and published risk assessments of how the FGP are applied inconsistently, how the reliability of these data can be questioned, and instances where data are available to

support and further assessment conclusions, but have not been utilised, and provide some recommendations of best practice and highlight issues associated with not making data available, using all available data and assessing data for reliability and relevance.

7.13.T-02 MassBank: An Open and FAIR Mass Spectral Data Resource

Steffen Neumann¹, René Meier², Michael Wenk², Anjana Elapavalore³, Takaaki Nishioka⁴, Tobias Schulze⁵, Michael Andrej Stravs⁶, Hiroshi Tsugawa⁷, Fumio Matsuda⁸ and Emma Schymanski⁹, (1)Computational Plant Biochemistry (CPB), Leibniz Institute of Plant Biochemistry & German Centre for Integrative Biodiversity Research (iDiv), Germany, (2)Computational Plant Biochemistry (CPB), Leibniz Institute of Plant Biochemistry, Germany, (3)Luxembourg Centre for Systems Biomedicine, University of Luxembourg, Luxembourg, (4)The Mass Spectral Data Working Group of the Mass Spectrometry Society of Japan, Japan, (5)UFZ-Helmholtz Centre for Environmental Research, Germany, (6)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (7)Department of Biotechnology and Life Science, Tokyo University of Agriculture and Technology, Tokyo, Japan, (8)Department of Bioinformatic Engineering, Graduate School of Information Science and Technology, Osaka University Osaka, Japan, (9)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg

MassBank was initiated in 2006 in Japan as the first open source, open-access and cross-vendor database for mass spectra. MassBank.EU was launched in 2011, which increased spectral contributions related to compounds of environmental and toxicological concern. Since then, MassBank has evolved into a cornerstone infrastructure for FAIR (Findable, Accessible, Interoperable, and Reusable) chemical data supporting small molecule-based research activities.

A redesigned web interface launched in 2025 provides improved accessibility and performance. All records are maintained under version control. Each release is archived as an independent dataset with a digital object identifier (DOI), ensuring long-term traceability. Automated validation has been setup to improve the data quality upon submission and to detect issues with existing records. The MassBank data format has been refined to include richer metadata, and the semantic data integrates spectral data within the wider ecosystem of linked open data. Furthermore, the SPectraL hASH (SPLASH) enables content-based access. With contributions from >50 partners worldwide, MassBank currently hosts 130,420 spectra of 20,206 compounds.

MassBank is fully interoperable with major global resources, including the MassBank of North America (MoNA), Global Natural Products Social Molecular Networking (GNPS), PubChem, the US EPA CompTox Dashboard, the NORMAN Database System (NDS), RforMassSpectrometry and more. These cross integrations have further enhanced the availability and reusability of spectra data across different platforms empowering many mass spectrometry-based investigations and supporting chemical identification, exposure assessment and risk analysis workflows. One example highlighting the impact of open spectral libraries is a recent Parkinson's disease exposomics pilot study by Talavera Andújar et al., where several of the significantly different compounds implicated in PD penetrance were annotated with Level 2a confidence using non-targeted LC-HRMS and all publicly available MS/MS libraries (including MassBank) integrated within MS-DIAL and MetFrag.

The growing number of resources using MassBank spectra and the increasing number of new contributions embracing the GitHub-based submission system exemplifies how coordinated FAIR-aligned infrastructure can foster cross-disciplinary collaboration and underpin data-driven environmental and human health risk assessments.

7.13.T-03 Using collaboration and iterative refinement to create customised, community-agreed FAIR (meta)data supporting systems: Data Management Plans

Indrani Mahapatra¹, Fred van de Brug², Gerhard Burger³, Dario I. Bijker³, Dirk Devriendt⁴, Katarina Rihackova⁵, Rob Stierum² and Iseult Lynch⁶, (1)University of Birmingham, United Kingdom, (2)Nederlandse organisatie voor toegepast-natuurwetenschappelijk onderzoek (TNO), Netherlands, (3)University of Leiden, Netherlands, (4)Vlaamse Instelling voor Technologisch Onderzoek (VITO), Belgium, (5)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (6)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom

The Partnership for the Assessment of Risks from Chemicals (PARC) project is committed to the development of a FAIR (Findable, Accessible, Interoperable, Reusable) data culture and the provision of technical methods, tools, and infrastructure for harmonisation to aid effective exchange of data and information generated and reused in different disciplines pertaining to chemical risk assessment (CRA). Due to the large size (~200 partners) and scale (7 years) of the PARC project, and various requirements for data management in the disciplines relevant to CRA, the research objectives in PARC are being met via a set of projects (smaller size

and fixed duration), each having a Data Management Plan (DMP) derived from and extending the overarching PARC DMP.

To address the data management needs of the individual projects, we introduced a customised machine-actionable DMP (ma-DMP) within the Data Stewardship Wizard (DSW) tool – a JSON-encoded mind map for data management and planning. The ~650 questions and sub-questions in the DSW DMP Knowledge Model (KM) are customisable to PARC's needs. Thus, a core part of the effort to create project specific ma-DMP was (i) developing the initial short list of questions by PARC's FAIR data experts, (ii) pilot testing the reduced question set with representative projects from toxicology domain, and (iii) revising (and refining) the initial list of questions after the pilot test. Additionally, domain-specific communities in PARC choose the FAIR Enabling Resources (FERs) and FAIR Supporting Resources (FSRs), e.g., Persistent identifier services, metadata schemas, controlled vocabularies, repositories, ontologies to develop the domain-specific reference FAIR Implementation Profiles (rFIPs) to help the automatic choices in the ma-DMP.

The user-friendliness of the PARC-project level DMP KM, reflected in factors, such as ease of use, questionnaire design, guidance, automation features like prefilling, and interoperability with other research information documents was appreciated during the pilot sessions and is expected to enrich the information contained in the DMPs. These ma-DMP can help to analyse the quality of information in the DMPs and detect convergence of FERs. In addition, the answers in the project-level DMPs will serve as an input for future updates of this overarching DMP and the answers can also feed back into updates of the domain-specific reference FIPs, promoting FAIR (meta)data in Chemical Risk Assessment.

7.13.T-04 eData: A tool and format for rapid extraction of exposure data from scientific articles

Sam Welch¹, Li Xi¹, Viviane Girardin¹, Pierre Blévin², Camden Karon-Klefbom¹ and Knut Erik Tollefsen¹,
(1)Norwegian Institute for Water Research, Norway, (2)Akvaplan-NIVA, Norway

Data collection, extraction and formatting is among the most tedious elements of conducting an environmental risk assessment (ERA). Maintaining oversight and quality control of heterogeneous datasets require expert knowledge and many hours of work. This makes it an obvious candidate for automation, as the potential to save time and money through a consistent, reproducible workflow is considerable. As more emphasis is placed on the Findable, Accessible, Interoperable and Reusable (FAIR) principles, need for such tools will increase.

We have developed a toolkit to address these issues in exposure data collection, consisting of a) an exposure data reporting format (DRF) in collaboration with Partnership for the Assessment of Risks from Chemicals (PARC), and b) an interactive data extraction app (eData) that walks users through the processing of data into this format.

Data are extracted from a source document using a Large Language Model (LLM). To reduce LLM randomness, we use a structured data extraction to constrain the output to the DRF and a controlled vocabulary. The user then validates and explores the data across a series of modules that cover relevant data and metadata, before entering measured values (generally chemical concentrations). This approach blends the advantages of LLM extraction (speed, efficiency) with human interpretation (accountability, reasoning ability) and speeds up extraction with minimal adverse effect on reproducibility. The tool also supports conducting a Criteria for Reporting and Evaluating Exposure Datasets (CREED) assessment using the extracted data, enabling rapid quantification of reliability and relevance of the paper's data.

Internally, we are testing eData tool on an Aggregate Exposure Pathway project assessing aquatic copper pollution in (near-)Arctic regions. However, we will recruit further testers to enhance its capability in related domains (terrestrial ecotoxicology, etc.) and overall user experience and design. In the long term, we will integrate this tool with a toxicity data toolkit (qData), with an eventual aim to providing an integrated platform for ERA.

This is to the authors' knowledge the most advanced exposure data extraction tool currently in development, and its degree of integration of human validation and LLM extraction is unique. Our toolkit will be a valuable addition to data-based ecotoxicology and contribute to the field's becoming FAIRer, to the benefit of scientists and stakeholders.

Disclaimer/Disclosure:

Funded by the European Partnership for the Assessment of Risks from Chemicals (PARC, EU Horizon Europe grant 101057014), the Research Council of Norway project EXPECT (RCN-315969), and NIVA's Computational Toxicology Program, NCTP (RCN-342628).

7.13.T-05 Applying the FAIR Principles to Personal Exposure and Health Data

Stijn Baken, Dirk Devriendt, Gertjan Bisschop, Laura Rodriguez Martin, Sylvie Remy, Caio Mescouto Terra de

Souza, Liese Gilles, Hanny Willems, Karel Styns, Karolien Castermans, Elke Voeten, Jos Bessems and Eva Govarts, Flemish Institute for Technological Research (VITO), Belgium

The exposome is defined as the combined exposures that individuals encounter throughout life. The exposome greatly affects health, but the linkages are complex and poorly understood. Human biomonitoring surveys typically gather information about citizens' personal exposure and health, e.g. information about chemical occurrence in body fluids, chemical occurrence in the personal environment, lifestyle, and health effects. Integrating such data across different studies increases sample size and statistical power. Combining such data with other sources of information (e.g. geospatial data, socio-economic data) presents huge opportunities to clarify how the exposome affects health. However, barriers to such large-scale integration remain, including heterogeneous reporting formats, lack of structured information, and compliance with data protection legislation. This limits large-scale analyses and delays evidence-based policy decisions. The Findable, Accessible, Interoperable, and Reusable (FAIR) principles provide a useful framework to overcome these barriers.

The Personal Exposure and Health (PEH) data platform was developed to harmonize, validate, store, and securely share personal exposure and health data, in compliance with data protection legislation. As part of the EU Partnership for the Assessment of Risks from Chemicals PARC, the platform architecture is enhanced to better implement the FAIR principles. The information in the PEH Data Platform is structured based on community-developed data standards and vocabularies, which enables harmonization and integration of different studies. For data providers, the PEH data platform offers a clear and user-friendly workflow that enables data FAIRification and increases visibility. For data consumers, the PEH data platform provides on-request access to a large, structured, and curated collection of personal exposure and health data.

The FAIRification of the PEH Data Platform increases interoperability with other research domains: it will be integrated into the Environmental Exposure Assessment Research Infrastructure EIRENE. This will help underpin a better characterization of the human exposome. The structured nature of FAIR data opens opportunities for novel analytical approaches, such as large language models. Ultimately, FAIR data will enable cross-disciplinary research, strengthen evidence-based policy making, and drive innovation in public health and environmental protection.

7.13.P The FAIR Principles in Environmental Toxicology and Chemistry: Enabling Data-Driven Insights

7.13.P-Mo445 qData – a web-based FAIRification workflow for (eco)toxicological dose(concentration)-response data

Knut Erik Tollefsen, Li Xie, Kim Leirvik, Sam Welch, Walter Zobl and Viviane Girardin, Norwegian Institute for Water Research, Norway

Effect-based methods produce data across biological levels, from molecular to apical, which vary greatly in structure and format. This heterogeneity hinders integration into mechanistic frameworks like Adverse Outcome Pathways (AOPs) and limits their use in hazard and risk characterization. To address this, we developed a Data Reporting Format (DRF) and prototyped a web-based user interface (qData UI) to streamline data collection, validation, and analysis of quantitative dose–response data from (eco)toxicological studies.

qData is currently under internal and external testing using example datasets, including a case study on Diuron toxicity in *Chlamydomonas reinhardtii*. This dataset spans multiple biological levels and time points (6–72 h), capturing endpoints such as PSII inhibition, mitochondrial membrane potential, ATP content, and growth. The interface supports structured data and metadata entry, submission to different repositories (e.g., NIVA Risk Assessment database and Zenodo), benchmark dose (BMD) analysis for event sensitivity ranking, and future implementations will facilitate structural equation modeling (SEM) to quantify causal relationships and time-dependent dynamics across the AOP continuum. The UI and connected workflows will ultimately be integrated into the Source-to-Outcome Predictor (STOPredictor; <https://www.niva.no/source-to-outcome-predictor>), an UI linking environmental exposure assessment with hazard characterization for the risk assessment of single substances and mixtures.

Disclaimer/Disclosure:

This work was supported by the Research Council of Norway project EXPECT (RCN-315969), the EU-HEU project PARC (#101057014), and NIVA's Computational Toxicology Program, NCTP (RCN-342628).

7.13.P-Mo446 Using Collaborative and Iterative Process to create a Community-agreed Semantic Framework unifying Materials Safety and Sustainability

Indrani Mahapatra¹, Francesca Lønstad Bleken², Jesper Friis², Dominic Russ¹, Hui Yang¹, Alexe Haywood¹, Georgios V. Gkoutos¹, Thomas Exner³ and Iseult Lynch⁴, (1)University of Birmingham, United Kingdom, (2)SINTEF, Norway, (3)Seven Past Nine GmbH, Germany, (4)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom

The EU's Safe and Sustainable by Design (SSbD) framework integrates functionality, safety and sustainability considerations into early innovation process for chemicals and (advanced) materials to facilitate life-cycle informed decision-making. Multiple disciplines converge in SSbD, including engineering and process design, toxicology, chemical, computational, environmental and social sciences. Each uses its own specialised lexicon, hence a shared semantic backbone for data exchange and comparison is imperative for the success of SSbD. Creating such a unified semantic framework means aligning concepts, identifiers (e.g., CAS, SMILES), existing relevant ontologies and metadata standards across disciplines to identify classes (sub-classes) and relationships, enabling establishment of an overarching upper-level ontology.

Within the PARC, PINK and INSIGHT projects, the necessary semantic framework is being built, through workshops with domain experts from relevant fields to reach a shared decision, to create rules that can be read (and verified) by machines. Interoperability is achieved by integrating relevant mid-and lower-level concepts under a mutually consistent top-level conceptualisation (upper-level ontology) that covers all SSbD criteria and the corresponding experimental and computational approaches. Available datasets are being annotated and mapped to the minimal / lightweight ontology schema (classes, properties, relations) and to instantiate ontology classes (i.e., create individuals). Feedback from domain experts is used to refine and extend the lightweight ontology schema in an iterative manner.

Existing features of upper-level ontologies (e.g., BFO or EMMO) and tools (e.g., OBO Foundry and the OntoCommons EcoSystem), and novel approaches based on Web Ontology Language and Semantic Web Rule Language are being used. The SSbD semantic framework enables new terms and their definitions to be proposed on-the-fly to constantly improve the semantic coverage, making these terms directly available by assigning provisional identifiers. Functionality is preserved via links and mappings, and automated semantic alignment and translation between ecosystems where necessary. The resulting consensus-driven ontologies are FAIR (Findable, Accessible, Interoperable, Reusable), ensuring efficient data sharing and optimum utilisation of resources. The unified semantic framework will facilitate consistent, interoperable, queryable decision support for SSbD activities.

7.13.P-Mo447 EIQuan: A Stacked Ensemble Learning-Based Predictor for Quantification of Nontarget Chemicals in GC-HRMS Analysis

Yi Liu, Qianli Dong, Jingrun Hu, Chao Yao and Weiling Sun, China (Mainland)

Nontarget analysis using gas chromatography coupled with electron ionization high-resolution mass spectrometry (GC-EI-HRMS) has become increasingly vital for identifying hundreds to thousands of compounds in complex environmental samples. Herein, we employed GC-EI-HRMS to profile chemicals in wastewaters from various treatment processes within an iron and steel corporation. To address the challenge of quantifying compounds without authentic standards, we developed a stacked ensemble learning model. A total of 910 compounds were identified in all wastewater samples, categorized into 19 subgroups mainly including heterocycles, esters, ketones, hydrocarbons, and alcohols with aliphatic, alicyclic, and aromatic structures. Considering these major categories, 278 reference standards were selected to develop a stacked ensemble learner. This model outperformed traditional semi-quantitative methods, with most of quantification errors falling within a 0.46-2.12-fold range (95% confidence interval). Total concentrations were quantified at 8.80×10^5 (influent) - 6.92×10^3 (effluent) $\mu\text{g/L}$ in coking wastewater and 309 (influent) -43.8 (effluent) $\mu\text{g/L}$ in mixed wastewater. Notably, 92.2% of compounds shared between the PubChem database and the NIST spectral library fall within the applicability domain of the model. To enhance accessibility, we developed a user-friendly predictor (EIQuan), an open-access predictor based on our quantification model, freely available on GitHub (<https://github.com/ECsPKU-LY/EIQuan.git>). This model provides an efficient tool for predicting response factors of environmental pollutants, significantly advancing the utility of complex GC-EI-HRMS data in environmental analysis.

7.13.P-Mo448 Exposure Assessment of Consumer Products Using an Integrated Aggregate Exposure Pathway (AEP)-Adverse Outcome Pathway (AOP) Framework: Insights From Korean Market Data

Ajaya Kumar Sahoo¹, Gaeul Yang¹, Chaein Chong¹, Yeonjung Park², Dawoon Jung³ and Jinhee Choi¹, (1)School of Environmental Engineering, University of Seoul, Korea, Republic of, (2)TO21 Co., Ltd, 350, Seocho-daero, Seocho-gu, Seoul, Republic of Korea, Korea, Republic of, (3)Korea Environment Institute, Sejong, Republic of Korea, Korea, Republic of

People are routinely exposed to a wide range of chemicals found in consumer products, including cleaning products, personal care items, toys and children's products, pesticides, and more. However, understanding the health effects of these chemicals remains a critical research gap, largely due to the lack of accessible product data, compounded by market globalization and limited transparency in product chemical composition due to the absence of stringent regulation and data reporting policies. To address this challenge, we utilized the Korean consumer product database, namely Ecolife, to conduct an exposure assessment of chemicals identified as high priority based on both exposure and hazard information. We accessed the products disclosed with complete chemical composition and harmonized the associated data using the vocabulary recommended by Organisation for Economic Co-operation and Development (OECD) and Government of Republic of Korea. Exposure data such as product information, chemical production volume and biomonitoring data were integrated with the hazard information from multiple sources to prioritize chemicals. Specifically, we focused on the chemicals cataloged in cleaning products and constructed their aggregate exposure pathways (AEPs) based on published evidence and monitoring data. To provide quantitative estimate, we performed exposure assessments for various conditions of use (COUs) and exposure routes using different exposure models to predict the chemical concentration at the target site. Subsequently, we applied the high-throughput toxicokinetics (HTTK) model to estimate the in vivo concentration present to initiate the biological response at the molecular level. This integrated approach establishes a framework for linking AEPs with the developed adverse outcome pathways (AOPs) for systemic toxicity of consumer product chemicals, thereby providing valuable insights to support regulatory decision-making and improve chemical management practices.

Disclaimer/Disclosure:

This work was supported by the Korea Environment Industry & Technology Institute (KEITI) through the Technology Development Project for Safety Management of Household Chemical Products, funded by the Korea Ministry of Environment (MOE) (RS-2023-00215309).

7.13.P-Mo449 From Plastic Chemicals to Human Impact: An Architecture for AI Agents to Navigate Relational Databases

Albert Anguera Sempere, Helene Wiesinger, Birgit Geueke and Jane Muncke, Food Packaging Forum, Switzerland

The global crisis of plastic pollution is escalating, with mounting evidence linking chemical exposure from plastics to serious health and environmental risks. As concerns regarding plastic chemicals hazards continue to grow, development of tools that support linking their toxicological effects and identifying safer alternatives is needed. If chemical hazard data were easier to navigate and connect, researchers and policymakers could make timely, science-based decisions to restrict harmful chemicals. Currently, extracting and connecting meaningful information from chemical databases is time-consuming and requires specialized technical knowledge, resulting in promising ideas stalling. This hinders innovation in areas where speed and clarity are critical, such as unveiling plastic-related chemical hazards.

Generative AI offers the opportunity to use intuitive natural language to access structured data, such as complex chemical databases. Despite its potential to make scientific data more Findable, Accessible, Interoperable, and Reusable (FAIR), its applications in chemical and human-health databases are still underexplored.

To address this gap, we developed an AI Agent that interacts with ChEMBL—one of the largest chemical databases—using natural language. ChEMBL was selected for its high data quality and complexity, making it a suitable benchmark for our approach. The Agent consists of three core modules: (i) Relevance Validation, which

checks if the user's query aligns with ChEMBL's domain; (ii) Query Enhancement, which enriches the query with missing context and logical steps; and (iii) Table Retrieval, which uses Retrieval-Augmented Generation (RAG) to match the enhanced query with relevant database tables stored in a vector database, and then generates a corresponding SQL query. If the query fails, the Agent enters a feedback loop: the error message is appended to the original query and used to regenerate the SQL. This process is repeated up to three times, to optimize computation and time. If no valid query is produced, the user is notified. Results are displayed in a user-friendly table, which can be refined through natural language and downloaded as a CSV file. The tool can be used to assess bioactivity effects of common plastic chemicals.

This architecture can be extended to other chemical databases, such as our food contact chemical and human-health databases—connecting food contact chemicals usage with exposure and adverse health effects.

7.14.P Tracing Past Pollution With Unconventional Proxies: Legacy Footprints Guiding Today's Environmental Risk Decisions

7.14.P-Th341 Historical Foraminiferal Collections as a Resource for Monitoring Anthropogenic Impacts on Marine Environments

Laura Cotton¹, Carlos Edo¹, Nivedita Naveen², Emanuel Larsson² and Helena Filipsson², (1)Natural History Museum Denmark, Denmark, (2)Lund University, Sweden

Foraminifera within Natural History Collections (NHC) represent an underutilized yet valuable resource for tracking environmental changes and anthropogenic impacts on marine ecosystems. Foraminifera are protists with a (usually) calcareous shell frequently used in biomonitoring studies across marine environment. Historical foraminiferal samples, collected during marine expeditions from the late 1800s to mid-1900s, therefore offer crucial baseline data pre-dating significant human influence. These samples, often accompanied by oceanographic data, can fill important knowledge gaps regarding past biodiversity, species distribution, pollution levels and ecosystem health, but many remain unstudied within the collections of Natural History Museums around the world. While challenges such as limited accessibility, uncertain sample histories, and methodological inconsistencies exist, modern analytical approaches, including non-destructive imaging and advanced image analysis and machine learning, greatly enhance their usability.

Here we highlight the potential of foraminiferal NHC via several case studies representing ongoing work at the Natural History Museum Denmark, including: microplastic baselines in foraminiferal/sediment samples from the 1950-52 Galathea II expedition, morphological analysis of foraminifera from the G. Winther collection collected in 1872 and biodiversity studies of samples from the H. J. Hansen collection collected in the 1970s. We strongly advocate for the preservation, digitization, and strategic use of historical micropaleontological collections. In addition, we invite other researchers to consider the use of foraminiferal NHC in future research, emphasizing their potential for providing essential long-term ecological insights and supporting conservation and climate mitigation strategies.

Disclaimer/Disclosure:

7.14.P-Th342 Foraminifera as historical archives of micro(nano)plastic contamination revealed by sub-micron O-PTIR spectroscopy

Carlos Edo¹, Elvis Genbo Xu² and Laura Cotton¹, (1)Natural History Museum Denmark, Denmark, (2)University of Southern Denmark (SDU), Denmark

Microplastics (MP) and nanoplastics (NP) are increasingly recognised as pervasive environmental contaminants, yet their long-term distribution in marine systems remains poorly constrained due to a lack of historical records. Agglutinated foraminifera, which incorporate external particles into their mineral-organic tests, represent a potentially valuable archive for reconstructing past contamination. This study aims to evaluate whether modern and historical foraminiferal specimens can retain small synthetic particles and thereby provide temporal insight into the deposition of microplastics and nanoplastics.

To address this, we apply a non-destructive workflow combining three-dimensional confocal fluorescence microscopy with sub-micron Optical Photothermal Infrared spectroscopy (O-PTIR). Confocal imaging is used to locate fluorescent micro-domains within the complex test structure, while O-PTIR analysis enables chemical

characterisation of these targeted regions at a spatial resolution of approximately 500 nm. Modern specimens from multiple regions are currently being analysed, and archived material from the Galathea II Danish expedition, collected before widespread plastic production, is being prepared to establish pre-impact baselines. Preliminary observations indicate that mineral autofluorescence can obscure natural signals, but dye-enhanced fluorescence improves the detection of regions of interest that may contain synthetic particles. Early results also confirm the feasibility of the integrated workflow for characterising fine-scale features within agglutinated tests. Historical samples will allow assessment of how synthetic particles entered these environments and how their incorporation has changed through time.

This study advances the development of high-resolution, non-destructive methods for detecting microplastics and nanoplastics below the approximate 20 µm limit of traditional techniques. The approach offers a new path to reconstruct the historical footprint of plastic contamination in marine sediments by using foraminifera as natural archives.

7.14.P-Th343 Non-Destructive Portable X-Ray Fluorescence for Multi-Metal Assessment in Mussel Shells from Port Phillip Bay, Australia

Damien Nzabanita, Ecotoxicology Research Group, RMIT University, Australia

Trace metal contamination remains a key pressure on urbanised coastal systems, yet long-term records of exposure are often limited. Mussel shells provide a stable archive of environmental metal uptake, and portable X-ray fluorescence (portable XRF) offers a non-destructive approach to analysing these materials directly. Despite this potential, its application in marine biomonitoring has not been comprehensively evaluated. This study examined the performance of portable XRF for quantifying multiple trace metals in shells of *Mytilus galloprovincialis* collected from Port Phillip Bay in southeastern Australia. Ninety-nine shells were cleaned and scanned using portable XRF, and the same samples were subsequently digested and analysed by inductively coupled plasma mass spectrometry (ICP-MS) to establish reference concentrations.

ICP-MS data showed wide variation in metal concentrations across shells, reflecting a combination of natural background levels and localised anthropogenic inputs within this semi-enclosed bay. Portable XRF produced precise measurements and demonstrated strong correspondence with ICP-MS for several environmentally relevant metals, including barium, manganese, nickel and zinc. These relationships indicate that portable XRF is capable of resolving both spatial and biological variability in shell chemistry through rapid, non-destructive scans.

This work provides the first baseline dataset of shell metal concentrations for Port Phillip Bay and demonstrates that portable XRF is a practical tool for screening multiple trace metals in calcified biomonitoring materials. Its portability and minimal preparation requirements make it well-suited for large-scale surveys, retrospective analyses of archived shells and long-term environmental assessments. Integrating shell-based monitoring with portable XRF could substantially enhance the efficiency and spatial coverage of coastal contamination surveillance.

7.15.P Valuing Water Together: Transdisciplinary Collaboration to Achieve Actionable and Inclusive Water Quality!

7.15.P-Th344 Towards a Cleaner Meuse: Collaborative Strategies for Micropollutant Reduction in the River Basin

Ruud Steenbeek¹, Andre Bannink², Marjolein van Eerd³, Tineke Slootweg⁴ and Janneke Snijders⁵, (1)Dunea, Netherlands, (2)RIWA, Netherlands, (3)RWS, Netherlands, (4)HWL, Netherlands, (5)Aa en Maas, Netherlands

The Meuse River is a critical source for drinking water and biodiversity. Unfortunately, it is increasingly impacted by organic micropollutants such as pharmaceuticals, industrial chemicals, and substances of very high concern (SVHC). The partners within the Clean Meuse Water Chain initiative (“Schone Maaswaterketen” in Dutch) aim to enhance the water quality of the Meuse River and its catchment area. This advocates an integrated framework comprising four strategic pillars: Prevention, monitoring, collaboration and data integration. Prevention emphasizes source protection, revision of permits and responsible discharge management in collaboration with water authorities, drinking water companies, the government and industry, whereas

monitoring identifies critical compounds and establishes target concentrations to safeguard drinking water quality. A comprehensive monitoring program has been established to quantify target compounds across 30 sampling sites, applying advanced monitoring approaches. In addition, both direct and indirect discharges are being identified and linked to industrial facilities through a custom-developed database. The SMWK program illustrates how multi-stakeholder collaboration, innovative monitoring, and data-driven source control can accelerate progress toward cleaner water systems. Lessons learned will inform national and international policy. Continued efforts will focus on strengthening cross-border cooperation, and addressing emerging contaminants to underscore the necessity to ensure the security of drinking water resources.

7.15.P-Th345 Catchment Communities: An Interdisciplinary Approach for Innovative Citizen Science Water Quality Monitoring Tools

Nathan Maréchal, Chloe Martin, Charlotte Bouffeteau, Juan Esteban Quintero Marín, Fiona Regan, Fiona Murphy, Pdraig Murphy and Susan Hegarty, Dublin City University (DCU), Ireland

One of the primary challenges in water quality monitoring, is the significant amount of resources required to monitor extensive freshwater networks. In the case of the Irish river network, only 4% of all river bodies are actively monitored by the Environmental Protection Agency (EPA), the small order bodies being excluded due to a lack of resources. Therefore, there is a critical need to implement additional and reliable means of data collection. Doing so would allow for better support of policy-making, and help authorities reach the goals established in the European Union Water Framework Directive (WFD).

In recent years, citizen involvement has emerged as an effective way to gather reliable water quality data with an improved spatial resolution, complimenting traditional monitoring approaches in a desirable way. In this optic, the Catchment Communities project aims to design a framework for the development of citizen science (CS) water quality monitoring projects, easily scalable to a national scale. In order to address all aspects of the WFD, the project will cover hydromorphological and physico-chemical elements, while also focusing on the anthropological considerations of citizen science and water quality. This interdisciplinary approach is a key output of the project, as its presence in the framework will be essential for the successful creation of future citizen science projects.

This presentation focuses on the physico-chemical part of the project, demonstrating the application of existing and new CS tools for improved data gathering, sample collection and citizen engagement. The scope of development is driven by WFD needs, data gaps, EPA water quality reports and the potential to develop new robust tools that are reliable and citizen science ready.

Disclaimer/Disclosure:

This research is funded by the Environmental Protection Agency (EPA) of Ireland.

7.15.P-Th346 Participatory research of water bodies as a strong tool to manage environmental problems.

Analia Mosqueira¹, Erika Arbildi² and Maria Laura Lavaggi³, (1)Sede Rivera, CENUR Noreste, Universidad de la República, Uruguay, (2)Laboratorio de Química Biológica Ambiental, Sede Rivera, CENUR Noreste, Universidad de la República, Uruguay, (3)University of the Republic Uruguay (UdelaR), Uruguay

The present investigation originated from concerns expressed by local social actors in the municipality of Vichadero, Rivera, Uruguay. Vichadero is a rural locality with very few nearby water bodies available for domestic, productive, and recreational use. The lack of information regarding the quality of these water sources had become a significant concern for residents of the village and surrounding areas. In response, local actors collectively demanded a scientific assessment of their water bodies.

Our research group conducted the first comprehensive study of the area using a participatory approach that incorporated local inhabitants' knowledge into the design of the monitoring strategy, including the selection of sampling sites, physicochemical parameters, and biological indicators. The objective was to identify the main environmental issues of the region through a socio-environmental diagnosis using participatory methodologies, while strengthening the collective capacity for knowledge production. This approach was complemented by a detailed analysis of physicochemical and biological parameters of surface water quality within the local micro-watershed.

The results revealed elevated concentrations of phosphorus in several water bodies, indicating potential

eutrophication risks. In addition, mutagenicity assays evidenced the presence of mutagenic compounds, raising concerns about possible impacts on environmental and human health.

These findings were presented to the community by the reference group that participated in the project, demonstrating local empowerment and an increased capacity to address their environmental challenges. Overall, this study provides evidence that similar participatory processes can successfully promote the engagement of local actors in monitoring and research initiatives linked to the environmental management of their territory.

7.15.P-Th347 Economic Valuation of Water for Better Policy Decisions

Thea Marcelia Sletten¹, Allan Provins² and Russell Drummond², (1)Economics for the Environment Consultancy (EFTEC), London, United Kingdom, (2)eftec, United Kingdom

Improving water quality requires evidence that captures the real benefits of reducing pressures on rivers, lakes and coastal waters. Yet much of the existing economic evidence is outdated or too narrowly focused to reflect today's challenges, including the growing importance of long-term chemical risks. This research addresses that gap by linking changes in waterbody condition to ecosystem-service outcomes using a pressure-to-benefit pathway. The valuation tasks focus on three clearly defined dimensions of condition: ecological status, suitability for contact recreation and long-term chemical risks such as those associated with PFAS, pharmaceuticals and microplastics.

The resulting evidence can be used to strengthen assessments for river-basin management planning, wastewater-treatment investment and chemicals policy by capturing benefits that have previously been difficult to quantify – particularly those linked to emerging or uncertain future risks. By combining ecological, recreational and chemical-risk dimensions within a single structure, the work offers a practical way to connect scientific understanding of pressures with the societal benefits of reducing them. This supports clearer prioritisation of actions and more coherent decision-making across sectors involved in protecting and improving the water environment.

Disclaimer/Disclosure:

The study is commissioned by Department for Environment, Food & Rural Affairs

7.15.P-Th348 Valuing micropollutants in LCA: are Waste Water Treatment Plants Good for the Environment?

Niels Jonkers¹ and Josje Brouwers², (1)Waternet, Netherlands, (2)KWR Water Research Institute, Netherlands

Dutch water authorities are increasingly using Life Cycle Assessment (LCA) as a decision making tool in water management projects such as dike improvement and wastewater treatment. In design variant studies, different options are evaluated on efficiency, costs and total environmental impact. Comparisons are made based on energy and chemicals consumption and the use of building materials. In these studies, the impact on water quality is often not specifically included, due to a lack of data or method availability. For the analysis of a wastewater treatment plant this could mean that only the environmental costs are taken into account, and not the environmental benefits.

Emissions of nutrients to water, such as nitrogen and phosphorus, could already be included in a relatively straightforward way. For emissions of micropollutants, this is a lot more complex. In the current project, we are taking on the challenge of quantifying the effects of micropollutants in LCA, with the evaluation of wastewater treatment techniques as a main application. The LCA impact assessment method most commonly used in the Netherlands by the construction sector and governments is EN15804 (with total scores expressed as an Environmental Cost Indicator, ECI or MKI). We aim to align with that method. The USEtox fate and effects model is used for deriving characterisation factors of micropollutants. Emission data is partly based on monitoring data and partly modeled.

In general this project hopes to contribute to an increasing awareness that water quality and in particular micropollutants should and could be taken more seriously when using decision making tools that consider total environmental impact, such as LCA tools.

7.15.P-Th349 Effect-Based Methods to Study the Occurrence and Fate of Antibiotics in Wastewater and Surface Water.

Jaimy de Schepper¹, Tjalf de Boer², Peter Cenijn³, Timo Hamers³, Thao Nguyen⁴ and Corine J. Houtman¹,

(1)Het Waterlaboratorium, Netherlands, (2)BioDetection Systems BV, Netherlands, (3)VU University Amsterdam (VU), Netherlands, (4)Stichting Waterproef, Netherlands

Risk assessment of antibiotics (ABs) in water typically relies on chemical target analysis of individual ABs, which may underestimate the total toxic pressure due to limited coverage of AB classes and their transformation products (TPs). This study evaluated three in vitro bioassays - the MicroGLO, the WaterSCAN and the E. coli FhuAT – to provide an integrated view on the occurrence and fate of ABs in water for water quality managers and drinking water companies. The MicroGLO and WaterSCAN were developed with five modules to distinguish between classes of ABs, whereas the E. coli FhuAT bioassay was developed as a general measure of AB activity.

Spiking experiments using ultrapure water and surface water (both spiked with AB and non-spiked) showed that these bioassays can successfully distinguish between water samples that contain ABs and those that do not.

Next, a field study was performed by using these bioassays on influent and effluent samples of three wastewater treatment plants, and five surface water bodies used for the production of drinking water. Chemical target analysis and targeted screening were performed in parallel to identify substances that might have contributed to activity observed in the bioassays and to assess whether the current chemical analysis provides a comprehensive view of ABs in the water cycle.

All three bioassays detected AB activity in wastewater, where the MicroGLO and E. coli FhuAT also detected AB activity in surface water. Effect-based trigger (EBT) values were exceeded in several wastewater effluent samples, indicating potential risk to the environment even after wastewater treatment. As such, water managers can use such bioassays as an early warning system for ecological risks of AB.

Comparison with chemical analysis revealed that bioassays often detected activity when target ABs were absent, and vice versa. This discrepancy between bioassay results and chemical analyses offers an opportunity for water authorities to revise monitoring strategies and incorporate effect-based methods into regulatory frameworks.

These findings demonstrate that bioassays can bring an added value to water managers and drinking water companies to study the occurrence and fate of ABs in wastewater and surface water. Their combined use with chemical analysis offers a more comprehensive insight in the occurrence and fate of ABs to support water quality monitoring and risk assessment.

Disclaimer/Disclosure:

This work was supported by two drinking water companies in the Netherlands.

7.15.P-Th350 Assessment of industrial wastewater treatment plant effluent quality using bioassays

Nessia Fausta¹, Marthe de Graaff¹, Astrid Fischer², Tineke Slootweg³ and Corine J. Houtman⁴, (1)Evides Industriewater, Netherlands, (2)Evides Waterbedrijf, Netherlands, (3)Water Laboratory, Netherlands, (4)Het Waterlaboratorium; Amsterdam Institute for Life and Environment (A-LIFE), VU University, Netherlands

Evides Industriewater operates several industrial wastewater treatment plants in the Netherlands. In line with the goals of the European Water Framework Directive in 2027, the company aims to deliver a leading effluent quality. The challenge lies in its tangible translation. Effect-based monitoring can help answer it. Therefore, EIW has applied bioassays to analyse the effluent from one treatment plant location. The objectives were to assess the effluent quality and identify the toxic compounds, with the ultimate aims to track down the sources to optimize the treatment process.

The selected location received the discharges from more than 60 industrial facilities. The assessment used a basic set of bioassays relevant to surface water quality: Cytotox-CALUX and Alivibrio Fischeri Bioluminesce (similar to Microtox®) for general toxicity, anti-AR- and ER α -CALUX for endocrine disruption, PAH- and PXR-CALUX (xenobiotic metabolism). Measured responses were benchmarked against effect-based trigger values for ecology. Exceedance of these trigger values gave directions to pinpoint the responsible compound groups and help investigate the sources.

Three samples were taken, one per month. Het Waterlaboratorium handled the pre-filtering, solid phase extraction and analysis for each assay. The analysis followed the Key Factor Toxicity method by STOWA. The

weight factor from the ratio between the unit and the respective trigger value determined the risk classification using colours: excellent (blue), good (green), medium (yellow), high risks (orange) and hazardous (red).

Activities indicative of general toxicity did not exceed the trigger values (blue and green), implying that no risks were expected. Risks of xenobiotic compounds could not be excluded, given the red colour for CALUX-PXR and CALUX-PAH, the latter likely caused by dioxins, PCBs and/or PAHs in the effluent. It is still unclear which specific compound(s) are responsible for these risks. Comparison with other types of surface water shows insights of the effluent quality and treatment performance.

The assessment indicates that the EIW's wastewater treatment plant performs comparably adequate to the drinking water intake points but requires further optimization to prevent the release of toxic effects into surface waters. The situation may vary due to changes in seasonal patterns and influent quality; additional samples during dry seasons and detailed influent quality analysis were recommended.

Disclaimer/Disclosure:

The comparison with a municipal wastewater treatment plant is under embargo. It can be published/presented after the authors receive approval from the related parties.

7.15.P-Th351 Integrated Approaches to Improve Chemical Water Quality in Surface and Drinking Water

Corine J. Houtman¹, Geert Corné Franken², Carla Van der Neut-Marchand², Yvonne van Oorschot² and Ruud J.C.A. Steen³, (1)Het Waterlaboratorium & Amsterdam Institute for Life and Environment (A-LIFE), VU University Amsterdam, Netherlands, (2)Het Waterlaboratorium, Netherlands, (3)Rijkswaterstaat West-Nederland Noord, Dutch Ministry of Infrastructure and Water Management, Netherlands

Surface waters used as sources for drinking water production are increasingly contaminated with chemicals of emerging concern, originating from wastewater effluents, agriculture, and industrial activities. Conventional monitoring based on targeted chemical analysis alone cannot capture the complexity of these mixtures or identify unknown compounds. This limits the ability of water authorities and regulators to assess risks and design effective measures.

To address this challenge, we applied a combined approach using a panel of in vitro bioassays and high-resolution targeted screening, complemented by multivariate statistics and effect-directed analysis. The methods were applied to waste water treatment plant (WWTP) effluent, and to surface water (SW), process water and drinking water (DW) of 4 DW companies in the Rhine and Meuse catchments. Bioassays revealed eight types of biological activity, including endocrine disruption and oxidative stress, some exceeding effect-based trigger values for ecological or human health risk. Targeted screening detected over 600 contaminants, with distinct patterns between the Rhine and the Meuse catchments: pharmaceuticals dominated in the river Rhine, while agricultural compounds and steroids characterized the river Meuse. Multivariate analysis clustered locations by contamination profiles and identified key compound groups driving water quality differences. Effect-directed analysis confirmed causative chemicals behind observed bioassay responses.

For water managers and policy makers, these findings provide actionable insights:

- Prioritization of measures: Focus on pharmaceuticals in Rhine and pesticides in Meuse catchments.
- Source control: Upgrade wastewater treatment and strengthen pesticide admission limits to meet Water Framework Directive goals.
- Risk-based monitoring: Integrate bioassays with chemical screening to detect unknown hazards and guide interventions.
- Strategic planning: Use clustering and correlation analyses to identify hotspots and shared emission sources, enabling targeted mitigation.

This integrated methodology advances water quality assessment beyond single-compound monitoring, offering regulators and drinking water companies a science-based framework to safeguard ecological health and drinking water safety.

Disclaimer/Disclosure:

This study was performed within the framework of the Joint Research Program of four Dutch dune water companies: Dunea, PWN, Waternet, and Evides (DPWE).

7.15.P-Th352 Seasonal Occurrence and Water Quality Hazards of Per- and Polyfluoroalkyl Substances in Estuarine Systems across a Gradient of Effluent Contributions to Base Flow

HyeongYoung Choi¹, Adam Wronski¹, Sara Kamanmalek², Jacelyn Rice-Boayue³, Jaylen Sims⁴, Kevin Stroski⁵, Chong Chen⁶, Alistair Boxall⁷, Kenneth M.Y. Leung⁶ and Bryan W. Brooks¹, (1)Baylor University, United States, (2)Howard University, United States, (3)North Carolina State University, United States, (4)Oak Ridge Institute for Science and Education (ORISE), United States, (5)University of Antwerp, Belgium, (6)City University Hong Kong, Hong Kong (Greater China), (7)University of York, United Kingdom

Global estuaries provide diverse benefits to human populations, biodiversity and ecosystem services. Similar to other coastal systems, Gulf of Mexico estuaries in Texas, USA experience diverse anthropogenic stress, including base flows that are influenced by upstream wastewater discharges. Given the limited global information for the occurrence and water quality hazards of per- and polyfluoroalkyl substances (PFAS) in estuaries, we employed a hydrological model to examine 14 Texas estuaries across gradients of annual precipitation (~60-140 cm/yr) and wastewater effluent contribution to base flows. Conventional grab and time-weighted composite samples over a 24-hour period were collected from these 14 estuaries during wetter (Spring) and drier (Fall) seasons of 2024, the hottest year in Texas since 1895. We quantitated surface water concentrations of 24 PFAS via isotope dilution LC-MS/MS. We employed a two-factor generalized linear model and identified sum perfluoroalkyl carboxylic acid (PFCA), long-chain PFAS, and precursors concentrations to significantly ($p < 0.05$) differ between seasons, with higher mean concentrations detected in spring. Concentrations of perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) did not exceed United States Environmental Protection Agency water quality criteria for aquatic life during either season across the 14 estuaries examined here. However, PFOS levels in these study systems consistently exceeded European environmental quality standards and Australian and New Zealand guideline values during both seasons by <99%. These results highlight an urgent need to better understand PFAS sources, exposure scenarios, and water quality hazards in global estuarine systems across gradients of urbanization and climatic conditions.

7.15.P-Th353 Gradually Emerging Threats and Their Impact on Sustainable Drinking Water Security: Dutch Insights

Dominique Narain-Ford, RIVM, Netherlands

Although monitoring drinking water as a final product has traditionally been the standard for determining its safety and quality, experience over the past decades has shown that this approach can often be insufficient—particularly in the context of gradually emerging threats. Such threats may go undetected until they have already impacted drinking water quality or supply. This article provides an integrated overview of current and emerging threats to the drinking water sector, offering insights from the Netherlands based on an analysis of supply plans from ten drinking water companies. The study identifies five main developments impacting water security: climate change, anthropogenic substances (including PFAS), socioeconomic trends, geopolitical relations, and the energy transition. Each development introduces specific challenges, ranging from the deterioration of water sources and stricter health standards to growing population demands, supply chain vulnerabilities, and infrastructural constraints.

The findings reveal that the achievement of key policy objectives—ensuring good quality and sufficient drinking water sources, as well as the sustainable production and supply of drinking water—is under increasing pressure. Anthropogenic substances and climate change particularly threaten source quality and availability, while socioeconomic developments such as population growth and labor shortages jeopardize infrastructure and service reliability.

To address these challenges, the article highlights the need for cross-sectoral collaboration and structural improvements in permitting, supervision, and enforcement. Recommendations include harmonizing threat descriptions across supply plans, supporting data-driven prioritization of local bottlenecks, and increasing attention to public trust and communication. The study underscores the urgency of timely, coordinated measures to safeguard the future security and quality of Dutch drinking water supplies.

7.15.P-Th354 A Transdisciplinary Journey to Establish Safe Operating Spaces in European Rivers

Jennifer Laurent¹, Katarina Cetinic², Paulina Ramirez-Monsalve², Anna Sobek³, James S. Sinclair⁴, Daniela Cortés Guzmán⁴, Elmar Becker⁵, Milo Leon de Baat⁶, Dennis Trolle⁷, Anders Nielsen⁷, Iris Pit⁸, Peter Haase⁴, Ciaran Murray⁹, Susanne Schneider² and Jes Rasmussen⁹, (1)Stockholm University, Sweden, (2)Norwegian Institute for Water Research, Norway, (3)Environmental Science, Stockholm University, Sweden, (4)Senckenberg Research Institute and Natural History Museum Frankfurt, Germany, (5)University of Amsterdam, Netherlands, (6)Chemical Water Quality & Health, University of Amsterdam (UVA), Netherlands, (7)WaterITech, Denmark, (8)Deltares, Netherlands, (9)Aarhus University, Denmark

The management of freshwater ecosystems increasingly requires approaches that integrate ecological, social, and institutional dimensions, and that recognize how water quality and quantity are defined and valued in practice. Despite significant scientific advances in understanding the multiple pressures on aquatic biodiversity, a gap remains between knowledge production and its operational use in water governance. The EU Biodiversa+ DESTRESS project (DEciphering temporal trends and safe operating spaces for river biodiversity within the context of multiple STRESSors) addresses this challenge through a transdisciplinary framework linking ecology, hydrology, toxicology, and social sciences.

DESTRESS investigates how interactions between flow regimes, chemical contamination, and land use influence river biodiversity across Europe. Using long-term macroinvertebrate time series and environmental data, the project aims to identify biodiversity change points and determine Safe Operating Spaces intended to guide sustainable water management that balances water quality and quantity needs for both riverine biodiversity and human society. Beyond modelling, DESTRESS involves water managers and authorities to co-create actionable solutions that balance human water uses with biodiversity conservation.

The transdisciplinary journey of the project highlights the challenges and opportunities of connecting scientific, regulatory, and local knowledge. Through collaborative workshops, dialogues, and iterative feedback processes, scientists and practitioners jointly explore what “good water quality” means in diverse socio-ecological contexts and how hydrological and chemical stressors can be better captured in assessment and management practice. Integrating social sciences helps reveal tensions between ecological objectives, regulatory requirements, and human water needs, while fostering mutual understanding among disciplines and institutions.

Building on co-creation dynamics and stakeholder engagement, this work aims to identify pathways through which transdisciplinary collaboration could lead to a more inclusive, context-sensitive, and actionable water governance. The experience gained from DESTRESS suggests that collectively valuing water—scientifically, socially, and institutionally—is essential for implementing adaptive, equitable, and resilient strategies that protect aquatic biodiversity and support multi-functional freshwater ecosystems under multiple stressors.

8.02.T-02 From Individuals to Landscapes: Scaling Mechanistic Individual-Based Models for Landscape Ecological Risk Assessment of Non-Target Organisms

Alice Johnston and Harriet Gold, Cranfield University, United Kingdom

Ecological responses to environmental stressors are characterised by emergent properties arising from interactions between mechanisms and processes operating at lower levels of biological organisation. Population responses of non-target organisms to plant protection products (PPPs), for example, cannot be inferred from toxicity measurements alone. Instead, population outcomes emerge from how individuals respond to PPP exposure in combination with ecological processes such as movement, reproduction and resource use across heterogeneous landscapes. These responses are further shaped by interacting stressors including agricultural management, habitat fragmentation and resource availability, which influence both exposure and population resilience. Predicting ecological consequences of environmental stressors therefore requires approaches capable of linking individual responses to population outcomes across space and time.

Mechanistic individual-based models (IBMs) provide a powerful framework for representing these cross-scale dynamics because they explicitly describe how physiology, behaviour and life-history processes interact with environmental conditions to determine survival, reproduction and dispersal. However, scaling such models to landscape extents relevant for ecological risk assessment remains challenging because of the persistent trade-off between ecological realism and computational tractability.

Here we present a framework for scaling spatially explicit mechanistic IBMs by identifying the spatial extent at which emergent population behaviour stabilises. The approach involves simulating IBMs across progressively larger spatial extents and quantifying how key population properties, including abundance, biomass and spatial structure, change with increasing extent. As model extent increases, the emergence of new behaviours diminishes, producing an area–emergence relationship from which a Critical Emergence Threshold can be identified. This threshold represents the smallest spatial extent at which emergent dynamics stabilise while computational costs continue to rise, defining the ‘Medawar Zone’, where ecological realism and tractability are jointly optimised.

This framework provides a pathway for integrating mechanistic IBMs with spatially explicit landscape simulations to support ecological risk assessment of non-target organisms by linking heterogeneous exposure and effects of PPPs and other landscape stressors to population-level outcomes.

8.02.T-03 Concepts, strengths and challenges of integrating landscape models into an environmental risk assessment for non-target terrestrial organisms

Pernille Thorbek, Apd/EE, BASF, United Kingdom
