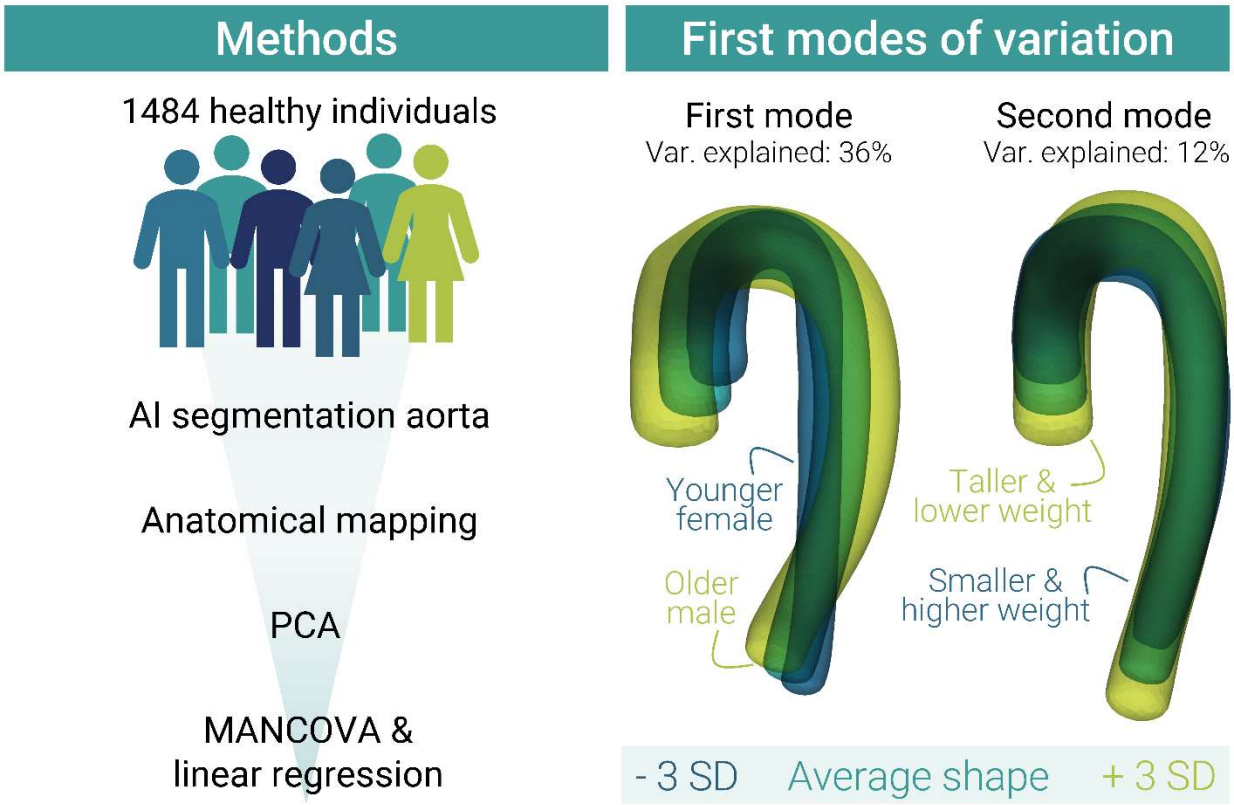
The MANCOVA results demonstrated that all considered covariates significantly influenced aortic shape. Based on Pillai's trace, which quantifies the effect of each variable while adjusting for all others, age showed the strongest overall effect on aortic shape (0.31), followed by sex (0.13) and height (0.12).



Age showed the largest effect on the first principal mode (see figure), explaining 36% of population variance and representing changes in aortic diameter and arch curvature; sex also mostly influenced this mode. Height and weight had the strongest impact on the second mode, explaining 12% of the variance, accounting for changes in length and in-plane curvature.

Discussion

The findings show that individual characteristics significantly shape aortic geometry, with age as the dominant factor, reflecting known age-related remodeling such as dilatation and increased curvature. Sex influences aortic geometry not only through scaling and dilatation but also through curvature, meaning male and female aortas are not simply scaled versions of one another.

Ongoing work will refine shape interpretation and enable generation of virtual aortic populations for *in silico* trials.

Towards a Single-Camera Markerless Approach to Quantify Upper-Limb Kinematics in Children with Cerebral Palsy

Ms. Jingwen Hu[1], Dr. Michelle Spirtos[1], Dr. Damien Kiernan[2], Prof. Ciaran Simms[1]

[1]Trinity College Dublin, Dublin, Dublin, Ireland. [2]Central Remedial Clinic, Dublin, Dublin, Ireland

Introduction

Upper-limb evaluation is essential for understanding movement difficulties and guiding treatment in children with cerebral palsy (CP). Conventional functional assessments rely largely on visual observation and are therefore qualitative and subjective. Marker-based multi-camera motion capture systems enable quantitative analysis but are costly, require dedicated laboratory environments, and do not reflect children's natural daily movements. A low-cost, single-camera markerless system (e.g., a mobile phone) that operates in everyday settings would greatly improve the accessibility of upper-limb kinematic assessment. This study investigates whether a transformer-based model can accurately and stably quantify upper-limb motion assessment in children with CP from single-camera recordings.

Methods

The transformer-based model predicts 3D upper-limb kinematics from single-camera 2D video. During training, to improve clinical applicability, the loss function was redesigned to incorporate not only keypoint position errors but also anatomically meaningful constraints, including skeleton segment-length consistency and joint-angle errors. Training data consisted of 3D motion-capture recordings collected with a marker-based multi-camera system. Model training and evaluation are planned to be conducted using upper-limb assessment data from children with CP.

Results

Preliminary training was performed using a small dataset of upper-limb assessment trials from six healthy adults. For the clinically relevant movement of shoulder abduction angle in upper-limb assessment, the model achieved a mean error of 3.1° with a standard deviation of 6.3°. Compared with an open-source baseline trained using a conventional loss function, the error of maximum shoulder adduction angle decreased from 6.7° to 4.1°. Continued training using the dataset of children with CP is expected to further reduce joint-angle errors and enable quantitative estimation across additional clinically relevant upper-limb assessments. These results will be presented.

Discussion

This transformer-based single-camera method may offer promising prospects as a low-cost and accessible tool for quantitative upper-limb assessment in children with CP. The current preliminary findings are limited to shoulder adduction, and further investigation is needed to determine whether the approach can provide reliable joint-angle measurements across other upper-limb functional tasks. Future work will include full training and testing on CP datasets, evaluation of repeatability, and assessment of agreement with clinical standards.

Prediction of Skin Growth and Deformation in Tissue Expansion using Neural Ordinary Differential Equations

Mr Joel Laudo, Dr Adrian Buganza Tepole

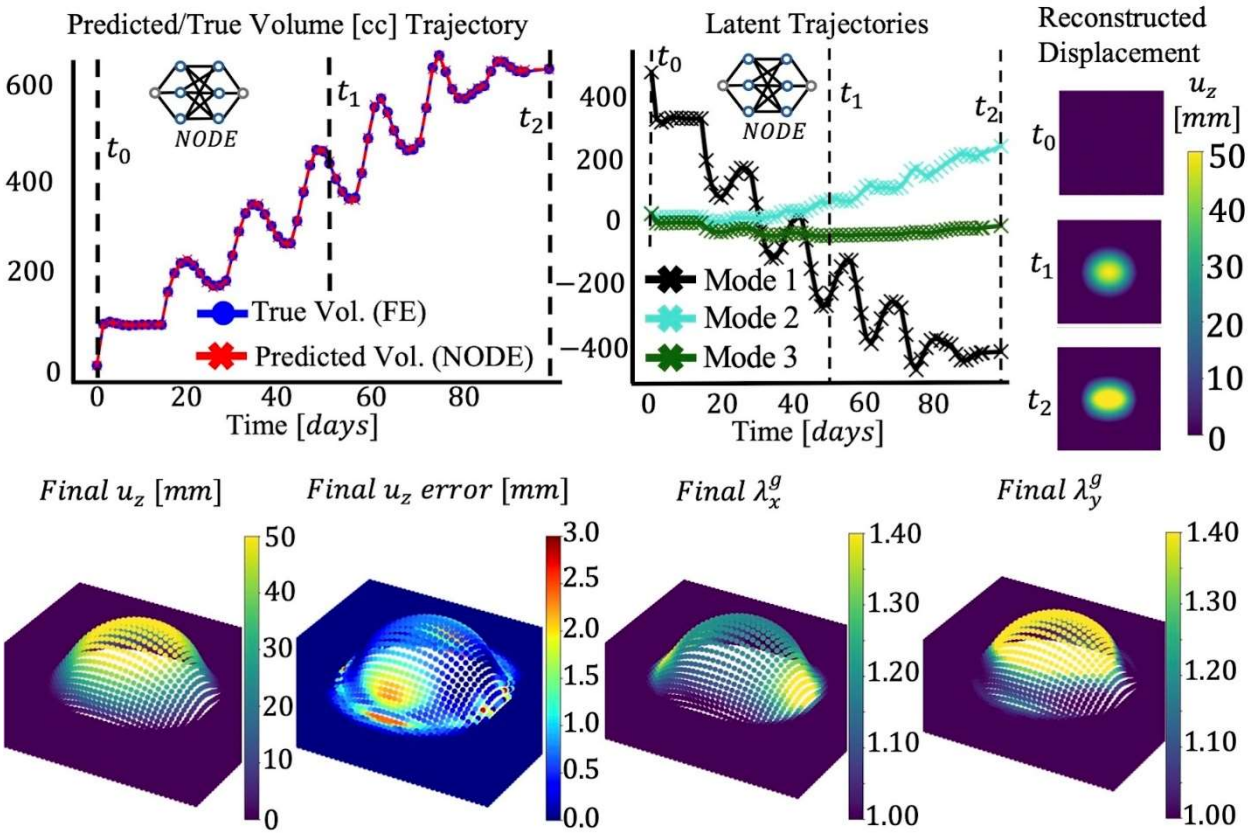
Columbia University, New York, NY, United States

Introduction

Tissue expansion (TE) is widely used in reconstructive surgery, where the gradual inflation of a subcutaneous expander induces skin growth through stretching. High-fidelity finite element (FE) models can accurately predict deformation and growth outcomes, including in patient-specific applications [1], but their computational cost limits clinical deployment. In this work, using an idealized skin patch geometry, we develop a Neural Ordinary Differential Equation (NODE) framework that learns the dynamics of an FE-based TE model as an essential step toward real-time predictive tools for clinical use.

Methods

We performed a 1000-simulation design of experiments using a 150 mm diameter expander inflating a 300 × 300 mm square patch of skin. Material properties, growth parameters, and final inflation volume were varied in a Latin Hypercube Sample. Displacement snapshots across the dataset were projected to a reduced basis ($r = 9$) via Principal Component Analysis. An NODE designed to match the dependencies of the underlying FE model was trained to predict latent displacement and volume trajectories using an 80/20 train–test split. The NODE input included features from the PI-based FE volume controller (setpoint, error, integrated error). From the predicted displacement fields (following projection from latent to physical space), we solved the growth ODEs to predict principal growth stretch trajectories.



Results

We tested the NODE approach on 185 unseen validation simulations. At the final predicted timepoints, the relative displacement error was 3.2 ± 2.1%, the relative volume error was 0.78 ± 0.23%, and the relative growth principal stretch error was 1.9 ± 2.2%. The total mean prediction time was 24.5 ± 9.2 seconds, with latent trajectory prediction taking 0.073 ± 0.012 seconds, full displacement field reconstruction taking 0.35 ± 0.035 seconds and growth integration taking 24.0 ± 9.2 seconds.

Discussion

Even on an idealized geometry, the NODE framework achieves >200× speedup over FE simulations while preserving excellent accuracy. Additional optimizations (i.e. code parallelization) can increase speedup even more. This approach provides a foundation for future patient-specific surrogate models capable of real-time prediction of skin growth and deformation. Ongoing work will investigate model enhancements, alternative time-series architectures and projection-based reduced order models to achieve rapid, trustworthy predictions.

Unsupervised Clustering of Temporal-Spatial Biomechanics Identifying Functional Phenotypes Independent of Anthropometric Constraints

M.Eng. Julia Wilk, D.Sc., Ph.D., M.Eng. Cezary Rzymkowski

Warsaw University of Technology, Warsaw, Mazovian, Poland

M.Eng. Julia Wilk

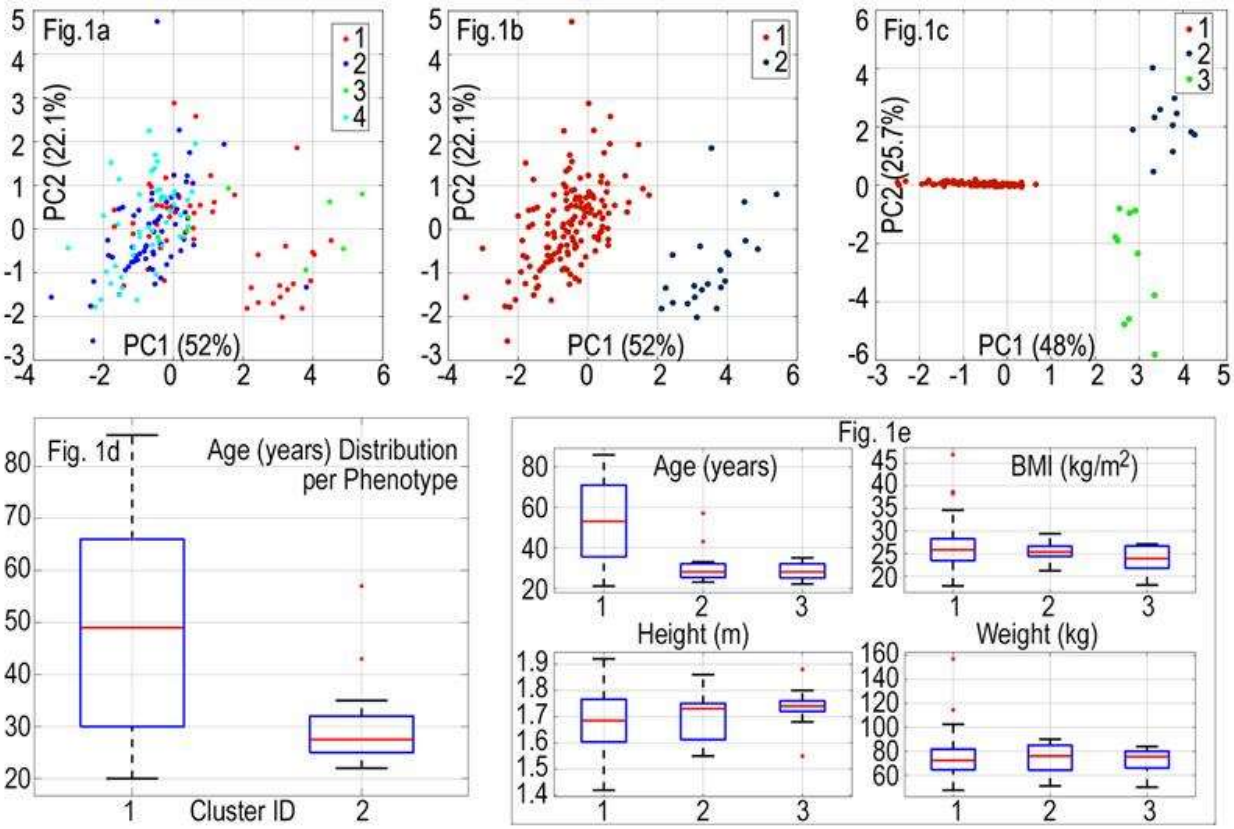
Introduction

Kinematic, dynamic, and EMG data were merged from heterogeneous sources, including Moreira [1], Baček [2], Van Criekinge [3], Lencioni [4], Scherpereel [5], and Wei [6]. The primary objective was to replace anthropometric clustering with direct unsupervised biomechanical clustering. It was hypothesized that functional phenotypes depend on the feature set; therefore, magnitude-focused features were compared against temporal-spatial controls to determine how feature granularity alters gait strategy identification. This approach facilitates development of generalized biomechanical models applicable across populations.

Methods

From a consolidated dataset of 289 subjects, a standardized gait subset (N=171) was isolated. Preliminary anthropometric labels were projected onto the biomechanical space for evaluation. Subsequently, two feature extraction pipelines were implemented: a magnitude-focused set prioritising peak exertion (e.g., peak force) and a temporal-spatial set prioritising motor control (e.g., impact loading rate). Features were averaged across limbs, then Z-score normalised and clustered using k-means.

Results



Anthropometric labels failed to predict movement strategy, evidenced by negative cohesion (Silhouette -0.109) where body-type clusters were dispersed randomly (Figure 1a). The magnitude-focused pipeline identified two age-correlated phenotypes (Silhouette 0.746), distinguishing between restricted-ROM/high-activation walkers and high-velocity/low-activation walkers (Figures 1b, 1c). Conversely, the temporal-spatial set revealed three clusters (Silhouette 0.858) (Figure 1d), distinctively isolating a "high-impact"

strategy characterized by a high loading rate. Demographic analysis (Figure 1e) confirmed these functional choices exist independently of anthropometric characteristic.

Discussion

The limitations of using anthropometry as a gait proxy are illustrated, as somatic labels failed to translate into distinct functional behaviours. While magnitude-based clustering recapitulated biological ageing, deeper insight was provided by temporal metrics, which isolated impact loading as a key discriminator. Distinct strategies were identified independent of body type, with the high-effort group demonstrating neuromuscular inefficiency via significantly higher muscle activation for standard stance times. Anthropometric clustering is rejected in favour of feature extraction to detect phenotypes missed by somatic data.

Introduction

Complex fractures, such as those of the proximal tibia, often pose a challenge in trauma surgery. The success of the operation depends, among other factors, on the experience of the surgeon [1]. Pre- and intraoperative support in the planning of the operation can help to provide more effective care for complex cases of repositioning and fracture stabilization. For this purpose, an AI-based algorithm was developed that provides evidence-based recommendations for anatomical repositioning and biomechanically optimal fracture fixation.

Methods

Starting from preoperative CT data, the workflow comprises several sub-algorithms, such as CT fracture segmentation using neural networks and virtual fracture reduction using spatial transformer networks, autoencoder architectures [2], and blackbox optimization for registration and prediction of the correct fragment repositioning. Subsequent fracture classification and landmark detection then enable recommendations for the selection and placement of the osteosynthesis using a decision algorithm based on surgical evidence from scoping reviews and retrospectively analyzed fracture cases with optional subsequent biomechanical evaluations (finite-element analysis). The main goal is to implement the planning algorithm on an internal server structure and make it accessible via a web-based application, supported by the Charité High-Performance Computing (HPC) cluster.

Results

After uploading a test case CT of a lateral tibial split depression fracture, the prototype of the web-based application executes the planning algorithm on an HPC cluster and provides recommendations for fracture reduction as well as implant type and placement. The results are displayed in several panels (Fig. 1), including a CT viewer (axial, coronal, sagittal) with segmentation, a text-based analysis section, and a 3D viewer for bones and implants.

Discussion

The initial website prototype was successfully implemented, and the first planning test case demonstrated correct plate selection and plausible positioning. However, several intermediate steps still required manual post-correction to ensure overall system functionality. Future work will focus on improving individual sub-methods, generating new training datasets for machine-learning-based CT segmentation, and adding automated biomechanical finite element analysis. At later stage, the application will be prospectively evaluated by surgeons in clinical practice.

Promoting Efficient and Robust Exploration in Predictive Musculoskeletal Simulation by Decoupling Control and Exploration Spaces

Mr. Jun Hyuk Lee Master's Student, Prof. Jooeun Ahn Ph.D.

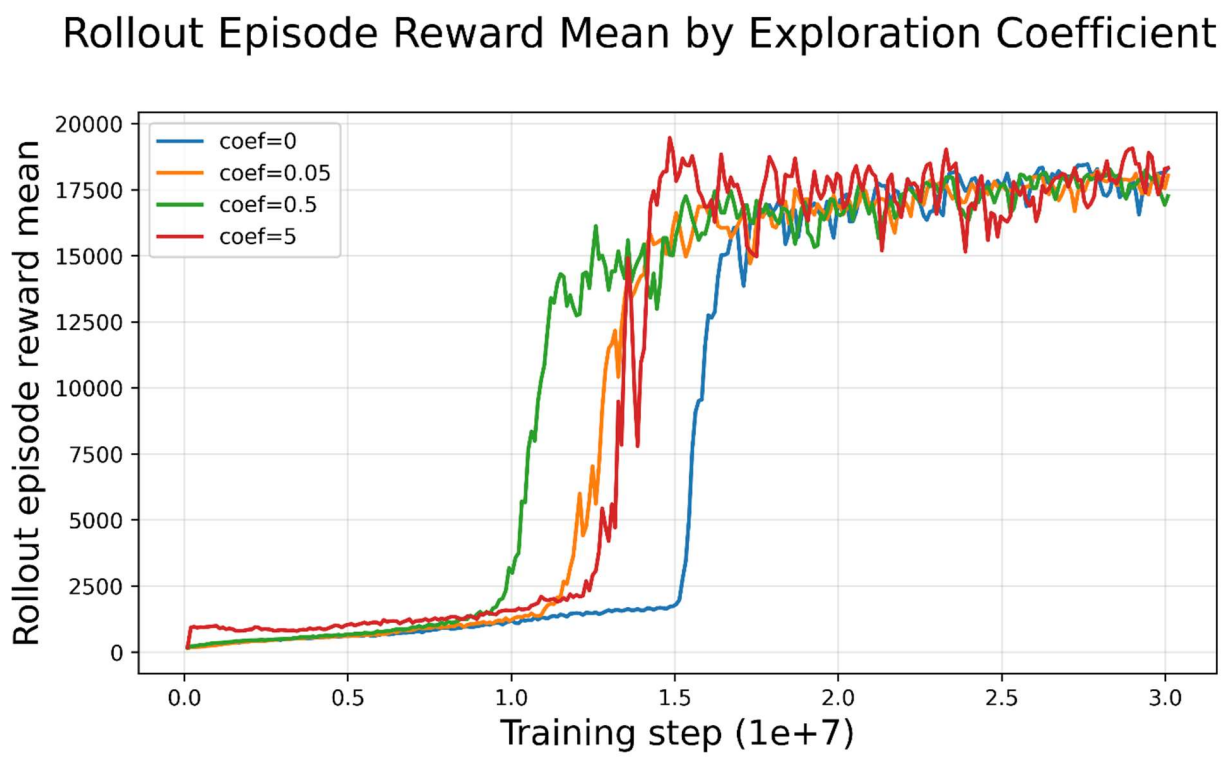
Seoul National University, Seoul, Seoul, Korea, Republic of

Introduction

Predictive musculoskeletal simulation is crucial in biomechanics for surgical support, rehabilitation, athletic performance optimization, and exoskeleton controller design. It also augments data when human experiments are limited or risky. Optimization in musculoskeletal simulation is harder than torque level robotics because the control space (muscle activations) and the exploration space (joint angles) are misaligned [1]. The activation–configuration mapping is highly nonlinear, making approximation difficult. Nevertheless, methods such as Proximal Policy Optimization (PPO) typically encourage exploration by maximizing entropy in the muscle activation space. This often yields inefficient exploration of the joint configurations that matter for task performance. We propose rewarding novelty directly in joint space to reduce this mismatch.

Methods

We used SCONE (Hyfydy) and Sconegym. We augmented the PPO reward with a Random Network Distillation (RND) [2] term. We applied RND to joint angle vectors and used the prediction error as a novelty score. The novelty score, scaled by an exploration coefficient, was added to the task reward. The policy acts in activation space, but the bonus is computed from joint space visitation. On a locomotion task, we evaluated whether broad early visits to diverse joint configurations improve early convergence and robustness.



Results

Increasing the exploration coefficient noticeably improved early convergence, indicating more efficient exploration. However, excessively large coefficients delayed early convergence due to over-exploration. At very large coefficients, joint trajectories became unpredictable across gait cycles during plateaus, yet the agent remained robust and did not fall.

Discussion

A joint space visitation bonus mitigates the control-exploration gap and enables more sample-efficient exploration. Excessive novelty weighting can undermine training stability, motivating coefficient scheduling or adaptive tuning across training phases. We will test whether this approach achieves better optima than conventional exploration and greater robustness to perturbations.

A Pilot Study on Utilization of a Conditional Generative Adversarial Network to Predict Wall Stress in Abdominal Aortic Aneurysm

Ms. Katherine Kerr[1], Dr. Indrani Sen MBBS[2], Dr. Joseph Wildenberg MD PhD[2], Dr. David Vorp PhD[1], Dr. Timothy Chung PhD[3]

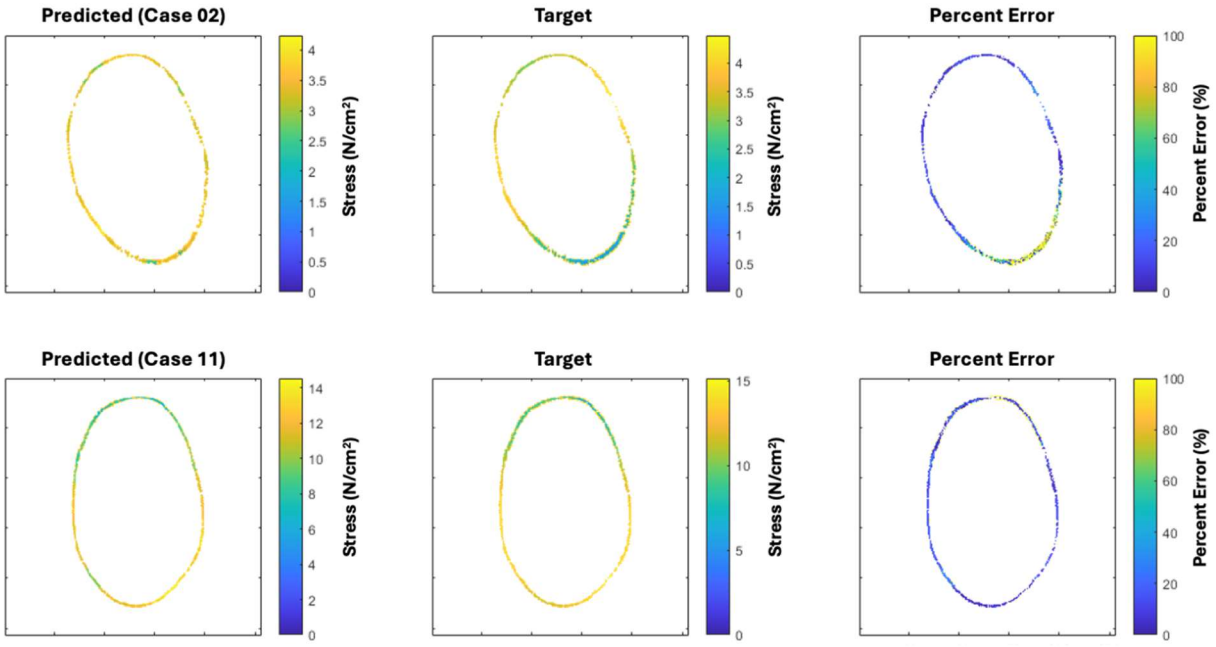
[1]University Of Pittsburgh, Pittsburgh, Pennsylvania, United States. [2]Mayo Clinic Health Systems, Eau Claire, Wisconsin, United States. [3]University of Texas at San Antonio, San Antonio, Texas, United States

Introduction

Abdominal aortic aneurysm (AAA) is a localized dilation of the infrarenal aorta. AAA rupture, a biomechanical failure of the aortic wall, carries up to a 90% mortality rate. Biomechanics plays an important role in AAA stability, but finite element analysis (FEA), the gold standard for stress analysis, is time and expertise intensive. Prediction of stress maps from medical images directly could expedite clinical adoption. In this preliminary work, we train a conditional generative adversarial network (cGAN), Pix2Pix, to output stress maps based on input sections of AAA.

Methods

Computed tomography scans were acquired from Mayo Clinic Health Systems through DUA00004445. Five AAA cases were randomly selected. Each AAA was segmented using 3D Slicer, and FEA was performed in Abaqus using a validated in-house pipeline. A minimum of 600 axial slices per AAA were acquired orthogonal to the centerline. For model training, these slices were labelled based on the Euclidean distance of the wall to the centerline (i.e., radius) and used for input while the von Mises stress was used for the target. Pix2Pix[1] was trained for 10,000 epochs using a NVIDIA GPU workstation. The model consisted of eleven upsampling layers, thirteen downsampling layers, and six discriminator layers. The model was tested using 20% holdout testing, and the predicted stresses were compared to the ground truth by root mean square deviation (RMSE).



Results

The RMSE for von Mises stress for each case was 1.11 N/cm^2, 3.67 N/cm^2, 2.20 N/cm^2, 2.43 N/cm^2, and 2.01 N/cm^2 (average: 1.45 N/cm^2) and the mean percent error was 21.76%, 47.35%, 37.61%, 32.83%, and 13.58% (average: 31.33%). Figure 1 shows example slices.

Discussion

Stress analysis provides insight into the stability of AAA, but FEA limits clinical adoption. The cGAN trained in this preliminary work was able to predict stress with an average percent error of 31.33%. Limitations of this study include only five cases from a single institution being included. In the future, we will include more cases in our model training and testing, train a model directly from DICOM images, and further train the model using a GPU cluster.

Dynamic Finite Element Analysis of Breast Motion under Bra Support: Effects of Internal Structure and Bra Type

Prof. Kohei Murase Ph.D.[1], Prof. Mariko Inui Ph.D.[2]

[1]University of Osaka, Toyonaka, Osaka, Japan. [2]Kurashiki City College, Kurashiki, Okayama, Japan

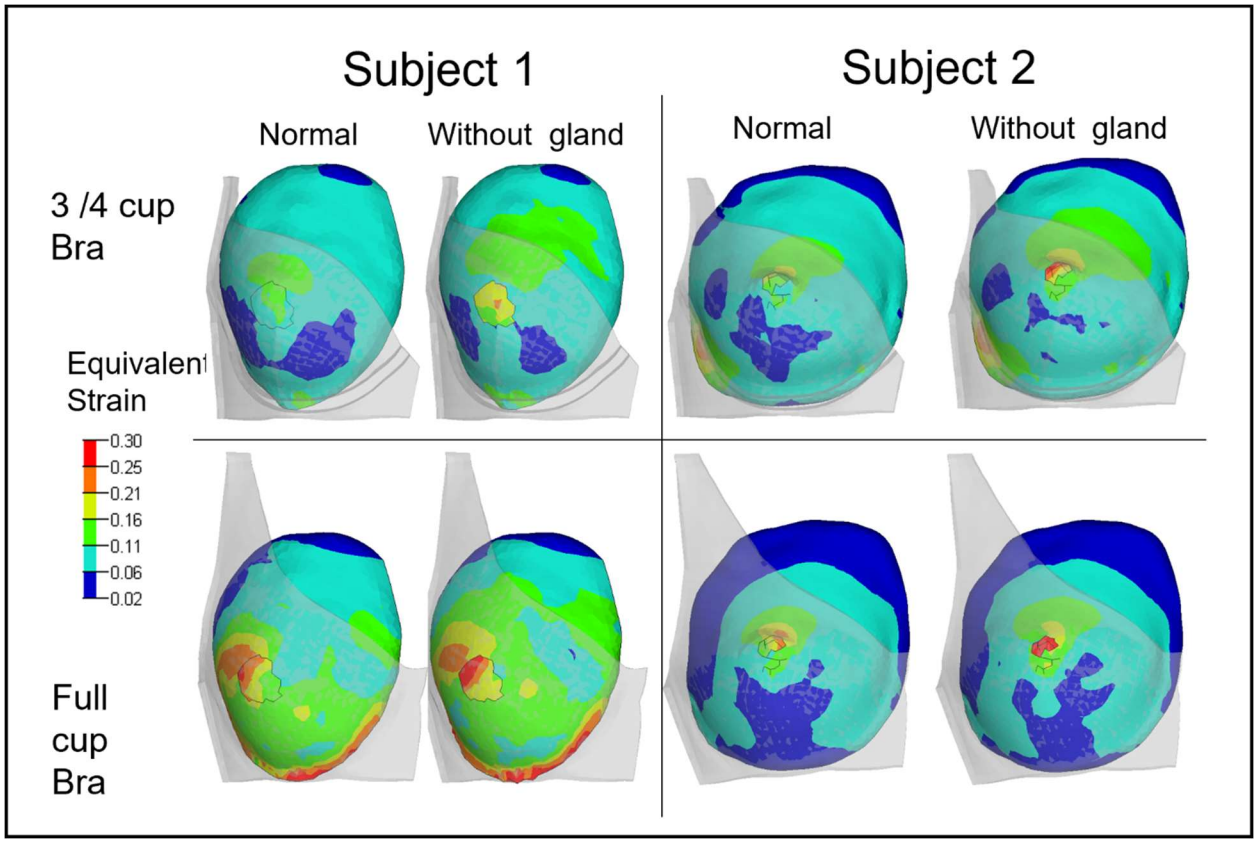
Introduction

Brassieres (bras) support breast weight, but breast shape and glandular tissue distribution vary widely among individuals, so cup size alone may be insufficient for bra selection. This study used finite element analysis of MRI-derived breast geometries to examine deformation under two bras and clarify how internal structure affects reshaping and vibration.

Methods

Breast MRI was obtained in two C-cup women, and finite element models were generated by segmenting skin, adipose, and glandular tissues, each modeled as Neo-Hookean hyperelastic material. A “three-quarter-cup” bra with resin underwire along the breast base line and a wire-free “full-cup” bra were laser-scanned. Bra fit was reproduced by prescribing displacements at the straps, center front, and side panels. After applying gravity, a 1 Hz vertical harmonic base excitation simulating trunk motion during walking was applied, and breast displacement and skin strain were evaluated.

Results



Simulated breast geometries under bra-wearing conditions closely matched those observed on upright MRI[1]. The three-quarter-cup bra produced greater cranial displacement and a more lifted contour, whereas the full-cup bra yielded a more compressed shape with limited upward movement. Despite the same cup size, the two subjects showed distinct skin strain patterns: in one, strain concentrated at the upper pole and medial region; in the other, it localized in the lower-lateral region. Under 1 Hz excitation, displacement amplitudes differed markedly between skin over glandular tissue and regions without glands, and larger, stiffer glandular regions were associated with higher skin strain around the gland boundary and nipple.

Discussion

These findings indicate that cosmetic and stabilizing effects of bras depend on breast morphology, particularly glandular volume and distribution, which decrease with age from

young adulthood to middle age [2], as well as on bra type and cup size. Dynamic vertical excitation made subject-specific differences in breast motion more evident. This simulation approach may support discussion of appropriate wearing conditions, such as strap adjustment and bra type selection according to individual morphology and age-related glandular changes, and provide a biomechanical basis for considering comfort and skin loading.

Temperature-Controlled Centrifuge Force Microscope for Exploring DNA-Protein Interactions

- Koushik Bar

Simon Fraser University, Burnaby, BC, Canada

Introduction

The development of technologies for precise single-molecule force measurements has substantially advanced research in single-molecule mechanics. This major successes has been aided by the development of instruments such as the AFM (Atomic Force Microscopy) and optical tweezers. Despite huge success, they come with a complex setup, high cost ($100,000+), difficulty in creating a large uniform force field, and can usually probe only one molecule at a time, making statistical analysis of single-molecule biophysics experiments notoriously tedious. Multiplexed magnetic-tweezer & early models of Centrifuge Force Microscopy (CFM) [1] are potential cost-effective alternatives, which can provide significantly higher-throughput measurements. Further development of CFM to increase throughput and features like temperature control can lead to significant improvement in fundamental molecular understanding of force-dependent biological interactions.

Methods

We have developed a temperature-controlled, cost-effective (~$200) CFM for single-molecule force spectroscopy with higher throughput, capable of measuring temperature-influenced force response of thousands of single molecules in parallel. This next-generation CFM is a further development of the work of Kirkness and Forde [2], where a commercial benchtop centrifuge was used for applying piconewtons forces to single molecules. In this new CFM, we incorporate remote temperature control with an accuracy of ±0.1 °C. We have massively increased the throughput (> 1000 molecules per run) compared to earlier models [1,2].

Results

To showcase the capabilities of our newly developed CFM, we are investigating the interaction between LacI proteins and DNA. This study focuses specifically on sequence-dependent dissociation rates and temperature-dependent kinetics measured at different forces. Our initial observations have revealed sequence-dependent off-rates. The next phase of this study focuses on quantifying the kinetics of these interactions at physiological temperatures.

Discussion

Although prior studies have explored LacI binding with force-dependent assays [3], they have been limited to room temperature and capture a significantly lower number of binding events than enabled by CFM. Our study leverages a much larger ensemble of single-molecule LacI-DNA interactions, which will help elucidate a more robust understanding of the binding mechanism of LacI to DNA. Furthermore, it serves as a powerful-demonstration of our newly-developed tool's capabilities.

Accurate Estimation of Articular Hip Loading in Hip Osteoarthritis From a Physics-Informed Smart Garment

Mr Bradley Cornish BExSc, A/Prof Claudio Pizzolato PhD, A/Prof David Saxby PhD, Dr Nathan Lyons PhD, Dr Yana Salchak PhD, Dr Matthew Worsey PhD, Prof Laura Diamond PhD

Australian Centre for Precision Health and Technology, Gold Coast, Queensland, Australia

Introduction

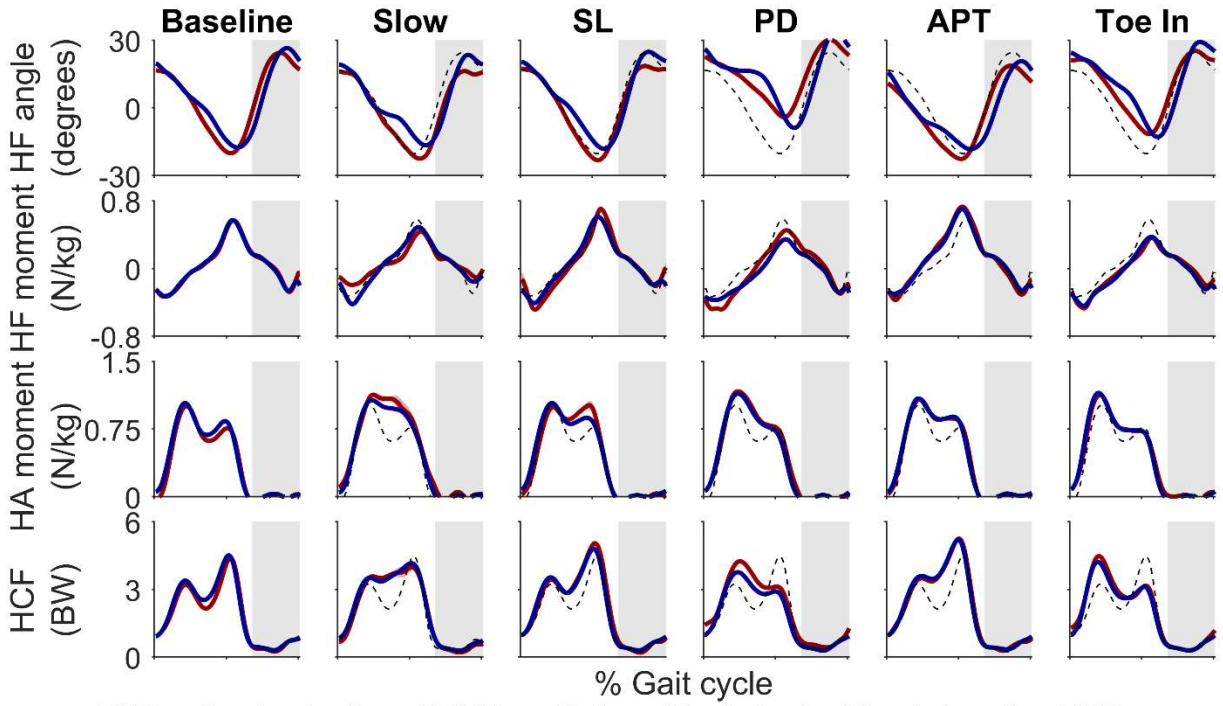
Articular loading is necessary for cartilage remodelling, though abnormal loading (insufficient, excessive, or concentrated) drives cartilage degeneration. Hip articular loading is modifiable with gait retraining, which may promote cartilage health and slow osteoarthritis (OA) processes, but cannot currently be measured in natural environments. This study assessed the validity of a smart garment that used a physics-informed neural network (PINN) to estimate hip angles, moments, muscle forces, and contact forces in a person with hip OA during walking.

Methods

One female participant with moderate hip OA completed two gait retraining sessions 1-week apart on an instrumented treadmill whilst equipped with optical motion capture, electromyography (EMG), and custom smart-shorts which included 3 inertial measurement units and recorded EMG from 4 muscles. The participant walked using nine gait modifications, aided by visual biofeedback.

Hip angles, moments, muscle and contact forces for each gait modification were calculated using OpenSim and an EMG-assisted NMS model. A previously developed PINN was finetuned using smart-short data recorded from the first session. The PINN was then used to estimate hip angles, moments, muscle and contact forces for smart-short data recorded during the second session and compared to NMS outputs.

Results



The PINN estimated hip angles, moments, muscle and contact forces with low error compared to NMS (RMSE: 5.71±1.05 degrees, 0.07±0.02 N.m/kg, 0.41±0.42 N/kg, and 0.24±0.06 BW, respectively) (Figure 1). Peak hip contact force showed excellent agreement between NMS and PINN (r^2: 0.82, slope: 0.91) with limits of agreement between -0.48 and 0.34 BW (-10.7 to 6.8% of peak). Gait modifications had distinct responses (i.e., increases

or decreases to peak contact force) for which the PINN correctly accounted. The minimum detectable difference at 90% confidence was 0.33 BW (~7.4% change from baseline peak).

Discussion

The smart garment detected small changes in hip motion and loading that occurred during gait retraining interventions, which are highly relevant to cartilage health and adaptation. Future work will retrain the PINN using a large sample of people with hip OA to provide a generalisable, affordable, and scalable gait retraining system capable of measuring person-specific hip biomechanics out of the laboratory.

Generative Ai and Synchrotron Imaging Uncover a Connectivity-Controlled Mechanical Regime in Bone

Prof. Laura Vergani[1], Dr. Federica Buccino[1], Dr. Milad Masrouri[2], Prof. Zhao Qin[2]

[1]Politecnico di Milano, Milano, Lombardy, Italy. [2]University of Syracuse, Syracuse, New York, United States

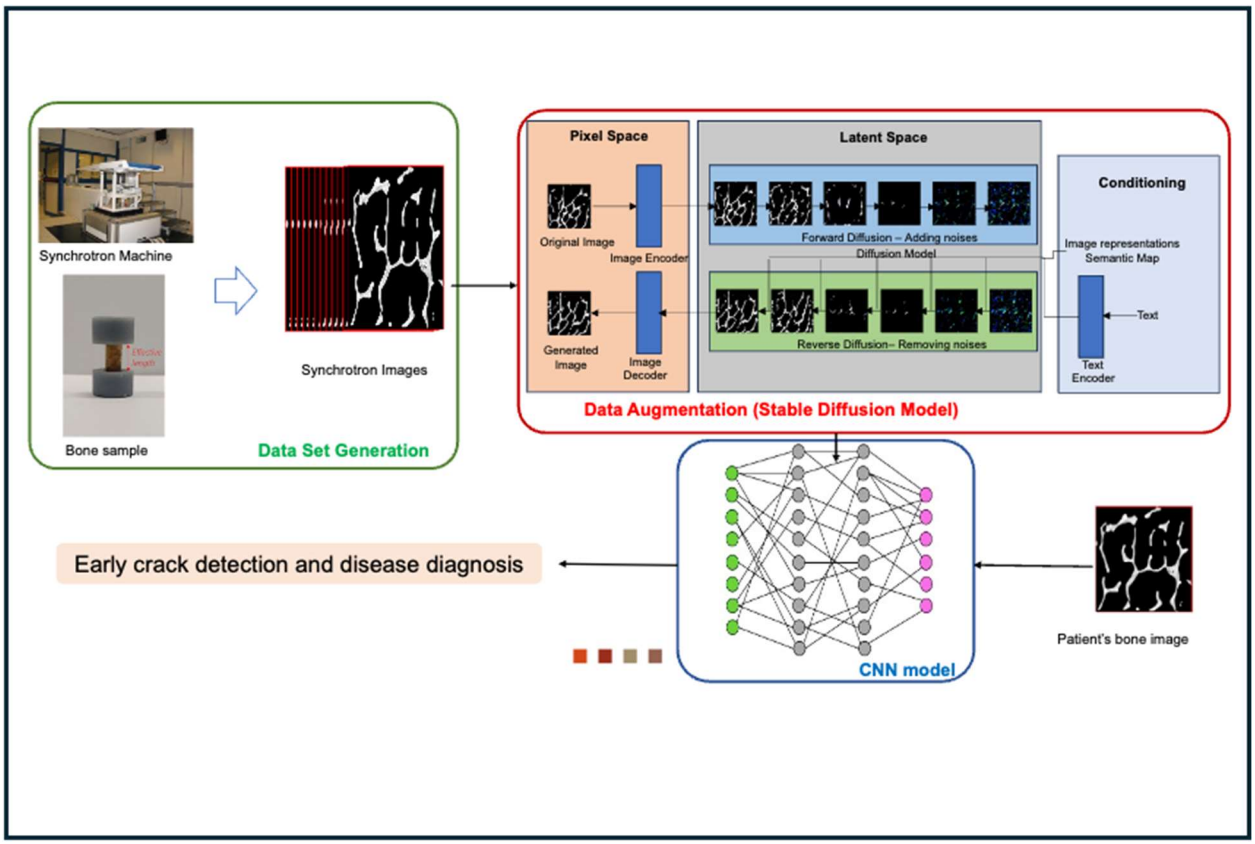
Introduction

Bone's mechanical competence emerges from its hierarchical architecture, yet how mechanical laws transition across scales—and how osteocyte lacunar morphology governs local stiffness—remains unresolved [1]. Traditional metrics such as bone mineral density poorly predict fragility, highlighting the need for mechanistic, architecture-informed descriptors.
This study integrates synchrotron imaging, physics-based micromechanics, and generative AI to reveal previously inaccessible structure–function relationships and to determine whether lacunar-scale mechanics follow a distinct scaling law beyond classical trabecular behavior.

Methods

In-situ synchrotron micro-tomography (voxel: 1.6 μm) was performed on human femoral trabeculae from healthy, osteoporotic, and Covid-19–affected donors. These scans provided both macroscopic deformation and lacunar-scale detail. To overcome the limited statistical sampling inherent to synchrotron imaging, we trained a class-conditional denoising diffusion probabilistic model on 1,500 slices, generating realistic synthetic microstructures with disease-specific morphological signatures.
Thousands of real and AI-generated tiles (160×160 μm^2) were used in tensile simulations using a bead–spring elastic network governed by a Morse potential calibrated to trabecular tissue. Morphology–mechanics surrogate models were trained to map lacunar descriptors and image embeddings to local stiffness, strength, and toughness.

Results



Macroscopic tests reproduced the classical Gibson–Ashby scaling ($E \propto (BV/TV)^2$). In contrast, lacunar-scale simulations revealed a hypersensitive stiffness law, E ∝ (BV/TV)^m, where $m \approx 6$, indicating a transition to a rigidity-percolation regime. A 5% decrease in local tissue fraction resulted in ≈25% loss of stiffness, consistent with stress-field coalescence around interacting lacunae. AI-generated microstructures reproduced pathological increases in lacunar density and oblateness, enabling robust statistical inference.

Surrogate models yielded high accuracy (R^2: stiffness 0.95), visualizing heterogeneity as compliant pockets embedded within stiff zones.

Discussion

AI-augmented multiscale mechanics revealed a scale-dependent transition in bone's mechanical law: from bending-dominated trabecular mechanics to topology-controlled lacunar percolation. This provides a mechanistic explanation for the fragility observed in osteoporosis and Covid-19–affected bone, where small morphological changes drive large stiffness losses. The work demonstrates how diffusion models, in silico testing, and surrogate mechanics overcome data scarcity, enabling patient-specific mechanical risk estimation.

Feasibility of Extracting Spatio-Temporal Gait Parameters from Foot-Mounted Inertial Sensors in Hereditary Spastic Paraplegia

Mr. Connor LaBo, Ms. Alondra Rodriguez, Mr. Peter Nguyen, Ms. Isha Verma, Ms. Jodi Mullet, Mr. Lauro Ojeda, Dr. John Fink, Dr. Hugo Gonzalez Villasanti

University of Michigan, Ann Arbor, MI, United States

Introduction

Hereditary spastic paraplegia (HSP) causes progressive gait disturbance [1]. Traditional assessments are resource-intensive, limiting routine use. Wearable inertial measurement units (IMUs) provide a compact, continuous alternative, though their utility in HSP is underexplored. This study evaluates whether foot-mounted IMUs can reliably extract spatio-temporal gait parameters in HSP patients. Demonstrating feasibility could support the wider use of wearable sensors for objective gait assessment in clinical care.

Methods

This study assessed the feasibility of extracting spatio-temporal gait parameters from foot-mounted IMUs in HSP patients. Forty-four participants (38 uncomplicated UHSP, 6 complicated CHSP [2]) who walked independently were recruited; those using assistive devices or with incomplete data were excluded. After consent, subjects performed a 2-minute walking test with Xsens DOT IMUs on both feet and trunk. Data were collected at 100 Hz (accelerometers ±16g, gyroscopes ±2000°/s) [3]. Signals were processed and stance/swing phases segmented [4]. Descriptive statistics compared parameters by diagnostic group.

Results

IMUs reliably extracted spatio-temporal gait parameters in HSP. Median stance time ranged from 0.421–0.582 s (UHSP) and 0.461–0.813 s (CHSP). Swing times were 0.649–0.729 s (UHSP) and 0.665–0.887 s (CHSP). Swing speed ranged from 1.32–1.86 (UHSP) and 0.728–1.61 (CHSP), showing longer swing phases and slower speeds in CHSP. The workflow was consistent and confirmed the feasibility of wearable IMUs for objective gait quantification in HSP.

Discussion

This study shows foot-mounted IMUs reliably capture spatio-temporal gait metrics in individuals with HSP. IMU-derived parameters, such as stance time, swing time, and swing speed, aligned with expected clinical patterns and were consistently obtained across the

cohort. IMUs offer a practical, portable alternative to traditional lab-based systems, supporting objective gait assessment and frequent, longitudinal monitoring. These findings highlight the promise of wearable IMUs for improving clinical care and research in neurologic gait disorders.

Roadmap for building the Virtual Human Twin

Prof. Dr. Liesbet Geris

University of Liège, Liège, Wallonia, Belgium. KU Leuven, Leuven, Flanders, Belgium. VPH Society, Leuven, Flanders, Belgium

Introduction

Research into the use of computer modeling and simulation in all areas of health and care has significantly increased over the past decades. It is known under many names, including in silico medicine, digital twins or virtual human twins. The common element they all share is the use of digital technologies, ranging from AI to mechanistic models, to answer specific problems related to prevention, diagnosis, treatment prediction and follow-up of the patient, or to design, optimize, de-risk and personalize medical therapies. While big strides have been taken in terms of technology development and regulatory science, many challenges remain that are holding back acceleration and uptake of the technologies in clinical practice.

Methods

From 2023 to 2025, the European Commission's EDITH project worked on proposing a strategy to address these challenges by bringing together the entire ecosystem and jointly developing a roadmap for the implementation of the Virtual Human Twin [1]. A wide range of online and onsite meetings was held with all stakeholders, including academia, industry, patients, healthcare providers, regulators, health technology assessment agencies and policy makers. Through these meetings, over 800 individuals from all across the world contributed to the initiative.

Results

The roadmap provides a comprehensive overview, starting with the current context, the identified challenges and the stakeholders' needs. It continues with a description of the available and required technologies, and possible infrastructural solutions that could facilitate the implementation and credibility assessment of digital twin solutions. Next, the regulatory, health technology assessment, standardization, legal, ethical and social dimensions are analysed. Subsequently, the market and business elements are discussed, along with possible incentives for stimulating the uptake of VHTs for different stakeholder

groups. Finally, 30 recommendations are formulated to facilitate and accelerate the development and adoption of VHTs in clinical practice.

Discussion

The roadmap provides a high level vision for realizing the potential of Virtual Human Twins, while also providing tangible tools for addressing challenges such as interoperability, access and hardware needs. As such, this roadmap can provide a tangible guide for the many digital twin initiatives and consortia, facilitating synergies through an interoperability-by-design strategy.

Towards Individualized Bone Conduction Hearing Models: A Benchmark Comarison With the State-of-the-Art Model

Mr. Linus Taenzer[1], Mr. Johannes Niermann[2], Dr. Ivo Dobrev[2], Dr. Paolo Tiso[3], Dr. Bart Van Damme[1]

[1]Empa, Dübendorf, Zürich, Switzerland. [2]Universitätsspital Zürich, Zürich, Zürich, Switzerland. [3]ETH Zürich, Zürich, Zürich, Switzerland

Introduction

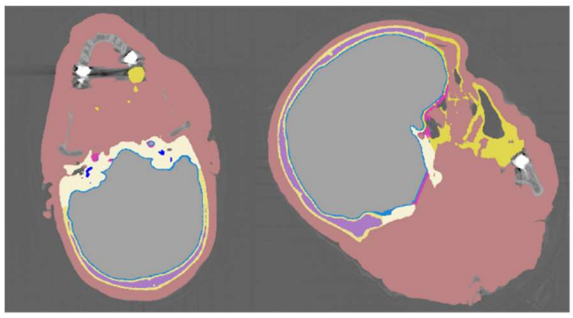
Despite its importance in hearing and device design, the role of the bone conduction transfer path is still not fully understood. The LiU head finite element (FE) model, widely used in research, represents one specific individual reconstructed from cryosectional images. While it has been compared to numerous experimental datasets from different subjects, the associated specim has not been measured [1,2]. Therefore, this study introduces a model from another individual to compare their differences. This model is the first of its kind to be eventually compared against experimental data from the same head.

Methods

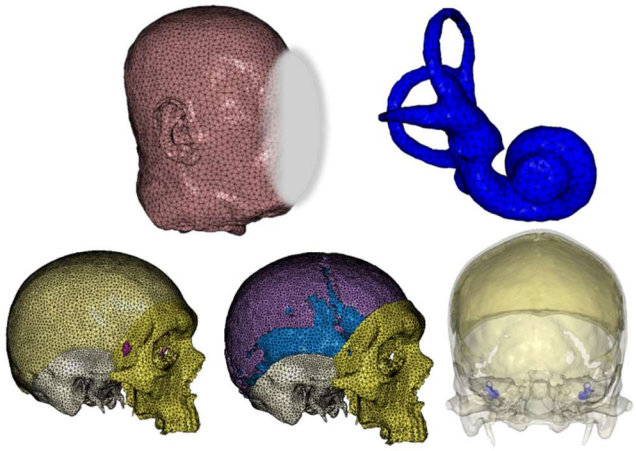
Subject-specific head models were generated using photon-counting CT scans, enabling high-resolution imaging of anatomical structures [3]. Segmentation was performed to define distinct domains with varying levels of geometric detail and accuracy using Simpleware (Synopsis, USA), Fig. 1. Regions critical to energy transmission of the bone conduction transfer path, such as the ear canal and cochlea, were modeled with fine resolution, while less sensitive areas were represented with coarser meshes. The model includes cortical bone, homogenized diploë, cerebrospinal fluid (CSF), brain tissue, and skin.

Finite element simulations were conducted to analyze wave propagation caused by an idealized bone anchored hearing aid. Comparative simulations were performed between personalized models and the LiU head to assess differences in vibration patterns and transfer paths.

Results



Thw results illustrate the frequency response functions between different excitation positions (BAHA, mastoid position) and the lateral and contralateral promontory position. The model is compared with transfer functions of the LiU head model, highlighting the



differences in magnitude between two different geometries. Additionally, the sensitivity of mask homogenization of the area in the ear canal is investigated, demonstrating the impact of local changes.

Discussion

The comparison between two FE models highlights the importance of accounting for individual anatomical variability in bone conduction simulations. The integration of tailored models could enable a more accurate prediction of bone-anchored devices and support individualized treatment strategies. Future work should focus on experimental validation across diverse anatomical datasets.

Remote Running Gait Analysis Using Smartphone Video and Monocular Pose Estimation: A Feasibility Study

Mr Luke VanKeersbilck, Dr Dustin Bruening PhD, Dr Iain Hunter PhD

Brigham Young University, Provo, UT, United States

Introduction

Running is a common form of exercise that comes with many health benefits; however, many people stop running because of the high injury risk. Running injury relates to biomechanical risk factors. Yet, these risk factors often show inconsistent and conflicting results across studies, partially due to small sample sizes. Low subject numbers may be related to the limitations of traditional motion capture. Monocular pose estimation offers a promising alternative by using machine learning to track body landmarks from a single camera, allowing data to be collected remotely. This study evaluated the feasibility of remotely collecting running biomechanics data using monocular pose estimation while exploring associations between running mechanics with running injury.

Methods

Participants were recruited via social media and flyers at running stores. They completed a survey on injury history and performance, then ran on their own treadmill at 3.35 m/s while recording themselves at 240Hz for 30 seconds. Mediapipe Pose was used to track body landmarks three-dimensionally. Logistic regressions were run between four injury categories (lower leg injuries, knee injuries, upper leg injuries, and bone injury) and running mechanics.

Results

A total of 310 people participated. Of those, just 69 videos were successfully uploaded but needed to exclude 24 people for poor camera quality or positioning. Significant predictors of prior injury were found in all but one of the injury categories.

Discussion

Monocular pose estimation can be used for the remote collection of running mechanics data but presents several key concerns. The number of subjects in the final analysis was low due to upload failures and video quality issues. Despite these issues, this study found significant predictors of injury consistent with previous literature but also several that have received little attention previously. These possible new predictors could be due to our larger sample size and inclusion of additional predictor variables. Even with this, a

significantly larger sample size is likely needed to improve confidence in the biomechanical risk factors. Future work will focus on more reliable methods for the submission of quality videos and work to further increase sample size.

Transtibial Limb Loss Reduces Metabolic Cost of Walking When Loosely Constrained to Track Able-Bodied Gait: A Simulation Study

Ms. Maliheh Fakhar, Dr. Jae Kun Shim PhD, Dr. Ross Miller PhD

University of Maryland, College Park, MD, United States

Introduction

Prior studies simulating walking with optimal control methods, that minimize a combination of metabolic cost and deviations from able-bodied gait mechanics, suggest that metabolic cost can remain unchanged after transtibial limb loss, especially if muscle strength is fully preserved [1,2]. Examining if limb loss and prosthesis use change the minimum possible metabolic cost of walking, regardless of gait deviations, could speak to whether limb loss *per se* increases metabolic cost. This study, therefore, tested the effect of transtibial limb loss on the minimum metabolic cost of walking. Identifying this absolute minimum metabolic cost is well suited to optimal control simulations, vs. studies of human participants where it is difficult to determine if metabolic cost was minimized absolutely.

Methods

Simulations of walking were performed using a full-body OpenSim model with 31 degrees of freedom and 120 muscles (Fig.1A; [3]). A transtibial limb loss model was created by removing the right ankle muscles and altering the joint and inertial properties of the right foot and shank (Fig.1B; [1]). For both models, OpenSim Moco computed muscle excitations that minimized a cost function defined as the weighted sum of metabolic cost and deviations from able-bodied gait mechanics, with constraints of periodicity and walking speed of 1.45 m/s [1,3]. Simulations were repeated with progressively reduced weight on the gait-deviation term, until further reductions no longer changed the metabolic cost.

Results

For both models, metabolic cost stabilized at a gait-deviation weight of ~10^{-3} (Fig.1C), indicating convergence toward the absolute minimum metabolic cost under minimally constrained tracking. At this minimum, the metabolic cost was 9% lower for the transtibial model vs. the able-bodied model (2.12 vs. 2.34 J/m/kg).

Discussion

Results support previous findings that transtibial limb loss does not necessarily increase metabolic cost of walking [1,2,4] and suggest transtibial limb loss in fact reduces metabolic cost. We speculate this result is due to low prosthesis mass, reducing energy requirements of leg swing, combined with prosthesis stiffness optimized for energy return during stance phase.

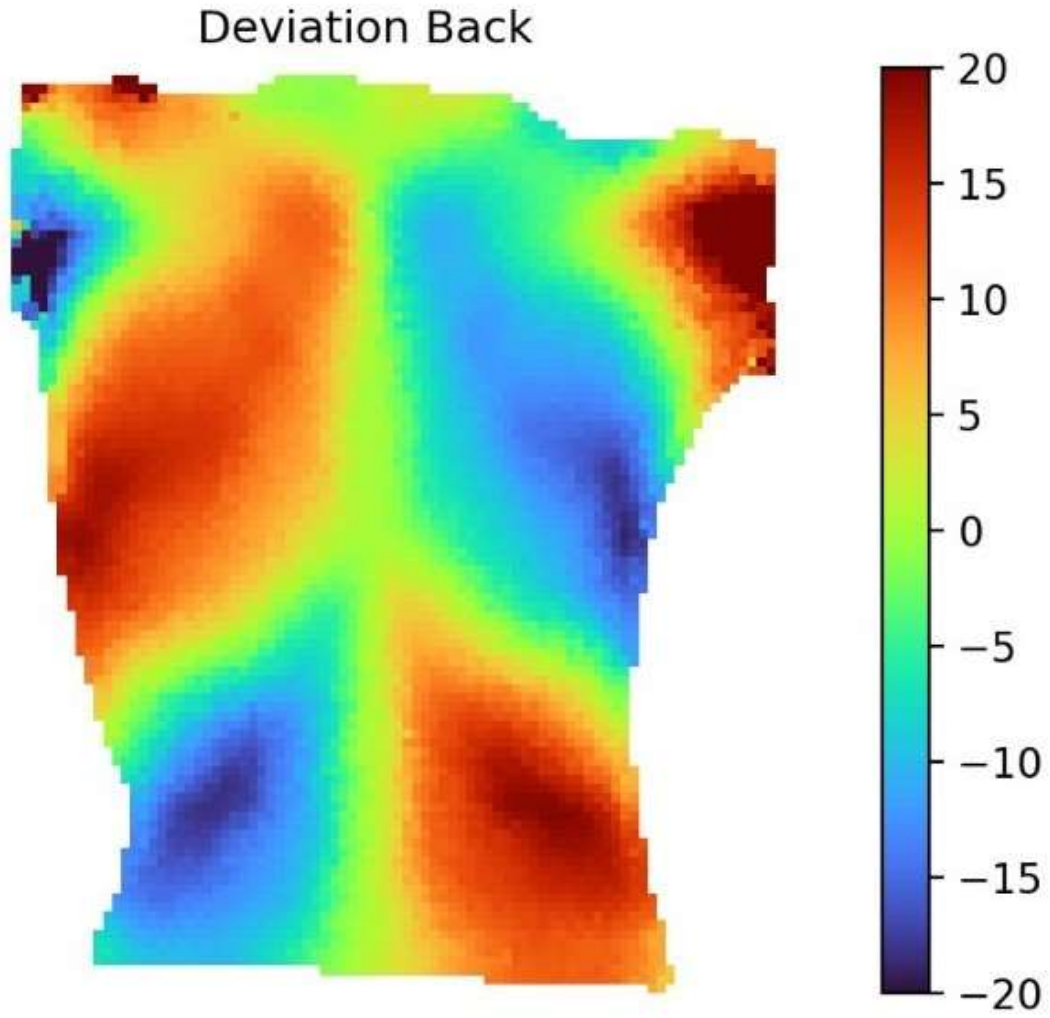
CNN-Based Deep Learning for Multi-Region Classification and Prediction of Cobb Angles from Markerless 3D Surface Topography in Adolescent Idiopathic Scoliosis

Graduate Research Assistant Mariam Ezzat, Graduate Research Assistant Mahmoud Hashim, Postdoctoral Scholar Bruna da Rosa, Assistant Lecturer Behzad Vafaeian, Assistant Professor Qipei Mei, Professor Samer Adeeb, Associate Professor Lindsey Westover

University of Alberta, Edmonton, Alberta, Canada

Introduction



Methods

Results

Discussion

This framework validates ST as a primary monitoring tool. The classification model shows strong performance in distinguishing Single versus Double curves, proving the system's reliability for initial curve typing. However, the model has slight difficulty distinguishing single curves as thoracic or lumbar, suggesting a refinement opportunity. The regression model meets the accepted clinical error for X-ray readings for lumbar CAs with a 3.29° MAE. Future efforts will focus on minimizing the thoracic MAE of 4.71°.

Three-dimensional Reconstruction of the Pelvis from Simulated Bi-Planar X-Rays using Deep Learning

Ms. Marie De Mey, Ms. Isabella Tierney, Mr. Jeffrey Lee, Dr. John McPhee, Dr. Stewart McLachlin

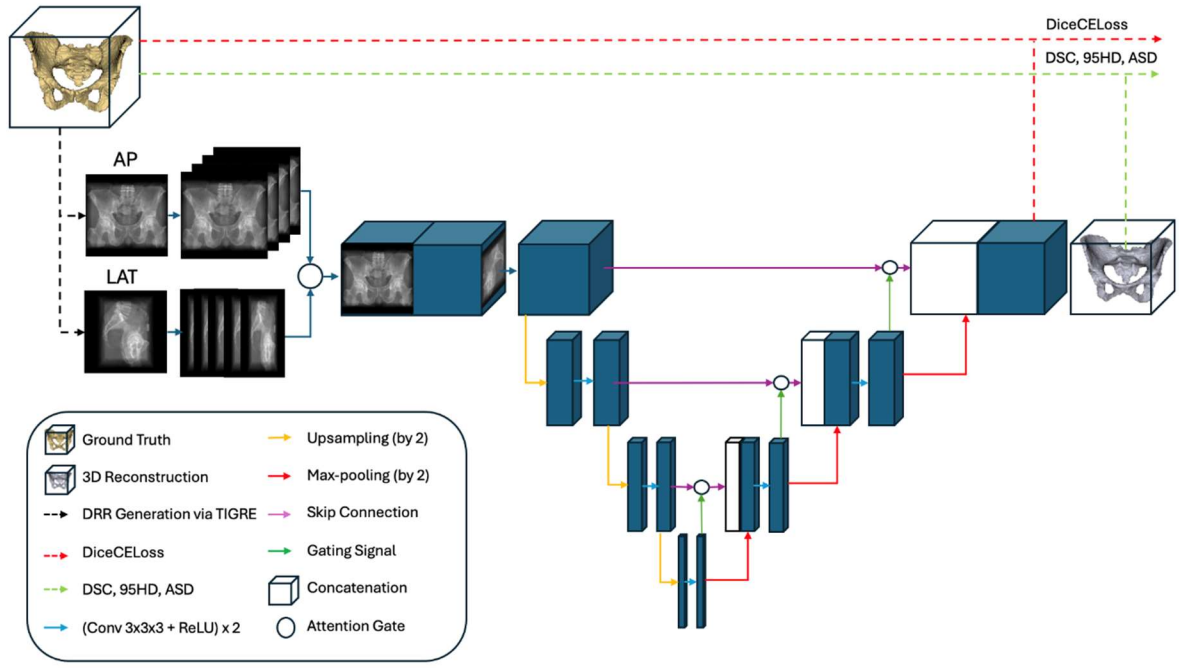
University of Waterloo, Waterloo, Ontario, Canada

Introduction

Patient-specific 3D models of the pelvis are essential to pre-operative surgical planning for joint arthroplasty. Although models are conventionally derived from segmented computed tomography (CT) scans, there is increasing motivation to generate 3D pelvic models from X-rays due to lower radiation exposure, lower cost, and improved accessibility. As a starting point towards this goal, we developed a deep learning (DL) pipeline that converts a CT scan to synthetic bi-planar digitally reconstructed radiographs (DRR) and reconstructs the corresponding 3D pelvis from the DRR using an Attention U-Net architecture [1].

Methods

Since paired datasets of X-rays and associated 3D CT scans are not publicly available, the model was trained on synthetic anterior-posterior and lateral DRRs developed from the CT pelvic scan dataset CTPelvic1k. The synthetic DRRs were generated using the TIGRE toolbox, a physics-based digital radiograph simulation framework. Additionally, to reduce the domain gap, we investigated the application of a bone-enhancement filtering algorithm to more closely resemble the appearance of a pelvis X-ray [2]. The model performance was evaluated using standard reconstruction metrics such as the Dice similarity coefficient (DSC), 95th percentile Hausdorff distance (95HD), and the average surface distance (ASD). To assess the performance of the model in a clinical context, an automatic detection algorithm was used to evaluate the Euclidian distance between eight pelvis landmarks on the ground truth and predicted output [3].



Results

Experiments on the test data determined that the model achieved an average DSC of 75.2%, an average 95HD of 9.3 mm, and an ASD of 3.1 mm. The model achieved average localization errors of 16.1 mm for the anterior superior iliac spines, 17.4 mm for pubic tubercles, 23.8 mm for the ischial spines, and 22.0 mm for the posterior superior iliac spines.

Discussion

Our 3D pelvis reconstructions show that this DL pipeline has the potential to enhance clinical end-use applications. Additional experiments and training data are planned to further evaluate the impact of the bone-enhancement filtering mechanism on model performance.

Auto-Classification of Manual Wheelchair Propulsion Stroke Patterns in Children with Spinal Cord Injury Using Machine Learning

Mr. Marko Vucelic BS, Dr. Alyssa Schnorenberg MS, PhD, Dr. Brooke Slavens MS, Phd

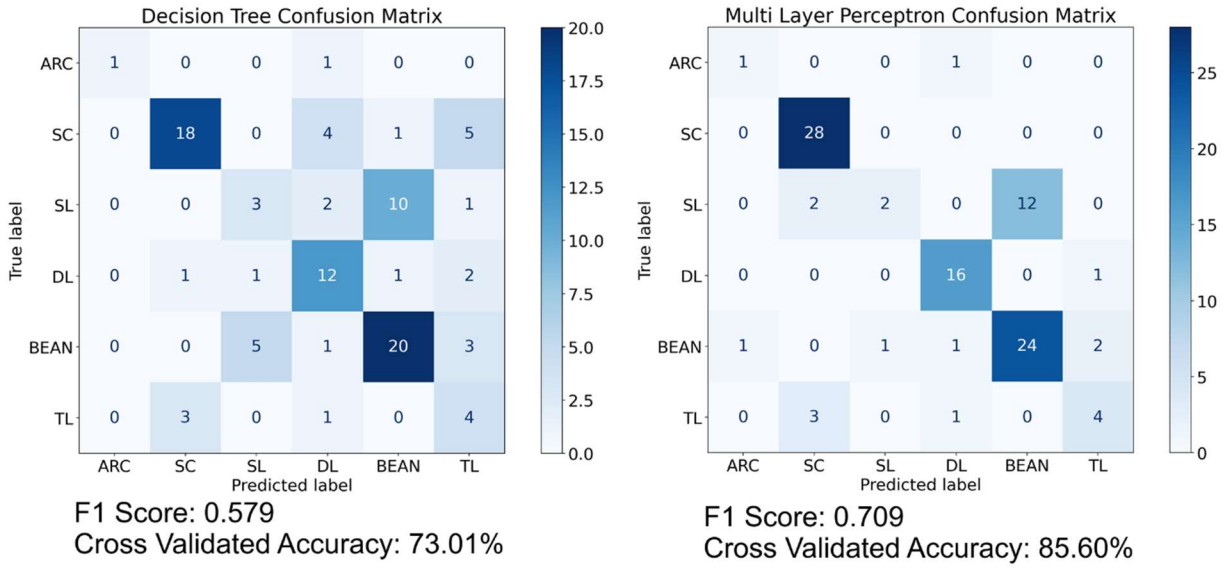
University of Wisconsin-Milwaukee, Milwaukee, Wisconsin, United States

Introduction

Manual wheelchair propulsion is a crucial activity of daily living for individuals with spinal cord injury (SCI), which affects an estimated 296,000 Americans. Hand motions during propulsion are classified into different types of stroke patterns, which vary significantly and impact musculoskeletal health and injuries. Currently, stroke patterns are visually, manually classified, which is time consuming and subjective. This project aims to develop and evaluate a machine learning (ML) framework for automated, objective classification of wheelchair stroke patterns using kinematic time-series data.

Methods

We developed and evaluated a ML-based classification pipeline using kinematic data (Vicon) of 508 stroke patterns from 36 children with SCI (aged 6-21 years). Datasets were trained with multiple supervised ML models, including k-nearest neighbors (KNN), decision tree (DT), random forest (RF), support vector machines (SVM), multi-layer perceptron (MLP), and recurrent neural networks (RNN). To expand training data, a variational autoencoder generated 600 synthetic cycles. Model performance was evaluated using standard ML metrics: accuracy, F1-Score, confusion matrices, and AUC-ROC curves. The classifications include four adult patterns and two novel pediatric patterns: arc, double over-looping (DL), single over-looping (SL), and semicircular (SC), bean (BEAN), and tiny loop (TL).



Results

Classification accuracies ranged from 73% to 85% across models (Figure 1). The MLP model achieved the highest performance, classifying DL most accurately and SL least accurately. SVM had the highest rate of incorrect classification instances. The introduction of synthetic data increased the accuracy by 15-25%.

Discussion

A machine learning approach for classifying six wheelchair stroke patterns proved feasible. MLP was the most accurate, however the training time was greater in comparison to the other models. The enhanced accuracy with synthetic data highlights its ability to enhance classification models in biomechanical applications where data may be sparse. Future directions will involve utilizing this classification model to assess pattern use and pathology in a larger dataset of manual wheelchair users across the lifespan. This approach will enable efficient and objective assessment of propulsion biomechanics for investigating musculoskeletal injury prevention.

Performance of OpenCap from Non-Recommended Viewpoints

Ms. Maya Ansu-Kyeremeh, Ms. Ishi Arora, Dr. Calvin Kuo PhD,P.Eng

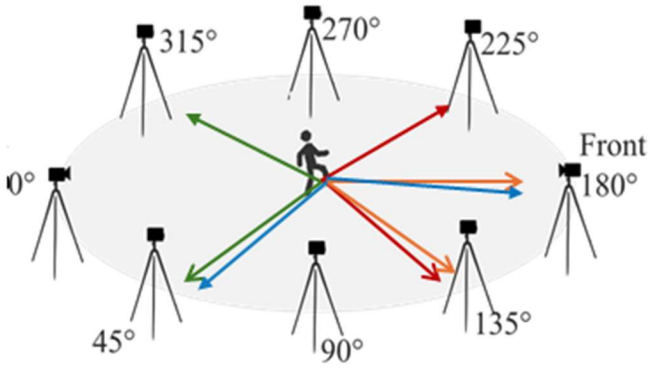
University of British Columbia, Vancouver, British Columbia, Canada

Introduction

Markerless motion capture technologies are becoming more popular to easily collect high-quality motion data in different out-of-lab environments. OpenCap is a markerless motion capture technology that uses two or more synchronized cameras to reconstruct 3D kinematics. OpenCap recommends a two-camera setup at a 30-45° angle off the participant's frontal line [1]. However, following these recommendations might not always be possible in constrained motion capture environments. The purpose of this study is to assess whether changes in the camera angles affect OpenCap knee joint angle estimates.

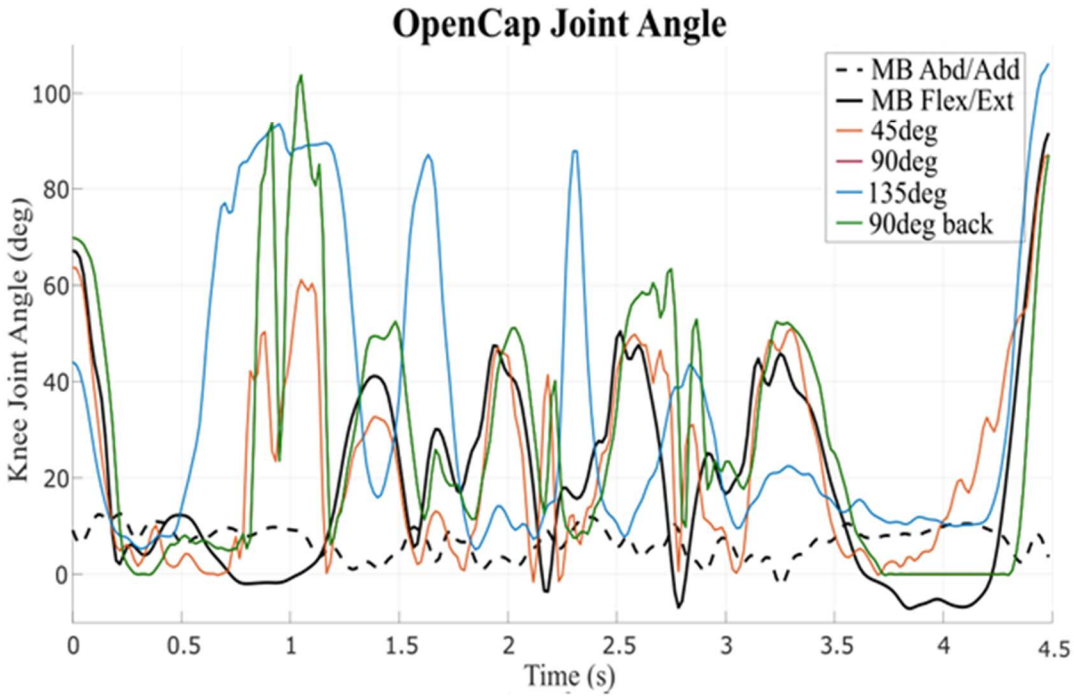
Methods

29 participants (24±4yo, 15F) performed dynamic movements related to return to sport assessment. The movement was captured by 8 Sony RX0II cameras (60Hz) spaced at 45-degree intervals around the participant. A localized version of OpenCap was used to compute knee joint angles using different combinations of cameras with spacings of 45°, 90°, 135°, and 180 ° from the front. We also used a camera pair spaced 90° from the back view. We computed normalized Root Mean Square Error (nRMSE) between OpenCap knee joint angle estimates against a marker-based motion capture (8-camera 960Hz PhaseSpace with 50 markers) estimate for each condition.



Results

For a single participant completing a single-leg triple crossover jump, we computed nRMSE with increasing camera spacing. The 45-degree spacing had the lowest nRMSE, and the 135-degree spacing had the highest. The 180-degree spacing did not time synchronize in OpenCap, so it was not included in the analysis. The 90-degree spacing from front and back had the same nRSME score of 0.3456.



Discussion

OpenCap is an established technology to estimate knee joint angles from a 2-camera markerless setup. These results suggest that OpenCap recommendations for camera spacing should be followed, but that they do not necessarily need to be from the front. The next steps for this project will assess other camera combinations from the 8-camera setup across more participants and movements to generalize findings.

Images (Optional)

Condition	RMSE
45°	0.2427
90° (front)	0.3456
90° (back)	0.3456
135°	0.5232

Effects of Altered Depth Perception on Gait in Virtual Reality Walking Tasks

Student Researcher Michael Thorne

UC Irvine, Irvine, California, United States

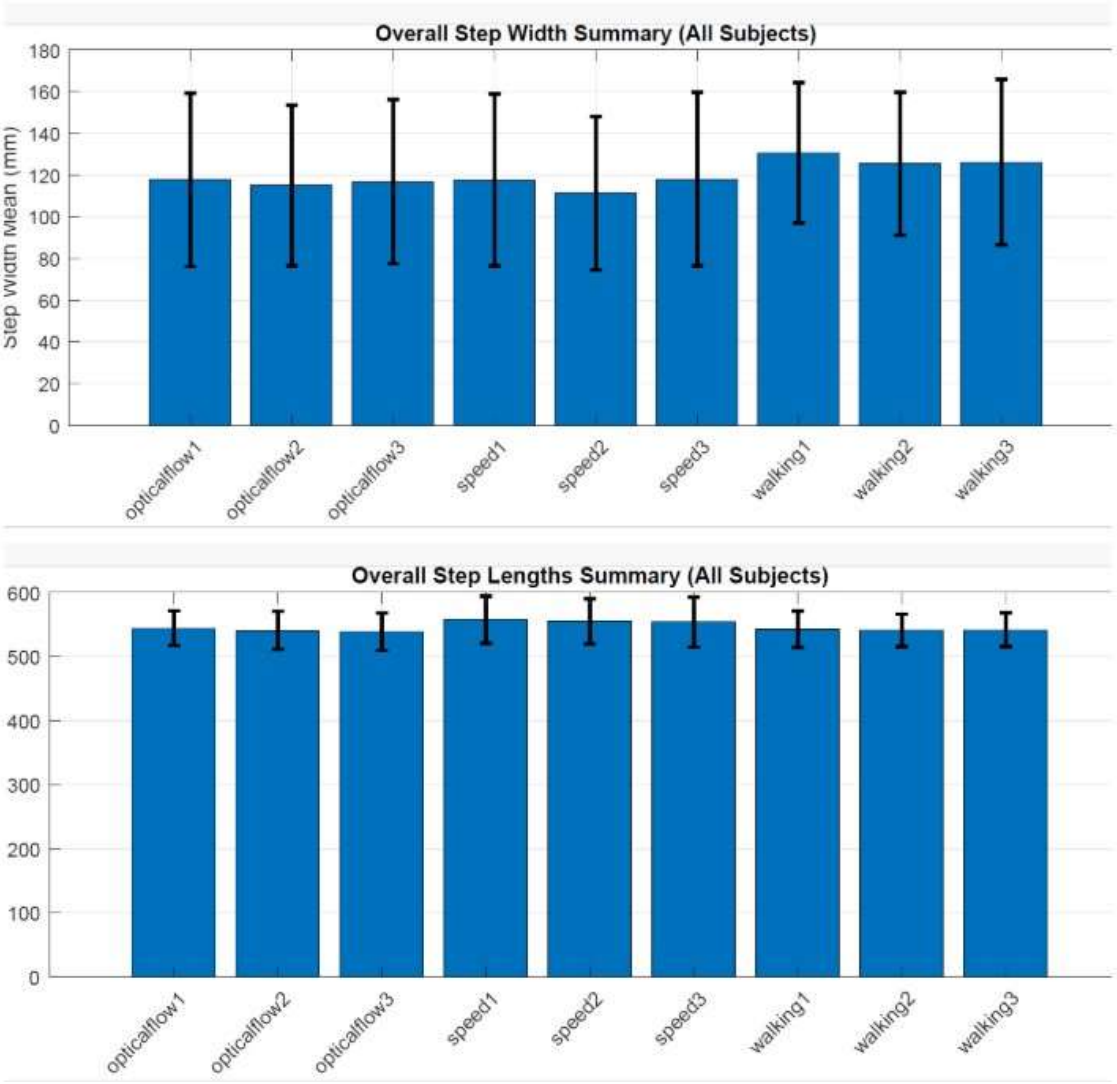
Introduction

Virtual Reality (VR) Environments are increasingly being used as tools for studying human locomotion adaptations during overground walking tasks. In particular, this work aims to examine how visual depth perception manipulation influences locomotor behavior, particularly during gait adaptation tasks. Differing levels of depth visibility allow for dynamic control of visual perception to learn how users perceive virtual environments of differing levels of vision and how this manipulation of vision can be used for training in rehabilitation, balance control, and spatial navigation.

Methods

Fourteen adults walked in Virtual Reality on a split belt treadmill in 3 different walking tasks each with 3 differing visual depth perception settings defined by a unity fog shader to change contrast, sharpness, and visibility of their surrounding environment. This allows for changing the amount of visual information the user is able to work with for each task and evaluate how different sensorimotor adaptations and compensations are utilized during each trial. Each test involved normal overground treadmill walking in each scene walking Vicon markers were utilized to analyze step lengths (SL), step widths (SW), torso sway, and each of their respective variabilities during the last 2 minutes of each 5 minute trial. Motion sickness questionnaires, particularly the Motion Sickness Susceptibility Questionnaire and Simulator Sickness Questionnaire were conducted to ensure participants were comfortable walking in Virtual Reality settings.

Results



Preliminary results show that participants tend to gravitate towards more cautious walking gaits which is illustrated in significantly smaller step widths and generally smaller step lengths on average for all participants.

Discussion

This experiment provides evidence that walking in virtual reality is an effective tool for introducing virtual perturbations in overground walking that can simulate real world

environments and be effective in assessing and training participants in their gait for specific tasks. Future work would include working with subjects with impaired levels of depth perception to test the usability of this work for training in Virtual Reality.

Shunt Hemodynamics Abnormalities In sublingual Microcirculation as Indication for Sepsis

Mr Kavin Vishnu[1], MD Matthias P Hilty[2], MD Alessandro Candreva[3], Dr Monika Colombo[1]

[1]Department of Mechanical and Production Engineering, Aarhus, Jutland, Denmark. [2]Institute of Intensive Care, Zurich University Hospital, Zurich, ZH, Switzerland. [3]Department of Cardiology, Zurich University Hospital, Zurich, ZH, Switzerland

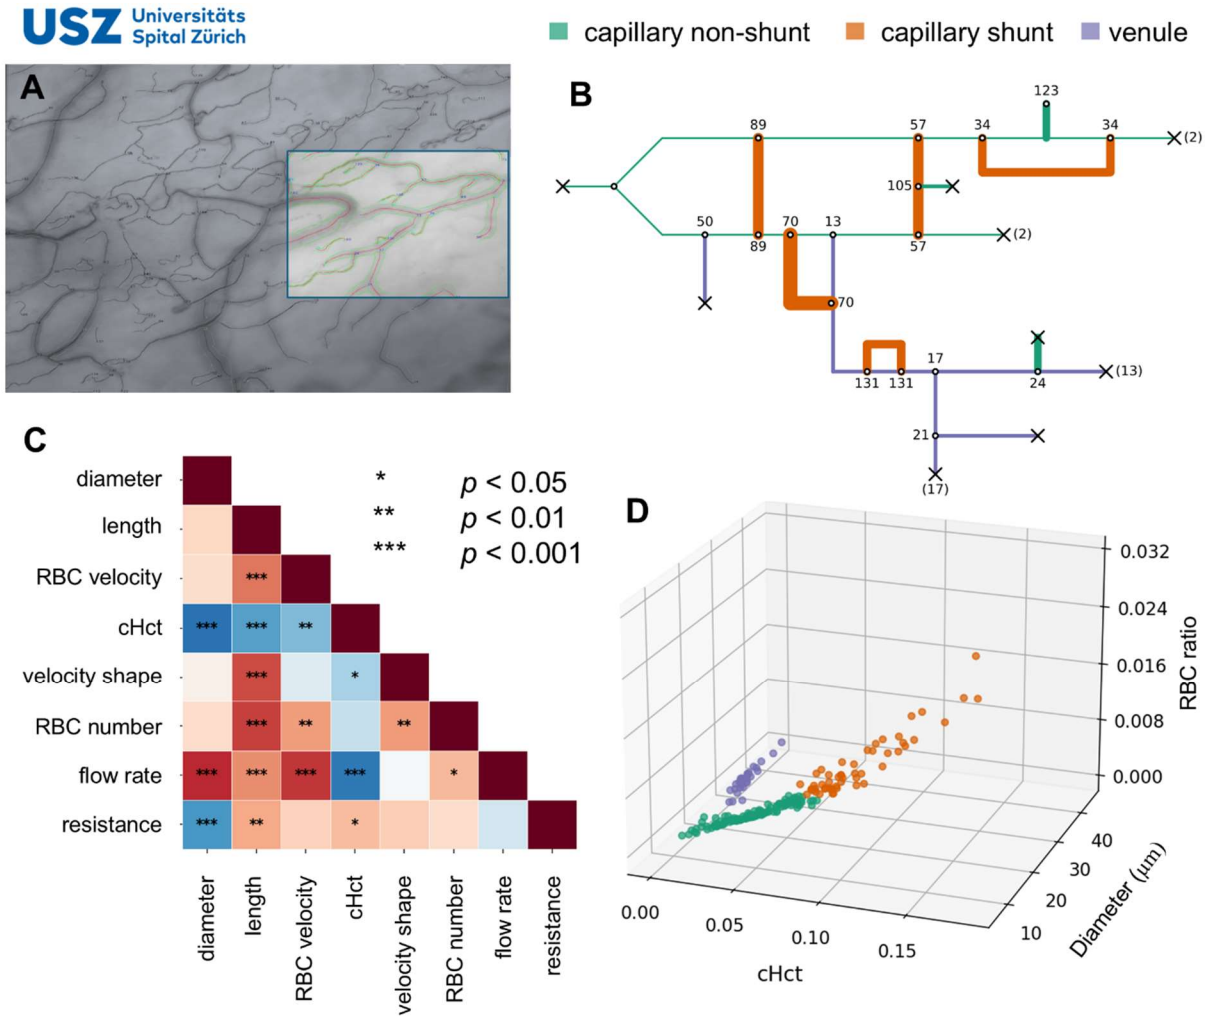
Introduction

The shunting theory of sepsis [1] states that venules shunting leads to impaired oxygenation in certain microvasculature regions. Impaired recruitment of the sublingual vessels caused by shunting can provide insight into the clinical state of sepsis [1]. Here we show, through a machine learning (ML) approach, that hemodynamic abnormalities detected in the sublingual microcirculation (SM), in terms of red blood cells (RBCs) velocity and concentration, contribute to detecting and classifying shunt within capillary network.

Methods

Handheld vital microscopy SM images (Fig. 1-A) and related hemodynamic data are derived from previous works of the group [2,3] and prospective data collection of coronary microvascular disease patients, considering both controls and altered hemodynamic conditions through the application of two vasodilators (nitroglycerin and acetylcholine) to increase capillary recruitment and total vessel density (TVD). The capillary network is visualized through electronic analogue in Fig. 1-B. Hemodynamic data and RBC properties are extracted for each detected vessel. We employed labelled data to calculate hemodynamics correlations (e.g. Fig. 1-C) associated with shunts. K-means clustering is applied using unlabeled data based on features representing these known hemodynamics correlations, aiming at sorting shunts in both controls and when vasodilators were applied.

Results



A grading scale for identifying shunts in the three cases (Fig. 1-B) was created based on ranges of hemodynamic properties, flow properties, and clustering, with the parameters of this grading scale optimized by further application of ML algorithms. Preliminary results demonstrate notable differences in the trends and strongly significant correlations between shunts and non-shunt SM allowing for identification. Further, cases with higher

TVD (following vasodilators application) additionally showed unique trends and clustering behavior (Fig. 1-D).

Discussion

The shunting grading scheme shows promising results in its ability to identify patients with sepsis. More data is expected to lead to a robust detection method for shunts in patients with different SM conditions, leading to the identification of underlying diseases such as sepsis, defining a paradigm shift in critical care management of patients.

[5]Department of Cardiology, Aalborg University Hospital, Aalborg, NA, Denmark. [6]Department of Clinical Medicine, Aarhus University Hospital, Aarhus, NA, Denmark. [7]Department of Mechanical and Production Engineering, Aarhus University, Aarhus, NA, Denmark

Introduction

High-quality cardiac CT imaging is essential for accurate coronary assessment and downstream machine learning (ML) applications [1]. Large-scale datasets often contain heterogeneous image quality due to variations in acquisition protocols, scanner models, and patient factors. Furthermore, a single CT-acquisition often contains several series, representing different phases and/or reconstructions. Manual quality assessment is time-consuming and subjective, motivating the need for automated solutions.

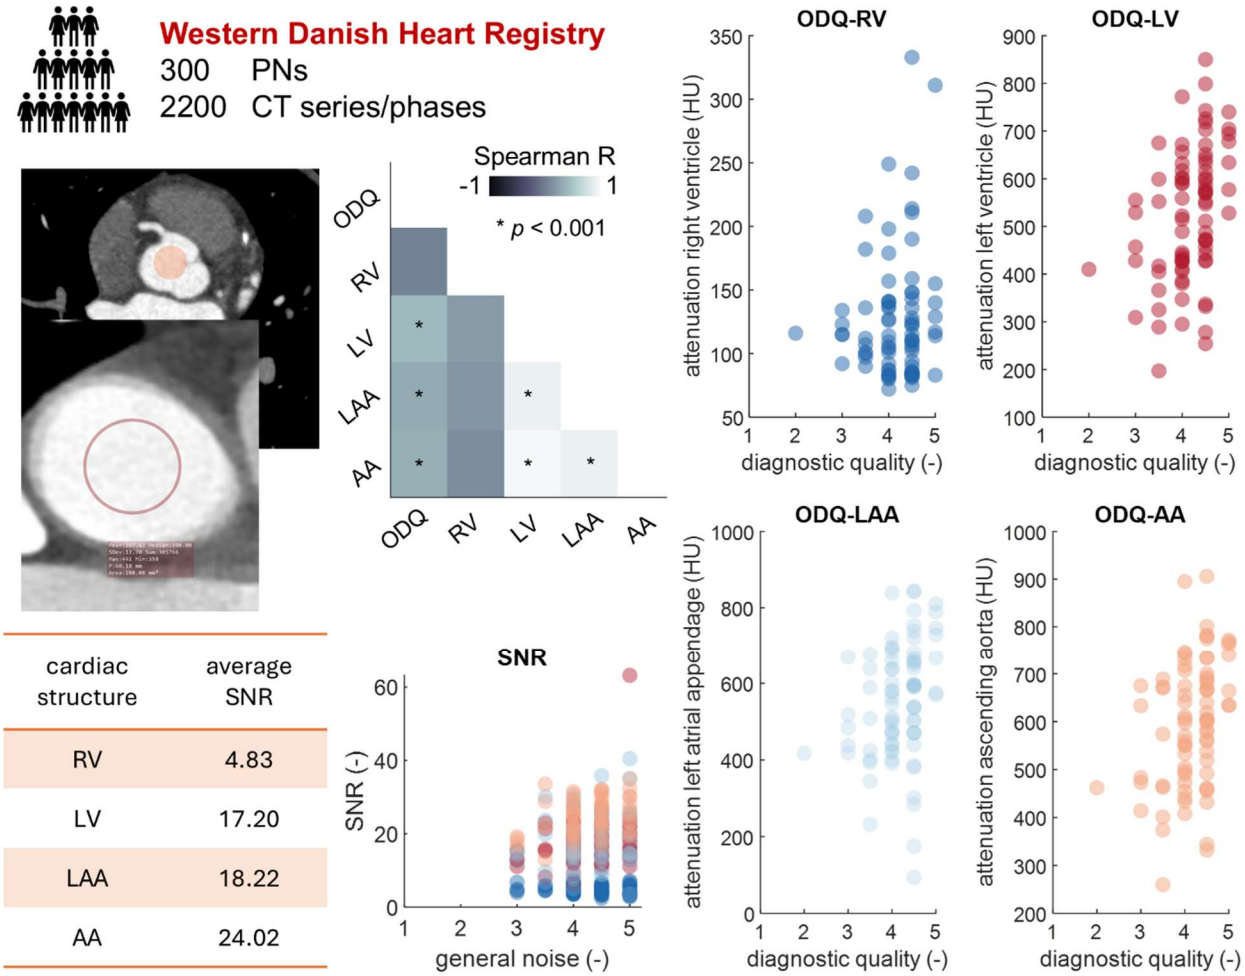
We propose a convolutional neural network (CNN)-based framework for direct comparison between clinical annotated and automatic overall diagnostic quality (ODQ). The model is trained on manually-extracted image quality scores to facilitate optimal series/phase selection in large cardiac CT datasets.

Methods

A cohort of 300 patients was selected from the Western Danish Cardiac CT Registry, with 1-10 different phases per patients yielding 2,203 axial, contrast-enhanced series. Patients were stratified by scan year and scanner model. Clinical annotation included Likert-scale categorical scoring of five quality classes at epicardial coronary segments, and attenuation values in right ventricle (RV), left ventricle (LV), left atrial appendage (LAA), and ascending

aorta (AA). These annotations served as ground-truth for supervised training and cross-validation (80%), and testing (20%).

The 3D CNN model [2], takes full image volumes as inputs, resampled to isotropic image dimensions. It outputs an ODQ score and evaluates: (1) general noise, (2) motion/sharpness, (3) contrast quality, (4) step artifact in LV and in (5) coronaries.



Results

Fig-1 shows the preliminary results on 100 series, highlighting strongly significant positive Spearman correlation between ODQ and contrast (HU) value in all cardiac structures but RV. Similarly, signal-to-noise ratio shows a linear positive association with the general noise (in Likert-scale).

Discussion

Our preliminary analyses demonstrate that the CNN effectively predicts overall quality and individual artifact classes, enabling automated filtering of suboptimal series. Automated CT IQA using deep learning can standardize phase selection and improve data integrity for ML applications in cardiac imaging. Future work will focus on including the CT IQA algorithm in a larger ML pipeline for fully automatic optimal selection and segmentation of our ~100’000 patients dataset.

Comparing Feature Sets for Motion Prediction Model Training

Mr. Cylus Robinson, Mr. Brandon Nunley MSBE, Mr. Praneel Seth, Dr. Justin Hart PhD, Dr. Nick Fey PhD

University of Texas at Austin, Austin, Texas, United States

Introduction

Motion prediction is an emerging technology in biomechanics and is becoming more utilized as data and greater computational power become more accessible to researchers. Fields such as engineering, biomechanics, prosthetics control, computer graphics, and more employ motion prediction to fill the gaps in trajectories and joint positions in many respective applications. In this study, we included segmental angular momentum as a training feature alongside joint positions, which we tested against the performance of a model trained exclusively on joint positions for predicting future joint positions.

Methods

The Theia3D markerless motion capture system employing fourteen Sony cameras was used to collect kinematic data of participants performing three diverse walking tasks. We collected over 1.25 million frames of data over approximately 150 trials, and computed segmental angular momentum locally using the kinematic data before training the model. Two non-autoregressive encoder-decoder transformer models with 128 dimensional embeddings were trained over 100 epochs: one with joint positions as input features, and the other using joint positions and segmental angular momentum. The model implemented two heads per transformer layer and two encoder and decoder layers.

Results

Model performance was evaluated using Mean Per Joint Position Error (MPJPE). Incorporating segmental angular momentum reduced prediction error by 66.7% at a 250 milliseconds horizon and by roughly 50% at 500–1000 milliseconds compared to joint positions alone.

Discussion

The superior performance of the model incorporating segmental angular momentum highlights the importance of selecting appropriate input features to improve motion prediction accuracy. Our results suggest that including segmental angular momentum can

significantly enhance predictive performance, and other features may further refine model predictions. Accurate motion prediction has important applications even now. For example, human–robot interaction relies on predicting human movements to optimize trajectory planning, and lower-limb prosthetics are tailored to enable more natural gait by using model predictions based on an individual's physical dimensions. Recognizing the importance of feature richness can improve predictions and drive innovations in modeling, advancing motion prediction across a range of applications.

3D Human Pose Estimation of Golf Swings using Multimodal Deep Learning Models

Mr Nishad Rajmalwar, Professor John McPhee

University of Waterloo, Waterloo, Ontario, Canada

Mr Nishad Rajmalwar

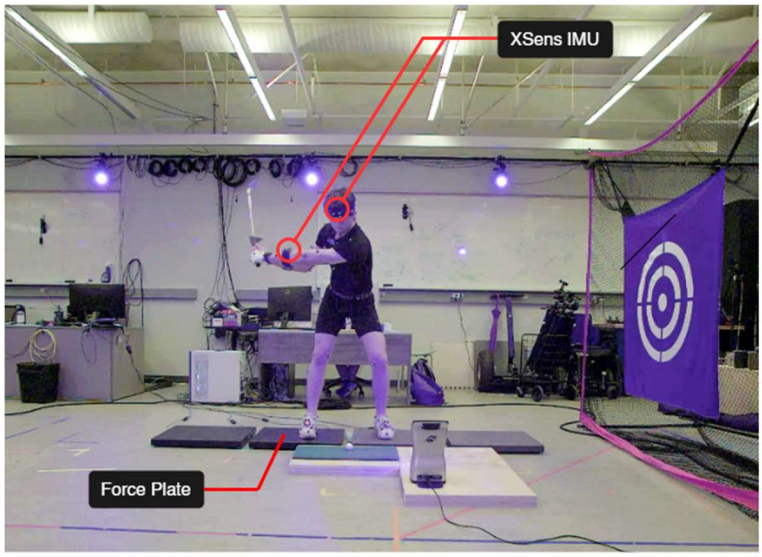
Introduction

Human pose estimation (HPE) in sports can improve performance analysis and injury prevention, but models trained on existing datasets generalize poorly to rapid 3D motions like golf swings. Vision-based methods often produce physically implausible poses due to occlusions of body parts and unconstrained limb lengths. Multimodal input data such as video, IMU, and depth information can improve accuracy by providing complementary information and enabling enforcement of segment length constraints. This study evaluates an existing model on golf data and develops a multimodal deep learning (DL) model using the TotalCapture dataset.

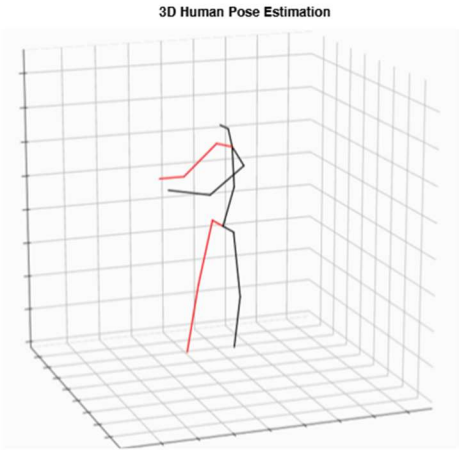
Methods

Golf swing data was collected from a male recreational golfer using a Vicon motion capture system (240 Hz) with synchronized Vue video camera (120 fps, frontal view) and Bertec force plates (960 Hz) under each foot. Full-body markers were used and 14 shots were captured using 3 clubs (Driver, 6 Iron, 9 Iron) to create variance in swing movement. 11 shots were used for training and 3 for testing to evaluate and train VideoPose3D, a DL HPE model pre-trained on the Human3.6M dataset.

Using a multimodal approach, a Vision Transformer (ViT) model was trained on the TotalCapture dataset using single-view video, IMU data from left forearm and forehead, and bone lengths. Data was fed to Spatial and Temporal Transformer Blocks to model spatial and temporal dependencies. The loss function included mean per-joint position error (MPJPE) weighted by joint distance from pelvis and segment length loss enforcing body segment length consistency.



Results



The pre-trained VideoPose3D model, despite performing well on Human3.6M benchmarks (MPJPE of 46.8mm), had an MPJPE of 138.8mm on our golf dataset. When trained from scratch on golf-specific data, the error reduced to 9.4mm. The ViT-based model achieved 62.4mm MPJPE on the TotalCapture test set.

Discussion

The poor performance of an existing model on our golf data demonstrates the need for domain-specific training. Qualitative analysis revealed unreasonable limb lengths and unrealistic joint angles. The ViT model showed encouraging results from multimodal input data for TotalCapture, so we will develop a ViT model using multimodal data from a larger golf data collection.

[2]Department of Ophthalmology, Centro Hospitalar e Universitário São João, Porto, Porto, Portugal. [3]Department of Surgery and Physiology, Faculty of Medicine, University of Porto, Porto, Porto, Portugal. [4]DEMec, Faculty of Engineering, University of Porto, Porto, Porto, Portugal

Introduction

Retinal vein occlusion (RVO) is the second most common retinal vascular disease after diabetic retinopathy, affecting approximately 16 million individuals worldwide and representing a major cause of vision loss [1]. Differentiating RVO-related macular edema from diabetic macular edema (DME) on OCT is challenging, as both conditions exhibit increased retinal thickness, which can lead to misclassification by non-specialists. Deep learning (DL) has shown promise in retinal imaging [2], but few studies have targeted OCT-based RVO detection [3]. This study evaluates stacked convolutional neural networks (SNNs) to enhance OCT-based classification, with a focus on differentiating RVO from DME.

Methods

This study used a private dataset from ULS São João (5360 OCT images; Normal, DME, RVO, Other). VGG16 and YOLOv8 architectures were fine-tuned with transfer learning and combined into an SNN configuration. Training employed weighted sampling, patient-wise data separation, augmentation, five-fold cross-validation, L_2 regularisation, and early stopping. Model performance was assessed with accuracy, precision, recall, F_2-score, and AUROC.

Results

Preliminary results show that the VGG16 and YOLOv8 networks achieved accuracies of around 84.6% and 85.8%, respectively. The stacked network of the two used models attained an accuracy of 92%. The F2-score of the single models reached around 87%, and the stacked network achieved an F_2-score of 93%.

Discussion

This study demonstrates that stacking CNNs enhances OCT-based classification of retinal diseases, particularly in distinguishing RVO-associated edema from DME. Performance improvements were linked to the number of features extracted:

- VGG16: 25,088 features
- YOLOv8:12,544 features.

Compared to fundus-based DL approaches, this SNN achieved superior diagnostic accuracy, aligning with or surpassing recent ensemble methods [3]. Limitations include a lack of external validation and a heterogeneous “other” pathology class. Future studies include multimodal integration and multi-device training for broader generalizability.

Integrating Near-Infrared Spectroscopy, Support Vector Machines, and Fibril-Reinforced Poroelastic Finite Element Modeling for Constituent-Specific Human Cartilage Characterization

Mr. Janne J. Kankkunen[1], Dr. Mithilesh Prakash[1], Dr. Jaakko Sarin[1,2], Prof. Juha Töyräs[1,3,4], Assoc. Prof. Isaac O. Afara[1,3], Adj. Prof. Petri Tanska[1,4]

[3]The University of Queensland, Brisbane, Queensland, Australia. [4]Kuopio University Hospital, Wellbeing Services County of North Savo, Kuopio, North Savo, Finland

Introduction

Fibril-reinforced poroelastic (FRPE) material properties of cartilage, particularly hydraulic permeability, are altered in osteoarthritis, and may serve as early OA biomarkers. We investigated whether near-infrared spectroscopy (NIRS) combined with finite element (FE) modeling and machine learning can estimate FRPE properties of human cartilage, with emphasis on permeability.

Methods

Human osteochondral samples (n=171, diameter 8 mm) were harvested from femur, tibia, and patella of seven cadavers (68-79 years; approval #150/2016) stored in phosphate buffered saline in -20°C. Before testing, samples were thawed and measured with a NIRS system (average of three spectra per sample [1], Fig 1A). Mechanical properties were assessed using indentation (12.5 kPa pre-stress and three indentation steps at 5% strain with 15 min relaxation; indenter diameter: 667 or 728 µm). Sample-specific FE models with FRPE cartilage were fitted to experimental force–time responses, yielding constituent-specific parameters: initial (E_0) and strain-dependent (E_ε) fibril network moduli, non-fibrillar matrix modulus (E_m), initial permeability (k_0), and permeability strain dependency (M) [2]. We compared several spectral dimensionality-reduction approaches (random forest, principal component analysis, partial least squares, support vector machine [SVM]) and selected SVM with the best preliminary predictive capability. SVM-derived spectral features were then used as fixed effects in a linear mixed effects (LME) model, cadaver, cartilage surface, and location on surface considered as random effects to account for within-subject dependencies. A leave-one-cadaver-out design with 10-fold cross-validation in training was used. Performance was quantified using Spearman's ρ, and spectral importance was inferred from SVM.

Results

FRPE fits showed excellent agreement with experiments (median R^2: 0.94; 25th-75th percentiles: 0.87-0.97). In training and testing, the SVM-LME model achieved ρ=0.68 and ρ=0.34 (Fig. 1B). E_0 and E_ε were associated with collagen bands, E_m with proteoglycan bands, and k_0 and M with water bands (Fig. 1C).

Discussion

NIRS with SVM-based dimensionality reduction, combined with physics-based FRPE modeling enables spectroscopy-based estimation of constituent-specific human cartilage properties, including permeability. Together with physically interpretable spectral features, this framework is a promising tool for evaluation of cartilage and engineered tissue mechanical properties with further validation.

Direct Regression of Kinematics, Keypoints, and Identity for Monocular and Multiview Video

Dr. R. James Cotton MD / PhD

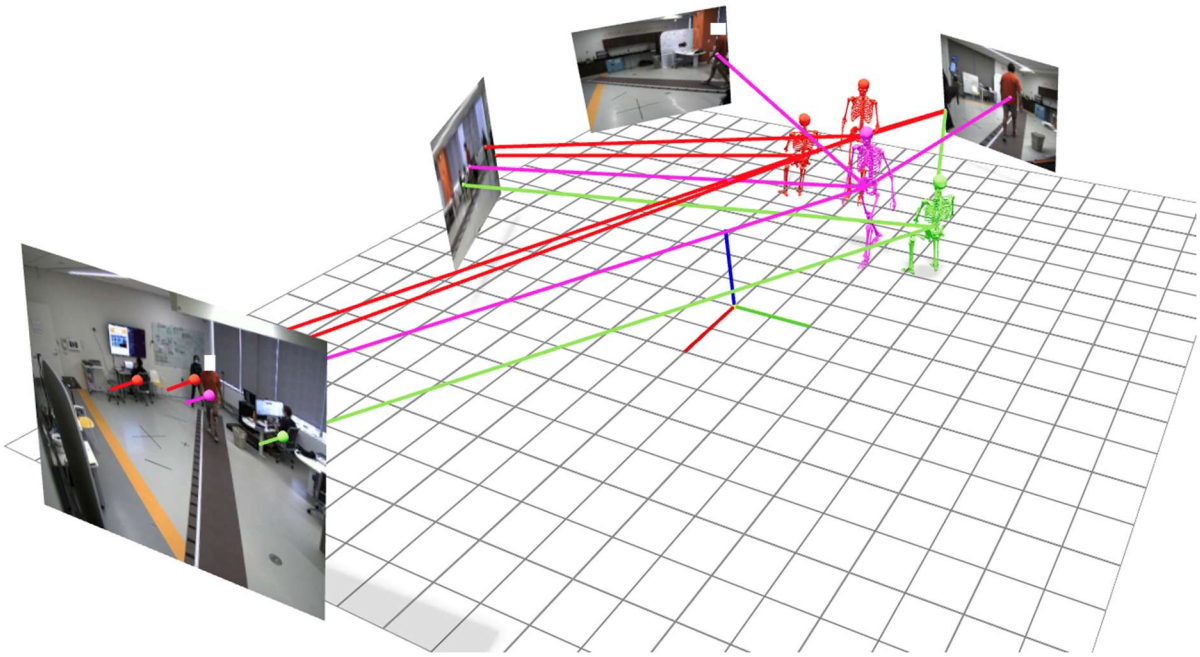
Shirley Ryan AbilityLab / Northwestern University, Chicago, IL, United States

Introduction

While markerless motion capture for biomechanics is advancing rapidly, it often relies on vision algorithms not designed for this purpose. This necessitates complex multistage pipelines including associating people across views and time, keypoint detection, and inverse kinematics. Additionally, the constituent models are trained on able-bodied individuals rather than clinical populations. Here, we developed a unified algorithm to simplify both monocular and multiview biomechanics and trained it on a dataset of clinical motion analysis.

Methods

Our model architecture is most similar to the recent Multi-HMR algorithm, but ours is adapted to regress kinematic parameters for a biomechanical model along with model scale and marker offsets. To support multi-view geometry, we extended it to output keypoint for the 87 keypoints in the BML-MOVI dataset. This enables us within-view and cross-view consistency between the predicted 3D marker locations on the biomechanical model and the heatmaps. Finally, we incorporated a re-identification head trained to learn a stable signal for identity and tracking, which was learned contrastively across views and time. This was trained on an extensive dataset of diverse clinical movements.



Results

In monocular mode, this algorithm achieves a mean absolute joint angle error of less than 5 degrees. While this underperforms our end-to-end optimization-based monocular approaches, it can perform in real time, and the results can be refined through additional optimization. The ReID head also achieves excellent separation between participants. This allows us to link detected people across views and refine the kinematics using multi-view geometry. Because this ReID association can be solved efficiently, it can be incorporated into training to enable additional biomechanically-constrained self-supervised learning. It can also be used during inference for multiview markerless motion capture.

Discussion

This model is an import step to wider use of markerless motion capture, as this architecture is expressly designed for the purpose of biomechanics with both direct regression of body scale and kinematics, which can be further refined by the set of biomechanically sufficient keypoints. In addition to achieving realtime performance and being trained on clinical data, this opens up important avenues for further improvement through biomechanically constrained self-supervised learning.

AI-Powered Real-Time Pose Estimation Linked with Biomechanical Simulation for Personalized Squat Injury Prevention

Dr. habil. Sabine Bauer[1], MA Ivanna Kramer[2], BA Lara Blomenkamp[2]

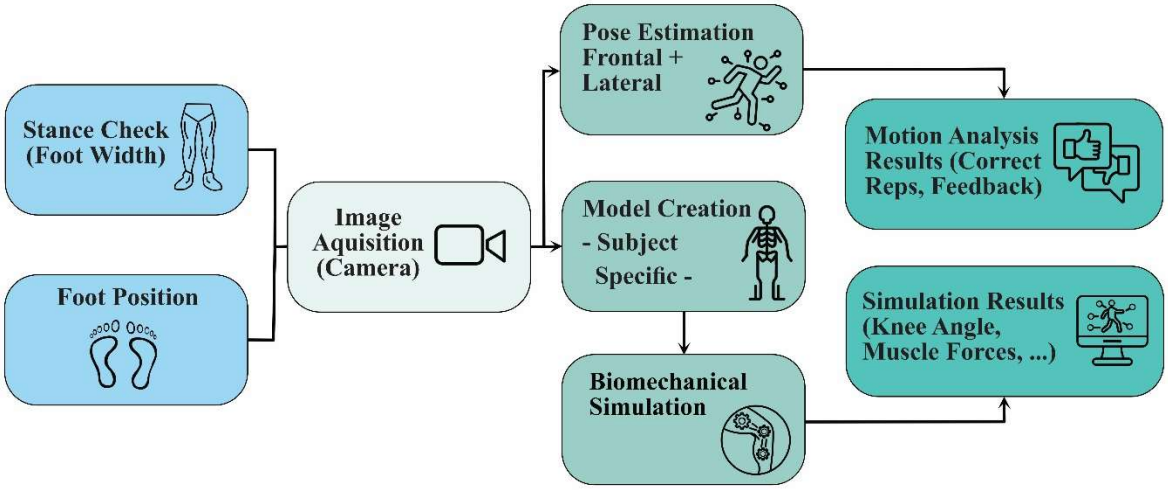
[1]University Sports, University of Koblenz, Koblenz, Rheinland-Pfalz, Germany. [2]Institute for Computational Visualistics, University of Koblenz, Koblenz, Rheinland-Pfalz, Germany

Introduction

Sports-related knee injuries such as ACL tears are common and increase the risk of long-term osteoarthritis, emphasizing the need for preventive strategies. Vision-based systems can classify major squat errors but cannot estimate internal loads. In contrast, biomechanical simulations can, yet they require markers or complex setups. We present a real-time, markerless, multi-view pipeline combining AI-based pose estimation with biomechanical modeling to provide kinematic feedback and subject-specific load insights for injury prevention.

Methods

Twelve healthy volunteers (six female, six male) performed three squats each, recorded from frontal and lateral perspectives using Intel RealSense cameras (30 fps). RTMPose extracted 2D keypoints, which were triangulated into 3D coordinates after calibration. Real-time rule-based feedback targeted three lateral criteria (heels flat, hip above knee, knee not beyond toes) and one frontal knee angle criterion [1]. For kinetic estimates, keypoints were scaled in an OpenSim musculoskeletal model (Pose2Sim), applying inverse kinematics and dynamics to derive joint moments and muscle forces. The system generated two types of outputs: frame-by-frame compliance indicators showing whether movement criteria were met at each instant, and trial-level summaries of muscle force distributions characterizing how loads were shared across muscles throughout the squat.



Results

Pose estimation achieved mean absolute errors of 3.5-4.2° for knee angles, consistent with marker-based systems, though larger maximum errors occurred due to occlusion and clothing. Simulation results showed ~6° deviation from ground truth producing physiologically plausible muscle force patterns. At maximal knee flexion, quadriceps dominated load distribution, with the vastus lateralis contributing >50%, consistent with published data. Hamstring contributions also matched literature ranges. The system thus delivered actionable kinematic feedback while producing load estimates aligned with established biomechanical findings.

Discussion

This pipeline links real-time AI-based pose estimation with subject-specific biomechanical simulation, enabling accessible, low-cost, and physiologically valid squat analysis. Although higher maximum errors indicate sensitivity to occlusion and visual conditions, overall accuracy supports markerless feedback for applied contexts. Real-time detection of dynamic knee valgus enhances clinical relevance for ACL injury prevention. Key strengths include real-time analysis, open datasets, and reproducibility, while limitations involve small sample size and a restricted population.

Evaluating the Impact of Camera Motion on Knee Angle Accuracy using World-Grounded Human Motion Recovery (GVHMR)

Ms. Sarah Dumont, Dr. Calvin Kuo

University of British Columbia, Vancouver, BC, Canada

Introduction

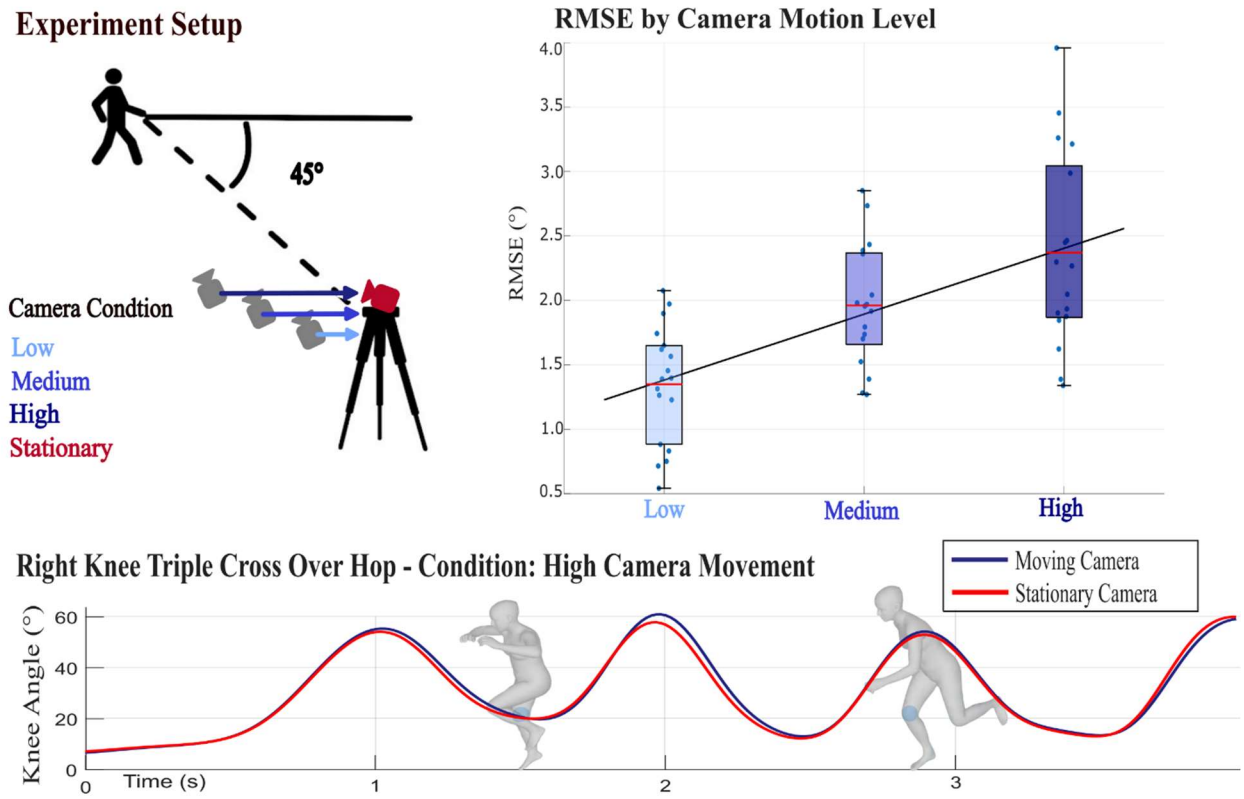
Advancements in computer vision have led to the development of pose estimation technologies, such as GVHMR. The markerless tracking system utilizes a single camera to generate 3D position data, presenting a potential solution for remote assessment to address the limitations of the marker-based gold standard [1]. However, before implementing this technology, it is critical to determine the practical constraints and recording conditions required to ensure accurate, meaningful data outputs. Specifically, this study aims to determine if a stationary camera is an important constraint to enforce during out-of-lab data collection.

Methods

We recruited three participants (22±1.7yo; 1F) to complete movements relevant to return-to-sport assessment, such as triple crossover hop and 45° cut. Participants were recorded simultaneously with two Motorola 5G (30Hz) cameras. One camera was affixed stationary to a tripod positioned approximately 45° relative to the participant. The second camera was handheld by the researcher and moved laterally following the participant. Camera movement was classified as low, medium, or high speed, with each condition repeated three times. All videos were processed using GVHMR to extract 3D joint position. Data was filtered and interpolated to compute knee joint angles (cosine law).

Results

The root mean square error (RMSE) of the knee angles was calculated relative to its corresponding stationary camera recording. A Kruskal-Wallis test indicated significant differences in RMSE across movement levels ($p = 0.00011$). Post-hoc Stepdown Dunn's tests showed:



- **Low vs. Medium:** $p = 0.0039$
- **Low vs. High:** $p = 0.000035$
- **Medium vs. High:** $p = 0.22$

Only comparisons involving the low movement condition reached statistical significance, showing that introducing movement increases error significantly, while increased movement has less effect. Despite this, the overall average RMSE across all trials and conditions was 2.1°, indicating good accuracy of GVHMR.

Discussion

Results show promise for out-of-lab data collection, as the reduced constraints make this technology more accessible and easier to use for nontechnical users. The next steps for this project will be to validate GVMHR joint angle estimates against marker-based data, as well as to look into other metrics used in return-to-sport evaluations.

Development of Automated Coronal Plane Alignment of the Knee Classifier Using Machine Learning With Digitally Reconstructed Radiograph

Dr. Satoru Ikebe[1], Dr. Takahiro Inoue[2], Dr. Takeshi Shimoto[3], Dr. Satoshi Hamai[2], Prof. Shingo Mabu[1], Prof. Yasuharu Nakashima[4], Prof. Hidehiko Higaki[5]

[1]Yamaguchi University, Ube, Yamaguchi, Japan. [2]Kyushu University, Fukuoka, Fukuoka, Japan. [3]Fukuoka Institute of Technology, Fukuoka, Fukuoka, Japan. [4]Kyushu University, Fukuoka, Fukuoka, Jordan. [5]Kyushu Sangyo University, Fukuoka, Fukuoka, Japan

Introduction

The coronal plane alignment of the knee (CPAK) classification is one method for evaluating lower leg alignment, and automated CPAK classifier have been developed. However, preparing sufficient training data for machine learning algorithms in the medical field is difficult because annotation requires specialized knowledge. Applying CT-based digitally reconstructed radiograph (DRR) as training data can reduce annotation costs. Therefore, this study aimed to develop an automated CPAK classifier using machine learning with DRR.

Methods

Pixels of target object in CT images were annotated to create annotated DRR. Annotated DRRs were created using seven lower limb CT images before total knee arthroplasty. The automated CPAK classifier was developed using object detection and segmentation algorithm. The femoral head, distal femur, proximal tibia, and ankle joint were detected using FCOS, and segmentation images were generated by HRNet, and landmarks were detected. Measurements of the lateral distal femoral angle (LDFA), the medial proximal tibial angle (MPTA), arithmetic hip-knee-ankle angle (aHKA), and joint line obliquity (JOL) were performed and CPAK was classified based on references by S. J. MacDessi et al. The automated CPAK classifier was evaluated using measurements from full-leg radiographs of 15 patients by clinicians.

Results

The feature objects were detected by FCOS and the detected images were segmented by HRNet. The landmarks for CPAK classification were detected from segmented images. The root mean square error (RMSE) result for LDFA was 1.6 degrees and MPTA was 1.9 degrees. The RMSE results for aHKA and JLO were 2.5 and 2.6 degrees, respectively. Classification accuracy of CPAK was 80%.

Discussion

FCOS and HRNet were trained using a total of 80,000 annotated DRR images created from seven lower limb CT images. Annotated DRR reduced annotation costs and allowed for object detection and segmentation using machine learning. The landmarks for CPAK classification were able to be detected from full-leg radiographs for evaluation. The accuracy of LDFA, MPTA, aHKA and JLO were within 3.0 degrees and classification accuracy of CPAK was 80%. High-accuracy landmark detection is required for automated CPAK classifiers, necessitating the addition of annotated DRRs from healthy subjects to the training data.

Observer Network: Validating Human Motor Control Policies via Q-network Knowledge Distillation

Mr. Seungju Mok MS Candidate, Prof. Ho Seon Choi Assistant Professor

Sejong University, Seoul, Seoul, Korea, Republic of

Mr. Seungju Mok

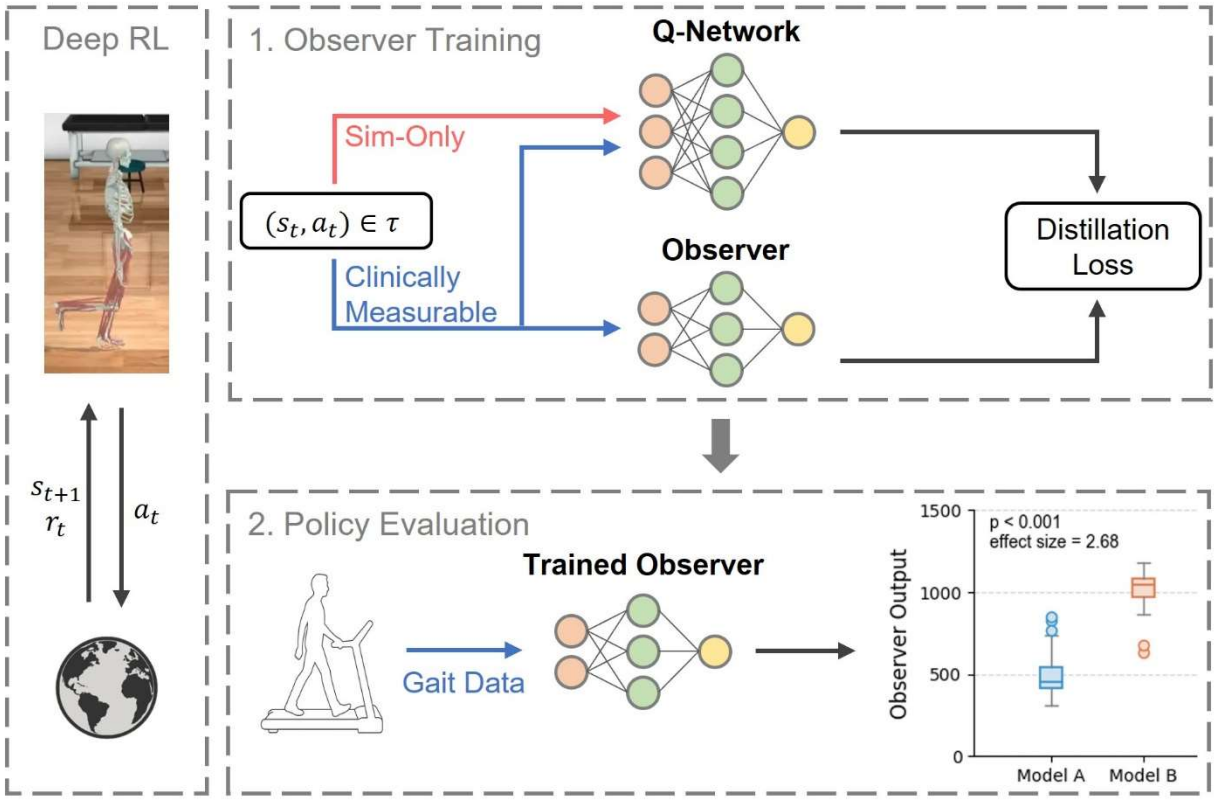
Introduction

Neuromusculoskeletal simulations are widely used in rehabilitation and neuroscience, and reinforcement learning (RL) is increasingly applied to train motor control policies. In Actor–Critic algorithms, a Q-network critic guides the actor toward actions with higher expected returns. Policy validation typically relies on comparing simulated joint kinematics/kinetics, or muscle activations with clinical measurements, but variability of biological systems limits the interpretability of such direct comparisons. To address this, we propose a novel validation framework that combines Q-network with knowledge distillation. Specifically, we introduce an observer network designed to quantify the similarity between learned policies and human motor control strategies.

Methods

RL state–action pairs include variables observable only in simulation and those measurable clinically. We designed an observer network that receives only clinically observable data but is trained to imitate the full Q-network through knowledge distillation. In the MyoSuite myoLeg environment, the musculoskeletal model features a 403-dimensional state space and an 80-dimensional action space. For the observer, we used sagittal-plane hip, knee, and ankle angles as state inputs and five lower-limb muscle activations as action inputs. The observer was trained using MSE against the corresponding Q-network output. Pre-trained locomotion policies, SAR and OptSyn, provided training data, and human gait data[1] were later used for evaluation. An overview of the framework is shown in the figure.

Results



Observers trained on SAR and OptSyn achieved rRMSE values of 0.11 and 0.08, and R^2 values of 0.92 and 0.83. For gait data from 20 subjects, observer outputs differed

significantly between the two policies (487.52 ± 47.44, $p < 0.001$, effect size = 2.68). Notably, OptSyn—also the policy with higher training return—yielded higher observer outputs. Corresponding box plots are provided in the figure.

Discussion

The observer's rRMSE and R^2 demonstrate successful knowledge distillation and accurate imitation of Q-network behavior. The higher observer outputs for OptSyn suggest that it not only generates more seemingly natural gait patterns but learns motor control strategies more consistent with human behavior. Beyond policy validation, the observer could potentially estimate impairment severity in neurological patients by quantifying deviations from healthy motor control strategies.

Sex-Hormone and Adipose Tissue Amounts Impact Magnitude of Breast Tissue Acceleration

Dr. Stacey Gorniak PhD, Ms. Saba Yazdekhasti MPO, Dr. Rebekah Maddox PhD, Dr. Emily LaVoy PhD

University of Houston, Houston, TX, United States

Introduction

Breast biomechanics studies have traditionally used 3D motion capture systems extensively to measure breast tissue acceleration based on passive marker displacement values without consideration of how health state covariates—including sex-hormone levels—may influence breast tissue kinematics. To address this issue, our study aimed to investigate potential physiological and anthropometric covariates of breast tissue acceleration magnitude in women with larger breasts.

Methods

In this study, 20 healthy female volunteers (33 ± 12 years of age, BMI = 30.2 ± 6.5 kg/m^2), spanning a range of D to G bra cup sizes, participated in a comprehensive breast motion analysis involving both a 3D motion capture system and Delsys Trigno sensors (built-in triaxial accelerometers) to assess breast acceleration during exercise. Potential covariates were collected via body composition via dual-energy X-ray absorptiometry (DXA) and a venous blood draw to assess the influence of sex-hormone levels and common cardiometabolic health markers on breast tissue kinematics.

Results

While differences emerged between breast acceleration values measured via triaxial accelerometry and traditional 3D motion capture, influences of sex-hormones such as sex hormone binding globulin (SHBG), progesterone, and cardiometabolic health via glycated hemoglobin all significantly influence the magnitude of breast tissue acceleration ($p < 0.01$). Additional anthropometric covariates related to trunk size (e.g., total body fat percentage and bra band size) also emerged ($p < 0.01$).

Discussion

This data supports our prior reports of differences in the magnitude of breast tissue acceleration values depending on measurement modality [1]. Additionally, these data point to important physiological and anatomical contributions to breast tissue acceleration magnitudes. Specifically, influences of the endocrine system through sex-hormone

secretion and glycated hemoglobin control were notable in the covariates found in this study. Contributions of increased trunk size and increased adipose tissue distribution within the trunk region also influenced the magnitude of breast tissue acceleration. These data enhance our understanding of how breast dynamics are influenced by physiological influences which are not typically considered in biomechanical studies.

A Data-Driven Approach to Optical Motion Capture Gap-Filling

Ms. Sarah Hynes, Mr. Jonathan Chu, Mr. Daniel Fournier, Dr. Clark Dickerson, Dr. Stewart McLachlin

University of Waterloo, Waterloo, Ontario, Canada

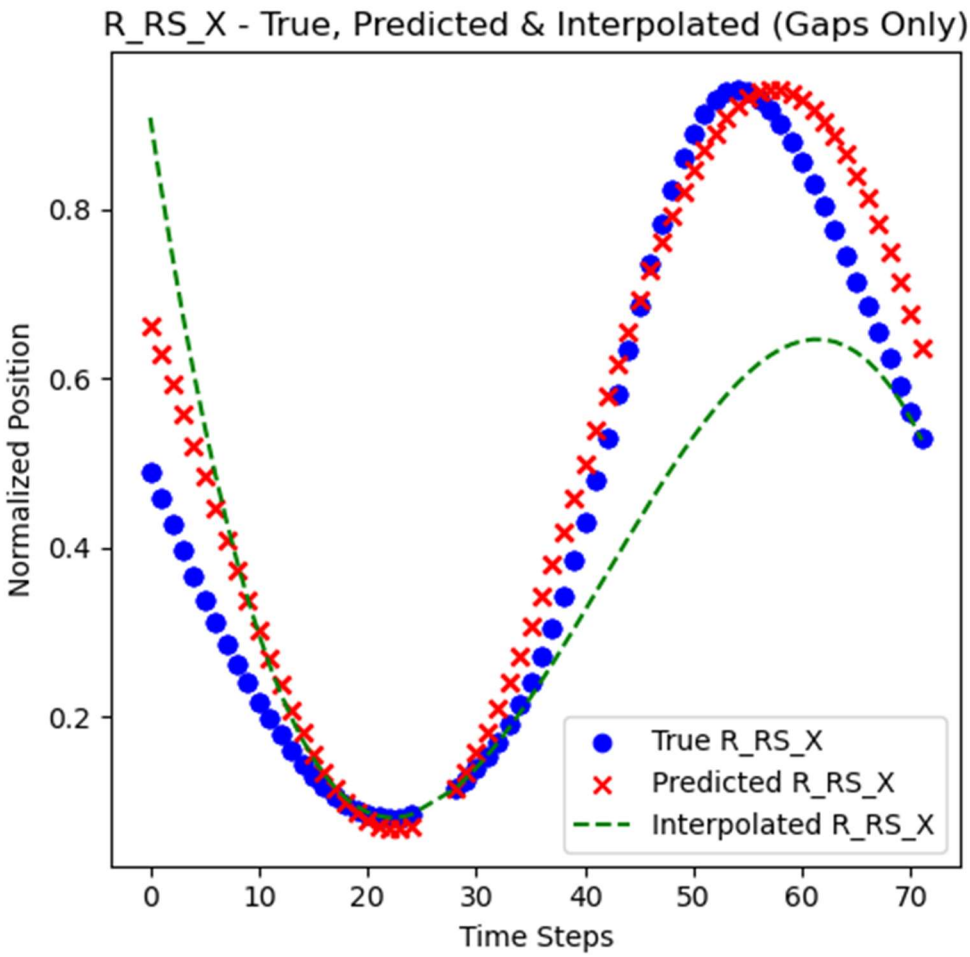
Introduction

Marker-based optical motion capture (MOCAP) is widely used for movement analysis, but marker occlusion creates gaps that require post-processing [1]. Traditionally, these gaps are filled manually using interpolation methods, a process that is time-consuming and prone to variability, particularly for longer gaps [2]. This study investigated the use of a machine learning (ML) approach to automate marker gap-filling by incorporating inertial measurement unit (IMU) data as a reference during marker dropout.

Methods

A dataset of 84 participants performing nine physiotherapy exercises while wearing seven markers on the right arm and upper torso was analyzed. Movements were captured using a 13-camera VICON MX20 motion capture system (VICON Motion Systems Ltd, Oxford, UK), while an IMU (Mobvoi TicE Smartwatch, Beijing, CN) was worn on the right wrist. The original MOCAP data was manually gap-filled to establish ground truth values. Artificial gaps ranging from 0.5 to 2 seconds were then introduced randomly across all markers. The incomplete MOCAP data and corresponding IMU signals were used as inputs for a long short-term memory (LSTM) recurrent neural network, designed to predict and reconstruct missing marker trajectories. The dataset was split into training (70%), validation (15%), and testing (15%) sets.

Results



The model converged after 54 epochs, achieving a mean squared error (MSE) of 0.0213 for training and 0.0212 for testing. Compared to traditional interpolation techniques, the model demonstrated superior performance during non-linear and complex movements, reducing error by up to 50% in certain cases.

Discussion

By combining IMU and MOCAP data, this ML-based approach effectively automated the marker gap-filling process and produced smooth, physiologically plausible trajectories during short-term marker loss. This method offers a consistent and less labor-intensive alternative to traditional gap-filling techniques. Future work will focus on model

optimization, comparative analysis with additional time-series architectures, and exploring potential real-time implementation.

Accuracy of AI-Based Multimodal Models in Automatically Detecting Falls in Older Adult from Video Footage

Ms. Teah Cribbie, Dr. Max Donelan, Dr. Stephen Robinovitch

Simon Fraser University, Burnaby, British Columbia, Canada

Introduction

Falls are the leading cause of injury in older adults (aged 65+). Often, older adults are unable to rise independently after falling, and the "long lie" increases the clinical consequences of the fall. Video cameras are increasingly accessible, and advancements in AI models are creating the potential for "smart" cameras that can automatically detect falls and alert care providers.

To date, research on the accuracy of video-based automatic fall detection has involved small numbers of simulated falls by young adults in artificial environments. Furthermore, no study to our knowledge has evaluated the video-based fall-detection performance of multimodal models (e.g., GPT or Gemini). We addressed this knowledge gap by evaluating the zero-shot performance of GPT 4.1 and Gemini 2.5 Pro in automatically detecting real-life falls by older adults in long-term care using video footage. We also assessed how model performance depends on video characteristics (resolution, lighting, distance from camera, occlusions, number of background individuals) and movement characteristics (non-fall activity, activity at time of fall, cause of imbalance leading to fall).

Methods

Videos of 20 falls and 24 non-falls (activities of daily living) were included in the analysis. Images were extracted from each video at 5 frames per second. A hierarchical prompt was used, specifying identity, instructions, fall definition, and context. The images and the prompt were sent to GPT 4.1 and Gemini 2.5 Pro for fall versus no-fall classification.

Results

The classification accuracy was 86% for Gemini 2.5 Pro and 80% for GPT 4.1. Both models were more likely to yield false negatives (i.e., classify falls as non-falls) than false positives (classify non-falls as falls). The sensitivity was 70% for Gemini and 65% for GPT, and the specificity was 100% for Gemini and 92% for GPT. Classification accuracy depended on both video and movement characteristics (Table 1).

Discussion

In this preliminary study, we found promising results of 80-86% accuracy for AI-based multimodal models in automatically detecting older adult falls from video footage. Ongoing work with a larger sample is examining how classification accuracy depends on the independent and interacting effects of movement and video characteristics, as well as the prompt design.

GO Viz: An Open-Source Application for the Visualization of Gene Ontology Enrichment Analysis Across Multiple Comparisons

Mr. Amevi Semodji, Dr. Trevor Lujan

Boise State University, Boise, Idaho, United States

Introduction

Gene ontology (GO) enrichment analyses have been instrumental in transcriptomics and proteomics to identify biological events associated with differential expression patterns. Although multiple online tools and statistical packages provide visualization capabilities, none support user-friendly comparisons across multiple experimental conditions. To address this limitation, we developed GO Viz, an open-source MATLAB-based standalone application that streamlines GO enrichment visualization through the handling of multiple comparisons and diverse input file types.

Methods

GO Viz offers a user-friendly graphical interface (**Fig. 1A**) that allows users to select multiple experimental comparisons as text- or spreadsheet-based files, which are common outputs from GO enrichment platforms. The application imports log2 fold enrichment and Benjamini-Hochberg (FDR) data, and after an optional filtering by statistical significance, creates a two-dimensional color-scale bubble plot with bubble size representing significance and color representing log2 fold. The resulting layout enables clear and direct comparison of GO terms across different conditions. Users can export visualization results as high-resolution images and editable MATLAB figures, facilitating tuning for publications. We tested the performance of GO Viz by visualizing generated GO data from 1, 5, 10, and 20 comparisons with up to 10,000 GO terms and in '.xlsx', '.tsv', and '.csv' formats.

Results

GO Viz successfully loaded and plotted data from all sets of comparisons and GO terms in less than 20 seconds (**Fig. 1B**). It also successfully loaded all three file formats with an average of 0.5 second and no significant difference in loading time between formats (**Fig. 1C**).

Discussion

GO Viz's objective is to visualize GO enrichment data across multiple experimental comparisons in an intuitive and user-friendly bubble format and thereby address limitations with current platforms. For example, REVIGO and GO Figure! only provide bubble-format visualization for single comparisons, while GO Term Viewer can handle multiple comparisons, but in a hierarchical manner that is difficult to visualize. Here we demonstrated that GO Viz can handle multiple comparisons and multiple file formats with significant amounts of GO terms. Future work will include reduced-redundancy implementation and GO term search.

Images (Optional)

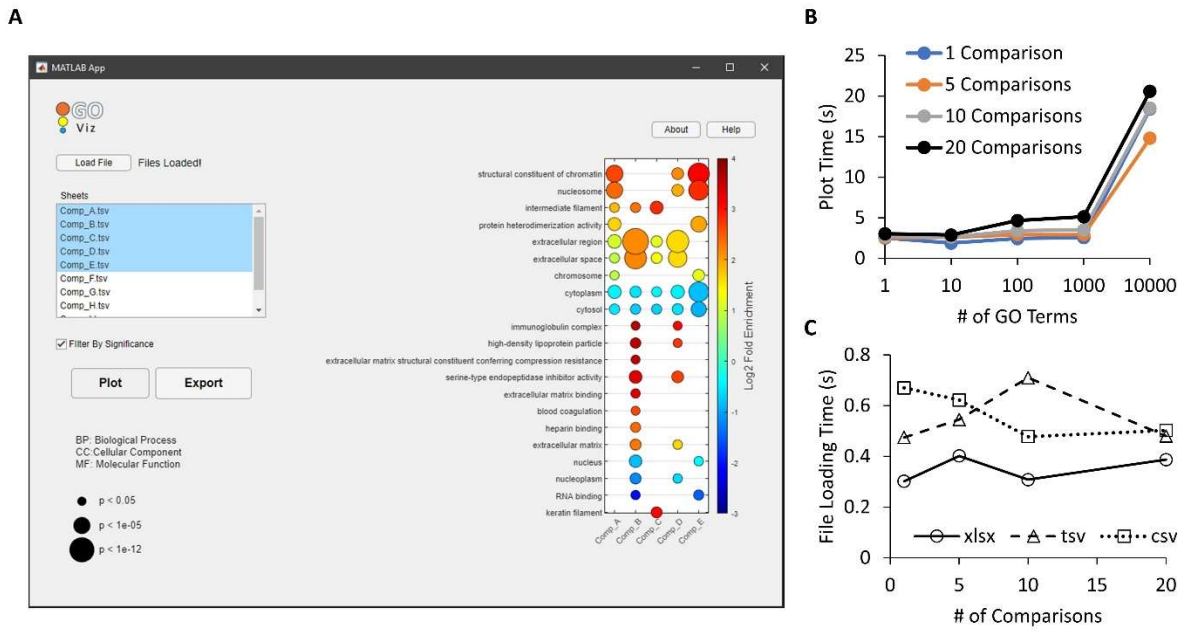

Figure 1: A) Graphical interface of GO Viz showing an example of plot across multiple comparisons. B) GO Viz successfully loaded and plotted data from 1, 5, 10, and 20 comparisons that each had 1, 10, 100, 1000, and 10000 GO terms. C) GO Viz successfully loaded different file formats for analysis with no minor differences in loading time between formats

Cognitive Load and Knee Motion While Driving in Teens After Anterior Cruciate Ligament Reconstruction Surgery

Dr. Valentina Graci[1,2], Ms Maitland Witmer MSE[1,2], Ms Chelsea Ward-McIntosh BS[1], Dr. Hasan Ayaz PhD[2], Dr. Divya Jain PhD[1], Dr. Catherine McDonald PhD[1,3], Ms. Kevin Landrum BS[4], Dr. J. Todd Lawrence MD, PhD[4], Dr. Theodore Ganley MD[4], Dr. Elliot Greenberg PT, DPT, PhD[4]

[1]Center for Injury Research and Prevention,Children's Hospital of Phialdelphia, Philadelphia, PA, United States. [2]School of Biomedical Engineering, Science and Health Systems, Drexel University, Philadelphia, PA, United States. [3]School of Nursing, Philadelphia, PA, United States. [4]Department of Orthopedic Surgery, Philadelphia, PA, United States

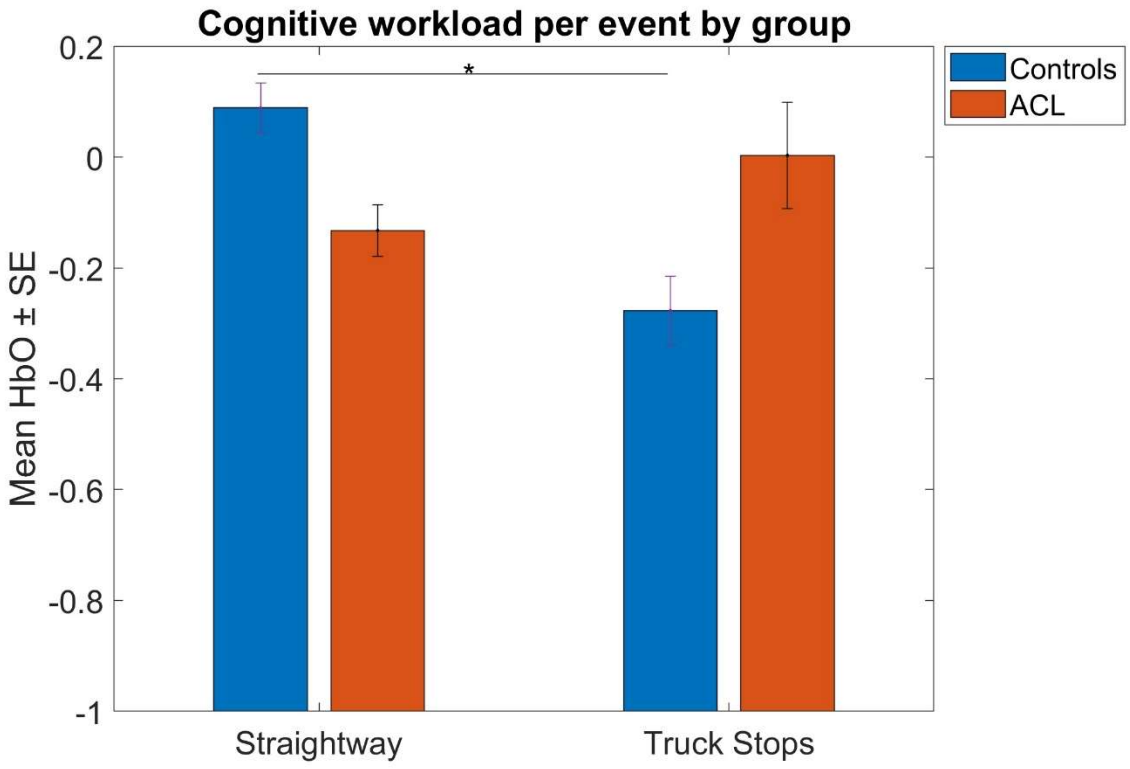
Introduction

Evidence-based guidelines to determine capacity to safely return-to-drive after Anterior Cruciate Ligament Reconstruction (ACLR) in teens are lacking. Although divided attention and cognitive tasks can influence knee biomechanics, the interplay between driving cognitive demands and lower limb motion remains unknown in teens post-ACLR. Our objective was to examine cognitive load, knee motion, and brake force in teens after ACLR versus healthy controls.

Methods

Six healthy teens (4 males, 2 females; age 16.7-18.9 years old) and four teens post-right ACLR (1 male, 3 female; age 16.9-19.6 years old; 30-64 days post-op) completed three 7–9 minute drives in a driving simulator, each including scenarios with a lead vehicle abruptly stopping. Inertial Sensor Unit system (IMU) recorded right knee movement. A portable functional near-infrared spectroscopy (fNIRS) measured prefrontal cortex oxygenation changes (HbO). Brake force (N) and knee angle (°) were averaged across drives and compared between groups with Mann-Whitney U tests. HbO was averaged during the brake event and during a ‘straightaway’ drive, and compared between events and groups with a linear mixed model ($p<=0.05$).

Results



Teens 4-6 weeks post-ACLR showed significantly decreased braking force (Control 11.2 ± 30.2 N vs post-ACLR 7.7± 21.0 N, $p=0.01$) but similar knee angle compared to the controls

(p=0.08). HbO showed a significant interaction effect in group*event ($p<0.05$). Post-hoc comparisons showed that the post-ACLR group had similar cognitive workload between events (p=0.5) while the controls demonstrated decreased cognitive workload in the braking event compared to the straightaway drive ($p<0.03$, Figure 1).

Discussion

In healthy teens, quick brake reactive actions may require less brain activity in the areas dedicated to executive functions, with non-primary motor areas and subcortical structures potentially being more active to rapidly produce the correct crash avoidance motor response. Post-ACLR teens may require higher cognitive workload to brake, which may delay motor output. This may help explain the reduced brake force in the ACLR group while maintaining a similar knee position as the controls. Cognitive workload may be an important metric to assess return-to-drive readiness in teens post-ACLR.

Sensitivity of Markerless 3D Reconstruction to Different Simulated Video Acquisition Scenarios

BSc. Vanessa Yelós Tellagorry[1,2], MSc. Ariel E. Stassi[1], AD. Martín Arévalo[1], PhD. Germán Pequera[1,2], PhD. Carlo M. Biancardi[2]

[1]Departamento de Ingeniería Biológica, CENUR Litoral Norte, Universidad de la República, Paysandú, Paysandú, Uruguay. [2]LIBiAM Biomechanics Lab, Dep. of Biological Sciences, CENUR Litoral Norte, Universidad de la República, Paysandú, Paysandú, Uruguay

Introduction

Markerless technique has been positioned as a valuable tool comparable to gait labs [1]. However, its ability to achieve reliable results in different video acquisition scenarios has been poorly explored. The objective of this ongoing work is to investigate the impact of changes in video features on 3D markerless reconstruction performance.

Methods

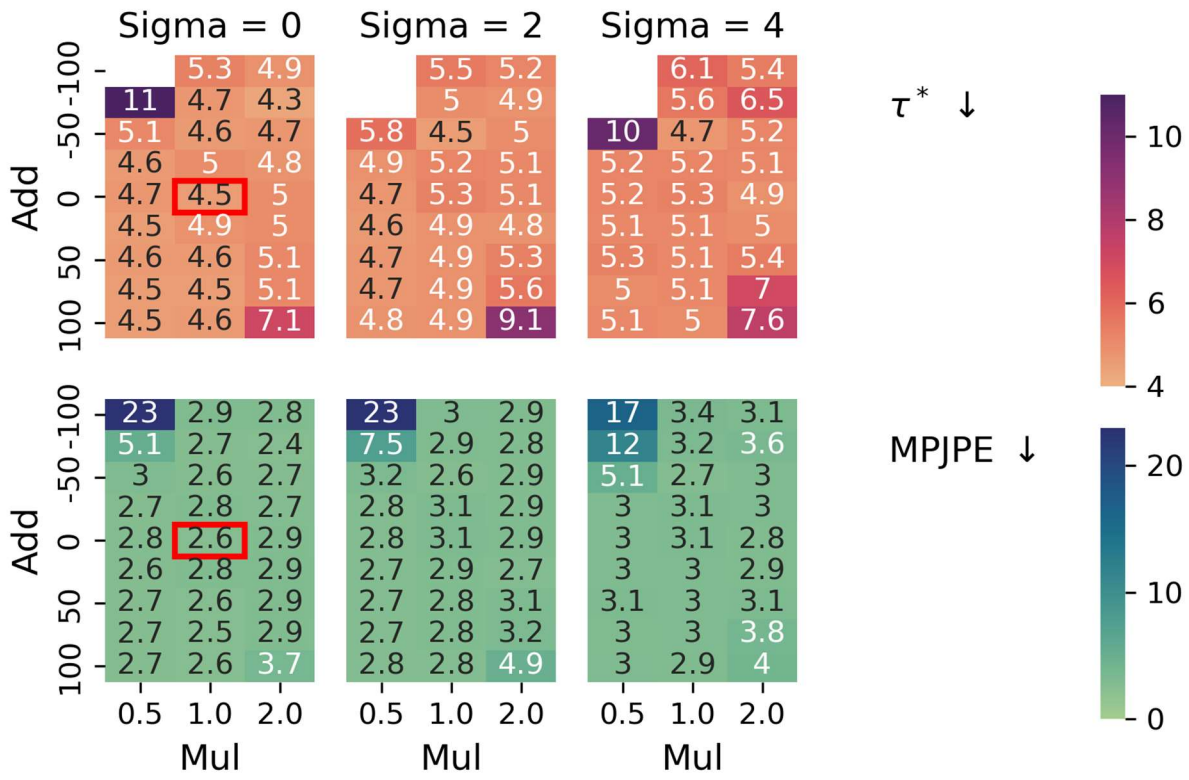
One subject (Male, 38 yr, height 174cm, weight 69.4 Kg), equipped with 18 markers [2], walked on a treadmill at 5 km/h. The study was approved by the university ethics committee.

Data acquisition: Kinematic data were acquired using a motion capture system (Vicon Motion Systems) with 8 cameras at 120 Hz, and a markerless system simultaneously, which was composed by 4 iPhone SE (Apple) to register videos at 60 Hz.

RGB video data augmentation: Videos were generated synthetically combining the modification of 3 parameters of the RGB videos: “Add” (impact on brightness), “Mul” (impact on contrast), and “Sigma” (impact on sharpness) using vidaug Github Library (https://github.com/okankop/vidaug). 63 combinations were generated from ordered sequences of video augmentations.

Markerless video processing: MMPose and Pose2Sim [2] were used to reconstruct the position of 18 keypoints. Two classic error metrics, MPJPE and threshold τ^* for MPJLE≥90% [3], were used to evaluate performance changes.

Results



Preliminary results showed that modifying the brightness with respect to the original scene (red box), didn't have a great impact. The same behavior could be seen when contrast was modified. When brightness and contrast perturbations were combined, the system

performance showed the worst results, mainly when brightness and contrast were decreased. However, extreme perturbations on brightness while contrast was increased, didn't worsen the performance. Blur the scene seems to have minimal impact on the markerless performance.

Discussion

Markerless system revealed robust behavior when different scenarios were simulated. Isolated brightness, contrast or sharpness modifications had little impact on performance. However, when the perturbations were combined in a certain way, the performance could decrease significantly.

Heel Strike Detection using IMU-Based Multi-Scale Temporal Convolutional Network

Mr. Jainil Patel[1], Ms. Celeste Thai[2], Mr. Chengkang Zhou[1], Dr. Tianxiang Gao[1], Dr. Ying Fang[2]

[1]DePaul University, Chicago, IL, United States. [2]Rosalind Franklin University, North Chicago, IL, United States

Introduction

Detecting heel strikes of gait cycles is critical in gait analysis that is relevant to rehabilitation. Standard techniques rely on ground reaction force (GRF), which can be measured by force plates that are often not available outside the lab. In our study, we trained a deep learning model using only inertia measurement unit (IMU) data to detect heel strikes to support real-world gait analysis.

Methods

GRF and IMU data (42 1-minute walking trials) from four young adults (walked at 8 speeds between 0.6-1.3 m/s) and 12 older adults (walked at self-selected speeds between 0.2-1.1m/s) was used for model training and evaluation. GRF data was used to determine ground truth heel strike labels. A Multi-Scale Temporal Convolutional Network (MSTCN) was trained using shank and thigh IMU data (MetaBase) as the input. The model outputs probability of stance phase at each frame, and a threshold of 0.6 was used to determine heel strike times (Figure 1). We used focal loss to account for the unequal swing and stance phase frames. We evaluated the model on a held-out test set of 10 walking trials from 4 young and 2 older adults.

Results

The model achieved an F1 score of 0.85±0.12, precision of 0.85±0.11, and recall of 0.86±0.11. The mean absolute error for the predicted heel strike time was 45±16ms.

Discussion

The current model achieved good performance (criteria: F1 score between 0.7-0.9) in distinguishing the stance and swing phase. Additionally, the error of predicted heel strike timing was within 3 frames (IMU data collected at 50 Hz), demonstrating the potential of using IMU-based TCN to distinguish gait cycles. The current model was evaluated on one held-out test set. When including different trials in the test set, we observed varied model performance that was influenced by walking speed and age group. Future work will include a larger training set with a wider range of walking speed and age, and use cross-validation for model evaluation. While prior studies have explored step detection using AI, few have

focused specifically on identifying the precise heel strike time, highlighting the novelty of our approach.

Images (Optional)

Quantitative-Feature Analyses of Fear of Falling Through Artificial Intelligence Methods

Dr. Zhanxin Sha[1], Dr Benjamin Meador[2], Mr. Yicai Yao[3], Dr Kesheng Wang[4], Dr Juefei Yuan[3]

[1]Geogia Southwestern State University, Americus, Georgia, United States. [2]Georgia Southwestern State University, Americus, Georgia, United States. [3]Southeast Missouri State University, Cape Girardeau, Missouri, United States. [4]University of South Carolina, Columbia, South Carolina, United States

Introduction

Fear of falling increases the risk of future falls and contributes to disability and declining health-related quality of life. Its assessment is challenging because it is influenced by multiple psychological, social, and balance-related factors. Artificial intelligence methods offer an alternative approach because they can work directly with different forms of input data, including manually selected features, automatically extracted features, or raw time-series signals. These methods may help researchers identify factors associated with fear of falling. However, there is a paucity of research examining features based on anthropometric characteristics, physical activity level, and static balance assessments in relation to fear of falling. The purpose of this study was to classify fear of falling using quantitative features through artificial intelligence methods.

Methods

The present study used a public dataset that included 147 healthy participants (aged 18–85 years). Each participant completed the Falls Efficacy Scale–International (FES-S, total score) and the International Physical Activity Questionnaire–Short Form (IPAQ). The dataset also included ground reaction forces (Fx, Fy, and Fz), ground reaction moments (Mx, My, and Mz), and center of pressure (COPx and COPy) collected under four conditions (eyes open vs. closed & firm vs. foam surface). 98 features were used as inputs, including anthropometric data, physical activity status, and time- and frequency-domain features calculated from kinetic signals. FES-S (classified as low, moderate, and high) served as the classification and prediction outcomes.

Three artificial intelligence methods were used to classify outcomes based on selected features: 1. Random Forest, 2. Fully Connected Neural Network (FCNN), 3. One-dimensional Convolutional Neural Network (1D-CNN).

Results

The 1D-CNN achieved the highest accuracy for classifying FES-S, with performance of 90.25%. FCNN and Random Forest models demonstrated moderate accuracy (85.94% and 85.49%, respectively). Feature importance analyses consistently identified physical activity level, age, foot length, and BMI as the most influential predictors of FES-S.

Discussion

The present study integrates quantitative features to predict and classify fear of falling in a healthy population. Future research is needed to validate these findings in clinical populations and to examine whether additional biomechanical or sensor-based features can further enhance predictive performance.

Delineating the Role of Right Ventricular Viscosity and Elasticity in Organ Performance Using a Lumped Parameter Multiscale Computational Model

Dr. Kristen LeBar[1], Dr. Lik Chuan Lee[2], Dr. Zhijie Wang[1]

[1]San Diego State University, San Diego, California, United States. [2]Michigan State University, East Lansing, Michigan, United States

Introduction

Myocardium is viscoelastic: both viscous and elastic resistances exist during deformation. We have shown marked increases in right ventricular (RV) viscosity and elasticity with disease, and *in vivo* reduction of RV viscoelasticity improves function. However, altering viscoelasticity experimentally induces multifactorial changes and prevents isolating the independent effects of viscoelasticity.

Multiscale computational models separate these factors, though myocardial viscosity is typically neglected. **Therefore, our goal was to develop a lumped-parameter model that incorporates RV elasticity and viscosity to predict RV pressure–volume (PV) behavior**. We hypothesized that viscosity and elasticity distinctly impact RV performance.

Methods

We modeled the cardiopulmonary circulation using a previously developed closed-loop lumped-parameter framework. RV viscoelastic stress was incorporated using a modified Kelvin–Voigt formulation. Passive stress ($\sigma_{passive}$) is given by

$$\sigma_{passive}=\sigma_{elastic}+\sigma_{viscous}$$

where

$$\sigma_{elastic}=2Cb_{ff}E_f\lambda_f^2e^Q,\ \sigma_{viscous}=-1.0*sign(Vdot)*1000*\eta(1/3)*((1/v)^{2/3}V_{RV}^{-2/3})*abs(Vdot)$$

Vdot: volume rate of change; C: passive stiffness; η: viscosity. We modulated C and η to mimic healthy and diseased RV mechanics, while keeping active stress (Hill model) unchanged under four conditions: 1) healthy viscoelasticity; 2) increased stiffness; 3) increased viscosity; 4) diseased viscoelasticity. We derived hemodynamic parameters to assess independent and combined effects of viscosity and elasticity.

Results

Changes in elasticity impacted RV pressures, volumes, and systolic function (green). RV contractility parameters (blue) consistently decreased with higher elasticity, whereas increased viscosity produced no change in dP/dt_{min} or ESPVR, but increased dP/dt_{max}. When elasticity and viscosity were increased together (disease) the contractile response resembled that of increased elasticity alone, indicating that stiffness dominates contractility. Increasing passive stiffness alone only slightly increased EDPVR, whereas viscosity markedly increased EDPVR, driving the larger diastolic stiffening seen in the diseased state.

Discussion

Our results reveal distinct effects of passive viscosity and elasticity on RV function. The findings suggest that stiffness dominates RV performance, but increased viscosity (as observed in disease) may be adaptive and preserve function. One limitation is that active stress was unchanged; future work should integrate viscoelastic effects on muscle contraction to fully capture organ physiology. Delineating the roles of viscosity and elasticity enhances our understanding of RV pathophysiology and points to potential therapeutic targets.

Identifying Fragile X Syndrome Biomarkers: a Supervised Machine Learning approach based on Gait Analysis data

Phd student Federica Beghetti[1], PhD Fabiola Spolaor[1,2,3], PhD Roberta Polli[3,2], Phd Elisa Bettella[3,2], MD Valentina Liani[2], Mr. Francesco Campulla[4], Prof. Stefano Sartori[5], Prof. Giorgio Perilongo[2,3], PhD, Prof. Damiano Varagnolo[6,1], PhD, Prof. Zimi Sawacha[1]

[1]Department of Information Engineering, University of Padova, Padova, Veneto, Italy. [2]Department of Women's and Children's Health, University of Padova, Padova, Veneto, Italy. [3]Pediatric Research Institute Città della Speranza, Padova, Veneto, Italy. [4]University of Padova, Padova, Veneto, Italy. [5]Child Neurology and Clinical Neurophysiology Unit, Padova University Hospital, Padova, Veneto, Italy. [6]Department of Engineering Cybernetics, Norwegian University of Science and Technology, Trondheim, Trøndelag, Norway

Introduction

Fragile X Syndrome (FXS), the most common inherited cause of intellectual disability and ASD [1], is often underdiagnosed due to inconsistent genetic testing. Because children with FXS frequently show gait alterations, such as flat feet, ligamentous laxity, and hypotonia, gait analysis (GA) offers an objective assessment method. Prior work has shown distinct kinematic and sEMG patterns in children with FXS compared to typically developing peers[2]. Therefore, this study investigates gait-based biomarkers for FXS by evaluating multiple supervised ML models using EMG-derived and kinematic features to discriminate among controls subjects (CS), full-mutation FXS (FXSFull), and mosaic FXS (FXSMos).

Methods

As FXS affects males more frequently due to their single X chromosome, the study analyzed 35 male children with FXSFull (BMI 19.12 ± 6.3 kg/m^2; age 10.4 ± 3.7 years), 20 with FXSMos (BMI 17.19 ± 7.8 kg/m^2; age 10.3 ± 2.5 years), and 14 age- and BMI-matched controls. GA was conducted at self-selected speed using four synchronized GoPro Hero7 cameras (60 fps) and an 8-channel Cometa sEMG system (2000 Hz) recording bilateral lower-limb muscle activity. Six trials per participant were processed to extract spatiotemporal parameters and muscle envelopes, from which DTW-based [3] and sEMG-derived features were computed [2,4]. Supervised ML models were trained with 5-fold cross-validation and evaluated on independent training and test set. Model performance, accuracy, precision, and recall, was assessed for three classification tasks: CS vs. FXS; CS vs. FXSFull vs. FXSMos; FXSFull vs. FXSMos.

Results

Classification performance reliably distinguished CS from FXS. Excluding CS from training improved discrimination between FXSFull and FXSMos.

Discussion

Classification between FXS phenotypes remained challenging, with lower accuracy irrespective of model or feature set. These findings suggest that although sEMG-derived gait features contain discriminative information about the presence of FXS, identifying a robust biomarker for distinguishing FXS subtypes may require additional data modalities or more advanced modeling techniques. Future research will integrate advanced learning methods to improve phenotype-level discrimination and move closer to a clinically actionable biomarker for FXS.

Stress Wave Induced High Shear Strain and Shear Strain Rates as a Potential Mechanism to Explain Blast Traumatic Brain Injury.

Mr. Aashutosh Kulakarni Prachet, Dr. Haneesh Kesari

Brown University, Providence, RI, United States

Introduction

Blast traumatic brain injury is a prevalent injury among modern military personnel, with adverse cognitive and behavioral effects. However, the mechanism of the injury in the brain is still unclear. In recent years, cavitation in the cerebrospinal fluid (CSF) has been pursued as a potential mechanism of injury. The short time scales of a potential cavitation event (~2 ms) has led to investigations of the blast event for durations around 10 ms [1, 2]. In this work, we perform numerical simulations to investigate the dynamics of simplified 2D and 3D models of the head for durations greater than 200ms when subject to blast overpressures close to 300 kPa.

Methods

The brain matter and CSF are modeled as nearly incompressible materials, and we use a mixed finite element formulation to address numerical challenges associated with simulating incompressible materials.

Results

We observe in our simulations that the shear strain peak reached at short time scales (< 5 ms) is only a local peak, and that the true shear strain peak occurs at longer time scales (> 50 ms) and are in the range to cause brain injury.

Discussion

The large strains are caused by flexural waves of the skull which propagate slower than the pressure waves and therefore cause large strains at later time durations. This indicates that the vibrational dynamics of the head may be a key mechanism causing brain trauma from blast events and presents immediate insights to manufacture better helmets.

A MRI-Safe, Pneumatic Rotation Device to Measure Large Brain Deformations using Tagged MRI

Mr. Peace Aina[1], Dr. Yuan-Chiao Lu[2,3], Dr. Joy Mojumder[2,3], Dr. Dzung L. Pham[2,3], Dr. Ahmed Alshareef[1]

[1]University of South Carolina, Columbia, SC, United States. [2]Uniformed Services University, Bethesda, MD, United States. [3]Henry M. Jackson Foundation, Bethesda, MD, United States

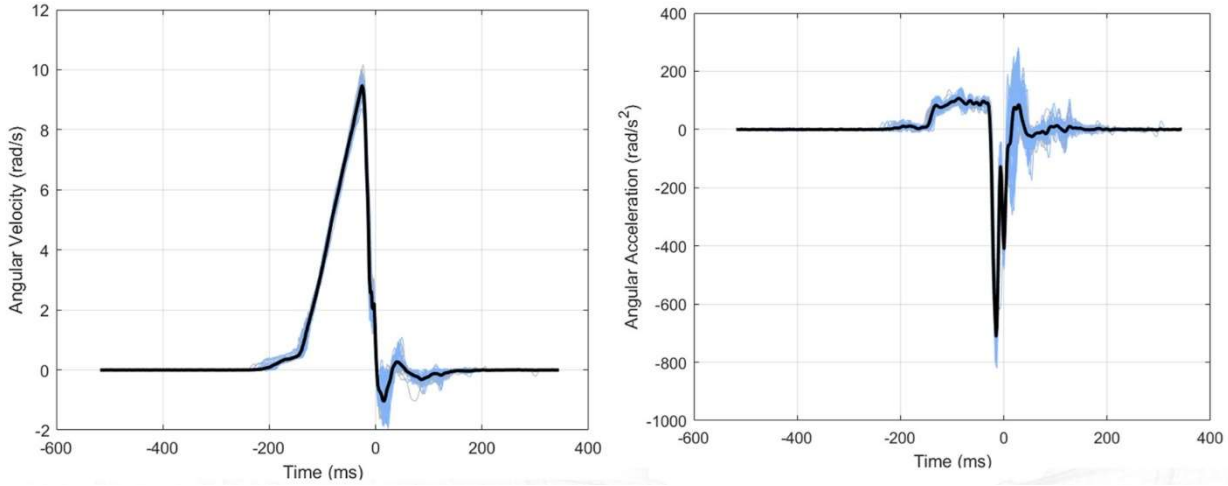
Introduction

Tagged Magnetic Resonance Imaging (tMRI) is currently used to measure in vivo brain deformation to understand tissue vulnerability to injury and calibrate computational models. In current experiments, a rotation device is used to impart low head accelerations, with peaks of 250-300 rad/ s^2. The primary aim of this study is to design a MRI-safe axial rotation device that induces higher accelerations with high repeatability to measure large brain deformations.

Methods

A head-rotation cradle and axle were 3D printed from carbon-fiber nylon and anchored within a Delrin bearing block. A MRI-safe optical position encoder was linked to the rotating axle to measure kinematics. A pin mechanism held the cradle level; once released, a counterweight rotated downward with gravity, driving the cradle 35° until it contacted a sorbothane pad. To allow for increased accelerations, a MRI-safe pressure chamber was mounted below the lever arm and was triggered after 2° of travel to boost angular velocity. The input pressure was calibrated based on an analytical solution of the system and desired angular kinematics (3-12 rad/s and 200-1400 rad/s^2). Initial tests were run to confirm peak kinematics and repeatability. Trials were conducted with and without piston assistance. 2D tagged MRI acquisitions were acquired on a Sylgard 527 clyndrical phantom and headform phantom on a Siemens 3T scanner.

Results



The new device yielded higher peak velocity, greater angular acceleration, and lower peak-value variability than those reported in previous tagged-MRI experiments. The piston-assisted device had accelerations of 1425 ± 18 rad/ s^2 at impact with excellent repeatability across 70 rotations (Figure 1). Single slice tagged MRI acquisitions in two phantom were successful at the low-severity (300 rad/s^2) and high-severity (1400 rad/s^2) conditions, with the piston (at 30 PSI) performing as expected with no safety concerns. Tag

tracking and strain calculations are ongoing to validate the strain fields against previous experiments and computational models.

Discussion

This MR-compatible head-rotation device delivers repeatable, axial rotations with higher accelerations. The design paves the way for high-acceleration tMRI experiments on head surrogates and cadaveric specimen that reproduce real-world traumatic loading and can refine next-generation computational brain-injury models.

Periodic Activation Functions for Identifying Injured Movement

Dr. Alex Dzewaltowski PhD, Dr. Christopher Connaboy PhD

Rosalind Franklin University of Medicine and Science, North Chicago, Illinois, United States

Introduction

Movement presents indicators of musculoskeletal injury but these indicators can be subtle. Machine learning methods may aid injury identification and early detection thereby, limiting injury progression and symptom severity. The purpose of this study was to assess changes in classification accuracy of injured or uninjured walking and running from exchanging activation functions.

Methods

Data analyzed were from a freely available dataset[1] composed of 1798 unique participants with and without a variety of musculoskeletal injuries. Retroreflective marker position collected via motion capture were tracked and filtered using a low-pass Butterworth filter with a cutoff of 10Hz. Sacrum, thigh, shank, and foot tracking marker positions and their derivatives for velocity and acceleration as well as the relative phase between leg segments relative to the sacrum were provided as inputs (90 features in total) to a multilayer perceptron with three linear layers each followed by a varying activation function, one linear layer with a Rectified Linear Unit (ReLU) activation function, and a final linear layer which outputs four likelihoods for the classification of uninjured walking, uninjured running, injured walking, and injured running. Three different models were trained, exchanging the varying activation function for either a sine function (SIREN), ReLU, or Exponential Linear Unit (ELU) using a train to test data split of 75% to 25%.

Results

Every model, regardless of activation function, perfectly classified walking versus running of test data. The model with SIREN had the most accurate test classification of uninjured vs injured movement (80%, F1-score = 0.84). The model with only ReLU had similar but slightly weaker performance to SIREN (77%, F1-score = 0.83). Model performance using ELU had a test accuracy of 71% and F1-score of 0.79.

Discussion

Inclusion of periodic nonlinearities in a simple machine learning model may have slightly improve classification of musculoskeletal injury. Despite ELU being similar to ReLU but including negative values, this resulted in a drop in classification accuracy. This work

supports future collection of a dataset which has the intent to support a machine learning model that monitors movement to minimize injury progression.

Development of Posture-Validated HBMs for Reclined Seating Use Cases

Mr. Alex Kalmar-Gonzalo B.S., Mr. Bharath Koya, Dr. F. Scott Gayzik PhD, M.S., B.S.

Wake Forest University School of Medicine, Winston-Salem, NC, United States

Introduction

The use of Human Body Models (HBMs) in the injury biomechanics and automotive regulatory space has gained significant momentum in recent years. Concurrently, alternative seating modes in vehicles are rapidly appearing in market, particularly with respect to reclined seating. While HBMs are typically validated using standard seated and pedestrian postures, there is no study validating initial posture in reclined seated environments. The goal of this study is to leverage published human volunteer data to generate posture-validated node sets for eight HBMs in 45° reclined seating configurations (F05, F50, M50, and M95 in simplified and detailed configurations).

Methods

This study employs the Global Human Body Models Consortium (GHBMC) series. We used regression algorithms published by Reed et al. 2019 [1]. HBM and environmental features such as stature, body weight, erect seating height, seatback angle, and head rest presence were used to calculate postural targets. Anthropometric data from the volunteers who were used to generate GHBMC models were used as inputs. The HBMs were then positioned according to predicted pelvis, lumbar, thorax, neck, head, and hip-eye angles using positioning tools in Oasys Primer (Arup, London UK). A fine-tuning step using Boundary Prescribed Final Geometry cards in LS-Dyna was used as needed to match postural targets within a 5% tolerance. Simulations were conducted using LS-Dyna R.12.2.1 (ANSYS, Cannonsburg, PA).

Results

The eight models were positioned in the 45° reclined posture based on predicted outcomes calculated through regression equations. All angle measurements were within 5% of their predicted measurements.

Discussion

HBMs are customarily delivered in a posture commensurate with a driver seatback angle of 23 degrees from vertical. These models, which are simply node sets describing the posture

change, provide a platform which will ease comparisons across reclined HBM studies using GHBMC models and will obviate the time consuming repositioning step typically required before injury risk analysis can begin. To date, pre-set and validated reclined postures of widely used HBMs have not been available. The presented models can be integrated with publicly available or OEM seats, and require gravity settling and belting for use in crash simulation.

Investigating the Relationship Between Kinematic Brain Injury Metrics and Brain Tissue Strain for a Football Helmet Test Standard

Mr. Alex Sanchez, Dr. Clara Karton, Dr. Thomas Blaine Hoshizaki

University of Ottawa, Ottawa, ON, Canada

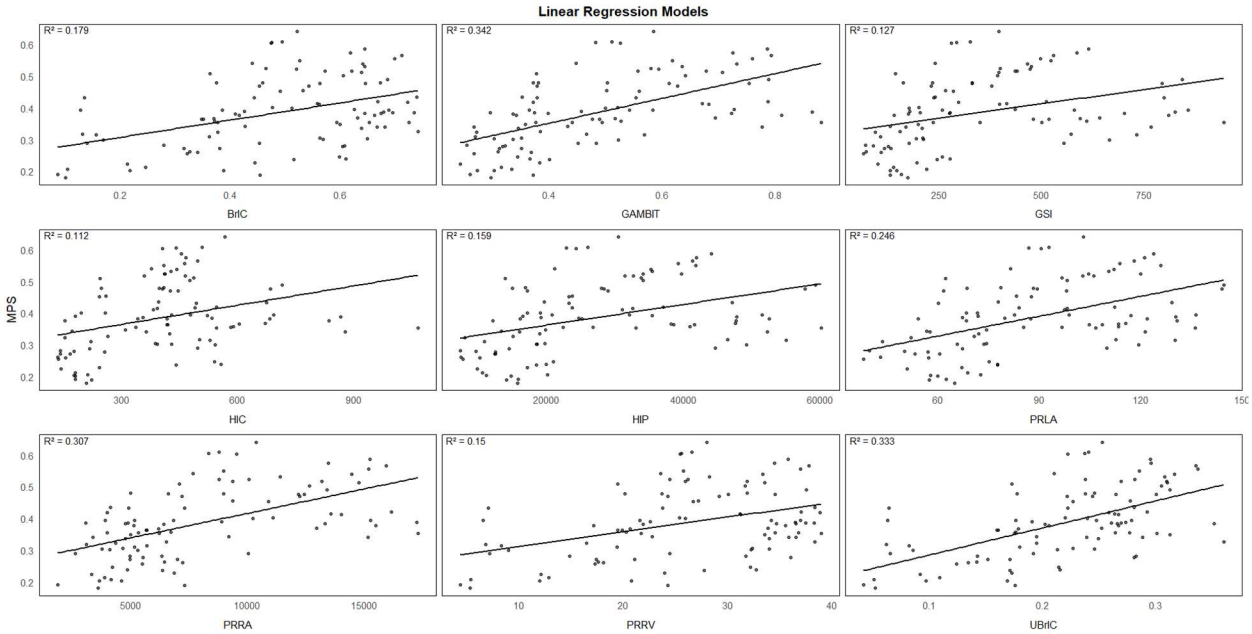
Introduction

Since the institution of helmet performance standards by the National Operating Committee on Standards for Athletic Equipment (NOCSAE), the incidence of traumatic brain injuries has significantly reduced in American football; however, concussions continue to be a common concern. This may in part be due to the limitations of the current helmet performance test metric, the Gadd Severity Index (GSI), to effectively measure concussive injury risk. Maximum principal brain tissue strain (MPS) has been demonstrated as an effective predictor for the risk of concussion; however, the computational time required to calculate MPS makes it unrealistic for helmet standards to incorporate as a performance measure. This research was designed to compare kinematic brain injury metrics obtained from NOCSAE football helmet testing to MPS values. Findings will inform the development of helmet performance criteria for evaluating risk of concussive injury.

Methods

NOCSAE-standard impact testing was conducted on three NOCSAE certified adult football helmet models, totalling 96 impacts. Resultant linear and rotational acceleration time histories of each impact were used to obtain peak kinematic values to calculate six kinematic brain injury metrics. MPS was calculated for each trial using the University College Dublin Brain Trauma Model 2.0. Each peak kinematic variable and injury metric was linearly regressed against MPS, and correlations were determined by each regression model's R^2 value.

Results



GAMBIT revealed the highest correlation with MPS ($R^2 = 0.342$), followed by UBrIC ($R^2 = 0.333$). Peak Resultant Rotational Acceleration (PRRA) demonstrated the highest correlation of all peak kinematic variables ($R^2 = 0.307$). The GSI had the second-lowest correlation ($R^2 = 0.127$), outperforming only HIC ($R^2 = 0.112$).

Discussion

Kinematic brain injury metrics were found to correlate poorly with MPS under NOCSAE-standard impact conditions, suggesting that alternative measurement criteria may be

helpful when evaluating the capacity of football helmets to mitigate the risk of concussive injury. This research contributes to a better understanding of football helmet performance in mitigating the risk for concussive injuries in football.

The Effect of Trochanteric Soft Tissue Thickness on Hip Protector Efficacy during Simulated Lateral Falls: Assessing Impact Force Attenuation using a Hybrid Cadaveric Soft Tissue-Surrogate Pelvis Testing System

Mr Steven Pretty, Ms. Alyssa Tondat, Dr. Andrew Laing

University of Waterloo, Waterloo, ON, Canada

Introduction

Hip protectors are designed to reduce the risk of hip fracture through impact attenuation during a fall; however, their biomechanical efficacy varies widely across products and testing systems/paradigms. A potential limitation of previous test systems is the use of surrogate materials (e.g., foams) of relatively thin thickness to represent the trochanteric soft tissues. Improved biofidelity and inclusion of biological variability in testing systems could enhance clinical guidelines for currently available protectors and inform the development of more effective designs. This study aimed to evaluate the influence of human cadaveric trochanteric soft tissue thickness (TSTT) on the force attenuation provided by hip protectors during simulated lateral-fall impacts.

Methods

Fresh (never frozen or fixed) trochanteric soft tissue samples (15x15 cm; TSTT = 1.0-4.7 cm) were extracted from 12 post-mortem human donors. They were affixed over a surrogate pelvis system, including a composite femur instrumented with a femoral neck load cell. Impact trials (velocity = 2 m/s) were completed with and without a commercial hip protector (HipSaver). Peak force at the femoral neck (F_{Neck}) and force platform ($F_{Surface}$) were extracted. Bivariate Pearson correlations were utilized to assess the influence of TSTT on hip protector effectiveness.

Results

The mean (SD) force attenuation provided by the hip protector was 7.0 (10.3) and 19.4 (14.3)% for $F_{Surface}$ and F_{Neck}, respectively. However, strong negative correlations were observed between force attenuation and TSTT ($r^2 > 0.79$). A 1 cm increase in TSTT was associated with a decrease in $F_{Surface}$ and F_{Neck} attenuation of 9.5 and 13.1%, respectively. Notably, for samples above 4 cm of TSTT, the hip protector provided negligible force attenuation (< 1%).

Discussion

This is the first study to evaluate hip protector efficacy using cadaveric tissues and provides novel insights for test system validations. Mean force attenuation from the tested hip protector is similar to previous research utilizing soft tissue surrogates [1], which supports their use as an alternative to cadaveric testing. However, low-TSTT testing/systems likely overestimate hip protector effectiveness across the target population. The current results highlight the importance of considering TSTT in hip protector interventions and future designs.

Mapping External Garment Pressure to Internal Vascular Loads: A Modular Rig Coupled with 3D–1D Hemodynamic Modelling

Dr Angelo Karunaratne PhD, MEng, CEng, Prof Hari Arora PhD, MEng

Department of Biomedical Engineering, Swansea University, Swansea, Wales, United Kingdom

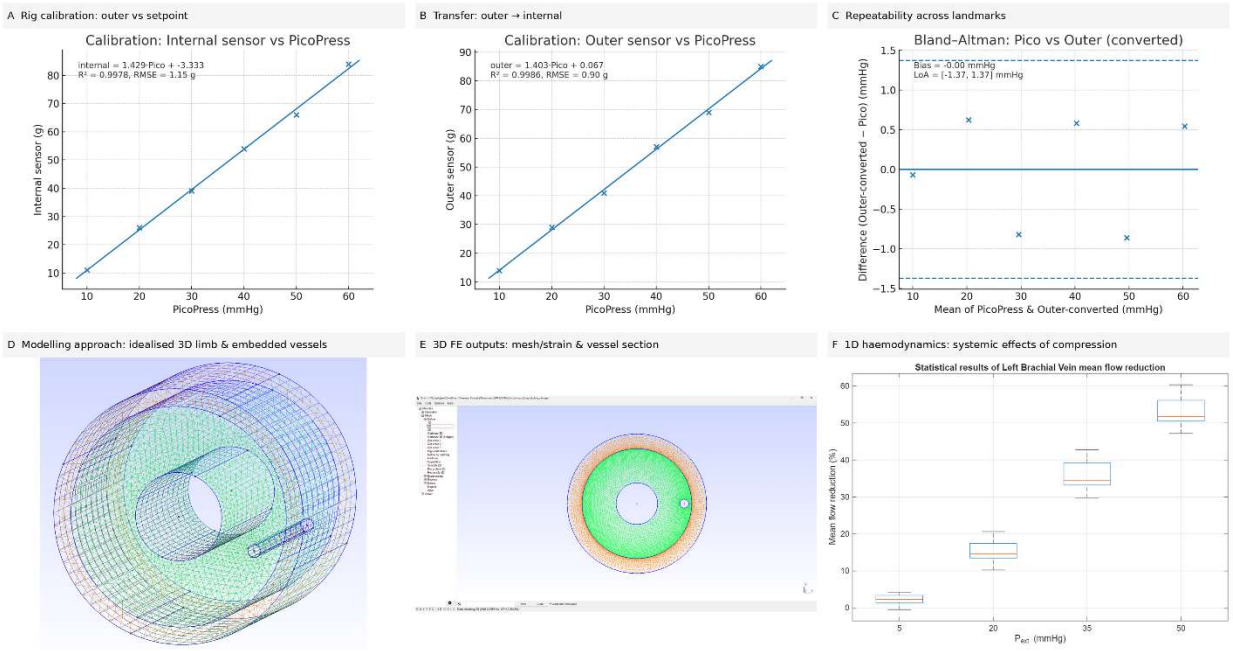
Introduction

Compression garments are widely used across sport and medicine, yet how skin-level pressure translates to internal vascular loads and hemodynamic impact on realistic limb anatomy remains poorly quantified. We aimed to map measured external pressure to vessel transmural pressure, shape change, and flow effects, providing an evidence path for safe, effective use.

Methods

We combined (i) a sensorized anthropometric limb rig to set/read circumferential pressure with PicoPress and estimate outer→internal transfer after a seating/rest protocol; (ii) bench wraps using 30-mm bands taken from commercial garments to confirm repeatability along the limb; and (iii) a modelling pipeline: rig pressures drove a 3D FE limb model (skin/muscle/bone with embedded vessels) to predict transmural pressure and cross-sectional change, which parameterized a 1D cardiovascular model to estimate local resistance and flow under controlled assumptions.

Results



Rig commissioning showed outer pressure closely matched setpoint (±1–2 mmHg) with a predictable internal shortfall (~10–15%), yielding stable boundary conditions. On representative 3D simulations, external compression produced depth- and location-dependent vessel responses: near-surface vessels experienced tens of mmHg transmural loads and ~30–37% area reduction; mid-depth vessels showed smaller shape change. Coupling to 1D flow indicated that such deformations can increase segmental resistance and reduce local flow, with sensitivity to vessel stiffness and surrounding tissue compliance. Together, the measurements and models form a pressure-to-outcome chain linking achievable garment pressures to likely vascular loading and flow consequences.

Discussion

This integrated rig-plus-modelling approach provides traceable, anthropometry-aware guidance for compression use in sport and medical settings. Rather than relying on labeled

“class,” internal loads depend on geometry, tissue properties, and donning, highlighting the need for standardized tests and pressure×time safety envelopes. The framework supports actionable specifications (target mmHg bands and tolerances) and prioritizes user-centered validation. Next steps include parameter sweeps for pattern/material choices, comparison with cuff literature and non-invasive in-vivo surrogates, and extension to dynamic tasks to understand time-varying effects.

Evaluation of a Device for Mitigation of Neck Muscle Fatigue in Fighter Pilots

Dr. Ritwik Rakshit Ph.D.[1], Ms. Kaylie McGuckin[2], Dr. Lucy Fitzgerald Ph.D.[3], Mr. Brandon Sheely B.S.[3], Dr. Kelley Virgilio Ph.D.[3], Dr. Anita Vasavada Ph.D.[1]

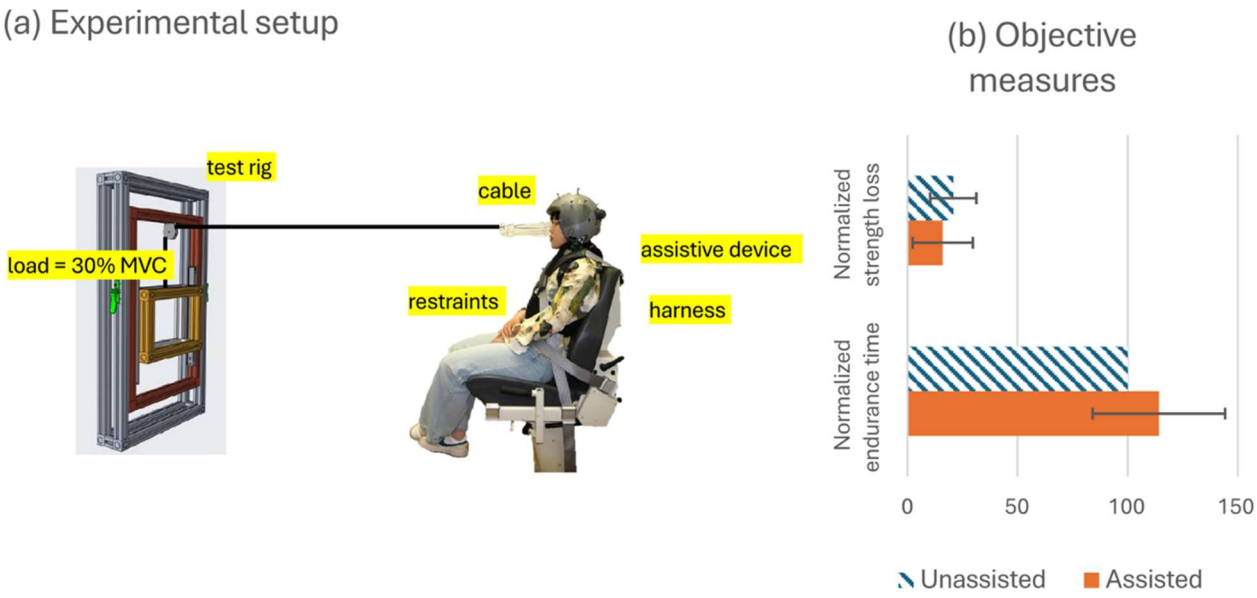
[1]Washington State University, Pullman, WA, United States. [2]University of Rochester, Rochester, NY, United States. [3]Luna Labs, Charlottesville, VA, United States

Introduction

Neck pain is a significant problem in military pilots. Luna Labs has developed a cervical spine protection device to decrease fatigue in neck muscles. We hypothesized that with the device, participants will experience less neck muscle fatigue during an endurance task.

Methods

15 participants (8 F, 7 M; age 18-35) visited the lab twice, 7-11 days apart. Subjective ratings of fatigue and neck extension strength were collected before and after an endurance test which consisted of supporting an extension load of 30% of maximum until exhaustion (Figure 1a). Muscle activity (EMG) was measured with surface electrodes in eight neck muscles. At one visit (randomized), the device applied a tensile force between a helmet and a harness on the torso (assistance condition). Paired t-tests or Wilcoxon signed rank tests were used to compare outcome measures (subjective ratings, endurance time, decrease in extension strength and changes in EMG amplitude and median frequency) with and without assistance.



Results

Participants exhibited fatigue during both assisted and unassisted conditions as evidenced by a decrease in maximum neck extension strength, increase in EMG amplitude and decrease in EMG median frequency. Normalized endurance time was 14% longer in the assisted condition ($p=0.045$; Figure 1b). With assistance, participants' maximum neck extension strength decreased less than without assistance (16% vs. 21%; $p=0.046$). However, subjective ratings of fatigue and the rate of EMG amplitude increase were not significantly different between conditions. The rate of EMG median frequency decrease between conditions was only significant for one muscle (left splenius capitis; $p=0.035$).

Discussion

The cervical spine protection device acts as an exotendon between a pilot helmet and harness on the torso, and it is expected that participants should require less neck muscle force to hold up the same load. With the device, participants exhibited objective differences in endurance time and loss of strength, but no significant differences in subjective measures of fatigue. EMG measures demonstrated evidence of muscle fatigue, but there was no significant effect of assistance. Helmet fit and participant motivation likely also played a role in device performance and endurance time.

Timing and Dominant Components of Peak Linear and Angular Head Accelerations in Low-Speed Rear End Collisions: A Study of Human Responses

Author Avery Scurlock[1,2], Co-Author Patrick Fischer[1], Co-Author John Abercrombie[1], Co-Author Richard Watson[1]

[1]Biodynamic Research Corporation (BRC), San Antonio, TX, United States. [2]University of Texas at San Antonio (UTSA), San Antonio, TX, United States

Introduction

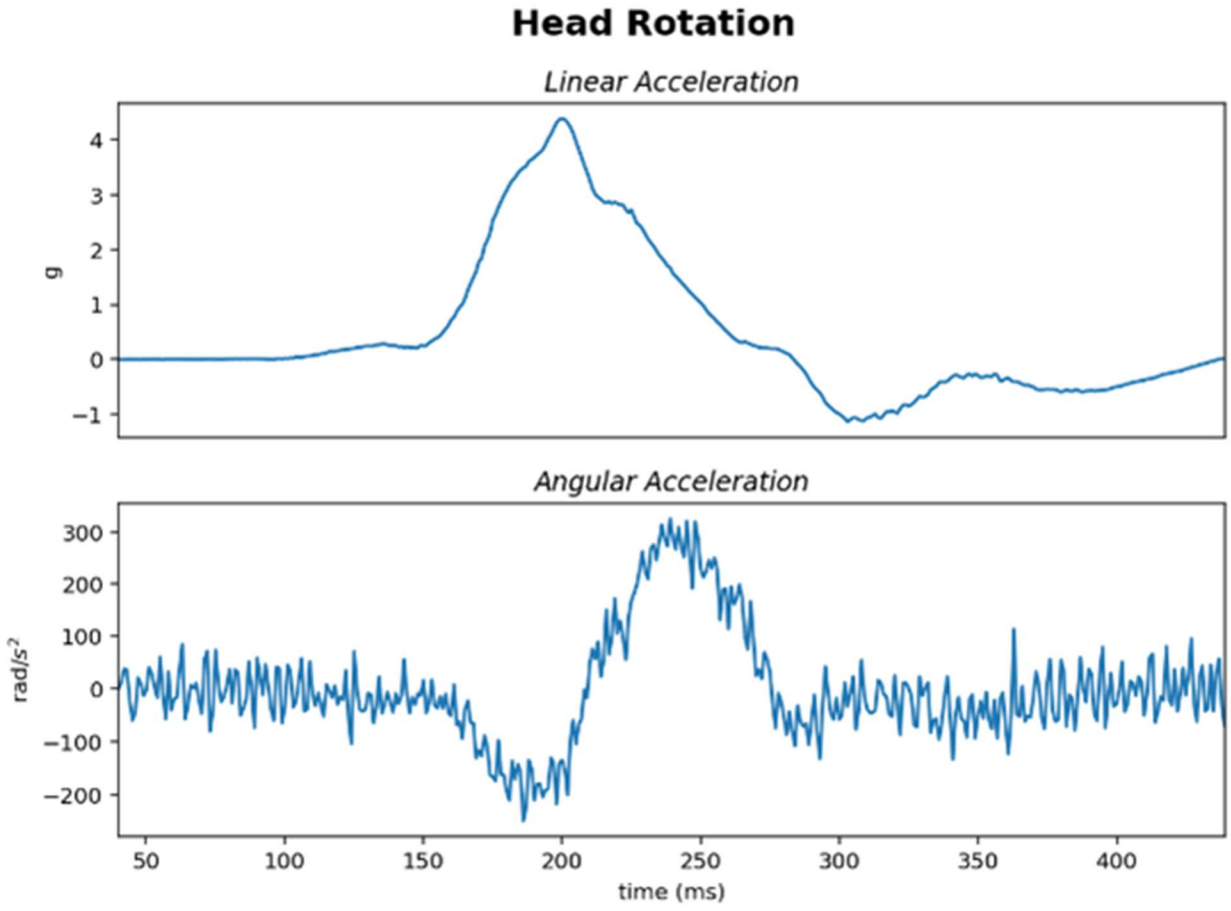
The Biofidelic Rear Impact Dummy (BioRID) is designed to replicate the human response during low-speed rear end collisions (LSRC). However, its design limits frontal and transverse head motion. Additionally, the BioRID may not appropriately capture energy dissipation achieved through selective neck muscle activation when the occupant rebounds into the seatbelt. This study addresses these limitations by analyzing LSRC with human test subjects to better assess the timing and predominant components of head acceleration as they relate to mild traumatic brain injury (mTBI).

Methods

Eleven instrumented LSRC were conducted. During a crash test, a human subject using a lap-and-shoulder belt was seated in a vehicle which was impacted from the rear, causing a back-to-front acceleration. Angular head accelerations were derived from angular velocity measures (**Figure 1**). Linear head accelerations were measured directly.

Results

For peak vehicle acceleration of 3.8±1.0g, peak linear head accelerations were 6.0±2.2g (range: 2.4-10.1). Linear accelerations peaked during the head contact phase with the headrest. Sagittal accelerations were predominant (96.3±4.2% of resultant). Compared to published tolerances, linear head accelerations in rear-end crash tests represented mTBI risk between 0.005%-0.006%.



Peak angular head accelerations were 249.1±124.7rad/s^2 (range: 90.0-407.2). Angular acceleration peaked ~50ms after peak linear head acceleration. Sagittal angular head accelerations were predominant (98.4±1.0% of resultant). Compared to published tolerances, angular head accelerations in rear-end crash tests represented mTBI risk between 0.004%-0.005%.

Combined effects of linear and angular acceleration represented mTBI risk between 0.004%-0.008%.

Discussion

This study suggests angular and linear accelerations are coupled in LSRC. Linear acceleration peaked during headrest contact, and angular acceleration peaked ~50ms after. As expected, back-to-front and sagittal components predominated the linear and rotational head accelerations, respectively, indicating a primarily sagittal response pattern. The belt-loading phase did not result in a second peak in head acceleration. The human response to LSRC involves gradual deceleration of head motion through selective muscle activation, minimizing inertial loading. Capturing the full sagittal response, including the rebound phase, provided a complete characterization of timing and signal behavior, thereby addressing prior uncertainties in BioRID analysis and confirming the LSRC rebound phase does not represent appreciable inertial loading in humans.

Mesh Convergence Depends on Element Formulation for Finite Element Brain Models

Ms. Azilis Even, Dr. Zhou Zhou, Prof. Svein Kleiven

Division of Neuronic Engineering, KTH Royal Institute of Technology, Stockholm, Stockholms län, Sweden

Ms. Azilis Even

Dr. Zhou Zhou

Introduction

Finite element head models are virtual tools to study brain biomechanics, but one prerequisite before usage is for these numerical surrogates to have a convergent behavior. Previous convergence studies focused on the influence of mesh size, but the potential compounding effect of element formulation was often ignored with the exception of a few studies [1]. This study aimed to evaluate the influence of element formulation on the mesh convergence responses of a finite element head model.

Methods

The base model for this study was the KTH Head model, with brain mesh size as 6.4 ± 1.9 mm [2]. We modified the mesh in the original model to generate three derivatives, all of which have the same mesh topology but different element sizes (Fig 1a), i.e., a coarse model (mesh size: 12 ± 4.0 mm), a medium model (mesh size: 3.2 ± 0.97 mm), and a fine model (mesh size: 1.6 ± 0.48 mm). Three commonly used element formulations (i.e., constant stress solid, selectively reduced (S/R) integration and fully integrated elements) were implemented to the brain elements in these four models. An experimental rotational loading profile (angular velocity peak: 40 rad/s, duration: 30 ms) along three anatomical directions was imposed to all models [3]. The 95^{th} percentile maximum principal stress (MPS) over the entire brain was analyzed and compared across the different cases.

Results

Regardless of rotational direction, selectively reduced integration yielded the best convergence results (Fig 1b), with less than a 25% difference at each refinement step, and less than a 5% difference between the original and medium meshes. In contrast, the constant stress solid and fully integrated element meshes did not converge when applying a mesh convergence criterion of less than a 5% difference in output between the medium and fine meshes.

Discussion

This study shows that the mesh convergence behavior of finite element brain models is affected by the choice of element formulation. Selectively reduced integration contributes to a faster mesh convergence behavior.

Effects of Cues to Walk Softly and Quietly on Gait Mechanics During Load Carriage

Dr. Caleb Johnson FACSM, Mr. David Zeppetelli, Mr. Cole Dempsey, Mr. Lucas Sarantos

U.S. Army Research Institute of Environmental Medicine, Natick, MA, United States

Introduction

Walking with load carriage is a common military activity, that also leads to high rates of musculoskeletal injury. Gait alteration cues to run softly/quietly have been shown to reduce external forces related to injury in runners. However, the effects of these cues have yet to be explored for walking with load carriage.

Methods

38 participants completed testing on an instrumented treadmill, while kinematics were tracked via optical motion capture. Participants first completed a habitual load carriage trial (HAB), at a self-selected pace (1.21 ± 0.11 m/s) and while carrying an 18kg weighted vest. They were given a 5-min warm-up followed by data collection. Participants were then cued to modify their gait by walking "quietly and softly" (SOF). They were given one minute for accommodation, followed by data collection. Outcome variables were averaged over 20 strides for the right leg, including: double-stance time, stride length, peaks and loading rates for vertical/posterior forces, peaks/excursion for sagittal/frontal plane hip/knee angles and moments (peaks only). Variables were selected based on their relevance for changes in gait or potential increases in injury risk with load carriage. Paired t-tests or Wilcoxon signed-rank tests were used to compare gait conditions.

Results

Full results are reported in the Table. The largest changes ($d > 0.8$) in gait in SOF were decreased 2nd peak vertical forces and increased peak hip and knee flexion angles and knee extension moments. Peak frontal plane moments were also consistently lower in SOF, for the hip and knee, although the effect sizes ranged from small to moderate.

Discussion

These results show significant changes in load carriage gait mechanics with cues to walk softly/quietly. While decreases in peak vertical forces and frontal plane moments may be associated with reduced injury risk, we also found an increase in peak sagittal plane angles corresponding to increased sagittal peak moments. Future research should focus on the implications of this trade-off in external forces, e.g. translation to tissue strain/stress, to better understand the real implications for injury risk.

Recovery of the lumbar intervertebral disc revealed by coupled mechanical testing and high-contrast soft tissue cryogenic microCT

Dr. Elizabeth Dimbath PhD[1], Mr. Blake Robertson BS[1], Ms Nicole Turpin BS[1], Mr Jason Kait MS[1], Ms Angela Abraham MS[2], Ms Anna Grunkemeyer BS[2], Dr. Laura Dalton PhD[1], Dr. Jason Luck PhD[1], Dr. Cameron Bass PhD[2]

[1]Duke University, Durham, NC, United States. [2]Wayne State University, Detroit, MI, United States

Introduction

Low back pain (LBP) is associated with intervertebral disc (IVD) hydration through avascular diffusion, remaining a leading cause of disability worldwide. Common occupational/military tasks involve poorly characterized repetitive combined spinal loading. Understanding how loading influences IVD recovery is crucial in identifying factors that influence fluid-flow/spinal pathophysiology. This study combines mechanical and imaging approaches to link IVD recovery after loading with three-dimensional structural changes, elucidating early contributors to LBP.

Methods

Occupationally relevant cyclic flexion-compression was applied to porcine FSUs at peak compressive stresses of 1-3 MPa and durations of 0.5-9 hours, followed by an unloaded recovery phase (load-controlled). Specimens were imaged with high-contrast cryogenic X-ray microCT. Six baseline specimens were tested at 1 MPa peak compressive stress for 1 hour to assess recovery at low loads. Three specimens not frozen and were used to assess freezing effects. Disc height recovery was measured using displacement-time data, and nucleus pulposus (NP) volume change was measured from semi-automated segmentation of scans obtained before loading, post-loading, and post-recovery. Peak compressive stress and loading duration were evaluated as statistical factors in IVD recovery.

Results

Mean disc height recovered to 100±30% in the imaged baseline specimens compared with 89±14% for the baseline specimens not exposed to cryogenic imaging (not significantly different). Recovery from displacement measurements (0.59±0.12 mm) matched changes in height measured from the microCT (0.54±0.19 mm). Regression analyses revealed that stress magnitude, but not duration, significantly influenced both NP volume change and overall height recovery. NP volume exhibited a nonlinear dependence on stress magnitude, indicating permeability-limited fluid transport, while height recovery followed a more linear

decline with increasing stress. MicroCT imaging also revealed previously unreported localized endplate compaction at higher loads, suggesting low-level microstructural changes that may restrict rehydration.

Discussion

This study demonstrated high rates of recovery *in vitro* following cyclic combined loading. Findings demonstrate that IVD recovery under cyclic combined loading is primarily governed by stress magnitude rather than duration, with higher stresses reducing both recovery fluid reabsorption and mechanical recovery. From a translational standpoint, understanding recovery is critical to identifying early mechanical dysfunction that may precede structural degeneration.

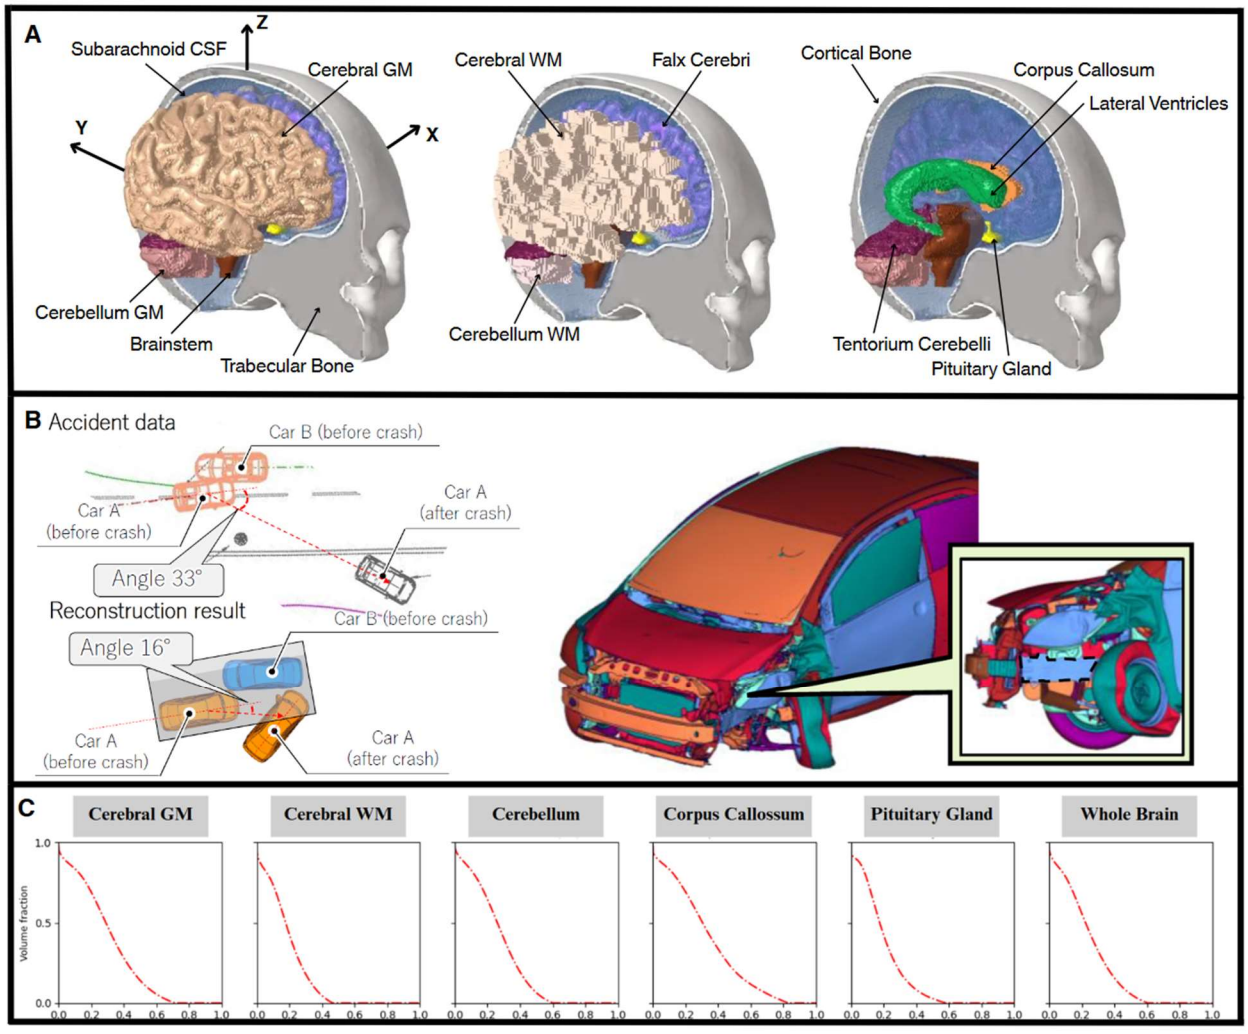
[4]ID+ - Research Institute for Design, Media and Culture, University of Aveiro, Aveiro, Aveiro, Portugal

Introduction

Epidemiological studies have reported a higher incidence of concussion in female athletes compared with males in sports where the two sexes compete against each other [1,2], and sex-dependent differences in both acute and long-term recovery have been observed [3]. This underscores the necessity for anatomically accurate, validated finite element head models (FEHMs) to comprehend brain biomechanics in real-world impacts. The present study proposes the validation and application of a detailed female FEHM (FeFEHM) [4] using cadaveric impact data and kinematic inputs from automotive crash reconstructions and female youth soccer players.

Methods

The improved FeFEHM includes a cortical–trabecular skull, dura mater, falx cerebri, tentorium cerebelli and ventricles. Brain tissues were assigned viscohyperelastic properties from experimental data. Validation used intracranial pressure measurements from the Nahum et al. cadaver impacts [5], comparing pressure–time histories at frontal, parietal, occipital and posterior fossa sites. Real-world loadings consisted of THUMS-based BASt automotive reconstructions and triaxial head accelerations recorded from youth female soccer players using Triax sensors. All loadings were applied at the head centre of gravity. Output measures included maximum principal strain (MPS), intracranial pressure and cumulative strain damage measure (CSDM).



Results

The FeFEHM reproduced the principal features of the Nahum curves, with CORA scores ranging from 0.452 to 0.889. BASt loadings produced the greatest deformation (whole-brain strain 0.37–0.53). Soccer headings generated lower responses but consistent regional patterns: cerebral GM and WM dominated volume fractions, whereas the corpus callosum and pituitary gland showed localized peaks. Peak MPS (95th percentile) ranged from 0.25 to 0.35.

Discussion

Automotive impacts produced the largest global deformation, aligning with expected crash biomechanics. Soccer impacts, although lower in magnitude, revealed regional strain distributions and sensivity. These findings demonstrate that the FeFEHM captures both severe and sub-concussive loading patterns, supporting its use in evaluating female-specific brain injury mechanisms across diverse real-world scenarios.

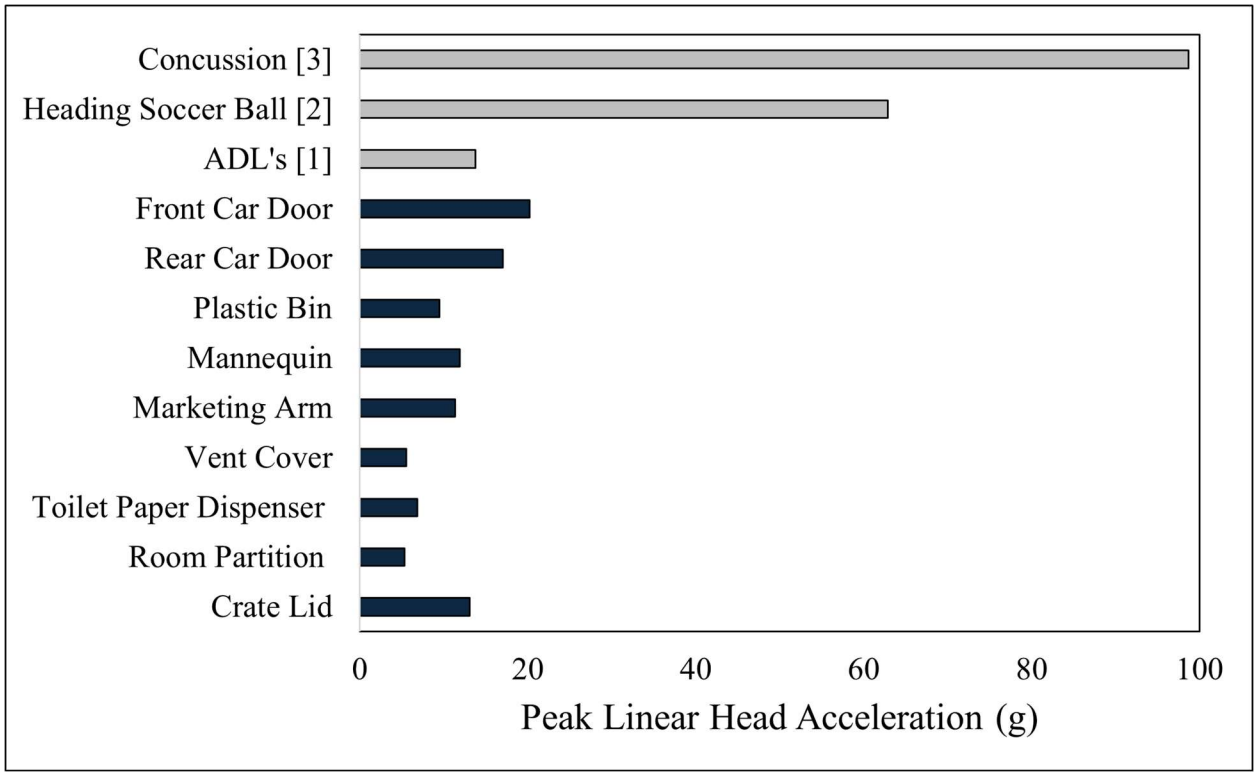
Introduction

Acceleration-based head injury metrics derived from anthropomorphic test devices (ATDs), human volunteers, and cadavers in a variety of loading events constitute a valuable source of data for understanding the biomechanical responses of the head during impact events and the associated risk of injury. This study expands the empirical literature (containing primarily controlled motor-vehicle or sports-related loading scenarios) by characterizing head-impact loading documented in forensic investigations of real-world injury claims, thereby widening the context in which head-injury biomechanics are evaluated.

Methods

In this study, the Hybrid III headform (the most widely used ATD worldwide) was instrumented with a triaxial accelerometer positioned near the estimated head center of gravity to quantify linear head acceleration. Nine head-impact scenarios derived from real-world forensic injury claims involving reported concussions were reconstructed experimentally. Acceleration data were sampled 1,250 Hz and retained in their unfiltered form for analysis.

Results



A total of 116 trials were performed across the nine reconstructed scenarios. Impacts involved a diverse set of objects striking the head, including a crate lid, a movable room partition, a toilet paper dispenser lid, a vent cover, a marketing arm (sign), a mannequin torso, an empty plastic bin, as well as a rear and front car closing door. Object drop heights or impact distances varied by scenario, ranging from 0.05 to 0.96 m, producing peak resultant head accelerations between 1.9 and 21.3 g.

Discussion

The accelerations observed in the reconstructed scenarios align closely with peak head accelerations experienced in activities of daily living (ADLs [1]) or associated with impacts from heading a soccer ball in girls youth soccer ([2]) and fall well below the linear head acceleration associated with concussion ([3]). The average peak resultant acceleration from each scenario is presented (Figure 1).

By synthesizing this data, this study provides a practical biomechanical reference for forensic investigations of reported head injuries. These findings underscore the importance of quantifying head impact magnitude when assessing the biomechanical plausibility of concussion within a forensic engineering context.

Head Kinematics and Pathology in a Large Animal Model of Non-Penetrating Head Impact

Mr. Charlie Magarey[1], A/Prof. John Finnie[1], Mr. Jim Manavis[1], Prof. Peter Blumbergs[1], Prof. Peter Cripton[2], A/Prof. Claire Jones[1]

[1]Adelaide University, Adelaide, South Australia, Australia. [2]The University of British Columbia, Vancouver, British Columbia, Canada

Introduction

Large animal models with well characterised head kinematics and pathology can help elucidate relationships between traumatic brain injury (TBI) mechanics and pathophysiology. Clinically, most TBIs result from head impact without skull penetration, but there is a lack of large animal models that simulate this injury mechanism. The aim of this study was to characterise pathology and head kinematics in a sheep model of closed head impact-induced head rotation, across several impact energies.

Methods

Fourteen anaesthetised sheep were instrumented with a skull mounted kinematics sensor array, and their head fixed to a planar constraint apparatus via a bite plate, limiting head motion to the sagittal plane (Fig. 1A). The frontal bone region was impacted, via an interface plate, at one of three energy levels (180 J n=6; 280 J n=2; 350 J n=6) resulting in approximately 110° of flexion rotation about the second cervical vertebra (Fig. 1B). Three animals were controls. Gross neuropathology was assessed via haematoxylin and eosin histology, and axonal and neuronal pathology were assessed via amyloid precursor protein (APP) immunohistochemistry, at 6h post injury. Linear mixed effects models were developed to assess associations between axonal/neuronal pathology scores and either experimental group or peak kinematics measures.

Results

In 2/6 animals, 350 J head impact caused penetrating skull fracture with contusion, laceration, haemorrhage, neuronal injury and diffuse axonal injury (DAI). Contusion, subarachnoid haemorrhage, and focal axonal injury were observed in the 350 J non-penetrating group, but not for lower energy impacts. Neuronal APP expression was elevated in all groups, compared to Control, and was positively associated with head peak angular

velocity (Fig 1D, E). Axonal APP expression was not higher than Control for any non-penetrating injury groups (Fig 1C) and was not associated with peak head kinematics.

Discussion

Widespread neuronal reaction, but not DAI, was observed for non-penetrating head impacts at three energy levels. In some animals, a 350 J impact resulted in penetrating skull fracture and severe TBI. Future studies with this model may explore additional markers of pathology, and the effects of increased post-injury survival time and repeated impacts on the pathological outcomes.

The effect of size on the male hand and forearm injury tolerance when subjected to loading representative of behind-shield blunt trauma

Dr. Julia de Lange Ph.D., P.Eng.[1,2,3], Mr. Liam Burrows M.A.Sc.[2], Dr. Cheryl Quenneville Ph.D., P.Eng.[2]

[1]30 Forensic Engineering, Toronto, Ontario, Canada. [2]McMaster University, Hamilton, Ontario, Canada. [3]University of Guelph, Guelph, Ontario, Canada

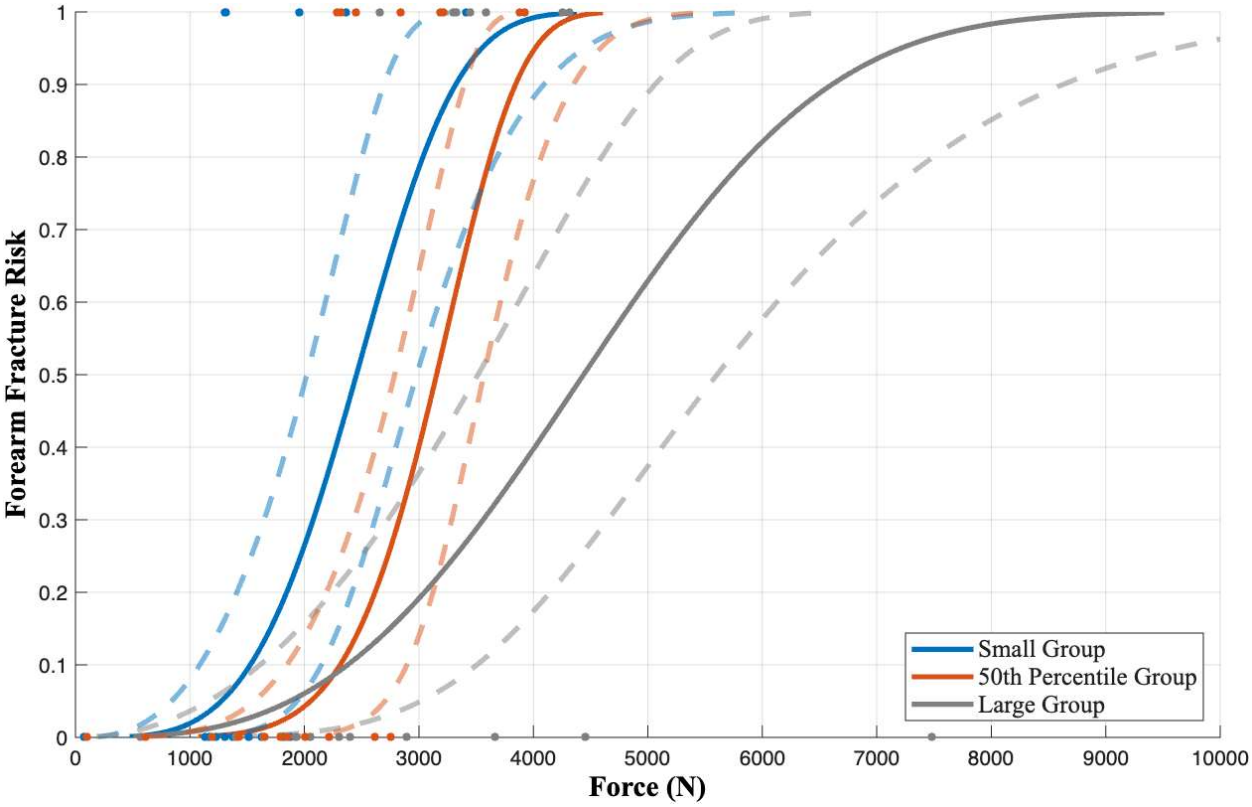
Introduction

Behind-shield blunt trauma (BSBT) is an injury mechanism associated with the deformation of a ballistic shield's back face into the user from a ballistic impact. The proximity of the arm to the back of the shield can lead to localized blunt trauma, resulting in different injury mechanisms and thresholds than automotive loading conditions, as demonstrated on 50th percentile male post-mortem human subjects (PMHS) [1]. While the military population has been primarily male dominated, there has been increasing participation of a wider range of demographics, as well as an overall growth in anthropometric measures within the population. This means injury metrics developed for traditional 50th percentile male size (78 kg, 1.75 m) may not protect all users of ballistic shields.

Methods

High-rate (14 m/s), short-duration (< 5 ms) impacts associated with BSBT were applied to two locations on both small (< 15th percentile by height and weight) and large (> 75th percentile by height and weight) PMHS cohorts (N = 8 each) to assess injury tolerance. The hand and forearm were selected as vulnerable locations based on their proximity to the shield and their independence of joint orientation. Specimens were impacted at increasing energy levels until fracture occurred, confirmed by x-ray imaging, and efforts to minimize the number of impacts on each specimen were taken.

Results



Upon inspection of collected specimen vBMD, one specimen in the small cohort was found to be osteoporotic; as such, was excluded from further analysis. At the hand, fractures were generated at forces of 3,072 ± 1,384 N in the small cohort, and 3,637 ± 774 N in the large cohort. Comparatively, forces of 2,267 ± 827 N and 3,647 ± 445 N were required to cause forearm fractures in the small and large cohorts, respectively. The

fracture threshold was significantly lower for the small group as compared to the large for the forearm ($p < 0.01$) but not the hand.

Discussion

The injury risk curves generated from these data varied among size groups (Figure 1), underscoring the importance of considering anthropometric size when developing and testing protective equipment for all.

Increased Age, Head on Collisions and Facial Impact Location Influence Head Injury in 353 RAIDS Motorcyclists in 2013-2025 Road Accident In-Depth Studies Data

Dr Claire Baker, Dr Mazdak Ghajari, Professor David Sharp

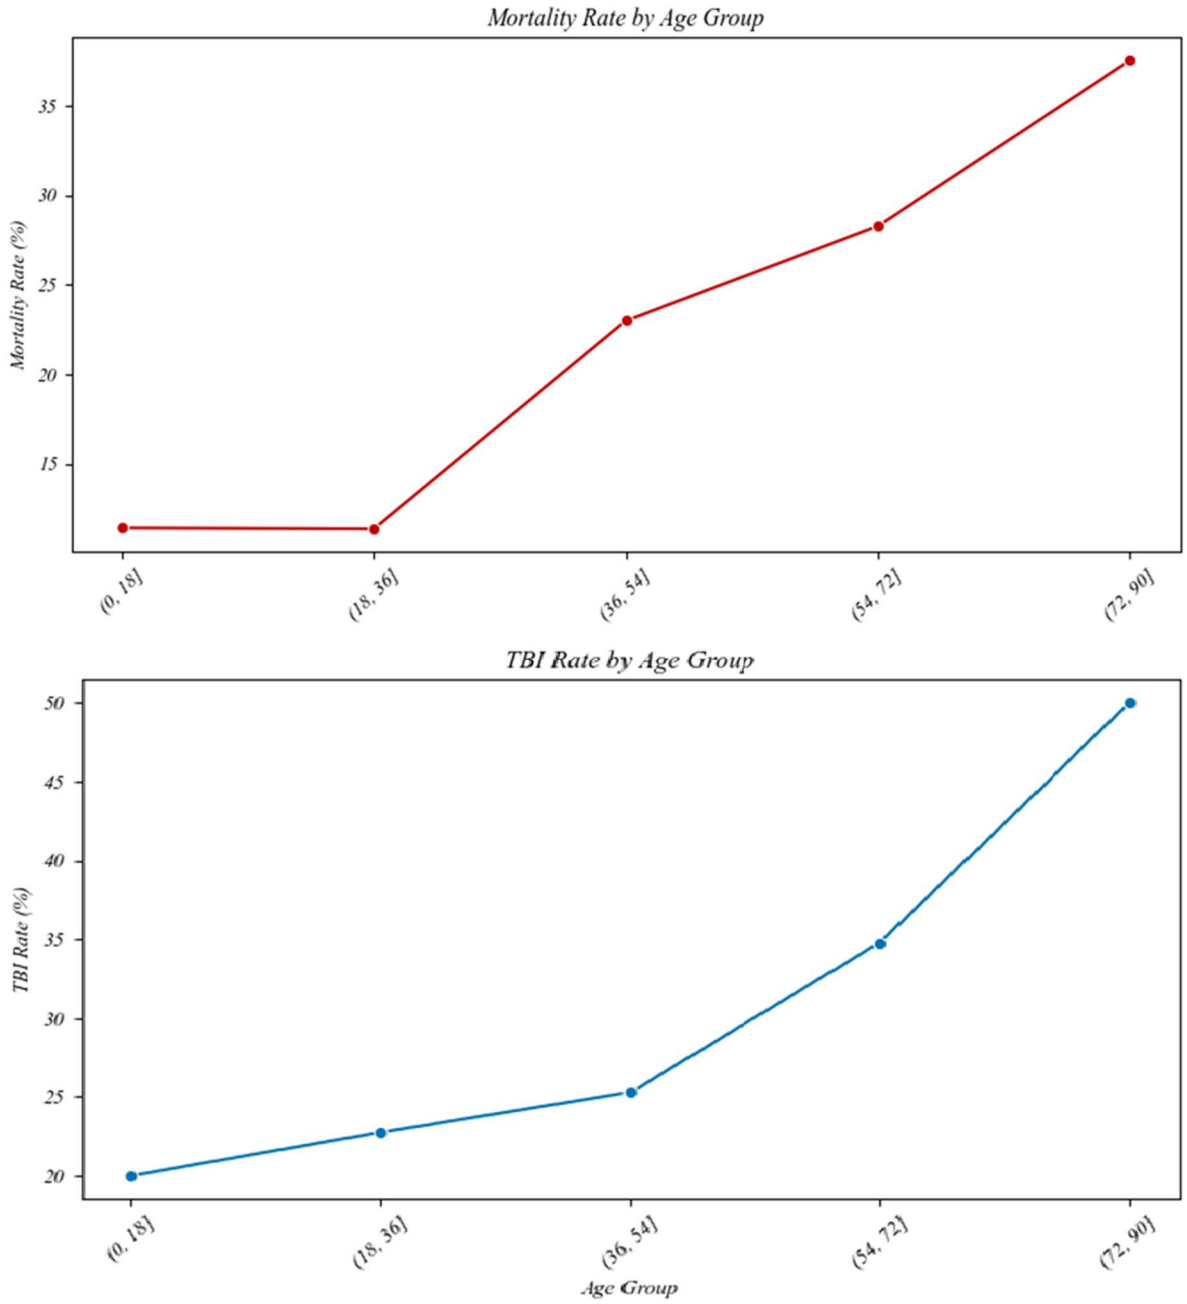
Imperial College London, London, Greater London, United Kingdom

Introduction

Motorcyclists and other powered two-and three-wheeler (PTW) riders make up over 30% of the 1.19 million annual road traffic deaths globally [1]. Despite being among the most vulnerable road users (VRUs), the popularity of PTWs is rising, with the number nearly tripling in the decade to 2021. Helmet use has shown reducing serious head and neck injury as well as fatality [1]. Despite this, brain injury remains a prevalent challenge, with a high association between traumatic brain injury (TBI) and the severest outcomes.

Methods

We analysed 353 motorcycle collisions over 12 years from Great Britain's Road Accident In-Depth Studies (RAIDS) collision database (April 2013 – March 2025). Injuries were classified using the abbreviated injury scale and free-text as previously summarized [2]. Interactions between speeds, collision configurations and ages (under 55yrs and 55+yrs) were analysed with Chi-squared (X^2) and Mann-Whitney (U_{MW}) statistics.



Results

Most (93.5%) of riders were injured (17% fatally injured) and a third (32.6%) sustained a head injury. Only 2% of riders did not wear a helmet. Half (50.4%) of damage-confirmed head impacts were to the facial region, with more impacts to the upper face and chinbar compared to the visor. One third of motorcyclists sustained one or more types of head injuries, 23.6% sustained a Mayo-classified TBI (16.9% moderate-severe). Age (Figure 1) significantly influenced both mortality (<55yrs versus 55+yrs: $p=0.008$, $X^2=6.95$) and TBI outcomes (<55yrs versus 55+yrs: $p=0.003$, $X^2=4.61$). Mortality ($U_{MW}=9364.0$, $p<0.000001$) and TBI ($U_{MW}=11587.0$, $p<0.000001$) occurred at higher travel speeds. Head on collisions were responsible for a significantly higher prevalence of TBI ($p=0.005$, $X^2=7.88$) and moderate-severe TBI ($p=0.006$, $X^2=7.53$), while loss of control on straight roads had reduced TBI prevalence ($p=0.023$, $X^2=5.14$).

Discussion

We present a large, contemporary study detailing motorcycle collision configurations, speeds and head impact locations and their associated TBI outcomes. Our results highlight that despite improvements in head injury rates since COST327, collision configuration and facial impact location influence outcomes. Our results identify outcome inequality in age and support ongoing data analysis to support better infrastructure and protective equipment design and testing.

Pathology and Head Kinematics in a Large Animal Model of Closed Head Trauma With and Without Head Impact

Mr. Charlie Magarey[1], A/Prof. John Finnie[1], Mr. Jim Manavis[1], Prof. Peter Blumbergs[1], Prof. Peter Cripton[2], A/Prof. Claire Jones[1]

[1]Adelaide University, Adelaide, South Australia, Australia. [2]The University of British Columbia, Vancouver, British Columbia, Canada

Introduction

Understanding relationships between traumatic brain injury (TBI) mechanics and pathology can drive design and evaluation of protective equipment and safety features, and help identify opportunities for clinical intervention. Head impact is known to cause focal pathologies in closed head TBI; however, the contribution of cranial impact to diffuse pathologies caused by rapid rotation of the head and brain, is not understood. The aim of this study was to compare head kinematics and pathology outcomes in a sheep model that induces rapid head rotation with and without head impact, with the same energy input.

Methods

Ten anaesthetised sheep were attached to a planar constraint via a bite plate. Rapid sagittal head rotation (~110°) was induced via impact to the frontal skull via an interface plate (head-impact, HI; n=4; Fig. 1A), or impact of the planar constraint apparatus (offset-impact, OI; n=6; Fig. 1B); three animals were controls. Impact energy in both configurations was nominally 350J. Head kinematics were measured with a skull mounted sensor array. Gross neuropathology was assessed via haematoxylin and eosin histology, and axonal and neuronal pathology were assessed via amyloid precursor protein immunohistochemistry, at 6h post injury. Associations between experimental group and axonal/neuronal pathology were assessed with linear mixed effects models.

Results

HI, but not OI, animals experienced an initial high magnitude, ~2ms duration, angular acceleration peak due to skull deformation; following this, resultant angular velocity traces were similar for both groups (Fig. 1C-D). Contusion and subarachnoid haemorrhage were observed in HI animals; no focal pathology was observed in OI animals. Axonal injury in the brain hemispheres was higher in HI animals than OI animals (Fig. 1E), due to focal axonal

injury adjacent to contusion sites. Neuronal pathology was increased compared to Control in both injury groups and qualitatively was higher for HI animals (Fig. 1F).

Discussion

Focal pathologies observed in HI animals were likely caused by local skull deformation. Diffuse neuronal pathology was apparently higher in HI animals, suggesting skull impact effects may have contributed. The neuronal APP expression likely represented a transient stress response. Further investigation of additional injury markers may elucidate relationships between diffuse pathologies and impact effects.

Characterizing Head Acceleration Events in Stock Car Auto Racing by Kinematic-Derived Principal Direction of Force (PDOF)

Mr. Cole Smith MS[1,2], Ms. Zoie Mink[1,2], Dr. Nicholas Pritchard PhD[1,2], Dr. Garrett Bullock PhD[1], Mr. Matthew Harper PE[3,1,2], Dr. Jillian Urban MPH, PhD[1,2], Dr. John Patalak PhD, PE[3], Dr. Joel Stitzel PhD[1,2]

[1]Wake Forest University School of Medicine, Winston Salem, NC, United States. [2]Virginia Tech - Wake Forest University School of Biomedical Engineering and Sciences, Winston Salem, NC, United States. [3]National Association for Stock Car Auto Racing, LLC, Daytona Beach, FL, United States

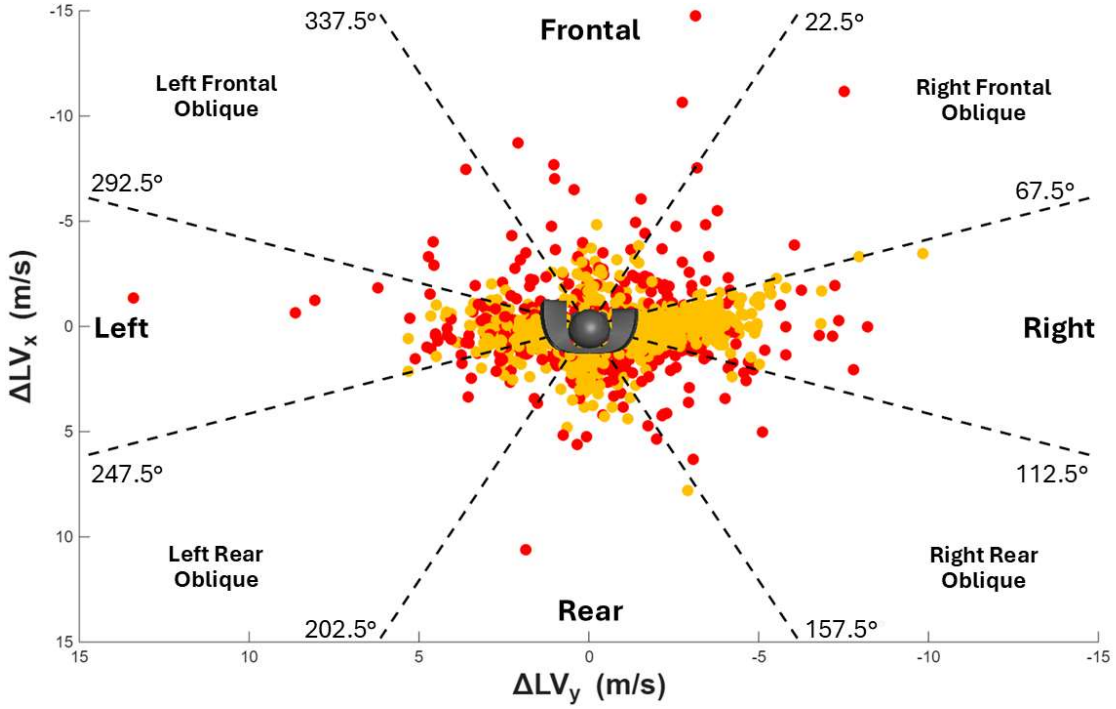
Introduction

Stock car auto drivers are exposed to non-concussive head acceleration events (HAEs) during active racing maneuvers or crashes, which may present a risk to brain health and function [1]. Research using principal direction of force (PDOF) derived from chassis data has found that right lateral vehicle impacts yielded lower driver injury risks [2]. This approach has not been applied to head acceleration data. The objective of this study was to characterize HAEs by PDOF using head kinematics measured with an instrumented mouthpiece system.

Methods

Head kinematic data was collected from 20 NASCAR Cup Series drivers during 41 races in the 2024 season using instrumented mouthpiece sensors (1600Hz, 4g threshold). Events were classified as race or crash events (i.e. a driver's vehicle interacted with an external object, resulting in a caution) and visually verified. Events with multiple impacts were separated into individual HAEs. Resultant linear acceleration was calculated in the transverse plane and HAE start/end times were approximated using thresholds of 5g (if peak >10g) or 2.5g (if peak ≤10g). Linear velocity was calculated by integrating acceleration data and the angle of velocity change assigned each HAE to a PDOF (Figure 1). Peak linear/rotational accelerations and velocities, ΔLV, and DAMAGE were calculated per HAE.

Results



3,156 events resulted in 5,198 HAEs. Events not exceeding 4g in the transverse plane (n = 720) were excluded yielding 4,478 HAEs (3,818 race; 85%, 660 crash; 15%) for analysis. Drivers experienced 2,476 right-side impacts, accounting for 55.3% of all HAEs. Median

ΔLV was greatest in right frontal oblique impacts for crashes (2.7 m/s) and frontal impacts for race events (1.5 m/s).

Discussion

This study characterized HAEs by PDOF during NASCAR Cup Series races. The PDOFs with maximum head loading differed between event types, with frontal and left-side events producing the largest ΔLVs for crashes and right-side events for races. Results can inform driver safety research and regulations in stock car racing. Future work should compare head kinematics-derived PDOF with vehicle chassis PDOF during crashes.

Comparison of Positive and Negative Mold Scanning Techniques for the Assessment of Back Face Deformation in Armor

Mr. Cristian Pampu[1], Ms. Katarzyna Ochocki B.S.[1], Mr. Donald Sherman M.S.[1], Mr. Andrew Davis MPH[1], Dr. Karin Rafaels Ph.D[2], Dr. Cynthia Bir Ph.D[1]

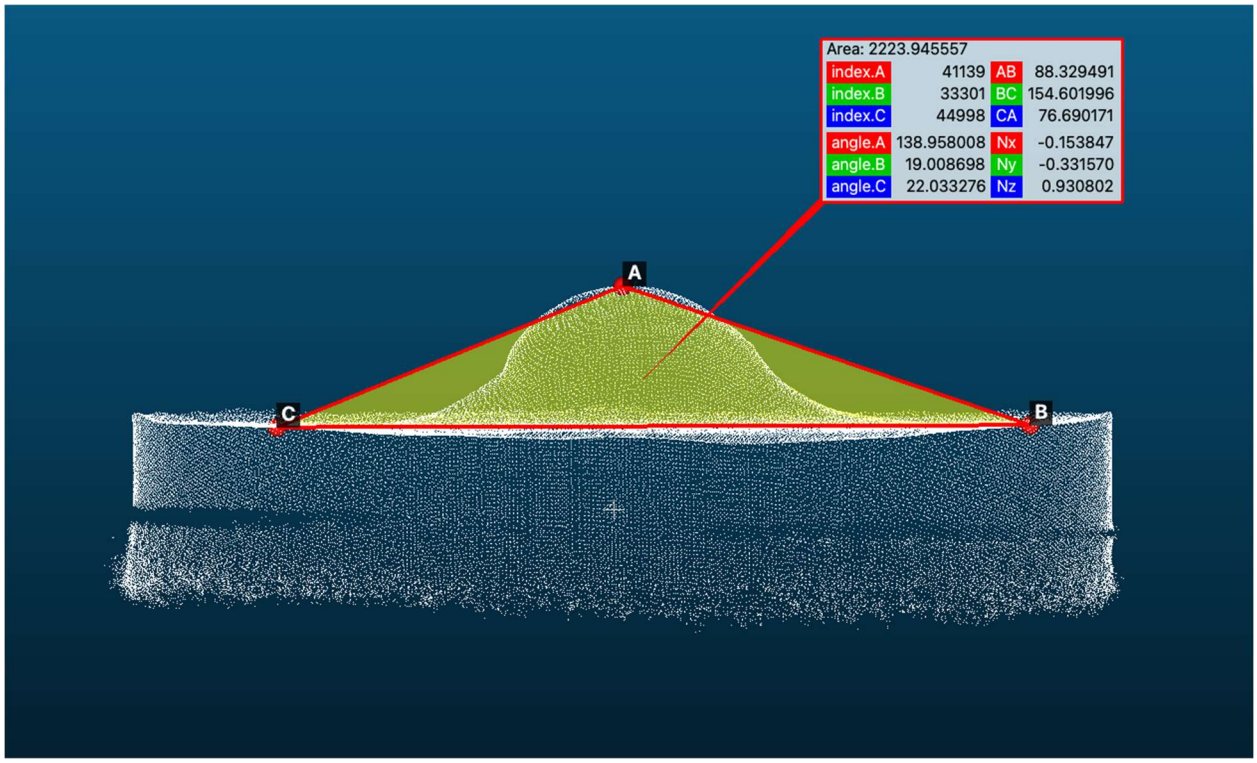
[1]Biomedical Engineering, Wayne State University, Detroit, MI, United States. [2]US DEVCOM Army Research Laboratory, Adelphi, MD, United States

Introduction

The measurement of back face deformations (BFDs) is a critical part of certification testing for soft and hard armor. Historically, these measurements were done with simple techniques such as depth calipers and include only peak deformation. Previous research suggests that the shape (volume, curvature) of the BFDs is also important to consider. As such, a 3-dimentional scanner was used to capture additional parameters; however, two varying techniques were assessed. The aim of this research is to compare these methods to provide guidance for future testing.

Methods

A total of sixteen ballistic impacts were conducted using 9 mm FMJ RN fired at 448 m/s against handgun 2 (HG2) armor panels placed in front of a witness material as previously described [1]. After each impact, the BFD was measured using depth calipers. In addition, the resulting deformation (negative) was scanned using the Revopoint Miraco Plus 3-D scanner (Revopoint, Los Angeles Ca). A positive mold of the deformation was also created using Polytek EasyFlo 60 (Polytek Development Corporation). After the mold cured, it was also scanned. The BFDs from calipers were compared to the positive and negative scans measured with CloudCompare.



Results

The average maximum BFD measured with calipers was 28.54 ± 0.01mm for a silicone composite clay and 27.54 ± 0.01mm for Roma Plastalina No. 1 (RP1). For the negative scans, the average maximum BFD was 29.23 ± 0.02mm for the silicone composite and 29.12 ± 0.02mm for RP1. For the positive scans, the average maximum BFD was 29.12 ± 0.02mm for the silicone composite and 27.6 ± 0.02mm for RP1. There was no significant difference ($p<0.05$) between any techniques for either witness material.

Discussion

The use of ballistic clay and a single maximum deformation point for the evaluation of BFD has long been the standard for armor certification. The use of scanning technology can provide more details about the BFD; however, accurate methodologies must be established before they can be widely used.

Quantifying Seated Pregnant Occupant Anthropometry Using a 3D LiDAR Scanner

Ms. Danielle Rowlands BASc.[1], Ms. Vivian Chung MASc., P.Eng.[1], Mr. Dean Harris[1], Ms. Jade Levine MASc.[1], Dr. Jason Burrows MD, FRCSC[1], Dr. Desiree Reichhardt DNP, NP(F), RDMS[1], Dr. Jason Forman Ph.D.[2], Dr. Jason Hallman Ph.D.[3], Dr. Ananna Ahmed Ph.D.[3], Dr. Peter Cripton Ph.D.[1]

[1]The University of British Columbia, Vancouver, British Columbia, Canada. [2]University of Virginia, Charlottesville, Virginia, United States. [3]Toyota Motor North America R&D, Ann Arbor, Michigan, United States

Introduction

Motor vehicle collisions are a leading cause of trauma death for pregnant women [1]. Anatomical changes occur throughout the pregnancy. Interactions between the seatbelt and external pregnant anatomy are neither well documented nor well understood. This study aims to explore how anthropometry may influence the seatbelt path during pregnancy through the use of 3D imaging.

Methods

Pregnant participants were provided NHTSA's guidelines demonstrating correct seatbelt placement during pregnancy. 3D images are then captured in two environments:

1. A hand-held LiDAR scanner captures a 3D image of participants wearing their seatbelt while seated in a simulated vehicle seat.
2. A GoPro camera captures a video of participants wearing their seatbelt in their own vehicle. A 3D image is then reconstructed using photogrammetry.

Data collection is currently ongoing, with 259 of the targeted 500 participants scanned thus far.

Results

Initial analyses of 101 scans examine shoulder belt placement and offset from the jugular notch (JN). Preliminary results suggest that the horizontal distance from the JN to the shoulder belt varies, with values ranging from 13.42-97.06mm. However, trends can be noted:

The horizontal distance from the JN to the shoulder belt tends to increase with an increase in sitting height (regression coefficient=2.89; R^2=0.253; p-value=3.75E-07) and standing height (regression coefficient=1.18; R^2=0.173; p-value=4.09E-05). The horizontal JN to

shoulder belt distance tends to decrease as gestational age increases (regression coefficient=-0.85; R^2=0.095; p-value=0.00293).

Discussion

This study provides a large dataset demonstrating seatbelt placement for pregnant occupants. In examining the horizontal JN to shoulder belt distance, a decrease in this distance suggests that the shoulder belt is resting closer to the neck. This may result in the shoulder belt crossing over the breasts, impacting one's ability to accurately follow seatbelt placement guidelines [2].

The relatively weak correlations observed in preliminary results highlight the complexity of predicting the seatbelt path when high inter-subject variability is present. This further illuminates the effect that pregnant anthropometry may have over non-pregnant participants that have been previously evaluated [3].

Unexpected Source of Behind Armor Blunt Trauma (BABT) Lung Injury

Dr. Joost Op't Eynde PhD[1], Mr. Jason Kait MS[1], Mr. Derek Pang MS[2], Dr. Robert Salzar PhD[3], Mr. B. Joseph McEntire MS[4], Dr. Cameron R. 'Dale' Bass PhD[2]

[1]Duke University, Durham, North Carolina, United States. [2]Wayne State University, Detroit, Michigan, United States. [3]University of Virginia, Charlottesville, Virginia, United States. [4]US Army Aeromedical Research Laboratory, Fort Rucker, Alabama, United States

Introduction

The typical behind armor blunt trauma (BABT) injury paradigm in the lung is based on the hypothesis that a large displacement into the lung causes lung contusions. The speed of sound in the lung is approximately (~) 20 m/s. Since armor backface/chest wall velocity often exceeds 20 m/s, there is a potential for compressive shock wave development in the lung. This study elucidates the theoretical basis for shock development, experimental shock pressure measurements, and characteristic injuries for this new principal injury mechanism of BABT.

Methods

An ideal theoretical framework was developed to assess shock wave development in the live adult porcine lung. Experimentally, a BABT indenter representing a realistic rifle threat (7.62x51 NATO) impacted the torso at representative velocities between ~20 and 80 m/s. Indenter motion was tracked using high speed video and acceleration was measured with a triaxial accelerometer. Pressure was measured in the lungs bilaterally. Post-test necropsy assessed local lung injury.

Results

Theoretical shock formation distance was calculated in the lung ~10 mm from the pleural interface inside the lung, and formation time was less than 0.5 ms. Shock formation distance and time increased with decreasing velocity. This is consistent with shocks occurring in the lung from backface velocity. Researchers saw strong evidence of fast rising pressure and shock formation from the lung pressure data taken in the trachea. Histology showed lung damage distant from the impact site with less damaged tissue closer to the site (Figure 1). For the higher velocity tests, this damage often progressed into the contralateral lung.

Discussion

This is the first study to show a theoretical and experimental basis for lung shock injuries in BABT. Given the typical BABT chest wall velocity ranges (between ~20 and 100 m/s), this is likely a principal wounding mechanism that competes with wounds caused by rib displacement, depending on the armor characteristics. This result, especially the deep injuries in the unimpacted lung, is difficult to explain based on previous strain-based lung injury concepts.

Images (Optional)

Acoustic Source Localization of Fractures in Heterogenous Biological Tissue

Ms. Diana D. Tarakhovsky[1], Dr. Karin A. Rafaels[2], Dr. Cameron R. 'Dale' Bass[1]

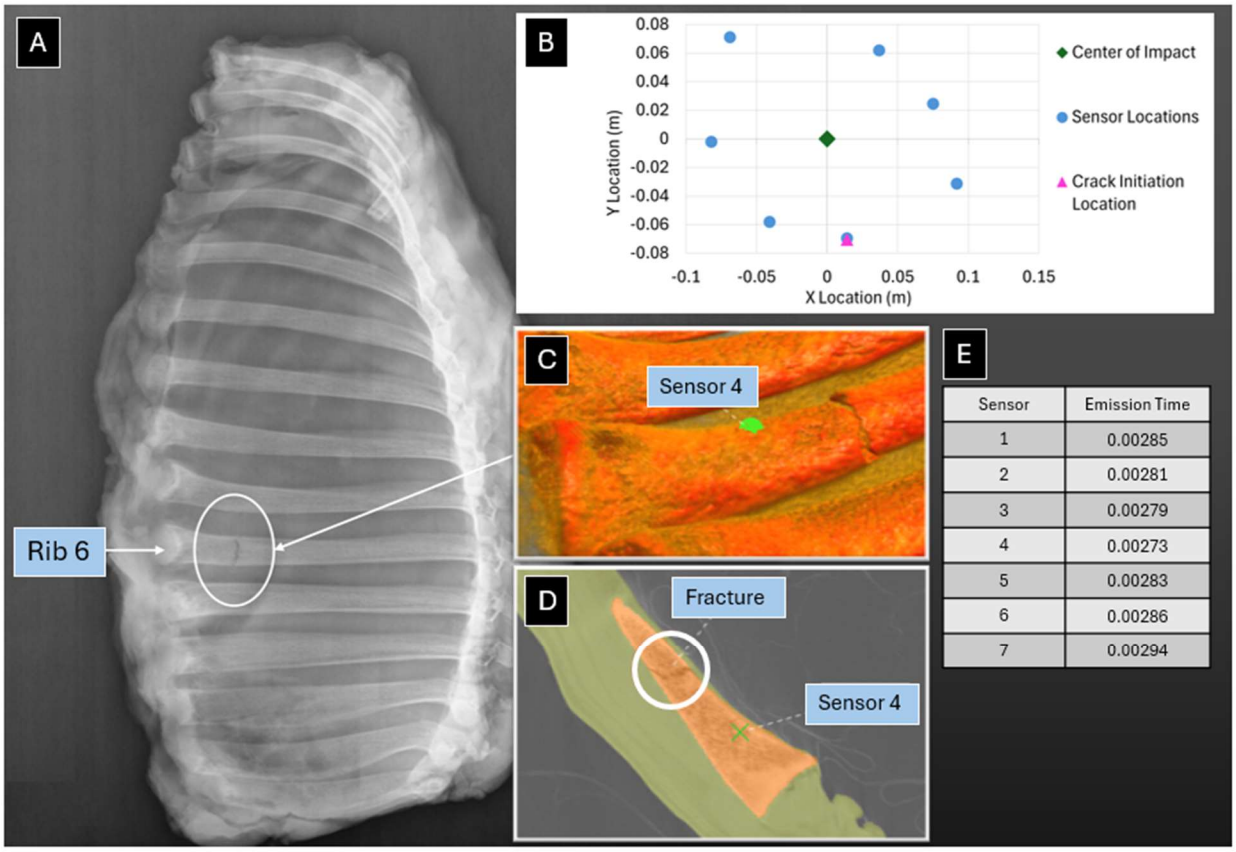
[1]Wayne State University, Detroit, MI, United States. [2]US DEVCOM Army Research Laboratory, Adelphi, Maryland, United States

Introduction

Acoustic emission (AE) is a powerful, noninvasive tool for detecting and localizing fractures. To avoid disrupting tissue and remain truly noninvasive, acoustic sensors must be mounted on the skin and not directly on bone. However, because hard tissues and soft tissues exhibit different mechanical behaviors and wave propagation characteristics, accurate source localization using conventional approaches that assume homogeneity with a constant propagation speed is inadequate. This study applies an effective speed-of-sound method to improve predictive diagnostics in biomechanical applications compared to using a speed-of-sound based only on soft-tissue propagation.

Methods

To expand on the previous analysis that assumed a constant propagation speed, post-test CT-scans of the porcine specimens were analyzed to obtain soft tissue, bone, and fracture geometries. CT-based segmentations defined anatomical boundaries and impedance changes used to ray-trace propagation and estimate an effective speed-of-sound. The fracture localization obtained using the original method and the effective speed-of-sound in this study were compared with each and other and to the actual fracture locations.



Results

Post-test CT-scans were segmented into soft tissue, bone, and fracture regions, providing the anatomical basis for analyzing waveform propagation. Through numerical optimization, the multilateration algorithm identified the most probable fracture location and emission onset-time relative to the eight-sensor array. Localization results aligned with anatomical inspection, rib projections, and post-impact X-rays. The method utilizes an effective speed-of-sound accounting for the acoustic signal propagating through multiple tissue types, improving the localization of fractures.

Discussion

This study provides a noninvasive method of localizing initial fractures, demonstrating potential as a real-time tool for advancing understanding of skeletal fracture-mechanics. A limitation is the use of an effective speed-of-sound, which simplifies the complex wave behavior across material interfaces. Acoustic emissions propagate as compressional, shear, surface, and plate waves, each influenced by sensor position. This paper presents experimental methods, algorithmic strategies, and validation for noninvasive AE-based fracture localization using an effective sound speed in multi-tissue systems. These findings support the feasibility of fracture-source localization and the integration of AE techniques in biomedical-engineering and tissue-mechanics research.

Head Impact Kinematics in Reconstructed Youth Body-First Rear Falls

Ms. Emilie Ethier, Mr. Thomas Hoshizaki MSc, Ms. Taylor Sims BSc, Dr. Thomas Blaine Hoshizaki PhD

University of Ottawa (Neurotrauma Impact Science Lab), Ottawa, Ontario, Canada

Introduction

Body-first falls are a common event in youth sport, with observational data reporting 90% of impacts involve the body contacting the surface before the head. Youth have lower neck strength and neuromuscular control than adults, which influence head kinematics and injury risk (1). Adult surrogate studies show neck stiffness affects linear and rotational head impact accelerations; however, few studies have investigated body-first head impacts in youth. This study compared peak linear (PLA) and rotational acceleration (PRA) for body-first head impacts at 2 and 4 m/s using a youth specific neck spring apparatus (2).

Methods

Impacts were conducted using a drop-rig system and the University of Ottawa Neck Spring Apparatus (UONSA). Youth neck stiffness was, set to 70 % of adult neck stiffness (60% MVC) Video body-first youth football falls footage was used to guide impact reconstruction. The Hybrid III 5th percentile head form was dropped onto a MEP anvil in two conditions: (1) body-first falls onto compliant vinyl nitrile foam pad and (2) direct head impacts. Two velocities (2 and 4 m/s) were tested 3 times per condition. PLA and PRA were recorded using a slice accelerometer.

Results

The body-first impacts at 2 m/s resulted in a mean PLA of 17.47 g (SD 1.30) and mean PRA of 2783.5 rad/s^2 (SD 166.7). At 4 m/s, body-first PLA increased to 91.73 g (SD 4.04) and PRA to 10335.1 rad/s^2 (SD 343.8). Direct 2 m/s impacts produced far higher PLA 90.87 g (SD 0.70) and a lower PRA 4206.1 rad/s^2 (SD 260.0). At 4 m/s, direct impacts recorded the highest PLA values 207.37 g (SD 4.24) and PRA values of 10930.4 rad/s^2 (SD 2791.1).

Discussion

These findings revealed direct impacts produced 4–6x higher linear accelerations, while body-first falls generated rotational accelerations approaching direct impacts at 4 m/s. Since rotational acceleration is linked to head injury risk, these results highlight the need to

evaluate both linear and rotational loading when assessing youth fall-related head injury risk.

Images (Optional)

Table 1: Mean linear and rotational acceleration values.

		Body First Impacts	Direct Impacts
2m/s	Linear acc. (g)	17.5g (SD 1.4)	90.9 g (SD 0.7)

Evaluation of Female Head X-Acceleration Responses Between Volunteers and Anthropomorphic Test Devices in Frontal and Frontal-Oblique Sled Tests

Ms. Emily Arana Barcala, Ms. Keya Zambare, Dr. Kevin Adanty, Dr. Sean Shimada

Aperture LLC, Davis, CA, United States

Introduction

Female occupants face higher injury risks in frontal crashes [1]. Currently, female head responses are characterized by female anthropomorphic test devices (ATDs) including the 5th-percentile THOR-05F and the Hybrid III (HIII-5F), a scaled-down male ATD [1]. To our knowledge, no comparative analysis has evaluated whether both existing female ATDs accurately capture head kinematics of human female occupants. While studies have evaluated female ATD biofidelity at low speeds [2], it remains unclear whether these findings extend across varying crash severities. Therefore, this study aims to compare 5th-percentile female volunteers with THOR-05F and HIII-5F ATDs in frontal and frontal-oblique impacts to assess female ATD head x-acceleration biofidelity.

Methods

Anteroposterior head x-accelerations were collected from (1) low-speed frontal-oblique (impact angle: 330°) sled tests with unbraced 5th-percentile female volunteers and (2) low-to-high-speed frontal (0°) and frontal-oblique (0±30°) sled tests with THOR-05F and HIII-5F ATDs. Data was sourced from literature [2] and the National Highway Traffic Safety Administration Biomechanics Database, respectively. Head x-acceleration plots were normalized by peak sled acceleration and crash duration (%CD).

Results

Frontal-oblique volunteer and frontal ATD acceleration responses peaked at similar times (31.0%CD and 31.8–33.3%CD). Further, frontal-oblique HIII-5F (345° and 15°) peaked at comparable times to volunteer tests (29.3-29.9%CD), whereas THOR-05F (330°) peaked later (60.6%CD) (Figure 1). Statistical analysis demonstrates that frontal THOR-05F and HIII-5F closely matched volunteer curves (r=0.959-0.967; RMSE=0.137-0.152). Frontal-oblique HIII-5F pulse alignment to volunteers was moderate (r=0.644-0.687, RMSE=0.196-0.221), however THOR-05F alignment was weak (r=0.118, RMSE=0.441).

Discussion

Frontal-oblique female volunteer acceleration pulses aligned more closely with ATD pulses in frontal than frontal-oblique impacts. Although limited by sample size, these results

suggest weaker frontal-oblique head x-acceleration biofidelity for current female ATDs, particularly THOR-05F. Normalized ATD head-to-sled acceleration magnitudes increased with crash severity, suggesting that female ATD head response may not scale proportionally with greater sled accelerations. Consequently, these findings are consistent with previous reports of greater volunteer–ATD differences at greater sled accelerations [2]. This underscores the need for expanded female datasets to refine frontal-oblique ATD head responses, improve injury prediction, and strengthen female-specific safety standards.

Electromyographic Activity in Frontal and Rear End Sled Tests and Activities of Daily Living

Ms. Emily Arana Barcala, Mr. John Caraan, Dr. Kevin Adanty, Dr. Sean Shimada

Aperture LLC, Davis, CA, United States

Introduction

The forces acting on the cervical spine in a motor vehicle accident (MVA) are often compared to those generated in non-injurious activities of daily living (ADLs) to evaluate potential injury risks in MVAs. However, when compared to ADLs, there may be distinctions in the underlying muscle activity of critical neck stabilizers during whiplash-type responses in MVAs [1]. These differences in neuromuscular activation may explain the greater injury potential associated with MVAs. This study compares neck muscle activity reported in previous literature between low-speed simulated sled tests (front and rear-end impacts) and common ADLs to quantify the differences in muscle activity for each respective scenario and identify potential injury risk.

Methods

Electromyographic (EMG) activity, represented as percent maximum voluntary contraction (%MVC), was collated from peer-reviewed literature. An analysis of sternocleidomastoid (SCM) and trapezius EMG activity was performed to identify differences between ADLs and unexpecting occupants in low-speed frontal-oblique and rear sled tests. ADLs included sitting, overhead work (OW) described as pushing a load up a vertical distance, holding a 1kg camera at eye level, and shrugging both shoulders towards the ears.

Results

SCM and trapezii EMG activity for frontal-oblique and rear sled tests and ADLs were plotted (Fig. 1) [1-3]. Sled test EMG values were consistently greater in the primary activated muscle than those measured during ADLs. The SCM and trapezius EMG activity during rear and frontal-oblique impacts, respectively, exceeded those reported during ADLs. Trapezius EMG activity was greatest for ADLs during shrugging and was most comparable to frontal-oblique sled tests at 0.5g accelerations.

Discussion

Overall, findings suggest that EMG activity during MVAs exceeds that measured during ADLs. These differences may be attributed to ADLs producing low-intensity muscle activation patterns, whereas MVAs generate rapid, high-amplitude muscle activation

responses of the neck muscles driven by sudden acceleration [1]. Elevated neck muscle activation during sled tests indicates a stabilizing role during unexpected loading and should be considered by forensic engineers as it may contribute to increased neck injury risk relative to ADL tasks.

Slopes, Spirals, and Splashes: Rider Biomechanics on Three Common Recreational Water Slides and Rides

Dr. Emily Bliven PhD, Mr. Noah Schneider BS, Dr. Elaine Serina PhD

Talas Engineering, Inc., Hayward, CA, United States

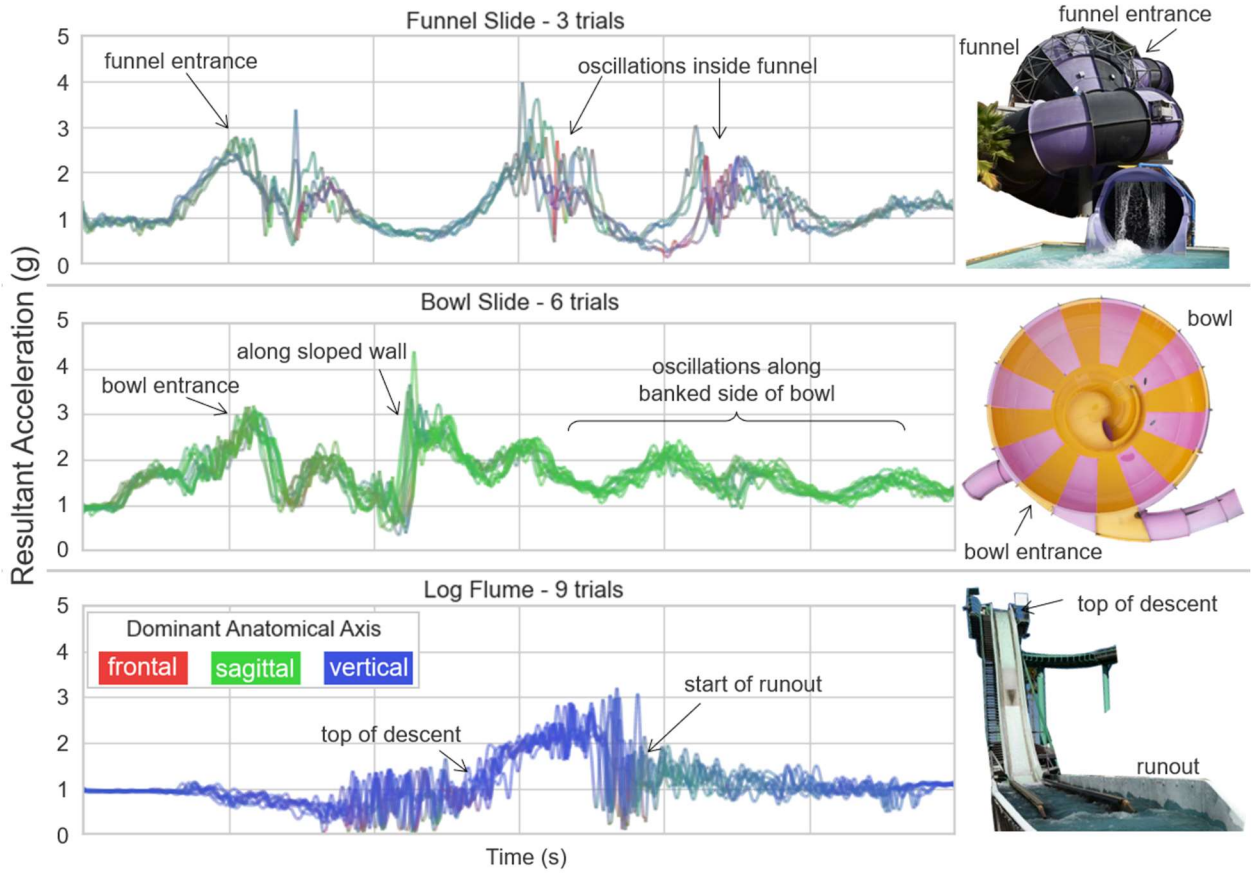
Dr. Emily Bliven

Introduction

Water slides and rides are popular forms of recreation found at resorts and amusement parks. Like roller coasters, water rides carry riders through prescribed courses while imparting forces and accelerations on their bodies. Biomechanics research on water slides and rides is nascent; however, such data is essential for understanding ride dynamics and "thrill" aspects. Our objective was to characterize rider accelerations on water rides with consideration of ride features (e.g., curves and descents).

Methods

Testing was conducted on a funnel slide, bowl slide, and log flume. The slides each had two riders seated in a two-person tube, with rider weights representative of a 25th percentile male and female. The log flume had two riders seated in the log vehicle: a 144-lb female and 343-lb male. A triaxial accelerometer was mounted near the center of mass of each tube rider and of the log vehicle. Data was collected for the entirety of each ride at a minimum rate of 100 Hz and filtered per SAE J211 with cut-offs of 5 Hz. Subsections were isolated to analyze features of interest identified via video review. The data presented includes gravity.



Results

Average peak resultant accelerations for the funnel slide, bowl slide, and log flume were 3.2 g, 3.3 g, and 2.9 g, respectively. Resultant accelerations during any ride did not exceed 4.4 g. Higher acceleration values were associated with features like travel into or along sloped bowl and funnel walls. With respect to rider anatomical axes, accelerations were predominately sagittal for the bowl slide, and vertical for the log flume.

Discussion

This study is one of the first to characterize rider biomechanics on water slides and rides, expanding on previously published data of water slide rider exit velocity [1]. The accelerations presented are comparable to those of activities of daily living like running and jumping. This suggests that rides provide "thrill" aspects through experiences like splashing or darkness, rather than excessive ride dynamics. Future work would include larger rider populations and other types of water rides.

Plantar Pressure while Running in Advanced Footwear Technology: Implications for Navicular Stress Fracture Risk

Ms. Gayatheri Mahesh Hema Iyer[1], Dr. J.J. Hannigan[2]

[1]Oregon State University, Corvallis, OR, United States. [2]Oregon State University - Cascades, Bend, OR, United States

Introduction

Advanced Footwear Technology (AFT), characterized by a carbon fiber plate embedded within compliant midsole foam, has recently improved long-distance running performances. However, a case series [1] reported multiple navicular stress fractures (NSF) in runners using AFT, suggesting a potential link between AFT shoe design and NSF risk. Elevated plantar loading has been observed in athletes with NSFs [2]. However, in-shoe plantar pressure has not been directly compared between AFT and non-AFT footwear, and it remains unclear whether increasing foot–plate distance can reduce potentially harmful loading. Therefore, the purpose of this study was to compare plantar pressure across three conditions: a standard AFT shoe (AFT), a modified AFT shoe with an additional 3-mm insole (AFT+), and a non-AFT control shoe (CON). We hypothesized that medial midfoot pressure would be significantly higher in AFT compared to CON and AFT+.

Methods

After warming up, ten competitive runners completed 5-minute treadmill trials at their marathon pace in each footwear condition in randomized order. Plantar pressure was collected at 150 Hz using the XSENSOR in-shoe pressure system during the final minute of each run. Primary variables were peak and average whole-foot and regional (medial midfoot and 1st metatarsal) plantar pressure (Fig 1). Repeated-measures ANOVAs ($\alpha = .05$) tested for differences across conditions with follow-up Bonferroni-corrected pairwise comparisons.

Results

Medial midfoot peak pressure was significantly higher in the AFT condition (10.7±3.2 N/cm^2) compared to the AFT+ condition (9.5±2.9 N/cm^2), p=.032. Whole-foot peak pressure was significantly higher in the CON condition (37.9±5.1 N/cm^2) compared to the AFT+ condition (34.6±6.7 N/cm^2), p=.006. No other significant differences were identified (p>.05).

Discussion

Increasing foot-plate distance through additional insole cushioning effectively reduced medial midfoot plantar loading in AFT shoes, suggesting a modifiable design feature that may lower NSF-related loading. However, no differences were noted between AFT and CON footwear, suggesting that the NSF injuries in AFT may result from additional factors beyond elevated plantar pressure. Future work should incorporate kinetic and kinematic analyses at the foot to better understand navicular loading mechanisms.

Can Wearable-Sensor Errors Confound the Mechanics Responsible for Concussion Injury?

Dr. Gunter Siegmund PhD[1,2], Dr. Benjamin Elkin PhD[3], Dr. Stephanie Bonin PhD[1]

[1]MEA Forensic Engineers & Scientists, Laguna Hills, CA, United States. [2]University of British Columbia, Vancouver, BC, Canada. [3]MEA Forensic Engineers & Scientists, Toronto, ON, Canada

Introduction

Field data sometimes show that concussion injury risk correlates best with peak linear head acceleration [1,2]. Animal and computer models, however, suggest that diffuse brain injuries like concussion are caused by angular kinematics [3,4]. Our goal was to evaluate if on-field measurement errors might explain these contradictory findings.

Methods

We used Monte-Carlo methods to assess how concussion-injury risk functions are affected by sensor errors in linear and angular kinematics. We simulated a cohort of 58 players who experienced head impacts with combinations of peak linear acceleration (a=20−140g) and peak angular acceleration (α=1.2−10krad/s^2) based on reconstructed data [1]. Angular velocity (ω) was integrated from the sinusoidal angular acceleration (random pulse duration 7.5−12.5ms). We then assumed a hypothetical injury risk function based solely on angular velocity (50% risk at 34.5rad/s; risk=1/[1+exp[-18.13+0.525ω]]) and used it to probabilistically determine if a concussion occurred. To address our goal, we introduced field errors into the linear (±10%, ±20%…±100%) and angular (±10%, ±20%…±200%) accelerations [5], and re-calculated injury risk functions using the field data with simulated errors. For each combination of linear- and angular acceleration errors, we ran 500 iterations of the cohort to generate 500 sets of injury risk functions and calculated the percentage of risk functions where concussion correlated better with linear acceleration than with angular velocity.

Results

Higher angular acceleration errors yielded a higher likelihood that concussion correlated better with linear acceleration than with angular velocity (Fig. 1). Concussion was likely to correlate better with peak linear head kinematics at angular acceleration errors above ±70%.

Discussion

Wearable sensors can yield large errors, particularly for angular kinematics [5]. Even if concussions are solely caused by angular head kinematics, large errors in the angular data can make it appear as though concussion injury correlates better with linear kinematics. These findings highlight the importance of understanding on-field sensor errors and the need for better angular sensors to avoid confounding the head kinematics responsible for concussion injuries.

Head Injury Risk in Low-Height Falls: Comparative Analysis Using THUMS Human FE Model and Hybrid III Dummy Experiments

Dr. HAEYOUNG KIM Researcher[1], Dr. HIROKI TAKAHASHI Researcher[1], Mr. YASUMICHI HINO Researcher[1], Dr. KATSUTOSHI OHDO Researcher[1], Dr. HIDEKI OYAMA Researcher[1], Dr. MASAHIRO OKAMURA Researcher[2]

[1]National Institute of Occupational Safety and Health, Japan, Kiyose, Tokyo, Japan. [2]JSOL Co., Tokyo, Tokyo, Japan

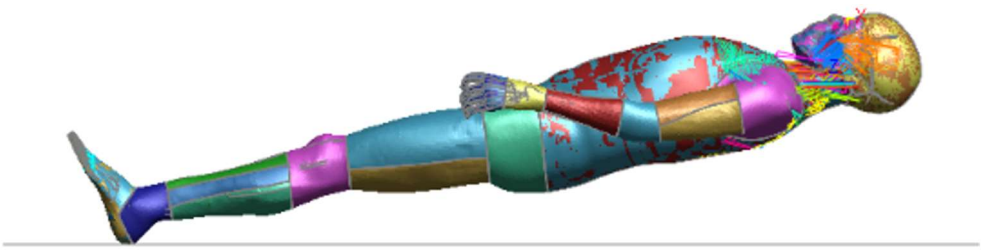
Introduction

Falls from heights of 2 meters or less remain a leading cause of serious occupational injuries, particularly in the construction industry where head trauma is common even at low elevations. However, the injury mechanisms associated with low-height falls are not well understood, and the protective effectiveness of industrial helmets under such conditions has not been fully quantified. This study aims to clarify head injury risk by combining finite element (FE) simulations and full-scale experiments, evaluating how fall angle, initial head height, and helmet use influence resultant head acceleration and injury severity.

Methods

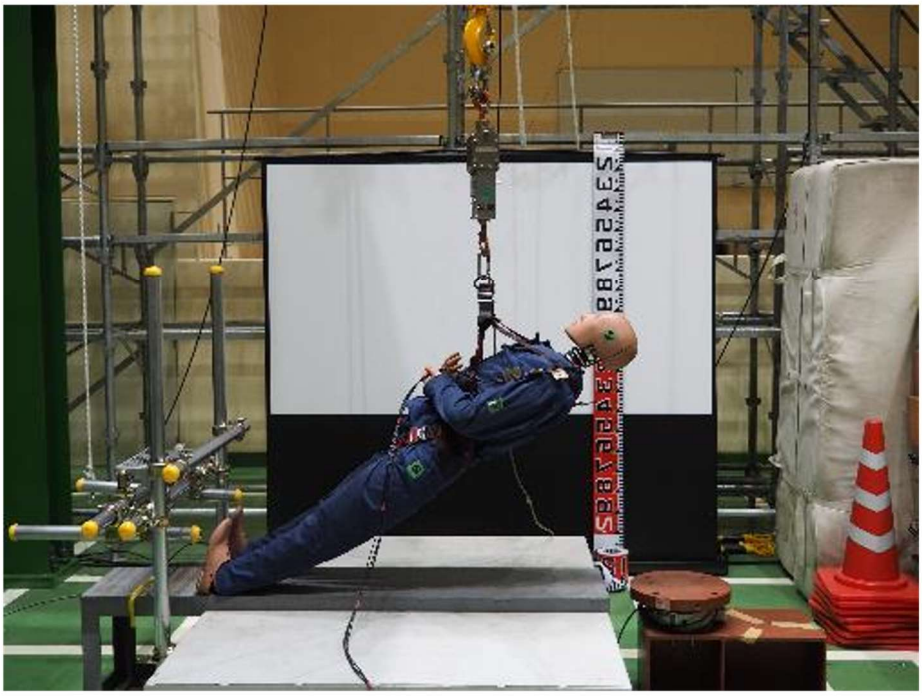
A 50th percentile adult male model from THUMS Version 4 was used to conduct FE simulations in LS-DYNA. Fall scenarios were modeled with four impact angles (10°, 20°, 30°, 40°) and head heights ranging from 41 to 107 cm. Helmet and non-helmet cases were included.
In parallel, fall experiments were performed using a Hybrid III 50th percentile pedestrian dummy equipped with tri-axial head accelerometers. A release mechanism ensured a consistent initiation of the fall. Experimental configurations replicated the numerical cases. Data collection included time histories of resultant head acceleration and calculation of HIC15.

Results



Both simulations and experiments demonstrated that head acceleration increased with fall height and impact angle. Experimental peak accelerations ranged from 117 G to over 700 G, and HIC15 frequently exceeded 3000 for head heights above 88 cm, indicating a high probability of AIS 6 injury. Analytical results showed similar trends. Helmet use reduced

peak acceleration by about one-third and lowered HIC15 from 5189 to 1288, demonstrating substantial protective effects.



Discussion

The results confirm that severe head injuries may occur even from falls below 1 m. Differences between simulations and experiments largely reflect challenges in reproducing human defensive actions in both models. Helmet use consistently decreased acceleration magnitude and injury metrics, demonstrating its critical effectiveness for preventing head trauma in low-height falls.

Design and Additive Manufacturing of Tunable Triply Periodic Minimal Surface (TPMS) Lattices to Enhance the Biomechanical Impact Protection of Hip Protectors

Mr. Haoming MO PhD Candidate, Prof. Yi-jian YANG Professor, Prof. Xu SONG Professor

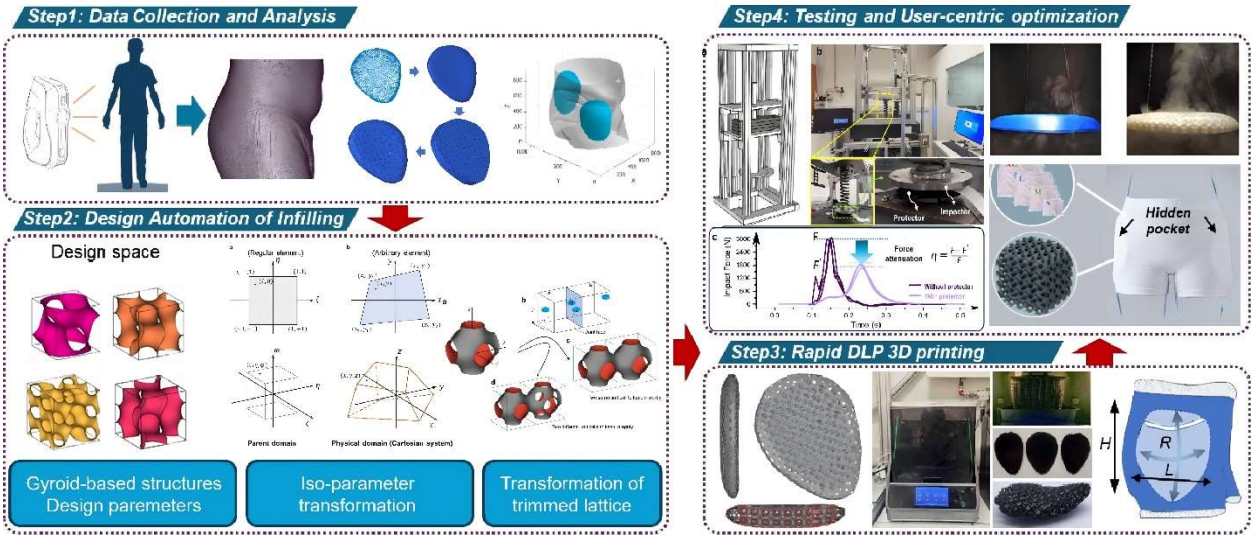
The Chinese University of Hong Kong, Shatin, N.T., Hong Kong

Introduction

Hip fracture is a leading cause of injury-related hospitalization in older adults. Although hip protectors have been promoted to prevent fractures, existing models often underperform due to poor mechanical stability and low breathability, resulting in low adherence. Additive manufacturing (3D printing) has emerged as a transformative approach for mass customization and fabrication, enabling complex lattice structures with tailored mechanical properties for effective impact protection. Hence, we exploited this capability to (i) create tunable TPMS lattices with enhanced energy absorption and (ii) integrate them into lightweight, mass-customized hip protectors to improve comfort and long-term adherence.

Methods

P-type TPMS shell–lattice units were "trimmed" by introducing controlled holes to tune layer-by-layer crushing and stabilize stress fluctuations. A hyper-elastic Marlow model calibrated from tensile data was used in ABAQUS/Explicit; 4×4×4 unit-cell meshes with sensitivity checks captured non-periodic post-yield behavior. Pelvis geometries of 32 older adults were captured via 3D scanning and reconstructed for iso-parametric mapping of TPMS lattices onto patient-specific contours. Lattice hip protectors were printed using elasticity photopolymer 3D printing. Impact performance followed CSA Z325:20, while air permeability was tested per ISO 9237:1995 (100 Pa). A pilot trial evaluated adherence and comfort across three one-month rounds.



Results

Trimming systematically reduced stress fluctuation and mitigated buckling, leading to stable post-yield responses and tunable energy absorption through varying hole size and location. The 3D-printed hip-protector prototype achieved force attenuation of 40–43% with >96% retention after 150 impacts and a one-year follow-up. Air permeability reached 6501 $L/m^2/s$, supporting thermal comfort. Simulation stress–strain curves exhibited concordance with compression tests across trimming designs. Participants reported high adherence score and comfort score , indicating improved user compliance and consistent wearing behavior comparing to conventional protectors.

Discussion

Trim-based modification of TPMS lattice design offers a robust method to stabilize nonlinear mechanical responses while preserving geometry-induced mechanical property tunability and air permeability, addressing the longstanding trade-off between protection and wearing comfort. The integration of inverse design, iso-parametric lattice mapping, and polymer additive manufacturing enables scalable mass customization based on anatomical variation. Both finite element simulation and experimental evidence support the fact of performance gain in biomechanics.

P3-096

Effect of a Rapid Transition From Concentric to Eccentric Contraction on Fiber Strain in the Rectus Femoris

Mr. Hayata Egawa B.S, Prof. Yoshimori Kiriyama Ph.D, Prof. Katsumasa Tanaka Ph.D

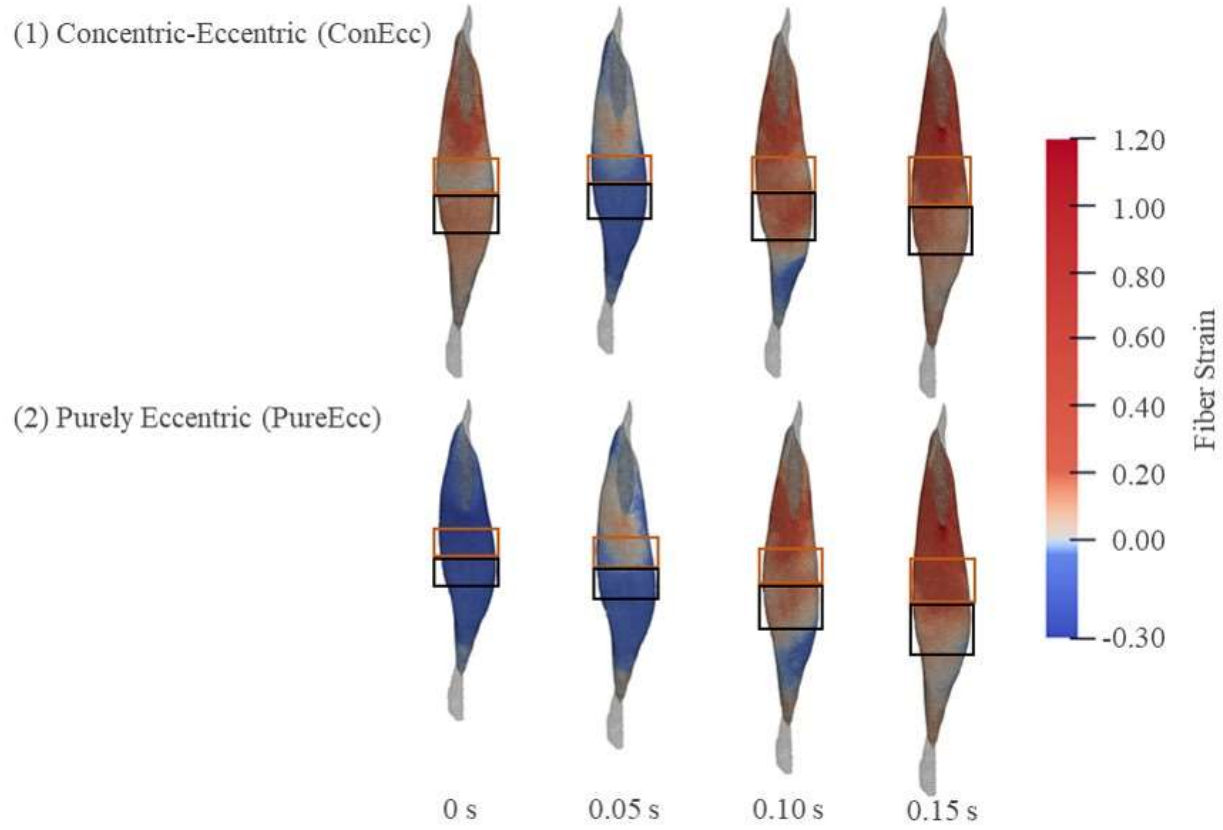
Kogakuin University, Shinjuku, ToKyo, Japan

Introduction

Rectus femoris injuries during change-of-direction tasks can occur even when the muscle–tendon unit (MTU) is not maximally lengthened. Before foot contact the muscle contracts concentrically to increase joint stiffness, and immediately after landing it is stretched and loaded eccentrically. Because concentric contraction generates relatively low force, this rapid transition may permit over-lengthening and muscle damage. How such abrupt changes in contraction mode affect fiber strain remains unclear; this study used finite-element (FE) analysis to examine how the pre-eccentric contraction pattern influences rectus femoris fiber strain.

Methods

An FE model of the rectus femoris and tendons was generated from MRI of one female. The proximal tendon was fixed and a prescribed displacement was applied to the distal tendon to reproduce MTU length changes. Muscle was modelled as a transversely isotropic hyperelastic material with passive and active components; the active part incorporated Hill-type force–length and force–velocity properties. Two loading histories were simulated: ConEcc, where MTU strain decreased from 0.05 to 0.00 at $-1.0\ s^{-1}$ and then increased to 0.10 at $1.0\ s^{-1}$; and PureEcc, where MTU strain increased from −0.05 to 0.10 at $1.0\ s^{-1}$. Muscle activation was fixed at 0.4. Dynamic Implicit FE analyses were performed and fiber-direction strain was evaluated.



Results

At 0.10 and 0.15 s both conditions showed strain concentrations near the proximal myotendinous junction. The orange and black boxes indicate regions near the largest cross-sectional area along the direction of stretch. At 0.05 s fiber strain in the orange box was smaller in ConEcc than in PureEcc, whereas at 0.10 and 0.15 s strain in the black box was more broadly distributed in ConEcc.

Discussion

Regardless of condition, eccentric loading concentrated fiber strain near the myotendinous junctions, consistent with discontinuity between muscle and tendon and typical injury locations. In ConEcc, mid-belly shortening between 0 and 0.05 s, when fibers were near optimal length and generated little force, appears to have reduced resistance to subsequent stretch and broadened tensile strain after 0.10 s. Thus, a rapid transition from concentric to eccentric contraction may spread tensile fiber strain widely at the onset of eccentric loading.

Multi-Dimensional Joint Angle Analysis for Pitching Fatigue Detection: A Skeleton Detection and Deep Learning Approach

Ms. Hung-Chun Huang[1], Mr. Jing-Min Liang[1], Mr. Hsuan-Wei Chu[1], Mr. Sheng-Jie Kao[2], Prof. Tsì-Uí Ík[2], Prof. Wel-Lan Wu[1]

[1]Kaohsiung Medical University, Kaohsiung, Kaohsiung, Taiwan. [2]National Yang Ming Chiao Tung University, Hsinchu, Hsinchu, Taiwan

Introduction

Baseball pitching practice is characterized by high repetition and high physical loads, potentially leading to fatigue accumulation and musculoskeletal injuries. AI-based deep learning pose estimation methods are increasingly mature and can be used as auxiliary tools for sports training through real-time motion recognition. This study aimed to analyze kinematic features under continuous pitching and develop a fatigue detection model using Long Short-Term Memory (LSTM) networks.

Methods

Seven college baseball players with recent competition records in University Baseball League were recruited into this study. The camera lens was positioned on the throwing-arm side, at a height of 125 cm above the ground and a linear distance of 450 cm from the pitcher's plate. The simulated game protocol: 20 pitches/inning, 6-min rest between innings until stopping criteria were met (velocity drops ≥8 km/hr from max for 3 consecutive pitches or rating of perceived exertion (RPE) ≥18). The fatigue onset was labeled at the inflection point of the smoothed velocity trajectory (moving average, window=5) followed by a sustained decrease below the average speed. A total of 428 pitches were collected, consisting of 326 non-fatigue and 102 fatigue trials. Python (3.12.7) and MediaPip were employed for 33 skeleton keypoints with hip-centered coordinates. Six pose parameters were calculated (elbow flexion, shoulder horizontal abduction, shoulder abduction, shoulder external rotation, pelvic rotation, trunk rotation) as the input data. The LSTM architecture featured two hidden layers (64/32 units) with dropout. To address class imbalance, Focal Loss and SMOTE were applied. The dataset was divided using an 80/20 stratified train-test split. Training incorporated early stopping to prevent overfitting, with model validity assessed via the F1-score.

Results

Experimental results demonstrated that the model effectively distinguishes fatigue states with an overall Accuracy of 71.3%. For injury prevention, the model had a high recall of 83.6% for the fatigue class, ensuring that the majority of at-risk instances were identified.

Discussion

In conclusion, this study provides a viable deep learning approach for monitoring pitching fatigue. The high recall rate suggests its potential as a robust screening tool to minimize injury risks, offering valuable insights for players and coaches to manage training loads.

Punch-Type-Dependent Effect of Neck Muscle Strength on Brain Injury Risk in Boxing

MSc Carola Birk[1], MSc Talha Üzümcü[1], Prof. Wolfgang Potthast[1], Dr. Igor Komnik[1,2]

[1]Insitute of Biomechanics and Orthopaedics, German Sport University Cologne, Cologne, North Rhine-Westphalia, Germany. [2]Institute of Movement and Sport Gerontology, German Sport University Cologne, Cologne, North Rhine-Westphalia, Germany

Introduction

Repetitive head impacts in boxing are linked to acute concussion and long-term neurodegeneration, yet the mechanical determinants of brain loading remain poorly understood. Neck muscle strength is a proposed modifiable factor to mitigate head motion, but experimental evidence is inconsistent and may depend on impact direction. The aim of this study was to quantify how the protective effect of neck muscle strength on brain injury criterion (BRIC) depends on punch type during simulated boxing impacts.

Methods

A musculoskeletal head–neck model was used in OpenSim for forward dynamic simulations of boxing impacts. Force–time histories for four punch types (cross chin, cross nose, hook chin, hook temple) were experimentally derived from impacts to a crash-test dummy head (THOR-50M) and scaled to peak forces between 500 and 3000N (15 steps). Neck muscle strength was scaled from 0.5 to 2.0 times average male capacity (15 steps). Head kinematics were exported to compute BRIC. A General Linear Model (GLM) was fitted to BRIC with punch type, punch force and muscle strength as predictors, along with two-way interaction terms (punch type×strength, punch type×force and punch type×force^2).

Results

Across 900 simulations, the GLM explained 99.9% of variance in BRIC (R^2 = 0.999). At average strength and force, cross-chin produced the highest BRIC (1.52); compared with cross-chin, cross-nose, hook-chin and hook-temple had lower BRIC with β = –0.391, –0.433 and –0.656, respectively (all $p < 0.001$). Neck strength reduced BRIC most in cross-chin (β = –0.21) moderately in cross-nose (β = –0.14), and minimally in hook impacts (β = –0.02 and –0.03).

Discussion

This simulation shows that the protective effect of neck muscle strength is strongly punch-type dependent. Cross punches to the chin produced the highest BRIC values, but also the largest strength-related reductions (12.3% with doubled neck strength; Fig.1). In contrast, hook punches generated lower BRIC overall and gained little additional protection (hook-chin: 1.8% and hook-template: 3.7%). This might be since cross punches load the head primarily in the sagittal plane, where strengthened flexors can effectively oppose motion, while hook punches involve complex frontal/transverse plane rotations that are less amenable to simple co-contraction.

ACL Injury Resilience Score Differs Between Preadolescent and Adolescent Female Athletes

Dr. Jack Williams PhD, Dr. Julie Kolesar PhD, Dr. Kirsten Seagers PhD, Dr. Krithika Swaminathan PhD, Dr. Sam Hamner PhD, Ms. Julie Muccini MS, OTR/L, Dr. Jennifer Hicks PhD, Dr. Scott Delp PhD

Stanford University, Stanford, CA, United States

Introduction

ACL injuries are common among young athletes and disproportionately affect females. Biomechanical risk factors are well-documented and considered modifiable targets for injury prevention. We have developed the ACL Injury Resilience (AIR) Score to compare biomechanics during athletic maneuvers to population data adjusted for known injury thresholds, represented as z-scores. Subscores are calculated for the trunk, hip, knee, and foot, and then averaged to compute a total score. While prior work suggests preadolescent and adolescent biomechanics differ[1] and that both may display more biomechanical risk factors for ACL injury than adults[2], it is unknown if the AIR Score can identify differences across pubertal stages. Thus, we aimed to compare AIR Scores between preadolescents and adolescents, hypothesizing that we would see differences between groups.

Methods

This secondary analysis used baseline data from a cohort of female soccer players ($N_{Preadolescent}$ = 43; $N_{Adolescent}$ = 37) performing single-leg drop jumps and run-cuts[3]. The AIR Score and subscores were calculated for each participant using metrics from both activities. We used a two-tailed t-test to compare the total AIR Score between groups, and a MANOVA to assess differences among subscores. Post-hoc subscore analyses included two-tailed t-tests with Bonferroni corrections and effect size (ES) characterization using Cohen's d.

Results

On average, adolescent athletes displayed higher total AIR Scores compared to preadolescents ($p < 0.001$; ES: 0.62); however, only the foot subscore, which incorporates ankle flexion at initial contact and peak vertical ground reaction force, was significantly different ($p_{MANOVA} < 0.001$; $p_{Foot} < 0.001$; ES_{Foot}: 1.30; Figure 1).

Discussion

The higher average AIR Score observed in adolescents supports our hypothesis, demonstrating sensitivity to differences between groups. While this average provides valuable insight into sample-wide trends, most participants will not sustain an ACL injury. This is reflected in our data, where all metrics were positive, indicating that, on average, both groups were more aligned with uninjured populations. Future work focused on those who deviate most from the uninjured population may provide a more nuanced and clinically valuable understanding of injury risk in these age-groups.

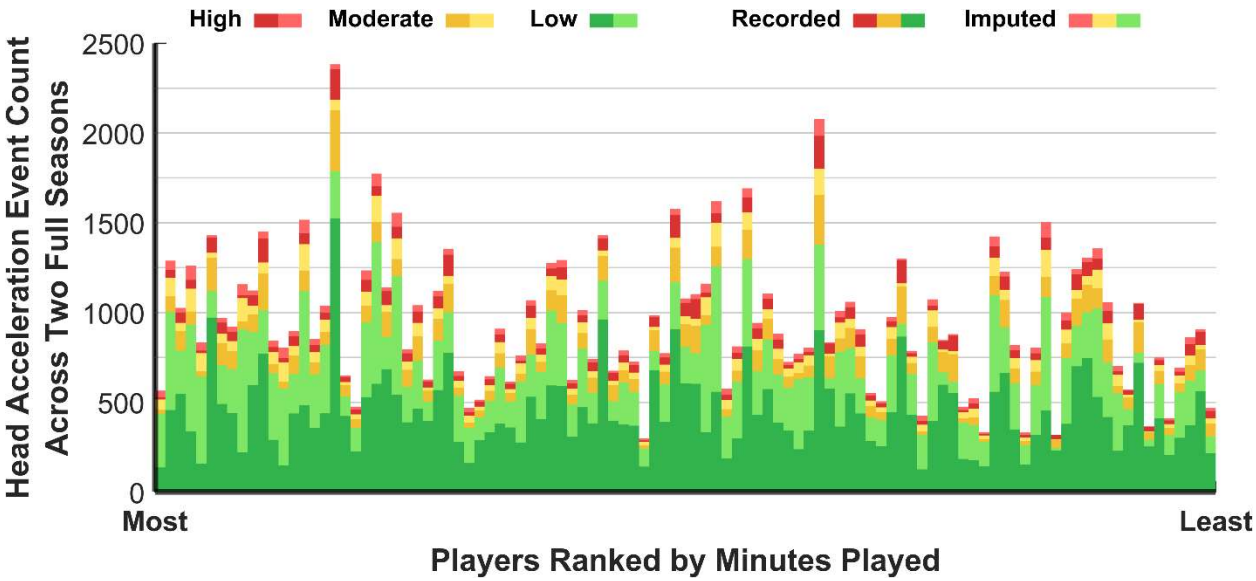
Introduction

Cumulative exposure to head acceleration events (HAEs) in sport is linked to chronic neurological conditions, including chronic traumatic encephalopathy and neurodegenerative diseases. Accurate quantification of cumulative HAE exposure is essential to investigate these risks. Instrumented mouthguards (iMGs) provide objective measurements but often produce incomplete datasets due to player non-compliance or device failures. This study developed a predictive model using video-derived metrics to estimate total HAE exposure among male professional rugby league players when iMG data are missing.

Methods

A prospective study collected data across the Men's Super League 2024–2025 seasons from 347 iMG-wearing players, recording 49.1% (n=4,645) of their player-matches. HAEs were classified into low, moderate, and high magnitude bands using combined peak linear and angular acceleration thresholds with an elliptical boundary: 10*g*/1000 rad/s^2, 25*g*/2000 rad/s^2, and 40*g*/3000 rad/s^2, respectively. A generalised linear mixed model (GLMM) predicted HAE counts using a range of predictors derived from commercial video analysis data, such as minutes played and number of tackles and carries made. Predictive performance was evaluated via mean absolute error (MAE) and root mean squared error (RMSE). Cumulative HAE exposure over two seasons was estimated for players with at least five iMG-recorded matches in each season (n=104).

Results



The MAE (normalised to HAE count) of prediction was 1.9 (13.2%), 1.3 (39.0%), and 0.9 (53.9%) for low-, moderate-, and high-magnitude HAEs, while RMSE (normalised to HAE count) was 2.4 (16.8%), 1.6 (49.5%), and 1.3 (74.3%). The median (interquartile range [IQR]) estimated HAE count across two seasons was 667 (551-904), 142 (96-188), and 73 (50-99), for low-, moderate- and high-magnitude HAEs. Exposures were right-skewed with outliers

(Figure 1), including 18 players exceeding 1,000 low-magnitude HAEs and one with 250 high-magnitude HAEs.

Discussion

These findings demonstrate the feasibility of using video-derived variables to impute missing iMG HAE data, improving estimates of cumulative head impact exposure. Such comprehensive exposure assessment is critical for understanding potential neurological risks and monitoring pre- and post-season variations linked to HAE load. Notably, exposure variability suggests subsets of players may face elevated risk from high cumulative HAEs, warranting targeted surveillance and intervention. Future model refinement may improve accuracy.

Adaptive Flyband® ExoBoot Improves Proximal Joint Mechanics Without Restricting Ankle Function

Miss Gabrielle Moser[1,2], Miss Jania Williams[1,2], Dr. Corbin Rasmussen[1,3], Dr. Farah Fallahtafti[1,2], Dr. Arash Mohammadzadeh Gonabadi[1,4], Mr. Keith Eriks[5], Mr. Thomas Cotton[5], Mr. Mark Roser[5], Dr. Sara Myers[1,2]

[3]Dept. of Exercise Science & Pre-Health Professions, Creighton University, Omaha, Nebraska, United States. [4]Institute for Rehabilitation, Madonna Rehabilitation Hospitals, Omaha, Nebraska, United States. [5]Results Group LLC dba Motive Labs, Glastonbury, Connecticut, United States

Introduction

Musculoskeletal overuse injuries are the leading cause of lost duty time in U.S. service members, with lateral ankle sprains being the most common. Conventional military boots and braces stabilize the ankle, but they limit natural ankle motion and increase compensatory knee and hip loads. The Flyband® ExoBoot, with an exoskeleton and interchangeable carbon-fiber cartridges, aims to preserve ankle mobility while enhancing lateral stability. This study evaluated knee and hip joint mechanics in Flyband compared to conventional configurations.

Methods

Healthy adults (19–45 yrs) completed walking trials under six randomized conditions: conventional boot/bracing conditions including low, medium, high brace stiffness, and Flyband configurations with matching low, medium, and high cartridge stiffness in the lateral sides. Three-dimensional motion capture (17 cameras, 100 Hz) and force plates (1000 Hz) recorded knee and hip joint angle, moments, and powers across the gait cycle. Discrete peak variables were analyzed using repeated-measures ANOVA ($p < 0.05$). Statistical Parametric Mapping (SPM) identified time-varying differences across the gait cycle (Sidak-Holm corrected).

Results

Flyband conditions produced meaningful improvements in knee and hip kinetics compared with conventional boots. Conventional configurations generated higher knee flexion torques in early and late stance (Figure 1; $p < 0.05$), while Flyband use increased early- and mid-stance knee power absorption and reduced frontal-plane knee abduction torque

during initial loading ($p < 0.05$). At the hip, Flyband conditions increased energy absorption during early stance and reduced swing-phase power demands.

Discussion

The proximal kinetic changes observed with the Flyband configuration suggest a more efficient and coordinated transfer of frontal-plane loads through the lower limb, reducing the compensatory torque patterns commonly associated with stiff military boot designs. These changes, along with the redistributed energy absorption during stance, indicate that the Flyband system may create a mechanical environment that better supports the ankle's ability to manage inversion–eversion demands. Importantly, this improved proximal control may help stabilize the ankle without restricting its natural motion. Taken together, these findings highlight the potential for optimizing knee and hip mechanics to indirectly reduce distal inversion loading, offering a promising strategy for mitigating lateral ankle sprain risk in operational settings.

Images (Optional)

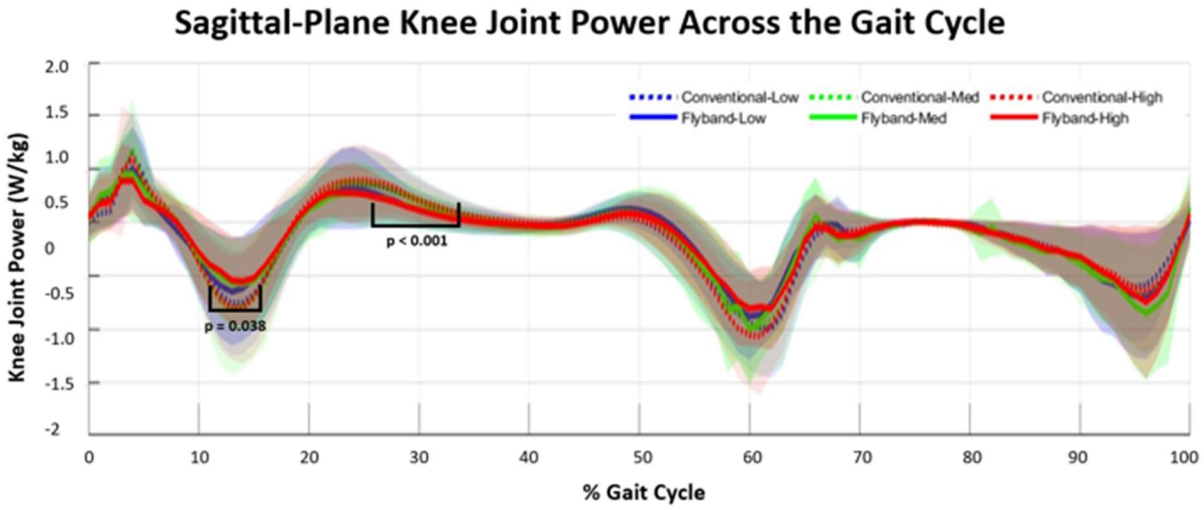

Figure 1. A significant main effect of boot condition on knee joint power was observed at 10–15% ($p = 0.038$) and 25–35% ($p < 0.001$) of the gait cycle.

Head Impact Exposure Device Validation Through Variation in System Coupling

Mr. Blake Robertson MS, Dr. Mitchell Abrams PhD, Dr. Jason Luck PhD

Duke University, Durham, North Carolina, United States

Mr. Blake Robertson

Introduction

Traumatic brain injury research focusing on characterizing head impact exposure (HIE) in sports has spawned a variety of measurement systems. Historically, these systems have varied attachment methods resulting in wide variations in coupling. With coupling being a core consideration in how a system accurately measures head kinematics, it is important to assess the effects of coupling variations on data quality, especially when this data is used to progress scientific understanding of head injury.

Methods

A modified anthropomorphic test device (ATD) head incorporating an "ear" attachment, that accommodates individualized ear canal inserts was used to assess the effects of variation in sensor coupling. A wearable HIE sensor (Duke DASHR) was placed in the ATD "ear" and dropped at three heights (10, 30, 60 cm), yielding impacts ranging from ~25g to ~110g . A Riddell Speed helmet was placed on this modified Hybrid III 50^{th} male headform. Two conditions were tested (coupled, "less" coupled) and drops were conducted at the vertex of the helmeted ATD, with three replicates of each condition. A six-degree-of-freedom reference block (Endevco 7264C-2000; DTS ARS PRO-8K) was placed at the ATD center of mass (CoM). Data was sampled at 100kHz for 1300 ms (650 ms of pre-trigger). Raw signals were filtered with an eighth-order Butterworth low-pass filter with a 300Hz cutoff frequency. DASHR data was transformed from the location of the ear to the headform CoM. Peak resultant linear accelerations between the DASHR and reference were compared for the two conditions.

Results

Initial findings indicate good agreement between the DASHR and reference in impacts under both conditions (Figure 1a/1b). Regression slopes for linear acceleration were similar between the coupled (m=0.93; R^2=0.998) and "less" coupled condition, (m=0.92;

R^2=0.996). On-going testing will evaluate the two conditions in frontal, facemask, oblique, parietal and occipital impacts.

Discussion

These findings demonstrate proof-of-concept for a novel wearable testing platform and methodology, incorporating subject-specific anatomic features and variable degrees of coupling. This enables testing and validation of wearables for use in exposure conditions, and provides the potential to evaluate best and worst case coupling states for instrumentation prior to field deployment, better contextualizing system error and field collection results.

Images (Optional)

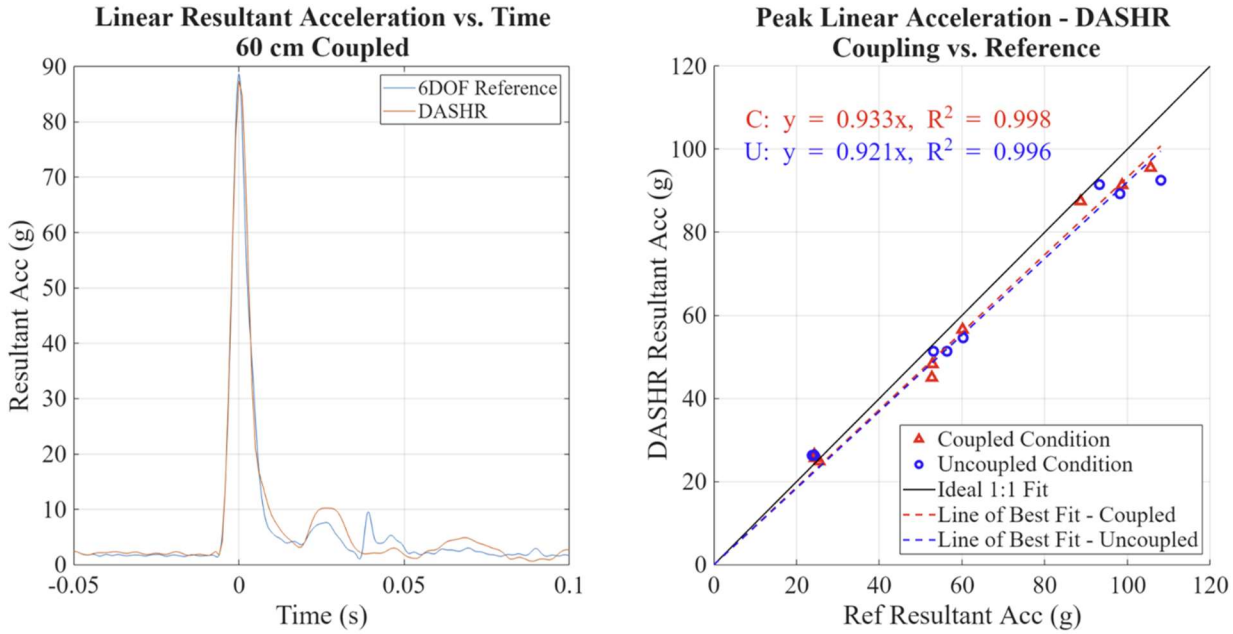

Figure 1: (a) DASHR and 6DOF resultant linear acceleration from a 60 cm helmeted vertex impact and (b) DASHR accelerations in both coupled conditions are similar to 6DOF reference

A Regularized Framework for Accelerometer-Only Determination of Rigid-Body Motion, With Applications in Mild Traumatic Brain Injury

Ms Jeetika Patangia, Dr Haneesh Kesari

Brown University, Providence, Rhode Island, United States

Introduction

Rapid accelerations and decelerations can cause mild Traumatic Brain Injury (mTBI). Continued exposure to mTBIs can lead to the onset of neurodegenerative diseases, such as Chronic Traumatic Encephalopathy (CTE). Because mTBIs often lack clear and immediate symptoms, quantities related to head kinematics, such as those used in the Head Injury Criterion (HIC) and the Brain Injury Criterion (BrIC), are commonly used as measures of the risk of injury (RoI) during falls and blunt impacts. The availability of comprehensive and high-quality kinematic data enables the development and application of improved RoI measures.

Methods

Recent work has introduced algorithms that provide comprehensive information about the head's kinematics from four surface-mounted tri-axial accelerometers. These algorithms are referred to as the Accelerometer-Only (AO) algorithm [1, 2]. In these algorithms the head's motion is approximated as that of a rigid body. Among other quantities they yield an estimate the head's angular acceleration. This is quite a valuable quantify since it is significantly involved in creating brain strains, and strain rates and hence mTBI; and the only other way of obtaining it is through the numerical differentiation of angular velocity, which that method is known to greatly amplify the experimental noise.

Results

However, the AO algorithms are constrained by the fact that the sensors cannot be placed arbitrarily. When the four sensors get close to a planar configuration, a matrix involved in its application becomes ill-conditioned. In the present work, we address this limitation by using Tikhonov regularization to invert the ill-conditioned matrices. We show that using Tikhonov regularization it is now possible to apply the AO algorithm to cases on which it previously failed. We demonstrate this using both synthetic and experimental data.

Discussion

For head-worn applications, sensors are commonly positioned along accessible regions like the forehead, where stable contact can be ensured. This inevitably creates a nearly coplanar layout, making the regularized AO approach especially useful for preserving reconstruction accuracy.

Relationships Between Applied Force and Selected Anthropometric Measures on Hand-Arm Vibration Transmissibility During Hand-Held Power Tool Use

Mr. Jeffrey Lim B.Eng., Dr. Karen Gordon Ph.D., P.Eng., Dr. Michele Oliver Ph.D., P.Eng.

University of Guelph, Guelph, Ontario, Canada

Introduction

Hand-arm vibration (HAV) syndrome can occur from the use of handheld power tools. ISO 5349-1 provides guidance on hand-arm vibration exposure limits; however, anthropometric and force application factors are not incorporated into the standard. The purpose of this research was to determine if selected anthropometric and force factors are correlated to unweighted and ISO 5349-1 weighted HAV transmissibility.

Methods

7 males (22.6±2.5 yrs.; 176.0±9.4 cm.; 77.2±12.3 kg.) and 5 females (22.4±1.1 yrs.; 162.4±7.4 cm.; 60.8±4.7 kg.) took part in the study. Refer to Table 1 for additional anthropometric measures used. Using 2 triaxial ICP accelerometers, one attached to the tool and one to the wrist as per ISO 5349-2, data was collected while participants completed 2 tasks using a drill (drilling a hole or inserting a screw) and 2 tasks using a sander (sanding using 60 or 220 grit sandpaper). Each task took approximately 5 seconds and 3 trials of each task were completed in random order. Unweighted and weighted (as per ISO 5349-1) transmissibility was calculated for each task and trial using a vector sum of the tool and the wrist accelerations. A force plate placed below the work surface collected triaxial force data and participants stood on a variable height platform, which was adjusted such that their elbow angles were approximately 90º. Correlations between weighted and unweighted transmissibility, applied force (X,Y,Z, vector sum), and anthropometric measures were quantified using Spearman's Rank correlation coefficients. All statistics were performed using IBM SPSS ($p \leq 0.05$).

Results

Significant correlations ($p<0.05$) are presented in Table 1.

Discussion

Unweighted transmissibility showed increased correlation with higher significance than weighted transmissibility. Unweighted correlations showed drilling a hole correlated positively with vector sum force and negatively with height. Both sanding tasks correlated positively for the vector sum and Z-axis applied force and negatively for height, hand length, and arm length. The reduced correlation for the weighted transmissibility may be due to the non-linear weighting from ISO 5349-1's effect on the monotonic Spearman test. This research suggests that ISO 5349-1 should consider applied force and anthropometric variables due to their correlations with transmissibility.

Images (Optional)

Table 1: **Spearman's Rank Correlation for ISO-5349 weighted and unweighted transmissibility.** Results from Spearman Rank Correlation tests correlating weighted and unweighted transmissibility in each task using anthropometric and force factors. Variables were included if $p<0.05$ and $|\rho|\geq 0.4$.

Modeling How the Neck Constrains Head Motion in Contact Sport Impacts: Sex and Directional Differences

Miss Jessica Toone, Mr. Zaryan Masood, Dr. Lyndia Wu PhD

University of British Columbia, Vancouver, British Columbia, Canada

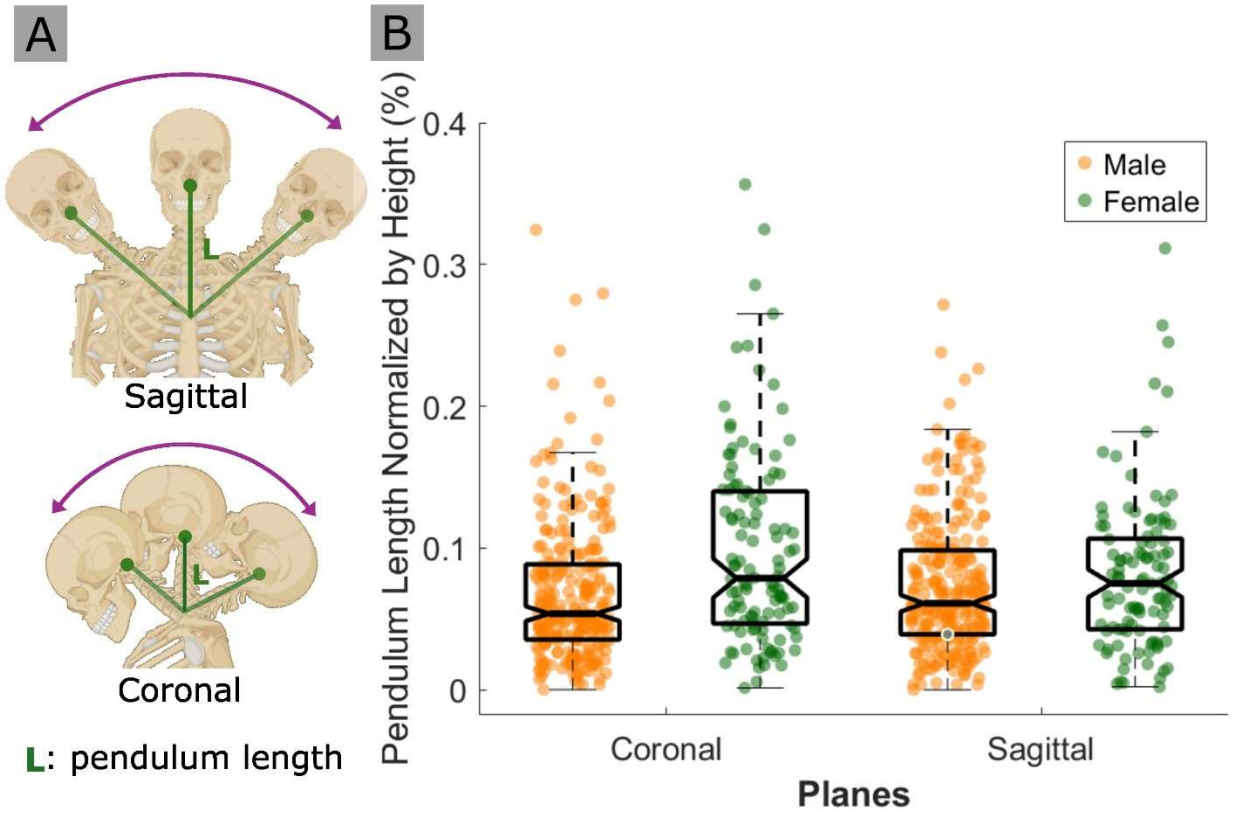
Introduction

Contact sports athletes experience hundreds of head impacts per season [1]. During these impacts, linear and angular kinematics are coupled through the head-neck musculoskeletal system, which can be modeled as an inverted pendulum [2]. The pendulum's effective length, represented by the distance between the head's center of gravity (CoG) and a pivot point along the spine, may reflect neck and torso engagement during impacts. This study examined the effects of plane and sex on pendulum length during impacts.

Methods

Head impact kinematics were collected using Prevent Biometrics instrumented mouthguards (iMGs) for women's rugby and men's hockey. Only video-verified direct head impacts were included. Raw iMG data was processed using a standardized pipeline and transformed to the head's CoG. Pendulum length was calculated as the ratio between linear and angular accelerations in the sagittal and coronal planes. Values were normalized by athlete height. Only impacts consistent with the inverted pendulum assumption (with positive lengths) were included. A linear mixed effect model tested the effects of plane and sex on mean pendulum length, with player ID as a random effect.

Results



Of 608 men's hockey and 411 women's rugby impacts, 291 and 162, respectively, had positive pendulum lengths in either plane. Mean lengths were 13.7 cm in the sagittal plane and 14.0 cm in the coronal plane. Males exhibited shorter pendulum lengths than females. Sagittal lengths were on average 1.7 cm lower than coronal values. A significant plane-by-sex interaction indicated plane differences varied by sex.

Discussion

This study provided insights into how the spine constrains head motion during impact. Longer coronal pendulum lengths align with prior findings [2]. The finding that males have shorter pendulum lengths is unexpected given that males have longer necks than females [3]. These results may reflect sport-specific impact scenarios rather than purely

anatomical differences A key limitation is sex comparisons were drawn from different sports. Future studies should investigate sex-based differences within the same sport to better isolate biomechanical contributions to head–neck kinematics.

Multi-directional volunteer fall experiments during bus braking maneuvers

Mr Jia-Cheng Xu MSc[1,2], Mr Zhou Zhou PhD[1], Mr Christer Ahlström PhD[2], Professor Svein Kleiven PhD[1]

[1]KTH Royal Institute of Technology, Huddinge, Stockholm, Sweden. [2]VTI, Swedish National Road and Transport Research Institute, Linköping, Östergötland, Sweden

Introduction

Bus transport is central to sustainable urban mobility, yet non-collision accidents such as harsh braking often lead to fall-related injuries, including traumatic brain injuries and hip fractures. Preventing such falls is essential to promote safe public transport use. However, bus-related falls remain understudied. Understanding fall kinematics and impact configurations can inform both active safety (driver maneuvers) and passive safety (impact-friendly floors and handrails).

This study presents the first volunteer fall experiments in three fundamental directions (forward, sideways, backwards) during realistic braking maneuvers. The objective is to evaluate impact sequences and kinematics during falls from standing height inside a moving vehicle.

Methods

Nineteen healthy adults (20–43 years, 7 females and 12 males) participated. To avoid impacts with bus handrails, the experiments were conducted on a truck bed, equipped with 30 cm gymnastic mattresses. Participants wore helmets and wrist guards for safety. They initially held a vertical handrail during acceleration but released it well before the braking phase to ensure natural falls. Participants were instructed to remain upright and avoid compensatory stepping. The truck accelerated to a constant velocity of 20 and 25 km/h, then braked to produce average peak decelerations of 2.5 and 3.5 m/s^2.

Results

Preliminary observations indicate distinct impact patterns for each fall direction. Forward falls generally resulted in initial hand and wrist impacts, reducing direct head contact. Sideways falls typically began with the ipsilateral leg or knee, followed by hip impact and

occasional rotational head contact in the frontal plane. Backward falls started with the buttocks and outstretched hands absorbing the initial impact, but were consistently followed by a clear head impact in the sagittal plane.

Discussion

Compared to laboratory fall experiments, the longer duration of braking maneuvers (several seconds) may increase head injury risk. Our findings will inform bus safety simulations using finite element human body models to predict common injuries to the head, hip, and wrist.

Comparison of Cervical Spine Compression, Tension, and Shear Forces in Low Speed Rear-End Collisions

Mr. Jordan Ogbu Felix, Ms. Keya Zambare, Dr. Kevin Adanty, Dr. Sean Shimada

Aperture LLC, Davis, CA, United States

Introduction

Studies often cite compression as a potential mechanism for neck injury during motor vehicle collisions. However, rear-end impact studies show that the greatest occupant neck force magnitudes are in the transverse plane, generating shear and tensile forces on the spine [1]. This study compares anteroposterior shear, tensile, and compressive forces in the cervical spine during rear-end impacts. Quantifying relative magnitudes of these forces may clarify which loading mechanism most warrants mitigation efforts to reduce neck injury risk in rear-end collisions.

Methods

Peak upper (C1-occipital condyles) and lower-neck (T1) tension, compression, and anterior/posterior shear forces were obtained during head-restraint contact from rear-end sled tests from the Insurance Institute for Highway Safety database (n=322). All tests used belted BioRID-II ATDs, simulating 16 kph delta-v impacts. Peak neck force magnitudes and corresponding peak force times were compared using a one-way repeated-measures ANOVA.

Results

Upper Neck

Tension loads (603±43N) were significantly greater than shear and compression ($p<0.001$) (Table 1). There were no significant differences between posterior and anterior shear loads ($p=0.20$) and between anterior shear and compression ($p=0.19$). Time-to-peak differed significantly between all loading mechanisms ($p<0.001$) except between posterior shear and compression ($p=0.58$).

Lower Neck

Anterior shear loads (352±85N) and tension (252±163N) were significantly greater than posterior shear and compression ($p<0.001$). Differences in time-to-peak were not significant between tension and compression ($p=0.27$) and between anterior shear and

compression ($p=0.17$) but were significant between all other loading mechanisms ($p<0.05$).

Discussion

In the upper neck, tension loads were the greatest, while shear forces were the lowest. Conversely, in the lower neck, anterior shear and tension loads were the greatest, with posterior shear being the lowest. These patterns align with studies indicating tension has the greatest magnitude in upper cervical loading [2] and that lower cervical segments experience elevated shear and tension loads [3]. Our results suggest that tensile and shear forces generally exceeded compressive forces in rear-end crashes, therefore, future research should prioritize strategies that mitigate these dominant loading mechanisms to help reduce neck injury risk.

Images (Optional)

Table 1: Cervical spine average peak forces and time to peak force

Neck Region	Load Type	Average Peak Force (N)	Average Time to Peak force (ms)
Upper Neck	Anterior Shear (n=318)	91.3 ± 91.9	130 ± 14.4
	Posterior Shear (n=97)	91.8 ± 38.6	91.3 ± 14.7
	Tension (n=310)	603 ± 282	93.4 ± 40
	Compression (n=216)	105 ± 43.3	110 ± 13.6
Lower Neck	Anterior Shear (n=127)	352 ± 188	115 ± 14.1
	Posterior Shear (n= 243)	33 ± 14.2	93.4 ± 49.2
	Tension (n=319)	242 ± 163	111 ± 15.8
	Compression (n= 146)	175 ± 90.4	113 ± 36

THUMS AM50 Upper Extremity Response to Ballistic Shield Loading in Comparison to Experimental Data

Dr. Julia de Lange Ph.D., P.Eng.[1,2,3], Dr. Cheryl Quenneville Ph.D., P.Eng.[2]

[1]30 Forensic Engineering, Toronto, Ontario, Canada. [2]McMaster University, Hamilton, Ontario, Canada. [3]University of Guelph, Guelph, Ontario, Canada

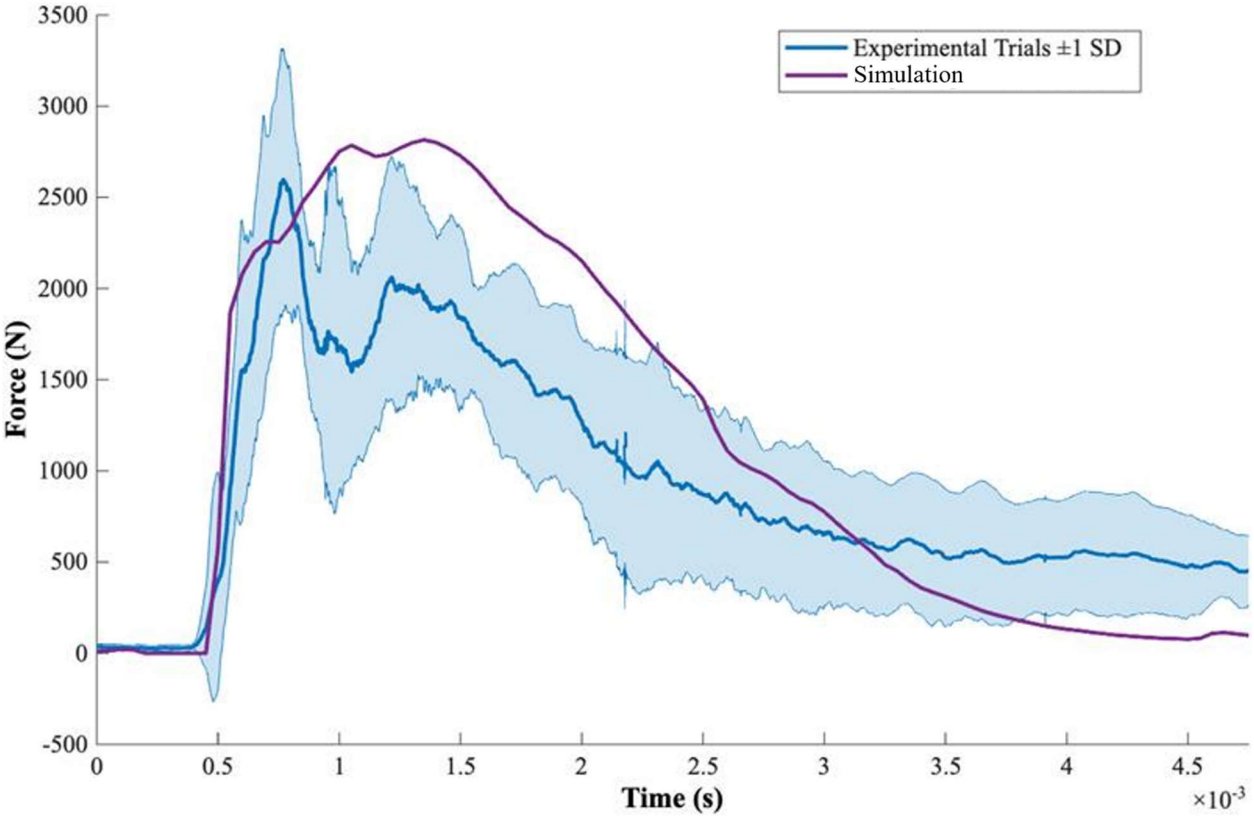
Introduction

Innovative finite element models are important for the design and advancement of safety systems due to the complexities surrounding post-mortem human surrogate (PMHS) and physical surrogate testing. To ensure biofidelity, these models must be verified against experimental data. Behind shield blunt trauma (BSBT) is an injury mechanism that describes blunt trauma resulting from rapidly deforming ballistic shields. This unique loading condition to the upper extremity has resulted in vastly different injury mechanisms and thresholds than automotive loading conditions [1]. Models like the Total Human Model for Safety (THUMS) can help with developing protective devices but must have an appropriate response under this unique injurious scenario. The THUMS upper extremity has been previously shown to agree with experimental fracture data at airbag-level loading rates (3 m/s and 7.6 m/s) [2]. The purpose of this study was to assess the fracture response of the THUMS forearm to BSBT impacts through comparison with previous experimental work.

Methods

Experimentally, eight mid-sized male PMHS were impacted at the forearm at loading rates representative of a deforming ballistic shield (velocity of 16.9 m/s) [1]. One specimen was instrumented with triaxial strain gauges at the mid-radius and mid-ulna to collect bone strain. The THUMS 50M upper limb was used, with fracture implemented using an element erosion technique. Critical plastic strain was informed by the radial strain (1.26%) measured during the experimental impact. The impact conditions that resulted in fracture were recreated against the THUMS model.

Results



The peak applied force during the THUMS simulation was 2,815 N (<1% lower than the experimental test of the gauged specimen). Both the ulna and radius fractured in the simulation, in agreement with the experimental impact; however, unlike the experimental

results, the radius only fractured at one location. Additionally, the force-time curve did not display a drop after the initial peak, as occurred experimentally.

Discussion

Additional computational modelling is ongoing to improve the model response. Once validated, these models may be useful for early shield design and corresponding injury risk assessment.

Effectiveness of Restraint Use in Reducing Lower-Extremity Injury Severity During High-Speed Frontal Collisions: A Case Study Utilizing MADYMO

Dr. Kari Verner Ph.D., P.E.[1], Dr. Delanie Lynch Ph.D.[2], Mr. Dominic Demma M.S.[3], Dr. Steve Rundell Ph.D., P.E.[3]

[1]Explico, Englewood, Colorado, United States. [2]Explico, Englewood, colorado, United States. [3]Explico, Novi, Michigan, United States

Introduction

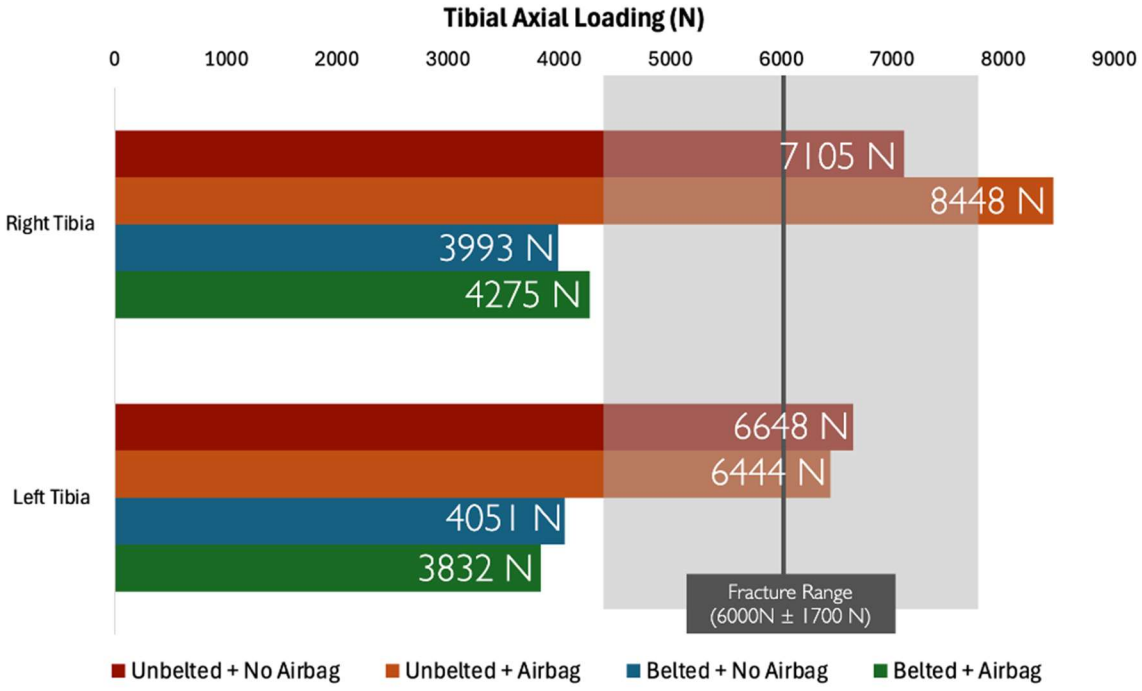
High-severity frontal impacts can cause AIS 2+ lower-extremity injuries, even for restrained occupants[1], and intrusion further increases incidence and severity of these injuries[2].

The objective of the present study was to quantify the influence of restraint use (seatbelt and frontal airbag) on tibial axial loading during a high-severity frontal impact with measurable occupant compartment intrusion. We hypothesized that seatbelt use would decrease the effective mass transmitted to the lower extremities and, consequently, reduce the likelihood of tibial fracture even under intrusion conditions representative of a real-world crash.

Methods

A MADYMO simulation was developed to replicate a real-world frontal collision scenario using the EDR-recorded crash pulse (delta-V = 41mph), 3D geometry of the damaged occupant compartment, and a virtual Hybrid III 50th percentile ATD scaled to the actual driver's height and weight (72in, 265lb). Airbag deployment and seatbelt pretensioner firing were modeled according to the EDR-recorded data. Four scenarios were simulated: Unbelted+No Airbag, Unbelted+Airbag, Belted+No Airbag, and Belted+Airbag. Tibial axial loading was determined in both legs for each scenario.

Results



In belted conditions, tibial loads were similar between sides and remained below the experimental fracture range (4.8kN-7.6kN)[3] regardless of airbag deployment. In contrast, unbelted scenarios were all within or greater than the fracture range, with higher forces on the right. The absence of a seatbelt increased tibial axial force by 64-98% (Figure 1).

Discussion

Seatbelt use reduces tibial plateau fracture risk in high-speed frontal collisions with occupant compartment intrusion, while airbag deployment alone had minimal effect. Higher forces on the right tibia were observed in unbelted scenarios, likely due to leg entrapment between the brake pedal and dash. This finding, and the findings in general, align with the actual subject injuries: the unrestrained driver sustained bilateral tibial plateau fractures, with the right side more severe.

Consistent with prior research, our findings show that seatbelts mitigate lower-extremity injuries in high-energy frontal collisions, while airbags alone may actually increase injury severity[1].

Development of a Subject-Specific MADYMO Model Predictive of Tibial Plateau Fractures in a High-Speed Frontal Collision Case Study

Dr. Kari Verner Ph.D., PE[1], Dr. Delanie Lynch Ph.D.[1], Mr. Dominic Demma MS[2,3], Dr. Steve Rundell Ph.D., PE[2]

[1]Explico, Englewood, CO, United States. [2]Explico, Novi, MI, United States. [3]Wayne State University, Detroit, MI, United States

Introduction

Despite the low incidence of tibial plateau fracture (~10% of lower extremity injury [1]) in motor vehicle crashes, these high-energy fractures carry poor long-term outcomes.

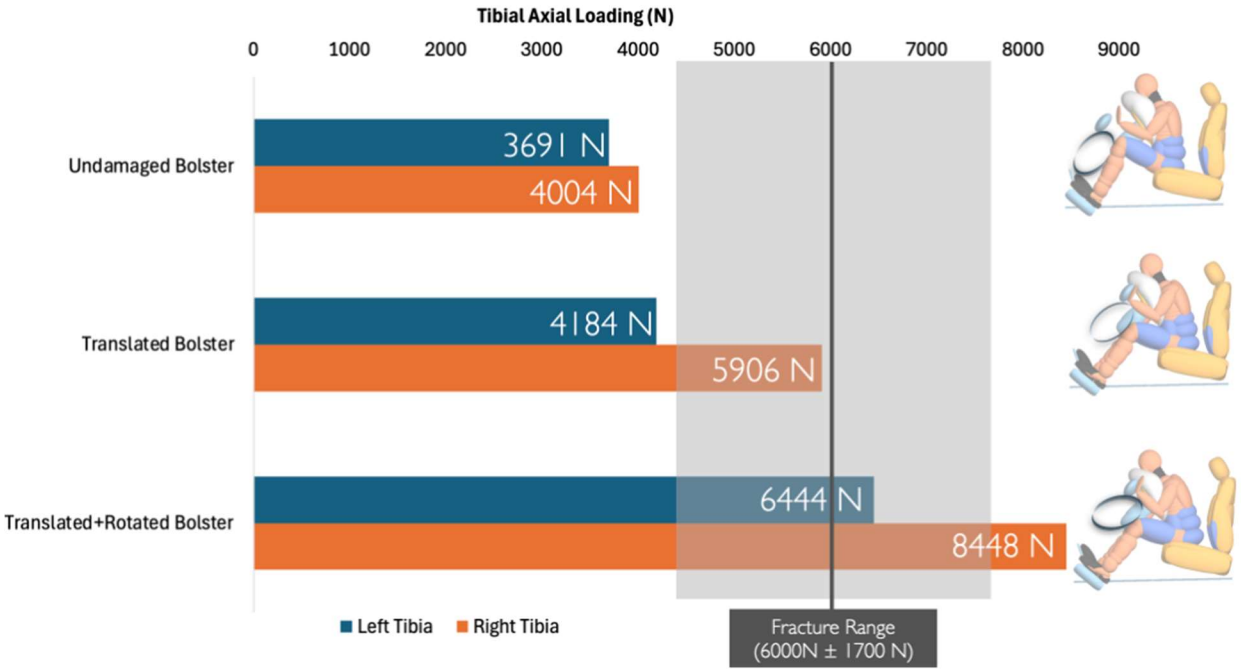
We encountered a case study of a high-energy frontal crash (EDR recorded longitudinal delta-v: -41 mph) with significant underride and an unbelted driver who sustained bilateral tibial plateau fractures, with greater severity on the right. The objective of the present study was to develop a computational model capable of simulating a this high-energy frontal collision with substantial occupant compartment intrusion and an unrestrained occupant. We hypothesized that modeling of the occupant compartment intrusion would result in forces on the lower extremities consistent with the real-world injuries.

Methods

The vehicle interior was modeled in MADYMO based on a 3D point cloud of an undamaged exemplar vehicle. A virtual Hybrid III 50th-percentile ATD ellipsoid model was scaled to the subject driver's height and weight (72 in, 265 lb) and positioned using the driver's testimony and post-incident seat photos. The steering wheel airbag was deployed but a seatbelt was not utilized.

The knee bolster initial position was modeled based on the undamaged exemplar, and then iteratively translated and rotated to simulate increasing amounts of intrusion. The amount of intrusion was assumed to be completed by the time the occupant interacted with the knee bolster.

Results



Increasing rearward and upward translation with clockwise rotation of the knee bolster led to higher axial tibial loads bilaterally, with forces about twice as high as those predicted by

the undamaged exemplar configuration [**Figure 1**]. Additionally, in all configurations, loads in the right tibia were greater than the left.

Discussion

In the fully translated and rotated condition (representative of intrusion), the tibial loading predicted by the model was consistent with both the real-world resulting injuries (bilateral tibial plateau fractures) and published fracture tolerances. The predicted axial loads in the tibia were within experimental ranges for tibial plateau fractures (4.8kN-7.6kN) [1]. Notably, the model also predicted higher forces in the right tibia relative to the left, which was consistent with fracture severities documented in the real-world scenario.

Calculating Low Back Moments of Personal Support Workers using Bottom-up Models Driven by Smart Insoles Versus Top-down Models Driven by Estimated Hand Forces

Ms Kate M. Posluszny MSc, Mr. Justin B. Davidson MSc, CSCS, Dr. Steven L. Fischer PhD, RKin, CCPE

University of Waterloo, Waterloo, ON, Canada

Introduction

Community-based personal support workers (PSWs) need effective interventions to reduce the high prevalence of low-back musculoskeletal disorders. However, effective interventions require insight on exposure where knowledge of PSWs' low back loads is sparse. Few methods are available to measure low back exposure data in-field with sufficient rigor necessary to inform intervention. Therefore, this study aimed to test how peak lumbar (L4/L5) extensor moments calculated using top-down quasi-dynamic model differed from those calculated using a bottom-up model with ground reaction forces estimated using a field-ready insole sensor.

Methods

Kinematic and kinetic data were collected from 20 PSWs (17F, 3M) simulating 12 PSW tasks [1], where this abstract focused on a patient repositioning task. Top-down quasi-dynamic and bottom-up inverse dynamic rigid link models were developed in Visual3D x64 Professional™ (HAS-Motion Inc., Boyds, MD, USA) to calculate PSWs' lumbar extensor moments. Model inputs included whole-body 3D kinematics collected using a 12-camera Vicon© motion capture system (Centennial, CO, USA), and peak hand forces collected with a Mark-10© force gauge (Copiague, NY, USA) (top-down analysis) or dynamic ground reaction forces collected using Loadsol® pro-mlp (Novel Electronics Inc., St. Paul, MN, USA) (bottom-up analysis). Wilcoxon Signed Rank tests were conducted with JASP© (Amsterdam, Netherlands) to compare differences between the top-down and bottom-up estimated peak extensor moments.

Results

Statistically significant (p=.01) differences in PSWs' extensor moments emerged. Specifically, bottom-up model outputs estimated an average peak extensor moment of 72.6(±60.2)Nm, while the top-down models estimated an average peak extensor moment of 104.6(±38.6)Nm.

Discussion

Due to the use of a hand force matching to estimate peak hand forces, the top-down model estimates may be influenced by subjective errors, while the bottom-up models may provide more reasonable extensor moment estimates. However, further analysis is required to confirm whether the models are primarily influenced by the model's force inputs. It is further important to highlight that criterion kinematics were used to develop these models, which may not be suitable for in-field use. Consequently, future research will also examine the use of wearables to obtain PSWs' position data when in-field.

Investigation of Cushion Type for Mitigating Lumbar Spine Loads caused by Under Body Blasts

Ms. Katerena Sirhan MS[1], Mr. Mark Shafer MS[2], Mr. David Weyland MS[2], Dr. Cameron 'Dale' Bass PhD[1]

[1]Wayne State University, Detroit, MI, United States. [2]GVSP, Warren, MI, United States

Introduction

Seated personnel exposed to underbody blast (UBB) in military vehicles have an increased risk for lumbar spine injuries owing to direct inferior to superior compression caused by the blast. The purpose of this study is to determine seat pan material that could improve force mitigation to the lumbar spine during an UBB event. A range of simulated UBB events were conducted using a Sub System Drop Tower (SSDT).

Methods

The instrumented 50th Hybrid III ATD was placed on a rigid seat mounted to the SSDT platform with three different energy absorbing (EA) material configurations: (1) polyurethane (PU) foam, (2) PU foam layered over EA insert A and (3) PU foam layered over EA insert B. Two analysis methods were used to assess injury risk of the lumbar spine. The first method utilized Injury Assessment Reference Value (IARV) percentages, created by Occupant Centric Platform Technology Enabled Capability Demonstration (OCP TECD). Trendlines were created for each foam thickness comparing IARV% and peak platform acceleration. Acceptable (75%) and Not Acceptable (100%) threshold values were calculated to compare foam thickness to peak platform acceleration.

The second method is the compression/flexion cadaveric lumbar injury criterion proposed by Ortiz-Paparoni et. al. (2020). The lumbar injury criterion (L_{ic}) risk is calculated: (Image)

F_r is the lumbar resultant force, My is the y-axis lumbar moment. L_{ic} is the risk of sustaining a vertebral body injury. MATLAB (MathWorks, Inc) was utilized to calculate constant k created from the resultant force and My.

Results

The relationship between peak platform acceleration and thickness of foam correlating to 75% and 100% IARV were further explored to determine the optimal EA cushioning combination appropriate for any given threat within the tested range.

Increasing L_{ic} values are generally associated with increasing seat acceleration. There is a clear asymptotic effect in the data for sufficiently large accelerations. The 76 mm thickness PU foam results were statistically different from the other test conditions ($p>0.01$).

Discussion

The results show a nonlinear relationship between Lic injury assessment criterion and OCP TECD IARV Percentages. Future work will investigate cushion characteristics to identify viable EA solutions up to the desired acceleration range

Voxel-Wise 3D Multiparameter Hyperelastic Tissue Characterization Through Combining Physics-Informed UNet and Optimal Input Loading Dataset Design

PhD Student Amir Asadi AA, Associate Professor Kaveh Laksari KL

UCR, Riverside, California, United States

PhD Student Amir Asadi

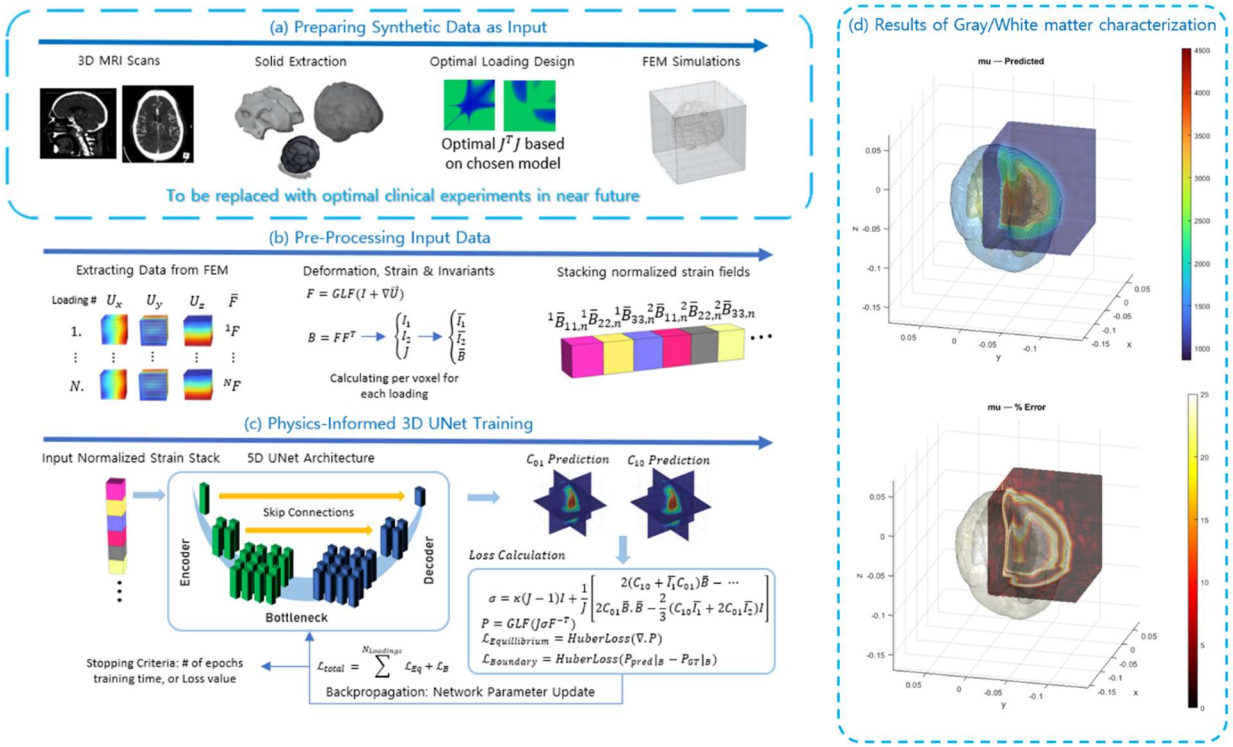
Introduction

Brain tissue is heterogeneous, exhibiting different mechanical characteristics depending on anatomical function and location. These characteristics change in inured tissue or tumors, which renders them as important disease biomarkers. However, mechanical characteristics maps are usually limited to simple linear materials or homogenous approximations for deformation and stress fields, which leads to dismissal of valuable information and inaccurate identification of pathologies [1, 2]. Moreover, it has been demonstrated that material parameter identification is highly sensitive to loading modes and magnitudes as well as measurement noise [3]. Here, we present an optimal experimental design framework to improve robustness of inverse material characterization, and subsequently develop a physics-informed UNet (PI-UNet) framework to determine voxel-wise material parameters for a hyperelastic Mooney-Rivlin model.

Methods

Our novel optimal experimental design framework quantifies conditioning of a given loading scenario by its stress-material Jacobian matrix, motivated by Fisher Information of the inverse problem.

Once optimal loading scenarios are determined, we set out to determine the heterogeneous material parameters of several simulated examples of a cubic sample with various internal structures, including homogeneous matrix with a stiff spherical inclusion, and matrix embedded with tumorous brain tissue. Without a priori knowledge of the distribution of material properties within the cube, and having access only to boundary stress values and 3D displacements, PI-UNet can determine the hyperelasticity and recover the internal structure accurately.



Results

The optimal loading conditions roughly reduce number of required measurements to third to achieve the similar conditioning as random loadings. Using these optimal loads, the PI-UNet framework successfully approximated the material parameters and reconstructed each tissue region by less than 5% error. Moreover, the use of unsupervised clustering within the tumor in brain example led to localization of the lesion based on shear modulus values with Dice similarity of 96%, significantly improving the solely displacement-based approach that assumes a uniform stress distribution leading to Dice similarities of 20-30%.

Discussion

We introduce two novel methodology and validate them on synthetic noisy FE data, demonstrating the feasibility for potential clinical use to achieve more reliable/sophisticated biomarkers in detecting/treating pathologies, surgical planning, and twin modeling.

Raman Microscopy Identification of Overstretch-Induced Collagen Damage in Cerebral Arteries

Mr. William Anderl[1], Ms. Yawen Xue[2], Ms. Nathalie Munoz[2], Dr. Jiaqi Jin PhD[2], Dr. Kenneth Monson PhD[1]

[1]University of Utah, Department of Mechanical Engineering, Salt Lake City, UT, United States. [2]University of Utah, Metallurgical Engineering, Salt Lake City, UT, United States

Introduction

Aside from acute effects, TBI is associated with a variety of long-term sequelae including stroke [1] and neurodegenerative illness [2]. The underlying causes of these prolonged risks are unknown but may be influenced by subtle damage to embedded blood vessels. Detection of sub-failure damage in cerebral vasculature has given mixed results, particularly when examining vessels stretched below yield [3]. Raman microscopy may allow for more precise measurement of subtle vessel damage.

Methods

An ovine middle cerebral artery (MCA) was cut into control, heat denatured, and mechanically damaged sections. The heat denatured vessel was heated at 68˚C for 10 minutes. The mechanically damaged vessel was secured on canulae and pulled axially until failure. Each vessel was fixed and wet mounted on glass slides. Raman spectra were captured using an Invia Qontor microscope (514 nm, 2400 g/mm). For each vessel, two randomly selected areas within the adventitial layer were imaged resulting in 200 sampled points. After preprocessing, intensity ratios were calculated at 1670/1640 cm^{-1}.

Results

Both the mechanical ($p = 0.003$) and heat-denatured ($p<0.001$) vessels showed an increase in the ratio relative to the paired control. Additionally, the mechanically damaged vessel had a lower ratio than the heat denatured sample ($p=0.002$).

Discussion

Unal et al. demonstrated that an increasing 1670/1640 ratio is indicative of collagen triple-helix damage[4]. This is consistent with our findings, in which both mechanically and thermally damaged collagen resulted in an increase in mean ratio (control = 1.24, mechanical = 1.39, heat = 1.476). The ratios are consistent with expected damage levels,

with heat denaturing causing widespread damage. Our findings suggest that Raman microscopy is an appropriate tool to measure focal collagen damage in cerebral arteries, and its implementation may improve future understanding of vessel collagen damage.

Images (Optional)

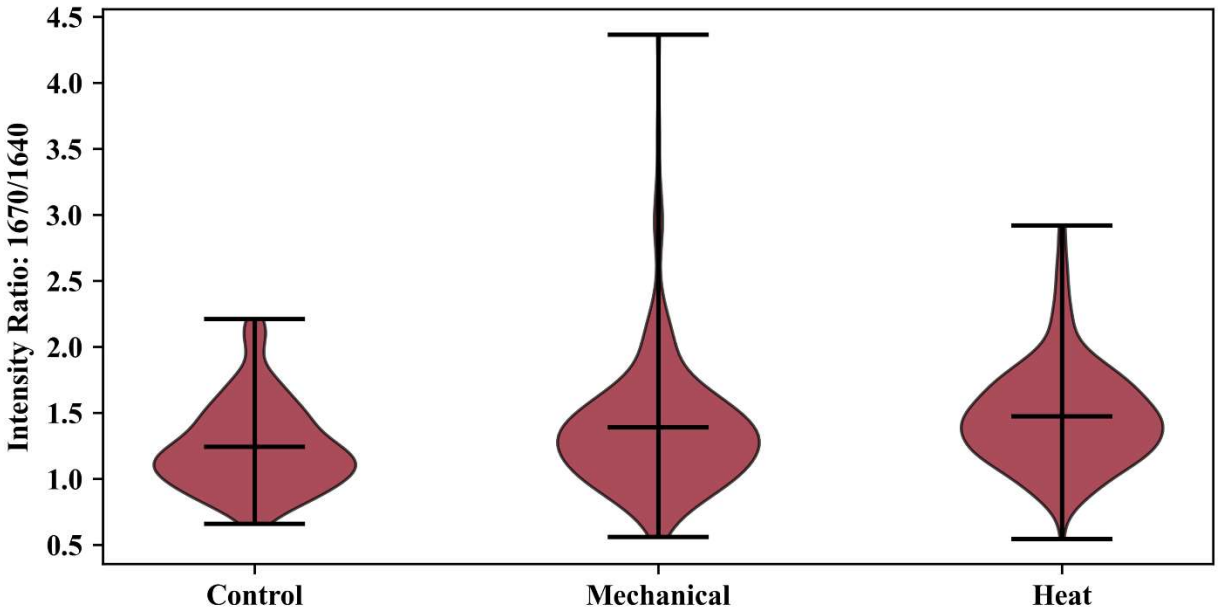

Figure 1. Violin plots of the 1670/1640 intensity ratio for control, mechanical, and heat groups. Central horizontal bars indicate mean, while upper and lower horizontal bars show the full data range. The red violins show the distribution of ratios within each group, where wider portions mark more frequent values. All groups differ significantly from one another, with higher mean ratios in the heat group consistent with more severe global damage compared to mechanical damage.

[6]Womack Army Medical Center, Fort Bragg, NC, United States. [7]Uniformed Services University of the Health Sciences, Bethesda, MD, United States

Introduction

Lower extremity musculoskeletal injuries (MSKI) are a leading problem in military personnel. Thus, rapid and accurate injury screening is crucial for maximizing readiness. A single leg squat (SLS) is a promising screening tool as it is functionally demanding and identifies movement quality impairments associated with injury risk. Machine learning can facilitate automated assessment of motion quality to identify or classify injury status, a precursor to risk prediction. This study determined if machine learning can differentiate between injured and uninjured service members performing SLS

Methods

153 service members with (n=72) and without (n=81) low back or lower extremity MSKI participated in this study (22 F/129 M, mean±SD age:23.8±5.2yr, BMI: 26.7±4.0kg/m^2). Participants performed three SLS per leg while full body motion was collected using markerless motion capture (100Hz, HumanTrak, VALD). We estimated 3D center of mass (COM) peak velocities, accelerations, forces, and power along each axis using a custom Python script. Recursive feature elimination (RFE) identified 7 of 26 top variables for classification, which were used in a linear discriminant analysis (LDA) to classify injured and uninjured participants with an 80-20 train-test split.

Results

Top RFE variables included peak velocity, acceleration, and force in the mediolateral and vertical directions. The LDA model correctly identified 12/15 injured and 12/16 uninjured

participants from the test dataset and accurately classified 77% of injured from uninjured participants with an F1 score of 0.774 and ROC-AUC of 0.804 (Fig. 1).

Discussion

COM control during SLS is linked to lower limb joint alignment, an injury risk factor. Using COM outcomes, model performance was moderate at injury status classification. Influence of the variables varied with inputs into the RFE, model split and sample size. Model refinement, including lower limb kinematics, will likely improve classification. SLS can be especially challenging while injured, thus future research should examine whether other assessments (e.g., double-limb squat, hip strength) could improve modifiable risk factor identification and facilitate earlier treatment.

Images (Optional)

Pure Shear Loading in the Cervical Spine: Replicating Injurious Boundary Conditions

Mr Luis Dias P. Eng[1], Dr Shun Yamamoto[2], Dr Thomas Oxland P. Eng[1], Dr Peter Cripton P. Eng[1]

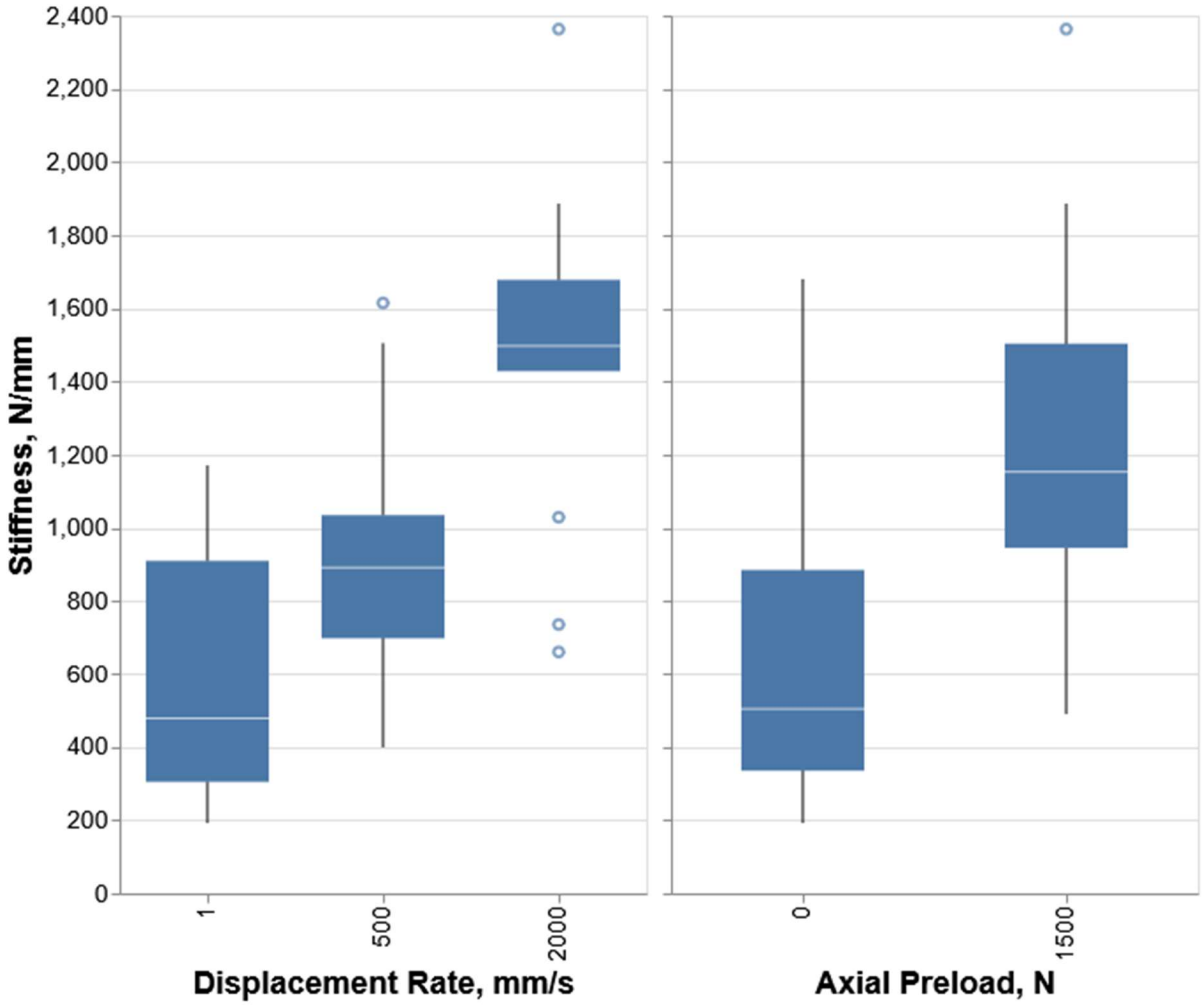
[1]UBC, Vancouver, BC, Canada. [2]Jikei University School of Medicine, Minato, Tokyo Prefecture, Japan

Introduction

Shear is an understudied loading mode in the cervical spine, especially considering its significant role in the formation of fracture-dislocation (FD) injuries [1]. There is a particular paucity of data on pure shear loading under high rates and in combination with a compressive axial preload, which are boundary conditions present in the impact scenarios that result in FD injuries. The objective of this study was to determine the effect of realistic shearing rates and compressive preloads on the sagittal stiffness of the lower cervical spine under pure shear loads.

Methods

Thirty-nine *ex vivo* human Functional Spinal Units (FSUs) were potted in bone cement and attached to a shear loading fixture on a high-rate tensile testing machine. Each FSU was loaded to failure at one of three rates (1, 500, 2000 mm/s) and under one of two compressive preloads (0, 1500 N). Sagittal stiffness was measured from the slope of the pre-failure load-displacement response, and the effects of the displacement rate and compressive preload were evaluated using multivariate linear regression, controlling for demographic (donor age and sex) and anthropometric (disc and facet joint degeneration, bone volume fraction (BV/TV), Anteroposterior width) factors.



Results

Shearing rates of 1, 500, and 2000 mm/s resulted in mean stiffnesses of 588 (SD=332), 915 (SD=367), and 1482 (SD = 463) N/mm, respectively. In the presence of a combined axial preload, specimens had a mean stiffness of 1249 (SD=456) N/mm, compared to specimens with no preload, with a mean stiffness of 693 (SD=465) N/mm. Shearing rate and combined axial preload were both strongly correlated with sagittal stiffness ($p<0.001$ for both), as illustrated in Figure 1. Anteroposterior width and BV/TV were also positively correlated with sagittal stiffness, with $p=0.005$ and $p=0.011$, respectively.

Discussion

Our findings suggest that, under boundary conditions representative of real-world injuries, the cervical spine is much stiffer in shear. As the overwhelming majority of existing *ex vivo* data for the human spine is quasi-static, these findings are particularly salient for computer model validation, especially when such models are to be used for injury simulation.

Sensitivity of Disc Herniation Risk to Variations in Occupant Posture and Seat Positioning During Rear End Collisions

Ms. Yun Cai[1], Dr. Stephanie Rossman[2], Dr. Steven Rundell[1], Dr. Luis Nolasco Ph.D.[1]

[1]Explico, Novi, MI, United States. [2]Explico, St. Petersburg, FL, United States

Introduction

The potential effect of an occupant's posture on spinal loading and disc herniation risk during a rear-end collision has not been previously evaluated. The objective of this study was to use validated computational simulations of rear-end collisions to evaluate how spinal compressive loading responds to variations in occupant posture and seat position. We hypothesized that realistic changes in posture and seat positioning would have minimal influence on spinal compression and, consequently, would not meaningfully affect the risk of intervertebral disc herniation.

Methods

Computational models of the seats of a 2019 Nissan Altima and 2013 Buick Encore were validated using publicly available physical test data of a 10-mph delta-V rear-end collision. Multiple positions and postures were modeled for a 50th percentile male seated in the aforementioned seats. These positions and postures included seatback angle, head facing to the side, torso leaned to the side, and torso twisted. All positions and postures were exposed to a rear-end impact with a change in velocity of 5 mph and an impulse of 100 msec.

Results

The seatback deformation predicted by the computational simulation matched closely with that occurring during the physical crash test (Figure 1). In general, the compressive force experienced at the cervical and lumbar spine was not influenced meaningfully by the variations in occupant posture and seat position. The average peak compression in the cervical and lumbar spine for the Altima seat was 23±1.5 lbs., and 151±10 lbs., respectively. The average peak compression in the cervical and lumbar spine for the Buick seat was 28.5±9 lbs., and 231±18 lbs., respectively.

Discussion

Intervertebral disc herniation is generally associated with compressive loading of the spine, whether arising from a single high-load event or from repetitive loading cycles. In the present study, spinal compressive forces generated during moderately severe rear-end collisions were found to be low relative to both injurious and commonly non-injurious loading thresholds reported in the literature. These findings support the hypothesis that realistic variations in occupant posture and seat positioning do not meaningfully increase spinal compression and, as a result, do not introduce a biomechanical risk of disc herniation.

Comparison of Gelatins as Surrogates for Backface Deformation Analysis of Soft Armor

Ms. Madeleine Tarter, Mr. Andrew Davis, Mr Donald Sherman, Dr. Cynthia Bir

Wayne State University, Detroit, MI, United States

Introduction

Ballistic gelatins are widely used as soft tissue simulants to assess dynamic backface deformation (BFD) of soft body armor to provide insight into armor performance and potential injury risk. Although synthetic gelatins offer shelf stability and reusability compared to the historical gold standard, ordnance gelatin, the comparability of BFD responses between various gelatin formulations remains unknown. This study aims to compare the BFD responses of different gelatin formulations as backing materials using Level II (HG1) soft body armor panels.

Methods

High speed video (20,000 fps) was used to evaluate a total of six different simulants including ordnance gelatine in 10% and 20% concentrations, Clear Ballistics 10% and 20% products, a Perma-Gel 10% product, and a Styrene-Ethylene-Butylene-Styrene (SEBS)-based gel. Ballistic tests were performed using 9 mm FMJ Luger 124-grain projectiles at a velocity of 1140 ± 20 ft/s. Each gelatin type was shot three times from a standoff distance of 5 feet. Post-impact, video analysis was performed using MATLAB scripts[1] to quantify the maximum deformation depth (D_{max}), maximum deformation velocity (DV_{max}), maximum volume (VOL_{max}), and volume growth rate (VGR).

Results

Independent samples t-tests (Table 1) show that 10% ordnance gelatin, 10% Clear Ballistics, and 10% Perma Gel showed no key differences in BFD characteristics. 20% ordnance gelatin and 20% Clear Ballistics gelatin differed in VOL_{max} and VGR with the ordnance gelatin being statistically significantly larger ($p<0.05$). SEBS gel exhibited a smaller VGR than 10% ordnance gelatin and showed significant differences from 20% ordnance gelatin across all metrics ($p<0.05$).

Discussion

Given the variety of gelatins currently being used by the ballistics community, it is important to understand if and how they differ. The SEBS used in the current study was a 30/70% powder/mineral oil composition which was significantly different from the 20%

ordnance gelatin but compared well with the 10% ordnance gelatin. Characterizing the differences in performance will improve interpretation of BFD outcomes and aid in simulant selection for ballistic testing.

[3]The University of British Columbia, VANCOUVER, British Columbia, Canada. [4]Fédération Française de Rugby, Marcoussis, Ile de France, France

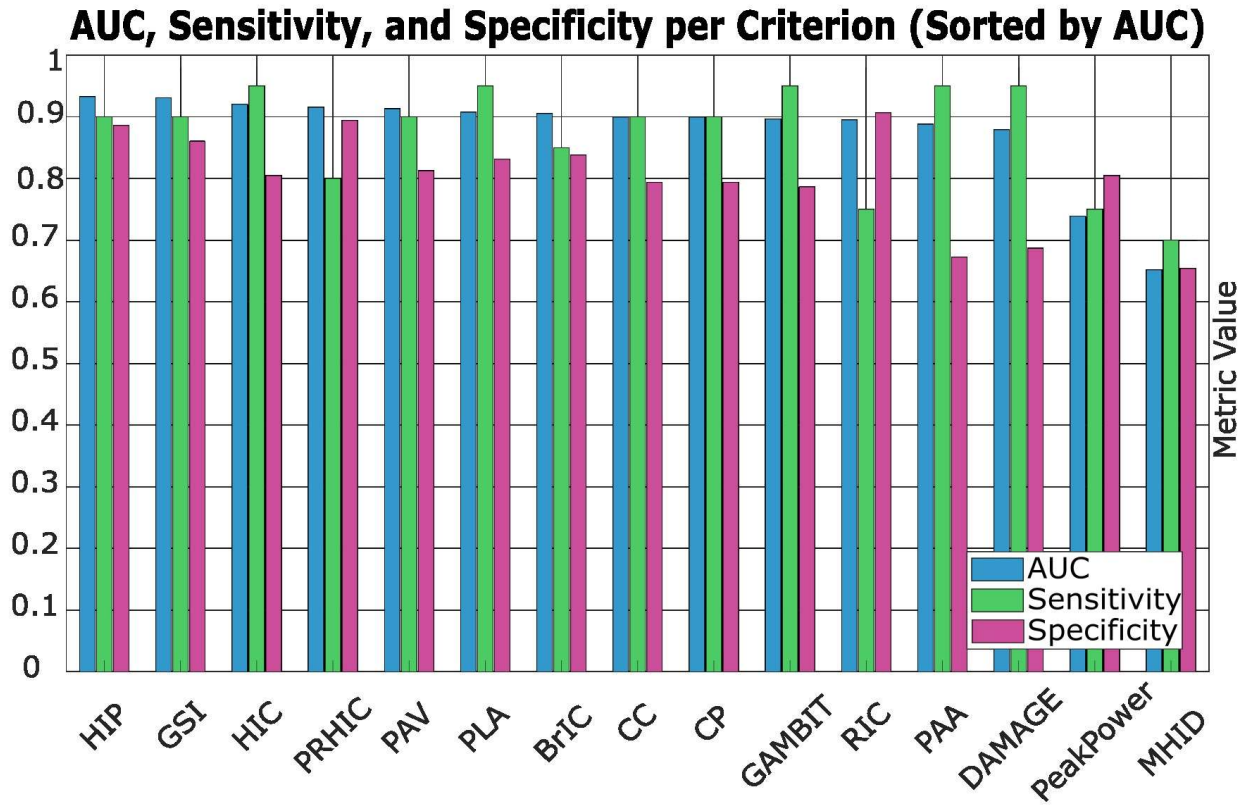
Introduction

Brain injuries remain a major concern in contact sports, and no practical, reliable on-field method currently exists to detect concussions in real time. Medical staff must rely on observable symptoms, which are often subtle or delayed. This study aims to improve concussion detection under real-game conditions using data from instrumented mouthguards that recorded both concussive and non-injury head impacts across multiple men's and women's contact sports.

Methods

A total of 4,846 verified head impacts, including 20 concussions, were collected from male and female athletes of the French National Rugby Teams and varsity rugby and ice hockey players at the University of British Columbia. Each impact included a 50 ms window of linear acceleration, angular acceleration, and angular velocity sampled at 3200 Hz using Prevent Biometrics mouthguards. Signals were processed using two filtering pipelines: the manufacturer's proprietary filter and a 4th-order Butterworth low-pass filter at 300 Hz.

From these signals, several biomechanical criteria—such as BrIC, HIP, and DAMAGE—were computed to discriminate concussive from non-injury events. Model performance was evaluated using three complementary approaches: global detection ability using the area under the ROC curve (AUC), game-oriented evaluation prioritizing specificity followed by sensitivity, and constrained evaluations fixing true positive or false positive rates to allow direct comparison with World Rugby thresholds (75 g and 4500 rad/s^2 for men; 65 g and 4500 rad/s^2 for women).



Results

The best global detection model used the HIP criterion and achieved an AUC corresponding to 93% accuracy. HIP also produced the best specificity-prioritized model, reaching 0.992 specificity. Under fixed TP and FP constraints, the GSI and HIC criteria outperformed others, matching the number of concussions detected by current World Rugby thresholds while reducing false positives by one.

Discussion

Instrumented mouthguards combined with optimized biomechanical criteria show strong potential for improving on-field concussion detection. This approach could support medical decision-making by identifying players who require sideline assessment, improving player safety, limiting unnecessary removals, and helping reduce long-term neurological risks associated with repetitive head impacts.

Differences in Lower Extremity Posture between Male and Female Drivers

Dr Matthew Reed PhD

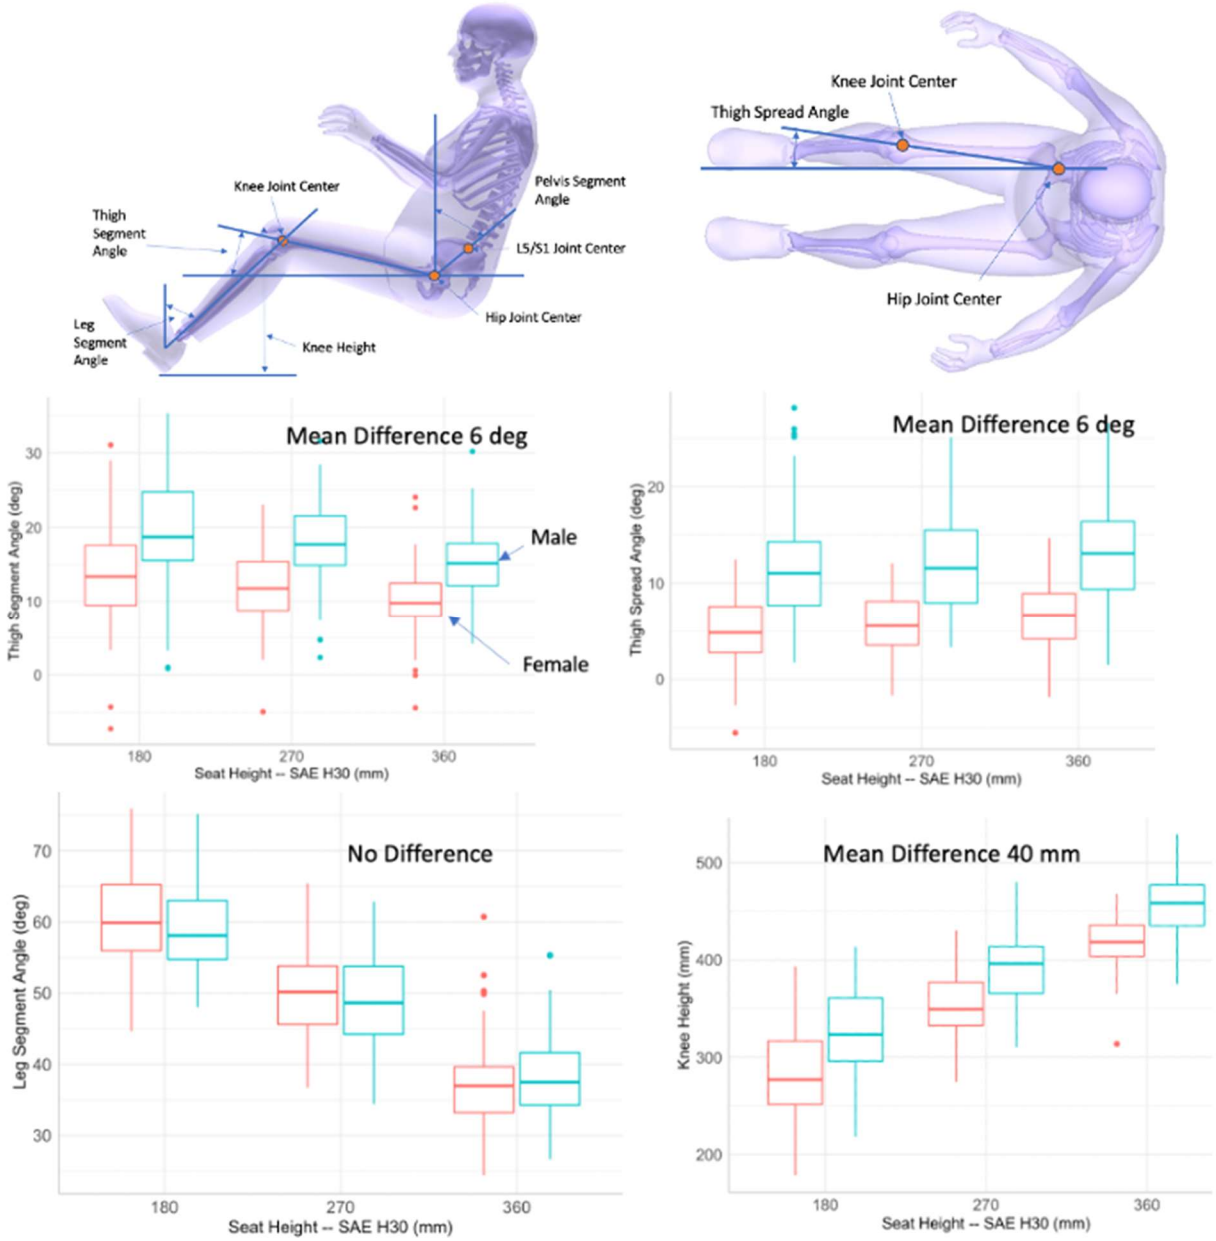
University of Michigan, Ann Arbor, MI, United States

Introduction

Analyses of crash injury data have shown that female drivers are at increased risk of lower-extremity injury in frontal crashes [1]. Some of the difference in risk persists after accounting for vehicle differences that are not fully addressed by adjusting for delta-V [2]. On average, female drivers have shorter stature and sit further forward in the vehicle [3]. Few studies have addressed sex differences in lower-extremity posture for drivers.

Methods

As part of a laboratory study of driver and passenger body shape, posture, and belt fit [4], driving postures were recorded for 97 male and female drivers as they sat in a laboratory mockup in up to 9 different package conditions characterized by different seat heights and steering wheel positions.



Results

Female drivers sat with their thighs closer to horizontal in side view (12±5˚ for female, 17±6˚ for male) and closer to fore-aft in top view (6±3˚ for female, 12±5˚ for male). Across package conditions, about 75% of the driver postures with a side-view thigh angle within 10 degrees of horizontal were female. Leg segment angles with respect to vertical in side view were not significantly different between male and female drivers (49±3˚ for female, 49±5˚ for male). Although the mean values of the thigh side-view angle and leg segment angle varied with seat height and steering wheel position, the sex differences were not significantly different across conditions. Due to shorter leg lengths for female drivers and similar leg angles, the knee was lower and more forward for female drivers.

Discussion

Driver posture may affect lower extremity injury risk in frontal crashes by changing the loading patterns. Simulation studies suggest that a flatter initial thigh angle may result in the knee being driven down the bolster, increasing the axial load on the leg and increasing the risk of ankle injury. This study is limited by the static laboratory setting with a single vehicle seat and short duration.

Towards a Biofidelic Test for Evaluating Equestrian Helmet Performance During Crush Scenarios

Miss Jasmin Stoff[1], Prof Michael Gilchrist[2], Prof Aisling Ni Annaidh[2], Miss Megan Barnes-Wood[1], Dr Peter Theobald[1]

[1]Cardiff University, Cardiff, Wales, United Kingdom. [2]University College Dublin, Dublin, Ireland, Ireland

Introduction

Horse-related crush injuries pose a significant risk to riders. Currently, equestrian helmet standards assess lateral crush resistance using quasi-static loading between two metal plates, typically only up to about 0.8 kN [1]. This method does not accurately simulate real accident conditions and is further compromised by the absence of a headform during the tests. This study investigates whether existing crush certification tests, and the pass/fail criteria associated with lateral helmet deformation, represent a meaningful measure of head injury risk during horse crush scenarios.

Methods

Finite element (FE) models of multiple horse regions (sacral, lumbar, side) and a PAS015-certified equestrian helmet were developed and validated against equine cadaveric impact data [2]. Impacts were then simulated onto both a rigid standard headform and a biofidelic finite element head model (FEHM) [3] across a range of surfaces, including deformable turf, synthetic and dirt tracks, and a rigid flat steel anvil.

Results

The FE horse impactors were validated against cadaveric data, with 8–24% mean error. The biofidelic FEHM consistently reported higher peak forces than the rigid headform, typically 22% or more. Deformable surfaces reduced peak forces and increased impact duration relative to the rigid flat, steel anvil (Figure 1). However, even the most favourable surface conditions produced forces well above established skull fracture criteria in both the FEHM and headform simulations.

Discussion

The results indicate that modifying the current test method by integrating a FEHM or physical headform creates opportunity to better understand ‘real life’

interactions. Replicating such tests, the FEHM far exceeded the skull fracture thresholds [4]. Such risk is not captured by the current lateral crush test, which omits a headform and therefore cannot quantify skull deformation or loading levels associated with severe injury. These findings highlight the need to revise certification protocols to include headform, or preferably biofidelic FE simulations, to ensure helmet designs are evaluated against metrics that reflect the true injury mechanisms present in equestrian crush incidents.

Head Acceleration Exposure Incidence and Severity in University-Level Female Rugby Players

Miss Megan Barnes-Wood, Mr Edward Williams, Dr Peter Theobald

Cardiff University, Cardiff, Wales, United Kingdom

Introduction

Acute, severe head acceleration exposures (HAE) can cause concussion, whilst a high incidence of sub-concussive HAEs are strongly associated with long-term neurological risk, especially chronic traumatic encephalopathy. Rugby union manages player welfare using head injury assessment (HIA) thresholds and return-to-play protocols; however, these are primarily developed from male data [1], [2]. Women now represent over a quarter of global rugby participants [3], though their head impact biomechanics remain poorly understood. Safety protocols have adopted a peak linear acceleration (PLA) threshold (65g) 12% lower than male data; however, the peak angular acceleration (PAA) threshold, with a stronger association to brain trauma, remains 4500 rad/s^2. This study provides the first insight into the relative risks faced by amateur female athletes in top-tier, university-level rugby.

Methods

Twenty-six female university-level rugby players wore instrumented mouthguards (iMGs) for a longitudinal head impact monitoring study. For this analysis, data were extracted from four competitive fixtures, with each game involving 11-15 players wearing iMGs. The iMGs captured kinematic data for all impacts exceeding an 8 g threshold. Internal quality auditing verified true head contacts.

Results

HAE incidence-severity curves are presented in Fig 1 (a, b). A high incidence of low severity kinematic data was recorded (19.1 impacts per player hour at > 8 g; PAA: 17.9 impacts per player hour at > 500 rad/s^2), declining when considering higher severity HAEs. An average 4 impacts occurred above the 65g HIA PLA, and PAA, thresholds across 4 games.

Discussion

University-level female rugby players are exposed to significant HAEs. Incidence and severity exceeded elite data (Fig 1 c, d), meaning the player pool at greatest risk of short-

and long-term brain injuries should be expanded beyond just professional athletes. Further work will use iMG-derived kinematics in finite element analysis to relate measured impacts to internal brain loading and injury risk, whilst also aspiring to determine how thresholds should be adjusted to reflect female physiology.

Images (Optional)

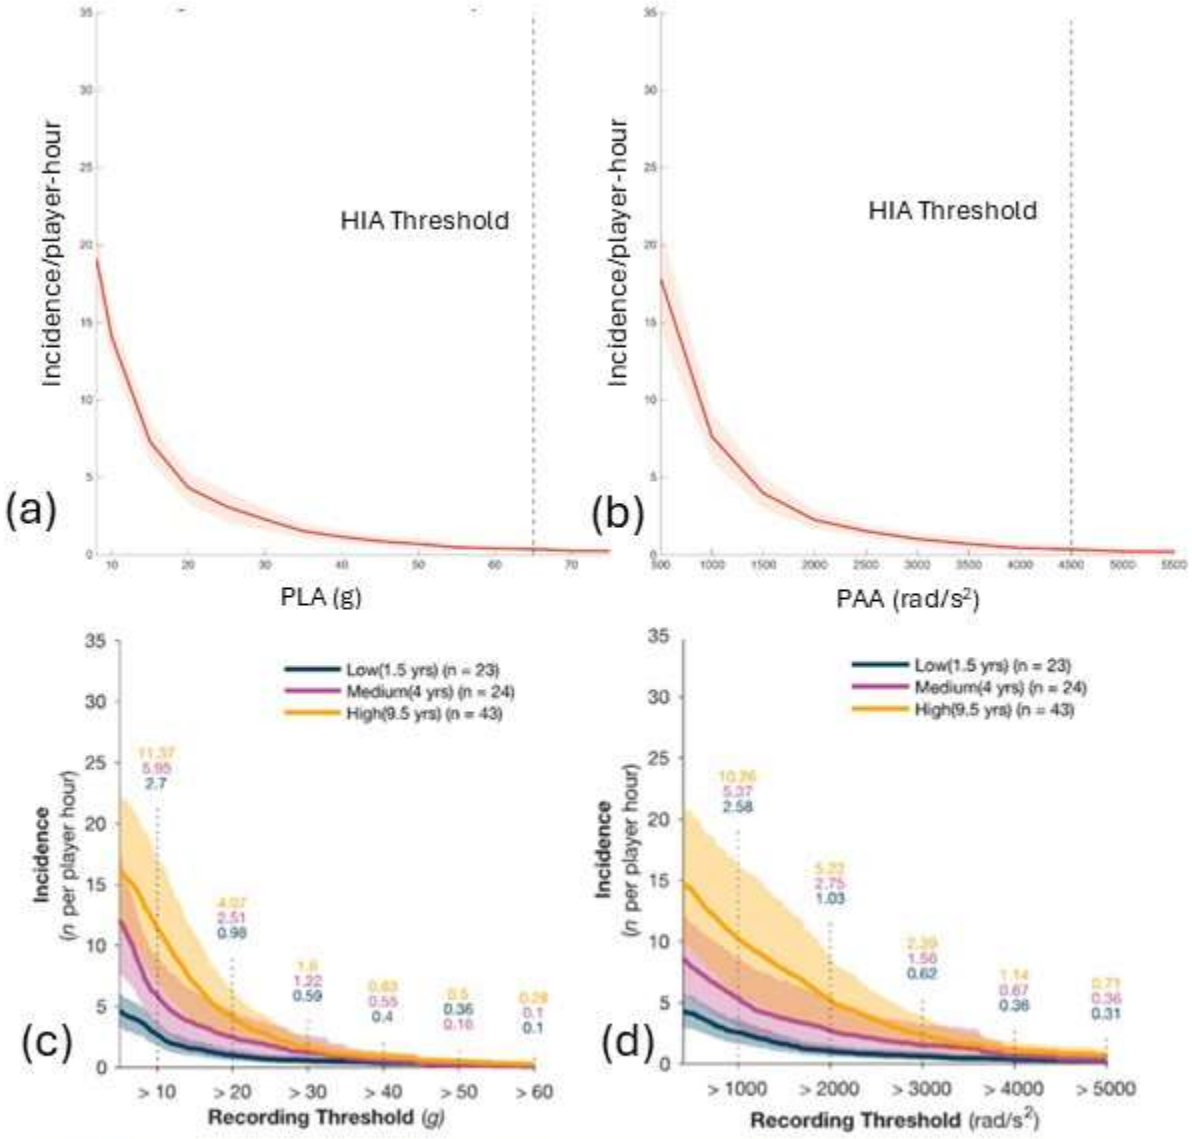

Figure 1. HAE incidence-severity curves describing iMG data from female rugby players. (a) Mean curves for PLA across the 4 analysed games of the university-level rugby team. (b) Mean curve for PAA across the 4 analysed games of the university-level rugby team. (c) PLA, and (d) PAA data, adopted from [4] that describes comparative HAE data drawn from elite women's rugby team, classified based on experience.

Examining Plantar Pressure and Tibial Acceleration Patterns to Identify Biomechanical Variations Associated With Patellofemoral Pain – a Pilot Study

Miss Megan Gordon M.S.[1], Dr. Eddie Austin Ph.D., DPT[2], Dr. Luke Bunch DPT[2], Dr. Hyun K Kim Ph.D.[1], Mr. Derek D Calvert AT[3]

[1]Louisiana State University, Baton Rouge, Louisiana, United States. [2]Ochsner Physical Therapy, Baton Rouge, Louisiana, United States. [3]Louisiana State University Athletics, Baton Rouge, Louisiana, United States

Introduction

Patellofemoral pain (PFP) is a common overuse injury [1]. Identifying biomechanical variations in individuals with PFP may improve understanding of its underlying mechanisms. This study aimed to determine key regional plantar pressure and tibial acceleration features associated with PFP during functional tasks.

Methods

Five participants with unilateral PFP (4F, 1M; 23.4±3.8yrs) and five healthy controls (3F, 2M; 23.6±3.6 yrs) performed walking, running, and single-leg squat (SS) tasks. Plantar pressure distribution was recorded using XSENSOR insoles (Calgary, Canada). Tibial acceleration was measured using inertial measurement units (IMUs; Xsens) placed on the anterior-medial aspects of the distal tibia. For gait tasks, peak tibial acceleration (g), resultant tibial acceleration (RTA=square root of $ax^2+ay^2+az^2-1$) and peak plantar pressure (kPa) were averaged across strides. For the SS task, ascent and descent phases were determined, and the same variables were obtained. The symmetry index (SI%; $X_r-X_l)/0.5(X_r+X_l)\times100$) was calculated to quantify side-to-side differences. Two-way mixed ANOVAs (group × condition) assessed main and interaction effects on peak pressure, SI%, and tibial acceleration variables. Paired and independent t-tests examined within- and between-group peak values.

Results

A significant interaction for peak RTA (p=.026) was found. Also, a significant group effect was identified for RTA (p=.008). Furthermore, significant condition effects were found for symmetry index of RTA (p=.003) and for peak tibial acceleration (p<.001) and peak RTA (p<.001), with running producing the highest values. Finally, independent t-tests showed between-patient asymmetry (injured limb vs dominant limb), with higher lateral heel loading on the injured side (p=.04) during walking. No overall group effects were found for plantar regions.

Discussion

Across all tasks, participants with PFP exhibited higher RTA. Specifically, the interaction effect shows as functional load increased from walking to running, PFP participants demonstrated disproportionately greater increases in RTA, suggesting increased tibial loading and reduced shock absorption. These findings are consistent with previous research suggesting elevated RTA is linked to increased knee joint loads and higher patellofemoral stress which is accentuated via pain in the knee [2].

Musculoskeletal Injuries in American Ballroom Dancers—A Survey-based Study

Mr Mohammad Salsali[1], Dr Meredith Wells[2], Dr Feng Yang[1]

[1]Department of Kinesiology and Health, Georgia State University, Atlanta, Georgia, United States. [2]Exponent, Inc. Biomechanics Practice, Farmington Hills, Michigan, United States

Introduction

Ballroom dance demands high physical control, flexibility, and endurance [1], which increase the risk for musculoskeletal injuries, particularly in the lower limbs [2]. Despite growing evidence on ballroom-related injuries [3], no study has been dedicated specifically to investigating ballroom dancers in the U.S., nor has it recorded the impact of injuries. Therefore, this study aimed to determine the prevalence, anatomical location, and impact of musculoskeletal injuries among ballroom dancers in the U.S.

Methods

A total of 138 American ballroom dancers completed an online survey, which focused on their dance experience, injury history, and the impact of injuries. Descriptive statistics were conducted in SPSS v29 (IBM) to quantify injury incidence, anatomical injury location, and injury impact.

Results

Among the surveyed dancers, 80 were female, and 56 were male. The sex of two participants was unspecified. Their ages ranged from 18 to 85 years, and their ballroom dance experience ranged from 1 month to 62 years. 71 (51.4%) and 50 (36.2%) reported at least one injury and multiple injuries, respectively. Among reported injuries, the most commonly injured locations were the feet/toes (18.9%), knees (13.4%), ankles (12.2%), back (11.8%), and shoulders (10.5%, Fig. 1). Injured dancers reported negative impact on performance (41%), quality of life (44%), financial situation (20%), and love of dance (6%).

Discussion

The current study provides insights into the prevalence and impact of musculoskeletal injuries among ballroom dancers in the U.S. Our finding that the lower leg is most prone to injuries confirms previous research [3]. Although lower limb injuries are the most common, especially in the feet, knees, and ankles, some injuries affect the upper body. Many dancers also reported significant impacts of injuries on performance, finance, and quality of life. These findings suggest that ballroom dancers in the U.S. need improved education on rehabilitation services to prevent injuries. Future studies involving large, diverse sample populations are needed to expand our understanding of how ballroom dancing causes injuries.

Airbags for Neck Protection: A Computational Analysis of Head-First Motorcycle Crash Dynamics

Dr. Mohammad Nasim[1,2], Mr. Muhammad Asif Zawad[1], Ms. Tahia Ilham[1], Prof. Ugo Galvanetto[2]

[1]Islamic University of Technology, Dhaka, Dhaka, Bangladesh. [2]University of Padova, Padova, Padova, Italy

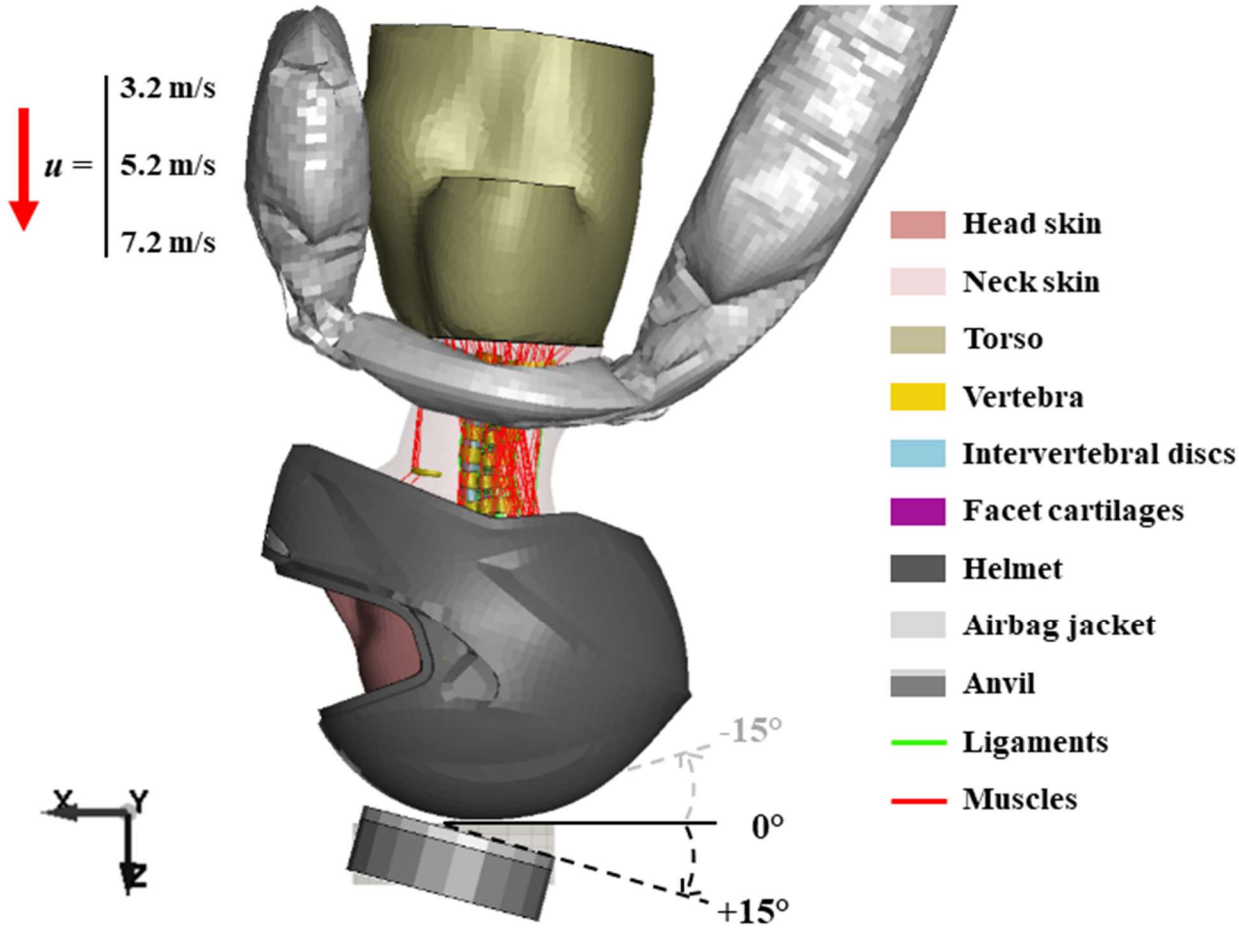
Introduction

Motorcyclists are among the most vulnerable road users. Cervical spine injuries due to direct or transmitted impact forces remain at significant injury risk during a motorcycle accident. While traditional neck braces aim to restrict head movement to protect the neck, their bulky design often compromises comfort and rider dynamics. This study investigates the potential of airbag technology as an adaptive solution for mitigating neck injuries during motorcycle crashes.

Methods

Using the validated D-Neck finite element (FE) model, two airbag jacket configurations (one-layer and two-layer) were evaluated alongside helmet-only scenarios to assess their protective performance during head-first compressive impacts. Simulations were conducted across impact velocities of 3.2 m/s, 5.2 m/s, and 7.2 m/s, and at impact angles of +15°, 0°, and –15°. The effectiveness of each design was quantified based on predicted AIS2+ and AIS3+ neck injury risks using the neck injury criterion (Nij).

Results



Both airbag jacket configurations substantially reduced neck loading compared to the helmet-only condition, particularly at low impact velocity. At 3.2 m/s, the one-layer and two-layer airbags consistently decreased peak upper-neck forces and resulted in noticeably lower predicted AIS2+ and AIS3+ injury risks. At higher velocities (5.2 m/s and 7.2 m/s), however, the protective benefits were not fully sustained; in several cases, the airbags produced greater neck forces than the helmet-only condition, indicating potential performance limitations under more severe impacts.

Discussion

The one-layer airbag consistently outperformed the two-layer configuration across most conditions, underscoring the importance of achieving an optimal balance between support and mobility; excessive stiffness or bulk can inadvertently restrict natural neck motion and

elevate injury risk. Airbag performance was also strongly dependent on impact angle: the most substantial risk reductions occurred at +15°, while responses at 0° and –15° were more variable, indicating sensitivity to impact direction and load path. To enhance robustness, future airbag systems should incorporate optimized or adaptive design features that adjust stiffness, inflation behavior, or geometry to impact direction and severity, maximizing protection without introducing secondary risks.

[13]Centre for Health, and Injury and Illness Prevention in Sport, Bath, Somerset, United Kingdom

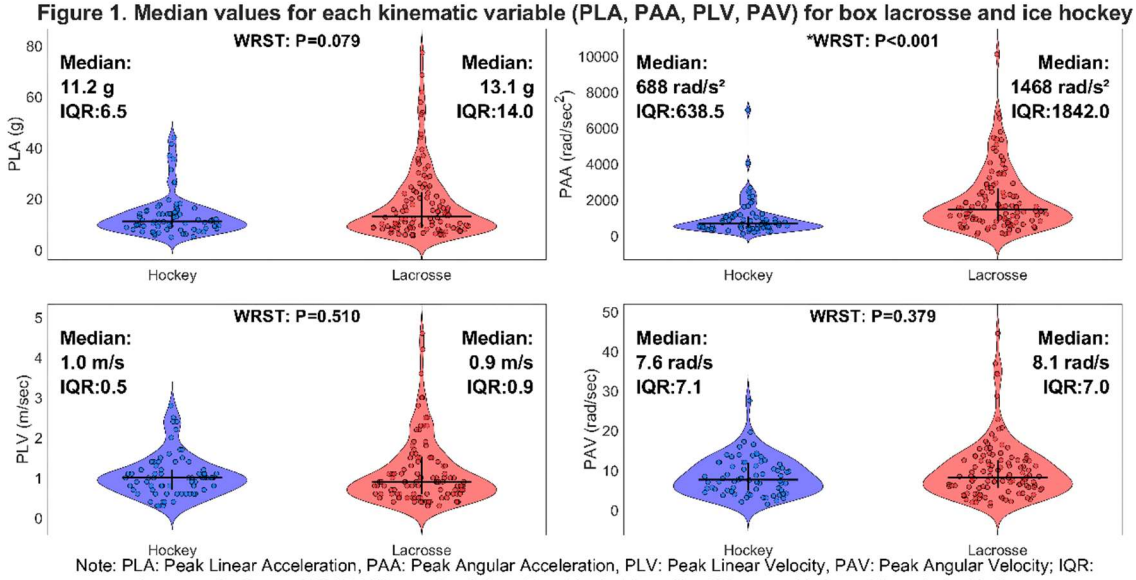
Introduction

Ice hockey and box lacrosse are collision sports with elevated concussion rates. Head acceleration events (HAEs) quantify biomechanical loading and impact exposure. Limited data exist for head kinematics in adolescent athletes. Instrumented mouthguards (iMGs) offer accurate HAE measurement. To compare HAE incidence rates and head kinematics using iMGs and player-to-player contact metrics via video analysis between adolescent male hockey and lacrosse players.

Methods

A prospective cohort study was conducted during the 2024 lacrosse and 2024–2025 hockey seasons involving one male U17A lacrosse team (ages 15-16;n=19;iMG=9) and one male U16AA ice hockey team (ages 14-15;n=20;iMG=11). HAEs were video-verified using synchronized iMG data following standard protocol. Median kinematic values were compared using the Wilcoxon rank sum test. Player-to-player contacts were analyzed by video analysis. Statistical analysis included Poisson regression to estimate incidence rates and rate ratios with 95% confidence intervals.

Results



Across six games/sport, iMG athletes recorded 110 HAEs in lacrosse (22.2 HAEs/game; 95% CI:18.6–27.0) versus 71 in hockey (12.0 HAEs/game; 95% CI:9.6–15.0) (IRR=1.55; 95% CI:1.15–2.09). Peak angular acceleration was significantly higher in lacrosse (median:1,467.5rad/sec^2; 25th-75th%:803.0-2,645.0) compared with hockey (median:688rad/sec^2; 25th-75th%:425.0-1,063.5), while peak linear acceleration, linear velocity, and angular velocity did not differ (Figure 1). Video analyzed head contact rates were 1.67-fold higher in lacrosse (IR=18.0/game; 95% CI:15.6–20.4) than hockey (IR=10.8/game; 95% CI:7.8–13.8) (IRR=1.67; 95% CI:1.25–2.22). Direct head contact rates were 2.66-fold higher in lacrosse (IR=16.8/game; 95% CI:14.4–19.2) than hockey (IR=6.0/game; 95% CI:3.0–11.4) (IRR=2.66; 95% CI:1.49–4.73), primarily due to cross-checking (71% of total contacts) in lacrosse and body-checking (79%) in hockey. The cross-checking rate was 9.44-fold higher in lacrosse (IR=433.8/game; 95% CI:410.4–458.4) than hockey (IR=45.6/game; 95% CI:34.8–60.0) (IRR=9.44; 95% CI:7.24–12.30) and body-checking rates were 2.80-fold higher in hockey (IR=154.8/game; 95% CI:127.2–187.8) (LacrosseIR=55.2/game; 95% CI:45.6–67.2) (IRR=0.35; 95% CI:0.27-0.46).

Discussion

Lacrosse demonstrated higher rates of HAEs, angular accelerations, direct head contacts, and head-contact mechanisms compared with hockey (which revealed higher body-checking rates). These findings highlight sport-specific biomechanical profiles, with lacrosse characterized by higher rotational loading. Results can inform tailored prevention strategies including rule changes, equipment design, and education.

Detecting Functional Spinal Stenosis Using Cerebrospinal Fluid Dynamics: A Pre-Clinical Study in the Pig

Ms. Nikoo Soltan[1], Dr. Madeleine Bessen[1,2], Dr. Najmeh Kheram[2,3], Dr. Vartan Kurtcuoglu[2], Dr. Carl Zipser[3,2], Dr. Claire Jones[1]

[1]Adelaide University, Adelaide, SA, Australia. [2]University of Zurich, Zurich, Zurich, Switzerland. [3]Balgrist University Hospital, Zurich, Zurich, Switzerland

Introduction

Traumatic spinal cord injury can result in swelling-induced compression of the neural tissues and stenosis of the cerebrospinal fluid (CSF) space. Timely and sufficient decompression of the spinal cord is recommended to improve injury outcomes. However, routine structural imaging has constraints in quantifying functional stenosis and postoperative restoration of spatial conditions. Given the close coupling of the spinal cord and CSF system, CSF pressure/flow dynamics could be functional biomarkers of spinal stenosis and aid clinical management. CSF dynamics are affected by many interacting physiological factors including arterial carbon dioxide partial pressure ($PaCO_2$). Using a pre-clinical pig model, the aim of this study was to determine if $PaCO_2$ modulation of CSF pressure is differentially altered superior and inferior to spinal stenosis.

Methods

Eight anaesthetized pigs (27±3 kg, Ethics: SAM-24-011) underwent surgical placement of fiber-optic pressure transducers in the brain lateral ventricle (LV) and spinal CSF space cranial (SCr) and caudal (SCa) to the planned level of stenosis (Fig.1A). Spinal stenosis was modelled via surgical extradural ligation of the intrathecal space at the T12 spinal level, and $PaCO_2$ was modulated by delivering CO_2 in the ventilatory circuit to increase end-tidal CO_2 from 38±4 (normocapnia) to 69±2 mmHg (clinically permissive hypercapnia). Mean CSF pressures ($CSFP_m$) at each site were measured in normocapnia and hypercapnia, pre- and post-ligation. The effect of $PaCO_2$ modulation on $CSFP_m$ was assessed using a linear mixed-effects model with random effect of animal (α=0.05).

Results

Pre-ligation, $CSFP_m$ increased during hypercapnia, compared to normocapnia, at all three sites (LV: +18%, p=0.045; SCr: +19%, p=0.037; SCa: +35%, p=0.003). Post-ligation,

$CSFP_m$ increased during hypercapnia at the supra-stenotic sites (LV: +25%, p<0.001; SCr: +26%, p=0.001) but not at the infra-stenotic site (SCa: +10%, p=0.418) (Fig.1B).

Discussion

$CSFP_m$ response to hypercapnia was limited to the supra-stenotic compartment in the presence of complete extradural ligation. These data suggest that the absence of an infra-stenotic $CSFP_m$ response to $PaCO_2$ modulation could be a functional indicator of upstream spinal stenosis. Although infra-stenotic $CSFP_m$ measurement is clinically feasible via lumbar puncture, ongoing pre-clinical work will investigate if non-invasive CSF flow measurements can detect a similar compartment-dependent response.

Contextualizing Head Accelerations During Rear-End Collisions: A Pilot Study

Dr. Patrick Fischer[1], Ms. Avery Scurlock[1,2], Dr. John Abercrombie[1], Dr. Richard Watson[1]

[1]Biodynamic Research Corporation, San Antonio, Texas, United States. [2]University of Texas, San Antonio, San Antonio, Texas, United States

Introduction

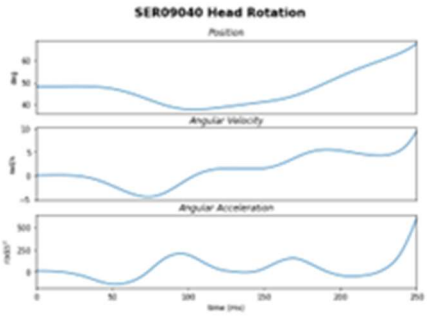
Mild traumatic brain injuries (mTBI) pose a diagnostic challenge following automotive collisions; biomechanical analysis of post-mTBI neuromuscular adaptations are not standard practice. The purpose of this study was to quantify linear and angular head accelerations during simulated rear-end collisions, and to contextualize the results with respect to mTBI risk.

Methods

Twenty simulated collisions from the Insurance Institute for Highway Safety (IIHS) were analyzed. During an IIHS test, an ATD is positioned in a production car seat, restrained with a seatbelt, and subjected to a 10-g forward acceleration while kinematic and high-speed video data are recorded. Head linear accelerations were collected in accordance with SAE J211. Head angular acceleration data were derived from sagittal video recorded during each test: markers at the head center-of-gravity and chin were tracked to determine sagittal head rotation (**Figure 1**). Angular accelerations were determined using numerical differentiation.

Results

Peak linear head accelerations were 20.9±2.0g (range: 17.8-25.7). Front-to-back linear accelerations were predominant for all tests (20.7±2.0g). For all tests, linear head acceleration peaked during the head contact period with the headrest. Peak linear head accelerations during IIHS tests represented mTBI risk between 0.008%-0.011%.



Peak angular head accelerations were 324.6±94.4rad/s2 (range: 167.7-606.4). Angular head acceleration did not peak at consistent phases across trials. Peak angular head accelerations during IIHS tests represented mTBI risk between 0.004%-0.006%.

Combined effects of linear and angular acceleration represented mTBI risk between 0.009%-0.019%.

Discussion

Preliminary results suggest linear and angular head accelerations experienced by a belted occupant do not represent an appreciable risk of mTBI during rear-end collisions up to 10-g. We noted that linear and angular accelerations may peak at different phases of the crash sequence. Combined effects of linear and angular head accelerations on mTBI risk in a rear-end collision is best determined as a time-history analysis of the crash sequence. We expect that frontal and transverse head angular accelerations were negligible compared to sagittal accelerations during IIHS tests, given that linear front-to-back head accelerations predominated the resulting head motion and translate to sagittal head rotation. However, further work is needed to confirm at the cohort level.

[4]Exercise Science and Neuroscience Unit, Department of Exercise and Health, Paderborn University, Paderborn, Paderborn, Germany. [5]Faculty of Health, Master Performance Sport and Health, Amsterdam University of Applied Sciences, Amsterdam, Amsterdam, Netherlands

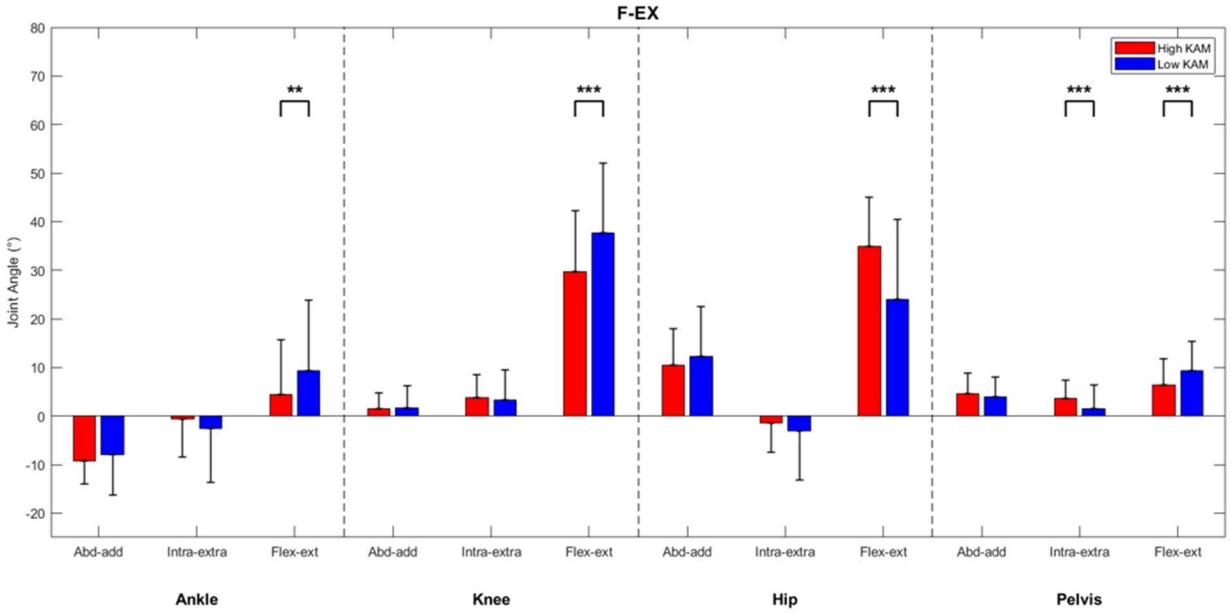
Introduction

ACL injuries in female youth soccer are strongly influenced by the interaction between athlete, task, and environment, making on-field assessment essential for ecological validity. Building on a previously trained lab-based machine learning model[1], this study uses wearable sensors to estimate knee abduction moments (KAMs) during real-game contexts. Specifically, it investigates how kinematics, performance, and task complexity influence joint loading in real game conditions.

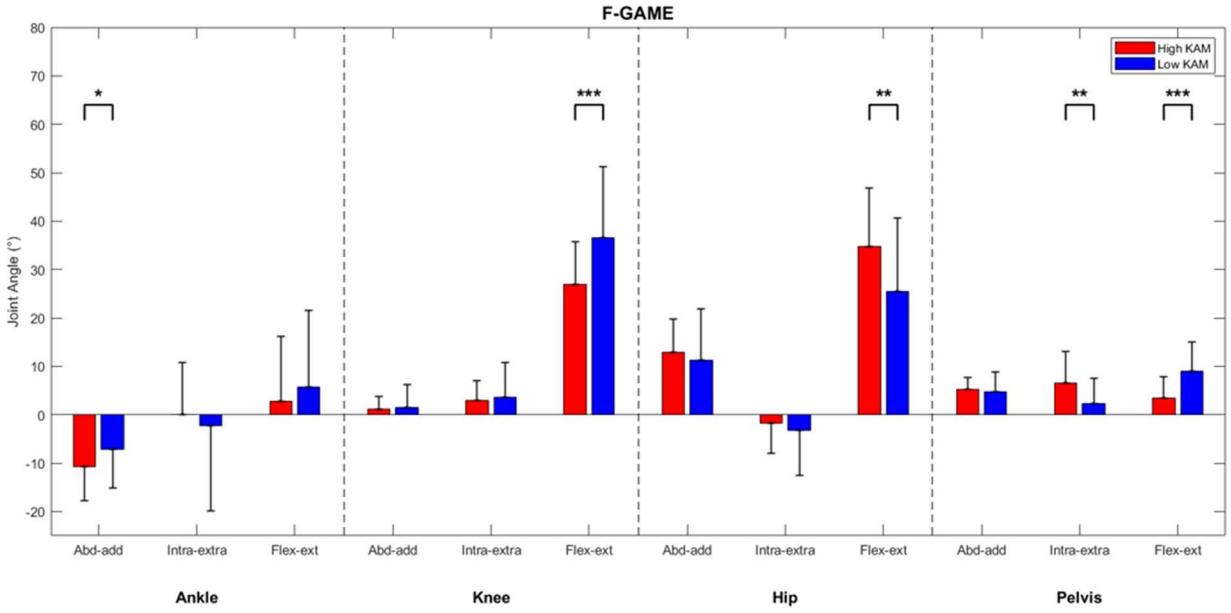
Methods

On-field data were collected on fifty-two healthy elite female soccer players (14.8±0.9 years), using a validated 17-IMU full-body system (240Hz; Xsens Technologies). A 75-min training including soccer-specific exercises (F-EX) and a training match (F-GAME) was recorded for each player[1]. Dominant-limb cutting movements were manually identified. Lower-limb and pelvis kinematics was extracted in three anatomical planes, and calculation of performance metrics (cut angle, center-of-mass velocity, acceleration during entry and exit phases of the cut stance phase). A previously developed Fine Gaussian SVM model[1] classified each trial as high or low KAM. The two groups were compared using Student's t-tests, separately for F-EX and F-GAME conditions. Effect sizes were quantified using Cohen's d.

Results



Analysis included 662 cutting trials (442 F-EX, 220 F-GAME). Trials classified as high KAM were 54 (12.2%) for F-EX and 20 (9.1%) for F-GAME. In high KAM trials, players exhibited



lower knee flexion ($p<0.001$), reduced pelvis anteversion ($p<0.001$), higher hip flexion ($p<0.004$), and greater pelvis ipsilateral rotation ($p<0.008$) in both F-EX and F-GAME. Lower ankle dorsiflexion was observed in F-EX ($p=0.005$), and greater ankle inversion ($p=0.042$) in F-GAME. The high KAM group showed smaller cut angles in F-EX (41°vs.55°,$p=0.013$) and higher entry peak acceleration in F-GAME ($p=0.040$). No differences were observed for peak velocity ($p>0.05$).

Discussion

On-field cutting tasks were classified as high KAM in 9–12% of trials. Lower knee and ankle flexion angles and higher accelerations were noted in the high compared to low KAM trials. Findings suggest considerable exposure to knee joint loading during sport-specific cutting tasks and primary ACL injury prevention strategies targeting biomechanical and neuromuscular control. Future work should validate interventions on-field and explore longitudinal injury risk outcomes.

Helmet Protective Performance in High Velocity Oblique Impacts for Electric Bicycle Riders

Dr. Qi Huang, Dr. Chengbin Li, Dr. Zhou Zhou, Prof. Svein Kleiven

KTH Royal Institute of Technology, Stockholm, Stockholm, Sweden

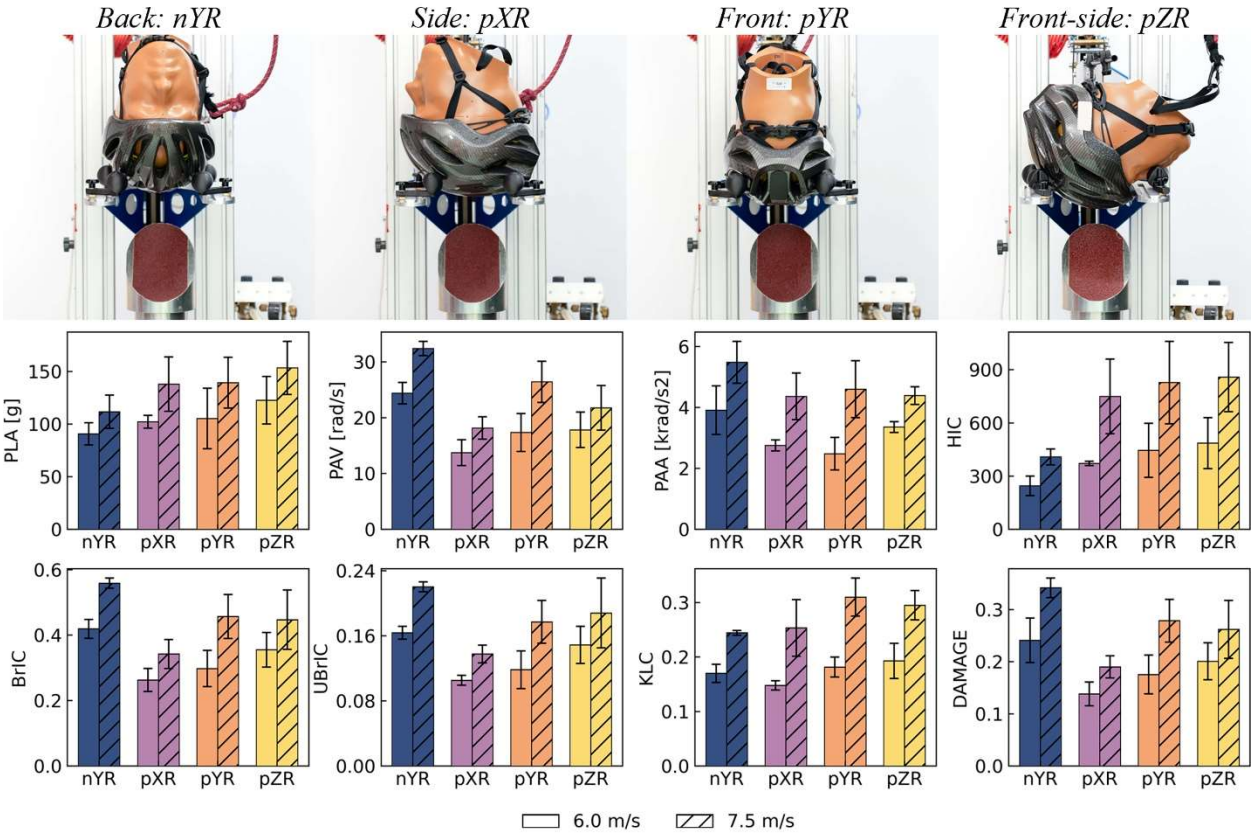
Introduction

Electric bicycle (e-bike) riders generally travel at higher speeds than conventional cyclists [1], yet limited research has evaluated how effectively helmets protect e-bike users from traumatic brain injury. With the introduction of a new standard that requires helmet evaluation at higher impact velocities, there remains a need to understand helmet protective performance under higher-velocity oblique impacts. This study aimed to assess the protective performance of helmets associated with traditional and electric bicycles.

Methods

Three helmet models, all equipped with one rotational mitigation system, were evaluated following a previously established test protocol [1]. A newly developed headform according to EN17950 standard was used to provide a better representation of the moments of inertia and the coefficient of friction of the human head. Each helmet was subjected to four oblique impact configurations (side:pXR, front:pYR, rear:nYR, and front-side:pZR, see Figure 1) at two velocities (6 m/s and 7.5 m/s) against a 45° anvil, resulting in a total of 24 tests. These two velocities represent the head-impact speeds of conventional and e-bike cyclists.

Linear and rotational kinematics were recorded using a wireless data acquisition system and were filtered to compute injury metrics, such as peak linear acceleration (PLA), peak angular velocity (PAV), Head Injury Criterion (HIC), and Brain Injury Criterion (BrIC).



Results

Among the four impact locations, nYR impact generated the lowest linear-based injury metrics (e.g., PLA, HIC) but produced the highest rotational-based metrics (e.g., PAV, BrIC). Increasing the impact velocity from 6 m/s to 7.5 m/s elevated all injury metrics, e.g. average PLA increased by 29% and average PAV by 35% at the higher velocity (see Figure 1).

Discussion

The substantial increases in injury metrics with higher velocity highlight the importance of evaluating helmets for e-bike riders. Our preliminary investigation only includes three helmet models and one rotational mitigation system, which limits the generalizability of the findings. We are expanding the test to a broader range of helmet designs and protective technologies, and including repeatability assessments and finite element simulations to better characterize helmet performance under high-velocity impacts.

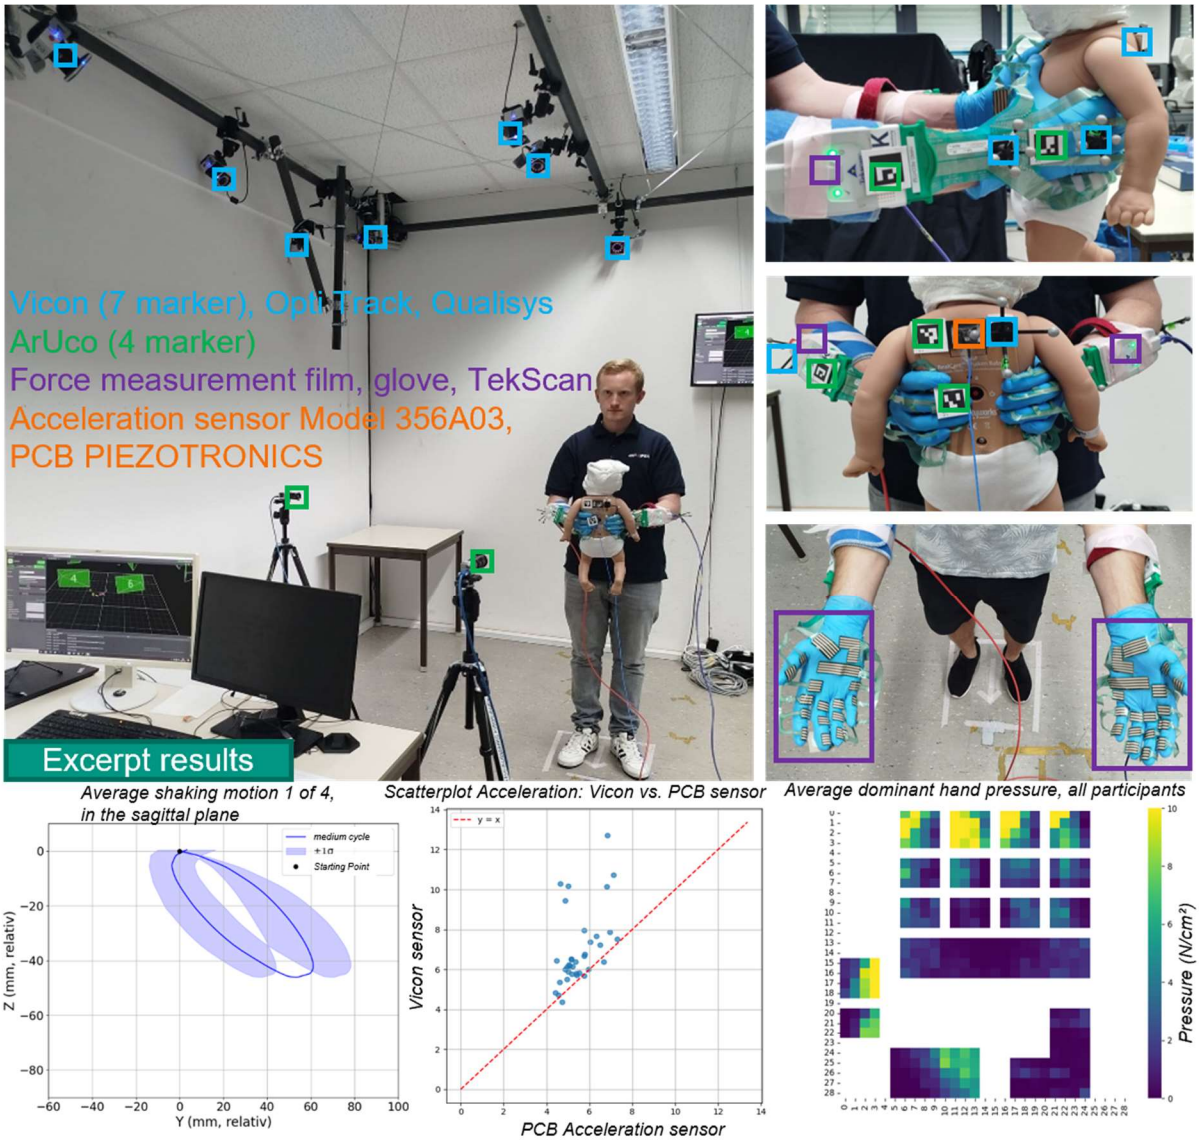
Introduction

Shaken Baby Syndrome is the leading non-natural cause of death in infancy, yet its biomechanical mechanisms remain insufficiently understood. The scarcity of clearly identifiable cases and limited reliable validation data hinder a differentiation between abusive and non-abusive injury patterns. Existing shaking studies have primarily examined the motion response of non-biofidelic infant dummies, leaving the underlying initial excitation unexplored and failing to reflect offender-related demographic profiles or the applied contact forces that contribute to associated injuries. This work addresses this gap by experimentally characterizing the initial excitation and realistic load cases of shaking events.

Methods

The study employed complementary, time-synchronized sensor systems to obtain robust coherent multimodal measurements. After ethics and data protection approval, 25 participants (aged 21-35) completed pre-study questionnaires to record anthropometrics and screen for exclusion criteria (e.g. musculoskeletal injuries, psychological disorders). The setup combined two marker-based motion-tracking systems (Aruco/Vicon), an accelerometer, and a force-sensing film placed on the palmar surfaces. Grip selection was left unconstrained to reflect natural handling. Participants were instructed to shake the 7lb, 21-inch dummy fast and forcefully in three trials. Trained observers documented all sessions to clarify potential measurement deviations retrospectively. Sensor data are recorded in CSV-format and processed and analyzed using Python scripts.



Results

All participants consistently selected a grip position at the dummy´s thorax. The primary motion occurred in the sagittal plane with peak-to-peak displacements ranging from 20-100mm. Four foundational movement patterns were identified. The motion-tracking systems showed consistent agreement in measured motion patterns. Mean shaking frequencies were 5.5Hz (accelerometer) and 6.3Hz (Vicon). Measured pressure values ranged 50-194N/cm^2, showing substantial inter-individual variability while still revealing clear overall trends. The highest loads were concentrated at the middle finger tip. No clear sex differences have been observed.

Discussion

The observed movement patterns and shaking frequencies indicate an expanded range compared to previously limited data. Participants of offender age shake at higher frequencies than reported in literature. The simultaneous measurement of forces applied to the dummy is conducted here for the first time, highlighting a further research gap. Future work will include additional participants and incorporate a preliminary stress induction to better simulate realistic shaking motions.

Estimated Ankle Ligament Strains During Roundhouse Kicks at Different Heights

Miss Renee Alexander, Dr Timothy Derrick

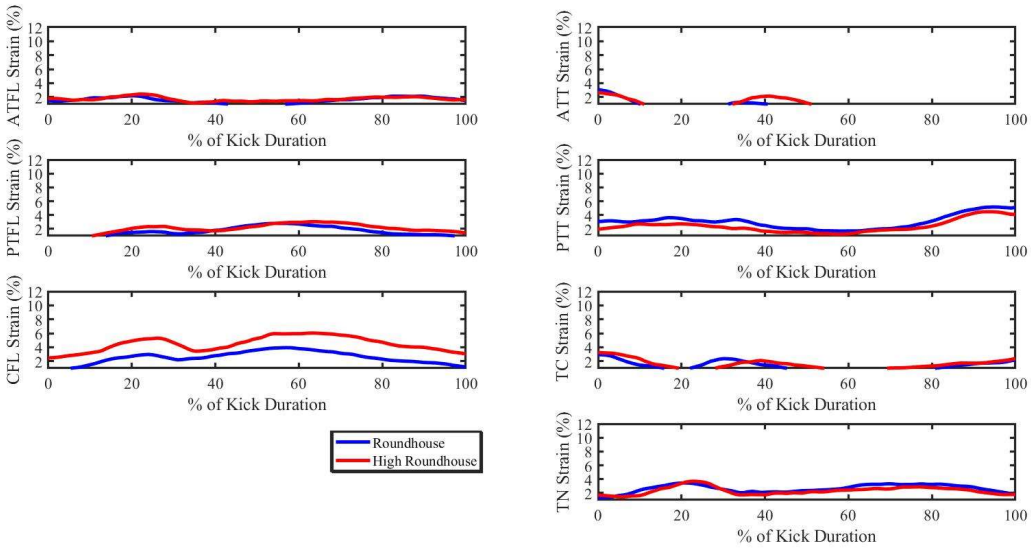
Iowa State University, Ames, Iowa, United States

Introduction

Over half of injuries during taekwondo sparring and demonstrations are ankle injuries [1]. However, there is limited research on the supporting leg during martial arts kick to varying heights and less on the supporting ankle or ankle injury risk related to kicking height. It was hypothesized that higher kicks would change estimated medial and lateral ankle ligament strains.

Methods

Twenty-six black belts were recruited. Marker clusters were placed on both legs and on the left ankle and foot. 3D kinematics were collected during five trials of roundhouse kicks to a paddle held at hip height and then at neck height. Trials were trimmed based on the kicking foot leaving and returning to the ground. Ankle angles were derived based on the relative motion of their segment markers using helical angles. Kinematic data were used to animate the talus, leg, and calcaneus of a musculoskeletal model of the foot. SPM with an alpha of 0.05 was used to compare strains based on kick height.



Results

Estimated anterior talofibular ligament (ATFL) strains for higher kicks were close to those estimated for kicks to the waist (Figure 1). Posterior talofibular ligament (PTFL) strains were higher until 40 to 55% of the kick with increased height. Height increased strains in the calcaneofibular (CFL) ligament throughout the entire kick. Anterior tibiotalar (ATT) ligament strains increased between 34 and 50% of the kick, while posterior tibiotalar ligament (PTT) strains were decreased throughout with an increase in kick height. Strains were increased in the tibiocalcaneal (TC) ligament until 20% and after 36% of the kick. Tibionavicular (TN) strains were decreased except before 4% and 20 to 30% of the kick. No statistically significant differences were found.

Discussion

Estimated ligament strains in the lateral ligaments generally increased with an increase in kicking height, while strains in the medial ligaments decreased. There may be a lateral shift in the ankle as height increases. Further testing and analysis is needed to determine any increased injury risk at the supporting ankle due to increasing kick height.

Biomechanical Effects of a NiTiNOL Staple and Buttress Plating in Pauwels III Femoral Neck Fractures: A Cadaveric Comparison with Cannulated Screws

Dr. Rita Aoun Ph.D.

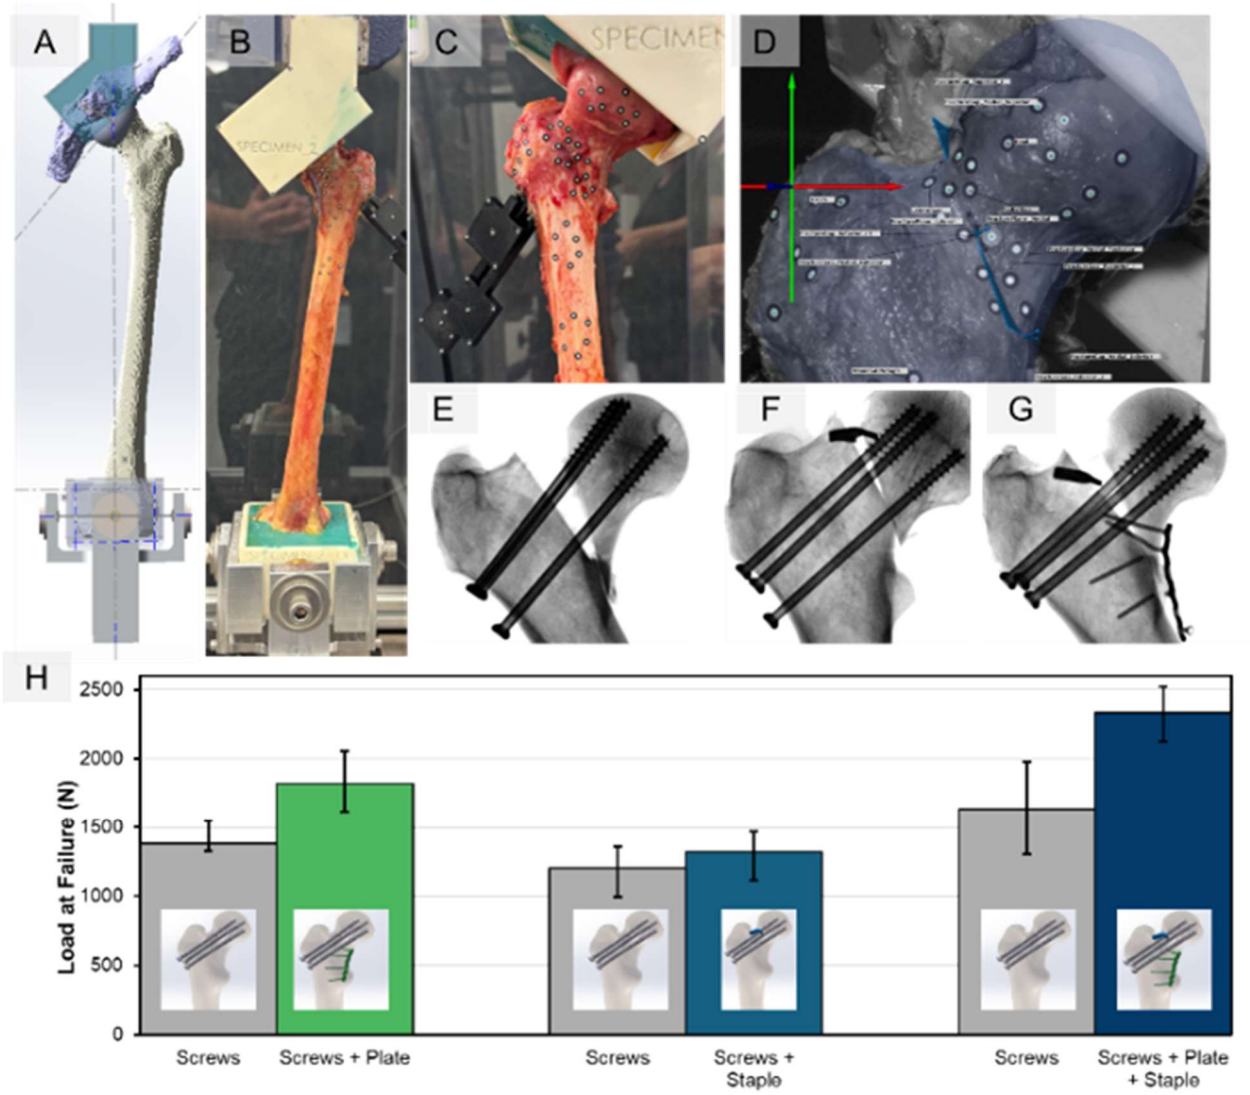
Arthrex, Naples, Florida, United States

Introduction

Vertical Pauwels III fractures, commonly due to high-energy trauma, are associated with complications like nonunions, necrosis, and implant failure and the reconstruction approach is controversial.[1,2] Standard three screws colinearly to the neck help reduce but may not prevent shear motion.[3] An inferomedial buttress plate can resist shear motion but may result in asymmetric stabilization, with probable superior gapping.[4,5] A NiTiNOL staple superio-anteriorly provides compression and stabilization. The purpose was to evaluate the fracture gap and biomechanically compare strengths of constructs with or without buttress plate and NiTiNOL staple.

Methods

Twenty-one matched pairs of fresh-frozen cadaveric femurs were contralaterally assigned to three screws (3S) versus 3S + buttress plate (3S+P), 3S + a NiTiNOL (DynaNite, Arthrex), staple (3S+St), or 3S + buttress plate + NiTiNOL staple (3S+P+St). Fracture creation and fixation were surgically applied under fluoroscopic guidance.[5] Specimens, dissected with the acetabulum intact, were CT-scanned and potted in 3D customized fixtures to keep alignment of the mechanical axis. Ramped compression to 500N (15N/s) followed by cyclic loading at 2Hz were applied, increasing the peak by 100N every 100 cycles until failure. Motion tracking was conducted to detect failure.



Results

Mean load to failure was highest in 3S+P+St group, occurring at loads 43% higher than its respective 3S control. Second highest failure loads were in 3S+P group, 32% higher than its respective 3S group and failure was observed superiorly. 3S+St group had larger failure loads than its respective control, and 60% failed simultaneously at all point pairs. Across all control (3S) specimens, 48% failed simultaneously at all point pairs.

Discussion

Shear failure was most apparent in constructs without plates. Plates provided increased load to failure, resulting in screw breakage. Superior gapping may be mitigated by adding a staple, resulting in the highest failure loads.

BIPED mk2 Finite Element Model Pressure Sensitivity in a Helmeted Impact Protocol

Mr. Robert Chauvet[1], Mr. Aaron Brice[2], Mr. Simon Ouellet[3], Dr. Lindsey Westover[1,4], Dr. Christopher Dennison[2]

[1]Department of Mechanical Engineering, University of Alberta, Edmonton, Alberta, Canada. [2]Department of Biomedical Engineering, University of Victoria, Victoria, British Columbia, Canada. [3]Defense Research and Development Canada, Valcartier Research Center, Quebec, Quebec, Canada. [4]Department of Biomedical Engineering, University of Alberta, Edmonton, Alberta, Canada

Introduction

Accurate prediction of intracranial pressure during head impacts is critical for evaluating traumatic brain injury (TBI) risk and helmet performance [1]. The Brain Injury Protection Evaluation Device (BIPED mk2) is a physical surrogate, that can be used in impact experiments and has a finite element (FE) twin [2]. There is evidence that the FE pressure outputs are sensitive to nodal keypoint location [3], an undesirable trait. It is unproven whether the twin can detect coup/contra mechanics. This study tests the hypothesis that keypoint node mismatch relative to physical sensor location can lead to pressure errors; and, that the model can detect coup/contra mechanics.

Methods

We performed tests using The Advanced Combat Helmet test protocol [4]. Measured kinematics from the collected experimental data were applied as boundary conditions in FE simulations. Pressure outputs were calculated from elements at the nominal sensor location and adjacent nodes (≈5mm offset) in three directions. Percent differences were computed to assess positional sensitivity. Additionally, pressure gradients along the impact line were analyzed to determine if the sensor nodes captured both positive and negative pressures (coup/contra mechanics).

Results

Results indicate an overall sensitivity of 6.4% to sensor location, with a directional bias parallel to the impact (up to 15.1% for far sensors). Perpendicular offsets produced minimal variation (<4%). Gradient analysis confirmed that coup/contrecoup pressures follow a near-linear distribution across the brain slice. While the two-sensor nodes characterized frontal and rear impacts, it did not capture the coup/contrecoup pressures for crown and lateral impacts, where sensor nodes were not aligned with the impact direction.

Discussion

These findings show that mismatch between physical sensor location, and location in an in-silico model, can drive discrepancies in physical and in-silico pressure results. Further, that pressure sensors should be placed to capture coup/contra mechanics. This study shows the importance of sensor location and fidelity between in-silico and physical models and the extent to which lack of fidelity can pose limitations on the validity of results.

Design of 3D-Printed Biomimetic Porous Architectures for Head-Protective Materials

Prof. Satoshi Yamada[1], Prof. Yuelin Zhang[2], Mr. Keita Kawashima[3], Dr. Saori Miyajima[3], Mr. Yugo Motoi[1], Mr. Ryuki Sunada[1]

[1]Hokkaido University, Sapporo, Hokkaido, Japan. [2]Sophia University, Chiyoda-ku, Tokyo, Japan. [3]Hokkaido Research Organization, Sapporo, Hokkaido, Japan

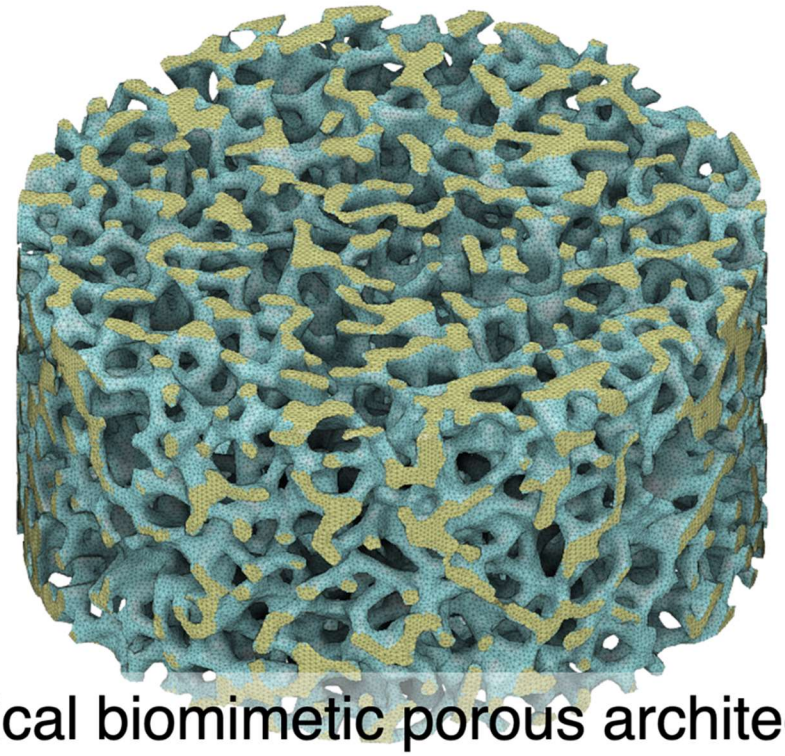
Introduction

We developed a three-dimensional (3D)-printed biomimetic porous architecture [1] inspired by cancellous bone biomechanics [2], providing high design freedom, 3D isotropy, and excellent energy absorption for advanced shock-absorbing applications. Expanded polystyrene (EPS), a conventional helmet-liner material, provides good impact absorption and is light in weight. However, it poses several limitations such as poor durability under repeated impacts, limited personalization, and low breathability. This study aimed to investigate the use of the proposed architecture—synthesized from thermoplastic polyurethane (TPU) via 3D printing—as a next-generation head-protective material. Initially, its shock-absorbing performance was evaluated and compared with EPS.

Methods

Architectures were generated stochastically by iterating the creation and branching of struts according to probability distributions for strut length and bifurcation. Nine isotropic models (50-mm diameter and 25-mm height) with volume fractions from 15% to 50% were designed by adjusting the strut parameters including diameter, length, and bifurcation. An additional anisotropic model was developed by distributing the length along the orientation. All specimens were additively manufactured through material extrusion using six commercial TPU filaments of different stiffness. Drop-tower impact tests at 50 J were conducted, with each specimen subjected to up to three consecutive impacts. Further, maximum force and deformation were assessed. EPS specimens of three helmet-grade densities were tested under similar conditions.

Results



TPU-based biomimetic specimens withstood all three impacts and altogether exhibited lower maximum forces and deformations than the lowest-density EPS specimens, which collapsed after the first impact. Exceptions occurred for low-volume-fraction specimens fabricated with soft filaments. Isotropic models showed parabolic relationships between maximum forces and deformations, based on volume fraction and material stiffness,

whereas structural variations had minimal influence. The anisotropic model demonstrated higher stiffness, and the maximum force value changed accordingly.

Discussion

These results indicate that 3D-printed biomimetic architectures exhibit EPS-comparable impact absorption while providing improved multi-impact resistance and tunable performance. Further studies are warranted to clarify their head-protection performance.

Comparison of football helmet performance with and without Guardian Cap

Mr. Sean Bucherl MS, Dr. Eric Nauman PhD

University of Cincinnati, Cincinnati, Ohio, United States

Introduction

With the NFL approving Guardian Cap usage for practice and games, Guardian caps, or similar after-market additions, will inevitably find their way into lower levels of play. It is important therefore, to determine their effect on impact severity.

Methods

Two models of helmets (Riddell SpeedFlex and Vicis Zero2 Elite) were tested with and without the Guardian Cap, resulting in four test cases compared to a baseline bare Hybrid 3 50th percentile male head. Three helmets within each model were tested. Helmets and Guardian Caps were fitted to an instrumented Hybrid 3 head and neck mounted to a steel base. Each helmet - Guardian Cap combination was tested by delivering 20 impacts each, to 14 different locations (4 each within 5 different impact ranges). The recorded impact impulses, and peak linear and angular accelerations at the head form center of mass were used to calculate dimensionless parameters and corresponding functions for linear and angular acceleration. Comparing the effect size between the helmeted head and the bare head made it possible to determine the effect that the helmet – Guardian Cap combination has on the resultant linear and angular accelerations.

Results

Both helmets demonstrated improvement in protection with the Guardian Cap, but this improvement was not uniform. The SpeedFlex helmet exhibited the most overall improvement. However, normalizing the effect sizes for the mass of the helmet, or helmet with Guardian Cap, nearly erases the observed improvements. However, even after mass-normalizing, the SpeedFlex does show some improvement in mitigating angular accelerations with the Guardian Cap.

Discussion

With the Guardian Cap increasing the mass of each helmet ~9%, it is possible that the observed improvements seen were primarily due to the additional mass of the system, but further testing is needed to test this theory. The improvement observed in the SpeedFlex after mass-normalizing could be due to the fact the Guardian Cap is providing a slip layer that moves during impact but this also needs to be investigated further.

Injury Reponses of an Undulated Male Axon in Dynamic Stretch Loading

RA Chaokai Zhang, Professor Songbai Ji

Worcester Polytechnic Institute, Worcester, MA, United States

Introduction

Understanding how axons respond mechanically to stretch is crucial for deciphering mechanisms of traumatic axonal injury. Most axonal injury models assume a straight axon. However, axon undulation is common in a living brain, which may influence substructural injury risk. This study investigates the significance of axonal undulation on cytoskeletal responses in stretch.

Methods

A male axon injury model [1] was modified to incorporate a sinusoidal undulation (wavelength: 28 μm, amplitude: 3 μm) based on morphological measurements [2]. The undulated axon's centerline (~15.5 μm) was ~10% longer than a straight 14 μm axon of equal end-to-end length. A rotational anti-symmetric periodic boundary condition was developed to halve the model for simulation. Straight and undulated axons were subjected to an identical stretch (peak strain of 10% and strain rate ~10 s^{-1}).

Results

While the straight axon became undulated after stretch and recovery, the initially undulated axon retained its wavy geometry, as the applied stretch magnitude was not enough to straighten it. This led to substantially lower peak strain in microtubules (MTs; 7% vs. 13%) and tau failure (0% vs. 2.2%) than the straight axon. However, the initially undulated axon also resulted in higher axolemma peak strain (19.2% vs. 17.3%) and a much higher neurofilament failure (13.1% vs. 2.8%) due to increased local contact between MTs and axolemma during the flattening of its morphology. **Figure 1** compares their responses in a local Ranvier node region.

Discussion

The initial axonal morphology is a significant biomechanical mediator to alter strain and damage distribution within the cellular substructure. An initially undulation axon protects microtubules and tau proteins during rapid stretch at the expense of higher neurofilament failure and peak strain in axolemma. Therefore, it is important to incorporate undulation into the axonal injury model, where appropriate, to study injury mechanisms. The anti-symmetric periodic boundary condition is shown effective in substantially reducing

simulation runtime. Future work will extend to different levels of peak strain and strain rate, as well as to the female axonal injury model.

Effect of Center of Mass Height on Hip Impact Forces During Simulated Sideways Falls from Standing Height

Ms. Soyeon Yoon PT, Dr. Kitaek Lim PT, PhD, Mr. Junwoo Park PT, MSc, Dr. Seyoung Lee PT, PhD, Mr. Sungmin Chun PT, Mr. Donggeon Kim PT, Prof. Woochol Joseph Choi PT, PhD

Injury Prevention and Biomechanics Laboratory, Yonsei University, Wonju, Gangwon-do, Korea, Republic of

Introduction

Falls are a major cause of hip fractures in older adults. Although fall risk increases by 37% for every 1% rise in center of mass (COM) height [1], few studies have investigated how COM height influences impact severity during a fall. In this study, we examined how fall kinetics were affected by variations in COM height.

Methods

Ten young adults self-initiated sideways falls on a mat (Figure 1). Trials were acquired with three knee positions at landing (knees together, knee on the mat, and knee free), and with three COM heights (1% increased, 1% decreased, and unchanged) (Figure 2). Fall kinetics and kinematics were collected using a force plate positioned beneath the mat and a motion capture system, respectively. Body contact area was measured to determine the mat stiffness at impact, which was then used to estimate the actual (unattenuated) hip impact force using a mass–spring model consisting of two springs in series. Outcome variables included body stiffness (k) and unattenuated hip impact force ($F_{unattenuated}$) that normalized to body weight (BW). A two-way repeated measures ANOVA was performed to assess whether these outcomes were influenced by COM height and knee position.

Results

$F_{unattenuated}$ was associated with knee position ($F=6.86$, $p=0.006$), but not with COM height ($F=1.66$, $p=0.218$) (Table 1). $F_{unattenuated}$ was the smallest with the knee on mat. Similarly, k was associated with knee position ($F=3.67$, $p=0.046$), but not with COM height ($F=1.50$, $p=0.247$).

Discussion

Our results indicate that hip impact severity is strongly influenced by lower-extremity kinematics at landing, consistent with previous findings [2]. Although a higher center of mass (COM) is theoretically associated with increased impact energy, we did not observe a corresponding increase in impact severity when COM height was adjusted by ±1%

(approximately a 1 cm difference for a 170 cm individual). These findings suggest that such a small change in COM height does not meaningfully affect impact severity or hip fracture risk.

Images (Optional)

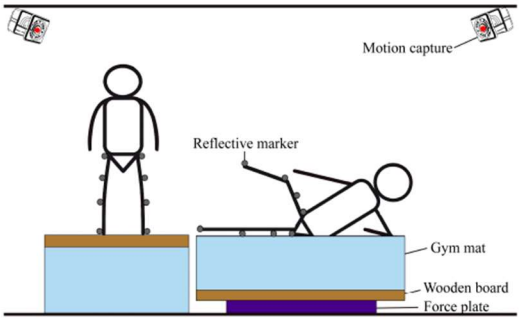

Figure 1. Experimental setup

Sex Impacts Resultant and Cumulative Tibial Bending during a Walk, Jog, and Run

Mr Thomas Wenzel[1,2], Ms Iona Halliday[1], Dr Tyler Brown[1]

[1]Boise State University, Boise, ID, United States. [2]lululemon, Portland, Oregon, United States

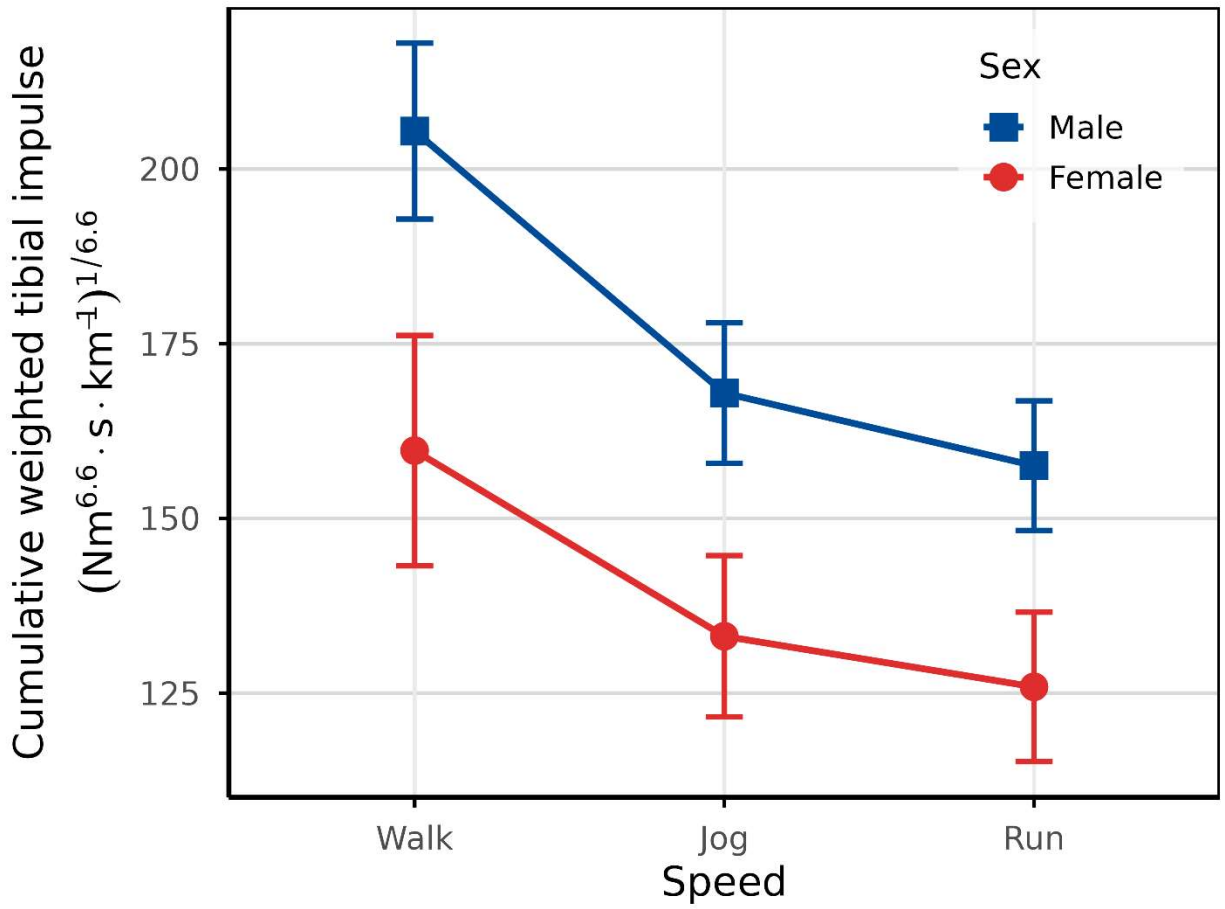
Introduction

Women are twice as likely to suffer tibial stress fractures as men [1]. During locomotion, tibial bending reportedly produces damaging bone stresses that lead to tibia stress fracture [2]. Yet, it is unknown whether discrete (peak and mean) or cumulative resultant tibial bending of locomotion differ between sexes or are impacted by common locomotion factors, like speed and surface.

Methods

Twenty-four recreational runners (12 M, 12 F) had tibial bending quantified as they walked (1.3 m/s), jogged (3.0 m/s), and ran (4.5 m/s) over a flat, uneven, and medial and lateral banked surfaces. Peak and mean resultant tibial bending moment and cumulative-weighted tibial bending impulse (CWTI) were submitted to a 3-way mixed model ANOVA.

Results



Significant sex by speed interactions were observed for mean and peak resultant tibial bending and CWTI (all: $P<0.001$), as men exhibited greater resultant bending and CWTI (all: $P<0.001$), and larger increases in resultant bending and CWTI due to speed than women (all: $P<0.001$). Significant speed by surface interactions (all: $P<0.025$) were observed for mean and peak resultant tibial bending. Resultant bending was smaller on uneven and banked surfaces compared to flat surface (all: $P<0.041$) but only differed between surfaces during jog and run (all: $P<0.001$). Speed increased mean and peak tibial bending (all: $P<0.001$), but decreased CWTI (all: $P<0.001$).

Discussion

Despite having lower tibial stress-fracture rates, men may be more susceptible to hazardous bone microdamage during each step. They demonstrated greater discrete and cumulative resultant bending and larger speed related increases in tibial bending than women. Faster locomotor speed may increase bone microdamage likelihood as discrete resultant tibial bending was larger with each addition of speed. But unexpectedly, cumulative tibial bending decreased with 1 km of jogging and running. Challenging surfaces may decrease injury risk or potential bone damage, as discrete resultant tibial

bending was smaller on the uneven and banked surfaces. Yet, further study on the impact of injury risk is needed as surfaces did not lead to a similar reduction in cumulative tibial bending.

Finite Element Analysis of Force Transmission in Behind Armor Blunt Trauma Across Different Backing Materials

Dr. Alan Goertz Ph.D.[1], Mr. Tony Hatzigeorgiou[2], Mr. Donald Sherman MS[2], Dr. Cynthia Bir Ph.D.[2], Dr. Karin Rafaels Ph.D.[3]

[1]SURVICE Engineering, Detroit, MI, United States. [2]Wayne State University, Detroit, MI, United States. [3]US DEVCOM Army Research Laboratory, Aberdeen, MD, United States

Introduction

Behind armor blunt trauma (BABT) arises when the kinetic energy of a non-penetrating projectile is transferred through body armor, resulting in trauma to the underlying tissue. Traditional certification methods rely on backface deformation (BFD) measurements in surrogate materials such as ballistic clay or gelatin, yet the metrics from these surrogate materials inadequately capture tissue-level stress and injury risk. To help relate the responses witnessed in these backing materials to the human body, a quantification of the force responses of ballistic clay, gelatin, and the human body could be used to develop improved injury evaluation methods.

Methods

In this study, we employed detailed finite element (FE) simulations to quantify the forces induced on backing materials of differing mechanical properties. Backing materials modeled included ballistic clay (Roma Plastilina No. 1), ballistic ordnance gelatin, and a validated human torso FE model representing the 50th percentile male. The behind-armor blunt impact model in the simulations was derived from high-velocity ballistic experiments on hard armor. Force transmission to each backing material was extracted and analyzed over time to produce contact force profiles for comparison.

Results

Results indicate that stiffer backing materials, such as ballistic clay, produced higher peak impact forces, whereas more compliant gelatin reduced peak forces but altered the duration of applied loads, potentially affecting predicted injury patterns. The shape of the loading profile of the homogenous surrogates differed from the structurally complex human body.

Discussion

The simulations highlight the sensitivity of backing material characteristics on the measured response from BABT impacts and emphasize the necessity of understanding the

relationship between test materials and the human body for properly predicting the potential for injury. These findings advance the understanding of energy transfer in non-penetrating ballistic events and provide a framework for optimizing armor design and evaluation criteria to mitigate behind armor blunt trauma. The study further demonstrates the efficacy of FE modeling as a tool to systematically investigate BABT mechanisms across a range of backing configurations.

Introduction

For pregnant women, motor vehicle collisions (MVCs) are a leading cause of injury and traumatic fetal loss [1]. To understand these injury mechanisms, anatomical data acquired in realistic automotive postures is needed to advance the development of pregnant human body models (HBMs) [2]. In this study, we present anatomical data captured using Upright Open MRI to explore how posture influences uterine geometry and lumbar curvature.

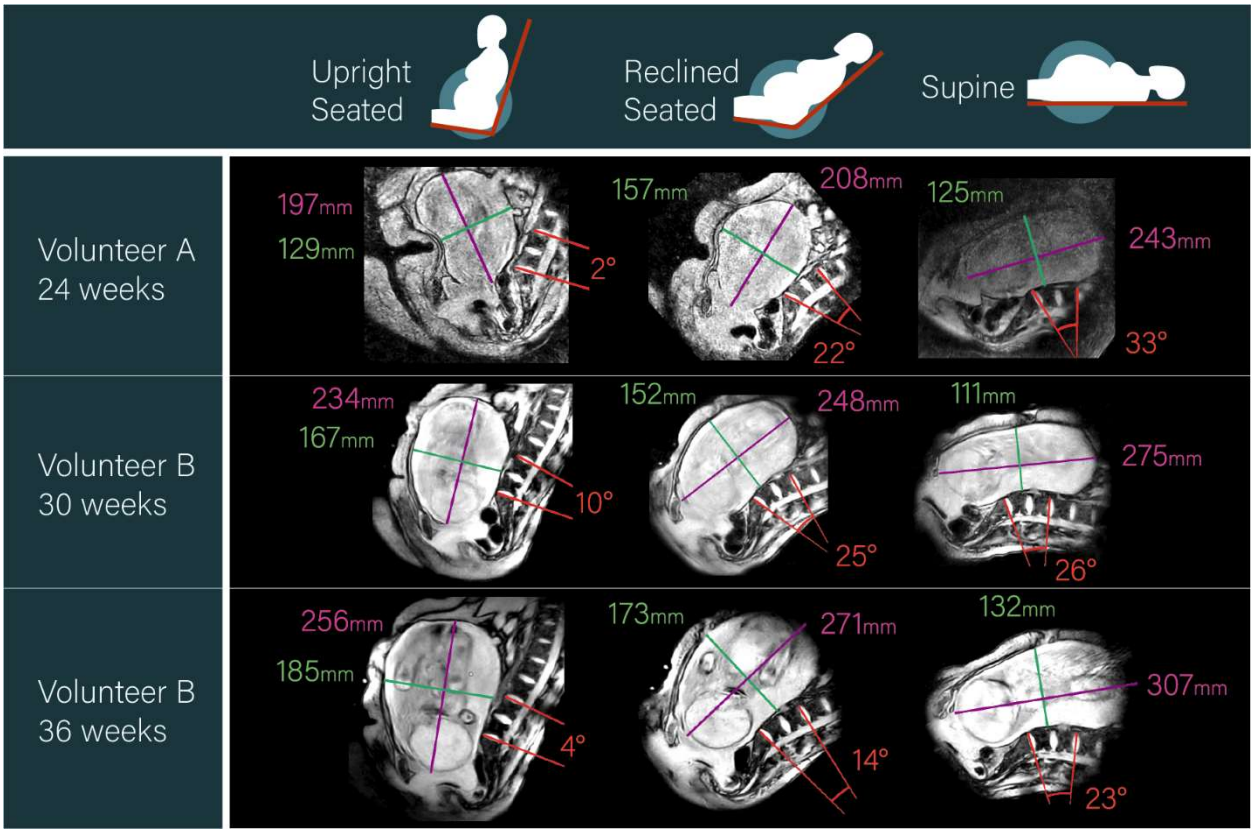
Methods

Pregnant volunteers were scanned in three postures: upright driving (seated), reclined (seated), and supine. Volunteer 'A' was scanned during her 24-week gestation, and volunteer 'B' was scanned in her 30th and 36th weeks of gestation. All measurements were acquired using the mid-sagittal image.

Given the available field of view, lumbar curvature was approximated by measuring the sagittal Cobb angle from the L4 to S1 vertebrae. Uterine length and width measurements were acquired along the uterine long and short axes – identified using principal component analysis (PCA) of 30 digitized points along the uterine outline.

Results

The uterine width in supine was on average 38 mm less than that of the upright posture. In the 30th and 36th week scans, this difference was particularly pronounced at 56 and 53mm, respectively. As backrests were lowered from upright to reclined - we saw a 5% average increase in the uterine length-to-width ratio, which was further increased by 52% in supine, indicating an elongation of the uterine shape as the backrest approached horizontal.



From upright to supine, the lumbar curvature increased by 22° on average.

Discussion

This study offers a first look into the internal anatomy of pregnant women across three postures relevant to automotive travel. The results demonstrate that the uterus is a highly pliable structure that changes shape with posture, highlighting the importance of developing HBMs using geometries acquired in the posture that the HBM intends to model.

As lumbar curvature also plays a role in MVC injury risks [3], the interplay between lumbar curvature and uterine shape at various stages of pregnancy should be further investigated.

Investigating Soft Tissue Contributions to Thoracic Responses with a Whole Human Body Model

Dr. Wei Zeng

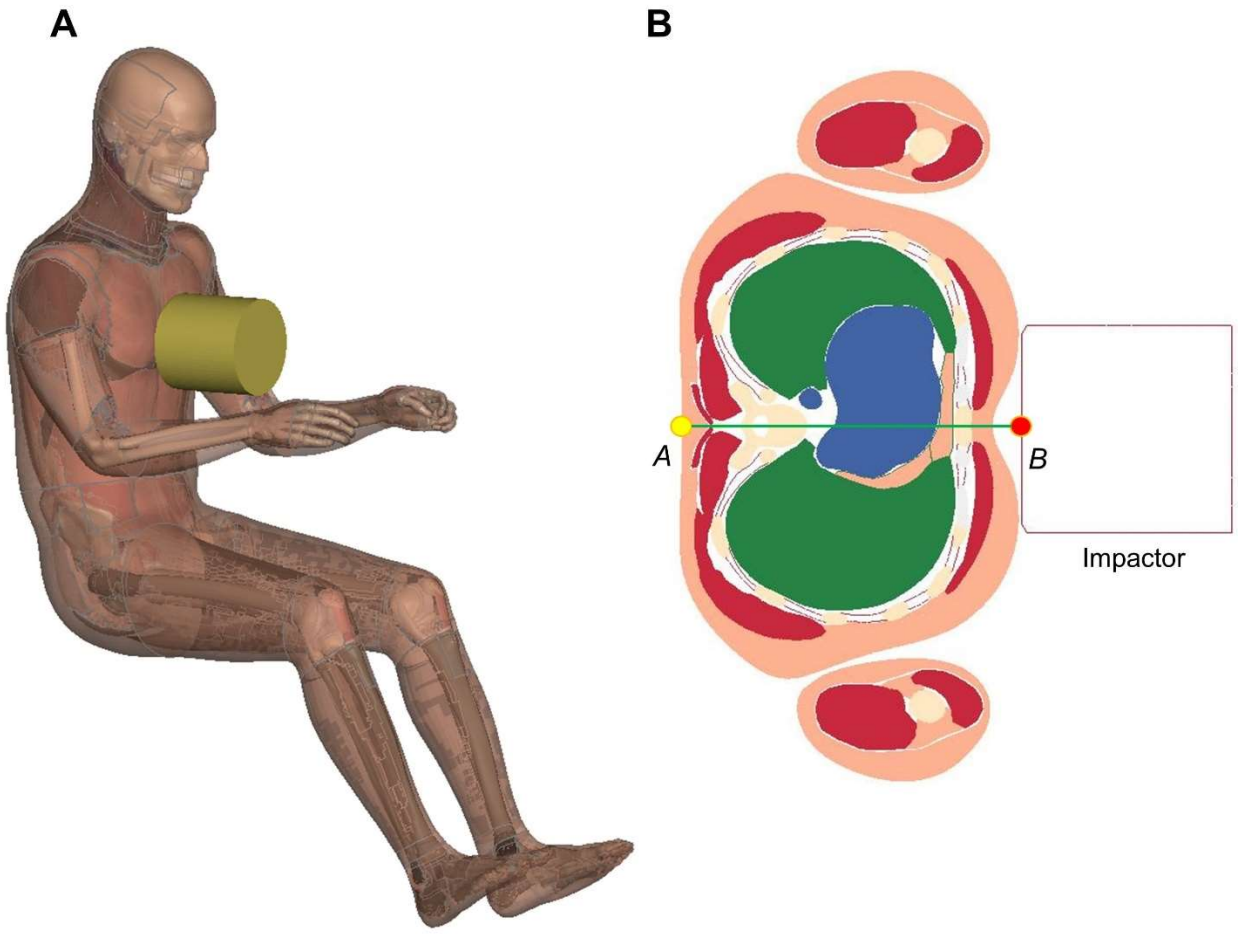
New York Institute of Technology, Old Westbury, New York, United States

Introduction

The human thorax is a mechanically complex structure in which the rigid ribcage and surrounding soft tissues jointly determine global and local responses. While the bony skeleton provides the primary load-bearing framework, the musculature, adipose layers, skin, and intrathoracic organs also contribute to energy absorption and deformation patterns during impact. These tissues exhibit viscoelastic behavior that can modulate thoracic stiffness, yet their contributions remain insufficiently quantified in human body models (HBMs). This study evaluates how variations in soft tissue properties, geometry, and organ–organ interaction modeling affect thoracic responses under frontal impact.

Methods

Dynamic frontal pendulum impact simulations were performed using a detailed mid-sized male HBMs (GHBMC M50-O). Soft tissue characteristics were varied independently, including material properties of chest muscles, adipose tissue, skin, and lungs; geometric features such as intercostal muscle volume and anterior chest flesh thickness; and intrathoracic interaction modeling using sliding tiebreak contact (STBC). Thoracic responses—sternum deflection, impact force, and force–deflection behavior—were compared with established PMHS corridors.



Results

Soft tissue representation produced distinct changes in response. STBC slightly increased peak deflection and reduced peak force (<5%). Lung material properties had the greatest influence: simplified rubber and Hill-foam materials increased deflection by 7% and 20% and reduced force by 8% and 13%, respectively, with delayed timing. Increasing anterior chest flesh thickness reduced deflection by 12.8% with minimal effect on force (<1.2%). Modifying intercostal muscle geometry (greater thickness or 2D-to-3D elements) produced negligible changes (<3.6% in force, ~1% in deflection). Stiffer passive muscle, adipose, and skin properties stiffened the response, with skin affecting force more than deflection. Overall, lung material updates and STBC softened the response, whereas increased chest flesh and stiffer tissues increased thoracic stiffness.

Discussion

Soft tissues—particularly the lungs, passive muscles, and adipose layers—substantially shape the magnitude and timing of chest deformation. Lung influence reflects its large volume and material sensitivity. Intercostal geometry changes were minimal, highlighting the importance of tissue volume and placement. Anterior chest flesh primarily altered compressibility, while organ contact mechanics had modest effects. These findings highlight the need for accurate soft tissue modeling to improve HBM thoracic injury prediction.

Preliminary Analysis of Spatial Position and Observed Airway Risks in a Bedsharing Environment

Ms Yafa Benavidez Graduate Research Assistant[1], Ms Megan McCartney Undergraduate Research Assistant[1], Ms Laina Beasley Undergraduate Research Assistant[1], Mr Christopher Wilson[1], Dr Kyran Quinlan MD[2], Dr Gina Lowell MD[2], Dr Erin Mannen PhD[1]

[1]Boise State University, Boise, Idaho, United States. [2]Rush University Children's Hospital, Chicago, Illinois, United States

Introduction

Sharing a sleep surface (i.e. co-sleeping or bedsharing) nearly triples the risk of sleep-related Sudden Unexpected Infant Death [1]. Airway-obstruction or chest compression from soft bedding, wedging, overlay, or a combination of these can lead to suffocation in a bedsharing environment [2]. However, there is little biomechanical understanding of bedsharing and the associated risks. The purpose of this study is a preliminary analysis of pilot data collected for a larger longitudinal study on the biomechanics of bedsharing.

Methods

Three mother-infant dyads were recorded using a single night-vision camera (Phasm Cam) during bedsharing at home. Infants were aged 1.0-2.9 months. A calibration grid (checkerboard-pattern) was used to calibrate a 2D-plane on the sleep surface. Videos were reviewed to mark movement-events, mother-infant contact, and instances of observed airway-obstruction risks. A method for mapping mother-infant positions throughout the night was developed using Python and OpenCV. Frames between movement-events were extracted, and mother-infant positions were identified to create visual maps representing spatial body positions over time. These were used to calculate bedspace occupied by mother and infant, overall bedspace used, and mother-infant overlap.

Results

Each mother-infant dyad presented unique posture and movement data (Figure-1). Mothers occupied 59% and infants 9% of the total bedspace, and combined occupied 60%. Of the bedspace occupied, mother and infant overlap ranged from 0-19%. Dyads 1, 2, and 3 were in contact 100%, 79%, and 0% of the time spent bedsharing. Duration of possible airway-obstruction instances relative to time spent bedsharing was 20.4%, 2.9%, and 0.1% for dyads 1, 2, and 3, respectively.

Discussion

We developed and piloted a novel method of evaluating mother-infant biomechanics during bedsharing in an at-home environment. Each dyad in this study presented unique bedsharing habits. Mothers 1 and 2 slept with their infants in close proximity. Mother 3 placed their infant in an in-bed sleeper. The position map results indicate overlapping bedspace for 2 of the dyads, which may enable suffocation risks. Future work will increase sample size and infant ages to more fully capture the biomechanics of bedsharing.

Head Protection Performance of 3D-Printed Biomimetic Porous Architecture Using Child Head Impactor Drop Analysis

Prof. YUELIN ZHANG[1], Prof. SATOSHI YAMADA[2]

[1]Sophia University, Tokyo, okyo, Japan. [2]Hokkaido University, Sapporo, Hokkaido, Japan

Introduction

The development of head-protection materials capable of effectively mitigating impact forces remains an important challenge in injury-prevention research. We have been experimentally and numerically developing protective materials that provide reliable head protection while maintaining the ability to be used repeatedly and ensuring adequate breathability. These materials incorporate a biomimetic porous architecture [1] and can be fabricated through 3D printing, enabling customization for individual users. In this study, we evaluated the head-protection performance of the developed material using drop analyses with a child head impactor to clarify the relationship between its structural characteristics and impact-mitigation behavior.

Methods

Drop analyses were conducted from a height of 1.5 m onto disk-shaped samples of the protective material with a diameter of 200 mm and a thickness of 25 mm. The acceleration at the center of gravity of the impactor was measured during impact. Thermoplastic polyurethane (TPU) was used for the porous structures, and samples were prepared with volume fractions of 20%, 30%, and 40%. For each configuration, the peak acceleration and the Head Injury Criterion (HIC) were calculated from the measured acceleration time histories. The compressive properties of the porous structures were characterized through drop-tower tests, while tensile properties were obtained from uniaxial tensile testing.

Results

The results showed that samples with higher solid volume fractions (lower porosity) tended to produce lower peak accelerations. Regarding the HIC, the 30% volume-fraction sample produced the smallest value, indicating the most effective impact mitigation under the tested conditions.

Discussion

The 20% volume-fraction sample, having the lowest bending stiffness and the softest structure, was almost completely crushed upon impact, causing the ground effect to dominate the response; consequently, both the peak acceleration and HIC were the

highest for this configuration. Although the 40% volume-fraction sample exhibited a lower peak acceleration than the 30% sample, its shorter impact duration resulted in a higher HIC value. These findings suggest that an optimal balance between stiffness and deformation capacity exists within the biomimetic porous architecture.

Directional Dependence of Multiscale White Matter and Axonal Injury Metrics from Real-World Head Impacts

Mr. Zaryan Masood[1], Mr. Chaokai Zhang[2], Mr. Daniel Bondi[1], Mr. Alexander Jaffray[1], Mr. David Luke[1], Dr. Rebecca Kenny[1], Dr. Adam Clansey[1], Dr. Paul van Donkelaar[1], Dr. Alexander Rauscher[1], Dr. Songbai Ji[2], Dr. Lyndia Wu[1]

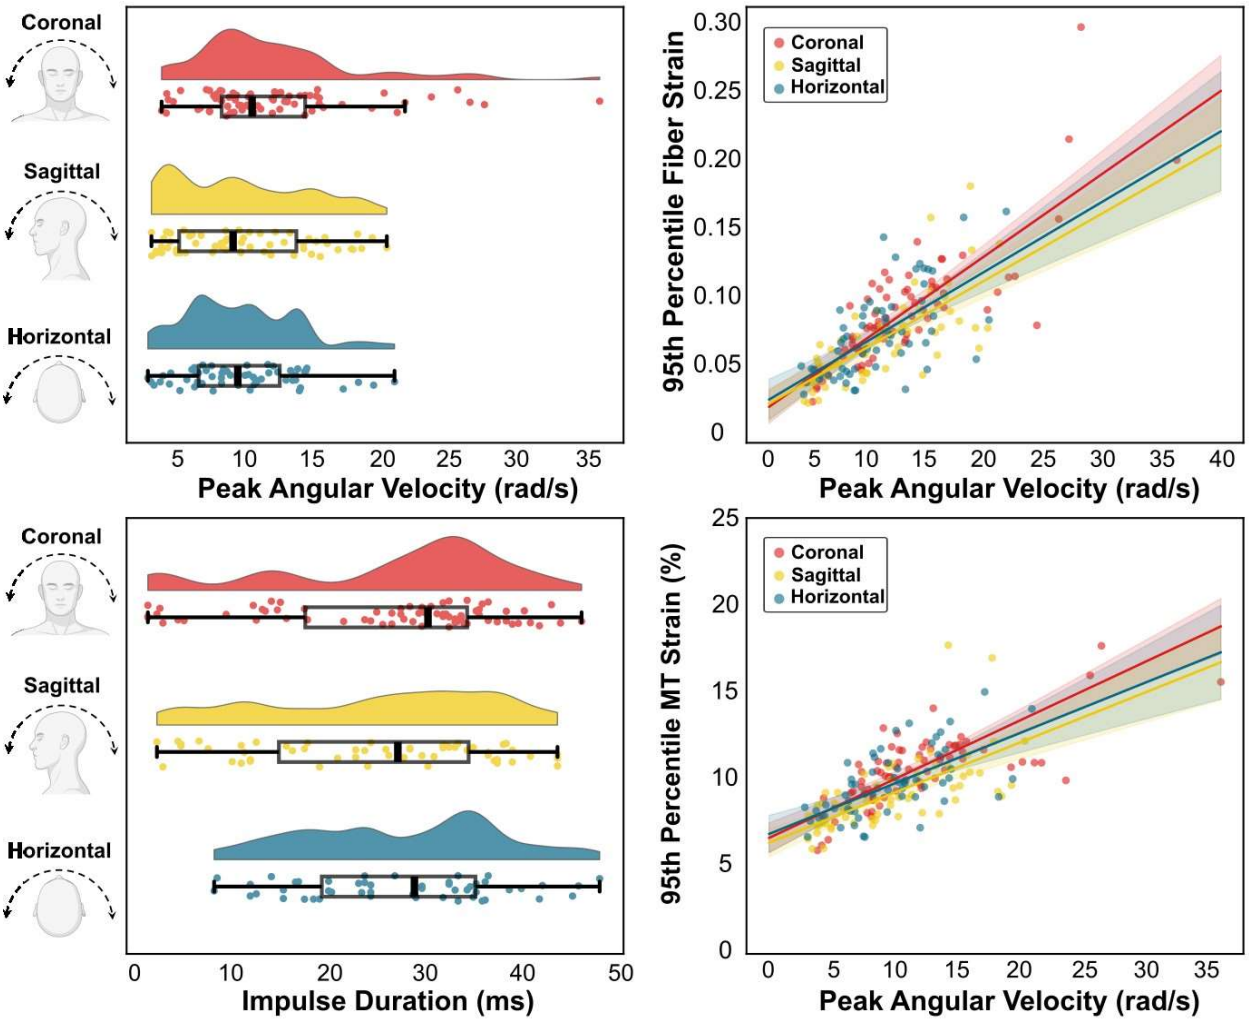
[1]University of British Columbia, Vancouver, British Columbia, Canada. [2]Worcester Polytechnic Institute, Worcester, Massachusetts, United States

Introduction

Traumatic axonal injury (TAI) has shown directional vulnerability in animal studies[1], but this remains less understood in humans, particularly at microstructural scales. Advances in wearable sensors, neuroimaging, and computational modeling now allow large-scale subject-specific simulations of real-world head impacts to estimate deformation from whole-brain to axonal structures. This study examined the directional dependence of white matter fiber strain and axonal substructural damage.

Methods

University men's ice hockey athletes (n = 18; UBC ethics: H21-00400) wore custom instrumented mouthguards (iMGs) over one season, and completed a structural brain MRI scan for subject-specific modeling. We simulated voxel-wise white matter fiber strains and axonal substructural deformations using a deep-learning model[2]. An impact was classified coronal-, sagittal-, or horizontal-dominant when the peak angular velocity in that plane exceeded 90% of the resultant magnitude. We used linear mixed-effects models to determine how rotational plane and peak angular velocity influence 95th percentile fiber strains and axonal substructural injury metrics, with subject ID as a random effect.



Results

We analyzed 608 impacts: 88 coronal-dominant, 86 sagittal-dominant, and 61 horizontal-dominant. Coronal-dominant impacts showed the highest median peak angular velocity (10.5 rad/s) and longest impulse durations (30.3 ms) compared with sagittal (8.4 rad/s, 26.1 ms) and horizontal (8.7 rad/s, 29.7 ms). Coronal- and horizontal-dominant impacts produced significantly higher fiber strains (coronal: $\beta = 0.0087$, $p = 0.028$; horizontal: $\beta = 0.0043$, $p = 0.313$) and microtubule strains (coronal: $\beta = 0.801$, $p = 0.004$; horizontal: $\beta = 0.290$, $p = 0.312$) compared with sagittal-dominant impacts. Neurofilament and tau failure did not differ by rotational plane. Between-subject variance was low, indicating consistent directional effects.

Discussion

Our study uniquely examined the directional dependence of microstructural injury risk using real-world head impact data and neuroimaging-enabled subject-specific multiscale modeling. Coronal- and horizontal-dominant impacts may pose a higher risk for axonal damage relative to sagittal-dominant impacts. The directional vulnerability is further compounded by higher severity coronal impacts sustained on-field, warranting protective equipment improvements and potential rule changes to mitigate high-risk impact directions.

Comparison of Impact Loads during Simulated Falls of 3D-Printed versus Plaster Wrist Casts

Mr. Zhenhao Yang, Mr. Christopher Coluni, Mr. Carl Iven, Ms. Longyu Li, Mr. Yunseo Min, Ms. Iris Zhao, Dr. Peter Cripton, Dr. Agnes d'Entremont

The University of British Columbia, Vancouver, British Columbia, Canada

Introduction

Wrist fractures are common skeletal injuries, inducing great societal and personal costs. Secondary wrist fractures were observed in many patients after treatment, which traditionally involves the use of a circumferential wrist plaster cast. Although effective in stabilising the primary injury, the protection offered in a fall after treatment, leading to a secondary impact, is unknown. A study of the impact loads of novel 3D-printed and plaster casts is needed to assess their comparative performance under secondary impacts.

Methods

The impacts were replicated using a drop tower with a vertical translating carriage at 40 cm high, weighing 14.2 kg to simulate the effective mass of the arm, shoulder, and torso. The impact anvil was tilted at 50 degrees, mimicking oblique hand-to-ground impacts (Fig.1). A six-axis load cell on the carriage recorded reaction loads at 10,000 samples per second. The proximal ends of the custom-made thermoplastic polyurethane distal forearm models were attached to the load cell (Fig.1). The two forearm models were housed in the plaster and 3D-printed (polylactic acid) casts, whose Voronoi cell structure was generated using Blender. A high-speed camera (Phantom v1212) (Fig.1) evaluated qualitative motion and failure evaluation at 19,000 frames per second.

Results

The 3D-printed cast exhibited more proximal deflection and slightly deformed shells, whereas the plaster cast deflected less proximally and showed thin surface cracks. The peak axial impact forces of 706 N and 1049 N were recorded for the 3D-printed and plaster casts, respectively. Due to the larger deflection angle, the 3D-printed cast generated a greater peak proximal moment (My) of 17 Nm versus 8.6 Nm of the plaster cast.

Discussion

The experiment represented the secondary impacts on immobilised broken wrists. Given the larger deflection and moment of the 3D-printed cast, the novel design is stiffer around the wrist, thus offering better structural integrity to maintain the wrist fracture stabilisation.

The higher force and fracture surfaces on the plaster cast suggest less deformation versus the 3D-printed cast, showing no damage and lower force due to its cellular structure. These findings prove that both casts prevented excessive wrist motion, and better compliance and protection were associated with the 3D-printed cast.

Constructing Characteristic Signals of Head Acceleration Events in Stock Car Racing

Miss Zoie Mink[1,2], Mr. Cole Smith[1,2], Dr. Nicholas Pritchard[1,2], Dr. Garrett Bullock[1], Mr. Matthew Harper P.E.[3,1,2], Dr. Jillian Urban[1,2], Dr. John Patalak[3], Dr. Joel Stitzel[1,2]

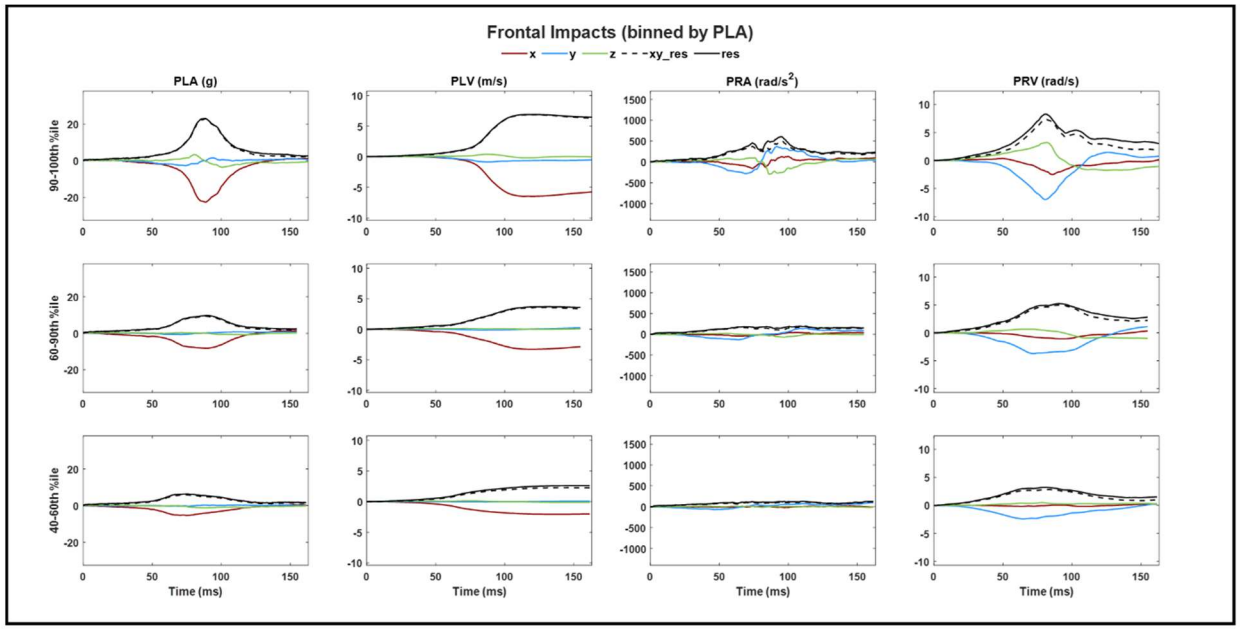
Introduction

Drivers in stock car racing are exposed to head acceleration events (HAEs) during racing. While methods exist to create representative corridors in sports, such as soccer headers, no such corridors have been developed in a motorsports setting [1]. The variability of loading in motorsport HAEs may not be adequately accounted for using these approaches. Therefore, ARCGen was employed which uses arc-length reparameterization and signal registration to develop representative corridors in a wide range of settings [2]. The objective of this study was to characterize HAEs in a motorsport setting using ARCGen-generated representative corridors.

Methods

Head kinematics were collected from 20 NASCAR Cup Series drivers over 41 races during the 2024 season using instrumented mouthpiece sensors configured to collect linear and rotational head kinematics (1600 Hz, 4g threshold). HAEs containing multiple impacts exceeding the trigger threshold were separated into individual impacts. For each impact, peak kinematics including peak linear velocity/acceleration (PLV/PLA) and peak angular velocity/acceleration (PRV/PRA) were calculated. Impacts were grouped into bins by principal direction of force (PDOF), kinematic percentile, and event type (race, crash, combined). ARCGen was used to generate representative kinematic corridors for each bin (x, y, z, x-y resultant, and x-y-z resultant) [2]. Signals were time-aligned using the optimal alignment of PLA.

Results



3,156 HAEs, separated into 4,478 impacts (n=3,818 race, n=660 crash), were recorded during the 2024 season. Corridors, or characteristic signals, were generated for 2,880 distinct bins (Figure 1). When binning the combined dataset by PLA, 40-60th percentile x-y-z

resultant PLA peaks ranged from 3.89 to 6.83 g's while 90-100th ranged from 11.6 to 27.5 g's. Right side impacts had the lowest PLA peaks across percentile bins when binning by PLA and PRA, while rear impacts had the highest when binning only by PLA.

Discussion

Characteristic signals reflecting stock car racing HAEs were created. These may inform driver safety including helmet testing standards, finite element analysis and model validation, and safety system enhancements. This work facilitates cross-sport comparisons to contextualize motorsport racing HAEs relative to other environments.

Fluid Dynamics and Diffusion Study of an Open-Source 3D-Printable Bioreactor and Mechanical Loading System for E*x Vivo* Bone Culture

Ms. Alejandra Correa-Belloso Ph.D. (c)[1], Dr. Mahsa Zojaji[2], Dr. Roshni Rainbow[1], Dr. Heidi Ploeg[1]

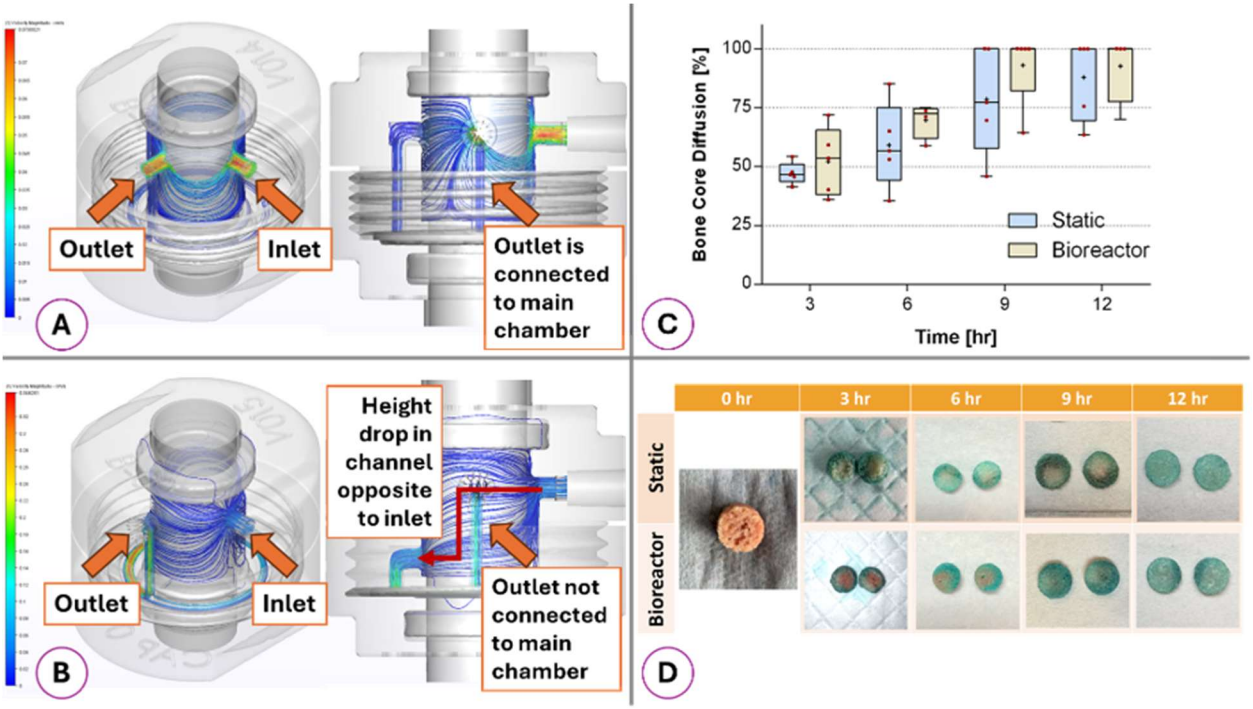
[1]Dept. of Mechanical and Materials Engineering, Queen's University, Kingston, Ontario, Canada. [2]Dept. of Kinesiology and Health Sciences, University of Waterloo, Waterloo, Ontario, Canada

Introduction

Bioreactors are used to study the response of *ex vivo* bone tissue to mechanical stimulation. An open-source 3D-printable chamber was designed [1] to be more cost-effective/adaptable than the original Zetos system. However, the culture media dynamics within the 3D-printable bioreactor chamber (BC), and whether it allows media diffusion to the bone core to maintain tissue viability, remain unknown. This study aimed to **(1)** evaluate the culture media dynamics in the 3D-printable BC, and **(2)** assess culture media diffusion using *ex vivo* bone cores in bioreactors.

Methods

(1) Computational-Fluid-Dynamics (CFD) analyses were performed within the BC (flowrate=6.6mL/hr). Culture medium was modelled as water and bone core as 10×10mm (height×diameter) solid cylinder. **(2)** 10×10mm *ex vivo* bovine-bone cores were used to evaluate the diffusion time of culture medium to the core in static and dynamic (6.6mL/hr) culture. Phosphate-buffered-saline+10% disulphine-blue stain mimicked culture medium. Each bone core was cut in half to measure radial stain infiltration at 3, 6, 9, and 12hr (n=5/group). An Aligned-Rank-Transform, followed by post-hoc tests, were used to assess statistical significance (α=0.05).



Results

(1) Most of the fluid left the BC without diffusing through the bone core due to the closeness between inlet-outlet channels (Figure-A). The BC design was modified and consecutive CFD validation is shown (Figure-B), where zero-velocities are observed surrounding the core. **(2)** Time showed a significant effect in media diffusion ($p<0.001$) (Figure-C). Complete diffusion was observed between 6-9h (Figure-D). After 9h, 80% of the bioreactor samples were completely stained, but only 40% in static-control.

Discussion

Our main findings suggest that 10×10mm bone cores are fully immersed in culture media within the first 6-9h in the 3D-printable BC. The advantageous zero-velocities surrounding the core allow for isolation of mechanical loading as the only source of external stimulation in *ex vivo* bone studies. The validated design is shared with the scientific community to promote *ex vivo* bone research. Future work will improve the accuracy of CFD analyses using bone core models for a better understanding of culture media dynamics and potential shear stresses in bone cells.

Fiber Rearrangement Redistributes Energy and Modulates Intrinsic Cutting Energy in Bovine Glisson's Capsule

Mr Shaobo Zhan[1], Dr Shelby Hutchens[1], Dr Amy WagonerJohnson[1,2]

[1]University of Illinois, Urbana Champaign, Urbana, IL, United States. [2]Chan Zuckerberg Biohub Chicago, Chicago, IL, United States

Mr Shaobo Zhan

Dr Shelby Hutchens

Introduction

In collagenous membranes like bovine Glisson's capsule (bGC), fiber networks redistribute energy during deformation, but how this fiber rearrangement contributes to fracture energy remains unclear. Y-shaped cutting [1] localizes crack-tip stress field and separates intrinsic cutting energy, Gcut*, from boundary effects that confound standard tearing tests. Coupling cutting with in-situ SHG imaging, our objective is to measure how blade radius and fiber rearrangement influence cutting-based fracture descriptors, aiming to guide design of collagen-based biomaterials and tissue surrogates.

Methods

We use Y-shaped cutting on fresh-frozen bGC, with different blade radii and applied far-field tearing according to [1]. We measure cutting and tearing energies to establish Gcut* and the corresponding critical blade radius, r^*, while imaging with SHG to capture fiber rearrangement.

Results

With sharp blades and small tearing, apparent cutting energy converges to an intrinsic cutting energy, Gcut*. At $r \geq r^*$, the slope of cutting energy vs blade radius describes sensitivity to cutting tools [1]. Gcut* is larger and r^* is smaller for bGC [2], but its Gcut*

from cutting is ~2x lower than expected from tearing-based fracture tests [3]. bGC's apparent cutting energy increases with blade radius at a rate ~17x that of silicone, suggesting that local energy redistribution contributes to far-field fracture resistance. The applied-vs-cutting energy slope shows that bGC is less efficient in transmitting far-field energy to crack tip. Together, these energetic signatures are consistent with crack-tip fiber rearrangement, energy redistribution, and higher fracture resistance.

Discussion

Classic fracture tests entangle intrinsic fracture energy and boundary condition effects. Y-shaped cutting allows for Gcut* measurement, along with multiple other size-independent failure descriptors. Results here show that bGC isolates crack tip, likely due to fiber rearrangement, and increases fracture resistance compared to silicone. We will examine fiber rearrangement in depth using glutaraldehyde (GA) treatment, which increases crosslinking without altering fiber network. We expect that increased crosslinking will raise Gcut* by increasing fiber failure cost, whereas GA-stiffened fibers will resist rearrangement and thus lower sensitivity to blade radius and far-field tearing.

Images (Optional)

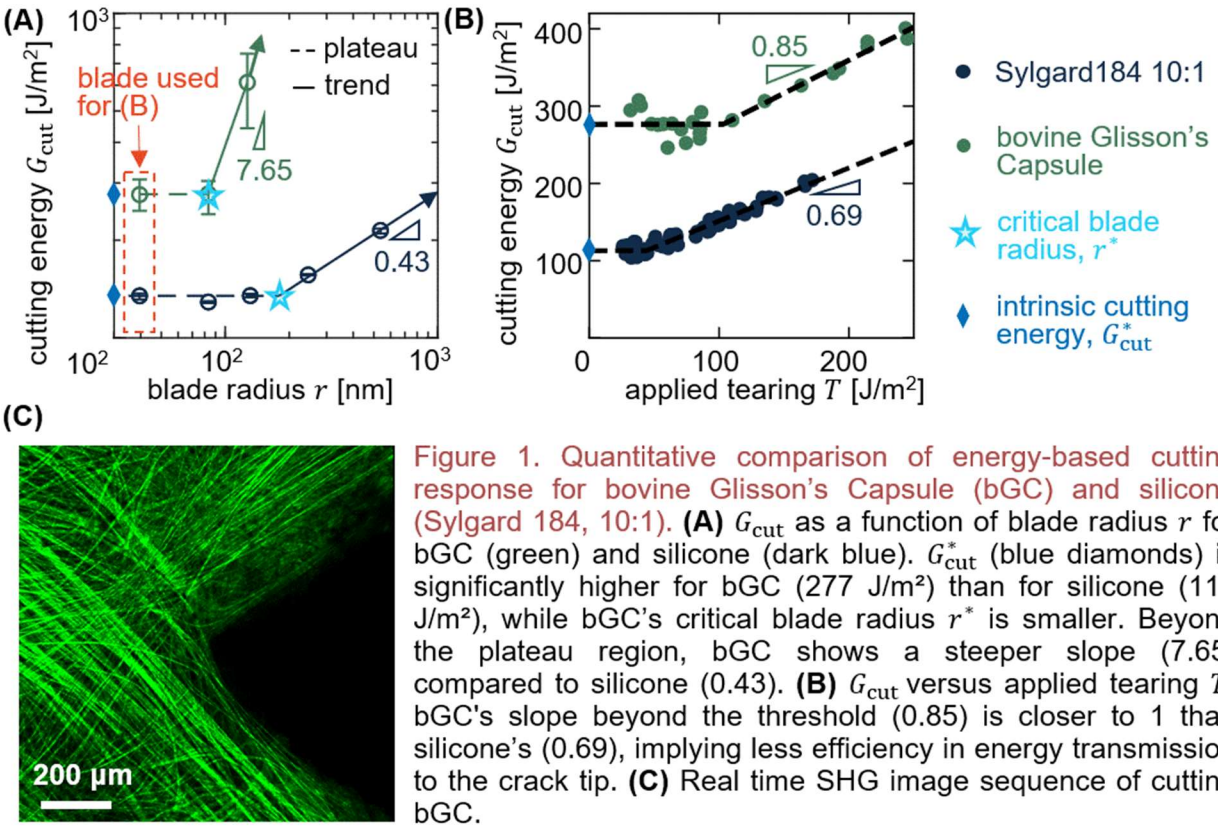

Figure 1. Quantitative comparison of energy-based cutting response for bovine Glisson's Capsule (bGC) and silicone (Sylgard 184, 10:1). **(A)** G_{cut} as a function of blade radius r for bGC (green) and silicone (dark blue). G^*_{cut} (blue diamonds) is significantly higher for bGC (277 J/m²) than for silicone (113 J/m²), while bGC's critical blade radius r^* is smaller. Beyond the plateau region, bGC shows a steeper slope (7.65) compared to silicone (0.43). **(B)** G_{cut} versus applied tearing T. bGC's slope beyond the threshold (0.85) is closer to 1 than silicone's (0.69), implying less efficiency in energy transmission to the crack tip. **(C)** Real time SHG image sequence of cutting bGC.

Improving Tissue Deformation Tracking in Blood Vessel Burst Pressure Tests

Ms. Kaitlyn Murphy[1], Mr. Michael Queenan[1], Ms. Erin Gibbons[1], Mr. Joseph Maucieri[1], Mr. Joe Orban[2], Mr. Don Wilson[2], Dr. Isaac Macwan[1], Dr. Ana Estrada[1]

[1]Fairfield University, Fairfield, Connecticut, United States. [2]Intuitive Surgical, Orange, Connecticut, United States

Introduction

Burst pressure mechanical tests are a key assessment of the effectiveness of blood vessel ligation techniques, and they also serve as an important tool for comparing the material properties and failure modes between natural tissue and synthetic graft alternatives. The project presented here is focused on improving previous burst pressure protocols by incorporating tissue deformation tracking in order to better measure and compare the material properties of porcine renal and carotid arteries to synthetic alternatives.

Methods

We developed a low-cost burst pressure testing accessory table that allows us to record full tests and track tissue deformation. The testing table is a custom-designed 3D printed structure with a camera holder allowing full recordings of sample inflation and pressure sensor readings, as well as a lower platform with 1mm notches to serve as a reference of total sample deformation. The samples, both porcine renal and carotid arteries or synthetic alternatives, are ligated at the free end and connected by a mechanical iris to a needle that pressurizes them with water at a flow rate of 200ml/hr. After the test, the open-source application Tracker is used to calculate the deformation based on markers on the surface of the sample.

Results

We performed preliminary tests on fresh porcine renal arteries (n = 5), with an average time to failure of 93 ± 3 seconds (mean ± 1SD) and a pressure of 2072 ± 366 mmHg. Two initial successful tests yielded an axial strain of 0.40 ± 0.21 and circumferential strain of 0.93 ± 0.32.

Discussion

Preliminary tests demonstrate that the custom-built testing accessory table allows us to properly capture full burst pressure tests and measure tissue deformation. Additional refinement of the testing protocol will allow us to collect more data on porcine and synthetic vessels. This new testing protocol will also be broadly applicable to other

vasculatures. A finite element model of the burst pressure test is being developed in conjunction with the mechanical tests, in order to help characterize and fit material properties of native porcine tissue and synthetic alternatives. This characterization will help us optimize new synthetic graft materials for testing of blood vessel ligation techniques.

Subject-Specific Characterization of the Trochanteric Soft Tissues Improves Impact Force Predictions during Lateral Falls on the Hip: A Comparison of Non-Destructive Inverse Finite Element Modelling and Shear Wave Elastography Approaches

Mr. Steven Pretty, Ms. Alyssa Tondat, Dr. Andrew Laing

University of Waterloo, Waterloo, ON, Canada

Introduction

Increased trochanteric soft tissue thickness (TSTT) is associated with reduced hip fracture risk through impact attenuation during a fall. Beyond thickness, subject-specific variations in the stress-strain behavior of these tissues likely influence impact-loading; however, conventional material characterization approaches are not applicable for clinical screening. The study objectives were to: 1) validate and compare non-destructive trochanteric soft tissue characterization approaches; and 2) evaluate the influence of material behavior on impact attenuation during a fall.

Methods

Fresh soft tissue-femur complexes were extracted from 12 post-mortem human donors. Each side was randomly assigned to one of two tissue characterization approaches.

1. Inverse-Finite Element Modelling (iFEM): Visco-hyperelastic models were defined through iterative-optimization. The objective function was to minimize RMSE between experimental and simulated force-time histories during indentation and stress-relaxation trials. Force-time histories during dynamic loading trials were utilized for validation.

2. Shear Wave Elastography (SWE): Acoustoelastic models were defined through linear fitting of instantaneous shear modulus data across indentation depths applied with an ultrasound transducer. Material parameters and predicted stress-strain responses were compared to contralateral iFEM models to assess agreement.

Following characterization, soft tissues were isolated and mounted to a surrogate pelvis system. Fall simulations were performed at 2 m/s, and peak femoral neck impact force (F_{Neck}) was extracted from an in-line load cell. Pearson correlations and linear regressions were utilized to assess the influence of iFEM and SWE-derived material parameters on F_{Neck}.

Results

Mean (SD) normalized RMSE for iFEM-predicted dynamic loading forces was 5.6 (2.5)%. Absolute agreement between iFEM and SWE models was poor; however, hyperelastic material parameters were moderately to highly correlated (r^2 = 0.54-0.82). For both iFEM and SWE model parameters, non-linear shear modulus was the only predictor of F_{Neck} independent of TSTT (r^2 = 0.36-0.43). iFEM and SWE-predicted strain energy densities improved the explained variance in F_{Neck} by 5.2-7.0%, compared to TSTT alone.

Discussion

Our results suggest both iFEM and SWE characterization methods can improve impact force predictions compared to TSTT alone, driven primarily by subject-specific variation in tissue non-linearity. The more clinically-applicable SWE method exhibited similar performance in assessing material parameter differences between tissues; however, absolute values should be cautiously interpreted.

Parameters Affecting Shear Modulus and Shear Wave Speed in Pressurized Biological Tissues

Ir. Ariana Cihan[1], Prof. Dr. Patrick Segers[1], Dr. Annette Caenen[1,2]

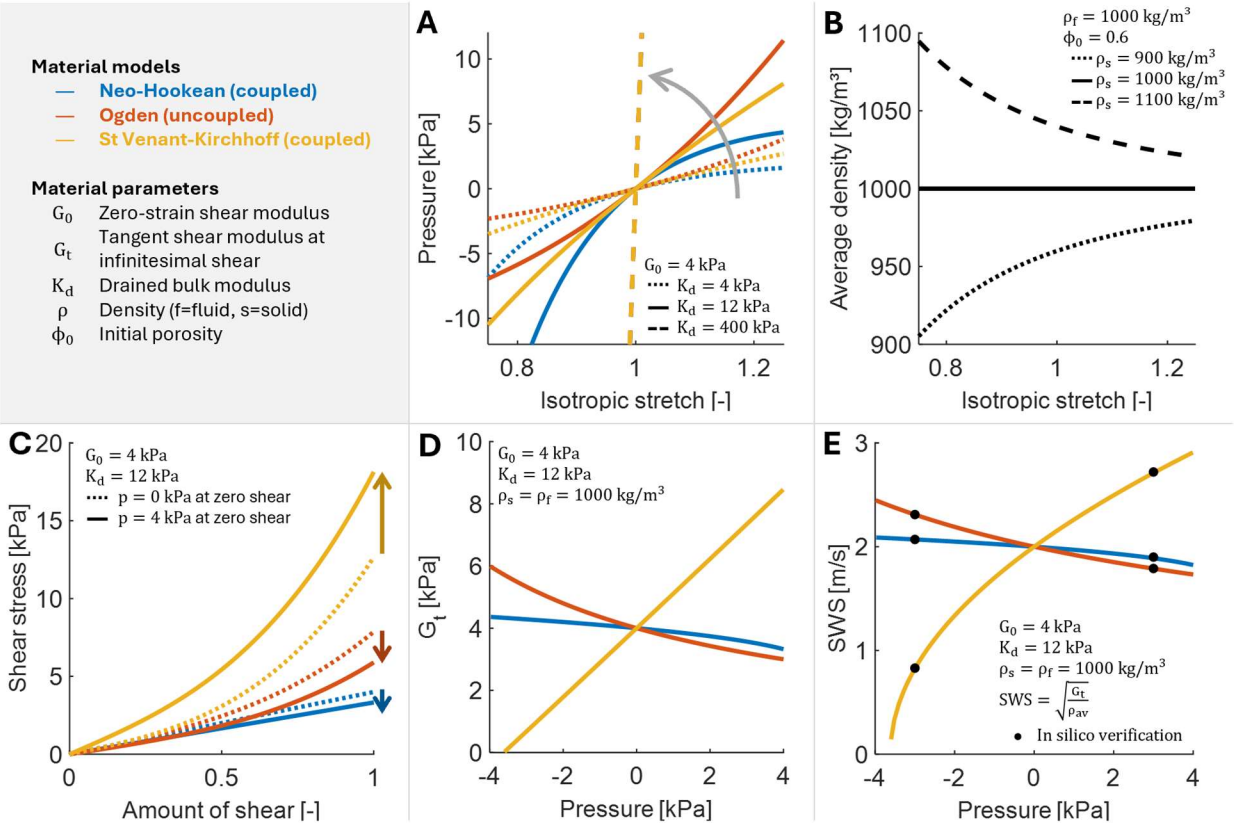
[1]Ghent University, Ghent, Oost-Vlaanderen, Belgium. [2]KU Leuven, Leuven, Vlaams-Brabant, Belgium

Introduction

Shear wave elastography (SWE) estimates stiffness by tracking induced shear waves. As shear wave speed (SWS) reflects interstitial fluid pressure (IFP) in biological tissue[1], SWE may enable non-invasive IFP evaluation, advancing non-invasive diagnosis of a.o. cerebral, hepatic, or renal disorders. To study how pressure affects shear modulus and SWS, we consider poroelastic materials with altered fluid pressure subjected to shear deformation and conduct a parameter study.

Methods

We study the strain energy density of pressurized porohyperelastic materials subjected to simple shear: coupled Neo-Hookean (NH), uncoupled Ogden (OG), and coupled St. Venant-Kirchhoff (SVK). We derive shear stress, tangent shear modulus, and average density analytically. Pressure-dependent SWS is calculated from density and shear modulus at infinitesimal shear strain. This method deviates from the approach of incremental waves in prestressed media[2]. We verify the method using finite element models of acoustically induced shear waves[3]. An initial shear modulus of 4kPa and a pressure range of –4-4kPa were considered.



Results

The strength of pressure-stretch coupling is governed by the drained bulk modulus (Fig. A). The average density is affected by the resulting dilatation (Fig. B) and initial porosity (not shown); it decreases with pressure for a denser solid and vice-versa. Fig. C demonstrates how shear stress-strain curves shift downwards for NH and OG and upwards for SVK at 4kPa. Fig. D quantifies the change in tangent shear modulus with pressure at infinitesimal shear. Fig. E shows the pressure-dependent SWS. Simulation results are added for verification. Over –4-4kPa, SWS decreases by 0.27 and 1.72m/s for NH and OG, and increases by 2.9m/s for SVK.

Discussion

This study introduces a novel analytical framework to estimate SWS in pressurized porohyperelastic materials. Results demonstrate that SWS sensitivity to pressure strongly depends on selected material models and parameters. Of the models examined, only SVK follows the experimentally-observed SWS increase with pressure in ex vivo livers and breasts[1,3]. This highlights the need for future work on experimental calibration and validation. The framework can also be inverted for pressure estimation through SWE.

Evaluating Stiffness and Volume Changes in Pressurized Ex Vivo Kidneys With Ultrasound and Magnetic Resonance Imaging

Ir. Ariana Cihan[1], MSc Yanglei Wu[2], MSc Jennifer Heyl[2], Mr. Pedro Dantas de Moraes[2], MD Paul Spiesecke[2], Prof. Dr. Jing Guo[2], Prof. Dr. Ingolf Sack[2], Prof. Dr. Patrick Segers[1], Dr. Annette Caenen[1,3], Dr. Tom Meyer[2]

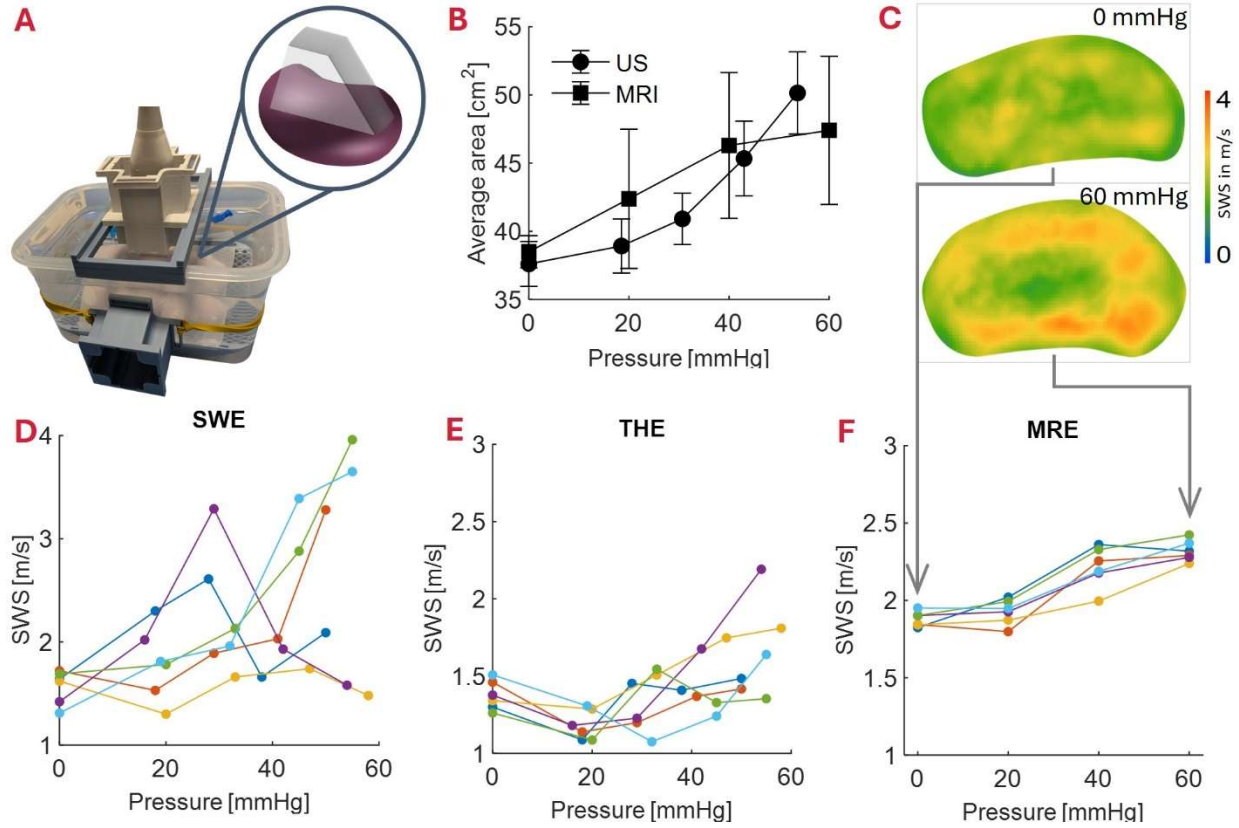
[1]Ghent University, Ghent, Oost-Vlaanderen, Belgium. [2]Charité – Universitätsmedizin Berlin, Berlin, Berlin, Germany. [3]KU Leuven, Leuven, Vlaams-Brabant, Belgium

Introduction

Renal elastography is influenced by both intrinsic tissue stiffness and intrarenal pressure, hindering accurate differentiation of fibrosis and pressure. Evaluation of pressure-induced changes in both volume and stiffness may help towards uncoupling these effects, as proposed for the liver [1] using magnetic resonance imaging/elastography (MRI/MRE). To assess the applicability of this strategy to the kidney, we applied MRI and ultrasound modalities to pressurized ex vivo pig kidneys.

Methods

Six ex vivo pig kidneys were pressurized through the renal artery (0-60mmHg) with ligated renal vein and ureter. Cross-sectional areas were measured from anatomical views in 3D (MRI) and 2D (US) as a proxy for volume. Elastography measurements were performed first on ultrasound-based time harmonic elastography (THE; GAMPTmbH), and clinical shear wave elastography (SWE; Canon Aplio i800) and MRE (3T Siemens Lumina) at another timepoint. Stiffness was estimated based on the propagation speed of shear waves (SWS) induced acoustically (SWE) or external vibration (THE & MRE, 60-80Hz). Fig. A shows the measurement setup with transducer fixations. Regression slopes for volume and parenchymal stiffness over pressure were calculated per kidney and are reported as median [min.,max].



Results

Volumes estimated with MR and ultrasound were sensitive to pressure (Fig. B), with slopes of 0.23[0.20,0.26]cm^2/mmHg. Changes of SWS with pressure are shown in Fig. D-F. The median slopes are 0.0154[0.0009,0.0450]m/s/mmHg for SWE, 0.0041 [0.0003,0.0152]m/s/mmHg for THE, and 0.0082[0.0066,0.0095]cm^2/mmHg. Fig. C displays representative MRE elastograms at baseline and maximum pressure with visible increases in parenchymal stiffness and volume.

Discussion

We present the first combined assessment of renal volume and stiffness changes across controlled pressure levels. Preliminary findings indicate that imaging-based assessment of volume as proxy for pressure combined with stiffness may support uncoupling of fibrosis and pressure. Consistent trends across ultrasound and MRE modalities underscore the potential of this approach, despite differing sensitivities potentially caused by different wave frequencies and transducer locations. Ongoing analysis of the full dataset (including fiber tracking, dispersion, and 3D-ultrasound volume) and biomechanical model calibration will provide further insights into the pressure-volume-stiffness relationship.

Averaging Material Parameters in Hyperelastic Models: Impact of Polynomial vs Exponential Forms

Vanier Scholar Arya Amiri[1], Associate Professor Thomas Willett[1], Assistant Professor Taisiya Sigaeva[2]

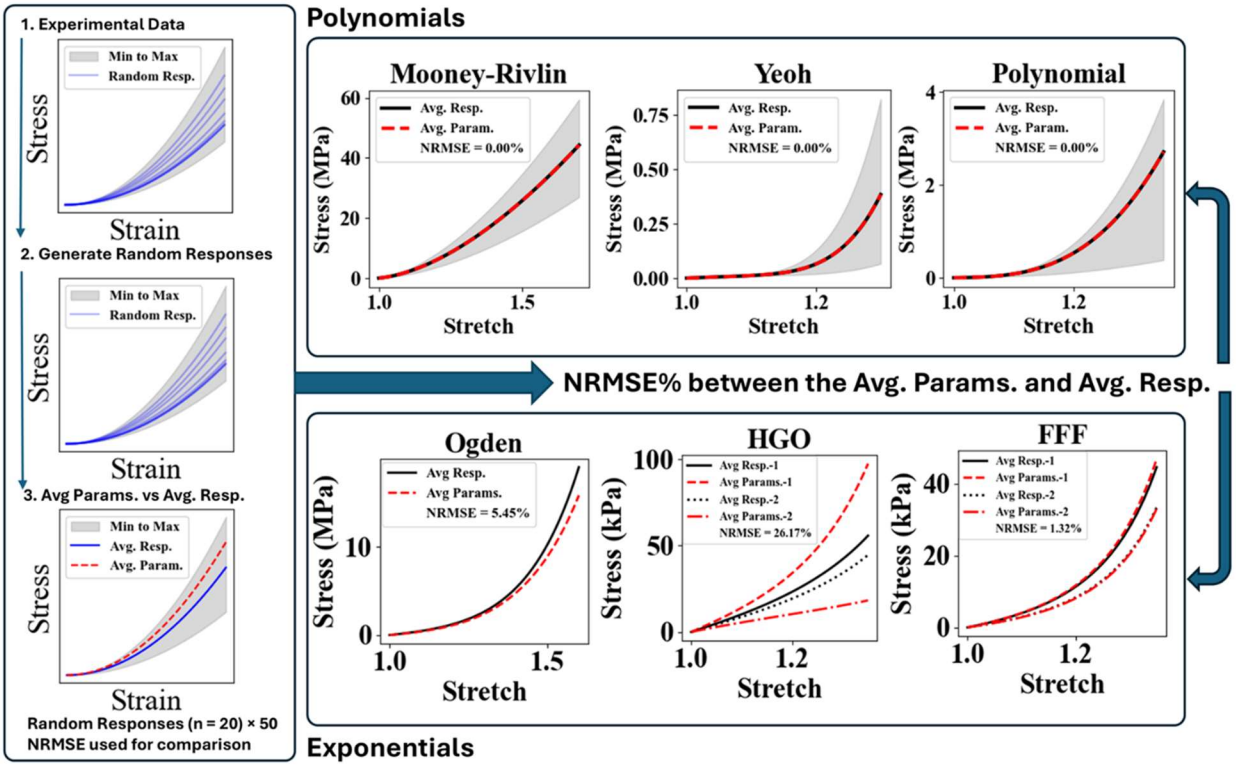
[1]University of Waterloo, Waterloo, Ontario, Canada. [2]University of Calgary, Calgary, Alberta, Canada

Introduction

Hyperelastic constitutive models are mathematical expressions that relate deformation to stress in soft biological tissues. Each model has one or more parameters that are identified by fitting the model to experimental stress-deformation data. For a group of specimens, a single set of parameters is often reported to represent the average behavior. While linear algebra properties like “additivity” and “homogeneity” can predict when averaged parameters yield an average response, it is generally thought that nonlinearity of these models prevents this [1]. The objective is to investigate whether average parameters can reproduce the population’s average responses for several commonly used models and to assess any discrepancies.

Methods

Three polynomial (Mooney-Rivlin, Yeoh, and Polynomial) and three exponential models (Fung, Holzapfel-Gasser-Ogden, and Four-Fiber-Family) were investigated. Uniaxial data was used for the first four models, and equibiaxial data for the last two. Two approaches, algebraic and statistical, were employed for the analysis. The normalized root-mean-square error (NRMSE) was used to quantify the discrepancy between the predicted responses from averaged parameters and the actual averaged responses.



Results

Both algebraic and statistical results show that constitutive models can be classified into two categories: polynomial and exponential. For polynomial models, average parameters reproduce the average response, despite their nonlinear behavior. In contrast, for exponential models, the deformation level affects how well average parameters predict the average response.

Discussion

A new finding that has not been previously reported is that for polynomial models, average parameters reproduce the mean mechanical response without any discrepancy, suggesting that model type, not nonlinearity alone, is the key factor. Even for exponential models, average parameters can predict the mean response of the population with an NRMSE as low as 2.5% at typical experimental stretches, although the discrepancy increases at higher stretches. These results clarify the behavior of various constitutive models and support using average parameters to represent a population when appropriate. As a limitation of this study, it should be noted that although the algebraic approach allows generalization to all constitutive models, only six models under uniaxial and equibiaxial testing protocols were investigated.

Musculoskeletal–finite element modeling of knee joint mechanoinflammation and cartilage adaptation

Dr. Atte Eskelinen Ph.D.[1], Dr. Joonas Kosonen Ph.D.[1], Mr. Joose Peitola M.Sc.[1], Prof. Rami Korhonen Ph.D.[1], Adj. Prof. Petri Tanska Ph.D.[1,2], Dr. Amir Esrafilian Ph.D.[1]

[1]Department of Technical Physics, University of Eastern Finland, Kuopio, North Savo, Finland. [2]Cancer Center, Kuopio University Hospital, Wellbeing Services County of North Savo, Kuopio, North Savo, Finland

Introduction

Abnormal biomechanics and joint inflammation are key factors for knee osteoarthritis progression. Previous joint-level computational models have typically considered cartilage stresses and strains [1] and inflammation as separate candidate mechanisms for disease progressors, thereby overlooking their combined effects. Specifically, mechanical activation of mechanosensitive cell receptors resulting in cellular release of cartilage-degrading enzymes, termed mechanoinflammation, has not been implemented in joint-level models. The objective of this proof-of-concept study was to establish the first computational knee joint model that integrates cartilage mechanical responses from musculoskeletal–finite element (MS–FE) analysis, subsequent chondrocyte responses with downstream mechanoinflammation, exogenous pro-inflammatory cytokine diffusion, and adaptation of tissue composition and mechanical properties.

Methods

Knee magnetic resonance imaging- and motion capture-based personalized MS–FE model [2,3] was created for a single subject (Fig. 1A). MS model provided inputs (knee flexion angle, medial vertical joint contact force) to FE model of medial tibiofemoral joint with fibril-reinforced poroviscoelastic cartilage (Abaqus). FE simulation estimated cartilage maximum shear strain distributions, used as input to mechanoinflammatory model (COMSOL Multiphysics), with strains >15% [1] triggering phenotypic transition of chondrocytes from “healthy” to “damaged” state. Damaged cells and cells interacting with diffusing pro-inflammatory cytokines (94 pg/ml at synovial fluid–cartilage-interface [4]) released aggrecan-degrading enzymes. Resulting aggrecan loss was linked to increased permeability, and tensile stresses >7 MPa to collagen loss in iteratively updated material [1]. Three consecutive iterations estimated 3-year cartilage adaptation.

Results

The 3-year simulation transitioned 30% of total cells into “damaged” state in cartilage contact region with excessive shear strains (Fig. 1B). Aggrecan content decreased by 53% in this region and 31% in regions experiencing only exogenous inflammation at 3-year timepoint.

Discussion

Mechanoinflammation was localized as opposed to cytokine diffusion, with cell state distribution and aggrecan loss similar to experimental *ex vivo* estimates although needing rigorous *in vivo* calibration [4]. MS–FE-mechanoinflammation modeling helps designing interventions such as gait retraining and anti-inflammatory drugs.

Images (Optional)

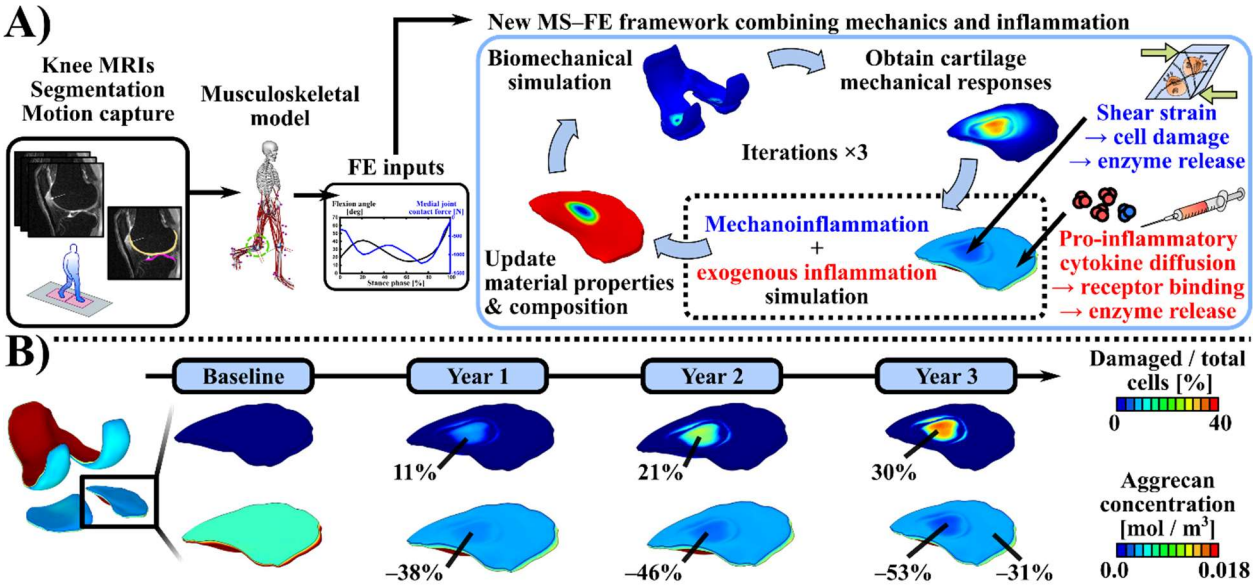

Figure 1. (A) Knee MRIs were used to create a personalized musculoskeletal (MS) and a finite element (FE) model. The MS model and motion data were used to obtain FE model inputs. The FE model estimated cartilage mechanical responses, out of which the shear strain response (→ cell damage → mechanoinflammatory ADAMTS enzyme release) was simulated together with exogenous pro-inflammatory cytokine diffusion. The framework within the blue box was looped over three iterations, with updated material properties and composition. **(B)** In the mechanoinflammatory simulation, the cell damage decreased locally in highly sheared regions, resulting in ~50% local aggrecan loss between baseline and 3-year timepoint. Exogenous inflammation led to ~30% aggrecan loss.

Biomechanical and Structural Characterisation of Perineal Tissues Across Multiple Scales

PhD Beatrice Bisighini[1], PhD Cristina Cavinato[2], PhD Sarah Iaquinta[3], Prof Anne-Sophie Caro[3], PhD Baptiste Pierrat[1]

[1]Sainbiose, Mines Saint-Étienne, Saint-Étienne, Auvergne-Rhône-Alpes, France. [2]LMGC, Université de Montpellier, Montpellier, Occitanie, France. [3]LMGC, Mines Alès, Alès, Occitanie, France

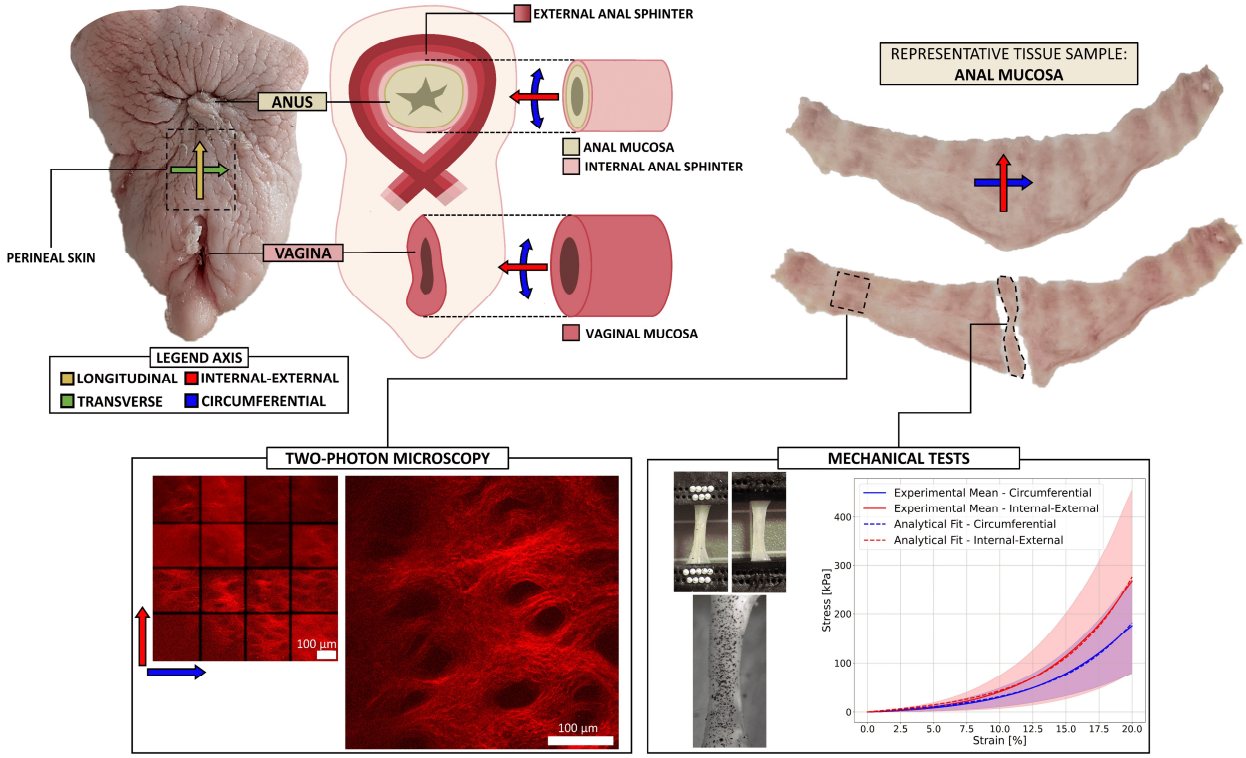
Introduction

Perineal tears affect more than 85% of primiparous women undergoing vaginal delivery and can involve multiple tissue layers, leading to long-term consequences. Yet, the mechanical behaviour of the perineal tissues remains poorly characterised, limiting the accuracy of existing biomechanical models [1]. To address this gap, this study provides a comprehensive, multi-scale assessment of the mechanical behaviour and structural organisation of five porcine perineal tissues: the skin, vaginal and anal mucosae, and internal and external anal sphincters.

Methods

Ex-vivo tissue samples cut into dog-bone specimens along two perpendicular directions–except for the external anal sphincter, tested only along its main axis. Mechanical experiments were designed to reproduce the in-vivo loading conditions of labour, performing uniaxial tensile tests under cyclic loading at different strain levels up to specimen rupture. Digital image correlation ensured accurate strain measurements. The mechanical response of each tissue was characterised through inverse analysis using a Veronda–Westmann hyperelastic model. Structural characterisation complemented mechanical testing: two-photon excitation microscopy quantified 3D microscale collagen organisation of each layer, while micro-CT imaging provided 3D information on the fibrous architecture of whole perineum.

Results



The five perineal tissues exhibited distinct mechanical responses. During the cyclic loading, the anal and vaginal mucosae demonstrated the highest stiffness, the skin showed an intermediate response, and the sphincters presented the lowest stiffness, consistently with literature [2]. Direction-dependent behaviour was observed, especially for the internal anal sphincter. Structural imaging revealed distinct collagen architectures aligning with mechanical behaviour. The skin contained thin, transversely oriented fibres,

whereas the anal mucosa exhibited a laminar structure with pores slightly elongated circumferentially. The vaginal mucosa showed a more compliant, loosely arranged collagen network. Both sphincters contained thick, wavy collagen fibres. Micro-CT confirmed the anisotropic architecture of the sphincters and highlighted the folded morphology of the anal mucosa and skin in their physiological configuration.

Discussion

The study established essential baseline mechanical and structural markers for perineal tissues, emphasising their anisotropy and layered heterogeneity. Future developments will include in-situ-imaging under controlled loading to better reflect in-vivo fibre orientation, high-rate tests, and detailed viscoelastic characterisation.

Variations in the Contribution of Fluid Pressurization to Compressive Muscle Stiffness from Local to Global Indentation

Dr. Benjamin Wheatley[1], Mr. Gianni Valentine[1], Dr. Pierre-Yves Rohan[2]

[1]Bucknell University, Lewisburg, Pennsylvania, United States. [2]ENSAM, Paris, Ile-de-France, France

Introduction

Fluid pressurization has been proposed as a contributor to passive skeletal muscle stiffness under compression. However, it remains unclear whether this behavior depends primarily on global fluid drainage conditions or on local fluid–solid interactions arising near the contact region. Our working hypothesis is that global stiffness is relatively insensitive to changes in global drainage, while local deformation scale and permeability would modulate the extent of fluid pressurization, with smaller indenters generating proportionally greater fluid-supported loads.

Methods

Micro-indentation tests were performed on passive skeletal muscle under two drainage configurations: intact (whole) and sectioned (to increase global fluid escape) on three different muscles (n=20 each, lateral gastrocnemius, medial gastrocnemius, and vastus intermedius). Each test involved a pre-load via an outer sheath followed by 0.4 mm indentation with an inner indenter. Statistical comparisons across muscle groups were performed using one-way ANOVA with post-hoc tests, with significance set at $p < 0.05$. An axisymmetric finite element model (Figure 1A-B) was developed using (i) a biphasic formulation with Holmes–Mow hyperelasticity (E = 0.01 MPa, nu = 0.1, beta = 4, Phi0 = 0.01) with isotropic permeability (k = 0.075), and (ii) an equivalent solid-only formulation. Indenter radius was varied from 0.5–5 mm to evaluate scaling effects on pressurization and load sharing.

Results

Any effects of whole versus sectioned or muscle group on peak indentation force (515 mN, p=0.20) and relaxation rate (-17 mN/sec, p=0.14) were not statistically significant. In contrast, simulation results showed a clear scale effect, specifically the fraction of

indenter reaction force due to fluid pressurization increased with increasing indenter radius (Figure 1C-D).

Discussion

Results indicate that skeletal muscle stiffness under compression - specifically the contribution of fluid pressurization to tissue stiffness - depends on deformation scale. Our experimental results show that global fluid drainage does not affect local tissue stiffness. The rapid increase in fluid-supported load with increasing indenter radius observed in our finite element simulations suggests that fluid pressurization dictates compression stiffness under volumetric compression. These findings can help understand specific mechanisms of clinically relevant compressive muscle behavior *in vivo*, such as the interaction with a prosthetic socket.

Images (Optional)

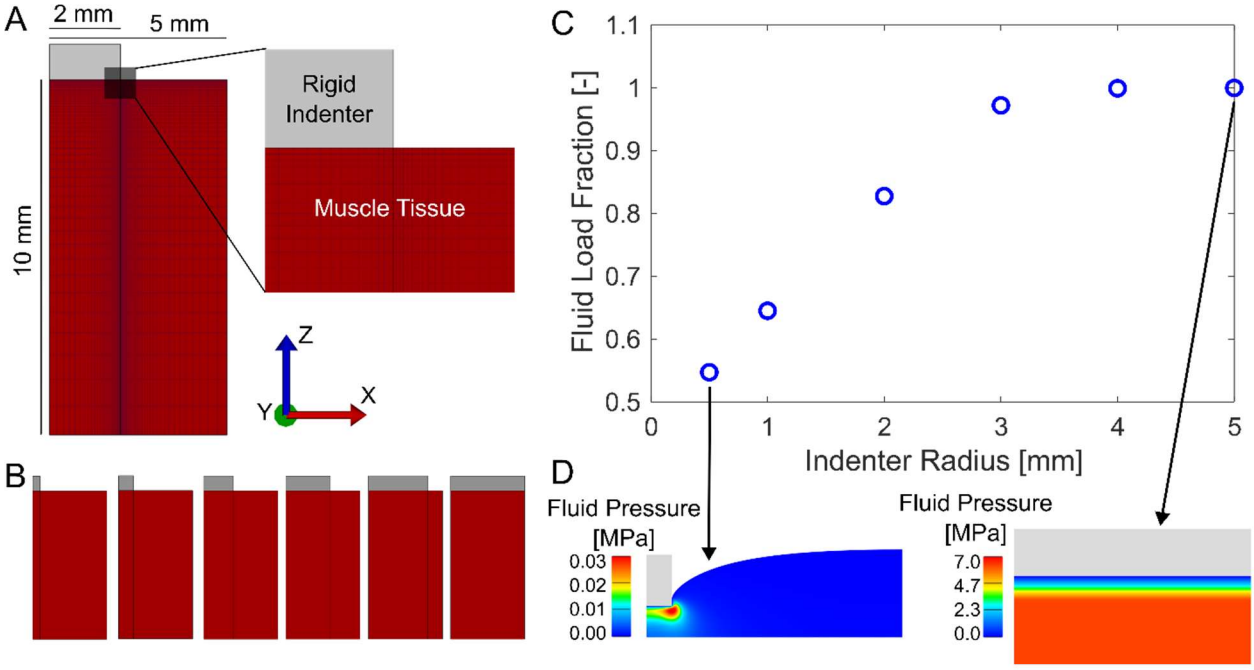

Figure 1. A) Indentation finite element model geometry with enlarged region showing finer mesh density. Top surface of the muscle was defined as free draining with all other surfaces as no fluid flow. Indenter was prescribed a 1 mm (10% nominal strain) displacement in the -Z direction over 1 second. Displacement boundary conditions on lateral sides of the muscle created an axisymmetric, confined condition. B) Six model geometries used for the six different indenter sizes. C) Fluid load fraction (defined as 1 - the ratio between solid-only model and biphasic model indenter reaction forces) as a function of indenter radius. This describes the evolution the fluid-pressurisation to the global compressive stiffness. D) Fluid pressure [MPa] distribution in muscle tissue for indenter radius of 0.5 mm (left) and 5 mm (right) respectively.

Characterizing the Cyclic Viscoelastic Response of Human Penile Tissues for Improved Inflatable Penile Prosthesis Applications

Dr. Jhaleh Amirian[1,2,3], Dr Majid Akbarzadeh Khorshidi[1,2,3], Mr. Brian Watschke[4], Mr. Thomas Sinnott[5], Prof. Caitríona (Tríona) Lally[1]

[4]Urology, Boston Scientific Corp, Inc, Minnetonka, MN, United States. [5]Urology, Boston Scientific Corp, Inc, Clonmel Co, Tipperary, Ireland

Dr. Jhaleh Amirian

Introduction

More than half of men aged 40–70 experience erectile dysfunction (ED) [1,2]. Inflatable penile prostheses (IPPs) are the gold-standard treatment for patients who do not respond to medical therapy [3]. Their long-term performance is, however, often limited by damage or erosion to surrounding penile tissues, whose complex composition and viscoelastic behavior have remained poorly characterized [3]. Understanding penile tissue biomechanics is crucial to evaluating IPP-tissue interactions [1]. Among these tissues, the corpus cavernosum (CC) and tunica albuginea (TA) play the most influential roles during implantation [2]. Considering that successful implantation and long-term function of IPPs are dependent upon the biomechanical properties of the TA and CC, this study explores the effects of strain rate and loading history on these tissues.

Methods

Three human penises (75–89 years, post-mortem interval 1–5 days) were obtained from Science Care. Segments were prepared from TA (5:1 length-to-width ratio) and CC (6 mm length, 4.6 mm diameter) (Figure 1a–b). TA samples underwent tension to 10% strain and CC samples compression to 50%, with three loading cycles applied, each followed by 10 minutes of holding at maximum strain and 10 minutes relaxation.

Results

Both CC and TA displayed nonlinear stress-strain behaviour and clear viscoelasticity (Figures 1c–d). Both tissues displayed increased stiffness with strain rate (CC: 4.7 → 12.4 MPa; TA: 4.5 → 9.3 MPa) (Figure 1e–f). Following a 30-minute relaxation period, CC demonstrated a noticeable return to its original shape, confirming a time-dependent behaviour. CC and TA exhibit viscoelasticity, strain-rate dependence, and time dependence, which is crucial to understanding the interaction between IPPs and tissue.

Discussion

Both CC and TA showed viscoelastic and strain-rate–dependent behavior. Strain rate strongly increased tissue stiffening in both CC and TA, linking tissue response directly to IPP inflation rate. These findings show that the IPP inflation rate significantly affects tissue stresses and should be considered in device design and in user inflation guidelines to reduce the risk of tissue damage.

Images (Optional)

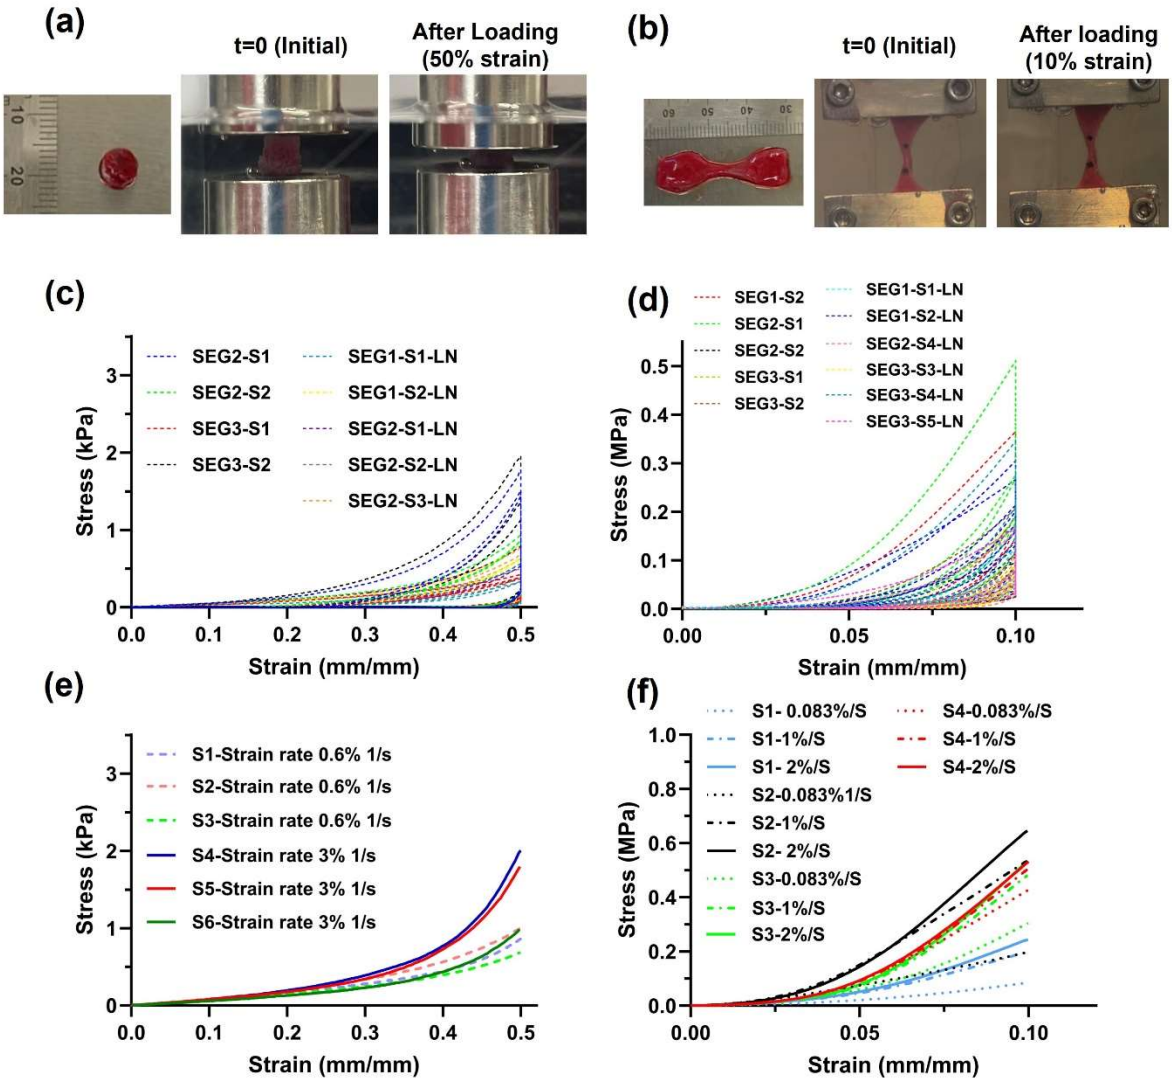

Figure 1 (a) CC before and after 50% compression; (b) TA before and after 10% tension; (c–d) three loading cycles with 10-min hold and 10-min relaxation for CC and TA, respectively (n≥4); (e–f) strain-rate dependency of CC and TA, respectively (n=3).

A Virtual-Fields-Based Metric to Assess Elastography Data Quality for Anisotropic Inversion

Mr. Adam Quin, Prof. Callan Luetkemeyer Ph.D.

University of Illinois Urbana-Champaign, Urbana, IL, United States

Mr. Adam Quin

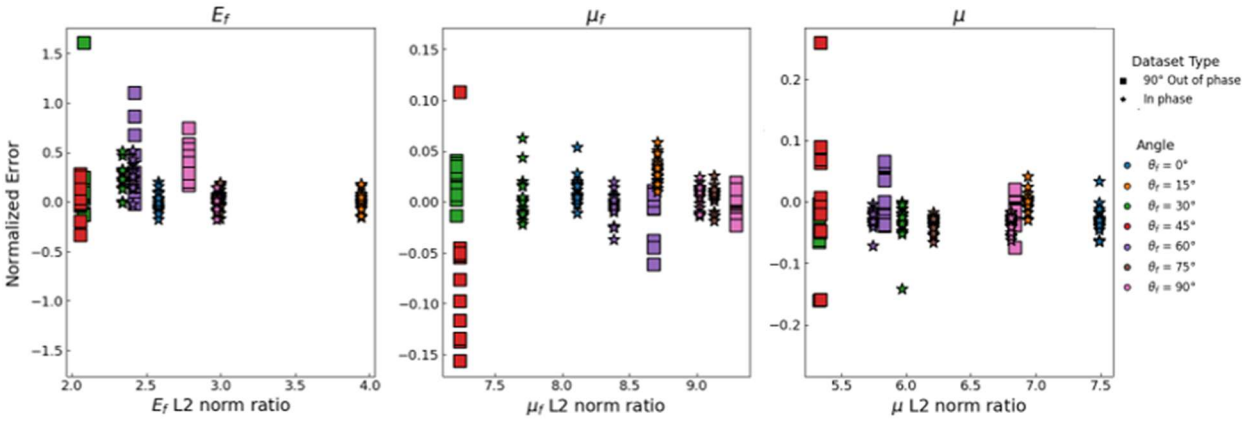
Introduction

Magnetic resonance elastography (MRE) estimates tissue mechanical properties from displacement fields, but traditional inversion methods assume isotropy, limiting diagnostic specificity for anisotropic tissues like brain white matter. The optimized virtual fields method (OVFM) is a robust, computationally efficient approach to the inverse problem, enabling implementation of microstructure-informed constitutive models. However, its performance hinges on whether experimental data contain adequate information to reliably calibrate parameters, which likely depends on directions of wave propagation and relative to fibers. To guide experimental design and interpretation, we propose a robust metric for assessing data quality prior to inversion.

Methods

Steady-state harmonic finite element simulations were performed in Abaqus to mimic elastography experiments on a cube of transversely isotropic material, with single or dual harmonic actuations. Simulated displacement fields were processed through the OVFM pipeline to estimate homogeneous material properties. To test noise robustness, 20 Gaussian noise copies ($\sigma = 5\%$) were added to each displacement field prior to inversion. Performance was evaluated across datasets varying fiber orientation, actuation phase offset, and number of actuation directions. The proposed metric was defined as the ratio of the L2 norm of the OVFM constraint vector for each parameter to the same value computed on a noise-only field, providing a signal-to-noise-like measure for each constitutive parameter.

Results



Higher L2 norm ratios consistently predicted improved inversion performance, reflected by reduced error variability and increased convergence. Data quality was strongly influenced

by fiber orientation (performance degraded near 45°), number of wave propagation directions (dual actuation outperformed single), and relative phase of dual waves (out-of-phase was superior to in-phase).

Discussion

These findings demonstrate that the proposed metric effectively captures data richness and predicts inversion reliability for anisotropic OVFM. Results highlight the sensitivity of elastography inversion to experimental factors and underscore the importance of thoughtful experimental strategies. Future work will apply this metric to experimental datasets to guide elastography protocol design and provide confidence measures for estimated parameters.

Biophysics-informed Computational Platform of Shear Wave Elastography for Assessing Cervical Remodeling

Postdoctoral Researcher Camilo Duarte-Cordon Ph.D.[1], Undergraduate Researcher Eden Katz[1], Assistant Professor Ivan Rosado-Mendez Ph.D.[2], Professor Kristin Myers Ph.D.[1]

[1]Columbia University, New York, New York, United States. [2]University of Wisconsin Madison, Madison, Wisconsin, United States

Introduction

Spontaneous preterm birth (sPTB) is the leading cause of neonatal death, affecting 1 in 10 pregnancies worldwide. Unfortunately, sPTB rates have remained stagnant, partly due to the lack of effective diagnostic methods. Shear Wave Elastography (SWE) is a promising ultrasound technology for evaluating sPTB risk. Shear wave speed (SWS), a SWE parameter, can be used to estimate tissue stiffness as shear waves travel faster in stiffer tissues. Given that some pathways leading to sPTB induce premature cervical softening, SWS may serve as a biomarker for sPTB. However, SWS measurements are highly variable due to the cervix's complex mechanical behavior and microstructure, which limit SWE application in obstetrics.

Methods

To better understand the effects of cervical mechanics and microstructure on SWS, we implemented a SWE finite element (FE) platform in the software FEBio. Shear waves are generated by applying a transient Gaussian body force at a focal point within the geometry. This simulates the application of an acoustic radiation force (ARF) field by an ultrasound transducer. FE simulations of shear wave propagation in the cervix are run using two 3D geometries (see Fig. 1): a representative volume element (RVE) of the cervical stroma and a cylindrical model that accounts for the cervix's layered collagenous structure. A constitutive material model was assigned to each geometry, which captures the cervix's microstructural anisotropy, nonlinear elasticity, and viscoelasticity at non-pregnancy and late pregnancy. SWS was estimated as the shear-wave group velocity using the time-to-peak displacement algorithm, which employs the FE node-displacement field.

Results

Our results indicate that SWS is sensitive to material properties, including the initial fiber stiffness of collagen fibers, fiber dispersion, anisotropy, and the degree of nonlinear elasticity within the tissue. Consequently, as gestation progresses, SWS decreases as fiber

dispersion increases and stiffness decreases. Additionally, SWS is sensitive to the anatomical location at which it is measured.

Discussion

This work emphasizes the importance of accounting for tissue anisotropy, nonlinear stiffness, and viscoelasticity when estimating tissue stiffness from SWS. Future efforts should focus on developing SWE protocols that account for biological sources of variability and maximize sensitivity to cervical remodeling pathways that are early predictors of sPTB.

Images (Optional)

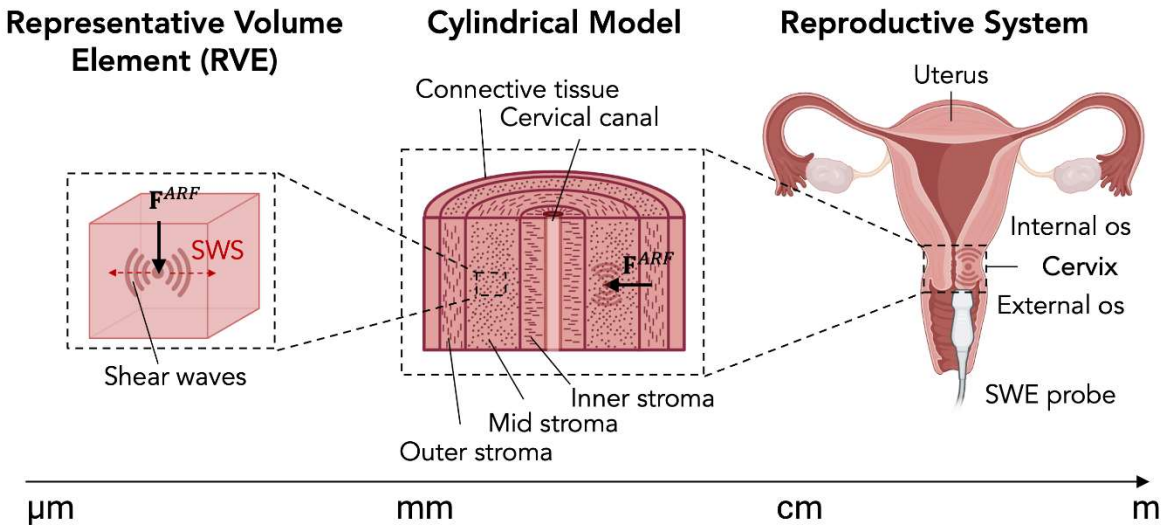

Fig. 1. 3D geometries used for finite element simulations of shear wave propagation, including a representative volume element (RVE) of cervical tissue from the mid stroma and a cylindrical model depicting the cervical canal, the inner stroma with radially oriented collagen fibers, the mid stroma with circumferentially oriented fibers, the outer stroma with longitudinally oriented fibers, and an outer layer of connective tissue.

Vascularisation Dynamics in Endometriotic Lesions: A Mathematical Model of Angiogenic Factors and Blood Flow

Ms Cécilia Olivesi, Prof Alys Clark, Dr Claire Miller

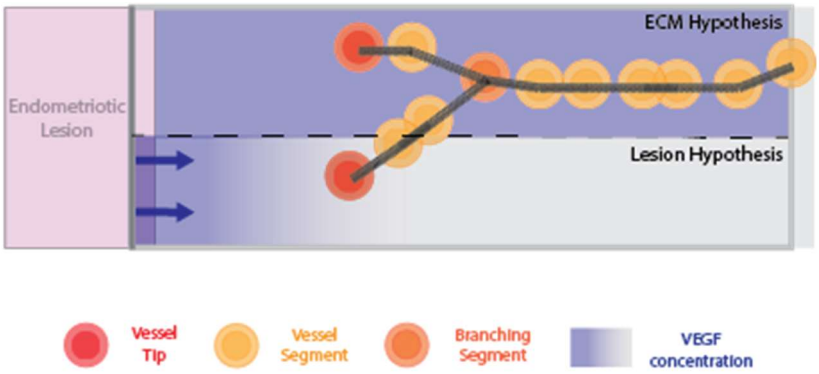
Auckland Bioengineering Institute, the University of Auckland, Auckland, Auckland, New Zealand

Introduction

Endometriosis, a condition where endometrial-like tissue grows outside the uterus, impacts 1 in 10 women of reproductive age. For endometriotic lesions to implant and grow they require a blood supply, which is established via angiogenesis. Lesions are categorised based on characteristics related to vascularisation: red lesions are highly vascularised and active (presence of inflammation with ongoing cell proliferation); black lesions are less vascularised with old blood deposits; and white lesions are mostly inactive. VEGF, an angiogenic factor, has been found in higher concentration near red lesions in comparison to other lesion types. This study aims to test if the primary source of VEGF influences the lesion's level of vascularisation and how it affects the structural and hemodynamic characteristics of the blood network.

Methods

We apply an agent-based model of angiogenesis to the microenvironment of an endometriotic lesion, using an overlapping spheres method for describing vessel dynamics and a continuum model of VEGF concentration. Blood flow through the emergent vascular network is described using Poiseuille's law, assuming low Reynolds number flows. System behaviour is assessed under two VEGF scenarios: 1) an increased extracellular matrix (ECM) VEGF concentration in the lesion microenvironment (ECM hypothesis); 2) a high production of VEGF inside the lesion diffusing into the ECM (lesion hypothesis).



Results

The model predicts a higher number of branches under the ECM hypothesis compared to the lesion hypothesis; therefore, the total vascular supply inside the lesion is increased. However, under the lesion hypothesis, the vascular network reaches the lesion faster, which could increase the lesion's survival prospects. In the lesion hypothesis, the vascular network grows predominantly in the direction of the lesion compared to the ECM hypothesis, in which the network supplies both the lesion and its surrounding tissue.

Discussion

Our study shows that different VEGF profiles could explain the heterogeneity in endometriotic lesion vascular networks. In the future, we aim to explore if the ECM and lesion hypotheses could describe the different vascular networks observed in red and black lesions by comparing our computational results to imaging.

Regionally Varying Biomechanical and Structural Remodeling of the Murine Colon in an Acute Model of Inflammatory Bowel Disease

Ms. Chastity Chavez[1], Mr. Soto Kubo[1], Ms. Piper Welsh[1], Ph.D. Christy Gliniak[2], Ph.D. Philipp Scherer[2], Ph.D. Jacopo Ferruzzi[1]

[1]The University of Texas at Dallas, Richardson, TX, United States. [2]University of Texas at Southwestern, Dallas, TX, United States

Introduction

Inflammatory bowel disease (IBD) is characterized by excessive immune responses within the gastrointestinal tract which trigger extracellular matrix (ECM) remodeling. This process involves structural modifications in fibrillar collagen that disrupt colonic function and create a risk for IBD-induced colon cancer. Prior literature used microindentation testing to demonstrate an increased stiffness in human IBD samples but failed to capture the physiologically relevant multi-axial loading state. Here, we hypothesized that acute inflammation impacts the biomechanical function of the colon in a regionally heterogenous manner, reflecting structural differences along the length of the colon.

Methods

Adult mice (C57BL/6J, 12-week-old) of both sexes (18 females and 18 males) were randomly assigned into treatments groups of 0%, 2.5%, or 5% dextran sodium sulfate (DSS) in drinking water to trigger acute IBD. After five days of DSS exposure, the colon was harvested and divided into four cylindrical sections: two proximal (P1 and P2) and two distal (D1 and D2) regions. Each region underwent biaxial inflation-extension mechanical testing to obtain circumferential and axial properties. Fixed sections were stained with Hematoxylin and Eosin (H&E) and Picro–Sirius Red (PSR) for microstructural analysis.

Results

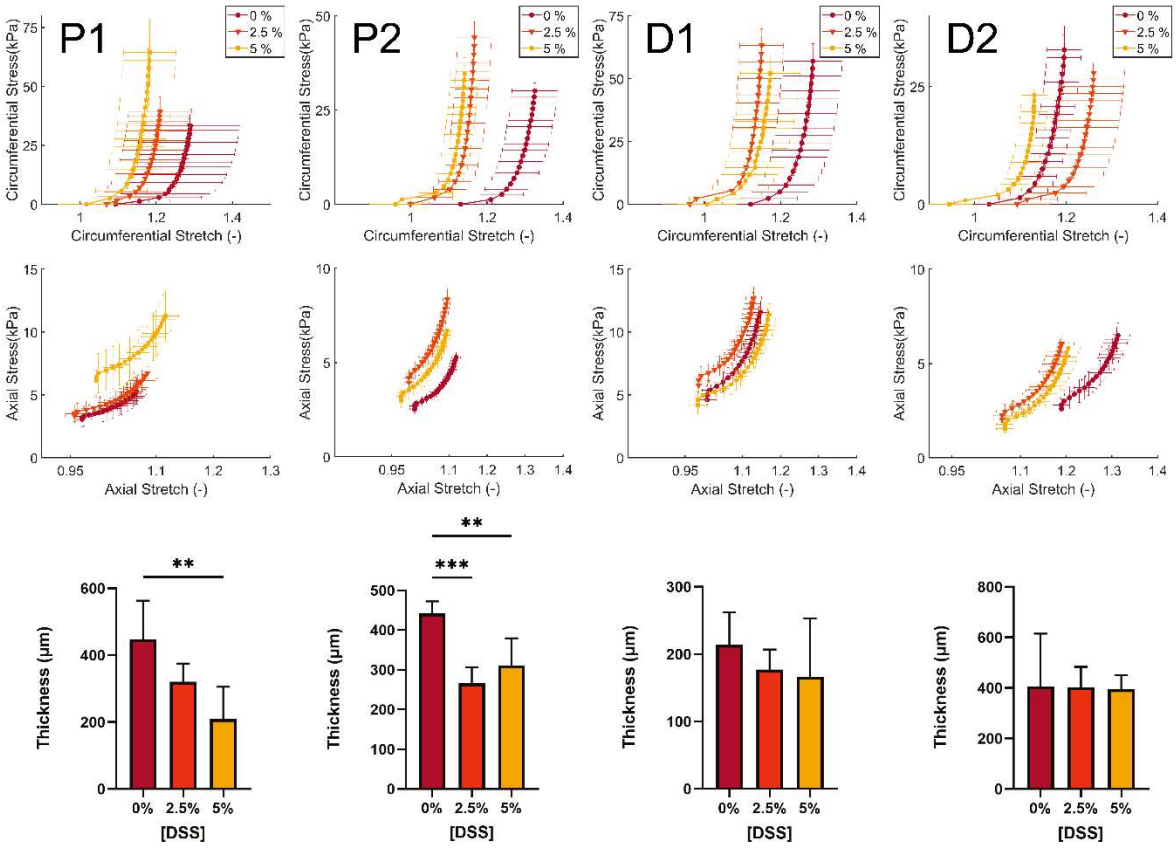

Fig. 1 shows the regional stress-stretch and unloaded thickness plots in response to different DSS concentrations for the male cohort. We found that proximal regions displayed circumferential stiffening and decreasing wall thickness with increasing DSS exposure. Instead, the distal regions were structurally unaffected. Remarkably, the most distal section of the colon (D2) displayed axial stiffening. This axial stiffening correlated with an

increased content of fibrillar collagen in the submucosal layer, as observed from the analysis of PSR-stained colonic cross sections.

Discussion

Despite recent advances in treating gastrointestinal diseases, there is limited knowledge on structure-function relationships for the normal and diseased colon, particularly in IBD which continues to affect millions worldwide. In this study, we demonstrated that colonic remodeling in response to an acute form of IBD exhibits regional heterogeneity with circumferential stiffening proximally and axial stiffening distally. These findings suggest that IBD-induced alterations in mechanical function are regionally specific and may require targeted therapies. Future work will investigate whether these patterns persist in chronic IBD.

Canine Cadaveric Validation of Epidural needle Insertion Force Versus Displacement in Novel Physical Simulator

Ms. Claudia Smith M.A.Sc., B.Eng., Dr. Carolyn Kerr DVM, DVSc, PhD, Diplomate A.C.V.A., Dr. Scott Brandon PhD, P.Eng.

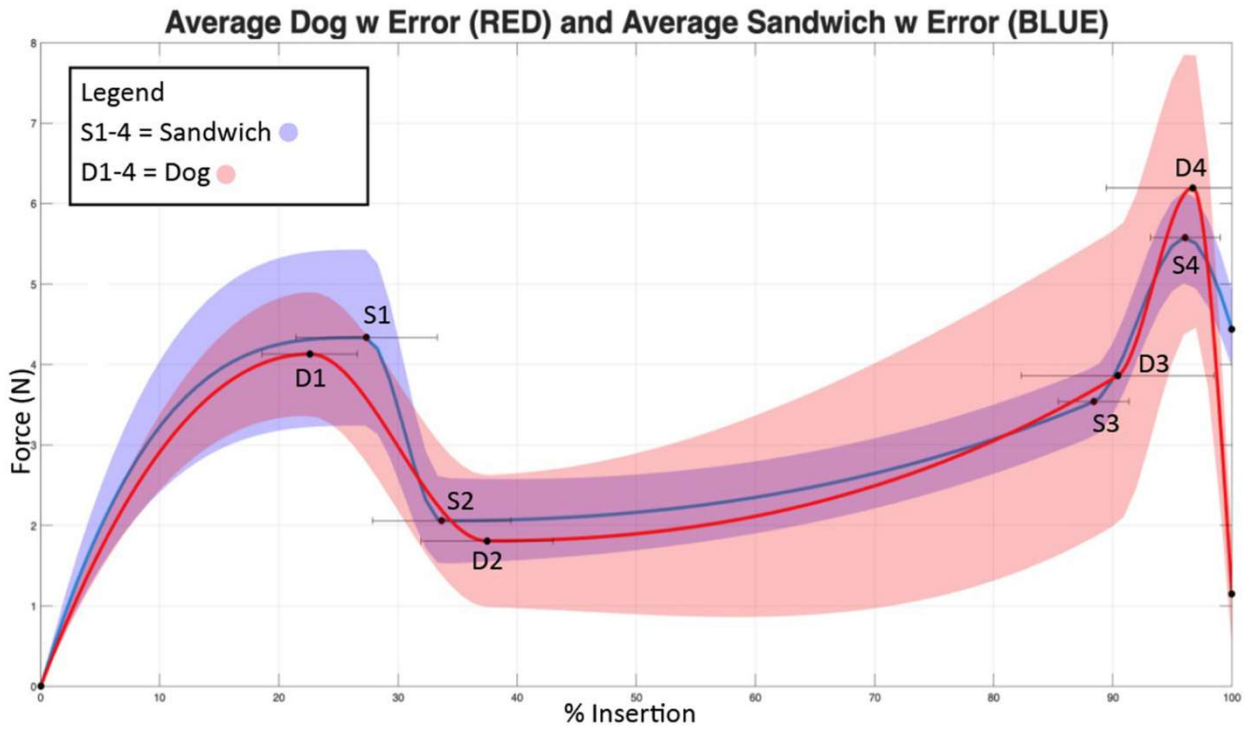
University of Guelph, Guelph, Ontario, Canada

Introduction

In medical education, simulators allow clinicians to practice skills in a safe, repeatable environment before attempting procedures on living patients. Simulator materials are often chosen based on subjective feedback from expert clinicians. However, there is a lack of objective validation of the force-insertion relationship as a needle passes through skin, muscle, and ligament, particularly in canine-specific simulators. Therefore, the objective was to develop a novel, multi-layer composite material "sandwich" simulator that replicated the peak forces of relevant tissues during epidural needle insertion in canines.

Methods

Potential synthetic materials (textiles, hydrogels, and polymers) were puncture-tested at 2mm/s using a Mechanical Testing Machine (Instron) loaded with a 2.5", 20 gauge, Quincke spinal needle. Samples were cut to approximately 50 x 50mm and clamped in place. Materials were iteratively tested to identify layers, and layer thicknesses, that replicated peak tissue puncture forces from prior fresh, ethically-sourced cadaveric data. A final three-layer "sandwich" simulator was assembled and tested. Local force maxima and minima were identified and compared.



Results

Iterative testing resulted in a final simulator design consisting of 2mm of vinyl leather (skin), 24mm of upholstery foam (muscle), and 1 mm of 100% polyurethane (ligament). All force peaks and drops in the artificial material data were within the variance found for the corresponding points in the cadaver data. Peak forces for the simulator (cadaver) were: a) skin = 4.3N (4.1N), b) muscle = 3.5N (3.9N), and c) ligament = 5.6N (6.2N).

Discussion

Tissue mechanics are crucial for an accurate epidural training simulator so the force required to puncture each tissue feels correct. The local maxima (S1, S3, S4) and minima (S2) in the artificial materials were within the variability of the cadavers, however, artificial skin had larger variance than cadaver skin (0-33% Insertion in Fig 1). This was the most challenging material to replicate, as despite the many skin simulators available on the market, these samples did not accurately replicate the needle/skin mechanics during insertion. This novel simulator has the potential to reduce costly clinical errors by enabling more training and therefore reducing the use of live animals in medical education.

Print-A-Punch: A Customizable 3D-Printed Cutting System for Tensile Testing of Soft Biomaterials

Mr. Cody Willson, Mr. Steven Szymeczek, Dr. Trevor Lujan

Boise State University, Boise, Idaho, United States

Introduction

Tensile tests are an essential experiment for characterizing fundamental mechanical properties of biological tissues and biomaterials. To ensure validity and reproducibility, these tensile tests should be performed using sectioned test specimens, called coupons, that are dumbbell-shaped [1]. Our group previously developed the Print-A-Punch cutting system to provide researchers with a reliable and economical tool to punch dumbbell-shaped specimens from layers of soft materials (Fig. 1A) [2]. This build-your-own device, composed of 3D-printed parts and flexible razors, has been an asset to the biomechanics community, yet limitations exist. In particular, the narrow gauge section was not uniform due to razor "spring back", which can cause undesirable failures outside of the coupon mid-section. Also, the coupon dimensions were not customizable, and users had difficulty printing the device. Our objective was to enhance the dimensional accuracy of the Print-A-Punch for a broad range of coupon dimensions, and to make this device more accessible to the biomechanics community.

Methods

To reduce spring back, we developed a custom device to rapidly and repeatedly plastically deform the flexible razors prior to inserting into the punch (Fig. 1B). The dimensional accuracy of these pre-bent blades was compared to standard straight blades for variable gauge sections (4-14mm) using an automated image processing program. Ten elastomer coupons were cut from each gauge length and were pulled to failure. A Prusa MK4S 3D-printer with polylactic acid filament was used for printing.

Results

Pre-bent razors had gauge width variability of 0.019 ± 0.003 mm, an improvement of 59% relative to straight razors (Fig. 1C). On average, 90% of the specimens punched with the pre-bent blades failed in the mid-section, compared to only 65% of the specimens punched with straight razors.

Discussion

The Print-A-Punch offers researchers an accurate and customizable solution to conducting tensile tests on soft biomaterials. This technology can facilitate the broad adoption of standard test methods that improve the quality and reproducibility of tensile tests in biomechanics. To improve accessibility, we are launching a website where users can order a Print-A-Punch with customizable dimensions.

Extracellular Matrix Mechanics and Collagen Architecture Remodeling in Tissue Regeneration: A Microstructural Analysis

M.Sc Florian Pouzet[1], PhD Sarah-Maud Sombris-Picot[2], Dr Corinne Lorenzo[1], Dr Marielle Ousset[1], Dr Cristina Cavinato[2], Dr Jenny Paupert[1]

[1]University of Toulouse, CNRS UMR 5070, INSERM U1301, EFS, ENVT, Institut RESTORE, Toulouse, Occitanie, France. [2]LMGC, University of Montpellier, CNRS, Montpellier, Occitanie, France

Introduction

After injury, adult mammals typically heal by scar formations, resulting in structural and functional loss, whereas newborn can regenerate completely [1]. Tissue function is closely linked to tissue architecture, with fibrillar collagen–a major extracellular matrix (ECM) component–governing passive mechanical response through its abundance, configuration, and degree of cross-linking. Our previous work showed that transient inhibition of collagen cross-linking after adipose tissue resection in adult mice can shift repair from scarring to regeneration, suggesting that ECM organization may influence repair outcomes [2]. A better understanding of the microstructural and micromechanical properties of the ECM under physiologic loading conditions, could help prevent functional decline associated with architectural alterations occurring during repair, chronic inflammation, or ageing. Here, we investigate how ECM mechanical properties relate to regenerative potential by analyzing fibrillar collagen organization using an induced regeneration model in mouse adipose tissue over time.

Methods

Uninjured, scarred and regenerated subcutaneous adipose tissues were mechanically tested performing *ex vivo* uniaxial tensile tests coupled with *in-situ* synchronized multiphoton scanning microscopy at multiple strain levels allowed quantify micromechanical and microstructural metrics. Microstructural analysis was assessed by computing structure tensors, volume fractions and fiber geometrical distributions, enabling quantification of fiber density, alignment and anisotropy as a function of uniaxial mechanical conditions. Mean axial stress was calculated from axial force normalized by local cross-sectional area measured with Optical Coherence Tomography.

Results

Based on our current data, quantitative microstructural analysis revealed that scarring tissues have lower initial fiber anisotropy in the unloaded configuration, which increased

rapidly with strain, suggesting a higher deformability. In contrast, healthy tissues displayed higher mean axial stress and maintained a more stable reorientation scheme throughout loading with a delayed fiber alignment, reflecting greater mechanical resistance and a more robust load-bearing structure.

Discussion

Together, these findings indicate that scar tissue is mechanically more compliant, and structurally more labile, while healthy tissue exhibits higher stiffness and a more organized collagen framework, providing insight into how ECM mechanics may regulate tissue repair and regenerative potential.

Site-Dependence of Frictional Properties in the Anterior Cruciate Ligament

Mr. Hayato Inoue B.S.[1], Mr. Daichi Ishii Ph.D[1], Prof. Hiromichi Fujie Ph.D.[1,2]

[1]Graduate School of Systems Design, Tokyo Metropolitan University, Hachioji, Tokyo, Japan. [2]Research Center for Medicine-Engineering Collaboration, Hachioji, Tokyo, Japan

Introduction

For efficient joint motion, low friction is required in all tissue-to-tissue contacts. Ligaments are not immune to contact with surrounding tissues during tensile loading due to the presence of surrounding tissues. The present study focuses on the anterior cruciate ligament (ACL). The ACL encounters the posterior cruciate ligament (PCL), medial meniscus, and the femoral articular cartilage during joint motion [1] (Fig). Although Qu et al. have determined the overall average frictional property of the ACL [2], the local frictional property of the ACL has not been quantified. The authors found the frictional property of the ACL portion that encounters the PCL is significantly lower than that of other portions [3][4]. Therefore, the objective of the present study is to determine the distribution of frictional properties throughout the entire ACL.

Methods

Porcine ACLs were divided into four regions: 3 regions that encounter the PCL, lateral femoral condylar cartilage, and medial meniscus, and a contact-free region near the femoral insertion. For comparison, the central medial portion of the patellar tendon (PT) was chosen. Reciprocating friction tests were performed for each portion at a load of 0.5 N against an alumina ceramic ball of 6 mm in diameter. Compression DMA were performed to investigate the effect of ploughing friction.

Results

Results revealed that the coefficient of dynamic friction was significantly lower in the PCL-contact and medial meniscus-contact regions than in the lateral condyle cartilage-contact and the PT. The storage modulus Was significantly higher in the meniscus-contact region than in other contact regions.

Discussion

Plowing friction may be more severe in the PCL-contact region, because more deformation occurs due to lower modulus than in the meniscus-contact region. It is suggested that the sliding frictional property is superior in the PCL-contact region compared to those in other contact regions.

Testing the Hypothesis That Axons Passing Through Large Lamina Cribrosa Pores Suffer Larger Deformations Than Those Passing Through Small Pores

Dr Ian Sigal, Dr. Susannah Waxman, Ms Sofia Lusvardi, Dr. Yuankai Lu, Ms Yingzhe Han, Ms. Ashley Linton, Mr. Qi Tian, Dr. Miriam Bohlmann Kunz, Dr. Bingrui Wang

University of Pittsburgh, Pittsburgh, PA, United States

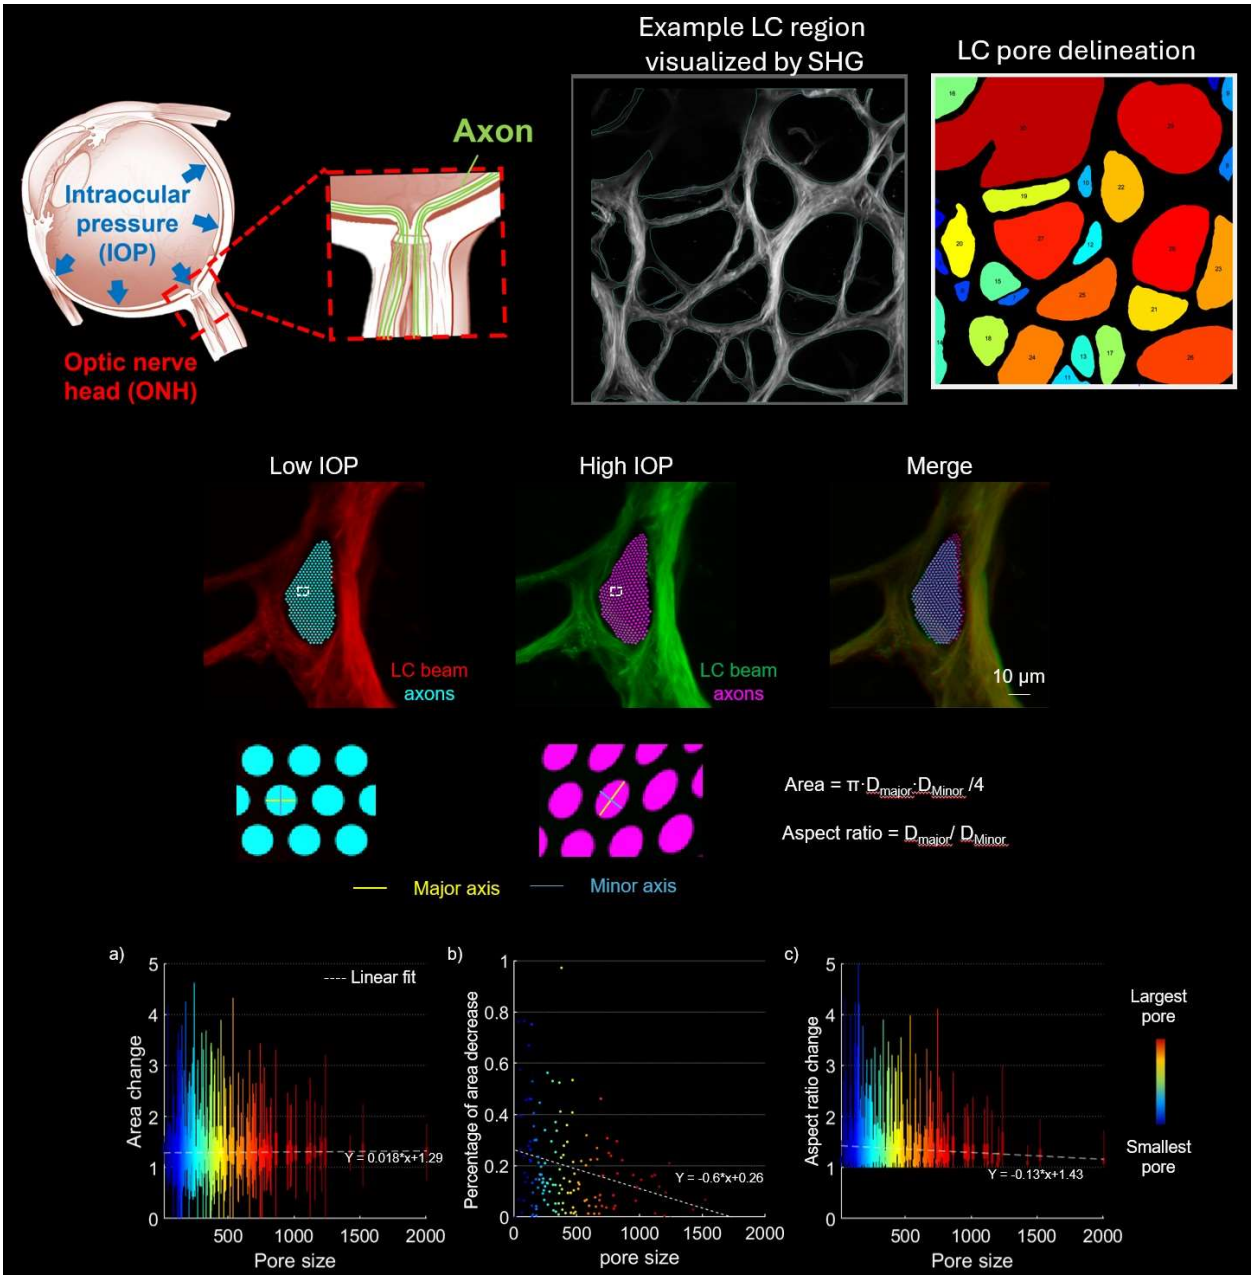
Introduction

The collagen beams of the lamina cribrosa (LC) provide mechanical support to the frail axons passing through the LC pores. A long-standing theory states that larger LC pores cannot provide as good mechanical support to the axons as smaller pores, rendering the axons at increased risk of damage. Our goal was to test the hypothesis that large LC pores provide worse protection to the axons from increased IOP than small pores.

Methods

We used a combination of experiments and computational modeling to test the hypothesis. The LC of 6 fresh sheep eyes was exposed by sectioning the optic nerve transversely, and imaged by second harmonic generation microscopy at low (5 mmHg) and high (40 mmHg) intraocular pressures. Digital image correlation was used to measure the deformations of the collagenous beams. We manually segmented and reconstructed pore-specific finite element models of the visible pores and assigned boundary conditions from the beam deformations. Pore interior was assumed to be formed of retinal ganglion cell axon bundles embedded surrounded by astrocytes. Axons and astrocytes were assumed to have the same mechanical properties. To account for variations in axon size we repeated the study using axon diameters varying from 0.5μm to 2μm. We measured the axonal distortion using the FE-produced changes in local tissue aspect ratio

Results



A total 148 pores were analyzed. With 1 um-wide axons this led to 46 to 10,102 axons per pore, depending on pore size. The aspect ratio change of the axons was 1.33 ± 0.45 (mean ± SEM), with the lowest value of 1 (no change) and the 95th percentile of 1.98. The aspect ratio change was significantly negatively correlated with the initial pore size ($p<1e-5$, Fig), indicating that larger pores had smaller deformations.

Discussion

The results show that overall axons in smaller pores actually suffer larger deformations than axons in larger pores, contrary to our hypothesis. The axons suffered anisotropic

distortions that are known to be particularly detrimental to axons. There were, however, wide variations in pore and axonal distortions, with many axons in small pores suffering only small deformations.

Using High-Resolution MRI in Quantification of Passive Elastic Modulus of Muscle in Stepwise Tensile Testing

Mr. Iraj Dehghan Hamani[1], Dr. Stephen H. M. Brown[2], Dr. Thomas R. Oxland[1]

[1]University of British Columbia, Vancouver, BC, Canada. [2]University of Guelph, Guelph, ON, Canada

Introduction

Passive mechanical properties of skeletal muscles, particularly elastic modulus, are important in joint mechanics and muscle pathology. Therefore, their precise quantification is valuable. Although elastic modulus is typically derived from static tensile tests, these experiments often lack rigorous verification. Specifically, potential slippage at gripping interfaces is rarely examined, which affects strain accuracy. Additionally, physiological cross-sectional area (PCSA) calculations often rely on literature values for muscle density rather than direct measurement [1]. Notably, prior studies have not directly measured muscle volume during stretching. In this study, we aim to improve stress–strain calculation and elastic modulus assessment, using a high-field MRI to record muscle length and PCSA during stepwise tensile testing.

Methods

Ten tibialis anterior muscles from five male Sprague-Dawley rats underwent stepwise tensile testing (6% strain/step) immersed in Tyrode's solution in a 9.4 T Bruker BioSpec MRI scanner. T2-weighted RARE MRI scans (0.2 mm isotropic voxels) were acquired at each 4-minute interval. Muscle volume (length and PCSA) was measured using 3D Slicer. Muscle elongation was utilized to calculate strain, and muscle volume at slack length determined PCSA. Stress was calculated by dividing the measured force at each step by the PCSA. Fitting a quadratic curve to stress–strain data enabled elastic modulus calculation.

Results

Average stress-strain data revealed a robust quadratic relationship ($R^2 = 0.99$) (Fig. 1). The specimens also showed an average volume increase of ~13% when stretched from their slack state to nearly 35% muscle strain. Average elastic moduli are shown in Fig. 1 for different strains.

Discussion

MRI scans provided 3D geometry of each specimen at every stretch, enabling consistent quantification of strain and PCSA. High-resolution imaging allowed for repeated assessments and result verification. Notably, this novel method enabled precise measurement of actual muscle length rather than grip-to-grip distance, thereby accounting for potential slippage or tendon effect in muscle-tendon unit elongation. Also, the observed volume increase during stretching likely results from fluid absorption by the muscle [2]. This method holds significant value for 3D muscle modeling and tensile testing simulations.

Placental Tissue-Mimicking Materials for Ultrasound Elastography: A Preliminary Study of Polyvinyl Alcohol Cryogels and Silk Hydrogels

Ms Jennifer Chimwaza PhD student[1,2], Dr Andrew N Cookson Senior Lecturer[1,2], Dr Katharine Fraser Senior Lecturer[1,2]

[1]University of Bath, Bath, South West, United Kingdom. [2]Centre for Bioengineering and Biomedical Technologies, Bath, South West, United Kingdom

Introduction

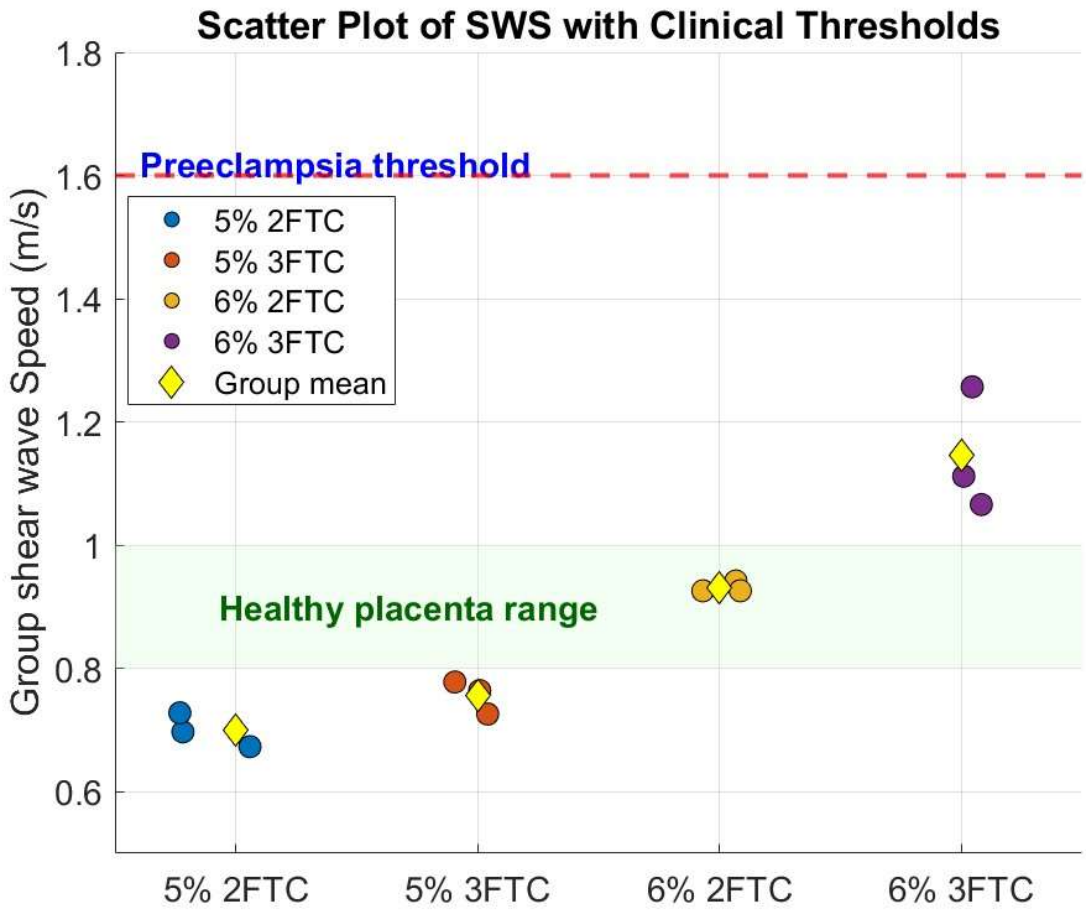
Preeclampsia (PE) causes 2–8% of maternal morbidity worldwide. Literature suggests elevated placenta stiffness may be an early indicator of PE as it is linked to altered angiogenesis during placenta development. Ultrasound shear wave elastography (US-SWE) is a non-invasive technique that may be used to measure stiffness of the placenta, but the changes in stiffness with gestational age need to be better characterised to make this a reliable clinical biomarker.

Tissue mimicking materials (TMMs) provide a cost-effective means of understanding soft tissue non-invasively by considering easily accessible materials with varying stiffness to ascertain placenta biomechanics in PE.

The aim of this research was to characterise Polyvinyl alcohol cryogel (PVA-c) and self-gelled silk fibroin (SG-SF) phantoms as placenta TMMs by comparing their stiffness and acoustic properties with clinical values.

Methods

Homogenous PVA-c and SG-SF phantoms were fabricated. US-SWE speeds were taken at five locations per phantom using a Verasonics Vantage 256 system with multiple tracking, coupled with a 5 MHz, 192-element linear transducer. Compression stress relaxation tests were done on the phantoms using an Instron 5965 system to validate the SWE measurements. Elastic (storage modulus) and viscous (loss modulus) parameters were estimated from both ultrasound and mechanical data using a least-squares fitting of the Kelvin-Voigt Fractional Derivative (KVFD) model. Plane wave b-mode image data was used to compute speed of sound within each phantom.



Results

5-6% PVA-c phantoms (Figure 1) could mimic different placenta stiffnesses by varying the PVA concentration and freeze-thaw cycle (FTC) processes more easily and reliably than the SG-SF phantoms. The storage (1-2 kPa) and loss (0.15-1.5 kPa) moduli observed in PVA-c phantoms reflect the elastic behaviour of placental tissue better than SG-SF (>10*PVA-c) phantoms. The ultrasound acoustic speed was 1546±33 m/s (clinical reference=1540 m/s), and independent of PVA or SF concentration.

Discussion

PVA-c TMMs are a promising standardised tool for US-SWE in placental biomechanics, an under researched but important area. Increasing the PVA-c FTC processes could provide stiffer TMMs for investigating preeclamptic placenta. Combining mechanical test methods with US-SWE could provide an effective way of standardising results. Future work will explore embedding disease specific features in TMMs.

Estimating Large-Deformation Strain Fields in Soft Phantoms Using Ultrasound Digital Image Correlation: A Triangle-Based Approach for Full-Field Strain Determination and A Reference Subset Updating Strategy

Prof. Jin-Jia Hu[1], Mr. Chih-Chia Liu[2]

[1]Department of Mechanical Engineering, National Yang Ming Chiao Tung University, Hsinchu, Taiwan, Taiwan. [2]Department of Biomedical Engineering, National Cheng Kung University, Tainan, Taiwan, Taiwan

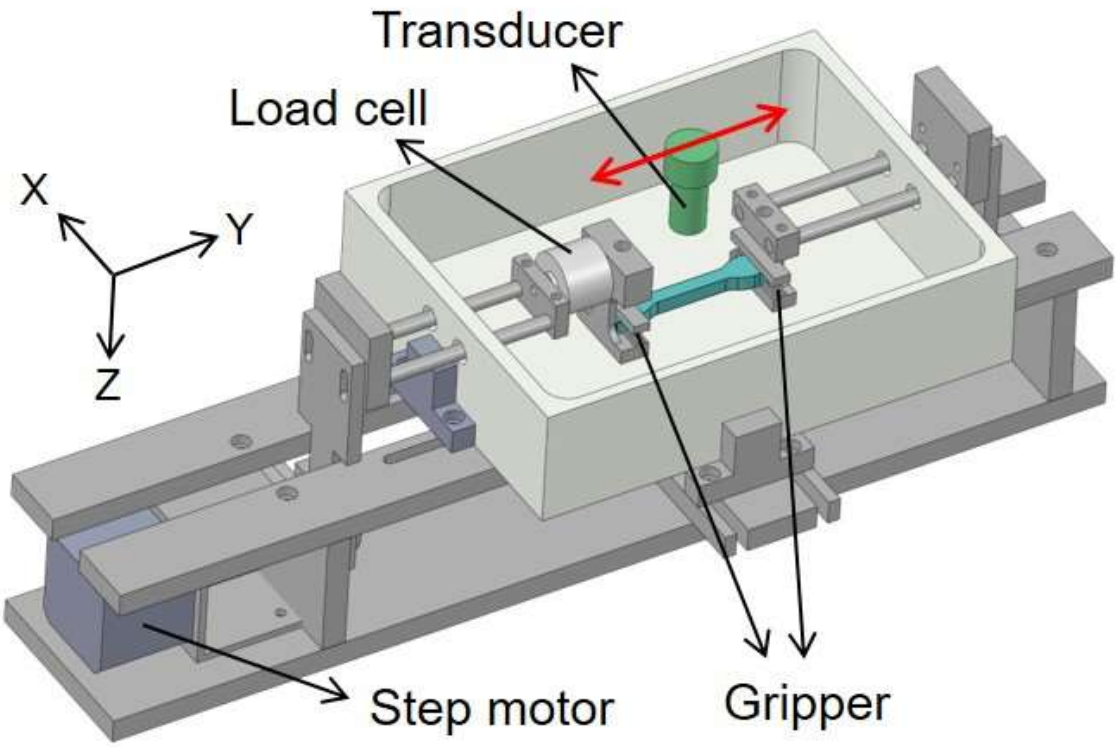
Introduction

Understanding internal strain distributions in soft tissues is essential for characterizing their mechanical behavior, yet optical methods are limited to surface measurements. This study developed an ultrasound-based digital image correlation (DIC) approach to quantify full-field internal strains in soft hydrogels during tensile loading. By combining high-frequency ultrasound imaging with a triangle-based strain formulation and an adaptive subpixel-wise reference-update strategy, we aimed to achieve robust, noninvasive strain estimation under large deformation while validating the method against commercial VIC-2D and optical tracking.

Methods

A 35-MHz ultrasound system acquired 301 B-mode frames during 300 tensile steps of 0.04 mm. RF data were envelope-detected and converted to grayscale images. Digital image correlation was performed on a structured node grid, with subpixel displacements obtained via nine-point Gaussian interpolation. An adaptive subpixel-wise reference-update strategy synthesized updated subsets using linear interpolation to reduce decorrelation. Full-field strain was computed using triangle-based deformation gradients. Three types of PVA hydrogels (uniform, stiffness-contrast, asymmetric) were tested and compared with VIC-2D and optical tracking.

Results



Subpixel-wise updating produced smoother and more stable strain fields than pixel-wise or no-update strategies, particularly along the ultrasound propagation direction. Tracking remained reliable across large deformations, whereas the no-update strategy failed by frame 109. Strain evolution showed strong agreement with VIC-2D, and localized strain reductions in stiffness-contrast and asymmetric samples were consistently identified. Adding 1% cellulose improved ultrasound scattering without altering tensile stiffness.

Stress–strain curves derived from ultrasound-based strain matched those from optical tracking, demonstrating accurate mechanical characterization.

Discussion

The proposed ultrasound-based DIC framework successfully quantified internal strain fields in soft hydrogels, overcoming surface-only limitations of optical imaging. Subpixel-wise reference updating proved critical for preserving speckle coherence during large deformation, enabling robust long-range tracking. Agreement with VIC-2D and optical data confirms the method's accuracy for heterogeneous and geometry-dependent strain patterns. While axial resolution and focal depth limit the usable imaging region, the results highlight ultrasound-based DIC as a promising tool for internal deformation analysis in soft biomaterials and tissue-mimicking phantoms.

Tuning Injection Flow Rate to Minimize Drug Leakage During Intratumoral Injection

Ms. Julia Ding[1,2], Mr. Jihoon Park[1], Ms. Claire Kelley[1], Ms. Lila Cheek[1], Dr. Alex Abramson[1]

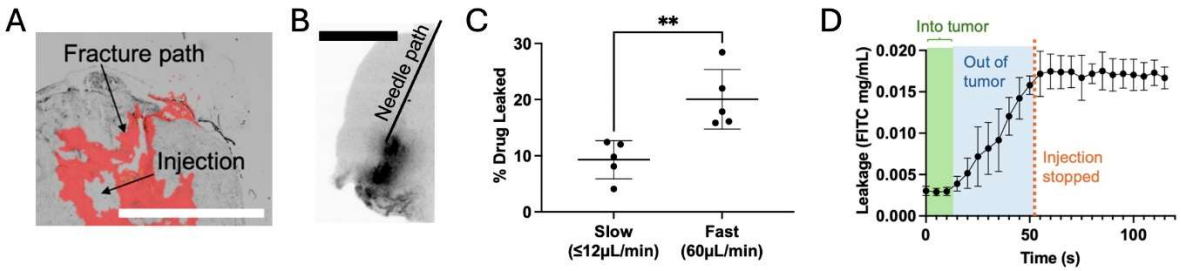
[1]Georgia Institute of Technology, Atlanta, GA, United States. [2]Emory University, Atlanta, GA, United States

Introduction

Compared to systemic delivery, intratumoral injection can increase local drug concentration while reducing systemic side effects. However, clinicians frequently report suboptimal drug accumulation in the tumor due to crack-like leakage pathways through tumor tissue [1]. The mechanical response of tumors to injection-induced fluid pressure is poorly understood. Here, we characterize pressure-driven fluid flow during intratumoral injection and identify injection flow rate as a simple, tunable parameter to improve delivery accuracy and reduce drug escape.

Methods

We characterized injection-induced leakage in ex vivo 4T1 murine breast tumors (100-200 mm^3). Fluid transport and fracture-like pathways were visualized using post-injection micro-CT and histological sectioning (n=3 per group). To quantify fluid leakage, tumors were submerged in phosphate-buffered saline, injected with a model drug fluorescein (FITC), and FITC concentration in the bath was measured over time. Tumors (n=3) were injected with fixed injection volume and rate (50 µL, 6 µL/min) and monitored for time course of leakage. To characterize the effect of flow rate on leakage, we then injected at high (60 µL/min) versus low flow rates (≤12 µL/min) and quantified leakage (n=5 per group).



Results

Histology and 3D reconstructions revealed fluid-driven fracture pathways, even at a very low flow rate of 6 µl/min (Fig. A, B, scale bar = 5mm). Injection flow rate strongly affects drug localization (Fig. C). High flow (60 µL/min) more than doubled leakage relative to low rates (≤12 µL/min; 20.1% leaked versus 9.3% injected dose leaked, $p<0.01$). Further, leakage occurred only during the active injection period (Fig. D). After injection onset, drug was initially localized to the tumor. When injection volume reached 7.29 ± 1.17% of total tumor volume, leaked drug suddenly increased, consistent with a yielding event. Stopping injection also stopped leakage, indicating that leakage is mechanically driven by injection pressure.

Discussion

These findings enhance our understanding of how injected drugs distribute in soft tissue, thereby facilitating mechanical approaches for optimizing drug delivery. We demonstrate that lowering flow rate reduces mechanically-driven drug escape, identifying injection rate as a simple yet powerful parameter to improve intratumoral therapy.

Indentation Modeling of a Saturated Poroelastic Multi-Layered Medium for Mechanical Characterization of Articular Cartilage

Assistant Professor Kotaro Miura[1], Professor Makoto Sakamoto[2], Professor Kazuhiko Sasagawa[1], Associate Professor Kazuhiro Fujisaki[1]

[1]Hirosaki University, Hiorsaki, Aomori, Japan. [2]Niigata Universirty, Niigata, Niigata, Japan

Introduction

Articular cartilage exhibits a depth-dependent layered structure and shows pronounced time-dependent deformation under indentation. However, the respective roles of layering and poroelastic fluid–solid interactions in governing stress relaxation remain insufficiently understood.

Methods

This study develops a semi-analytical solution for the axisymmetric indentation of a poroelastic multi-layer coating bonded to a poroelastic substrate. The layered system is modeled under a rigid, flat-ended cylindrical indenter, and the time-dependent consolidation response is evaluated. The governing formulations are based on the classical poroelasticity framework.

Results

Discussion

These findings demonstrate that the analytical formulation accurately captures time-dependent poroelastic behavior and is applicable to both single- and multi-layer configurations. The convergence with previously published results validates the numerical implementation and confirms the reliability of the solution framework under different permeability boundary conditions.

The findings of this work provide theoretical insight into the mechanisms governing stress relaxation in cartilage and establish a basis for interpreting indentation tests in terms of intrinsic material parameters.

Methodological Variability in Artificial White Spot Lesion Formation: Insights from A Meta-Analysis of Microhardness Outcomes

Mr. Lev Sushanek, Dr. Svetlana Komarova

University of Alberta, Edmonton, Alberta, Canada

Introduction

White spot lesions (WSLs) affect 25–50% of patients undergoing orthodontic treatment, due to the altered mechanical environment that disrupts enamel loading and promotes plaque retention. Developing a controlled protocol for creating artificial WSLs is essential for evaluating new strategies to prevent or treat these lesions. Our objective was to analyze existing in-vitro protocols for inducing WSLs in human enamel to assess their reproducibility.

Methods

The systematic search in Medline, Embase and Web of Science retrieved 4835 unique articles, of which 556 were included after title/abstract screening. Following full text screening, 118 studies describing de- and remineralization protocols using extracted human teeth were included.

Results

The protocols used molars 57/118, premolars 37/118 and incisors 6/118, and reported to create lesions within 2 weeks. Reported solution concentrations of Ca and PO4 were consistently around 2 mM, while Na, K and Cl had wider ranges. For meta-analysis, we identified 27/118 articles that reported tooth microhardness at multiple timepoints. The microhardness of intact teeth ranged from 259 to 569 N/mm^2 with the mean of 357 ± 67 N/mm^2, with no associations between microhardness values and method used (Knoop vs Vickers), load or dwell time. The single study effect size was percentage normalized mean difference, random effects model with restricted ML tau estimator was used for meta-analysis. Demineralization protocols led to an overall -49.8% reduction in microhardness with the 95% confidence interval of [-66.0, -33.6] and high heterogeneity, I^2 = 99.7%. Remineralization protocols of initially demineralized teeth resulted in overall increase in microhardness by 9.8% [1.5, 18.1], I^2 = 98.9%. Importantly, the overall effect of remineralization procedure compared to naïve teeth was similar to the demineralization protocols alone -53.6% [-71.0,-36.2], I^2 = 99.8%, and none of the studies reported complete tooth remineralization. Duration of demineralization and remineralization protocols was not associated with the outcome. Solution pH minimally affected the

outcome of demineralization, but was positively associated with the outcome of remineralization.

Discussion

We demonstrate substantial variability and limited reproducibility across in-vitro protocols for creating artificial WSLs, despite similar protocols. Establishing standardized lesion model is needed to support biomechanical investigations into how orthodontic appliances contribute to enamel demineralization.

A Virtual Fields Method for Estimating Optic Nerve Head Tissue Elastic Properties from Deformation Field

Dr Manuel Lucas Sampaio de Oliveira[1], Prof. Stephane Avril[2], Prof. Thao Nguyen[1]

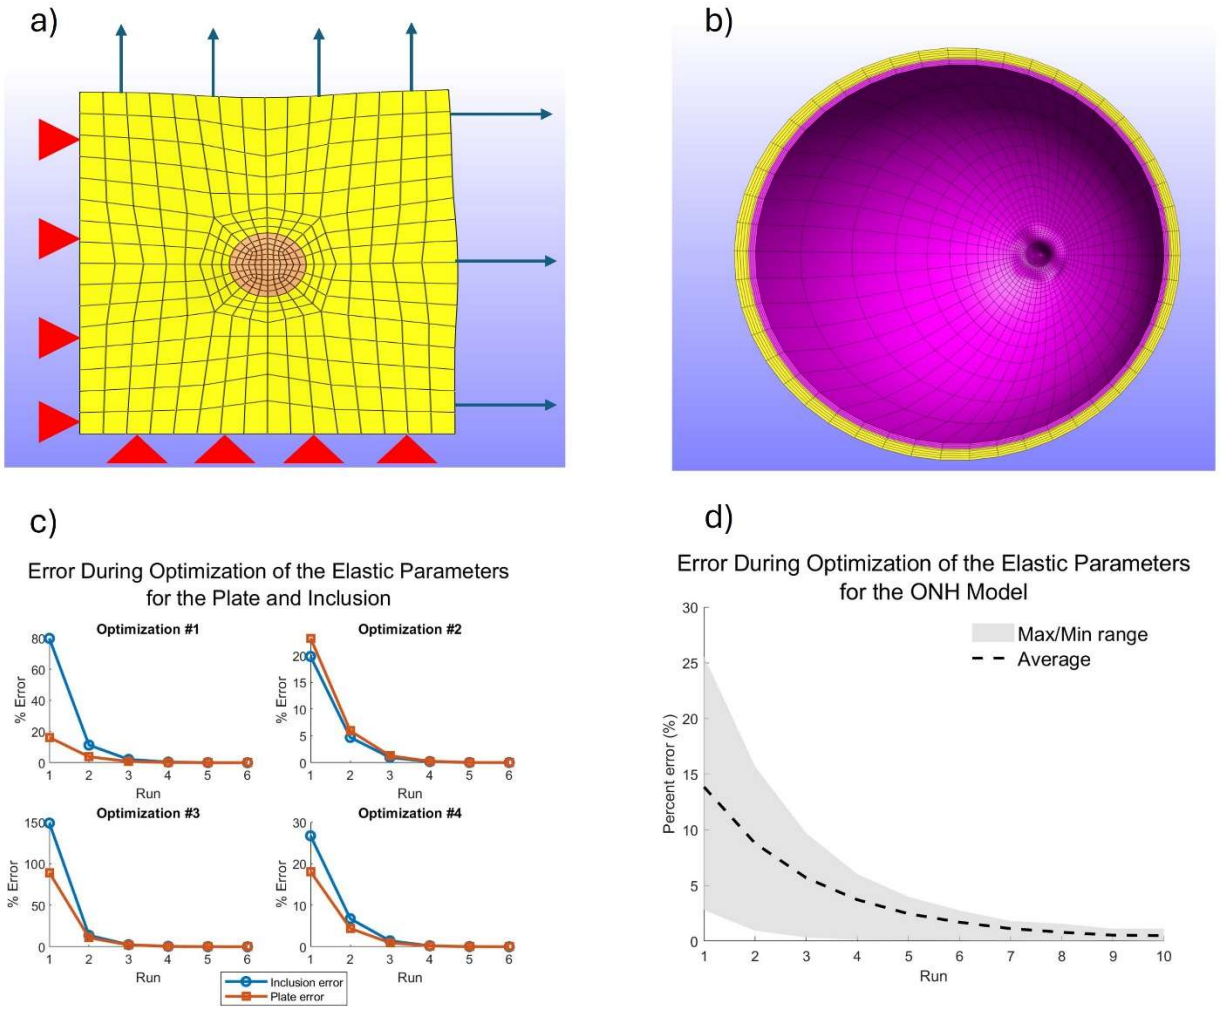
[1]Johns Hopkins University, Baltimore, MD, United States. [2]Mines Saint-Étienne, Saint-Étienne, Auvergne-Rhône-Alpes, France

Introduction

Glaucoma is characterized by progressive damage to the axons of retinal ganglion cells (RGCs) at the level of the optic nerve head (ONH). The extent of mechanical injury to the RGCs depends on the elastic properties of the ONH tissues. Previously, we developed a method to map the deformation response of ONH tissues to changes in the intraocular pressure (IOP) using digital volume correlation of optical coherence tomography images. We aim to develop a robust virtual field method (VFM) to determine the elastic properties of the ONH tissues from the DVC deformation map.

Methods

Applying VFM to analyze the in vivo deformation response of the ONH requires addressing three challenges: 1) the unknown pre-stress state in ONH tissues arising from the baseline IOP; 2) the complex deformation state of the ONH; and 3) limitations in the experimental methods to capture all ONH regions. We developed a VFM framework with the objective selection of virtual fields from perturbations in material properties and an optimization algorithm that estimates the prestress state of material properties. We demonstrated that the VFM framework can determine the material properties from FEA-generated synthetic data, first, for a simple structure of a soft inclusion in a stiff plate (Fig. 1a), and for the ONH structure in the posterior scleral shell (Fig. 1b). We examined the effect of uncertainties in the geometry and material properties of the tissues at the posterior ONH.



Results

We considered 4 random starting guesses for the material properties to determine the global optimum. The VFM framework was able to determine the elastic properties for the inclusion and plate with 99.9% precision. For each initial guess, the algorithm converged to the same values within 5 runs. Initial results for the ONH model show that the method recovered elastic parameters with 98.8% precision within 10 runs.

Discussion

We have developed a robust VFM framework to determine the material properties of ONH tissues from in vivo measurements of the ONH deformations. Current work involves adding contact to the problem, speeding up calculation of the internal virtual work, studying the sensitivity of the parameters that we don't have data.

Assessing synthetic bone surrogates: four-point bending and strain mapping of cortical bone vs Sawbones

Ms Marta Spataro[1], Mr Davide D'Andrea[1], Dr. Piyush Uniyal[2], Prof. G.Harry van Lenthe[2], Prof. Dario Francesco Santonocito[1], Prof. Dario Milone[1]

[1]Dept. of Engineering,University of Messina, Messina, Italy, Italy. [2]Dept. Mechanical Engineering, KU Leuven, Leuven, Belgium, Belgium

Introduction

Synthetic surrogates have been adopted for repeatable and cost-effective mechanical testing [1]. Questions remain regarding how closely they reproduce real cortical bone behaviour under mechanical loading. This study compares bovine cortical bone and Sawbones® under four-point bending using digital image correlation (DIC), evaluating displacement and strain evolution over time to assess how closely the synthetic material mimics the real bone

Methods

Prismatic specimens (N = 5, 7.68±0.42 × 8± × 60± mm^3) were prepared from mid-diaphysis bovine tibiae (14–15 months) and Sawbone®, ensuring comparable geometry [2]. Samples were speckled for digital image correlation (DIC) and tested in four-point bending. Displacement was applied at 0.01 mm/s on a uniaxial machine with a 25 kN load cell. A high-resolution camera enabled full-field deformation measurement Euler–Bernoulli beam theory was used to obtain stress–strain curves from load–displacement data and to evaluate flexural rigidity EI, which was further adjusted using DIC measurements (2). Python routines extracted DIC strain maps and time-dependent ε_{xx} in the constant-moment region.

Results

DIC maps showed localized deformation in Sawbone, enabling clear identification of the fracture site, whereas cortical bone displayed a more homogeneous strain field. Bone exhibited higher stiffness and a more brittle response. Failure strength was comparable (bone 142 ± 41 MPa; Sawbone 104.0 ± 23.3 MPa), but Sawbone showed much higher failure strain (2.24 ± 1.04 vs 0.59 ± 0.19). Flexural rigidity (EI) differed markedly (bone 7.09×10^6 ± 2.84×10^6 $N\cdot mm^2$; Sawbone 4.55×10^6 ± 5.63×10^5 $N\cdot mm^2$).

Discussion

The mechanical response of cortical bone and Sawbone composite showed marked differences in deformation behaviour. We found that Sawbone can reproduce load-to-failure response within the same order of magnitude but does not replicate the elastic behaviour nor the brittle failure mode of cortical bone. Caution should be taken when stiffness-driven mechanics are of interest. Preliminary observations indicate that certain regions, such as the posterior area, might be better approximated by the surrogate but further investigation is needed to verify this hypothesis.

Biomechanical Regulation of Liver Injury and Regeneration

Prof. Mian Long

Institute of Mechanics, Chinese Academy of Sciences, Beijing, Beijing, China. University of Chinese Academy of Sciences, Beijing, Beijing, China

Introduction

Mechanical niche of hepatic sinusoids is crucial for maintaining liver homeostasis and regulating injury and regeneration, but the underlying regulatory mechanisms remain largely unknown. This work focuses on elucidating the physiological and pathological alterations of hepatic mechanical microenvironment and their effects on the phenotype and function of hepatic cells.

Methods

This work combines in vivo experimental methods such as murine liver perfusion, partial liver resection, and liver fibrosis models, as well as in vitro biomechanical techniques such as microfluidic chips, biaxial stretch, stiffness-adjustable hydrogels, and osmotic pressure modulation, to analyze the mechanotransduction mechanisms in liver injury and regeneration.

Results

After partial liver resection, the blood flow per unit volume of residual liver is promptly augmented. On one hand, this alteration can increase the interstitial flow shear stress sensed by hepatocytes, promoting the nuclear translocation of Yes-associated protein (YAP) and facilitating hepatocytes re-entering the cell cycle [1]. On the other hand, it can enhance the mechanical stretch of blood vessels, activating the mechanocrine of liver sinusoidal endothelial cells (LSEC) through YAP pathway, releasing heparin-binding epidermal growth factor-like growth factor (HB-EGF), and promoting the proliferation of hepatocytes [2]. In the progress of liver fibrosis, LSECs can sense the increase in matrix stiffness through focal adhesion kinase, induce the activation of p38 and its downstream signaling pathways, and promote the LSEC defenestration in a cytoskeleton reorganization-dependent manner [3]. Meanwhile, the fenestrae of LESCs are found to be negatively regulated by cell membrane tension, implying mechanically-specific regulation in LESC capillarization.

Discussion

These findings further understand the roles of mechanical cues in liver injury and repair, offering new strategies to prevent and treat liver fibrosis and other diseases.

Deep learning surrogate of patient-specific finite element surgery simulations for fast optimization of refractive interventions

Dr Miguel Angel Ariza-Gracia[1], Yannic Eltschinger[1], Dr Theo Seiler MD[2,3], Dr Philippe Büchler[1]

[1]ARTORG / University of Bern, Bern, Bern, Switzerland. [2]Department of Ophthalmology/Inselspital Bern, Bern, Bern, Switzerland. [3]Institut für Refraktive und Ophthalmo-Chirurgie (IROC), Zürich, Zürich, Switzerland

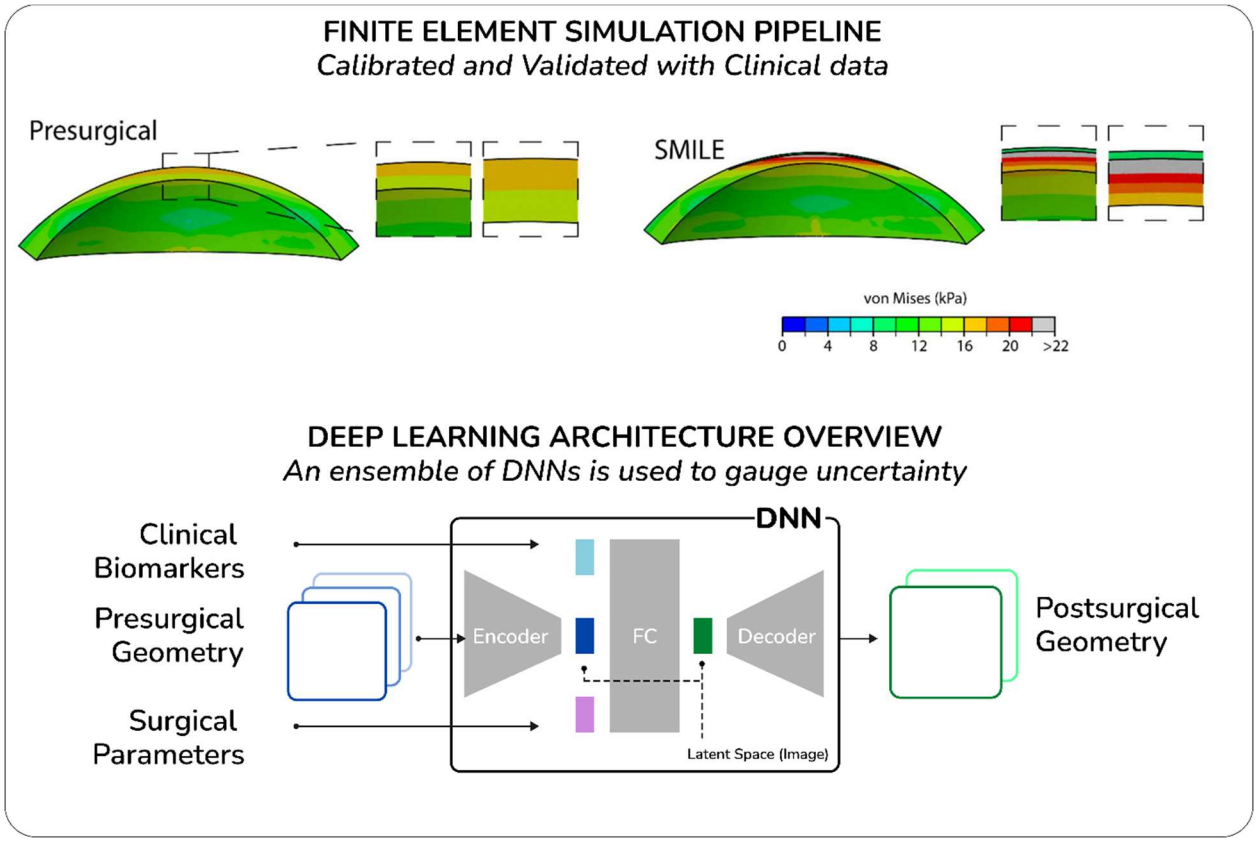
Introduction

Patient-specific finite element (FE) models can simulate refractive interventions and predict postoperative refractive outcome, but runtimes prevent surgical optimization and real-time planning. We present a hybrid pipeline where FE generates a simulation database, a deep learning (DL) surrogate replaces the FE solver, and the surrogate is used to optimize patient-specific surgical parameters.

Methods

Personalized corneal geometries from tomography were used to run FE simulations of PRK, LASIK, and keratorefractive lenticule extraction (KLEx) with structured hexahedral meshes (~80k elements), physiological intraocular pressure (IOP; 15 mmHg), depth-dependent anisotropic stromal behavior, and nonlinear contact for flap/cap interfaces. Postoperative optical metrics were computed from the deformed curvature [1]. To enable optimization, large-scale FE sampling on HPC generated thousands of simulations spanning patient geometries and intervention parameters (optical zone, ablation/lenticule profile, flap/cap settings, and refractive targets). These simulations defined supervised targets for a surrogate model: (i) scalars (sphere/cylinder prediction error) and (ii) spatial outputs (curvature-change maps). The surrogate leveraged a deep-learning autoencoder-style latent embedding of geometry, combined with a late-fusion fully connected network to integrate clinical biomarkers and produce the final predictions. [2]. Training minimizes a weighted loss combining refractive-output error and structured regularization for surgical consistency. Surgical planning is posed as constrained Bayesian optimization over intervention parameters using the surrogate as a fast forward model.

Results



The stromal constitutive model was calibrated and validated against three human ex-vivo tests. All FE procedures showed systematic undercorrection increasing approximately linearly with intended correction; for ~7 D spherical targets, undercorrection exceeded ~2

D in LASIK and KLEx, requiring planning adjustments up to ~50 µm depth. Preliminary deep-learning surrogate results indicated a 100–500× reduction in compute time versus the full FE pipeline, while maintaining prediction errors within an ophthalmically acceptable tolerance (±0.25 D).

Discussion

Clinical validation of the FE workflow supports its use as a reliable patient-specific reference model for refractive intervention simulation. DL surrogate permits near real-time, constrained Bayesian optimization of surgical parameters, while retaining FE-consistent predictions and enabling integration of imaging and clinical biomarkers.

Poromechanical Properties of Human Articular Cartilage Estimated from Creep Experiments Using Neural Network Models

Mr. Nurkeldi Iznat[1], Dr. Elizabeth Clarke[2], Dr. Ashvin Thambyah[3], Dr. LePing Li[1]

[1]The University of Calgary, Calgary, Alberta, Canada. [2]The University of Sydney, Sydney, New South Wales, Australia. [3]The University of Auckland, Auckland, Auckland, New Zealand

Introduction

Articular cartilage properties are needed to quantify tissue health and joint functions. They are conventionally determined from non-invasive indentation creep/relaxation experiments by iteratively fitting the data using finite element (FE) methods, which may not converge to the true material properties, e.g., a random initial guess can lead to an incorrect estimate. The objective of the present study was to develop a neural network (NN) surrogate model that adequately extracts cartilage properties from indentation creep data. Our ultimate goal is to establish such models that may be used by end-users without requiring FE analysis once trained on sufficient datasets.

Methods

Indentation creep experiments were performed on 146 human cartilage-bone samples from finger, elbow, shoulder, hip, knee and ankle joints of 8 donors (ethics approved). The loading included a 10-second ramp compression followed by one hour of creep, corresponding to an average pressure of 4.5 MPa on the cylindrical indenter. Experimental data included cartilage thickness and creep displacement–time curves from all specimens.

After initial evaluations, long short-term memory (LSTM) and transformer-based NN models were selected to independently estimate cartilage properties from indentation tests, given their ability to model sequential patterns and nonlinear load responses exhibited in creep. Each model was trained on ~3000 FE simulations spanning varied tissue properties, indenter sizes, and cartilage thicknesses.

Results

Despite variations in cartilage thickness among joints—and the corresponding need for multiple indenter sizes—both FE-trained NN models successfully estimated cartilage properties for all samples with similar results (Fig. 1). Statistical analysis of tissue

properties showed that knee cartilage differed significantly from elbow cartilage, whereas thumb cartilage did not differ significantly from elbow cartilage.

Discussion

Transformers are widely used in language, signal processing and computer vision applications. In our study, the transformer model was slightly more effective than the LSTM model in capturing the cartilage creep response. Nevertheless, both NN models streamline the extraction of cartilage properties from large experimental datasets by replacing traditional iterative curve-fitting and mitigating uncertainties caused by initial guess selection. We are further testing the model's robustness in producing unique results by using different training parameter configurations and architectures.

Images (Optional)

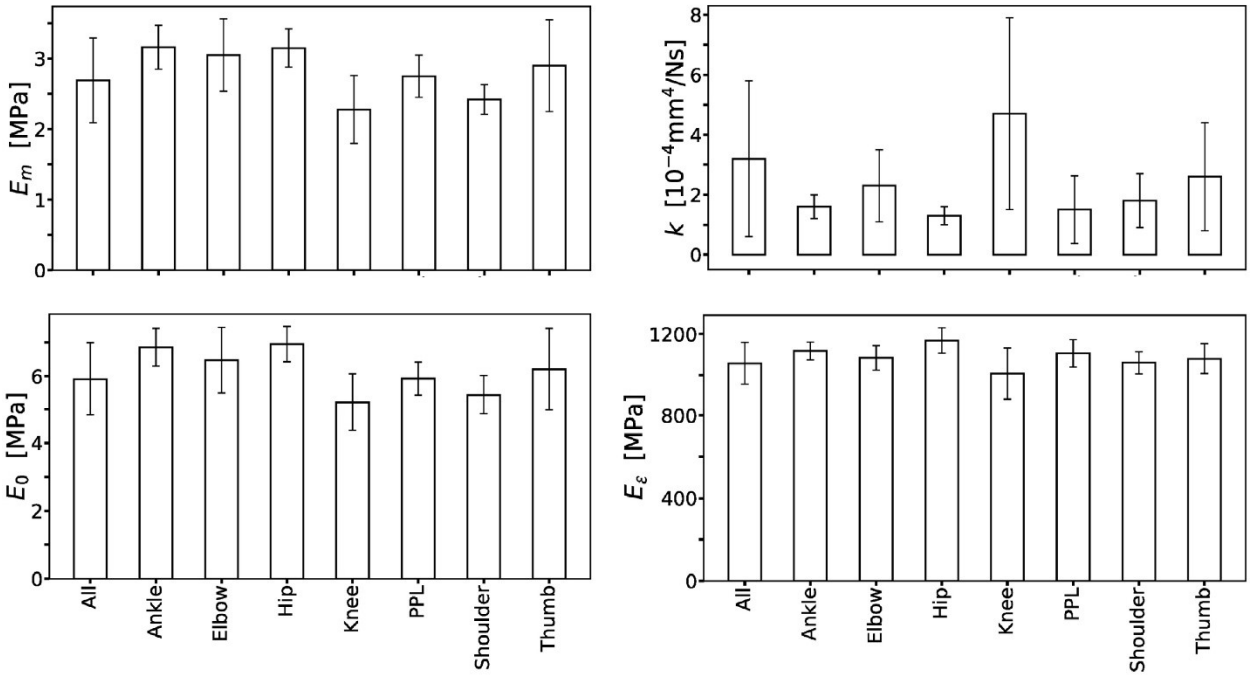

Figure 1. Mean and standard deviation of joint-specific cartilage properties. A fibril reinforced model was used: E_m – modulus of nonfibrillar matrix; $E_f = E_0 + E_\varepsilon \varepsilon$ – modulus of fibrillar matrix if $\varepsilon > 0$; $E_f = 0$ if $\varepsilon \leq 0$; k: permeability. PPL: Little finger metacarpophalangeal joint.

Correlative Microscale Mapping of Human Meniscus Biomechanics and Biochemistry by AFM Micro-Indentation and MALDI-FTICR Mass Spectrometry Imaging

MSc. Aleksandra Lebedeva[1], BSc. Matis Mühlpointner[1], Dr. Orestis Andriotis[1], Dr. Stefan Tögel[2], Dr. Lena Hirtler[2], Dr. Martina Marchetti-Deschmann[1], Dr. Philipp Thurner[1]

[1]TU Wien, Vienna, Vienna, Austria. [2]Medical University of Vienna, Vienna, Vienna, Austria

Introduction

Meniscus degeneration is a major contributor to chronic knee pain and osteoarthritis (OA) [1], while its biochemical–mechanical relationships remain unclear. The objective of this study was to establish a correlative workflow integrating atomic force microscopy (AFM) micro-indentation with matrix-assisted laser desorption/ionization Fourier-transform ion cyclotron resonance mass spectrometry imaging (MALDI-FTICR MSI) to determine how biochemical alterations correspond to local mechanical changes in healthy and osteoarthritic menisci.

Methods

Two human menisci were analyzed: one osteoarthritic sample from a patient >60 years undergoing knee replacement and one healthy cadaveric sample from a donor aged 72–99 years. For each specimen, three consecutive cryosections were examined. AFM micro-indentation was performed in the red-red (RR), red-white (RW), and white-white (WW) zones. In each zone, three 100 × 100 µm regions (50 µm step) were mapped with a 15 µm spherical probe under near-physiological conditions. Each map (20 × 20 µm, 4 × 4 pixels) produced 432 force–indentation curves, fitted with the Hertz model ($R^2 > 0.95$) [2]. Matched sections were analyzed by MALDI-FTICR MSI at 50 µm spatial resolution to quantify peptide distributions, particularly collagen-derived peptides. Stiffness differences across zones were assessed using the Kruskal–Wallis test ($p < 0.001$).

Results

Healthy menisci exhibited a strong zonal stiffness gradient (RR > RW > WW; $p < 0.001$) (Fig.1c). In OA samples, this gradient was markedly reduced, with RR stiffness substantially decreased and no significant difference remaining between RR and WW (Fig.1d). MSI showed corresponding biochemical changes: healthy tissue contained continuous collagen I/II/III gradients, whereas OA tissue displayed fragmented, irregular collagen patterns and loss of peripheral-to-central organization (Fig.1a,b) [3].

Discussion

The integrated AFM–MSI workflow demonstrates that healthy menisci maintain coordinated mechanical and molecular organization, while OA tissue exhibits mechanical softening and disrupted collagen distribution. This combined approach enables the detection of early degenerative alterations and supports identification of spatial biochemical markers relevant to OA progression.

Auxetic Lamina Cribrosa Beams Protect Axons and Capillaries Under IOP Elevation

Mr. Qi Tian BS[1,2], Ms. Yingzhe Han MS[1,2], Dr. Xuehuan He PhD[1], Dr. Po-Yi Lee PhD[3], Dr. Miriam Bohlmann Kunz PhD[1], Dr. Ian A. Sigal PhD[1,2]

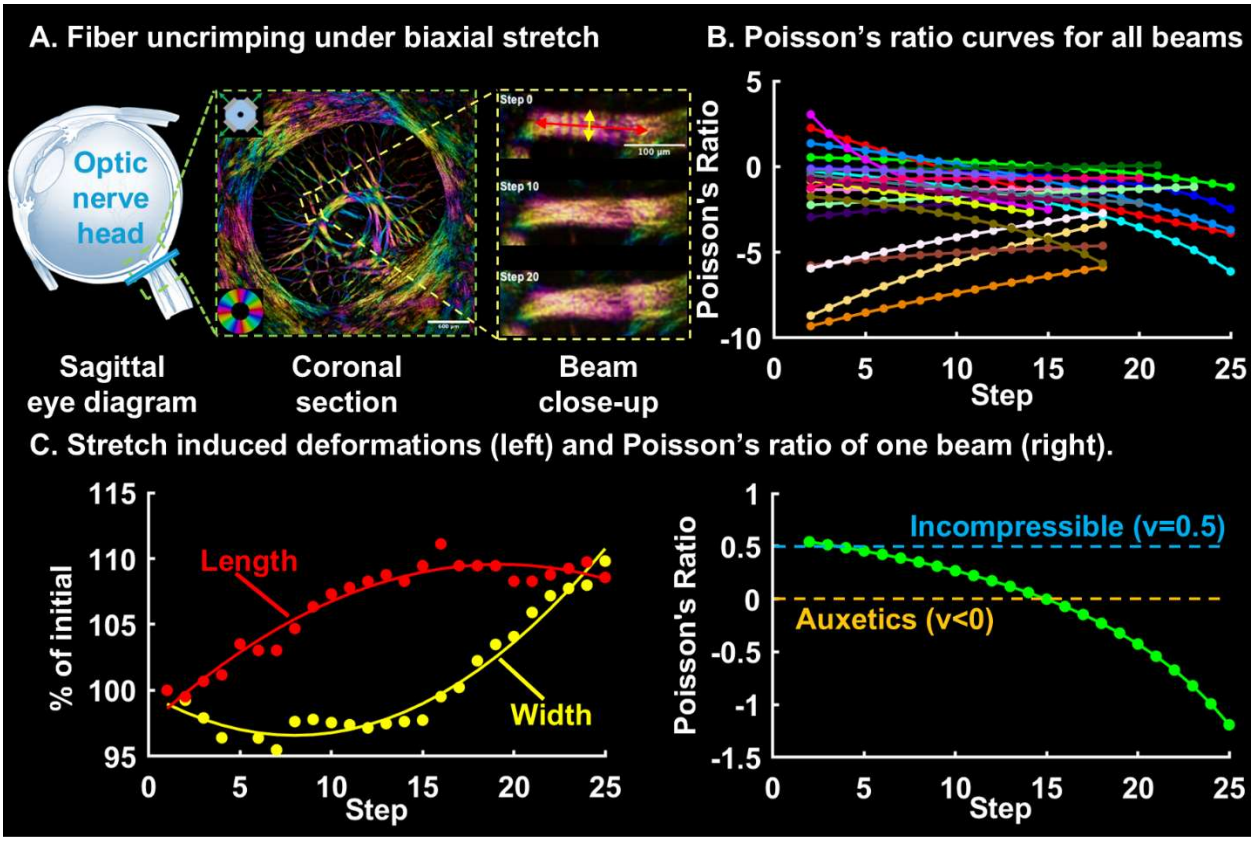
[1]Department of Ophthalmology, University of Pittsburgh, Pittsburgh, PA, United States. [2]Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States. [3]Wellman Center for Photomedicine, Massachusetts General Hospital, Boston, MA, United States

Introduction

The lamina cribrosa (LC) collagen beams provide mechanical support to both axons and capillaries within the optic nerve head. Because inadequate support from the beams is thought to lead to axon damage and vision loss, understanding how beams deform under load is of great interest. LC biomechanics studies have frequently assumed that the LC beams are incompressible. To the best of our knowledge, the incompressibility assumption has never been experimentally verified. Our goal was to characterize LC beam behavior under load experimentally and determine whether they are incompressible.

Methods

Twelve 45-μm-thick coronal LC sections from three sheep eyes were stretched biaxially while imaged with instant polarized light microscopy (IPOL) [1, 2]. For 20 well-visible and fully-contained beams we measured width and length during loading and calculated stepwise Poisson's ratios. IPOL's high spatial resolution enabled precise 2D tracking of beam deformation. Because ratio calculations are sensitive to noise, we fitted quadratic functions to the width and length curves and computed Poisson's ratios from the fitted values. To verify that 2D measurements reflected true volumetric behavior, we repeated the study for four beams but using second-harmonic generation (SHG) microscopy and measured their thickness changes.



Results

All 20 beams widened laterally during stretch, with Poisson's ratios shifted from −1.7 ± 3.3 (range −9.3 to 3.1) at the initial step to −2.7 ± 1.8 (range −6.1 to 0.1) at the last step, indicating strong auxetic behavior. Three of four beams imaged by SHG thickened under stretch, whereas the fourth one showed no significant change.

Discussion

Our findings directly contradict the long-standing assumption that LC beams are incompressible [3]. Instead, 96% of the LC beams widened under load, revealing a robust auxetic response. We suspect that this behavior helps avoid compressing capillaries within the beams, affecting hemodynamics, or stretching axons adjacent to the beams.

Introduction

Temperature control in perfused tissues is central to hyperthermia, cryotherapy, and organ preservation, yet predicting how heat propagates through tissue remains challenging. Current bioheat models, such as the Pennes equation (PE), assume instantaneous thermal equilibrium between blood and tissue [1, 2], an assumption that breaks down when perfusate and tissue temperatures differ substantially. To investigate this limitation, we performed continuous temperature measurements during alternating *ex vivo* perfusion of porcine kidneys to quantify transient gradients in temperature during perfusion and evaluate the extent to which Penne's equilibrium assumption fails, informing improved thermal control strategies for treatment and preservation.

Methods

Fresh porcine kidneys were perfused with an isotonic solution at 15 mL/min. Temperatures were continuously recorded at the inlet and four intrarenal locations using a multilevel thermocouple probe, with sensors located 10, 18, 22, and 30 mm from the renal artery. The kidneys were subjected to six thermal perfusion phases, alternating between normothermic (37 °C) and cold (5 °C) PBS, each lasting 20 minutes. We quantified the time lag (t_{lag}) in the onset of temperature change between the inlet and the kidney in response to a change in perfusate temperature. This was reported as the mean ± SD across all cycles. Data shown are from one kidney (six thermal phases); data for six additional kidneys are being collected.

Results

Mean t_{lag} increased with distance from the inlet: 22.4 ± 5.1 s at 10 mm, 34.9 ± 8.0 s at 18 mm, 79.2 ± 15.3 s at 22 mm, and 360.1 ± 2.5 s at 30 mm, indicating a velocity of thermal propagation through the kidney rather than instantaneous equilibration perfusate/tissue.

Discussion

These findings quantify the extent of thermal gradients during perfusion and demonstrate that the PE is insufficient to capture this behavior. Incorporating a perfusion-tissue coupling term or a two-parameter model could improve model fidelity in predicting temperature distribution in perfused organs. Such modification could improve predictive accuracy in thermal therapy, cryopreservation, and organ perfusion, where transient temperature gradients critically affect tissue function and viability.

Tactile Visualization of "Mochi Skin" Texture Using a Thin Triaxial-Stress Sensor

Graduate Student Rin Nagane, Professor Kazuhiko Sasagawa, Associate Professor Kazuhiro Fujisaki, Assistant Professor Kotaro Miura

Hirosaki University, Hirosaki, Aomori, Japan

Introduction

One of the ideal facial skin conditions is known as “mochi skin” in Japanese, characterized by a soft, elastic, and smooth texture. In daily life, the mochi-mochi feeling of the cheeks is detected by hand touching. Although various devices have been developed to measure skin surface conditions such as water and oil content, no quantitative indicator exists for evaluating "mochi skin". This study aimed to establish a quantitative evaluation method by visualizing tactile sensation.

Methods

Ten subjects (five males and five females, average age 22) participated. First, the water and oil content of the left cheeks were measured three times using a commercial device. Next, sensory evaluation experiments were conducted in which participants touched one another’s cheeks and rated the mochi-mochi feeling on a five-point scale (5: very mochi-mochi feeling, 4: rather mochi-mochi feeling, 3: undecided, 2: rather un-mochi-mochi feeling, 1: no mochi-mochi feeling sensation). Finally, the triaxial stress sensor was attached to the index fingertip, and subjects performed sliding motions three times so as lifting their own cheeks. Contact stresses during sliding were recorded.

Results

The instantaneous friction coefficient of the skin was calculated from the measured triaxial stresses. Results indicated that the maximum static friction coefficient showed the strongest correlation with the degree of mochi-mochi feeling, whereas the dynamic friction coefficient had little effect. The friction coefficient was calculated by dividing shear stress friction force by contact pressure vertical force. The maximum static friction coefficient was obtained just before the fingertip began sliding, while the dynamic friction coefficient was defined as the average of the plateau region during sliding. Using data of water and oil content, maximum static friction, dynamic friction, and sensory ratings, multiple regression analysis was performed to derive a predictive model for mochi skin evaluation.

Discussion

The derived model equation demonstrates potential as a novel quantitative indicator for evaluating "mochi skin", and further analysis is required to improve the reliability of the prediction equation.

[2]Translational Center for Regenerative Therapies, Fraunhofer Institute for Silicate Research, Würzburg, Bavaria, Germany. [3]University Hospital Würzburg, Department of Ophthalmology, Würzburg, Bavaria, Germany. [4]Faculty of electrical engineering, University of Applied Science Würzburg-Schweinfurt, Schweinfurt, Bavaria, Germany. [5]Esslingen University of Applied Sciences, Institute for Sustainable Energy Technology and Mobility (INEM), Esslingen, Baden-Wuerttemberg, Germany

Introduction

Porcine corneas are widely used as ex vivo models because their similarity to human tissue enables studies of epithelial wound healing, drug permeation and tissue preservation. However, ex vivo cultivation is mostly performed under static conditions, which lack physiological mechanical cues such as shear stress and do not recreate the continuous nutrient supply present in vivo. Available dynamic systems can reproduce some of these factors but are costly, technically demanding and difficult to adapt. To address this, we developed a customizable and accessible silicone-based flow bioreactor that applies intermittent medium flow within physiological shear levels to more closely mimic the physiological corneal microenvironment.

Methods

The bioreactor consisted of two PDMS components fabricated by SLA 3D printing and silicone casting. Corneas were mounted using a 3D printed clamping ring separating apical and basolateral circuits. Flow simulations estimated shear stress in the bioreactor based on pump-controlled flow rates. Corneas were cultured statically or under intermittent medium flow for up to seven days. To study the effect of dynamic culture on corneal healing, standardized 6 mm epithelial wounds were created by excimer laser ablation. Tissue morphology was analyzed by hematoxylin and eosin staining and

immunofluorescence. Wound healing was monitored by OCT, segmenting wound-margin distance (closure phase) and epithelial thickness over the wound bed (regenerative phase).

Results

Dynamic cultivation preserved the multilayered epithelium and maintained epithelial and limbal marker expression, including E-cadherin, CK12, CK14 and p63α, whereas static culture led to epithelial thinning and loss of marker expression. Flow simulations yielded shear stresses within the physiological tear-film range. Wound-margin progression during the closure phase did not differ between groups. During the regenerative phase, epithelial thickness diverged from day 5 onward, with significantly greater thickness under dynamic flow at day 7 ($p = 0.002$), approaching pre-wounding values, while static culture showed incomplete recovery.

Discussion

The silicone-based flow bioreactor provides an accessible platform for dynamic cultivation of ex vivo corneas. Intermittent medium flow supported epithelial regeneration and maintained a multilayered architecture. Further development, including integration of non-invasive monitoring tools, may extend its applicability beyond porcine models and offer an improved system for the storage of human donor corneas.

Whole Organ Multiscale Placental Perfusion Models to Assess the Effect of Fetal Sex on Vascular Structure and Function in Growth Restricted Pregnancies

Dr Sahan Jayatissa[1], Ms Mary Spring[2], Prof Joanna James[2], Prof Alys Clark[1]

[1]Auckland Bioengineering Institute, University of Auckland, Grafton, Auckland, New Zealand. [2]Department of Obstetrics, Gynaecology and Reproductive Sciences, Faculty of Medical and Health Sciences, University of Auckland, Grafton, Auckland, New Zealand

Introduction

Pregnancy disorders including fetal growth restriction (FGR) are associated with insufficiencies in placental function. Male fetuses are more likely to be growth restricted or stillborn, theorized to be related to a reduced placental reserve [1]. We aim to assess sex-specific features of the FGR placenta via a data-driven computational model of the placental vasculature.

Methods

Chorionic arteries (large arteries covering the fetal aspect of the placenta) were manually segmented from photographs of normal (female n= 20, male n=22) and FGR (female n =3, male n=6) human term placentae. Myography was conducted in isolated arteries. Vascular branch length and diameter were categorized by Strahler order and mapped onto an in silico placental volume with the distal vasculature generated using previously published algorithms [2]. Efficient algorithms for simulating Poiseuille flow in these networks were implemented in Python using graph theory [3]. The impacts of incorporating non-linear rheology, flow disruptions at bifurcations (due to asymmetry), and compliance were assessed in the computational model. Compliance differences between FGR and normal arteries were defined based on literature and myography data.

Results

Chorionic vessels were longer in with reduced diameter in male FGR placentae than normal male/female, or female FGR. Simulations of haemodynamics in population models predicted a 2.6 fold increase in vascular resistance in male FGR models compared to all other cohorts (normal male and female, female FGR). Simulating non-linear rheology had a small impact on vascular resistance, however, a larger increase in resistance is seen when incorporating effects of flow disruptions at bifurcations. Lower compliance was seen in FGR blood vessels, which further exacerbates predicted increases in resistance.

Discussion

Male FGR placentae have longer, smaller diameter blood vessels than normal male placentae, but this anatomical perturbation is not seen in female FGR. These structural differences combined with reduced vascular compliance in a haemodynamic population-based model suggests at least a 2.6 fold increase in vascular resistance, potentially contributing to increased vulnerability during pregnancy in male fetuses.

Differentiable Inverse Finite Element Solver for Multiaxial Characterization of Brain Tissue

Mr Saikat Pal, Mr. Umesh Gautam, Mr. Sitikantha Roy

IIT DELHI, New Delhi, New Delhi, India

Introduction

Differentiable simulation has emerged as a promising approach for automating the entire process of solving inverse problems involving material nonlinearity. This approach allows the numerical solution procedure to be represented as a computational graph, which can be differentiated using Automatic Differentiation (AD) and adjoint methods. The present study demonstrates the application of a differentiable inverse (FE) framework for solving inverse problems of quasi-static hyperelasticity modelling in brain tissue. The framework employs a differentiable FE solver to solve PDEs and efficiently compute gradients using AD-based adjoint methods.

Methods

In the computational pipeline, forward simulations were preserved as computational graphs using the JAX framework. The calculations for each element in the finite element method were vectorized so that they could be computed in parallel. This computational graph of the forward simulation helps automate the gradient computation process throughout the entire simulation. The adjoint method helps compute gradients through the iterative loop of the solver inside the simulation. We used the 2-term Ogden model to characterize the hyperelasticity of each region of the human brain. A normalized loss function was used as the objective function for the multi-objective minimization problem.

Results

All data from the different loading modes were considered for the hyperelastic parameter estimation for different regions of the brain. The average elastic response in each direction was optimized to obtain a parameter set that can be used to model multimodal and complex loading conditions. The parameters obtained indicated differences between the white and gray matter. Interestingly, white or gray matter properties also vary with respect to the anatomical region of the brain. We also observed that the gradients are in good agreement with the finite difference-based gradients in the Adjoint Sensitivity analysis.

Discussion

In this study, we performed multimodal multiaxial complex mechanical testing of human cadaveric brain tissues. In addition, we developed a differentiable inverse Finite Element solver scheme for parameter estimation using Automatic Differentiation and Adjoint Sensitivity methods. Our aim was to provide hyperelastic parameters for different anatomical regions of the brain that can be used in full-scale brain simulations.

Investigating the link between advanced diffusion imaging parameters and brain tissue mechanics using finite element models of the brain

Dr. Sarah Vandenbulcke[1], Dr. Christoffer Olsson[1], Prof. Thomas Christian Gasser[2], Prof. Lisa Prahl Wittberg[2], Prof. Rodrigo Moreno[1]

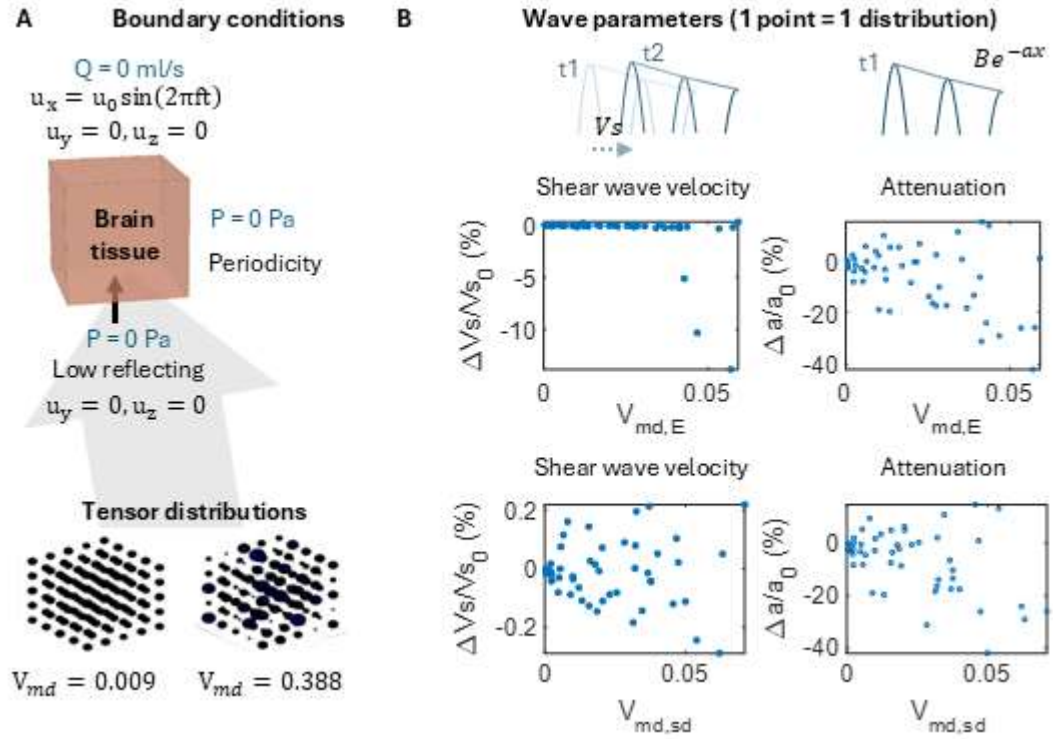
[1]Department of Biomedical Engineering and Healthy systems, KTH Royal Institute of Technology, Huddinge, Stockholm, Sweden. [2]Department of Engineering Mechanics, KTH Royal Institute of Technology, Stockholm, Stockholm, Sweden

Introduction

Magnetic resonance elastography (MRE) studies have shown that brain stiffness decreases with aging and in neurodegenerative disorders such as Alzheimer's disease [1]. Therefore, brain stiffness has been identified as a potential biomarker for neurodegeneration. Multidimensional diffusion magnetic resonance imaging (MD-dMRI) provides parameters describing the variation in the brain's microstructure at sub-voxel level [2]. By using these parameters as measures of structural heterogeneity, we could reveal the microstructural changes underlying this stiffness reduction, a link that is not yet fully understood. In this study, we investigate how microstructural variations measured with MD-dMRI can impact the brain's mechanical behavior.

Methods

MD-dMRI was connected to brain tissue mechanics by generating tensor distributions and incorporating them into a block-shaped finite element model of brain tissue as material parameter distributions. Each distribution consisted of tensors of varying sizes and shapes, characterized by a set of four MD-dMRI based parameters describing the mean and variance for each distribution [2]. Brain tissue was modeled as a linear poroelastic material in COMSOL Multiphysics. The mechanical response was evaluated under boundary conditions simulating MRE acquisition, with a 50 Hz horizontal displacement inducing shear wave propagation (Figure Panel **A**).



Results

Figure (Panel **B**) shows the relation between the variance in tensor size calculated across different distributions (with constant mean size) of the Young's modulus ($V_{md,E}$) and solid density ($V_{md,sd}$), and the wave characteristics shear wave velocity (Vs) and attenuation (a). The results show that changing $V_{md,E}$ or $V_{md,sd}$ can alter the attenuation coefficient by up to 50 %. Meanwhile, the shear wave velocity shows minor variations, except for a few outliers at higher $V_{md,E}$.

Discussion

Our results indicate that shear wave attenuation can differ significantly between voxels with the same mean Young's modulus and solid density, depending on the sub-voxel material parameter distribution. We hypothesize that this variation in sub-voxel distributions reflects the underlying variation in microstructure, which might be overlooked when assessing properties in MRE at voxel scale only. This motivates including measures that describe sub-voxel microstructure, such as MD-dMRI parameters.

A Testing Platform to Study the Deformation Mechanism of Epithelia

Miss Sristi Gurung, Professor Yuan Lin

The University of Hong Kong, Hong Kong, N/A, Hong Kong

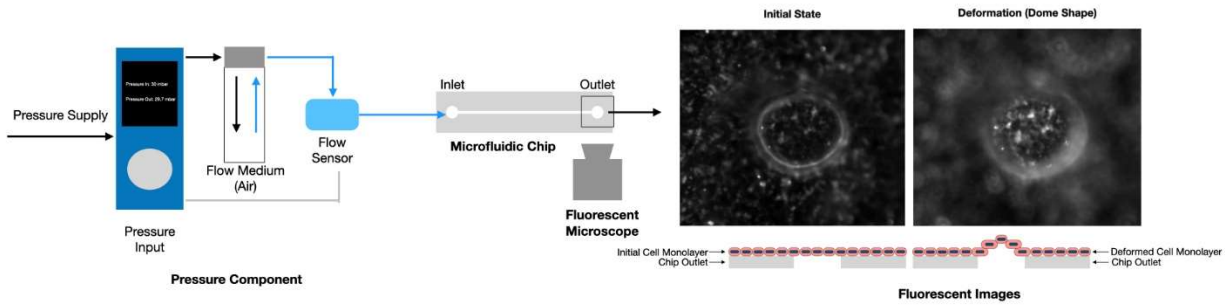
Introduction

Epithelia are sheets of cells lining the surface of many organs. They act as protective barriers and carry out numerous physiological functions such as absorption, secretion, transport and more. Studies have shown that disruptions in epithelia mechanics are often linked to diseases such as cancer. However, understanding of epithelia mechanics remain limited due to lack of proper equipment at tissue level. To combat this, we have developed a testing platform to measure the mechanical properties of epithelia through the deformation of epithelial cell monolayer which are the simplest form of tissue.

Methods

Polydimethylsiloxane (PDMS) microfluidic chip was fabricated with a designated inlet and outlet. A thin collagen scaffold was prepared at the outlet, on top of which Madin-Darby Canine Kidney (MDCK) cells were cultured until confluency. Collagenase was then used to digest the collagen scaffold such that the epithelial cell monolayer was freely suspended in air. The monolayer was then stained with Calcein AM for fluorescent and confocal microscope imaging. Desired pressure was input into the chip through the inlet and time-lapse images and videos were recorded during monolayer deformation. The data were then analyzed to get mechanical quantifications of the monolayer deformation against time.

Results



A blister test was conducted on the freely suspended epithelial monolayer using the testing platform. During deformation, fracture occurred either through delamination or by rupture in the monolayer. Delamination occurred when cell-substrate adhesion was weak and air escaped through the cell-substrate interface. On the other hand, rupture occurred when cell-cell adhesion was weaker than the cell-substrate adhesion. It was also recorded that an average of 53.8 mbar was needed to delaminate the cell monolayer from its substrate.

Discussion

It was observed that deformation of cell monolayers resulted in different types of fracture. This proved that monolayer response was directed by the adhesion energy difference at

cell-substrate and cell-cell level. Our testing platform allowed direct measurements of epithelial cell monolayer to study the deformation mechanisms of epithelia in a precisely controlled manner. By studying the mechanics of epithelial cell monolayer, we hope to bridge the gap between epithelia mechanics and disease mechanisms for better therapies in the future.

The Biomechanical Role of the Meniscus in Distributing Load and Providing Stability

Mr Sufyan Dalal, Dr Roberto L Diaz, Dr Marlène Mengoni, Dr Alison Jones, Professor Ruth Wilcox

University of Leeds, Leeds, West Yorkshire, United Kingdom

Introduction

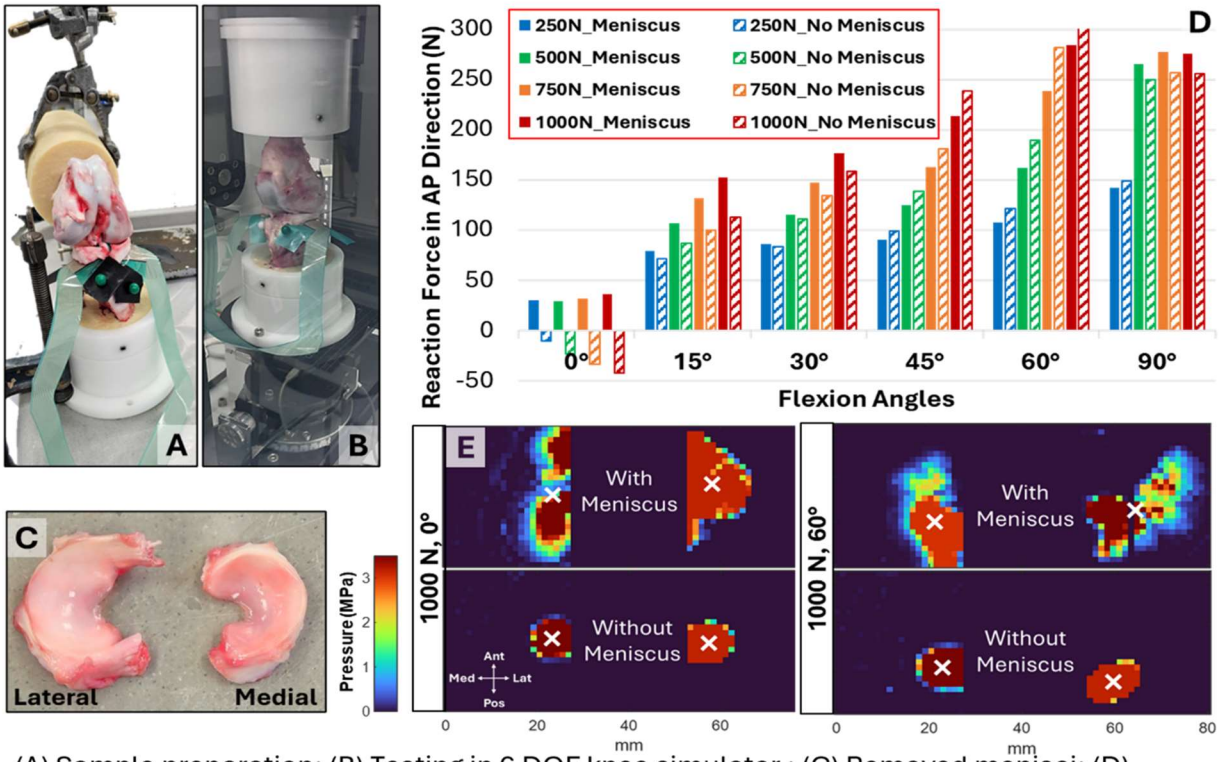
The menisci play an important role in knee biomechanics, with both meniscus extrusion and meniscectomy linked to the accelerated progression of osteoarthritis. There are emerging techniques to repair or replace menisci, but limited methods are available to compare their performance. The aim of this study was to develop an *in-vitro* testing method to evaluate the biomechanical role of the menisci in distributing load and providing stability across a range of flexion angles.

Methods

Testing was conducted using porcine knee specimens (N = 3). The natural knee position was secured using a brace before the removal of all surrounding tissue and ligaments. The specimens were then potted using a custom rig which was also used to align the centre of rotation.

A series of static tests were conducted with the meniscus intact and then removed using a six degree-of-freedom knee simulator. Loads of up to 1000 N were applied at different flexion angles (0°, 15°, 30°, 45°, 60° and 90°). The AP displacement was held and the reaction force measured whilst pressure sensors were placed below the menisci to map the contact pressure distribution.

Results



A reduction in contact area of up to 70% was identified after the removal of the meniscus. Pressure in the medial compartment of the knee increased after meniscus removal while there was little change in the lateral compartment. There were also differences in the AP reaction force between the intact and removed meniscus cases that were more marked at lower flexion angles.

Discussion

The results demonstrate the menisci's role in load distribution by increasing contact area and decreasing pressure, as well as a smaller role in providing stability particularly at

smaller flexion angles. The methods developed can be extended to assess other loading scenarios and evaluate different meniscus repair strategies

Classification of Healthy Placenta, Placenta Previa and Placenta Accreta Spectrum Using Machine Learning and Texture and Shape Features Extracted From Placental MRI.

Miss Suzie Coldman MSc[1,2], Mr Guanglong Zhou MSc[1,2], Mr Dengjiang Wu MSc[1,2], Dr Lingzhong Guo PhD[1,2], Dr Elspeth Whitby MBChB(hons) PhD[3], Dr Xinshan Li PhD[1,2]

[1]University of Sheffield, Sheffield, South Yorkshire, United Kingdom. [2]Insigneo Institute, Sheffield, South Yorkshire, United Kingdom. [3]Sheffield Teaching Hospitals NHS Foundation Trust, Sheffield, South Yorkshire, United Kingdom

Introduction

Abnormalities such as placenta accreta spectrum (PAS) and placenta previa (PP) are diagnosed using MRI. However, clinically only 30-66% of PAS pregnancies are identified before birth [1-3], due to limited resources and expert radiologists. The aim of this study was to determine if texture and shape features derived from placental MRIs could be used to classify healthy placenta, PAS and PP using machine learning.

Methods

48 healthy (33 pregnancies), 41 PAS (40 pregnancies) and 35 PP (35 pregnancies) MRIs were obtained by Sheffield Teaching Hospital (Siemens 1.5T, sagittal T2 HASTE). Using PyRadiomics 2525 texture and shape features were extracted from each MRI.

Training-test split was 80-20. The training set was used for feature selection, which involved intraclass correlation coefficient, zero-variance and variance inflation factor filters and lasso logistic regression (10-fold cross-validation and 750 bootstraps).

Four algorithms were trained on the selected features with 15-fold cross-validation: Logistic Regression (LR), Support Vector Machine (SVM), Random Forest (RF), Gradient Boosting (GB). Binomial (healthy and PP vs PAS) and multinomial (healthy vs PP vs PAS) classification were investigated with 3 repeats.

Results

LR and RF achieved the highest accuracy for multinomial and binomial classifications respectively (Table 1). Computational time was lowest for LR and SVM (minutes) and highest for RF and GB (hours/days). Across all four algorithms, multinomial classification

exhibited lower accuracy than binomial classification. In multinomial classification, the PP group displayed the lowest precision and sensitivity.

Discussion

MRI texture and shape features can be successfully used to classify healthy versus abnormal placenta, achieving an accuracy of 0.85 for binomial classification using LR, which required less than 5 minutes to run. In the multinomial case, PP was the most challenging group to classify. Clinically, PP is diagnosed by measuring the distance of the placenta to the os on MRI; this metric could be added to improve classification outcome. Future work will also involve comparing the classification ability of MRI indications and clinical factors such as maternal age and the number of previous c-sections, to texture and shape features.

Images (Optional)

Table 1: Evaluation Metrics for the four machine learning classification algorithms, including the mean (± standard deviation) accuracy, precision and sensitivity for binomial (healthy and PP vs PAS) and multinomial (healthy vs PAS vs PP) classification. LR = Logistic Regression, SVM = Support Vector Machine, RF = Random Forest, GB = Gradient Boosting.

	Accuracy		Precision		Sensitivity	
	Binomial	Multinomial	Binomial	Multinomial	Binomial	Multinomial
LR	0.81±0.02	**0.75±0.02**	0.83±0.03	0.74±0.05	0.81±0.02	**0.75±0.02**
SVM	0.84±0.06	0.71±0.02	0.82±0.05	0.70±0.02	0.81±0.05	0.71±0.02
RF	**0.85±0.04**	0.67±0.05	**0.86±0.04**	0.63±0.12	**0.85±0.04**	0.64±0.08

Crystal Interface Mechanics Control the Strength and Resilience of Cold-Water Coral Skeletons

Dr Nikolai Kvashin[1], Dr Ali Ozel[2], Dr Marta Peña Fernández[2], Dr Senthil Thangadurai[1], Prof. Dr. Uwe Wolfram[1]

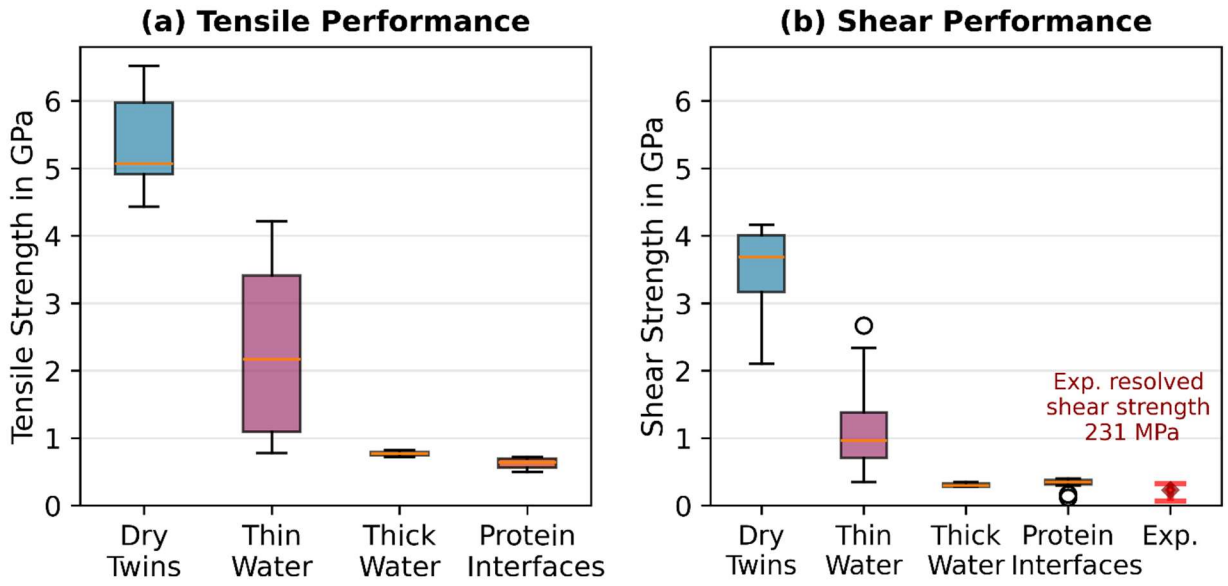
[1]Clausthal University of Technology, Clausthal-Zellerfeld, Lower-Saxony, Germany. [2]Heriot-Watt University, Edinburgh, Scotland, United Kingdom

Introduction

Biomineralized tissues exhibit exceptional mechanical properties due to complex material architectures [1,2]. For example, cold-water corals utilise strong aragonite crystals (4-6 GPa) to build their skeleton. Micromechanical experiments, however, show that the bulk skeletal tissue fails at ~462 MPa [1,3]. Understanding this mechanical scale transition is important for developing advanced bio-inspired materials and for predicting how these organisms will fare in climate change-affected oceans [1,4]. We aimed at investigating this scale transition and we hypothesised that it is controlled by the interface mechanics.

Methods

We performed molecular dynamics simulations to explore the mechanical response of crystal interfaces [3], contrasted by experimental results [1]. We performed tensile and shear tests on three limiting interface types: (i) dry aragonite twin boundaries, (ii) hydrated interfaces containing biomineralisation proteins which we confirmed through Raman spectroscopy, and (iii) interfaces separated by water layers of varying thickness. We analyse stiffness, strength, and failure mechanisms of each interface type.



Results

Simulations revealed an interface strength hierarchy (Fig. 1). Dry twin boundaries are strong (~6.5 GPa). Hydrated protein-mediated interfaces are significantly weaker (0.3-0.8 GPa), but exhibit damage tolerance through progressive reorganisation of water-mediated hydrogen bonds. Strength of pure water interfaces is thickness-dependent (>3 GPa for thin (<5 Å) and ~0.8 GPa for thick (>10 Å) layers). Experimental strength (~462 MPa [1]) is consistent with simulated shear strength of protein interfaces (~300 MPa). Resolved shear stress analyses links interface shear strength to ~600 MPa predicted compressive strength, confirming that failure is governed by interface decohesion.

Discussion

Cold-water coral skeletal tissue strength is controlled by decohesion of hydrated organic interfaces. These interfaces define bulk strength and may provide mechanisms for toughness and damage tolerance. We provide the first quantitative data on the mechanics of these interfaces, offering an explanation for the remarkable strength of the bulk tissue (10x that of concrete) [1]. Our findings may inform prediction of coral viability in climate change-affected oceans and development of advanced bio-inspired materials.

A Personalized In Silico Model of Brain Metastasis Development and Response to Radiation Treatment

Dr Eleftherios Ioannou[1], Mr Christos Panagiotis Papanikas[1], Dr Dimitra Flouri[1], Dr Loizos Siakallis[1,2], Dr Elisavet Papageorgiou[3], Dr Marilena Theodorou[3], Dr Vasileios Vavourakis[1,2]

[1]University of Cyprus, Nicosia, Nicosia, Cyprus. [2]University College London, London, London, United Kingdom. [3]Bank of Cyprus Oncology Centre, Nicosia, Nicosia, Cyprus

Introduction

Brain metastases (BMs), secondary brain tumours, affect an estimated 20% of cancer patients [1]. Current treatment typically involves surgery, radiation therapy or/and combined with systemic therapy. They can offer improved survival and reduced patient morbidity, while avoiding whole-brain radiotherapy, which causes cognitive impairment [2]. However, predicting patient response to treatment on an individual basis remains elusive, due to the lack of reliable digital tools for clinical decision-making for patients diagnosed with BMs.

Methods

We present an organ-scale *in silico* model that simulates the dynamics of BM in response to stereotactic radiotherapy (SRT) by incorporating key biological processes: the dynamics of the tumour enhancing region, necrosis and oedema. The model is formulated as a system of partial differential equations, discretised using finite elements, representing the spatiotemporal dynamics of each component and their interactions. It also integrates patient-specific data, i.e., the brain geometry (from MRIs), SRT dose distribution and tumour/necrosis/oedema region, to provide a personalised framework for predicting BM progression and treatment efficacy.

Results

The *in silico* model is applied to a recently published set of 40 BM patients [3]. It is calibrated based on the actual regions of tumour/necrosis/oedema derived from two to five time points per patient. Results demonstrate the model's capability to replicate the spatiotemporal evolution of metastatic brain tumours, including tumour growth, necrosis and oedema development. Further, a data assimilation technique was applied to predict tumour evolution using input from only one or two initial follow-ups and was able to predict tumour evolution in the remaining follow-ups for most cases.

Discussion

We demonstrate the ability of the proposed *in silico* model to predict BM progression and SRT outcome. By incorporating patient data, the model provides a personalised *in silico* framework that encompasses tumour heterogeneity and individual anatomical differences. The capability of data assimilation technique shows great potential for clinical application. Generating accurate predictions of BM evolution utilizing follow-up evidence after treatment can inform clinical decision-making, providing an early indication of SRT outcome trajectory.

Biomechanical Fatigue Analysis of Vertebral Endplates Under Four-Point Bending

Mrs Verushca Gasiorowski[1,2], Dr William Curry[2,3], Dr Brian Stemper[1,2,3]

[1]Department of Biomedical Engineering - Medical College of Wisconsin, Milwaukee, WI, United States. [2]Neuroscience and Biomechanics Research Laboratories - Zablocki VA Medical Center, Milwaukee, WI, United States. [3]Department of Neurosurgery - Medical College of Wisconsin, Milwaukee, WI, United States

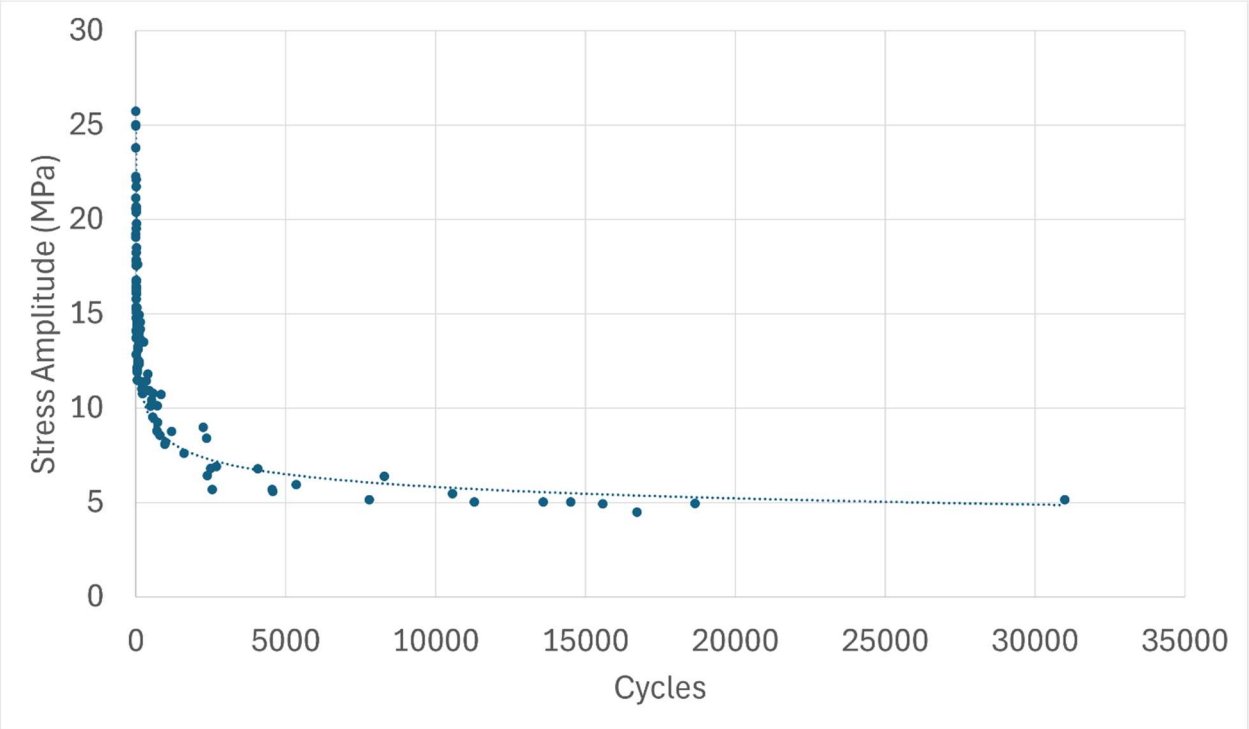
Introduction

Occupations like truck drivers [1], tractor drivers [2] and helicopter pilots [3] subject individuals to whole-body vibration (WBV) due to long-duration, repetitive loading at higher-than-normal frequencies [4] (5 Hz or higher). The spine provides structural support to the body during WBV. While the fatigue response of the intervertebral disc has been well-studied [5, 6] , vertebral endplate has received less attention despite its integral role in resisting compressive loads[7, 8]. This study explored endplate fatigue-life behavior to better understand chronic injury mechanisms and determine occupational exposure limits.

Methods

Porcine cervical endplate specimens (approximately 30 mm × 10 mm × 1.5 mm) were tested in 4-point bending at 5 Hz until failure. Fatigue curves and stiffness were analyzed in MATLAB, using the force-displacement data, and RStudio for statistical analysis.

Results



The figure shows the fatigue life curve of 115 tests (R^2= 0.90), identifying high-cycle (HCF) (n = 33, R^2 = 0.86) and low-cycle (LCF) (n = 82, R^2 = 0.77), which are separated when loading typically exceeds the yield point (41.02MPa), which was determined from previous failure testing we conducted. HCF stiffness showed an average drop of 23.97% (SD = 12.69%) from baseline to terminal stiffness. In the infinite-life region, the specimen did not break at a stress amplitude of 4.89 MPa or less, and the average stiffness drop between baseline and end-of-test stiffness was -0.49% (SD = 3.43%), which was significantly ($p<0.05$) different from HCF.

Discussion

A first-of-its-kind fatigue-life curve for endplates has been established. The stiffness of infinite-life showed minimal change across loading cycles and did not fail under >30,000 loading cycles. These findings can inform seat design criteria to limit stress, ensuring the

subject is in the HCF or infinite-life region, thereby preventing endplate fractures and the likelihood of disk degeneration and severe back pain.

In Vivo Assessment of Corneal Mechanical Properties After Corneal Collagen Cross-linking Surgery Based on Optical Coherence Elastography

Dr. Yuqi Liu[1], Prof. Haixia Zhang[1], Prof. Xiuqing Qian[1], Prof. Guoyang Li[2]

[1]Capital Medical University, Beijing, Beijing, China. [2]Peking University, Beijing, Beijing, China

Introduction

Corneal cross-linking (CXL) enhances corneal biomechanical properties, but quantitative and spatially resolved assessment methods remain limited. Optical coherence elastography (OCE) enables non-invasive measurement of localized corneal elasticity, providing an assessment tool for evaluating biomechanical changes following corneal cross-linking. This study aims to validate the feasibility of OCE technology in assessing corneal mechanical properties following corneal cross-linking surgery and to explore its capability in resolving localized mechanical inhomogeneities.

Methods

A homogeneous silicone corneal model was fabricated to verify the accuracy and repeatability of the OCE system, and a centrally softened heterogeneous silicone corneal model was fabricated to evaluate the system's ability to distinguish localized elasticity variations. Six rabbit corneas underwent half-CXL to establish a model of region-specific biomechanical enhancement, followed by in vivo OCE measurements two weeks postoperatively. Elastic wave propagation velocities were reconstructed using the phase-gradient method to generate spatial maps of corneal elastic modulus. After completion of the in vivo experiments, corneal tissues were immediately harvested, embedded, and processed into cryosections, followed by indentation testing to validate the results obtained from OCE.

Results

In the homogeneous silicone corneal model, the OCE-fitted modulus showed a highly linear correlation with the tensile modulus ($r = 0.998$, $P = 0.002$), described by the relationship $E_{OCE} = 2.11E_{tensile} - 0.07$, confirming the reliability of OCE in characterizing material mechanical properties. In the centrally softened heterogeneous silicone model, the wave speed in the softened region was markedly lower than in the surrounding area, and the modulus ratio matched the tensile testing results, demonstrating that OCE can

accurately resolve localized mechanical heterogeneity. In the half-CXL animal model, OCE clearly delineated the boundary between the half-CXL and non-CXL regions, and the reconstructed modulus maps visually revealed localized biomechanical enhancement. Indentation testing performed on corneal cryosections exhibited strong agreement with OCE measurements, further validating the reliability of OCE for assessing localized corneal elasticity changes in vivo.

Discussion

This study demonstrates that OCE technology reliably reveals variations in local elastic modulus, providing technical support for personalized CXL assessment. Given differences between rabbit and human corneas, subsequent research will further validate the stability and clinical applicability of OCE technology in human subjects.

Relationship Between the Structural and Mechanical Properties of the Semitendinosus Intermediate Aponeurosis: Implications for Hamstring Strain Injuries

Dr. Xiyao Shan[1,2], Mr. Masato Saito[2], Dr. Kanae Umemoto[2], Mr. Hiroki Kajiura[2], Dr. Shun Otsuka[2], Prof. Xiang Fan[1], Prof. Munekazu Naito[2]

[1]Department of Physical Education, Shanghai Jiao Tong University, Shanghai, Shanghai, China. [2]Department of Anatomy, School of Medicine, Aichi Medical University, Nagakute, Aichi, Japan

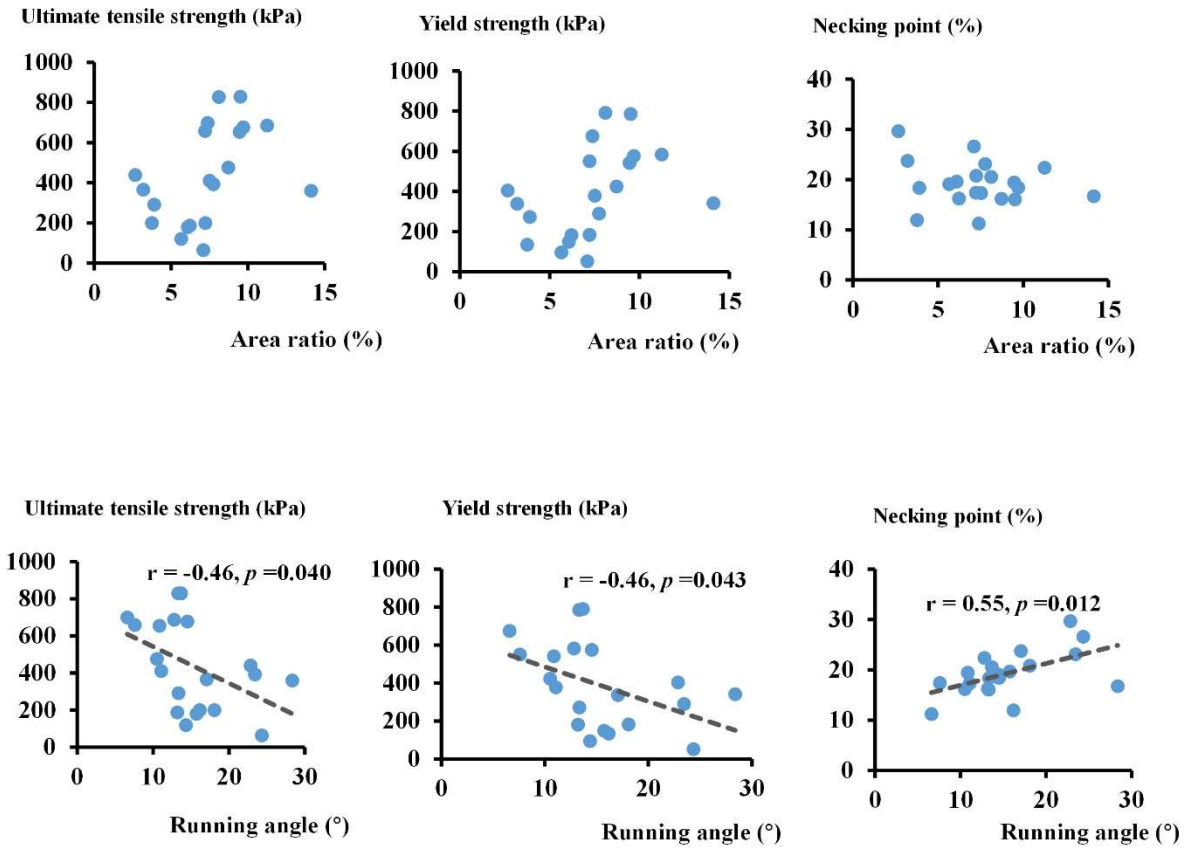
Introduction

The semitendinosus muscle (ST) in the hamstrings is the most frequently injured muscle in jumping sports. Within the ST, the intermediate aponeurosis located slightly proximal to the muscle belly has been identified as a potential risk factor for strain injuries. However, how its structure relates to the mechanical properties remains unclear. In this study, we conducted tensile tests on the ST specimens containing the intermediate aponeurosis to investigate the relationship between its morphological and mechanical properties.

Methods

ST specimens were obtained from twenty legs of ten human cadavers (5 males and 5 females, age: 86.6±8.4 years) donated to Aichi Medical University. First, the ratio of ST aponeurosis area (aponeurosis area/total muscle and aponeurosis area) and running angle were measured. Then, tensile tests until rupture were performed, and yield strength (YS), ultimate tensile strength (UTS), and necking point (NP) were determined from the strain-stress curves. Lastly, Pearson's correlation was used to analyze the correlations between the structural and mechanical properties of the ST intermediate aponeurosis.

Results



No significant correlations were found between the ratio of ST aponeurosis area and YS, UTS, or NP. There was a negative correlation between the running angle and YS and UTS, respectively (YS, $r = -0.46$, $p<0.05$; UTS, $r = -0.46$, $p<0.05$), whereas a positive correlation was found between the running angle and NP (NP, $r = 0.55$, $p<0.05$).

Discussion

A positive correlation was found between the running angle and NP, while a negative correlation was found between the running angle and YS and UTS. The mechanical

behavior of the ST would be influenced by the running angle of its intermediate aponeurosis. A larger running angle of the aponeurosis may contribute greater tissue extensibility prior to failure at the expense of reduced strength. Consequently, the running angle may be an important morphological factor influencing athletic susceptibility to ST strain injuries.

Direct Fiber Modeling of Lamina Cribrosa Beams Predicts Experimentally-Observed Behavior Better Than Continuum Models

Ms. Yingzhe Han, Dr. Xuehuan He, Mr. Qi Tian, Dr. Ian A. Sigal

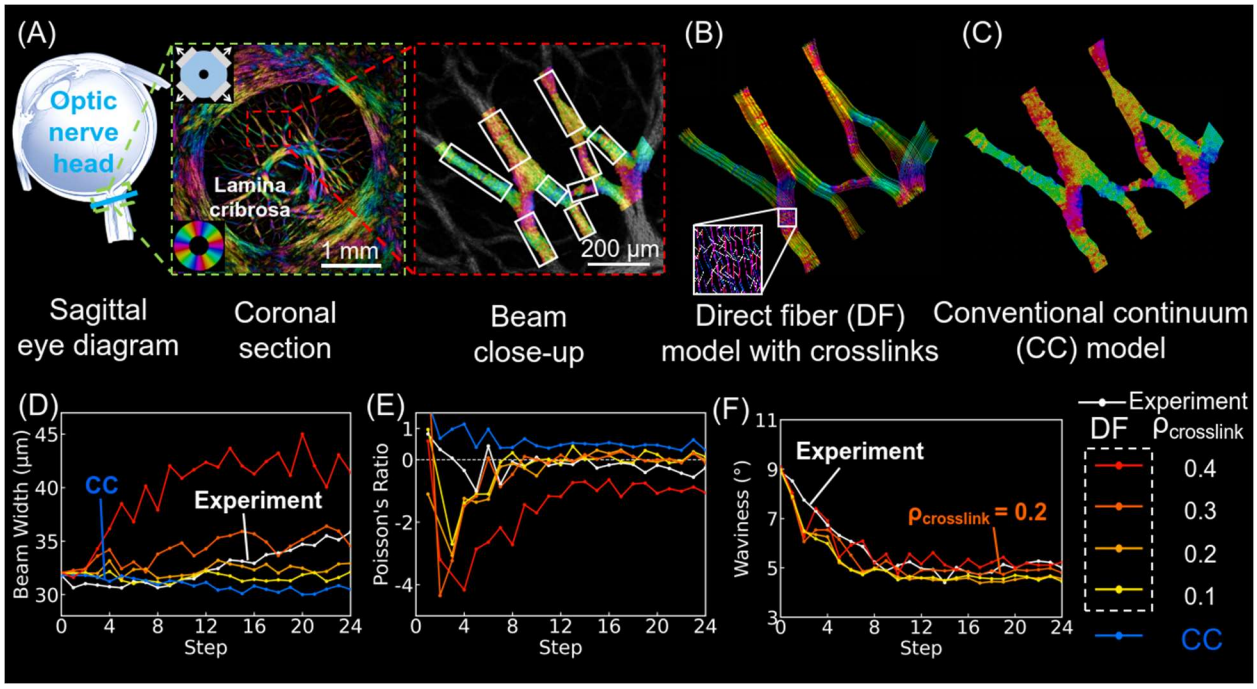
University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Collagen fibers are the primary load-bearing component of the lamina cribrosa (LC) beams in the back of the eye [1]. Nevertheless, most modeling efforts use continuum (CC) descriptions that do not account for potentially crucial fiber-level interactions or long-range load transmission, and often assume incompressibility. Direct fiber (DF) models have reproduced the mechanics of other eye fibrous tissues, including sclera [2]. We hypothesize that LC beam mechanics will be better predicted when their fiber architecture is explicitly represented. We test this hypothesis by comparing how DF and CC models of LC regions replicate experimental observations.

Methods

Sheep LC specimens were stretched biaxially while imaged with instant polarized light (IPOL) microscopy, and image registration provided in-plane displacements. Two LC regions of interest were selected, and about 10 beams were segmented in each. For each region we built (i) DF models in which discrete fibers followed local orientations and were interconnected by uniformly distributed crosslinks with prescribed densities, and (ii) a CC model using a Holzapfel-Gasser-Ogden (HGO) formulation with fiber orientation and dispersion mapped from the same data [3]. IPOL-measured displacements were applied as boundary conditions. Beam width, length, Poisson's ratio, tortuosity, and waviness were quantified across loading steps, and representative results from one region are shown.



Results

The CC model predicted narrowing of LC beams and consistently positive Poisson's ratios. DF models predicted widening and negative or near-zero Poisson's ratios, matching experimental trends more closely. Crosslink density altered DF behavior: lower densities produced greater waviness and larger beam widths, and across all metrics, increasing crosslink density moved DF predictions progressively closer to the continuum-like behavior observed in the CC model.

Discussion

Our results suggest that LC beam-level behaviors are better captured when fiber architecture is explicitly represented. The CC model's beam narrowing and positive Poisson's ratios highlight limitations of a continuum description, whereas DF models reproduced observed trends. Crosslink density influenced inter-fiber coupling: low densities allowed larger width and waviness changes, whereas higher densities yielded a stiffer, less widening response.

A Framework for Predicting Lamina Cribrosa Blood Flow and Oxygenation From Localized Vasculature Imaging

Dr Yuankai Lu, Ms Ashley Linton, Dr Ian Sigal

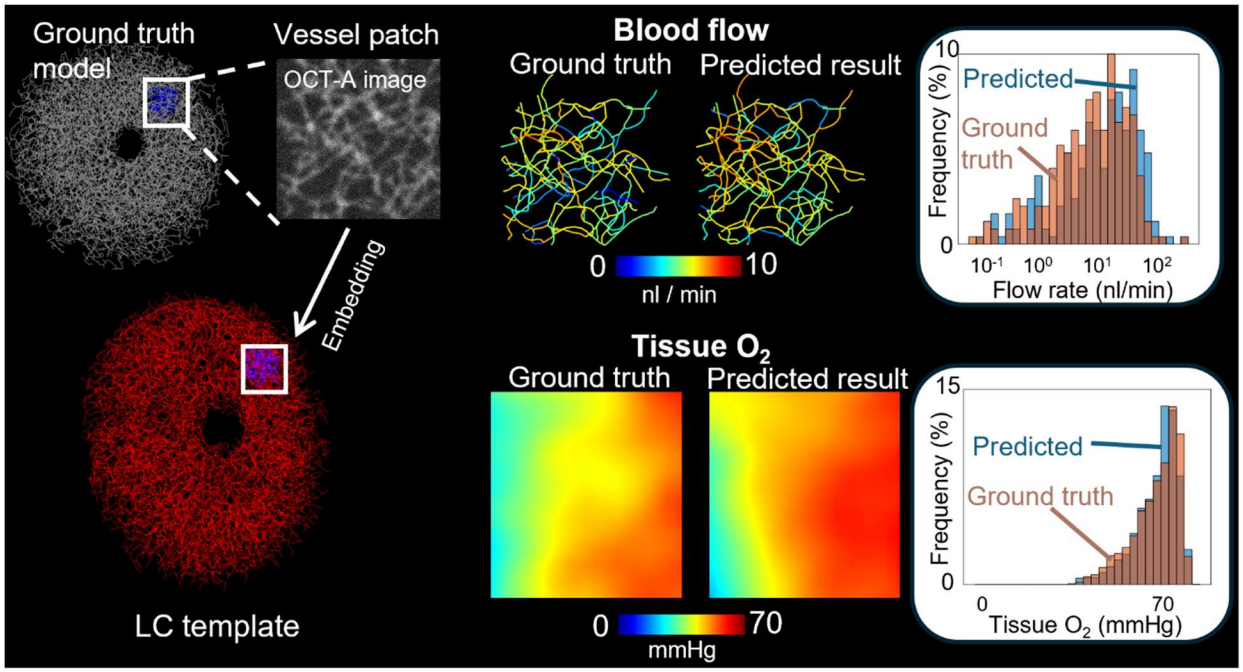
University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Despite its importance in the physiology and pathology of the eye, direct measurement of blood flow and oxygenation in the lamina cribrosa (LC) remains extremely challenging. Recent advances, such as adaptive-optics OCT angiography, enable some visualization but remain limited to small fields of view, resulting in patchy, incomplete vasculature. Methods that can infer physiology from such small, incomplete data are needed. We present a framework for predicting hemodynamics and oxygenation in a small, incomplete LC region. The framework is based on embedding the experimental data into a standardized whole-LC vascular model developed from detailed reconstructions of the complete LC vasculature, blood flow, and oxygenation.

Methods

Detailed 3D LC vascular networks from monkey eyes were reconstructed using histological imaging [1], and then combined to create a standardized vascular template representing typical LC geometry and boundary conditions. To predict flow and oxygenation in a localized region, its vessel network was aligned and embedded at the corresponding anatomical location within the template. Free ends were connected to nearby template network branches to provide physiological inlet and outlet conditions. Hemodynamic and oxygenation simulations were then performed [2], yielding predicted flow and oxygenation for the original localized region. For validation, small vascular patches were extracted from a fully reconstructed LC with existing ground-truth hemodynamics and oxygenation. Each patch was embedded and simulated using the same procedure, and the predictions were compared with ground truth to quantify accuracy.



Results

Across four test cases, the predicted oxygenation and hemodynamic fields showed strong agreement with ground truth. In the illustrated figure, both spatial patterns and histogram distributions matched the reference data. The mean oxygenation difference was 2.11 mmHg, and the mean flow difference was 0.47 nl/min.

Discussion

We present an embedding-based modeling approach that predicts blood flow and oxygenation from localized LC vasculature. The prediction matched the ground truth in validation tests. Future work will incorporate additional information, such as OCTA-derived flow metrics, to improve accuracy. This framework enables the physiological interpretation of small-field in-vivo data and extends localized measurements to whole-LC hemodynamic insights.

3D Matrix Confinement Induces Partial Epithelial-Mesenchymal Transition and Increases Chemoresistance

Mr. Yuta Iijima[1], Ph.D. Gen Hayase[2], Prof. Daisuke Yoshino[1]

[1]Tokyo University of Agriculture and Technology, Koganei, Tokyo, Japan. [2]National Institute for Materials Science, Tsukuba, Ibaraki, Japan

Introduction

Metastasis is a leading cause of cancer-related death, yet the process by which tumor cells leave their original environment is not fully understood. Cancer cells must adapt to various microenvironmental changes to survive. Epithelial-mesenchymal transition(EMT) plays a crucial role in breast cancer development by enabling cells to acquire migratory and invasive traits. EMT has also been strongly associated with the development of chemoresistance. In this study, we used a 3D spheroid model developed in our previous research [1, 2] to track changes in the morphology and protein expression of breast cancer cells as they escaped from the spheroid. We also analyzed whether escaped cells acquired resistance to anticancer drugs.

Methods

MDA-MB-231 spheroids were generated on a superhydrophobic substrate and cultured for five days. The cells that migrated outward were harvested, reseeded, and compared with conventional 2D controls. We analyzed their morphology and pseudopodia dynamics using phase-contrast and F-actin imaging. Immunoblotting was used to quantify EMT-associated markers and invasion-related enzymes. Doxorubicin-induced cytotoxicity assays were performed to evaluate chemoresistance.

Results

Escape from the spheroids led to significant cellular miniaturization and robust formation of lamellipodia- and filopodia-like protrusions. These changes were accompanied by strong upregulation of α-SMA, Snail, and N-cadherin, though ZO-1 remained essentially unchanged, indicating a transition toward partial EMT. Escaped and reseeded cells exhibited significantly elevated MMP-3 expression, whereas MMP-9 expression showed only modest variation. Both escaped and reseeded populations displayed pronounced resistance to doxorubicin, and this phenotype persisted even after cells were replated in 2D (Fig.1). This implies that confinement has a lasting effect.

Discussion

Physical confinement within a 3D matrix and subsequent release induced a cohesive set of changes involving partial EMT, cytoskeletal reorganization, and metabolic reprogramming. The sustained expression of mesenchymal markers and continued chemoresistance after reseeding highlight that even short-term confinement can exert durable influence on malignant potential. This spheroid-based platform rapidly generates invasive, drug-resistant populations and provides a practical tool for probing early metastatic events and for screening therapeutics aimed at preventing escape-driven disease progression.

Introduction

Malalignments in hip rotational version is associated with various pathologies[1-2] but determining the alignment of the hip non-invasively is difficult. The Craig's Test, designed to measure the alignment of the bony anatomy, has been used to measure femoral version[3] but it is possible that the mobility of the soft tissues around the hip joint could influence the results. Therefore, we examined the results of Craig's Test before and after squatting exercises requiring large ranges of motion at the hip joint. We hypothesized that the results would differ before and after the squatting protocol.

Methods

38 participants free of any musculoskeletal pathology volunteered for this study (20 males). Two sets of three repetitions of Craig's Test were done on each leg by a single experienced clinician, one set before doing the squat exercises, and one set immediately after. Craig's Test procedures are shown in Figure 1. Following the initial set of Craig's Tests, participants performed 22 total squats: 10 bilateral squats and 12 unilateral squats (6 per leg). For each squat, they were instructed to squat as low as they could comfortably control. The Craig's Test trials on each leg were averaged together to give one alignment score for each leg before and after the squatting trials. Paired sample *t*-tests were run separately on each leg to compare before and after squatting.

Results

All results showed Craig's Test scores increased following squatting. Right Leg Pre = 23.1 ± 9.3 deg, Right Leg Post = 25.3 ± 9.9 deg ($p<.05$). Left Leg Pre = 21.9 ± 8.2 deg, Left Leg Post = 24.3 ± 9.2 deg ($p<.05$).

Discussion

The primary finding of this research study is that any tightness in soft tissues around the hip joint can potentially alter the results of Craig's Test. Therefore, we recommend some form of warm-up involving movements requiring large ranges of motion at the hip joint before performing Craig's Test.

The Effect of Task on Cartilage T2 Relaxation Time in Osteoarthritic Knees

Mr Advait S. Madhekar[1], Mr Tejus Surendran[1], Ms Kyndall Tatum[1], Dr Dawn M. Elliot[2], Dr Daniel K. White[2], Dr Sophie Darwiche[3], Dr Ting Cong[3], Dr Axel C. Moore[1]

Introduction

Understanding how articular cartilage responds to activities of daily living is essential for identifying early signs of joint dysfunction and chondro-preserving activities. Previous work has demonstrated that tibiofemoral cartilage undergoes measurable thickness changes (deformation) in response to physiologic tasks, such as walking and lying supine. The present study examines whether T2 relaxation time, a quantitative MR metric that is correlated with water and proteoglycan content, is responsive to physiological tasks from daily activities in knees with osteoarthritis (OA).

Methods

We recruited eight participants with symptomatic knee OA. Each participant completed a fixed task series consisting of 30 minutes of standing (Standing_1), 10 minutes of walking (Walking), a second period of standing for 30 minutes (Standing_2), and finally lying supine for 50 minutes (Supine). After each task, a multi-slice, multi-echo T2-weighted scan was acquired on a 3T MR scanner using a 15-channel Tx/Rx knee coil.

Femoral and tibial cartilage were manually segmented. Each segmentation was registered to the baseline scan, which was acquired just before the task sequence. T2 relaxation times were computed on a voxel-by-voxel basis by fitting a mono-exponential decay function. The mean femoral and tibial T2 relaxation times were computed within the region of cartilage-cartilage contact. Non-parametric testing was used to detect significant effects (Friedman and Wilcoxon signed-rank tests).

Results

Relative to baseline, all tasks led to a decrease in T2 relaxation time; however, only the tibia was significantly affected by the task ($p=0.017$). Pairwise comparisons to baseline revealed significant reductions in T2 relaxation time following Standing_2 (-14%, $p=0.031$) and Supine (-13%, $p=0.031$).

Discussion

While this is a small cohort study in a highly diverse and variable musculoskeletal disorder, these findings provide evidence that the T2 relaxation time of OA cartilage is responsive to physiological tasks. Furthermore, these findings are consistent with our prior work investigating the effect of task on cartilage deformation. Taken together, this work begins to establish a framework for evaluating the effect of task on cartilage composition and mechanics in vivo. Elucidating the effect of task, intensity, and duration may inform safe and chondro-preserving activities.

Using a Biomechanics-Informed Neural Network for Fast Predictions of Activity-Specific Metastatic Femur Fracture Risk From 2D Radiographs

Dr. Alexander Synek[1], Ms. Luisa Scheuring[1], Dr. Willi Koller[2,3], Ms. Clara Egner[2,3], Mr. Kevin Kitir[2,3], Assoc. Prof. Hans Kainz[2,3], Prof. Dieter Pahr[1]

[1]Institute of Lightweight Design and Structural Biomechanics, TU Wien, Vienna, Austria, Austria. [2]Neuromechanics Research Group, University of Vienna, Vienna, Austria, Austria. [3]Centre for Sport Science and University Sports, University of Vienna, Vienna, Austria, Austria

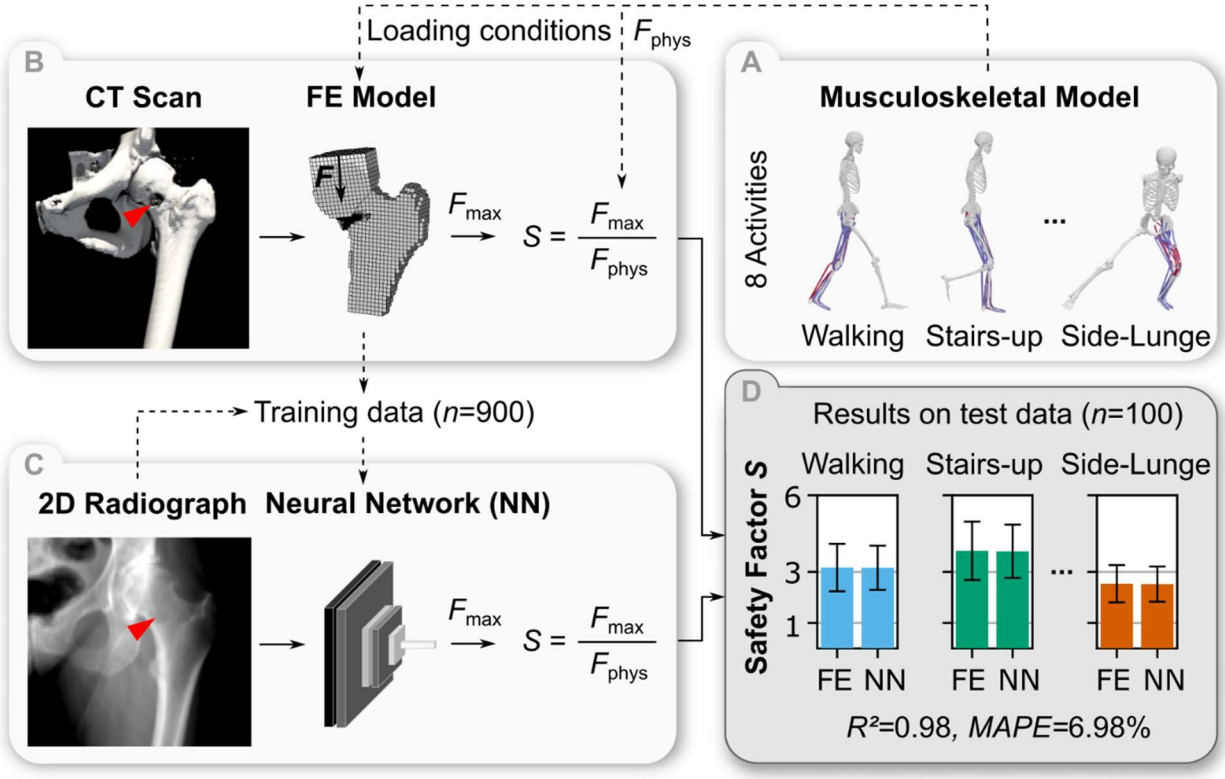
Introduction

Pathological femur fractures are a significant complication of metastatic bone disease, yet existing clinical tools demonstrate insufficient diagnostic accuracy [1]. Biomechanical models could enhance accuracy and even provide fracture risk estimations for specific activities. However, their requirements of 3D imaging, computational resources, and processing time limit clinical translation. Here, we present the proof-of-concept of a biomechanics-informed neural network to predict activity-specific femur fracture risk directly from 2D radiographs in a fast and highly automated way.

Methods

A virtual cohort representing a single patient with various cases of metastatic bone disease (n=1000) was created by randomly inserting lytic lesions into the CT scan of a healthy subject [2]. Physiological peak hip joint loads (F_{phys}) of a size- and weight-matched subject during eight activities (e.g. walking, side-lunge, jumping) were computed using a musculoskeletal model [3] (Fig1.A). Femoral failure loads (F_{max}) were assessed using validated, CT-based finite element (FE) models [4] accounting for the activity-specific hip joint load direction (Fig1.B). The safety factor $S=F_{max}/F_{phys}$ was calculated as the fracture risk metric for each activity. A convolutional neural network was then trained on 900 cases to predict the activity-specific failure loads directly from simulated 2D radiographs and the safety factors were computed (Fig1.C). Neural network and FE model predictions were compared on the remaining 100 cases.

Results



FE-predicted safety factors showed a wide range across all 1000 cases and activities (S=0.2–4.8). The neural network-predicted safety factors demonstrated excellent

agreement with FE results on the test cases (n=100, R^2=0.98, mean absolute percentage error=6.98%, Fig1.D), at an average prediction time of 77ms.

Discussion

The neural network predicted activity-specific metastatic femur fracture risk for a single subject in good agreement with CT-based FE modelling, while requiring only 2D radiographs and minimal processing time. With further development and validation on a larger cohort, this approach could offer a clinically viable tool for personalized activity guidance in patients with metastatic bone disease.

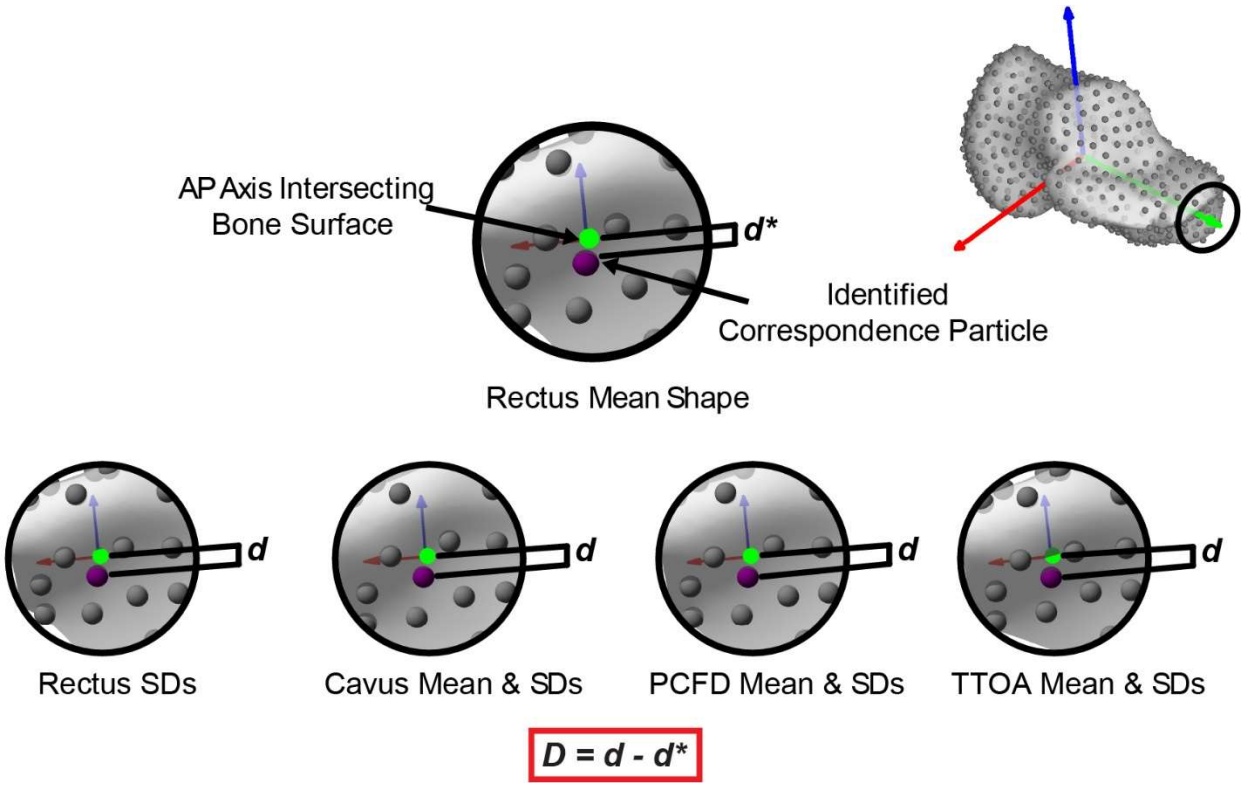
Introduction

Biomechanical 3D analyses are crucial to understanding the complex nature of the foot and ankle. A key component of 3D analyses is defining reliable and consistent anatomic coordinate systems (ACS) that are accessible to the biomechanics community. While several potentially viable automatic coordinate systems exist, their reliability is unclear. Unreliable coordinate systems may introduce nuisance variability and limit the ability to compare data across sites. This study aims to evaluate the reliability and accuracy of four ACSs to help determine standardized definitions for the foot and ankle.

Methods

Weightbearing CT scans from individuals representing four pathologies (rectus, cavus, flatfoot, and tibiotalar osteoarthritis) were used to generate 3D models of 14 bones. We generated statistical shape models (SSMs) to represent mean shapes and ±2 SD. ACS definitions [1-4] were applied to each bone.

Angular differences were calculated by comparing ACSs using rotation matrices to derive principal angles based on an XYZ convention. Intra- and inter-rater reliability was assessed on the Conconi and Siegler ACSs using ICC, while the Peterson and Thorhauer definitions are fully automatic. SSM particle locations were used to access reliability of each definition across pathologies.



Results

Comparison of ACS definition accuracy revealed sub-millimeter differences among definitions and across pathologies. The ICC analysis reported the Conconi method showed excellent agreement for the talus and good to excellent agreement for the calcaneus.

Discussion

This study highlights the status of standardized foot and ankle ACSs as part of an international task force [5]. Analyzing ACS methodologies across pathologies has implications for research and clinical practice. Our reliability analysis showed promising results with both automated and manual methods are highly reliable across pathologies. The results are encouraging because automated methods eliminate the requirement of time-consuming user input, specialized training, and repeated reliability assessments. This work ultimately aims to provide fully automated ACS definition that can be used as a standard for 3D biomechanical foot and ankle analyses.

Effect of Insoles on Joint Contact Forces During Walking and Running in Overpronated Foot Type

M.Sc. Andrea Arensmann[1], M.Sc. Thomas Stief[2], PD Dr. Marc de Lussanet[1,3], Dr. Kim Joris Boström[1], Prof. Dr. Heiko Wagner[1,3,4]

[1]University of Münster, Münster, North Rhine-Westphalia, Germany. [2](ts)^2, Osnabrück, Lower Saxony, Germany. [3]Otto Creuzfeldt Center for Cognitive and Behavioral Neuroscience, Münster, North Rhine-Westphalia, Germany. [4]Center for Data Science and Complexity (CDSC), Münster, North Rhine-Westphalia, Germany

Introduction

Excessive pronation is a common misalignment, that appears to increase the risk of various lower-extremity injuries. To prevent these injuries, insoles are often used to compensate for misalignments. Various studies have investigated the effect of insoles on the kinematics and kinetics of the lower extremities. However, their influence on joint contact forces (JCFs) received little research attention, even though high forces could lead to joint injuries and disorders. The aim of this study was therefore to investigate the effect of a pronation insole (ps), a bionic insole (bs) and no insole (ws) on JCFs in the hip, knee and ankle during walking and running

Methods

Data were recorded using the Gait Real-Time Analysis Interactive Lab (GRAIL, Motek Medical; Utrecht, Netherlands), a treadmill with two integrated force plates synchronised with 10 cameras (VICON Motion Systems Ltd.; Oxford, UK). 12 participants with an overpronated foot type walked (1.3m/s) and ran (2.5m/s) in each of the three conditions. JCFs were calculated using Computermyography (Predimo GmbH, Münster, Germany). All forces were normalized to subject's bodyweight and statistically analysed using a generalised linear mixed model.

Results

Overall, hardly any significant differences could be found between the conditions for walking or running. The JCFs in the ankle decreased in bs compared to the other conditions, but only during running. In the knee, only ps showed higher JCFs compared to bs. When walking, however, the JCF of bs is higher than that of ps. No differences in the JCFs were found in the hip. However, comparing the individual percentage changes reveals large differences in the direction and magnitude of the values (Fig.1).

Discussion

Our results show that bs insoles can reduce JCFs in the ankle and knee during running, although the effect sizes are very small. The hip is unaffected by the insoles. In walking only minor differences could be found. Overall, however, there are strong individual differences between participants, which may explain the small effect sizes and have also been observed in studies comparing different types of footwear. The results presented here are preliminary results, as not all participants have been evaluated yet.

Images (Optional)

Shape-Based Alterations in Cartilage Contact Mechanics Precede Radiographic Knee Osteoarthritis

Dr. Anthony Gatti[1], Ms Kathryn R. Marusich[1], Dr. Allison Clouthier[2], Dr. Carmichael Ong[1], Dr. McKenzie S. White[1], Dr. Amir Esrafilian[1,3], Dr. Constance Chu[1], Dr. Seth Sherman[1], Dr. Garry E. Gold[1], Dr. Scott L Delp[1], Dr. Feliks Kogan[1], Dr. Akshay S Chaudhari[1]

[1]Stanford University, Stanford, CA, United States. [2]University of Ottawa, Ottawa, ON, Canada. [3]University of Eastern Finland, Kuipio, Northo Savo, Finland

Introduction

Mechanics have long been linked to knee osteoarthritis (OA) initiation and progression.

While many studies investigate external mechanics, studies on tissue-level mechanics are limited due to challenges in estimating these at scale. Recent large-scale datasets and simulation methods could help elucidate mechanics at scale. **Purpose**: To test whether shape specific cartilage contact mechanics during gait are predictive of knee OA progression in participants from the Osteoarthritis Initiative (OAI).

Methods

We extracted data for three groups based on Kellgren–Lawrence (KL) grade: Healthy (KL < 2 at baseline and 4-years), Progressor (KL < 2 at baseline, KL ≥ 2 at 4 years), and Mild OA (KL = 2 at baseline).

We developed an automated pipeline to create personalized 24 degree-of-freedom knee models from baseline knee MRIs and simulated cartilage contact during gait. We autosegmented bones, cartilage, and menisci, and fit a Neural Shape Model to segmentations yielding smooth surfaces for simulations and implicitly matched points to update ligament attachments and wrap surfaces. All knee models were isotropically scaled to match the size of a reference knee. We used the Concurrent Optimization of Muscle Activations and Kinematics (COMAK) algorithm to simulate cartilage-cartilage and cartilage-menisci contact during gait[1]. Simulations tracked a single reference person's kinematics and ground reaction forces, isolating differences due to shape. We used SPM 1D ANOVA to test group differences in cartilage pressure and contact area.

Results

Simulations for 658 participants were included (222 Healthy, 226 Progressor, 210 Mild OA). Medial tibial cartilage pressure and contact area were different throughout stance (Figure 1). Healthy knees had higher medial pressure than OA knees throughout stance, and than Progressor knees in early stance. Mild OA had greater contact area than Healthy and Progressor groups.

Discussion

Higher contact area in OA knees is consistent with OA pathophysiology, where weight-bearing areas enlarge with disease. Lower pressure in Mild OA is likely due to distribution of similar loads over greater area. Graded medial pressure (Healthy > Progressor > Mild OA) suggests Progressors exhibit remodeling prior to radiographic OA, positioning shape-based mechanics as sensitive indicators of early disease susceptibility.

Images (Optional)

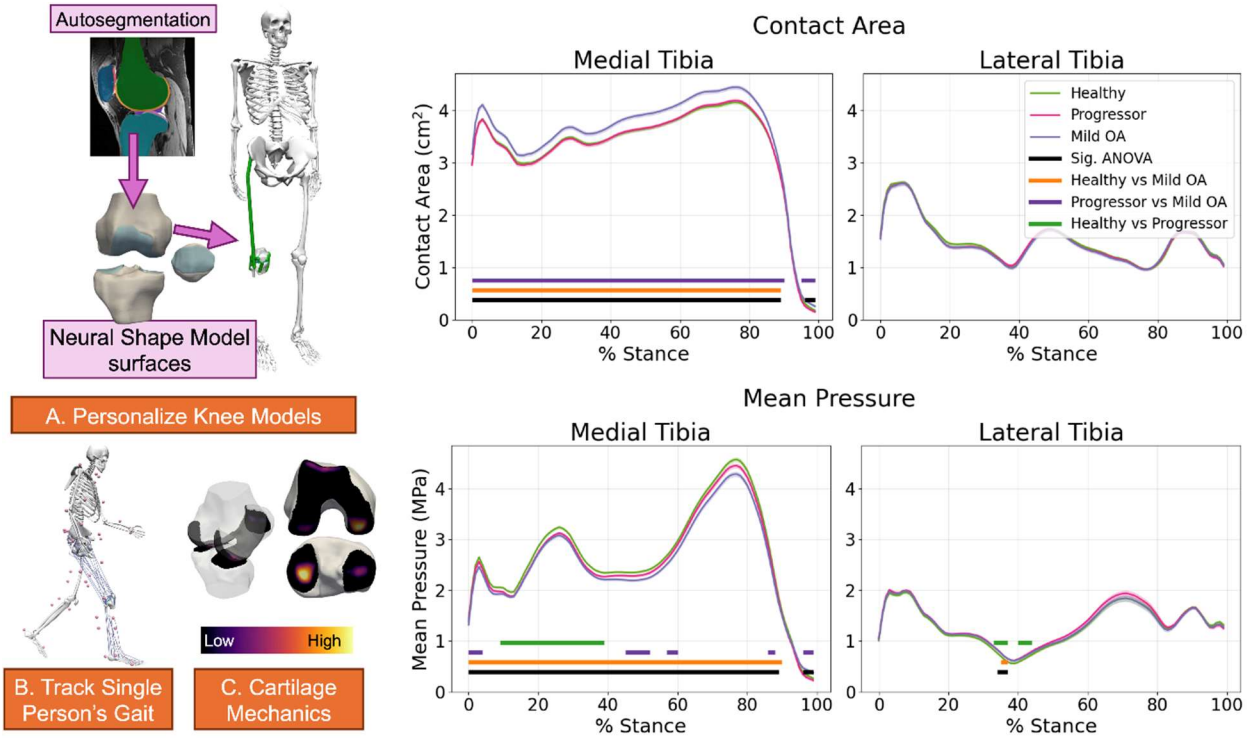

Figure 1. (Left) Automated pipeline: **A.** Neural Shape Model-based generation from MRI. **B.** Gait simulation using the COMAK algorithm with standardized kinematics and kinetics to isolate shape effects. **C.** Calculation of cartilage contact mechanics. **(Right)** Tibial cartilage mechanics during stance (mean ± SE). Horizontal bars at the bottom indicate significant differences ($p<0.05$, SPM 1D).

Representing Clinically Relevant Kinetic Gait Outcomes with a Wearable Inertial Sensor System in Patients Before and After Knee Arthroplasty

Mr. Ben MacDonald[1], Mr. Adam Dorrance[1], Dr. Michael Dunbar[1,2], Dr. Glen Richardson[1,2], Dr. Jennifer Leighton[1,2], Dr. Janie Astephen Wilson[1,2]

[1]Dalhousie University, Halifax, NS, Canada. [2]Nova Scotia Health, Halifax, NS, Canada

Introduction

The temporal patterns of frontal and sagittal plane knee joint moments are clinically relevant outcomes of knee arthroplasty (KA) surgery, having been associated with implant stability, and not meaningfully improving for many patients one year after surgery [1,2]. Specific temporal patterns of the knee flexion/extension (KFM) and knee adduction moments (KAM) are characterized by a lack of midstance unloading, or kinetic stiffening in both planes [3]. Traditionally, these outcomes have required optoelectronic motion capture and in-ground force plates in laboratory environments. Inertial measurement units (IMUs) offer a lower-cost alternative for out-of-lab assessments. The purpose of this study was to represent clinically relevant kinetic outcomes using an IMU system in patients before and after KA.

Methods

Twenty-one perioperative KA patients (100 trials) provided consent for gait analysis. IMUs (Opal, APDM) were placed on the shank, thigh, and foot of the affected leg. Data from the sensors were aligned to each segment using functional calibration [4], and strides were segmented [5]. Simultaneous data from a motion capture system (Motion Analysis) and in-ground force platforms (AMTI) were used to calculate knee joint moments. Principal component analysis was applied to KAM and KFM waveforms, with PC2 extracted to specifically represent the midstance knee stiffening pattern. Acceleration and angular velocity features were selected from IMU axes, informed by literature and univariate correlations with KAM and KFM PC2. Multivariate linear regression analysis was used to examine the association of KAM and KFM PC2 with independent IMU features.

Results

Optimal regression models were based on features of accelerations and angular velocities from shank and foot sensors (R^2=0.67 KFM PC2 model, R^2=0.69 KAM PC2 model; $p<0.05$; Table 1).

Discussion

These findings support the feasibility of predicting clinically relevant kinetic outcomes using IMU data in patients with end-stage knee OA. The models enable potential monitoring of knee joint loading profiles in natural environments to remotely monitor clinically relevant gait changes to support personalized clinical decisions.

An IMU Sensor System for Representing Sagittal and Frontal Knee Angles During Gait in Patients with Knee Osteoarthritis Before and After Arthroplasty

Mr. Ben MacDonald[1], Mr. Adam Dorrance[1], Dr. Michael Dunbar[1,2], Dr. Glen Richardson[1,2], Dr. Jennifer Leighton[1,2], Dr. Janie Astephen Wilson[1,2]

[1]Dalhousie University, Halifax, NS, Canada. [2]Nova Scotia Health, Halifax, NS, Canada

Introduction

Individuals with advanced knee osteoarthritis (OA) walk with significant differences in knee joint angles compared to healthy controls. Common patterns include a stiff-knee gait, defined by reduced magnitude and range of knee flexion/extension angles, and elevated knee adduction angles during stance [1]. Knee flexion and adduction angles during walking are key outcomes of knee arthroplasty (KA), yet stiff-knee gait patterns often persist after surgery [1]. These outcomes are typically measured with laboratory motion capture, limiting accessibility and clinical uptake. Inertial measurement units (IMUs) offer an affordable alternative and enable free-living data collection. The purpose of this study was to examine agreement between clinically relevant knee angle outcomes captured through optoelectronic motion capture and IMUs in knee OA.

Methods

Twenty-one perioperative KA patients completed overground gait trials with simultaneous optoelectronic (Motion Analysis) and IMU (Opal, APDM) motion capture. IMUs were placed on bilateral shank and thighs, with sensor-to-segment alignment performed using functional calibration, strides segmented and knee joint angles calculated using a quaternion-based filter [2,3,4]. Clinically relevant features of sagittal and frontal plane knee angles [1] were extracted and compared using Bland-Altman analysis.

Results

Across 21 patients, 100 gait cycles, IMU-derived outcomes demonstrated good agreement with motion capture for all knee angle measures ($p > 0.05$; Table 1). Mean bias for the flexion/extension range of motion (ROM) and adduction mean fell within previously reported minimal clinically important differences for this population [5]. Mean bias for flexion/extension ROM in stance, adduction ROM in stance, and ROM in early stance were smaller than inter-session variability [6].

Discussion

These findings indicate that IMU data from shank and thighs can be processed to capture clinically relevant sagittal *and* frontal plane knee kinematics in patients with end-stage knee OA. Sagittal plane knee angles have been represented with IMUs in past research, feasibility of capturing clinically relevant frontal plane knee angles during gait has been less studied.

Finite Element Analysis for the Design of Patient-Specific Offloading Ankle-Foot Orthosis

Mr. Benjamin Sarfati, Dr. Dana Solav, Mr. Lee Jordan, Ms. Eshraq Saffuri

Technion, Haifa, Haifa, Israel

Introduction

Complete offloading of an injured foot or ankle via an Ankle-Foot Orthosis (AFO) has been shown to provide potential improvements in gait biomechanics and recovery outcomes in comparison to more common assistive devices [1]. However, the AFO's brace shells (Figure 1a), which transfer ground reaction forces (GRFs) to the shank, must distribute stresses across soft tissues properly to minimize tissue damage or discomfort. Finite Element Analysis (FEA) can provide quantitative, evidence-based metrics to this end. This study constructs and validates a FEA framework for simulating the mechanical response of tissues subject to AFO loading to facilitate data-driven design.

Methods

MRI scans of a healthy participant's lower leg are obtained, followed by segmentation and 3D reconstruction. Skin geometry is used to model the AFO's brace shells (Figure 1b). Bones and brace shells are modelled as rigid bodies, whereas muscle tissue, patellar tendon, and neoprene liner are meshed with quadratic tetrahedral elements and each assigned hyper-elastic material parameters informed by experimental measurements. A dual-step FEA is implemented; the first step replicates AFO donning by tightening the brace around the shank. Then, GRF is applied to the brace to simulate standing. For validation, predicted reaction forces between brace shells are compared to measurements from load cells mounted on the AFO's fastening buckles.

Results

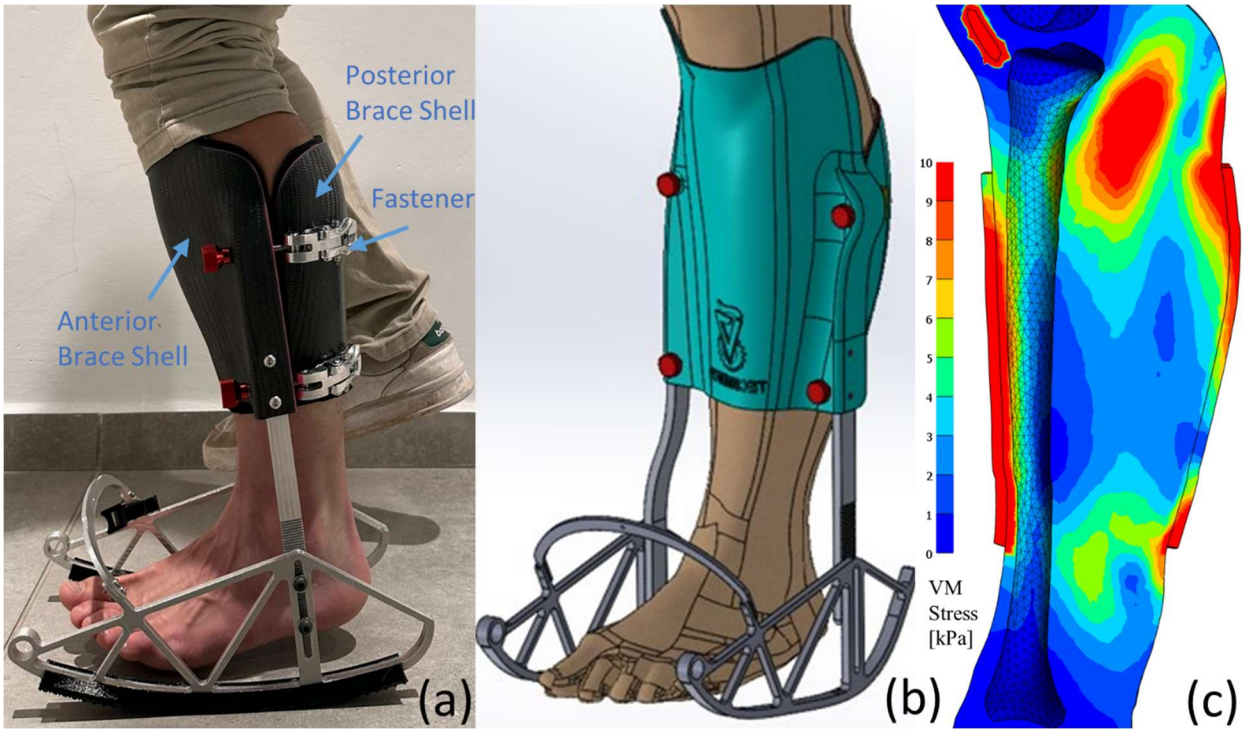

Figure 1c shows the results of Von-Mises stress values from standing with the donned AFO on a sagittal section at minimal anterior soft tissue thickness. Lower thickness soft tissue regions exhibit larger stresses. Significant shearing of the neoprene outer layer is evident, matching experimental observations.

Discussion

Current work further compares FEA predictions to experimental measurements. In the future, multiple simulated instances of the walking gait cycle will provide more comprehensive results. This work highlights the value of FEA in optimizing the tissue-

device biomechanical interface and advancing patient-specific orthotic and prosthetic design automation.

Do All Ultra-Congruent Knees Behave the Same? A Biomechanical Insight into Stability and Motion

Prof Bernardo Innocenti PhD

ULB, Bruxelles, Belgium, Belgium

Introduction

This study investigated whether different ultra-congruent (UC) total knee arthroplasty (TKA) designs display comparable biomechanical performance. Specifically, the Link SymphoKnee (LSK) UC was compared with the Zimmer-Biomet Persona (PRSN) UC to check similarities and differences in joint stability and tibio-femoral kinematics under different loading and motion conditions.

Methods

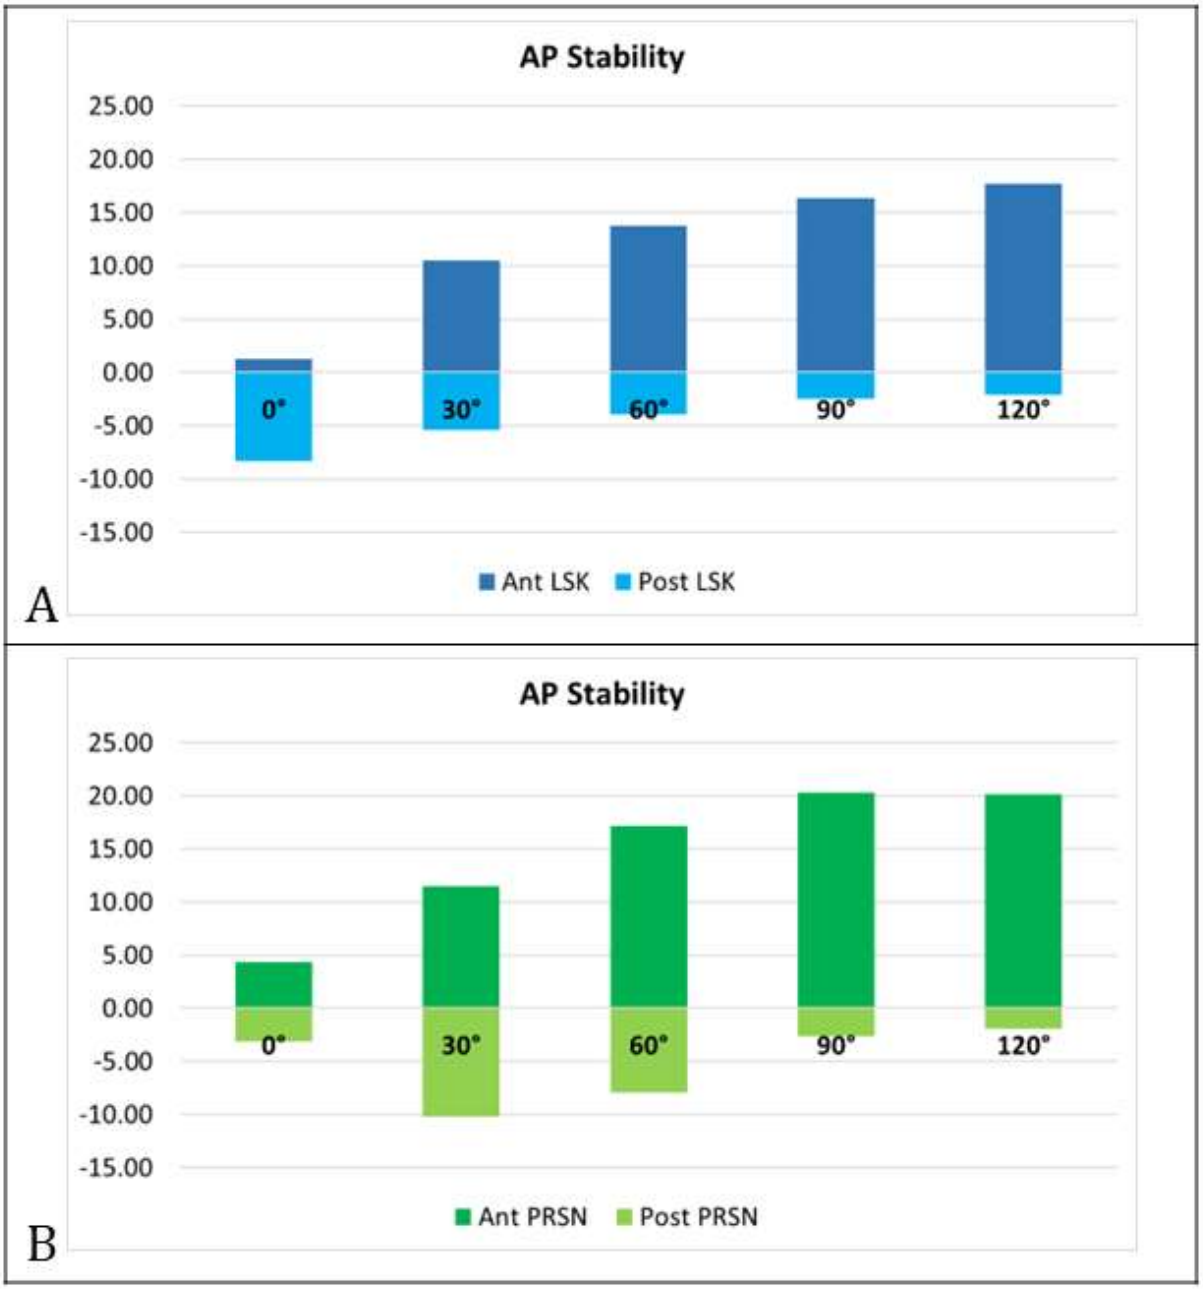
Both UC implants were analyzed, using validated finite element models, under standardized testing conditions, comparing:

1. antero-posterior (AP) stability under AP forces at different flexion angles from 0° to 120°;
2. internal-external (IE) stability under IE torques across the same flexion range;
3. tibio-femoral biomechanics during a gait cycle, using forces, torque and boundary conditions defined in accordance with ISO 14243-1 ;
4. tibio-femoral biomechanics during a squat up to 120° of flexion; the boundary conditions of this movement, in terms of flexion-extension angle, axial and anterior-posterior force, were taken accordingly to previously experimental activities

For the stability tests, femoral displacement relative to the fixed tibia was evaluated at each flexion angle and compared between the two implants.

For the dynamic activities, the following information was extracted analyzed and compared:

- Tibio-Femoral kinematics (in terms of internal/external rotation and antero-posterior translation);
- Medial and lateral contact area and antero-posterior displacement.



Results

Both UC implants demonstrated similar overall biomechanical trends. The LSK showed reduced displacements and rotations, indicating greater stability at all flexion angles except at 0° posterior, where PRSN was slightly superior (Figure 1). During walking, both implants exhibited almost identical tibio-femoral kinematics in AP translation and IE rotation, with comparable medial and lateral contact areas and contact point displacements. During squat, both designs showed analogous kinematics and contact mechanics across the full flexion range, with the LSK demonstrating more symmetrical medial-lateral contact behavior than the PRSN in deep flexion.

Discussion

Although both UC implants exhibited comparable biomechanical behavior in terms of stability, gait, and squat kinematics, subtle differences emerged. The LSK provided slightly enhanced stability and more symmetric kinematics, suggesting that not all UC implants behave identically. These findings underscore the importance of implant-specific design considerations in UC TKA selection.

Biomechanical Analysis of Surgical Technique on Distal Femoral Replacement Implant Performance

Prof bernardo innocenti PhD

Beams Department ULB, Bruxelles, Belgium, Belgium

Introduction

When distal femoral resection is required due to bone tumors, a Distal Femur Replacement (DFR) can restore joint function [1]. Implant stability depends on the integrity of the remaining femur and on the efficiency of the bone–implant interface in transmitting loads. Both cemented and press-fit fixation techniques are clinically used, and choices regarding resection height and stem length strongly influence lower-limb biomechanics. This study aims to provide surgical guidelines by evaluating the biomechanical effects of different DFR solutions through comparative stress analysis in multiple femoral configurations.

Methods

A validated finite element model was developed using the cortical bone geometry of a standard femur [2,3]. DFR components (stem, collar, shaft) were modeled based on Adler Ortho geometries (Cormano, Italy).

The following surgical parameters were investigated:

• press-fit vs. cemented stems;

• short vs. long stems (85 mm and 115 mm);

• short, medium, and large resections (97 mm, 147 mm, 207 mm);

• healthy vs. osteoporotic bone;

• axial (0°) vs. anteroposterior (AP, 90°) loading.

A total of 48 models were generated. Cortical bone was defined as transversely isotropic [2–5], whereas implant components were modeled as isotropic using manufacturer-provided properties [5,6]. Loads of 1000 N were applied either along the mechanical axis (0°) or anteriorly (90°), with the femoral head fixed. Stress distribution was evaluated qualitatively and quantitatively in selected bone and implant regions.

Results

Axial loading produced minimal variation in bone stress distribution across configurations. In contrast, AP loading generated substantially higher stresses, with resection height emerging as a major determinant. Larger resections led to increased stress concentration, especially in press-fit stems with incomplete bone–implant contact. Across all scenarios, cemented fixation consistently reduced cortical stress peaks and produced a more uniform stress distribution.

Discussion

While axial loading showed limited influence on bone stress, AP loading highlighted the critical importance of resection height and fixation technique. Cemented fixation demonstrated superior ability to mitigate stress concentration and stabilize the mechanical environment, particularly in large-resection cases where press-fit contact may be suboptimal.

[3]NIHR Leeds Biomedical Research Centre, Leeds, Yorkshire, United Kingdom. [4]institute of Rheumatic and Musculoskeletal Medicine, Leeds, Yorkshire, United Kingdom

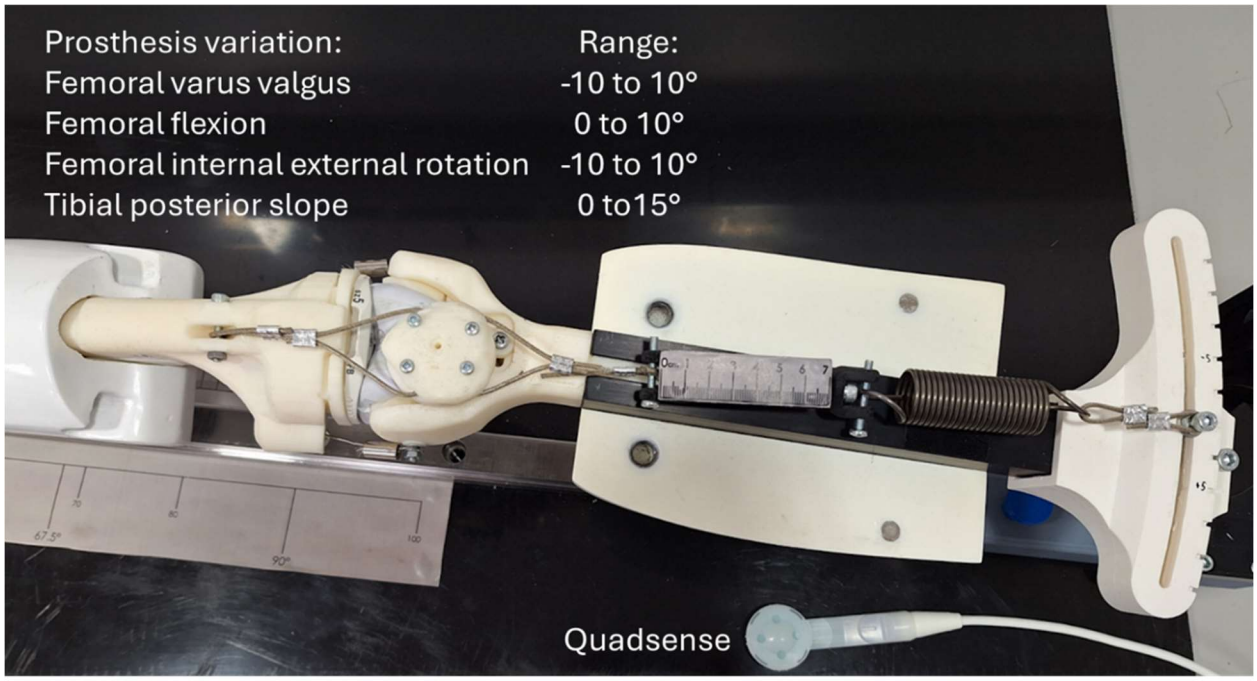
Introduction

Following total knee replacement there is a high occurrence of anterior knee pain linked to increased patellofemoral loads, namely overstuffing [1]. Anterior knee pain occurs irrespective of patella resurfacing [2]. The multitude of interrelating knee alignment variables makes their individual influence on the patellofemoral force vector difficult to consider. This study aimed to determine the sensitivity of tibiofemoral knee prosthesis alignment on the patellofemoral joint load using a multivariate analysis.

Methods

A novel in-vitro simulator was designed to allow for the simultaneous variation in mechanical alignment of a knee joint focussing on the relative patella height and position of the trochlear contact and its influence on intraoperative patellofemoral joint forces (Figure 1). A multivariable analysis was carried out varying the tibial posterior slope, femoral prosthesis flexion, femoral prosthesis valgus rotation and femoral prosthesis internal/external rotation. Loads were measured using Quadsense (Eventum Orthopaedics, UK), this records the distribution of the patellofemoral load across four pads. For each alignment combination, the knee was flexed from 0-90°. The distribution and magnitude of the patellofemoral load was recorded at peak flexion and compared between cases.

Results



Observed trends showed that increasing femoral valgus rotation generally caused average patellofemoral loads to increase by 4.3% above the mean. A high varus or valgus femoral position was the main indicator for patella dislocation. High tibial slope caused loads to drop 6.5% on average, whilst increasing femoral flexion and internal/external femoral rotation produced similar decreases. Despite these trends, specific alignment cases also

caused a deviation in this trend; this suggests there are secondary and higher order interactions between variables.

Discussion

Altering tibiofemoral alignment had a measurable effect on the magnitude and distribution of the patellofemoral force; this supports clinical observations of patellofemoral pain. The results highlight the complexity of knee biomechanics, while most variables followed trends, there were many specific alignment interactions between variables that caused the load to alter in unpredictable ways. Altering the varus/valgus femoral prosthesis rotation had the largest and least predictable effect on patellofemoral loads and patella tracking. Further experimentation is planned to vary the alignment of the patella.

Quantifying the effect of Quadriceps Alignment on Patellofemoral Force and Patella Tracking using a Novel in-vitro Experiment.

Mr Bulut Freear BA (Hons)[1], Dr Raelene M Cowie MEng, PhD[1], Dr Louise M Jennings MEng, PhD[1], Mr John Naybour BSc[2], Mr Hemant Pandit FRCS, DPhil[3,4], Dr Simon Talbot MBChB, FRACS[5], Dr Todd Stewart BSc, PhD[1]

[3]Leeds institute of Rheumatic and Musculoskeletal Medicine, Leeds, Yorkshire, United Kingdom. [4]NIHR Leeds Biomedical Research Centre, Leeds, Yorkshire, United Kingdom. [5]Department of Orthopaedic Surgery, Melbourne, Victoria, Australia

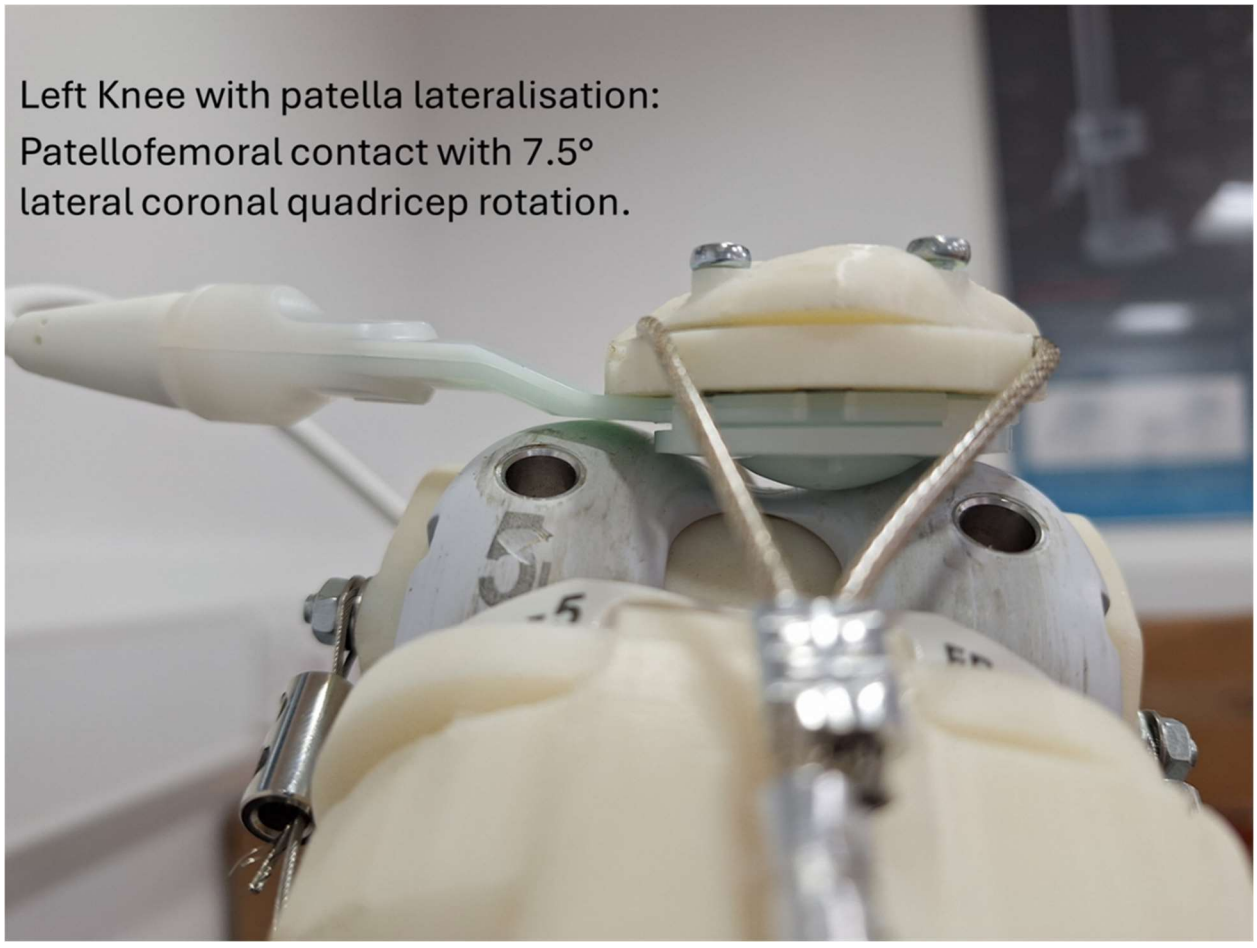
Introduction

Quadriceps Muscle weakness and imbalance have been linked to anterior knee pain post-TKA [1]. This suggests that an altered Quadriceps angle may change the load and contact conditions on the patella as it tracks the trochlea groove. The study aimed to vary the coronal angle of the quadriceps muscle and measure the effect on the magnitude and distribution of the patellofemoral load for a neutral, valgus and varus knee.

Methods

An in-vitro simulator was designed to replicate the clinical positioning of a knee joint allowing investigations into mechanical alignment focussing on the relative patella height and position of the trochlear contact. Quadriceps alignment was measured using the Quadriceps tendon coronal alignment (QTCA) [1]. Loads were measured using Quadsense (Eventum Orthopaedics, UK), this measures the distribution of the patellofemoral load across four pads. The QTCA angle was varied up to 7.5° medial and lateral from a neutral position. This was repeated with a neutral, 5° varus and 5° valgus femoral prosthesis. For each experiment the knee was flexed from 0° to 90° and the highest cumulative load reading was recorded along with the individual pad readings at this peak.

Results



During testing, the mediolateral patella position was observed to move with quadriceps angle (Figure 1). Increasing QTCA to 7.5 from -7.5 decreased cumulative load by 38%. Pairing a -7.5° QTCA rotation, with a valgus joint, resulted in high medial loads, with the patella riding against the medial side of the trochlea groove. In contrast, pairing the same -

7.5° QTCA rotation with a varus joint caused lateral loads to increase with visible patella lateralisation. The valgus joint had mean loads 9.5% higher compared to the neutral joint and the varus had loads 5.6% lower.

Discussion

The results suggest that the quadriceps angle can affect the relative patella height of the trochlear contact point, and thus the patellofemoral load vector, more than a varus/valgus deformity. This highlights the importance of considering the detailed quadriceps mechanism and any congenital deformities as these have a significant role in the magnitude and distribution of the patellofemoral force.

The Influence of the Rate of Knee Extensor Moment on Bone Mineral Density After an ACL Reconstruction

Dr. Camille Johnson PhD, Mr. Charles Eisner, Dr. Meredith Owen PhD, Mr. Douglas Long MS, Dr. Michael Samaan PhD, Dr. Darren Johnson MD, Dr. Christopher Fry PhD, Dr. Brian Noehren PT, PhD

University of Kentucky, Lexington, KY, United States

Introduction

Bone mineral density (BMD) deficits persist following ACL reconstruction (ACLR) and may be related to aberrant loading rates. Prior work has shown that the rate of knee extensor moment (RKEM) during walking and quadriceps rate of torque development (RTD) are reduced in the post-ACLR limb and may influence BMD recovery. The study purpose was to determine if changes in RKEM and RTD from baseline to six months post-ACLR influence BMD recovery. We hypothesized improved RKEM and RTD would correlate to improved involved limb BMD.

Methods

16 individuals (9F, 18.4±3.9yrs, height: 1.7±0.1m, BMI: 26.3±3.9kg/m2) participated in this study. Data were collected at baseline and six months post-ACLR. Dual-energy x-ray absorptiometry (DXA) scans of the involved distal femur and proximal tibia were acquired. Participants then performed an instrumented gait analysis walking at a self-selected speed while kinematic data and ground reaction forces were collected (200Hz, 2000Hz). Quadriceps RTD was assessed via four maximum voluntary isometric contractions.

Femoral and tibial BMD was quantified from segmented DXA scans. Knee extensor moments (KEM) were computed and RKEM was calculated ([KEM_max-KEM_min]/[delta time]). Paired t-tests or Wilcoxon tests assessed differences in RKEM, RTD, and BMD between timepoints. Spearman's correlations assessed relationships between changes in BMD, RKEM, and RTD between timepoints (significance: $p<0.05$).

Results

Average walking speed was 0.8±0.3m/s at baseline and 1.1±0.3m/s at follow-up. Involved limb BMD decreased 0.2±0.1g/cm^2 and 0.1±0.1g/cm^2 in the femur and tibia ($p<0.001$) (Figure 1-A). RKEM improved by 1.6±2.4([N*m]/[kg*m*s]) ($p=0.007$) (Figure 1-B) and RTD decreased by 1.0±2.5([N*m]/[kg*s]) ($p=0.230$) (Figure 1-C). Neither correlated to improved

BMD (RKEM: ρ_{Femur}=-0.083 [p=0.76], ρ_{Tibia}=0.119 [p=0.66]; RTD: ρ_{Femur}=0.240 [p=0.37], ρ_{Tibia}=-0.007 [p=0.98]).

Discussion

Despite improvements to RKEM during walking, RTD did not change, suggesting greater attention needs to be devoted to interventions that promote quick force development. The lack of correlation suggests that knee loading rate from walking may not be sufficient stimulus to promote BMD recovery. Evaluating recovery of BMD during higher impact activities at later stages of recovery may provide additional insights into factors that promote recovery of BMD after an ACLR.

[4]Computational Biomodeling (CoBi) Core, Lerner Research Institute, Cleveland Clinic, Cleveland, Ohio, United States. [5]Department of Biomechanics, Hospital for Special Surgery, New York, New York, United States

Introduction

Accurate representation of ligaments in finite element modeling is essential for reproducing physiologically relevant kinematics. Modeling outcomes are highly sensitive to variations in ligament attachment locations [1]. However, ambiguity remains, with studies reporting femoral ACL attachment variances up to 25.67mm^2 between researchers segmenting the same data [2]. Such variations can compromise the accuracy of models, especially in clinical settings. The 'KneeHub' project aims to unify knee modelling approaches through developing a consensus-based workflow. This study uses the workflow to determine ligament attachments in a systematic and reproducible manner.

Methods

A knee modeling workflow was developed by experienced modelers and followed by three novice modellers. Modelers manually segmented MR images of the same knee. ACL and PCL attachments were defined based on published anatomical descriptions. Ellipses were fit to attachment point clouds and divided into quadrants representing bundles. For the ACL, the proximal half of the femoral ellipse and the anterior half of the tibial ellipse define the anteromedial bundle, while remaining halves define the posterolateral bundle. Attachments were represented by springs positioned at quadrant centres and projected onto the bone surface. Modelers repeated segmentations twice, with inter- and intra-observer centroid variance evaluated.

Results

For three attachments, the centroid variance (σ^2) relative to the group mean decreased after the ellipse fit compared with the raw segmentation. The tibial ACL attachment showed the largest reduction in centroid variance, from 4.12mm^2 in the raw segmentation to 3.34mm^2 after ellipse fitting. Centroid intra-observer error did not consistently fall within twice the image resolution.

Discussion

Fitting the ellipse to the raw segmentation of the attachment site decreased the centroid variance between modellers. Variance in the tibial ACL attachment dropped to 3.34mm^2, nearly half the 6.33mm^2 reported in a prior study lacking a consensus workflow [2]. This method helps standardise and simplify modelling approaches across different modelers, making work reproducible and thus clinically relevant. Although intra-observer error values weren't consistently within the target range, additional segmentation rounds could improve consistency. In future, these techniques will be applied to all modeled ligaments.

Images (Optional)

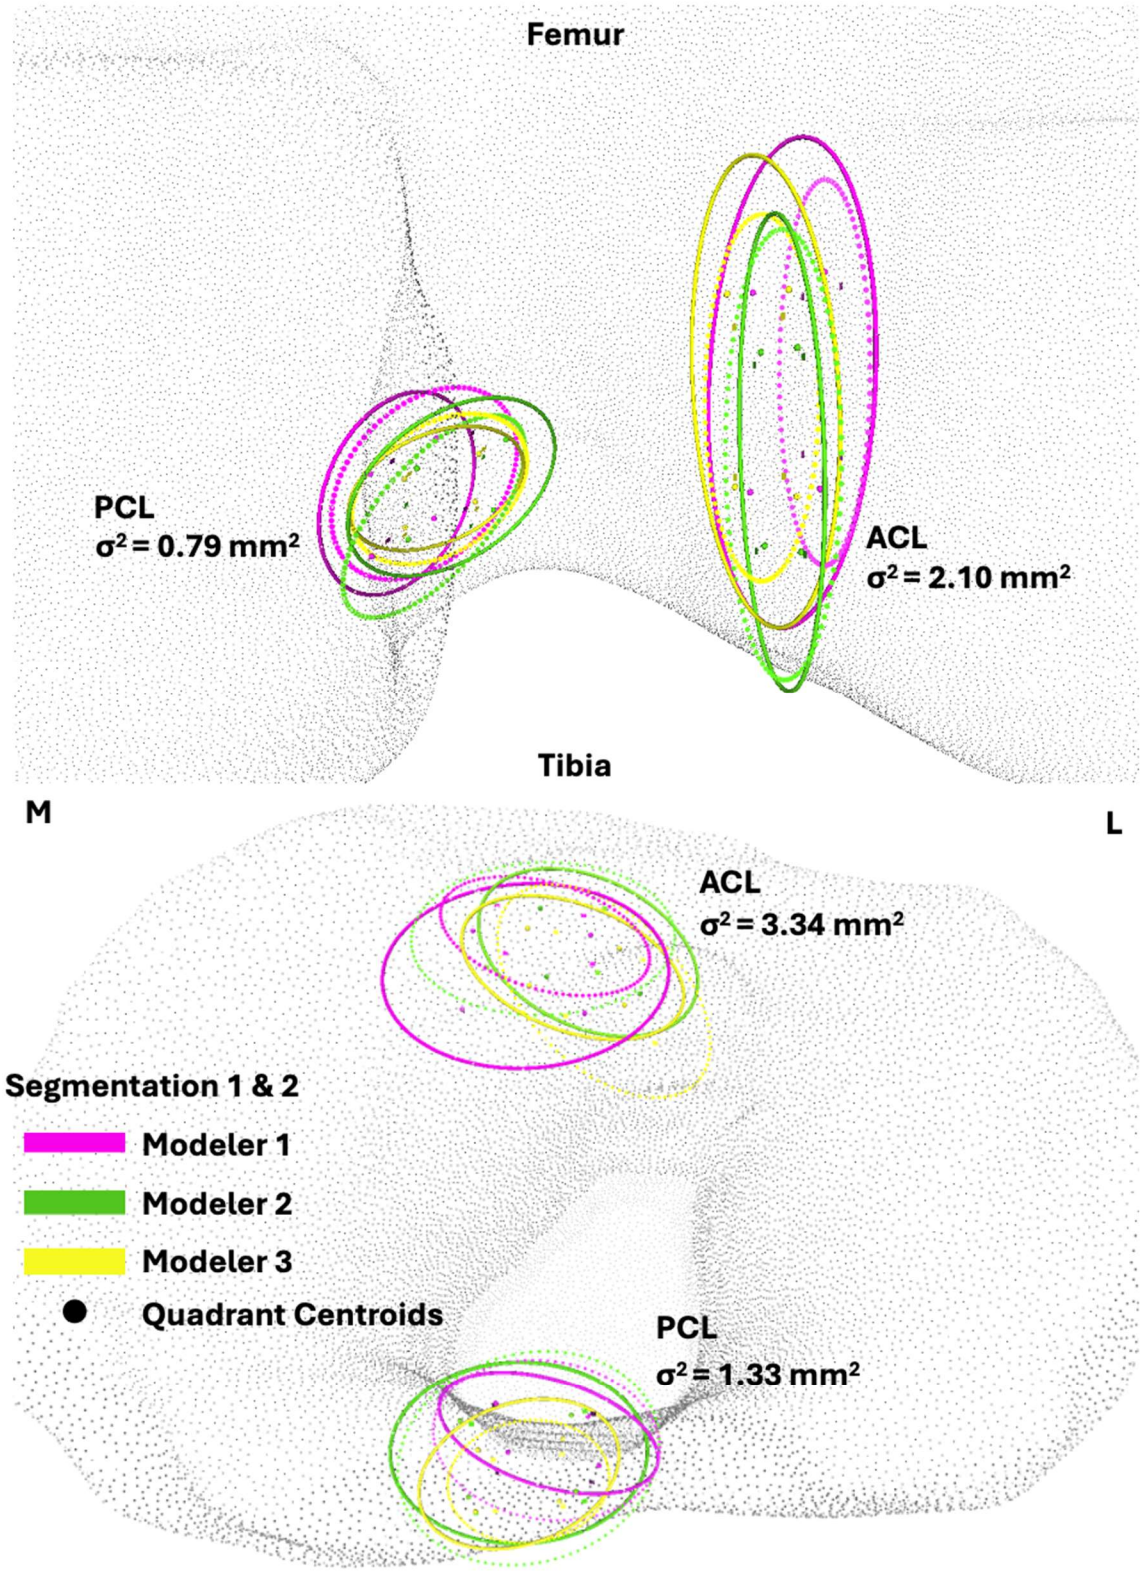

Figure 1. Femoral and tibial attachment sites of the ACL and PCL: segmented twice and fitted with ellipses by three modelers. The variance (σ^2) represents the distance between each modeler's centroid and the overall mean centroid for each site. The medial and lateral sides are labelled by M and L, respectively.

Influence of Stem Neck Design and Polyethylene Liner Configuration on the Range of Motion and Mechanical State of the Liner During Neck-Liner Impingement in Hip Prosthesis

Professor Changhee Cho

The University of Kitakyushu, Kitakyushu, Fukuoka, Japan

Introduction

Wear and damage of ultra-high-molecular-weight polyethylene (UHMWPE) liners after total hip arthroplasty cause serious clinical and biomechanical complications, thereby restricting the longevity of hip prostheses. In retrieved hip prostheses, wear and damage of the UHMWPE liner due to neck-liner impingement are frequently observed. It is well established that the neck-liner impingement significantly contributes to increases in wear and damage of the liner. This study aimed to investigate the influence of stem neck design and liner configuration on the range of motion (ROM) and mechanical state of the liner during neck-liner impingement.

Methods

Finite element simulations of neck-liner impingement were performed. The stem neck, femoral head, and acetabular cup were modeled using Ti-6Al-4V alloy, while the UHMWPE liner was defined as an elastic-plastic material with a Poisson's ratio of 0.45. Two types of neck geometries, a tapered neck and a cylindrical neck, were designed with an equivalent safety factor. Two liner configurations, a standard liner and an elevated rim liner, were also modeled, resulting in a total of four different neck-liner combinations. A coefficient of friction of 0.1 was assigned to all contact interfaces.

Results

Among the four combinations analyzed, the tapered neck with the standard liner showed the greatest ROM, whereas the cylindrical neck with the elevated rim liner showed the smallest ROM. Regarding the mechanical state of the liner during impingement, the cylindrical neck with the standard liner produced the lowest contact stress and plastic strain at the liner, whereas the cylindrical neck with the elevated rim liner resulted in the highest values. These results indicate that both stem neck design and its combination with the liner configuration markedly influence ROM and mechanical state during impingement.

Discussion

Accurate evaluation of the influence of stem neck design on neck-liner impingement in hip prosthesis requires comparisons to be performed using stem necks designed with equivalent safety factors. To minimize the wear and damage of the UHMWPE liner due to neck-liner impingement, the stem neck design should be optimized by balancing the safety factor, range of motion, and the mechanical state of the UHMWPE liner.

Lateral Wedge Insoles Modulate Lower-Limb Biomechanical Strategy During Level Walking in Patient with Anterior Cruciate Ligament Deficiency

Mr. Chia-Han Hu[1], Dr. Jr-Yi Wang[1,2], Dr. Shiuan-Huei Lu[1], Dr. Kuan-Wen Wu[3,4,5], Dr. Ting-Ming Wang[3,4,5], Prof. Tung-Wu Lu[1,4,5]

[4]Department of Orthopaedic Surgery, National Taiwan University Hospital, Taipei, Taipei, Taiwan. [5]Health Science and Wellness Research Centre, National Taiwan University, Taipei, Taipei, Taiwan

Introduction

Anterior cruciate ligament deficiency (ACLD) alters gait patterns and knee joint loading, potentially increasing the risk of secondary joint degeneration. Lateral wedge (LW) insoles have been proposed as a conservative intervention to redistribute joint loading [1], yet their effects on spatiotemporal behaviour and lower-limb kinetics—including joint moments and forces—during level walking in individuals with ACLD remain insufficiently understood.

Methods

Thirteen ACLD patients and twelve healthy controls performed level walking under three footwear conditions: control shoes, 3° lateral wedge, and 6° lateral wedge insoles. Spatiotemporal parameters and three-dimensional knee joint moments and forces were calculated using inverse dynamics [2]. Analyses were conducted at gait events—heel strike (HS), contralateral toe-off (CTO), contralateral heel strike (CHS)—and gait phases—initial double-limb support (IDLS), single-limb support (SLS), and terminal double-limb support (TDLS). Statistical significance was set at $p < 0.05$.

Results

Lateral wedges produced mechanics alterations across the hip, knee, and ankle during ACLD gait. Hip anterior force decreased at HS but increased during SLS and CTO, whereas proximal force decreased only in SLS and lateral force rose throughout IDLS–TDLS except at HS and TO. Knee mechanics showed reduced adduction moment at HS, increased early-stance flexion moment, and elevated anterior joint force across IDLS and SLS. Ankle mechanics demonstrated increased abduction moment at HS and CTO but decreased values during SLS and TDLS, with flexion moment elevated at HS and IDLS. Corresponding

joint forces increased anteriorly at IDLS, proximally at HS, and laterally at CTO, indicating phase-dependent redistribution of distal loading.

Discussion

Lateral wedges altered lower-limb kinetics through phase-dependent redistributions rather than uniform unloading. Increased hip and ankle loading during SLS and CTO suggests compensatory adjustments to maintain frontal-plane stability in ACLD gait, while reduced knee adduction moment at HS indicates partial medial-knee unloading. The selective increases in distal joint forces at IDLS and CTO further reflect shifts in foot–ground interaction that propagate proximally. Collectively, these findings highlight wedge-induced changes that modify—but do not normalize—the ACLD kinetic strategy.

Reliability of a Single Mobile Device Platform for Measuring Lower Extremity Joint Angles

Ms Rebecca Ward BSc physio[1], Prof Ciaran Knut Simms BA BAI PhD[1,2], Ms Alice Hussey BSc[1], Ms Thea Flanagan BSc[1], Ms Aileen Stenson BSc[1], Dr Fearghal Behan PhD[1]

[1]Trinity College Dublin, Dublin, Leinster, Ireland. [2]KineMo, Dublin, Leinster, Ireland

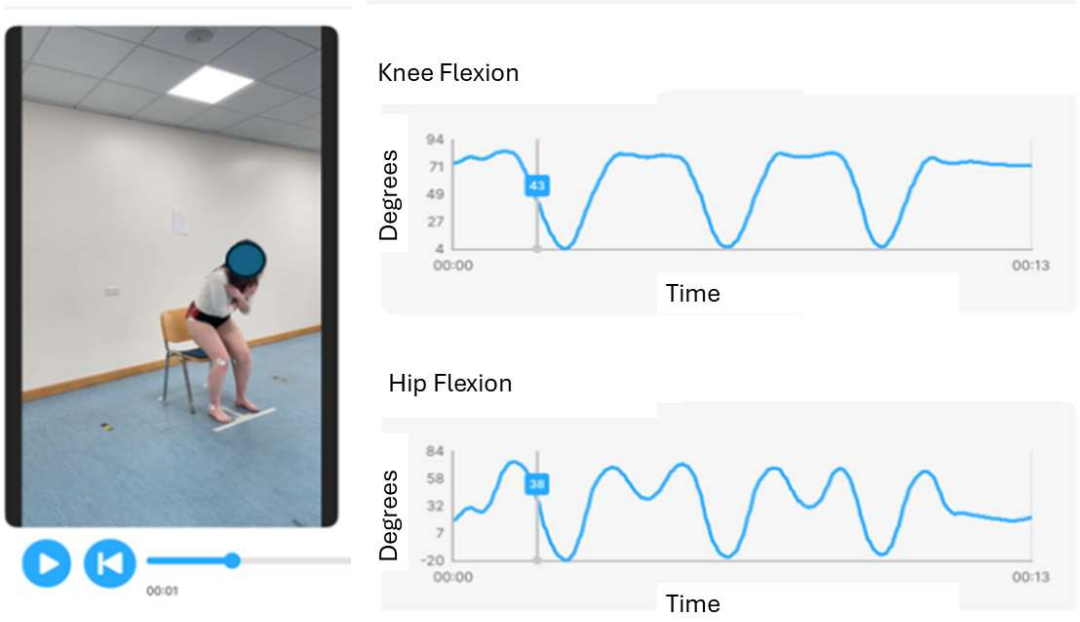
Introduction

There is a clinical need for a quick and accessible method to evaluate an athlete's movement quality to aid the prevention and treatment of injuries. However, visual observation is often the only method used to assess kinematics, due to challenges with using goniometers in non-static poses and the high cost and time-consuming process required with wearable sensors and multi-camera motion capture systems. A newly developed platform (KineMo), using a single mobile device camera, measures three-dimensional whole-body joint angles and aims to address this clinical need. Although the accuracy has been previously reported [1] and the platform is in use, the reliability and its suitability for clinical practice have not been previously assessed. Knee flexion angles during squatting movements have been found to decrease following ACL injury [2]. Therefore, tracking the return of knee flexion towards baseline is an important marker of injury recovery [2].

Methods

Following ethical approval, twenty-six healthy participants completed three commonly used clinical movements; back squat, sit to stand (STS) and single leg squat (SLS). Maximum and minimum knee flexion angles were extracted. Intra-rater reliability was assessed using the Intraclass correlation coefficient (ICC), minimal detectable change (MDC) and standard error of measure (SEM). Reliability was assessed by comparing two trials each consisting of three repetitions. Concurrent validity was also assessed using side view cameras.

Results



The platform demonstrated excellent intra-rater reliability (ICC values >.9). SEM ranged from 0.6-2.7 degrees and MDC 1.7-7.6 degrees. STS showed the lowest measurement error while SLS demonstrated higher SEM and MDC values, indicating reduced reliability with more complex tasks. Comparing knee angle range of movement measurements from

KineMo and side view cameras, the mean differences for back squat, SLS and STS were respectively 1, 3 and 5 degrees.

Discussion

The platform was found to be highly reliable for measuring knee flexion angles in squats, single leg squats and sit to stand movements in healthy adults. These findings suggest it may be suitable for reliably measuring lower limb kinematics in clinical practice.

Limb Asymmetry of Gastrocnemii Cross-Sectional Area in Individuals with Unilateral Achilles Tendinopathy

Dr. Claudia Kacmarcik PT, DPT, Dr. Stephanie Cone PhD, Dr. Karin Silbernagel PT, ATC, PhD, FAPTA

University of Delaware, Newark, Delaware, United States

Introduction

Achilles Tendinopathy is a chronic condition characterized by altered tendon structure, pain with activity, and functional deficits. The degree of impairment varies widely; however, it is unknown if this is related to pain, muscle atrophy, or both. Therefore, the purpose of this study was to assess gastrocnemius muscle size symmetry and changes over a 16-week exercise intervention in individuals with unilateral Achilles tendinopathy.

Methods

108 participants (59 female) aged 47.3±12.7, with unilateral Achilles tendinopathy participating in an IRB-approved, prospective, 16-week standard exercise program were evaluated at baseline, 8, and 16 weeks. Symptom questionnaires, pain with palpation and hopping, and ultrasound imaging were assessed.

Extended-field-of-view B-mode ultrasound (10MHz) was used to obtain cross-sectional area (CSA, cm^2) of the gastrocnemii at 1/3 tibial length. Gastrocnemii CSA limb symmetry (LSI, [(most symptomatic limb/least symptomatic limb)*100], %) was determined. Participants were grouped by baseline muscle size LSI: <90%, 90-110%, and >110%. One-way ANOVA assessed group differences in demographics, symptoms, and function, and a 3x3 Mixed Model assessed differences in gastrocnemii CSA LSI across groups over time, with post-hoc comparisons as needed.

Results

At baseline, there were no differences between groups in age, sex, BMI, Achilles tendon CSA, VISA-A score, pain with hopping, or pain with palpation (Table 1). The <90% muscle size LSI group had worse function, with lower heel-rise work LSI compared to other groups($F[2,102]=5.47$, $p=0.006$).

For gastrocnemii CSA LSI, there was a significant main effect of group ($F[2,88.93]=49.82$, $p<0.001$), but not timepoint ($F[2,84.11]=0.30$, $p=0.741$) and a significant interaction of

group and timepoint (F[2,84.37]=9.15, p<0.001). At each timepoint, limb symmetry was lowest in <90% and highest in >110%, except at 16 weeks when <90% was not significantly different from 90-110%. Compared to baseline, <90% LSI and >110% LSI were more symmetrical at 8 and 16 weeks.

Discussion

There were no differences in pain between groups, while gastrocnemii CSA LSI converged towards symmetry during a standard 16-week treatment. These findings suggest functional ties to muscle atrophy and indicate that exercise treatment for unilateral Achilles tendinopathy is effective in normalising muscular symmetry.

From Nanosheets to Joint Longevity: MXene-Enhanced CoCrMo for Orthopaedic Implants

Dr David Necas[1], Mr Daniel Nemecek[1], Dr Max Marian[2,3], Prof Martin Vrbka[1]

[1]Brno University of Technology, Brno, South Moravian Region, Czechia. [2]Universidad Católica de Chile, Santiago, Santiago, Chile. [3]Leibniz University Hannover, Garbsen, Garbsen, Germany

Dr David Necas

Mr Daniel Nemecek

Dr Max Marian

Introduction

Orthopedic implants face persistent challenges of wear and debris generation, limiting their longevity. Conventional alloys such as CoCrMo are strong and biocompatible but suffer from insufficient tribological stability. Two-dimensional (2D) nanomaterials, especially MXenes, have emerged as promising reinforcements, coatings, or lubricant additives due to their layered structure and self-lubricating potential. Recent studies suggest that MXenes embedded in metallic matrices or fluids may form tribo-films that reduce friction and wear. This study explores MXene-reinforced CoCrMo composites tested in simulated physiological environments, providing preliminary experimental validation of their tribological benefits.

Methods

MXene-reinforced CoCrMo pins were fabricated and tested using a pin-on-plate setup against UHMWPE plates. Two lubricants were applied: phosphate-buffered saline (PBS,) and simulated synovial fluid (SK). During sliding, the coefficient of friction (CoF) was continuously recorded. Before and after testing, worn surfaces were inspected to evaluate wear scars and detect possible nanoparticle embedding. Reference pins from stainless

steel were included for comparison. Surface preparation prior to testing ensured consistent contact conditions and reduced variability.

Results

The integration of MXenes into CoCrMo composites consistently improved tribological and mechanical performance. Reinforced samples demonstrated higher surface hardness, leading to better resistance against plastic deformation. Friction measurements revealed a more stable coefficient of friction compared to reference pins, with lower overall values in both lubricating environments. Wear analysis confirmed reduced surface damage on MXene-containing samples, where smoother wear tracks and fewer scratches were observed. Additionally, nanoparticles appeared embedded in the contact zone, suggesting the formation of protective tribo-layers. Biocompatibility assessments showed no adverse effects, supporting the potential for biomedical applications.

Discussion

Although preliminary, the findings indicate that MXenes enhance tribological stability of CoCrMo/UHMWPE pairs under physiological conditions. Differences between PBS and SK highlight the importance of lubricant chemistry, while nanoparticle embedding suggests a potential self-lubricating mechanism. Compared to stainless steel, MXene-reinforced CoCrMo demonstrated both lower CoF and reduced wear, supporting its promise for next-generation implants. Future studies should quantify wear volumes, extend testing durations, and optimize MXene concentration. Together, these early results contribute to the broader vision of integrating 2D nanomaterials into biomedical implants for improved durability and patient outcomes.

A Navigation-Guided A-mode Ultrasound System for Improving Non-Invasive Tibiofemoral Joint Kinematic Estimation

Mr. Dennis Christie[1], Dr. René Fluit[2], Dr. Guillaume Durandau[3], Prof. Massimo Sartori[1], Prof. Nico Verdonschot[1,4]

[1]University of Twente, Enschede, Overijssel, Netherlands. [2]University of Groningen, Groningen, Groningen, Netherlands. [3]McGill University, Montreal, Quebec, Canada. [4]Radboudumc, Nijmegen, Gelderland, Netherlands

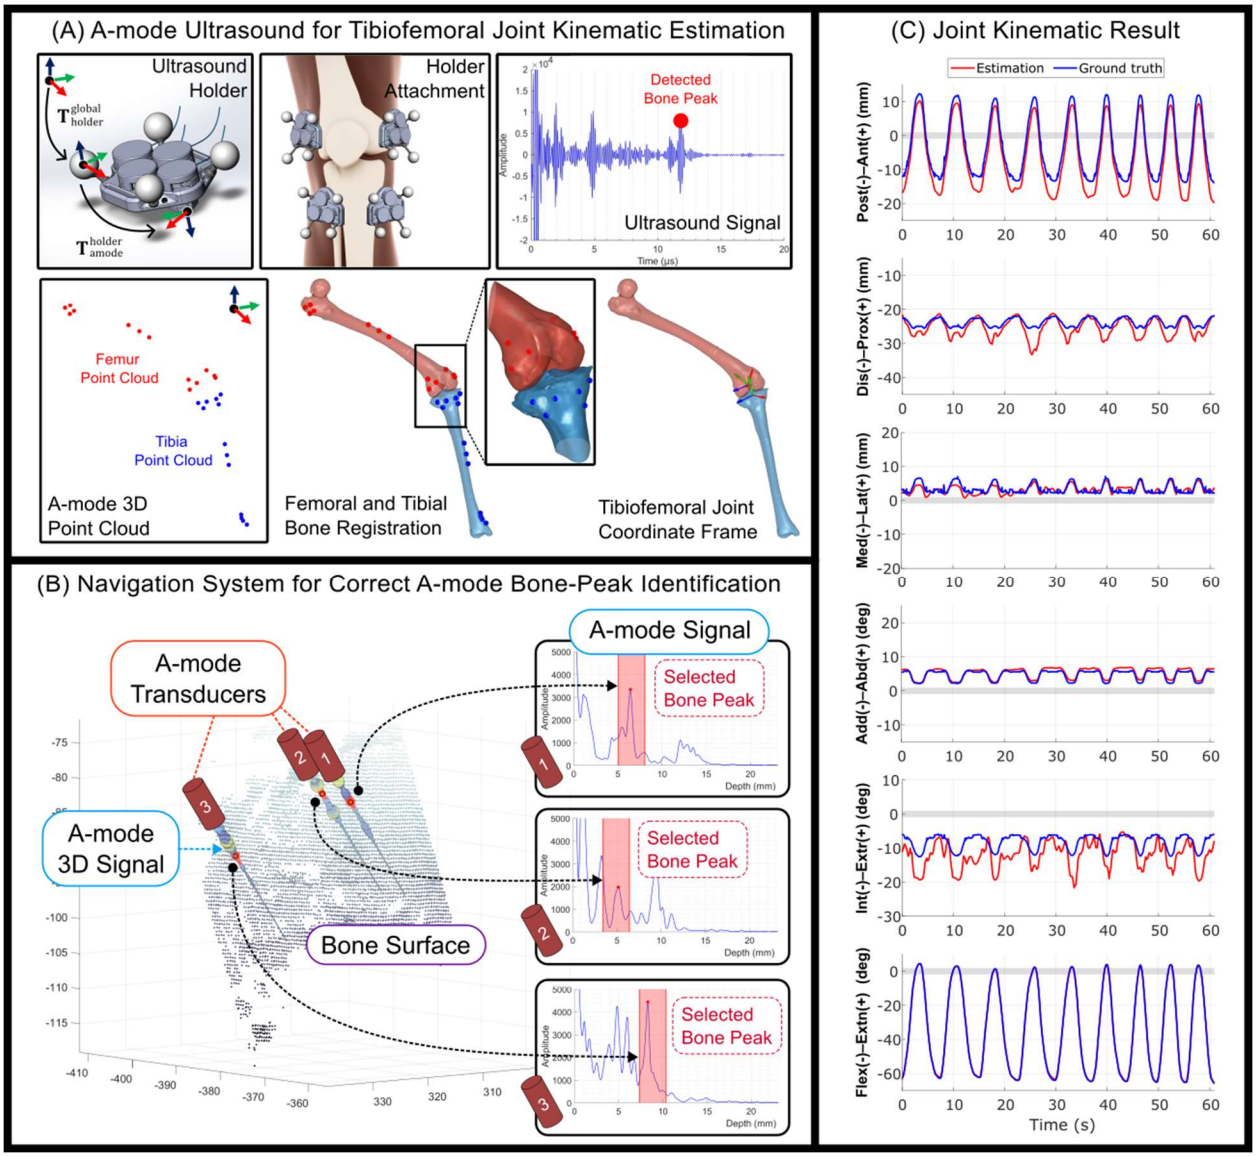
Introduction

Accurate measurement of knee joint kinematics is essential for studying musculoskeletal function, yet current imaging techniques are limited by radiation exposure or restrictive setups. A-mode ultrasound with optical trackers offers a safer alternative, but its dynamic reliability remains underexplored. Earlier proof-of-concept showed the method is technically feasible but failed to reproduce the ground-truth kinematic pattern. We argued that it originated from bone-peak misidentification in the one-dimensional A-mode signal. We addressed this by developing an intuitive guidance for A-mode placement. It used B-mode ultrasound to reconstruct bone surface to guide A-mode placement and peak selection, aiming to improve femoral and tibial pose and tibiofemoral kinematics.

Methods

A cadaveric leg was CT-scanned and instrumented with optically tracked bone pins as ground truth. During initialization phase, a tracked B-mode probe reconstructed local bone surfaces. A-mode beams were visualized relative to the surface to optimize placement and bone-peak selection. A-mode depths were converted into 3D bone points and rigidly registered to CT-derived tibial and femoral bone models. Tibiofemoral kinematics were computed using a joint coordinate system and filtered using Unscented Kalman Filter framework. Navigation-guided measurements were compared with non-navigated as the baseline.

Results



During cyclic flexion–extension task, the navigation-guided approach achieved joint kinematic RMSE 0.51±0.49° and 0.72±0.97° for adduction–abduction and flexion–extension, 1.00±0.97 mm for medial–lateral translation; distal–proximal and anterior–posterior translations were higher at 2.30±1.60 and 3.70±1.06 mm. Internal–external

rotation had the largest error at 4.56±2.52° yet still outperformed non-navigated baselines. Cycle-wise translation and rotation errors remained stable; linear fits showed no significant trends, with navigation-guided estimates consistently yielding the lowest errors per cycle. Throughout cycle, bone registration with navigation-guided yielded the lowest RMSE as well.

Discussion

Across experiments, the navigation-guided approach consistently outperformed the non-navigated baseline. By visualizing A-mode beams directly against B-mode–derived bone surfaces, bone-peak selection becomes a geometrically constrained task rather than a purely signal-driven guess. This stabilizes the full processing chain, from point-cloud generation to pose and joint kinematic estimation. Overall, the findings demonstrate a clear message: accurate initialization at the signal level is essential for reliable ultrasound-based tibiofemoral kinematics.

Effect of Custom In-Shoe Orthotics on the Talus-First Metatarsal Angle in Adult Flatfoot: A Pilot Study

Ms. Devin Wong BS, Dr. Bopha Chrea MD, Dr. Donald Anderson PhD, Dr. Jason Wilken PT, PhD

University of Iowa, Iowa City, IA, United States

Introduction

Progressive collapsing foot deformity, commonly known as flatfoot, affects as many as five million individuals in the US, causing foot pain and instability [1]. In-shoe orthotics are a primary non-invasive treatment to provide mechanical support, correct foot posture, and mitigate pain with flatfoot–however, efficacy data are inconsistent [2]. This study utilizes cone-beam weight bearing CT (WBCT) to explore changes in the physiologically loaded talus-first metatarsal angle (TFMA), a measure of foot collapse, in response to custom in-shoe orthotics in adults with flatfoot.

Methods

Individuals aged 18-65yrs with flatfoot who wear prescribed, custom, full-length, stiff, in-shoe orthotics were recruited. Standing bilateral foot and ankle WBCT scans (HiRise; CurveBeam AI) were obtained while shod: one with and without in-shoe orthotics. Scans were automatically segmented using a commercial service (BoneLogic; Disior) to obtain bone models. Bone local coordinate reference frames were obtained using the AAFACT toolbox [3]. The 3D TFMA was measured relative to the anterior-posterior axis using Euler rotation methodology and projected onto anatomical planes [4]. The 2D TFMA was manually measured from CT slices including the talus and first metatarsal using custom-written code (MATLAB; MathWorks) [5].

Results

Three participants (i.e., six feet) are included in this ongoing study (2F/1M, 43±4.4yrs, 1.71±0.10m, 66±4kg). The 2D TFMA was 15.0±6.6° without and 12.0±7.4° with an orthotic. The mean change between conditions was -4.1±4.9°. The 3D TFMA projections are displayed in Figure 1.

Discussion

These preliminary data show how custom in-shoe orthotics alter bony alignment in adults with flatfoot. The average 4.1° decrease in the 2D TFMA indicates that orthotics elevate the otherwise-collapsed medial arch. An improved understanding of how custom in-shoe

orthotics change bony alignment can inform orthotic design to mitigate pain and provide support.

Long Bone Pediatric Morphological Analysis of Charcot Marie Tooth Disease

Ms. Eliana Moreno, Ms. Melissa Requist, Mr. Andrew Peterson, Dr. Amy Lenz

University of Utah, Salt Lake City, UT, United States

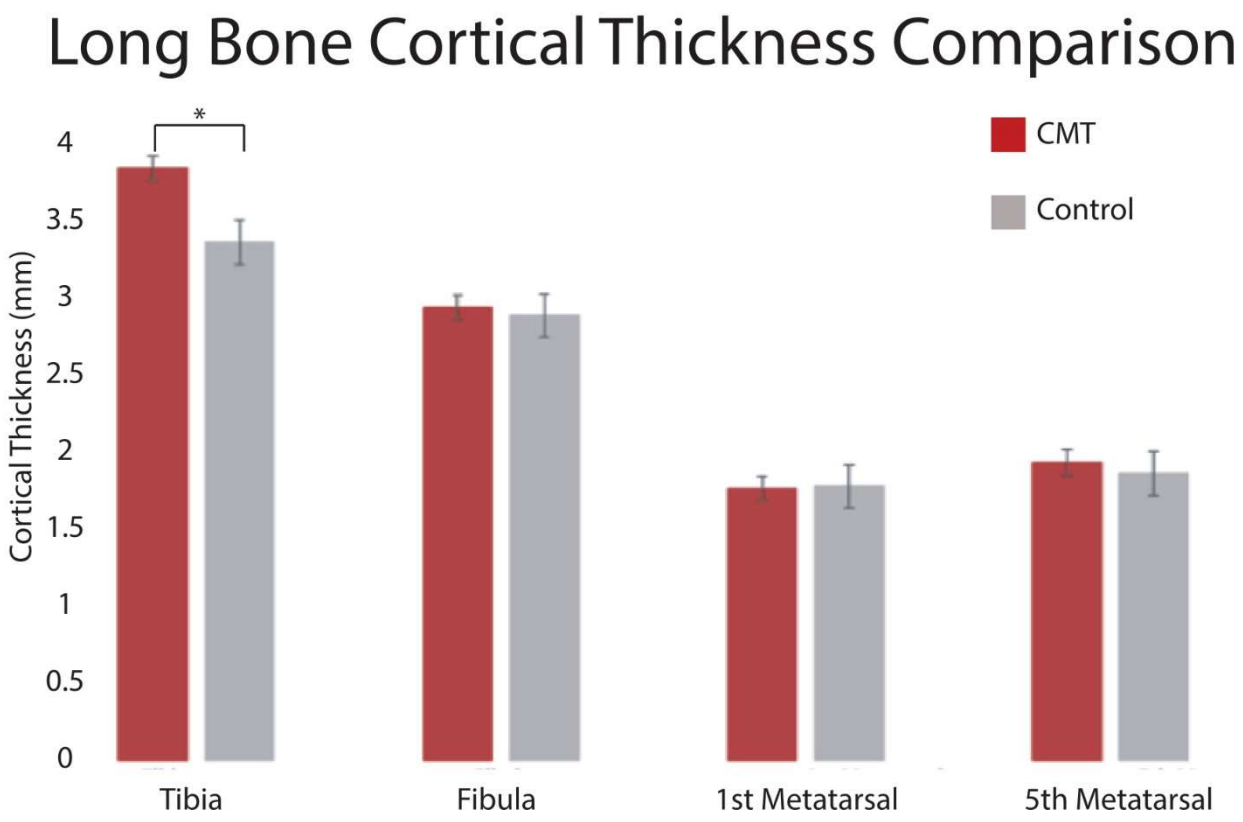
Introduction

Charcot-Marie-Tooth disease (CMT) is a sensory and motor neuropathy associated with cavovarus foot deformity, consisting of differences in foot alignment and bone structure. Cortical thickness and bone mineral density are correlated with muscle strength, which decreases in CMT. Health of long bones, specifically tibia, fibula, and metatarsals, can be measured by analyzing cortical thickness in the diaphysis. Decreased cortical thickness is associated with increased fracture risk. Increased fracture risk has been seen in children with CMT, as has variation in bone shape in the foot and ankle, but the impact of CMT on bone structure and health is not well characterized. This study investigates differences in cortical thickness between pediatric patients with CMT and controls to better understand fracture risk and bone health in this disease.

Methods

Weight-bearing computed tomography (WBCT) images were prospectively collected from pediatric patients, 5 with CMT and 5 controls, with no difference in age between groups. Segmentations were created semi-automatically, manually cleaned, verified, and thresholded to only include cortical bone. Three-dimensional parts were generated, aligned to an anatomic coordinate system, and consistently cut to isolate diaphyseal bone. Automatic cortical thickness analysis was applied and averaged across each bone. Differences in cortical thickness between CMT and control groups were tested using a two-tailed t-test (α=0.05).

Results



A significantly greater cortical thickness was seen in the CMT versus control groups in the tibia (p=0.02) (Fig. 1). However, there were no significant differences in cortical thickness between groups in the other bones, but the CMT group showed trends of higher cortical thickness.

Discussion

This data shows a significantly greater cortical thickness in pediatric CMT than in pediatric controls for the tibia. Factors contributing to differences may include differences in bone geometry, bone loading, or neurologic input between CMT and control during the

development of the foot and ankle bones. A higher fracture risk has been seen among children with CMT, but these data suggest this may not be due to cortical thickness. Inclusion of additional data may allow for better analysis of regional differences in cortical thickness in CMT. Further, analysis of bone density may better characterize bone structure within CMT.

Primary Stability of Percutaneous Implants for Transfemoral Amputees: A Biomechanical Ex Vivo Study

Mr Emir Benca[1], Ms Elise Joulain[2,1], Mr Pablo Vazquez Conde[1], Mr Andreas Strassl[1], Ms Lena Hirtler[1], Prof Reinhard Windhager[1], Prof Dieter Pahr[3], Prof Rickard Brånemark[4,5], Mr Gerhard Hobusch[1], Mr Alexander Synek[3]

[1]Medical University of Vienna, Vienna, Vienna, Austria. [2]École Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Waadt, Switzerland. [3]TU Wien, Vienna, Vienna, Austria. [4]Gothenburg University, Gothenburg, Västra Götalands län, Sweden. [5]Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

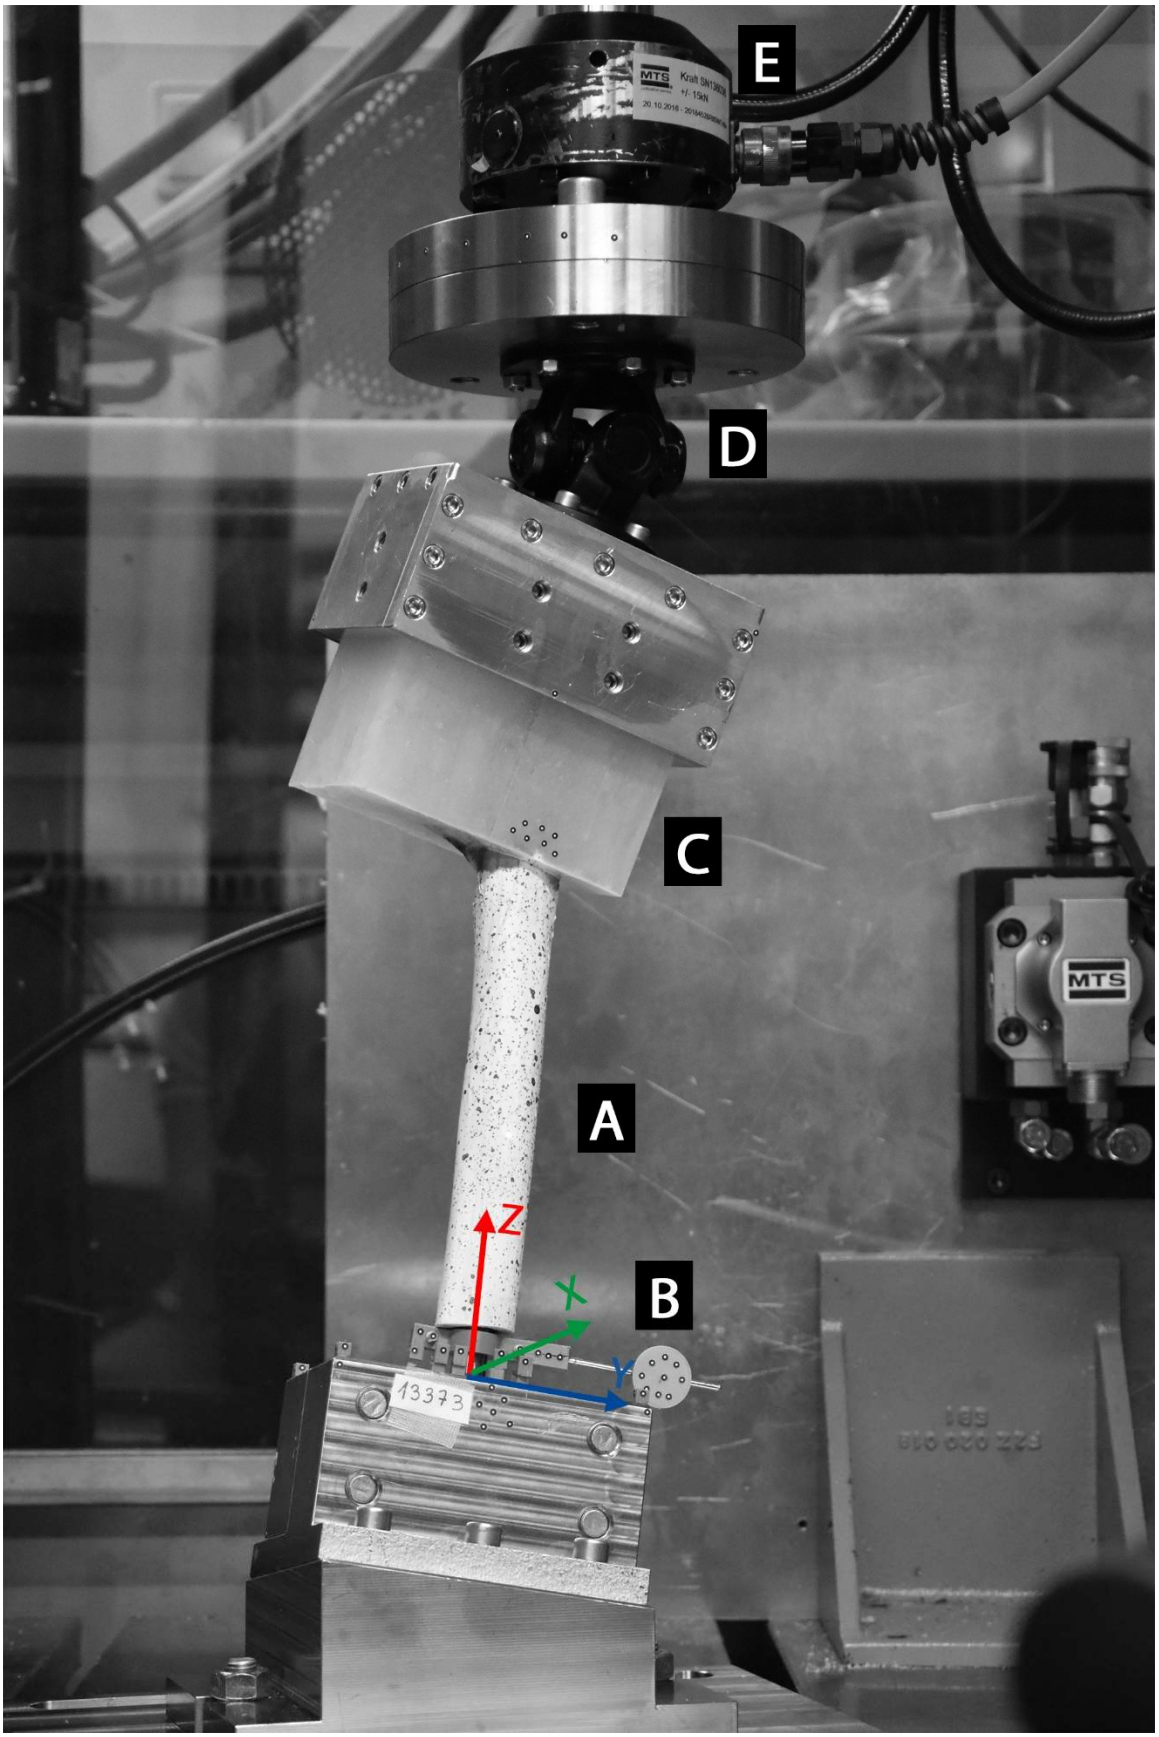
Introduction

The prevalence of lower extremity amputation is substantial. An alternative rehabilitation option is the direct attachment of the prosthesis to the bone following amputation via percutaneous osseointegration [1]. The treatment of transfemoral amputees with osseointegrated implants for prosthetic anchorage requires long rehabilitation periods to minimize relative motion between bone and implant, which could impair osseointegration and implant stability. This study aimed to assess the primary stability of the Osseointegrated Prostheses for the Rehabilitation of Amputees (OPRA) Implant System under uniaxial loading, with the goal of supporting earlier load bearing and patient mobilization.

Methods

Fifteen human femoral specimens were prepared and instrumented with the OPRA implant system. Each specimen was subjected to 4,750 loading cycles with amplitudes increasing from 200 to 2,000 N at 10° hip flexion and 10° hip adduction mimicking the heel strike position (Figure 1). Relative displacement between the implant system and the proximal, middle, and distal femoral shaft was measured using a motion tracking system, and stiffness was calculated at the corresponding positions.

Results



No implant failure or loosening was observed in any of the specimens. Maximum relative displacement of the proximal, middle, and distal femur remained below 80 µm, 60 µm, and 10 µm, respectively. Existing literature reports a mean micromotion of approximately 112

μm for implants that successfully osseointegrate, compared with about 349 μm for implants that fail to do so [2]. Stiffness did not change with increasing applied loads ($0.332 \leq p \leq 0.736$).

Discussion

The absence of stiffness changes and the low displacement values, particularly in the distal femur, indicate no loosening or failure at the bone–implant interface. These results suggest that the OPRA implant system provides sufficient primary stability under predominantly axial loading in more aggressive rehabilitation. Further research should investigate primary stability under bending and torsional conditions.

Injury-Specific Asymmetry in Achilles Tendon and Triceps Surae Morphology in Individuals With Achilles Tendinopathy and Achilles Tendon Rupture

Dr. Erica Bell PhD, Miss Meghna Annasagaram, Dr. Karin Gravare Silbernagel PT, ATC, PhD, FAPTA, Dr. Stephanie Cone PhD

University of Delaware, Newark, Delaware, United States

Introduction

The Achilles tendon is composed of three subtendons that insert at the medial gastrocnemius, lateral gastrocnemius, and soleus. Common injuries to the Achilles tendon include Achilles tendinopathy (repetitive overuse) and Achilles tendon rupture (acute overload). Although both pathologies involve the Achilles tendon, they have distinct etiologies, injury progressions, clinical indications, and treatments [1]. Thus, injury-specific research and clinical management is pivotal. The objective of this study was to identify specific morphological changes in the Achilles tendon and triceps surae muscles in individuals with Achilles tendinopathy and Achilles tendon rupture.

Methods

Fifteen subjects were recruited, with five subjects each in the healthy control (3F/2M, Age: 40.0 ± 19.4), Achilles tendinopathy (3F/2M, Age: 53.8 ± 9.9), and Achilles rupture groups (2F/3M, Age: 33.4 ± 12.5). Each subject completed a 3TMRI scan using published sequences [2]. Subtendon length was measured across injuries, and MRIs were segmented to measure muscle and tendon cross-sectional areas (CSAs) bilaterally. Two-way repeated-measures ANOVA (tissue x side) were conducted to determine effects of injury type on Achilles subtendon length and triceps surae muscles CSA.

Results

Gastrocnemius and soleus subtendons were significantly longer than the intact side in the previously ruptured group ($p<0.05$). Previously ruptured tendons had significantly larger CSA than both contralateral tendons and average tendinopathic and healthy groups ($p<0.05$). Soleus CSA was lower in limbs with prior Achilles rupture compared to the intact side ($p<0.05$). Along the length of each tissue, healthy subjects showed symmetrical, tissue-specific morphology, whereas previously ruptured subjects had the most severe between-limb asymmetry (Figure 1).

Discussion

Injury-specific morphometric changes indicate that tendon elongation and CSA vary between Achilles tendinopathy and rupture. Individuals with Achilles tendon rupture have the largest morphometric changes in the injured side compared to individuals with Achilles tendinopathy and healthy individuals. Ongoing work assessing functional outcomes will enhance understanding of the biomechanical impacts of these changes.

Introduction

In children with cerebral palsy (CP), foot deformities commonly develop due to altered motor control and loading. If these deformities become severe, orthopedic surgery is necessary to correct the alignment of the foot. However, due to the complex anatomy of the foot, accurate assessment of foot posture from 2D imaging is challenging. Weight-bearing CT (WBCT) enables evaluation of foot posture in three dimensions under natural loading and positioning [1]. However, this has not previously been used to evaluate treatment in children with CP. Therefore, our aim was to quantify the effects of surgery on foot posture using WBCT scans.

Methods

WBCT scans have been acquired before and one year after orthopedic foot surgery, according to clinical practice. From this dataset, we present one representative case. The child with bilateral spastic CP (age 16 years) underwent gastrocsoleus lengthening and plantar fascia release surgery to correct a plantarflexion contracture and cavovarus foot deformity. Local coordinate systems for each foot bone were automatically computed based on the inertial axes of the bones using custom software [2]. Bone translations and

rotations relative to the talus, and the differences between these values pre- and postoperatively, were calculated.

Results

The calcaneus, navicular and first metatarsal all translated more lateral relative to the talus post-operatively (Δ=-3.8, -5.0, -20.2 mm, respectively), and more superior (Δ=0.5, 1.2, 9.5 mm, respectively); see Figure 1. All three bones rotated around the x-axis (mediolateral) more towards dorsiflexion (Δ=-4.5, -4.8, -9.3°, respectively), and around the y-axis (longitudinal) more towards valgus (Δ=10.2, 15.3, 8.4°, respectively). Around the z-axis (transversal), the navicular and first metatarsal rotated more towards abduction (Δ=-17.7, -16.5°, respectively), while the calcaneus relative to the talus rotated slightly more towards adduction (Δ=1.3°).

Discussion

We quantified the effect of orthopedic surgery on a cavovarus foot, indicating the bones translate and rotate such that varus and adduction decrease, realigning the foot to a more neutral position. Based on the full dataset, it will be further investigated which foot posture parameters have most clinical relevance for describing foot deformity correction in CP.

Subtendon-Specific Load Sharing Modulates Achilles Tendon Stress Concentration: A Finite Element Analysis During Midstance

Mrs. Gisell Natalia Romero Delgado[1], Mr. Santiago Torres Serrato[1], Mr. Chandra Pasapula[2], Dr. Christian Cifuentes - De La Portilla[1]

[1]Universidad de Los Andes, Bogotá, Bogotá D.C, Colombia. [2]Queen Elizabeth Hospital Kings Lynn, King's Lynn, Norfolk, United Kingdom

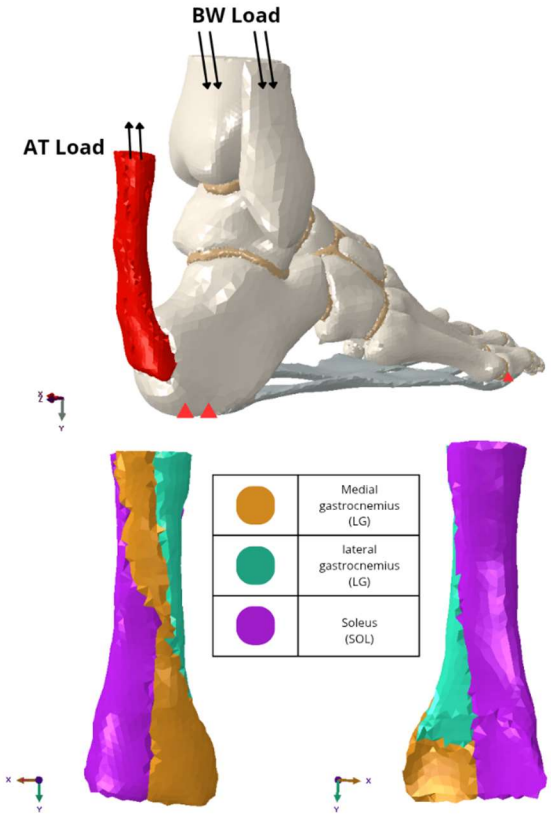
Mrs. Gisell Natalia Romero Delgado

Introduction

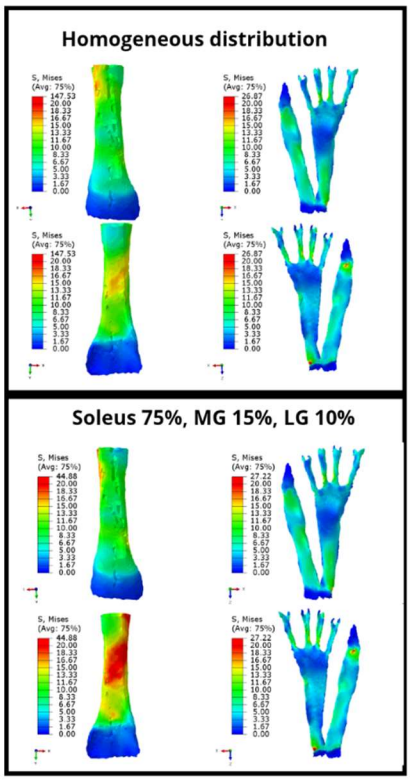
The Achilles tendon (AT) is composed of three subtendons arising from the soleus, medial gastrocnemius (MG), and lateral gastrocnemius (LG). Biomechanical studies suggest that variations in subtendon loading and the twist of the tendon may shape local stress patterns and contribute to the characteristic localization of mid-portion tendinopathy. However, the mechanical relationship between subtendon-specific force distribution and internal stress development remains poorly quantified. We designed a computational foot model that includes a detailed AT anatomy and evaluated its behavior during the midstance. Results suggests that physiologically relevant load patterns influence stress concentration within the tendon.

Methods

A three-dimensional finite element (FE) model of the foot and AT was developed, segmenting the three subtendons and incorporating physiologic fibre twist. The second rocker of gait was simulated, corresponding to maximal tendon elongation. Tendon tissue was modelled as transversely isotropic hyperelastic, and quadratic tetrahedral elements ensured spatial stress resolution. Different loading distribution scenarios for the soleus, MG, LG were applied based on triceps surae activation patterns. Von Mises stress, and deformation patterns were quantified and compared with baseline behavior and with estimates from a previously available simplified AT model.



Results



Increasing soleus loading produced the highest internal stresses, with focal concentrations in the medial–anterior mid-portion of the watershed zone. The loading distribution of Soleous (75%), MG (25%) and LG (10%) generated the greatest magnitudes and a superior migration of the hotspot, while the distribution of 40-40-20 reproduced this shift. Although the distribution 50-20-30 lowered overall stress, medial asymmetry persisted. A constricted narrowing further amplified these concentrations. In contrast, increased MG or LG loading did not redistribute or reduce stresses induced by soleus dominance. Only the subtendon model captured the resulting internal shear pathways and migrating stress clusters.

Discussion

Differential subtendon loading has a substantial mechanical effect on AT stress distribution, with soleus force emerging as a primary driver of focal stress in the watershed region. These findings provide a biomechanical explanation for the predictable anatomical location of Achilles tendinopathy and underscore the importance of subtendon representation in computational gait models. Understanding these mechanisms may inform both preventive strategies and targeted rehabilitation approaches for Achilles pathology.

Volumetric Wear Assessment and Wear Scar Analysis of Retrieved Tibial Liners in Unicompartmental Knee Arthroplasty: A Comparative Study of Polyethylene Types and Patient Characteristics

Ms. Carolina S. Haboba Nebel MS, Mr. Ajay S. Potluri BS, Ms. Aditya S. Yadav MS, Dr. Anne Debenedetti MS, Ms. Jennifer L. Wright, Ms. Deborah J. Hall, Dr. Robin Pourzal PhD, Dr. E. Bailey Terhune MD, Dr. Craig J. Della Valle MD, Dr. Hannah J. Lundberg PhD

Rush University Medical Center, Chicago, IL, United States

Introduction

Unicompartmental knee arthroplasty (UKA) is an established treatment for knee osteoarthritis in patients with intact cruciate ligaments. Despite favorable functional outcomes, long-term implant survival remains limited in part by polyethylene (PE) wear and osteolysis. This study evaluated retrieved tibial inserts made from conventional PE (CPE) and highly cross-linked PE (HXLPE) to characterize volumetric wear, wear scar morphology, and patient-related factors associated with wear patterns.

Methods

Forty-five liners collected between 2006 and 2024 were analyzed: 23 CPE (*ZUK, Zimmer Biomet*), and 22 HXLPE (*Sigma, DePuy*). Wear scar area, articulating surface area and centroidal shift between the articulating and worn regions were quantified using ImageJ. Volumetric wear was measured with an optical coordinate system (*OrthoLux, RedLux, UK*). The influence of implant type, sex, knee and compartment side, BMI, and time in situ was assessed using Kruskal Wallis, Mann Whitney U, and Spearman correlation tests. Analyses were performed on the full dataset, after excluding implants with <1 year in situ to avoid confounding due to early failure or infection, and comparing two subgroups: 1-5 years, and >5 years.

Results

Mean articulating surface area was 944.6 ± 445.5 mm^2, with wear scars averaging 34.2% of the surface. No significant differences were observed across PE types in wear scar area per year or centroidal shift ($p > 0.1$). Mean volumetric wear rate was 29.12 mm^3/year (CPE, >5 years) and 15.74 mm^3/year (HXLPE, >5 years), showing a trend toward higher values in CPE versus HXLPE for implants >5 years in situ ($p = 0.068$). No significant differences were identified in the 1-5 years group. Wear parameters demonstrated no significant correlation with time in situ, BMI, or sex; however, multivariable modeling identified male sex as an independent predictor of higher volumetric wear.

Discussion

We found a consistent trend toward higher long-term volumetric wear in CPE liners, confirming that HXLPE is more durable. The absence of correlations with BMI, side, or compartment indicates that patient-related mechanical factors may play a smaller role than implant design. Larger datasets are warranted to further evaluate long-term performance differences between PE types in UKA and corresponding tissue responses.

A Custom Musculoskeletal Model for Ankle Contact Loads at the Medial and Lateral Components

Dr. Hoon Kim[1,2], Mr. Taewoong Kong[2], Dr. Danilo Catelli[3,4]

[1]Department of Sports Medicine, Soonchunhyang University, Asan, Chungcheongnam-do, Korea, Republic of. [2]Department of Software Convergence, Soonchunhyang University, Asan, Chungcheongnam-do, Korea, Republic of. [3]School of Human Kinetics, University of Ottawa, Ottawa, Ontario, Canada. [4]Department of Physical Activity Science, Université du Québec à Montréal, Montreal, Quebec, Canada

Introduction

Uneven distribution of load between the medial and lateral compartments of the ankle has been implicated in the development of post-traumatic osteoarthritis and chronic instability. However, most musculoskeletal models estimate ankle joint contact forces at a single point and cannot resolve compartment-specific contact loading. Experimental estimations of talar-dome force distribution typically require high-cost CT- or MRI-based modeling, limiting their feasibility in many applications. Extending compartment-based approaches previously applied to the knee, we developed a custom model to estimate medial and lateral ankle contact forces during dynamic tasks.

Methods

Five participants performed three trials of level walking and squats with a bar of 50% of their body weight (BW). Using a generic model designed for large hip and knee flexion, two massless bodies, “med_comp” and “lat_comp”, were attached to the “talocrural_articulation_frame” via CustomJoints at offsets (mediolaterally ±0.01 m). The “talar_dome” was welded to “lat_comp” and constrained to “med_comp”, defining medial and lateral ankle contact frames for compartmental load decomposition. Data were validated by confirming that mediolateral ankle contact forces and impulses matched the original single-point values.

Results

Across level walking and squat trials with a 50%BW weighted barbell, the summed medial and lateral ankle contact forces closely matched the original single-point ankle joint contact force. The lateral compartment carried 65% (squat) and 53% (walking) of total impulse, with the medial compartment carrying 35% and 47%. Normalized-root-mean-

squared-error in joint contact force and impulse were 0-1% across all trials and participants. The findings support the internal consistency and numerical validity of the compartmental ankle model.

Discussion

Compartmentalizing the ankle joint into medial and lateral contact frames allowed us to resolve side-specific loading patterns while preserving overall joint reaction force estimates and the integrity of the original model scheme. The close agreement between the summed compartmental forces/impulses and the original single-point ankle force/impulse indicates that the remodeling did not introduce substantial numerical artifacts. These findings supported the use of the proposed model to study medial and lateral load distribution during walking and squatting, providing a foundation for future analyses of ankle osteoarthritis mechanisms, surgical strategies, or footwear-induced shifts in compartment loading, and targeted rehabilitation.

Images (Optional)

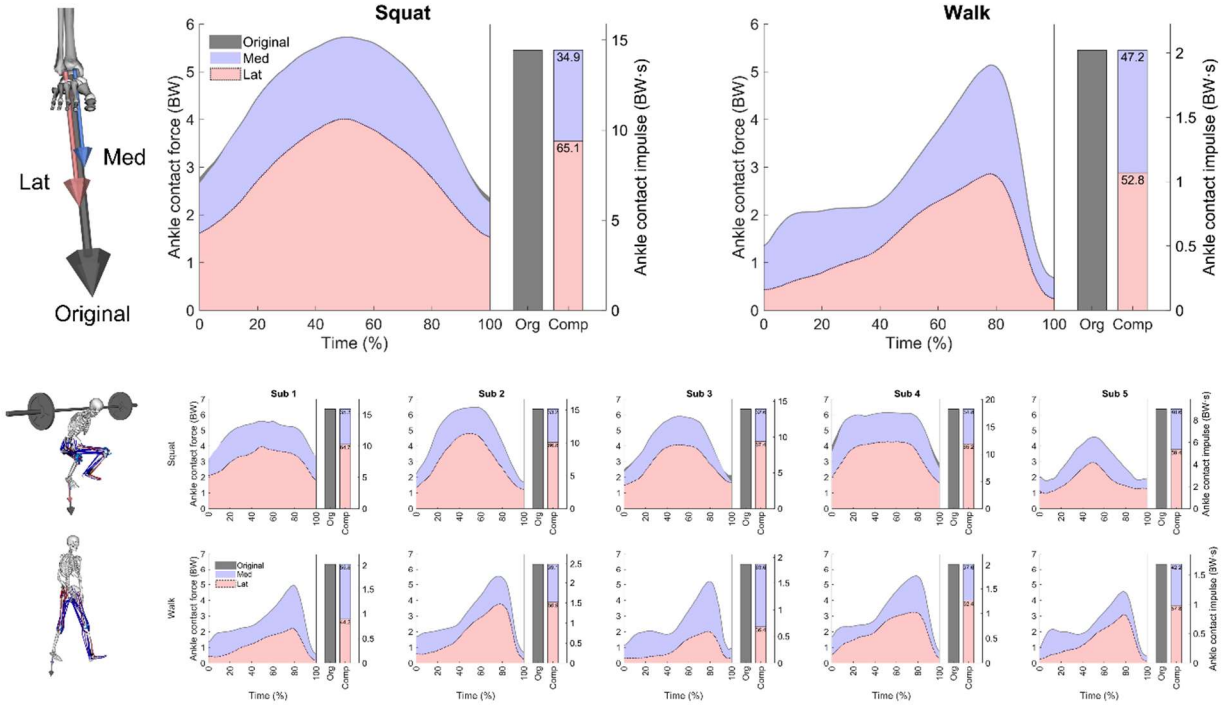

Figure 1. Consistency of ankle joint loading between the original single-point ankle joint and the medial and lateral ankle compartments. The top row shows mean ankle joint contact force-time curves and corresponding impulses for the original single-point, medial, and lateral components during squats with a 50% body-weight barbell (left) and level walking (right). The ten panels in the lower rows present the same measures for both tasks in all five subjects, illustrating the reproducibility of the compartment-based decomposition at the individual level.

Stiffness-Graded Octet-Truss Lattices: Mitigating Stress Shielding in Orthopaedic Implants

Mr Arandeep Prehar, Mr Jack Clarke, Mr James D. Clark, Dr Peter Ellison

University of York, York, Yorkshire, United Kingdom

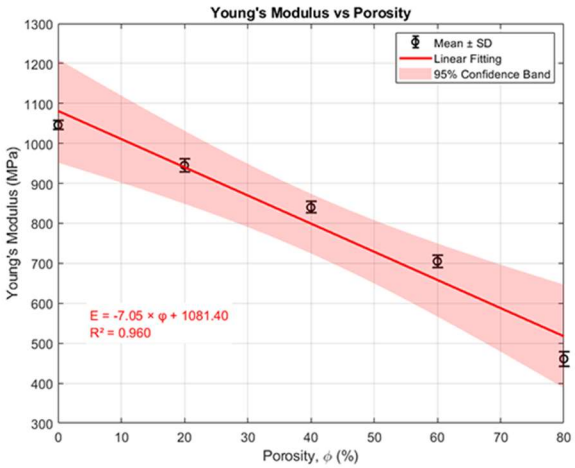
Introduction

The stiffness mismatch between traditional orthopaedic implants and natural bone often leads to stress shielding, resulting in bone loss and eventual implant loosening. 3D printing can manufacture structures of varying porosity offering a path to mitigate stress shielding, match implant stiffness to bone, and significantly enhance implant longevity. This work investigated functionally graded porous lattice structures, focusing on the octet-truss geometry. The aim was to develop a relationship between unit cell geometry and the resulting stiffness, enabling the implants to be tailored to individual's bone properties.

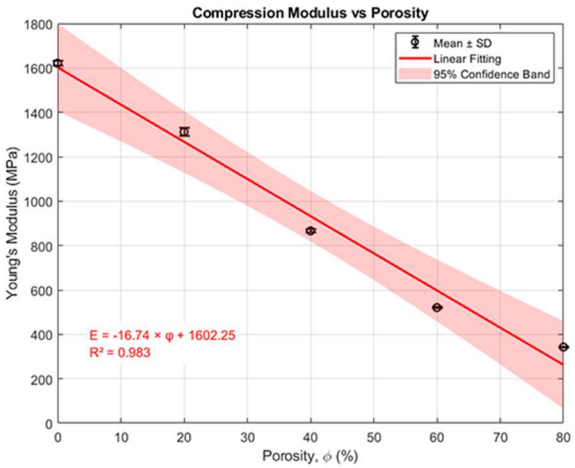
Methods

Lattices with four porosity levels (ϕ = 20%, 40%, 60%, 80%) and a solid control were manufactured (n = 6 per group) in polylactic acid (PLA) using fused filament fabrication (FFF) to evaluate how porosity influences compressive and tensile mechanical performance. Specimens were based on modified versions of ASTM standards, with gauge regions consisting of 6mm^3 OT unit cells to ensure consistent lattice geometry across density groups. To account for the relative density, stress-strain was calculated using the effective cross-sectional area of the lattice.

Results



The Elastic modulus (E) was calculated from the linear region of stress-strain curves. Experimental data showed a linear relationship between porosity (ϕ) and both the tensile (E_t) and compression (E_c) moduli.



Discussion

Fundamentally, this study was successful in showing that the relative mechanical properties of an PLA FFF 3D printed octet lattice can be varied as a function of its porosity. A negative correlation was demonstrated between the porosity and the elastic modulus. The linear model between the elastic modulus would allow for the non-discrete selection of any desired modulus within the measured range. By implementing functionally graded

volume fractions across cell arrays, mechanical properties can be patient-specifically tailored to closely replicate native bone stiffness. This approach promises to significantly improve load distribution, mitigate the stress shielding effect, and ultimately enhance long-term patient recovery and implant outcomes.

Assessment of Lower Extremity Kinematics, Kinetics, and Patellar Tendon Loading Pre- and Post-Fatigue

Mr. Jack Felipe, Mr. Kingsley Royal, Dr. Stephanie Cone

University of Delaware, Newark, DE, United States

Introduction

In the United States, 200,000 people receive anterior cruciate ligament (ACL) reconstruction (ACLR) surgery each year [1]. Unfortunately, individuals with a history of ACLR are up to 6 times more likely to tear an ACL compared to previously uninjured individuals. Current return to play criteria lacks a focus on fatigue effects, highlighting a need for improved understanding of the effect of fatigue on knee function following ACLR. To establish fatigue effects on knee function, the purpose of this study was to evaluate the effect of fatigue on interlimb symmetry in gait biomechanics in a healthy population.

Methods

19 healthy adults (11 M, 8F, 25.8±5.1 years) were recruited. Participants were fitted with shear wave tensiometers [2] bilaterally over the patellar tendons to measure dynamic tendon load and 39 retroreflective markers to track skeletal movement. Participants walked on an instrumented treadmill at a self-selected speed for 30 seconds to measure joint kinematics, kinetics, and patellar tendon loading patterns. Participants completed bodyweight squats to failure at a set tempo (160-1600 total repetitions). Immediately following fatigue, participants walked at the same speed as pre-fatigue. A mixed model with a post hoc paired t-test in 1D statistical parametric mapping was used to identify differences in joint kinematics, kinetics and patellar tendon loading patterns between limb and fatigue state.

Results

There was a significant main effect of fatigue across several metrics (Figure 1). On average, tendon shear wave speed increased by approximately 28% in a fatigued state ($p<0.05$). There were significant decreases in knee ($p=0.006$) and hip flexion angle ($p=0.005$) of approximately 8% and 10%, respectively. In addition, there was a significant decrease in knee moment ($p<0.001$) of roughly 17%.

Discussion

Knee function varied significantly from pre- to post-fatigue with changes in the magnitude of shear wave speed and sagittal hip angle, knee angle, and knee moment at both heel

strike and toe off. These effects of fatigue in healthy gait biomechanics motivate future work assessing these effects on movement quality and performance in athletes with a history of ACL injury.

Investigating the Effects of Eccentric Calf Exercise on Achilles Tendon Fluid Content Using Magnetic Resonance Imaging

Mr. Jarod Forer, Dr. Jolinda Smith, Dr. Nick Willett, Dr. Michael Hahn

University of Oregon, Eugene, Oregon, United States

Introduction

Achilles tendinopathy is a common diagnosis without a universally effective solution. Rehabilitative eccentric exercise can be successful as a treatment, but the mechanisms by which it improves tendon health are not well understood. Through repetitive loading and straining of the tendon, rehabilitative exercise is hypothesized to drive fluid movement in human Achilles tendons. However, while Achilles tendon fluid content has been modeled with Magnetic Resonance Imaging (MRI), it has not been studied in the context of the temporal response to exercise. We hypothesized that fluid content in healthy Achilles tendons would decrease immediately after exercise as shown with T2* values captured from ultrashort-time-to-echo (UTE) MRI.

Methods

3 healthy participants (1F, 26±3.56 years old) completed an eccentric exercise protocol between three separate MRI scans. The exercise consisted of 100 continuous unilateral heel drops on a raised platform, 50 with an extended knee and 50 with a slightly flexed (20°) knee. The scans took place immediately before (Pre), immediately after (Post), and 2 hours after exercise (2Hr Post). MRI scans were acquired on a 3T Skyra (Siemens) and included 2 acquisitions of a UTE 3D Radial sequence with 4 echo times each. The tendon midsection was segmented using a semi-automatic method in ITK-SNAP. T2* values were calculated by fitting voxel-wise normalized intensity data with a biexponential decay curve. Statistical analysis was conducted using a one-way repeated measures ANOVA in Prism (GraphPad) with an alpha of 0.05.

Results

No significant differences were found in tendon midsection volume, the short component of $T2^*$, the long component of $T2^*$, or the short fraction of the biexponential fit (Figure 1, all $p>0.05$).

Discussion

No conclusions can be made as to the effects of eccentric exercise on Achilles tendon fluid content based on a preliminary cohort of participants (expected sample size of ten).

Further analyses should also investigate the insertional and myotendinous regions of the Achilles tendon. Through the calculation of T2* relaxation times, this work provides the first data modeling fluid content of the human Achilles tendon in response to exercise.

KneeHub: A Consensus Context of Use for Simulation-Based Prediction of Movement After ACL Reconstruction and Risk Assessment of Post-Traumatic OA

Mr Jason Halloran[1], Mrs Snehal Chokhandre[2], Ms Kate Moyle[3], Ms Nancy Kim[3], Ms Maryam Nazem[4], Mr Scott Sibole[1], Mr Peter Laz[4], Mr Thor Besier[3], Mr Carl Imhauser[5], Mr Ahmet Erdemir[2]

[1]Washington State University, Spokane, WA, United States. [2]Cleveland Clinic, Cleveland, OH, United States. [3]University of Auckland, Auckland, Auckland, New Zealand. [4]University of Denver, Denver, CO, United States. [5]Hospital for Special Surgery, New York, NY, United States

Introduction

Modeling and simulation requires a clear context of use (CoU), which promotes informed decisions on the construction, orchestration, credibility, and communication of simulation studies. The NIH-sponsored “KneeHub” project has disseminated how modelers’ preferred workflows affect simulation outcomes [1]. The project now aims to establish consensus-based workflows to serve as community standards, to augment reproducibility, and to streamline multi-center studies. The goal of this abstract is to present the CoU for an internal consensus among the five teams that participate in the KneeHub project. This internal effort complements an ongoing external community-based Delphi study to define a second CoU and corresponding workflow.

Methods

The participants conducted a literature search in knee modeling and met weekly to discuss CoUs with pragmatic consideration of available data, contemporary modeling approaches, and potential clinical implications. Ultimately, the group focused on pinpointing the limits of simulation capabilities in a data-rich setting, i.e., research that may transform into clinically meaningful simulation workflows. While anatomy can be acquired in the clinic (e.g., MRI), joint- or tissue-level mechanics may be missing. Our framing helped define a clinically relevant CoU, and later a CoU-specific workflow, with the intent to establish the bounds of model fidelity and predictive quality.

Results

CoU summary - For an active female with an anterior cruciate ligament (ACL) injury, a physician would like to understand the biomechanics before injury, joint- and tissue-level consequences of the injury, performance of a reconstruction, and changes after surgery as potential indicators of reinjury or post-traumatic OA. The injury presents as complete tears

of the ACL and posterior root of the lateral meniscus. The surgery aims for ideal graft placement and tension using the patellar tendon with preservation of the meniscus using sutures at the horn insertion.

Discussion

We summarize our internal consensus CoU to inspire discussion and complement related progress toward a community-wide Delphi-based second CoU and workflow. We hope to present this alongside our work defining and testing a corresponding modeling workflow. In the future, the CoU and its workflow will serve as the basis for customization, with potential losses evaluated to accommodate the data constraints of a clinical setting.

KneeHub – A Consensus Workflow for Simulation-Based Prediction of Movement After ACL Reconstruction and Risk Assessment of Post-Traumatic OA

Mr Jason Halloran[1], Mrs Snehal Chokhandre[2], Ms Nancy Kim[3], Ms Kate Moyle[3], Ms Maryam Nazem[4], Mr Scott Sibole[1], Mr Peter Laz[4], Mr Thor Besier[3], Mr Carl Imhauser[5], Mr Ahmet Erdemir[2]

[1]Washington State University, Spokane, WA, United States. [2]Cleveland Clinic, Cleveland, OH, United States. [3]University of Auckland, Auckland, Auckland, New Zealand. [4]University of Denver, Denver, CO, United States. [5]Hospital for Special Surgery, New York, NY, United States

Introduction

Modeling and simulation requires a clear context of use (CoU) and workflow, which promotes informed decisions on the construction, orchestration, credibility, and communication of simulation studies. The NIH-sponsored "KneeHub" project has disseminated how modelers' preferred workflows affect simulation outcomes [1]. The project now aims to establish consensus-based workflows to serve as community standards, to augment reproducibility, and to streamline multi-center studies. The goal of this abstract is to present a CoU-specific categorically-defined workflow that was determined by an internal consensus among the five teams in the KneeHub project. This internal effort complements an ongoing external community-based Delphi study to define a second CoU and corresponding modeling workflow.

Methods

The seeding CoU: A physician would like to understand the joint- and tissue-level biomechanics of a female patient with anterior cruciate ligament and lateral meniscus posterior root tears before the injury, after the injury, and any post-surgery (patellar graft) changes as potential indicators of reinjury or post-traumatic OA. The CoU focused on adoption of an extensive experimental data set as foundational work towards clinical translation.

Over a six-month period, the team met weekly to discuss and document the CoU-specific workflow with pragmatic consideration of data, contemporary modeling approaches, and potential clinical implications. We broke down the modeling process from high level objectives to task-specific activities, including credibility and outreach. For some tasks, consensus focused on target outcome measures versus prescription of specific methods,

particularly when an objective strategy was not identifiable. Consensus was achieved when all teams agreed to specific workflow details.

Results

Workflow summary: “Broad design of the simulation study” encompasses the why (not “how”), which we delineated into context relevant categories (Fig. 1). The specifics (the “how”) include: development and calibration, benchmarking, use and outreach, and credibility. Documentation is largely complete with two KneeHub groups implementing the workflow (Fig. 1).

Discussion

Internal implementation of the CoU-specific modeling workflow has informed deployment of the complementary community wide Delphi process (expert-informed consensus). Further, the CoU and its workflow were designed to serve as the basis for customization, with potential losses evaluated to accommodate the data constraints of a clinical setting.

Principal Component–Based Analysis of Bilateral Knee Morphology in ACL-Injured Patients

Dr. Jeongseok Oh[1], Prof. Joonho Wang[2], Prof. Seungbum Koo[1]

[1]KAIST, Daejeon, Daejeon, Korea, Republic of. [2]Samsung Medical Center, Seoul, Seoul, Korea, Republic of

Introduction

Anterior cruciate ligament (ACL) rupture has long been linked to underlying anatomical factors, yet prior work has largely focused on population-level associations without fully clarifying which specific morphological features drive injury risk [1,2]. Recent statistical shape modeling studies have demonstrated that variations in bony morphology can meaningfully influence joint loading and ACL vulnerability, but the extent to which subtle bilateral differences within the same individual contribute to rupture remains insufficiently understood [2]. Examining side-to-side morphological asymmetries may offer new insight into shape features associated with ACL injury.

Methods

Thirty patients with unilateral ACL rupture were included, providing a total of 60 knee shape datasets, of which 20 patients had previously undergone single-bundle or double-bundle ACL reconstruction. Three-dimensional knee models were reconstructed using biplanar fluoroscopy and fitted into a pre-established statistical shape and intensity model (SSIM) to extract shape weights. Registration was done with 20 principal component (PC) weights for each model. Independent t-tests were conducted to compare SSIM weights between the injured and uninjured sides, with significance defined at $p < 0.05$.

Results

Four PCs of the femur showed statistically significant differences between sides, and the morphological changes associated with each PC are illustrated in Figure 1. The first PC indicated a sharper femoral shaft with mediolateral narrowing of the medial condyle. The second PC similarly reflected shaft sharpening accompanied by anteroposterior hypertrophy of the medial condyle. The third PC represented a relatively narrower intercondylar notch. The fourth PC demonstrated mediolateral enlargement toward the condylar region. No statistically significant components were identified in the tibia.

Discussion

Bilateral comparison of skeletal morphology revealed femoral shape characteristics associated with ACL rupture. A relatively narrower intercondylar notch may increase the likelihood of ACL impingement against the medial wall of the femur. The mediolateral enlargement of the condyle may alter the joint's rotational axis and increase the stabilizing demand placed on the ACL during tibial rotation. These findings provide insight into anatomical risk factors and may contribute to improved strategies for ACL injury prevention.

Images (Optional)

A Novel Quasi-Static Loading Profile for Tearing the ACL in Cadaveric Studies

Jeremy Loss MS, Miss Elizabeth Pace, Dr. Robb Colbrunn PhD, Dr. Tara Nagle PhD

BioRobotics Core, Cleveland Clinic Research, Cleveland, OH, United States

Introduction

The anterior cruciate ligament (ACL) is one of the most commonly injured knee ligaments. Many researchers study the biomechanics of ACL reconstruction (ACLR) on cadavers. However, the methodology for creating the rupture oftentimes requires a surgeon to arthroscopically incise the ACL. This method does not provide any insights into the biomechanics of the knee during the ACL rupture. Previous studies found that high tibiofemoral compression force, valgus moment, and internal rotation (IR) torque produce the highest force on the ACL at 30° flexion [1]. However, these studies did not examine damage to other structures. We aimed to build upon these target loads to develop a novel loading profile for tearing the ACL that mimics non-contact injury to the ACL without damaging other structures.

Methods

Two knees were tested using a simVITRO 6 degree-of-freedom robotic testing system. We chose not to include a valgus moment to preserve the meniscus. First, the knee was flexed to 30° and the IR position at 5 Nm IR torque with 20 N compression was recorded. The ACL tear trajectory consisted of: 1500 N compression, the aforementioned IR position at 5 Nm, and anterior tibial displacement ramped at 1 mm/sec until failure. All other loads were minimized. Lachman tests consisting of 134 N anterior drawer and 20 N compression at 30° flexion were run pre- and post- failure to measure anterior displacement (Table 1). After failure, each knee was dissected and inspected for both intentional and unintentional damage.

Results

Post-testing dissection on both knees revealed ruptured ACLs with no discernible damage to other internal structures. Failure metrics can be seen in Table 1. The Lachman test showed a substantial increase in anterior translation after failure, indicating a damaged ACL.

Discussion

Additional specimens are required to validate the efficacy of this profile. However, this is a promising method for reliably tearing the ACL robotically, removing the need for a surgical

resection. Additionally, the ability to measure kinetics and kinematics throughout the failure trajectory may be especially valuable for researchers interested in ACL and ACLR failure mechanisms.

Images (Optional)

Table 1: Failure forces/torques and displacements/rotations for position-controlled degrees of freedom (Anterior, IR, Flexion), and pre-tear and post-tear Lachman test displacements.

	Sample 1	Sample 2
Anterior Force at Failure (N)	342	512
Anterior Displacement at Failure (mm)	18.6	25.8
Internal Rotation Torque at Failure (Nm)	2.72	3.25
Internal Rotation Angle (at 5 Nm)	24.4°	18.7°
Extension Torque at Failure (Nm)	5.96	7.93
Pre-tear Lachman Anterior Displacement (mm)	6.91	7.03
Post-tear Lachman Anterior Displacement (mm)	25.9	20.4

The Effect of Changes in Bone Density on the Mechanical Response of THA Femurs

Dr. Jonas Pramudita, Mr. Kei Matsushita, Mr. Yosei Ooba

Nihon University, Koriyama, Fukushima, Japan

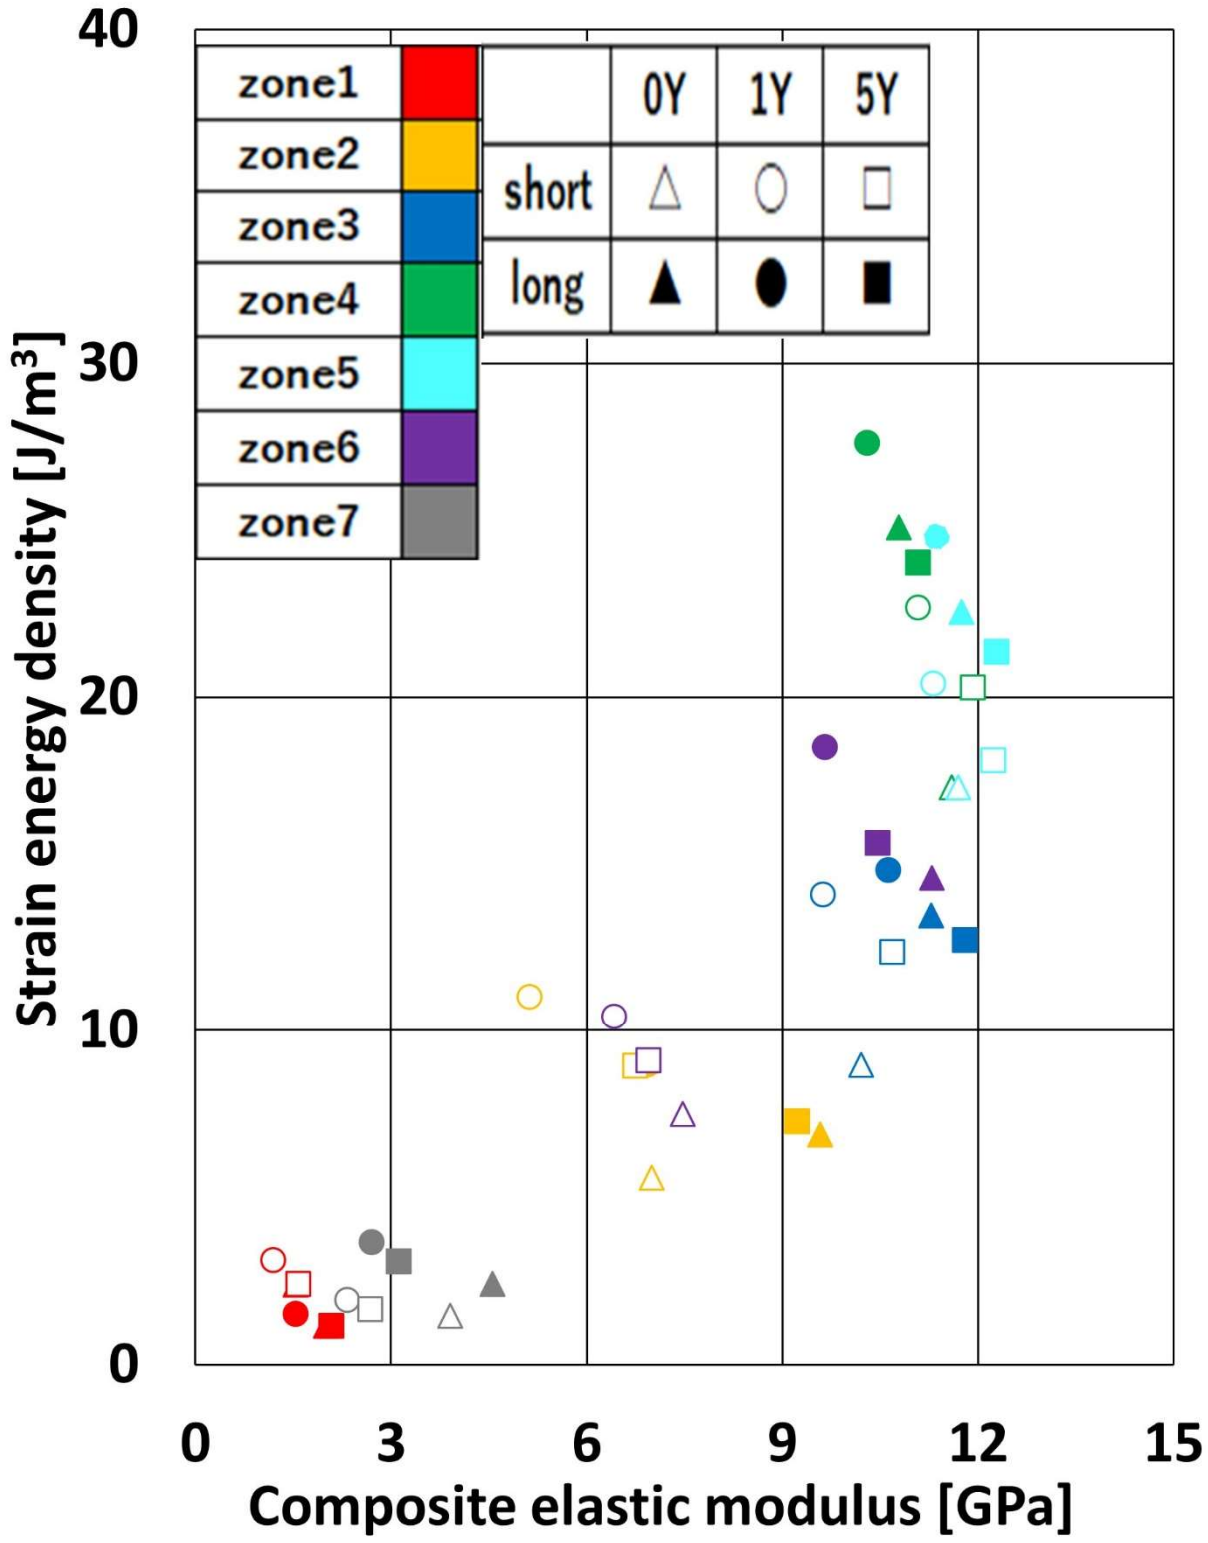
Introduction

Bone mineral density (BMD) of the femur is known to change after total hip arthroplasty (THA). However, the influence of long-term postoperative changes in BMD on the mechanical response of the femur has not yet been sufficiently investigated, and the change in fracture risk associated with the change of BMD remains unclear. Therefore, we incorporated postoperative temporal changes in BMD and Young's modulus into a previously developed femoral finite element (FE) model to evaluate their effect on the mechanical response of the femur and to assess fracture risk based on the implementation of a fracture criterion.

Methods

Femoral FE models developed in a previous study [1] were used. Bone density and Young's modulus were estimated from the Hounsfield units of patient CT images. Postoperative changes in bone density were assumed to follow the trend reported in the literature [2]. FE models reflecting the bone density distribution at 1 year (1Y) and 5 years (5Y) after surgery were generated by applying the ratio of BMD change in each Gruen zone. FE analysis was then conducted under the same boundary and loading conditions as in the previous study. A fracture criterion was additionally incorporated to evaluate the postoperative risk of fracture.

Results



The figure showed the relationship between strain energy density and composite elastic modulus for short- and long-stem models at 0Y, 1Y, and 5Y. The strain energy density at 0Y tended to be lower than at 1Y and higher than at 5Y. From the fracture evaluation, the maximum proportion and volume fraction of failed elements were 0.17% and 0.41%, respectively.

Discussion

At 1Y, reduced BMD due to stress shielding increased femoral deformation, leading to higher strain energy density. At 5Y, increased BMD caused by bone–stem adhesion and recovery of physical activity resulted in reduced strain energy density. The postoperative fracture risk was considered extremely low. Although the long-stem model and the 1Y

model showed a slightly higher proportion of failed elements than the short-stem model and the 5Y model, the difference remained small.

Mr. Bernhard Weisse

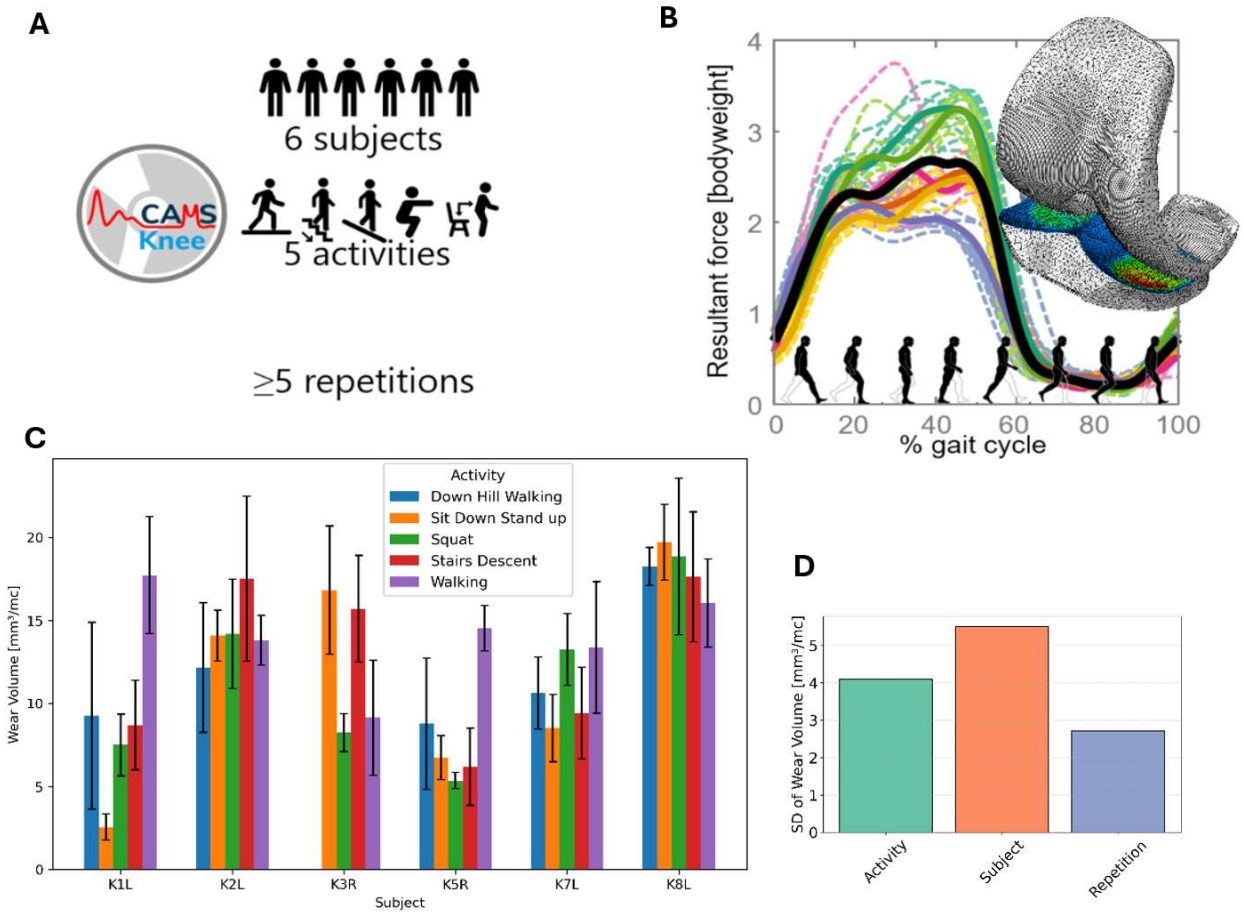
Introduction

Polyethylene wear remains a major cause of long-term failure in knee arthroplasty. Understanding how patient-specific tibio-femoral loading&kinematics drive abrasive wear is therefore essential. In this study, we investigated subject, activity, and repetition variability on knee prosthesis wear. We hypothesized that the most dominant influence on wear is the activity, followed by subject and repetition.

Methods

In vivo tibio-femoral loads&kinematics from six CAMS-Knee subjects [1] performing several repetitions of five activities were used as inputs to an FE-based framework [2] to compute wear volume over one million cycles (mc), yielding more than 150 simulations for the INNEX FIXUC prosthesis (ZimmerBiomet, Switzerland). A statistical analysis was carried out to determine the influence of subject, activity (walking, downhill walking, stair descent, sit-to-stand-to-sit, and squat), and repetition on wear. Furthermore, a machine-learning (ML) analysis using a linear mixed-effects model was trained to identify which of the surface contact variables most influenced the resulting wear.

Results



The wear volume varied substantially across subjects and activities, not allowing any clear ranking. The statistical analysis contradicted the hypothesis, showing that variation of subject (5.51 mm^3/mc) was the largest contributor to the wear variability, followed by

activity (4.10 mm^3/mc), and then repetition (2.71 mm^3/mc), see Figure. No significant difference in wear could be found between most activities, except for level-walking, which shows slightly a higher impact on wear. The findings of the ML analysis highlight that beside contact pressure and sliding distance, cross-shear and implant alignment are also important wear influencing factors.

Discussion

The relatively low variability of wear between repetitions demonstrates the repeatability of wear patterns. Therefore, the observed differences in wear related to activity and subject are not due to any inaccuracies in the in-vivo loading and kinematic measurements, but most likely because of the individual movement and loading patterns occurring as a result of anatomical and muscle recruitment differences, as well as implantation. Future work will focus on refining predictive models to better identify the key subject-specific biomechanical factors influencing implant wear.

Friction in Artificial Hip Joints: In Vivo Insights into Tribologically Relevant Parameters

M.Sc. Julian N. Zierke[1], Dr. Alwina Bender[1], M.Sc. Maurice Weiß[2], Dr. Stefan Schröder[2], Prof. Jan Philippe Kretzer[2], Prof. Georg N. Duda[1], PD Dr.-Ing. Philipp Damm[1]

[1]Julius Wolff Institute, Berlin Institute of Health at Charité – Universitätsmedizin, Berlin, Berlin, Germany. [2]Research Center of Biomechanics and Implant Technology, Department of Orthopaedics, Heidelberg University Hospital, Heidelberg, Baden-Württemberg, Germany

Introduction

Aseptic loosening remains a major cause of implant revision [1], with friction and wear being key contributing factors [2] investigated through in-vitro simulators [3]. While they allow systematic parameter variation, their underlying model assumptions often fail to capture realistic loading conditions, kinematics, and lubrication, leading to discrepancies compared to in-vivo observations. It was shown that friction in-vivo is highly dynamic and patient-specific, influenced by loading and kinematics as well as implant position and joint coverage [4]. To bridge the gap, the project aims to integrate both approaches and systematically analyze friction in-vivo to achieve a deeper understanding of its influencing factors.

Methods

A combinatorial approach is applied, integrating in-vivo measurements, in-vitro simulators, and in-silico models to investigate hip joint friction. Rheological analyses of patient synovia are conducted to characterize lubrication properties. Numerical and experimental studies will assess the influence of fluid characteristics, implant orientation, and activity-dependent loading on joint friction.

Results

The joint force (F_res) showed typical double-peak pattern with non-linear offset induced by additional body weight. While F_res increased linearly with the added load, the friction (M_res) demonstrated phase-dependent and non-linear behavior (Figure-1A). M_res rose during stance phase, peaked shortly after contralateral heel strike, dropped during transition into flexion, and increased again toward terminal stance. With an additional load, M_res elevated throughout, however, a further increase of weight produced only phase-specific increases, and at the time of peak force, M_res was even lower than during unloaded walking. Complementary rheological analyses of the patient's synovia revealed

non-Newtonian behavior (Figure-1B), differing from synthetic synovia (ISO-14242) commonly used in simulators.

Discussion

The findings indicate a complex interaction between joint forces and friction in-vivo. Contrary to in-vitro studies, in-vivo data reveal distinctly phase-dependent friction behavior, consistent with dynamic lubrication influenced by joint kinematics and loading. The properties of the synovia and its deviation from synthetic lubricants further underline the importance of individual lubrication environments. Future work will integrate these fluid characteristics, implant orientation effects, and kinematics into in-vitro and in-silico models. This enables systematic parameter-variation with aim to develop tribologically optimized Safe Zones for implantation and activity recommendations.

Changes in Midflexion Knee Laxity in Multiple Planes Between 3-Months and 1-Year After Cruciate-Retaining Total Knee Arthroplasty

Ms. Julianna Villella, Mr. David Z. Shamritsky, Mr. Swaneet Jha, Mr. Claude Regis, Dr. Timothy M. Wright PhD, Dr. Stephen Lyman PhD, Dr. Cynthia A. Kahlenberg MD, Dr. Eytan M. Debbi MD, Dr. William J. Long MD, Dr. Geoffrey H. Westrich MD, Dr. David J. Mayman MD, Dr. Peter K. Sculco MD, Dr. Brian P. Chalmers MD, Dr. Carl W. Imhauser PhD

Hospital for Special Surgery, New York, New York, United States

Introduction

Instability after total knee arthroplasty (TKA) can arise from excessive ligamentous laxity in several anatomic planes. Surgeons often perceive that knee laxity increases between early and later post-operative time-points. However, the amount by which laxity changes over time after TKA remains poorly understood. We are conducting a prospective study in patients undergoing cruciate-retaining (CR) TKA with the objective of measuring the mean and variance of laxity changes between 3-months and 1-year.

Methods

With IRB approval, 46 subjects (48% female; mean age: 64±6 years; mean BMI: 29±3) were prospectively enrolled and underwent robotic-assisted TKA with a single design of PCL-retaining implant. Laxity testing occurred 3 months (mean follow-up: 96±15 days) and 1 year after surgery (mean follow-up: 383±28 days). Knee laxity was measured at 30° of flexion in response to varus-valgus (VV) moments (±6 Nm) and anterior-posterior (AP) forces (30 N posterior and 50 N anterior) using a custom-designed multiplanar arthrometer. Four cycles of loads were manually applied, and laxity was defined as translation or rotation from the position at no applied load to the load target in each direction. Mean changes in laxity between 3 months and 1 year after TKA were assessed using paired t-tests ($\alpha = 0.05$). In addition, the standard deviation (SD) of laxity changes between the two time-points were reported to describe the inter-subject variance.

Results

No mean increases in anterior, posterior, varus, or valgus laxities were detected between 3 months and 1 year. The SD of laxity changes were 3.2 mm and 2.0 mm in the anterior and posterior directions, respectively, and 1.4° and 1.3° in the varus and valgus directions, respectively (Figure 1).

Discussion

Our findings suggest that while laxity, on average, does not change for all patients, individual patients may have increases or decreases in laxity over time. This analysis is part of a larger prospective study to relate patients' laxity measures to any perceptions of instability or other complications after CR-TKA. This will establish thresholds for clinically meaningful changes in laxity which can lead to improved intra-operative decision-making.

Personalized Finite Element Analysis of Knee Contact Loading During Level Walking and Sit-to-Stand Movement Before and After High Tibial Osteotomy

Dr. Kao-Shang Shih[1], Mr. Yu-Ting Chen[2], Mr. Jing-Huei Siao[2], Mr. Kuan-Hsien Wu[2], Prof. Tung-Wu Lu[2,3,4]

[1]Department of Orthopedic Surgery, Shin Kong Wu Ho Su Memorial Hospital, Taipei, Taiwan, Taiwan. [2]Department of Biomedical Engineering, National Taiwan University, Taipei, Taiwan, Taiwan. [3]Department of Orthopaedic Surgery, School of Medicine, National Taiwan University, Taipei, Taiwan, Taiwan. [4]Health Science and Wellness Research Centre, National Taiwan University, Taipei, Taiwan, Taiwan

Introduction

High tibial osteotomy (HTO) corrects varus malalignment and reduces medial tibiofemoral loading in medial knee osteoarthritis. However, whether load redistribution after HTO is consistent across common daily activities remains unclear. This study quantified postoperative changes in contact force distribution during level walking and sit-to-stand (STS) using subject-specific finite element (FE) analysis driven by in vivo fluoroscopic kinematics.

Methods

Eight patients with medial osteoarthritis (62.5 ± 6.0 yrs) were evaluated before and six months after open-wedge HTO. Subject-specific bone and cartilage geometries were reconstructed from computed tomography and magnetic resonance imaging. Dynamic biplane fluoroscopy recorded knee motion during level walking and STS. Tibiofemoral kinematics were obtained using validated 3D/2D registration and served as boundary conditions for FE simulation. Compartmental contact forces normalized to body weight (BW) were compared between time points using paired t-tests ($\alpha = 0.05$). Walking analyses focused on stance phase peak loading, while STS forces were extracted across representative flexion angles to characterize task-dependent loading responses.

Results

After HTO, lateral loading increased and medial loading decreased during both activities (Table 1). In walking, lateral peak force increased (75.32% BW to 89.74% BW), while medial peak force decreased (134.87% BW to 110.28% BW), reflecting a shift toward more balanced load sharing during stance. STS demonstrated a similar but more pronounced redistribution throughout the movement cycle, especially at deeper flexion associated with higher joint demand. The timing of loading also changed postoperatively, with reduced

medial dominance during the transition from sit to full extension. Peak total loading showed consistent improvements in load distribution but was not statistically significant due to variability in individual responses.

Discussion

HTO successfully improved tibiofemoral load sharing during both gait and functional movement. The larger effect observed in STS indicates that task demand influences how realignment translates into joint-level mechanics. Fluoroscopy-driven personalized FE analysis provides a sensitive framework to evaluate functional outcomes of HTO beyond radiographic alignment, offering clinically relevant insight for rehabilitation strategies focused on restoring knee loading during everyday activities.

Lateral Pivoting Prevalence Across Coronal Plane Alignment of the Knee (CPAK) Phenotypes Increases Progressively From Type I to Type III During Squatting

Mr. Orçun Taylan MSc[1], Mr. Gérard Peersman[1], Dr. Junya Itou MD, PhD[2], Dr. Geert Peersman MD[3], Prof. Dr. Johan Bellemans MD, PhD[4], Prof. Lennart Scheys PhD[1]

[1]IORT, KU Leuven, Leuven, Vlaams Brabant, Belgium. [2]Tokyo Women's Medical University, Tokyo, Honshu, Japan. [3]ZAS, Antwerp, Antwerp, Belgium. [4]AZ Vezalius, Limburg, Vlaams Brabant, Belgium

Introduction

Medial pivoting has long been considered the dominant kinematic pattern of the native knee during flexion. Nevertheless, recent evidence shows that lateral pivoting frequently occurs during functional tasks. Prior studies have demonstrated distinct kinematic patterns in varus and valgus knees. The recently introduced Coronal Plane Alignment of the Knee (CPAK) classification expands traditional varus, neutral, and valgus categories into nine phenotypes by combining the arithmetic hip–knee–ankle angle (aHKA) with joint line obliquity (JLO). However, the relationship between CPAK phenotype and pivoting motion remains unexplored. This study evaluated pivoting across all CPAK phenotypes during *ex vivo* simulated squatting.

Methods

Tibiofemoral kinematics from 69 fresh-frozen cadaveric knees were analyzed. Specimens with bone-pin–mounted markers were subjected to dynamic squatting (35°–100°) on a knee simulator while 3D trajectories were recorded (Vicon, UK). CPAK phenotype was determined from full-leg CT scans. Pivoting was assessed using the Instantaneous Center of Rotation (ICOR). The femoral medial–lateral flexion axis was projected onto the tibial transverse plane, and intersection points of this projected axis were computed for each flexion interval, producing ICOR positions as a function of flexion. ICOR medial or lateral to the tibial knee center indicated medial or lateral pivoting. Specimens were classified as lateral-pivot dominant if >50% of flexion angles exhibited lateral ICORs. A generalized linear mixed-effects model assessed the influence of aHKA, JLO, and flexion angle.

Results

Lateral pivoting occurred in CPAK types I–III. The probability of lateral pivoting was 28% in CPAK I (1/8 dominant), 39% in CPAK II (10/28 dominant), and 48% in CPAK III (8/17 dominant). In Type III, all knees demonstrated lateral ICORs, predominantly at flexion angles ≥58.5°. Across groups, the likelihood of lateral pivoting increased with flexion.

Flexion angle was a significant predictor of pivoting behavior, whereas aHKA and JLO showed no significant effects.

Discussion

All analyzed CPAK types exhibited lateral pivoting during squatting, with increasing prevalence from varus- to valgus-aligned phenotypes, reflecting a lateral shift in the load-bearing axis. These findings suggest that phenotype-specific assessment of knee kinematics may play an important role in surgical planning. Further work integrating patella contributions and three-dimensional morphology is warranted.

Images (Optional)

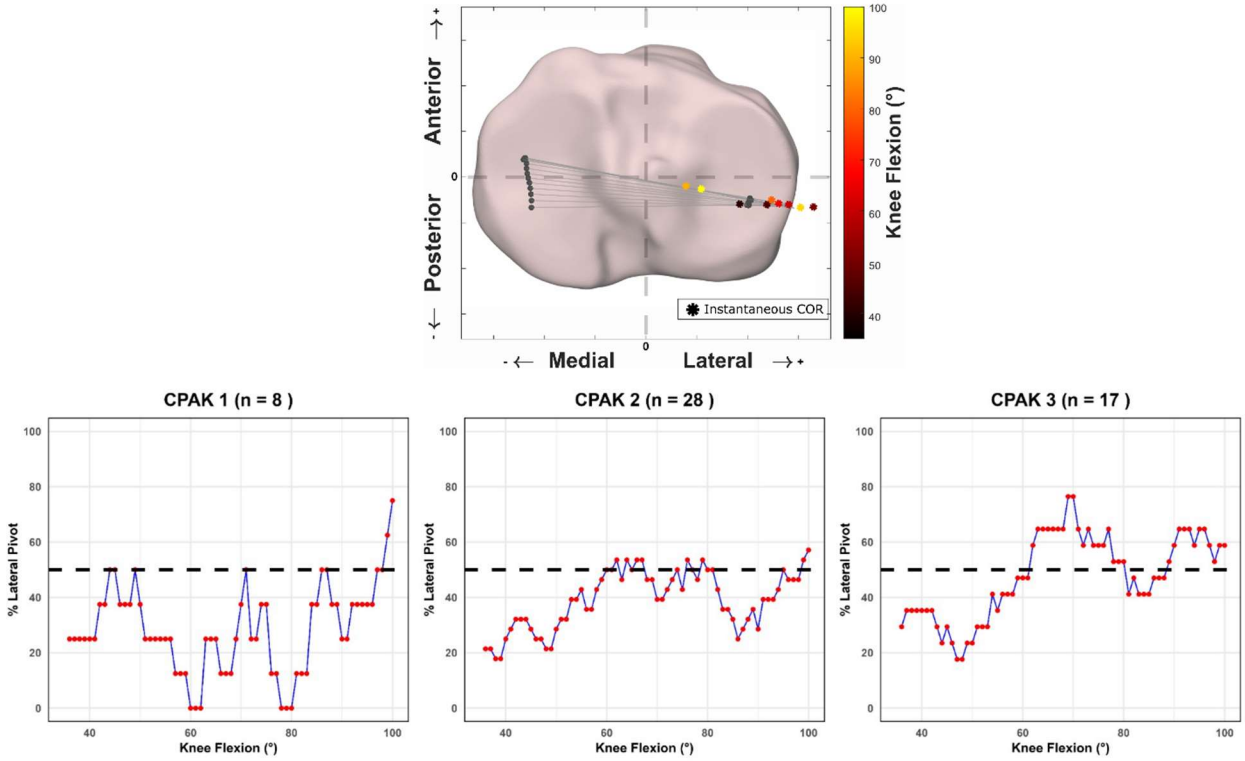

Figure 1: Instantaneous center of rotation (ICOR) as a function of knee flexion angle (top row), and the proportion of lateral pivot motion across CPAK Type I–III specimens (bottom row). Only these three CPAK types were present in the dataset.

Benefits in Terms of Fit-and-Fill and Implant Primary Stability of a OsteoCustom Stem for Transfemoral Amputees

Ph.D Giulia Galteri[1], Ms. Silvia Casadei[1], Mr. Edoardo Hirschberg[1], Dr. Domenico Alesi[2], Prof. Stefano Zaffagnini[2], Mr. Kavin Morellato[3], PhD. Emanuele Gruppioni[3], Prof. Luca Cristofolini[1]

[1]UNIVERSITY OF BOLOGNA, BOLOGNA, EMILIA ROMAGNA, Italy. [2]ISTITUTO ORTOPEDICO RIZZOLI, BOLOGNA, EMILIA-ROMAGNA, Italy. [3]Centro Protesi INAIL, VIGORSO DI BUDRIO, EMILIA-ROMAGNA, Italy

Introduction

Commercial transfemoral osseointegrated prostheses often do not match the patient's femoral canal, leading to mechanical instability or patient ineligibility. OsteoCustom is defined by discrete parameters' combination that should better match anatomical variability. Its actual benefits remain unclear, and a quantitative assessment is still missing. The aim of this study is to quantify the fit-and-fill and cortical bone removal to evaluate potential advantages of OsteoCustom, and to investigate whether these metrics correlate with implant primary stability.

Methods

Twelve paired human cadaveric femurs were used. Pre-implant CT scans were acquired (slice-thickness=0.625mm; in-plane-resolution=0.512mm). Surgical planning and implantations were performed by orthopedic surgeons, followed by post-implant CT acquisition. Each pair was implanted with a commercial OFI-C on one femur and the OsteoCustom stem on the contralateral femur. Compression-flexion and torsion tests were performed. A 3D-DIC system was used to measure the primary stability in terms of elastic micromotions and permanent migration. CT-images were upscaled fourfold (SRCNN,final in-plane-resolution=0.128) and segmented. Stem-bone contact area was computed along the stem (Matlab). Cortical bone removal was quantified subtracting the co-registered pre- and post-implant CTs, using the Goldman eight-sector method to evaluate bone loss locally and globally. A Wilcoxon paired-test was used (Prism9.5.1, $p<0.05$). Moreover,_a preliminary anatomical analysis explored the correlation between the primary stability and the contact area and the bone removal.

Results

For both loading scenarios, the OsteoCustom stem showed inducible micromotions more than threefold lower than those of the OFI-C stem($p<0.05$), and permanent migration more

than 1.5-fold lower($p<0.05$). The OsteoCustom showed benefit compared to the commercial one, with a significant increase in stem-bone contact area($p=0.041$) and a reduction in cortical bone removal ($p=0.026$) across all twelve paired femora. Contact area was linked to primary stability: specimens with >75% contact, whether implanted with the commercial or the OsteoCustom stem, consistently exhibited good primary stability. Conversely, bone removal did not show a direct correlation with primary stability.

Discussion

Nevertheless, preserving bone stock remains clinically crucial, as it reduces fracture risk and facilitates potential revision surgery. Although larger cohorts are needed, these preliminary findings highlight the potential advantages of OsteoCustom in terms of fit-and-fill and primary stability.

Predicting Tibial Contact Mechanics Following Osteotomy: A Systematic Review and Meta-Analysis

Mr. Mahziyar Darvishi PhD candidate[1], Dr. Stavan Amin Clinical Fellow[2], Mr. Christopher fenelon MD[1], Mr. Michael Catapano Assistant Professor[1], Dr. David Wasserstein Assistant Professor[1], Dr. Timothy Burkhart Assistant Professor[1]

[1]University of Toronto, Toronto, Ontario, Canada. [2]Sunnybrook Holland Centre, Toronto, Ontario, Canada

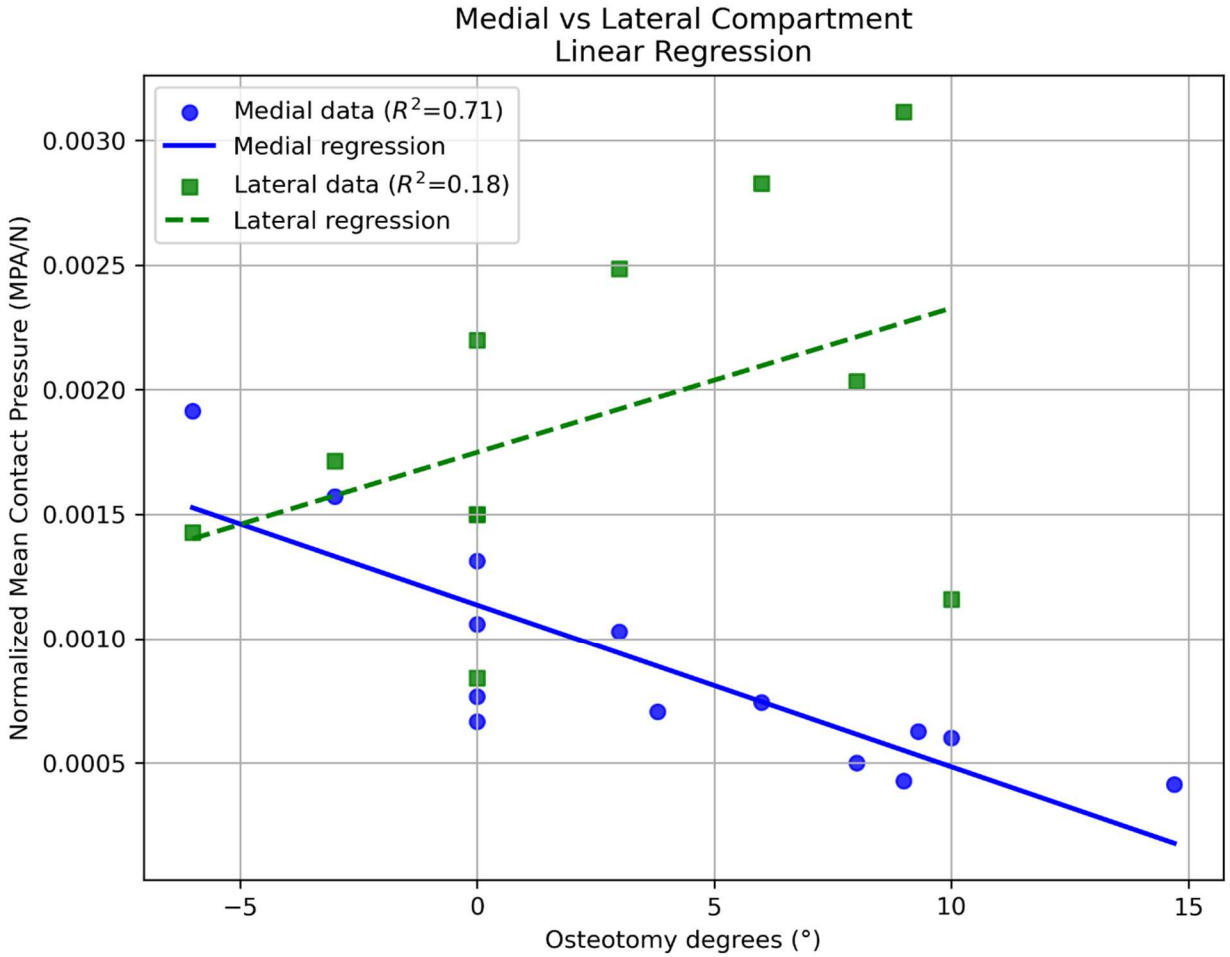
Introduction

Lower limb malalignment, including varus and valgus deformities, alters knee joint loading and accelerates unicompartmental osteoarthritis [1]. Tibial osteotomy aims to restore alignment and redistribute contact forces across the tibial plateau [1]. Although postoperative changes in contact pressure and contact area are widely reported, the relationship between correction magnitude and resulting contact mechanics remains inconsistent. This lack of a predictive framework limits preoperative planning. The objective of this study was to quantify the relationship between tibial osteotomy correction magnitude and postoperative tibial contact mechanics using a systematic review and meta-analysis.

Methods

A systematic literature search identified experimental in vitro studies of tibial alignment manipulation in cadaveric knees across neutral, varus, and valgus configurations. Studies using tibial osteotomy or controlled mechanical realignment and reporting mean contact pressure, peak contact pressure, and/or contact area under controlled loading were included. Contact pressures were normalized to the applied axial load reported in each study. Outcomes were analyzed separately for medial and lateral compartments. Correction magnitude was quantified using mechanical tibiofemoral angle (TFA) and tibial plateau width percentage (TPW%), yielding regression models to predict post-osteotomy tibial contact mechanics.

Results



Nine studies met the inclusion criteria. Across all outcome metrics, consistent compartment-specific trends were observed (Figure 1). Increasing correction toward valgus alignment reduced medial mean and peak contact pressures with corresponding increases in lateral compartment loading. Meta-regression revealed predominantly linear relationships between correction magnitude and normalized contact mechanics in both

compartments. Contact area demonstrated complementary redistribution with increasing correction. Similar linear associations were observed using TFA or TPW%, indicating that both descriptors captured postoperative changes in tibial contact mechanics.

Discussion

These findings align with biomechanical theory that valgus-directed correction redistributes loads from the medial to the lateral compartment. Quantifying the relationship between correction magnitude and contact mechanics advances prior experimental work toward a predictive framework. Using both angular and geometric descriptors improves generalizability across experimental protocols. One limitation is that the included studies relied on cadaveric models and simplified loading. Future work will validate these relationships using subject-specific data and incorporate them into osteotomy planning tools.

Biomechanical Analysis of Cotton Osteotomy in Flat Feet Using Finite Element Simulations

BSc Student Laura Valentina Muñoz Estevez BSc (Biomedical Engineering) in progress[1], BSc Student María Alejandra Bustos Bautista BSc (Biomedical Engineering) in progress[1], PhD Javier Bayod[2], PhD Christian Javier Cifuentes de la Portilla PhD[1]

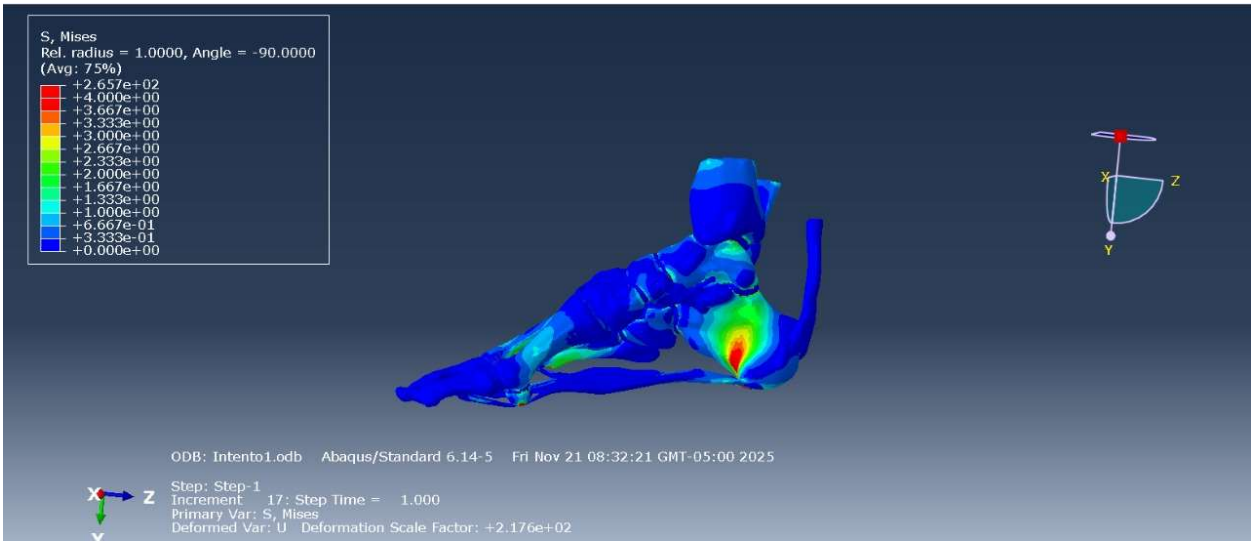
[1]Universidad de Los Andes, Bogotá, Cundinamarca, Colombia. [2]Universidad de Zaragoza, Zaragoza, Aragón, Spain

Introduction

Flatfoot is a common deformity characterized by collapse of the medial arch and hindfoot valgus, which can lead to pain, functional limitation, altered load distribution, and progressive joint degeneration. In severe cases, one surgical option is the Cotton osteotomy, which involves making an opening in the medial cuneiform and inserting a wedge-shaped graft to restore the longitudinal arch and improve alignment, thereby promoting more adequate load distribution and reducing pain. However, its effectiveness depends on factors such as the opening angle, the location of the cut, and the type of graft used, decisions that are often based on the surgeon's experience. Therefore, this project proposes the use of computer simulations to evaluate different surgical configurations and support clinical decision-making.

Methods

To develop this project, three wedges measuring 4, 6, and 8 mm were modeled in Fusion 360. Each was positioned in the medial cuneiform using ICEM, simulating the procedure and allowing for the geometric reconstruction of the medial arch. Subsequently, a mesh with tetrahedral elements between 1 and 2 mm was generated, and in the same environment, bar-type elements and the fixation and load conditions were defined. The final simulation was performed in Abaqus CAE.



Results

Preliminary results show that, as expected, the size of the wedge is directly related to the increase in the longitudinal arch, affecting not only the position of the first metatarsal but also tissues such as the plantar fascia. A concentration of stress is also observed in the calcaneus, rearfoot, and metatarsals, while no significant stress is evident in the midfoot, possibly due to the fixation conditions applied.

Discussion

These findings suggest that osteotomy could reduce stress in medial areas, particularly in the hallux, by redistributing the load thanks to the restoration of the arch. In accordance with the literature, an increase in stress in the medial and middle regions of the ankle joint and a decrease in the lateral and posterior areas would be expected [6].

Total Knee Arthroplasty Rehabilitation Augmented with Electroencephalogram Biofeedback Training to Accelerate Achievement of Delayed Functional Milestones: A Case Study

Mr Matthew Varano BA[1], Mr. Henry Eilen BA[1], Ms. Camilla Antognini MS[2], Dr. Felipe Gonzalez MD MS[2], Dr. Christopher Knowlton PhD[2], Dr. Johnathan Gustafson PhD[2], Dr. Markus Wimmer PhD[2], Dr. Craig Della Valle MD[1], Dr. Brian Forsythe MD[1]

[1]Midwest Orthopaedics at RUSH, Chicago, IL, United States. [2]RUSH University Medical Center, Chicago, IL, United States

Introduction

Total knee arthroplasty (TKA) is an effective treatment for advanced degenerative joint disease, yet a subset of patients experience delayed functional recovery despite appropriate postoperative rehabilitation. Visualization-based therapies have shown potential to enhance strength, motor control, and functional outcomes when used with standard physiotherapy, although their role in patients with persistent postoperative deficits remains unclear. This case study describes the clinical course of a patient who failed to meet rehabilitation milestones after TKA and subsequently underwent EEG biofeedback training as an adjunct to therapy.

Methods

A 55-year-old female developed persistent quadriceps weakness, anterior knee pain, and restricted terminal knee extension four months after an uncomplicated TKA. She completed eight EEG biofeedback training sessions over four weeks while continuing standard physiotherapy. Training uses an EEG-based brain–computer interface to quantify neural engagement during visualization of functional movements. Biomechanical assessment, surface EMG, and isokinetic and isometric strength testing were performed immediately before and after the EEG biofeedback intervention. PROMs included KOOS JR., IKDC, and TSK-11.

Results

Motion analysis demonstrated increased external knee flexion moments across gait, squat, and lunge tasks after biofeedback, accompanied by improved knee flexion angle during loading response and more symmetrical bilateral loading. Hip flexion moments and contralateral knee loading decreased. Strength testing revealed consistent gains in knee extension torque, total work, and power at both 60°/s and 120°/s, along with improved muscular endurance. EMG showed increased vastus medialis activation and reduced

rectus femoris overreliance, although quadriceps avoidance and compensatory hamstring recruitment persisted. PROMs improved modestly but did not reach minimal clinically important difference thresholds.

Discussion

Four weeks of EEG biofeedback training combined with physiotherapy produced measurable biomechanical and strength improvements in a patient with delayed recovery following TKA. Enhanced knee loading capacity, improved symmetry, and early correction of stiff-knee gait characteristics suggest that EEG biofeedback training may support restoration of more physiologic movement patterns. Although findings are limited to a single case and natural recovery may have contributed, this preliminary evidence indicates that EEG biofeedback training may serve as a valuable adjunct for patients who fail to progress with standard rehabilitation. Further controlled studies are warranted.

Biomechanical Analysis of Secondary Stability in Cementless Femoral Hip Stems: An Ex Vivo Post-Mortem Study Part 2

Prof. Matthias Woiczinski[1], Dr. Manuel Kistler[1], Dr. Lena Hirtler[2], Dr. Gilbert Schwarz[2,3]

[1]Experimental Orthopaedics University Hospital Jena, Campus Eisenberg, Waldkliniken Eisenberg, Germany, Jena, Thüringen, Germany. [2]Center for Anatomy and Cell Biology, Medical University Vienna, Vienna, Austria, Vienna, Vienna, Austria. [3]Department of Orthopedics and Trauma-Surgery, Medical University of Vienna, Vienna, Austria, Vienna, Vienna, Austria

Introduction

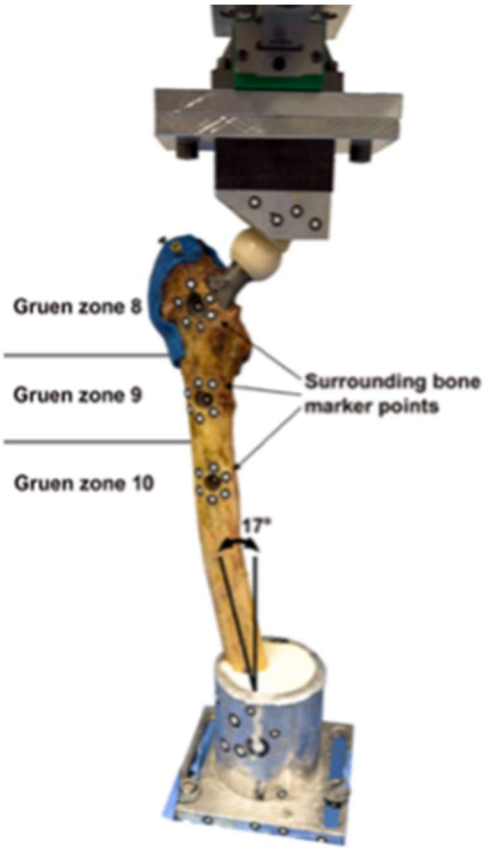
Secondary stability, particularly with respect to micromotion, is a critical determinant of the long-term survival of cementless femoral hip stems following osseointegration.[1,2] This study investigates micromotion at the bone–implant interface in proximally loosened total hip arthroplasty (THA) stems ex vivo and compares these findings with Part 1 of the study, in which fully integrated stems were analysed. The results are further interpreted in the context of the established 150-micron threshold[3], commonly regarded as the upper limit for successful osseointegration. These insights aim to support the refinement of validation criteria for implant performance and long-term durability.

Methods

12 fresh-frozen human femora from body donations with cementless hip stems (Alloclassic® Zweymüller®) were analyzed. Standardized force alignment was ensured with a 17° adduction and 11° flexion angle, and micromotion at the bone-implant interface was measured in Gruen zones 8–10 using a 3D optical system (ARAMIS accuracy: 11.2 µm in-plane). Specimens underwent dynamic loading (11Hz, 300–1186.5N) and corresponding to body weight. Data analysis included MATLAB and GraphPad, with significance set at $p<0.05$. Ethics Committee of the Medical University of Vienna (2111/2017).

Results

For the fully integrated stems, the mean 3D micromotion was 209.7 µm ± 147.9 µm, with the highest values occurring in Gruen zone 8 and the lowest in zone 9. Stems that were radiologically loosened in the proximal region exhibited notably higher micromotion, particularly in zone 8, with a mean of 287 µm ± 104 µm.



Discussion

Micromotion analysis revealed significant differences among Gruen zones, underscoring the critical influence of localized load transmission at the bone–implant interface on secondary stability. In fully integrated stems, micromotion frequently exceeded the classical 150-µm osseointegration threshold described by Pilliar yet without documented clinical complications, highlighting that this limit may be more nuanced under physiological anchorage conditions.

In contrast, proximally loosened stems demonstrated substantially higher micromotion, where values were markedly elevated.

The micromotion patterns observed across both test series provide essential insights for optimizing implant and further emphasise the diagnostic relevance of recognising fixation deficits.

Center of Pressure Displacement and Plantar Pressure in Individuals With a Minor Lower Extremity Amputation.

PhD(c) Maxime Acien, PhD(c) Ahmed Dami, DPM Pier-Luc Isabelle, DPM, Pr. Virginie Blanchette, DPM, Pr. Gabriel Moisan

Université du Québec à Trois-Rivières, Trois-Rivières, Québec, Canada

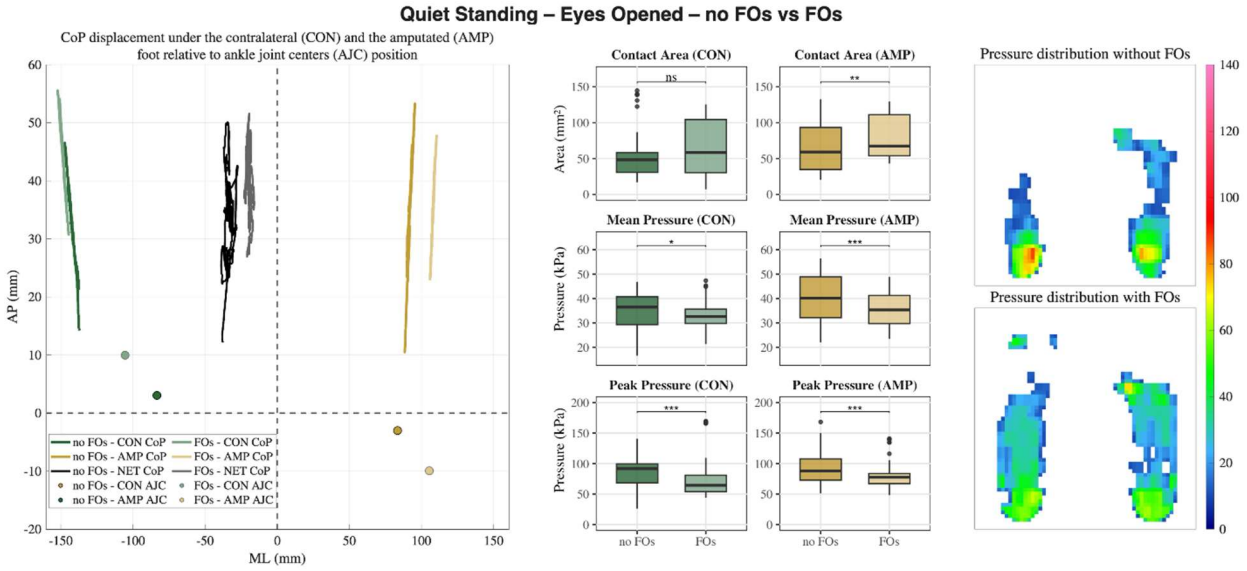
Introduction

Minor lower extremity amputation (LEA) prevalence is increasing worldwide, mainly driven by diabetes-related neuropathic and vascular complications. Minor LEAs induce biomechanical alterations affecting postural control and plantar pressure distribution, with repercussions on mobility and reamputation risks [1,2]. Foot orthoses (FOs) are commonly prescribed to redistribute loads and improve stability, but their effectiveness in this population remains unclear due to limited evidence [3]. This study aimed to assess FOs-induced changes in center of pressure (CoP) and plantar pressure.

Methods

Nine participants with a minor LEA (65.9 ± 8.9 years) performed six 15-seconds quiet-standing trials, each foot on a force plate (AMTI) while plantar pressure was recorded using instrumented insoles (Pedar-NovelX). Ankle joint centers were determined using two kinematic markers to normalize CoP. Two conditions were compared: shoe-only and with custom-FOs. Outcomes included CoP length, root mean square (RMS), range and position in anteroposterior (AP) and mediolateral (ML) directions, as well as contact area, mean and peak plantar pressure. Data were summarized using medians (interquartile) and compared using rank-based mixed-effects models assessing the two conditions while accounting for repeated measures.

Results



No significant changes were observed in CoP outcomes across AP/ML directions when using FOs ($p>0.05$), except for a reduction in CoP-ML-RMS (23.7 (21.4) to 19.3 (17.3) mm, $p=0.039$).

On the LEA side, FOs increased contact area (59.1 (58.6) to 67.4 (57.2) mm^2, $p=0.003$), while decreasing global mean plantar pressure (40.1 (16.7) to 35.3 (11.5) kPa, $p<0.001$) and global peak pressure (88.0 (34.8) to 77.6 (16.6) kPa, $p<0.001$). On the contralateral side, there was no change in contact area ($p=0.128$), but both global mean and peak plantar pressures decreased significantly ($p=0.010$ and $p<0.001$, respectively).

Discussion

FOs induced limited changes in postural sway but modified plantar pressure distribution. On the LEA side, the larger contact area redistributed pressure away from the rearfoot towards more distal regions, reducing global mean and peak values. On the contralateral side, global pressure also decreased despite any area changes, which may suggest reduced loading and improved bilateral charge distribution.

Which Uncemented Stem Designs Used in Total Hip Replacement Do Benefit From a Collar?

Prof. Michael Morlock, Dr.-Ing. Gerd Huber, Dr.-Ing. Katja Brand

Institute of Biomechanics, TUHH Hamburg University of Technology, Hamburg, Hamburg, Germany

Prof. Michael Morlock

Dr.-Ing. Gerd Huber

Introduction

A collar has been shown to be beneficial in reducing peri-prosthetic femur fractures (PPF) and revisions in uncemented total hip arthroplasty using tapered press-fit stems (revision rate at 15 years 4.8% compared to 6.1% for collarless [1]). The purpose of this study was to develop a numerical model to quantify the benefit of a collar and to apply it to different designs.

Methods

Collared and collarless CORAIL stems (DePuy Synthes) were inserted into two human cadaveric femurs until failure using a material testing machine (constant velocity 0.1 mm/s). Shear, axial compressive, tangential tensile strains and fracture loads were recorded using Digital Image correlation and compared between the two conditions. A finite element model (FEM) based on a CT scan of one femur was used to estimate numerically the same parameters for three different stem types with vs. without collar (CORAIL, EMPHASYS, ACTIS all DePuy Synthes).

Results

The collar increased axial compressive strains and reduced the critical tangential tensile strains (hoop strains), which can cause a PPF during loading for all designs [2]. This results in substantially higher loads required for a PPF (Figure 1). In the experimental part of the study, the collar increased the fracture load for the CORAIL stem by nearly 100% (6824N vs. 3465N, benefit ratio 1.96). The results of the FEM model yielded a similar tendency for the

CORAIL stem but overestimated the benefit ratio (3.37). The EMPHASYS stem showed very similar results (3.24), whereas the ACTIS stem showed a smaller benefit ratio (1.67).

Discussion

All stem designs investigated did benefit from a collar reducing the hoop strains for a given load. As a consequence higher loading can be sustained before a critical strain magnitude is reached. The ACTIS stem benefits less from the collar due to its fit-and-fill design in the metaphyseal region, which is associated with a larger width compared to the other stem designs investigated. The presented approach can be used to investigate the benefit of a collar for other uncemented stem designs.

Estimating Contact Pressure via Strap Tension in Rehabilitative Devices

Ms. Natasha Anderson, Dr. Qingguo Li

Queen's University, Kingston, Ontario, Canada

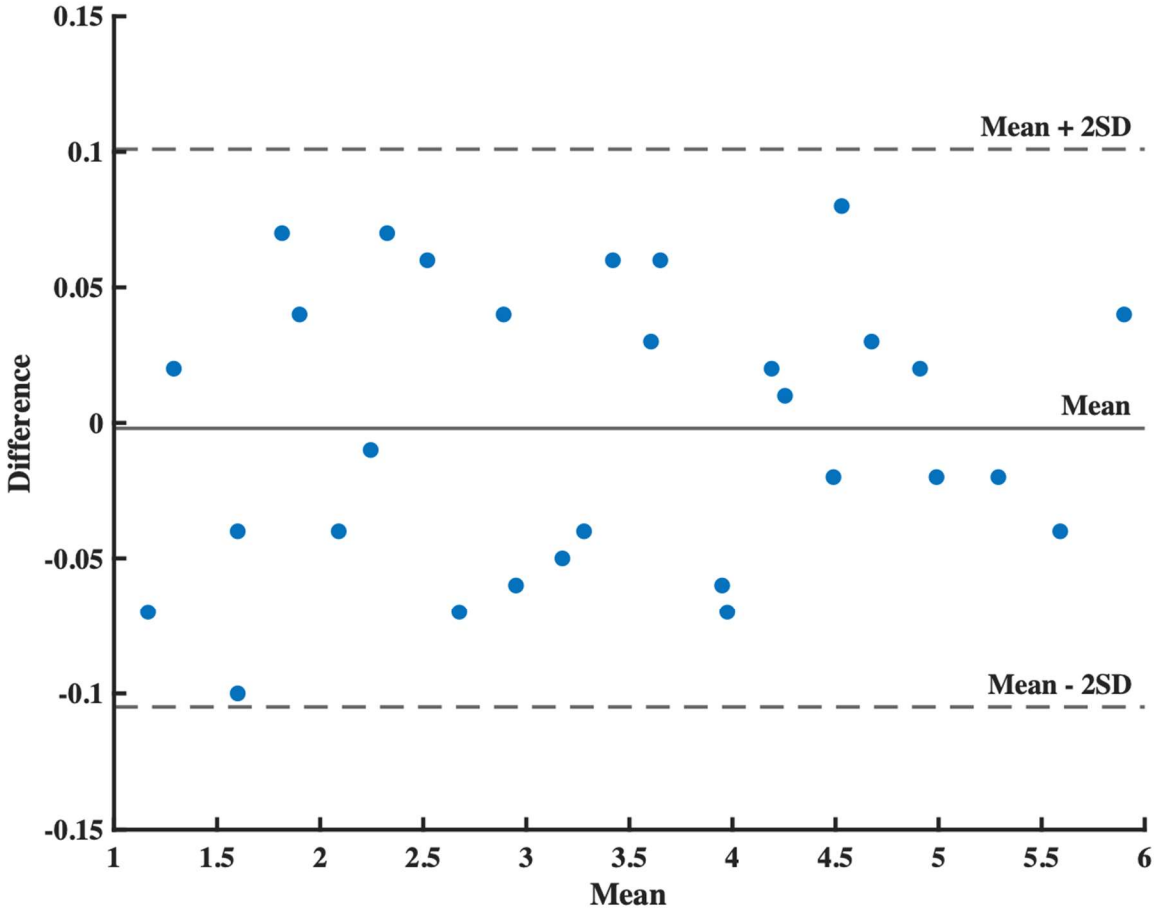
Introduction

Osteoarthritis (OA) is a common knee disease, that causes significant pain and functional impairment. Unloader braces are often prescribed to alleviate stress on the joint through strap tension. However, excessive pressure at the skin-brace interface can cause patient discomfort [1]. Direct pressure measurement methods such as force sensing resistors (FSRs) are often inaccurate, noisy, and costly [2]. This study aimed to investigate the relationship between strap tension and contact pressure, proposing strap force sensors (SFSs) as an alternative measurement approach for controlling pressure distribution around an injured knee.

Methods

Pressure and tension measurements were collected simultaneously in two experiments: first, on a curved surface apparatus (CSA) that simulated the skin, and second, with a knee brace on a participant. FSRs were placed between the skin and the brace, and SFSs on the straps. CSA testing explored the pressure-tension relationship at three locations from the direct point of load application (0, 20, 40 degrees). This was then validated in the second experiment, where direct and derived pressure measurements were compared to test for interchangeability.

Results



Tension and pressure show a linear relationship, in which proportionality depends on proximity to the point of load application. Bland-Altmann analysis showed narrow limits of agreement (full range=0.206 kPa) and no significant bias (grand mean difference=-0.002 kPa). A two-tailed t-test showed no significant differences in the means of SFS and FSR pressure values ($p=0.19$).

Discussion

The results confirm that pressure predictions from strap tension measurements are interchangeable with direct pressure measurements. These findings suggest that SFSs can be effectively used to monitor and control pressure in knee braces and other rehabilitative

devices, enabling the development of smart braces that optimize therapeutic outcomes while minimizing risks associated with excessive pressure. However, the study was performed under static loading conditions and in real-world applications, dynamic movements would alter strap tensions and pressure distributions, potentially changing the determined relationships. Further work should include comprehensive pressure mapping around the entire knee and consider more diverse conditions, to simulate real-world conditions.

Surgical Releases During Direct Anterior Approach for Total Hip Arthroplasty: Impact on Surgical Exposure

Mr. Joshua Bland MBME, Dr. John Kelly MD, Dr. Brandon Cabarcas MD, Mr. Alexander Hooke MA, Dr. Mario Hevesi MD, Nathan Flath BS

Mayo Clinic, Rochester, MN, United States

Introduction

The direct anterior approach has considerably increased in popularity among total hip arthroplasty surgeons in the past 10-15 years. Proponents of the direct anterior approach cite its muscle-sparing nature, faster recovery, and decreased risk of postoperative dislocation as potential advantages compared to more conventional posterolateral or direct lateral approaches. Obtaining adequate surgical exposure when utilizing the direct anterior approach is critical to obtaining optimal surgical efficiency and successful outcomes. The goal of this study is to investigate the biomechanical impact of sequential soft tissue releases on femoral surgical exposure during this approach.

Methods

8 fresh-frozen cadaveric hip and full lower extremity specimens (4 left hips and 4 right hips) were obtained and prepared for dissection. A direct anterior approach was carried out, and the following sequential soft tissue releases were performed: inferomedial capsular release, superior capsular release, obturator internus followed by piriformis or piriformis followed by obturator internus, obturator externus, quadratus femoris, tensor fasciae latae, sartorius, and rectus direct head. Directly following each release, the femur was lifted from an eyelet screw placed in the medial calcar of the proximal femur using a pneumatic actuator based system. During the lift, a load cell and linear potentiometer measured the vertical load and displacement.

Results

When the obturator internus was released before the piriformis, the average femur displacement at 70 N of load was over 15 mm greater than when the piriformis was released first; at 110 N of load, this difference was just over 12 mm (Figure 1). After the obturator internus and piriformis were both released, the increase in displacement per sequential release became noticeably less.

Discussion

This study and future work will be important to understand the minimum number and optimal order of soft tissue releases required to adequately access the femur during direct anterior total hip arthroplasty.

PTH Does Not Attenuate Joint Damage Due to Daily Compression of the Mouse Tibia

Mr. Omar Dervisevic, Dr. Ana Witkowski, Dr. Marjolein C. H. van der Meulen

Cornell University, Ithaca, NY, United States

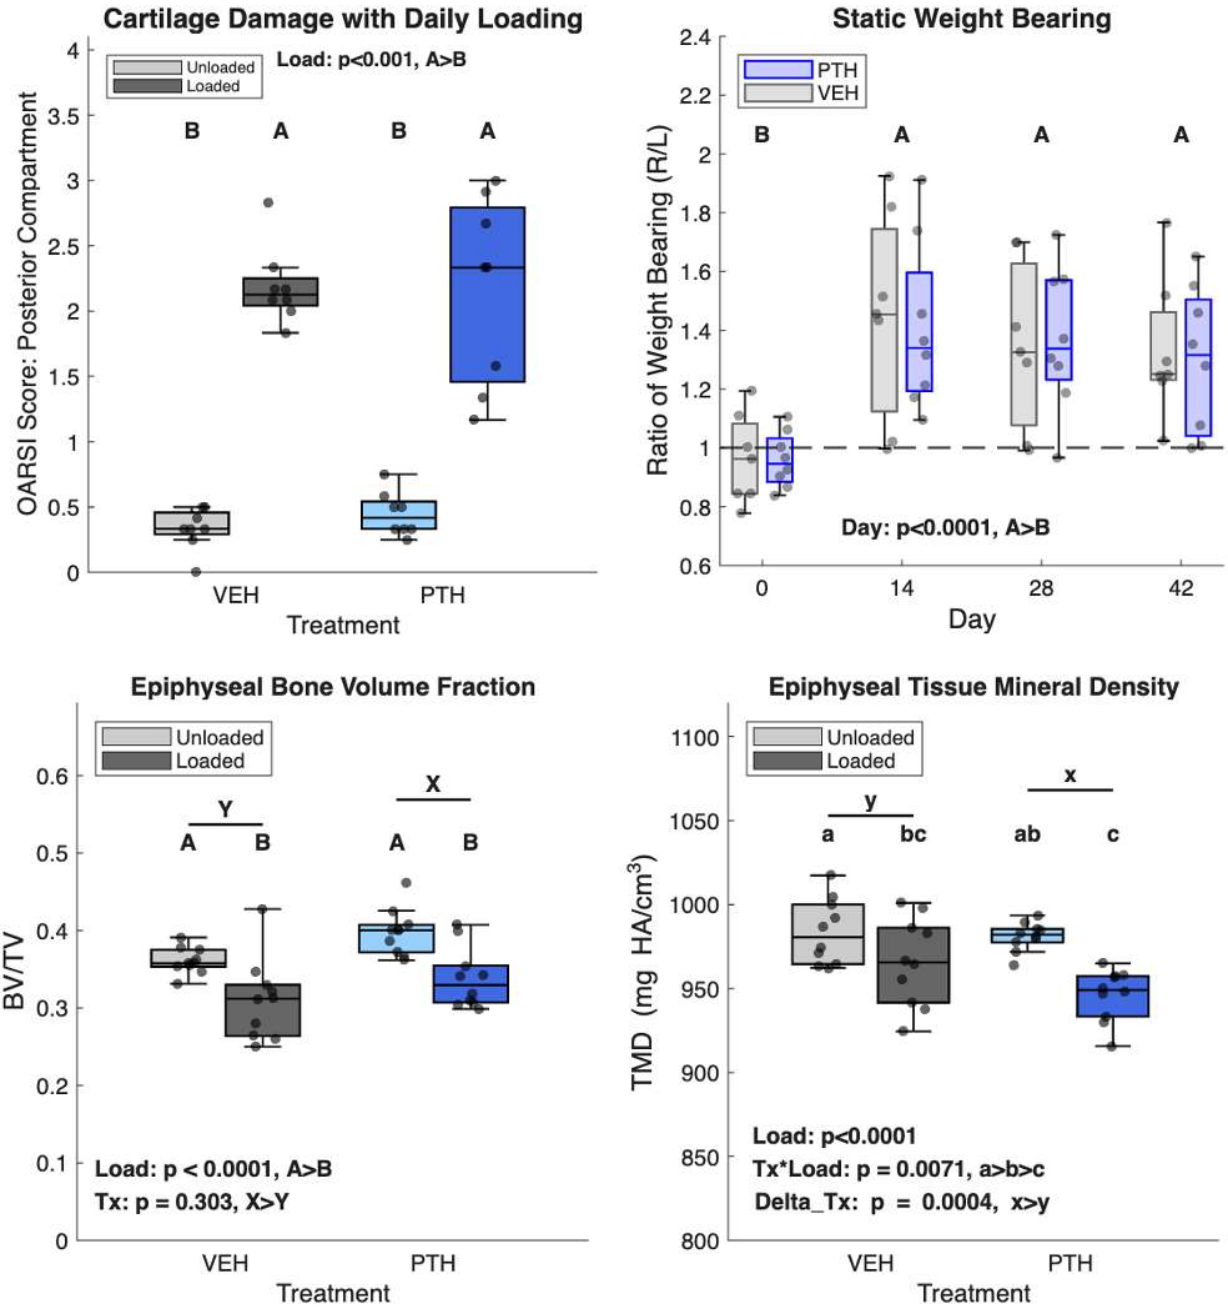
Introduction

Early-stage osteoarthritis (OA) is characterized by increased bone remodeling, motivating interest in subchondral bone–targeted therapies. Parathyroid hormone (PTH), an FDA-approved anabolic osteoporosis treatment, promotes bone formation and reduces joint degradation and pain in surgical OA models. We investigated whether PTH, administered concurrently with daily mechanical loading, could reduce pain-related behaviors, attenuate cartilage damage, and increase bone mass in a load-induced OA model.

Methods

With IACUC approval, 26-week-old male C57BL/6J mice underwent 6 weeks of daily cyclic compression (9N, 1200 cycles, 4 Hz) on the left tibia; right limbs were contralateral controls. Mice were randomized to saline (VEH, n=8–10) or PTH (40 μg/kg/day, n=8–10) administered subcutaneously 5 days/week immediately after loading. Static weightbearing was assessed biweekly. After 6 weeks, knees were collected for microCT analysis of epiphyseal cancellous bone and subchondral cortical bone, and for Safranin-O staining with OARSI scoring. Treatment and loading effects were analyzed using linear mixed-effects models with Tukey post-hoc tests.

Results



Daily loading produced significant cartilage damage, and PTH treatment did not alter the severity. Hindlimb weightbearing progressively shifted towards the control limb, and PTH did not reduce this pain-related behavior. As expected, PTH increased epiphyseal bone volume fraction (BV/TV). Loading reduced epiphyseal tissue mineral density (TMD); the reduction of TMD was greater in PTH-treated limbs.

Discussion

While PTH reduced pain and cartilage degeneration in surgical OA models, concurrent administration with compressive loading did not attenuate cartilage damage or pain behaviors. Differences across OA models may reflect differential effects of mechanical loading on cartilage biology or the interaction of PTH and loading to influence joint health.

PTH increased epiphyseal bone mass, whereas loading reduced TMD—an effect amplified with PTH—indicating enhanced remodeling under combined treatment. Despite these bone changes, joints were not protected from damage, suggesting distinct mechanisms through which PTH and loading act in joint damage. Ongoing work to define the early transcriptomic pathways will provide additional insights into the mechanisms by which PTH modulates cartilage responses to mechanical loading.

Changes in Knee Kinematic Gait Scores from Pre to Post Knee Arthroplasty

Mr. Owen Falkenham[1], Ms. Stephanie Civiero[2], Dr. Michael Dunbar[1,2], Dr. Jennifer Leighton[1,2], Dr. Glen Richardson[1,2], Dr. David Wilson[1,2], Dr. Janie Astephen Wilson[1,2]

Introduction

The adoption of markerless motion capture in clinic spaces reduces participant burden for gait capture, and therefore increases the feasibility of clinical uptake of gait biomechanics to support clinical decisions. Understanding variability in patients' gait biomechanics response to arthroplasty can support efforts toward personalized surgical decisions that account for joint-level mechanics. The purpose of this study was to develop a multivariate knee kinematics gait score that can be captured readily in-clinic, and to examine differences and subgroups of patients based on pre-to-post-surgical changes.

Methods

Overground gait kinematics were collected in an orthopaedic clinic hallway using markerless motion capture (Theia 3D; 10-Sony RX0II cameras) pre-surgery and 3-months after surgery. Stepwise linear discriminant analysis (LDA; 2% improvement step condition) combined with waveform principal component analysis [1] was used to select gait features that optimally separated pre-operative from non-OA participant gait patterns, with discriminant scores representing the severity of knee OA gait. Individuals were classified as either 'improving', 'declining', or 'stable' if their pre-to-post-surgery score change exceeded the minimal detectable change of the non-OA participants subset who underwent three repeatability trials [2]. Subgroup differences in pre-operative kinematics were evaluated with ANOVA or Kruskal-Wallis tests, and where appropriate, with a Tukey HSD assessment (α=0.05).

Results

Fifty-three patients with advanced knee OA were included (F/M: 35/18; age = 63 +/- 9.6; BMI = 34 +/- 7.5). There were no significant group-level score changes pre-to-post-surgery. Significantly higher pre-operative gait scores (i.e. less severe gait) were found in those declining than those improving ($p<0.01$), dominated by significantly higher knee flexion/extension ranges of motion (PC2) during walking ($p<0.05$). No significant differences in anthropometrics or demographics were found among subgroups.

Discussion

These results highlight the variability in knee function response to arthroplasty among patients, and how it links to pre-operative gait function. Accounting for this variability in personalized decisions can have important implications for clinical outcomes, which we will characterize with further longitudinal assessment of clinical and gait recovery trajectories.

Physical Activity Fragmentation in Patients with Knee Osteoarthritis before and after Arthroplasty

Mr. Owen Lindsay MSc[1], Mr. Adam Dorrance BEng[2], Mr. Arsh Singh BEng[1], Dr. Janie Wilson PhD[1,3], Dr. Jennifer Leighton MD[1,3], Dr. Michael Dunbar MD[1,3], Dr. Glen Richardson MD[1,3], Dr. David Wilson MD[1,3]

[1]Dalhousie University, Halifax, Nova Scotia, Canada. [2]Dalhousie, Halifax, Nova Scotia, Canada. [3]Nova Scotia Health, Halifax, Nova Scotia, Canada

Introduction

Physical activity monitoring in knee osteoarthritis (OA) traditionally emphasizes volume-based metrics, yet patients accumulating similar daily steps may exhibit markedly different movement patterns relevant to disease severity and surgical recovery. Activity fragmentation, quantified as the Active-to-Sedentary Transition Probability (ASTP), reflects the probability of transitioning from activity to rest. In aging populations, higher fragmentation is associated with adverse health outcomes [1,2] independent of activity volume. Despite potential as a clinical indicator, fragmentation remains largely uncharacterized in knee OA. This study examined relationships between ASTP and clinical status in end-stage knee OA and evaluated its responsiveness to change following arthroplasty.

Methods

Patients with end-stage knee OA undergoing knee arthroplasty surgery (KAS) wore lower-leg inertial measurement units (Axivity AX6, 100Hz) continuously for seven days pre - and 12-months post-surgery. Mean amplitude deviation thresholds (0.0167g [3]) classified one-minute epochs as active or sedentary. ASTP was calculated as the inverse of mean active bout length, expressed as a percentage. Patient-reported outcome measures (PROMs) included the Oxford Knee Score (OKS), Numerical Pain Rating Scale (NPRS), and EQ-5D-5L. Pearson correlations assessed pre-operative associations between ASTP and PROMs (n=43), while paired t-tests compared pre- to post-operative changes in ASTP (n=14) and PROMs (n=10).

Results

Pre-operatively, ASTP showed no significant correlations with NPRS ($r(41) = 0.23$, $p = 0.14$), EQ-5D-5L ($r(41) = -0.20$, $p = 0.19$), and OKS ($r(41) = -0.19$, $p = 0.21$). ASTP remained unchanged from pre-surgery (M=46%, SD= 10.8) to 12-months post-surgery (M=43.4%,

SD=10.4; t(13)=1.35, p=0.20). Conversely, significant improvements occurred in NPRS (t(10)= 4.9, p<0.001), EQ-5D-5L (t(10)= -6.0, p<0.001), and OKS (t(10)= -7.9, p<0.001).

Discussion

Activity fragmentation demonstrated limited sensitivity to self-reported clinical status and surgical intervention in end-stage knee OA, despite patient-reported improvements post-arthroplasty (Figure 1). Compared to similarly aged adults (M=20-34%) [2], fragmentation levels were elevated both before (M=46%) and after surgery (M=43.4%), suggesting that ASTP may reflect a dimension of OA not captured by PROMs or corrected by joint replacement.

Images (Optional)

Introduction

The current focus of the KneeHub project is on enhancing reproducibility and credibility in computational knee modeling through the development of consensus-based workflows [1]. Models, typically developed with anatomy from imaging, are calibrated to available experimental data. However, wide variations in reported ligament stiffness and reference strain values lead to a broad search space. The objective of this study is to quantify bounds for ligament properties from the literature and to assess how sensitive an uncalibrated model is to these variations, with the potential to inform subject-specific tuning.

Methods

A representative model of the knee was developed per the consensus-based workflow. Bone, cartilage, and ligament structures were segmented from MR images. Ligaments were modeled using multiple bundles of one-dimensional nonlinear spring elements. To define the design space for optimization, ligament properties describing the force-elongation data were aggregated from various studies [2-6]. To explore sensitivity, an initial finite element model (uncalibrated) was subjected to a simulated anterior tibial translation test with varying ACL bundle stiffness and reference strain at minimum, mean, and maximum levels from the literature.

Results

Mean, lower, and upper bounds derived from the literature are summarized (Figure 1) and represent plausible initial estimates for developing a running model. An initial sensitivity study explored changes in the ACL properties. Variations in the reference strain produced significantly larger differences in the kinematics (4.6 mm difference in anterior tibial translation between upper and lower bounds, Figure 1) than variations in stiffness (0.7 mm difference).

Discussion

Ligament properties in the literature are highly variable and known to significantly influence knee joint mechanics. When developing a knee model for a clinical context of use, data are often limited. In vivo and intraoperative measurements of joint laxity may be available, but direct measurement of ligament properties is not possible. The literature values and their bounds ensure physiological accuracy in patient-specific calibration of models and/or enable sensitivity quantification when calibration is not possible.

Images (Optional)

Ligament	Number of Springs	Stiffness [N/mm] mean (lower, upper)	Reference Strain mean (lower, upper)
ACL	4	118.5 (189.2, 47.0)	0.971 (1.05, 0.90)
PCL	4	91.8 (219.0, 4.7)	0.975 (1.10, 0.76)
MCL	3	59.9 (169.4, 0.0)	1.010 (1.08, 0.80)
LCL	1	63.5 (197.0, 7.8)	0.974 (1.05, 0.97)

Paradoxical Kinematics at the Tibial Plateau After Total Knee Arthroplasty Does Not Necessarily Indicate Non-Physiological Kinematics at the Anterior Articular Surface

Dr.-Ing. Philippe Moewis[1], Dr. Rainald Ehrig[2], MS Leonie Krahl[1], Dr. Adam Trepczynski[1], PD.-Dr. Hagen Hommel[3], Prof. Georg Duda[1]

[1]Julius Wolff Institute, Berlin Institute of Health at Charité – Universitätsmedizin Berlin, Berlin, Berlin, Germany. [2]Zuse Institut Berlin, Berlin, Berlin, Germany. [3]Krankenhaus Märkisch-Oderland, Wriezen, Brandenburg, Germany

Introduction

Total knee arthroplasty (TKA) is a well-established and successful treatment for advanced osteoarthritis of the knee. However, approximately 10% of patients remain dissatisfied with the postoperative outcome. Anterior knee pain remains as one of the most cited causes of patient's dissatisfaction after total knee arthroplasty, with non-physiological knee joint kinematics patterns during flexion and patellar maltracking being frequently associated with it. The analysis of in vivo knee joint kinematics after TKA can provide objective insights into how specific TKA-design characteristics influence motion patterns—both at the anterior articular surface and at the tibial plateau.

Methods

Results

All TKA-systems demonstrated some degree of anterior translation in the medial compartment. These compartment-specific translation patterns resulted in an external rotation of the femoral component relative to the tibia (Figure-1B). The anterior aspect of the femoral component displayed a posterior translation toward maximum flexion. Both distal and anterior motion patterns produced comparable overall external rotation across all implant groups.

Discussion

Although a pronounced anterior translation in the medial compartment and a reduced posterior rollback of the lateral condyle were observed, phenomena that are typically considered as paradoxical kinematics, a consistent posterior translation of the anterior femoral aspect was also present.

While this posterior translation represents an indirect indicator of patellar motion, the combination of this motion with the femoral external rotation on the tibia plateau may potentially contribute to improved patellar-tracking. Accurate interpretation of knee joint kinematics may therefore assist in selecting the most appropriate TKA-system to properly address the specific needs of the wide range of individual patients.

OpenSim JAM-based Subject-Specific Standardized Biomechanical Simulations of ACL Forces during a Standardized Test

Mr. Pratham Singh[1,2], Mrs. Anoosha Pai[2], Dr. Marianne Black[2], Dr. Katherine A. Young[2], Dr. Seth Sherman[2], Dr Constance Chu[2], Dr. Brian Hargreaves[2], Dr. Garry Gold[2], Dr. Feliks Kogan[2], Dr. Akshay Chaudhari[2], Dr. Timothy Burkhart[1], Dr. Anthony Gatti[2]

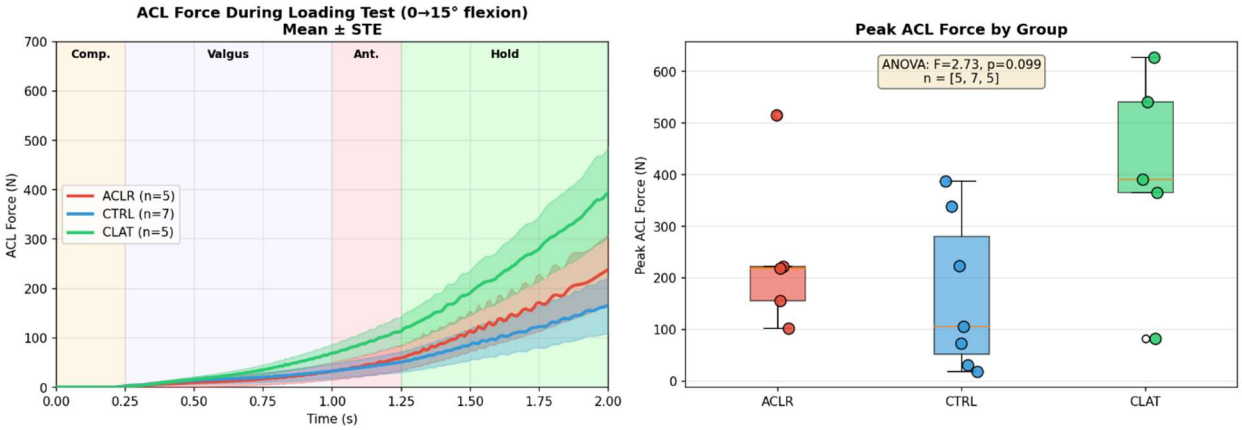
[1]University of Toronto, Toronto, ON, Canada. [2]Stanford University, Stanford, CA, United States

Introduction

Anterior cruciate ligament (ACL) injuries remain a challenge clinically, with reconstruction outcomes varying across patients. MRI imaging and computational modeling offers a powerful approach to understanding the biomechanical factors influencing ACL loading. Biomechanical simulations have identified bone features that are correlated to ACL loading during a standardized test [1]. The purpose of this study was to simulate the same standardized test using an open-source simulation pipeline comparing ACL forces in three groups: ACL-reconstructed (ACLR, n=5), contralateral limbs of ACL-injured patients (CLAT, n=5), and healthy controls (CTRL, n=7).

Methods

We used an automated MRI segmentation and neural shape modeling pipeline to generate 12 degree of freedom knee models (6 tibiofemoral, 6 patellofemoral) from 3D DESS knee MRIs. Forward dynamic simulations were performed to simulate an ACL injury mechanism using OpenSim Joint Articular Mechanics (JAM) toolkit [2]. OpenSim JAM models cartilage-cartilage contact, enabling simulation of contact pressures and ligament strains and forces. The loading protocol flexed the knee from 0 to 15° of flexion over 2 seconds while ramping up tibial compression (0-100N from 0-0.25s), a valgus moment (0-8Nm from 0.25 to 1.0s), and an anterior shear force (0-30N from 1-1.25s). After the ramp, each force/moment was held constant. The total ACL force over 12 strands representing the two ACL bundles was summed. Time histories of the ACL forces and the peak ACL force was compared between groups.



Results

During the simulation, ACL forces gradually increased from the start of the valgus moment (0.25s) until the end of the simulation. One-way ANOVA did not reveal statistically significant differences in peak ACL force between groups ($p>0.05$); the contralateral group had the greatest ACL force.

Discussion

The results show that when applied using an open-source toolkit, previously developed standardized simulations of ACL forces gradually stress the ACL. Our peak forces were higher than the previous investigation (~50-600N vs. ~25-200N) [1]. Counter to our hypothesis, the CLAT group had the highest forces. Future work will unlock tibial-meniscus degrees of freedom, explore alternative ACL reference strain normalization techniques, and increase the sample size.

Dose-Response Effect of Toe Spring on the Running Biomechanics of Foot-Ankle Complex

Associate Professor Qichang Mei[1,2], Ms Chen Liu[1]

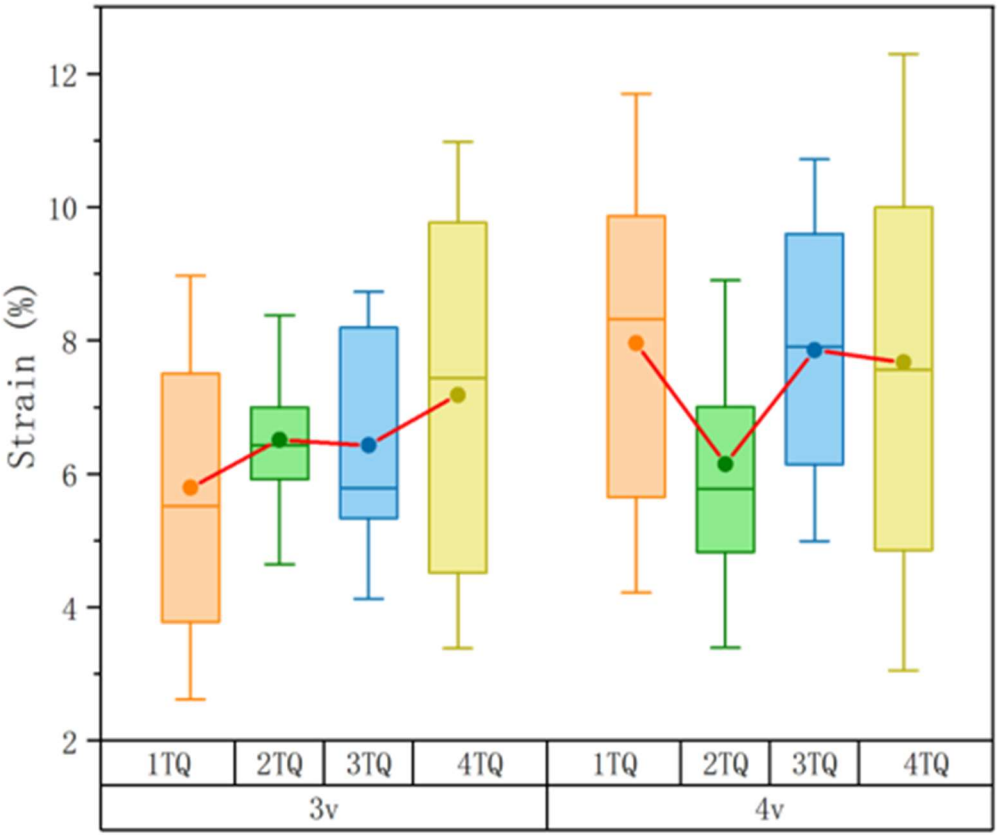
[1]Ningbo University, Ningbo, Zhejiang, China. [2]The University of Auckland, Auckland, Auckland, New Zealand

Introduction

Toe spring, featured by the upward curvature in the forefoot region, is a key structure in the footwear that facilitate the forward rolling and propulsion during push off of stance. However, the biomechanical effects of varying toe-spring angles in the AFT (advanced footwear technology) shoes at different running speeds remain unclear. Prior studies link forefoot stiffness and plantar tissue strain to propulsion efficiency and overuse injuries, underscoring the need for optimal structural design. This study investigates how toe-spring angle variations affect the foot biomechanics during jogging and racing.

Methods

Eighteen elite runners performed jogging (3.3 m/s) and race (4.0 m/s) running in a motion capture lab while collecting marker trajectories and ground reaction force. Running shoes with systematically developed toe-spring angles (TQ1: 28.6°, TQ2: 27.4°, TQ3: 26.1°, TQ4: 24.9°) was employed with consistent features and properties across all footwear. Joint kinematics (IK), kinetics (ID), Achilles tendon force (static optimization), and plantar fascia strain (point kinematics) were analysed using OpenSim based musculoskeletal modelling. Two-way repeated-measures ANOVA and statistical parametric mapping were applied for statistical analysis.



Results

The increased running velocity from 3.3 m/s to 4.0 m/s significantly elevated peak Achilles tendon force, with TQ1 showing the largest increase (+0.55 ± 0.21 BW) and TQ2 the smallest (+0.06 ± 0.27 BW). PF strain amplitude generally increased from 3.3 m/s to 4.0 m/s, with the largest percentage rise observed in TQ1 (+37.4%) and TQ3 (+22.2%). In contrast, TQ2 showed a slight decrease (–5.6%) (Figure 1).

Discussion

In this study, moderate designs (TQ2, TQ3) demonstrated superior regulation of plantar fascia strain and Achilles tendon loading, reducing excessive peaks at higher speeds. Subtle differences in toe-spring may contribute to the mechanical variations by altering roll-over mechanics and anterior lever arm function. These findings emphasize the importance of optimizing toe-spring design to balance performance benefits with reduction of injury risks.

Online Sensorimotor Control Pre- and Post-Fatigue Following ACL Reconstruction

Mr. Quinn Mulligan, Dr. Timothy Burkhart

University of Toronto, Toronto, Ontario, Canada

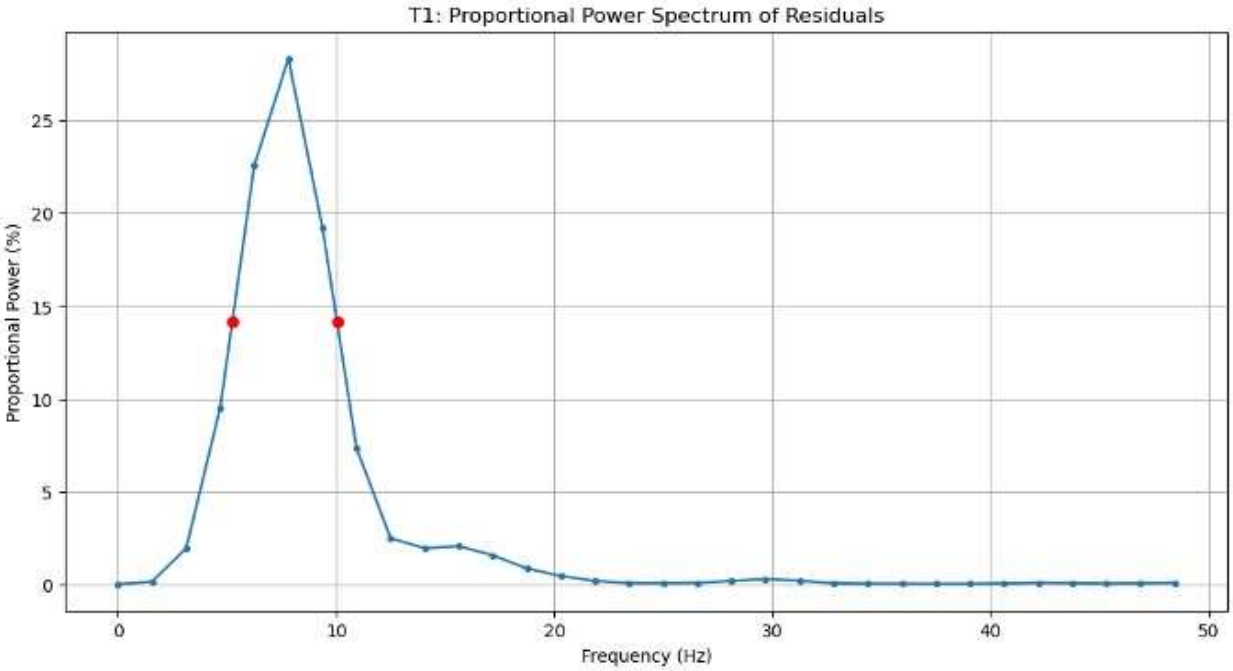
Introduction

ACL reconstruction (ACLR) patients often present with impaired sensorimotor function of the lower extremity, characterized by impaired proprioception, inhibition of the quadriceps, and increased excitation of the hamstrings of the reconstructed limb [1]. Sensorimotor impairments may compromise dynamic knee stability and contribute to the increased risk of secondary injury following primary ACLR [2], especially in fatigued conditions [3]. Therefore, the purpose of this study is to quantify sensorimotor control in ACLR patients pre- and post-fatiguing exercise.

Methods

Preliminary data has been collected on two ACLR patients (one male, one female), and five healthy controls (two male, three female) with the goal of recruiting 18 of each. Inertial measurement units (IMUs; Xsens, Enschede, NL) placed above the midfoot sampled acceleration data at 100Hz. A leg extension task was completed before and after a fatigue protocol consisting of isometric quadriceps contractions, vertical jumps, and high knees at 140BPM. Electromyography (EMG) data of the quadriceps were collected bilaterally, and the real-time mean power frequency (MnPF) was monitored for signs of fatigue, defined as a 10% decrease from baseline. Accelerations from the leg extensions in both the X and Z axes were fit with a fifth-order polynomial and the residuals, which represent trajectory-correcting accelerations, were isolated and converted to the frequency domain using a fast Fourier Transform. The proportional power spectrum (pPower) of the residuals was computed (Fig. 1), and the relative power of corrective accelerations at specific frequencies (i.e., latencies) were assessed as a representation of online sensorimotor control processes.

Results



There were no significant differences between groups or fatigue condition for frequency content nor distribution in the X and Z axes ($p > 0.05$).

Discussion

Online sensorimotor control does not appear to be affected by ACLR or fatigue in this preliminary sample This initial work suggests that sensorimotor control mechanisms of the

lower extremity may remain functional, and the integration of proprioceptive information is unimpaired following ACL injury and reconstruction.

Fatigue-Induced Changes in Jumping Mechanics Following ACL Reconstruction

Mr. Quinn Mulligan, Dr. Timothy Burkhart

University of Toronto, Toronto, Ontario, Canada

Introduction

Following ACL reconstruction (ACLR), patients have an increased susceptibility to fatigue, as neuromuscular impairments are exacerbated and kinematics deteriorate at a greater rate compared to healthy controls [1]. It is possible that the fatigue-induced kinematic changes may contribute to the six-fold increase in risk of injury following primary ACLR [2]. Therefore, the purpose of this study is to quantify jump kinematics pre- and post-fatigue in ACLR patients and healthy controls.

Methods

Preliminary data has been collected on one male ACLR patient, and five healthy controls (two male, three female) with the goal of recruiting 18 of each. Knee valgus angles were quantified using a set of seven inertial measurement units (IMUs; Xsens, Enschede, NL) sampling at 100Hz. Participants were instrumented with six electromyography (EMG) sensors placed bilaterally over the quadriceps muscles. Knee valgus angles (KVA) were computed during three vertical jumps before and after a fatiguing exercise circuit at initial contact, and 200ms post-contact. The circuit was completed until a 10% decrease in the mean power frequency (compared to the start of the first cycle) of the EMG signals was detected.

Results

Results At initial contact, mean KVA of the ACLR participant increased post-fatigue from 24.2º to 30.2º, and 19.2º to 24.4º in the involved and non-involved limbs, respectively, compared to a decrease from 27.2º (± 13.3) to 23.5º (± 9.6) of the dominant limb of the healthy controls. At 200ms post-contact, KVA increased from 71.6º to 83.4º and 73.4º to 86.6º in the involved and non-involved limbs, respectively, compared to a decrease from 70.3º (± 10.9) to 68.4º (± 6.8) of the dominant healthy control limb. These differences were non-significant ($p > 0.05$).

Discussion

This initial work shows that the KVAs of the ACLR participant increased following fatiguing exercise, whereas mean KVAs decreased in healthy controls. Greater KVAs have been

associated with higher risks of injury [3], suggesting a potential fatigue-induced decrease in movement quality.

Stress-Shielding Reduction and Fatigue Reliability: Topological Optimization of a TPMS Hip Prosthesis

Ms. Roberta Cromi[1], Ms. Michela Paola Miuccio[1,2], Mr. Mattia Concari[1,2], PhD Francesca Berti[1], Prof. Stefano Foletti[2], Prof. Tomaso Villa[1]

[1]Department of Chemistry, Materials and Chemical Engineering "Giulio Natta" (LaBS) – Politecnico di Milano, Milan, Italy, Italy. [2]Department of Mechanical Engineering (MetaMAT Laboratory) – Politecnico di Milano, Milan, Italy, Italy

Introduction

Total hip arthroplasty remains the gold-standard treatment for several hip pathologies, yet over 35% of implants encounter stress-shielding [1]. Anatomical stems enhance physiological load transfer; however only the advances in architected materials, particularly triply periodic minimal surface (TPMS) structures, allow microscale tailoring of mechanical properties [2]. In this context, this work aims to design a stem balancing stiffness reduction and fatigue resistance by optimizing the TPMS density distribution.

Methods

CT scans of an adult female patient's femur were used to reconstruct the geometry and map the bone's Young modulus (E). A titanium anatomical stem was designed with a core TPMS zone, while preserving both neck and distal end solid, for mechanical and surgical compatibility. Diamond, Gyroids and Schwartz sheet-based TPMS were computationally tensile-tested to assess their E-tensile fatigue strength ratio at multiple density level. Stress-shielding reduction and fatigue resistance were assessed both under a 70kg physiological gait [3] and ISO7206-4 loading configuration. Three stem designs were compared: bulk, homogeneous TPMS-distribution (H-TPMS) and optimized TPMS-distribution (O-TPMS). The optimization algorithm was based on [4] (Fig.1): starting from a H-TPMS, given the inputs and constraints, the algorithm distributes TPMS density obtaining an O-TPMS solution that optimizes fatigue performance under ISO loading condition.

Results

The CT-based mapping resulted in a E range of 0.5-22GPa. The H-TPMS stem, even with a non-ideal Diamond relative density of 0.5, achieved a stress-shielding reduction higher than 60%. However, regarding fatigue resistance, H-TMPS failed in both tensile and compressive regions under ISO loading conditions: to ensure compliance to the standard, the O-TPMS solution included high density subzones, corresponding to solid at manufacturing level, partially compromising the stiffness reduction request.

Discussion

A homogenized TPMS-distribution within a partially porous hip stem is proper in terms of bone loss reduction, yet the structure undergoes fatigue failure. A TPMS-optimized density distribution ensures ISO7206-4 fatigue resistance; nevertheless, the inclusion of quasi-solid subzones limits its potential to achieve substantial stress-shielding reduction.

Images (Optional)

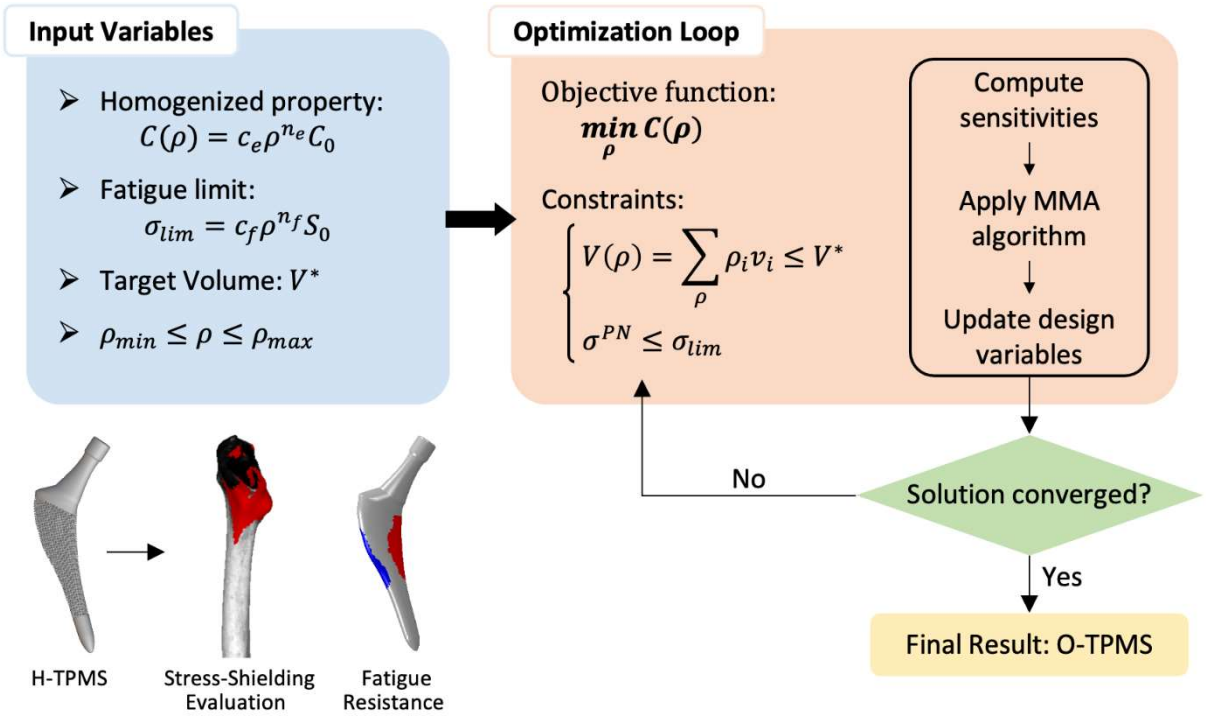

Fig.1: Using the optimization MMA method, the algorithm updates elements' densities -modeled as TPMS- to achieve minimum compliance under target volume and fatigue-stress limit constraints.

Introduction

The patellar tendon (PT), a thick fibrous structure connecting the patella to the proximal tibia, enables extension of the knee [1]. Loss of the PT insertion during endoprosthetic reconstruction can compromise the knee extensor mechanism, negatively impacting knee function [2]. Current surgical interventions include reattaching the PT to a metal prosthesis [3]; however, achieving a robust interface between soft-tissue and metal remains challenging [4]. We propose a biosynthetic endoprosthesis that incorporates bone and ligament, acting as a bridge between the PT and prosthesis. Our objective was to validate surgical feasibility in a cadaver and then identify the first point of mechanical failure under load.

Methods

We designed the prosthesis (fig.1A) to house a bone block in the antero-proximal aspect of the tibial component and conducted a cadaveric dissection to verify prosthesis morphology. We then harvested i) the vascularized medial femoral condyle (MFC) bone block with the medial collateral ligament (MCL) intact and ii) the patella with the PT intact (fig.1B). The MFC was screwed onto a stainless-steel bracket to simulate attachment of bone to the prosthesis (fig.1C). The PT and MCL were whipstitched together. The patella was potted in polymethyl methacrylate, and a manipulator robot (KR-210, KUKA) pulled on the construct until failure.

Results

The implant fits within the geometric envelope of a standard knee endoprosthesis. The MFC bone block was successfully harvested with its vasculature intact and secured to the bracket (fig.1D). The MCL-to-PT attachment failed first at 30.2 mm displacement with a load of 160.1 N from suture rupture, while the tissue remained intact (fig.1E). No failure was observed in the MFC-to-bracket or MCL-to-MFC interfaces.

Discussion

The tendon-ligament rupture occurred at a relatively low force, demonstrating the importance of long-term healing between the MCL and PT in supporting sustained quadriceps loading. Robustness of the MFC bone block through screw-anchoring indicates this may have sufficient primary stability as a landing pad for soft-tissue attachment. Next steps will focus on understanding relative strength of MFC-to-implant and MCL-to-MFC interfaces.

Ex Vivo Study on Porcine Knees under Physiological Loads to Evaluate an Innovative Synthetic Anterior Cruciate Ligament Augmentation

M.Sc. Saskia Hesse[1], M. Sc. Julietta Bandel[1], B. Sc. Alina Farchmin[1], Dr. Ing. Benedict Bauer[1], Dr. med. Sabine Roth[2], Mr. Rald Groven[2], Mr. Deniz Özman[2], M. Sc. Viktoria Kiaulehn[2], Dr. Ing. Maximilian Praster[2], Univ.-Prof. Thomas Gries[1], Prof. Dr. med. Christian Weber[2], Dr. Ing. Caroline Emonts[1]

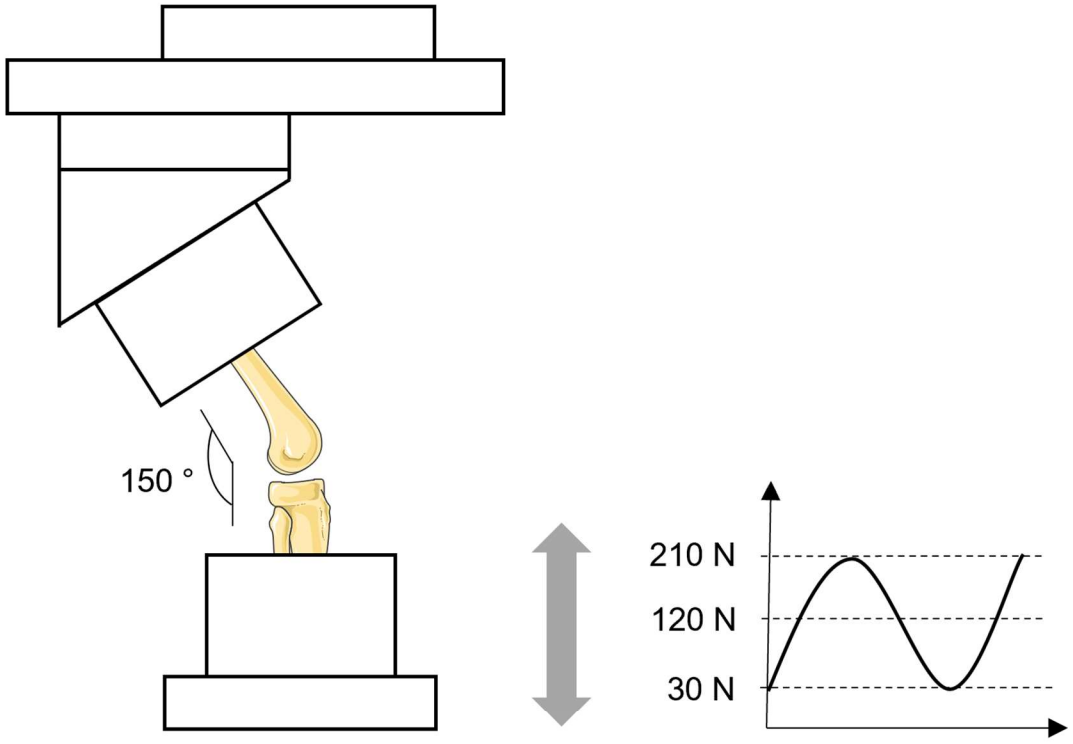
[1]Institut für Textiltechnik of RWTH Aachen University, Aachen, NRW, Germany. [2]Department of Orthopaedic, Trauma and Reconstructive Surgery, RWTH University Hospital, Aachen, NRW, Germany

Introduction

Nowadays autologous implants are still the most common used anterior cruciate ligament (ACL) replacements. Previous work has shown the great potential of braided structures regarding their mechanics [1]. The aim of this study is to perform an ex vivo study to evaluate the performance of these structures under physiological conditions and cyclical loading in porcine knees.

Methods

The scaffolds are made of Poly-e-caprolactone (PCL) filaments which are 3D-braided into a multilayered interlaced structure. The porcine knees are prepared by removing tissue except menisci and the cruciate ligaments. The study includes four groups (five samples each): native tissue, the reconstructed native ligament, the scaffold as augmentation and the scaffold as total replacement. The testing protocol includes cyclical and load-to-failure tests and enables a comparison of each knee with itself before and after surgery. The cyclical test simulates 10,000 steps per knee with 1 Hz and a loading range of 30 N to 210 N [2]. The load-to-failure test has a testing speed of 40 mm/min.



Results

Each knee is tested with native tissue first and then according to the testing group configuration. The native tissue shows no plastic deformation during the cyclical testing and maximal loads over 2000 N during the load-to-failure. The focus of further experiments lays in analyzing the elastic and plastic deformation of the scaffolds during the cyclical testings and evaluating the stress-strain-behavior of the load-to-failure.

Discussion

This ex vivo study contains cyclical and load-to-failure tensile testings with native tissue and scaffold variations. This evaluates the initial mechanics of the scaffolds under physiological load and further parameters as scaffold-bone friction. Furthermore, it shows the interaction of fixation systems with the innovative scaffold and their loading limit. Due to a high degree of individuality of each porcine knee this study has some limitations. These are minimized by preventing multiple freezing cycles in preparation and documentation of variations due to natural variations in knee geometry.

Inappropriate Reference Configuration Leads to Overestimation of ACL Strain:Evidence from High-Resolution 3D Scanning in Robotic Knee Loading Tests

Dr. Satoshi Yamakawa PhD[1], Dr. Shoji Konda PhD[1], Dr. Tomoya Ono MD, PhD[2], Dr. Jumpei Inoue MD, PhD[2], Dr. Issei Ogasawara PhD[1], Dr. Tomoki Ohori MD, PhD[1], Dr. Akira Tsujii MD, PhD[1], Prof. Ken Nakata MD, PhD[1], Prof. Volker Musahl MD[2], Prof. Richard E. Debski PhD[2]

[1]Graduate School of Medicine, The University of Osaka, Suita, Osaka, Japan. [2]University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Because the non-uniform structure of the anterior cruciate ligament (ACL) makes experimental stress distribution analysis difficult, strain analysis—used as an indirect indicator of stress—has been widely employed to assess its mechanical function. However, although the reference configuration is fundamental to strain-based deformation analyses, its definition has remained ambiguous in many ACL studies. Without a consistent and mechanically reasonable definition of the initial ACL length, interpretations of ligament behavior may be substantially distorted.

Thus, the objective was to examine the effect of the choice of reference configuration on the ACL strain distribution by combining a robotic testing system with a hand-held 3D scanner—a novel approach that enables high-resolution analyses.

Methods

Porcine knees (n = 4) were mounted on a robotic testing system at 30° of flexion, and two reference configurations were defined: the unloaded neutral position (Unloaded group) and the position under 10 N anterior tibial loading (ATL group), selected to impose modest pretension and create a physiologically reasonable initial state. After applying 50 N anterior tibial loading as the main test, the resulting knee position was recorded. These two reference configurations and the 50 N loading condition were then reproduced following removal of the medial femoral condyle, and the ACL in each condition was scanned using a hand-held 3D scanner (Figure). ACL strain distribution was calculated from the deformation between each reference configuration and the loaded condition.

Results

Both groups showed higher fiber strain near the attachment sites than in the mid-substance; however, the ATL group exhibited markedly smaller strain values, with

differences reaching approximately fivefold in Unloaded group (5.6%) compared to ATL group (1.1%).

Discussion

That such a small load difference (10 N) produced such a large discrepancy in strain demonstrates how easily strain can be overestimated when the reference configuration lacks adequate pretension. Although previous studies have used full extension as the reference configuration, the present findings suggest that additional loading is necessary to achieve an appropriate initial state. Collectively, these results highlight the importance of defining the initial ACL length under a physiologically meaningful level of loading to avoid misinterpretation of ligament mechanics.

Non-Uniform Strain Distribution of the Anterior Cruciate Ligament Under Pivot Shift loading: A Three-Dimensional Surface Scanning Study in Cadaveric Knees

Dr. Shoji Konda PhD[1], Dr. Satoshi Yamawaka PhD[1], Dr. Tomoya Ono MD, PhD[2], Dr. Jumpei Inoue MD, PhD[2], Dr. Issei Ogasawara PhD[1], Dr. Tomoki Ohori MD, PhD[1], Dr. Akira Tsujii MD, PhD[1], Prof. Ken Nakata MD, PhD[1], Prof. Volker Musahl MD[2], Prof. Richard Debski PhD[2]

[1]Graduate School of Medicine, The University of Osaka, Suita, Osaka, Japan. [2]University of Pittsburgh, Pittsburgh, PA, United States

Introduction

The anterior cruciate ligament (ACL) is thought to restrain complex multi-planar knee loads, however, the three-dimensional (3D) distribution of the non-uniform surface strain has not been fully characterized. This study determined the principal strain distribution and orientation in the ACL during simulated pivot shift loading in a cadaveric knee using 3D surface scanning.

Methods

Two fresh-frozen cadaveric knees were prepared, and the ACL was exposed by removing the medial femoral condyle and soft tissues. Small reference dots were drawn along the ACL fibers, then the knee was mounted on a robotic joint testing system with the knee fixed at 0 degree of flexion. A 10 N anterior drawer force was applied as a pre-loading reference condition, and a combined tibial internal rotation and valgus torque (pivot shift loading) was then applied. Under both conditions, the shape and texture of the ACL were captured with a hand-held 3D scanner. The coordinates of reference dots were semi-automatically extracted from the scanned models using color thresholding and used to construct triangular surface meshes. Green–Lagrange strain tensors were computed for each element, and the magnitude and direction of the maximum principal strain were obtained by eigen decomposition and mapped onto the ACL surface.

Results

Across all surface elements of the two knees, maximum principal strain ranged from −0.0139 to 0.0970 (median 0.0261, mean 0.0311 ± 0.0245). In the femoral and tibial attachment regions, maximum principal strain was higher and decreased with increasing distance from the attachment, and the corresponding eigenvectors were primarily aligned with the macroscopic fiber orientation (Figure 1). In the tibial-side mid-substance, principal strains were also higher, but the eigenvectors of maximum principal strain tended to be oriented approximately perpendicular to the macroscopic fiber direction (Figure 1).

Discussion

These findings indicate that pivot shift loading does not produce a uniform axial elongation of the ACL but rather regionally distinct deformation patterns. The observed differences in principal strain magnitude and direction between the attachment regions and the tibial-side mid-substance may be due to the interaction between regional fiber organization and multi-planar loading.

Images (Optional)

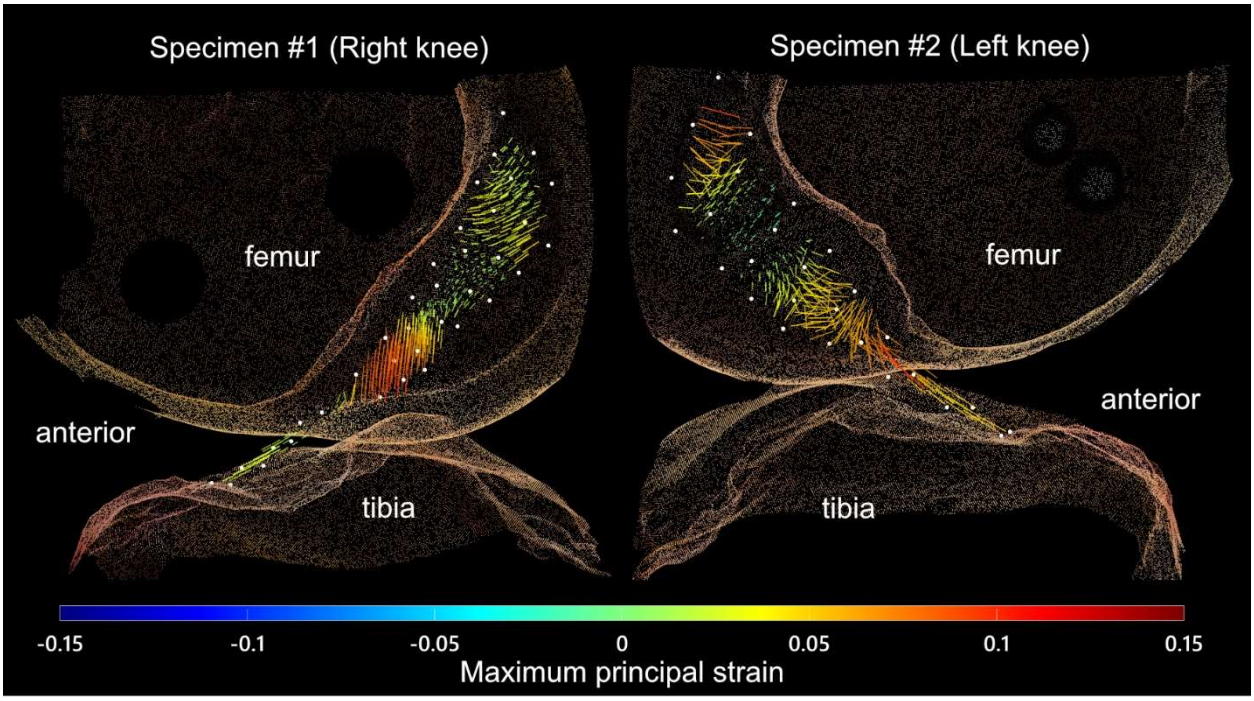

Figure 1. Maximum principal strain magnitude and direction on the ACL surface during pivot-shift loading in two cadaveric knees at 0° of flexion. Colored line segments indicate the direction of the maximum principal strain at each surface element; both their color and length represent the strain magnitude according to the scale bar.

Introduction

There is a lack of standardized workflows for computational knee biomechanics studies making reproducibility, credibility and clinical application challenging.
The *KneeHub* project showed that variability in modeling decisions influences M&S outcomes even if the target simulations and source data were controlled [1]. KneeHub now aims to develop consensus-based workflows for computational M&S through a structured Delphi process involving experts across knee biomechanics, computational modeling, musculoskeletal care, and regulatory science. Our first goal is to recruit and qualify a panel of experts involved in a consensus-based Delphi study, which we summarize in this abstract. The experts will identify an impactful context of use and establish workflows for the given context.

Methods

The study is divided into 5 sub-studies (Figure 1): context of use (Study 1), consensus for decisions on broad simulation study design (Study 2), model development and calibration (Study 3), model benchmarking and credibility (Study 4), and model use and communication (Study 5). Each Delphi study (Studies 1 to 5) will rely on structured rounds of surveys to achieve a data-driven consensus.

Before these studies, we reached out to experts to take a survey (Study 0) establishing their expertise to qualify participation in one or more studies. Expertise area include knee biomechanics research, computational musculoskeletal joint biomechanics research, knee- or extremity joint-focused musculoskeletal care, science of reproducibility, verification, validation and credibility as applied to physics-based modeling, and regulatory science (or regulation) of musculoskeletal joint medical devices.

Results

We identified 213 experts and invited them to participate in Study 0. The ongoing survey has gathered commitment from 50 experts so far. At least 26 experts are interested in participating in each sub-study. All respondents have advanced degrees, 10+ years of experience and at least 5 relevant publications. Studies 1-5 are scheduled to be completed within an 18 month period.

Discussion

Consensus-based workflows built with the experts' perspectives pave a path forward for improving reproducibility and credibility of M&S in knee biomechanics. The outcomes of the consensus-based workflows would serve to incease confidence in M&S use for scientific explorations and clinical applications.

Experimental and Numerical Evaluation of Hinge Fracture in Open-Wedge Distal Femoral Osteotomy Using Sawbones

Mr. Sohrab REZAEI LAFMEJANI [PhD Candidate][1,2], Dr Massamaesso BILASSE [Assistant Professor][1,2], Dr Yamen OTHMANI [Assistant Professor][1,2], Pr Matthieu EHLINGER [Full Professor][1,3]

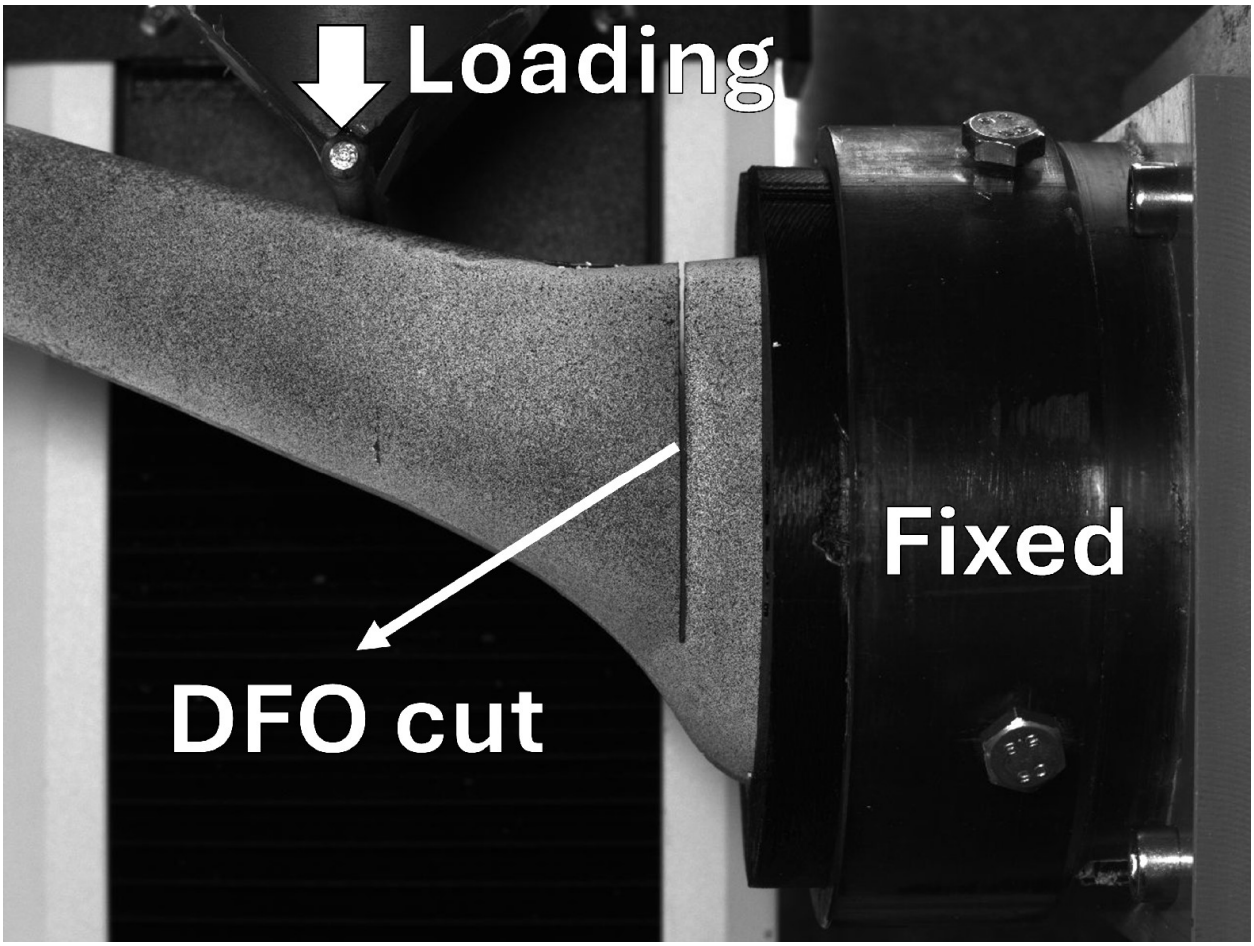
Introduction

Opening-wedge distal femoral osteotomy (DFO) is a primary surgical intervention for correcting valgus knee malalignment. However, the procedure carries a risk of hinge fracture, which can compromise postoperative stability and outcomes. This study aimed to experimentally simulate the opening stage of DFO using Sawbones composite femurs and to develop a numerical model capable of predicting hinge fracture incidence.

Methods

Fourth-generation Sawbones femurs were prepared, using a patient-specific cutting guide and oscillating saw to create the osteotomy cut. The epiphysis was fixed, and a vertical load was applied to the diaphysis to simulate the opening (Figure 1). Opening angles and forces were recorded up to fracture. Standard material characterization tests including uniaxial tension/compression, shear, and single-edge notch bend (SENB), were conducted to define the properties of the cortical and trabecular analogues for numerical modeling. Finite element models using two fracture simulation methods including a transversely isotropic phase-field (PhaFi) model and the Extended Finite Element Method (XFEM), were developed to simulate fractures in both SENB and DFO tests.



Results

A total of five DFO opening tests were performed. The maximum force recorded was 63.4±5.7N. Fracture initiated at opening angle of 1.5°±0.1° and completed at 4.4°±0.2°. Characterization of the cortical material (58 samples) revealed strong transverse isotropy, with tensile elastic moduli of 15.3±2.7GPa (longitudinal) and 10.5±1.3GPa (transverse). The trabecular material (37 samples) was isotropic with compressive modulus of 278.3±18.0MPa. Both PhaFi and XFEM numerical models successfully predicted cortical fractures in SENB tests, with crack completion angle errors of ±0.5° and ±0.7°, respectively.

Discussion

Experimental data from DFO opening tests showed results comparable to both a human cadaveric study on wedge-opening in high tibial osteotomy[1] and an experimental study on porcine femurs on DFO[2]. The characterization tests revealed strong anisotropic behavior in the cortical layer of Sawbones femurs, which aligns with the expected behavior of native bone. Regarding the numerical simulations, both PhaFi and XFEM methods demonstrated promising results in SENB tests and will be applied to the final DFO opening simulations.

The Associations Between Pre-Operative Knee Joint Kinematics During Walking with Frontal Plane Knee Laxity Measured Intra-Operatively Through Robotic Arthroplasty Surgery

Ms. Stephanie Civiero MASc[1,2], Dr. Jennifer Leighton MD[1,2], Dr. Michael Dunbar MD, PhD[1,2], Dr. Glen Richardson MD, MSc[1,2], Dr. David Wilson MD, MASc[1,2], Dr. Janie Astephen Wilson PhD, MASc[1,2]

[1]Dalhousie University, Halifax, Nova Scotia, Canada. [2]Nova Scotia Health, Halifax, Nova Scotia, Canada

Introduction

Many patients continue to walk with deficits after knee arthroplasty surgery (KAS)[1]. KAS planning approaches account for anatomical and morphological variability, but not joint dynamics despite their relevance to outcomes[2]. We aimed to examine the associations between preoperative knee kinematics during gait and intra-operative joint laxity measures as a step toward more mechanics-informed surgical planning.

Methods

Patients awaiting robot-assisted KAS (MAKO, Stryker; n=45; age: 67.7 +/- 8.0 years, BMI: 32.8 +/- 7.4 kg/m^2, 26 female) participated in pre-operative gait assessments using a 10-camera optical motion capture system (Sony-RX0II; Theia3D) installed in the clinic hallway using a repeatable protocol[3]. Clinically relevant sagittal and frontal plane knee angle features[3] were computed (Visual3D; HAS-motion).

Intra-operative variables included: passive maximum knee extension; passive frontal plane knee alignment; and frontal plane knee laxities (relative motion from passive alignment) under maximal varus and valgus stresses in extension (10° flexion) and flexion (90° flexion). Correlations between intra-operative variables and pre-operative kinematics were examined ($\alpha = 0.05$).

Results

Greater varus alignment was associated with larger knee adduction angles during stance (PC1: $r=0.74$; $p < 0.00001$), and a trend toward lower stance phase flexion range of motion (ROM)(PC4: $r=-0.28$; $p=0.06$). Lower maximal knee extension angles (intra-operatively) were associated with lower knee flexion ROM from late stance to swing (PC2: $r=0.46$; $p=0.001$).

Greater valgus laxity in extension was associated with lower knee flexion angles (PC1: $r=0.30$; $p < 0.05$) and greater range of adduction angles in stance (PC3: $r=-0.29$; $p=0.05$).

Greater valgus laxity in flexion was associated with less stance flexion ROM (PC4: $r=0.36$; $p=0.015$). Greater varus laxity in flexion was associated with higher knee adduction angles in early and late stance relative to more abducted knees mid-stance (PC2: $r=0.29$; $p=0.05$).

Discussion

Kinematic gait assessments may capture clinically relevant joint instability responses that passive pre-operative tests miss (due to pain/guarding). Future work will combine joint biomechanics data with morphology and alignment data in larger samples to inform surgical planning strategies to optimize dynamic joint function.

Optimal Stem Spacing to Prevent Inter-Prosthetic Femoral Fractures in Ipsilateral Hip and Knee Arthroplasty: A computational study

Prof. Tae Soo Bae[1], Mr. Jin Ho Kim[1], Prof. Dai-Soon Kwak[2], Prof. Woowon Jeong[3]

[1]Jungwon University, Goesan-gun, Chungbuk, Korea, Republic of. [2]The Catholic University of Korea, Seoul, Seoul, Korea, Republic of. [3]Yonsei University Mirae Campus, Wonju, Kangwon, Korea, Republic of

Introduction

Ipsilateral total hip replacement and total knee replacement are increasingly performed in elderly patients, and recent clinical observations have reported a rise in inter-prosthetic femoral fractures among individuals receiving both implants. This study aims to quantify how the inter-prosthetic distance influences femoral stress distribution and to identify spacing conditions that may reduce fracture risk during combined arthroplasty.

Methods

A three-dimensional femur model and four-point bending jig were constructed from a single patient CT dataset, and finite element analysis was performed using homogeneous material properties for both normal and osteoporotic bone. The total hip replacement stem length was held constant, whereas the total knee replacement stem length was varied across 9 configurations (22~102 mm with 10 mm intervals) to generate corresponding inter-prosthetic distances. Multidirectional bending was simulated by applying loads perpendicular to the jig in four directions: lateral-to-medial, medial-to-lateral, anterior-to-posterior, and posterior-to-anterior. Stress values at the distal femoral isthmus were extracted to evaluate the effect of implant spacing on mechanical demand related to fracture susceptibility.

Results

The finite element analysis showed that an inter-prosthetic distance of 32 mm produced the highest maximum stress values in both normal and osteoporotic femora across all simulated loading directions. In contrast, an inter-prosthetic distance of 62 mm consistently resulted in the lowest maximum stress values under all loading conditions. These trends indicate that reduced spacing between stems increases stress concentration in the isthmus region, whereas greater spacing mitigates stress regardless of bone quality.

Discussion

The findings demonstrate that inter-prosthetic distance is a critical determinant of femoral stress in cases involving simultaneous hip and knee arthroplasty, with shorter distances substantially elevating the mechanical conditions associated with fracture. The results suggest that maintaining larger implant separation may contribute to biomechanical safety by reducing stress amplification in the isthmus region. The use of homogeneous bone models represents a limitation, and future studies incorporating heterogeneous bone properties are expected to enhance the clinical applicability of these conclusions.

Introduction

Knee osteoarthritis (KOA) is a fast-growing global public health condition affecting 1-in-5 people over the age of forty. Open-wedge High Tibial Osteotomy (OWHTO) is a preferred treatment option for young and active patients. Despite its advantages, the outcomes largely depend on surgical planning decisions and current approaches are unsatisfactory.

This study aims to develop a surgical planning tool that determines the optimal patient-specific correction angle using musculoskeletal (MSK) modelling, considering individual knee loading profiles during activities of daily living.

Methods

Motion data will be collected from 10-12 patients planned to undergo OWHTO during daily tasks, both pre- and post-surgery. It will be used as an input to create individualized MSK models in addition to using three distinct scaling approaches.

First, a basic scaling approach will be implemented based on marker distances. Next, an accurate model will be generated from CT/MRI imaging data to produce 3D meshes. Finally, for a patient-specific planning of OWHTO, a partially-individualized 3D anatomy will be approximated based on clinical 2D X-ray images and statistical 3D shape and intensity models.

The scaled models will be used to perform virtual surgeries and to predict post-surgery knee adduction moments (KAM). Actual post-surgery data will serve as a validation for the prediction accuracy of different scaling approaches.

Results

As this is an ongoing research project, the following outcomes are the expected results. The primary outcome is the validation of the simulation process, with high correlations

expected between predicted KAM values from simulations and actual post-surgery measurements.

Additionally, the study aims to compare different scaling approaches. It is anticipated that the partially-individualized scaling method will achieve accuracy levels comparable to CT/MRI-based models, offering a more cost-effective alternative.

Discussion

OWHTO is an important treatment option for young and active patients with KOA. However, current planning methods remain insufficient, relying on oversimplified one-size-fits-all static approaches to a dynamic problem. There is a need to translate advances in computational modeling into clinical practice. Accurate prediction of KAM could significantly enhance OWHTO longevity and improve functional outcomes. Furthermore, 2D-to-3D reconstruction techniques developed in this project have the potential to be applied to other orthopedic interventions.

Establishing an Open-Chain Squat Protocol to Identify Biomechanically Optimal Toe-Out Angles: Preliminary Reliability Results

Dr. Teresa Szu-Hua Chen PT, PhD, Mr. Ethan Gray SPT, Miss Holly Geyer SPT, Miss Kiersten Gravuer SPT, Miss Lily Holden SPT, Mr. Matthew Mitros SPT

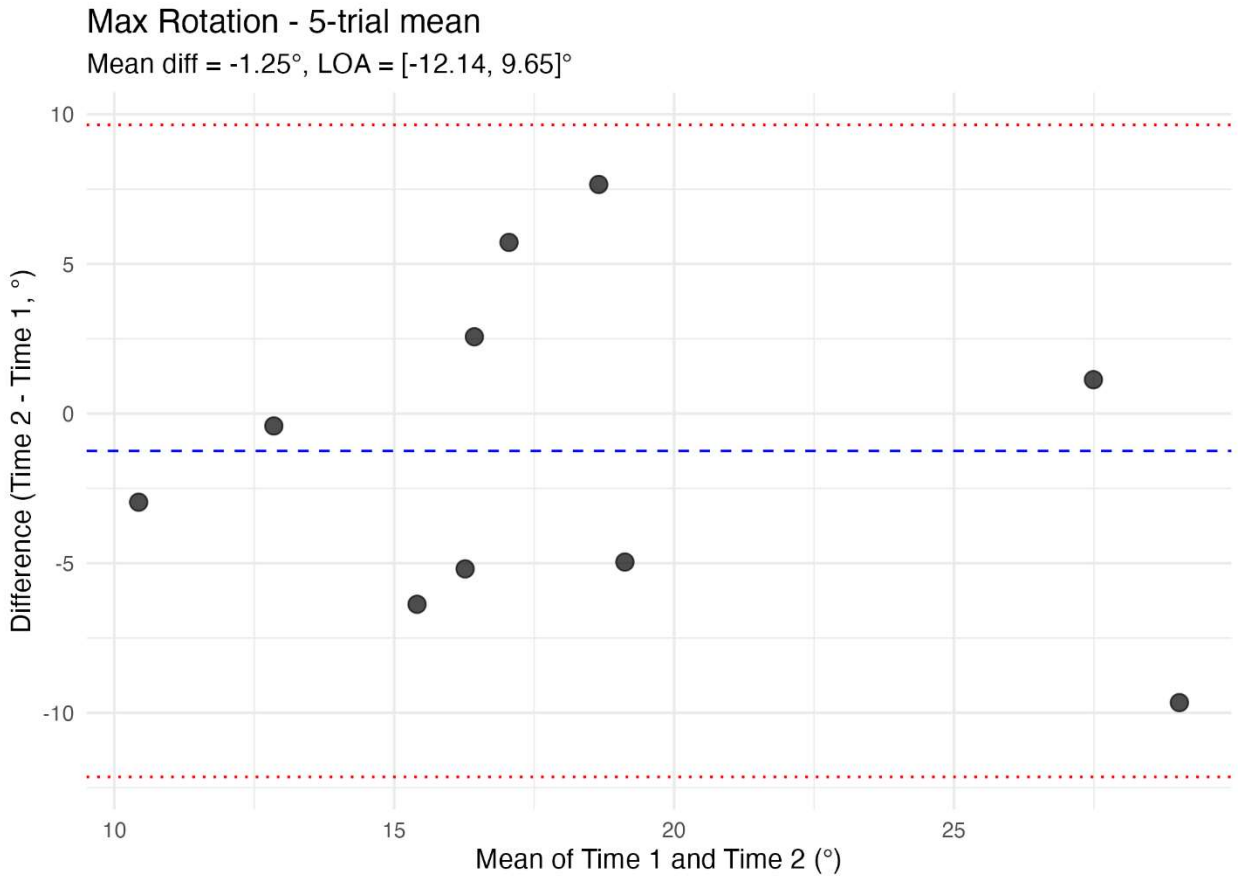
Ithaca College, Ithaca, NY, United States

Introduction

Squats are a fundamental exercise in physical training and rehabilitation, offering significant benefits for function, strength, and injury prevention. During deep squats, external rotation of the feet ("toe-out") is frequently observed, particularly when foot-floor friction is low. This “toe-out” is thought to be linked to anatomical features such as tibial torsion and soft tissue restrictions (e.g., tight calves). Since squats are performed closed-chain with fixed feet, limiting toe-out can create torsional loads at the knee or hip that may strain structures not designed to resist them. The purpose of this study was to establish an open-chain squat protocol to determine optimal toe-out angle during squats. We hypothesized the protocol would demonstrate moderate to good test-retest reliability.

Methods

Five individuals with pronated feet participated (2 females; age: 21.6±0.6 years; height: 174.4±7.6 cm; mass: 83.1±18.7 kg). Pronated foot was confirmed by navicular drop test >9mm. Each participant stood on two footprint devices that allow foot rotation and performed five bodyweight squats at two time points on the same day. Each device consisted of two wooden plates, with the top footprint-shaped plate attached to the bottom plate via a rotational mechanism at the rearfoot. The spacing of two footprint devices matched each participant's natural squat width. Three-dimensional motion analysis captured squat movements using reflective markers on the plate's front and rear edges, representing toes and heels. Maximum toe-out angle was calculated using VBA Excel. Test-retest reliability was assessed using intraclass correlation coefficient (ICC), minimal detectable change at 95% confidence (MDC_{95}), standard error of measurement (SEM), and Bland-Altman analysis.



Results

Toe-out angle measurement showed moderate test-retest reliability (ICC = 0.64, 95% CI [0.07, 0.90]) with SEM of 3.78° and MDC_{95} of 10.48°. Bland-Altman analysis revealed minimal systematic bias between sessions (Figure).

Discussion

These findings support that the open-chain squat protocol using footprint devices is moderately reliable for quantifying toe-out angle. This measurement may help individuals who naturally adopt greater toe-out angles during squats—such as those with tight calves, abnormal tibial torsion, or pronated feet—identify their optimal foot position during squats without imposing torsional loads up the kinetic chain.

Effects of Traumatic Muscle Injury to Adjacent Tendon Mechanics and Structure

Mr. Trent Hardwick[1], Mr. Patrick Hinkle[1], Mr. Fuad Bin Enam[1], Dr. Jeremy Eekhoff[2], Ms. Elena Woo[1], Mr. Evan Fry[1], Mr. Brady Huggins[1], Dr. Koyal Garg[1], Dr. Alex Reiter[1]

[1]Saint Louis University, St. Louis, MO, United States. [2]Pennsylvania, Philadelphia, PA, United States

Introduction

Volumetric muscle loss (VML) is characterized by an irrecoverable loss of skeletal muscle, resulting in chronic functional deficits.[1] The inflammatory response and altered mechanical environment following injury and throughout recovery could lead to concomitant detrimental changes to the entire musculotendinous unit. However, tendinous changes due to adjacent VML injury have not been explored. The purpose of this study was to characterize the mechanical and structural changes to the Achilles tendon in a rat model of gastrocnemius VML injury.

Methods

Female Sprague Dawley rats (n=9, 10-12 weeks old, 200-275g, Inotiv) received a surgically induced VML injury bilaterally in the gastrocnemius, followed by four weeks of cage activity. Aged-matched controls (n=7) were included. Animals were euthanized and Achilles tendons were prepared for mechanical testing (n=7-12 limbs) and histological analysis (n=6-7 limbs). Mechanical testing consisted of preconditioning, 10-minute stress relaxation at 6% strain, and a quasistatic ramp-to-failure. Data were analyzed in MATLAB. Unpaired t-tests assessed group differences in mechanical outcomes (p<0.05). Histological analysis is ongoing.

Results

No significant differences were found between control and VML-injured tendons in maximum force, stiffness, maximum stress, tangent modulus, cross-sectional area, or percent relaxation (Fig. 1).

Discussion

These preliminary results suggest VML injury does not induce concomitant mechanical changes in the adjacent tendon. It should be noted that this injury model allows full weight-bearing activity immediately following VML. While a substantial inflammatory response is present, the mechanical loading environment may be only partially altered. Furthermore, pending histological analysis may reveal structural changes in the tendon that do not manifest as mechanical changes at the 4-week post-injury timepoint. However, if further investigation confirms tendons are unaltered, then research should remain focused on treating the primary VML injury with little concern for uninjured adjacent tissues in this model.

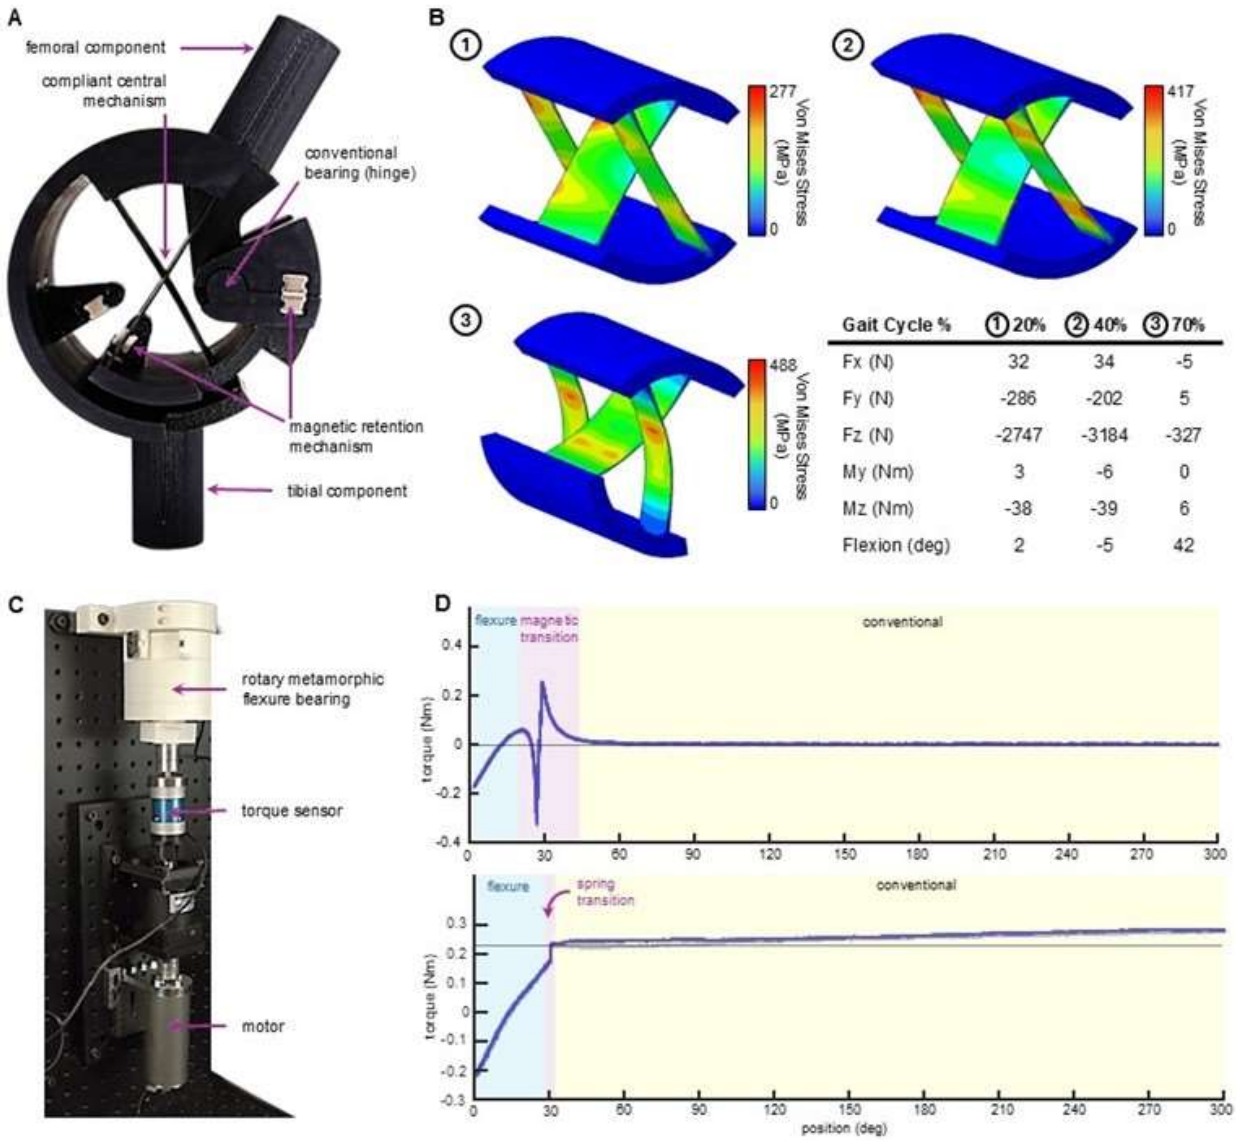
Introduction

Total knee arthroplasty (TKA) is an effective treatment for advanced osteoarthritis; however, as primary TKA volume has increased, so has revision TKA incidence. Primary causes of failure include aseptic loosening, tibiofemoral instability, and polyethene wear. Compliant mechanisms are a promising solution to mechanical implant failure because they are wear-free and inherently stable. However, they cannot typically support the full range of knee motion needed for activities of daily living [1]. To address this, we developed a *metamorphic* compliant TKA implant. This implant functions as a wear-free compliant mechanism during high-cycle-count activities, such as walking, then transitions to a conventional mechanism for activities that require larger ranges of motion.

Methods

A rotary metamorphic flexure bearing was designed using off-the-shelf components and a 3D printed housing. The compliant central mechanism was optimized in FEA (Abaqus, Dassault Inc.) to operate under loads and displacements typical of walking. Torque vs. angular displacement was recorded for two different retention mechanisms (magnetic and spring-based) using a motorized test-bench (Fig. 1C). We used the resultant data to design a metamorphic knee implant.

Results



Peak stress in the central mechanism remained below 490 MPa during simulated walking (Fig. 1B), consistent with an almost 100-year fatigue life. The magnetic retention mechanism exhibited large torque perturbations at the transition zone but did not introduce sustained retention torques during flexure or conventional modes (Fig. 1D). The constant stiffness retention mechanism did not exhibit large torque perturbations at the transition zone but introduced a sustained torque during conventional-bearing mode (Fig. 1D). From these observations, we designed a metamorphic knee implant with a magnetic

retention mechanism (Fig. 1A); this was chosen to avoid sustained resistive torque during conventional-bearing mode.

Discussion

These results demonstrate mechanical feasibility of a metamorphic compliant TKA implant. We packaged the system within the envelope of a conventional revision TKA implant. Our FEA results show that the central mechanism can potentially withstand decades of gait-relevant loading within the body, and our experimental testing shows smooth and reliable transition between the two bearing modes. This approach has the potential to create lifetime TKA implants.

A Multiscale Computational Framework for Investigating Blood-Induced Cartilage Degradation in Haemophilic Arthropathy

Mr Venkata Sai Mahesh Peddapeta, Dr Hazel Fermor, Dr Greg de Boer, Dr Marlène Mengoni

University of Leeds, Leeds, England, United Kingdom

Introduction

Haemophilic arthropathy (HA) results from recurrent joint bleeds triggering inflammatory cascades and rapid cartilage degradation [1]. However, the quantitative progression from acute molecular events to tissue-scale mechanical failure remains poorly understood. This study introduces a multiscale framework integrating validated biochemical dynamics with poroelastic tissue mechanics to quantify disruptions in cartilage biomechanics.

Methods

At the biochemical scale, a 32-species ODE network simulated the inflammatory response to blood exposure. Model parameters were calibrated within literature-derived ranges to ensure physiological steady-state stability. The model was validated against experimental data [1, 2, 3, 4] for acute cytokine activation [4] (1–3h) and cumulative matrix depletion [1, 2, 3] (4 days). At the tissue scale, a 2D axisymmetric poroelastic FE model simulated confined compression. Tissue permeability and hygroscopic swelling were defined as empirical functions of glycosaminoglycan (GAG) content [5], linking mechanical function to biochemical degradation.

Results

The biochemical model reproduced acute inflammatory profiles observed in literature (Figure 1A). Over a 4-day bleeding window (Figure 1A, Inset), the simulation indicated 18% GAG loss and 26% proteoglycan synthesis inhibition, aligning with explant studies [1, 2, 3] (18–40% loss; 22–45% inhibition). Mechanically, this GAG loss increased intrinsic permeability 1.6-fold and reduced relaxation time by ~30% (Figure 1C). Consequently, the aggregate modulus decreased by ~8% (Figure 1B).

Discussion

This framework captures haemarthrosis kinetics, validating inflammation and matrix suppression against experimental data. Linking these outputs to poroelastic mechanics reveals that early GAG depletion initiates a transition towards a mechanically unstable

tissue: the corresponding increase in permeability and reduction in relaxation time signify a compromised capacity for load support. This framework provides a mechanistic understanding of the disease, establishing a quantitative tool to evaluate therapeutic strategies.

Images (Optional)

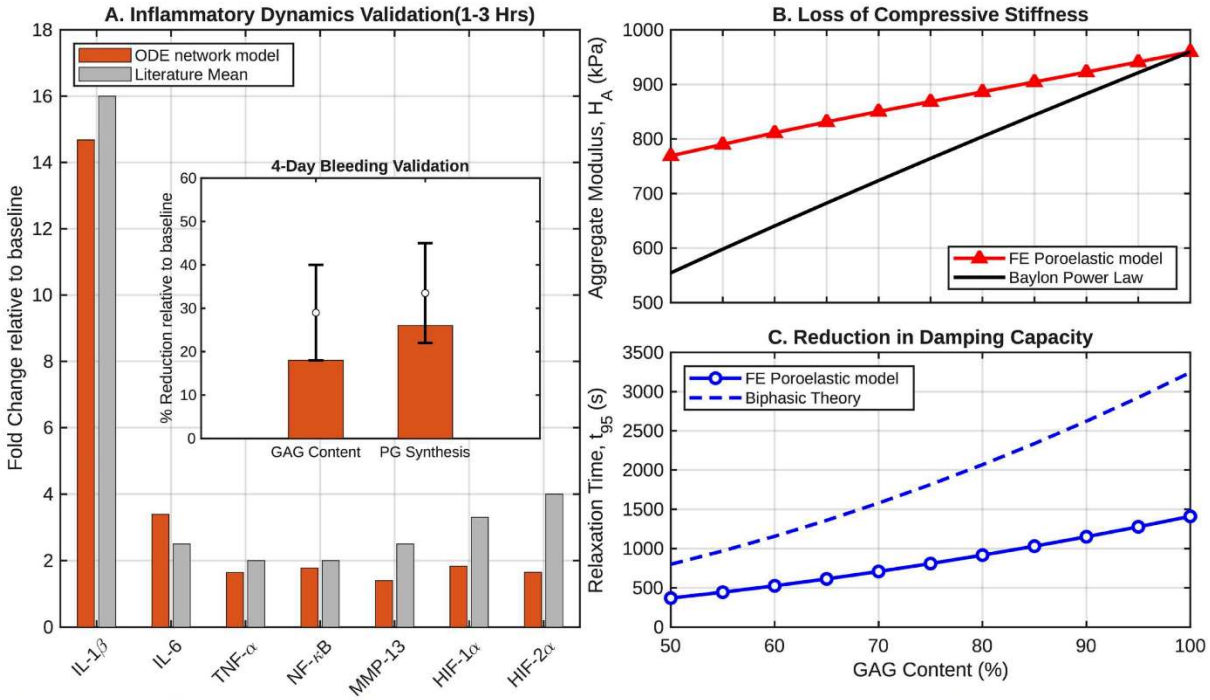

Figure 1 (A) Verification of acute (1–3h) inflammatory dynamics against literature means. (Inset) Day-4 matrix degradation simulations align with experimental (error bars) explant ranges [1, 2, 3]. (B) Loss of aggregate modulus (HA). The FE model (red) captures the qualitative trend of the Baylon power law [6] ($HA \propto GAG^{0.791}$, black), with quantitative deviations attributed to the stabilizing effect of the intact collagen network in confined compression. (C) Reduction in relaxation time (t_{95}). The FE simulation follows the trend of the 1D analytical biphasic theory [7] (dashed), with offsets resulting from realistic 2D flow and boundary effects inherent to the finite element formulation.

Differentiation between gait and non-gait weightbearing tasks using plantar pressure insole data: procedures for task-differentiation during daily tasks

Dr. Willa Ma, Dr. Susan Sigward

University of Southern California, Los Angeles, California, United States

Introduction

Insole measures of surgical loading during daily weightbearing activities suggest individuals following anterior cruciate ligament reconstruction practice underloading behaviors ecologically. However, it's not clear how types of daily activities influence these behaviors as current procedures do not differentiate loading across tasks. The purpose is to determine the accuracy, reliability, and validity of a gait detection algorithm that differentiates gait and non-gait activities from using plantar pressure insole data by quantifying force impulse and limb loading symmetry.

Methods

Twelve healthy participants performed gait at five speeds intermixed with non-gait daily activities for 12 minutes on two testing days. Vertical ground reaction force (Bertec: treadmill force plates) and plantar force (Novel Electronic: loadsol pro) were collected concurrently. A gait detection algorithm differentiated gait from non-gait using the following parameters to identify stance: threshold of 50N for heel-strike and toe-off, peak stance force >0.85x bodyweight, force duration 0.25-1.5 seconds, time between strides <1.5 seconds, and ≥5 consecutive strides. Time (minutes) classified as gait and non-gait for each system determined sensitivity and specificity relative to force plate-derived gait events (gold standard). Force impulse (area under force-time curve) for each limb and system were used to calculate limb loading symmetry (LLS: non-dominant/dominant). Intraclass correlation coefficients (ICC3,k) assessed between-system validity and between-day reliability for impulse and LLS. Bias, standard error of measure (SEM), and limits of agreement (LOA) were calculated.

Results

Sensitivity and specificity were 99.4% and 99.3% respectively (Figure 1). Impulse ICCs were 0.91 for gait and 0.86 for non-gait activities, whereas LLS demonstrated ICCs of 0.38 and 0.86. Bias between systems was ±2% for LLS and LOA within ±9% for gait and ±12% for non-gait. Reliability ICCs were 0.93 and 0.24 for gait and non-gait impulse and 0.37 and

0.65 for LLS. SEM was 0.01 BW*s for gait and 12.1 BW*s for non-gait impulse, and 0.03-0.05 for LLS.

Discussion

Accurate detection of gait and non-gait activities with only 4.1/622.1 minutes misclassified, excellent between-day reliability for gait impulse, and small LOA and bias between systems for impulse and LLS support the use of insoles to detect loading asymmetries differentiated by activity in ecological environments.

Increases in Finite Element-Based Bone Strength Metrics Post Partial Volume Correction Evaluated at the Proximal Tibia of Persons With Spinal Cord Injuries

Mr. William Kuo[1], Dr. Christopher M. Cirnigliaro[2], Dr. William A. Bauman[3], Dr. Saikat Pal[1]

[1]New Jersey Institute of Technology, Newark, New Jersey, United States. [2]James J. Peters Veterans Affairs Medical Center, Bronx, New York, United States. [3]Icahn School of Medicine at Mount Sinai, New York City, New York, United States

Introduction

Persons with spinal cord injuries (SCI) experience rapid bone loss and are at high risk of fragility fractures, with the most common site being the knee joint (proximal tibia and distal femur) [1]. Studies have described computed tomography (CT)-based finite element (FE) methods to be better than radiographic measurements in evaluating the mechanical competence of bone [2]. However, 3-D models from CT imaging are prone to partial volume effects (PVE) and result in errors at the morphological boundaries. One specific error is reduction of cortical bone density due to averaging of bone and soft tissue pixels' greyscale values at the boundaries (Figs. 1A-B). Such PVEs directly affect the surface-based failure criteria used to determine FE-based bone strength metrics: torsional stiffness (K_t), torsional strength (T_{ult}), compressive stiffness (K_c), and compressive strength (C_{ult}) [2, 3]. The effects of partial volume correction (PVC) on FE-based bone strength metrics remain unclear. As such, the **goal** of this study was to quantify the increases in FE-based bone strength metrics due to PVC evaluated at the proximal tibia of persons with SCI.

Methods

We recruited 22 participants with SCI (15M, 7F) and 5 AB controls (4M, 1F) with procedures approved by our IRB. FE-based bone strength metrics were computed from 43 SCI and 10 AB proximal tibias through torsional (K_t, T_{ult}) and compressive displacement (K_c, C_{ult}). We applied element-based PVC, where local surface elements were converted to the highest density of adjacent elements. We quantified the increases in FE-based bone strength metrics following PVC at the proximal tibias of all participants.

Results

From all participants, PVC resulted in an average increase of 32%, 41%, 30%, and 61% for K_t, T_{ult}, K_c, and C_{ult}, respectively (Fig. 2). The increases in FE-based bone strength metrics were greater in the SCI compared to the AB participants.

Discussion

This study highlights the importance of PVC when quantifying FE-based bone strength metrics from persons with severely osteoporotic bones, such as those with SCI.

Images (Optional)

Do Implant Designs React Differently to Malalignment? Clinical Implications for TKA Stability and Longevity

Ms. Simone Sommer, Prof. William R. Taylor, Dr. Seyyed Hamed Hosseini Nasab

ETH Zurich, Zurich, Zurich, Switzerland

Ms. Simone Sommer

Prof. William R. Taylor

Introduction

Component alignment strongly influences total knee arthroplasty (TKA) function, stability, and longevity. Although malalignment affects joint mechanics, implant designs may differ in their mechanical tolerance to alignment errors. This study quantifies the sensitivity of three contemporary TKA designs – ultra-congruent (UC), posterior-stabilised (PS), and medial-stabilised (MS) – to implantation errors and identifies design-dependent risks for instability, abnormal joint loading, and implant failure.

Methods

A previously validated musculoskeletal model [1] was implanted with UC, PS, and MS configurations (Fig.1). A Monte Carlo framework introduced random perturbations up to ±5° to the femoral and tibial component alignments in all planes, producing 500 simulated implantation scenarios per design. Skin-marker trajectories and ground reaction force data from a walking trial were used as input to the COMAK algorithm [2] to estimate tibiofemoral kinematics, joint loading, and muscle activations. Mechanical sensitivity was quantified by correlating component implantation angles with joint kinematics at peak tibiofemoral force.

Results

Although MS was the most sensitive design overall, kinematic responses to malalignment were highest in MS and UC. However, the highest axis-specific kinematic sensitivity occurred in the PS design, which showed the largest anterior-posterior (AP) translation response to tibial sagittal malalignment (up to 1.16 mm/°). PS also demonstrated the

greatest sensitivity in medio-lateral (ML) loading, particularly under tibial coronal perturbations (up to 26.9 N/°). Muscle activations were largely insensitive to alignment variation; the only consistent deviation occurred near toe-off, where activation levels increased to stabilise the joint, particularly in PS and MS configurations.

Discussion

These findings reveal distinct, design-specific responses to malalignment. While MS and UC showed broad kinematic sensitivity, the PS design demonstrated pronounced axis-specific changes, which may increase asymmetric tibial loading and thereby elevate the risk of tibial component loosening. The higher muscle activation demands near toe-off in PS and MS further indicate reduced intrinsic stability. Therefore, surgeons should be aware that certain designs are less tolerant to alignment variability, meaning that meticulous surgical technique and accurate instrumentation are critical to reduce the risk of instability, abnormal wear, and early revision.

Finite Element Analysis of the Optimal Plate Positioning and Screw Length in Medial Open-Wedge High Tibial Osteotomy

Dr. Yasushi Oshima MD, PhD[1], Dr. Kohei Murase Ph.D[2], Dr. Makoto Hirao MD, Ph.D[1]

[1]Nippon Medical School, Tokyo, Tokyo, Japan. [2]The University of Osaka, Osaka, Osaka, Japan

Introduction

In medial open-wedge high tibial osteotomy (MOWHTO), the fixation plate is typically positioned on the medial tibial surface, and the most proximal screws are ideally inserted to reach beyond the lateral intercondylar eminence without penetrating the lateral cortex. However, the biomechanical implications of anteromedial plate placement and shortened screw length have not been fully clarified. We hypothesized that excessive anteromedial plate positioning, particularly when combined with shorter screws, would reduce fixation strength and increase the risk of implant failure and loss of alignment correction. This study aimed to evaluate mechanical loading changes in the proximal tibia and implants associated with variations in plate positioning and screw length using finite element analysis.

Methods

A simulated adult tibia model (Sawbones, USA), consisting of separated cortical and cancellous bone layers was generated with an average element size of 0.8 mm. An MOWHTO model with a postoperative proximal tibial medial angle of 93° was created. Finite element models were constructed using the TriS medial HTO plate purple (OSferion Biomaterials, Japan) placed on the true medial surface and at 10°, 15°, 20°, and 30° anteromedial orientations. Screw length conditions included long (reaching near the lateral cortex), short (ending just beyond the lateral intercondylar eminence), and intermediate lengths. Tibial mechanical loads of 750 N medially and 1250 N laterally were applied in vertical and 30° posterior-oblique directions. Young's modulus and Poisson's ratio of the titanium plate and screws were assigned according to the previous literature (Murase K, 2007). Stress distribution was analyzed using LS-DYNA software (Ansys, USA).

Results

Compared with true medial plate placement with long screws, anteromedial plate positioning with the combinations of shorter screws resulted in stress concentration around the proximal second-row screw hole. Moreover, changing the load direction from

vertical to oblique shifted the stress concentration from the anterior to the posterior portion of the plate.

Discussion

The plate breakage around the second-row screw hole has recently been reported. In this study, the stress concentration increased with anteromedial plate placement and shorter screws, and the plate stress location shifted with load direction. Thus, excessive anteromedial plate placement combined with shortened screws should be avoided in MOWHTO.

In Silico Analysis of Etiology-Dependent Cortical and Cancellous Bone Remodeling in Osteoporosis

Dr Yoshitaka Kameo, Mr Hiroki Kazuno, Mr Yuto Niwayama

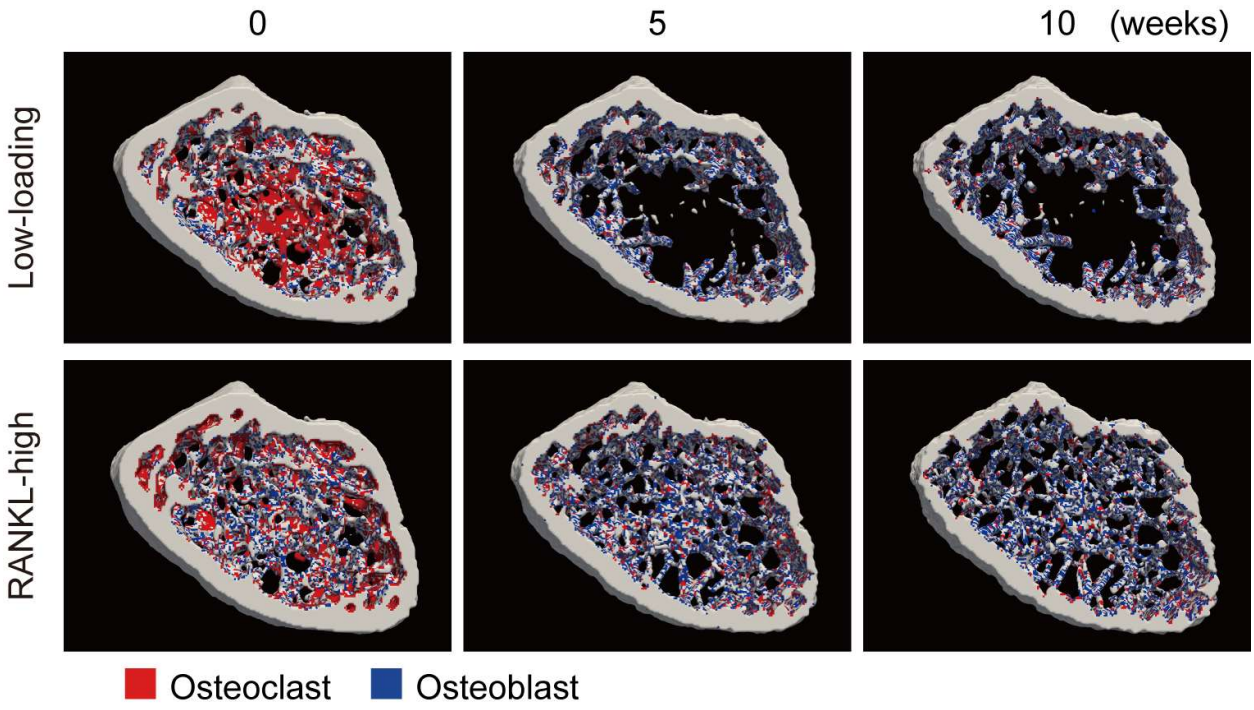
Shibaura Institute of Technology, Koto-ku, Tokyo, Japan

Introduction

Osteoporosis is a metabolic bone disease characterized by cortical thinning and a reduction in cancellous bone density, resulting from an imbalance between bone resorption and bone formation. Major etiological factors include reduced mechanical loading due to disuse and the accumulation of bone resorption–promoting factors associated with decreased sex hormone levels. These distinct etiologies are known to lead to different pathological patterns. Therefore, understanding and predicting morphological changes in cortical and cancellous bone via remodeling in response to mechanical environments is essential for developing effective preventive and therapeutic strategies for osteoporosis. This study aimed to elucidate the effects of osteoporosis-inducing factors on cortical and cancellous bone morphology from molecular and cellular perspectives by using bone remodeling simulations based on a mathematical model of bone metabolism.

Methods

A bone remodeling simulator, V-Bone, which integrates a mathematical model of bone metabolic processes and links microscopic molecular/cellular interactions to macroscopic tissue/organ adaptation, was employed [1, 2]. Bone remodeling simulations were performed using a mouse femur model to analyze changes in cortical and cancellous bone morphology under conditions of reduced mechanical loading and increased expression of RANKL, a signaling molecule that promotes osteoclast activation and bone resorption.



Results

The simulations showed that in osteoporosis caused by reduced mechanical loading (Low-loading model), cancellous bone volume rapidly decreased while cortical bone was relatively preserved. In contrast, in osteoporosis induced by elevated RANKL expression (RANKL-high model), both cortical and cancellous bone exhibited chronic and progressive loss (Figure).

Discussion

The etiology-dependent differences in pathological responses were qualitatively consistent with clinical and experimental observations. In RANKL-induced osteoporosis, only enhancement of bone resorption occurred, whereas in osteoporosis caused by reduced mechanical loading, both increased bone resorption and suppressed bone formation were observed due to elevated levels of sclerostin, a mechanosensitive signaling molecule. These distinct molecular mechanisms are considered to underlie the differences in cortical and cancellous bone abnormalities observed in osteoporosis.

[6]Research Center for Medicine-Engineering Collaboration, Tokyo Metropolitan University, Hachioji, Tokyo, Japan

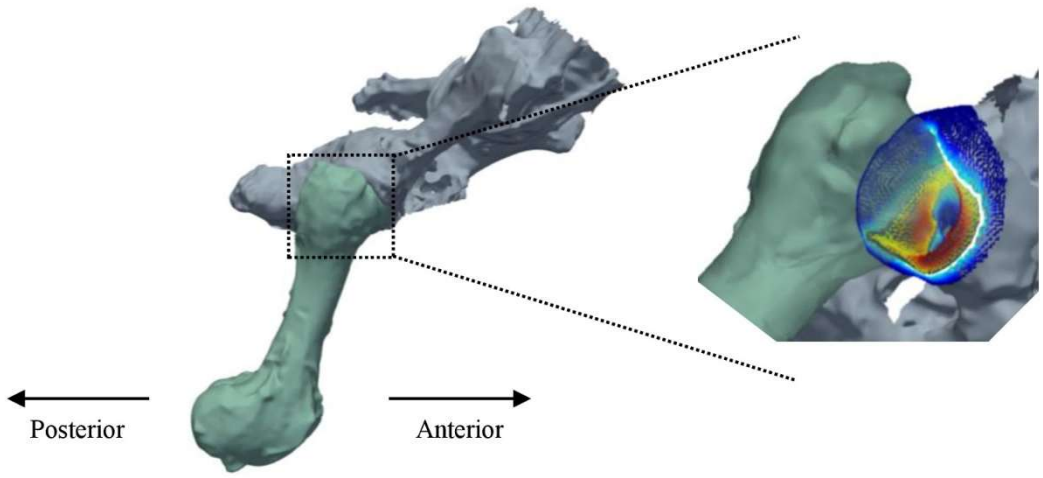
Introduction

Internal rotation in flexion is believed to increase the loads applied to the acetabular labrum, and induce labral tears and subsequent osteoarthritis. Quantitative evaluation of labral loading and subluxation is needed for the prevention and improved treatment of those clinical problems. This study aimed to develop a framework combining robotic testing and computational modeling to reconstruct 3-D contact states, quantify subluxation, and assess acetabular labral load and stress in porcine hip joints.

Methods

Porcine hip joints were fixed to a 6-DOF robotic system (FRS-2015, Technology Service, Japan), and the hip joint coordinate system was defined according to the ISB recommendation [1]. During internal-external rotation applied up to ±600 Nmm at 0°, 20°, and 40° of flexion, hip kinematics were recorded, followed by digitization of joint surface geometry with a 3-D scanner (EinScan Pro HD, SHINING 3D, China). By combining the measured kinematics and surface geometry, a detailed hip joint model was reconstructed. This model allowed for the visualization of relative 3-D joint motion using custom-made Python programming software. To assess subluxation, the distance between the centers of curvature of the femoral head and acetabulum was determined.

Results



Subluxation distance varied with flexion and internal-external rotation. At 0° of flexion, the distance remained less than 1.2 mm regardless of rotation. However, at 20° of flexion, subluxation increased compared to that at 0°, with the largest value of 3.2 mm in internal rotation. At 40° of flexion, the distance took intermediate values, between those at 0° and

20° of flexion. Visualization indicated a severe, concentrated contact of the femoral head with the acetabular labrum in internal rotation at 600 Nmm.

Discussion

This study successfully conducted a hip joint loading test relative to the hip joint coordinate system and visualized the contact between the femoral head and acetabulum. Results indicated that internal rotation at light flexion poses the greatest risk to the hip, aligning with clinical findings [2]. Further research is required to examine load and stress on the acetabular labrum during this motion.

Images (Optional)

Characterization of Lumbar Spine Biomechanics Using Multidimensional Motion Trajectories

Dr. Emma Coltoff PhD[1], Mr Alexander Hooke MA[2], Dr. Asghar Rezaei PhD[3,2], Dr. Philip Brown PhD[1]

[1]Department of Biomedical Engineering, Wake Forest School of Medicine, Winston-Salem, NC, United States. [2]Mayo Clinic Department of Orthopedic Surgery, Rochester, MN, United States. [3]Mayo Clinic 2Department of Physiology and Biomedical Engineering, Rochester, MN, United States

Introduction

Spinal motion and deformities occur in multiple dimensions, yet conventional biomechanical assessment largely relies on uniaxial bending kinetics and kinematics. Coltoff et al.[1] introduced a multidimensional cervical spine testing method using compound, multidirectional bending to link path directionality with biomechanical response. This study aimed to adapt that technique for the lumbar spine, with a future goal of utilizing it to correlate imaging-detected bone deformities with biomechanical function.

Methods

Two lumbar cadaveric spines from L1-L5 were used for this study: one “intact” spine with no evidence of deformities and one “deformed” spine with severe degradation and 3D deformities from L3 to L5, confirmed by CT imaging. Specimens were mounted to a 6-DOF robotic system. A set of 7.5Nm torque-limit boundary condition trajectories were run to determine each spine’s unique range of motion in the transverse plane. These results were used to create 5 multidimensional trajectories to move the spine through its full range of motion: “petals” clockwise (CW) and counterclockwise (CCW), “circles” CW and CCW, and rays (Figure 1A). Specimen kinematics and kinetics were recorded throughout each test. ARCMap[2] was used for statistical analysis between both specimens and between CW and CCW loading of the circles and petals trajectories.

Results

The deformed spine showed a 73% decrease in the multidimensional ROM versus the intact spine. The resultant load and stiffness behavior associated with each trajectory was plotted and normalized to a unit circle for comparison and calculation of differences between specimens and trajectories (Figure 1B). Resultant load differences reached 4.9Nm between specimens with the largest differences occurring in extension-driven

poses. Path directionality also indicated significant differences ($p < 0.05$) identified between the CW and CCW petals trajectories for the deformed specimen.

Discussion

The multidimensional loading presented highlights biomechanical behavior of the spine that traditional planar loading cannot identify. This includes a significant effect of bending path direction and its ability to highlight functional limitations due to deformity.

Images (Optional)

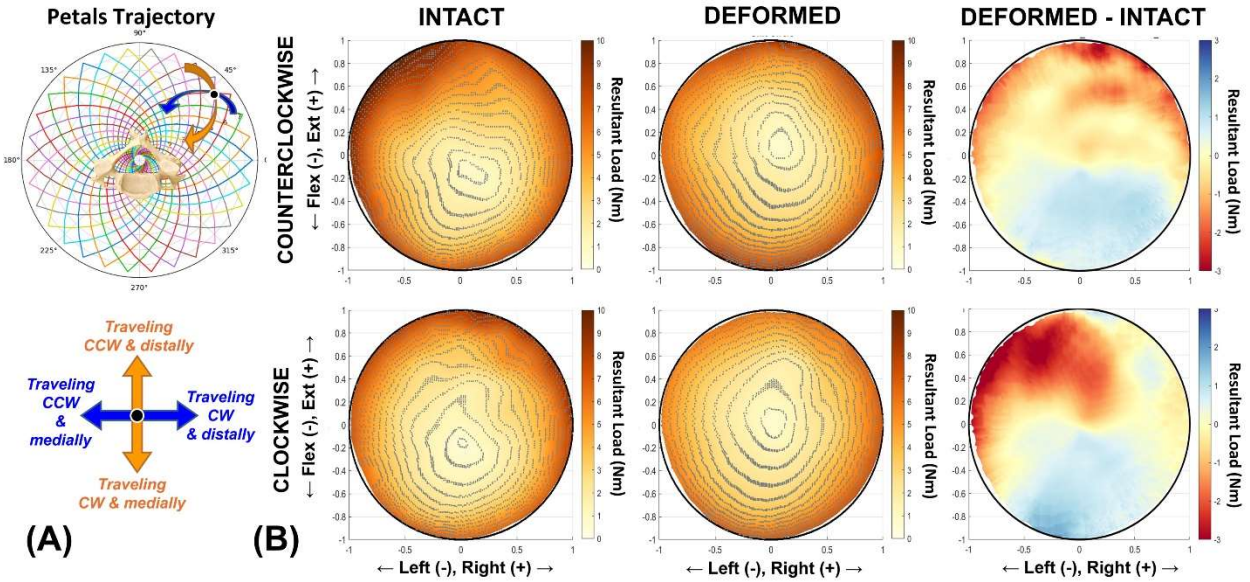

Figure 1: A) Visual representation of petals trajectory. B) Resultant load heatmaps normalized to unit circles with flexion/extension position (y-axis) versus lateral bending position (x-axis) during petals clockwise (bottom) and counterclockwise (top) loading. Contours indicate every 0.5 Nm. Intact specimen (left column), deformed specimen (middle), and difference between deformed and intact (right). Blue indicates deformed stiffness > intact. Red indicates intact stiffness > deformed.

Strain Based Structural Optimization of Highly Porous Bioresorbable Cages for Spinal Fusion

MsC Aline Gouveia[1], Dr. Joeri Kok[1], Dr. Claire Villette[2], Prof dr. Keita Ito[1,3], Dr. Bert van Rietbergen[1], Dr Miguel Dias Castilho[1]

[1]Eindhoven University of Technology, Eindhoven, N/A, Netherlands. [2]Queen Mary University of London, London, N/A, United Kingdom. [3]University Medical Center Utrecht, Utrecht, N/A, Netherlands

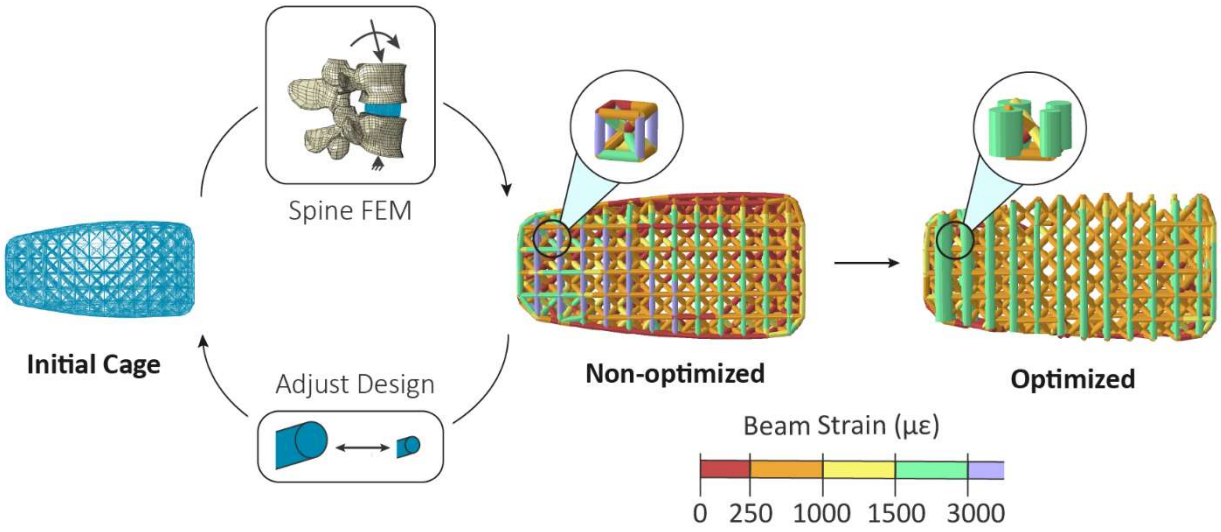
Introduction

Existing cages for spinal fusion surgery are typically made from non-resorbable materials and often fail to stimulate bone ingrowth, increasing risks of delayed fusion and complications. Fusion rates can be improved by creating a biomechanical environment that mimics native bone to favour quick bone growth, while the use of bioresorbable materials may reduce late-stage stress-shielding and enable stable fusion. 3D-printable trussed cage designs can be tuned to reach optimized mechanical and resorption characteristics through topology optimization. The aim of this project is the structural optimization of fully bioresorbable interbody cages to maximize initial bone ingrowth through mechanical stimulation.

Methods

A spinal fusion cage made from a biomimetic polymer-ceramic composite [1] was designed with a repeating body-centered cubic lattice unit cell. The design was iteratively adjusted using a strain optimization method based on finite element (FE) simulations with beam elements [2]. In each iteration, patient-specific loading was simulated using a FE model of the spine from a cohort of patients eligible for spine fusion, and the strut strains were calculated. The cross-sectional area of each beam was then adjusted until convergence to a target strain value of 2250με, within the bone apposition range according to the Mechanostat hypothesis [3].

Results



The converged strut design produced a total cage porosity of 60% while ensuring mechanical integrity under spinal loading. Preferential directionally of strut thickening was evident, and aligned with the expected trajectory of load transfer. During the optimization,

undeformed beams were removed and remaining elements converged to either the target strain or the extremes of the acceptable diameter range (Figure).

Discussion

The results indicate that a considerable increase in struts in the target strain is possible, while keeping adequate overall cage stiffness and strength. Compared to earlier topology optimization studies, the use of a strut adaptation approach simplifies the optimization workflow and applicability, as initial cage shape, unit cell size, topology, and acceptable strut thickness can be adjusted to ensure manufacturability and prevent material failure. It also enables easy implementation of resorption to simulate later fusion stages.

Simulating Scoliosis Movement with a 1000 Degrees-of-freedom Joint-link Mechanism

Dr Athena Jalalian, Dr Soheil Arastehfar

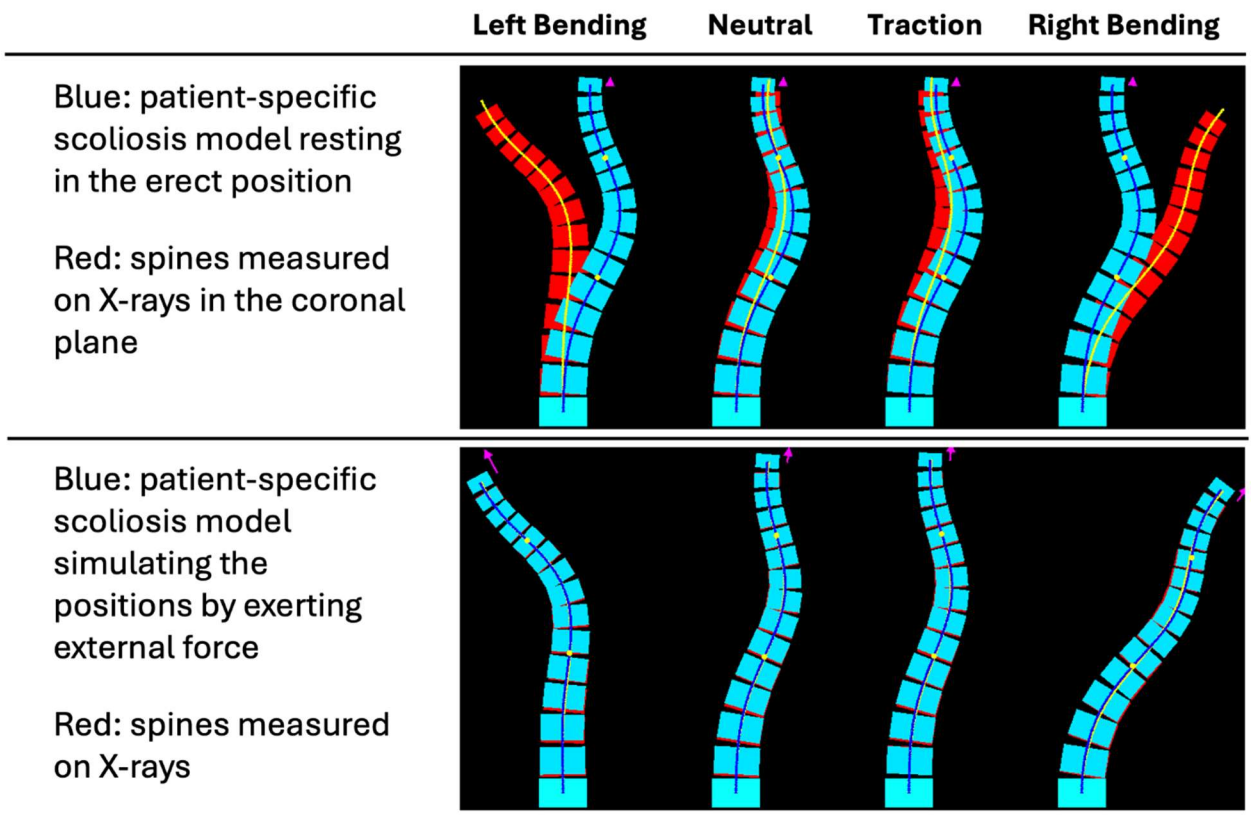
University of Twente, Enschede, Overijssel, Netherlands

Introduction

Scoliosis is a complex 3-dimentional structural deformity of the spine. It causes wedged intervertebral discs resulting in S and C shape spines. Such deformity introduces asymmetry in the tissues surrounding the spine, e.g. stronger muscles in one side of the trunk compared to the other side. Therefore, the analysis of spine response to load becomes very complicated. In our previous work [1], we showed that simply introducing asymmetry in the spine models might not properly simulate scoliosis condition. We introduced an articulated mechanism with 1000 degrees-of-freedom that outperformed an existing model in reconstructing the spine in different positions in the coronal plane. However, we are yet to show if the mechanism can accurately simulate the spine under loads.

Methods

We added non-linear torsion springs at the rotary joints of the mechanism to capture the spine stiffness. We produced patients-specific scoliosis models for our cohort of 18 patients. For each patient, the stiffness of these springs was set by using lateral bending test, where an optimization problem was solved to define the stiffness that resulted in best reconstruction of the spine in the left and right bending positions. X-rays of five spine positions were available: erect, left bending, right bending, neutral, and traction. The first three were used for personalization and the latter two for testing the model capability for reconstruction of the spine in these positions. We compared the results with a benchmark model based on an existing scoliosis model. Root-mean-square-errors (RMSE) of the location and orientation of the vertebrae were used indicators of accuracy spinal column reconstruction.



Results

RMSE for the benchmark model was 1.8 mm and 2.4 degrees for the location and orientation respectively. Our model was significantly more accurate with RMSE of 0.5 mm and 1.0 degrees, respectively.

Discussion

This can show that to simulate scoliosis we do not need to incorporate all the elements, such as muscles, ligaments and facet joints to create a complex model with questionable values for the geometry and stiffness, but rather we can capture the responses accurately through a simplified and out-of-the-box approach.

CT-Like MRI as a Novel, Radiation-Free Alternative for Personalized Modelling and In Vivo Kinematics Estimation of the Healthy and Deformed Spine

Ms Birgitt Peeters[1], Mr Tom Leppens[1], Prof. MD. PhD. Sebastiaan Schelfaut[2], Prof. MD. PhD. Lieven Moke[2], Prof. PhD. Lennart Scheys[1]

[1]Institute for Orthopaedic Research and Training, KU Leuven, Leuven, Flemish Brabant, Belgium. [2]Department of Orthopaedics, UZ Leuven, Leuven, Flemish Brabant, Belgium

Introduction

Personalized spine models are essential for understanding spine biomechanics in pathological spines, but remain challenging to create. Conventional approaches rely on palpation-dependent skin-marker scaling, or ionizing imaging, such as CT and biplanar radiography (BiXR). This study introduces an efficient, radiation-free workflow based on MRI to create personalized spine models for motion simulation and pilots its use in both healthy and pathological subjects.

Methods

A patient with degenerative spinal deformity and a healthy subject were studied. The pipeline integrates supine CT-like MRI with MRI-visible motion capture markers, automated bone segmentation, spinal joint and alignment definition, and semi-automatic marker definition in CT-like MRI. Postural changes from supine to standing (free-standing & SRS-pose) and walking were simulated. Model accuracy was evaluated by comparing vertebral positions and orientations with BiXR.

Results

Vertebral position and orientation errors were low (7.4 mm, 6.1°). Both subjects showed increased pelvic anteversion from supine to stance, with overall trunk extension in the healthy and flexion in the deformity subject. The healthy subject also showed the opposite flexion-extension intersegmental distribution compared to the deformity subject. Interestingly, the deformity subject demonstrated a redistribution of lateral bending in the lumbar segments (Fig.1).

In the SRS-pose, the deformity subject shifted into pelvic retroversion with increased spine flexion compared to the healthy subject.

During walking, the deformity subject showed increased pelvic anteversion and a drop toward the swing leg with trunk flexion and lateral trunk bending against the coronal deformity compared to the healthy subject.

Discussion

This CT-like MRI workflow accurately reconstructed 3D spinopelvic alignment and captured *in-vivo* kinematics. The deformity subject exhibited static and dynamic asymmetries, especially at the lumbar region. Increased pelvic anteversion and trunk flexion indicated an inability for malignment compensation, and the combined spine-pelvis lateral tilt contributed to a waddling gait. Pelvic retroversion in the SRS-pose was artificially introduced due to limited BiXR space, as the hands had to be placed on the wall. The healthy subject maintained a stable posture and uniform motions. These findings highlight the functional impact of spinal deformities and demonstrate the value of this radiation-free, patient-specific pipeline for assessing compensatory mechanisms and motion in clinical practice.

Effects of Cervical Support Height on Neck Muscle Activity and Stiffness in Individuals With and Without Chronic Neck Pain

Mr. Chongpeng Wang

University of Michigan - School of Kinesiology, Ann Arbor, Michigan, United States

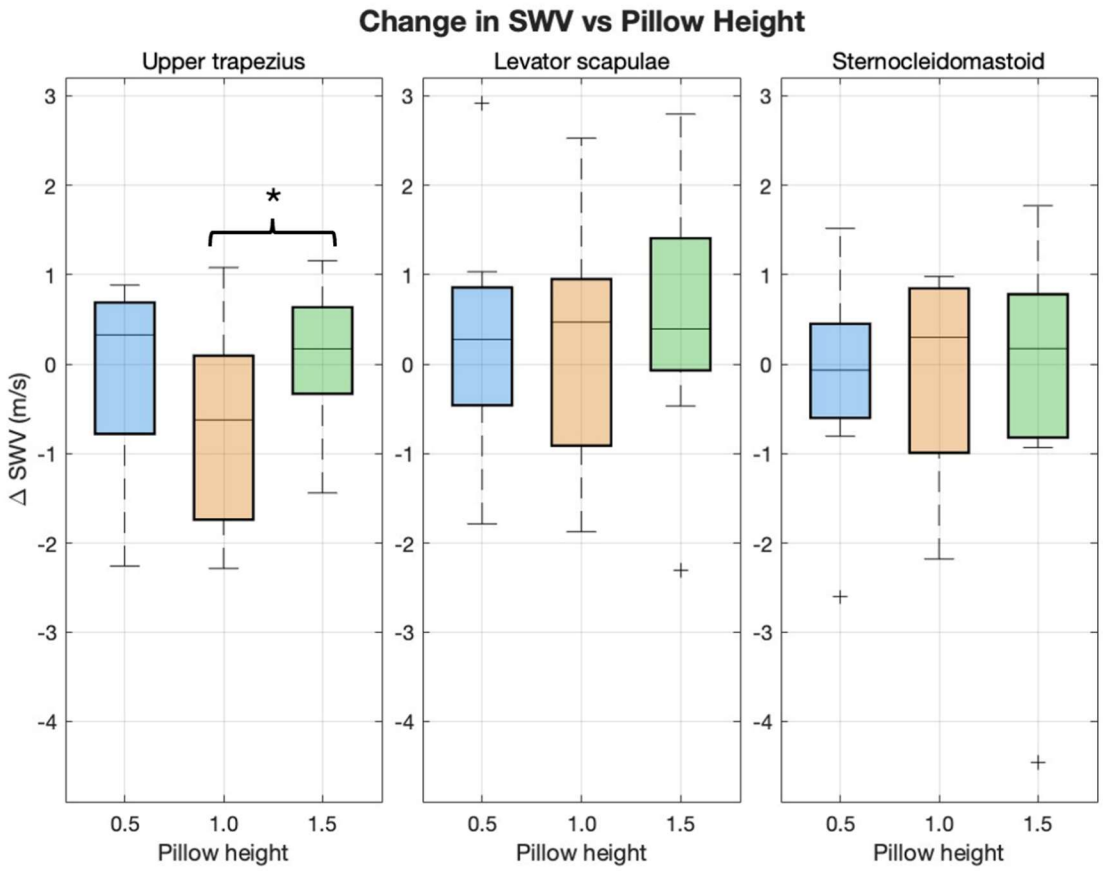
Introduction

Chronic neck pain (CNP) is a common musculoskeletal disorder that negatively impacts sleep [1]. Pillow design may modify symptoms by altering cervical alignment and neck muscle loading, yet there is little evidence to guide pillow height selection. The Set-up for Spinal Sleep (SSS) personalizes pillow height based on alignment, but its effects on neck muscle mechanics are unclear [2]. We examined how pillow heights around each person's SSS value influence neck muscle stiffness and activity during side-lying.

Methods

We examined 12 side-sleeping adults (8 with idiopathic CNP and 4 pain-free controls). Participants laid on their preferred side with individualized SSS pillow heights at 0.5×, 1.0×, and 1.5× in a randomized order. Each 5-minute side-lying trial was followed by 5 minutes of seated rest. Ultrasound shear-wave elastography quantified the change in shear-wave velocity (SWV) of the contralateral upper trapezius, levator scapulae, and sternocleidomastoid during the 5-minute trial. Surface electromyography (EMG) recorded contralateral upper-trapezius and sternocleidomastoid activity relative to relaxed sitting. Repeated-measures ANOVAs examined the effect of pillow height on these outcome measures.

Results



Changing pillow height between 0.5×, 1.0×, and 1.5× SSS produced small changes in ΔSWV and ΔEMG. For the upper trapezius, there was a main effect of height ($p = 0.045$), with post-hoc tests indicating greater stiffness at 1.5× than 1.0× SSS ($p = 0.013$). Pillow height did not significantly affect any other muscles' SWV or EMG measures.

Discussion

Within an individualized SSS-based range, pillow height during a short side-lying session affects the stiffness of the upper trapezius muscle. The lower ΔSWV at 1.0× and higher values at 1.5× are consistent with an intermediate height being better for preserving neutral alignment, while higher pillows may increase passive tension in the upper cervical muscles. Interpretation is limited by the small sample and pooled CNP/control data.

Ongoing recruitment will increase the total sample size to 30 participants to clarify whether individuals with CNP respond differently.

A Virtual Distributed Fiber Model to Reproduce the Lumbar Intervertebral Disc Response in Experimental Spine Testing

Ms Claire Thompson[1], Dr Ryan Willing[2], Dr Stewart McLachlin[1]

[1]University of Waterloo, Waterloo, ON, Canada. [2]Western University, London, ON, Canada

Ms Claire Thompson

Dr Ryan Willing

Introduction

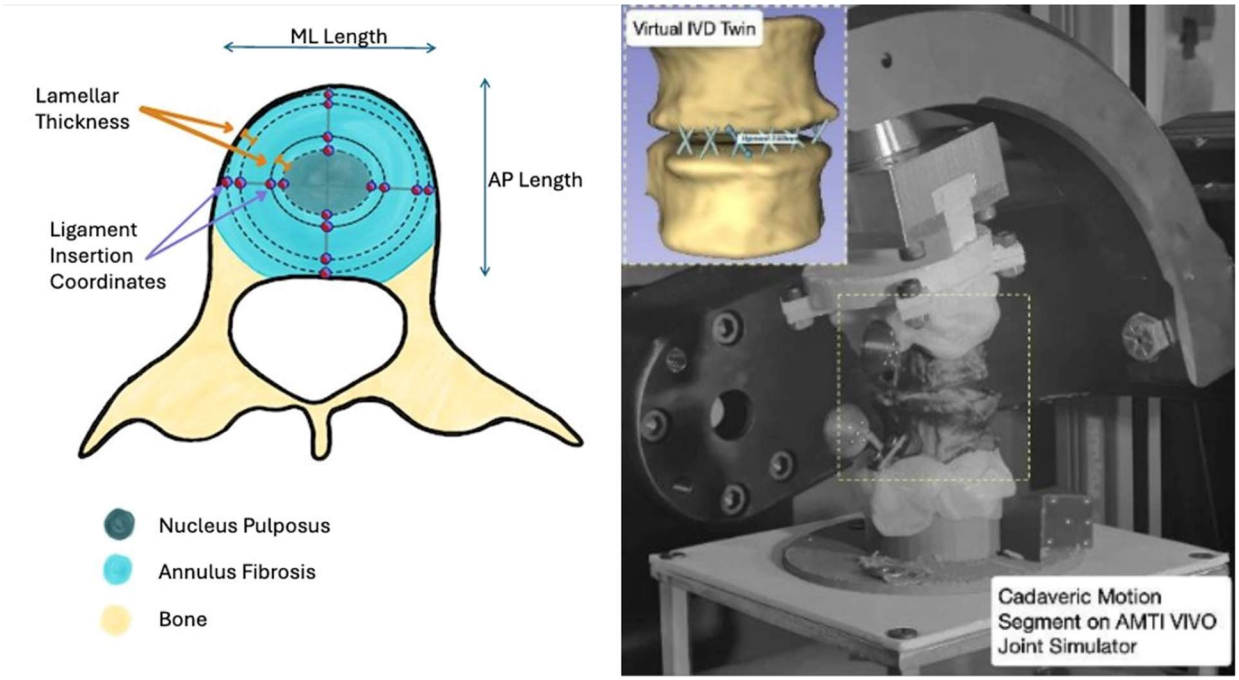
Pre-clinical experimental testing of spinal implants is necessary to characterize device efficacy [1]. However, a key gap in benchtop testing is the simplification of the intervertebral disc (IVD) response, which is poorly represented in pre-clinical tests like ISO12189 [2]. The goal of this study was to develop a virtual distributed fiber model that is parameterized to reproduce the IVD response of the lumbar spine in experimental spine testing. It was hypothesized that a configuration of virtual ligaments (VL) within the AMTI VIVO software could be designed to reproduce the six degree-of-freedom (6DOF) response of the IVD.

Methods

Non-linear VL fibers within the VIVO control system are represented by 1DOF springs and governed by four parameters: proximal and distal insertion coordinates, stiffness (K), and laxity (E_ref). The summed response of the individual fibers act as a 6DOF constraint in the VIVO control system.

To generate a virtual IVD, the geometry was defined based on proximal (superior) and distal (inferior) endplate coordinates using clinical CT measurements. To enable generation of 6DOF constraint forces and moments, paired VL coordinates were placed equidistantly around concentric ellipses representing the endplate surfaces with two anti-parallel VL connecting the proximal and distal coordinates at a prescribed angle to represent fibers of the annulus fibrosus. A generalized stiffness matrix of the IVD response was used to create a single targeted 6DOF force profile based on an input displacement waveform that included flexion-extension (up to ±1 deg), lateral

bending (±1.5 deg), and axial rotation (±1 deg) [3]. A custom MATLAB optimization script, informed by previous data for the IVD response, identified the best K and E_ref parameters to match the summed VL constraint forces and moments with the targeted force profile.



Results

At the peak displacements, the error was 0Nm for flexion/extension, 0.84Nm for lateral bending, and 0.51Nm for axial rotation between the target and the generated VL constraint moments.

Discussion

These results indicate potential of a virtual IVD in spine experiments; however, future work is needed to investigate the sensitivity of the model parameters.

In Vivo Assessment of Mechanical Stresses within Cervical Intervertebral Discs in One-Level and Two-Level Fusion Subjects

Ms Soumaya Ouhsousou, Mrs Clarissa M. LeVasseur, Dr. Jeremy Shaw, Dr. William Anderst, Dr. John C. Brigham

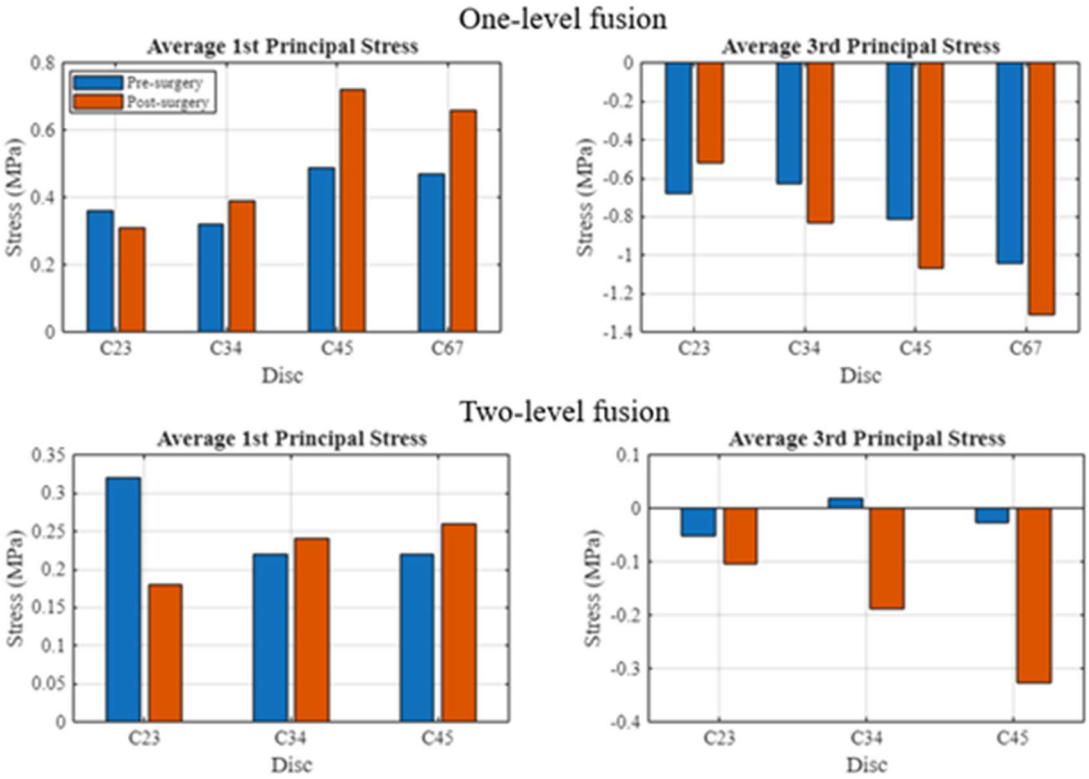
University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Intervertebral disc degeneration is often related to aging and mechanical factors. Spinal fusion is the most common surgical procedure to treat symptomatic disc degeneration. However, post-surgery, patients may experience adjacent segment disease, which is assumed to be linked to the altered mechanical stresses within the cervical spine due to the fusion. To better understand how mechanical stresses change after fusion surgery and their impact on individual intervertebral discs, we developed a novel approach to estimate the intervertebral disc stresses *in vivo* using subject-specific finite element models.

Methods

3D geometries of the cervical vertebrae (C2 to C7) were extracted from CT scans. Then, intervertebral disc geometries, including annulus with embedded fibers and nucleus, facet cartilage, and ligaments were approximated. Each tissue component was assumed to be homogeneous with isotropic material properties, and material parameters were assigned to each component based on published values. Intervertebral motion data from multiple motion trials, acquired with submillimeter accuracy using biplane radiography, were then used to estimate the subject-specific spine loading to reproduce the flexion motion of the subject. Stresses within the intervertebral discs were computed and compared between pre-surgery and post-surgery spine models for both one-level (C56) and two-level (C567) fusion subjects.



Results

Tensile and compressive stresses within the adjacent discs were higher in post-surgery compared to pre-surgery both in one-level and two-level fusion patients (Figure 1). A greater increase in the compressive stresses was observed superior to the two-level fusion compared to the one-level fusion.

Discussion

This study demonstrates an advancement in the effort to estimate *in vivo* stresses within the discs using bone kinematics obtained from biplane radiography as input to subject-specific finite element analysis. The increase of biomechanical stress within the adjacent discs in the post-surgery subject could be an important factor driving adjacent disc degeneration.

Evaluation of Upper Instrumented Vertebra Anchor Strategies to Prevent Proximal Junctional Fracture Following Adult Spinal Deformity Surgery Using Bone Microfracture Analysis

Mr. Tomoya Aki MS[1], Dr. Yusuke Hori PhD, MD[2], Dr. Takashi Namikawa PhD, MD[2], Dr. Akira Matsumura PhD, MD[2], Mr. Humiaki Oomoto[3], Prof. Daisuke Tawara PhD[4]

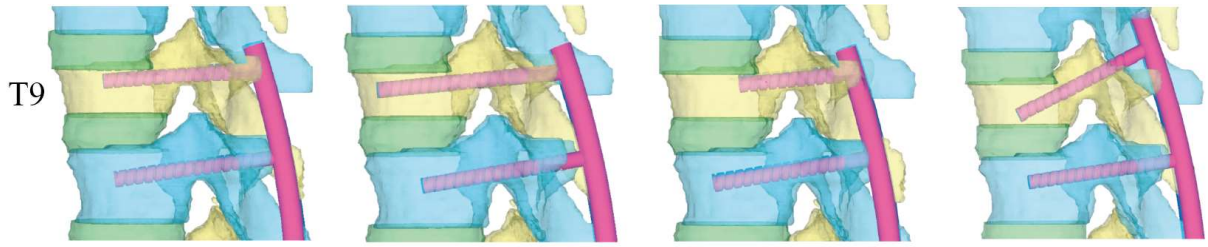
[3]Department of Mechanical Engineering and Robotics, Otsu, Shiga, Japan. [4]Department of Mechanical Engineering and Robotics, Ryukoku University, Otsu, Shiga, Japan

Introduction

Proximal junctional fracture (PJFr) is a critical complication following adult spinal deformity (ASD) surgery and often leads to vertebral collapse requiring revision surgery [1]. Although surgical techniques have advanced, the optimal fixation strategy at the upper instrumented vertebra (UIV) remains unclear. We hypothesized that both the length and direction of pedicle screw (PS) insertion at the UIV significantly affect stress distribution and the risk of microfracture. This study aimed to biomechanically evaluate UIV screw configurations using finite element (FE)–based bone microfracture analysis.

Methods

Four finite element (FE) models of ASD surgery from T7 to the pelvis, with posterior instrumentation from T9 to the pelvis, were constructed based on patient CT data. At the UIV, three different screw lengths (short, medium, and long for horizontal direction) and different insertion direction (caudal direction) were simulated. Vertebrae were assigned a heterogeneous Young's modulus distribution to reflect realistic bone quality [2]. Microfracture analysis was performed [3] using gradually increasing compressive loads applied to the cranial endplate, while the pelvis was constrained [4] using Mechanical Finder software (RCCM Co., Ltd., Japan).



Results

Short screw models showed widespread occurrence of microfracture elements across T9, whereas long screw models demonstrated limited and localized failure. Caudally directed screws distributed mechanical stress more broadly within the vertebra, leading to a lower concentration at the bone–screw interface. In contrast, horizontally directed and shorter screws exhibited increased stress concentration and greater accumulation of microfracture elements.

Discussion

Longer pedicle screws inserted in a caudal direction at the UIV may reduce the risk of PJFr by enhancing load distribution and decreasing stress concentration due to wider contact area of bone and the screw where they are important for load transfer and support. This fixation strategy may contribute to improved mechanical stability at the proximal junction and represents a promising approach for preventing PJFr in ASD surgery.

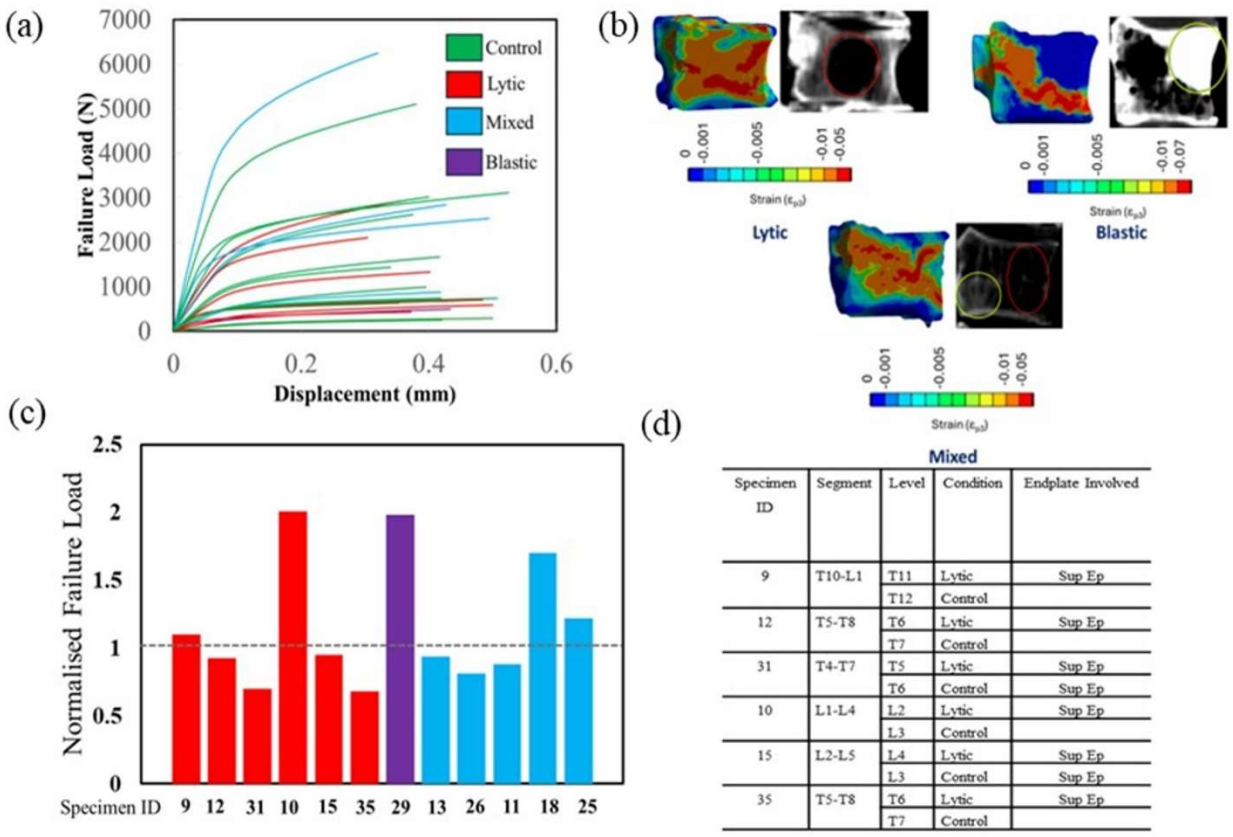
Introduction

Spinal Instability Neoplastic Score (SINS) helps to assess the effect of lesion on vertebral instability when the score is either low (0–6; stable) or high (13–18; unstable). It has less clinical value in the intermediate range. Biomechanical computational studies [1-2] have been limited to isolated lesion types or vertebral bodies, lacking direct comparison between metastatic vertebrae and their controls (adjacent healthy vertebrae). This study introduces **densitometrically calibrated quantitative Computed Tomography (qCT)-to-Finite Element (FE) pipeline** to assess how lytic, blastic, and mixed metastatic

phenotypes differentially modulate vertebral strength and strain distribution using a unique paired design.

Methods

Twelve human spine segments, each containing one metastatic vertebra and one adjacent lesion-free control, were scanned using qCT. Lesions were classified: lytic (n=6), blastic (n=1), or mixed (n=5). Subject-specific vertebral geometries were segmented and meshed (10-noded tetrahedra). Heterogeneous, density-dependent elasto-plastic isotropic material properties were assigned using qCT-calibrated Bone Mineral Density (BMD) [3]. Models were subjected to quasi-static axial compression until 1.9% apparent strain [1]. **Failure load(FL)** and **strain distributions** were computed. **Normalised intra-segment strength metric** (metastatic'FL/control'FL) was used to isolate lesion-specific biomechanical effects from inter-patient variability.



Results

Predicted failure loads between metastatic and controls showed no significant differences overall ($p>0.05$), but varied by lesion type (Lytic: 1.3±0.9 kN; Mixed: 2.6±2.2 kN; Blastic: 0.5 kN). However, **Normalised Failure Load** (Fig.1) varied widely **(−32% to +102%)**, reflecting lesion-specific behaviour. Lytic lesions predominantly reduced strength (<1 in 4/6 cases); the blastic case showed marked strength increase, and mixed lesions were variable. High compressive strains (>0.019) were **frequently concentrated near endplates** (14/24 vertebrae), especially in lytic cases, indicating under-recognised failure mechanism not captured by current clinical scoring. Notably, in blastic lesion, high-strain regions clustered away from sclerotic areas due to local load-shielding.

Discussion

This study shows lesion-induced load redistribution governing vertebral strength, revealing vulnerabilities like endplate-driven failure. These insights highlight SINS limitations and support subject-specific FE modelling as more robust quantitative tool for fracture-risk evaluation and digital-twin-based personalised oncology.

Pre-Clinical Assessment of a New Bioceramic Cage for Spinal Interbody Fusion

Mr Davide Ninarello MSc.Eng., Associate Professor Luigi La Barbera PhD

Deptartment of Chemistry, Materials and Chemical Engineering “G.Natta”, Politecnico di Milano, Milan, Italy, Italy

Introduction

Lumbar interbody fusion (LIF) is the gold-standard treatment for severe degenerative disc conditions. Bioceramics are a promising emerging alternative to address the limitations of standard Ti6Al4V and PEEK materials. However, their brittleness requires careful design to ensure sufficient strength under complex spinal loadings. This study aims to perform a comprehensive in-silico pre-clinical assessment of a new bioceramic cage both under realistic post-surgical conditions and standard testing.

Methods

A calibrated transversely isotropic constitutive model described the ceramic’s mechanical behaviour. The cage geometry, previously optimized, consisted of a lateral LIF cage featuring one longitudinal and one transverse hole. Two finite element models were developed to assess its mechanical resistance.

(1) A lateral LIF surgery at the L4–L5 undergoing combined functional loadings (Fig.1A)[1]. Range of Motion (RoM) and the percentage of cage failed volume, comparing numerical strain with the material limit, were extracted.

(2) An in-silico replica of ASTM F2077-18 standard tests (Fig.1B) evaluating cage strength under axial compression, torsion, and shear, yielding the corresponding failed volume percentage.

Results

The LIF model, validated against experimental in-vitro data [2], demonstrated that surgery reduced RoM by over 85% relative to the intact model (Fig.1C). Failed volume remained below 5% across all motions, with flexion being the most critical (Fig.1D).

In standard testing conditions, the cage showed <1% failed volume (Fig.1E), considering the forces acting on the cage obtained from LIF model and in-vitro tests [2].

Discussion

The bioceramic cage withstood typical post-surgical loads, showing minimal failed volume, mainly influenced by the sharp cage–vertebra interface. Under standard testing, the cage exceeded ISO 23089-2:2021 acceptability criteria, based on over-dimensioned titanium cages, imposing unrealistically high forces. Under realistic loads, the ceramic cage consistently showed <1% failed volume.

In conclusion, the bioceramic cage successfully passed both functional spinal loadings and the in-silico standard tests, supporting its suitability for prototyping and further experimental validation.

Rapid intradiscal pressurization consistently induces clinically relevant posterior ring fractures in the spine

Dr John McMorran PhD[1], Ms Olena Klahsen MSc[2], Ms Aliza Siebenaller MSc[3], Mr Andra Neptune BSc[1], Mr Noah Chow MSc[1], Dr Stephen Brown PhD[3], Dr Diane Gregory PhD[1]

[1]Wilfrid Laurier University, Waterloo, Ontario, Canada. [2]University of Ottawa, Ottawa, Ontario, Canada. [3]University of Guelph, Guelph, Ontario, Canada

Dr John McMorran

Introduction

Apophyseal ring fractures occur primarily in adolescent populations and are typically associated with high-loading scenarios such as sports participation or motor vehicle accidents. Although these injuries are externally driven, the underlying fracture mechanism is thought to involve rapid intradiscal pressurization that develops in response to sudden external loading. The aim of this study was to determine whether ex vivo rapid intradiscal pressurization led to fracture patterns assessed using micro computed tomography (CT) that mirrored clinical observations.

Methods

Six motion segments were excised from porcine cervical spines and further dissected to remove the posterior elements. Each motion segment then underwent a previously established rapid intradiscal pressurization protocol [1]. Briefly, a needle attached to a hydraulic pump was inserted anteriorly into the disc and positioned at the centre of the nucleus pulposus. Fluid was slowly injected until resistance was felt, then additional fluid was rapidly injected by forcefully depressing the pump handle. An in-series pressure transducer recorded intradiscal pressure throughout testing. Following pressurization, each motion segment was scanned using micro-CT and three independent raters classified fracture types according to the Takata classification [2] using reconstructed volumes and 3D renders.

Results

All six motion segments developed Type I apophyseal ring fractures following rapid intradiscal pressurization. Type I is defined as an arc-shaped (arcuate) fracture of the posterior cortical rim of the vertebra, without extension into the cancellous bone of the vertebral body (Figure 1). Further, all fractures occurred in the superior vertebra of the motion segment.

Discussion

These findings demonstrate that rapid intradiscal pressurization reliably produces posterior apophyseal ring fractures ex vivo, and that the resulting injuries closely mirror clinically observed Type I fractures in CT imaging. The consistent reproduction of arcuate cortical rim fractures strongly favours the use of this model for future inquiry into this fracture pattern and provides further evidence to support the hypothesis that sudden external loading such as that experienced during sports or trauma, results in a transient spike in disc pressure that concentrates stress at the posterior vertebral rim leading to failure.

Images (Optional)

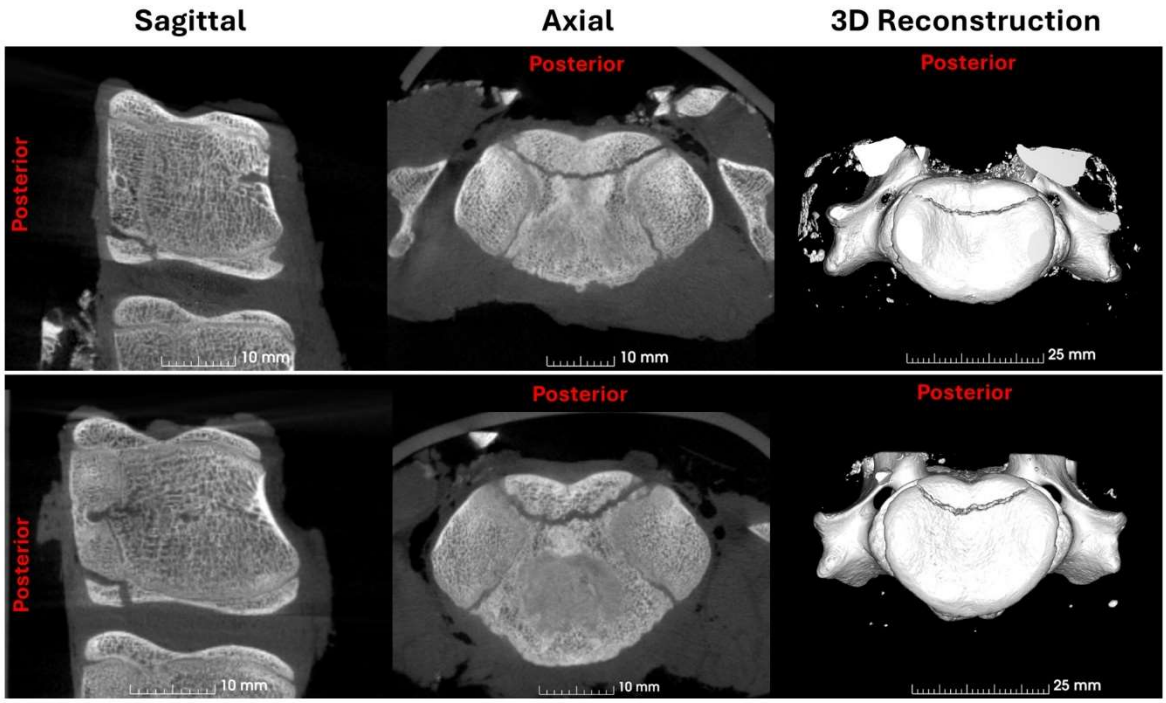

Figure 1. Two samples with Type I posterior apophyseal ring fractures. The arcuate fracture line is visible in both the axial and 3D reconstruction views. In the sagittal view, the fracture is in the posterior region of the superior vertebra and confined to the cortical rim.

Impact of Retroverted Tilt on Facet Joint Stability and Annulus Fibrosus Microdamage in a Porcine Model

MSc Parisa Akhlaghi[1], PhD Remco Doodkorte[1], PhD Bert van Rietbergen[1], MD, ScD Keita Ito[1,2], Mrs. Federica Incatasciato[1]

[1]Eindhoven University of Technology, Eindhoven, Noord Brabant, Netherlands. [2]University Medical Center Utrecht, Utrecht, Utrecht, Netherlands

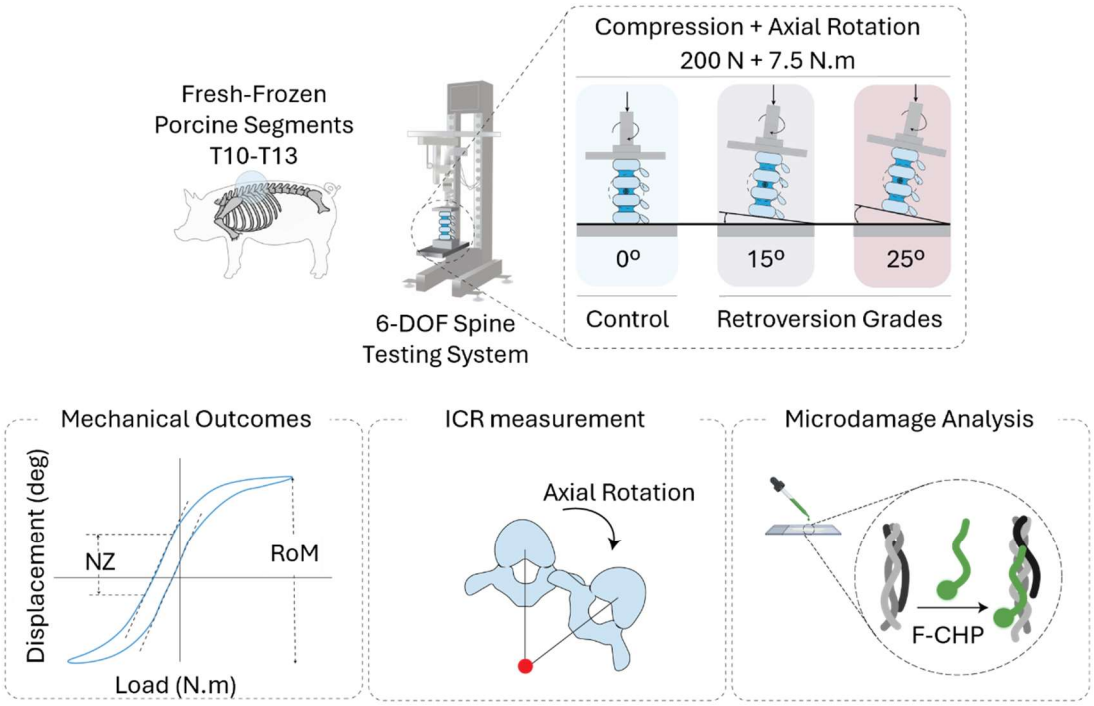
Introduction

Adolescent idiopathic scoliosis (AIS) involves asymmetric adaptation that alters posture and produces a three-dimensional deformity. As the disease and our upright posture are unique to humans, the latter may initiate the former by retroverting spinal segments and imposing dorsal shear loads on it. Although facet joints normally stabilize spinal rotation, dorsal shear forces may disengage them and amplify the rotational instability. During adolescence, increased loading with retroversion and rotational instability may accelerate annulus fibrosus (AF) microdamage and eventual deformity of the intervertebral disc. This study aimed to investigate whether retroverted tilt (1) promotes facet joint unlocking and (2) induces microdamage in the AF.

Methods

18 fresh-frozen porcine spines (T10-13) are tested in a 6-DOF spine testing system to apply 200 N load and ±7.5 Nm cyclic axial rotation with three inclination angles: 0°, 15° and 25° to induce retroversion (Fig 1). Range of Motion (RoM), Neutral Zone (NZ) and NZ stiffness are measured. Individual vertebrae are tracked by LED-marker triplets over the entire RoM to calculate the instantaneous center of rotation (ICR) and level-specific rotations. Rotational instability is defined as increased RoM and NZ, reduced NZ stiffness, and larger shifts in ICR. T11–T12 segments are fixed in 3.7% formaldehyde, decalcified in 0.5 M EDTA, paraffin embedded and sectioned for microdamage analysis using F-CHP staining. The correlation between mechanical outcomes and AF damage is studied to evaluate associations between retrotilt and damage.

Results



In initial testing, inclining the spine by 15° only slightly increased total RoM but substantially, increased the NZ (2.4° to 8.0°) and reduced NZ stiffness (0.37 to 0.29

N·m/deg). Comparing adjacent-level rotations showed a shift in the location of maximum rotation; T10–T11 at 0° (ROM=15°), whereas T12–T13 at 15° inclination (ROM=10°).

Discussion

Introducing 15° retroversion changed both the magnitude and distribution of motion by increasing NZ, decreasing NZ stiffness, and shifting max rotation from the upper to the lower adjacent level. Currently, more samples and inclusion of 25° retroversion are being conducted. Quantification of the ICR and assessment of microdamage in AF, to better connect the mechanical changes to the structural deformity, will complete the study.

Translating Spine Biomechanics From Animal Trials to Humans Through Parametric Finite Element Models

Dr. Joeri Kok[1], Dr. Bert van Rietbergen[1], Prof. Dr. Moyo Kruyt[2], Prof. Dr. Gabriëlle Tuijthof[3], Dr. Malte Asseln[3]

[1]Eindhoven University of Technology, Eindhoven, N/A, Netherlands. [2]University Medical Center Utrecht, Utrecht, N/A, Netherlands. [3]University of Twente, Enschede, N/A, Netherlands

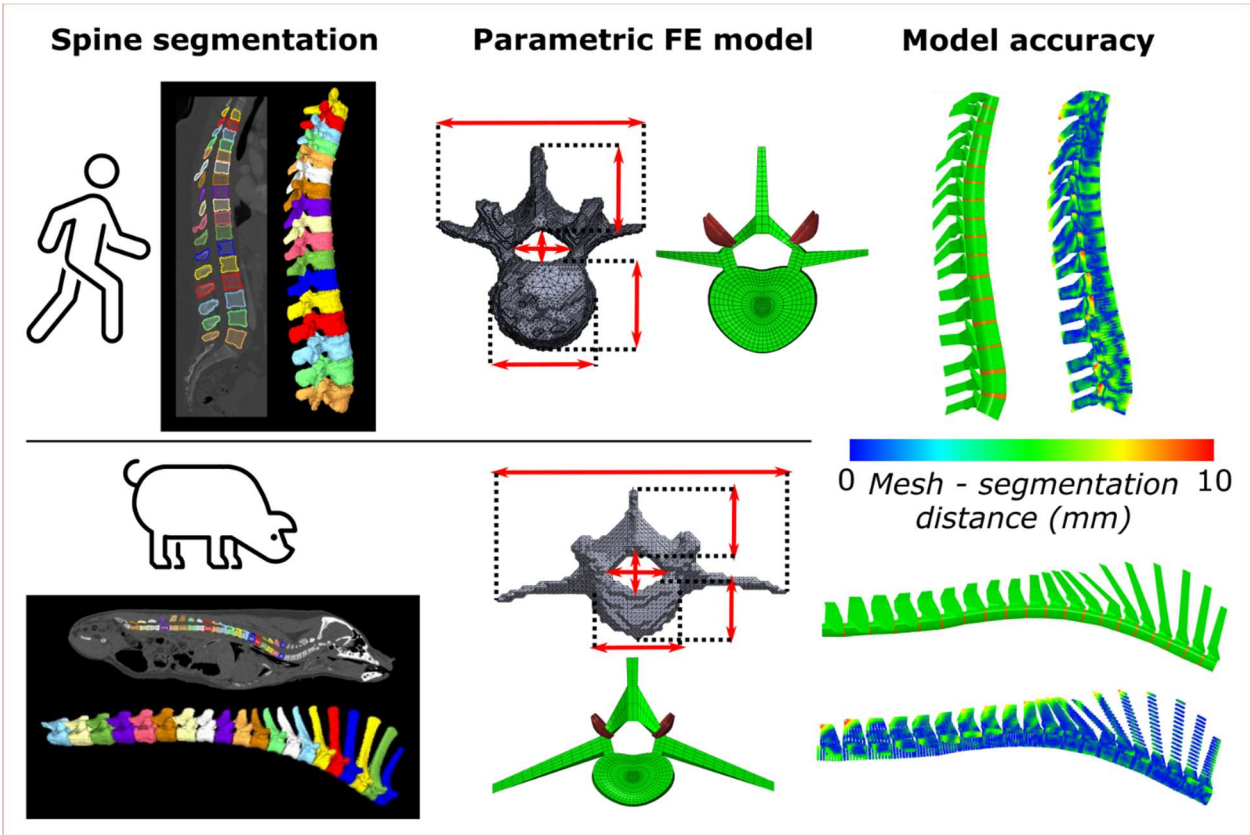
Introduction

The biomechanical performance and safety of spinal implants, e.g., growing rods for scoliosis correction, or cages for intervertebral fusion, are typically evaluated in preclinical animal experiments. However, due to the unique anatomy and function of the human spine, it is not ultimately valid to transfer results from animal models directly. Finite element (FE) models can be employed to study spinal biomechanics in animals and humans. However, differences in models can easily lead to variation in predicted outcomes.

In this study, we aimed to develop a parametric model that can be used to generate meshes for FE models of human and porcine spines. This way, transferability is improved. This can help us translate preclinical data to clinical to improve safety for both humans and animals.

Methods

A parametric model previously developed to create FE models of the human spine has been adapted to also allow for the replication of porcine spines. In the updated model, the number of vertebrae are not limited, and angles and height of the transverse processes and curvature of the facet joints can be added as input. One CT of an adult human with available segmentation of vertebrae [1] and one CT of an 8-month-old Göttingen minipig, where vertebrae were semi-automatically segmented, were used (figure). Morphological parameters were measured from the segmentations and used to automatically generate a mesh of the spine, including vertebrae, intervertebral discs, endplates, and facet joints.



Results

The mean distance remaining between the resulting mesh and the original segmentation was 2.8 ± 2.0 mm for the human spine and 1.3 ± 0.9 mm for the minipig spine (figure). Largest deviations occurred at the ends of the spinous and transverse processes.

Discussion

The multispecies parametric model gives good geometric correspondence for the whole spine, most importantly also capturing changes in spinal curvature and axial rotation, enabling the study of spinal deformities. Furthermore, a robust option for including subject-specific facet joints, including asymmetry, has been added. This way, the accuracy of the modelled load transfer between vertebrae is ensured.

Predicting Growth and Correction of Scoliosis With a Double Spring Reduction System

Dr. Joeri Kok[1], Dr. Bert van Rietbergen[1], Mr. Abdiqani Abdi[2], Ms. Marieke Wesselink[3], Prof. Dr. Moyo Kruyt[2], Prof. Dr. Gabriëlle Tuijthof[3], Dr. Malte Asseln[3]

[1]Eindhoven University of Technology, Eindhoven, N/A, Netherlands. [2]University Medical Center Utrecht, Utrecht, N/A, Netherlands. [3]University of Twente, Enschede, N/A, Netherlands

Introduction

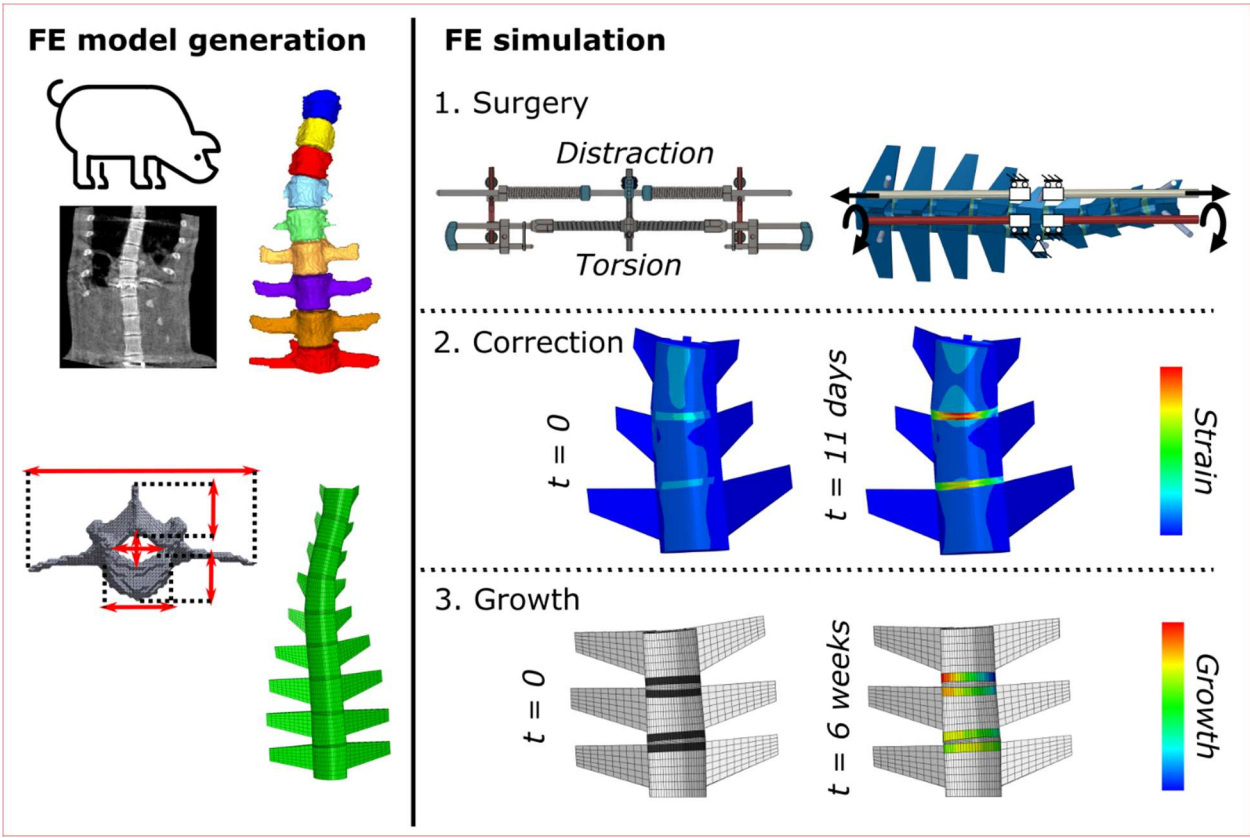
Adolescent idiopathic scoliosis (AIS) is a progressive 3D deformity of the spine often ending in some treatment through correction and spinal fusion. In the past years, non-rigid fixation through a spring distraction system allowing for continuous growth and correction of the curvature has reached the clinics. As a recent advancement, torsional springs have been added to create a double spring reduction (DSR) system, countering axial rotation in addition to correcting the coronal curvature. Currently, no method exists to patient-specifically predict how much force is required to obtain optimal correction. This is partly due to the complexity of predicting the early adaptations of the spine after surgery.

In this study, we aim to calibrate and validate a 3-step finite element (FE) modelling approach to predict scoliosis correction with a DSR system. Models are calibrated and validated against an *in vivo* Göttingen minipig scoliosis model.

Methods

The FE model is created from CT images after induction of scoliosis, before surgical correction. Individual vertebrae are segmented, reconstructed in 3D, measured, and meshed using a previously developed parametric model [1]. The simulations consist of 3 steps (figure): immediately post-surgery, where the spine deforms due to elasticity following 75 N distraction forces and 2 Nm torsion applied through the springs; relaxation and remodelling of the soft tissue, represented with viscoelastic material properties; and asymmetric growth due to pressure on the growth plates. Each step is independently validated, respectively, through post-op x-ray images and a CT at termination.

Results



Before calibration of the correction and growth parameters in the FE model, from a baseline Cobb angle (22.9°) and axial rotation (11.8°), reduction was calculated directly

post-surgery (20.3° and 9.7°), after 11 days of correction (17.3° and 7.2°), and after 6 weeks of growth (16.8° and 7.1°).

Discussion

Calibration of the correction and growth steps in the FE model will follow from planned *in vivo* studies in the first half of 2026. With more insight into the individual correction phases, patient-specific optimization of the spring loads to be applied can be performed. This way, patient outcomes will improve, and complications can be prevented.

Biomechanical Design and Analysis of Porous Compliant Flexures for Cervical Artificial Disc Replacement

Mr Jonah Leinwand, Dr Mihaela Vlasea, Dr Stewart McLachlin

University of Waterloo, Waterloo, Ontario, Canada

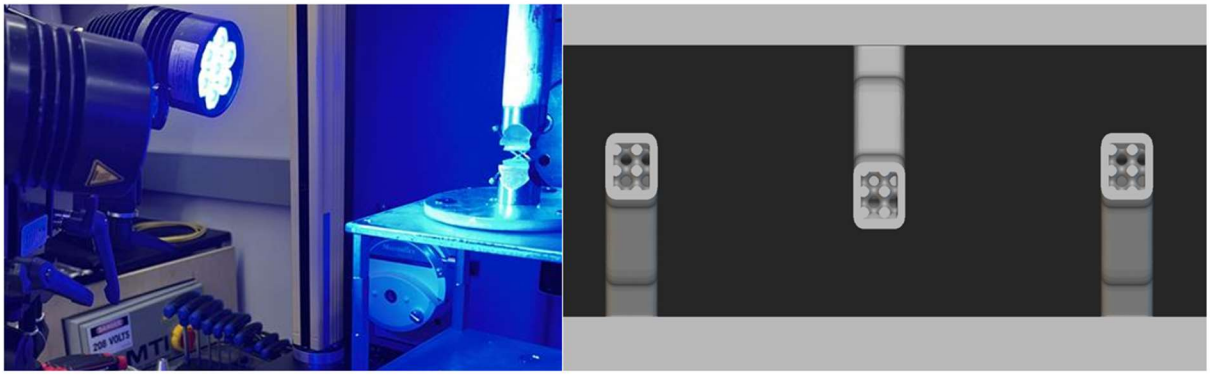
Introduction

Adjacent segment disease (ASD) is a common problem following spinal fusion surgery, where the mechanical mismatch between the stiffness of rigid implant materials and the surrounding bone and joint tissues can accelerate degeneration at the untreated levels. To address this, we have previously explored design of compliant implants for cervical artificial disc replacement (c-ADR), consisting of thin flexural members, to reduce stiffness [1]; however, to date, there have been no biomechanical investigations combining this concept with porous structures. The goal of this study was to design, manufacture, and test porous compliant flexures (PCF), additively manufactured in a titanium alloy using laser powder bed fusion (PBF-LB), to explore the mechanical response of PCF-based implants under physiologically-relevant loads.

Methods

PCF were designed using nTopology software (nTop, NY). Hollow, gyroid-, schwarz- and auxetic-latticed flexures were printed (n=3) in Ti6Al4V via PBF-LB (EOSM290). Implants were designed with PCF elements 1mm-thick in diameter, with a 0.3mm shell filled with latticed material or a hollow gap. Depowdering holes were added on endplates for removal of loose powder. The implants' mechanical response were tested based on applied physiologic loading values reported for the cervical spine to mimic the targeted application of c-ADR. Designs were tested in compression (up to 30% strain) and flexion-extension bending (up to 6°) on the AMTI VIVO joint motion simulator. Flexural displacements and strains were measured using the ARAMIS 3D digital image correlation system.

Results



Latticing and hollowing the PCF elements' interior maintained the strength of the implant compared to a solid infill design. All three latticed infills increased the compressive stiffness of the PCF elements compared to the solid infill design. Solid (11.4kN/mm), gyroid

(17.6kN/mm), schwarz (26.7kN/mm), auxetic (37kN/mm), and hollow (3.8 kN/mm). All flexures could bend 6° in both flexion and extension without signs of failure or cracking.

Discussion

Ongoing work is investigating failure mechanisms of the flexures, including finite-element modelling of crack propagation **in the PCF** titanium structures under physiologically-relevant loading. This failure analysis **is a critical step before future clinical studies,** aimed at addressing issues related to ASD following spine surgery**.**

Pelvic Rigidity and Gait Performance in Older Adults With Degenerative Lumbar Disease

PT Jr-Shiuan Lin

National Taiwan University, Taipei, Taipei, Taiwan

Introduction

Elders with degenerative lumbar disease (DLD) often limit pelvic movement during walking because of pain. Since pelvic motion plays a key role in dynamic stability and gait control, reduced pelvic mobility could impact overall walking performance. The purpose of this study was to compare pelvic rigidity, pelvic tilt excursion, and spatiotemporal gait characteristics between elders with DLD and healthy elders.

Methods

Twenty-five DLD patients and twenty-five healthy elders performed a ten-meter walk at a self-selected pace. Pelvic motion was assessed using an inertial measurement unit placed over the pelvis that recorded accelerations in the anteroposterior, mediolateral, and vertical directions. Pelvic rigidity was quantified using root mean square acceleration. Pelvic tilt excursion in anteroposterior, mediolateral, and rotational directions was calculated as the angular range within each gait cycle. Spatiotemporal gait parameters, including cadence, step length, stride length, step width, and velocity, were obtained using OpenCap motion capture. Group differences were examined with the Mann-Whitney U test(alpha=0.05).

Results

Pelvic RMS acceleration showed significant group differences in all directions. The DLD group exhibited lower anteroposterior RMS acceleration (2.81 ± 1.60 vs. 4.59 ± 1.01 m/s^2, $p < .001$), mediolateral RMS acceleration (1.80 ± 1.03 vs. 2.57 ± 0.54 m/s^2, $p = .002$), and vertical RMS acceleration (8.09 ± 4.32 vs. 15.04 ± 2.02 m/s^2, $p < .001$). Pelvic mediolateral excursion was significantly smaller in the DLD group (12.21 ± 3.36° vs. 14.28 ± 3.56°, $p = .040$), as was pelvic rotational excursion (6.09 ± 1.31° vs. 7.91 ± 1.56°, $p < .001$). Cadence was significantly lower in the DLD group compared with controls (108.74 ± 12.85 vs. 119.41 ± 13.13 steps/min, $p = .007$). Stride length was also significantly reduced in the DLD group (1.21 ± 0.12 vs. 1.31 ± 0.16 m, $p = .011$).

Discussion

Elders with DLD showed lower pelvic RMS acceleration and reduced mediolateral and rotational excursion, indicating more restricted pelvic motion during walking. These mobility limitations were accompanied by lower cadence and shorter stride length. Therefore, these findings suggest that DLD is associated with decreased pelvic movement and alterations in gait strategy. Interventions aimed at improving pelvic mobility may be beneficial for enhancing gait function in patients with DLD.

Biomechanical Evaluation of Anti-Migration Performance of an Expandable Lumbar Interbody Cage With Different Expansion Degrees

Research Fellow Kuo-Chih Su

Taichung Veterans General Hospital, Taichung, Taiwan, Taiwan

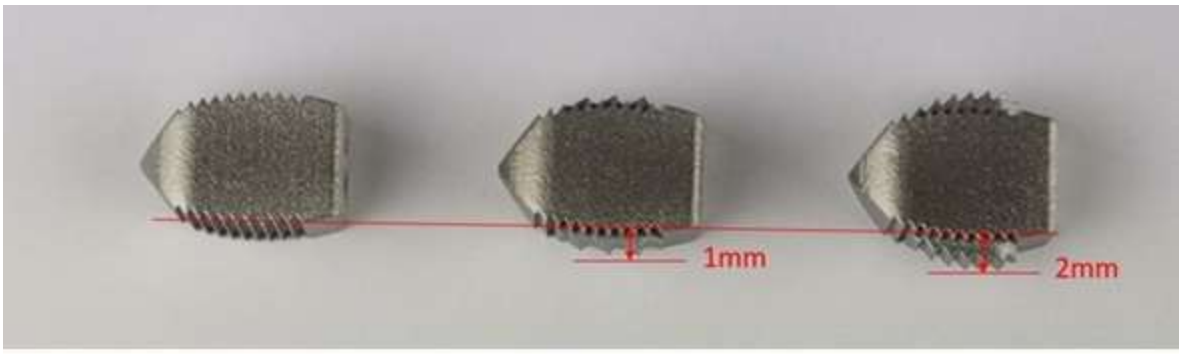
Introduction

Lumbar interbody fusion combined with pedicle screw fixation is a common surgical treatment for spinal instability [1]. However, postoperative complications such as cage migration, subsidence, and adjacent segment degeneration remain clinical concerns. Expandable lumbar interbody cages have been developed to restore disc height and enhance segmental stability, yet the biomechanical effectiveness of different expansion degrees in preventing cage migration has not been fully clarified. Understanding how expansion degree influences cage fixation is essential for optimizing implant design and reducing postoperative failure.

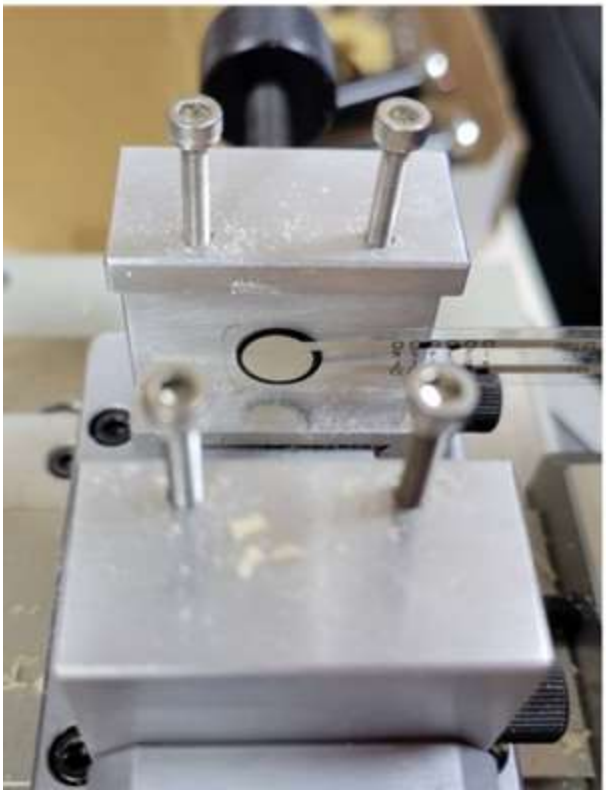
Methods

In this in vitro biomechanical study, three custom-designed lumbar interbody cages with different expansion degrees were fabricated using metal 3D printing (titanium alloy): non-expandable (0 mm), mildly expandable (1 mm), and highly expandable (2 mm). For each group, ten repeated pull-out tests were performed. Each cage was clamped between two polyurethane foam blocks (Sawbone, 20 PCF density) to simulate normal vertebral bone quality. A compressive preload of 200 N was applied to replicate physiological conditions. Pull-out tests were conducted using a small-scale mechanical testing system [2], and the maximum pull-out force was recorded as an indicator of anti-migration performance, following established testing approaches.

Results



The highly expandable cage (2 mm) demonstrated the highest mean pull-out force (282.07 ± 63.05 N), indicating superior resistance to migration. The non-expandable cage (0 mm) exhibited a moderate pull-out force (242.34 ± 54.71 N). In contrast, the mildly expandable cage (1 mm) showed the lowest pull-out force (221.56 ± 37.75 N), which was lower than



that of the non-expandable group. These findings suggest that limited expansion may reduce effective contact area or mechanical engagement between the cage and the surrounding bone surrogate.

Discussion

The results indicate that cage expansion does not necessarily improve anti-migration stability unless sufficient mechanical interlocking is achieved. Insufficient expansion may compromise fixation by reducing effective structural engagement. Adequate expansion appears critical for enhancing cage stability and preventing migration. These preliminary findings provide valuable biomechanical insight for the design optimization of expandable lumbar interbody cages. Ongoing work includes further biomechanical evaluation under additional loading conditions.

Biomechanical Evaluation of Different Fixation for Oblique Lumbar Interbody Fusion Using Finite Element Analysis

Research Fellow Kuo-Chih Su

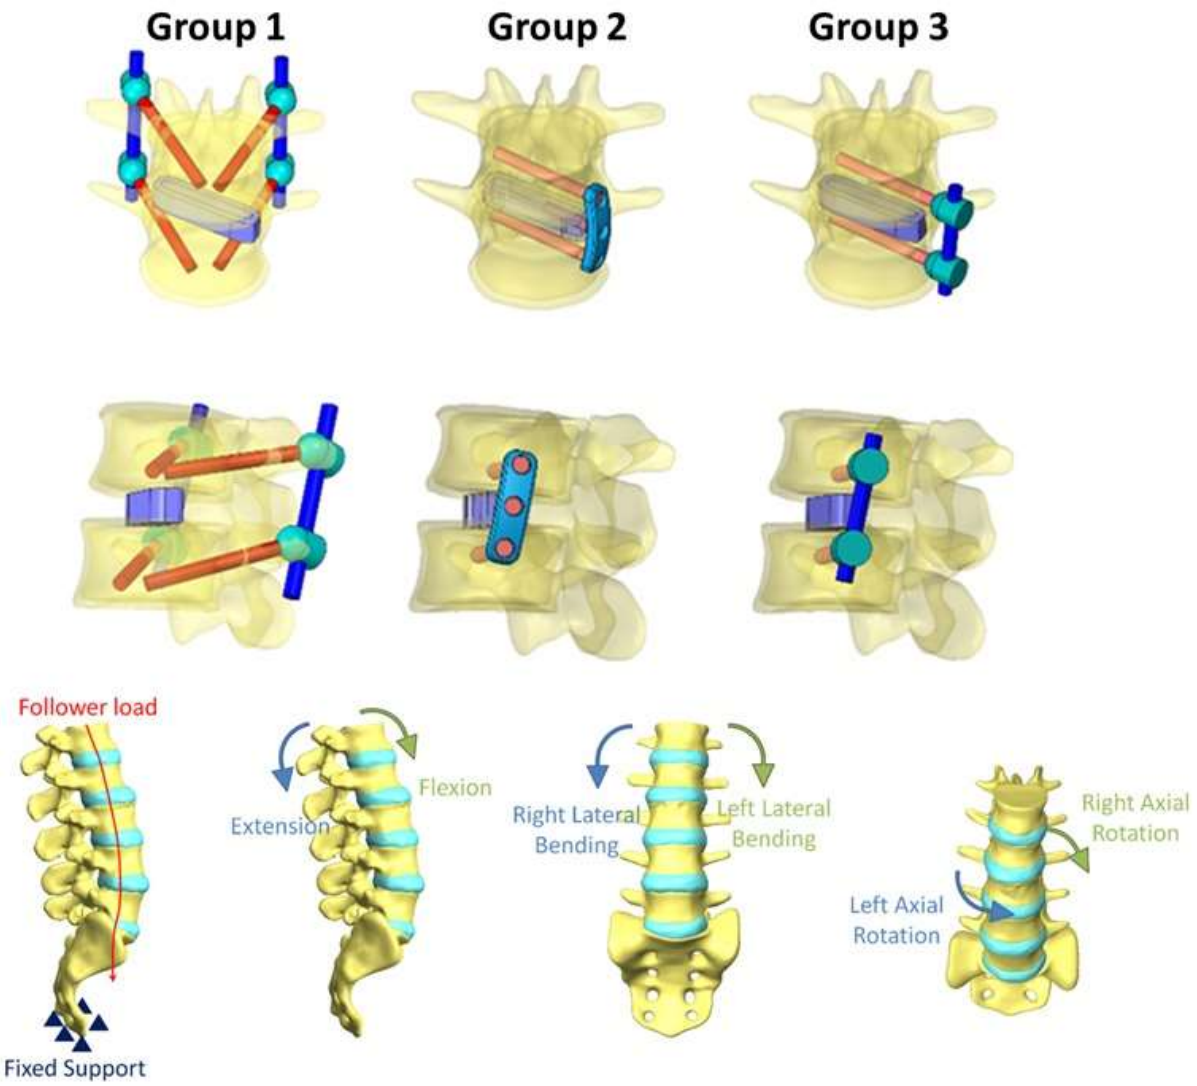
Taichung Veterans General Hospital, Taichung, Taiwan, Taiwan

Introduction

Oblique lumbar interbody fusion (OLIF) is increasingly used to restore disc height and spinal alignment while minimizing posterior soft tissue injury. Conventional OLIF is commonly supplemented with posterior pedicle screw fixation to ensure stability; however, the combined anterior posterior approach increases operative time, surgical invasiveness, and postoperative morbidity. Alternative anterior or lateral fixation strategies using lateral plates or anterior pedicle screws have been proposed, but their biomechanical effectiveness has not been fully evaluated. This study aimed to compare the biomechanical performance of different OLIF fixation strategies using finite element analysis.

Methods

A three-dimensional finite element model of the lumbar spine (L1–S1) was developed based on computed tomography images of a lumbar Sawbone model. The model included cortical and cancellous bone, intervertebral discs with nucleus pulposus and multilayered annulus fibrosus, vertebral endplates, posterior elements, and major spinal ligaments. Three fixation constructs were analyzed: (1) OLIF with posterior traditional pedicle screw fixation, (2) OLIF with an anterior locked lateral plate system, and (3) OLIF with anterior pedicle screw fixation. All implants were virtually implanted following clinical surgical techniques. The sacrum was fully constrained, and physiological loading conditions were applied using follower loads and moments to simulate flexion, extension, lateral bending, and axial rotation. Total deformation and von Mises stress at adjacent endplates were evaluated.



Results

The anterior locked lateral plate construct demonstrated the smallest total deformation under most loading conditions. Flexion produced the greatest deformation in all models, whereas extension resulted in the least deformation. Peak von Mises stresses at the inferior endplate of L2 and the superior endplate of L5 were generally lower in the anterior locked lateral plate group than in the other constructs, particularly during flexion, lateral bending, and axial rotation. Differences among groups were minimal under extension.

Discussion

The results indicate that OLIF supplemented with an anterior locked lateral plate provides biomechanical stability comparable to, or better than, conventional posterior pedicle screw fixation. The locked lateral plate effectively restricts motion and reduces adjacent endplate stress without posterior instrumentation. These findings suggest that a single-approach OLIF fixation strategy may achieve adequate stability while potentially reducing surgical invasiveness.

Introduction

Metastatic vertebrae can be significantly weaker than healthy ones, exposing patients to critical fracture risk. About 30% metastatic patients suffer vertebral fractures, and another 30% undergo unnecessary surgeries. The standard-of-care is the Spine Instability Neoplastic Score (SINS). However, the SINS provides unclear indications for ≈60% patients, mainly because it gives limited consideration to the structure of the vertebrae and to spine biomechanics. The METASTRA project aims to improve the evaluation of the fracture risk through a combination of credible AI and physiology-based biomechanical virtual human twin (VHT) models.

Methods

We are developing and validating two types of models to be deployed in cascade (Figure 1) to assess the fracture risk. The first step relies on Explainable AI, combining parameters semi-automatically extracted from medical records and images. The AI models also provide an indication of confidence. Patients which are not reliably stratified through AI, are examined through detailed VHT models, capturing the subject-specific anatomy, material properties etc. To test the model credibility, the METASTRA project includes large

multicentric retrospective (2000+ cases), prospective (200+ cases) and cadaveric (120+ specimens) studies.

Results

The AI models for identifying spinal structures and metastases, and predicting fractures, are being trained on data from the retrospective study (nearly complete). They will be validated using data from the prospective study (recently initiated). Personalised VHT models with dedicated sub-models for the healthy and metastatic tissues, disc, interfaces and biomaterials implanted were developed [1]. They are under validation against data obtained from the cadaveric study [2], which is measuring properties (morphology, strains, displacements, failure loads and mode) at different scales (from spine- to tissue-level).

Discussion

METASTRA is in its third year (of five). The METASTRA decision support system is expected to cut the indeterminate diagnoses from the current 60% down to 20% cases, with significant benefits for the patients in terms of quality of life and risk reduction. METASTRA will allow better use of resources by preventing fractures (expected saving: ≈1'000M€/year in EU, thanks to timely instead of late surgery), and reducing unneeded surgeries (expected saving: ≈1'400M€/year).

Temporal Changes in Sagittal Spinal Alignment After Fusion and Nucleotomy in a Large-Animal Model

Dr. med.vet. Sandra Reitmaier, Mr. Marcel Simon Reich, Mr. Maxim Bashkuev, Ms. Nicole Bormann, Univ.- Prof. Dr. biol. hum. Hendrik Schmidt

Julius-Wolff-Institute, Berlin Institute of Health at Charité – Universitätsmedizin Berlin, Berlin, Berlin, Germany

Introduction

Surgical interventions that influence segmental stiffness, such as fusion and nucleotomy, can affect load distribution and spinal posture. While fusion limits motion and may provoke compensatory alignment changes, nucleotomy preserves mobility but may induce localized hypermobility or altered disc pressurization. How they affect global sagittal alignment remains unclear. This study quantified time-dependent postural adaptations after spinal fusion and nucleotomy in an ovine model using radiation-free surface topography combined with Statistical Parametric Mapping (SPM), providing a biomechanical perspective on procedure-specific alignment changes.

Methods

Twenty-four female Merino-mix sheep were randomized to fusion, nucleotomy, or sham. Fusion utilized an interbody cage with pedicle-screw fixation, nucleotomy removed approximately 0.2 g of nucleus pulposus, and sham animals underwent surgical exposure only. Posture was assessed via surface topography from the first thoracic vertebra to the lumbosacral junction. Posture was measured twice preoperatively (baseline), on day 1, and at weeks 1, 4, 8, and 12, with three trials per time point averaged for analysis.

Results

Healthy sheep have an inverted sagittal profile relative to humans, thoracic lordosis and lumbar kyphosis. Fusion produced an increase in lumbar kyphosis on day 1, with cranial extension of the kyphotic segment (SPM(t)-max=10; d-max=3.2; Fig. 1a). By week 1, significant clusters were limited to L1–L4, and by weeks 4–12 alignment returned to baseline. Nucleotomy did not change global alignment early, but by week 12 a thoracic cluster displayed increased lordosis (SPM(t)-max=5.8; d-max=1.6; Fig. 1b). Between groups, fusion showed greater lumbar kyphosis than sham on day 1 and week 1 (SPM(t)-max=12.3; d-max=3.7). At week 12, nucleotomy resulted in higher lumbar kyphosis than fusion or sham (SPM(t)-max=8.0; d-max=2.5; Fig. 1c-d). These changes indicate procedure-specific adaptations.

Discussion

Fusion induced an acute lumbar kyphotic shift with later thoracic compensation, likely driven by pain-avoidance postures and cranial load transfer around the rigid construct. Nucleotomy caused delayed increases in thoracic lordosis and lumbar kyphosis, suggesting reduced disc pressurization, enlarged neutral zone, and enhanced neuromuscular stabilization demands. Integrating surface topography with SPM provides a sensitive, radiation-free framework to detect alignment changes relevant for validating surgical techniques and translational spine biomechanics.

Images (Optional)

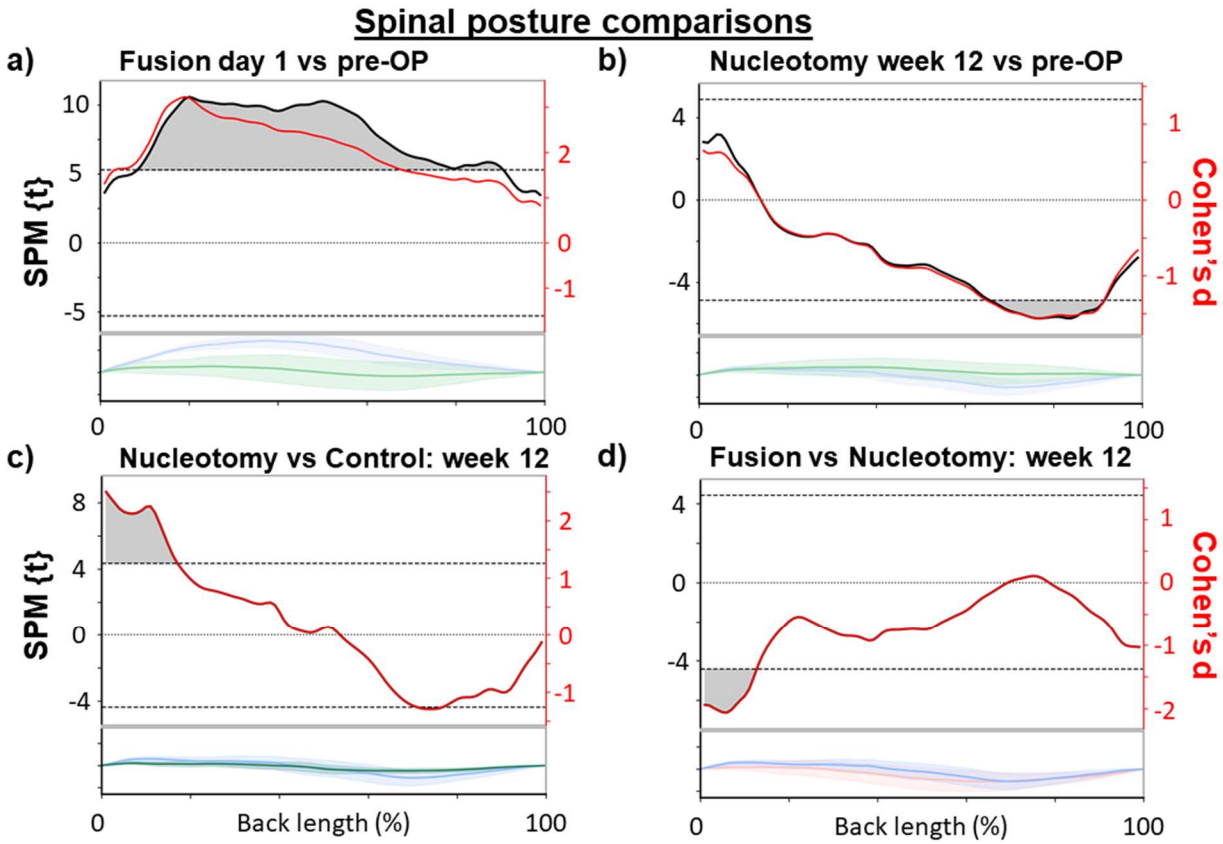

Fig. 1 Statistical parametric mapping (SPM{t}) comparison of sagittal spinal posture. (a) Fusion group one day after surgery vs presurgical baseline. Fusion shows a broad suprathreshold positive cluster over the mid-to-caudal back, showing increased lumbar kyphosis with cranial extension of the kyphotic region; **(b)** nucleotomy at twelve weeks vs baseline. Nucleotomy at week 12 exhibits an extended negative cluster in the thoracic spine, reflecting increased thoracic lordosis;**(c)** fusion vs sham on postoperative day 1. Compared with sham, nucleotomy shows greater lumbar kyphosis at week 12; **(d)** nucleotomy vs sham at week 12. Compared with fusion, nucleotomy likewise displays a more pronounced lumbar kyphosis at week 12; All significant clusters were associated with large effect sizes (Cohen's d > 1). In each panel, the lower graph shows mean spinal posture (a,b: blue = postsurgical, green = presurgical; c,d: red = fusion, blue = nucleotomy, green = sham). The x-axis represents normalized back length (0 = lumbopelvic junction, 100 = withers), the y-axis spinal curvature. The upper graph displays SPM{t} and Cohen's d (red line); horizontal dashed lines indicate the critical SPM{t} threshold for significance. Positive values show a more kyphotic posture in the first-named group, negative values a more lordotic posture.

Intervertebral disc degeneration alters the strain patterns and failure location in the adjacent vertebrae

Miss Margherita Pasini[1], Miss Giulia Cavazzoni[1], Prof Christine Le Maitre[2], Prof Luca Cristofolini[1], Prof Enrico Dall'Ara[2], Dr Marco Palanca[1]

[1]University of Bologna, Bologna, Italy, Italy. [2]University of Sheffield, Sheffield, United Kingdom, United Kingdom

Introduction

Prediction of the risk of fracture in pathological vertebrae, whether osteoporotic or metastatic, remains a challenge. Although multiple mechanical factors influence vertebral failure, the contribution of the intervertebral disc (IVD) and the impact of its degeneration are often neglected. We hypothesize that IVD degeneration has a pivotal role in altering the load transfer across the vertebrae and drives failure mechanisms.

We aimed to quantify how vertebral strain patterns and failure locations differ when loaded through healthy and degenerated IVDs.

Methods

Eleven thoracic spine segments, consisting of a healthy (control) vertebra and a vertebra with lytic metastases, were prepared to be tested in axial compression while imaged inside a microCT (VivaCT80,Scanco,Switzerland; isotropic voxel size=0.039mm).

Six specimens had healthy IVDs, whereas five underwent enzymatic degeneration using collagenase to induce severe nucleus degradation[1,2]. All specimens were imaged and mechanically tested both in the elastic regime—reaching a minimum principal strain of 2000 microstrain[3]—and to failure. Volumetric strains were measured by global Digital Volume Correlation (BoneDVC).

Strain distributions and magnitudes in the healthy-IVD group were compared with the degenerated-IVD group (Mann-Whitney U test). Failure locations were identified by rigid registration of unloaded and post-failure scans.

Results

Similar loads were necessary to reach the target strains (1238N-degenerated vs 1050N-healthy) and to induce the failure (1917N-degenerated vs 1626N-healthy) in the metastatic vertebra.

The vertebrae loaded through healthy IVDs exhibited relatively homogeneous strain patterns, whereas degenerated IVDs showed marked strain concentrations.

Imaging revealed different failure locations: healthy IVDs predominantly led to endplate failure, degenerated IVDs increased cortical shell strain, triggering cortical failure [Fig. 1].

Discussion

These findings highlight the pivotal role of the IVD in directing load transfer and triggering different vertebral fracture patterns. Both IVD degeneration and trabecular/cortical integrity are essential parameters in vertebral failure prediction. Neglecting IVD condition and applying generalized boundary conditions may hide clinically relevant mechanical behaviour and jeopardise fracture risk prediction.

Biomechanical effects of Erector Spinae Role in Sagittal Balance of Adolescent Idiopathic Scoliosis using Patient-specific and Parametric Finite Element Models

Eng. Maria Alejandra Velasquez, Eng Cristian Nikolas Morales Garcia, M.Sc. David Felipe Landinez Leon, Ph.D Christian Cifuentes-De La Portilla

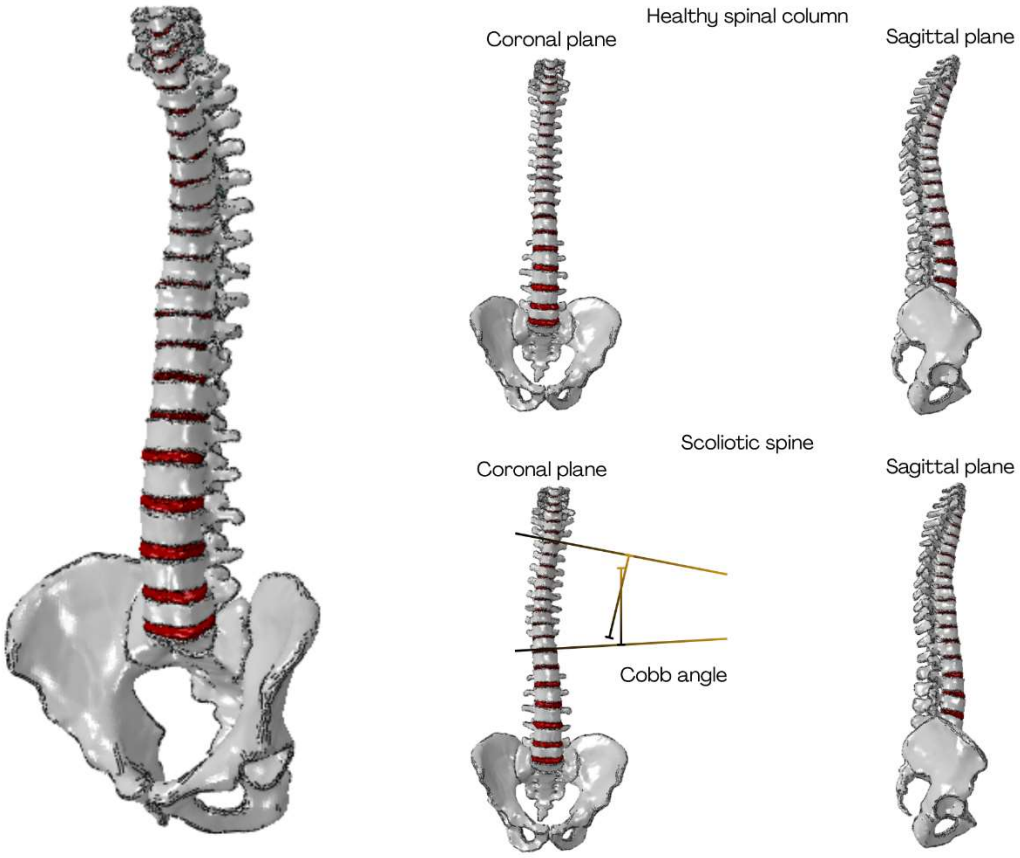
Department of Biomedical Engineering, Bogota D.C, Bogota, Colombia

Introduction

Adolescent idiopathic scoliosis (AIS) is a three-dimensional deformity in which thoracic curve severity strongly correlates with loss of thoracic kyphosis ($r = -0.75$) [1]. The Lenke classification explicitly uses sagittal thoracic alignment as a key modifier of progression and treatment strategy. Despite this clinical relevance, the biomechanical role of erector spinae muscles — the primary sagittal stabilizers — in counteracting sagittal imbalance in AIS remains unquantified using realistic spinal anatomy.

Methods

Two finite element models were developed. (1) A patient-specific model of the complete spine–pelvis complex (C4–sacrum) was reconstructed from clinical CT scans and geometrically corrected in Blender to restore physiological standing alignment. Scoliosis was induced by asymmetric reduction of intervertebral disc stiffness (1000-fold in damaged partitions) following the validated protocol of Landinez et al. [2]. (2) A fully parametric model was designed in Fusion 360, considering anatomical parameters for systematic validation. Longissimus and spinalis muscles were explicitly modeled with forces applied at their anatomical insertions, together with body weight and follower load. Four scenarios were simulated in Abaqus: healthy spine ± muscle activation, scoliotic spine ± muscle activation.



Results

Both models successfully generated deformation in the coronal plane and reproduced the characteristic thoracic hypokyphosis of AIS. Results clearly demonstrate that erector spinae muscles play a very important role in modifying sagittal curvature: in the scoliotic configuration, muscle activation visibly restored thoracic kyphosis and markedly improved global sagittal alignment compared to the scoliotic case without muscle action. Minimum principal compressive stress distribution in apical vertebrae and discs was significantly reduced with muscle activation. The parametric model confirmed identical behavior.

Discussion

This is the first study combining an anatomically detailed model derived from clinical images with a parametric model to demonstrate that erector spinae muscles generate sufficient posterior loading to actively induce thoracic flattening and sagittal decompensation caused by scoliosis. These findings provide biomechanical evidence supporting the clinical correlation reported by Sullivan et al. [1], reinforce the importance of Lenke sagittal modifiers, and strongly justify muscle-strengthening and motor-control rehabilitation in conservative AIS management.

Topology Optimization for Spinal Fusion Cages: Local Strain Constraints to Promote Bone Ingrowth

MsC Martina Paganelli[1], Dr. Remco J.P. Doodkorte[1], Dr. Bert van Rietbergen[1], Dr. Ondrej Rokos[1], Prof. Dr. Keita Ito[1,2], Prof. Dr. J. J. Chris Arts[1,3], Dr. Joeri Kok[1]

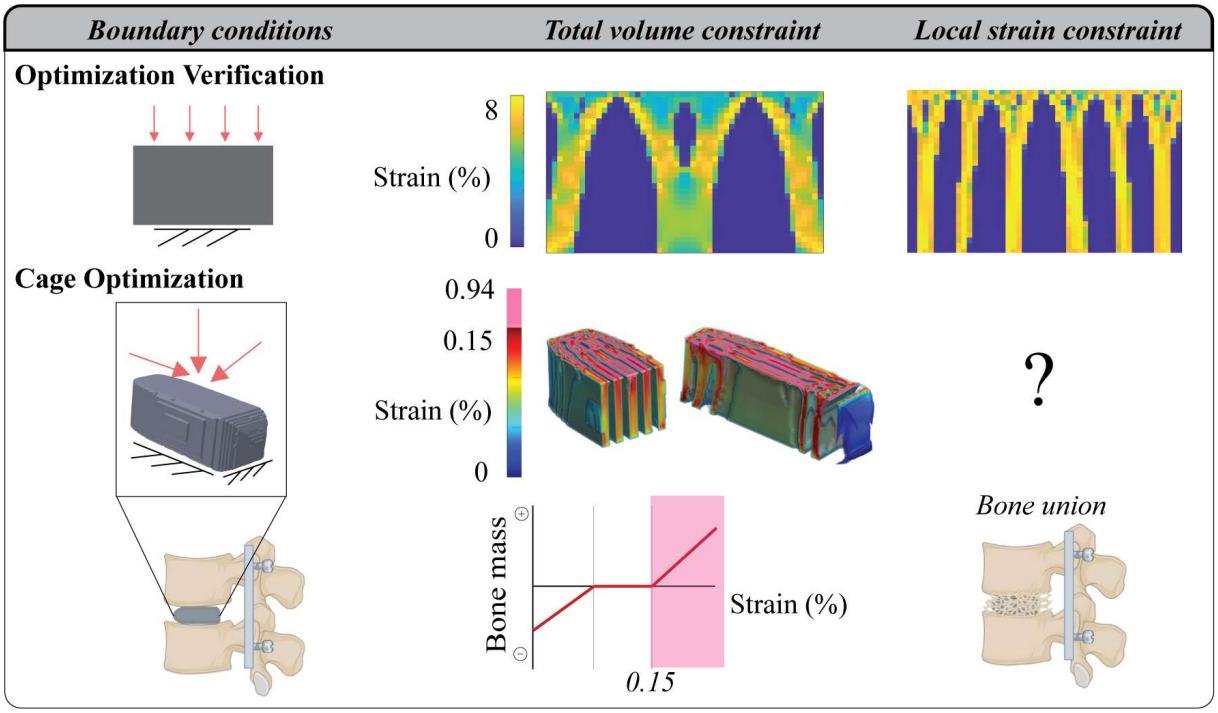
[1]Eindhoven University of Technology, Eindhoven, N/A, Netherlands. [2]University Medical Center Utrecht, Utrecht, N/A, Netherlands. [3]Maastricht University Medical Center+, Maastricht, N/A, Netherlands

Introduction

Topology optimization (TO) has been used to improve implant designs such as for lumbar interbody fusion (LIF) cages. Common TO strategies aim at maximizing stiffness under given mass. However, for optimal fusion and cage stability, enhancing bone ingrowth while maintaining structural integrity should be the goal. As mechanical strains are known to be an important stimulus for bone formation [1], an optimization procedure aimed at favoring strains in the osteogenic range may help to improve fusion outcomes. Therefore, the purpose of this study is to develop a new strain-based TO strategy and to elucidate how cage geometries and strain distribution differ when optimized with a default and local strain-based TO approach.

Methods

This two-stage study evaluated two TO strategies: a default approach minimizing overall strain energy density under a mass/volume constraint (max. 30%) and an in-structure local-strain constrained approach with total volume minimization. The TO strategies were first applied to a 30x50 elements 2D structure simulating compression for algorithm verification. Subsequently, the algorithm was applied to a 3D design representing a titanium posterior LIF cage (41x120x49 elements) subjected to an evenly distributed load in axial compression and two transverse directions of shear [2].



Results

The 2D optimization showed distinct differences in final topology. Moreover, the novel approach resulted in a more homogeneous structural strain distribution, i.e., a lower coefficient of variation (12% vs. 22%). The 3D optimization with the default approach resulted in a structure with a peak stress (423.5 MPa) below the ultimate stress. Strains in the osteogenic range were mostly present on the loaded surface of the structure (Figure).

Discussion

Although 3D local strain-based approach results are still pending, the 2D outcomes demonstrate that incorporating local strain control yields a more homogeneous and targeted strain pattern within the optimized structure. This suggests that geometries optimized with local constraints may better achieve target strain levels. In contrast, the 3D cage optimized with mass/volume constraint exhibit non-homogeneous strain patterns, with limited regions reaching the osteogenic range.

The Role of the Deep Multifidus During Static and Dynamic Activities in a Healthy Population: A Pilot Study

Dr Mona Fre, Dr John Charles Snow, Dr Greg Pearcey, Dr Diana DeCarvalho

Memorial Univeristy of Newfoundland, St. John's, NL, Canada

Introduction

The deep lumbar multifidus (DLM) has been proposed to be crucial for spinal stability [1]. However, since surface electrodes cannot measure muscle activity of deep LM fibers [2], little is known about the activity of DLM during functional tasks. We hypothesized that the DLM shows greater activity during tasks that challenge spinal stability while the SLM showed greater activation during tasks requiring extension. **Our purpose was to characterize the muscle activation of the deep multifidus using intramuscular EMG in comparison to the superficial LM (SLM) using surface EMG.**

Methods

Data from five (4M, 1F) asymptomatic participants was collected using intramuscular and surface EMG. Fine wire electrodes were inserted unilaterally (right side) at the L3, L4 and L5 levels, and surface electrodes were placed bilaterally at the L4 level. Participants completed three trials of fifteen different movements (Table 1) in a randomized order. Presented here are the mean, peak and minimum electromyography signals expressed as %MVC for each task (averaged across the 3 trials).

Results

Normalized EMG for the DLM and SLM at L4 for each task can be seen in table 1. Within each category, tasks are sorted in ascending order of DLM activity highlighting the increase in DLM but not SLM activity with increasing lateral and rotational demands. Average SLM activity ranged from 1-6%MVC while a larger spread was found for DLM. Similarly, a higher range (minimum to peak) of activity was observed for DLM for each task, as well as greater within-subject variability between the three trials of each task. Additionally, we observed between-level differences of the DLM with higher variability at L3.

Discussion

Our findings support that the DLM may contribute to spinal stability varying in activity depending on the task demand while the SLM was less variable. This highlights the importance of considering the DLM for low back pain rehabilitation and modelling of complex tasks using spinal finite element models. Additional analyses will investigate the

roles of the DLM and SLM throughout dynamic movement tasks and pilot motor unit decomposition for the DLM.

Introduction

Brace treatment is a common second-line intervention for adolescents idiopathic scoliosis (AIS) in continental Europe. It is usually indicated when the curve progression persists despite physical therapy, and the Cobb angle exceeds 20°-30° [1]. Bracing applies corrective forces to the trunk and supports posture but restricts trunk mobility during daily activities. This study aimed to compare trunk muscle activation during an object lifting task performed with and without a brace.

Methods

Five female adolescents with main thoracic right convex mild to moderate AIS (Cobb angle: 34°±11°, age: 13.6 ±1.5 years) performed an object lifting task five times with and without wearing their personal customized braces, all manufactured by the same company using 3D scanning and printing. Surface electromyography (EMG) electrodes were placed bilaterally over the upper longissimus thoracic, the lower longissimus thoracic, and the iliocostalis lumborum (T5, T9, and L3 levels, respectively), as well as over the obliquus externus and rectus abdominus muscles. Muscle activity was recorded using a 16-channel telemetric EMG system. Signals were filtered, rectified, smoothed, and normalized to percentages of maximum voluntary contractions (%MVC). Mean muscle activity during the lifting and lower phases was computed for each trial and averaged across repetitions. Condition-specific differences were calculated by subtracting braced from unbraced values and considered if they were larger than 5 %MVC.

Results

Two participants showed changes in upper thoracic longissimus (left side) and lower thoracic longissimus (right side) activation when wearing the brace, but these changes were reciprocal across subjects: one exhibited higher activation, the other lower. Three participants showed no thoracic muscle changes. All subjects tended to activate the iliocostalis lumborum more when braced, while abdominal activity remained unchanged.

Discussion

This exploratory analysis revealed no consistent changes in trunk muscle activation when wearing a brace. The individual responses observed, particularly the reciprocal thoracic longissimus patterns, could not be linked to age, curve type, curve severity, or other characteristics. Overall, bracing may modulate neuromuscular activation in some individuals but not others. The absence of differences in abdominal muscle activity likely reflects their comparatively minor contribution to the lifting task assessed.

Discriminative Morphable Shape Modeling of Lumbar Spine Geometry in Spondylolisthesis Assessment

Mr. Reza Rahimi PhD Student, Dr. Allison Clouthier Assistant Professor

University of Ottawa, Ottawa, Ontario, Canada

Introduction

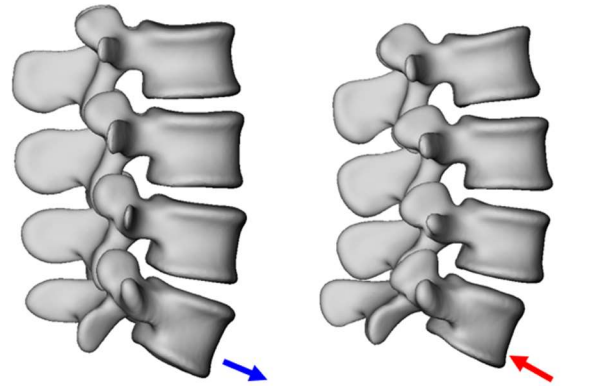
Quantifying how 3D lumbar shape varies with demographics and pathology is crucial for understanding dysfunction. Statistical shape models (SSMs) are widely used to quantify geometric variation; however, typical methods impose a single, linear relationship between shape and pathology. This likely oversimplifies the complex variation existing within different populations. We present a decision-informed morphable SSM that encodes nonlinear shape–diagnosis dependencies as coherent, anatomically plausible deformation patterns across populations.

Methods

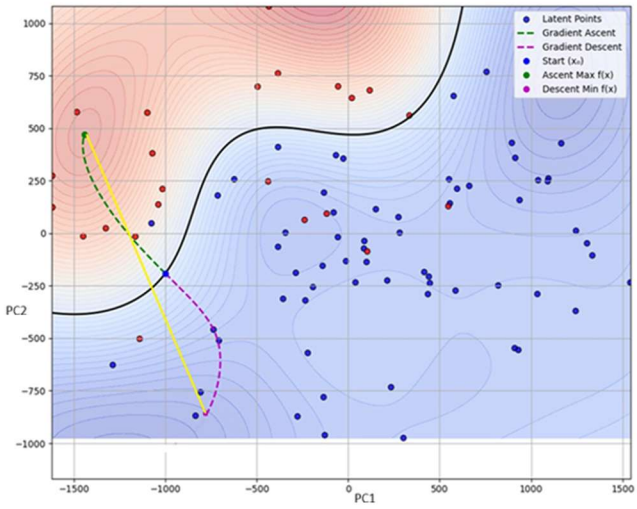
Participants and data processing:

We retrospectively analyze 87 lumbar CT scans from The Ottawa Hospital (2013–2018), approved by the University of Ottawa and Ottawa Hospital Research Institute REBs. Each case is labeled for the presence or absence of spondylolisthesis. High-resolution vertebral meshes are extracted, quality-controlled, and brought into dense point-wise correspondence (CPD) through standardized alignment and non-rigid registration, forming the basis for robust shape analysis.

Method Pipeline: (i) learn a label-informed, low-dimensional shape space with partial least squares (PLS) regression; (ii) train a nonlinear support vector machines (SVM) decision boundary on PLS scores, evaluated with nested cross-validation to avoid selection bia; and (iii) obtain morphs by sampling the SVM boundary, then from each boundary seed stepping a small margin into each class along the gradient of the decision function, and mapping the latent difference back to vertex displacements.



Results



On 87 aligned, corresponded meshes, the model achieved accuracy 87.2%, AUC 0.88, and F1 67.8% for spondylolisthesis classification. Learning curves showed training and validation performance rising and converging with sample size, indicating good generalization. Performance exceeded the proposed PLS and PCA baselines

Discussion

Decision-aligned morphs emphasize pathology-specific changes (vs variance-driven methods) and, unlike a single linear PLS discriminant, reveal multiple, distinct deformation pathways actually used by the classifier. Recovered patterns matched known morphology—anterior L4/L5 slip with disc-height loss and foraminal narrowing, facet sagittalization, and dysplastic signs such as a trapezoidal L5—supporting face validity and clinical interpretability

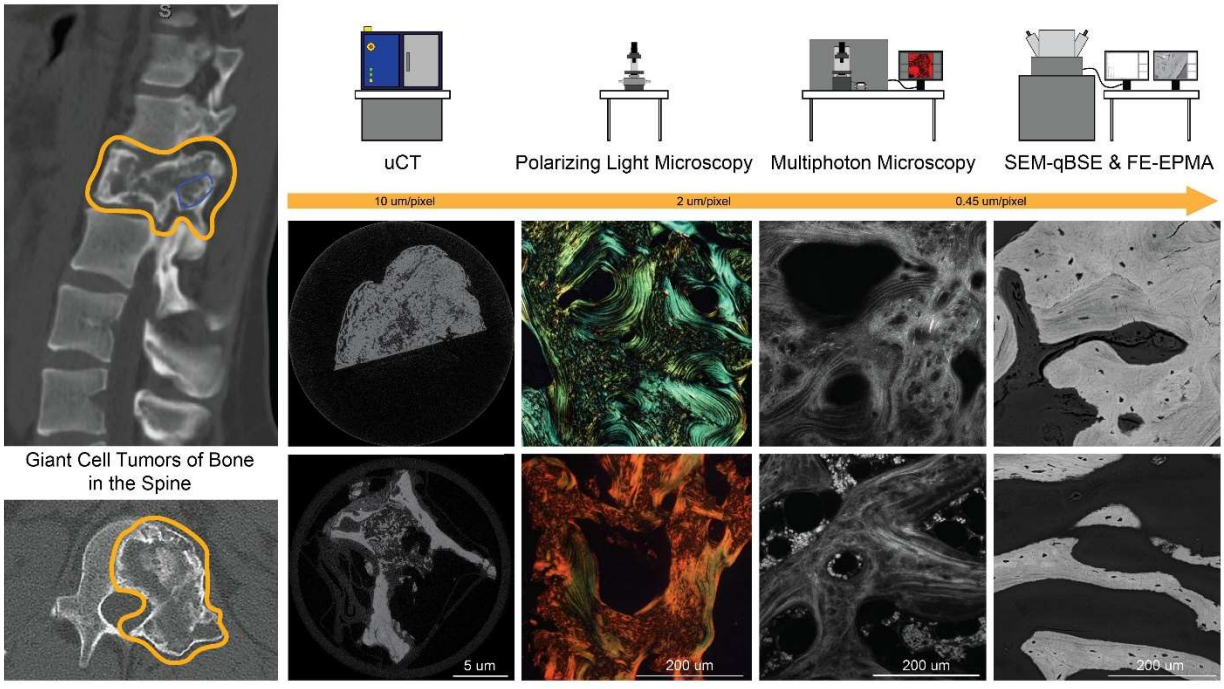
Introduction

Giant cell tumor of bone (GCTB) is a rare, locally aggressive but benign tumor that typically arises near joint surfaces. Spinal GCTB is even rarer, accounting for ~1% of cases. These tumors erode bone turning it into a soft tumor, compromising stability of a joint, also overtaking vital structures such as arteries and nerves. Denosumab, a monoclonal antibody delivered by subcutaneous injection, inhibits RANKL and suppresses osteoclast activity, promoting mineralized bone formation within the tumor. Although denosumab has been used clinically for over a decade, its long-term effects on bone remineralization in spinal GCTB remain unclear.

Methods

We compared five denosumab-treated samples to five region-matched vertebral controls. Bone microarchitecture was assessed by microCT. Mineralization and lacunar morphology were evaluated using quantitative backscattered electron microscopy (6–16 regions per sample) to measure calcium weight percent and two-dimensional lacunar shape. Collagen organization was quantified using second harmonic generation imaging (3 regions per sample) across a 15 μm depth to assess collagen alignment changes with depth. Group differences were tested using Mann–Whitney U and Kruskal–Wallis tests for unpaired data.

Results



Denosumab treatment produced two bone phenotypes (woven and lamellar) and appeared to alter the mineralization process. qBSE demonstrated increased calcium weight percentage with extended treatment durations ($p<0.001$). Furthermore, the weight calcium

percentage between the lamellar and woven bone showed significant increases ($p<0.001$). The woven bone exhibited increased lacunar density ($p<0.001$) and greater circularity($p<0.05$). Additionally, the woven bone showed a decrease in the collagen alignment compared to lamellar bone ($p<0.001$), with large deviations in the angle of alignment with depth.

Discussion

Overall, denosumab-treated bone was more highly mineralized but showed disorganized collagen alignment and increased lacunar density—features consistent with a mixed woven/lamellar structure. Based on established relationships between bone composition and mechanics, these microstructural changes are expected to alter material properties such as modulus and hardness and may influence long-term vertebral strength and stability in patients receiving prolonged denosumab therapy. Future work will focus on linking these structural findings to functional mechanical outcomes, clarifying inter-patient variability, and defining whether there is an optimal treatment window that balances tumor control with bone quality.

Development of Seating Device Focused on Pelvic Mechanical Environment for Reducing Low Back Pain During Sitting

Dr. Ryota Toyohara, Mr. Tsubasa Takahashi, Mr. Chihiro Wakamatsu, Prof. Toshiro Ohashi

Hokkaido University, Sapporo, Hokkaido, Japan

Introduction

Mechanical environments of pelves differ between standing and sitting postures. In standing, loads are transmitted from femora to pelves and lumbar spines via hip joints, whereas in sitting, loads are transferred from ischial tuberosities of buttocks to lumbar spines [1]. This difference implies that standing produces slightly lateral load direction, creating a mechanical environment in which the hip bones compress the sacroiliac joints. A clinical report [2] demonstrated that compression applied to femoral greater trochanters can relieve low back pain and extend sitting time. Therefore, in order to reduce low back pain by improving the mechanical stress environment in lower backs, we aim to develop a seating device that applies lateral loads to pelves by incorporating slopes into a seat pan.

Methods

Seating devices were designed using finite element analysis (FEA) to evaluate stress environments on lower backs. Subsequently, seat pressure distributions were measured in participants using prototypes of the seating device and the stress environments were analyzed again using FEA based on the measure pressure distributions.

Results

The FEA results showed that the seat pan with slopes altered the direction of the seat reaction force to produce lateral compression on the pelves. The seating pressure distribution measured in participants exhibited a similar pattern to the FEA predictions; however, in the prototype used in this study, lateral loads did not increase.

Discussion

The concept of a seating device that compresses the pelves laterally using slopes on seat pans was supported by the FEA results. However, in the pressure measurements obtained with the prototype, loads were mainly applied to the ischial tuberosities, producing a mechanical environment in which pelvic bones were distracted at the sacroiliac joints, which was opposite to the intended effect. These findings suggest that the pelvic contact position on the seat pan may be critical for achieving the desired load transmission in the proposed seating device.

In Vivo Spinal Stiffness Quantification in Adolescent Idiopathic Scoliosis

MSc Salvatore Conticello[1,2], MSc Noelia Bracher[1], MSc Philippe Bähler[1,2], Dr. Stefan Schmid[2,3], Dr. Philippe Büchler[1]

[1]ARTORG Center for Biomedical Engineering Research, University of Bern, Bern, Bern, Switzerland. [2]Spinal Movement Biomechanics Group, School of Health Professions, Bern University of Applied Sciences, Bern, Bern, Switzerland. [3]Faculty of Medicine, University of Basel, Basel, Basel, Switzerland

Introduction

A detailed understanding of spine biomechanics is essential for better understanding the progressive behavior of adolescent idiopathic scoliosis (AIS). Standard clinical assessments measure only displacement and therefore cannot determine true mechanical stiffness, which depends on both applied load and resulting deformation. To address this limitation, we developed a spinal traction device (Figure), which is compatible with EOS radiographic imaging system. The device delivers controlled axial traction through a head halter while a force-sensor platform simultaneously records load, enabling quantitative assessment of spinal mechanical response. The objective of this study was to derive patient-specific spinal stiffness in a patient with AIS.

Methods

A 15-year-old patient with mild thoracolumbar AIS underwent EOS imaging with and without spinal traction. Spinal stiffness was evaluated by reconstructing patient-specific 3D vertebral configurations in standing and traction conditions. Vertebral geometry was segmented from MRI images from the same patient and incorporated into an articulated spine model. This model was fitted to EOS imaging data for both loading states to recover full 3D vertebral positions and intervertebral motions (Figure1). For each vertebra, translation and rotation matrices were extracted and used as inputs for stiffness estimation. A simplified finite element representation of the spine was built using rigid connectors linked by rotational stiffness elements. Stiffness values along the three anatomical axes (Kx, Ky, Kz) were identified through Nelder–Mead optimization, which minimized the rotational and translational discrepancies between the simulated and reconstructed traction configurations.

Results

Vertebral positions were successfully reconstructed in both standing and traction conditions from EOS imaging data. The stiffness estimation revealed higher rotational

stiffness in the thoracic region (Kx=1.44 Nm/deg, Ky=2.85, Kz=1.36) compared with the lumbar region (Kx=0.21, Ky=0.72, Kz=0.68).

Discussion

The quantified stiffness values align with previously reported ranges (0.7–3.7 Nm/deg), indicating validity of our measurement and modeling framework. These results show that traction-based stiffness estimation offers supplementary quantitative data beyond standard radiographic measurements. Overall, this pilot analysis suggests that combining traction imaging with model-based reconstruction is a promising approach to better characterize individual spinal responses. Future work will include a larger cohort to further assess the variability of stiffness patterns across patients.

In Vitro Experimental Validation of Human-Spine Finite Element Models: A Narrative Review

Ms. Sophie Beauchesne[1,2], Ms. Ariane Parisien MASc[1], Dr. Eugene Wai MD MSc[1], Dr. Matthew Coyle MD MSc[1]

[1]The Ottawa Hospital Department of Orthopaedic Surgery, Ottawa, Ontario, Canada. [2]The University of Victoria, Victoria, British Columbia, Canada

Introduction

Finite element analysis (FEA) enables evaluation of spinal mechanics, including segmental kinematics, stiffness, and implant or tissue stress. Because FEA uses simplified anatomy and material properties, in vitro testing is essential to verify accuracy, confirm clinical relevance, and provide realistic loading conditions and specimen-specific behavior. Cadaveric testing provides direct measurements of spinal motion and loading but is limited by specimen variability, non-physiological loading, and the restricted number of implants or configurations. This review summarizes how FEA and cadaveric experiments complementary characterize spinal biomechanics.

Methods

A systematic review included publications from January 2010 to September 2025. Searches targeted studies combining FEA with in vitro cadaveric testing, using keywords such as “finite element,” “FEA,” “spine,” “lumbar,” “fusion,” “cadaveric,” and “in vitro.” Titles and abstracts were screened by one author, followed by full-text review of eligible studies; inclusion required human-spine FEA studies with cadaveric validation, whereas studies restricted to computational models or involving non-human or synthetic specimens were excluded.

Results

The search yielded 356 records and 335 unique articles; five studies met all inclusion criteria. These studies examined multi-rod constructs after pedicle subtraction osteotomy, interbody fusion approaches (LIF, TLIF, ALIF), hybrid pedicle screw/cortical bone trajectory fixation, and interspinous process devices. Validated FE models reproduced experimental kinematics and loading responses, enabling evaluation of stress distributions, implant strain, and construct stability. In vitro tests used between 6 and 8 fresh-frozen lumbar segments (L1–S2, T12–S1, or L2–L5), with motion capture quantifying intact and

instrumented ROM across flexion–extension, lateral bending, and axial rotation. Rotational loading ranged from ±5 to ±10 Nm, with some aligning with the standardized ±7.5 Nm pure-moment protocol. Axial loading included physiologic preloads of 400–500 N and compressive forces up to 600 N. Across all studies, instrumentation reduced ROM relative to intact spines, and FE models consistently reproduced these reductions while identifying internal stress concentrations not measurable experimentally.

Discussion

Combined FEA and cadaveric testing provides a thorough approach for evaluating spinal mechanics. Remaining challenges include small sample sizes, bone-quality variability, simplified anatomy, and inability to model long-term adaptation. Advancing specimen-specific modeling and physiologic multi-loading will strengthen clinical relevance.

Biomechanical Investigation of the Effects of Different Cage Heights and Posterior Compressions on the Cage Migration in Transforaminal Lumbar Interbody Fusion Surgery.

Mr. Chi-Sheng Li BS[1], Dr. Ming-Kai Hsieh MD, PhD[2], Dr. Ching-Lung Tai PhD[3], Dr. Weng-Pin Chen PhD[1]

[1]Department of Mechanical Engineering, National Taipei University of Technology, Taipei, Taiwan, Taiwan. [2]Department of Orthopaedic Surgery, Spine Section, Bone and Joint Research Center, Chang Gung Memorial Hospital and Chang Gung University College of Medicine, Taoyuan, Taiwan, Taiwan. [3]Department of Biomedical Engineering, Chang Gung University, Taoyuan, Taiwan, Taiwan

Introduction

In TLIF(Transforaminal lumbar interbody fusion) surgery, suboptimal cage height due to endplate morphology can lead to posterior cage migration, often requiring posterior compression. This study uses finite element analysis to evaluate how different cage heights and posterior compression forces affect biomechanical stability.

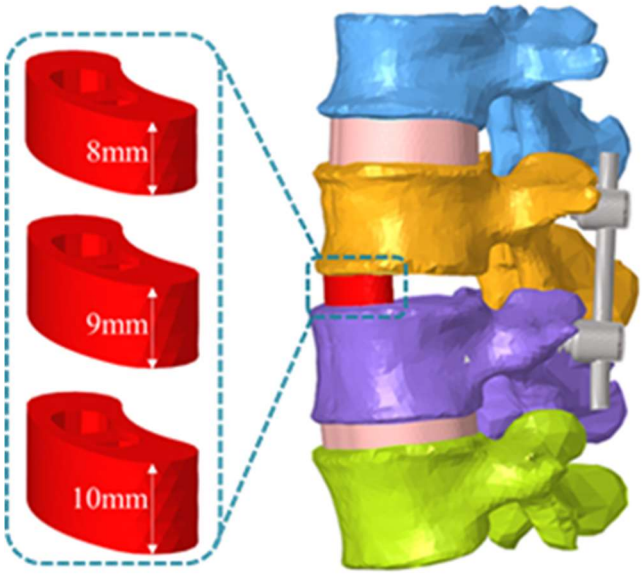
Methods

In this study, a lumbar spine model was established using CT images imported into Amira (TGS, San Diego, CA, USA) for vertebral reconstruction. The intervertebral discs were then modeled in SolidWorks (SolidWorks Corp., Boston, MA, USA), and the full geometric model was constructed in HyperMesh (Altair Engineering, Inc., Troy, MI, USA). The implanted device used in this study was a Banana Cage (Wiltrom, Taiwan) with three size variations of 30 × 8/9/10 × 10 mm, as shown in the figure. The completed finite element model was subsequently imported into Abaqus/CAE (Simulia, Providence, RI, USA) for analysis.

The loading conditions were defined based on the work by Yamamoto et al. (1989) [1]. Displacement-controlled loads of 0, 1, 2, and 3 mm were applied at the L3 pedicle screw heads to simulate posterior compression preload. Flexion was selected as the primary physiological motion for biomechanical evaluation.

Results

Based on our analysis results, the stress distribution shifts toward the posterior region of the cage as the posterior fixation compression increases, and the stress magnitude rises



accordingly. In contrast, implanting a higher-sized cage does not produce a significant increase in stress.

The stress distribution on the endplate shows that, with greater compression, the stress shifts posteriorly, which contributes to improved cage stability.

Discussion

Based on the findings of this study, when surgeons encounter endplate anatomy that prevents the insertion of an appropriately sized cage during TLIF procedures, applying compression through the posterior fixation system can effectively stabilize the cage and reduce the risk of posterior cage migration during physiological activities. Our analysis also indicates that using a higher-sized interbody cage does not substantially improve resistance against migration. Therefore, it is recommended that surgeons may opt for a lower-sized cage combined with posterior compression to achieve better stability in clinical practice.

Biomechanical Evaluation of Spinal Fixations Using Novel Dual-Trajectory, Traditional-Trajectory, and Cortical-Bone-Trajectory Screw Systems Under Normal and Osteoporotic Bone Conditions

Mr. Sin-Yan Lee BS[1], Dr. Yun-Da Li MD, PhD[2], Dr. Ching-Lung Tai PhD[3], Dr. Weng-Pin Chen PhD[1]

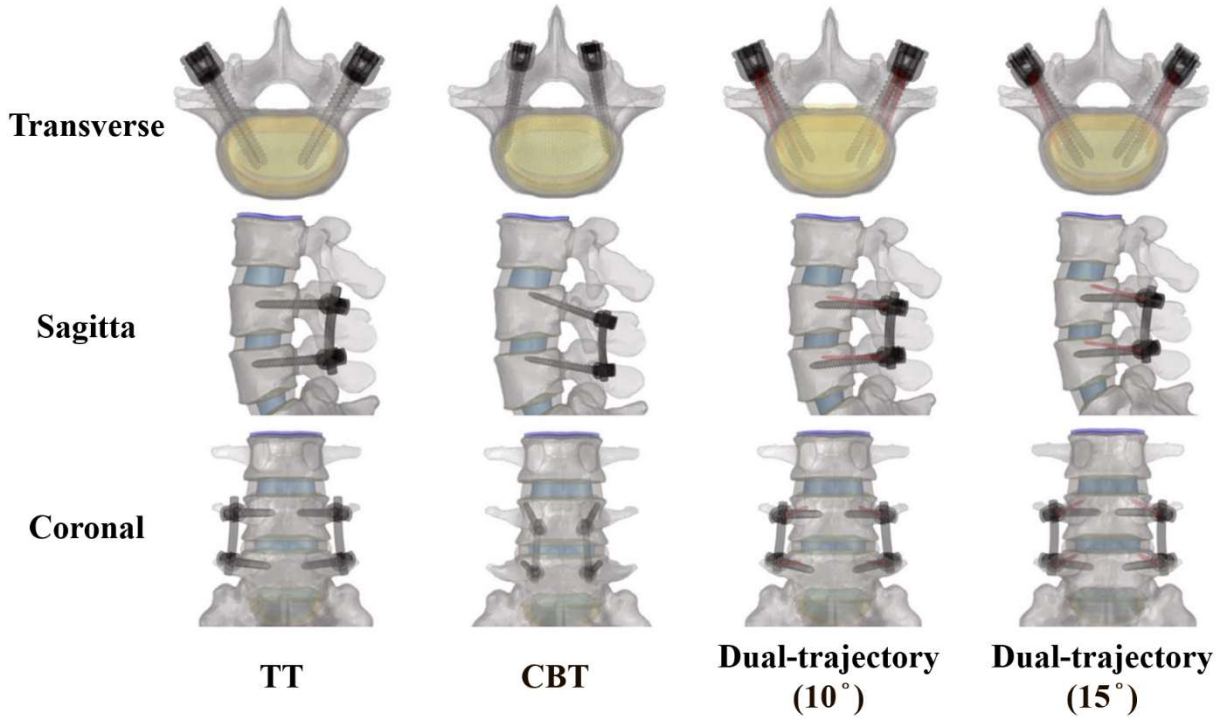
[1]Department of Mechanical Engineering, National Taipei University of Technology, Taipei, Taiwan, Taiwan. [2]Department of Orthopedic Surgery, New Taipei Municipal TuCheng Hospital, New Taipei City, Taiwan, Taiwan. [3]Department of Biomedical Engineering, Chang Gung University, Taoyuan, Taiwan, Taiwan

Introduction

Improving pedicle screw fixation in osteoporotic spines has long been a clinical challenge. While combining the traditional trajectory (TT) with the cortical bone trajectory (CBT) increases screw number and enhances stability, this approach is limited by pedicle anatomy and the need for additional fixation components. [1,2] To overcome these limitations, this study proposes a dual-trajectory (DT) pedicle screw system composed of a primary screw and an adjustable-angle auxiliary mini-screw, aiming to improve anatomical adaptability and fixation performance.

Methods

A finite element model of L3–S1 was developed from 1-mm CT slices of a 55-year-old male. Vertebrae, discs, endplates, and ligaments were reconstructed, meshed, and assigned literature-based material properties. Four screw constructs were modeled: TT, CBT, and DT systems with 10° and 15° auxiliary mini-screws as shown in figure. Pure moments of 10 N·m in all motion directions, gravitational loading, and a 400 N follower load were applied. Outcomes included segmental range of motion (ROM), adjacent-disc equivalent stress, and auxiliary screw stress, under both normal and osteoporotic bone conditions.



Results

Under normal bone density, the TT and DT systems showed similar ROM, indicating comparable stabilization. In osteoporotic conditions, the 15° configuration provided the greatest ROM reduction in all directions. Adjacent-disc stresses were similar among TT and DT models, whereas CBT produced lower stress in extension but higher stresses in flexion, lateral bending, and axial rotation. Peak stresses in auxiliary screws occurred at the screw-to-screw interface but remained well below the yield strength of Ti-6Al-4V; the 15° model showed lower and more uniform stresses than the 10° model.

Discussion

The DT system offers meaningful benefits primarily in osteoporotic bone, whereas the 15° auxiliary screw improves multi-axial stability and reduces micromotion without increasing adjacent-segment loading. In contrast, the higher stiffness of CBT constructs may elevate adjacent-level stress. The more favorable stress distribution in the 15° configuration suggests improved fatigue resistance and long-term reliability. Overall, the optimized DT system represents a promising strategy for enhancing fixation in osteoporotic spines.

Biplane Videoradiography Reveals Segmental Motion Changes Following Spinal Manipulation Therapy: Preliminary Results

Mr. Yaqoub Yusuf MS[1], Mr. Wyatt Cheney[1], Ms. Susan Burnap[1], Dr. Richard Hills PT, DC[2], Dr. Paul Osterbauer DC, MPH[3], Dr. Arin Ellingson PhD[1]

[1]University of Minnesota, Minneapolis, MN, United States. [2]Institute for Orthopedics & Chiropractic, Minneapolis, MN, United States. [3]Lexington Square Chiropractic Center, Minneapolis, MN, United States

Introduction

Spinal Manipulative therapy (SMT) is a commonly used force-based manipulation approach used by chiropractors, physical therapists, and osteopaths to treat back and neck pain by applying force to mobilize a spinal joint and improve function. While research supports its clinical effectiveness, little is known about its mechanism of action, which has been long theorized to normalize spinal motion, particularly at the intersegmental level.

The overall goal of this randomized clinical trial (RCT) is to determine the extent to which SMT can modulate, or normalize, intersegmental motion in patients with neck pain.

Methods

A single participant's (39-year-old male) data, randomized to the SMT arm, is presented herein as a case study. The remaining RCT is ongoing. The participant was evaluated by a licensed Chiropractor (RAH) and intended treatment level (C6-C7) was identified. The participant performed two kinematic assessment sessions, one before and one after SMT. The participant received a low velocity (Maitland grades 3-4) posterior-anterior (AP) glides of C6. Each kinematic assessment included two trials of flexion–extension, lateral bending, axial rotation, and protraction–retraction (FE, LB, AR, PR). Intersegmental kinematics at C4–C5, C5–C6, and C6–C7 were derived from biplane videoradiography. Summary statistics herein include on-axis rotational ROM for each motion (FE, LB, AR, PR) and associated AP translations for FE and PR.

Results

Results suggest a consistent increase in intersegmental motion across all activities (FE, LB, AR, PR) following treatment (SMT). Pain decreased from 4/10 (7/10 worst in past week) to 3/10, with the patient noting less sub-axial restriction and resolution of radicular symptoms.

Discussion

This case study provides preliminary evidence that SMT may positively influence cervical intersegmental motion concomitant with an improvement in self-reported pain and function. The observed increases in ROM across all movement trials suggest that even a single mobilization session can produce measurable biomechanical changes. Although currently limited to one participant with short-term follow-up, we can see that SMT may normalize or enhance segmental mobility, offering insight into its potential mechanism of action. Ongoing RCT data will be essential to confirm these trends and determine their clinical relevance for patients with neck pain.

Images (Optional)

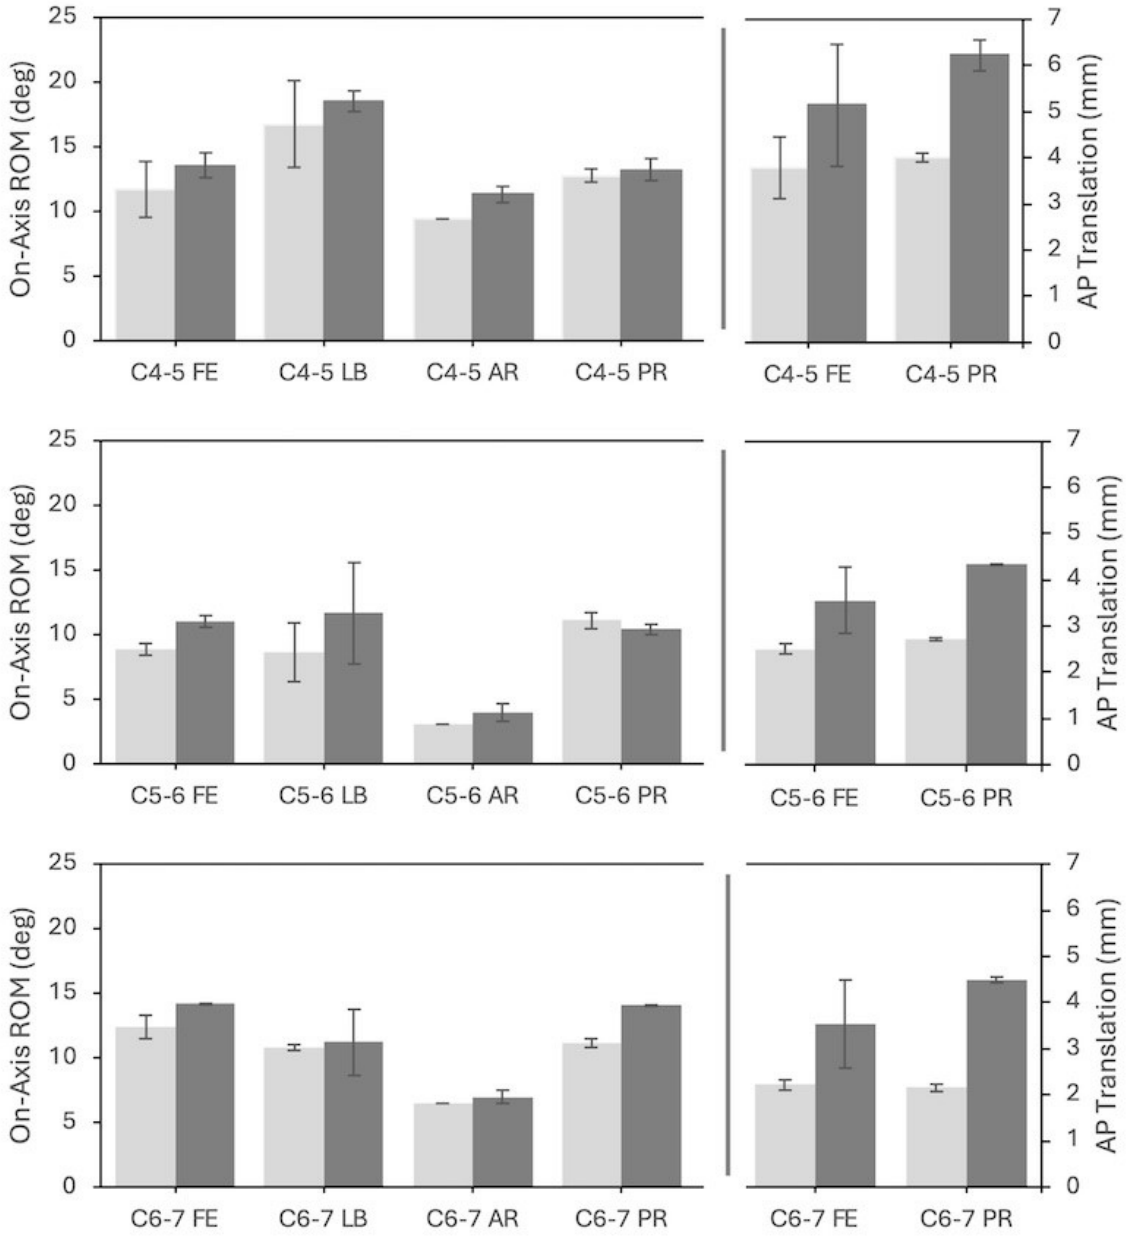

Figure 1. Results demonstrating the Average ROM occurring before and after SMT at the C4-C5 level for all motions; Flexion-Extension (FE), Lateral-Bending (LB), Axial-Rotation (AR), Protraction-Retraction (PR), and Translations (FE-T and PR-T). (E) Similar to D, E demonstrates our findings at the C5-C6 level for the average ROM occurring pre-and post-SMT. (F) Also shows our findings, reporting the average ROM at the C6-C7 level for pre- and post-SMT.

Do Craniovertebral Angle Measurements Accurately Reflect Forward Head Posture in School-Aged Children?

Ms. Zahra Heydari PhD Student, Biomedical Physiology & Kinesiology (BPK), Simon Fraser University

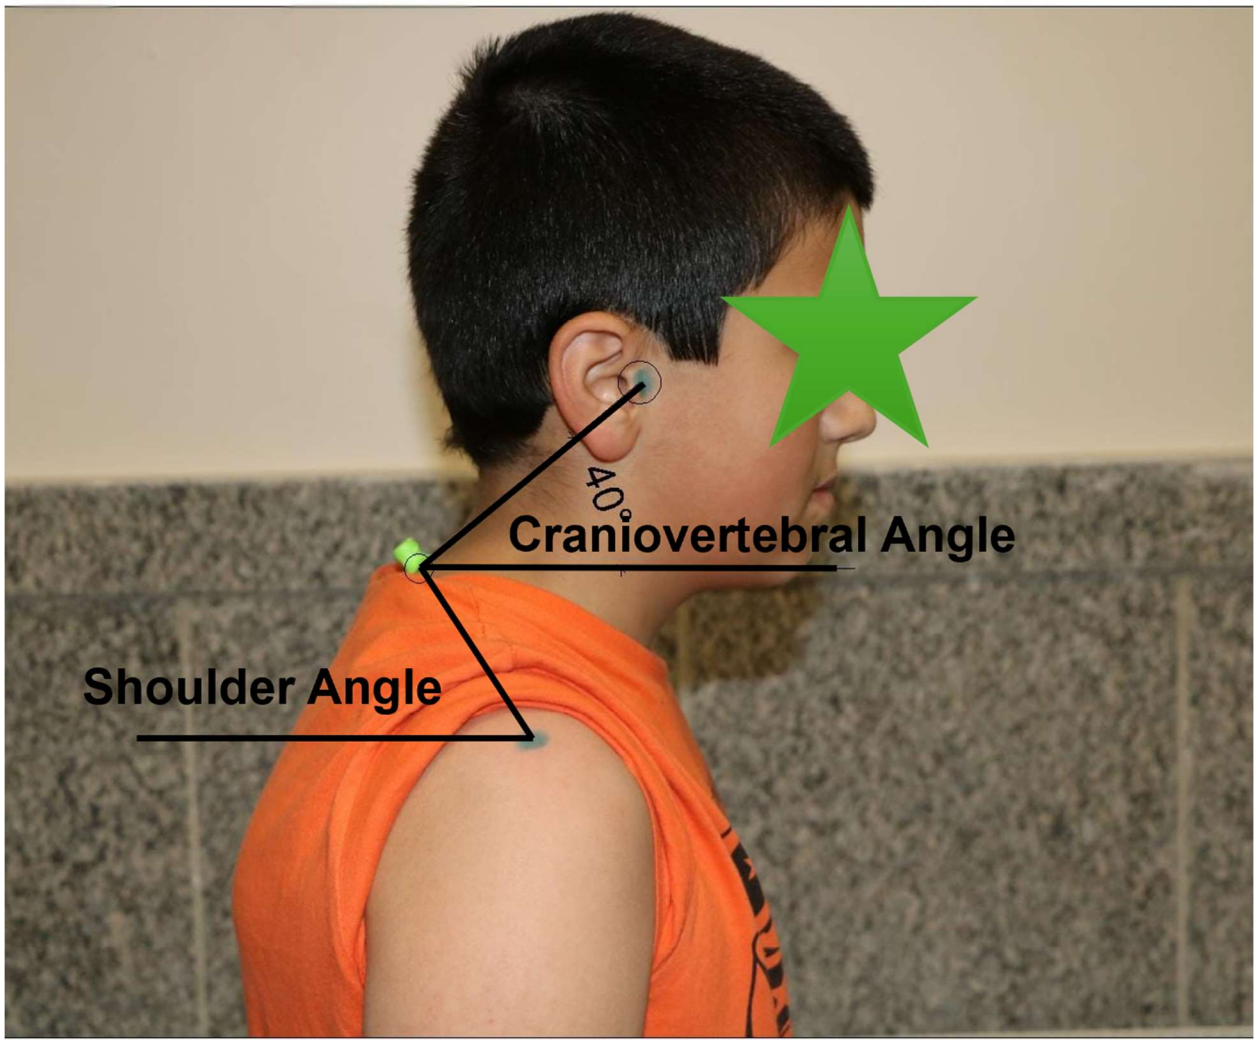
Simon Fraser University, Burnaby, British Columbia (BC), Canada

Introduction

Children spend many hours each day using smart devises. This increasing screen use appears to be positively associated with a higher frequency of Forward Head Posture (FHP). For school-aged populations, simple and reliable tools that can screen for FHP are therefore clinically important. Two common approaches are photogrammetric measurement of the Craniovertebral Angle (CVA; with FHP often defined as CVA < 50°), and visual posture index (the New York Posture Rating (NYPR) scale) which are still widely used in educational and clinical environments.

Methods

Within the framework of a cross-sectional study, baseline data from 260 school students (130 boys aged 10–14 years and 130 girls aged 13–15 years) were analysed. Markers were attached to the spinous process of the seventh cervical vertebra, the tragus of the ear and the acromion process. For each participant, three standardized lateral photographs were obtained using a fixed camera distance (D5600, Canon Camera). CVA and Shoulder Angle (SHA) were derived from the images using AutoCAD software (release 33), and students were categorized according to FHP status. In parallel, the same images were scored by three specialists independently, using the NYPR scale (scores of 1, 3 or 5) to describe the presence and severity of FHP. All statistical analyses were performed using Principal Component Analysis (PCA) implemented in Mathematica (Wolfram 10.0) to examine the correlation structure among the variables. This study was approved by the relevant ethics committee with the ethical code: IR.ATU.REC.1400.012.



Results

The correlation between CVA and the visual posture scores was r = 0.423, whereas the correlation between SHA and the visual scores was r = -0.302, indicating only moderate agreement between angle-based and observational methods.

Discussion

These results indicate that commonly used clinical and visual tools for FHP do not fully align and that determining the presence or absence of FHP likely requires additional postural measures, such as Shoulder Angle, to categorize children more effectively. Further work is needed to refine angular cut-off values and to develop complementary or composite assessment strategies that enhance FHP screening in school and clinical settings

Differences in Overhead Throwing Biomechanics in Youth Softball Players Based on Age

Dr. Jonathan Santana DO[1], Ms. Abigail Padilla BS[1], Mr. Raul Arrioja BS[1], Mr. Shawn Roberts MS[1], Dr. Tishya Wren PhD[1,2]

[1]Children's Hospital Los Angeles, Los Angeles, CA, United States. [2]Viterbi School of Engineering, University of Southern California, Los Angeles, CA, United States

Introduction

Injury rates in fastpitch softball exceed those in baseball, but there is a dearth of research on biomechanics in softball, especially the development of overhead throwing mechanics. This study examines differences in overhead throwing biomechanics between younger and older youth softball players.

Methods

Players from local youth softball teams completed a throwing session captured by a Theia3D markerless motion capture system. Players threw 5 times to a target 60 feet away. The three fastest throws that hit the target were analyzed. Kinematics were compared between younger (<12 years) and older (≥12 years) players at foot strike, maximum shoulder external rotation (MaxER) during the late cocking phase, and ball release using Wilcoxon Rank Sum tests.

Results

Nineteen female softball players with a median age of 14 years (IQR 5), six <12 and thirteen ≥12 years old, completed the biomechanical assessment. The younger players demonstrated greater shoulder external rotation (73.2 vs. 46.8 deg, p=0.04), greater shoulder elevation (-106.1 vs. -76.4, p=0.04), and less elbow flexion (96.8 vs. 122.1 deg, p=0.01) at the time of foot strike. The younger group also showed more external rotation at MaxER (181.1 vs.168.3 deg, p=0.06). However, shoulder external rotation excursion from foot strike to MaxER was smaller in the younger group (105.2 vs. 126.0 deg, p=0.22). The average throwing velocity in the younger players was significantly lower than older players (37.7 vs. 46.0 mph, p<0.01).

Discussion

Younger softball players demonstrated less efficient throwing mechanics, including less pelvis-to-arm dissociation, which reduces energy transfer and decreases throwing velocity. To compensate, they rely more on shoulder external rotation and elevation earlier in the

throwing cycle, which may increase stress on the shoulder and elbow. These findings highlight developmental differences that may elevate injury risk in youth softball. Recognizing these compensatory mechanics is important for developing age-appropriate training, injury prevention, and rehabilitation strategies.

Using Inertial Sensors to Detect Clinically Meaningful Knee Kinematic Landing Asymmetries

Mr. Adam Dorrance[1], Dr. Scott Landry[1,2], Mr. Ben MacDonald[1], Dr. Nathan Urquhart[3,1], Dr. Janie Astephen Wilson[1,3]

[1]Dalhousie University, Halifax, NS, Canada. [2]Acadia University, Wolfville, NS, Canada. [3]Nova Scotia Health Authority, Halifax, NS, Canada

Introduction

Between-limb asymmetries in knee flexion and knee abduction motion during landing are thought to increase the risk of anterior cruciate ligament (ACL) reinjury after reconstruction surgery [1].

Inertial measurement units (IMUs) enable feasible in-clinic assessment of landing mechanics. Therefore, evaluating whether IMU-derived measures can accurately detect meaningful knee movement asymmetries during landings is important for clinical uptake.

This study examined agreement in knee flexion and knee abduction excursions during drop vertical jump (DVJ) landings, and between-limb asymmetries in excursions, between optoelectronic and IMU systems, as well as the sensitivity and specificity of detecting clinically meaningful excursion asymmetries with the IMU-based system.

Methods

Patients six months to two years post-ACL reconstruction (ACLr) completed three DVJs while knee kinematics were computed using processed data from IMUs secured to both shanks and thighs, (Opal, APDM), and an optoelectronic motion capture system (Motion Analysis; processing through Visual3D, HAS-Motion). IMU processing included sensor-to-segment alignment and sensor fusion [2,3]. Primary outcomes included knee flexion and abduction excursions and their surgical/non-surgical limb asymmetries during the deceleration phase of landing [4]. Bland–Altman analysis assessed agreement between systems. Clinical thresholds for excursion asymmetry were assumed at 9 and 8 degrees (flexion, abduction respectively) based on [1,5], calculated from the optoelectronic data, with sensitivity and specificity of categorizing clinically-meaningful asymmetry with the IMU system calculated.

Results

Nine ACLr patients (6M/3F;age=28±9 years;BMI=25±2 kg/m^2;12±5 months post-ACLr) were recruited (Table 1).

Discussion

The systems showed good agreement for flexion and abduction excursions, with biases and LOA falling within the joint angle error range previously suggested for clinical interpretation [6]. Across 27 DVJs, the IMU system detected between-limb differences exceeding the thresholds with 100% sensitivity and specificity (Table 1).

These findings support the feasibility of novel IMU-based assessments for out-of-lab monitoring of biomechanical deficits relevant to ACL re-injury risk and clinical decision-making. While sensitivity and specificity were excellent, further confirmation with larger samples and stronger validation links of these thresholds with longitudinal clinical outcomes is needed.

Images (Optional)

Table 1: Agreement in knee flexion and abduction excursion outcomes on the surgical (^{S}) and non-surgical (^{N}) limb and the inter-limb asymmetries (calculated as between limb differences) during the deceleration phase of DVJ captured by an IMU and an optoelectronic motion capture. Sensitivity and specificity outcomes based on clinical thresholds of asymmetry are presented as true positive (TP), false positive (FP), true negative (TN), and false negative (FN) classifications. Sensitivity and specificity are calculated using the ratios TP/(TP+FN) and TN/(TN+FP), respectively.

Outcome	Measurement System		Agreement		Sensitivity, Specificity (TP,FP,TN,FN)
	Optoelectronic	IMU	Mean Bias (SD)	LOA	
Flexion Excursion^S (°)	54.3 (9.0)	53.5 (8.7)	1.8 (1.6)	0.3 - 3.3	
Flexion Excursion^N (°)	54.8 (8.5)	53.8 (8.9)	1.9 (1.5)	0.5 - 3.3

[7]School of Mathematics, Statistics and Actuarial Science, University of Essex, Colchester, Essex, United Kingdom

Introduction

Total hip arthroplasty (THA) is increasingly offered to active patients who wish to resume sport. Yet most in silico and in vitro THA analyses use few loading scenarios, typically walking and stair-climbing. This work presents a THA loading library with mean joint and muscle forces for 21 tasks to support in silico and in vitro biomechanical assessment of implants and periprosthetic bone integrity, and to guide graded return-to-sport protocols.

Methods

Eleven adults with unilateral THA (55.9±9.8 years, 68.9±10.7 kg), ≥1-year post-surgery and cleared for exercise, performed 21 tasks spanning walking, running, hops, jumps, landings and 45–180° change-of-direction cuts. Marker-based motion capture and force plates drove a scaled AnyBody musculoskeletal model to compute operated-hip contact and muscle forces in body-weight-normalised and absolute units. Hip joint contact forces were the primary metric to compare tasks; muscle-force cycles were also provided. Multivariate Dynamic Time Warping Barycenter Averaging (DTW-DBA) yielded cohort-representative waveforms; loading cycles with the highest peak resultant defined “worst-case” loading.

Results

Peak resultant hip joint contact forces (Figure 1) ranged from ≈4.7 body weights (BW) during walking to ≈7.5–8.2 BW during unilateral hopping; running and 45–180° cuts produced ≈6.8–7.9 BW. Ranking subjects by BW-normalised peaks identified a normal-BMI participant as worst case for most walking and running tasks, whereas ranking by absolute forces shifted treadmill and bilateral hopping conditions to the heaviest subject, thereby illustrating how joint demands vary with body mass. Normalised peak hip joint contact forces were benchmarked against in vivo telemetric THA measurements and in silico simulations and were consistent with previously reported hip loading [1, 2].

Discussion

This loading library provides DTW-DBA averaged and worst-case joint and muscle load histories that can be implemented as boundary conditions for in silico and in vitro implant biomechanical tests, complementing instrumented-implant resources such as OrthoLoad while including multi-muscle forces rather than joint contact forces alone. It offers a resource for implant benchmarking and periprosthetic bone assessment. Additionally, it may inform graded, evidence-based return-to-sport counselling for THA patients with sporting ambitions in routine clinical practice.

Images (Optional)

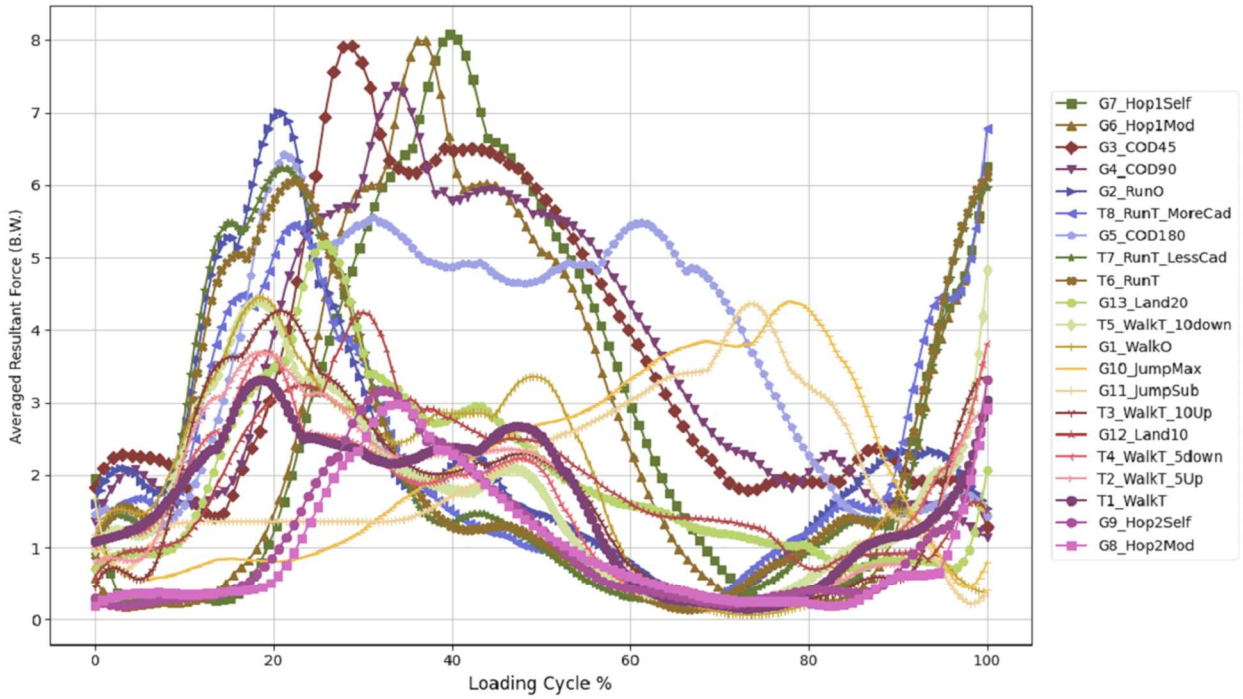

Figure 1 Averaged hip joint contact force (HJCF) data from 11 subjects across 21 movements *(prefixes: over-ground movements G1–G13, treadmill movements T1–T8). Dynamic legend of movements is ordered by maximal peak HJCF. Movement labels: level walking and running (WalkO: over-ground walk; WalkT: treadmill walk; RunO: over-ground run; RunT: treadmill run; RunT_LessCad/MoreCad: treadmill running at fixed speed with - 10%/+10% cadence), inclined treadmill walking (WalkT_5Up/10Up: +5°/+10° upslope; WalkT_5Down/10Down: - 5°/- 10° downslope), hopping (Hop1Mod/Hop1Self: unilateral hopping at moderate/self-selected cadence; Hop2Mod/Hop2Self: bilateral hopping at moderate/self-selected cadence), jumping/landing (JumpMax/JumpSub: maximal/submaximal countermovement jump; Land10/20: landing from 10/20 cm), and change-of-direction cuts (COD45/90/180: 45°/90°/180° cuts).*

Ms. Aleksandra Kozicka

Introduction

Orthopedic injuries account for approximately 1 million hospital visits annually, as well as considerable physical, psychological, and socioeconomic burdens. Various studies have explored valid and low-cost screening tools to identify biomechanical risk factors for musculoskeletal (MSK) injuries and unfavorable clinical outcomes. Jumping tasks have emerged as a prominent option within these assessments. However, existing findings remain fragmented or focus primarily on anterior cruciate ligament (ACL) injuries. This review aimed to determine whether jumping tasks can identify biomechanical risk factors for musculoskeletal injuries beyond ACL tears and whether they can also reveal factors associated with unfavorable clinical outcomes.

Methods

This systematic scoping review followed PRISMA guidelines and was registered in PROSPERO. Searches were conducted with support from an experienced librarian in PubMed/MEDLINE, Scopus, Cochrane CENTRAL, IEEE Xplore, and Google Scholar. Eligible studies included longitudinal designs evaluating jumping tasks as a predictive screening tool for MSK injuries. Exclusion criteria were ACL-focused studies, nonhuman or robotic models, and case reports/series. Three reviewers independently screened studies, extracted data, and assessed risk of bias using the NIH quality assessment tool. The primary outcome was MSK injury risk associated with biomechanical factors

identified during jumping tasks; secondary outcomes included other clinical outcomes linked to these biomechanical factors.

Results

A total of 60 studies were included. Most (51) evaluated young, healthy people. In 37 of these studies, jumping tasks identified individuals at higher risk of sustaining MSK injuries, such as traumatic injuries, overload injuries, and low back pain (Table 1). The remaining 9 studies involved participants with baseline orthopedic conditions, such as Achilles tendinopathy and ankle sprain; 6 of these studies linked poor performance on jumping tasks to worse clinical outcomes, including prolonged recovery times and higher risk of chronicity.

Discussion

Jumping tasks are a promising tool for identifying higher risk of MSK injuries, beyond ACL tears, in healthy, young, athletic populations. In individuals with pre-existing orthopedic pathologies, poor performance on jumping tasks is associated with unfavorable clinical outcomes. However, given the heterogeneity and methodological limitations of the included studies, clinicians should interpret these findings with caution and use jumping tasks alongside other clinical assessments.

Quadriceps Muscle Imbalance in Patients with Unilateral Patellofemoral Pain- A Pilot Study

Mr. Charles Scheuermann[1], Dr. Hyun Kim Ph.D.[1], Dr. Efthymios Papadopoulos Ph.D.[1], Ms. Megan Gordon[1], Mr. Derek Calvert ATC[2]

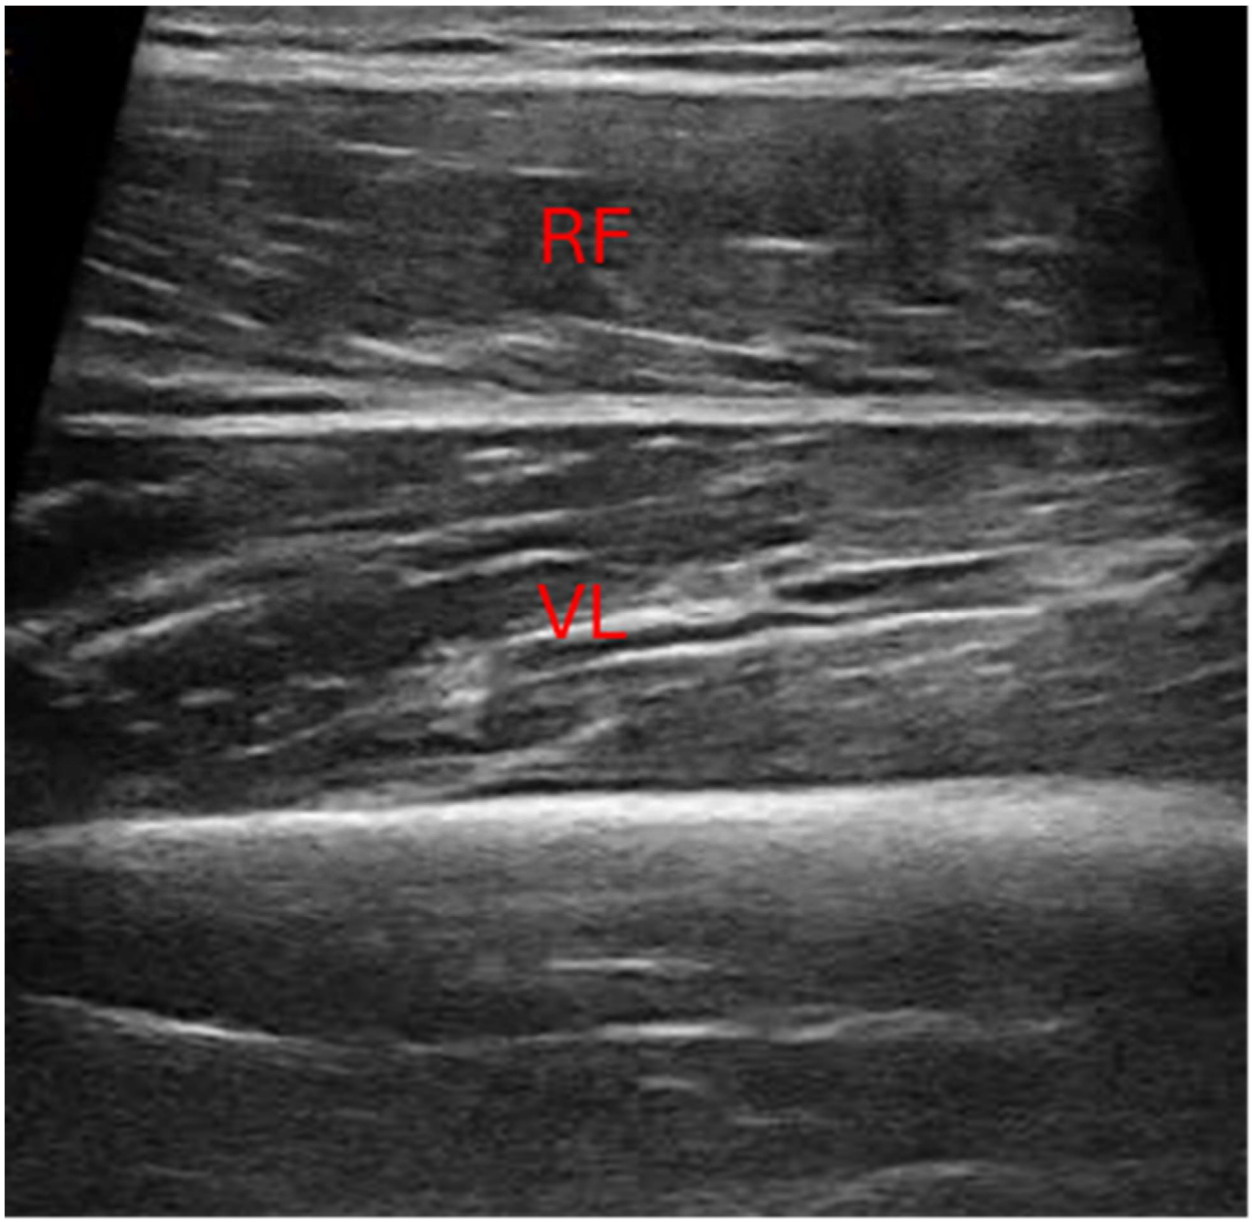
[1]School of Kinesiology, Louisiana State University, Baton Rouge, Louisiana, United States. [2]Louisiana State University Athletics, Baton Rouge, Louisiana, United States

Introduction

Patellofemoral pain (PFP) is common among physically active individuals. Previous research has highlighted the importance of the balance between the vastus medialis oblique and vastus lateralis [1], as mal-tracking may contribute to PFP. The study aimed to investigate quadriceps muscle imbalance in individuals with unilateral PFP against healthy controls. We hypothesize that participants with PFP would show greater quadriceps imbalance.

Methods

Four individuals with unilateral PFP (2M, 2F; 24.5±4.8yrs; 178.8±16.6cm; 78.8±11.3kg; diagnosed < 2 months; data collection ongoing) and 25 healthy controls (15M, 9F; 22.4±4.2yrs; 173.7±11.1cm; 80.5±19.8kg) without lower-limb injuries participated; four matched individuals were used for statistical analysis. Muscle thickness (cm) of rectus femoris (RF), vastus medialis (VM), and vastus lateralis (VL) on both sides was measured using a handheld ultrasound (Clarius L15 HD3) with participants supine. Measurements followed the previously described protocol [2,3]. Each muscle was measured three times, and the mean value was analyzed. Within-group comparisons (injured vs. non-injured sides) used paired t-tests, and between-group (PFP vs control) differences in VL/VM ratios and symmetry index (SI%; Xinjured-Xnon-injured)/0.5(Xinjured+Xnon-injured)×100) were tested with independent t-tests.



Results

The injured side showed a significantly lower VL/VM ratio than the non-injured side in PFP patients (0.71±0.04 vs. 0.77±0.05, p=0.01). The PFP group also demonstrated a significantly higher SI% for the VL than healthy controls (8.81±1.70 vs. 2.90±3.14, p=0.02), indicating greater asymmetry. No significant differences were found in individual muscle thickness between groups or between legs.

Discussion

The lower VL/VM ratio on the injured side suggests quadriceps imbalance, with reduced lateral relative to medial development in individuals with PFP. This imbalance may contribute to altered patellar tracking and increased joint stress. The higher symmetry index indicates greater side-to-side asymmetry, supporting that imbalance and asymmetry are key features of PFP. However, the absence of significant differences in absolute thickness suggests that relative proportion, not overall muscle size, may be more relevant to PFP-related adaptations.

Ankle Laxity Quantified via Optical-Flow Based Bone-Tracking Relates to Clinically Relevant Characteristics After Ankle Sprains in Division-I Collegiate Basketball Athletes

Ms Claire Tanaka MS[1], Dr. Matthew Blomquist PhD[1], Dr. Naoaki Ito DPT, PhD[1], Ms Katharine Carter MSc[2], Dr. Bryan Heiderscheit PT, PhD, FAPTA[1]

[1]University of Wisconsin, Madison, WI, United States. [2]GE HealthCare, Waukesha, WI, United States

Introduction

Ankle sprains are highly prevalent in sports, with ~75% involving the anterior talofibular ligament (ATFL). Assessments such as the reverse anterolateral drawer test (RALD) classify ATFL laxity, but their binary interpretation limits quantification of joint displacement. Advancements in ultrasound (US) bone-tracking enable measurement of the talus-fibula displacement at the ATFL during RALD, yet its relationship to symptoms is unknown. This study aimed to compare US-derived maximum ankle displacement (i.e., laxity) with clinical RALD grading and to examine the relationship between displacement and athlete-reported chronic ankle instability using the Cumberland Ankle Instability Tool (CAIT).

Methods

CAIT scores and B-mode US cine loops of the ATFL (Figure 1a) during RALDs were collected bilaterally in 29 Division I basketball athletes (Female|Male: n=14|15, age= 20.9±1.3|20.8±1.6years, BMI= 23.4±1.5|24.9±1.7kg/m^2). RALDs were graded by one of two physical therapists. Maximum ATFL displacement was quantified using an optical-flow bone-tracking algorithm that measured talus-fibula distance across cine loop frames during RALD. Linear mixed effects models assessed (1) the fixed effect of RALD grade (+/-) on maximum displacement (mm), and (2) the fixed effect of maximum displacement on CAIT score (0-30, lower = worse symptoms). Both models included random effects of rater and athlete, with sex included as a covariate.

Results

Positive RALD grade related to greater ATFL displacement ($p < 0.001$; mean difference [95%CI] = 0.92 [0.46, 1.37] mm; Figure 1b). Greater ATFL displacement also related to worse CAIT score ($p = 0.03$, estimate [95%CI] = -1.1 [-2.1, -0.14]), with the marginal R^2 of the model limited to 0.086 (Figure 1c).

Discussion

A positive RALD was associated with 1mm greater ATFL displacement, however, the large spread in displacement within the positive and negative groups must be acknowledged. Similarly, 1mm greater displacement of the ATFL was related to 1-point lower CAIT score, but the fixed effects of the model only explained 9% of the variance. Quantifying ATFL laxity with US bone-tracking may provide an objective metric to inform prognosis for recovery, refine injury risk, and enhance injury-prevention strategies with greater precision than has previously been considered.

Anterior Cruciate Ligament Reconstruction with Orthobiologic Injections Improves Muscle and Joint Function

Dr Colin Smith PhD, Mr Austin Carcia BS, Ms Kristen Seballos MS, Ms Rachel Conley BS, Dr Armando Vidal MD, Dr Johnathan Godin MD, Dr Thomas Hackett MD, Dr Peter Millett MD, Dr Matt Provencher MD, Dr Johnny Huard PhD, Dr Scott Tashman PhD

Steadman Philippon Research Institute, Vail, CO, United States

Introduction

Despite advances in surgical technique and rehabilitation, recovery from anterior cruciate ligament reconstruction (ACLR) still requires over one year. Orthobiologic injections such as Platelet Rich Plasma (PRP) and Bone Marrow Aspirate Concentrate (BMAC) aim to accelerate healing, however, evidence for their benefits is mixed [1]. We performed a clinical trial to evaluate whether PRP and BMAC accelerate healing and improve muscle and joint function after ACLR.

Methods

We recruited 43 unilateral anatomical bone-patellar-tendon-bone ACLR patients (22 Female, Age = 29±7) for a three-arm (PRP, BMAC, control) randomized clinical trial. Injections were performed at the time of surgery. At 6 and 12 months post-surgery, each participant underwent a CT Scan, MRI, blood test, muscle strength test, Dynamic Stereo Xray (DSX) assessment of knee function, and answered pain surveys. DSX imaging was collected at 120 Hz during downhill running. CT bone models were registered to the biplane x-ray images to assess knee joint kinematics and ACL strain. Group differences in limb asymmetry were assessed separately at 6 and 12 months using one-way ANOVA, followed by Tukey's post hoc tests for pairwise comparisons. Statistical Parametric Mapping (SPM) was used to perform an ANOVA to assess the differences in ground reaction forces, knee kinematics, and ACLR graft strain between the treatment groups.

Results

At 6 months post-ACLR, the PRP group exhibited significantly smaller quadriceps peak torque asymmetries compared to the controls (mean difference=−19.80%, p=0.046). During downhill running, SPM revealed significantly increased ground reaction forces in the BMAC group compared to the controls (p<0.001) across 14–48% of the stance phase. Compared to the control group, the ACL strain was increased during running at 6 months in both the PRP (p<0.001, 6-30% stance) and BMAC (p<0.001, 12-30% stance) groups. No

differences were found between the PRP and BMAC groups in any of the statistical comparisons.

Discussion

The results of our clinical trial indicate that both PRP and BMAC injections accelerated healing and loading of the injured knee at 6 months. This suggests that these orthobiologic treatments may compliment early-loading rehabilitation to improve recovery of function.

Images (Optional)

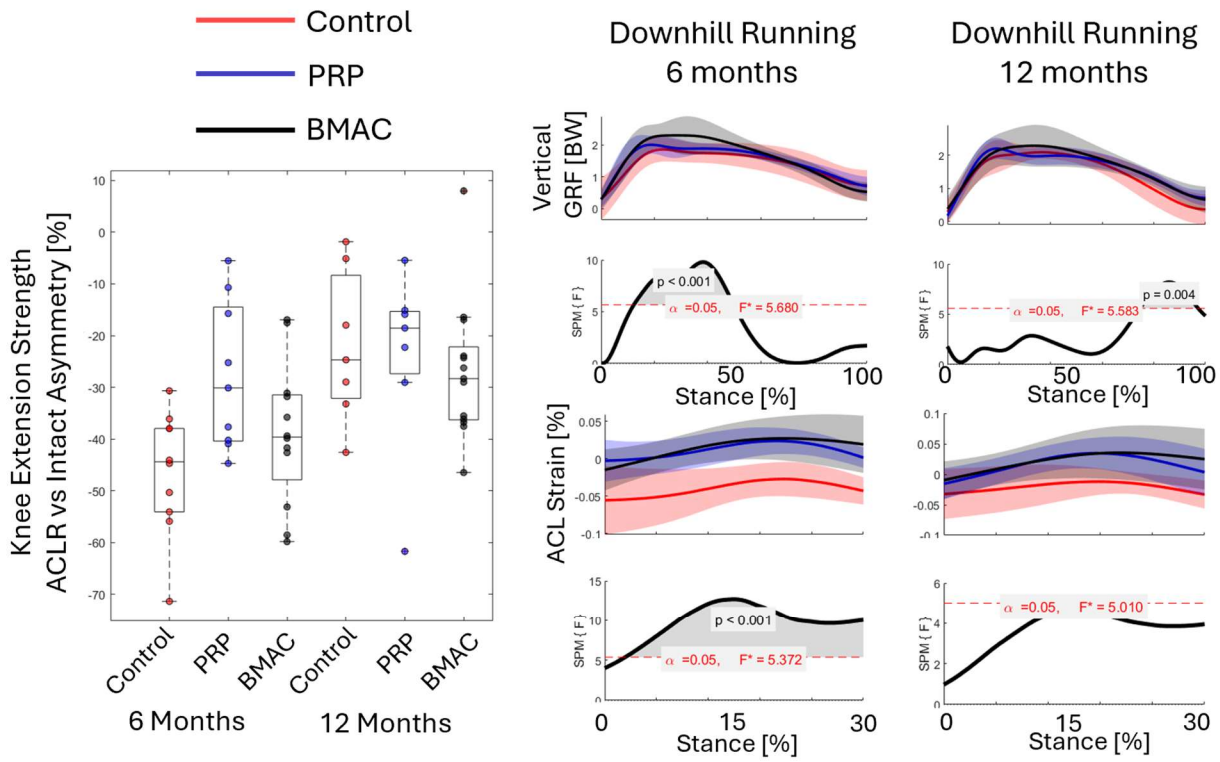

Figure 1 – (Left) The PRP and BMAC groups showed improved strength in the ACLR limb compared to the control at 6 months. (Right) Compared to the control, the PRP and BMAC groups showed increased ground reaction forces on the ACLR limb and strain in the ACLR graft during downhill running at 6 months indicating an accelerated recovery of function.

Biomechanical Evaluation of Orthopedic Suture Knot Constructs: A Comparative Analysis

Dr David Rouault, Ms Cameron Scott, Dr Lindsay Westover, Dr Ahmed Samir Ead, Ms Stephanie Nathanail, Mr Richard Roberts, Dr Abdulrehman Abuhaimed, Dr Martin Bouliane, Dr Joseph Cavanagh

University of Alberta, Edmonton, Alberta, Canada

Introduction

Suture knot constructs are fundamental in Orthopedic surgery and are often used for soft-tissue fixation, bone block stabilization, and fracture cerclage. The performance of these constructs depends on suture material and knot security under both dynamic and static loads, yet comparative biomechanical data combining both knot types and different suture materials in physiological environments remains limited. The objective of this study was to evaluate how suture material, testing environment, and knot configuration influence creep behavior and the force required to reach a clinically relevant failure threshold (3 mm of displacement) after dynamic loading.

Methods

Ninety-six constructs (n = 3 per condition) were tied using four knot types (Standard Nice, Modified Nice 1, Modified Nice 2, Surgeon's knot) with #4 Ultrabraid or #5 Ethibond. Constructs were tested in air or phosphate-buffered saline at room temperature (22°C). Two load protocols were applied: (1) static creep at 100 N for 10 minutes and (2) cyclic loading (10–45 N, 1.8 Hz, 1,000 cycles) followed by load until failure. Outcomes were creep rate and force at clinical failure. Linear regression and ANOVA assessed main and interaction effects.

Results

Our testing revealed that environment (air vs fluid) had no significant effects on our outcomes; thus, results from both environments were pooled for further comparison. Material and knot configurations were strong predictors of creep and failure performance. For creep testing, Ethibond and Modified Nice 2 had the lowest creep rate ($1.37\pm0.41\times10^{-4}$mm/s), while Ultrabraid and Surgeon's knot had the highest ($3.58\pm0.52\times10^{-4}$ mm/s; difference 2.21×10^{-4} mm/s, 95% CI 1.58–2.83, $p<0.001$). After

cyclic loading, Ultrabraid and Modified Nice 2 produced the highest force at 3 mm failure (404.8±86.1 N), exceeding Ethibond and Surgeon's knot (136.2±30.3 N; difference 268.7 N, 95% CI 187.2–350.1, $p<0.001$).

Discussion

Suture material and knot configuration significantly affected construct performance, whereas testing environment did not. No suture material demonstrated consistent superiority during our testing protocols, while the modified Nice 2 knot consistently demonstrated increased performance. These findings support evidence-based selection of suture-knot constructs and warrant further investigation including additional suture types.

Images (Optional)

Table 1. Suture and Knot Testing Results

Material	Knot	Average Force at Clinical Failure (N)	Standard Deviation (N)	Average creep rate (x 10^{-4} mm/s)	SD (x 10^{-4} mm/s)
Ethibond	Modified Nice 1	178.80	16.56	1.46	0.31
Ethibond	Modified Nice 2	209.47	16.37	1.37	0.41
Ethibond	Regular Nice	171.17	4.41	1.49	0.39

Accuracy of Markerless Motion Capture for Clinical Hop Testing: An OpenCap Validation Study

Dr. Deborah King Ph.D., Dr. Teresa Chen PT, Ph.D., Dr. Karen Lomond Ph.D.

Ithaca College, Ithaca, NY, United States

Introduction

After anterior cruciate ligament reconstruction only 66% of athletes return to pre-injury level [1] and risk of re-injury is 40%[2]. Return to activity (RTA) 'hop-test' performance inconsistently predicts successful RTA warranting movement quality assessment for RTA decision making [3]. OpenCap (OC), an opensource iPad/iPhone motion capture system, may provide clinicians with objective measures of movement quality. Hop-test kinematics using OC have good to moderate validity; joint kinetics were not examined [4]. The purpose of this study was to validate OC knee and hip biomechanics during hop landings.

Methods

Three vertical hop landings from 15 healthy adults were analyzed to compare sagittal plane knee angles ($\theta_{K_FL/EX}$) and moments ($M_{K_FL/EX}$) and tri-planar hip angles ($\theta_{H_FL/EX}$, $\theta_{H_AB/AD}$, θ_{H_ROT}) and moments ($M_{H_FL/EX}$, $M_{H_AB/AD}$, M_{H_ROT}) between OC and Vicon. Vicon and OC data were processed in Visual3D and Python, respectively. Matlab was used to synchronize, filter, and average all trials for each participant and calculate peak angles, moments, cross correlations (R_{xy_max}), and mean absolute error (MAE). Intraclass correlations (ICC) were calculated (Jamovi).

Results

Maximum $\theta_{K_FL/EX}$ and $\theta_{H_FL/EX}$ had moderate to good agreement (ICC_{Knee}=0.769 & ICC_{Hip}=0.619) averaging 6° difference between systems for θ_{K_FL/EX_MAX} and 13° for θ_{H_FL/EX_MAX}; OC underestimated θ_{H_FL/EX_MAX} (Table). $\theta_{K_FL/EX}$ and $\theta_{H_FL/EX}$ MAE and R_{xy} were moderate to good (Table). θH_AB/AD, θ_{H_ROT}, and all moments had poor to moderate agreement (ICC=0.080 – 0.619) with large MAE. R_{xy} was moderate ($\theta_{H_AB/AD}$, θ_{H_ROT}), good ($M_{H_FL/EX}$), and excellent ($M_{K_FL/EX}$, $M_{H_AB/AD}$, M_{H_ROT}) (Table).

Discussion

OC provided acceptable $\theta_{K_FL/EX}$ measures during hop landings supporting previous findings [4]. Hip flexion accuracy was less consistent, though cross-correlations were excellent. Joint moments and non-sagittal hip angles had unacceptable accuracy for clinical decision making. Calculating moments was time-consuming, required computer

expertise, and seems currently untenable for clinical use. Further research into OC is warranted for kinematic data and RTA applications.

Identifying Sport-Specific Kinematic Drivers of Primary Cam Morphology-Associated Impingement Using a Computational Hip Model

Mr Harry Manship[1], Professor Amy Zavatsky[1], Professor Stephen Mellon[2,1], Professor Siôn Glyn-Jones[1]

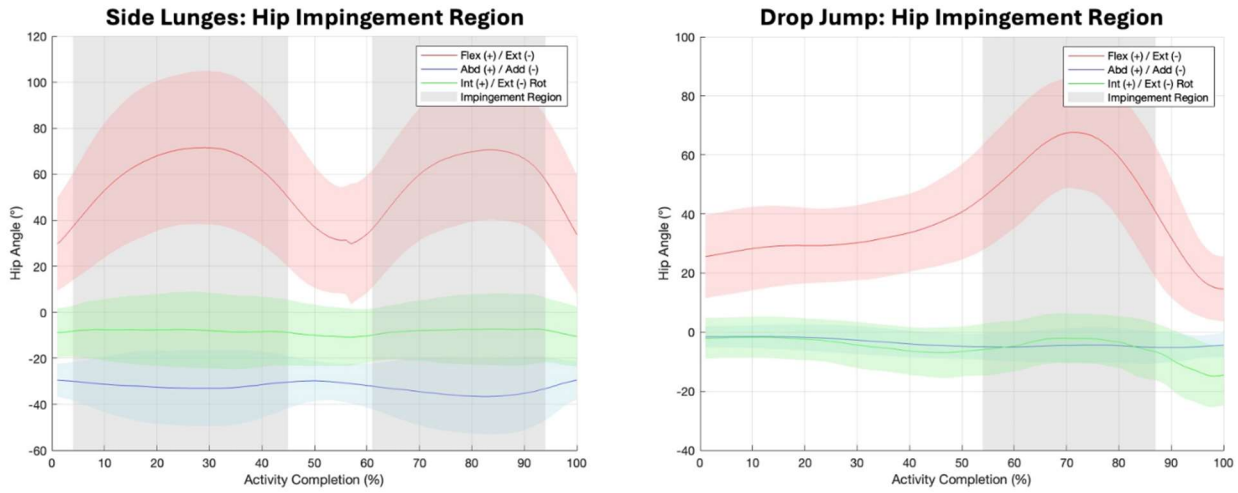
[1]University of Oxford, Oxford, Oxfordshire, United Kingdom. [2]University of Southern Denmark, Odense, Region Syddanmark, Denmark

Introduction

Femoroacetabular impingement syndrome (FAIS) due to primary cam morphology causes hip pain and osteoarthritis in young athletes [1]. Early identification facilitating activity management and treatment relies on static imaging and range-of-motion tests but misses dynamic femoroacetabular joint interactions [2]. An open-source computational model [3] has been developed to evaluate the role of individual hip kinematics on impingement, but previously studied motions were not sport-specific. We applied this model to test the hypothesis that impingement incidence, location, and severity across sport-specific motions are systematically associated with characteristic combinations of hip rotations.

Methods

The model [3] was used to simulate four cam positions, each with a peak alpha angle of 80° at varying anterosuperior femoral head-neck locations. Impingement risk was determined using a 3D motion capture dataset curated by Zhao et al. [4] of 183 athletes (153 males, 30 females; age = 20.35 ± 4.20 years) performing 25 athletic exercises. Linear mixed-effects regression quantified the relationship between hip orientation and impingement severity (defined as angular overlap of structures).



Results

For all activities, all cam positions impinged primarily in the anterosuperior region of the acetabular rim. The anterior cam position produced the most frequent impingement and exercises involving lateral movement and greater hip flexion, such as side lunges (shown in figure), showed higher impingement incidence. Across cam positions, mixed-effects regression indicated that impingement severity was most strongly driven by adduction (Main effect: ß = -7.98 ± 0.71), with flexion-internal rotation coupling also increasing severity (Interaction effect: ß = 2.71 ± 0.43). As the cam position was moved more anteriorly, flexion became an increasingly dominant contributor to impingement severity.

Discussion

Across cam positions, the model identified position-specific rotational patterns that produced bony impingement. This demonstrates its capacity for use to identify the precise rotational conditions that cause impingement and, following suitable validation, it may contribute to the establishment of a pipeline aimed at supporting the clinical management of patients with suspected FAIS.

Hierarchical Clustering Analysis Suggests a Relationship between Hamstring Muscle Cross-Sectional Area Profiles and Injury Risk

Dr. Jack Martin PhD[1], Prof. Silvia Blemker PhD[2], Prof. David Opar PhD[3], Dr. Brett Mortensen PhD[4], Prof. Bryan Heiderscheit PT, PhD[1]

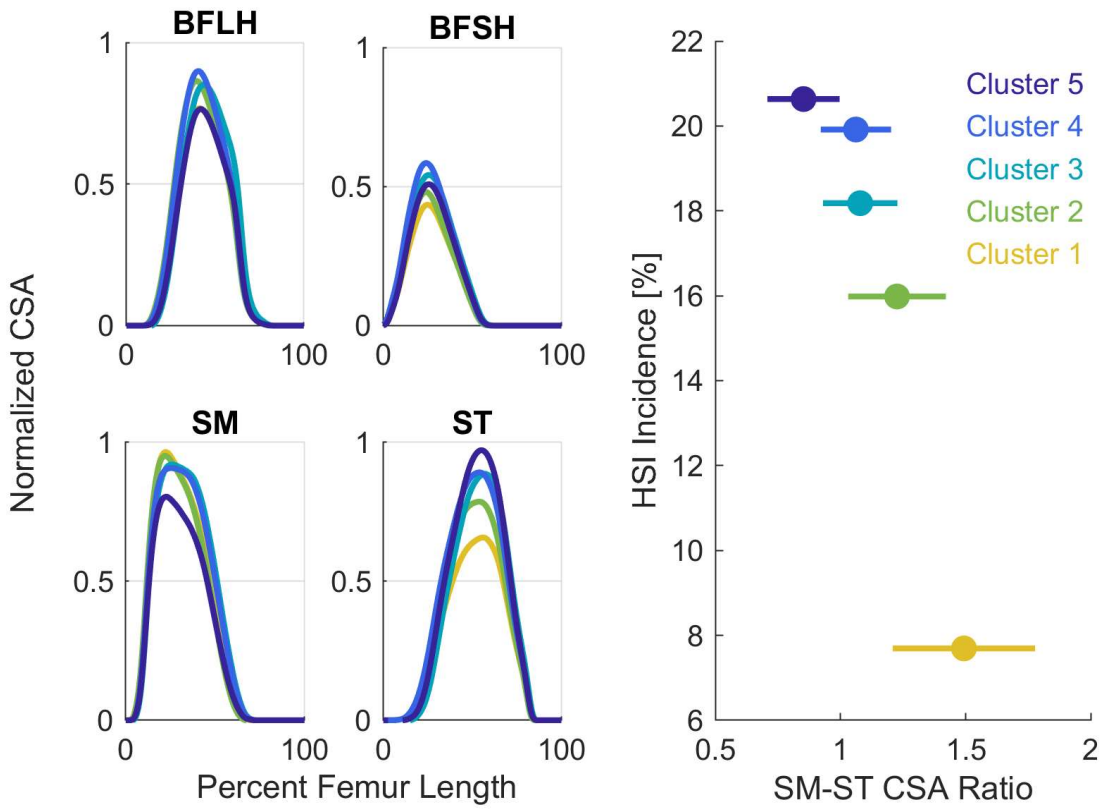
[1]University of Wisconsin-Madison, Madison, WI, United States. [2]University of Virginia, Charlottesville, VA, United States. [3]Australian Catholic University, Melbourne, VIC, Australia. [4]Brigham Young University, Provo, UT, United States

Introduction

Hamstring injury (HSI) risk in athletes has remained challenging to predict, and simple metrics like overall hamstring size and strength have not proven useful. While the four individual hamstring muscles (BFLH, BFSH: biceps femoris long, short heads; SM: semimembranosus; ST: semitendinosus) are generally highly redundant, relative force production between them is affected by joint angles [1], and they have distinct activation patterns during sprinting [2]. Hence, it is possible that the relative size and strength of individual hamstring muscles may affect force distribution during various tasks, thereby affecting injury risk. The purpose of this analysis is to assess the relationship between HSI incidence and relative differences in cross-sectional area (CSA) profiles of the hamstring muscles.

Methods

This analysis used data from 443 Division-I collegiate football athletes in the HAMIR study [3]. MRI examinations were performed and the hamstring muscles were segmented. Hamstring CSAs were normalized to the maximum value across all four muscles. CSA profiles for each muscle were interpolated from 0-100% femur length. Principal component (PC) analysis was performed on collated CSA profiles. Hierarchical clustering was performed on PC scores to reveal distinct hamstring CSA profile phenotypes. Clusters were inspected to determine metrics of interest and these were compared with HSI incidence.



Results

HSI occurred in 74 athletes (17%). Five distinct clusters of athletes exhibited differing hamstring CSA profiles. Peak CSA of the SM and ST muscles differed across clusters, as did the ratio between them. HSI incidence and the mean SM-ST ratio differed by factors of 2.7 and 1.8, respectively, across clusters. HSI incidence was correlated with the SM-ST CSA ratio (R^2=0.45).

Discussion

The results of this analysis indicate that relative size of the individual hamstring muscles may affect injury risk. Interestingly, despite the BFLH being the most often injured muscle, the SM and ST CSA profiles differed more across clusters and were more strongly related to HSI incidence. The reasons for this are unclear and will require further mechanistic investigation.

Knee Brace Function Throughout Flexion in Response to a Valgus Torque: A Cadaveric Study

Dr. Luke T. Mattar PhD[1], Mr. Tianyu Chen MS[1], Dr. Jumpei Inoue MD[1], Dr. Martin Fagerström PhD[2], Dr. Volker Musahl MD[1,3], Dr. Richard E. Debski PhD[3,1]

[1]Department of Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA, United States. [2]Department of Industrial and Material Science, Chalmers University of Technology, Gothenburg, Västra Götaland County, Sweden. [3]Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Although knee braces are prescribed to protect ligamentous structures in the tibiofemoral joint, injuries to the medial collateral ligament (MCL) often occur. The objective of this study was to determine how the resultant force in a knee brace changes throughout flexion in response to a valgus torque in uninjured and MCL deficient (MCLD) cadaveric knees.

Methods

Seven fresh-frozen cadaveric knees (age 37-77 years) were utilized. A 10Nm valgus torque was applied to each knee using a 6-DoF robotic testing system in two knee states during continuous flexion: 1) Native Ideal Brace and 2) MCLD Ideal Brace. To create the “ideal brace”, the knee brace was rigidly fixed to the tibial and femoral clamps on the medial and lateral sides of the knee. Utilizing the principle of superposition, the resultant force in the ideal knee brace was quantified. Spearman’s correlations were then used to determine the association between flexion angle and resultant force in the ideal knee brace for each state (significance $P<0.05$).

Results

In the Native Ideal Brace state, no association was found between flexion angle and resultant force ($P>0.05$, Figure 1A). However, a positive association between flexion angle and resultant force in the knee brace was observed in the MCLD Ideal Brace state ($P<0.05$, Figure 1B). Thus, as knee flexion angle increased, the resultant force in the ideal knee brace increased.

Discussion

The major finding was that the resultant force in the ideal knee brace increased with flexion angle in the MCLD knee, but not in the Native knee. The implications of the finding are that ideal knee bracing carries similar low magnitude loads in the Native knee throughout flexion, however, the knee brace carries increased loads throughout flexion in response to a valgus torque when the MCL is injured. Thus, knee brace function may change with flexion angle and injury state. Based on this data, practitioners may consider custom braces to address different functional limitations in uninjured and MCL injured knees.

On-field assessment of performance and joint coordination in ACL-reconstructed football players: expanding the ACL-IRD algorithm

Dr. Stefano Di Paolo[1], Dr. Margherita Mendicino[1], Dr. Pietro Margheriti[1], Dr. Marianna Viotto[2], Dr. Chiara Valastro[1], Prof. Alberto Grassi[1,3], Prof. Stefano Zaffagnini[1,3]

[1]2nd Orthopaedic and Traumatologic Clinic, IRCCS Rizzoli Orthopaedic Institute, Bologna, Emilia Romagna, Italy. [2]Pediatric Orthopaedic and Traumatology, IRCCS Rizzoli Orthopaedic Institute, Bologna, Emilia Romagna, Italy. [3]Department of Biomedical and Neuromotor Sciences, University of Bologna, Bologna, Emilia Romagna, Italy

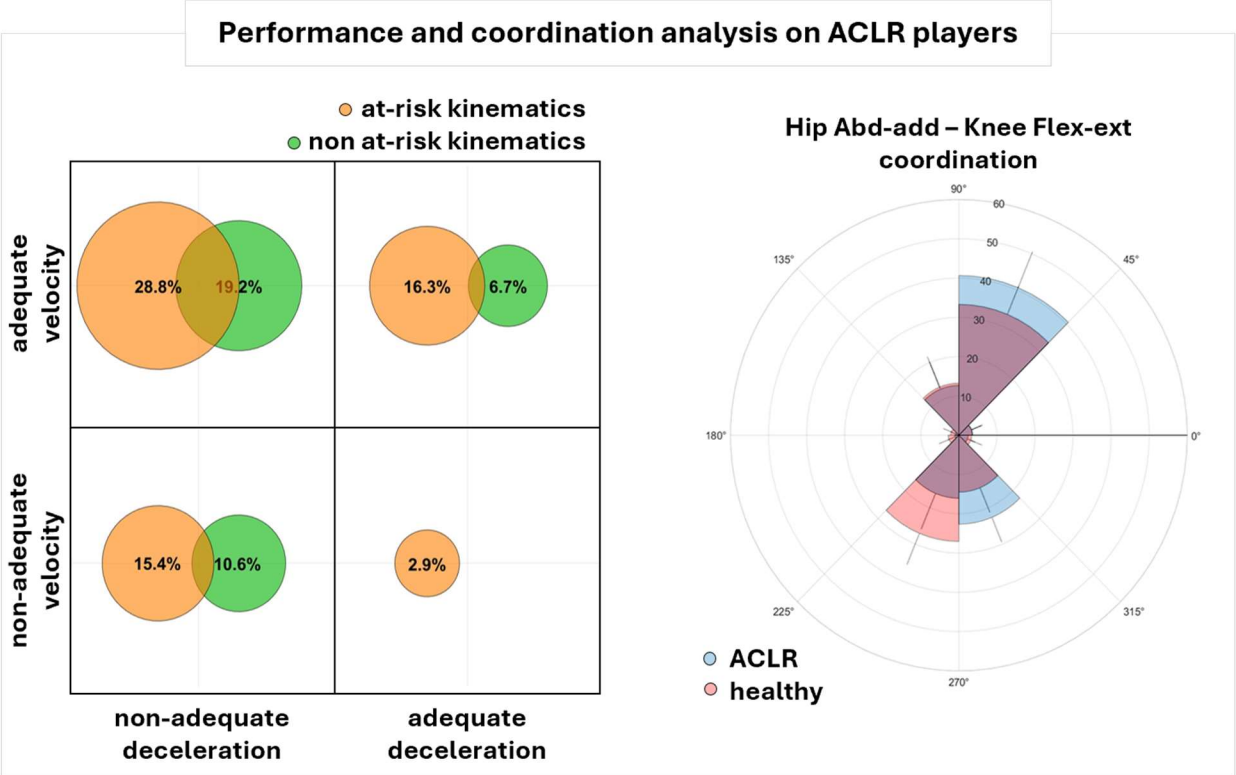
Introduction

The “Anterior Cruciate Ligament Injury Risk profile Detection” (ACL-IRD) algorithm is a clinician-friendly kinematic-based method for quantifying biomechanical risk in ACL-reconstructed (ACLR) football players during on-field cutting tasks [1], based on kinematics. Considering the “performance-injury conflict” [2], indicating that risky biomechanics cannot be interpreted in isolation, this study extends the ACL-IRD framework by integrating joint coordination and performance with kinematics, to better assess functional movement quality during return-to-sport in ACLR players.

Methods

Sixty-one football players (40 healthy, 21 ACLR; 16.2±2.2 years) performed pre-planned Agility T-test and unplanned football-specific cutting tasks (FS deceiving action) [1]. Lower limb and trunk kinematics was collected through 8 validated inertial sensors (100Hz, MTw Awinda, Movella). Cut braking strategy and propulsive ability performance were assessed through approaching deceleration and exit velocity. ACLR trials were classified against healthy normative data (1st and 3rd terciles) for binary indications of “adequate”/“non-adequate” execution for approaching deceleration, kinematics, and exit velocity. Joint coordination was evaluated through vector coding technique of lower limb angle–angle couplings.

Results



The ACL-IRD algorithm detected at-risk biomechanics in ~35% of trials in both Agility T-test and FS deceiving action. Knee/hip flexion ratio, knee valgus, and hip abduction frequently emerged as risk factors regardless of the task. Nearly 48% of ACLR clustered into a performance profile characterized by suboptimal braking strategy but preserved propulsive ability. Overall, 74% of ACLR trials exhibited inadequate approaching deceleration, 60% of which also presented at-risk kinematics, indicating altered patterns predominantly

emerging with braking deficits. Coordination analysis revealed greater deviations of the ACLR players from the normative in FS deceiving action vs. Agility T-test (9 vs. 3 of 16 angle-angle couplings). The main difference highlighted a greater hip abduction – knee flexion distal-dominant coordination of ACLR players ($p<0.001$, $d=0.68$).

Discussion

This study advances the ACL-IRD algorithm by introducing joint coordination and integrating on-field performance alongside risk profile analysis, providing a holistic interpretation of ACLR football players cutting technique. This approach could help clinicians target key factors during rehabilitation continuum, to optimize performance while minimizing injury risk.

Development of Simulated Osseointegration to Reduce Age and Sex-Based Disparities with In-Vitro Orthopedic Biomechanics Research

Mr. Logan Shannon, Ms. Elizabeth Pace, Dr. Tara Nagle PhD, Robb Colbrunn

Cleveland Clinic, Cleveland, Ohio, United States

Introduction

Poor bone quality of some cadaveric specimens, which can be exacerbated in female and elderly specimens, can lead to in vitro biomechanics research not accurately reflecting the patient population of interest. Studies aiming to compare surgical interventions relying on secure fixation of devices into the bone (e.g. suture anchors, buttons, etc.) are often compromised due to fixture loosening, which is rarely observed clinically and can be attributed to poor bone quality in cadavers and lack of device osseointegration.

Methods

Two male fresh frozen matched pair cadaveric knees, with a mean age of 74 years, were utilized to explore the application of two commercially available adhesives. The two adhesives (SB02 and SB150) were cyanoacrylate based and were modified with the addition of silica nanoparticles (1.5 wt%). Surrogate PEEK suture anchors were inserted into the bone of the cadaveric knees using a digital torque wrench. The bones were placed on an Instron MTS 858 to perform anchor pull-out tests. Maximum insertion torque and failure force was recorded.

Results

Twenty-eight pullout tests and insertion torque measures (n=14 per donor) were evaluated. The matched pair treated with the polymer adhesive SB02 experienced an average increase of 200N in pullout force across the seven insertion sites compared to the control side (Fig. 1a). The second matched pair, treated with the polymer adhesive SB150, experienced an average increase of 379N in pullout force across the seven insertion sites compared to the control side. Both treatment groups displayed an average 51% increase in maximum insertion torque compared to the matched control (Fig. 1b).

Discussion

Cyanoacrylate-based polymer adhesives modified with silica nanoparticles show potential to be a feasible solution to improve device fixation for in vitro biomechanics testing.

Cyanoacrylate glues form strong polymer matrices and provide quick cure times in addition to their low viscosities, allowing them to infiltrate and improve the density of the bone. This is displayed by the increase in both maximum pullout force and maximum insertion torque of PEEK anchors. Future research in this area will focus on evaluating various wt% additions of silica nanoparticles and optimize the application technique.

The Effectiveness of Wrist Bracing for Reducing Biomechanical Risk Factors Associated With Gymnast Wrist

Miss Stefania DiLeo[1], Miss Erin Day[2], Dr. Ashley Stirling[1], Dr. Ryan Paul[3], Dr. Andrea Chan[3], Dr. Timothy Burkhart[1]

[1]Faculty of Kinesiology and Physical Education, University of Toronto, Toronto, Ontario, Canada. [2]Temerty Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada. [3]Divisions of Orthopaedic and Plastic Surgery, University of Toronto, Toronto, Ontario, Canada

Introduction

Gymnasts often feel pressured to conceal pain and injury to support their likelihood for success, leading to long term health consequences. As such, preventative measures that safeguard gymnasts against common biomechanical injuries are critical. Distal radius physeal stress reaction, or Gymnast Wrist (GW), is prevalent in adolescent gymnasts due to repeated high force loading at the extended wrist. Wrist braces have shown to attenuate such forces. However, their efficacy for reducing GW risk in young female gymnasts is unknown. Therefore, this research aimed to establish the effectiveness of anti-hyperextension wrist braces for reducing biomechanical GW risk factors in young female gymnasts.

Methods

Wrist biomechanics were quantified in 14 adolescent female artistic gymnasts (mean [SD] age = 13.6 [2.4] years; gymnastics level 6-8) who performed three floor tasks (front handspring, round-off, back handspring) and the front handspring vault with and without bilateral anti-hyperextension wrist braces (Tiger Paws, Albuquerque, USA). Gymnasts' lead (LH) and non-lead (nLH) hand extension angles and impact forces were measured using inertial measurement units (Xsens MVN Awinda, Enschede, the Netherlands) and pressure sensors (Tekscan Flexiforce 5260, Norwood, USA), respectively. ANCOVAs were conducted. Exit surveys were administered to obtain feedback on brace use.

Results

During all tasks, wrist braces significantly reduced ($p < .05$) the magnitude of wrist extension at initial hand contact with the apparatus for the LH and nLH (mean reduction across tasks = 33.0° and 35.7°, respectively). Wrist braces also significantly reduced wrist extension at the time of peak hand impact force for the LH (Fig. 1) and nLH (mean reduction across tasks = 43.1° and 43.0°, respectively). However, braces did not significantly

influence the magnitudes of hand impact force ($p > .05$). In general, gymnasts perceived wrist braces to decrease wrist pain and/or increase wrist support, while causing little to no perceived changes in performance.

Discussion

This research is foundational as it provides support for wrist bracing as a potential strategy to reduce GW risk in young female gymnasts, an athlete population largely underrepresented within current literature. Focused research efforts on GW are not only imperative for protecting the growing gymnast, but also for safeguarding these vulnerable athletes.

Images (Optional)

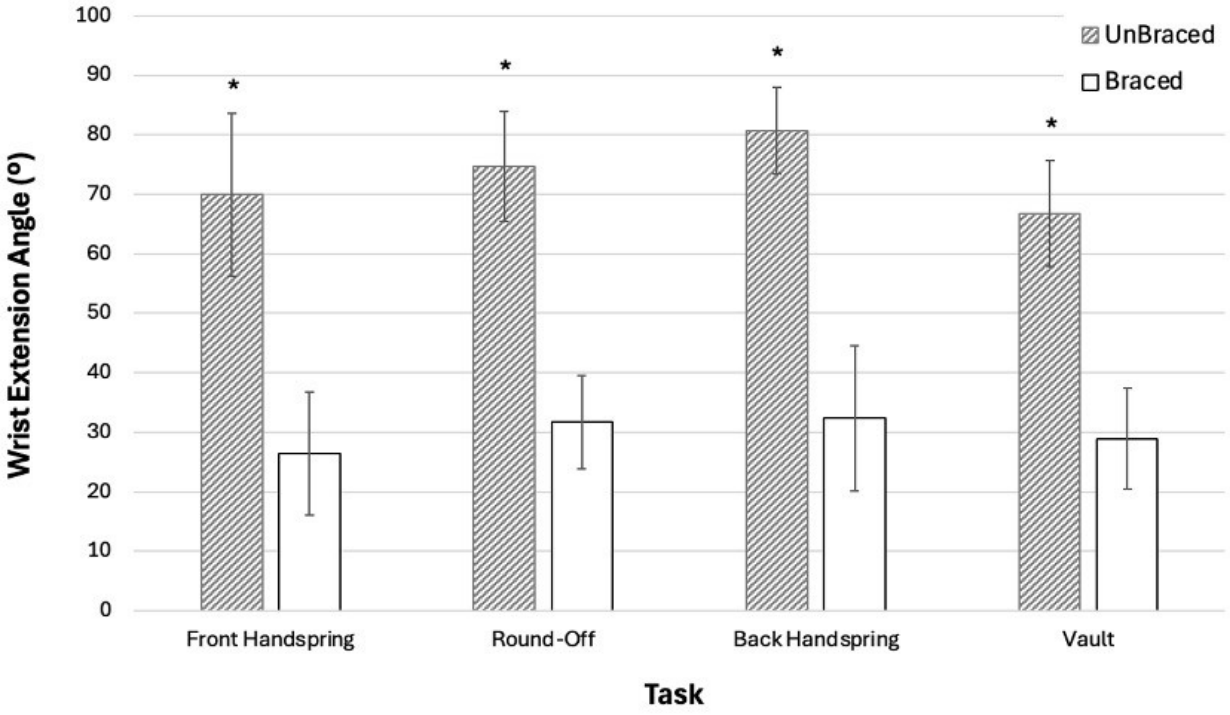

Figure 1: Braced vs unbraced wrist extension angles at peak hand impact force of the lead hand. Mean (SD) wrist extension angles are depicted in degrees (°) for each task. Asterisks denote a statistically significant difference between bracing conditions at $p < .05$.

Development of an Instrumented *in Vitro* and *in Silico* Knee Joint Model to Measure Cruciate Ligament Forces

professor António Ramos University of Aveiro[1], Professor José Simões ESAD[2], Msc Ana Matos University of Aveiro[1]

[1]University of Aveiro, Aveiro, Aveiro, Portugal. [2]ESAD-ID, Matosinhos, Porto, Portugal

Introduction

The anterior cruciate ligament (ACL) and posterior cruciate ligament (PCL) play fundamental biomechanical roles in knee stability. Among young and physically active individuals, particularly athletes exposed to rapid changes in direction and rotational loads, ACL injuries are highly prevalent worldwide. This study presents the development of an experimental instrumented in vitro knee model and in silico to designed to replicate native knee joint mechanics and quantify forces transmitted through the ACL and PCL.

Methods

An in vitro knee model (Figure 1) was constructed using synthetic composite bone structures of the left tibia, femur, and patella (Sawbones). Articular cartilage was reconstructed from MRI data using CAD tools to realize the in-silico model. Realistic geometries and anatomical insertion points for the menisci, ACL, PCL, medial collateral ligament (MCL), and lateral collateral ligament (LCL). The cartilage and menisci were manufactured using additive manufacturing. The ACL and PCL were simulated using tensioned cable assemblies to reproduce ligament-like behaviour. Knee flexion was driven in experiment under position control from full extension to 90° at 50 mm/min.

Results

A representative ACL force–flexion curve is shown in Figure 2. The curve morphology is consistent with patterns reported in cadaveric experiments [1,2], although the peak measured force was higher (≈255 N). The experimental model exhibited some instability during flexion, likely due to condylar contact dynamics and alignment variations between the tibia and femur.

Discussion

This in vitro model demonstrates good agreement with published ACL loading behaviour, supporting its potential for biomechanical evaluation of knee ligament function. However, improvements are needed, particularly in reducing friction within ligament tunnels and optimizing cartilage mechanical behaviour, as slight displacement during testing increased joint friction. Additionally, refining the stiffness properties of collateral ligaments will further enhance the model's accuracy for biomechanical simulation and testing.

Design of an Overlay Restoration Using 3D Functionally Graded Materials

Dr. Laurent Tapie[1], Dr. Ariane Martin[2], Dr. Vincent Fouquet[3], Pr. Elsa Vennat[2], Dr. Aurélie Benoit[3]

[1]Université Sorbonne Paris Nord, Paris, Ile-de-France, France. [2]CentraleSupélec, Gif-sur-Yvette, Ile-de-France, France. [3]Université Paris Cité, Paris, Ile-de-France, France

Introduction

The main cause of failure in bonded ceramic restorations is material fracture due to excessive stress concentration at the base of the prosthesis [1]. The design of restorative functionally graded materials (FGM) could represent a major advance in dissipating mechanical stresses during occlusal contacts. Using a biomimetic approach, an optimal configuration of FGM was defined on a simplified finite element model (FEM) of an overlay, considering constraints related to additive manufacturing of the material [2]. However, the more complex geometry of a clinical restoration may influence stress distribution. The aim of the present work is to evaluate the influence on FGM efficiency of three parameters: gradient orientation, the presence of an external protective shell, and the design of the preparation required to remove damaged dental tissues before restoration.

Methods

A topological decomposition based on anatomical entities was applied on segmented cone beam data of a healthy molar to build a 3D computer aided design (CAD) model (Fig.1) using 3DExperience (Dassault Systèmes). Different FEM were created from this healthy tooth by introducing multilayer FGM with different gradient orientations (1D/3D), preparation designs, with/without including an external shell. The FGM consisted of five 0.1mm-thick layers with linearly increasing Young moduli from 30 to 70 GPa towards the occlusal surface. The external shell's Young modulus is set at 80 GPa. All materials are considered isotropic and linear elastic. The external surface of the root is fixed and the tooth is vertically loaded up to 120 N with a rigid spherical indenter in contact with a soft food bolus.

Results

With more realistic 3D geometry, FGM continues to reduce stress at the basis of the prosthesis with no significant difference between a unidirectional and a 3D gradient. Stress

reduction improves with a protective shell and is more pronounced for realistic dental preparations that result in thinner thicknesses.

Discussion

The external shell both transmits forces more effectively to the stiffer enamel and ensures the prosthesis is sealed. FGM ceramics offers clinical potential for more lasting and less invasive dental restorations.

From Non-Union to Union: Computational Modeling of Magnesium-Enhanced Bone Healing

Dr. Sakip Onder[1], Dr. Leyla Noroozbabaee[2], Ms. Matilde Marradi[2], Dr. Aurélie Carlier[2]

[1]Yildiz Technical University, Istanbul, Istanbul, Turkey. [2]Maastricht University, Maastricht, Maastricht, Netherlands

Dr. Sakip Onder

Dr. Leyla Noroozbabaee

Ms. Matilde Marradi

Introduction

Magnesium (Mg^{2+})-based biomaterials are being explored for the treatment of bone fractures. As their effect on bone regeneration is dose dependent, a more mechanistic understanding of Mg^{2+}-mediated effects on the bone healing process is required to optimize the timing and spatial distribution of controlled Mg^{2+} release.

Methods

In this study, we extend a previously published bone healing model [1] (Figure 1). The inflammatory and repair phases of bone fracture healing are modeled by a system of nonlinear ordinary differential equations (ODEs) based on mass-action kinetics, assuming spatially homogeneous concentrations within a fixed volume. To better mimic Mg^{2+} concentrations at the fracture site three time-dependent Mg^{2+} release functions were defined: (1) a constant release profile, (2) a high burst release profile, and (3) a precisely controlled delayed release profile with a low initial burst. A local sensitivity analysis was conducted to evaluate the effects of Mg^{2+} delivery profiles and concentrations on bone mass dynamics in both union and non-union cases. All simulations were performed using Jupyter Notebook.

Results

We identified 1–5 mM Mg^{2+} as the optimal concentration range that promotes anti-inflammatory macrophage polarization, stem cell proliferation, and effective bone matrix formation. In contrast, Mg^{2+} concentrations ≥10 mM disrupted regeneration. Our analysis further reveals that controlled release strategies mitigate the cytotoxic effects of Mg^{2+} while preserving regenerative sensitivity in key parameters such as bone and stem cell proliferation.

Discussion

In summary, our results demonstrate that Mg^{2+} exerts concentration- and profile-dependent effects on key biological processes across all healing phases—from early immune activation to later-stage bone formation. As such this study offers a mechanistic basis to optimize Mg^{2+}-based therapies. Future work will focus on incorporating the role of angiogenesis and mechanical stimulation.

Images (Optional)

RNASeq Links Therapeutic Exercise Response in Fatigue Injured Tendon to Differentially Regulated Cell-Matrix Connection Genes

Mr. Benjamin Johnston[1], Dr. Nelly Andarawis-Puri PhD[1,2]

[1]Cornell University, Ithaca, New York, United States. [2]Hospital for Special Surgery, New York, New York, United States

Introduction

Tendinopathy treatment efficacy is limited by a lack of markers to optimally time therapeutic intervention. Our lab has developed an in-vivo model to induce sub-rupture patellar tendon (PT) fatigue injury and observed that while resuming physiological exercise 14-days-post-injury (dpi) is beneficial, resuming 1-dpi is detrimental[1]. Mechanisms driving this phenomenon remain unclear. This study identifies genes and pathways which may determine the capacity to respond positively to physiological exercise. We hypothesize that cell-extracellular matrix (ECM) interactions are transiently disrupted post-injury, shifting exercise toward a degenerative stimulus when resumed prematurely.

Methods

Left PTs of 9–10-month-old female Sprague-Dawley rats underwent fatigue loading per IACUC approved protocol[2]. Animals were sacrificed as uninjured controls (n=3) or at 1-, 4-, 7-, or 14-dpi (n=3-4). RNA was isolated and sequenced to a depth of 20 million raw reads. DEGs between groups were calculated using DESeq2, with limits $|\log2(FC)| \geq 1$, p-adjusted < 0.05, and ncounts > 100. Analysis was performed with Qiagen Ingenuity Pathway Analysis and R.

Results

Principal component analysis demonstrates clustering within timepoints (Fig. 1A). 14-dpi and 1-dpi samples show distinct genetic profiles, but 7-dpi and 14-dpi profiles overlap heavily (Fig. 1B-D). Top up- and downregulated pathways 14-dpi vs. 1-dpi dictate cell-ECM interactions and cell-cycle regulation, respectively (Fig 1E).

Discussion

Upregulation of both collagen synthesis and degradation pathways 14-dpi vs. 1-dpi may indicate a homeostatic-like turnover wherein damaged collagen is effectively replaced by properly aligned collagen. *Cdk1*, a gene essential for cell-ECM connectivity during cell

division, is transiently downregulated 1-dpi vs. control and returns to baseline 14-dpi, exhibiting a similar temporal pattern to cell-cycle regulation[3]. Immediately post-injury, cells divide rapidly without producing genes required to maintain cell-ECM connections. This may generate a large population of aberrantly loaded cells, which supports our hypothesis. Overlap between the therapeutic 14-dpi profile and 7-dpi profile suggests that resuming exercise 7-dpi will yield similar therapeutic outcomes, confirmation of which will identify key markers which could be used to diagnose when injured tendons will respond positively to exercise.

Images (Optional)

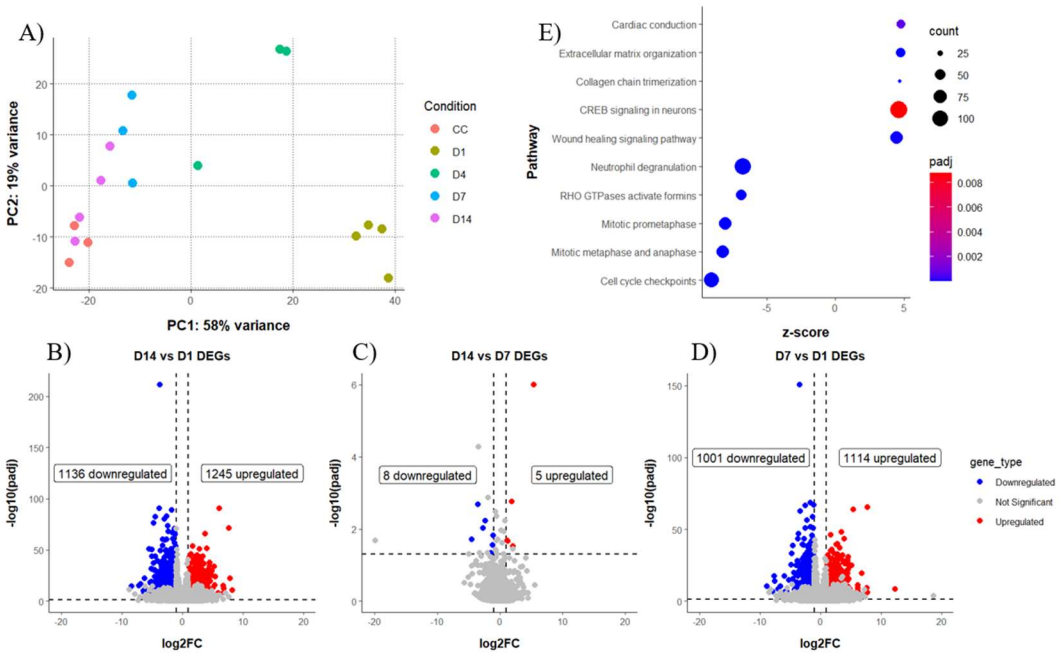

Figure 1) A) Principal component analysis of variance across all timepoints showing clustering within each group. PC1 accounts for 58% of the variance and PC2 accounts for 19%. Volcano plots show DEGs between **B)** 14-dpi and 1-dpi, with 1136 downregulated and 1245 upregulated genes, **C)** 14-dpi and 7-dpi, with 8 downregulated and 5 upregulated genes, and **D)** 7-dpi and 1-dpi, with 1001 downregulated and 1114 upregulated genes. **E)** Dot plot of the 5 most up- and downregulated pathways by z-score between 14-dpi and 1-dpi. Molecular counts ranged from 22 to 122, while adjusted p-values ranged from $3.17*10^{-14}$ to $8.78*10^{-3}$.

Preliminary Investigation into Optimizing Injection Molding Techniques for a Novel Universal Talus Bone Implant

Ms. Cameron Scott M.Sc., Mr. Nadr Jomha Dr., Mrs. Lindsey Westover Dr., Mr. Ahmed Ead Dr.

University of Alberta, Edmonton, Alberta, Canada

Introduction

Total talar replacements (TTR's) aim to restore both ankle mobility and weight bearing capacity after injury. TTRs involve replacing the damaged talus with a custom metal implant. However, the metal implants against biological cartilage have been found to cause joint deterioration. A coated talus implant could address this challenge.

This research investigates the preliminary prototyping methods required to make a coated talus bone implant, utilizing universal talus shapes proposed by our group. The presented work highlights the iterative process of the injection mold design.

Methods

The foundation of the implant started with Size 5 universal talus bone [1]. The Size 5 talus model was imported into SolidWorks® with feature recognition enabled. A draft angle of 3° was set to ensure that the implant could be removed from the die easily. Two parting lines were found, one that ran horizonal to the bone and another that ran through the talus-calcaneus joint. The injection mold die was designed around the parting lines and aimed to achieve a minimum coating of 2 *mm* [2].

For prototyping purposes, high-density polyethylene was used as the coating. The die was 3D printed and its ability to coat the talus bone was tested. The design was tested by qualitatively observing the coating on the implant.

Results

The initial design of the mold was able to coat six implants successfully; however, issues appeared during the injection mold process that necessitated addressing for future versions. The qualitative inspections of the prototype showed the coating thickness was, on average, 2 *mm* as targeted. There were regions of insufficient coating in the superior neck of the talus and the articular surface for the navicular (Figure 1).

Discussion

The second version of the injection mold die aimed to fix the areas of absent coatings through the addition of three internal support pins. This resulted in the neck of the implant being coating, however, insufficient coating on the navicular joint was still present. Another version of the injection mold is required prior to large scale manufacturing.

The Role of the Deltoid and Syndesmotic Ligaments on the Ankle Joint Kinematics

Dr. Daniela Warnecke[1], MD Sebastian Baumbach[2], MD Nasef Abdelatif[3], M.Sc. Samuel Bachmaier[1]

[1]Arthrex GmbH, Munich, Bavaria, Germany. [2]OrthoPlus Munich, Munich, Bavaria, Germany. [3]Orthopedic Foot and Ankle Department, OrthoClinic, Cairo, al-Qahira, Egypt

Introduction

The deltoid ligament (DL) complex on the medial side of the ankle joint comprises superficial (SDL) and deep layers (DDL) and plays a crucial role in joint stabilization [1]. A previous study showed that DL and syndesmotic injuries had a similar effect on rotational ankle instability [2]. This study aimed to analyze changes in the ankle kinematics following syndesmotic and DL injuries.

Methods

Twenty-eight distal tibia amputee cadaver specimens were assigned to 3 groups. Sequential dissections of the anterior inferior tibiofibular and interosseous ligaments (AiTFL+IOL), SDL, and DDL were performed in varying orders (Figure 1). Specimens were initially loaded up to 7Nm to evaluate time-zero rotation at 2.5, 4.0, 5.5, and 7Nm, representing intact conditions, followed by rotation-controlled loading after each dissection. 3D motion was captured using an optical system (ZEISS ARAMIS) with marker sets placed on the proximal tibia and fibula, and virtual points on anatomical landmarks. Outcome parameters also included the fibular rotation angle (FRA) and anterior tibiofibular distance (aTFD) [3]. After initially confirming no group differences within the same dissection stage by one-way ANOVA, data were pooled and further analyzed using RM ANOVA with Bonferroni post-hoc t-tests.

Results

Each dissection step increased fibular and tibial internal rotation, with significant differences between intact and “unstable ankles”. DL injury shifted both bones laterally, while AiTFL+IOL dissection shifted them medially. Additionally, posterior fibular translation was observed for syndesmotic injuries, which further increases with DL involvement. No significant changes were observed for tibial anterior-posterior translation or FRA. In contrast, aTFD increases threefold after syndesmotic dissection, while DL injury alone had no effect.

Discussion

This study supports previous findings that both a two-ligament syndesmotic injury or a complete DL rupture have comparable effects on ankle joint (in)stability [2]. By adding kinematic measurements, current results complete the analysis of these injuries and demonstrate that sequential ligament dissection significantly alters ankle kinematics. Although no differences were observed between syndesmotic injuries with concomitant SDL or DDL involvement, the data underline DL's functional relevance as a medial stabilizer of the ankle joint.

Simulation-Based Assessment of Magnesium vs. Titanium Fixation Using Human Mandibular Magnesium Mini Plates

Mr. Dawei Zhang[1], Dr. -Ing Songyun Ma[1], Prof. Dr. med. Dr. med. dent. Carsten Rendenbach[2], Mr. Thomas Kött[3], Univ.-Prof. Dr.-Ing. Dr. h. c. (PSACEA) Bernd Markert[1], Dr. -Ing Agnes Beckmann[3]

[1]Institute of General Mechanics, RWTH Aachen University, Aachen, NRW, Germany. [2]Department of Oral and Maxillofacial Surgery, Charité - corporate member of Freie Universität Berlin, Humboldt-Universität zu Berlin, Berlin, Berlin, Germany. [3]KLS Martin SE & Co. KG, Mühlheim an der Donau, BW, Germany

Introduction

Titanium osteosynthesis is the current standard treatment for mandibular reconstruction. However, in cases of osteoradionecrosis, healing efficacy and implant integration remain challenging, motivating the development of resorbable biomedical materials such as magnesium alloys. In particular, PEO-coated WE43 magnesium alloys have emerged as promising biodegradable materials for mandibular reconstruction, and their successful first clinical application represents an important milestone in resorbable implant technology [1]. This study presents a computational approach to evaluate the degradation behaviour of PEO-coated WE43 implants and their interaction with tissue differentiation during fracture repair. Specifically, the biomechanical performance of these magnesium miniplates is numerically assessed over six weeks and compared with conventional titanium instrumentation, based on a first-in-human clinical case.

Methods

The finite element model of an instrumented mandible by Rendenbach et al. was extended to a mechano-regulation framework incorporating biphasic stimuli for tissue differentiation and a continuum damage model to simulate pitting corrosion in magnesium [1, 2]. A bite force of 100 N was applied perpendicular to the occlusal plane at the first right molar, with muscle forces ensuring equilibrium. Both condyles were fully constrained to ensure static determinacy of the model [3]. Screws were modelled as cylinders with screw heads and tied to the bone, while frictional contact was defined at implant-bone and screw head-implant interfaces. Implant stresses were evaluated using von Mises criteria relative to material yield strengths.

Results

The predicted corrosion process of the implants is shown in Fig. 1. On day 14, minimal corrosion occurred due to the protective coating. On day 42, the corrosion damage of the bone plate and screws had extended to many elements on the corrosion surface, reducing load-bearing areas and compromising mechanical integrity.

Discussion

The simulation demonstrates that PEO-coated magnesium implants maintain sufficient mechanical integrity during the early healing stage, supporting the potential of resorbable magnesium implants as a viable alternative to permanent titanium devices in mandibular reconstruction.

In Vivo Assessment of Distal Femur Fracture Motion via Weightbearing Computed Tomography

Dr. Eric D. Thorhauer PhD[1,2], Dr. William R. Ledoux PhD[1,2], Mr. Nick Entress BS[1], Dr. Scott Telfer EngD[1,2], Dr. William D. Lack MD[1,2]

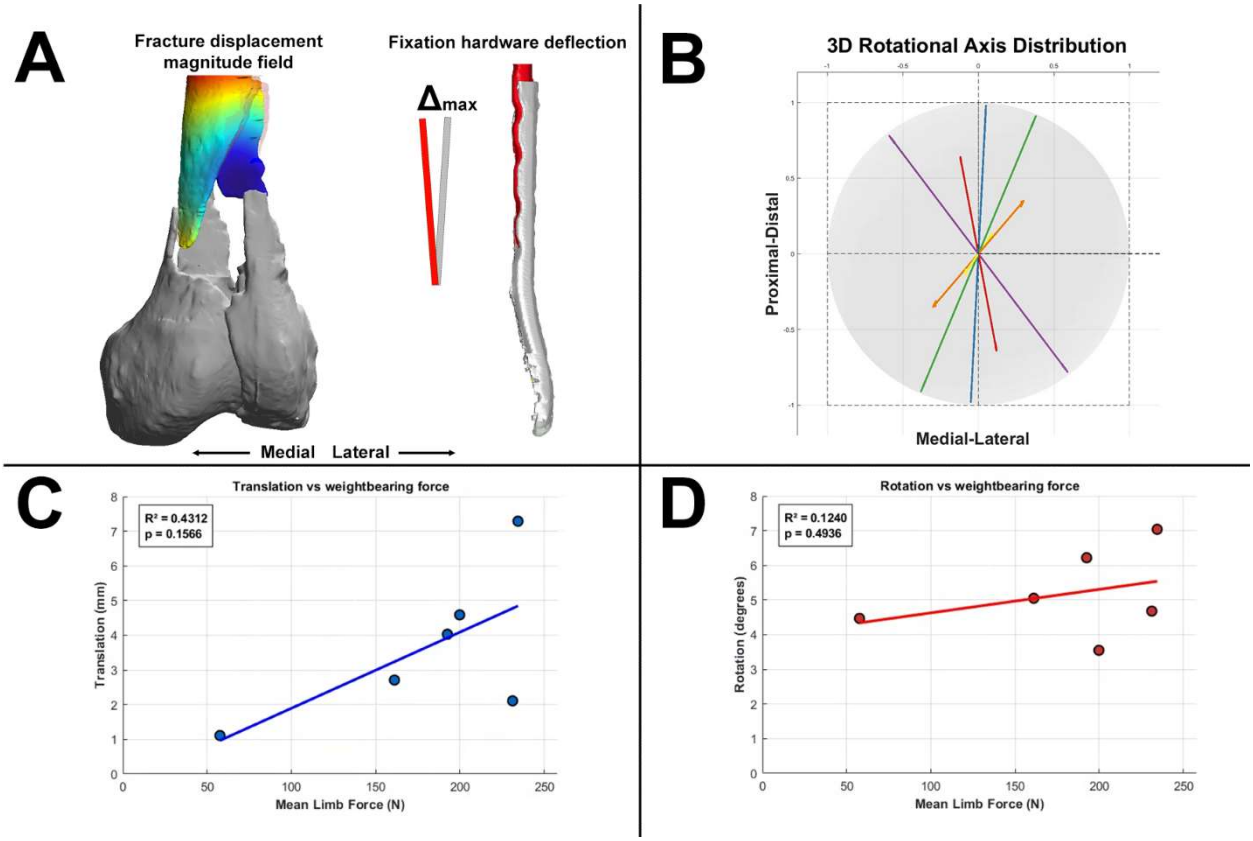
[1]Center for Limb Loss and MoBility (CLiMB), Seattle, WA, United States. [2]University of Washington, Seattle, WA, United States

Introduction

Distal femur fractures are associated with a high risk of delayed and/or failed healing that has been qualitatively associated with suboptimal fracture site mechanics [1,2]. We developed a method of quantifying in vivo distal femur fracture motion via weightbearing computed tomography (CT) to allow further investigation of the role of mechanoregulation in distal femur fracture healing.

Methods

Distal femur fracture patients (N = 9) were recruited and enrolled from an orthopaedic clinic; 8 subjects completed the protocol and data for 6 has been processed (5 male; 1 female; age 48.3 ± 24.9 yrs; body weight 79.8 ± 12.9 kg). Non-weightbearing (NWB) and weightbearing as tolerated (WBAT) CT scans of the distal femur were acquired using a CurveBeam LineUp conebeam CT scanner while novel pedar in-shoe sensors recorded vertical ground reaction forces bilaterally. Subject-specific fracture fragment models were generated using the Mimics segmentation suite. Using MATLAB, anatomical coordinate systems were established, and the poses of relevant fragments in the NWB and WBAT positions were reconstructed in Geomagic to determine fracture site kinematics. The volumetric nature of CT allows for analysis of the interfragmentary displacement fields (Figure 1A) and the deflection of the fixation hardware (Figure 1A) in response to weightbearing.



Results

The mean magnitude of fracture motion across subjects was 3.64 ± 2.19 mm for translations and 5.17° ± 1.26° for rotations. Orientation of the axes of motion varied between subjects, but transverse and frontal plane rotations were the two primary modes observed (Figure 1B). The magnitudes of fracture site translation and rotation trended toward increasing magnitudes of motion with greater limb loading (Figure 1C, 1D).

Discussion

These results demonstrate feasibility of quantifying in vivo distal femur fracture mechanics under physiological loading. Load-dependent motion patterns may inform clinical care and our understanding of osseo-biomechanics. Limitations include a small, heterogeneous sample, and natural variability in loading tolerance. Recently awarded funding will facilitate a larger cohort study correlating dynamic fracture kinematics with radiographic evidence of healing progression and outcomes.

Subject-Specific Finite Element Modeling of KANON Cohort Reveals Individualized Mechanical Consequences of Anterior Cruciate Ligament Deficiency

Postdoc Researcher Sana Jahangir[1], Postdoc Researcher Amir Esrafilian[1], Professor Martin Englund[2], Academy Research Fellow; Adjunct Professor Petri Tanska[1,3], Professor Rami K. Korhonen[1], Professor Hanna Isaksson[2]

[1]University of Eastern Finland, Kuopio, North Savo, Finland. [2]Lund University, Lund, Skåne, Sweden. [3]Kuopio University Hospital, Wellbeing Services County of North Savo, Kuopio, North Savo, Finland

Introduction

The KANON trial[1] compared early anterior cruciate ligament (ACL) reconstruction with exercise therapy versus exercise therapy with optional delayed reconstruction in young adults. While the cohort is well characterized, mechanical consequences of ACL deficiency remain poorly understood. Both abnormally high and low joint loading have been reported after ACL injury. This proof-of-concept study uses subject-specific finite element (FE) knee models from KANON participants to quantify how ACL deficiency alters tibiofemoral contact mechanics and tissue loading during gait—providing insight into mechanical factors relevant to longer-term joint health.

Methods

MRIs from five KANON cohort subjects[1] (ACL rupture treated non-operatively; age 22–28 years) were used to generate subject-specific FE knee models with a validated atlas-based framework[2]. All subjects had no baseline cartilage damage (anterior cruciate ligament osteoarthritis (ACLOAS) score = 0). Literature-based gait kinematics and kinetics[2] were applied to simulate walking. Each subject was evaluated with (1) intact ACL and (2) ACL-deficient, modeled by reducing ACL stiffness to 0.1% of its intact value. Model outputs included posterior–anterior translation, tibiofemoral and meniscal contact areas, location of center-of-pressure (COP) on tibial plateau, and maximum principal cartilage stress (mean of upper quartile).

Results

ACL deficiency increased posterior femoral translation during mid-stance, reduced medial and lateral tibiofemoral and meniscal contact areas, and shifted the COP posteriorly.

Group-averaged mean of upper-quartile values of cartilage stress at the cartilage-cartilage contact area showed only modest differences between intact and ACL-deficient knees (Fig. 1). In contrast, lateral tibial cartilage peak-stress increased 7.2 ± 3.0 MPa across five subjects (Fig. 1).

Discussion

ACL deficiency consistently altered tibiofemoral contact mechanics, with reduced contact area and a posterior COP shift, indicating load transfer to smaller, more posterior regions. Peak cartilage stress generally increased, but the magnitude varied widely, likely due to anatomical differences under identical gait loading. Overall, although peak stress increased in some individuals, contact mechanics remained most consistent indicator of altered joint loading. These subject-specific insights provide a basis for investigating loading-related mechanisms after ACL injury.

Images (Optional)

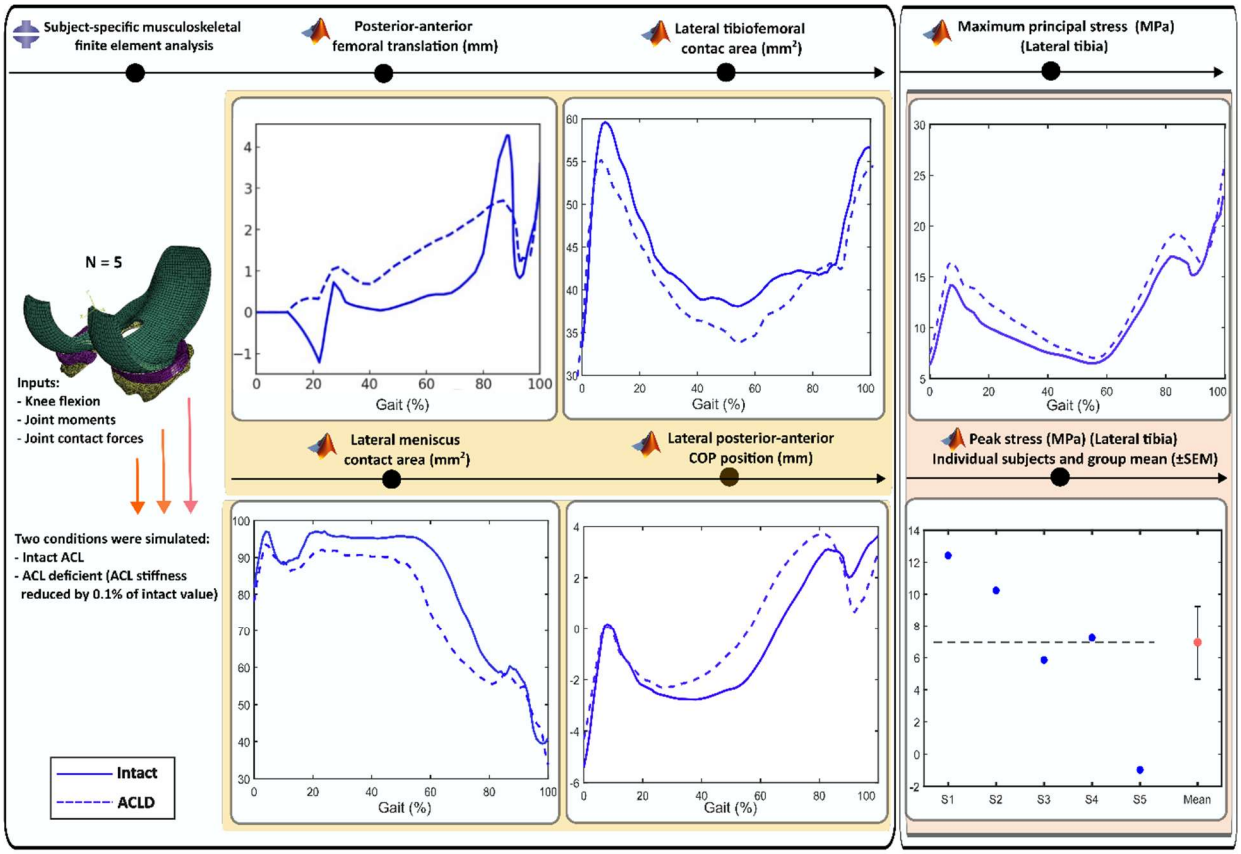

Fig 1: FE-derived changes with ACL deficiency (N = 5) over the stance phase of gait. The knees showed reduced lateral contact area and posterior COP shift. Grouped-averaged mean of upper quartile of maximum principal stress at lateral tibia is shown. Individual subjects' peak-stress changes (blue dots) and group mean ± SEM are also presented.

Bovine Osteochondral Plug Viability in Explant Culture Maintained for Up to 14 Days Post Injurious Loading

Doctoral Researcher Ida Antikainen[1,2], Doctoral Researcher Sanna Hakonen[1], Postdoctoral Researcher Özge Karadaş[1,2], Doctoral Researcher Alara Kara[1,2], Doctoral Researcher Siiri Keränen[3], Postdoctoral Researcher Atte Eskelinen[1], Professor Rami Korhonen[1], Academy Research Fellow Petri Tanska[1,2], Professor Petteri Nieminen[3], Senior Researcher Anne-Mari Mustonen[3], Senior Researcher Mikael Turunen[1,2]

[1]Department of Technical Physics, University of Eastern FInland, Kuopio, North Savo, Finland. [2]Kuopio University Hospital, Wellbeing Services County of North Savo, Kuopio, North Savo, Finland. [3]Institute of Biomedicine, University of Eastern Finland, Kuopio, North Savo, Finland

Introduction

Post-traumatic osteoarthritis (PTOA) can be initiated by injurious overloading[1]. Experimental explant models are therefore needed to investigate how excessive loading affects disease progression, cell metabolism and viability. As simultaneous changes in cartilage and bone during PTOA are underexplored, we aimed to establish an experimental PTOA model using osteochondral, cartilage-on-bone plugs subjected to traumatic injury and cultured up to 14 days. Specifically, we focused on assessing post-injury metabolic activity and chondrocyte viability.

Methods

Osteochondral plugs were harvested from bovine tibiae and femora by drilling (N=3 animals, Figure 1A) and divided into free-swelling control (n=12) and impact injury groups (n=11). Impact injury was performed on day 0 with a previously established drop-tower protocol by imposing a momentum of 0.387 kgm/s (500 g weight from height of 15 cm) onto the sample[2]. Explants were then cultured for up to 14 days in supplemented, low-glucose, serum-free DMEM, and the media were changed every three days. Metabolic activity was analyzed from culture media on days 1, 4, 7, and 14 with alamarBlue™ HS assay (Ex/Em: 570/600 nm). Cell viability was qualitatively assessed from the plugs using confocal microscope on days 1 and 14 (Zeiss LSM700; calcein AM/propidium iodide live/dead staining). Paired t-test was used for statistical analysis.

Results

Mean metabolic activity increase in control and impact injury groups was 164% and 136%, respectively, with no significant differences between the groups ($p > 0.05$) (Fig. 1B).

Qualitative cell viability was lower in the injury group compared to control, exhibiting substantial cell death but retaining a viable cell population until day 14 (Fig. 1C).

Discussion

Our findings suggest that bovine osteochondral, cartilage-on-bone plugs remain metabolically active and retain chondrocyte viability over a 14-day culture, indicating post-harvest recovery and adaptation, possible extracellular matrix synthesis and proliferation of progenitor cells. This provides a suitable explant model for studying mechanoinflammatory cell responses related to PTOA in both cartilage and bone.

Images (Optional)

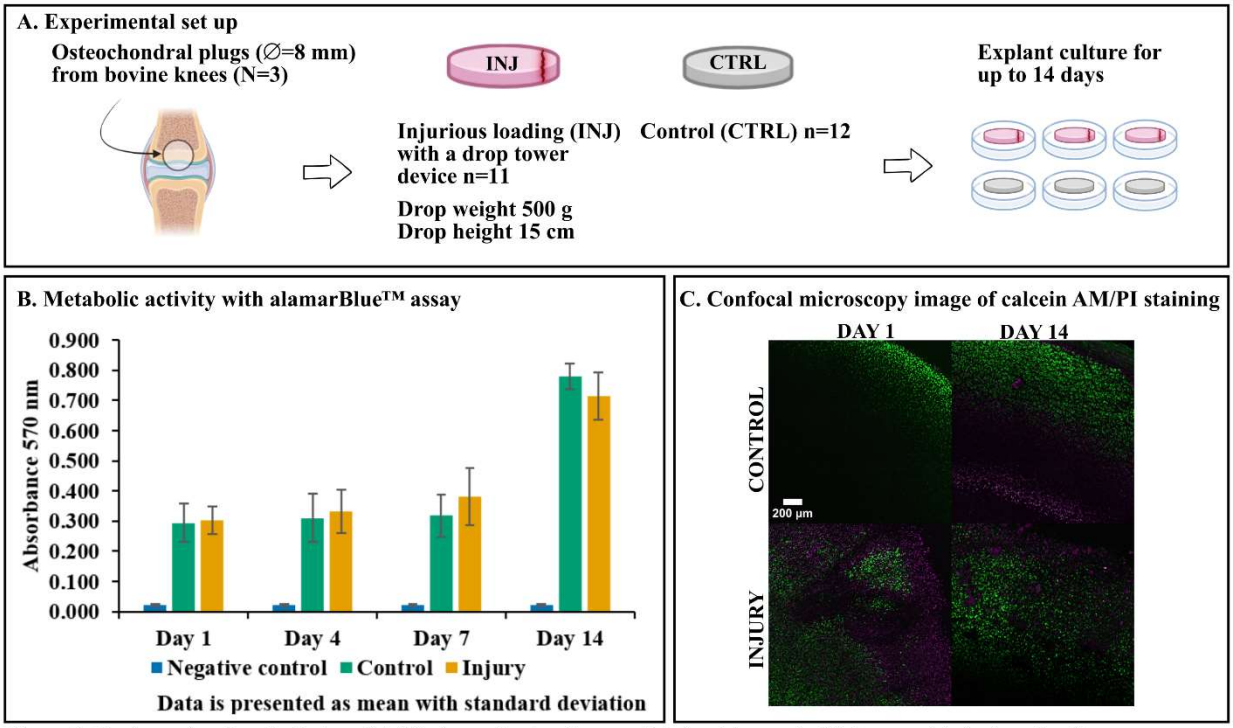

Figure 1. Bovine osteochondral plug viability in explant culture maintained for up to 14 days post injurious loading.
A. Experimental setup. B. Metabolic activity with alamarBlue™ assay: a higher absorbance value indicates greater metabolic activity and thus higher cell viability. C. Confocal microscopy image of chondrocyte calcein AM/PI staining: visualization of live (green) and dead (magenta) cells.

Mechanical Modeling of Distraction Osteogenesis

Mr Alexandre Hamma[1], Associate Professor Jean Boisson[1], Professor Natacha Kadlub[1,2], Dr Cortet Pierre-Philippe[3], Prof Poulard Christophe[4], Prof Picard Arnaud[2]

[1]Laboratory of Mechanics and its Interfaces, ENSTA, IP-Paris, Palaiseau, Ile de France, France. [2]Maxillofacial and Plastic Surgery, Necker Children Hospital, APHP, Paris, Ile de France, France. [3]FAST, Saclay, Ile de France, France. [4]LPS, Saclay, Ile de France, France

Mr Alexandre Hamma

Associate Professor Jean Boisson

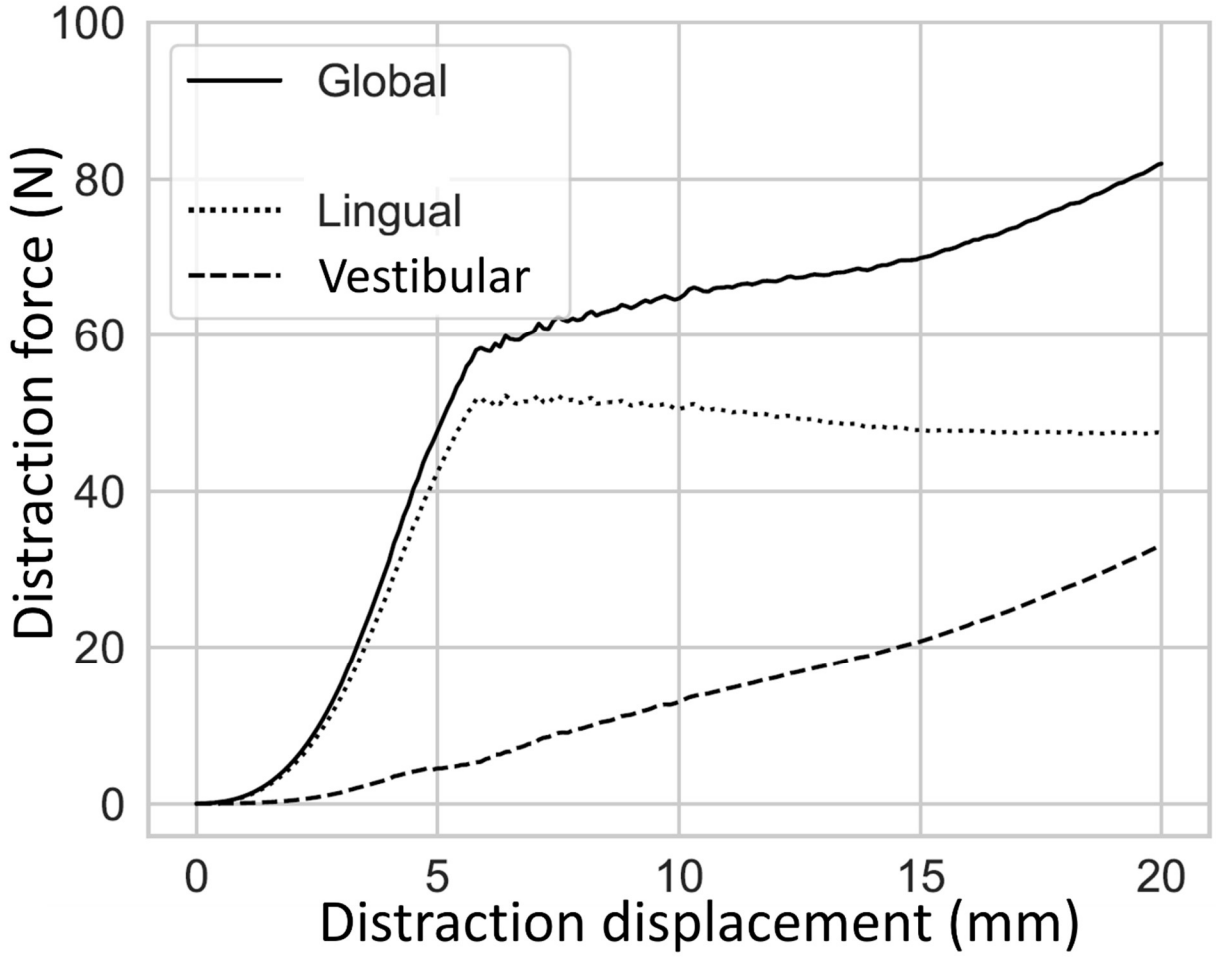
Introduction

Osteogenic distraction is a surgical procedure that has been widely used since the 1950s. It enables gradual bone lengthening by elongating a callus following a surgical fracture. This technique is now essential for treating congenital facial malformations in children. Indications are either functional, such as occlusal or respiratory issues, or morphological. Since its introduction to maxillofacial surgery, technical improvements have focused on reducing iatrogenic complications, increasing patient comfort, and improving effectiveness. However, many studies are based on cadaveric or animal models without considering the origin of the forces involved in distraction. Here, based on experimental tests and numerical simulations, we propose a complete description of the mechanical process of mandibular distraction that can be extended to any osteogenic distraction.

Methods

This study used the finite element method to simulate numerically a mandibular distraction osteogenesis. All simulations were performed using Abaqus (Dassault Systèmes). After validation of a simplified mandibular geometry, we simulated a complete 20-mm distraction. The cortical bone was modeled as an isotropic, linear, elastic material, while, the periosteum as a custom visco-hyperelastic, transversely isotropic constitutive law. We modeled the periosteum attachment to the bone using a bilinear traction-separation law to simulate the initiation and propagation of contact damage. The parameters of this law were identified through a series of periosteum peeling tests on pig

mandibles, along with a sensitivity analysis. Finally, we modeled the complex interface between the periosteum and bone to account for surgically manipulated and undisturbed adhered regions.



Results

The evolution of the resulting force of distraction is in very good agreement with an experimental campaign conducted on cadaveric subjects, which showed an increase in force for the first five millimeters, followed by a plateau characteristic of a peeling phenomenon. The force distribution is also greater on the lingual side than on the vestibular side.

Discussion

These results validate the entire study and highlight the important role of the periosteum in distraction osteogenesis. Additionally, we demonstrate that surgical dissection geometry controls the plateau of force level, as well as the distraction vector, which is critical in cases of craniofacial dysjunction, for example.

Analysis of the Influence of Spinal Screw Length in Spinal Fusion in Young People and Those With Osteoporosis

Dr Krzysztof Jankowski, Dr Roman Grygoruk

Warsaw University of Technology, Warsaw, Mazovia, Poland

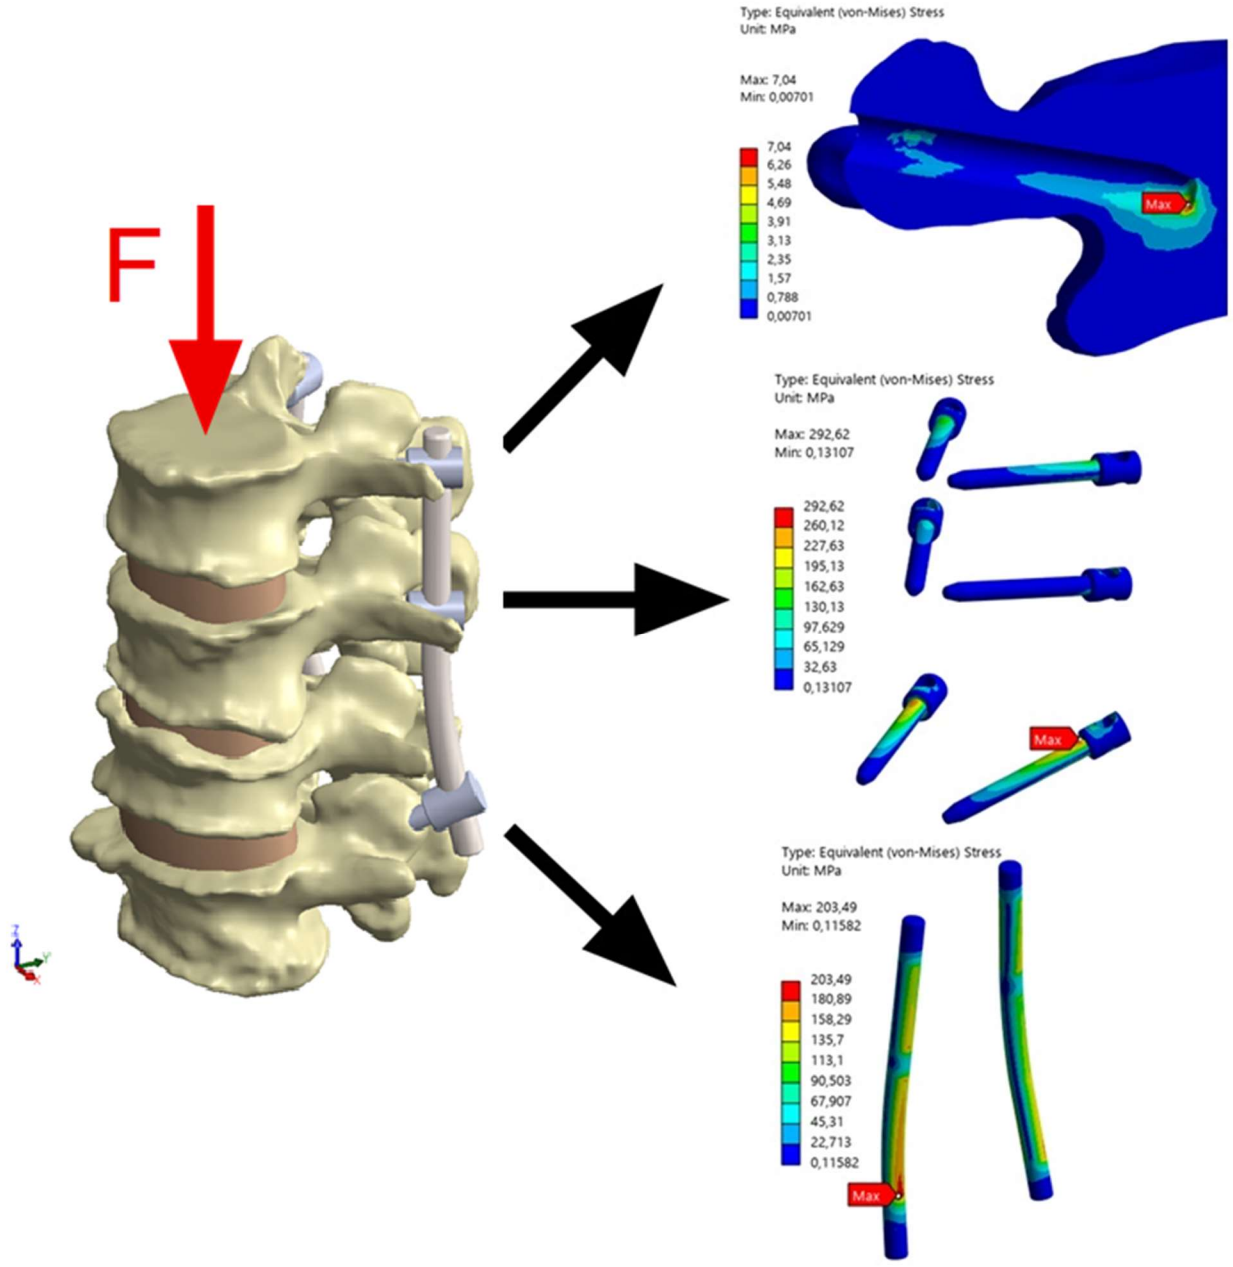
Introduction

Vertebral fractures are serious injuries that prevent normal functioning. In young and middle-aged individuals, these injuries may be caused by traffic accidents or sports-related accidents, while in older individuals, especially those with osteoporosis, a fall from a height may be sufficient. These fractures are treated with the use of fixators, which are secured with screws inserted into the vertebrae located above and below the fractured vertebra. This relieves the load on the fractured vertebra. The aim of this study was to determine whether, from a biomechanical perspective, it is better to use longer or shorter screws, taking into account the condition of the cortical and trabecular bone (healthy tissue and osteoporotic) in the vertebrae.

Methods

Based on computed tomography (CT) scans of patients with a fractured vertebra, 3D models of the vertebrae were created, divided into cortical and trabecular bone. The rods and screws of different sizes were modelled based on the catalogue and used in various configurations of virtual spinal fusion. These models were used in finite element simulations of uniaxial compression of the spine with a fixator performed in ANSYS. The variable between configurations was the screw length, as well as the material properties of cortical and trabecular bone (healthy and osteoporotic).

Results



As a result of the simulations, stress and strain distributions in the vertebrae (cortical and trabecular bone structures), rods and screws were obtained (Fig. 1), which were compared and analysed.

Discussion

Simulations showed the differences in stress and strain distributions in healthy and osteoporotic vertebrae. In ‘healthy spine’, longer screws caused lower values of max stress and strain in bone tissues than shorter, but greater in rods and screws. In ‘osteoporotic spine’, longer screws caused greater values of max stress and strain in bone tissues, but smaller values on rods and screws. It was caused by the condition of osteoporotic

trabecular bone, which is much weaker in the middle of the vertebrae. Hence, the screws have a greater chance of causing damage to it and loosening themselves.

The Effect of Braid Parameters on Soft Tissue Repair Devices

Miss Lydia Jordan[1], Professor Sam Evans[1], Dr Hayley Wyatt[1], Ms Vicky Graham[2]

[1]Cardiff University, Cardiff, UK, United Kingdom. [2]Lockdown Medical Ltd, Redditch, UK, United Kingdom

Introduction

Successful artificial ligament and tendon repairs depend on restoring joint strength and stability while preventing re-rupture or over-constraint of the joint. Braided artificial ligaments and tapes are widely used in orthopaedic reconstruction, yet the relationship between braid structure and mechanical behaviour remains poorly quantified. This study investigates how variations in braiding manufacture influence mechanical performance and develops predictive models to optimise the design of soft tissue repair devices.

Methods

Nine groups of braided samples, based on the LockDown Shoulder Stabilisation System, were produced with systematic variations in:

1. Manufacturing speed
2. Number of cores (sub-structures running vertically through the braid)
3. Core material
4. Number of bobbins (the threads that are braided around each other and the cores).
5. Fibre material

Each group contained multiple samples tested in uniaxial tension to failure, with strain measured using video extensometry. Mechanical outputs - ultimate load (N), stiffness (N/mm), engineering stress (N/mm^2), and strength efficiency ratio (actual failure load/theoretical failure load) - were analysed to identify relationships between structure and mechanical behaviour. Linear regression models were then developed to predict mechanical performance from design parameters, with goodness of fit evaluated using the coefficient of determination (R^2).

Results

Increasing total strand count produced an increase in strength and stiffness while reducing local stress, indicating there may be a more efficient load distribution within the braid as the strand count increases. Manufacturing speed had limited influence on stiffness but

affected mechanical response variability, suggesting a more complex relationship that cannot be immediately identified with these methods. Figure 1 shows the correlation map with significance indicated for each factor. Predictive models achieved strong fits ($R^2 > 0.8$) for most groups, allowing reliable estimation of mechanical behaviour from most braid inputs.

Discussion

The study demonstrates how predictive modelling can be used as an effective design tool. It links braid-manufacture parameters to mechanical behaviour, providing a quantitative framework for optimising soft tissue repair devices. These models enable intentional design of constructs with mechanical properties that better replicate native tissue behaviour, improving joint stability and long-term device performance. Ultimately, such optimisation can help maintain joint biomechanics, preventing excessive laxity or over-restriction following reconstruction.

Images (Optional)

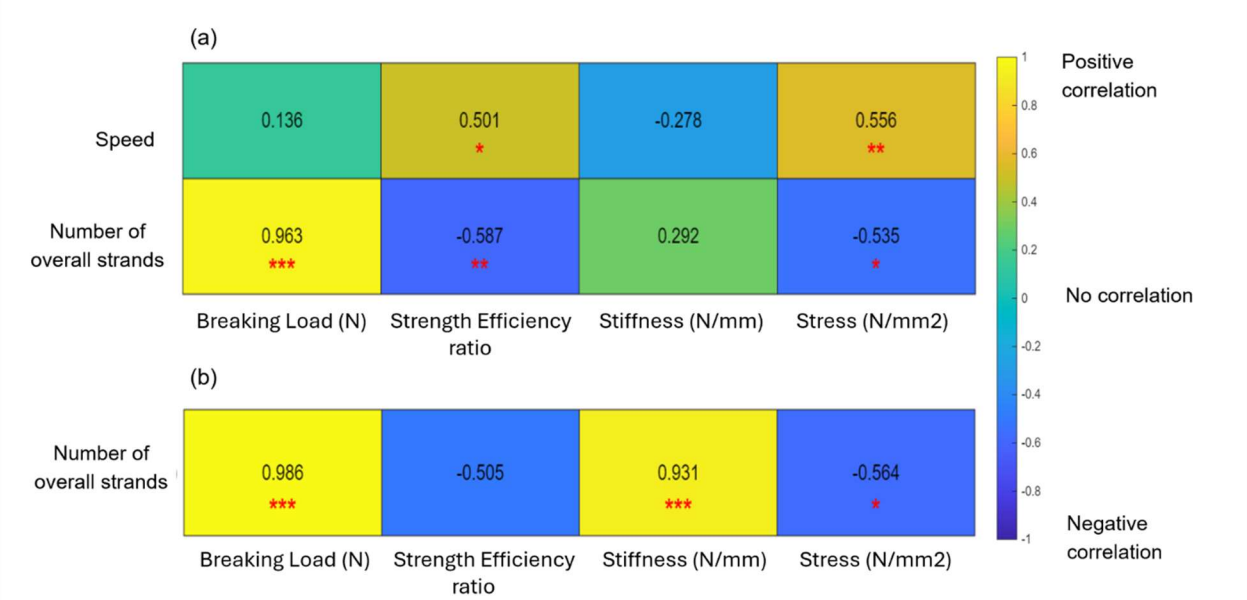

Figure 1 Shows the correlation map for the input parameters against output measurements. (a) The take-up speed varied groups; (b) the groups where another non-speed factor was varied. The correlation coefficient R is shown in each section and significance is indicated (P<0.05, **P<0.005, ***P<0.001). The heat map shows negative and positive or no correlation.*

[5]Department of Biomedical Engineering, University of Alberta, Edmonton, AB, Canada. [6]Mike Petryk School of Dentistry, University of Alberta, Edmonton, AB, Canada

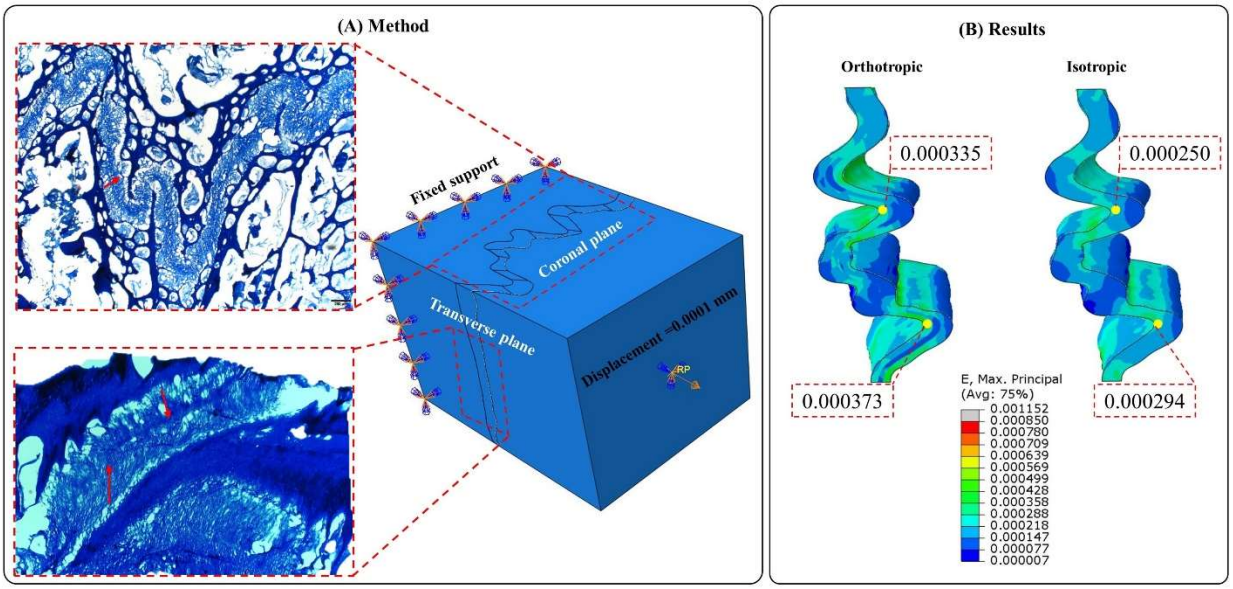
Introduction

Cranial sutures are fibrous joints that connect skull bones and contribute to cranial growth and load transfer throughout life. Their complex interdigitated morphology and heterogenous collagen fibre architecture produces anisotropic mechanical behaviour. However, many finite element (FE) models have assumed isotropic or oversimplified anisotropic properties, limiting the understanding of how local fiber orientation influences suture mechanics. This study developed a 3D anisotropic FE model of the swine internasal suture and applied a response surface methodology (RSM) to optimize anisotropic material model constants using experimental data. It is hypothesized that using anisotropic material modeling will produce significant differences in strain distribution from isotropic modeling.

Methods

Internasal sutures from three swine were scanned using micro-computed tomography (9 resolution) to establish FE geometry, and three samples were extracted along the posterior-anterior axis for each specimen. Tensile testing was performed at 0.2 mm/min. Bone was modelled as isotropic (E= 2000 MPa, Poisson ratio=0.27), while the suture was assigned an orthotropic linear elastic material model with nine independent constants governing stiffness in the principal fibre directions. Fibre orientations in coronal and transverse planes were quantified from Masson's trichrome staining and mapped into the FE model using region-specific coordinate systems. A central composite design (CCD) was generated to explore nine independent anisotropic parameters and determine their optimum value within physically-relevant bounds. A 0.0001 mm displacement simulated

physiological strain. RSM was used to build response surfaces and identify parameter combinations minimizing error between simulated and experimental force-displacement curves.



Results

The RSM identified an optimal set of anisotropic parameters for each sample, with FE outcomes closely mimicking experimental measurements. Anisotropic models produced distinct stress and strain distributions compared to isotropic models. Regions where fibers aligned with loading showed reduced strain energy, while oblique orientations caused greater deformation.

Discussion

The comparison between anisotropic and isotropic models showed that utilizing anisotropic properties altered both the magnitude and spatial distribution of stress and strain, enabling the FE model to capture localized mechanical behaviour that isotropic properties could not reproduce. Results confirmed that collagen fibre alignment influences load-bearing response and demonstrated the value of optimization-based anisotropic modeling for characterizing suture mechanical behaviour.

Influence of Depression Elevation on the Force Distribution of Tibia Plateau

Mr. Mahziyar Darvishi PhD candidate, Mr James Campbell Orthopaedic Surgery Resident, Dr. David Wasserstein Assistant Professor, Dr. Joseph Schatzker Professor Emeritus, Dr. Timothy Burkhart Assistant Professor

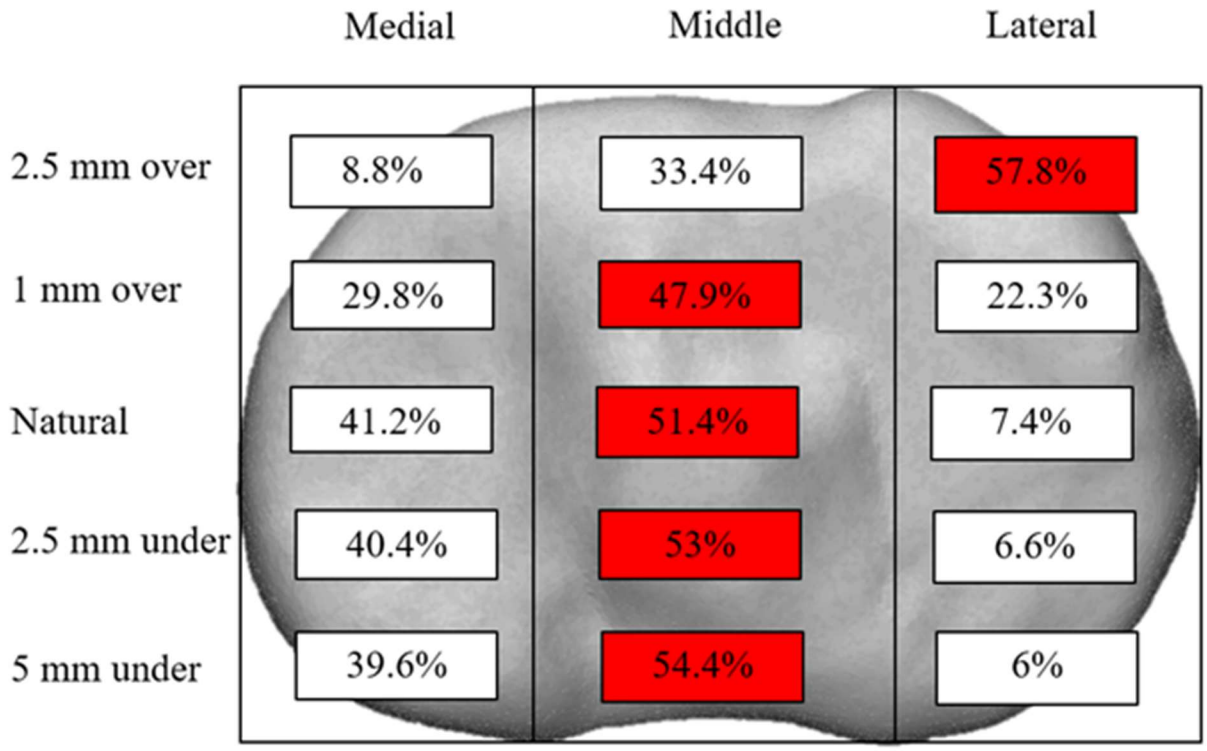
University of Toronto, Toronto, Ontario, Canada

Introduction

Schatzker type II tibial plateau fractures often involve an articular depression, where elevation during reduction influences tibiofemoral biomechanics. Although surgical thresholds of approximately 4–5 mm of depression correction are widely used [1], they rely largely on clinical consensus rather than biomechanical evidence. Consequently, the effects of under- and over-correction beyond native alignment remain poorly defined. Therefore, the objective of this study was to evaluate biomechanical effects of varying tibial plateau elevation by comparing stress and displacement across under-corrected, naturally corrected, and over-corrected configurations using finite element modeling (FEM).

Methods

A patient-specific finite element model was generated from a CT image of a Schatzker type II lateral tibial plateau fracture. Five fracture reduction conditions were evaluated: natural correction, 2.5-mm and 5-mm under-correction, and 1-mm and 2.5-mm over-correction. Each model was subjected to standardized physiological axial displacement. Von Mises stress and displacement in the tibial cartilage and subchondral bone were calculated and compared across correction conditions.



Results

The naturally corrected model showed stress and displacement values consistent with literature. The 2.5-mm over-correction yielded the highest cartilage displacement (1.34 mm) and stress (9.59 MPa). Under-correction increased cartilage stress relative to natural correction (up to 9.19 MPa vs. 7.56 MPa); however, load distribution remained predominantly medial, consistent with physiological load sharing in a healthy knee. Figure 1 demonstrates progressive lateralization with increasing correction, with lateral stress rising from 6–7% in under-corrected and naturally corrected models to 22.3% at 1 mm and 57.8% at 2.5 mm of over-correction, accompanied by reductions in medial and middle stress contributions.

Discussion

These findings indicate that over-correction disrupted native load distribution, producing lateral overload and greater biomechanical alterations compared to the under-correction. Although under-correction increased stress relative to natural alignment, it preserved more physiological medial loading patterns. The results are limited by model simplifications, including a single patient-specific geometry and omission of soft tissues. Future studies incorporating additional subjects and experimental validation are needed to define safe correction margins.

Ms Francesca De Vecchi

Ms Victoria Marino

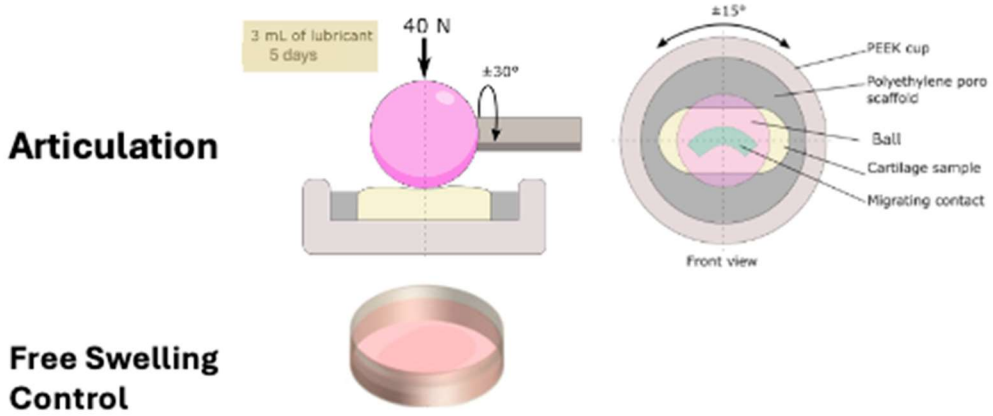
Introduction

Ethical and regulatory constraints continue to limit animal use in preclinical testing, increasing the need for physiologically relevant in vitro systems in biomechanics and orthopedic research. Joint-preserving procedures such as hemiarthroplasty further underscore the importance of models capable of replicating native cartilage mechanics when articulating against implant materials. Because only one surface is replaced, long-term success depends on how the biomaterial interacts with living cartilage under complex tribological loading. Existing in vitro systems rarely capture the combined rolling–gliding motion, cyclic compression, nutrient transport, and biochemical responses characteristic of in vivo articulation. The objective of this study was to develop and validate an in vitro cartilage wear model that reproduces key biomechanical features of the joint environment, enabling systematic evaluation of cartilage–biomaterial compatibility while reducing reliance on animal testing.

Methods

A multi-station joint articulation system applied physiological rolling-gliding motion under 2 MPa compressive load. Fresh bovine patellofemoral cartilage explants (14 × 20 mm) from a slaughterhouse were articulated against spherical samples of cobalt–chromium (CoCr), zirconia-toughened alumina (ZTA) ceramic, hydrophobic and hydrophilic UHMWPE, titanium nitride (TiN), PEEK, and PEKK (n = 8 per material). Culture medium served as lubricant and nutrient source and was renewed at standardized intervals. Samples

experienced 5,400 cycles/day at 0.5 Hz for five days; free-swelling controls received identical handling without loading. Outcomes included chondrocyte viability, histological matrix integrity, and biochemical wear quantified through collagen (hydroxyproline) and sGAG release. Wear rates were obtained from linearized release curves.



Results

The model maintained >80% viability and produced reproducible wear signatures across materials. Polyethylene-based surfaces caused the greatest superficial matrix disruption and cell loss, accompanied by 30–100× higher collagen and 2.5–3× higher sGAG release relative to CoCr and ZTA. TiN and PEEK induced intermediate wear, whereas PEKK produced moderate wear. CoCr and ceramic maintained smooth surfaces with only mild superficial cell death.

Discussion

The model reproduced key features of tribological loading and effectively distinguished cartilage compatibility among materials. Findings aligned with clinical and biomechanical evidence identifying CoCr and ceramics as gold-standard articulating surfaces. This system offers a translational platform for preclinical biomaterial screening and the development of joint-preserving technologies.

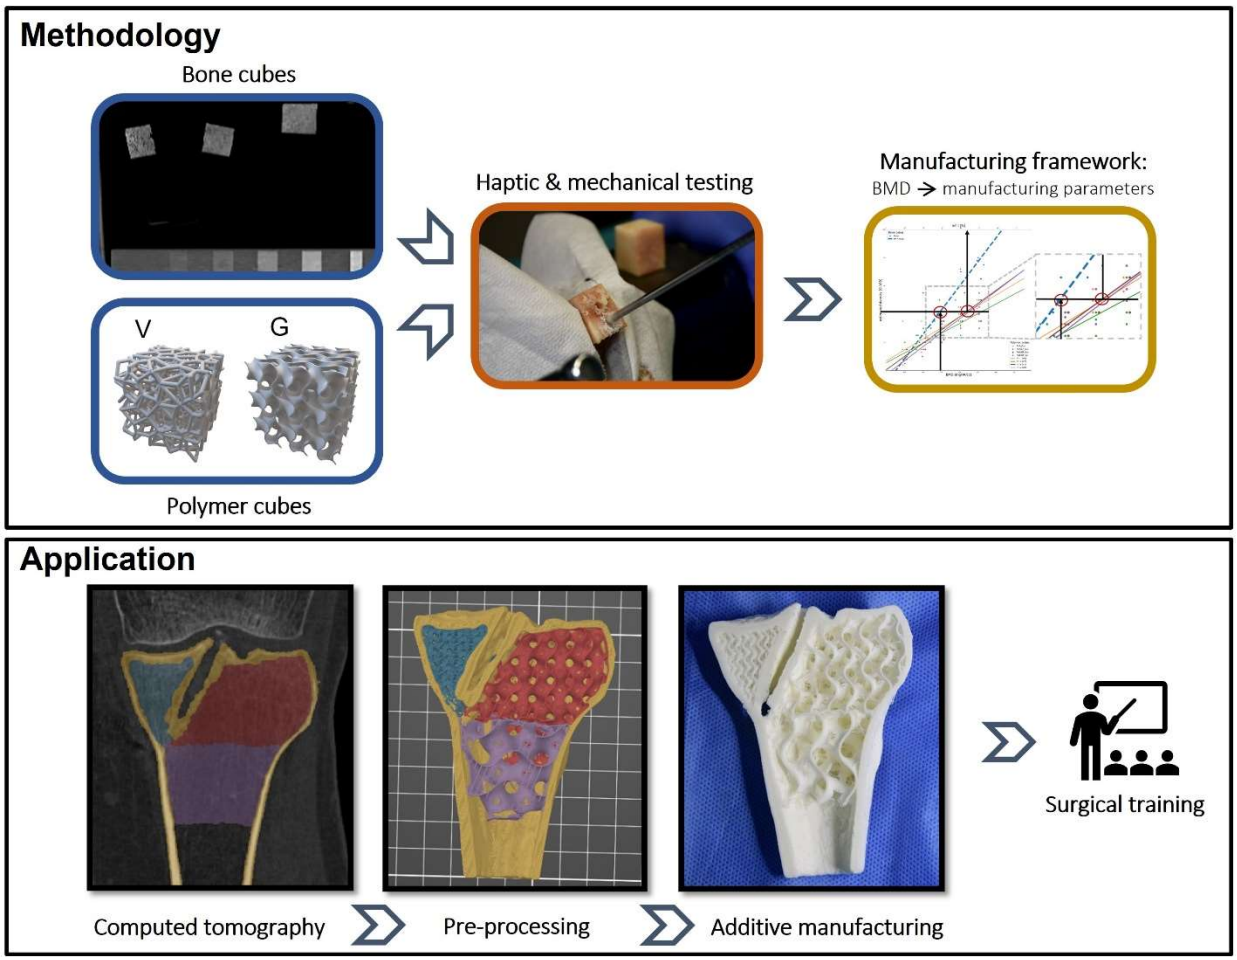
[3]Karl Chiari Lab for Orthopaedic Biology, Department of Orthopedics and Trauma Surgery, Medical University of Vienna, Vienna, Vienna, Austria. [4]Department of Biomedical Imaging and Image-guided Therapy, Medical University of Vienna, Vienna, Vienna, Austria. [5]Polymer Institute SAS, Bratislava, Bratislava, Slovakia

Introduction

Additively manufactured anatomical bone models are used for medical education and surgical training. Manufacturing of patient-specific anatomies and rare pathologies has advanced rapidly, enabling training opportunities previously restricted to limitedly available anatomic specimens. [1] However, imitating patient-specific trabecular bone microstructure in printed bone models remains inadequately addressed. [2] This study aimed to evaluate the feasibility of imitating patient-specific trabecular bone structures by linking bone mineral density (BMD) assessed by clinical computed tomography (CT) to manufacturing parameters of fused filament fabrication (FFF) 3D-printing (i.e., infill densities, materials and lattice structures).

Methods

Test specimens in form of Gyroid and Voronoi lattice cubes were manufactured via FFF-printing at varying densities with polylactide (PLA), polylactide/carbon fiber composite and polyamide (PA6)/glass fiber composite filaments, and submerged in gelatin. Additionally, trabecular bone cubes were removed from bovine femoral specimens and the bone mineral density (BMD) assessed utilizing quantitative CT. Subsequently, haptic drill resistance and realism were evaluated by four orthopedic and trauma surgeons, and the mechanical drill resistance was assessed using a load frame (see Figure).



Results

Multiple polymer lattice structures and material configurations were evaluated by the surgeons with average Likert scores regarding haptic realism between 2.60 and 3.00. Correlation between the maximum indentation depth (mechanical testing) and the surgeons' drill-resistance assessments revealed a strong correlation ($R^2 = 0.82$). Regression analysis of the surgeons' evaluations of trabecular bone ($0.75 \leq R^2 \leq 0.98$) and the polymer lattice cubes ($0.66 \leq R^2 \leq 0.89$) enabled the extraction of practical manufacturing guidelines, linking patient-specific BMD with manufacturing parameters for FFF-printers.

Discussion

The strong correlation between the mechanical testing and surgeons' haptic assessments supports the feasibility of trained surgeons accurately estimating haptic material density. Likert score evaluations further demonstrate that trabecular bone structures can be effectively imitated in anatomical bone models produced via FFF-printing. By linking patient-specific BMD values with manufacturing parameters, the proposed framework enables a reproducible, cost- and time efficient production of anatomical bone models with patient-specific haptic feedback, which can be used for preoperative planning and surgical training.

Quantifying early biomechanical changes in an equine model of intra-articular soft tissue injury

Ms Olivia Kenny, Dr Kasara Toth, Dr W. Michael Scott, Dr W. Brent Edwards, Dr Thilo Pfau, Dr Roman Krawetz, Dr Holly Sparks

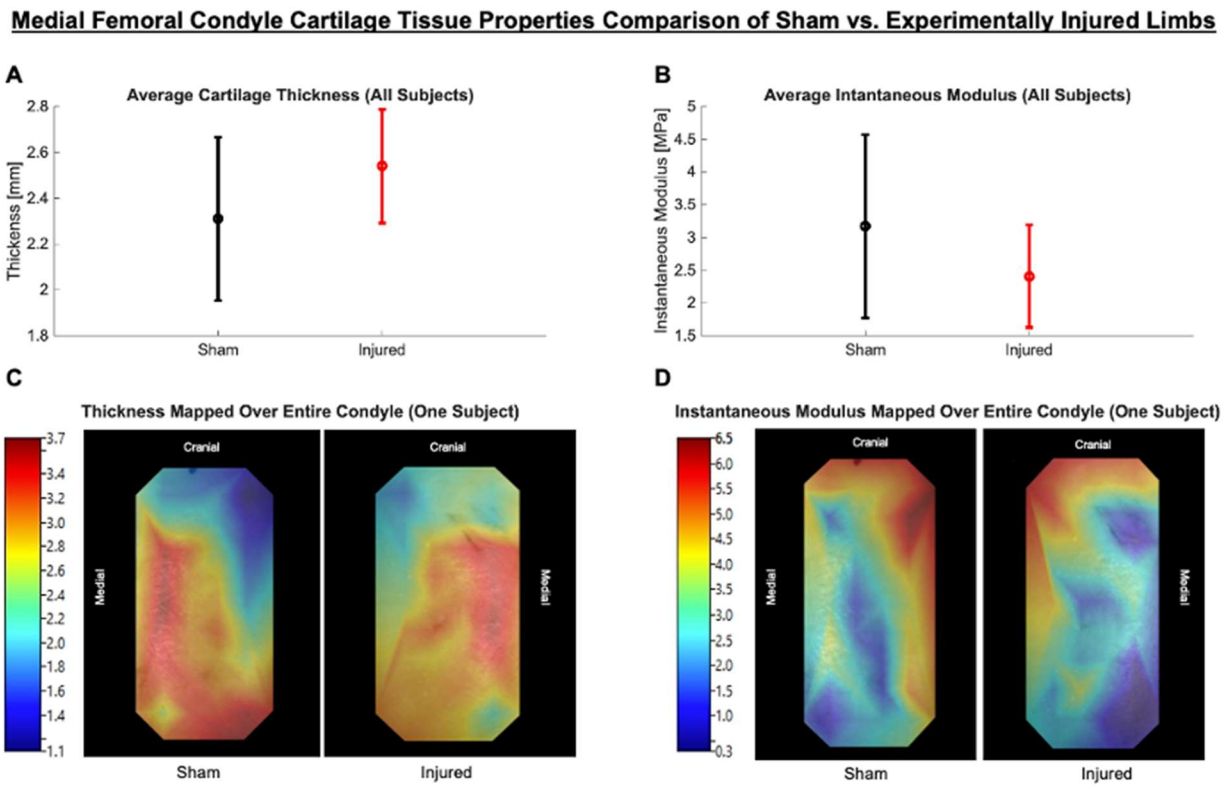
University of Calgary, Calgary, Alberta, Canada

Introduction

Post-traumatic osteoarthritis (PTOA) is common amongst human and animal athletes alike. While murine models of destabilizing joint injury have improved our understanding of PTOA, the risk for development of PTOA in clinical cases is difficult to predict. Further, PTOA has been reported to develop after considerably more mild forms of joint injury. Therefore, this work seeks to understand early biomechanical change both within the joint and affecting gait following mild intra-articular injury using an equine model.

Methods

In four horses, a minimally invasive technique was used to unilaterally create a defect along the length of the craniomeniscotibial ligament in the medial femorotibial joint mimicking a naturally occurring injury in equine athletes. As in other species, intra-articular injury can initiate chronic synovitis potentially predisposing the animal to PTOA [1]. Objective gait analysis data was collected using body-worn inertial measurement units (IMUs) (EquiGait, Cheshunt, UK) to quantify and compare vertical movement asymmetry throughout the study. A Mach-1 mechanical tester (Biomomentum Inc, Laval, Canada) was used for thickness and indentation tests on the intact medial femoral condylar (MFC) surfaces ex vivo. Cartilage tissue parameters, including thickness and instantaneous modulus were analyzed on the injured and sham-operated MFCs.



Results

Objective gait analysis showed an average difference in vertical displacement asymmetry of 5.3 mm compared to baseline, throughout the duration of the study. On average, the cartilage thickness was higher on the experimentally injured MFC, and the instantaneous modulus was lower, shown in Figure 1.

Discussion

This injury model produced minimal vertical displacement asymmetry changes, correlating with the absence of overt clinical lameness. Additional IMU data analysis is ongoing to evaluate if lower limb kinematics differ between the injured and sham limbs. Biomechanical properties mapped across the condylar surface are being further analyzed. As part of a larger study, histological methods are being used to describe the tissue response at a cellular level. The combined effects of potential differences in joint loading and changes in cartilage tissue properties will be explored as prospective indicators of early PTOA development.

Microdamage in Cortical Bone Induced by Screw Insertion and Pull-Out Revealed by Sequential Fluorescent Staining

MSc Saeideh Saeidi[1], PhD Mina Petrovic[2], Univ.Prof. Dieter Pahr[1]

[1]Institute of Lightweight Design and Structural Biomechanics, TU Wien, Vienna, Vienna, Austria. [2]Institute of Materials Science and Technology, TU Wien, Vienna, Vienna, Austria

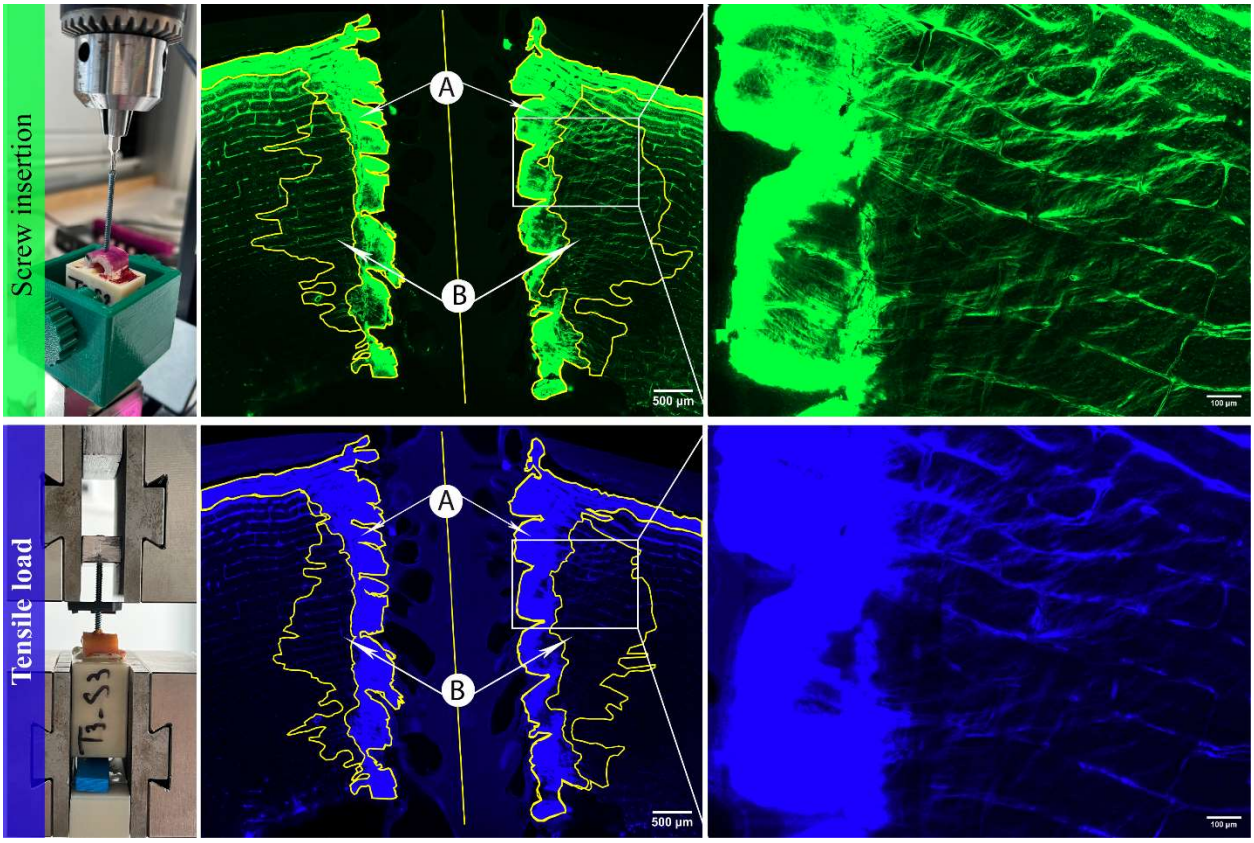
Introduction

In orthopaedic implants, primary stability is significantly affected by bone damage induced during implantation procedures. This study explores the relationship between screw insertion, pull-out loading, and microscopic bone damage. We visualize and characterize various damage stages, aiming to enhance the predictive accuracy of finite element models and ultimately improve implantation outcomes.

Methods

Seven cortical bone samples were dissected from fresh frozen ovine tibia diaphysis. The sequential fluorescent staining approach [1] is adapted including xylenol orange, calcein and calcein blue to label bone damage in different stages from pre-drilling to tensile loading. First, specimens were drilled and stained with xylenol. A locking screw (Medartis, Switzerland) was implanted, then unscrewed, followed by calcein staining to identify damage caused by screw insertion. Following screw re-insertion, a tensile test was conducted until a 5% drop in measured force was detected. After screw removal, specimen was stained with calcein blue to identify load induced damage. Samples were glued on microscope slide, milled using an ultramiller till the hole centerline, and imaged using a confocal laser scanning microscope (CLSM).

Results



Force-displacement curves showed maximum force as 956.9 ± 175.6N. CLSM results revealed negligible damage due to drilling. Figure presents CLSM images illustrating bone damage induced by screw insertion (green) and tensile loading (blue). Both show complex damage including diffuse damage (region A) occurred in a narrow area adjacent to bone-screw interface, followed by a dense area of elongated bundles of linear cracks (region B) propagating along the weakest planes of lamellar sheets with specific orientation. Damage percentage is calculated as area of damage divided by pilot hole area. Total damage of 98.3

± 13.0% was caused by screw insertion, including 43.4 ± 6.8% diffuse damage and 54.9 ± 14.1% linear cracks. Total damage of 83.2 ± 12.3% was caused by tensile loading, including 48.2 ± 5.8% diffuse damage and 33.3 ± 12.4% linear cracks.

Discussion

Screw insertion generated the significant damage, dominated by more linear cracks. Despite causing less total damage, tensile loading expanded diffuse damage rather than linear crack growth. Our study highlights the critical role of bone damage in refining finite element models accuracy.

Bendable Osteochondral Allografts for Carpometacarpal Arthritis Treatment Eliminate Sex-based Differences in Contact Pressures in Computational Model

Ms. Sarah Deiters, Dr. Katherine Spack PhD, Mr. Thomas Gardner, Dr. Clark Hung PhD, Dr. Melvin Rosenwasser MD, Dr. Gerard Ateshian PhD

Columbia University, New York, NY, United States

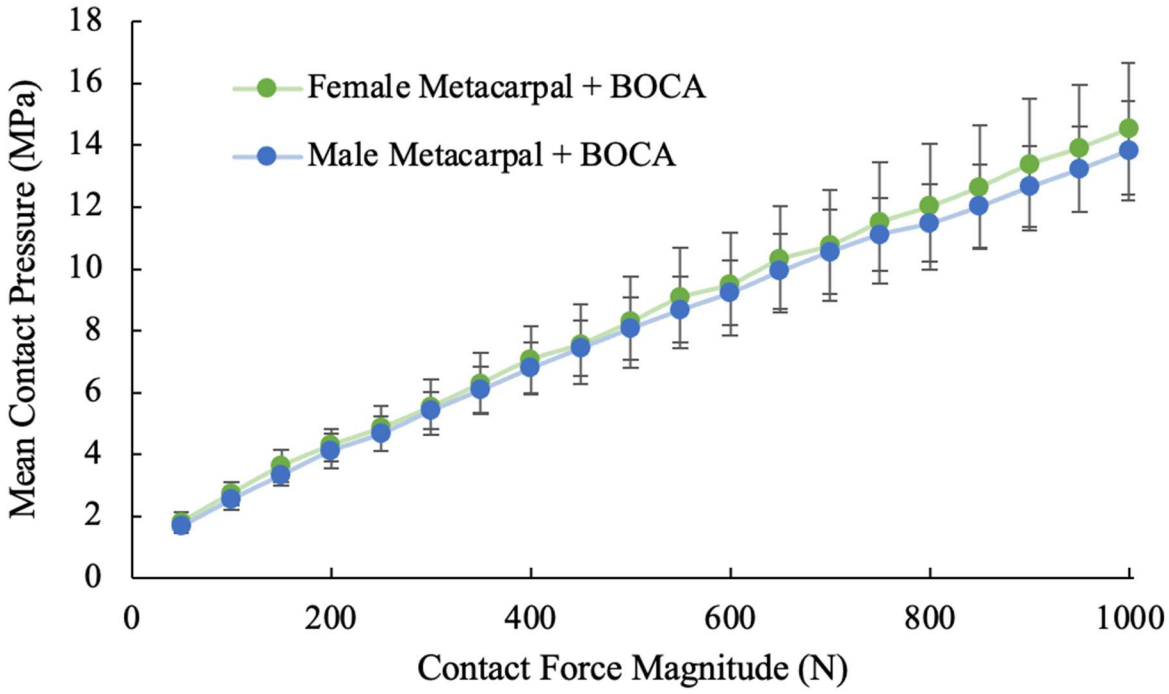
Introduction

A Bendable Osteochondral Allograft (BOCA) from a donor's femoral trochlea offers a potential treatment for carpometacarpal (CMC) osteoarthritis (OA), which disproportionately impacts women, by providing a thicker articular cartilage layer[1,2]. Females experience higher healthy CMC contact pressures than males[3,4], which must be considered when evaluating BOCA treatment. We hypothesize that male and female metacarpals experience comparable contact pressures when in contact with BOCA.

Methods

Finite element contact analyses in FEBio[5] simulated male and female metacarpal contact with a BOCA to determine average joint contact pressure during simulated pinch. Prior stereophotogrammetry scans[6] of 5 female and 4 male human metacarpals with Stage IV OA were used, and the BOCA model was constructed as described previously[1]. Metacarpal bone surfaces and BOCA were meshed with Quad8/Tri6 and Tet10 quadratic elements then aligned neutrally. 1000N contact force was applied in the proximal-distal direction. We calculated average contact pressure from the ratio of force and contact area. After determining data normality (Shapiro-Wilk) and equal variances (F-test), we used a two-tailed Student's t-test (α=0.05) to determine if a difference exists between male and female joints.

Results



Male and female metacarpals in contact with BOCA at 1000N experienced mean contact pressures of 13.84 ± 1.61 MPa and 14.54 ± 2.12 MPa, respectively, which were not statistically different (p=0.603). For comparison, we recently showed that contact pressures for healthy male and female CMC joints are significantly different (Male 26.1 ± 6.7 MPa versus Female 38.6 ± 4.9 MPa, p=0.014)[4].

Discussion

Our previous analyses[1,4] indicated that BOCA-treated joints experience lower contact pressures than healthy CMC joints, and healthy female CMC joints experience higher

contact pressures than male joints, which may explain higher OA incidence in women[7]. Results of the current study indicate that BOCA treatment for CMC OA may eliminate sex differences in contact pressures, supporting the potential benefits of this novel treatment.

Analysis of the Design Freedom of Round Braided Resorbable Synthetic Ligament Augmentation Scaffolds

M.Sc. Saskia Hesse, Dr. Ing. Benedict Bauer, Univ.-Prof. Thomas Gries, Dr. Ing. Caroline Emonts

Institut für Textiltechnik of RWTH Aachen University, Aachen, NRW, Germany

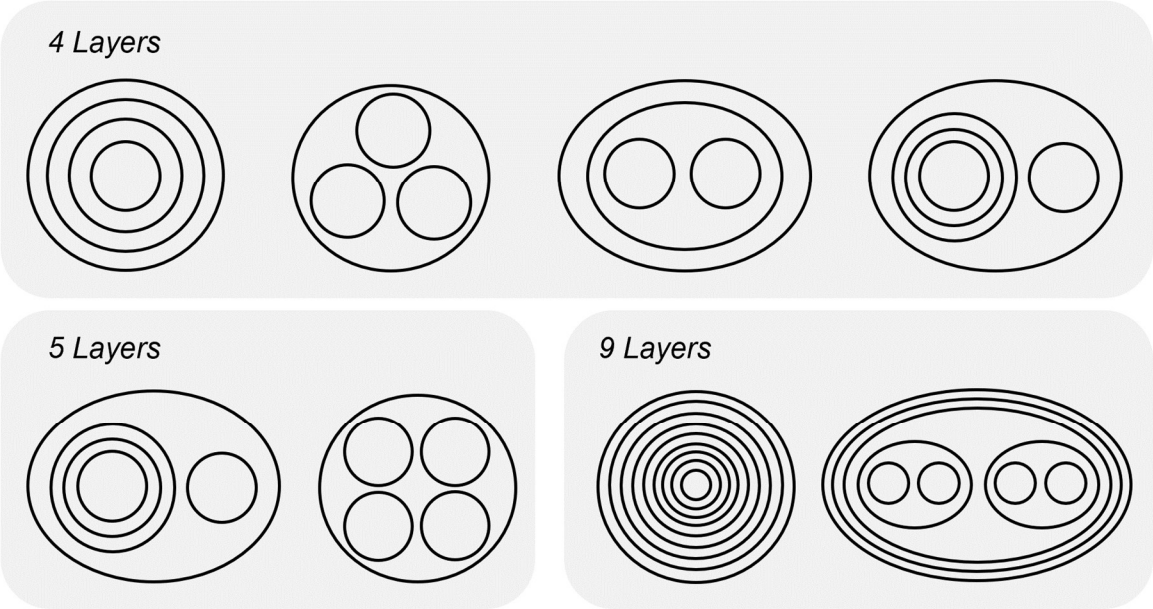
Introduction

Ligament augmentation implants have gained renewed interest to enhance the mechanical stability of reconstructed ligaments. Contemporary techniques integrate synthetic or hybrid materials to address graft elongation and postoperative laxity [1]. But there remains a need for bioresorbable and mechanically designed augmentations. Therefore, bioresorbable synthetic textile implants are developed. The aim of this study is to show the design freedom of morphological and mechanical variations of round braided augmentation scaffolds to design biomimetic load carrying implants. Previous work has shown the great potential of this braided textiles regarding their mechanics [2].

Methods

The synthetic scaffolds are made of Poly-e-caprolactone (PCL) monofilaments which are braided into multilayered structures on a round braiding machine with 48 yarn carriers. For morphological analysis µCT-scans and diameter measurements are performed. The mechanical behavior is tested in tensile load to failure testings with a gauge length of 40 mm and a testing speed of 40 mm/min.

Results



The textile round braiding process brings great design freedom to design ligament scaffolds. Multilayered designs made of bundles can be used as approach to match the structure of native ligament tissue. The trials show that the number of layers and their arrangement can be varied in different ways (Fig. 1). Depending on the arrangement the cross-sectional shape can be altered. The testings show that with constant process parameters but changing layer arrangements the mechanical performance differ. The ultimate tensile strength can vary by up to 10 % within a group with the same number of layers.

Discussion

Round braided multilayered scaffolds offer design freedom for developing biomimetic ligament augmentation implants. By varying the number of layers and their arrangement

the morphology and mechanical performance can be tailored. Future work will explore additional layer arrangements and braiding configurations. Extended mechanical testing will show the stability under physiologically conditions. Ultimately, adapting scaffold architecture to replicate the structural features of native ligament tissue may enable the development of next-generation augmentation implants.

In Silico Design of Degradable Joint Implants for Optimal Balancing of Tissue Formation and Implant Degradation

Ms. Sophie Nguyen[1], Dr Mojtaba Barzegari[2], Prof. Dr. Liesbet Geris[1,3]

[1]Biomechanics Section, Department of Mechanical Engineering, KU Leuven, Leuven, Flemish Region, Belgium. [2]TU Eindhoven, Eindhoven, North Brabant, Netherlands. [3]Biomechanics Research Unit, GIGA In Silico Medicine, University of Liège, Liège, Walloon Region, Belgium

Ms. Sophie Nguyen

Dr Mojtaba Barzegari

Introduction

Successful bone regeneration after joint arthroplasty requires both stability and sufficient regenerative capacity. Clinical data show that 20 years after the primary total hip arthroplasty placement, revision rates reach up to 40% for patients younger than 50 years [1]. Revision surgeries inevitably remove additional surrounding bone, resulting in critical-size defects that cannot repair spontaneously. A promising strategy involves the design of composite implants consisting of a permanent component to ensure joint integrity and a porous biodegradable component to fill the defect and stimulate bone ingrowth. The degradable structure will gradually be replaced by newly formed bone, mitigating defect enlargement after each revision. Here we developed a multi-factorial *in silico* model to study the balance between the kinetics of porous scaffold degradation and the rate of bone formation.

Methods

A set of partial differential equations (PDEs) was established describing the chemistry of corrosion of a magnesium implant, as well as bone ingrowth through the spatio-temporal concentration of bone cells. The model implicitly tracks the degradation and bone formation fronts in a phase-field framework, including curvature-based effects. The PDEs are solved numerically using the finite element method and implemented in FreeFEM [2]. The interface between the scaffold and bone is refined over time through a mesh

adaptation procedure, allowing accurate tracking of the moving interfaces. The model outputs are the concentration of bone cells and magnesium ions, the geometry of the degrading scaffold, and the density of new bone over time.

Results

The model is applied to a gyroid scaffold, investigating various differences in speed between the bone formation and implant degradation. Fig. 1 shows the results of the simulation where both processes occur at comparable speed, showing scaffold degradation while new bone is forming at the scaffold surface and filling the pores.

Discussion

The presented *in silico* model, once validated, is intended be used as a design tool, providing longitudinal data to assess the interplay between scaffold degradation and bone ingrowth, and the optimized geometry to promote bone regeneration.

Do Novel Dynamizers Designed to Increase Axial Interfragmentary Motion at the Fracture Site Increase Unwanted Shear in Trauma Frames?

Mr Thomas Irish MEng, BEng[1], Dr Hemant Sharma MCh (Trauma & Orthopaedics), FRCS (Trauma & Orth)[2], Dr Ross Muir FRCS[2], Dr Todd Stewart PhD[1], Dr Marlène Mengoni PhD[1], Dr Peter Watson PhD[1]

[1]Institute of Medical and Biological Engineering, Leeds, West Yorkshire, United Kingdom. [2]Department of Trauma and Orthopaedics, Hull University Teaching Hospitals NHS Trust, Hull, East Yorkshire, United Kingdom

Introduction

Circular external fixators are used for long bone fractures to control micromotion at the fracture site and promote axial interfragmentary motion, stimulating healing, while simultaneously limiting shear which is known to hinder healing [1]. Two new devices (dynamizers) have been introduced that are intended to increase axial interfragmentary motion and thus promote faster healing. However, the effect of dynamizers on changes in shear is unknown. This study measured, for the first time, axial and shear interfragmentary motion in comparable frames with and without dynamizer technology offered from two manufacturers.

Methods

Frames were constructed with central polycarbonate tubes, 4 rings, pins and wires to represent a fixated transverse fracture. Frames were loaded separately in axial (+/- 700N), torsion (+/- 25Nm) and bending (+/- 20Nm) regimes to represent bodyweight load. Ten cycles were completed for each regime providing a measure of variance. Load was held for 5 seconds at distinct loading steps. The movement at the fracture site was tracked optically for each step using a OptoTrak camera system with an accuracy of 0.1mm.

Results

Under axial loading comparison of interfragmentary motion between the classic and dynamized frames showed that both frames had increased axial deformation by 1mm with dynamizers. However, shear increased in FrameA (+0.25mm) but decreased in FrameB (-0.35mm).

Under torsion, axial motion was low (<0.4mm) in both frames. The dynamized FrameB produced negligible shear compared to the classic FrameB while the dynamized FrameA produced 2mm greater shear than FrameB and 0.7mm more than the classic FrameA.

Under bending, dynamizers introduced 0.5mm and 0.2mm increased shear for the FrameA and FrameB respectively but all frames maintained low axial motion (<0.4mm).

Discussion

This is first time that frames incorporating Dynamizers have been compared mechanically. The Dynamizers investigated were from 2 companies and were entirely different in their construction, hence, it was not surprising that variations were observed in their performance. With associated increases in axial motion and predominantly low values of shear across loading regimes, the dynamizers likely achieve their goal. Variability observed in torsion suggests that correct implementation of dynamizers is still paramount.

Biomechanical Evaluation of Fixation Strategies for Complex Mandibular Fractures: A Finite Element and Experimental Study

Prof. Ting-Sheng Lin[1], Dr. Chien-Chung Chen[2], Mr. Kai-Chieh Chuang[1]

[1]I-Shou University, Kaohsiung, Yanchao District, Taiwan. [2]E-Da Hospital, Kaohsiung, Yanchao Distric, Taiwan

Introduction

Complex mandibular fractures involving simultaneous condylar and symphyseal/parasymphyseal regions present significant clinical challenges. Optimal fixation strategies remain controversial, with inadequate reduction potentially leading to malocclusion, temporomandibular joint dysfunction, and facial deformity. This study systematically evaluates the biomechanical stability of various plate-screw configurations for complex mandibular fractures using finite element analysis (FEA) validated by experimental testing.

Methods

Synthetic mandible models (Synbone 8950, Switzerland) were CT-scanned and reconstructed into 3D models incorporating cortical and cancellous bone. Two fracture patterns were analyzed: (1) unilateral condylar with parasymphyseal fractures, and (2) bilateral condylar with symphyseal fractures. Thirty-five combinations of titanium mini-plates (2.0mm) and micro-plates (1.2mm) with corresponding screws (Stryker, Germany) were evaluated. FEA simulations incorporated physiological muscle forces (masseter, temporalis, medial pterygoid) with bilateral condyles fixed. Stress distribution, strain, and displacement were analyzed. Three-dimensional digital image correlation (3D-DIC) was employed for experimental validation.

Results

For unilateral fractures, dual three-hole micro-plates at 120° arrangement at the condyle combined with vertical dual four-hole plates at the parasymphysis demonstrated optimal stress distribution. Parametric analysis revealed condylar fixation methods had greater influence on overall stress distribution than symphyseal/parasymphyseal fixation ($p<0.001$). For bilateral fractures, condylar combinations C and D significantly reduced plate and screw stress compared to combinations A and B ($p<0.001$). Dual plating with at least four screws at the condylar site provided superior biomechanical stability.

Discussion

Complex mandibular fracture fixation requires strategic consideration of both fracture sites, with condylar fixation being the primary determinant of overall construct stability. Dual plating with appropriate screw distribution provides optimal biomechanical stability while potentially reducing complications and healthcare costs. These findings provide evidence-based guidelines for clinical decision-making in treating complex mandibular fractures.

Novel Investigation of the Biomechanical Properties of Circular Frames for the Foot

Professor Todd Stewart PhD, BSc[1], Doctor Sarah Johnson-Lynn FRCS (T&O)[2], Mr. Tom Irish MEng[1], Doctor Peter Watson PhD, BSc[3], Doctor Paul Harwood FRCS (T&O)[4]

[1]The University of Leeds, Leeds, West Yorkshire, United Kingdom. [2]South Tees Hospitals NHS Foundation Trust, Middlesbrough, South Teeside, United Kingdom. [3]University of Leeds, Leeds, West Yorkshire, United Kingdom. [4]Leeds Teaching Hospitals Trust, Leeds, West Yorkshire, United Kingdom

Introduction

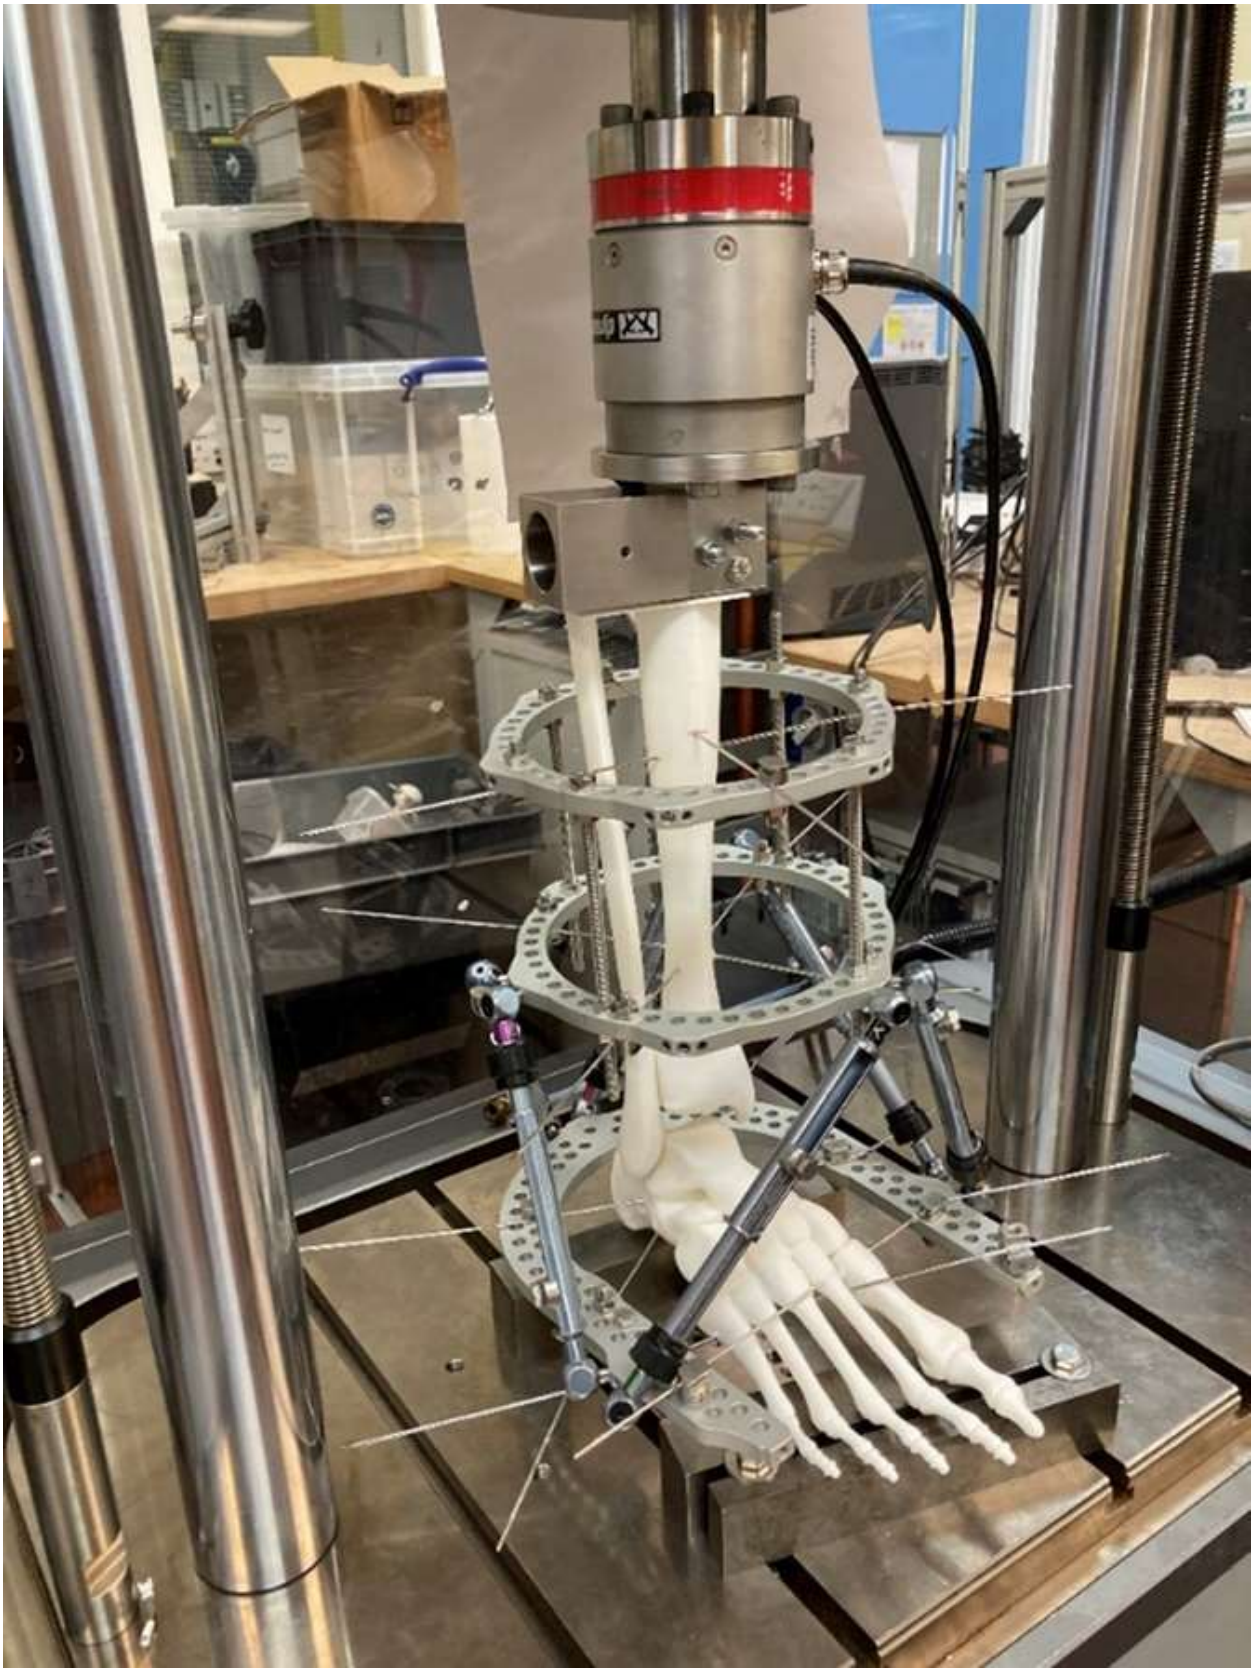
The most frequently used foot frame constructs are a Charcot frame with a flat foot plate, used to commonly to offload the ankle, a Butt frame controlling the hindfoot with a U-plate allowing correction across the midfoot with a forefoot ring, and a Mitre frame with 2 rings at 45 degrees, independently controlling the hindfoot and midfoot.

The aim was to test, for the first time, the deformation and stiffness of the three most common trauma foot frame configurations.

Methods

Three frames of each geometry were constructed using Orhofix TL-HEX components (Orthofix Medical inc., USA). All frames were constructed with 2 tibial rings with 2 wires on each ring, foot elements were attached with 2 calcaneal wires and 2 forefoot wires. The Mitre frame foot was additionally tested sectioned vertically across the calcaneus and cuboid. To investigate relative stiffness an 8mm gap between the distal tibia and the proximal talus was adopted. A max vertical axial load of 700N was applied to simulate standing using an Instron E10000 Universal Testing machine (Instron, UK) . A base platform was constructed such that the 1st and 5th metatarsals and calcaneus contacted at the base forming 3 points of inferior support (Figure 1).

Results



Maximum average deformation found that the Butt frame had the least deformation (7.1mm) whereas the Charcot frame had the greatest deformation (10.2mm) . Sectioning the foot showed an increase in deformation by 10% and the most variability.

All frames increased in stiffness as the applied load increased. The Charcot frame showed the least construct stiffness of 93N/mm at a load of 700N, whereas the Butt frame generally produced the greatest construct stiffness of 122N/mm. The Mitre frame with sectioned foot had a reduced stiffness under the lower loads (32N/mm), but the stiffness was comparable to the non-sectioned foot at 700N (104N/mm).

Discussion

The response of the frames to load provides key information to surgeons to inform frame construction for foot and ankle pathologies. The Charcot frame having the lowest stiffness is an important finding as these frames are frequently used in patients with peripheral neuropathy, where increased robustness is required to encourage bone healing.

A Robotic Evaluation of Posterior Shoulder Stability in Cadaveric Specimens: Bipolar Bone Loss and Allograft Reconstruction

Mr Alex Brady MS

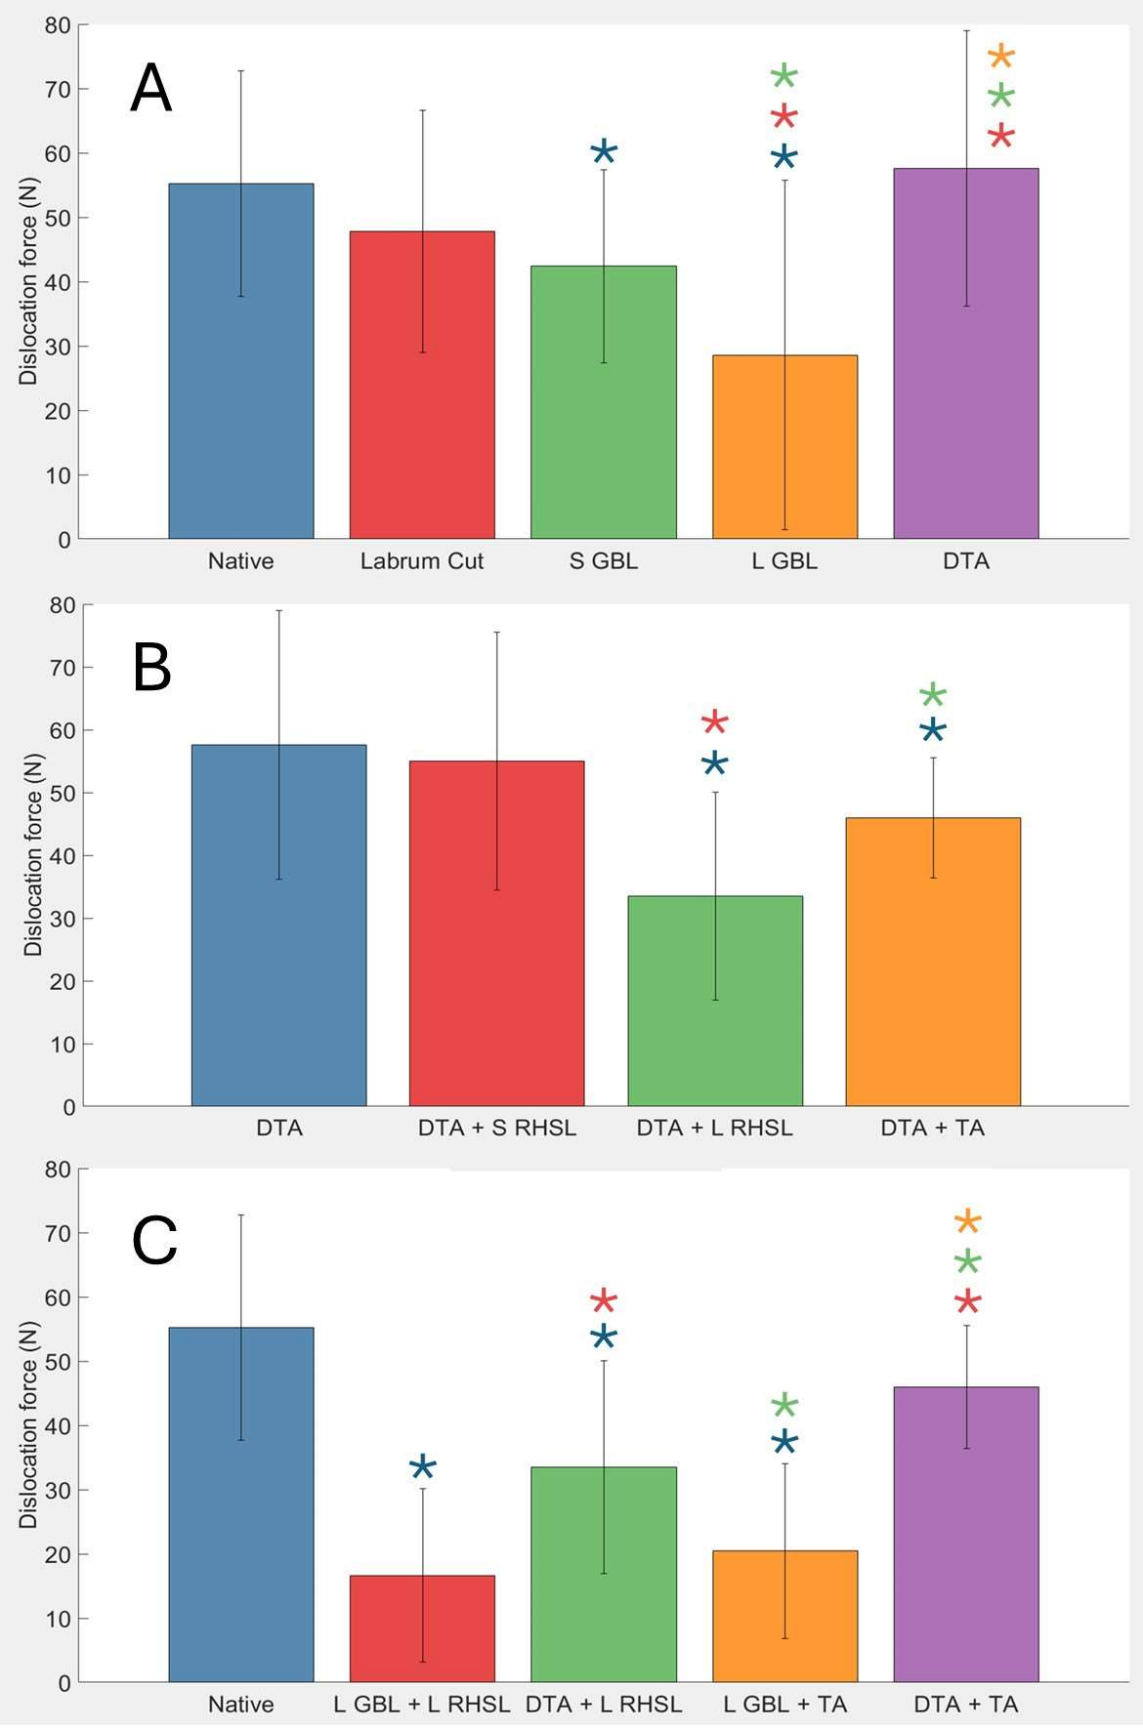
Steadman Philippon Research Institute, Vail, CO, United States

Introduction

Posterior shoulder instability is a challenging condition, frequently associated with posterior glenoid bone loss (GBL) and Reverse Hill-Sachs Lesions (RHSL). Objective: to characterize the decrease in dislocation force associated with GBL and RHSL and the benefits of distal tibial allograft (DTA), and talus allograft (TA) reconstruction, respectively.

Methods

Eight fresh-frozen cadaveric shoulders were dissected free of all soft tissue (mean age: 62.3, 5F,3M). Each specimen was mounted to a 6-degrees-of-freedom robotic arm and tested across nine states: 1) Native, 2) Posterior labrum removed, 3) Small GBL (12.5%) 4), Large GBL (25%), 5) DTA 6) DTA +Small RHSL 7) DTA + Large RHSL 8) DTA + TA, 9) LGBL + LRHSL. Posterior dislocation testing was performed at 90° of shoulder flexion with the arm internally rotated by 30 degrees. The humerus was translated postero-inferiorly along the 7 o'clock axis of the glenoid clockface by one humeral head radius, while maintaining an 80 N compressive load, and sagittal plane dislocation force was measured. The data were analyzed using a one-factor linear mixed effects model in three groups: A: Glenoid (states 1-5); B: Humerus (states 5-8); C: Bipolar (states 1, 7-9).



Results

Figure 1 shows dislocation force by state in each group. Stars show significant differences ($p<0.05$) from the state of associated color. Group A showed, decreasing force with progressive glenoid bone loss, and restored native force with DTA. Group B showed no significant change with small RHSL, decreased force with large RHSL and partial restoration with TA. Group C showed a severe decrease in force with bipolar bone loss, partial restoration with DTA alone, no significant improvement with TA alone, and restored native force with DTA+TA.

Discussion

Posterior instability with bipolar bone loss remains a difficult problem, and surgical decision-making is often based on limited evidence. This investigation provides the first robotic analysis of posterior dislocation across a range of clinically relevant lesion sizes and reconstructions and demonstrates that DTA and TA can improve stability in shoulders with significant bone loss. These findings support the use of structural allografts to manage posterior bipolar lesions and provide a biomechanical foundation for guiding surgical treatment algorithms.

Does Age or Pathology Drive Changes in Thumb Muscle Architecture?

Ms. Alexis Benoit MS, Dr. Jennifer Nichols PhD

University of Florida, Gainesville, FL, United States

Introduction

Thumb motion is driven by nine muscles that cross the carpometacarpal (CMC) joint. Fascicles influence a muscle's force-generating capacity and range-of-motion, and small changes in length can alter performance on the force-length and force-velocity curves. Common CMC osteoarthritis (OA) symptoms (e.g., weakness, reduced motion) are likely related to changes in fascicle length. However, in the thumb, fascicle lengths have only been quantified in small cadaveric studies or young healthy adults using extended field-of-view ultrasound (EFOV-US). Thus, this study aimed to quantify thumb muscle fascicle lengths in older adults and evaluate whether changes relative to young adults were due to age versus OA.

Methods

Twelve older adults (6 female, age=67.8±10.3 years) were stratified by symptomatic and radiographic CMC OA. Symptomatic cohorts were classified by average Australian Canadian Hand Osteoarthritis Index (AUSCAN) pain scores: non-symptomatic (AUSCAN<1; n=6) vs. symptomatic (AUSCAN≥1; n=6). Radiographic cohorts were defined by modified Eaton-Littler stages: healthy (0-I; n=5) vs. pathologic (II-IV; n=7). EFOV-US images of six thumb muscles were taken from the dominant/affected arm of each participant. Ten fascicle lengths per muscle were measured as the distance between superficial and deep aponeuroses. Unpaired t-tests compared older adult to published young adult data. Two separate two-way analyses of variance assessed the effects of cohort and muscle on fascicle length.

Results

Significant differences in fascicle length were observed between young and older adults in five muscles ($p<0.05$) (Fig. 1A). When stratified by symptomatic cohorts, fascicle lengths differed between young and symptomatic groups in three muscles ($p<0.05$) and between young and non-symptomatic groups in one muscle ($p<0.05$) (Fig. 1B). When stratified by radiographic cohorts, fascicle lengths differed between young and pathologic groups in three muscles ($p\leq0.01$) (Fig. 1C).

Discussion

These results suggest that aging alone does not fully account for changes in thumb muscle architecture. The most pronounced differences in fascicle length occurred in individuals with symptomatic or radiographic CMC OA, indicating that pathology-related factors likely influence these changes. Given the importance of both age- and pathology-related components, continued investigation of thumb muscle fascicles is needed to advance our understanding of muscle function in the context of CMC OA.

Identification of Key Factors Affecting Primary Stability of Short Humeral Stems in Reverse Shoulder Arthroplasty: A QCT-Based Finite Element Analysis of the Prima Stem Prosthesis

Ms. Annalisa Bertoni[1], Mr. Cristiano Pizzamiglio[1], Mr. Andrea Fattori[1], Mr. Alex Drew[2], Mr. Michele Pressacco[1]

[1]Enovis, Villanova, Italy, Italy. [2]Enovis, Austin, Texas, United States

Introduction

Short humeral stem implants in shoulder arthroplasty preserve proximal bone and facilitate future revisions through metaphyseal fixation while sparing the diaphysis. However, there is limited knowledge on how bone mineral density (BMD) and patient-specific factors affect primary stability in reverse shoulder arthroplasty (RSA). The aim of this study is to evaluate through finite element analysis (FEA) how these factors correlate to primary stability of the Prima Stem in RSA.

Methods

Three-dimensional bone models of 45 post-mortem white adult humeri (23 male, 22 female) were segmented from anonymized CT scans calibrated with a hydroxyapatite phantom for spatial bone properties assignment using quantitative CT. Proximal resections were performed at 135° neck-shaft angle and 20° retroversion; distally cut at mid-diaphysis. Implant (Prima Stem, Enovis, US) positioning was computed automatically using Figura, a proprietary research and implant development tool. FE models were distally fixed, and abduction loads (216.46N at 45°, 321.17N at 75°) with no hand weight were applied via a semi-spherical actuator, based on prior biomechanical RSA simulations. Mesh convergence resulted in a 1.2mm second-order mesh for bone and implant. Primary stability was assessed at the trabecular titanium ring by calculating relative displacement between implant and corresponding bone nodes. BMD was measured in this trabecular region.
Donors were grouped by age (U60, 60-80, 80+). Micromotion values were log-transformed and a two-way ANCOVA was performed to evaluate sex and age effects on micromotions, with BMD and BMI as covariates.

Results

Average maximum micromotions slightly increased with abduction (45°: 32.59±9.01µm; 75°: 43.30±10.43µm).
ANCOVA indicated that BMD was the only significant predictor (45°: $p<0.001$, $\omega^2_p = 0.379$; 75°: $p<0.001$, $\omega^2_p=0.405$), with lower BMD associated with higher micromotions [Fig.1]. BMI had a marginal effect (45°:$p=0.039$, $\omega^2_p=0.073$; 75°:$p=0.051$, $\omega^2_p=0.064$); sex and age were not significant.

Discussion

Primary stability of the studied design in RSA is largely determined by BMD, with minimal influence from age or sex and only a minor effect of BMI. For the analyzed loading conditions, micromotions remained below the critical threshold of 150µm, supporting the mechanical reliability of short-stem designs across a wide range of bone qualities and patient profiles.

The Influence of Different Radiation Therapies Regimens on Upper Extremity Nerve Tension in Breast Cancer Survivors

Mr. Chun-Kai Tang PT, MSc.[1,2], Dr. Josiah Nieto MD.[3], Prof. Yi-Fen Shih PT, Ph.D.[2], Dr. David B. Lipps Ph.D.[1]

[1]School of Kinesiology, University of Michigan, Ann Arbor, Michigan, United States. [2]Department of Physical Therapy and Assistive Technology, National Yang Ming Chiao Tung University, Taipei, Taiwan, Taiwan. [3]Department of Radiation Oncology, University of Michigan, Ann Arbor, Michigan, United States

Introduction

Breast cancer survivors (BCS) often experience chronic shoulder pain and dysfunction due to treatment-related musculoskeletal and neural changes, including fibrosis. Breast radiation therapy (RT) can expose the brachial plexus to incidental dose, particularly in standard regimens that target the whole breast or chest wall (WB), or by adding regional nodal irradiation (RNI) for more advanced cases. While research has predominantly examined musculoskeletal factors, neural tissue responses remain less explored in BCSs following RT. Standard neurodynamic tests often cannot distinguish nerve tension from adjacent tissue stiffness. This study compared brachial plexus and median nerve stiffness between healthy controls and BCSs treated with different RT regimens.

Methods

We studied BCSs who completed RT 1–3 years ago: 10 received WB (Age: 59.50±8.54, BMI: 27.39±4.11), eight received WB+RNI (Age: 62.75±10.71, BMI: 30.86±9.46), alongside 16 healthy controls (HC) (Age: 58.31±10.15, BMI: 27.50±5.97). Ultrasound shear wave elastography assessed shear wave velocity (SWV) at the brachial plexus (neck) and median nerve (elbow, mid-forearm, and wrist) during the Upper Limb Neurodynamic Test (ULNT1) at initial, submaximal (end-range minus 5°), and end-range positions. The use of SWE during neurodynamic testing provides a novel assessment of both nerve stiffness and mechanical properties under standardized limb positioning [1]. End-range ROM was recorded during the ULNT1 test. Group differences in ROM, initial SWV, and changes in SWV (ΔSWV) were analyzed using Kruskal-Wallis tests.

Results

Both WB and WB+RNI groups had significantly decreased elbow and wrist extension ROM during ULNT1 (standard: $p<0.001$; proximal: $p=0.026$). The WB group had greater initial C5 nerve stiffness compared to the HC and WB+RNI groups ($p=0.024$). The ΔSWV between the submaximal and end-range wrist position was larger in WB and WB+RNI groups than HCs ($p=0.015$).

Discussion

This study is the first to directly characterize nerve stiffness in BCSs using elastography during neurodynamic testing across different RT regimens. Both RT groups demonstrated increased nerve tension—manifesting as reduced ROM and greater nerve stiffness changes—suggesting RT reduces neural compliance. These findings underscore the need for targeted interventions that address neural fibrosis in BCSs following RT.

The Secondary Stabilizers Preventing Scapholunate Instability During Wrist Movements

Prof. Dai-Soon Kwak[1], MS. Seonjin Shin[1], Prof. Il-Jung Park[1], Prof. TAE SOO BAE[2]

[1]The Catholic University of Korea, Seoul, Seoul, Korea, Republic of. [2]Jungwon University, Goesan, Chungcheongbuk-do, Korea, Republic of

Introduction

Isolated injury of the scapholunate interosseous ligament (SLIL) will not produce static instability of the scapholunate joint. For this, secondary stabilizers also must be compromised. There is no consensus on the secondary stabilizer most critical in preventing static scapholunate instability (SLI), but many studies have reported the importance of dorsal intercarpal (DIC), scaphotrapeziotrapezoid (STT), and long radiolunate (LRL) ligaments.

Methods

Thirty-six fresh-frozen upper extremity cadaveric specimens were prepared. A wrist simulator with a linear guide rail system (tendon load/motion-controlled system) and five motion capture systems were used. The experimental groups were as follows: (1) intact wrist and ligaments, (2) SLIL transection, (3) DIC transection, (4) STT transection, and (5) LRL transection. The DIC, STT, and LRL ligament transections were randomly assigned. The scapholunate distance, radioscaphoid angle (RSA), radiolunate angle (RLA), and scapholunate angle (SLA) were measured during continuous flexion-extension and ulnar deviation–radial deviation movements.

Results

Isolated transection of the SLIL was not sufficient to alter the normal kinematics of the SL joint. However, when the DIC ligament was transected in the first stages, a significant increase in the scapholunate distance was observed, and significant changes were observed in the RSA and SLA. Furthermore, when the DIC was transected in the second and third stages, the increase in scapholunate distance was significantly greater than that with transection of the other ligaments.

Discussion

The DIC ligament demonstrated the greatest influence on both distraction and rotational stability of the scapholunate joint. During treatment of scapholunate dissociation,

intraoperative assessment of the DIC ligament is crucial, and its repair or reconstruction should be considered for surgical management.

From Kinematics to Coordination: Modelling Scapular Dyskinesis and Periscapular Muscle Activation

Ms Delaney Meek[1], Dr Peter Pivonka[1], Dr Wolbert van den Hoorn[2], Dr Maxence Lavaill[1]

[1]Queensland University of technology, Brisbane, QLD, Australia. [2]University of Queensland, Brisbane, QLD, Australia

Introduction

Scapular dyskinesis (SD), defined by abnormal scapular function, is commonly associated with shoulder pain and injuries [1]. SD is typically classified into four abnormal scapulothoracic kinematic patterns: increased anterior tilt (pattern 1), increased internal protraction (pattern 2), excessive (pattern 3a) or insufficient (pattern 3b) scapular upward rotation [1]. Limited studies showed altered activations of serratus anterior (SA), upper (UT), middle (MT), and lower (LT) trapezius muscles for patterns 1 and 2 only. This study aims to describe periscapular muscle activation for each dyskinetic pattern by simulating healthy and SD motions with musculoskeletal (MSK) modelling.

Methods

A control shoulder flexion motion was developed from bi-plane fluoroscopy kinematic data [2]. For each SD pattern, the control motion was modified by altering posterior tilt, protraction, or upward rotation based on literature values. These motions drove a shoulder MSK model [3] with a 4-degree-of-freedom scapulothoracic joint actuated by 33 muscle-tendon units. Static optimisation estimated muscle activations, particularly of UT, MT, LT and SA. Each dyskinetic motion was evaluated against control to determine estimated muscle activation differences.

Results

Pattern 1 displayed decreased SA (6%) and LT (2%) activation, and increased UT (8%) activation. Pattern 2 (Figure 1) displayed decreased SA (2%), LT (2%), and UT activations (4%). Pattern 3a exhibited increased SA (2%) and LT (5%) activations, with decreased UT (3%) activation. Pattern 3b demonstrated decreased SA (8%), UT (4%) and LT (2%) activations.

Discussion

The muscular activations of patterns 1 and 2 align with literature values. Novelly, for pattern 3a, increased SA and LT activation was shown to be biomechanically consistent with increased upward rotation and reduce UT activation. In pattern 3b, decreased activation of SA and LT is consistent with reduced upward rotation. Instead of typical increased compensatory UT activation, pattern 3b displayed increased activation of the infraspinatus and coracobrachialis muscles. Understanding muscle alterations for each SD pattern can inform targeted rehabilitation strategies. The relationship between SD pattern and muscle activation will be further examined through upcoming biplane fluoroscopic data collection of SD kinematics.

Using Wavelet Coherence To explore the Relationships Between Scapular Kinematics and Muscle Activation

Ms. Denise Balogh MSc, Dr. Angelica Lang PhD

University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Introduction

Evaluating the coherence (similarity in frequency content) between the continuous wavelet transforms (CWTs) of electromyography and kinematic signals provides a means of quantifying how the relationship between muscle activation and kinematics evolves over time [1,2]. This study is the first to apply wavelet coherence as a tool to explore the relationship between scapular kinematics and muscle activation.

Methods

Electromyography (EMG) of the upper trapezius (UT), lower trapezius (LT), and serratus anterior (SA) and motion of the scapula were assessed on the dominant side of 11 healthy participants. Participants performed repeated frontal plane arm elevations for 60s at a frequency of 30bpm (full cycle frequency = 0.25Hz). Using a modified version of the Wavelet Coherence Toolbox [3], the CWT coherence between scapular upward rotation (UR) and the linear enveloped muscle activations were computed. The mean coherence (value of 0 – 1) and mean phase angles across the 60s at the 0.25Hz frequency were calculated. Linear regression was also applied to determine if the coherence at 0.25Hz significantly changed across time during the task.

Results

Strong coherence between each muscle and scapular UR at the 0.25Hz frequency (Figure 1) was present across the full 60 seconds (mean coherence ± std: UT=0.99±0.004; LT=0.97±0.037; SA=0.99±0.022). Regression analysis demonstrated no significant change in coherence across time between any of the muscles and scapular UR. A task with a greater fatiguing element may generate changes or greater variability in coherence as muscle recruitment strategies change. Mean phase angles indicated that the UT (19.97º) and SA (22.81º) preceded the UR movement, while the LT (-46.28º) activated after movement initiation.

Discussion

This study provides proof of concept for the application of wavelet coherence to scapular kinematics and muscle activation. Future research should employ CWT and CWT

coherence methods to a scapular fatiguing protocol to better understand how muscle activation and recruitment patterns change relative to kinematics with fatigue.

Images (Optional)

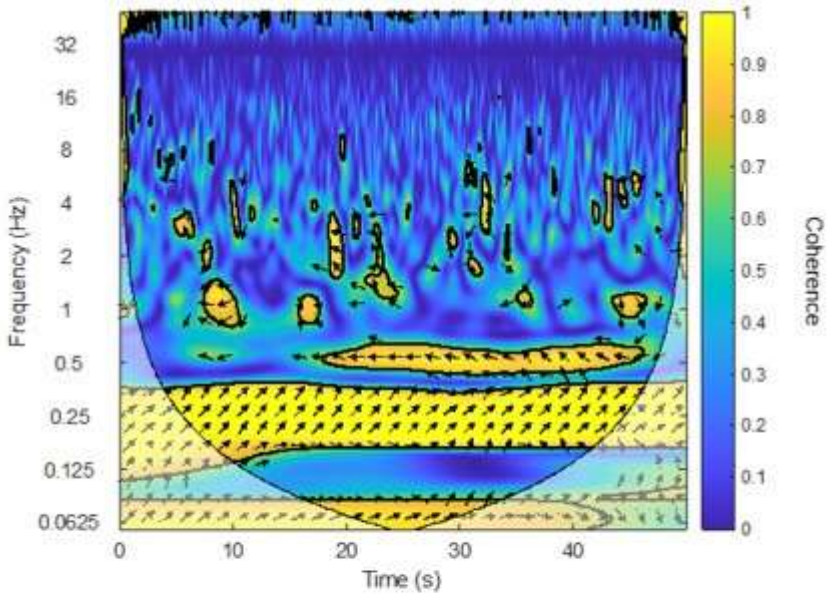

Figure 1. Coherence and phase plot for scapular upward rotation and UT from one representative subject. Strong coherence is seen at 0.25Hz frequency. Up-right direction of arrows indicate muscle activation leads kinematics by less than 90°.

Do Subscapularis Integrity and Posterosuperior Cuff Tear Severity Affect Osseous Impingement and Joint Subluxation in Reverse Total Shoulder Arthroplasty?

Mr. Donghwan Lee BSc[1], Prof. Joo Han Oh MD, PhD[2], Prof. Choongsoo Shin PhD[1,3]

[1]Department of Mechanical Engineering, Sogang University, Seoul, Mapo-gu, Korea, Republic of. [2]Department of Orthopaedic Surgery, Seoul National University Bundang Hospital, Seongnam, Bundang-gu, Korea, Republic of. [3]Research Institute for Smart Design & Manufacturing Technology, Sogang University, Seoul, Mapo-gu, Korea, Republic of

Introduction

Osseous impingement and joint subluxation during external rotation (ER) are commonly observed in patients with reverse total shoulder arthroplasty (RTSA) [1]. However, how subscapularis and posterosuperior cuff (supraspinatus and infraspinatus) tear (PCT) severity in RTSA affects impingement and joint stability remains unclear. This study aimed to investigate the effects of subscapularis integrity and PCT severity on osseous impingement stress and joint subluxation in RTSA.

Methods

The RTSA model was developed by importing prosthetic bone geometries (Coralis® Reverse Shoulder System; Corentec Co., Ltd., Seoul, Republic of Korea) into a previously validated anatomical shoulder model [2]. Twelve male *in vivo* experimental datasets, collected during 45° of ER, were used as consistent inputs for the RTSA model. Model simulations were performed under subscapularis-repaired and -torn conditions, across three stages of PCT severity: Stage I, isolated supraspinatus tear; Stage II, complete supraspinatus tear and superior half infraspinatus tear; and Stage III, complete supraspinatus and infraspinatus tears. Post hoc paired t-tests were conducted to compare peak osseous impingement stress and peak joint subluxation between subscapularis-repaired and -torn conditions across three PCT stages.

Results

Subscapularis repair in Stages I–III significantly reduced peak impingement stress by 16.7–26.2% ($P < 0.05$ for all comparisons). The same repair stages also significantly decreased peak joint subluxation by 27.5–58.9% ($P < 0.001$ for all comparisons).

Discussion

The main finding of this study is that subscapularis repair in RTSA can reduce osseous impingement stress and joint subluxation during ER, even in the presence of PCTs. Joint subluxation is commonly associated with impingement and arises from an unbalanced force couple between the anterior (subscapularis) and posterior (infraspinatus and teres minor) cuffs caused by cuff deficiency [3]. Therefore, our results suggest that subscapularis repair in RTSA can mitigate osseous impingement and improve joint stability in patients with PCT deficiencies.

Patient-Specific Biomechanical Modeling of Scapular Forces Following Reverse Total Shoulder Arthroplasty

Medical Student Ecem Kilic[1], Medical Student Zachary Rickmeyer[1], Medical Student Nathan Harward[1], Medical Student Kaleb Barker[1], Associate Professor Lucas Timmins PhD[2], Orthopedic Surgeon Bradley Edwards MD[3]

[1]Texas A&M School of Engineering Medicine, Houston, Texas, United States. [2]Texas A&M University, Houston, Texas, United States. [3]Fondren Orthopedic Hospital, Houston, Texas, United States

Introduction

Scapular spine stress fractures are a complication following reverse total shoulder arthroplasty (rTSA). The implant reconfigures shoulder center of rotation (COR), increasing deltoid loading across the scapular spine. The changes raise concern for stress concentrations that may predispose patients to fracture. This study evaluates a patient-specific finite element (FE) workflow designed to predict potential fracture regions in the scapula after rTSA.

Methods

Muscle force vectors, registered to the implant COR, were extracted from an open-source shoulder model for abduction and applied to a scapular FE model generated from preoperative CT scans. Bone density and Young's modulus were mapped to each FE element using CT Hounsfield units. FE model outputs were processed to quantify first principal (FP) stresses and strains within Levy zones (LZ) I–III, and compared to the postoperative fracture site. Model stability was assessed through mesh convergence, and sensitivity to muscular boundary condition (BC) selection was evaluated across six independent observers using Intraclass Correlation Coefficient (ICC) and Linear Mixed-Effects Model (LMM).

Results

Stresses and strains were highest in LZ-II, with highest values during 10-20% abduction (peak FP stress I/II/III:17.4/34.6/24.6 MPa; peak FP strain: 0.00788/0.00875/0.00563) (Figure 1). Mean FP stresses followed (1.25/4.36/3.14 MPa), as did mean FP strains (0.00125/0.00212/0.00178). Max FP stress demonstrated the closest spatial agreement with the postoperative fracture site (<5mm), while FP strain was less accurate. Observers

showed agreement in overall FEA patterns (ICCs: 0.93-0.99), though the LMM detected differences in absolute magnitudes ($p<0.05$). BC selections showed moderate similarity (DICE: 0.653).

Discussion

Patient-specific FE modeling differentiated loading patterns across LZs with LZ-II exhibiting the highest stresses. This zone-dependent behavior mirrors reports identifying the scapular spine and acromial base as vulnerable regions after rTSA. FP stress localized most accurately to the fracture site, supporting its potential as a biomechanical risk marker. BC variability had minimal influence on overall patterns, supporting robust zone-level predictions. Expanding the number of scapulae analyzed will strengthen model generalizability and further validate zone-specific trends.

Images (Optional)

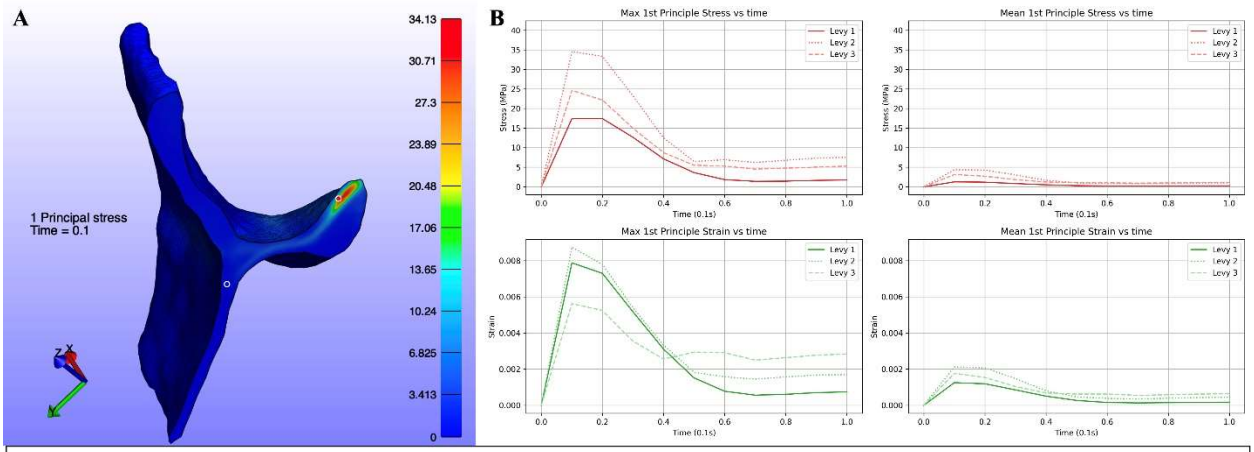

Figure 1. Stress and strains in scapula. A) Maximum (red) and minimum (blue) FP stresses within scapular spine. B) Maximum and mean FP stress and strain vs time in all three LZs.

Biomechanical Performance Assessment of Anatomical Scapula Body Fracture Fixation Plates – A Comparative Finite Element Analysis

Dr. Habtamu Yimam[1,2], Dr. Roopam Dey[1], Prof. Stephen Roche[1], Prof. Sudesh Sivarasu[1]

[1]University of Cape Town, Cape Town, Western Cape, South Africa. [2]Addis Ababa University, Addis Ababa, Addis Ababa, Ethiopia

Introduction

Displaced and unstable scapular body fractures are commonly treated with surgical fixation, primarily using plates and screws. Anatomically contoured plates serve as a template during fracture reduction and maintain fixation stability. The purpose of this study was to compare the biomechanical performance of new anatomical scapula body plates with commercial plates using the finite element analysis method.

Methods

First, a two-part osteotomy of the scapula body fracture was created, and three fixation constructs were performed using the new long lateral & medial border plates (LBP-L & MBP-L), short lateral & medial border plates (LBP-S & MBP-S), and ACUMED's ten-hole lateral & nine-hole medial border plates (SLB10 & SMB09). Then, the glenohumeral joint contact force of 400 N was applied at 90° arm abduction with a fixed boundary condition at the medial border. Finally, the response of the fixation constructs was assessed based on stress in the plates, strain in the bone around the screw holes, and fracture gap displacement (interfragmentary strain).

Results

The maximum stresses of the lateral border plates: LBP-L, LBP-S, and SLB10 were 166.0 MPa, 108.4 MPa, and 175.0 MPa, respectively. Similarly, the maximum stresses of the medial border plates: MBP-L, MBP-S, and SMB09 were 88.0 MPa, 65.0 MPa, and 86.6 MPa, respectively. Additionally, the maximum strains of the LBP-L, LBP-S, and SLB10 fixation constructs were 0.22%, 0.16%, and 0.28%, respectively, in the lateral border. In the medial border, the maximum strains of the MBP-L, MBP-S, and SMB09 fixation constructs were 0.49%, 0.36%, and 0.29%, respectively. Furthermore, the interfragmentary strain (fracture gap displacement) of the new long and short scapula body fixation constructs and the ACUMED plate fixation construct were 2.81%, 2.25%, and 3.48%, respectively.

Discussion

This study evaluated the biomechanical performances of anatomical scapula body plates using the FEA method. The results of the maximum stress in the plates, maximum strain in the bone around the screw holes, and fracture gap displacement in the three fixation constructs demonstrated that the new plates achieved better results compared to the ACUMED plates. The new plate designs with long and short size options could be a viable option for the fixation of challenging scapula body fractures.

Influence of Cup Positioning of Dual Mobility Thumb Carpometacarpal Joint Replacement on Principal Stress Projection in Trapezium

Ms Hind Alyahya, Dr Angela Kedgley

Department of Bioengineering, Imperial College London, London, Greater London, United Kingdom

Introduction

Dual mobility is the latest innovation in the design of thumb carpometacarpal (CMC) implants [1]. Its primary goal is to restore the balance between joint stability and mobility. The success of CMC joint replacement surgery is influenced by surgeon-related factors. To regain the full functionality of the thumb, implant position is critical [2]. We hypothesised that the inclination of the implant cup influences stress on the trapezium, risking postoperative complications.

Methods

An FE model of the thumb CMC joint with a dual-mobility implant simulating lateral pinch was developed. The geometry of the trapezium and first metacarpal were modelled with linearly elastic, isotropic material properties. A Maia (Groupe Lepine, France) implant was inserted into the bones, where the cup was placed at the centre [2-3]. Ligaments were modelled as 1D elements with rotational stiffness obtained from an in-house study conducted on healthy volunteers. A compressive load was applied to the top surface of the metacarpal bone, resulting from a 2.7 kg lateral pinch [4]. Simulations were run in MSC.Marc (MSC Software Corporation, USA).

Results

Cup inclination relative to the trapezium surface affected the minimum principal stress distribution in the trapezium under lateral pinch force (Fig.1). This parameter was used as an indicator of the primary compressive load transmitted to the CMC joint.

Discussion

Groupe Lepine advises that the implant's cup should be placed at the centre of the trapezium with no requirement for inclusion [3]; however, centring the cup may not be achievable, leading to placement with some degree of inclination and/or off-centre [2]. This study is ongoing to investigate the complications associated with these parameters, including the potential for PE liner wear and/or cup loosening. The results will be validated

against an in vitro experiment. This study is expected to help define standards, develop products, and guide surgeons for better clinical outcomes.

Stiffness of Thumb Carpometacarpal Joint: an In-vivo Study

Ms Hind Alyahya, Dr Angela Kedgley

Department of Bioengineering, Imperial College London, London, Greater London, United Kingdom

Introduction

The thumb carpometacarpal (CMC) joint is a primary contributor to hand dexterity due to its unique biconcave-convex shape [1]. Seven primary ligaments passively support the joint, all unique in morphology and mechanical properties [2-3]. Quantifying joint stiffness, which may differ by age and sex, helps understand, diagnose, and treat diseases effectively. In this study, we measured in-vivo thumb CMC joint stiffness. We hypothesised that rotational stiffness is a direction-dependent property due to the nonuniformity of the joint geometry and variations in the intrinsic properties of the passive tissues.

Methods

The dominant hand of 12 younger (5 men, 7 women; aged 27.6±3.2 years) and 8 older (4 men, 4 women; aged 58±3.7 years) participants were tested in a custom-designed setup for measuring moment-rotation response. Measurements were taken from three primary directions of thumb CMC joint motion: extension, flexion and abduction. Five thumb muscles were monitored during testing using surface electromyography to ensure relaxation. Rotational stiffness was quantified as the slope of the linear portion of the moment-rotation response. Nonparametric Wilcoxon signed rank and Wilcoxon rank sum tests were used for analysis.

Results

Results indicated differences between flexion and extension, and between flexion and abduction within each group, with flexion being less stiff (Fig.1). Sex had a significant effect on extension stiffness in the older group only. Age had no effect on the stiffness in any direction.

Discussion

The rotational stiffness for flexion is the lowest compared to extension and abduction, implying that the structure of the joint and the moment arm play a role, even though Young's modulus of the dorsal ligaments is reported to be higher than that of the volar and ulnar ligaments [2]. In the older group, women exhibited greater stiffness than men, which

may be due to post-menopausal hormonal changes [1]. Data will support developing a computational model of the joint to investigate new surgical techniques.

Biomechanical Rationale and Functional Impact of the External Rotation Torsional Humeral Osteotomy on Shoulder Kinematics in Older Children With Obstetric Brachial Plexus Palsy

Prof JAGDISH MENON MS(Ortho), MRCS(Edin), FACS, PGDHQM, Dr Ragavendra K MS(Ortho)

JIPMER, Pondicherry, Pondicherry, India

Prof JAGDISH MENON

Introduction

A significant number of children with upper trunk type of obstetric brachial plexus palsy (OBPP) have persistent residual motor deficit that extends into late childhood, leading to secondary effects like progressive internal rotation contracture, posterior subluxation of the humeral head and glenoid dysplasia, profoundly altering shoulder kinematics and upper limb function. The torsional derotation osteotomy of the humerus is a corrective surgery optimizing the mechanical alignment of the arm in space thereby improving joint function. We examined the biomechanical rationale and functional consequences of humeral derotation osteotomy in older children with OBPP focusing on shoulder kinematics, muscle mechanics, and clinical outcomes.

.

Methods

Torsional humeral external rotation osteotomy was performed on children with upper trunk OBPP with fixed internal rotation deformity of the shoulder Manual muscle testing, active/passive range of motion and functional assessment by the modified Mallet score was recorded. Radiological evaluation was performed by standard X-rays and MRI. Preoperative and post operative range of motion, strength and functional scores were measured. Compensatory mechanism like changes in the scapulothoracic rhythm and forward body lean was also recorded.

Results

14 children (5 males and 9 females) with a mean age of 12.6 +/- 2.15 years were treated by the torsional derotation external rotation osteotomy of the humerus. Significant improvements were observed in active and passive external rotation (mean gains of 33° and 53°, respectively; $p < 0.01$) and in abduction (mean increase 44°; $p < 0.01$). Pre-operative Modified Mallet score improved from 11.81 +/- 2.1 to 16.4 +/- 1.8 post operatively. All domains of the modified Mallet score showed significant improvement. All children reported an increase in power of elbow flexion. A reduction of compensatory winging was seen in 11 out of 17 patients. Excessive forward lean improved from 18° +/-6° to 8° +/-4°. No major complications were recorded and all osteotomies healed uneventfully.

Discussion

The external rotational torsional humeral osteotomy improves shoulder function in older children with obstetric brachial plexus palsy with internal rotation contracture, and/or advanced glenohumeral joint deformity. The surgery enhances rotational range of motion, increases external rotation strength, and reduces compensatory trunk flexion, leading to more efficient and functional upper limb use.

Comparison of Upper Extremity Anthropometry among Manual Wheelchair Users using Marker-Based and Markerless Biomechanical Models and Radiographic Imaging Segmentation

Mr Jeremy Lohmann[1], Ms Hannah Panchal[1], Ms Jungsun Moon[1], Dr Matthew Hanks PhD, ATC[1,2,3]

[1]Department of Health and Kinesiology, University of Illinois Urbana-Champaign, Urbana, IL, United States. [2]Beckman Institute for Advanced Science and Technology, University of Illinois Urbana-Champaign, Urbana, IL, United States. [3]Disability Resources and Educational Services, University of Illinois Urbana-Champaign, Champaign, IL, United States

Introduction

Upper extremity anthropometry is necessary to optimize manual wheelchair setup and reduce propulsion pathomechanics and risk of musculoskeletal injury. Motion analysis and radiographic imaging are systematic methods that can be used to measure upper extremity anthropometry, yet little research has compared measurements derived from these different methods. The purpose of this study was to evaluate the level of agreement in humerus and forearm segment lengths measured using marker-based and markerless biomechanical models and radiographic imaging segmentation.

Methods

Twenty-two manual wheelchair users (n=22; 12 male/10 female; age: 20.74±1.78 years) participated. Participants were affixed with 34 passive markers on their trunk and upper extremities then propelled their wheelchair overground while three-dimensional (3D) marker trajectories (120 Hz) and two-dimensional (2D) videos (60Hz) were obtained simultaneously using a 14-camera Qualisys system. Marker and video data were processed in Qualisys Track Manager and Theia3D software then exported into Visual 3D software to construct marker-based and markerless biomechanical models, respectively. In each model, humerus length was measured as the distance between the shoulder and elbow joint centers, and forearm length was measured as the distance between the elbow and wrist joint centers. Participants then underwent dual energy x-ray absorptiometry, and the scans were analyzed in ImageJ software. Humerus length was measured as the distance between the top of the humeral head and elbow joint center, and forearm length was measured as the distance between elbow and wrist joint centers. Intraclass correlation (ICC) and repeated measures MANOVA were used to assess the agreement among the methods.

Results

Strong ICC values were observed among the methods for the humerus (ICC3k=0.95) and forearm (ICC3k=0.98) segment lengths. A significant main effect of measurement method was observed (Wilks' Lambda=0.17, $F_{8,78}$=13.92, p<0.001, ηp^2=0.59). Post hoc analyses are presented in Table 1.

Discussion

Though significant differences in segment lengths were observed between the methods, the magnitudes of differences were small (≤1.5cm) with the markerless model consistently yielding the smallest measures. Additionally, ICC values were very strong indicating that all methods were highly reliable. These findings suggest that any of these methods could be used to reliably measure upper extremity anthropometry in manual wheelchair users.

Images (Optional)

Table 1. Post hoc pairwise comparisons of differences between measurement methods (mean±SD).

Segment (cm)	[1]Image Segmentation	[2]Marker-Based	[3]Markerless	$p_{1,2}$	$p_{2,3}$	$p_{1,3}$

Determinants of Supraspinatus Occupation Ratio During the Bench Press: The Role of Shoulder Elevation Kinematics and Sex

Ms. Jodi Motlagh[1], Dr. David Lipps[2]

[1]Wayne State University, Detroit, MI, United States. [2]University of Michigan, Ann Arbor, MI, United States

Introduction

Optimal form during the bench press is vital for injury prevention. Shoulder injuries are common in powerlifters, and anatomical factors such as an increased supraspinatus occupation ratio are associated with greater shoulder impingement [1]. In a standard bench press position, biological females have a higher supraspinatus occupation ratio than males, along with altered glenohumeral kinematics during bench press sets. Combined, these factors may put female lifters at increased risk of shoulder impingement and instability. Therefore, this study aimed to investigate whether glenohumeral elevation and biological sex could help predict the supraspinatus occupation ratio among competitive powerlifters.

Methods

Nineteen competitive powerlifters (8M, 11F) consented to participate in this study. Ultrasound imaging of the acromiohumeral distance and supraspinatus tendon was completed in the standard bench press position. The ratio of supraspinatus tendon thickness to acromiohumeral distance (e.g., supraspinatus occupation ratio) was calculated. Markerless motion capture (Theia) was used to calculate the peak glenohumeral elevation (corresponding to the highest bar position) across three bench press sets. Linear regression analysis predicted the supraspinatus occupation ratio based on glenohumeral elevation angle and biological sex.

Results

The overall regression model was significant, $F_{(2, 16)} = 15.73$, $p < 0.001$, explaining 66.3% of the variance ($R^2 = 0.663$). Both glenohumeral elevation angle (B = -0.008, SE = 0.002, t = -3.44, p = 0.003) and biological sex (B = -0.146, SE = 0.051, t = -2.89, p = 0.011) significantly predicted supraspinatus occupation ratio in a standard bench press position.

Discussion

The supraspinatus occupation ratio was strongly predicted by peak glenohumeral elevation angles during bench press sets and biological sex. By quantifying these relationships, our

model provides a practical framework for optimizing bench press form and developing targeted injury-prevention strategies—particularly for female athletes. A limitation was the inability to capture dynamic ultrasound images while athletes lowered the barbell, due to physical obstructions from the bench. Future research should explore the impact of different techniques, training volumes, and rehabilitation strategies on the supraspinatus occupation ratio, ideally across longitudinal datasets.

Subject Specific Micro Finite Element Modeling of Proximal Humeral Neck Trabecular Bone: Validation and Structure Function Insights.

MSc. Eng. Johannes Eichwalder, PhD Mahsa Zojaji, PhD Nikolas Knowles

University of Waterloo, Waterloo, Ontario, Canada

Introduction

Stemless humeral head components are a popular choice for patients undergoing shoulder arthroplasty for end-stage osteoarthritis (OA).[1] OA is known to alter bone density in the humeral head, which can compromise implant stability and increase the need for surgical revision.[2] However, quantitative structure function data for humeral neck trabecular bone remain limited compared with the hip and spine. Micro-finite element (micro-FE) analysis has proven effective in linking trabecular architecture to mechanical properties in other skeletal sites. This study evaluated how local trabecular microarchitecture in the lateral proximal humeral neck relates to stiffness and apparent elastic modulus.

Methods

A 10 mm section was extracted directly below the humeral anatomic neck of cadaveric humeri, micro CT scanned, and tested in uniaxial compression obtain apparent elastic modulus. Trabecular cores (13 mm x 13 mm) from the superolateral region were segmented from each micro CT image. Bone morphometry was quantified for each core. Micro FE models were generated with linear elastic isotropic homogeneous tissue modulus and boundary conditions reproducing the experimental protocol to compute apparent elastic modulus.

Results

Trabecular cores BV/TV ranged from 4.4 to 19.7%, with corresponding FE-based apparent elastic modulus from 21.5 to 689.2 MPa. Experimental apparent modulus of the entire 10 mm humeral sections ranged from 7.3 to 37.7 MPa. FE apparent modulus showed strong positive correlations with BV/TV ($r = +0.93$), degree of anisotropy ($r= +0.72$), trabecular thickness ($r = +0.83$), and connectivity density ($r = +0.56$), and a negative correlation with trabecular separation ($r= -0.63$).

Discussion

Local trabecular architecture of the lateral proximal humeral neck strongly governs apparent stiffness and modulus, with BV/TV, degree of anisotropy, trabecular thickness, trabecular separation and connectivity density emerging as key predictors, consistent with prior structure function work in the humeral head.[3]

Assessing Accuracy of Glenohumeral Joint Center of Rotation Estimates Using Traditional Motion Capture Versus Bi-Plane Fluoroscopy

Dr. Julia Dunn PhD, Ms. Ola Alsaadi MS, Dr. Kevin Shelburne PhD, Dr. Michelle Sabick PhD

University of Denver, Denver, CO, United States

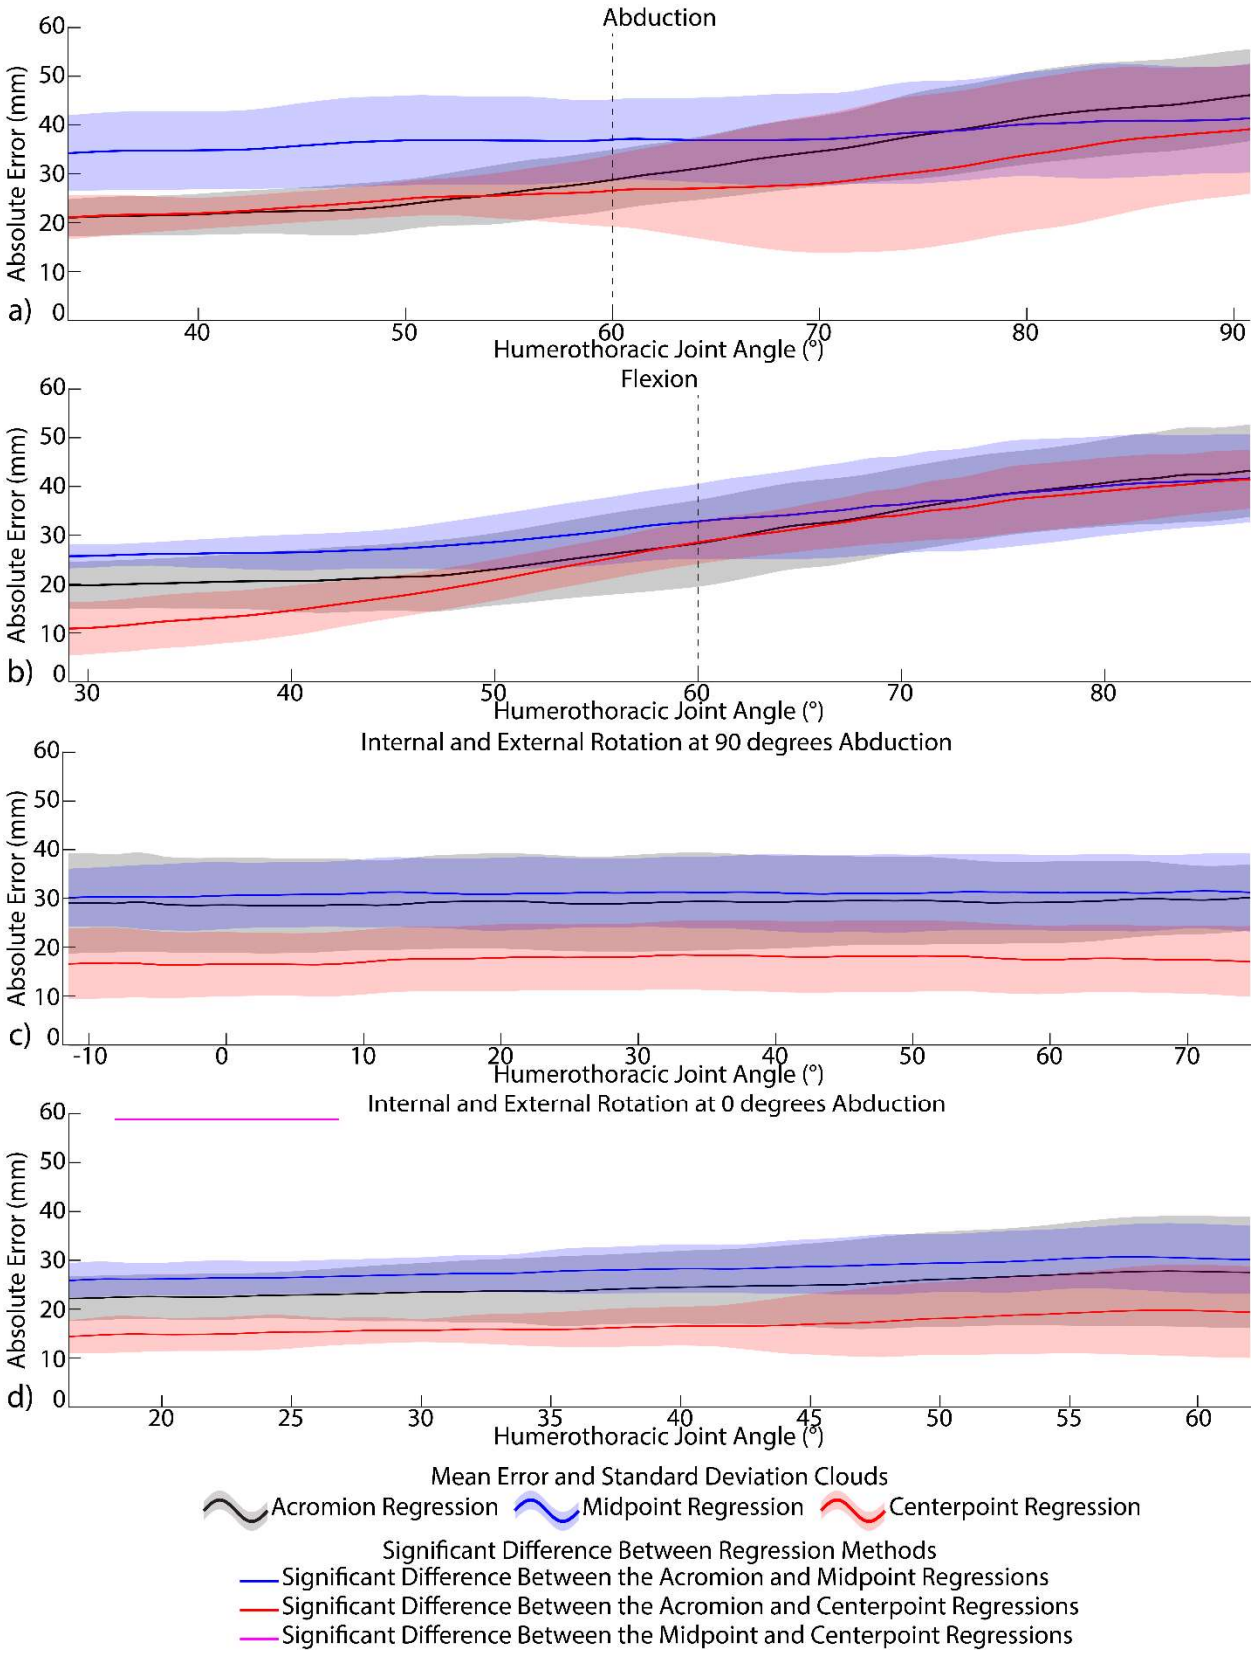
Introduction

The glenohumeral joint (GHJ) is located deep below skin and muscle, so its center of rotation (CoR) cannot be located by palpation alone. Accurate estimation of the GHJ CoR is essential for modeling of shoulder motion. While prediction methods using bony landmarks are commonly used, their accuracy throughout the entire range of shoulder motion has not been fully assessed. This study compared three predictive approaches for locating the CoR to results obtained from bi-plane fluoroscopy.

Methods

Five healthy adults performed controlled shoulder abduction, flexion, and external rotation movements in adducted and 90° abducted positions. Optical motion capture was used to estimate GHJ CoR via three predictive methods: acromion offset, midpoint of two technical markers, and center point of acromion plus technical markers. Bi-plane fluoroscopy was used to establish the reference location of the CoR. Absolute and axial errors were calculated across normalized ranges of motion. Statistical parametric mapping and repeated measures ANOVA assessed differences in error among methods compared to the reference location from bi-plane fluoroscopy.

Results



None of the predictive methods met clinically relevant thresholds for accuracy (absolute error >10mm; axial error >±5mm). Absolute error increased significantly with humeral elevation beyond 60°, reaching up to 46mm during abduction and 43mm during flexion. In contrast, error remained stable during internal/external rotation. The use of technical markers slightly reduced axial error but did not substantially improve overall accuracy. In addition to error magnitude, directional biases were observed: the acromion method produced anterior, medial, and superior errors, while the midpoint and center point methods tended toward medial and inferior errors.

Discussion

All of the commonly used predictive methods for determining GHJ CoR are unreliable for high-elevation tasks, such as overhead sports, due to significant increase in error with

elevation and susceptibility to soft tissue artifact. They may remain suitable for low-elevation activities (e.g., gait), but adjusting the offsets will be critical. Future work should explore humeral marker placement and functional methods to mitigate soft tissue artifact and improve estimation accuracy. Validating optical motion capture-based methods against bi-plane fluoroscopy will enhance consistency in calculating and reporting outcomes in shoulder biomechanics research.

EMG Validation of Subject-Specific RTSA Musculoskeletal Models in Dynamic Tasks

Ms. Kaitlyn B. Kuchinka[1,2], Dr. Heath B. Henninger PhD[2], Dr. Joshua W. Giles PhD[1]

[1]University of Victoria, Victoria, British Columbia, Canada. [2]University of Utah, Salt Lake City, Utah, United States

Introduction

Reverse Total Shoulder Arthroplasty (RTSA) produces altered muscle activations, and compensatory movement patterns characterized by shifted glenohumeral and scapulothoracic contributions. Previous RTSA musculoskeletal models (MSkM) used kinematics from controls, or large reserve actuators. Crucially, these assumptions prevent considering interactions between kinematics, activations, and loading. This work parametrically generated subject-specific RTSA MSkMs. Open-source distribution of the dataset is planned following validation.

Methods

Participants (N=3) with RTSA performed scapula abduction (SA) and forward elevation (FE). Optical motion capture, biplane fluoroscopy (BF), and both surface and fine-wire electromyography (EMG) were recorded.

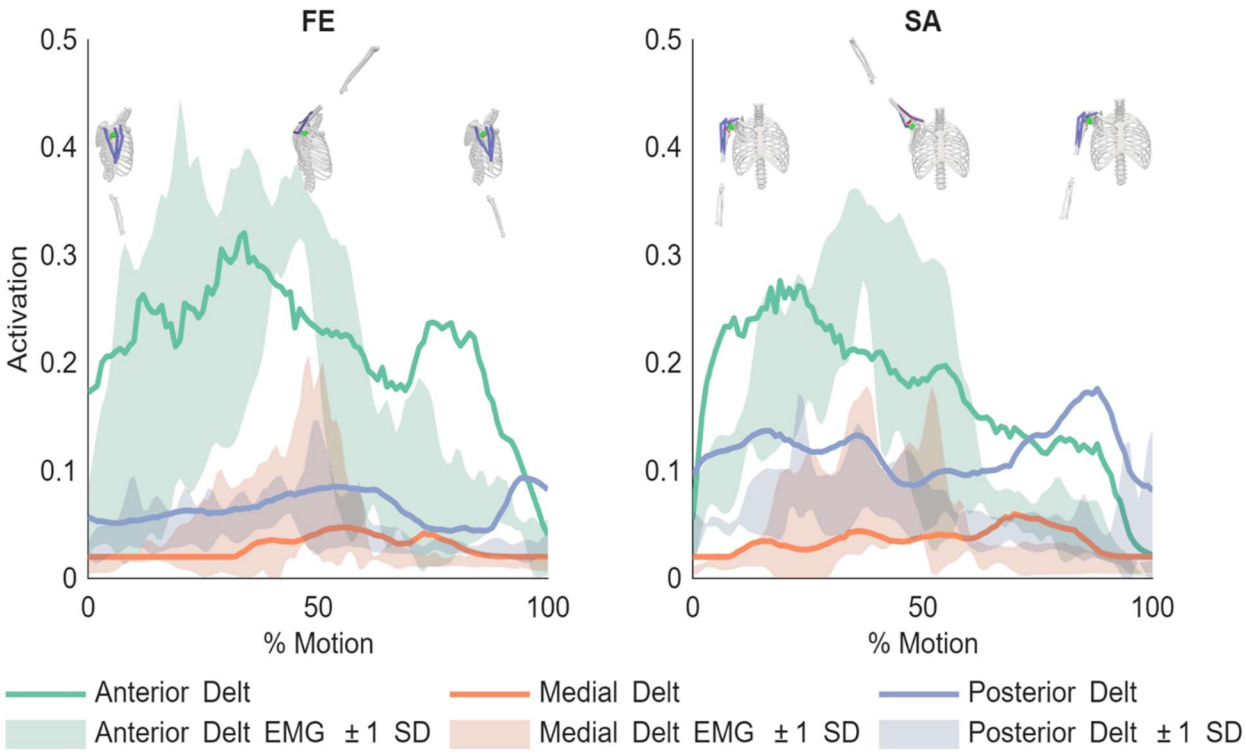
A generic MSkM [1] was modified using the OpenSim 4.4 MATLAB API. Pre-operative Computed-Tomography segmentations were registered to respective body-segment frames. Non-rigid point-cloud registration determined subject-specific muscle attachments. Wrapping objects and via-points were adjusted according to attachments and defined anatomic landmarks. Post-operative least-squares glenohumeral joint centres were calculated, and deltoid wrapping geometry modified accordingly.

Bilevel optimization minimizing scapula tracking error specified scapulothoracic joint ellipsoid geometry. An iterative approach calculating musculotendon (MTU) properties used strict criteria to determine optimal muscle fibre and tendon slack lengths that produce normalized fibre lengths within [0.5,1.5], and initial lengths within ±0.10 in similar motions in the target model. Computed Muscle Control (CMC) determined muscle activations.

Results

Inverse Kinematics RMSE distances were 4.5±0.6mm. Fig.1 shows CMC-calculated deltoid activations. Peak glenohumeral Joint Reaction Forces (JRF) were 95.1±21.0%BW for FE and

94.1±15.8%BW for SA. JRFs at 90° humerothoracic elevation were 71.5±11.1%BW for FE and 74.8±13.7%BW for SA.



Discussion

CMC-EMG activations show moderate agreement. Peak JRFs fall within reported ranges for controls, and 90° JRFs are within RTSA ranges.

Strengths of this work are the automation of a commonly manual process and comparison against EMG. Quantifiable, measurable workflows are required for elucidating clinical conclusions, and understanding how methodological parameterization vs. personalization affect outputs.

Findings emphasize key areas to direct efforts developing clinically relevant upper-limb MSkMs. Geometric personalization alone is insufficient. MTU calibration requires improvement through suitable mapping of fibre lengths or collecting experimental measures of passive force. These varying limitations are insurmountable in isolation, and increased multi-disciplinary collaborative efforts are encouraged.

Effect of Glenoid Lateralization and Humeral Offset on Acromial and Scapular Spine Strains: Preliminary Results of an In-Vitro Active Shoulder Motion Simulator

Mrs Inês Santos[1], Ms Lea-Marie Ocker[1], Mr Daniel Ritter[1], Mrs. Maxi Tengler MD[1], Mr Patrick Raiss MD[2]

[1]Arthrex Department of Orthopedic Research, Munich, Bavaria, Germany. [2]OCM, Munich, Bavaria, Germany

Mrs Inês Santos

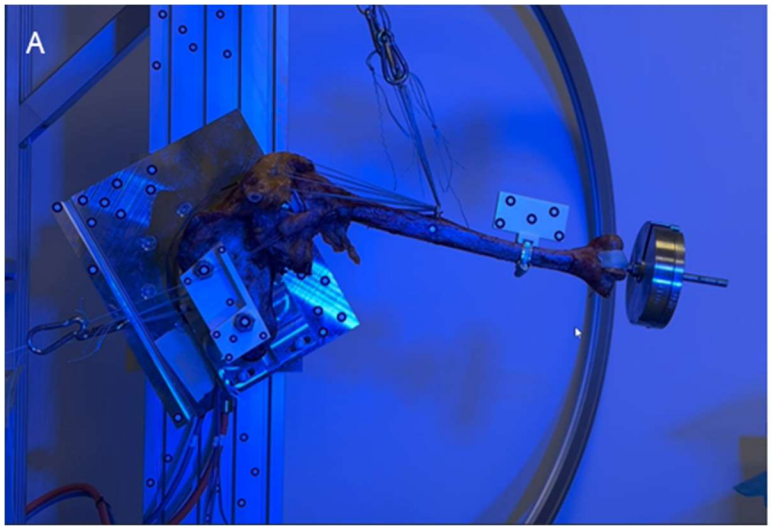
Ms Lea-Marie Ocker

Introduction

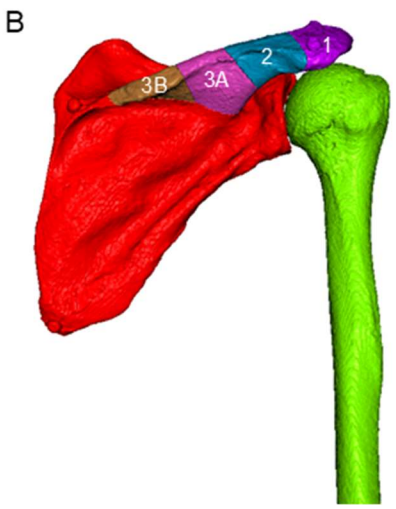
Acromial and scapular spine fractures after reverse total shoulder arthroplasty (RSA) can lead to substantial functional impairments, and the few biomechanical studies investigating this effect do not show consistent results. The purpose of this ongoing cadaveric biomechanical simulator study was to evaluate the role of glenoid lateralization and humeral offset on scapular spine strain.

Methods

Two fresh-frozen cadaveric shoulders with an implanted RSA were mounted to an active motion shoulder simulator (Fig.1A). The three portions of the deltoid were individually sutured with FiberTape to ensure force distribution along each insertion and routed to electric linear actuators with force transducers. The subscapularis and infraspinatus/teres minor were each loaded with 10 N, and the supraspinatus was removed to simulate rotator cuff tear. Four strain gauges were placed in Levy scapular spine fracture zones [1] (Fig.1B) to measure microstrain (strain $x10^{-6}$). Optical tracking markers were attached to the humerus and scapula, allowing the acquisition of physiological kinematic data [2]. Abduction at 7°, 20°, 40°, 60°, and 90° was simulated in the scapular plane and a glenohumeral to scapulothoracic motion ratio of 2:1 was applied [3], for three RSA design configurations: (1) 0 mm glenoid and humeral offset, (2) +4 mm glenoid offset and (3) +6 mm humeral offset.



Results



Strains measured in Levy zones 1 and 2 were higher than all other regions. The greatest increases in strain due to RSA design change were observed in Levy zones 3A and 3B. Increased humeral offset resulted in higher strain increases in zone 3A than glenoid lateralization. Increasing humeral offset led to an average increase of 36.79±4.95 in Levy zone 3A and 28.88±5.54 in Levy zone 3B. Strains in all regions were associated with increases in arm elevation.

Discussion

Increasing glenoid lateralization and humeral offset, despite its advantages in improving range of motion, increases scapular spine strains. Understanding the relationships between RSA implant design and acromial and scapular strains is crucial for optimizing outcomes and avoiding complications.

Differences in Glenohumeral Joint Function in Individuals with Symptomatic Isolated Supraspinatus Tears and Healthy Controls

Ms. Lidya Canturk BS[1], Ms. Clair Smith MS[2], Dr. Luke Mattar PhD[3], Dr. Adam Popchak PhD[2,3], Dr. William Anderst PhD[3,1], Dr. Volker Musahl MD[3,1], Dr. James Irrgang PT PhD FAPTA[2,3], Dr. Richard Debski PhD[1,3]

[1]Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States. [2]Department of Physical Therapy, University of Pittsburgh, Pittsburgh, PA, United States. [3]Department of Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Individuals with a rotator cuff tear experience impaired shoulder function, such as restricted range of motion (ROM), decreased strength, and posterior capsule tightness [1]. The objective was to determine the differences in maximum active glenohumeral elevation, isometric strength, and passive ROM in individuals with a symptomatic isolated supraspinatus tear in comparison to healthy controls up to 5 years after a 12-week personalized exercise therapy program.

Methods

One hundred and nine individuals with symptomatic isolated supraspinatus tear (age 60.9 ± 9.9 years, BMI 28.7 ± 5.0 kg/m^2, 48.6% females), and 63 sex-, age-, and hand-dominance frequency matched healthy controls (age 61.4 ± 9.9 years; BMI 26.6 ± 5.6 kg/m^2; 46.0% females) were enrolled in the study. Maximum glenohumeral elevation was quantified during active scapular plane abduction using biplane radiography; isometric strength measured with a dynamometer; and passive glenohumeral ROM measured with a goniometer were determined at 3-time points for subjects with a tear and at a single time point for healthy controls [2]. Outcomes were compared between groups with independent samples t-tests (two-sided, α=0.05)

Results

The maximum active elevation in healthy controls was significantly greater than individuals with a symptomatic isolated supraspinatus tear at baseline ($p<0.01$), 12 weeks ($p<0.01$), and 5 years ($p<0.01$) (Figure 1A). At baseline ($p<0.001$) and 12 weeks ($p<0.01$), isometric strength was decreased in comparison to controls across both tasks; however, at 5 years,

no differences were found between the tear and control groups (Figure 1B). Differences in passive ROM for abduction ($p<0.03$) and internal rotation at 90° abduction ($p<0.02$) between the tear group and healthy controls were observed (Figure 1C).

Discussion

The findings indicate that even though similar isometric strength was observed in individuals with a supraspinatus tear at 5 years compared to healthy controls, differences in active in-vivo glenohumeral elevation and passive ROM may imply impaired neuromuscular control of the shoulder complex and passive glenohumeral joint function, respectively. Thus, activity limitations and participation restrictions need to be further investigated and may warrant changes in and/or additional personalized exercise therapy.

Images (Optional)

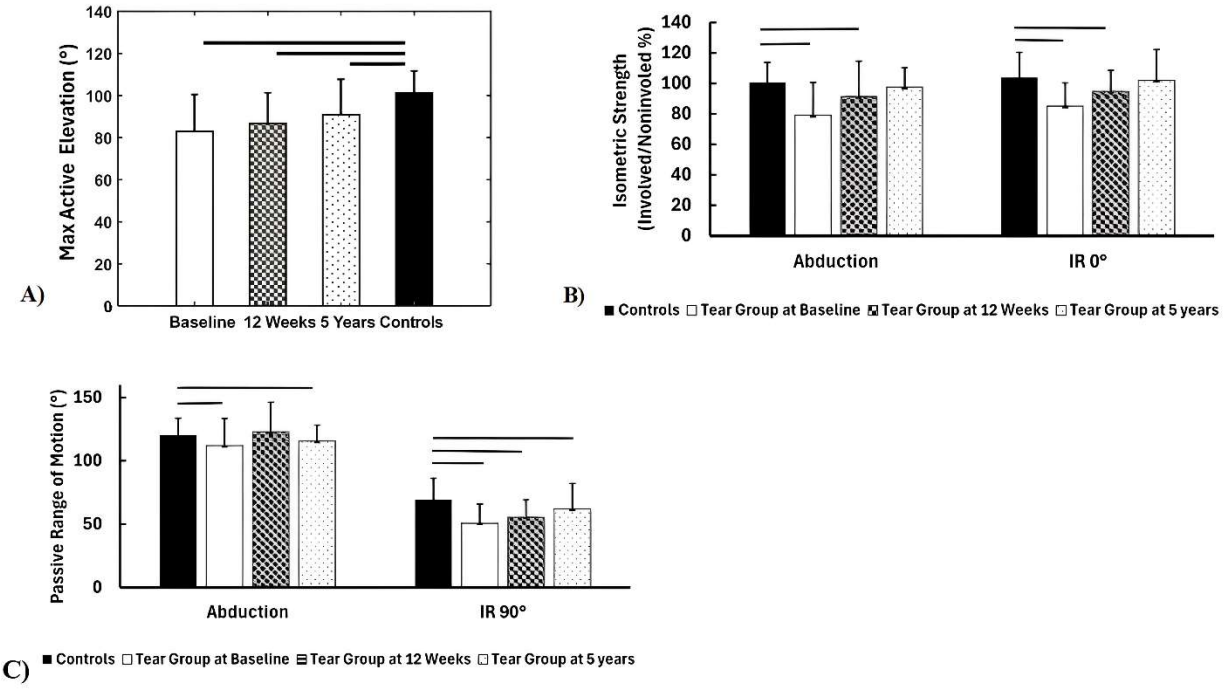

Figure 1. A-B-C) Maximum active elevation, isometric strength, and passive ROM at baseline (n=102,109,109), 12 weeks (n=96,95,95), and 5 years (n=67,76,76) for individuals with an isolated supraspinatus tendon tear and at baseline for healthy controls (n=61,63,63) (Sample sizes differed from the total number of participants in the study due to lost to follow-up and missing data).

[3]Medical Device Innovation Center, National Cheng Kung University, Tainan, Taiwan, Taiwan

Ms. Lu Yen

Assistant Professor Chieh-Hsiang Hsu

Assistant Researcher Fellow Charlie Chen Ma

Introduction

True motor expertise lies in the mastery of fundamental elements. While traditional metrics (e.g., standard deviation) capture overall stability, they miss the temporal-spectral dynamics of motor variability. This study utilizes Discrete Wavelet Transform (DWT) to investigate whether skilled pianists (SS) employ distinct neuromuscular strategies during fundamental tasks (T1-T4) compared to amateurs (SA), hypothesizing that experts demonstrate superior "spectral efficiency."

Methods

Two groups (fifteen subjects each), Skilled (SS, >10 years training) and Amateur (SA, <5 years), performed fundamental tasks on a force-instrumented piano (1000 Hz) [1]. Tasks included single-finger tapping (T1), simultaneous chords (T2-T3), and sequential movements (T4). We applied DWT to decompose vertical force signals into Approximation (low-frequency) and Detail (high-frequency) bands. Key features extracted were Wavelet Energy Ratio and Wavelet Entropy to quantify control complexity and spectral energy distribution. Independent t-tests compared groups ($p < 0.05$).

Results

Analysis revealed distinct control signatures even in the simplest tasks. In T1 (single-finger), Amateurs exhibited a significantly higher Energy Ratio in the low-frequency A5 band compared to Skilled pianists ($p < 0.05$), alongside higher force variability (SD_A5). This indicates Amateurs rely on "reactive" gross motor corrections to maintain stability. Conversely, Skilled pianists displayed a balanced energy profile across T1-T4, achieving stability with optimized spectral energy, reflecting a "predictive" and automated control strategy free from excessive corrective noise.

Discussion

We successfully identified a "spectral signature" of expertise in fundamental movements. Amateurs' reliance on low-frequency energy suggests an inefficient, feedback-dependent strategy, while experts exhibit high spectral efficiency. These findings validate wavelet-based metrics as sensitive biomarkers for motor skill. Clinically, this protocol offers a simplified assessment tool for detecting fine motor deficits (e.g., in Parkinson's disease) by analyzing spectral properties of basic tapping, eliminating the need for complex testing tasks.

The Role of Palmaris Longus in the Generation of Wrist Flexion-Extension Torque: What Is the Consequence of Harvesting It for a Tendon Graft?

Mr. Mahdi Mohseni, Dr. Angela Kedgley

Department of Bioengineering, Imperial College London, London, Greater London, United Kingdom

Introduction

The palmaris longus (PL) tendon is widely harvested as a graft for surgical procedures [1]. PL has the largest wrist flexion moment arm; however, its physiological cross-sectional area is small compared to other forearm muscles [2]. This study aimed to determine the effect of PL tendon removal on the wrist flexion-extension torque (FET). We hypothesised that due to PL's large moment arm, the subsequent changes in other muscle forces in the absence of PL would increase the wrist FET.

Methods

An 11-muscle dynamic physiologic hand simulator was used with a three degree of freedom (two for wrist and one for fingers) custom-made hand model. The hand was mounted with the fingers pointed vertically upward. Kinematics were input into a PID-based cascade controller to recreate six cycles of 40° wrist flexion-extension, with the fingers held in a neutral posture. Simulated muscle forces were applied via cables by servo-linear actuators and were controlled with feedback from loadcells. FET and optimised muscle forces were calculated with and without the PL.

Results

Kinematic root mean square (RMS) errors of flexion-extension for both conditions were ≤ 0.35°. The maximum of the mean force applied by PL was 8.2 N, resulting in an 18.0 N.cm FET (Figure 1). After PL removal, the forces applied by two other wrist flexor muscles, flexor carpi ulnaris and radials, were increased (RMS of mean changes = 6.8 N and 9.1 N, respectively). Consequently, the RMS of the mean FET difference between the two conditions was 30.3 N.cm. The changes in other muscle forces increased the FET by 8.5% of its maximum value.

Discussion

Wrist flexion is a fundamental part of everyday activities. As a repetitive task, the increase in the wrist flexor forces and FET in the absence of PL may increase the risk of wrist injury. PL plays an important role in reducing the other wrist flexor muscle forces and, therefore, reducing the total wrist FET. Thus, it is recommended to harvest tendon grafts from other donor sites, such as plantaris [1].

The Impact of Pectoralis Minor Tightness and Subsequent Interventions on Scapular Kinematics: A Systematic Review

Dr. Marcos Amstalden Barros MD[1,2], Dr. Renato Miyadahira MD[2], Ms. Vennela Challagondla BS, MPH[3], Dr. Caroline Popovicz Nunes MD[1,2], Dr. Tiago Zimerman MD[1,2], Dr. Felipe F. Gonzalez MD[1,2], Dr. Jonathan A. Gustafson PhD[1,2], Dr. Grant E. Garrigues MD[1,4], Dr. Gregory Nicholson MD[1,4], Dr. Jorge Chahla MD, PhD[1,4], Dr. Gustavo Leporace MSc, PhD[2], Dr. Leonardo Metsavaht MD, PhD[2]

[1]Rush University, Chicago, IL, United States. [2]Instituto Brasil de Tecnologias da Saúde (IBTS), Rio de Janeiro, RJ, Brazil. [3]The University of Illinois Chicago, Chicago, IL, United States. [4]Midwest Orthopaedics at Rush, Chicago, IL, United States

Introduction

Pectoralis minor (PM) tightness contributes to altered scapular mechanics, postural deviations, and shoulder dysfunction. Muscle shortening may increase scapular anterior tilt and internal rotation, restricting scapulothoracic motion and narrowing the subacromial space. However, the extent of scapular and spinal compensation remains unclear, and the comparative effectiveness of stretching, manual therapy, exercise, and surgical release has not been systematically reviewed. This systematic review aimed to evaluate biomechanical and postural alterations associated with PM tightness and determine whether targeted interventions improve scapular kinematics and thoracic alignment.

Methods

This review followed PRISMA 2020 guidelines. Eligible studies included clinical or biomechanical investigations assessing PM tightness, scapular motion, thoracic or cervical alignment, or targeted interventions. Databases searched included PubMed/MEDLINE, Scopus, Embase, CINAHL, CENTRAL, and Google Scholar (2004–2024). Screening, data extraction, and risk-of-bias assessment were performed using NIH/NHLBI tools. Given substantial heterogeneity, results were synthesized qualitatively.

Results

Forty-nine studies met inclusion criteria, representing 2,644 analyzed shoulders (Table 1). Cross-sectional research showed that PM tightness was associated with greater scapular anterior tilt and internal rotation, scapular dyskinesis, and altered postural patterns.[1,2] Interventional trials indicated that PM stretching, proprioceptive neuromuscular

facilitation, self-myofascial release, and scapular stabilization exercise increased PM length and improved scapular kinematics, pain, and function.[3] Multimodal exercise programs produced longer-term improvements in forward shoulder posture, pain, and mobility.[3] External supports such as figure-8 bracing acutely improved scapular alignment and muscle activation patterns. Surgical PM release was effective for refractory cases.[4]

Discussion

Across diverse populations and methodologies, PM tightness was associated with altered scapular kinematics and postural deviations. Interventions targeting PM length, including stretching and stabilization programs, demonstrated improvements in scapular motion, posture, and symptoms. Surgical release was effective for select refractory cases. Future research should standardize measurement methods and intervention parameters to improve comparability and guide clinical application.

Table 1. Summary of Included Studies on Pectoralis Minor Tightness and Interventions

Category	Key Focus	Main Outcomes / Findings
Overall Sample	49 studies; 2,644 shoulders	Clinical and biomechanical investigations of pectoralis minor tightness, scapular motion, posture, and interventions
Cross-sectional Studies	PM tightness vs scapular & postural variables	Increased scapular anterior tilt, internal rotation, scapular dyskinesis, and forward shoulder posture
Stretching & Manual Therapy	PNF stretching, self-myofascial release, soft-tissue mobilization	Immediate increases in PM length; improvements in scapular kinematics, pain, and function
Exercise Programs	Scapular stabilization & flexibility training	Longer-term improvements in posture, pain, and shoulder mobility
External Supports	Figure-8 bracing and postural supports	Acute improvements in scapular alignment and muscle activation patterns
Surgical Intervention	Pectoralis minor release for refractory cases	Improved pain, motion, and function in persistent scapular dyskinesis

Table 1. Summary of biomechanical and clinical findings from 49 studies (2,644 shoulders) evaluating pectoralis minor tightness and related scapular and postural alterations. Cross-sectional studies consistently associated PM tightness with increased scapular anterior tilt, internal rotation, and dyskinesis. Interventional studies demonstrated that stretching, manual therapy, exercise programs, and external supports improved PM length, scapular mechanics, posture, and symptoms. Surgical pectoralis minor release was effective for refractory cases.

Design and Preliminary Validation of an In-Vitro Elbow Joint Simulator for Quantitative Assessment of Injury-Related Kinematics

MSc. Mateus Enzenberg, Dr. med. Lukas Dankl, Curator Romed Hoermann, Univ.-Prof. Dr. med. Rohit Arora, Univ.-Prof. Dipl.-Ing. (FH) Dr. Werner Schmoelz

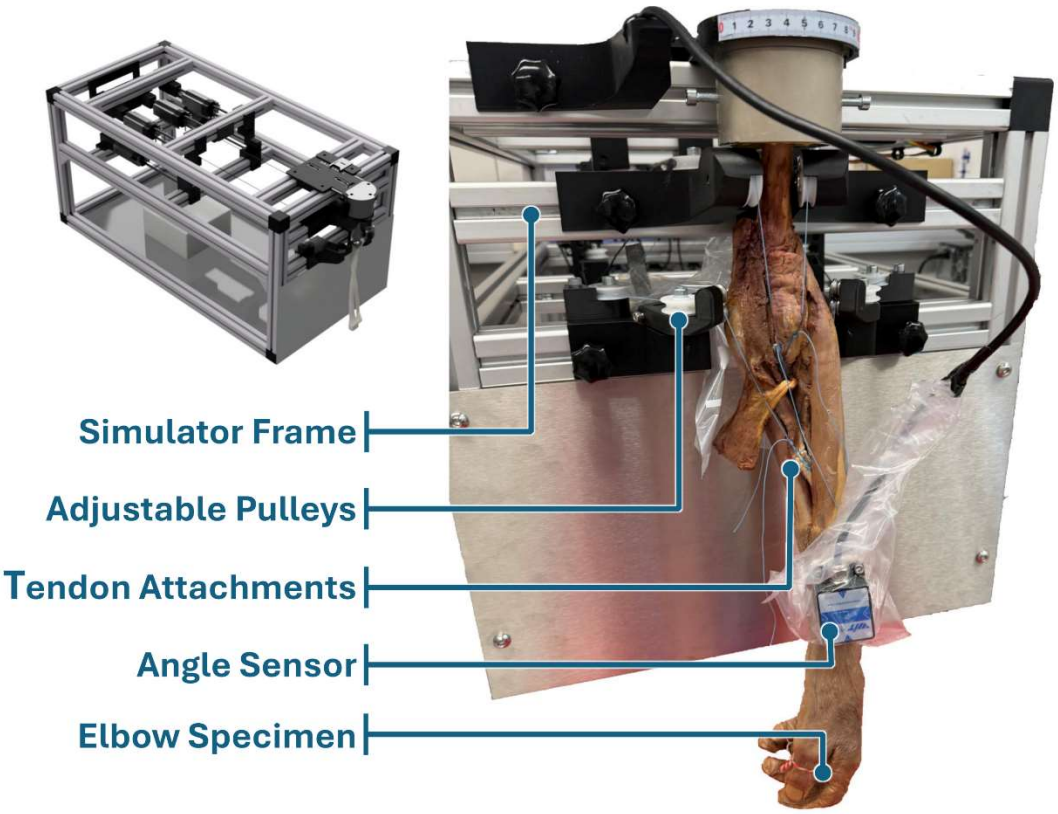
Medical University of Innsbruck, Innsbruck, Tyrol, Austria

Introduction

Elbow injuries can alter joint motion and affect upper limb function. Understanding these effects supports decisions on the need for surgical intervention and rehabilitation planning. Existing test setups that aim to identify such changes often lack the ability to produce repeatable physiological motions. In vitro simulators that apply controlled muscle-driven actuation offer a platform to study elbow kinematics under defined conditions.

Methods

An active elbow joint simulator was developed to reproduce flexion and extension by applying physiologically driven muscle forces. Tendons of a cadaveric elbow specimen were connected to electromechanical actuators through high strength braided suture strands routed along anatomical paths (see Figure 1). Actuators were moved using a cascaded control strategy based on estimated muscle forces and activation profiles. Each actuator features a defined elastic element to more closely mimic physiological muscle behavior. The humerus was mounted in a defined orientation, and an angle sensor attached to the wrist was used to capture joint kinematics. Flexion-extension cycles were performed at different forearm rotations and loading conditions. Following intact testing, a radial neck osteotomy was performed to simulate a radial head fracture and enable preliminary evaluation of the injured state.



Results

The simulator reproduced controlled elbow flexion between 0° and 120° while maintaining forearm orientations at neutral, pronated, and supinated targets. Rotational positioning remained within ±3° of the intended angles. Muscle force trajectories were highly repeatable, with mean cycle-to-cycle RMSE values between 0.14 and 1.23 N across actuators (maximum 3.3 N) in neutral configuration. After the radial neck osteotomy, the specimen demonstrated similar flexion profiles while rotational deviations increased, suggesting that the system can detect changes in forearm motion associated with the simulated injury.

Discussion

The designed and constructed simulator was able to produce consistent elbow motion and enabled continuous measurement of joint kinematics and muscle forces. The intact tests demonstrated stable control of flexion and forearm orientation. The injured configuration showed altered rotational behavior, indicating that the setup can detect the changes in joint mechanics. Ongoing work focuses on expanding tests across multiple specimens and incorporating defined external joint loading to investigate additional clinically relevant injury patterns.

Validation of an Upper Limb musculoskeletal Model Against Cadaverix Muscle Moment Arms and Instrumented Implant Data

Dr Maxence Lavaill PhD[1,2], Prof Peter Pivonka PhD[1], Dr Ehsan Sarshari PhD[2]

[1]Queensland Univerisity of Technology, Brisbane, QLD, Australia. [2]Stryker GmbH, Selzach, Solothurn, Switzerland

Introduction

Accurate estimation of shoulder muscle forces and glenohumeral (GH) joint loading is essential for understanding shoulder function, guiding rehabilitation, and informing implant design. While musculoskeletal (MSK) models provide powerful non-invasive estimates, their validity remains dependent on comparisons with high-quality experimental data. This study validates an upper-limb MSK model, previously developed by Sarshari et al. [1], through two complementary approaches: (1) comparison of model-derived muscle moment arms against cadaveric reference datasets [2], and (2) direct validation of predicted GH joint reaction forces using *in vivo* measurements from an instrumented shoulder prosthesis (OrthoLoad) [3].

Methods

The MSK model (Figure 1A-1B) was adapted to match the anatomy of six OrthoLoad patients implanted with an instrumented hemi shoulder arthroplasty. A 2.4 kg weighted abduction task was simulated to drive the model. Muscle moment arms for major shoulder muscles were computed across the elevation range and compared to published cadaveric values [2]. Predicted GH joint reaction forces were then compared to *in vivo* implant data [3], with detailed analysis presented for the representative patient S8R.

Results

Model-predicted moment arms of patient S8R showed strong agreement with established cadaveric datasets, capturing both magnitude and functional trends across elevation angles (Fig1C). Validation against the OrthoLoad implant demonstrated high correspondence between predicted and measured GH joint forces during weighted abduction (Fig1D). Model–implant agreement remained consistently close across the full task, with errors ranging from –104 to +68 N and an average absolute error of 53 N.

Discussion

This study provides robust validation of the upper-limb MSK model [1] through comparison with cadaveric moment arm data and *in vivo* implant data. The high agreement observed,

particularly the close replication of GH joint forces in S8R, supports the model's ability to accurately estimate shoulder muscle mechanics and joint loading in arthroplasty patients. These findings strengthen the model's translational potential for clinical evaluation, implant optimisation, and personalised rehabilitation planning. Future work will expand the validation to more patients and a broader range of shoulder tasks.

Capturing Wrist Kinematics Using Principal Component Analysis

Mr. Daniel McDermott Sc.B.[1], Dr. Nicola Sancisi Ph.D.[2], Dr. Michael Rainbow Ph.D.[3], Dr. Michele Conconi Ph.D.[2]

[1]Harvard Medical School, Boston, MA, United States. [2]University of Bologna, Bologna, BO, Italy. [3]Queen's University, Kingston, ON, Canada

Introduction

Principal component analysis (PCA) enables the compact description of the motion of a complex group of bones by intrinsically capturing the kinematic coupling introduced by fibrous tissues and articular contacts. The benefits of this approach have been recently demonstrated for the foot [1], where four motion synergies explained more than 95% of the total mobility. In this work, we test the same approach to represent wrist kinematics.

Methods

We used segmented CT scans of 9 wrists in 11 postures [2]. We defined a novel anatomical reference system (ARS) for each carpal bone in the neutral scan, using a morphological approach designed to optimize kinematic description by minimizing the cross-talk among motion components. Neutral bones were registered on all the other postures, expressing the bone's relative pose using a variation of the Grood and Suntay convention for the wrist. Like the foot [1], we performed PCA on the bone poses, searching for the minimum number of synergies that explain more than 90% of the total variability. We used correlation coefficients to test if synergies are constant within the population.

Results

Two synergies explained more than 91.9% of the total motion variability in all 9 subjects. The first synergy maps flexion and extension, and the second the radial-ulnar deviation (Fig. 1). Both synergies are highly correlated across wrists: 0.96 for the first synergy and 0.89 for the second synergy.

Discussion

Synergies allow a compact description of intrinsic kinematic coupling of carpal bone motion: PCA results suggest that the wrist can be considered as a 2-degree system, which aligns with the clinical perspective, to which all the bones participate at once. This information may help identify abnormal carpal bone motion in patients and support

treatment and device innovation to advance patient care, for instance by the definition of detailed musculoskeletal models of the wrist.

Reliability and Concurrent Validity of a Commercially Available Load Cell Dynamometer in Measuring Shoulder Rotational Torque and Rate of Torque Development

Lieutenant Commander Pollyanna Crane PT, DPT[1], Dr. Shawn Stout PT, DPT, DSc[1], Dr. Gregory Freisinger PhD[2], Dr. Jamie Morris PT, DPT, DSc[1], Dr. Will Pitt PT, DPT, PhD[3]

[1]Keller Army Community Hospital - Baylor University Division 1 Sports Physical Therapy Fellowship, West Point, NY, United States. [2]United States Military Academy, West Point, NY, United States. [3]University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Shoulder rotational strength deficits are common in individuals with shoulder injuries or who have undergone shoulder surgery. Both strength and rate of force development (RFD) are important considerations when determining athletes' readiness to return to sport or activity. Manual muscle tests are commonly used in clinical practice, however only provide categorical strength ratings and demonstrate a ceiling effect in stronger individuals. Isokinetic dynamometers (IKD) are considered the gold standard in muscle testing, but are rare in clinics due to high costs. Hand-held dynamometers (HHD) are useful alternatives, but do not measure RFD. The Tindeq-Progressor (TP) (BLIMS, AS, Norway) is an inexpensive dynamometer that measures peak force and RFD. The TP has demonstrated accuracy and repeatability in measuring tension loading, and is superior to the HHD in assessing knee extension torque. Reliability and validity using the TP for shoulder rotational strength has not been assessed.

Methods

External (ER) and internal rotation (IR) neuromuscular function were assessed in 12 healthy participants (24 limbs) using the TP and IKD (HUMAC NORM, Stoughton, MA) in the seated position. Order of device testing and side tested were randomized. Three 2-second isometric warm-up repetitions were completed at 50%, 75% and 90% effort. This was followed by three 2-second maximal isometric contractions with 30-seconds of rest between repetitions. Participants were cued to push as hard and as fast as possible. Force and RFD were converted to torque and RTD to compare values with the IKD. Reliability and concurrent validity were assessed with intraclass correlation.

Results

The TP had excellent intra-rater reliability for all shoulder peak torque measures, and for ER RTD. The TP had poor to moderate intra-rater reliability for shoulder IR RTD. Agreement with

the gold standard was good to excellent for all peak torque measures. Concurrent validity for RTD was poor for all measures.

Discussion

The TP showed excellent reliability and validity for measuring shoulder rotational peak torque, indicating it may serve as a practical alternative to traditional strength assessments. RTD showed substantial variability between assessments, indicating the need for more controlled testing conditions to improve measurement accuracy.

Stemmed Pyrocarbon in Shoulder Hemiarthroplasty: Functional Outcomes and Complications Compared With CoCrMo Alloy—a Systematic Review and Meta-analysis

Dr. Renato Miyadahira MD[1], Mr. Robin Pelia[2], Dr. Marcos Amstalden Barros MD[3,1], Dr. Robin Pourzal PhD[3], Dr. Marcus A. Wimmer PhD[3], Dr. Grant E. Garrigues MD[3,4], Dr. Jonathan A. Gustafson PhD[3,1]

[1]Instituto Brasil de Tecnologias da Saúde (IBTS), Rio de Janeiro, RJ, Brazil. [2]University of Illinois Chicago (UIC), Chicago, IL, United States. [3]Rush University Medical Center, Chicago, IL, United States. [4]Midwest Orthopaedics at Rush, Chicago, IL, United States

Introduction

Conventional metal hemiarthroplasty is often complicated by painful glenoid erosion between cobalt–chromium–molybdenum (CoCrMo) alloys and cartilage. Pyrocarbon (PyC), with an elastic modulus closer to bone and favorable tribological properties, has been proposed as a bone-preserving alternative. The clinical performance of stemmed PyC implants, however, remains uncertain. We aimed to systematically review and meta-analyze the outcomes of stemmed PyC hemiarthroplasty, evaluating functional improvements compared with preoperative status and summarizing complications.

Methods

This review was registered with PROSPERO (CRD420251028801) and conducted following PRISMA guidelines. PubMed, Scopus, and Cochrane Library were searched on September/2023. Eligible studies included adult patients undergoing stemmed PyC hemiarthroplasty with ≥6 months follow-up, reporting range of motion (ROM), functional scores, complications, or revision causes. Random-effects models pooled pre to postoperative changes in ROM and Constant-Murley scores. Complications were summarized qualitatively. Risk of bias was assessed using the NIH Quality Assessment Tool.

Results

Twelve studies met inclusion criteria. Meta-analysis demonstrated significant postoperative improvements with stemmed PyC: active elevation +45.6° (95% CI 35.0–56.3), external rotation +18.0° (95% CI 11.3–24.7), internal rotation +9.0° (95% CI 0.4–17.6), and Constant-Murley score +42.8 points (95% CI 36.6–49.0) (all $p < 0.05$) (Table 1). Across

studies, gains ranged from +34.1° to +68.0° elevation, +5.5° to +27.0° external rotation, and +31.0 to +54.0 points Constant score. Heterogeneity was considerable for all outcomes (I^2=77–93%). Reported complications most frequently included rotator cuff insufficiency (n=10) and pain/overstuffing (n=8), followed by infection (n=4), humeral migration (n=2), glenoid erosion (n=1), and trauma (n=1).

Discussion

Stemmed PyC hemiarthroplasty provides clinically meaningful functional improvements compared with baseline, supporting its role as a bone-preserving option in younger, active patients. Nevertheless, high heterogeneity, small observational cohorts, and variable outcome definitions limit the certainty of these findings. While registry and in-vitro evidence suggest potential advantages over metal implants, consistent clinical superiority remains unproven. Stemmed PyC hemiarthroplasty improves range of motion and functional scores compared with preoperative status, with complications most often related to cuff insufficiency and implant sizing. High quality prospective studies with standardized outcome reporting and long term follow-up are required to clarify its comparative role against conventional metal implants.

[5]Research Institute, BC Children's Hospital, Vancouver, British Columbia, Canada. [6]Department of Orthopedics, Faculty of Medicine, UBC, Vancouver, British Columbia, Canada. [7]Outpatient Orthopedic Clinic, BC Children's Hospital, Vancouver, British Columbia, Canada

Introduction

The Motion Lab (TML), BC Children's Hospital performs gait analysis using motion capture (MoCap), focusing on lower extremities. As TML delves into upper extremity research, a suitable MoCap model is required. Pre-existing models require numerous markers [1], which can cause discomfort, hinder movements, and there may be insufficient space on a child's arm for all markers. Other models are complex, involving shoulder and trunk kinematics [2], which is beyond TML's interest in elbow range of motion (eROM). Comparison studies between marker-based and markerless MoCap for upper extremities are limited [3]. This project aims to compare simplified marker-based upper extremity models with markerless data for future research.

Methods

Retro-reflective markers are placed on anatomical landmarks on the arms. Participants performed elbow extension-flexion movements. Data was collected using Qualisys MoCap system (12 Oqus, 12 Miqus cameras). Two variations of marker models were explored: (1) markers were placed at three shoulder landmarks (anterior acromion (AA), posterior acromion (PA), Neviaser's Portal (NP)) to define the humeral vector; (2) two combinations of tracking markers were used to track the humerus ((a) one upper arm cluster, medial and lateral humeral epicondyles; (b) two upper arm clusters and lateral humeral epicondyle), resulting in six models. Markerless data was processed with Theia. All data was analysed using Visual3D. Each model's eROM was compared to clinical exam for validation.

Results

Participant 1 (female, 20y) had 0.0° extension and 145.0° flexion during clinical exam (Figure 1). At extension, Variation 2a's marker-based angles were 8.0° (AA), -1.0° (PA) and 4.0° (NP); variation 2b found 9.0° (AA), 0.0° (PA) and 5.0° (NP); markerless was 5.0°. At flexion, Variation 2a's marker-based angles were 141.0° (AA), 133.0° (PA) and 137.0° (NP); variation 2b found 148.0° (AA), 138.0° (PA) and 143.0° (NP); markerless was 155.0°.

Discussion

Compared to clinical eROM, PA and Variation 2a were the closest at flexion; NP and Variation 2b closest at extension. Markerless data presented flexion bias at both end ranges. Additional participant data is required for further analysis.

Images (Optional)

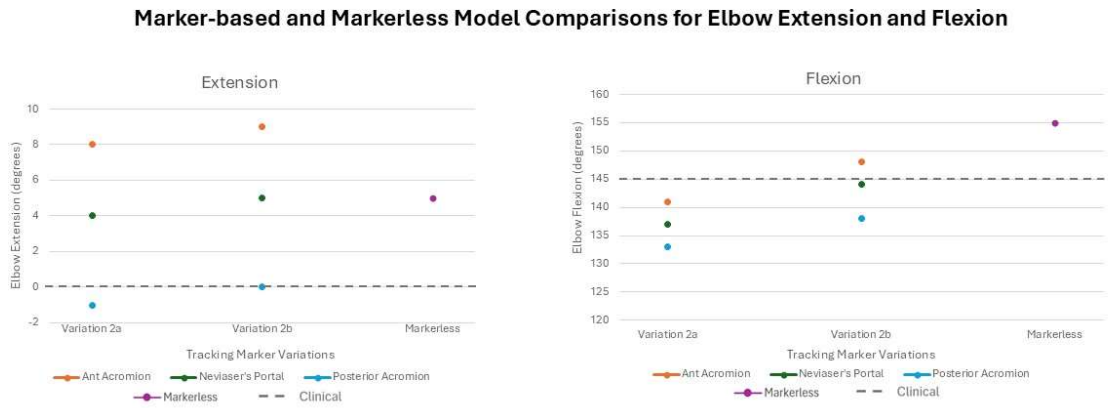

Figure 1 – Elbow extension and flexion using various marker-based models and markerless MoCap compared to clinical exam (grey dotted line). Combinations of each variation: shoulder markers (Anterior Acromion: orange, Navieser's Portal: green, Posterior Acromion: blue), markerless (purple) and tracking markers (Variations 2a and 2b). Positive/larger angles represent flexion and negative/smaller angles represent extension.

Three-Dimensional Movement Variability is Not Associated with Fastball Accuracy in High School Baseball Pitchers

Ms. Tzu-Hsin Han, Mr. Yi-Hsuan Weng, Mr. Jiu-Jenq Lin

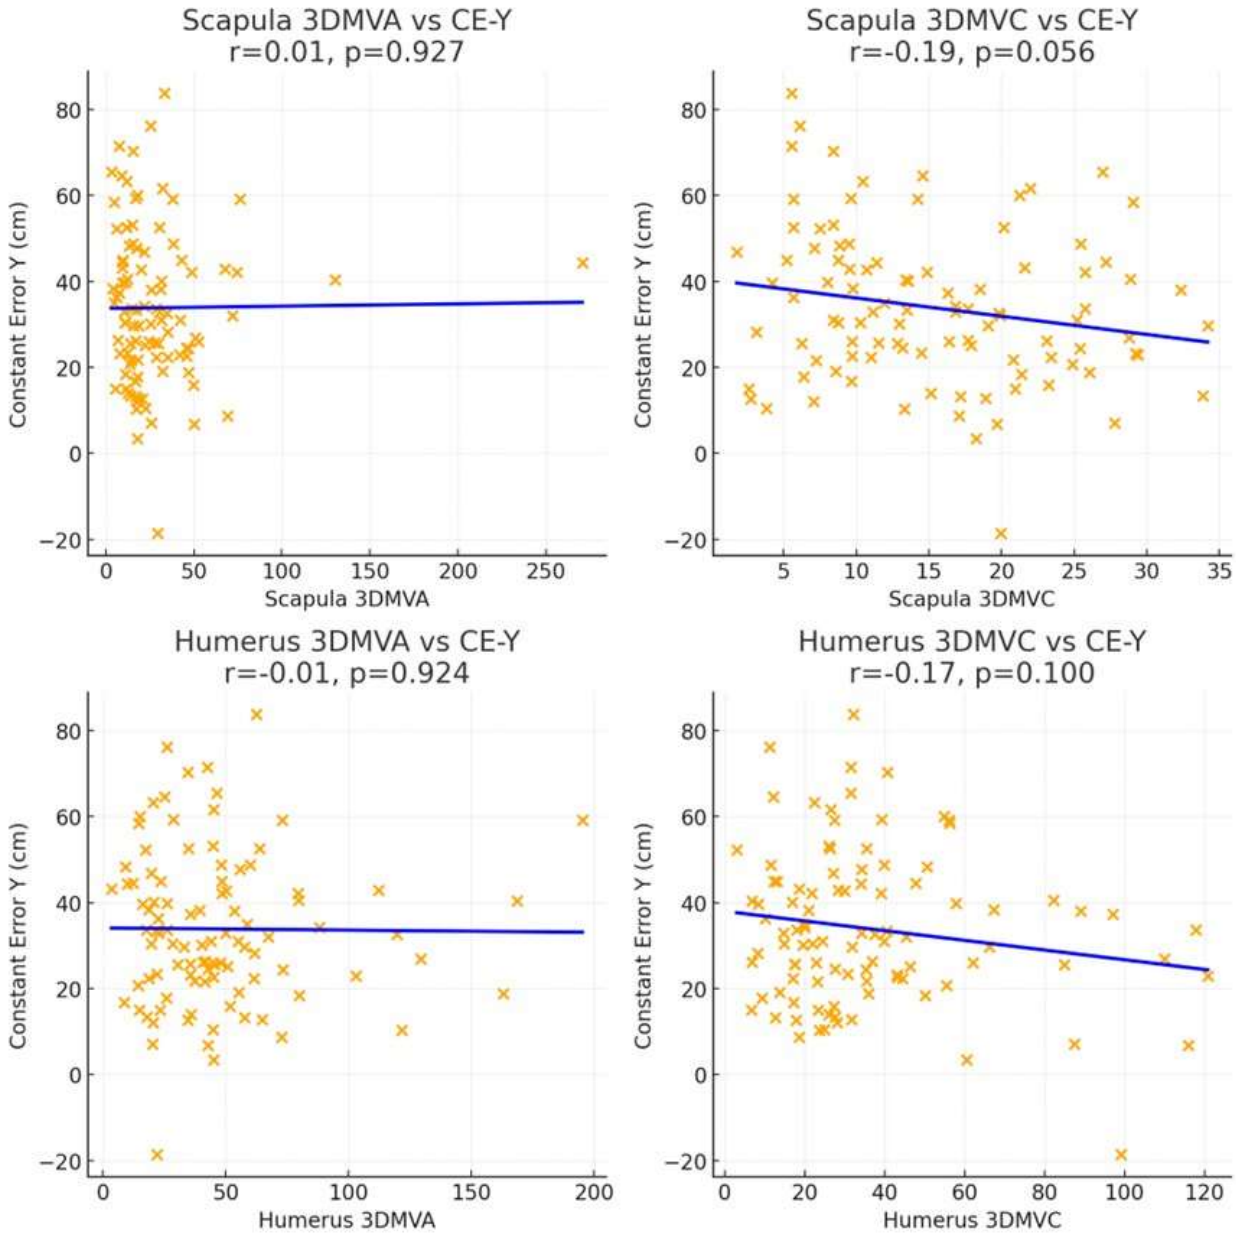
School and Graduate Institute of Physical Therapy, College of Medicine, National Taiwan University, Taipei, Taiwan, Taipei, Taipei, Taiwan

Introduction

Proprioception is crucial for coordinating the rapid, multiplanar motions required in baseball pitching. Pitchers often show altered shoulder position sense, impaired scapular control, and increased movement variability. These adaptations stem from conditions like glenohumeral internal rotation deficit. Proprioceptive deficits are linked to changes in muscle activation and pitching mechanics. However, it remains unclear if 3-Dimensional Movement Variability (3DMV) contributes to throwing accuracy. Given the accuracy's importance in both performance and injury prevention, this study examined the relationship between scapular/humeral 3DMV and fastball accuracy in high school pitchers.

Methods

One hundred and seven male high school players were recruited, with data from 68 players used for the final analysis. 3DMV was quantified as the trial-to-trial angular deviation of segmental kinematics. Variability was extracted at two key phases: 3DMVC (Cocking phase at maximum external rotation) and 3DMVA (Acceleration phase at ball release). Accuracy was determined using mediolateral (X-axis) and anteroposterior (Y-axis) absolute errors and constant errors in a controlled target task. Pearson correlations were used to test the associations between 3DMV and throwing accuracy.



Results

Scapular 3DMVC and 3DMVA averaged 15.1 ± 8.1° and 27.4 ± 32.8°, respectively. Humeral values were 35.9 ± 24.5° and 45.1 ± 31.4°, respectively. Average accuracy errors were 32.5 ± 8.8 cm (absolute X), 42.6 ± 13.4 cm (absolute Y), 15.5 ± 17.9 cm (constant X), and 33.6 ± 17.9 cm (constant Y). Correlations between 3DMVC and throwing accuracy were small and non-significant ($r \leq 0.19$, all $p \geq 0.056$). The strongest observed trend was between scapular 3DMVC versus anteroposterior constant error ($r = -0.19$, $p = 0.056$), suggesting that lower variability might be associated with a greater directional bias.

Discussion

Proprioception-related 3-dimensional movement variability was not clearly associated with throwing accuracy in high school pitchers. Pitching accuracy is likely a more complex skill, potentially depending more on factors such as visual-motor integration, tactical execution, or whole-body kinetic-chain coordination. Therefore, a multifactorial approach is necessary for performance assessment and the design of pitching training strategies.

Three-Dimensional Shoulder Biokinetics and Passive Range of Motion in "Strong" Versus "Weak" Shoulders With Subacromial Pain Syndrome and Contralateral Healthy Shoulders

Dr. Renato Miyadahira MD[1], Dr Felipe F. Gonzalez MD, MSc[2,1], Dr. Eliane Guadagnin PhD[1], Dr. William Felipone MD[1], Dr. Matheus Vilela MD[1], Dr. Marcos Amstalden Barros MD[2,1], Dr. Carolline Popovicz Nunes MD[2,1], Dr. Tiago Zimerman MD[2,1], Dr. Vitor La Banca MD[1], Dr. Grant E. Garrigues MD[2,3], Dr. Gustavo Leporace MSc, PhD[1], Dr. Leonardo Metsavaht MD, PhD[1], Dr. Jonathan A. Gustafson PhD[2,1], Dr. Jorge Chahla MD, PhD[2,3]

[1]Instituto Brasil de Tecnologias da Saúde (IBTS), Rio de Janeiro, RJ, Brazil. [2]Rush University Medical Center, Chicago, IL, United States. [3]Midwest Orthopaedics at Rush, Chicago, IL, United States

Introduction

Subacromial pain syndrome (SAPS) is a prevalent cause of shoulder dysfunction, frequently associated with rotator cuff weakness and altered kinematics. While strength deficits are well documented, the interplay between weakness and movement adaptations remains unclear. Our objective was to verify the effects of shoulder strength (weak and strong) and pathology (affected and contralateral healthy shoulder), and their interaction on passive mobility and shoulder kinematics.

Methods

Thirty-eight patients (24 were male and 14 female, with a mean age of 42 ± 11.8 years) with unilateral SAPS underwent bilateral biokinetic assessment, including passive range of motion with a digital inclinometer, isometric rotator cuff strength with handheld dynamometry (external and internal shoulder rotators), and three-dimensional motion capture during shoulder elevation in the scapular plane. Shoulders were classified as weak or strong using median splits of strength values from external rotators. A two-way repeated-measures analysis of variance was applied to evaluate the effects of pathology (affected and healthy) and strength (weak and strong) on glenohumeral, scapular, and humerothoracic kinematics, with post hoc tests conducted where appropriate. Effect sizes and 95% confidence intervals (CI) were reported.

Results

There was a significant interaction between Strength and Pathology for scapulohumeral rhythm below 90° during the eccentric phase ($F = 4.36$, $P = 0.040$) (Table 1). Post hoc analysis showed that this interaction was driven by differences between the affected-strong and affected-weak groups, with a moderate effect size (Cohen's d = 0.687, 95% CI [0.03, 1.34]). No additional main effects or interactions were observed for shoulder kinematics or passive range of motion, indicating preserved passive mobility across groups.

Discussion

Shoulder weakness amplifies the kinematic alterations associated with SAPS, particularly during eccentric lowering below 90° of elevation, whereas passive motion remains unaffected. These findings indicate that SAPS associated with weakness primarily disrupts dynamic motor control rather than structural mobility, emphasizing the clinical relevance of targeted strengthening and eccentric training to restore normal scapulohumeral coordination. Identifying whether targeted external rotator strengthening in SAPS can optimize shoulder mechanics offers a promising direction for future rehabilitation strategies.

Fascicle-Level Adaptation in SLAP Lesion Surgical Repairs

Dr. Wendy Murray PhD[1,2], Ms. Jorie Budzikowski MS[1,2]

[1]Northwestern University, Evanston, IL, United States. [2]Shirley Ryan AbilityLab, Chicago, IL, United States

Introduction

Superior labrum anterior to posterior (SLAP) lesion is an orthopaedic injury where the labrum and attached long head of the biceps tendon (LHBT) become detached from their glenoid origin. Three surgical repair options exist: (1) SLAP repair reattaches the labrum and LHBT to their glenoid origin, (2) tenotomy releases the LHBT and allows for distal retraction, and (3) tenodesis repair reattaches the tenotomized LHBT distally on the humerus. The rationale for choosing one intervention over another is debated; standardized functional assessment scores find few differences between interventions despite different patient reported outcomes for both satisfaction and return to activity [1]. Because biceps muscle-tendon geometry differs post-operatively, we hypothesize fascicle adaptation can differentiate surgical repair groups.

Methods

24 participants were enrolled (n=6 SLAP repair, n=6 tenotomy, n=8 tenodesis, and n=4 controls). EFOV-US images of the biceps were obtained, and fascicle lengths were measured in both arms using established methods [2]. We compared interlimb differences in fascicle length between the surgical and nonsurgical arms in participants with unilateral repairs and between dominant and nondominant arms in control participants.

Results

Our data suggest that surgical repair strategy influences chronic fascicle adaptation. Tenotomy exhibited the largest difference relative to the non-surgical limb (-18.2 +/- 4.3%). Fascicle lengths were also shorter (-10.1 +/- 3.7%) in the surgical limb for tenodesis, but less severely ($p < 0.003$). Interlimb differences in the SLAP repair (+4.5 +/- 5.0%) were not significantly different ($p = 0.982$) than controls (+4.5 +/- 7.1%).

Discussion

Surgical under-tensioning could be the impetus for shorter fascicle lengths observed in the tenotomy and tenodesis groups [3]. We observed larger interlimb differences in the control

group in this study than we observed in two previous studies where control participants did not participate in arm-dominant sports. Understanding fascicle adaptation and concomitant functional strength differences may help resolve debate about choice of surgical intervention. Our data also identifies fascicle adaptation associated with athletic activity as a potential confounding factor to be considered.

Images (Optional)

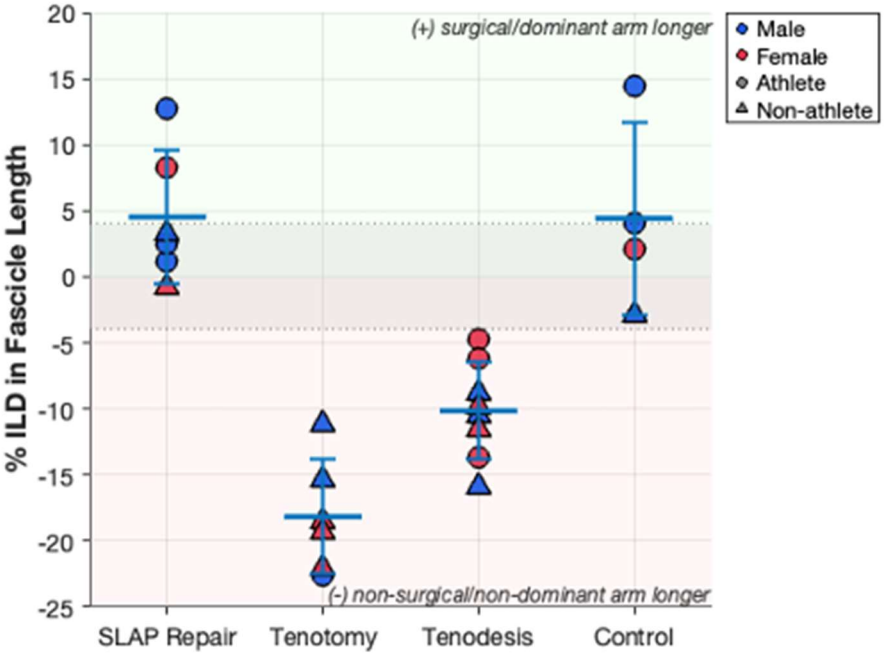

Figure 1: Interlimb difference in fascicle length. Circles indicate participants with a history of participation in unilateral, arm-dominant sports (e.g., baseball, softball, tennis, volleyball). Interlimb differences between ±4% fall within the resolution of our measurement methods [2].

Total Deltoid Force Magnitude Alone Is Insufficient to Predict Physiological Shoulder Motion

MS. Woonhoe Goo, Prof. Namkeun Kim

Sogang University, Seoul, Kyeonggi-do, Korea, Republic of

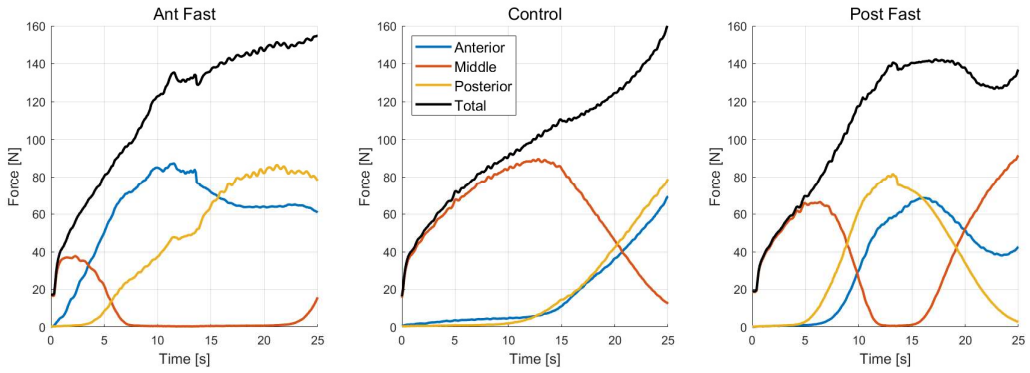
Introduction

Current cadaveric shoulder biomechanics protocols often simplify deltoid loading by focusing solely on total force magnitude. However, the deltoid consists of distinct anterior, middle, and posterior heads that act with unique moment arms [1]. We hypothesized that the vector distribution of force among these heads is the primary determinant of kinematic trajectory rather than the scalar total force. This study demonstrates that ignoring physiological force ratios leads to significant kinematic divergence even under identical total force conditions.

Methods

We utilized a custom force-controlled shoulder simulator with human cadaveric specimens. The anterior, middle, and posterior deltoid tendons were independently actuated to isolate the effect of force distribution. We applied three force profiles while keeping the total force constant. These conditions included a balanced profile with equal pulling force across all, an anterior-dominant profile where the anterior head force was predominant, and a posterior-dominant profile where the posterior head force was predominant. Real-time tendon forces were measured using load cells, and glenohumeral abduction angles were recorded using inertial measurement unit sensors.

Results



Despite comparable peak total forces across all three conditions, the resulting kinematics exhibited drastic divergence. The anterior-dominant condition caused significant deviation into the anterior plane and shifted away from the scapular plane. Conversely, the posterior-dominant condition led to significant external abduction. Only the balanced condition maintained a stable and physiological abduction trajectory. Analysis of total force versus abduction angle revealed distinct motion patterns and confirmed that identical total force magnitudes can produce opposing motions depending on the force ratio.

Discussion

These findings challenge the validity of using total deltoid force as an independent variable in cadaveric experiments. Mechanically, the deltoid acts as a vector sum, so neglecting the

physiological balance between the anterior and posterior heads generates erroneous kinematics. We conclude that force distribution ratio is the primary determinant of motion direction independent of force magnitude. Consequently, future cadaveric protocols must standardize target force ratios to ensure clinical relevance and the accurate reproduction of physiological shoulder kinematics.

Introduction

Ischemic strokes, caused by cerebral vessel occlusions, account for 55–90% of global stroke cases [1]. Mechanical thrombectomy is the gold-standard treatment; however, its impact on vessel mechanics and function remains poorly understood. Age-related changes in cerebral arteries, including increased stiffness and reduced vasodilatory capacity, further influence post-thrombectomy vessel behaviour [2]. Mechanical irritation from stent retrievers or aspiration catheters can induce vasospasms: transient constrictions that may affect device performance [3]. Therefore, tissue models that replicate the microstructural, mechanical, and functional properties of human cerebral arteries are needed to improve device testing as existing models inadequately capture this complexity. This study investigates whether porcine coronary arteries can serve as surrogates by characterising their microstructural, mechanical and functional properties

Methods

Uniaxial ring tests were conducted on left porcine coronary arteries (N = 5; n > 8 rings/animal). Each vessel was sectioned into 3-mm rings from the proximal to the distal regions. Testing began with a 0.05 N preload followed by five preconditioning cycles (0–10% strain at 10 mm/min) and then the samples were loaded to failure. Stress–strain curves were generated, and the initial and final moduli were calculated from the first and last 10% strain intervals, respectively. Linear regression analysis in GraphPad was used to determine coefficients of determination (R^2) for both moduli. Histology of proximal and distal

segments were stained with H&E, Picrosirius Red, Alcian Blue, and Verhoeff's to evaluate microstructural differences.

Results

Mechanical testing revealed a gradient along vessel length: distal segments exhibited lower failure strains and increased stiffness, with higher initial and final moduli. Histology showed reduced wall thickness in distal segments, especially in the medial layer.

Discussion

hese findings support further evaluation of porcine coronary arteries as models for aged cerebral vessels. Future work will compare these properties with human cerebral vessels [4] and quantify vasoactivity, providing a physiologically relevant tissue model for device testing.

Images (Optional)

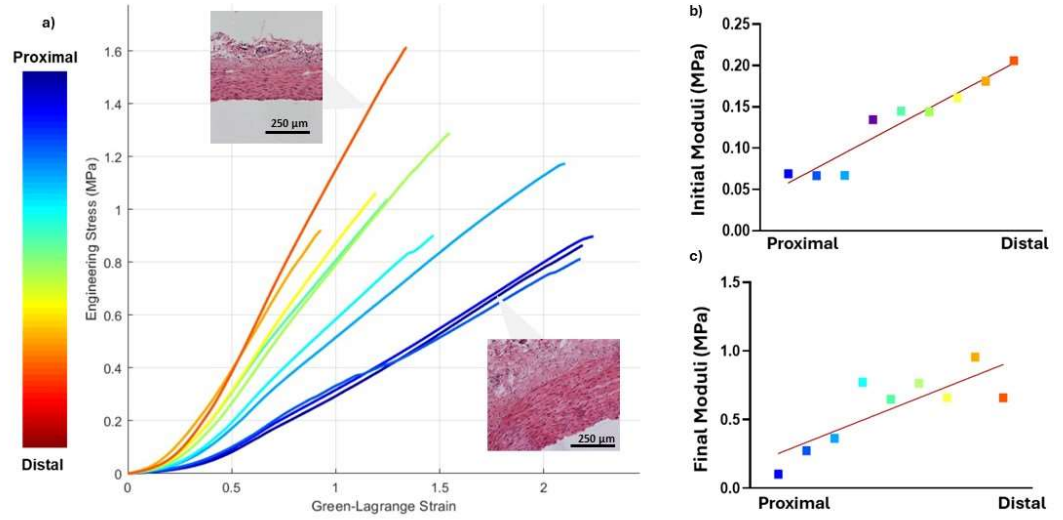

Figure 1: (a) Stress–strain curves of the left porcine coronary artery along its length. Representative H&E-stained images of the most proximal and distal segments are shown. (b) The initial (R^2 = 0.9190) and (c) final moduli (R^2 = 0.6581) along the vessel length are also presented (N = 1; n = 10).

Optimizing ultrashort-pulsed laser cutting of magnesium coronary stents for improved cut quality and mechanical performance

MSc João Cruz[1,2], MSc Diego Blunda[1,3], MSc Benedikt Bornschlegel[2], MSc Simon Pöstges[1], Dr.-Ing. Christian Rüdiger Hinke[2], Prof. Dr. rer. nat. Constantin Leon Häfner[2], Dr.-Ing. Alexander Kopp[1]

[3]School of Engineering and Institute for Health Discovery and Innovation, College of Science and Engineering, University of Galway, Galway, Galway, Ireland

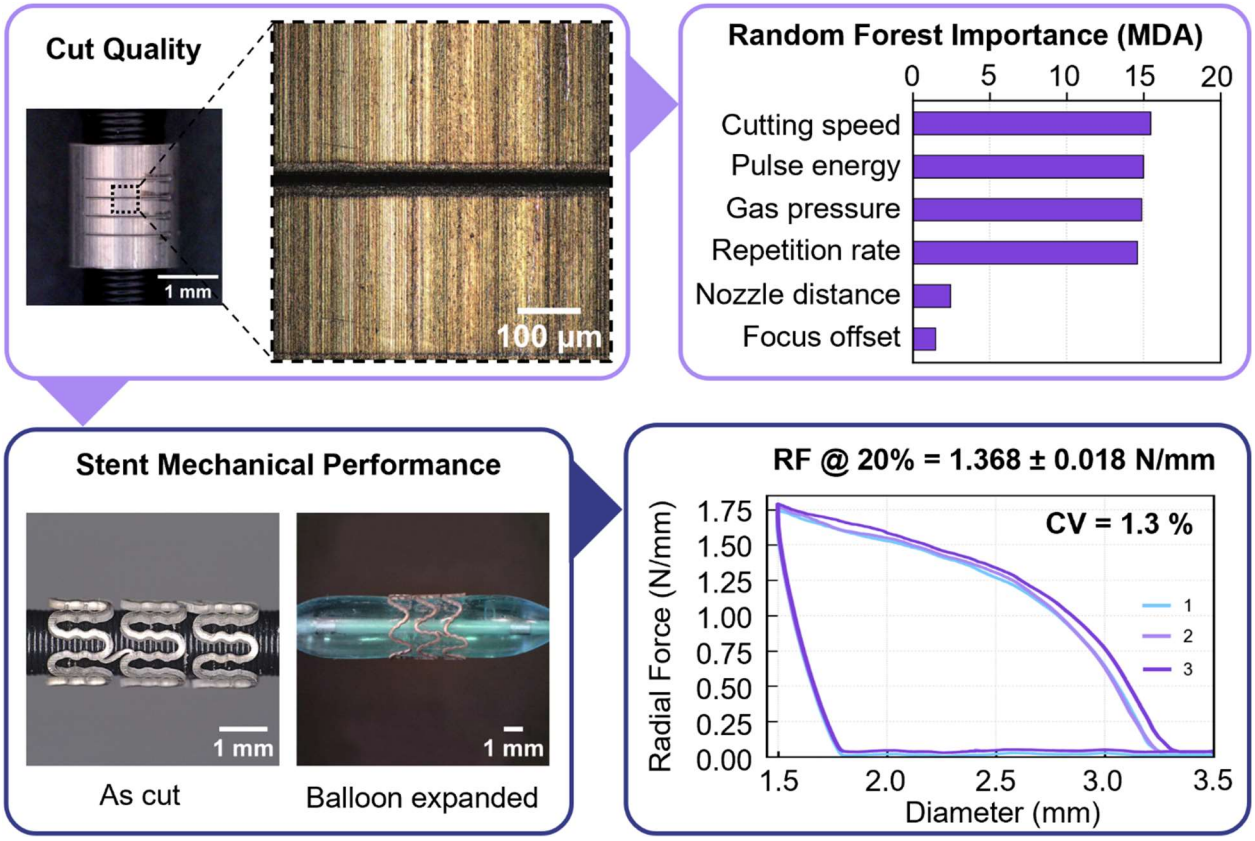
MSc João Cruz

Introduction

Bioabsorbable magnesium (Mg) stents are a promising alternative to permanent implants, where mechanical performance is critical to maintaining vessel patency during early healing [1]. This performance is strongly influenced by the fabrication process, which affects geometry, corrosion, and material properties [2]. Ultrashort-pulse (USP) laser cutting offers the required precision but remains largely unexplored for Mg. This study establishes a systematic, mechanics-driven optimization framework for USP laser cutting of Mg alloy WE43MEO coronary stents, linking process parameters to cut quality and radial mechanical performance.

Methods

Experiments were performed on WE43MEO microtubes using femtosecond laser cutting and a two-step design of experiments. The first step used a fractional factorial screening design (n = 21) to evaluate six process parameters and identify main effects. The second step applied a Central Composite Design (n = 29) to model parameter interactions and enable process optimization. Both ring samples and stents were produced, with cut features assessed via laser-scanning microscopy and SEM. All stents were crimped, balloon-deployed, and radially compressed according to ASTM F3067-14.



Results

Random-forest variable-importance analysis of cut quality outcomes, based on mean decrease in accuracy (MDA), identified pulse energy, cutting speed, repetition rate, and assist gas (argon) pressure as the dominant parameters (MDA = 14.6–15.5), whereas focus offset and nozzle distance showed minimal influence (MDA = 1.5–2.4). A central parameter set within the feasible window was selected to manufacture prototype stents (n = 3), which were successfully crimped, balloon-deployed, and radially compressed. Radial force curves showed a consistent behavior, with a mean radial strength at 20 % diameter reduction of 1.368 ± 0.018 N/mm and low variability (CV = 1.3 %).

Discussion

These results establish a clear pathway for linking laser processing parameters to cut quality outcomes and, ultimately, to the mechanical behavior of WE43MEO coronary stents. The strong separation between high- and low-influence parameters defines a focused region of interest, while the consistent radial performance from centrally selected settings confirms the mechanical relevance of this window. This foundation enables upcoming modeling to quantify parameter interactions and guide multi-objective optimization.

In-Silico Patient-Specific Model of Diastolic Filling Through a Mitral Valve Model With Transcatheter-Edge-to-Edge Repair

MSc Valérie Kulka[1], Dr. Natalie Simonian[2], Prof. Dr. Michael Sacks[2], Prof. Dr. Dominik Obrist[1]

[1]ARTORG Center, University of Bern, Bern, Bern, Switzerland. [2]James T. Willerson Center for Cardiovascular Modeling and Simulation, The Oden Institute for Computational Engineering and Sciences and the Department of Biomedical Engineering, The University of Texas at Austin, Austin, Texas, United States

Introduction

With mitral regurgitation (MR), blood flows pathologically back into the left atrium during systole, affecting approximately one in twelve people above the age of 75 [1]. Particularly for these potentially high-risk patients, transcatheter-edge-to-edge repair (TEER) offers a minimally invasive repair option.

The impact of TEER during diastolic filling of the left ventricle remains unclear, especially on the changed blood flow dynamics and the reduction in the open mitral valve area (MVA).

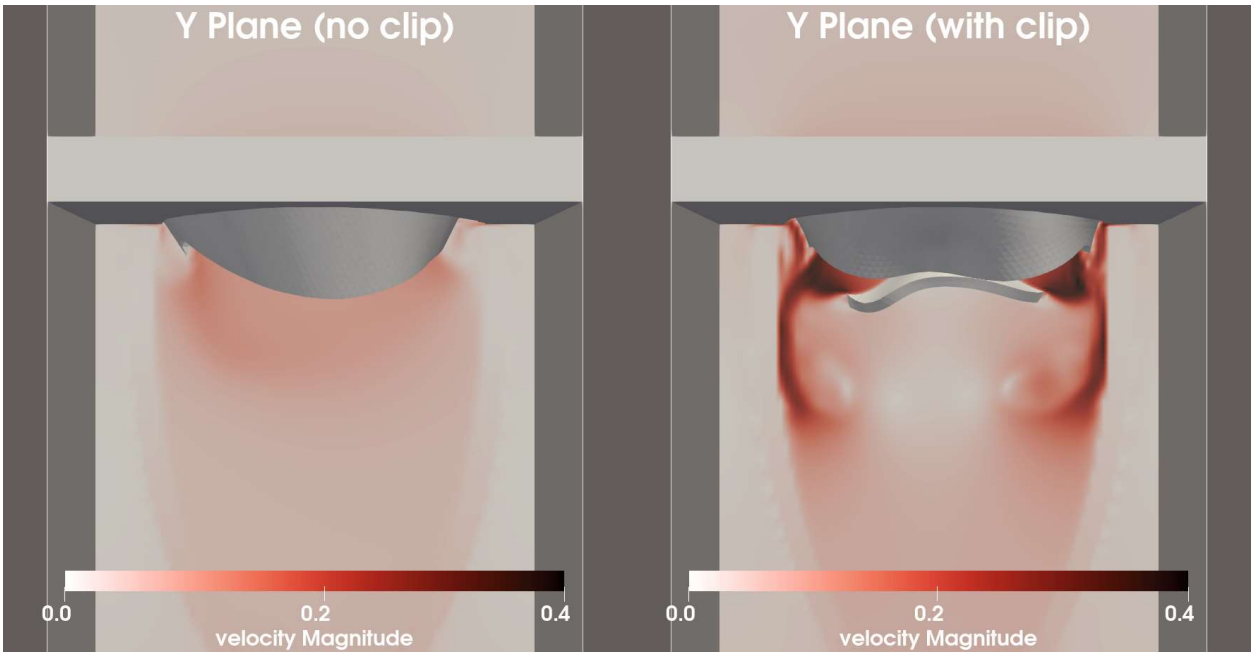
To address this question, we developed a patient-specific in-silico model with TEER to simulate the interaction between the valve tissue and blood flow during diastole, thereby gaining further insights.

Methods

We use a fluid-structure-interaction code [2] to couple blood flow and structural mechanics of the valve tissue.

The mitral valve (MV), segmented from an Echocardiogram and fitted with B-spline curves, is modelled using the Holzapfel-Gasser-Ogden material model. The MV is then attached to a plane, separating the fluid domain into the left atrium and the left ventricle. An expanding left ventricle simulates the diastole. For the TEER, the two leaflets of the MV are brought together (“clipped”) before the simulation of the diastolic phase. Five different MV geometries and four different clip positions are tested.

Results



Measurement of the MV opening area (MVA) and of the pressure drop across the clipped MV shows how different TEER positions affect the MV function. Furthermore, we study how

the turbulence characteristics of the filling jet change before and after TEER. This enables us to determine specific MV characteristics, before and after clipping.

Discussion

With the patient-specific fluid-structure-interaction model, changes in the MV function due to TEER can be characterized. We can examine how the clip position is changing the MVA and fluid dynamics during diastole. Comparison of different simulations provides a causal relationship between clipping position and MV function for every individual MV. Despite the small sample size, this study may provide some initial insights that can potentially guide future TEER interventions.

Intraventricular Hemodynamics under Impella implantation: effect of placement, power setting and pre and after load. An in vitro experimental study using Particle Image Velocimetry

Dr Fanette Chassagne[1], Dr. Claudio Bravo[2], Ms Jennifer Beckman[3], Dr Claudius Mahr[4], Dr Alberto Aliseda[3]

[1]Ecole de Mines, Saint Etienne, Rhone-Alpes, France. [2]UCSF, San Francisco, CA, United States. [3]University of Washington, Seattle, WA, United States. [4]Medical City Hospital System, Dallas, TX, United States

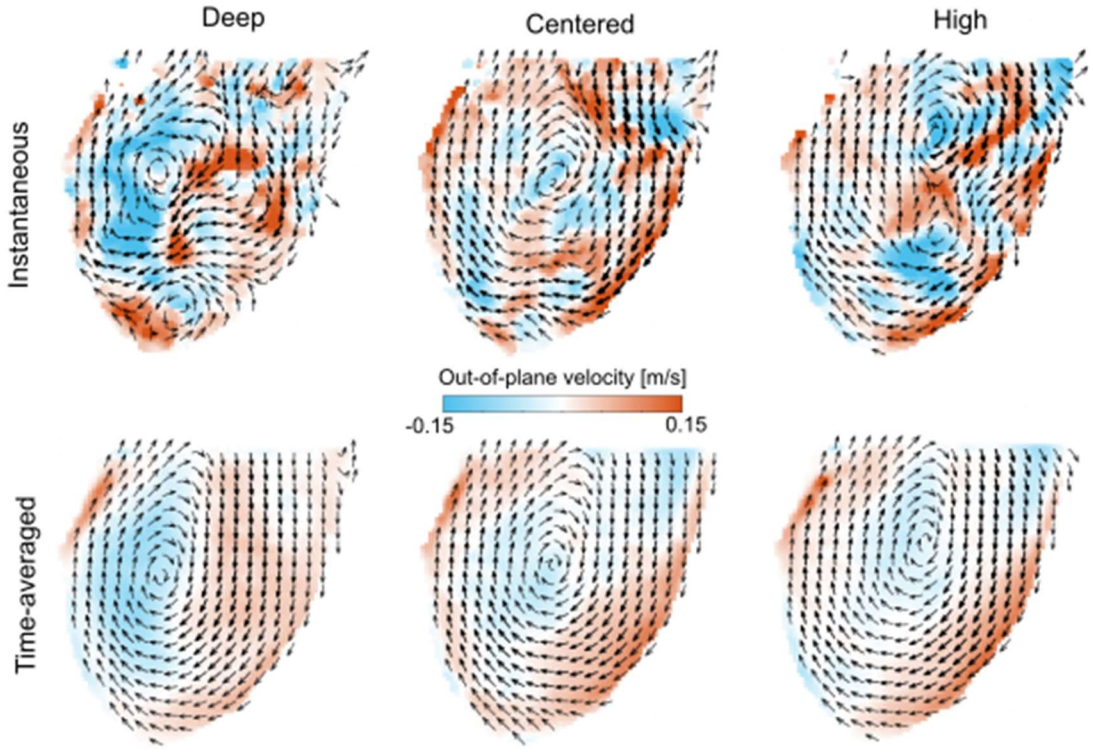
Introduction

Mechanical circulatory support is an effective therapy for heart failure, including for acute cardiogenic shock. Impella is a novel catheter-based ventricular assist device that has emerged as a clinically-preferred therapy, from hours to weeks. There is, however, a strong need to understand intraventricular hemodynamics under Impella support. Specifically, very little is known about how Impella positioning and operating conditions affect intraventricular hemodynamics.

Methods

We placed Impella through the ascending aorta into a silicone flow phantom created from segmented medical imaging of a patient's left ventricle (LV). This was connected to a flow loop where a reservoir and pulsatile pump can modify intraventricular pressure, mimicking residual native contractility. High resolution, time-resolved stereoscopic Particle Image Velocimetry provides the three components of the velocity in a coronal plane that cuts the ventricle including the mitral valve and the aortic valve annuli.

Results



Ultrasonic flow rate measurements show the inaccuracy of the Impella-reported output and pressures. Impella output depends strongly on power, with a 35% increase between the two cases tested. Intraventricular hemodynamics under Impella support shows a strong dependency on pump placement and power setting on the mitral vortex formation and propagation. This modification of the filling vortex and its propagation inside the ventricle towards the ventricular apex has a marked influence on residence time of blood near the apex, a common site of thrombus formation in ventricles under Mechanical

Circulatory Support. Likewise, the placement of Impella at different distances from the Left Ventricle Outflow Tract influences flow near the LVOT exiting the Left Ventricle via the Impella, as opposed to via the opening aortic valve.

Discussion

Impella-induced hemodynamics creates recirculation in the LVOT, under the non-opening valve, and this can lead to thrombus formation intraventricle. Native contractility of the failing Left Ventricle results in increased pre-load, which contributes significantly to pump output and intraventricular flow circulation, with reduced residence times, at a given pump power setting. Quantitative metrics such as ventricular circulation and Ventricular Stagnation Index are provided as means to quantify placement and power dependency, suporting development of better guidelines for Impella placement and power setting personalized for each patient's anatomy and support needs.

Mechanical Characterization of Retrieved Cerebral Thrombi Reveals Occlusion Site–Dependent Stiffness Influencing Endovascular Thrombectomy Success

Mr. Luca Bontempi[1,2], Ms. Janneke Cruts[1], Dr. Rachel Cahalane[1,3], Dr. Nikki Boodt[1], Dr. Daniel Bos[1], Dr. Behrooz Fereidoonnezhad[2], Mr. Pieter Jan van Doormaal[1], Prof. Aad van der Lugt[1], Prof. Diederik Dippel[1], Prof. Frank Gijsen[1,2]

[1]Erasmus MC, University Medical Center, Rotterdam, South Holland, Netherlands. [2]Delft University of Technology, Delft, South Holland, Netherlands. [3]University of Limerick, Limerick, Limerick, Ireland

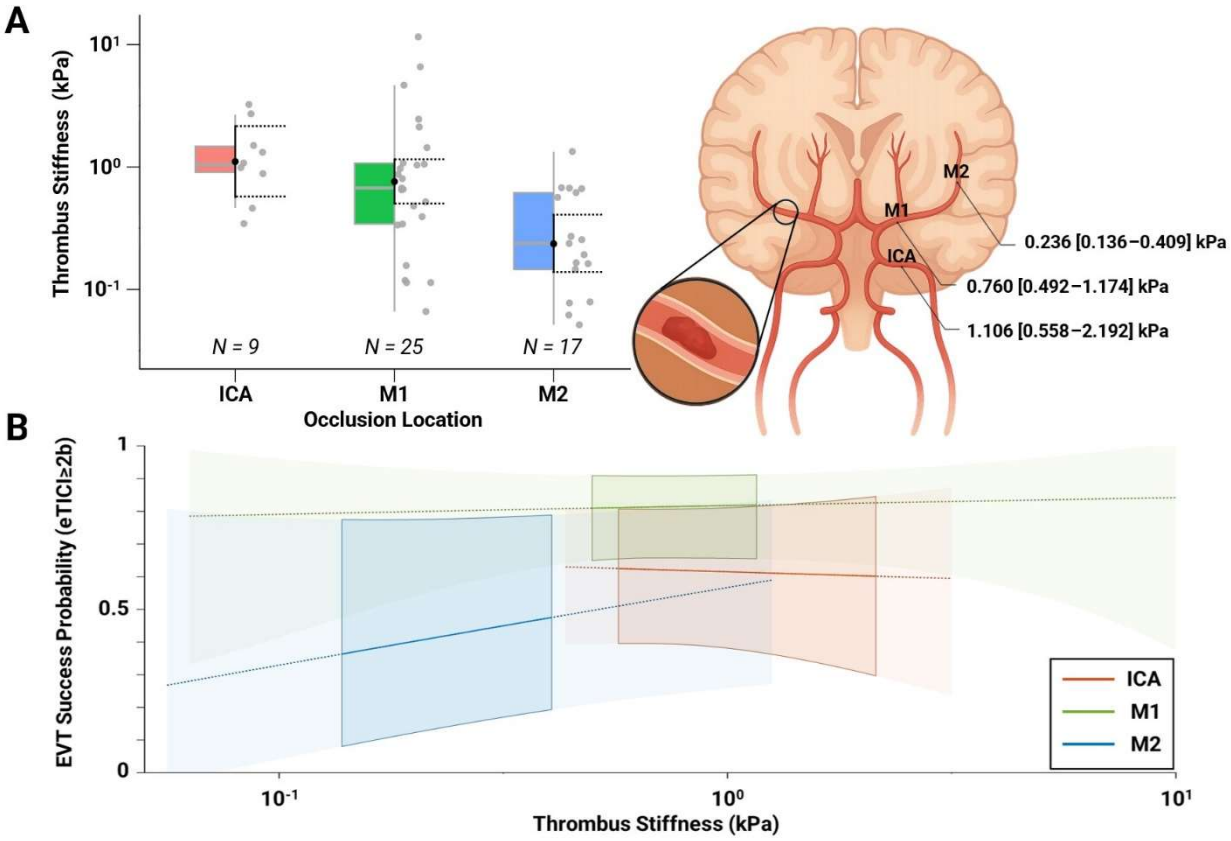
Introduction

Endovascular thrombectomy (EVT) is the standard treatment for acute ischemic stroke (AIS), yet nearly 40% of patients fail to achieve complete revascularization on the first EVT attempt. Differences in the mechanical properties of cerebral thrombi may underlie these variations in procedural efficacy. [1] This study aimed to characterize AIS thrombus stiffness, identify its clinical and histological determinants, and assess its influence on EVT success.

Methods

Thrombi retrieved during EVT from 73 patients were sectioned for mechanical testing and prepared for histology within six hours. Unconfined quasi-static compression tests were performed using a custom-made compression tester to determine bulk stiffness (low-strain secant modulus). [2] A total of 346 thrombus sections (median number per patient = 6.5, IQR = 4–11) were compressed to 80% strain for 20 cycles, at a strain rate of 10%. Histological composition was quantified using Martius-Scarlett-Blue staining and $CD42b^+$ immunostaining for RBCs and platelets, respectively. Linear mixed-effects regression (LMR) identified predictors of stiffness, while generalized LMR evaluated associations with first-pass EVT success (eTICI≥2b), accounting for age, sex, occlusion site, and first-pass EVT technique (stent retriever only or combination with aspiration catheters).

Results



Thrombus stiffness decreased with more distal occlusions: internal carotid artery (ICA) 1.106 kPa (95% CI, 0.558–2.192), M1 segment 0.760 kPa (95% CI, 0.492–1.174) and M2 segment 0.236 kPa (95% CI, 0.136–0.409) of the middle cerebral artery (Fig. 1A). Multivariable analysis confirmed these differences were independent of thrombus composition and patient factors, with occlusion location explaining 14.3% (95% CI, 0.2–34.8) of thrombus stiffness variance. The probability of first-pass EVT success reflected

occlusion site-dependent thrombus stiffness (Fig. 1B): M1 thrombi showed consistently high first-pass success rates, while stiffer ICA thrombi and softer M2 thrombi had lower success probabilities, reflecting distinct mechanical thrombus-device interaction challenges during EVT.

Discussion

Distal thrombi are significantly softer than proximal ones, qualifying occlusion site as a clinical surrogate for thrombus stiffness. The relationship between stiffness and recanalization success varies by occlusion site, underscoring the need for stiffness-specific EVT techniques and device designs.

Introduction

Endovascular thrombectomy (EVT) is the primary treatment for acute ischemic stroke, which involves using a stent-retriever to remove the blood clot from a cerebral artery. This procedure must be performed rapidly, leaving limited time for pre-procedural planning. While patient-specific high-fidelity computational simulations can predict EVT outcomes [1,2], they are computationally intensive and time-consuming. To address this challenge, this study proposes a machine learning-based classification model, trained on high-fidelity knowledge-driven EVT simulations, that can rapidly predict the probability of a successful procedure.

Methods

Cerebrovascular anatomies from 94 stroke patients were reconstructed from medical images and used to run finite-element simulations of the EVT procedure, as described in [1]. Results showed 81 successful (clot removed) and 13 unsuccessful outcomes (clot not removed) (Fig.1A). These simulation results were used to train a classification model, built with a two-step approach. Firstly, a dimensionality-reduction technique was applied to condense the complex vascular anatomies into a limited number of parameters (Fig.1B). Secondly, a kernel-function was trained using a restricted semidefinite-positive optimisation method, which considered the anatomy and clot properties of each virtual patient. The optimised kernel-function groups patients into clusters based on EVT success.

The resulting model can then classify data from new patients, providing an estimate of the likelihood of success of an EVT intervention.

Results

Results of the classification were evaluated using 70% of the samples for training the model and 30% for testing, and a 10-fold cross-validation was performed by changing the testing group at each iteration. Training samples were correctly clustered at each iteration (Fig.1C). The average rate of correct predictions of testing samples was 83%, with 10%false-negatives and 7%false-positives rates.

Discussion

The kernel-optimisation approach used to train the classification model appears promising, as it effectively clustered cases based on EVT outcomes and yielded good results when classifying test samples. However, the model proved weak in classifying samples with unsuccessful outcome, likely because this group is underrepresented in the training dataset. This limitation highlights the need for a significantly larger dataset of high-fidelity simulations to improve the model's performance, particularly in capturing the complex physical mechanisms underlying EVT procedures.

Influence of Blade Flexibility on LVAD Hydrodynamic Performance & Hemocompatibility

Ms Shweta Karnik[1], Dr. Maryam Bagheri[1], Ms Shobana Santhanam[1], Dr. Huang Chen[2], Dr. Lakshmi Prasad Dasi[1]

[1]Georgia Institute of Technology, Atlanta, GA, United States. [2]University of Las Vegas, Las Vegas, NV, United States

Introduction

Left ventricular assist devices (LVADs) are widely used in patients with end-stage heart failure as both destination therapy and bridge-to-transplant support. To match LVAD output with a patient's native cardiac output, pump speeds are frequently adjusted, which can adversely affect device hemocompatibility and long-term durability.

To overcome these limitations, we have developed a novel LVAD prototype incorporating flexible rotor blades. We hypothesize that the mechanoresponsive behavior of these blades will allow them to deform in response to complex, time-varying inflow conditions. With optimized geometry and flexural properties, this design is expected to enhance hemocompatibility while expanding the operational range over which the pump maintains high efficiency. In this study, we evaluate the hemocompatibility and hydrodynamic performance of flexible rotor blades in a centrifugal LVAD under adult physiological conditions (5 L/min, 90 mmHg).

Methods

A preliminary rotor prototype was developed, with the rigid rotor fabricated from acrylic and the flexible blades cast from polyurethane. Hydrodynamic performance was characterized in a benchtop flow loop using a 40% glycerin–water mixture, where pressure–flow behavior and efficiency were measured under adult physiological operating conditions.

High-speed 2D particle image velocimetry with fluorescent particles was used to visualize flow fields, enabling identification of stagnation zones and regions of elevated shear stress. Hemocompatibility was assessed using a recirculating blood loop.

Results

Flexible and rigid blades achieved comparable pressure–flow performance, but the flexible blades exhibited higher hydraulic efficiency.

Discussion

Initial results support our hypothesis, indicating promising performance of the flexible rotor blades.

On the Use of Nonlinear Elastic Membrane Analysis for Estimating Abdominal Aortic Aneurysm Wall Stress

Graduate research student Simon Rios Deossa[1], Master Vivian Reyna[1], MD Satish C. Muluk[2], PhD Ender Finol[1]

[1]UT San Antonio, San Antonio, Texas, United States. [2]ANH, Pittsburgh, Pennsylvania, United States

Introduction

Abdominal aortic aneurysm (AAA) is a dilatation of the infrarenal aorta, usually detected incidentally. Elective repair is guided by sex-specific maximum diameter thresholds (≥ 5.0 cm women, ≥ 5.5 cm men), which may not be sufficient to assess individual rupture risk. As wall stress is a direct biomechanical driver of failure, we evaluated the use of nonlinear elastic membrane analysis (NEMA) as an alternative to finite element analysis (FEA) for wall biomechanics.

Methods

Contrast-enhanced abdominal computed tomography (CT) scans from 16 AAA patients were used to identify the wall boundaries and build patient-specific wall and intraluminal thrombus (ILT) volume meshes with a uniform wall thickness (1.5 mm). FEA models used mean arterial pressure and six combined wall and two ILT constitutive material laws, yielding 420 simulations. The corresponding wall surface meshes were used for NEMA to compute first principal wall stress distributions and the 99th percentile wall stress (99thWS) for direct comparison with FEA.

Results

For all AAAs, NEMA yielded 99thWS estimates that were generally similar to their FEA counterparts, with notable discrepancies in two cases. The relative difference in 99thWS between NEMA and FEA was 15%-45% for all constitutive material combinations. The radar plot shows good agreement between NEMA and FEA in the distribution of 99thWS across the AAA cohort, with both methods highlighting the same aneurysms as having elevated peak wall stress, although FEA tended to predict slightly higher stresses in regions of significant asymmetry. Overall, a thin-membrane formulation, such as that used for NEMA, approximated FEA-based 99thWS reasonably while substantially reducing complexity.

Discussion

NEMA assumes the AAA wall is a thin membrane, neglects bending stresses and stress gradients through the wall, and operates directly on the deformed, pressurized CT-derived geometry. It does not require estimating patient-specific constitutive material properties or deriving an unloaded reference state. This shortens the setup and solution time compared to FEA, while supporting potential clinical translation. However, membrane-based assumptions may underrepresent the local mechanics in highly tortuous or thick-walled regions. Since true wall stress is unknown *in vivo*, broader benchmarking against high-fidelity models and clinical outcomes is needed before NEMA can be used for routine rupture risk assessment.

Images (Optional)

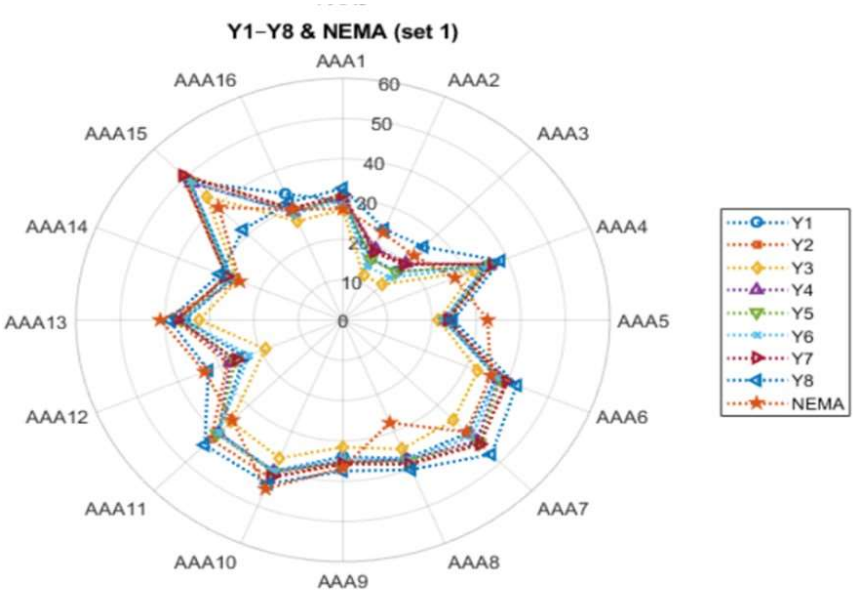

Figure 1. Radar plot of 99thWS across 16 AAAs for eight FEA material formulations (Y1–Y8) compared with NEMA, demonstrating consistent AAA-dependent stress patterns.

In Vitro Hemodynamics of a Bio-Inspired Polymeric TAVR with 3D-Shaped Leaflets

Ms Srujana Joshi BS, Ms. Kenia Zuniga-Gallegos BS, Dr. Lakshmi Prasad Dasi PhD

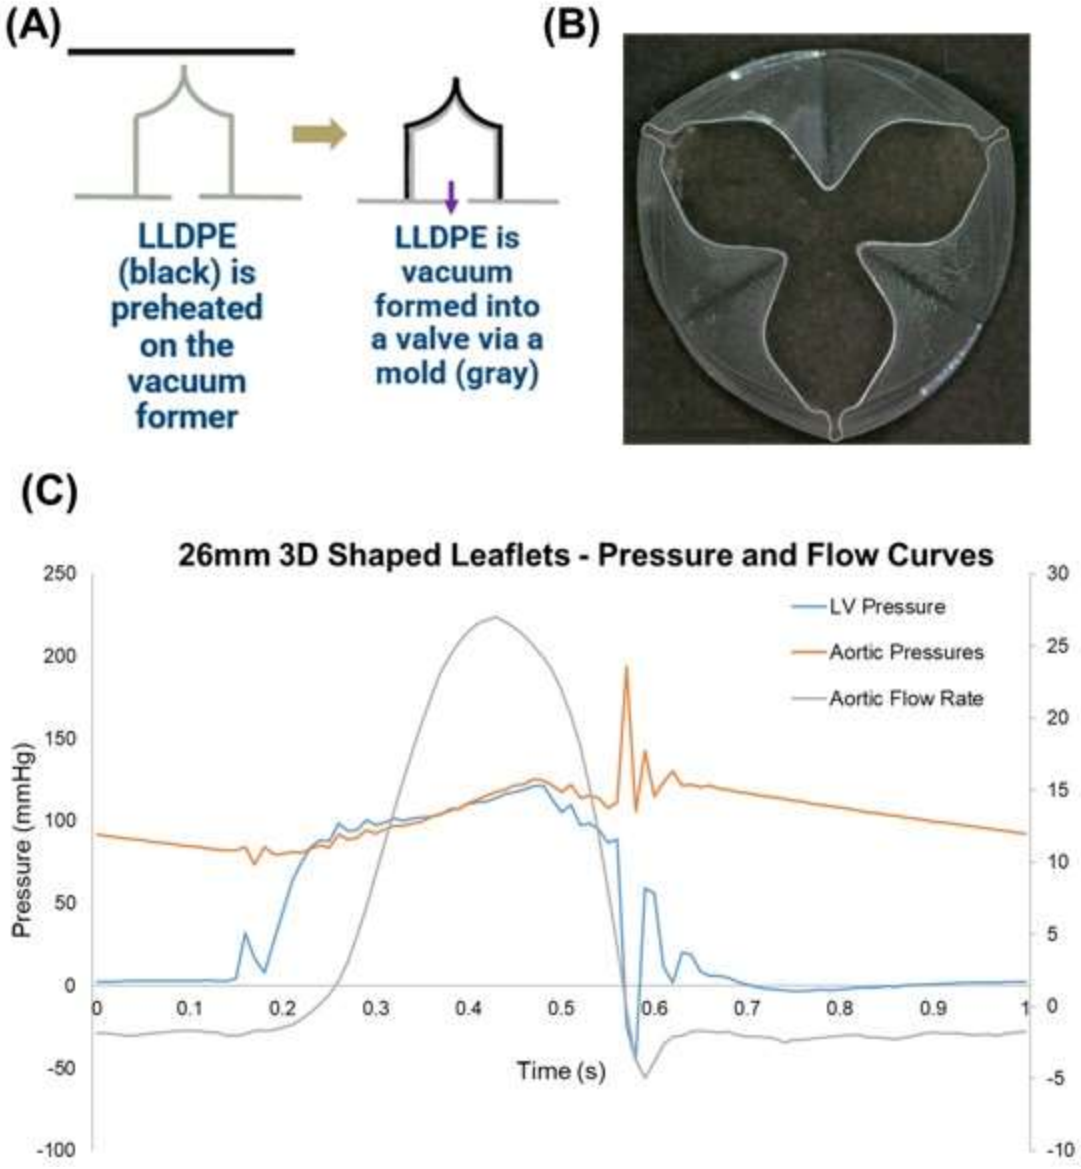
Georgia Institute of Technology, Atlanta, Georgia, United States

Introduction

Although transcatheter aortic valve replacement (TAVR) is widely used to treat aortic stenosis in older patients, current commercial devices still face major clinical challenges. Bioprosthetic leaflets are prone to calcification and thrombosis, leading to reinterventions and limiting their use in younger patients. Their reliance on animal-farming and labor-intensive hand-sewing also increases production costs. Thus, there is a clear need for a durable, biocompatible, and easy-to-manufacture leaflet material that addresses both performance and production limitations. This study investigates the hemodynamic performance of 3D shaped leaflets made from a novel bio-inspired polymer composed of an interpenetrating network of hyaluronan (HA) – a naturally occurring biomolecule with anti-thrombotic and anti-calcific properties – and linear low-density polyethylene (LLDPE), a polymer known for high tensile and tear strengths and excellent durability.

Methods

A 26mm outer diameter LLDPE leaflets were manufactured through vacuum thermoforming (Figure 1A) to produce 3D shaped leaflets, then assembled onto a balloon expandable stent frame (Figure 1B). The prototype was mounted in an idealized aortic chamber connected to an in vitro left heart simulator to test under physiological aortic conditions (120/80 mmHg, 5 L/min cardiac output). A 60/40 water/glycerin mixture was used as a blood analog. Bulk hemodynamic performance metrics, mainly mean pressure gradient and effective orifice area were evaluated. Additionally, particle image velocimetry (PIV) data was performed to characterize downstream flow. All measurements were repeated using a 26mm SAPIEN 3 for comparison.



Results

The 3D-shaped polymeric leaflets demonstrated favorable hemodynamics, with a mean pressure gradient of 3.62 mmHg and an effective orifice area of 2.02 cm^2, compared with 4.93 mmHg and 2.23 cm^2 for the SAPIEN 3. At peak systole, the polymeric TAVR exhibited a lower peak velocity (1.63 m/s) than the SAPIEN 3 (1.81 m/s).

Discussion

3D-shaped polymeric leaflets exhibited excellent hemodynamic performance, achieving an effective orifice area comparable to the SAPIEN 3 while generating a lower pressure gradient. PIV measurements showed that the polymeric TAVR produced lower peak systolic velocities than the SAPIEN 3. Overall, these results highlight the strong potential of 3D-shaped polymeric leaflets to deliver hemodynamics on par with current commercial devices.

Digital-Twin Technology to Derive Mechanical and Morphological Predictors of In-Stent Restenosis in the Femoropopliteal Segment

R&D Engineer Mar Alonso Chornet[1,2], Dr. David Perrin[2], Professor Jean-Noel Albertini[2], Professor Yann Goueffic[3], Dr. Alexandra Hauguel[4], Professor Stéphane Avril[1]

R&D Engineer Mar Alonso Chornet

Dr. David Perrin

Professor Jean-Noel Albertini

Professor Yann Goueffic

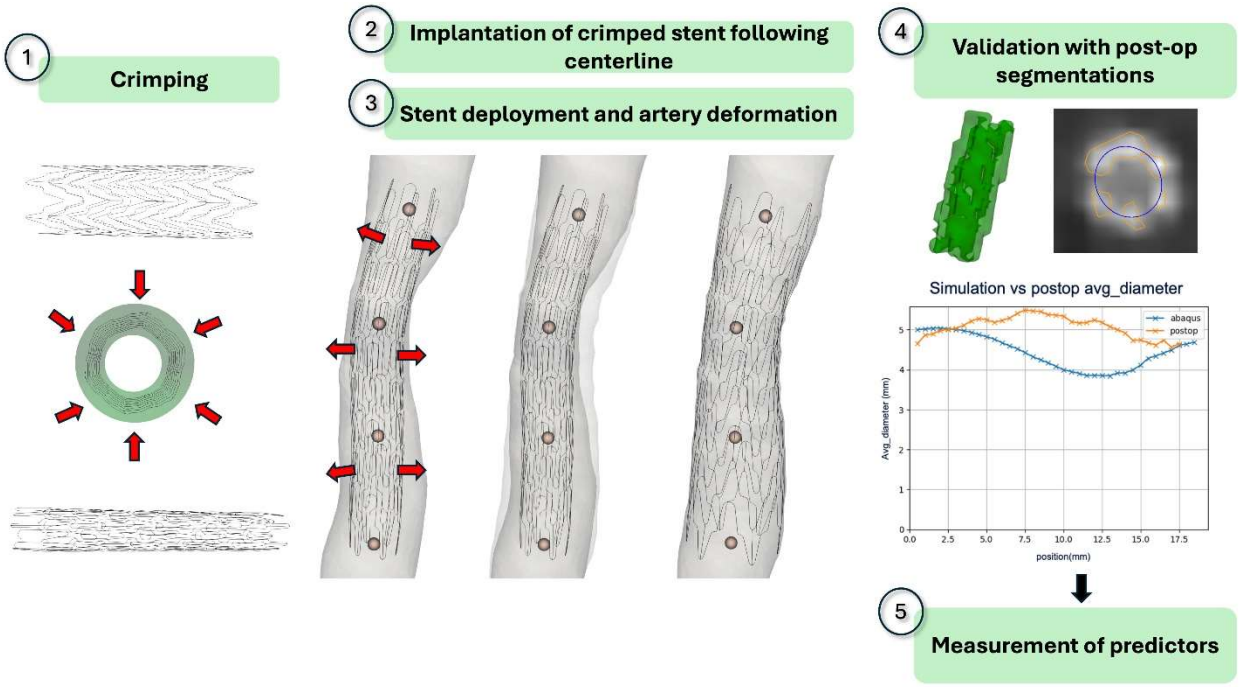
Dr. Alexandra Hauguel

Introduction

Atheromatous lesions of the femoropopliteal segment are commonly treated with endovascular revascularization techniques involving the implantation of stent devices. The long-term results of these procedures are often impacted by the outcome of in-stent restenosis (ISR), a condition that leads to lumen re-narrowing. Despite recent research, the identification of ISR predictors remains a challenge as ISR is a complex multifactorial condition in which the influence of the mechanical environment is not yet fully understood, and the outcomes depend on each patient's anatomical characteristics. The objective of this study is to develop a digital-twin-based approach to assess potential mechanical and morphological predictors of ISR.

Methods

First, patient-specific 3D arterial models were reconstructed from contrast-enhanced preoperative CT scans. Digital models of two stent designs were then crimped and deployed in the targeted region of the artery model through numerical simulations in Abaqus® software. The final stent geometries obtained from the simulations were compared with the corresponding stent reconstructions from post-interventional CT scans. The mean absolute error of the average stent diameter at each cross-section (MAE_{avg}) and the offset were computed. Finally, potential predictors were extracted from simulation results. A preliminary analysis with 10 patients was carried out to assess the reliability of the models.



Results

The general process was successfully simulated for all cases, involving the implantation of 14 stents ranging from 5 to 8 mm in diameter. The mean MAE_{avg} for all stents is 13.79 ± 5.6% relative to their reference diameter and an average offset of 11.18 ± 7.7% was observed in the models. The cross-sectional diameters of the femoropopliteal lumen and the final stent were measured from the models as potential ISR morphological predictors.

Discussion

The proposed approach provides a personalized tool designed for clinical application, enabling the estimation of ISR predictors which cannot be easily obtained from in-vivo measurements. However, the morphological differences between the postoperative and simulation results might indicate the influence of an additional factor, such as vessel preparation, e.g. angioplasty. The future scope of this study involves the inclusion of 30 patients for tool optimization, mechanical predictors measurement and the analysis of external factors generating the offset.

Mechanical and Physical Evaluation of the In Vitro Degradation of Layer-by-Layer Silk Fibroin Vascular Grafts

M.Sc. Maike Bittner[1,2], Dr. Benedetta Isella[2], Dr.-Ing. Alexander Kopp[2], Prof. Ted Vaughan[1]

[1]School of Engineering and Institute for Health Discovery and Innovation, University of Galway, Galway, County Galway, Ireland. [2]Fibrothelium GmbH, Aachen, North Rhine-Westphalia, Germany

M.Sc. Maike Bittner

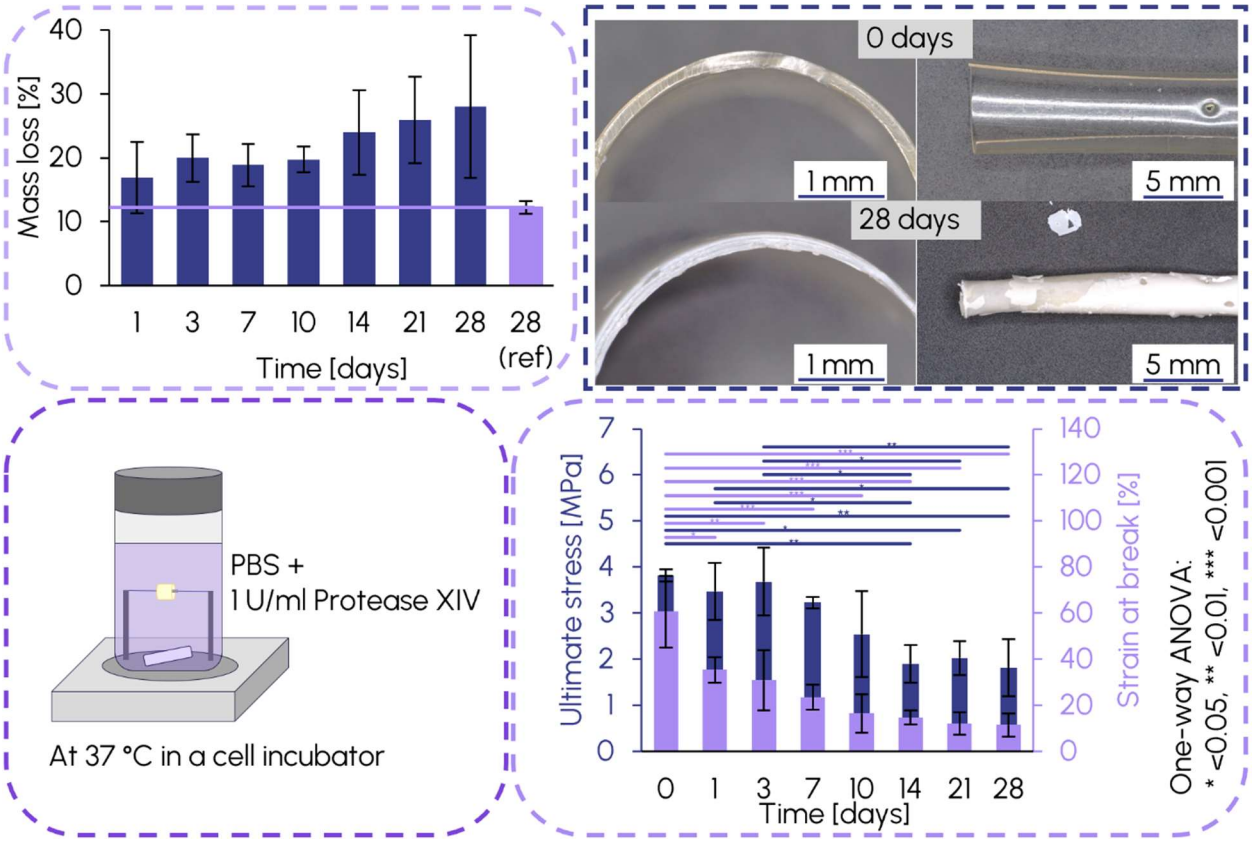
Introduction

Silk fibroin (SF) offers favourable mechanical and degradation behaviour with respect to other natural polymers [1] and could represent a promising material for vascular grafts, which often lack appropriate mechanical properties [2]. Layer-by-layer SF-based fabrication method could enable the modular and versatile production of vascular grafts, and this study will investigate for the first time their in-vitro degradation focusing on the mechanical and physical properties.

Methods

An in vitro degradation study of SF samples, produced through a layer-by-layer dip-coating process, was conducted over a period of 28 days (eight timepoints, four specimen types, n=4) in PBS + Protease XIV at 37 °C. References samples in only PBS were included as controls. Physical, structural (FTIR), thermal (DSC), and mechanical characterisation in hydrated state (burst pressure, uniaxial tensile tests, and circumferential tensile tests based on ISO 7198:2016) were performed.

Results



Mass loss increased from the first day across all samples, with mass loss in reference samples attributable to glycerol leaching. A gradual separation of the layers due to the degradation process was found starting from the first day. After one day, a significant decrease (p-value <0.05) in strain from 60.66 ± 15.66 % to 35.31 ± 5.53 % was observed in the uniaxial tensile test results and further decreases evident throughout the degradation. A decreasing trend was also observed for the ultimate stress after three days with a statistical difference (p-value <0.01) between day zero and 14 of 3.81 ± 0.14 MPa to 1.9 ±

0.41 MPa. This behaviour was observed throughout the entire mechanical characterisation.

Discussion

This study presented the first detailed mechanical characterisation of the in-vitro degradation process of SF. The mechanical properties especially showed that the material became progressively more brittle over time, with a more rapid decrease in strain. This suggests that the amorphous domains of the SF degrade earlier than the crystalline domains [1]. This study allows a more sophisticated understanding of the degradation mechanism of SF layer-by-layer structures, paving the way to a better design for these medical devices.

A personalized FSI model of complex congenital heart disease

Dr. Aaron Brown[1,2], Ms. Elena Martinez[1,2], Dr. Michael Ma[1,2], Professor Alison Marsden[1,2]

[1]Stanford University, Stanford, CA, United States. [2]Stanford Cardiovascular Institute, Stanford, CA, United States

Introduction

Understanding intracardiac blood flow is critical in congenital heart disease (CHD), where structural defects can profoundly disturb normal hemodynamics. Although advanced imaging methods such as 4D flow MRI, or computational approaches like image-based moving-boundary CFD, can reconstruct patient-specific flow, they remain limited to preoperative conditions. Postoperative prediction requires fluid–structure interaction (FSI) modeling, in which wall motion arises from a biophysically accurate myocardial mechanic model. Such FSI models enable virtual surgical planning, which could greatly enhance decision-making for complex CHD cases that currently depend heavily on surgeon experience. Towards this goal, we develop a patient-specific FSI model of a borderline single ventricle patient undergoing a Rastelli baffle procedure [1] and compare our model to preoperative and postoperative clinical data.

Methods

A patient-specific mesh of the myocardium and blood pool is constructed from clinical imaging using a semi-automatic pipeline based on our previous work [2]. We use the arbitrary Lagrangian-Eulerian (ALE) formulation to couple blood flow to myocardial mechanics, incorporating the Holzapfel–Ogden material law, active stress, and spatially varying epicardial boundary conditions. Valves are modeled with unfitted resistive immersed surfaces (URIS) [3]. We further couple the heart to a closed-loop LPN circulation, and all parameters are personalized to preoperative clinical data using a multistep calibration strategy inspired by our previous approach [2].

Results

A preliminary FSI model of a healthy left heart with a simple open-loop circulatory model was developed as a proof of concept. Figure 1 shows velocity arrows colored by pressure results at late diastole, mid systole, and early diastole. Blood flow, valve opening and closing, and myocardial deformation all follow expected patterns for normal left heart function.

Discussion

The preliminary model demonstrates the feasibility of patient-specific FSI modeling. Next, we will build a borderline single ventricle heart, couple it to a closed-loop circulatory model, personalize myocardial and circulatory parameters to match preoperative clinical data, and virtually insert the Rastelli baffle to compare predicted postoperative function with clinical data.

Reduced order model for fully coupled 3D Fluid Structure Interaction of transvalvular flow affected by Aortic valve stenosis

Ms Akshita Sahni MS[1,2], Dr. Imran Shah PhD[1], Dr. Thangam Natarajan PhD[1], Dr. Alessandro Veneziani PhD[2], Dr. Karthik Menon PhD[1], Dr. Lakshmi Prasad Dasi PhD[1,2]

[1]Georgia Institute of Technology, Atlanta, Georgia, United States. [2]Emory University, Atlanta, Georgia, United States

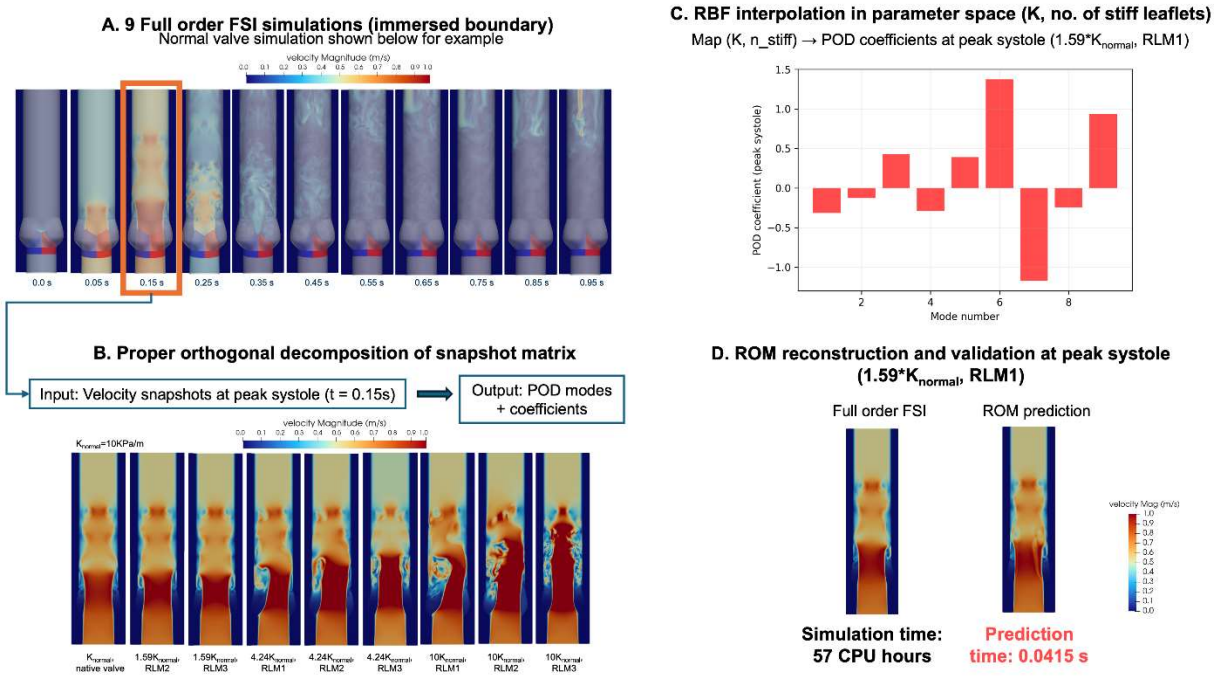
Introduction

Full order computational biomechanics simulations, such as computational fluid dynamics models of arterial flow or fluid-structure interaction (FSI) models of transvalvular flow, are increasingly used for pre-surgical planning. However, exploration of patient specific parameter variations is difficult due to high computational time. Model order reduction can accelerate such simulations while retaining key flow features. We develop a 3D reduced order model (ROM) of aortic transvalvular flow based on fully coupled FSI simulations.

Methods

An idealized aortic valve geometry was modeled with a two-way coupled FSI where leaflet motion is described by an ODE coupled to the flow solver through a stiffness parameter K and symmetric leaflet geometry; aortic wall was assumed rigid. High fidelity simulations using a sharp-interface immersed boundary method with 8.4 million points were run for leaflet stiffness values of 10 (normal), 15.9 (31% stenosis), 42.4 (47% stenosis), and 100 kPa/m (early thrombus like stiffening), each with reduced leaflet motion (RLM) in one, two, and three leaflets [1,2]. The combination of 15.9 kPa/m, RLM in one leaflet was used as test case for prediction. The remaining 9 combinations were used for training. A non-intrusive proper orthogonal decomposition (POD) based ROM was constructed using singular value decomposition on velocity snapshots at peak systole (t = 0.15s) from 9 FSI simulations. Radial basis function (RBF) interpolation in 2D parameter space (K, # stiff leaflets) was used to map parameters to POD coefficients.

Results



POD fitting required 2.07 s and RBF training was negligible, while ROM prediction + velocity field reconstruction required 0.0415s on a 48GB RAM laptop. In comparison, FSI simulation

of peak systole required ~57 CPU hours (576 cores) on supercomputing cluster. The ROM leads to ~5×10^6 speedup, with 18.6% relative L2 error on the 3D velocity field (Figure 1).

Discussion

The ROM recovered dominant transient flow structures over peak systole. Because the training data are fully coupled FSI simulations, the ROM predictions reflect coupled valve dynamics. We will showcase this framework for patient specific geometries and bioprosthetic transcatheter valves with RLM. We plan to include time varying hemodynamics and pressure gradient predictions by incorporating dynamic mode decomposition for large datasets.

Introduction

Endovascular Aneurysm Repair (EVAR) complications related to stent-grafts (SG) deployment in the renal arteries are poorly understood and diagnosed. They compromise short and long-term surgical outcomes. Predicting these complications (stenosis, occlusion, kink) pre-surgical intervention is challenging. Finite Element (FE) simulations of SG deployment in the renal arteries have not been conducted, and the hemodynamics changes induced by the procedure are only partially understood. Integrated structural-hemodynamics simulations can shed light on the link between procedural parameters, renal artery physiology and patients' outcomes.

Methods

This study covers five fenestrated-EVAR patients, two did not develop renal complications, and three who did. FE simulations analyzed SG deployment in the renal arteries, while CFD simulations assessed hemodynamics changes. We investigate variations in cross-sectional area along the artery, flow rate, and TAWSS, together with specific clinical metrics (Renal-Aortic Ratio or RAR) used to diagnose renal stenosis. We compare clinical and hemodynamics metrics between patients with and without complications.

Results

Renal artery lumen analysis showed decrease in cross-sectional area due to the stenting, resulting in a reduction in renal flow after fEVAR. Large TAWSS reduction post-fEVAR corresponded with regions where patients developed complications. Recirculation regions were detected downstream of the SG (Figure 1), corresponding to the stenosed area in Patient 1. High RAR values (>3.5) were found for all the patients who

suffered complications. We compared post-operative imaging against CFD simulation visualizations, to provide confidence in the validation of CFD results. Finally, CFD metrics were correlated with clinical RAR values and patient outcomes, in an effort to formulate metrics from computations that can complement or eventually replace highly uncertain and unspecific current clinical diagnosis metrics.

Discussion

This study integrates structural and fluid simulations of renal artery fenestrated stent graft placement, in patient-specific cases. The results from cases without complication are compared against those who did develop complications. The results show the potential of computational hemodynamics metrics to support prediction of complication risk, preoperatively. Clear differences exist between hemodynamics of patients with and without complications. Validation of these metrics on a much larger cohort is needed to demonstrate clinical translation of these hemodynamics simulation metrics for prediction of surgical complications.

Modeling the Effects of Right Ventricular Remodeling on Intramural Stress and Cardiac Outflow in Pulmonary Arterial Hypertension

Mr. Alex Barr, Dr. Jason Szafron

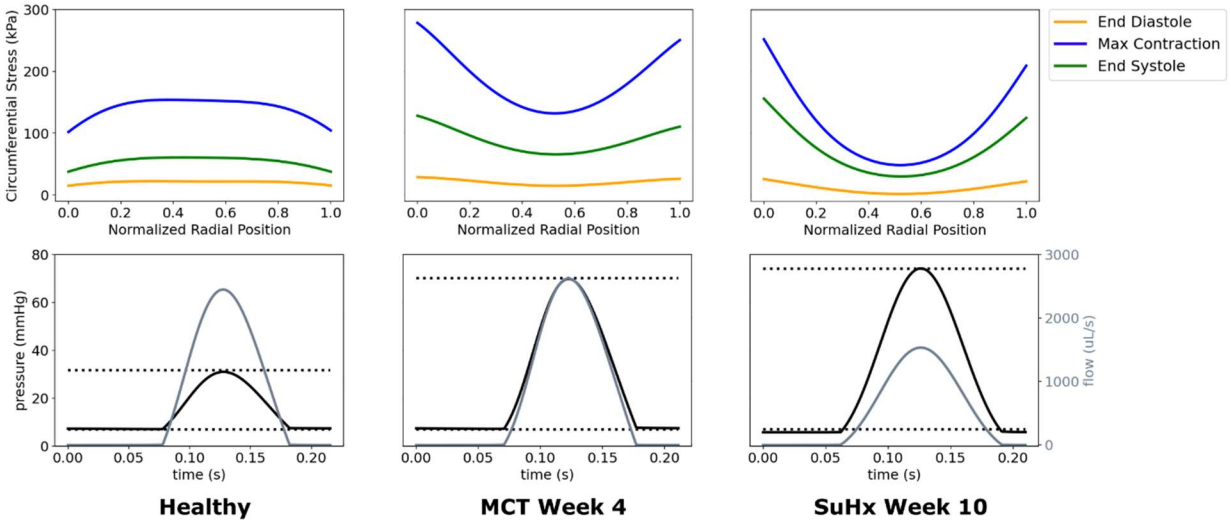
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Introduction

Pulmonary Arterial Hypertension (PAH) is a chronic condition with narrowed distal pulmonary arteries, causing increased resistance. To maintain cardiac output, the right ventricle (RV) remodels, resulting in long-term maladaptive changes in size, thickness, and material behavior. [1] Thin-walled models of the ventricle do not predict changes in wall stress distribution during remodeling. [2] Additionally, research directly linking concomitant changes in cardiac microstructure to flow in the pulmonary arteries is sparse. We investigated the effects of cardiac remodeling in PAH to analyze stress distributions in the vascular wall and predict changes in outflow to the pulmonary arteries.

Methods

We gathered cardiac data from prior studies that induced PAH in Sprague Dawley rats through monocrotaline or Sugen/hypoxia. A thick-walled, hollow cylinder model was used to capture right ventricular behavior by including both active and passive constituents of the heart wall. [3] Internal pressures and volumes were simulated for each phase of the cardiac cycle by varying load and contraction. By iteratively altering material parameters, the differences between the calculated Pressure-Volume (PV) loop and the cardiac data from the literature were minimized to simulate each stage of disease progression. Simulated cardiac data consistently fell within the standard deviation of the literature values. This pressure-volume data was used to generate flow inputs for reduced order models of pulmonary hemodynamics through recapitulation of an input pressure waveform for a lumped parameter model of the heart.



Results

PAH hearts exhibited increased circumferential stress at end systole and max contraction compared to healthy controls. While healthy hearts exhibited their highest stress in the midpoint of the wall, diseased models had a higher circumferential stress at the inner and outer wall compared to the midpoint. Additionally, we simulated changes in flow in the reduced order model across PAH progression and compared changing vascular parameters, such as compliance, with cardiac material properties.

Discussion

These simulations helped to identify the time-varying effects of different RV constituents in PAH and their relation to heart remodeling.

In-Vivo Comparison between Computational Fluid Dynamics Simulations and Xenon MRI of the Upper Airways in Obstructive Sleep Apnea

Assistant Professor Qiwei Xiao Ph.D[1,2], Assistant Professor Neil Stewart Ph.D[3], Assistant Professor Matthew Willmering Ph.D[1], Mr Keith McConnell[1], Dr Robert Fleck MD[1], Dr Raouf Amin MD[1], Assistant Professor Alister Bates Ph.D[1]

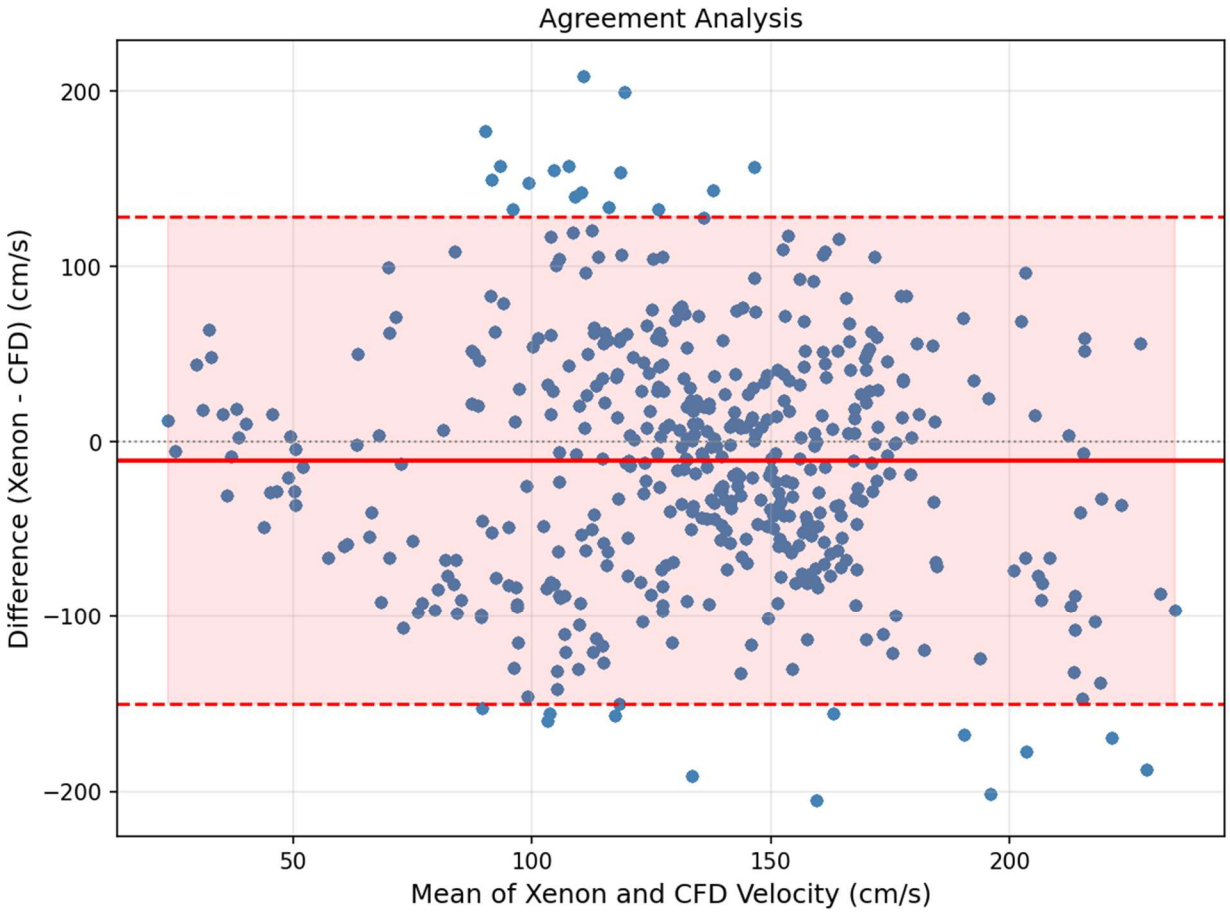
[1]Cincinnati Children's Hospital, Cincinnati, OHIO, United States. [2]University of Cincinnati, Cincinnati, OHIO, United States. [3]University of Sheffield, Sheffield, Sheffield, United Kingdom

Introduction

Computational fluid dynamics (CFD) simulations of upper airway airflow offer potential for identifying sites of obstruction contributing to respiratory symptoms in obstructive sleep apnea (OSA). Previous studies comparing CFD to hyperpolarized ^{129}Xe phase contrast (PC) MRI velocimetry have been limited to healthy subjects. However, OSA patients present complex airway geometries with multiple obstruction sites at the soft palate, retroglossal region, and epiglottis. Since both CFD and ^{129}Xe PC MRI have inherent limitations, demonstrating good agreement between these two independent techniques in OSA patients would provide reassuring consistency and support confidence in using CFD for clinical decision-making.

Methods

We performed subject-specific CFD simulations and hyperpolarized ^{129}Xe PC MRI velocimetry during normal breathing in one patient. Airway anatomies were derived from ^{1}H MRI, and respiratory flow rates were recorded during ^{129}Xe inhalation. CFD simulations employed large eddy simulation turbulence modeling with boundary conditions matching MRI acquisition. Velocity fields from CFD were spatially averaged to match PC MRI resolution. Agreement was assessed using Bland-Altman analysis.



Results

Bland-Altman analysis revealed a small mean bias of -10.9 cm/s (-8.1% of mean velocity), indicating CFD velocities were slightly higher than ^{129}Xe PC MRI measurements.

Discussion

This preliminary comparison of CFD and hyperpolarized ^{129}Xe PC MRI in OSA patients demonstrates initial feasibility of comparing the two techniques in a challenging population, supporting translation of CFD toward clinical application in OSA management.

Modeling Respiratory Mechanics in Neonatal Lung Disease: MRI–CFD Framework for Regional Work of Breathing Analysis

Dr Chamindu Gunatilaka PhD[1], Mr Christopher Boles BS[2], Dr Qiwei Xiao PhD[1], Dr Hamideh Hayati PhD[1], Mr Keith McConnell MS[1], Dr Samal Munidasa PhD[1], Dr Matthew Willmering PhD[1], Dr Nara Higano PhD[1], Dr Paul Kingma MD[1], Dr Erik Hysinger MD, MS[1], Dr Jason Woods PhD[1], Dr Alister Bates PhD[1,2]

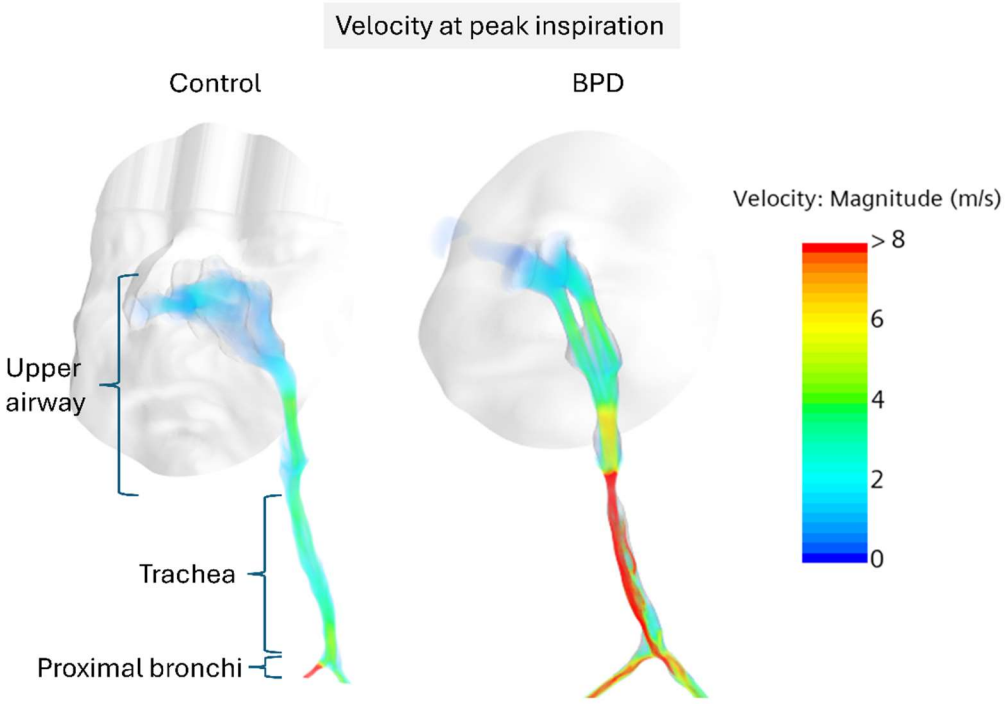
[1]Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States. [2]University of Cincinnati, Cincinnati, OH, United States

Introduction

Bronchopulmonary dysplasia (BPD) is a chronic lung disease that primarily affects premature infants. In addition to impaired lung development, many patients with BPD also present with central airway abnormalities. These overlapping airways and parenchymal impairments make it challenging to determine how much each component contributes to a patient's symptoms. Computational fluid dynamics (CFD) simulations based on magnetic resonance imaging (MRI), enable regional quantification of the kinetic energy required to move air through the airways, providing a noninvasive assessment of the resistive work of breathing (WOB). Overall respiratory workload was also calculated. Therefore, this analysis provides both the total respiratory effort, and calculates where and how that effort is spent, allowing precise phenotyping and targeted treatment plans.

Methods

A healthy respiratory control and a subject with BPD were imaged near term age using MRI to acquire three-dimensional images of the thorax. Esophageal pressure and nasal flow were recorded concurrently with MRI. Four respiratory-gated images throughout the breath were retrospectively reconstructed. Airway surfaces spanning from the nostrils to main bronchi were segmented at end-expiration, and image registration captured airway deformation across the respiratory cycle. Subject-specific geometry, motion, and measured airflow rates were used as CFD boundary conditions. The mesh consisted of polyhedral and prism cells, totaling approximately 5 million cells. Unsteady simulations employed second-order temporal discretization with a 0.8ms time step. The Large-Eddy Simulation (LES) turbulence model was used to model subgrid-scale effects. Simulations provided resistive WOB components for the upper airway, trachea, and proximal bronchi. Total resistive and elastic WOB values were integrated from lung pressure-volume loops.



Results

Relative to the control, the subject with BPD showed markedly elevated upper airway and tracheal resistive WOB, increasing by 1293% and 408%, respectively (figure). Resistive WOB in the proximal bronchi and distal airways decreased by 54% and 45%. Overall, total WOB (562%) and elastic WOB (1927%) were substantially higher in the BPD subject.

Discussion

These findings illustrate how integrated CFD and imaging methods can support phenotype-specific, computationally informed treatment strategies for neonatal respiratory disease. With additional cases, this approach could facilitate the development of patient-specific therapeutic plans.

[6]Institute of Cardiovascular Science, University College London, London, Europe, United Kingdom

Introduction

Biomechanical analysis of coronary atherosclerosis in 2D cross-sectional models have been shown to complement image-based assessment of plaque progression and identification of culprit lesions [1]. However, 2D models cannot appreciate complex vessel curvature and plaque volume distribution in patients [2]. Though, 3D reconstruction itself poses challenges in accurate plaque geometry recreation, time-consuming pre-processing and computational efficiency in typical workflows that limit large-cohort studies. This work aims to develop a fast structured-mesh-based reduced-order model of atherosclerotic coronary arteries as a practical computational method to facilitate the processing of large patient datasets, including demonstration of its efficacy to identify plaque progression.

Methods

10 patient-specific atherosclerotic coronary arteries were reconstructed from the fusion of X-ray angiogram, intravascular ultrasound and optical coherence tomography using end-diastolic frames during pull-back. All vessels were meshed using a conventional tetrahedral approach and the proposed grid-based method. Patient-specific intracoronary pressure at systole (98±24 mmHg) were used in stress analysis of each model. Because patient vessels are stressed by diastolic pressure at the time of imaging, pre-stress was calculated using inverse-elastostatics. Fibrotic tissue, calcium and lipid-rich tissue were modelled as hyperelastic materials and Von Mises stresses in the fibrotic tissue were used to assess the agreement between the two computational approaches.

Results

Tetrahedral and hexahedral approaches showed good agreement in lumen surface stress distribution, particularly in stress shielding regions caused by the calcium (Figure 1a), and cross-sectional stress distributions along the vessel (Figure 1b). The absolute agreement of the 95th centile stress was CCC = 0.93 (Figure 1c), with quantitative difference of 9.6% ± 10.2%. The time taken to produce results using the proposed method is four times faster than the conventional tetrahedral mesh.

Discussion

The proposed structured-grid-based approach was found to correlate well to the conventional approach in the estimation of stress distribution, which is produced in significantly faster time. Future analysis will extend the dataset to include 24 patients for the proposed method to investigate 3D atherosclerotic modelling in its ability to distinguish progressive and regressive patient vessels.

Impact of Reference State on Estimates of Passive Myocardial Stiffness in Hypertensive Patients

Mr Amirhossein Manzouri[1], Dr Debbie Zhao[1], Mr Stephen Creamer[1], Ms Mathilde Verlyck[1], Dr Vicky Wang[1], Dr Thiranja Babarenda Gamage[1], Prof Martyn Nash[1,2]

[1]Auckland Bioengineering Institute, University of Auckland, Auckland, Auckland, New Zealand. [2]Department of Engineering Science and Biomedical Engineering, University of Auckland, Auckland, Auckland, New Zealand

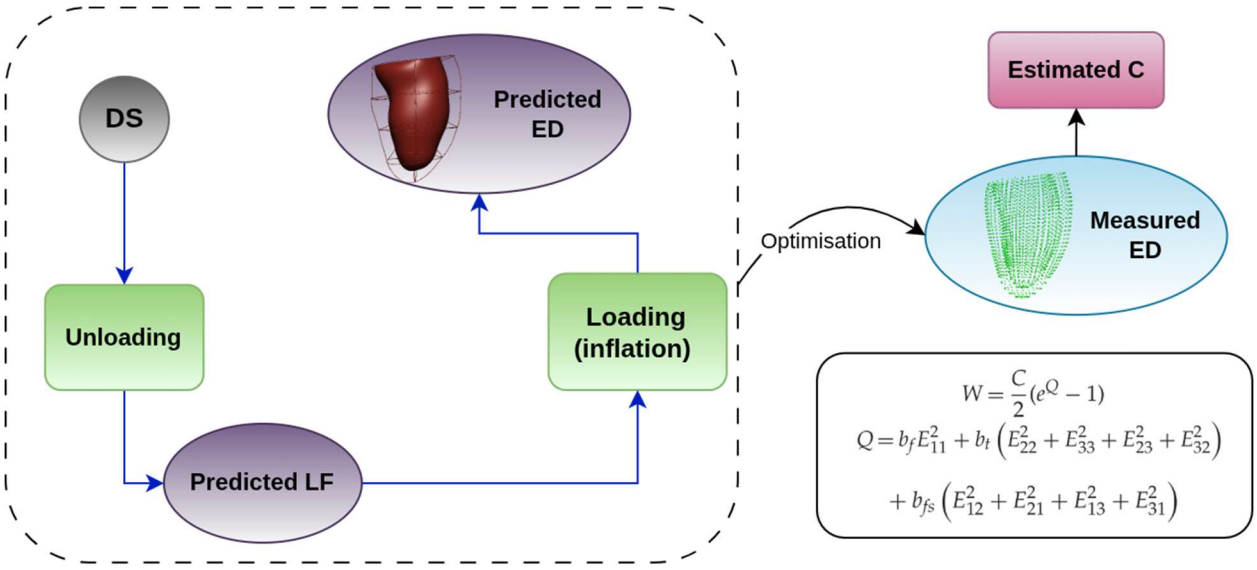
Introduction

Hypertension is a major driver of adverse cardiac remodelling and heart failure, yet clinical assessment still relies largely on chamber-level measures. Subject-specific biomechanical analysis has the potential to provide tissue-scale measurements of myocardial stiffness, offering mechanistic insights into disease processes. A key requirement for these models is a well-defined load-free (LF) reference state; however, this state cannot be directly observed in vivo because the left ventricle (LV) is typically exposed to load. It is often assumed that the ventricle reaches an LF configuration during diastole. In hypertensive patients, however, diastolic pressures are often elevated, meaning this assumption neglects substantial non-zero pressure at the assumed reference state. In this study, we investigate the impact of different reference state assumptions on myocardial stiffness estimates in patients with hypertension, using clinical data.

Methods

Clinical data from 34 hypertensive patients, comprising 3D echocardiography (3DE) and LV pressure recordings, were analysed. LV models were constructed by fitting finite element models to deep-learning-based segmentations of the LV myocardium. Myocardial stiffness (C) was estimated by minimising projection errors between model-predicted geometries and 3DE-derived surface data at end-diastole (ED).

Three approaches for handling the reference state were compared: (1) LF geometry estimation using the Rajagopal inverse method [1] with measured pressure at diastasis (DS); (2) “DS-offset” method, which subtracts the measured DS pressure from the measured ED pressure; and (3) “zero-pressure” method, which assumes DS pressure is zero, while using the measured ED pressure.



Results

The DS-offset and zero-pressure methods led to consistent overestimates of myocardial stiffness (C) compared to the LF-geometry approach. The zero-pressure approach yielded the largest bias, with stiffness values approximately 170% greater on average. The DS-offset method also showed systematic overestimation, with a more moderate but still notable mean overestimate of around 30%.

Discussion

In hypertensive patients, our clinical data show that simplifying assumptions about early diastolic pressures and neglecting the LF geometry introduce a systematic bias towards overestimating myocardial stiffness estimates. These findings highlight that accurate estimation of myocardial mechanical properties requires explicit estimation of the LF reference geometry, particularly in patients with elevated diastolic pressures.

Inverse Identification of mitral valve leaflet properties and chordal forces using a Physics-Informed Neural Network (PINN)

Ms. Anling Zhu[1], Dr. Ram Rohatgi[2,3,4], Dr. Pirooz Eghtesady[3,2], Dr. Fanwei Kong[1]

[1]Washington University in St. Louis, St. Louis, MO, United States. [2]Barnes-Jewish Hospital, St. Louis, MO, United States. [3]St. Louis Children's Hospital, St. Louis, MO, United States. [4]WashU Medicine, St. Louis, MO, United States

Introduction

Computational modeling demonstrates potential in simulating patient MV biomechanics. Standard- of- care imaging, echocardiograms, primarily resolve the geometry and motion of major leaflet structures, while chordal architecture remain partially visible. Thus, most established models assumed material properties and sub-valvular structures obtained from ex-vivo experiment data[1]. Recent machine learning developments allow inverse prediction of leaflet material properties using PINNs and leaflet motion[2,3]. However, these models are not yet applicable for MV because they do not account for the chordal forces. Thus, we explore a PINN framework to jointly estimate MV material properties and chordal forces by enforcing traction balance on the visible leaflet surfaces extracted from echocardiograms.

Methods

The PINN employs a quasi-static formulation assuming valve reaches near-mechanical equilibrium at peak systole. The network takes the nodal coordinates at mid-diastole as input and predicts displacements at peak systole. The predict displacement and Cauchy stress are computed using a Mindlin thick shell model. Losses enforcing momentum equilibrium, surface traction balance, and consistency with displacement data are incorporated. The leaflet material properties and nodal chordal traction are learnable parameters and jointly optimized with neural network parameters by minimizing the total loss function. The predicted parameters are tested in FEBio. The framework is tested on 3D TEE images of a pediatric patient with MV stenosis mainly in sub-valvular area.

Results

Our PINN demonstrates convergence in all losses and the predicted displacements match closely with ground truth at peak systole. MV structure simulated in FEBio coincides with mid-systole segmentation. Our current predicted chordal traction map does not yet reproduce physiologically realistic distributions.

Discussion

Because MV inverse biomechanics is inherently ill-posed, reliable parameter estimation requires strong regularization and the incorporation of prior knowledge. Ongoing work includes assimilating prior knowledge of chordal force patterns into the PINN framework and incorporating time-series dynamical models. Nonetheless, this approach may offer an alternative to manual, iterative parameter tuning and may substantially reduce the time required to build patient-specific mitral valve computational models.

Blood pressure modulation during heart-paced walking is explained by vertical body acceleration

PhD Candidate Aurora Rosato[1], Dr. Emanuele Perra[2], Dr. Seraina A. Dual[1]

[1]Intelligent Heart Technology Lab, Department of Biomedical Engineering and Health Systems, KTH Royal Institute of Technology, Stockholm, Stockholm, Sweden. [2]Getinge, Acute Care Therapies, Maquet Critical Care AB, Solna, Stockholm, Sweden

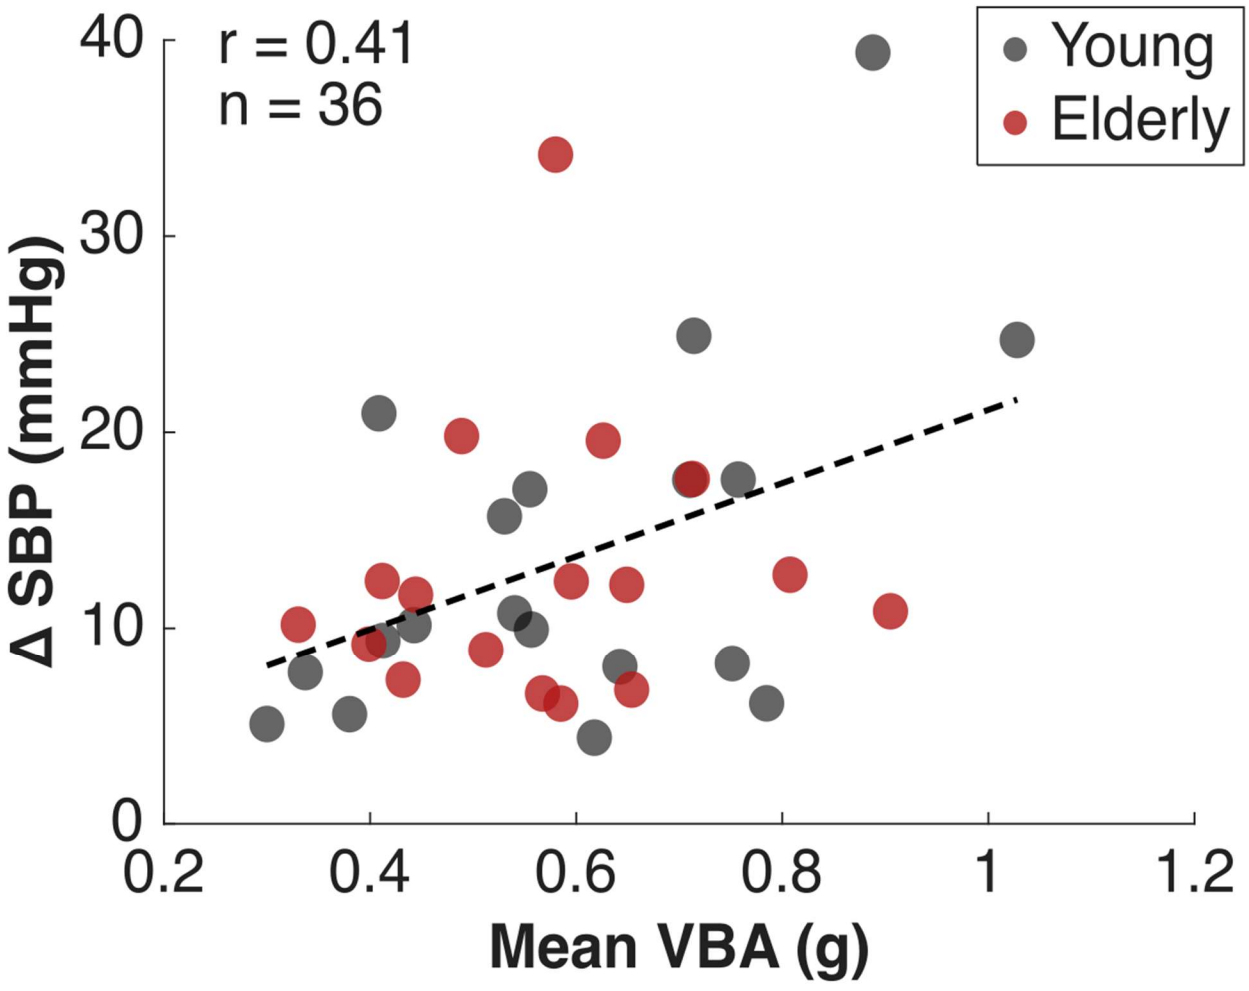
Introduction

Heart-paced walking can improve exercise capacity, but the underlying biomechanical mechanisms are not fully understood. During walking, blood pressure (BP) is influenced by cardiac pumping, skeletal muscle pumping, and vertical body acceleration (VBA). Here, we investigate how inertial forces induced by VBA peaks contribute to BP modulation using a computational model of the cardiovascular system and experimental measurements during heart-paced treadmill walking.

Methods

The cardiovascular model consisted of a 25-compartment lumped parameter network incorporating a four-chamber heart, pericardial and intrathoracic pressures, and baroreflex. Inertial effects were mechanistically modeled as hydrodynamic pressure sources in all vertically aligned vessels without additional parameters. We recorded data from 36 healthy participants (19 younger adults: 28±3 years; 17 older adults: 71±5 years), who performed bouts of phase-locked heart-paced walking guided by auditory cues in a randomized cross-over design. We non-invasively acquired continuous brachial BP, electrocardiogram, and stroke volume (SV), time-synchronized to VBA using a chest-worn sensor (Cometa Srl., Italy). We imposed the recorded heart rate and VBA from two subjects (P1: 31 years and P2: 26 years) onto the model and compared the morphology of the simulated aortic BP to the measured BP. In the full cohort, we analyzed the correlation between the maximum modulation of systolic BP across phases (ΔSBP) and mean VBA.

Results



The model successfully reproduces the distinct pressure waveform morphology observed experimentally during phase-locked heart-paced walking in the two subjects we simulated. Measured stepping timing across phases led to a substantial SBP and SV change in P1 (-25 mmHg ΔSBP, +68.9 mL SV), in contrast to P2 (-5mmHg ΔSBP, +15.6 mL ΔSV). These strong

effects were associated with higher measured VBA (0.71± 0.07 g vs. 0.29±0.05 g) and peak VBA (1.4±0.06g vs. 1.1±0.03g) in P1 vs. P2, respectively. ΔSBP exhibited a moderate positive correlation (R=0.41, p<0.05, n=36) with the mean VBA, Figure 1.

Discussion

Our findings suggest that VBA is a significant biomechanical player in the BP modulation observed during walking. The magnitude of VBA appears directly related to the observed hemodynamic effects. Future work will extend the computational modeling analysis across the full cohort, incorporating subject-specific effects.

Non-invasive, High-Resolution, and Quantitative Assessment of Cerebrovascular Reactivity Using a Whole-Brain 3D-1D-0D Geometric Multiscale Model

Graduate Student Zijie Wang, Professor Youjun Liu, Professor Liyuan Zhang, Professor Bao Li, Professor Mingai Li

Beijing University of Technology, Beijing, Chaoyang District, China

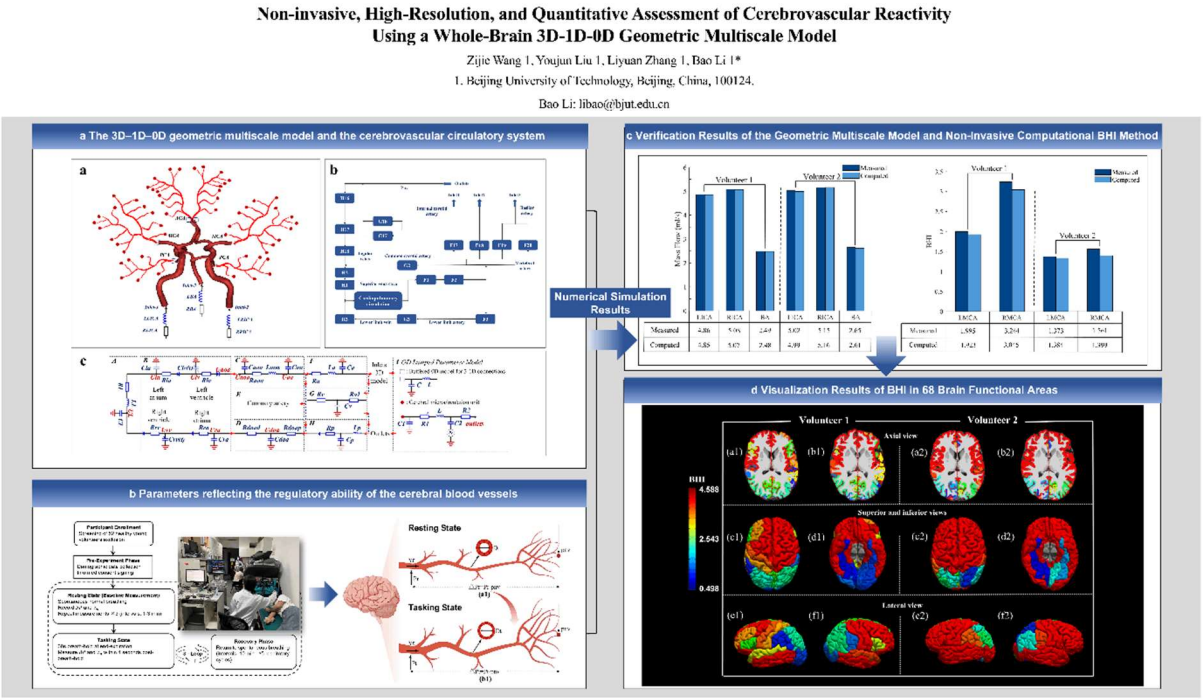
Introduction

Cerebrovascular Reactivity (CVR) is a core indicator for assessing ischemic stroke. Existing technologies face bottlenecks: MRI, despite high resolution, struggles to provide absolute quantitative measures of blood flow; TCD has low spatial resolution, missing whole-brain fine perfusion details. Furthermore, standardized gas induction (CO2 inhalation) is operationally complex and imposes a significant physiological burden on patients. Thus, developing a non-invasive, high-resolution, absolutely quantitative numerical simulation method is urgently required.

Methods

This study constructed a whole-brain 3D-1D-0D geometric multiscale model: a 3D model (Willis loop and major branches) reconstructed from CTA data; a 1D model (distal arteriolar tree) based on allometric scaling algorithms; and a 0D lumped parameter model characterizing microcirculation impedance. Based on standardized breath-holding experiments (52 volunteers), two key quantitative parameters—the mean resistance variation coefficient (R_v) and the diameter variation coefficient (D_v)—were derived via fluid dynamics. These parameters drive the model to simulate the hypercapnic state and calculate BHI. Crucially, the convection-diffusion equation was introduced to model blood transport within 3D brain tissue, achieving not only data calculation for 68 functional regions (DK atlas) but also precise millimeter-level voxel-wise analysis of whole-brain perfusion and BHI distribution.

Results



Resting flow validation showed high consistency with TCD (Mean Absolute Error, MAE = 0.0183). Inputting R_v = 0.5878 and D_v = 1.3286, the model successfully reproduced the hypercapnia-induced hemodynamic response, matching TCD BHI (MAE = 0.11925). The visualization of BHI and cerebral perfusion across the 68 functional regions confirmed the

model's high spatial resolution. Subsequent pathological simulation (MCA stenosis) verified the model's applicability in disease assessment.

Discussion

This study first quantitatively characterized the regulation of microcirculatory resistance and arteriolar diameter under hypercapnia. We propose a novel 3D-1D-0D geometric multiscale BHI calculation method driven by parameters reflecting cerebrovascular regulation capability. This approach overcomes traditional imaging limits in quantification and resolution, providing a non-invasive, high-resolution (functional region and voxel-level), and absolutely quantitative CVR assessment tool, offering a valuable technical pathway for individualized stroke intervention.

Real-Time Prediction of Stent Deployment for Brain Aneurysms Treatment Using Statistical Shape Modelling and Finite-Element-Based Surrogate Modelling

PhD Beatrice Bisighini[1], PhD Baptiste Pierrat[1], Prof Stéphane Avril[1], PhD Miquel Aguirre[2,3]

[1]Sainbiose, Mines Saint-Étienne, Saint-Étienne, Auvergne-Rhône-Alpes, France. [2]Universitat Politècnica de Catalunya, Barcelona, Catalunya, Spain. [3]CIMNE, Barcelona, Catalunya, Spain

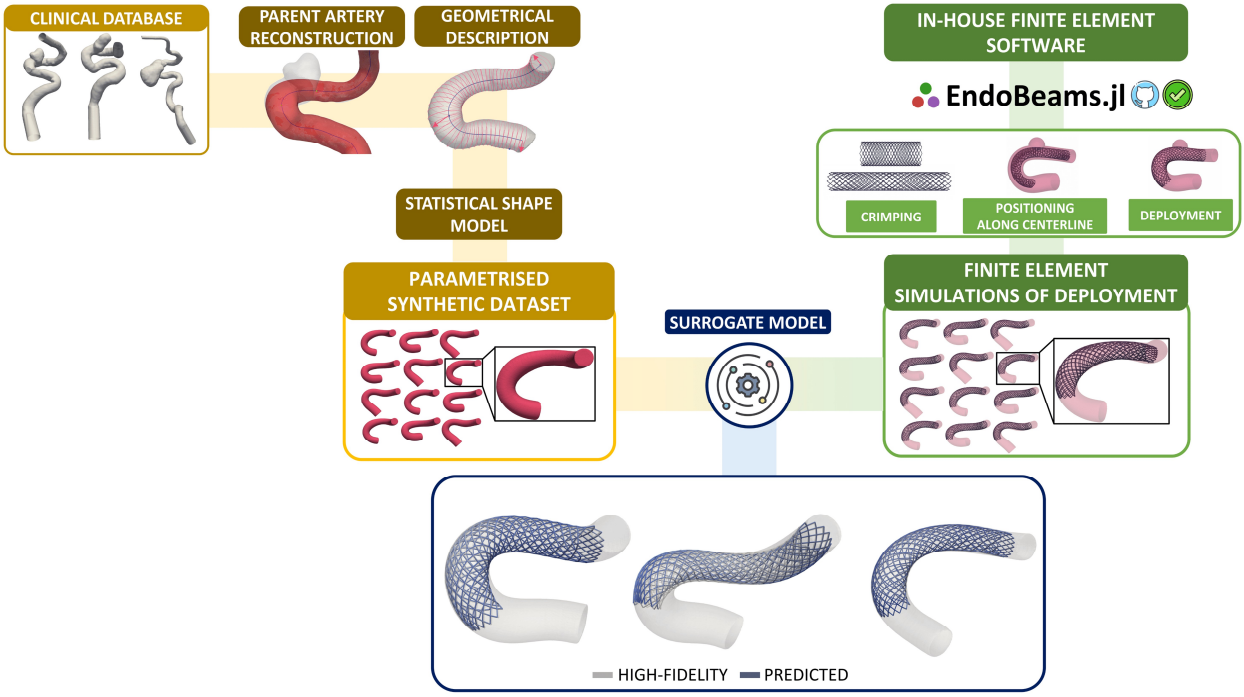
Introduction

The growing adoption of minimally invasive procedures has intensified the need for fast and reliable planning tools capable of predicting both operative outcomes. Finite-element-based surrogate modelling has emerged as a promising approach [1], yet significant challenges persist in cardiovascular applications. These challenges stem from the complexity of parametrising vascular anatomy, the limited availability of clinical data, and the substantial computational cost of high-fidelity simulations. In this study, we present a framework that integrates finite element modelling with statistical shape modelling and machine learning to achieve real-time prediction of stent deployment for the treatment of cerebral aneurysms.

Methods

We based our work on a clinical database of cerebral aneurysms and their associated parent arteries. Due to their substantial morphological variability, we focused on small-neck cases, where the effect of the aneurysm shape on stent behaviour is minimal. For each patient-specific geometry, the parent artery was reconstructed and used to build a statistical shape model, later used to parametrise the anatomies and augment the dataset through the generation of synthetic cases. Stent deployment was simulated for every synthetic artery using EndoBeams.jl, our open-source finite element software previously validated through benchmark studies and experimental tests [2]. A surrogate model, combining proper orthogonal decomposition with gaussian process regression, was trained to map statistical shape features of the arteries to their corresponding deployed stent configurations.

Results



Even with 400 samples, prediction accuracy remained high, with average positional errors below 8.6% and median errors around 1.6%. Expanding the training set to 4900 samples further improved performance, yielding a median positional error under 0.1 mm (0.97%)

and a maximum error of 0.5 mm (4.8%). The largest discrepancies appeared in the radial direction, whereas deployed stent length was consistently predicted with high accuracy.

Discussion

These findings demonstrate that surrogate modelling offers a robust and clinically meaningful solution for real-time prediction of stent deployment, even in complex scenarios. Future work will incorporate aneurysm–artery intersection features into the parametrisation, enabling extension of the method to large-neck aneurysms.

High Speed Acute Cardiac Infarct Simulations using High Fidelity Heart Data and the Neural Network Finite Element Approach

Mr. Benjamin Thomas, Prof. Michael Sacks Ph.D.

University of Texas at Austin, Austin, Texas, United States

Introduction

Simulations of cardiac disease remains a cornerstone of discovery and treatment development, yet current cardiac simulations remain unsuitable for near real-time clinical decision making due to time-intensive methods. To address this, simulations need to execute in a tractable clinical timeframe (execution times on the order of minutes). Scientific Machine Learning (SciML) exploits recent advances in machine learning to solve physics-based models. We utilized our neural network finite element SciML approach to perform realistic high-speed simulations of the normal and infarcted heart using a comprehensive heart model dataset. We demonstrate the ability to generate high fidelity pressure-volume (PV) and wall stress responses in a matter of 2-4 seconds.

Methods

We utilized a high-fidelity ovine heart dataset, including geometry, fiber structure, surface action potentials, and pressure-volume from a single heart. We extended our SciML "Neural Network Finite Element (NNFE)" method that utilized a finite elements mesh for problem geometry and directly solves the parameter-to-solution map by learning the displacement solution over the complete physiological range. To simulate myocardial infarction, the training regime was extended to include a range of infarct sizes and anatomical locations. The final JAX-based software platform, termed 'CARDIAX,' required no data as the NNFE method solves the same governing equations by minimizing the same residual that is used in the traditional finite element method.

Results

The NNFE neural networks for healthy and infarcted models were trained until the errors over the physiological range were within 0.1% error of the standard FE simulation displacements. This is checked after training and is not used during training. Once trained was completed, the time to evaluate the NNFE cardiac model was approximately 0.15 seconds, with a complete pressure-volume loop in about 1 second. In additional accurate displacement, stress, and strain tensors, the NNFE method was able to accurately predict the effects of randomly size/placed infarcts.

Discussion

We demonstrated the ability to learn the normal and acutely infarcted PV loop using a high-fidelity heart model using the ‘CARDIAX’ NNFE method. We are currently incorporating B-spline geometries allowing patient specific geometries and reduce the problem size to reduce training and execution times.

In Vivo Deformation of the Human Single Ventricle

Mr. Benjamin Thomas[1], Dr. Radomir Chabiniok M.D., Ph.D.[2], Prof. Michael Sacks Ph.D.[1]

[1]University of Texas at Austin, Austin, Texas, United States. [2]UT Southwestern Medical Center, Dallas, Texas, United States

Introduction

Single ventricle (SV) disease is a congenital condition where the ventricles fuse during in utero development. The abnormal shape of the SV directly influences the underlying biomechanics of the patient's heart and can lead to increased mortality.
We determined the local in vivo SV deformations over a single cardiac cycle to obtain regional strains fields and area changes. By determining the *in vivo* deformation, we can better understand this disease and develop better metrics to characterize the severity of the disease.

Methods

3D in vivo images of 3 patients with SV were segmented over the cardiac cycle, with 15-20 frames total per heart. To compute the 3D wall strains, we use truncated hierarchical B-splines (THB-spline) to encapsulate the SV endocardial and epicardial surfaces. Cubic order was used for the in-surface directions and linear order for the transmural direction. As in previous surface-based studies, we exploited the local support nature of B-splines to compute local deformations. Use of THB-splines further allowed local mesh refinement for regions of more complex geometry and deformation that are common to the SV. The resulting personalized mesh convects with the SV over the cardiac cycle, allowing 3D shape and strains to be directly computed.

Results

Use of THB splines resulted in high fidelity fits with far fewer control points than our previous NURBS based method, with no loss of accuracy. Results from all three patients demonstrated very complex, asymmetric, and generally very abnormal deformations patterns. These included focal regions of high deformation (>30% strain), irregular shape, and pronounced irregular end-diastole to end-systolic deformations. Some transmural shearing was also observed, especially mid-ventricle.

Discussion

We have shown the unique ability to compute the in vivo deformations of the single ventricle. This gives key insights into the local strain patterns that the ventricle undergoes.

An improvement to this method would be to also take into account the biomechanics of the tissue when tracking over time to fill in the 3D volume and give more accurate estimates throughout the ventricle. Use of THB-splines will facilitate direct translation to efficient computational modeling already in progress.

[5]Korea University Ansan Hospital, Ansan, Gyeonggi-do, Korea, Republic of

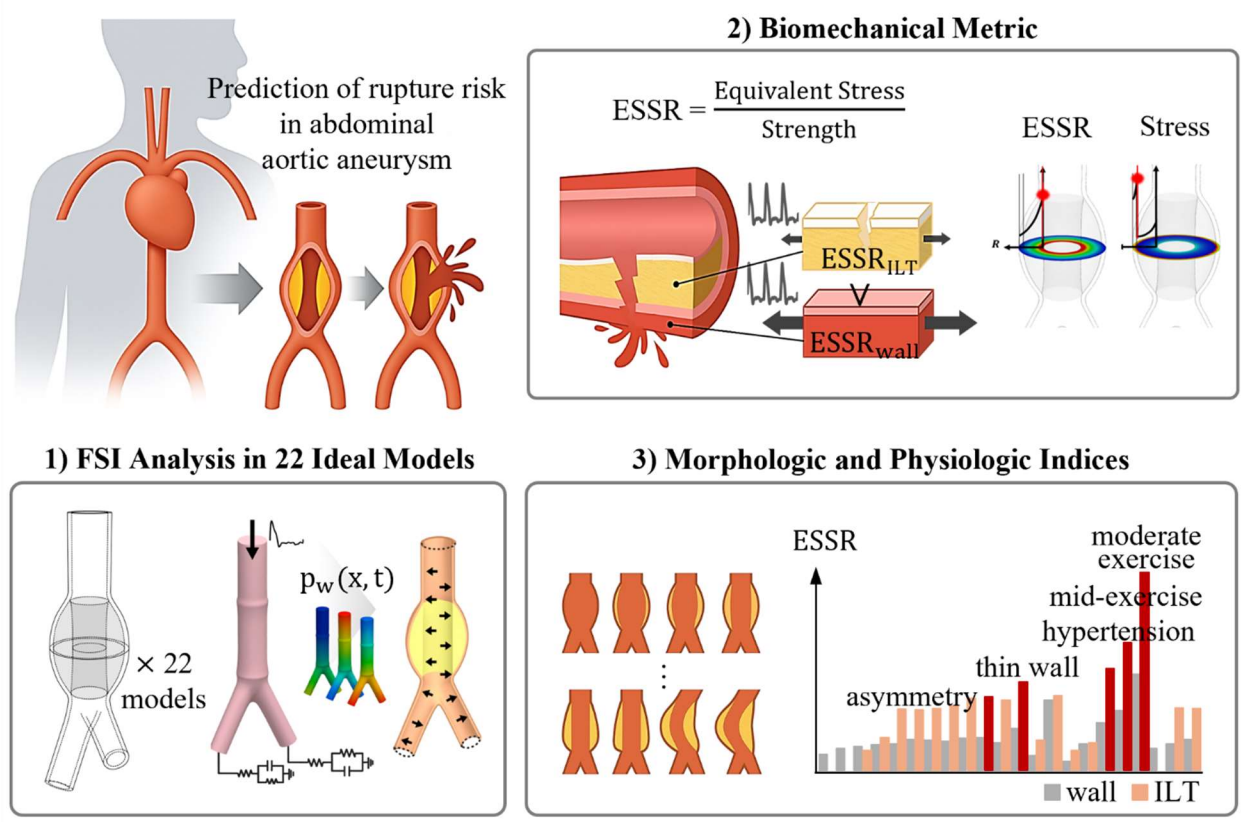
Introduction

Abdominal aortic aneurysm (AAA) is a prevalent cardiovascular disease in which rupture remains a major cause of morbidity and mortality. Reliable prediction of rupture risk and location is essential for effective clinical management. However, commonly used indices do not adequately capture the biomechanical behavior of the aneurysmal wall and the underlying mechanisms of rupture.

Methods

We present a biomechanical metric - the equivalent stress-to-strength ratio (ESSR) – that incorporates both arterial wall strength and pulsatile loading conditions. The performance of ESSR was evaluated across a broad range of biomechanical, morphologic, and physiologic conditions and compared against conventional stress- and strain-based indices. Twenty-two idealized AAA models with systematically varied geometric, material, and physiological parameters were analyzed using three-dimensional, one-way fluid–structure interaction simulation. ESSR, stress, and strain distributions were quantified and assessed in the context of clinically reported rupture scenarios.

Results



ESSR consistently predicted all clinically observed rupture-prone locations, whereas traditional biomechanical indices aligned with only a subset of these observations. ESSR indicated elevated rupture risk within regions of thick intraluminal thrombus (ILT) or in thrombus-free wall segments when ILT was thin. In cases with sagging ILT, the predicted rupture-prone region shifted toward areas of maximal thrombus thickness. Exercise and

hypertension increased overall rupture susceptibility, and aortic asymmetry and reduced wall thickness elevated localized rupture risk.

Discussion

ESSR effectively captures the interplay between mechanical loading and tissue strength, enabling more accurate prediction of AAA rupture scenarios than stress- or strain-based metrics. The results highlight the importance of ILT thickness, blood pressure, wall thickness, and geometric asymmetry in governing rupture risk. ESSR shows strong promise as a clinically useful biomechanical indicator for identifying high-risk AAA conditions.

Predicting Postoperative Cerebral Perfusion in Chronic Internal Carotid Artery Stenosis Through Patient-Specific Inference of Leptomeningeal Anastomoses

Mr. Chi Hang To MSc[1], Mr. Yuki Kotani BSc[1], Dr. Shigeki Yamada PhD[2], Dr. Marie Oshima PhD[1]

[1]The University of Tokyo, Tokyo, Tokyo, Japan. [2]Nagoya City University, Nagoya, Aichi, Japan

Introduction

Predicting regional cerebral perfusion under chronic carotid stenosis after surgery is crucial to prognosis [1], but remains challenging because leptomeningeal anastomoses (LMAs) and distal autoregulatory capacity cannot be imaged directly [2]. This study develops and validates a computational framework that (1) infers patient-specific LMA connectivity under distal vascular uncertainty, (2) incorporates autoregulation, and (3) integrates inferred collaterals into a 1D–0D whole-body circulation model to enable preoperative prediction of postoperative distal perfusion.

Methods

Ensembles of distal arterial networks were generated by probabilistic sampling of anatomical parameters constrained by Murray's law and projected onto the cortical surface. LMA connectivity was inferred per patient by minimising mismatch between simulated and preoperative SPECT perfusion using a genetic algorithm with preoperative 4D Flow MRI inflows as boundary conditions and LMA configuration as the decision variable. Postoperative perfusion was simulated using pre-optimised vasculature with postoperative inflows, incorporating a simplified flow-dependent autoregulation model. Inferred LMA characteristics were mapped to a lumped-parameter representation and incorporated into a 1D–0D whole-body circulation model.

Results

Four patients with internal carotid artery stenosis were analysed. For each, an ensemble of 200 optimised peripheral vascular configurations converged toward a coherent functional mode of collateral redistribution. Inferred redistribution patterns, LMA radii and counts were physiologically plausible and consistent with reported ranges. Postoperative simulations captured cerebral perfusion in three patients. In the remaining patient, perfusion was not fully captured, and incorporation of the simplified autoregulation model did not improve agreement. Initial tests indicate that the lumped LMA model can reproduce flow patterns consistent with detailed LMA simulations under baseline conditions.

Discussion

Results demonstrate that the framework produces physiologically plausible distal perfusion predictions, and that ensemble-based inference covers the range of possible collateral configurations without overfitting, enabling lumped 1D–0D representation. The mismatched case reflects pronounced autoregulatory impairment and non-uniform pial pressure under extreme stenosis. Limitations include small cohort and lack of patient-specific measurements for intracranial boundary conditions. Future work will validate predictive accuracy across more patients, refine autoregulation using acetazolamide-challenge data, and explore virtual-surgery scenarios to assess potential of model for preoperative planning.

A Multi-scale Modeling Approach for Understanding Cardiovascular Remodeling in Gender-Affirming Hormone Replacement Therapy

Mx. Christian Andrade Herrera, Mrs. Adhithi Lakshmikanthan M.S., Dr. Pim Oomen PhD

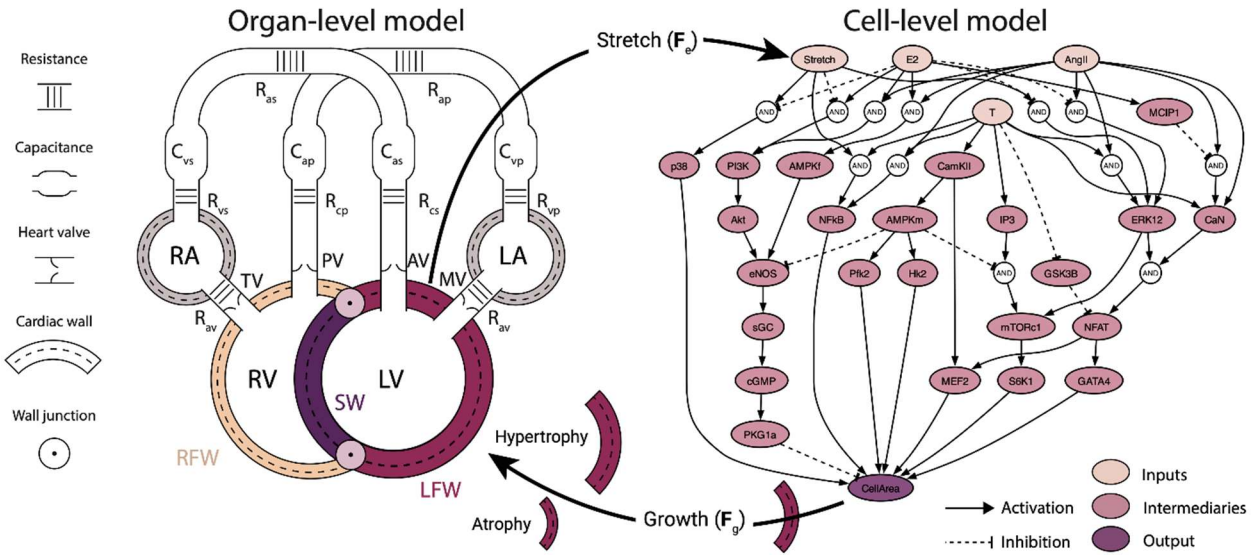
Department of Biomedical Engineering, Edwards Lifesciences Foundation Cardiovascular Innovation and Research Center, University of California, Irvine., Irvine, California, United States

Introduction

Gender-affirming hormone therapy (GAHT) induces physical changes by introducing or suppressing sex hormones. These treatments are lifesaving for transgender individuals, preventing suicide and depression. As GAHT becomes increasingly accessible, we are just beginning to observe and understand its long-term consequences across the lifespan. However, there is limited understanding of how GAHT impacts the heart, despite estrogen and testosterone's well-established impact on cardiac remodeling and function. Therefore, we use a novel multi-scale modeling approach to test the hypothesis that GAHT causes cardiac remodeling.

Methods

We created a multi-scale model by combining our recently published models of organ-scale cardiovascular mechanics [2] and cell-scale mechanobiology model of cardiomyocyte signaling [3]. The organ-scale sub-model employs a reduced-order model approach to simulate cardiac mechanics and hemodynamics. The cell-scale mechanobiology sub-model uniquely incorporates sex hormone-driven cardiomyocyte hypertrophic signaling. The sub-models were coupled using linear transfer functions [4], as shown in Fig. 1, creating a closed-loop system of organ-to-cell mechanics and cell-to-organ hypertrophy.



Results

We fine-tuned the organ-level model parameters to match the baseline volumes for trans-males and trans-females [5]. We prescribed the hormone dose (estrogen or testosterone) and calibrated the linear transfer function to match the 6-month post-GHRT change in LVESV and LVEDV: an 8.9% increase for transgender men and a 1.9% decrease for trans-females [5].

Discussion

Our preliminary findings align with reported data showing changes in LVEDV and LVESV. The more pronounced remodeling observed in transgender men compared to transgender women is consistent with testosterone's greater hypertrophic effect compared to estrogen. However, multiple assumptions were also made due to the available data. Future work will focus on matching individual patient data to further validate our model. In conclusion, we developed a multi-scale model that can match cardiac remodeling 6 months post-GHRT. Ultimately, our multiscale model could be used to elucidate whether changes in cardiovascular mass are due to hormonal, mechanical, or a combination of both factors.

Novel Method to Quantify Tracheal Work of Breathing During Exercise Using MRI-Derived CFD

Mr. Christopher Boles B.Sc.[1,2], Dr. Chamindu Gunatilaka Ph.D.[3], Mr. Keith McConnell M.Sc.[1], Dr. Qiwei Xiao Ph.D.[1], Dr. Hamideh Hayati Ph.D.[1], Dr. Alister Bates Ph.D.[1,2]

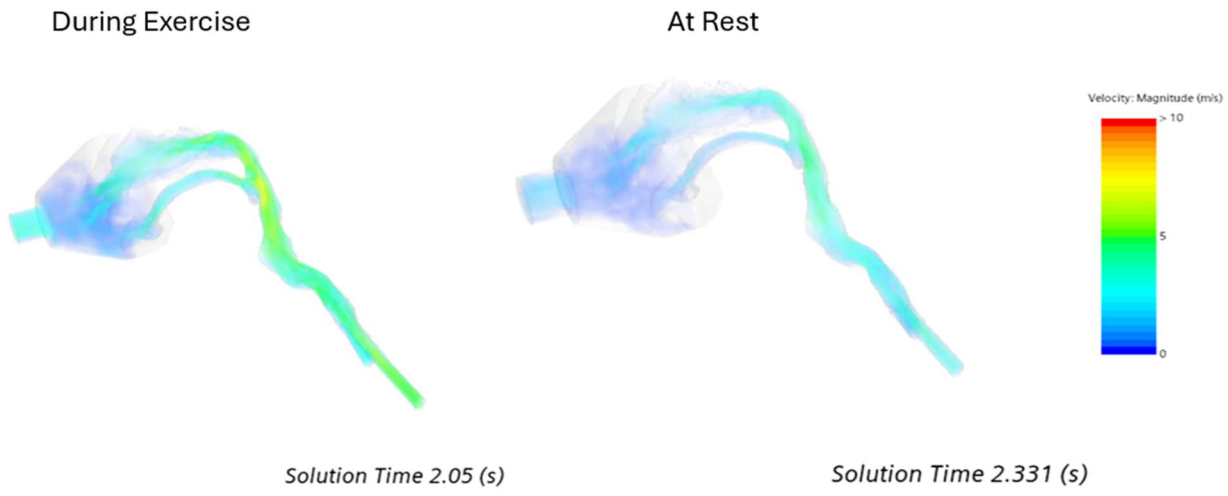
[1]Cincinnati Children's Hospital Pulmonary Medicine, Cincinnati, Ohio, United States. [2]University of Cincinnati Biomedical Engineering, Cincinnati, Ohio, United States. [3]Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio, United States

Introduction

Exercise intolerance from dynamic airway obstruction is common and frequently overlooked in youth. Inducible laryngeal obstruction and large airway collapse affect ~7.5% of youth and up to 34% of youth athletes, where increased ventilation reveals hidden collapse. Additionally, exercise-induced bronchospasm occurs in up to 90% of patients with asthma, and exercise-induced bronchoconstriction affects ~15% of youth athletes, further increasing the mechanical burden of breathing. Conventional cardiopulmonary exercise testing cannot localize obstruction location. Work of breathing (WOB) quantifies the effort needed to move air through the respiratory system and can be regionally decomposed using subject-specific computational fluid dynamics (CFD) informed by imaging. Cine magnetic resonance imaging (MRI) sequences visualize the airway mechanics. This study represents the first integration of exercise MRI and CFD to measure tracheal resistive WOB during exercise.

Methods

A healthy young male adult underwent MRI during moderate exercise and at rest. Moderate exercise was defined as achieving ≥100 bpm heart rate while operating an MRI-compatible stepper with resistance bands opposing motion. Imaging included e-THRIVE for cine imaging across the respiratory cycle and FLORET for static anatomy. The airway from nostrils to main bronchi was segmented using ITK-SNAP. Nasal airflow was collected and applied as the inlet boundary condition. CFD simulated a full respiratory cycle and calculated resistive WOB from regional kinetic energy losses between planes at the distal and proximal ends of the upper airway and trachea.



Results

MRI acquisition during exercise was successfully performed without significant motion artifact. Tidal Volume increased from 489 mL at rest to 690 mL during exercise. Tracheal resistive WOB per breath increased from 3.32 mJ at rest to 11.02 mJ during exercise. Tracheal WOB increased from 1.69 mJ/s to 4.48 mJ/s, demonstrating a 165% increase in breathing effort during exercise.

Discussion

This study represents the first demonstration of combining MRI and CFD to assess airway WOB during exercise. This framework enables quantification of how exercise stress alters airflow mechanics and may reveal ventilatory inefficiencies not present at rest. Future studies will include participants with a history of exercise intolerance to understand how to provide more accurate treatment and surgical procedures.

Changes in Heart Rate and Heart Rate Variability Pre, During, and Post a 6-Minute Walk Test in Older Adults based on Physical Activity Level

Ms Chyenne Neath BSc (Hons), Dr. Stephen Klassen PhD, Dr. Kimberley Gammage PhD, Dr. Nicole Chimera PhD, CAT(C), ATC, CSCS

Brock University, St Catharines, Ontario, Canada

Introduction

Heart rate (HR) and root mean square of successive differences (RMSSD) are inversely related parameters that assess cardiovascular health and cardiac autonomic regulation, respectively. Both provide insight into overall fitness levels. RMSSD differences have been explored across rest and exercise, but few studies have explored changes across physical activity (PA) levels in older adults. Understanding these differences is important as decreased autonomic function and fitness are associated with aging. This study aims to explore the impact of fitness level on HR and RMSSD pre-, during-, and post-6-minute walk test (6MWT) in older adults.

Methods

A quasi-experimental time-series design assessed HR and RMSSD in adults ≥55 years. The independent variables were PA (low, moderate, high) and time (pre-,during-,post-6MWT); Godin-Shephard Leisure-Time PA Questionnaire identified PA groups. Participants rested supine for 10 minutes pre- and post-6MWT; HR and RMSSD were recorded using Firstbeat Bodyguard 3 (BG30039243, Firstbeat Technologies Ltd, Jyväskylä, Finland) and calculated during a five-minute window in each timepoint. A two-way repeated-measures ANOVA (RM-ANOVA; $p<0.05$) determined HR and RMSSD differences across timepoints and between PA; Holm post-hoc tests assessed interactions. Analyses were performed in JASP (version 0.95.4).

Results

Twenty-eight older adults (16 females, 12 males;55-78 years) had HR and RMSSD assessed pre-, during-, and post-6MWT (Table 1). RM-ANOVA for RMSSD demonstrated statistically significant main effects for time ($p<0.001$); post-hoc tests demonstrated RMSSD was lower during- (12ms±6) versus pre- (26ms±17, $p<0.001$) and post- (26ms±24, $p=0.005$) 6MWT. RM-ANOVA for HR demonstrated statistically significant main effects for time ($p<0.001$); post-hoc tests demonstrated HR was larger during- (115bpm±21) versus pre- (61bpm±9, $p<0.001$) and post- (64bpm±11, $p<0.001$), and post- versus pre- (64bpm±11 vs. 61bpm±9, $p=0.012$) 6MWT. Despite no current significant interaction, there is a trend

towards significance in the main effect of PA (p=0.053) and the interaction between time and PA (p=0.051).

Discussion

Preliminarily, RMSSD is lower and HR is higher during- compared to pre- and post-6MWT and HR is lower pre- compared to post-6MWT; there are no differences between PA or between time and PA interactions. This suggests RMSSD and HR may vary similarly pre-, during-, and post-6MWT across PA groups.

Images (Optional)

Table 1. Average heart rate and RMSSD pre-, during-, and post-6MWT for participants in low, moderate, and high PA groups.

Cerebral Collateral Development Alters Circle of Willis Hemodynamics and Forces Experienced by the Occlusive Clot During Acute Ischemic Stroke - A Computational Fluid Dynamics Study

Mr. Cody Kubicki[1], Dr. Scott Simon[2], Dr. Keefe Manning[1,3]

[1]Department of Biomedical Engineering, The Pennsylvania State University, University Park, PA, United States. [2]Department of Neurosurgery, Penn State College of Medicine, Hershey, PA, United States. [3]Department of Surgery, Penn State College of Medicine, Hershey, PA, United States

Introduction

Cerebral collateral assessment has become a common metric for treatment planning in acute ischemic stroke patients [1] due to clinical evidence that well-developed collateral networks are correlated with favorable patient outcomes for reperfusion therapies [2]. However, the mechanisms driving these outcome disparities are not well clarified.

Methods

A computational fluid dynamics model developed in OpenFOAM was used to assess hemodynamic changes during large vessel occlusion (LVO) and to relate these changes to the mechanisms governing reperfusion therapy susceptibility. Blood flow and clot forces were quantified in a Circle of Willis model with varying collateral development levels during middle cerebral artery (MCA) occlusion. A lumped resistor model represented the collateral network based on the total applied hemodynamic resistance (R_{CN}). Five collateral development conditions were simulated, ranging from favorable (CS4 – R_{CN}=1x10^9 Pa·s/m^3), to poor (CS1 – R_{CN}=18x10^9 Pa·s/m^3), to absent (CS0 – R_{CN}=Inf Pa·s/m^3).

Results

MCA occlusion caused up to a 30% increase in systemic mean arterial pressure (MAP) but was less severe in favorable collateral cases. The ipsilateral collateral flow increased up to 20-fold following LVO, which elevated blood flow distal to the LVO. Favorable collaterals showed a 66% lower pressure drop across the clot compared to poor collaterals, which was modulated primarily by distal pressure changes. Lower pressure drops led to a linear decline in distal compaction forces experienced by the clot, ranging from 116.3 mN to 47.8 mN, similar to force estimates on clots *in vivo* [3] (see table).

Discussion

Our study indicated that collaterals serve multiple functions during stroke. First, collaterals compensate for lost blood flow to the affected brain region by permitting retrograde flow toward the distal end of the occluded vessel. Second, collaterals reduce the pressure forces on the clot, which can improve reperfusion therapy susceptibility. Overall, this study showed that we can leverage our computational model to better understand the importance of cerebral collateral circulation during stroke and the influence of collaterals on therapeutic outcomes in a realistic simulated physiological environment.

Controlled Intramural Fluid Injection Reveals Biomechanical Drivers of Thoracic Aortic Dissection

Dr Cristina Cavinato[1,2], Dr Baptiste Pierrat[3], Dr Ehsan Ban[2], Dr Mathieu Simon[3], Pr Jay D. Humphrey[2,4]

[1]LMGC, Univ. Montpellier, CNRS, Montpellier, France, France. [2]Department of Biomedical Engineering, Yale University, New Haven, CT, United States. [4]Vascular Biology and Therapeutics Program, Yale School of Medicine, New Haven, CT, United States

Introduction

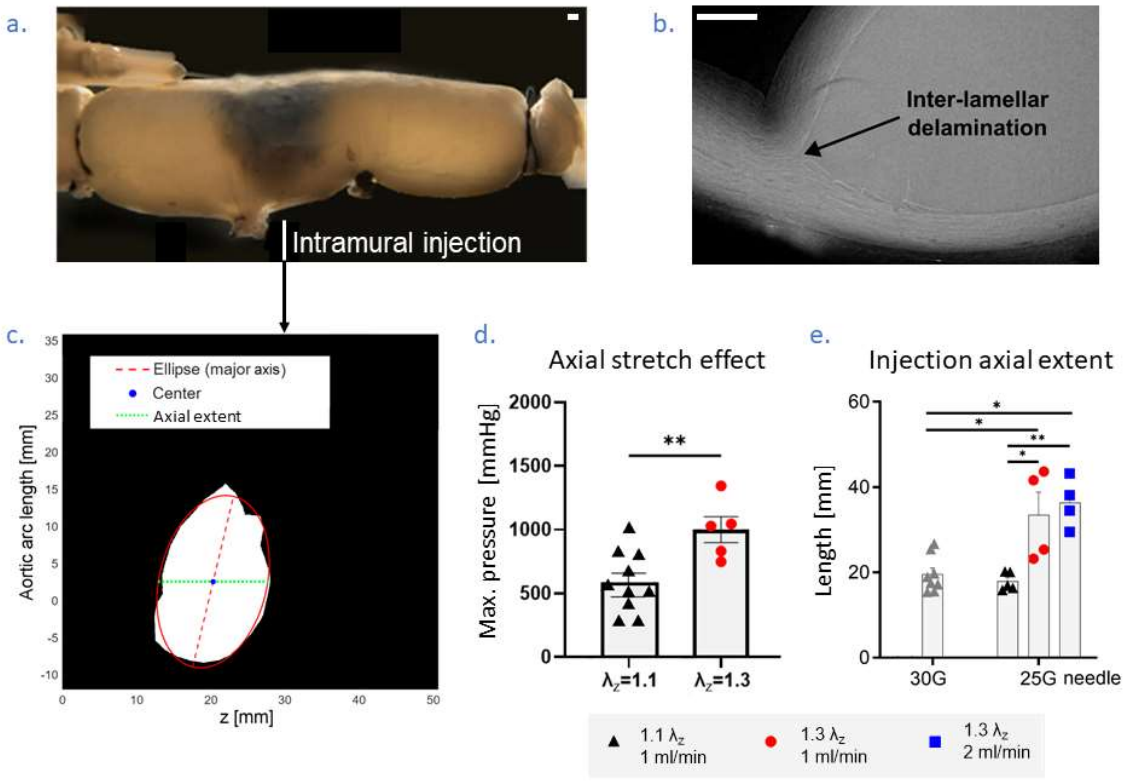
Thoracic aortic dissection remains a devastating clinical event whose progression depends on the interplay between global mechanical loads, local wall structure, and the morphology of an initiating tear [1]. Yet, the biomechanical conditions that govern intramural propagation— particularly the pressure and structural thresholds required to extend an existing lesion—remain poorly defined, largely due to difficulties in observing this process *in vivo* or reproducing it under physiologically relevant ex vivo conditions.

Methods

Controlled extension–distension loading was combined with intramural injection to quantify how mechanical and injection parameters modulate dissection initiation and propagation in intact porcine descending thoracic aortas (DTAs). DTAs were mounted in a controlled extension–distension system, equilibrated at physiological pressure, and mechanically characterized via a comprehensive protocol. A validated four-fiber family model captured their nonlinear, anisotropic behavior. Intramural injections were performed under fixed luminal pressure while varying axial stretch (1.1vs.1.3), injection rate (1 vs. 2 mL/min), and needle gauge (25Gvs.30G).

Results

Pressure–volume curves exhibited a steep rise followed by stepwise fluctuations, reflecting successive medial micro-failures before depressurization of the false lumen. Higher axial stretch increased peak pressures and injected volumes (Fig.1), whereas faster injection rates produced sharp pressure elevations at lower volumes, consistent with prior injection-



based delamination studies [2]. Smaller needles generated higher pressures for equivalent volumes, reflecting greater local stress concentration.

Quantitative image analysis—using synchronized orthogonal cameras, cylindrical surface reconstructions, and morphometric metrics—showed that axial stretch and injection rate are dominant regulators of dissection morphology. Increased axial stretch produced larger, elongated, and more anisotropic intramural patches, while higher injection rates promoted circumferential propagation and extensive interlamellar separation, corroborated by histomorphology. Synchrotron X-ray phase-contrast imaging of non-tensioned DTAs with contrast-agent injections revealed the interaction of the liquid with the lamellar structure before propagation and the subsequent dissection path, consistent with camera-based and histological measurements, reinforcing result robustness.

Discussion

Together, these findings demonstrate that axial loading and intramural flow rate critically modulate dissection propagation thresholds and morphology. Future work will integrate these results with computational modeling to refine criteria for tear progression.

Fractional Viscoelastic Modeling for the Heart and Arteries

Dr Will Zhang[1], Prof Daniel Beard[1], Prof Alexey Kamenskiy[2], Prof Gerhard Holzapfel[3], Prof David Nordsletten[1]

[1]University of Michigan, Ann Arbor, MI, United States. [2]University of Nebraska, Omaha, NE, United States. [3]TU Graz, Graz, Styria, Austria

Introduction

Cardiovascular tissues exhibit nonlinearity, anisotropy and viscoelasticity as hallmarks of their mechanical function, allowing for preferential distribution of load, progressive recruitment, and energetic dampening. Nonlinear fractional viscoelasticity theory provides mechanisms for characterizing this constitutive behavior across cardiovascular tissues – including muscular / elastic arteries and the heart.

Methods

In this work, we leverage mechanical data from arteries and the heart. Human femoropopliteal and thoracic aortic samples were cut from cadaveric arteries and tested with varying biaxial stretch experiments followed by stress relaxation experiment. Human myocardial data was tested cubic samples and biaxial sheets, examining shear, shear relaxation, and stretch. Finally, data considered in this presentation was acquired from mouse trabeculae and examined for passive mechanical response under uniaxial stretch, focusing on stress relaxation phenomena at varying calcium levels. All data was analyzed using nonlinear fractional viscoelasticity theory, providing a framework for the characterization of the response of the tested cardiovascular tissues.

Results

We show that for all three considered cardiovascular tissue types – including muscular arteries, elastic arteries and heart muscle – that the nonlinear anisotropic viscoelastic response can be well captured using nonlinear fractional viscoelastic theory (with errors for compounded stress responses typically below 9%). We also highlight the sensitivity of passive mechanics, particularly in the myocardium, to calcium which can amplify stresses 6-fold and significantly enhance hysteresis.

Discussion

This work demonstrates that nonlinear fractional viscoelasticity provides a unified and compact constitutive framework capable of capturing the complex mechanical behaviors of cardiovascular tissues. This suggests, while arteries and cardiac muscle exhibit different structural organization, their hierarchical organization yields power spectrum behavior well-suited for fractional operators, capturing the effects of multiscale mechanics without explicit modeling at each scale. This balance between model fidelity and parsimony is advantageous for both experimental interpretation and integration into large-scale computational simulations. This work also highlights the strong need for revising the theory of passive mechanics as a static state of tissue, highlighting that the biochemical response of tissue heavily influences its mechanical state.

RT3DE-Derived Finite Element Analysis of Functional Tricuspid Regurgitation and RV Free Wall Approximation

Mr. Davide Tondi[1,2], Prof. Francesco Sturla PhD[3,1], Prof. Riccardo Vismara PhD[1], Prof. Alberto Redaelli PhD[1], Prof. Emiliano Votta PhD[1]

[1]Politecnico di Milano, Milano, Italy, Italy. [2]ESB Member, Milano, Italy, Italy. [3]3D and Computer Simulation Laboratory, IRCCS Policlinico San Donato, San Donato Milanese, Italy, Italy

Introduction

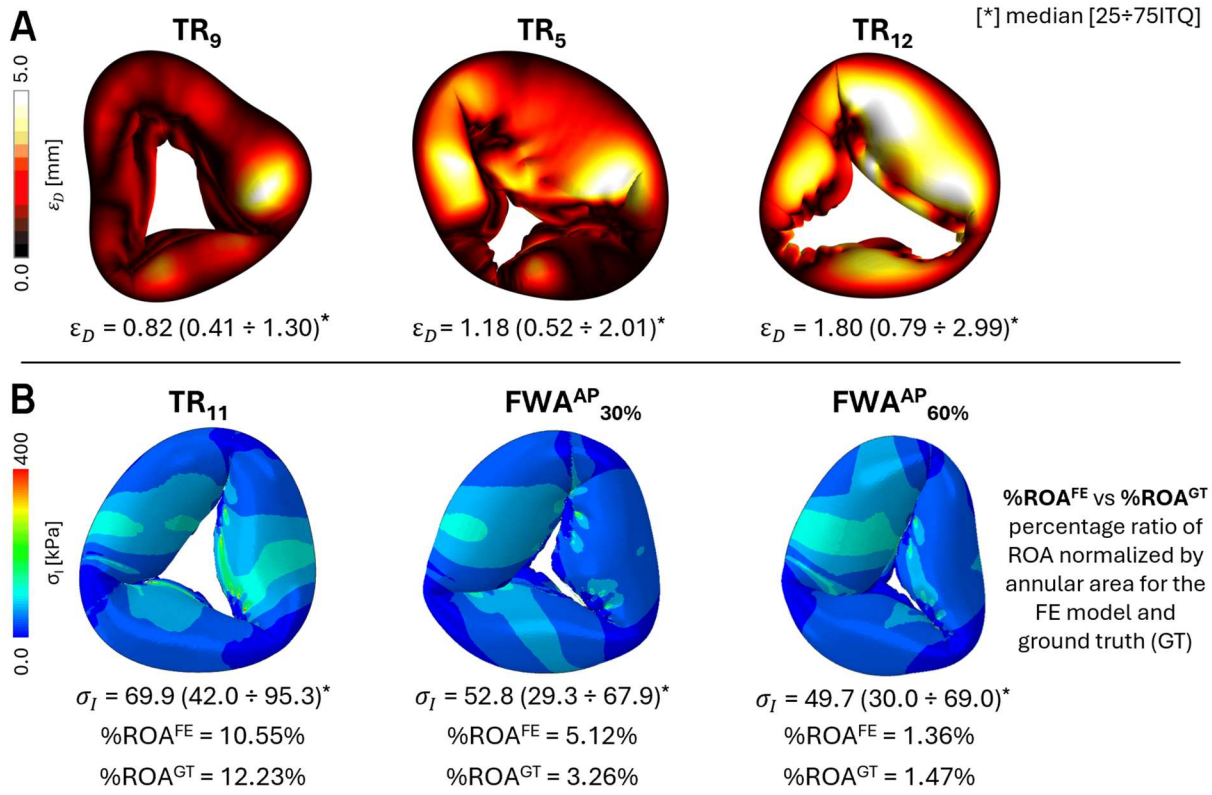
Tricuspid valve (TV) regurgitation (TR) affects approximately 1.6 million individuals in the USA [1], yet its pathophysiology and biomechanics remain underexplored. Recent evidence associating TR with increased mortality [1] has spurred interest in its biomechanical evaluation. We present a finite element modeling framework based on real-time 3D echocardiography (RT3DE) that enables 3D reconstruction and simulation of the TR condition, and prediction of TV biomechanics following TR treatment through right ventricular free wall approximation (FWA) along three directions.

Methods

RT3DE was performed on six explanted porcine hearts on a pulsatile test-bench in TR conditions and following FWA [1].

From pre-FWA RT3DE, the 3D geometry of TV annulus, leaflets and papillary muscles (PMs) tips was reconstructed at end-diastole (ED) and peak-systole (PS).

The ED TV configuration was complemented by a parametric chordae tendineae (CT) template [2]. Leaflet and CT tissues were described as anisotropic hyperelastic through the Holzapfel and Weiss model, respectively. CT initial lengths were calibrated by minimizing the mismatch between simulated and reconstructed leaflet configurations at PS in TR conditions [3]. For TR conditions, TV closure from ED to PS was simulated by prescribing physiological pressure conditions and annulus and PMs motion from RT3DE tracings. In post-FWA simulations, TV closure was preceded by the reduction of inter-PMs distance by 30% and 60% along three approximation directions. Predicted post-FWA configurations at PS were validated against post-FWA RT3DE reconstructions.



Results

Across the 6 TR configurations at PS, the median distance from simulated to ground-truth leaflet surface (ε_D) ranged between 0.82 and 1.80 mm (Fig.1A); leaflets median maximum principal stresses (σ_I) ranged from 42.6 to 69.9 kPa. FWA simulations predicted reduced regurgitant orifice area (ROA) at PS, consistent with *in-vitro* data, and a decrease in σ_I by up to 28.9% (Fig.1B) relative to baseline TR.

Discussion

Simulations closely replicated TV geometry at PS in TR conditions. The predicted reduction in ROA in post-FWA conditions was consistent with ground-truth evidence. The associated reduction in leaflet stresses suggests a beneficial biomechanical effect of FWA.

Assessing Potential Adjunct Medications such as Hydroxocobalamin and Methylene Blue, with REBOA, in the Management of Hemorrhage in a Large Animal (Sus scrofa) Model of Polytrauma

PhD Candidate Dena Norouzi

UThealth, San Antonio, Texas, United States

Introduction

Resuscitative Endovascular Balloon Occlusion of the Aorta (REBOA) is a critical lifesaving technique used to temporarily halt blood flow in the aorta to control severe hemorrhage. However, balloon deflation poses significant challenges, including cardiovascular collapse and the systemic release of ischemic metabolites such as nitric oxide, which can further destabilize the patient. We hypothesized that adjunctive therapies such as hydroxocobalamin (HOC) and methylene blue (MB), when administered alongside REBOA, may mitigate these risks and improve outcomes following Zone 1 REBOA.

Methods

Twenty-two male and female Yorkshire swine were anesthetized, intubated, and subjected to traumatic brain injury (TBI) using a commercially available powder-actuated device, followed by tibial fracture and controlled hemorrhage equivalent to 30–40% of total blood volume. After 60 minutes of aortic occlusion with REBOA and 5 minutes of balloon deflation, animals were randomized into three groups: (1) whole blood (WB) only, (2) WB plus HOC, or (3) WB plus MB. Physiological and laboratory parameters were monitored and analyzed.

Results

At 120 minutes post-balloon deflation, animals treated with WB+MB demonstrated significantly higher pH and lower lactate levels compared to controls ($p < 0.05$), indicating improved acid-base balance and metabolic recovery.

Discussion

Adjunctive MB significantly improved metabolic and acid-base parameters following REBOA balloon deflation compared to HOC or WB alone. These findings highlight MB's potential to enhance REBOA outcomes in severe hemorrhagic trauma, warranting further investigation into its long-term effects and prehospital applications.

[5]3D and Computer Simulation Laboratory, IRCCS Policlinico San Donato, San Donato Milanese, Milano, Italy

Introduction

Transcatheter Pulmonary Valve Implantation (TPVI) is performed in adult patients originally born with severe congenital defects and surgically treated when infants. Implant success and stability depend on the reliable pre-procedural quantification of right ventricle outflow tract (RVOT) size and deformability for correct device sizing, especially when treating complex anatomies with heterogeneous wall mechanical properties. Currently, pre-procedural analyses rely on static size measurements from computed tomography (CT) images; semi-automated methods based on time-resolved (4D) CT imaging have been recently proposed to quantify frame-by-frame RVOT size at multiple cross section [1] or 3D wall strains [2]. We present a fully automated method to quantify RVOT geometry and 3D wall strains from 4DCT imaging.

Methods

At each frame of the 4DCT dataset, the 3D geometry of right ventricle and pulmonary artery (PA) is automatically reconstructed via segmentation by TotalSegmentator, and remeshing and smoothing of the isosurfaces. At end-systole (ES), the isosurface (S_{ES}) is automatically trimmed to isolate RVOT and PA walls. Starting from S_{ES}, a non-rigid registration is iteratively performed between consecutive time-frames using Deformetrica, yielding the time-dependent perimeter (2p) at relevant cross-sections and displacement field over S_{ED}, which is used to compute the strain field. The method was applied to 30 patients: 19 TPVI recipients and 11 patients redirected to open-chest surgery (SPVR). 2p quantifications

were compared vs. those provided by [1] for 5 subjects from each group at the landing zone.

Results

2p quantifications well compared to those obtained by [1], with mean mismatches by 4.2% and 12.7% in TVPI and SPVR patients, respectively. Student t-test highlighted statistically significant differences ($p<0.0001$) in time-averaged perimeter between the two groups (Figure 1.a). Strain maps highlighted the heterogeneous extensibility of the wall (Figure 1.b). The entire workflow required 88 minutes on average.

Discussion

Our preliminary data suggest the reliability of the proposed approach and its potential to provide an exhaustive quantification of RVOT geometry and deformability to support TPVI planning. Full automation paves the way towards integration into the clinical workflow, although time-expense should be reduced by code optimization.

Personalized Computational Fluid Dynamics Simulations of Transarterial Embolization for Liver Cancer Treatment Planning

Mr. Enrico Sangiorgio MSc[1,2], Dr. Valentina Mazzi PhD[1], Dr. Giuseppe De Nisco PhD[1], Dr. Giuseppe Isu PhD[3], Prof. Diego Gallo PhD[1], Prof. Umberto Morbiducci PhD[1]

[1]Politecnico di Torino, Torino, TO, Italy. [2]Università degli Studi di Palermo, Palermo, PA, Italy. [3]Medics Srl, Torino, TO, Italy

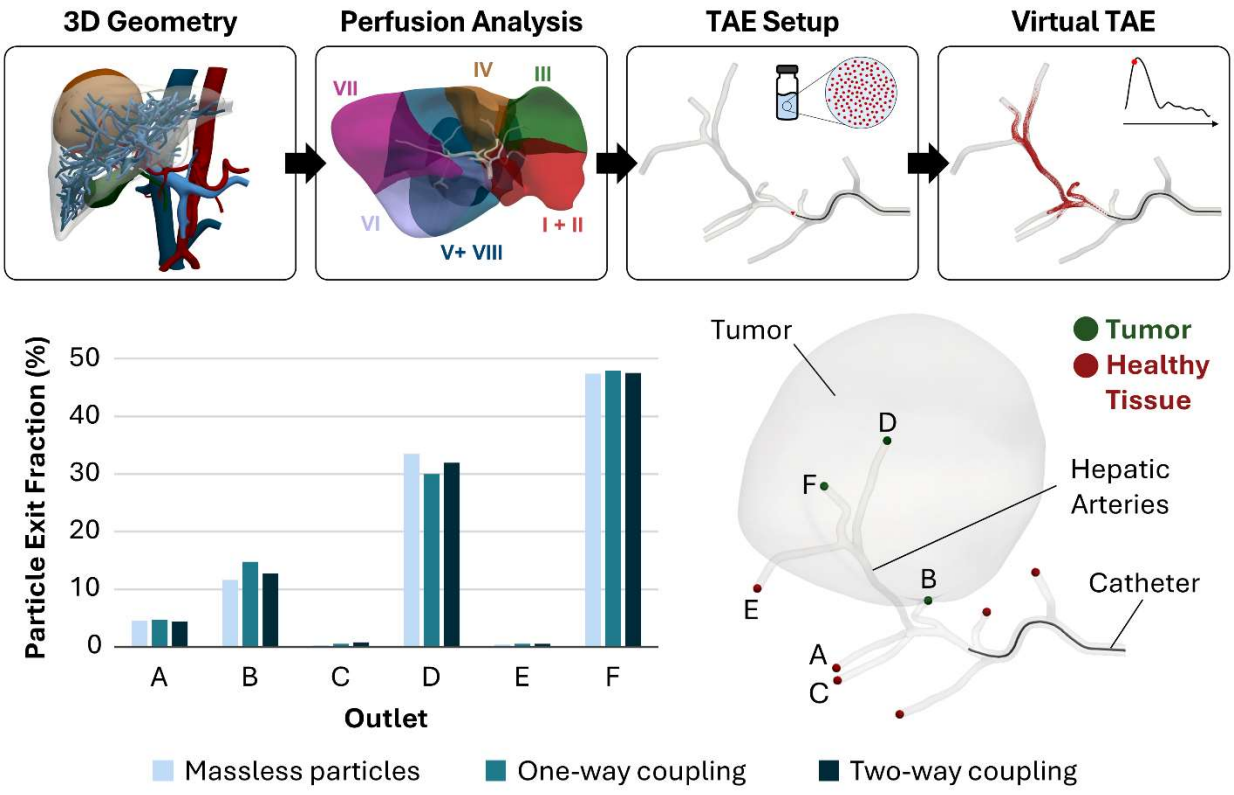
Introduction

Transarterial embolization (TAE) is an established treatment modality for patients with unresectable liver cancer. It involves the localized injection of microspheres via a catheter to selectively obstruct tumor-feeding hepatic arteries [1]. Embolization outcomes depend on procedural variables, such as catheter position and injection flow rate, as well as the clinical case, including tumor burden and hepatic arterial anatomy. In this study, we propose a computational framework that enables virtual TAE in personalized hepatic models.

Methods

Computational fluid dynamics simulations are performed on a patient-specific 3D anatomical reconstruction of the hepatic arterial vasculature, incorporating a virtually positioned catheter. Personalized boundary conditions are derived from liver and tumor perfusion analysis [2], adopting a distance-based method for vascular territory approximation [3]. Microparticles are virtually injected uniformly from the catheter tip and tracked over multiple simulated cardiac cycles. Alternative TAE modelling approaches are compared for outlet-to-outlet particle distribution estimation. Specifically, an Eulerian-Lagrangian approach that concurrently solves blood flow equations and predicts particle trajectories using Newton's second law is evaluated, considering both one-way and two-way coupling between continuous and discrete phases. We also examine a simplified approach that tracks massless particles by integrating the fluid velocity field. The impact of simplification strategies, including arterial geometry truncation and non-explicit modeling of injection fluid, is assessed.

Results



The *in silico* platform successfully replicated the embolization procedure in a patient-specific 3D truncated model of the hepatic arterial tree. Comparison of TAE modeling approaches revealed consistent predictions with a maximum 2% deviation from the two-way coupling strategy (used as reference approach) in outlet-to-outlet particle distribution.

Implemented simplification assumptions showed negligible impact on predicted TAE outcome.

Discussion

The proposed computational framework demonstrates potential to facilitate personalized treatment planning by enabling virtual testing of clinically relevant parameters in a digital twin of the patient. It is currently being refined and extended to additional patient-specific cases. Future developments will entail the integration of pharmacological models to estimate local drug exposure from simulation-predicted microsphere distribution.

Computational Framework Identifies Optimal Neural Operator for Forecasting Aortic Aneurysm Outcomes

Dr. Erica Schwarz[1], Dr. Qianying Cao[2], Dr. David Li[3], Mr. Colin Means[1], Dr. Roland Assi[4], Dr. George Karniadakis[2], Dr. Jay Humphrey[1]

[1]Yale University, New Haven, CT, United States. [2]Brown University, Providence, RI, United States. [3]University of Nebraska, Omaha, Omaha, NE, United States. [4]Yale School of Medicine, New Haven, CT, United States

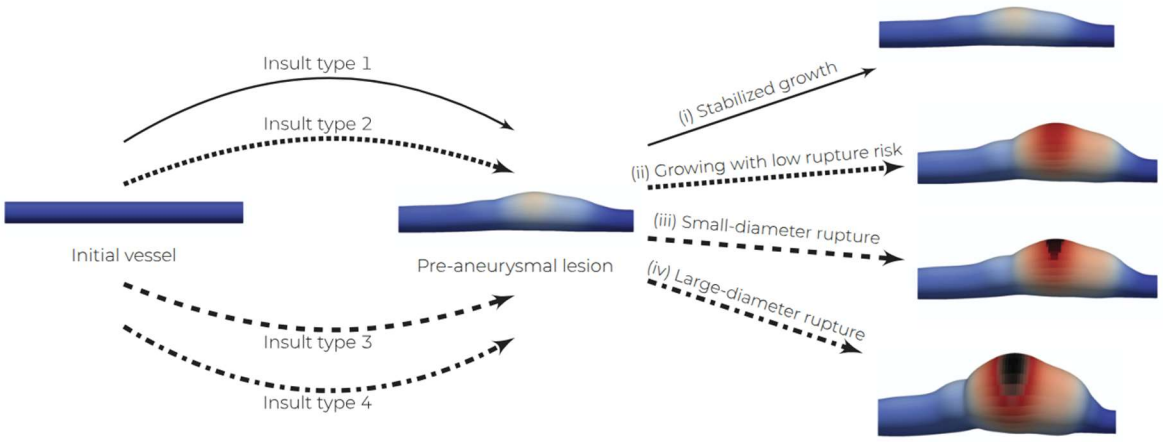
Introduction

Thoracic aortic aneurysms (TAAs) develop through a combination of biological and biomechanical mechanisms. Current clinical risk stratification relies on size and expansion rate, which do not reliably predict whether an aneurysm will stabilize, enlarge, dissect, or rupture. Large-data models have the potential to provide additional predictive capabilities, but are limited by the scarcity of clinical data. Mechanistic computational models can simulate clinically relevant phenotypes across a range of disease trajectories, and thus represent an alternative source of data for developing robust forecasting models. Here, we use a validated computational model of TAA development to identify the optimal neural operator for outcome forecasting.

Methods

We employed a constrained mixture theory framework to model aortic wall growth and remodeling under physiologic loading. The model incorporates rate-dependent processes that drive aneurysmal progression, including elastin fiber injury and reduced mechanosensitivity. We varied the mechanisms of progression to produce distinct aneurysm phenotypes. We then developed neural operator surrogates to perform short-term forecasting, long-term forecasting, and outcome categorization. Three neural operator architectures were evaluated, with a Laplace neural operator and two distinct temporal bundling strategies proposed for long-term prediction.

Results



The growth and remodeling framework reproduced clinically relevant phenotypes, including situations where aneurysms with initially similar dilatations later diverged to have diverse outcomes. Simulations distinguished stable, growing, and rupture trajectories. Neural operators were able to successfully forecast aneurysm outcomes, with accuracy

increasing with additional biomechanical data, greater longitudinal sampling, reduced sampling intervals, and use of temporal bundling.

Discussion

By integrating mechanistic simulations of aortic behavior with machine learning, this framework has potential to aid the translation of large-data models for aneurysm forecasting to the clinic. Ongoing work will incorporate uncertainty quantification and patient-specific data to further develop this approach.

An Innovative Real-time Windkessel-Based System for Dynamically Loading Isolated Heart Preparations

Mr Esau Mhandu

Auckland Bioengineering Institute, Auckland, Auckland, New Zealand

Introduction

The heart in vivo experiences beat-to-beat changes in cardiovascular load driven by dynamic vascular properties such as compliance, characteristic impedance, and peripheral resistance (R_p). These factors can be represented using a three-element Windkessel model. In *ex vivo* heart studies, however, afterload is typically imposed by adjusting the height of a pressure head, creating a constant-pressure load that fails to replicate physiological dynamics and prevents independent manipulation of vascular parameters. To overcome this limitation, we developed a system that delivers intrabeat dynamic loads to isolated hearts, modelling vascular impedance based on *in vivo*-derived Windkessel parameters. The system integrates a software-encoded Windkessel model with a feedback-controlled electromechanical valve to simulate arterial hydraulic impedance in real time. The model predicts instantaneous aortic pressure and flow from real-time left-ventricular pressure (LVP), while a control algorithm continuously adjusts valve aperture to match measured aortic pressure to model predictions.

Methods

We validated the system using isolated rat hearts (n = 10), recording pressure–volume loops, stroke volume, cardiac output, ejection fraction, and aortic flow under varying impedance conditions. Sudden changes in Rp were introduced to evaluate transient cardiac biomechanical responses.

Results

The system successfully reproduced physiologically realistic cardiac biomechanics. Pressure-volume loops closely resembled in vivo profiles. Increasing R_p elevated LVP and reduced stroke volume, cardiac output, ejection fraction, and aortic flow. Rapid step changes in R_p revealed transient cardiac responses, offering insights into the heart's intrinsic adaptive capacity on a beat-by-beat basis to fluctuating hemodynamic demands.

Discussion

This work establishes a real-time impedance-based loading system that addresses the limitations of static afterload models in isolated heart experiments. By enabling independent control of Windkessel parameters and capturing transient responses, the system provides a physiologically grounded tool for investigating cardiac function under realistic vascular loading. A current limitation is the use of constant preload; future integration of preload control to complement afterload modulation will further enhance physiological fidelity.

Fluid-Structure Interaction Modeling of the Intracranial Carotid Artery for Cerebrovascular Events and Treatments

Ms Federica Fontana[1,2], Prof. Frank Gijsen[1,2], Dr. Daniel Bos[2], Dr. Ali Akyildiz[1,2], Dr. Selene Pirola[1]

[1]Delft University of Technology, Delft, South Holland, Netherlands. [2]Erasmus Medical Center, Rotterdam, South Holland, Netherlands

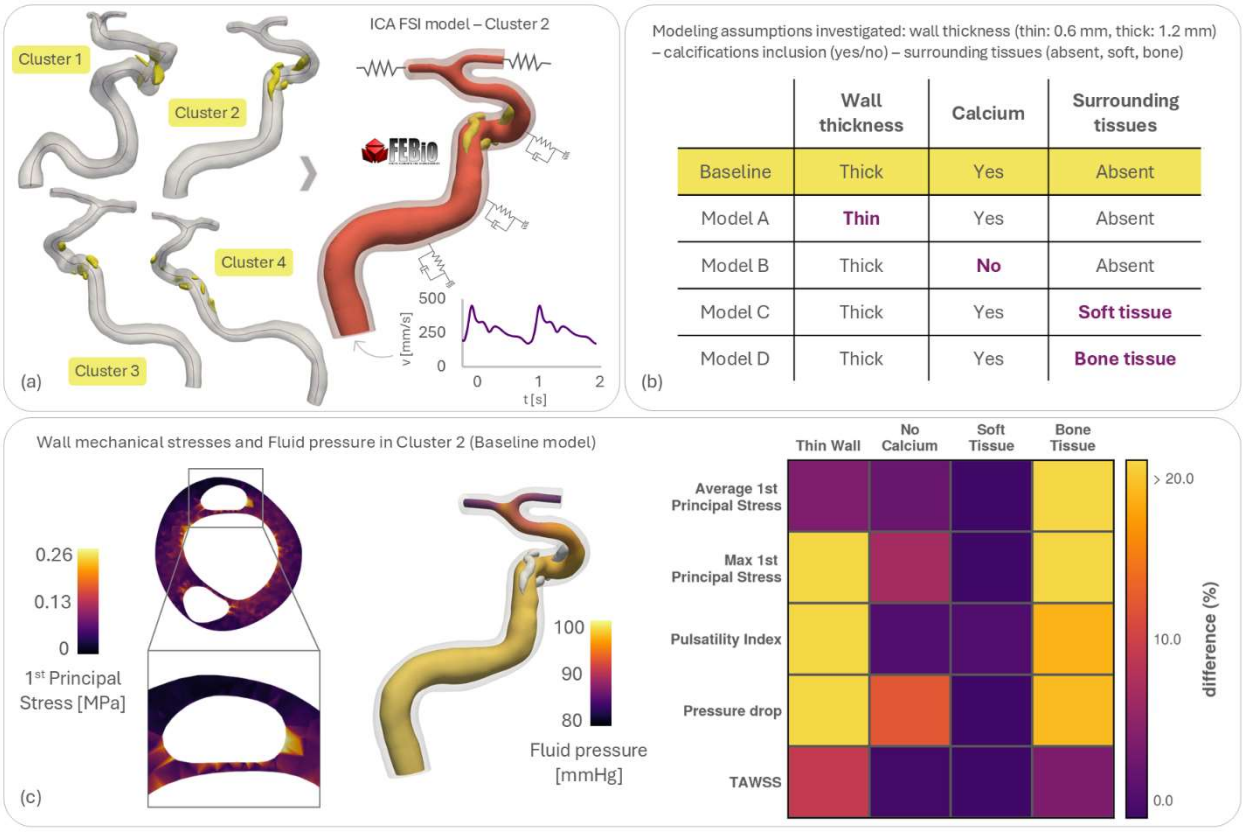
Introduction

The Intracranial Carotid Artery (ICA) is a key site for cerebrovascular disease and intervention, from atherosclerosis and aneurysm formation to endovascular procedures such as thrombectomy. Fluid Structure Interaction (FSI) models can help elucidate biomechanical factors that contribute to disease initiation and progression or procedural success, supporting studies addressing plaque vulnerability, initiation of wall remodeling, or interaction with medical devices. However, uncertainty remains on key modeling aspects, which are often overlooked or not obtainable from clinical imaging. In this study, a patient-specific FSI framework for the ICA is developed, and the effect of different model assumptions is evaluated to provide guidelines for robust modeling.

Methods

From Computed Tomography Angiography images of 100 stroke patients, the arterial lumen and calcifications of 200 ICAs were reconstructed. Morphometric features were quantified for each artery[1], and used to identify population-representative arteries via k-means clustering. For these, FSI models were built using FEBio (Fig.1a). Physiological pulsatile blood velocity was prescribed at the inlet; outlet boundary conditions were defined as fluid resistances, tuned to achieve physiological pressures. The following modeling choices were assessed: (1) surrounding bone and soft tissues, (2) arterial wall thickness, (3) inclusion of calcifications in the wall. Simulations were compared to a baseline scenario (Fig.1b).

Results



Initial results on one population-representative artery (Fig.1c) show that including surrounding bone tissue significantly alters all considered biomechanical factors, compared to simulating the artery in isolation (+42% in 1st Principal Stresses, +18% in Pulsatility Index and Pressure drop, +5% in TAWSS). Varying the wall thickness produces a

similar effect. Incorporating calcifications affects hemodynamic variables and mechanical stresses in the wall (+12% in Pressure drop, +10% in max 1st Principal Stresses).

Discussion

Surrounding bone tissue, typically neglected in FSI models, must be included to accurately capture both wall stresses and flow pulsatility in the ICA. Similarly, wall thickness is a crucial parameter. ICA calcifications present high shape complexity and variability, with varying impact on ICA hemodynamics and wall stresses. Currently, the work is being extended to include all four subgroups and additional outlier cases to capture the full spectrum of ICA anatomical variability.

Predicting Rhythm-Dependent Cardiac Remodeling in Atrial Fibrillation using a Novel Computational Model

Dr. Felix Plappert[1], Dr. Aasima Khan[2], Dr. Arnljot Tveit[2], Dr. Pim Oomen[1]

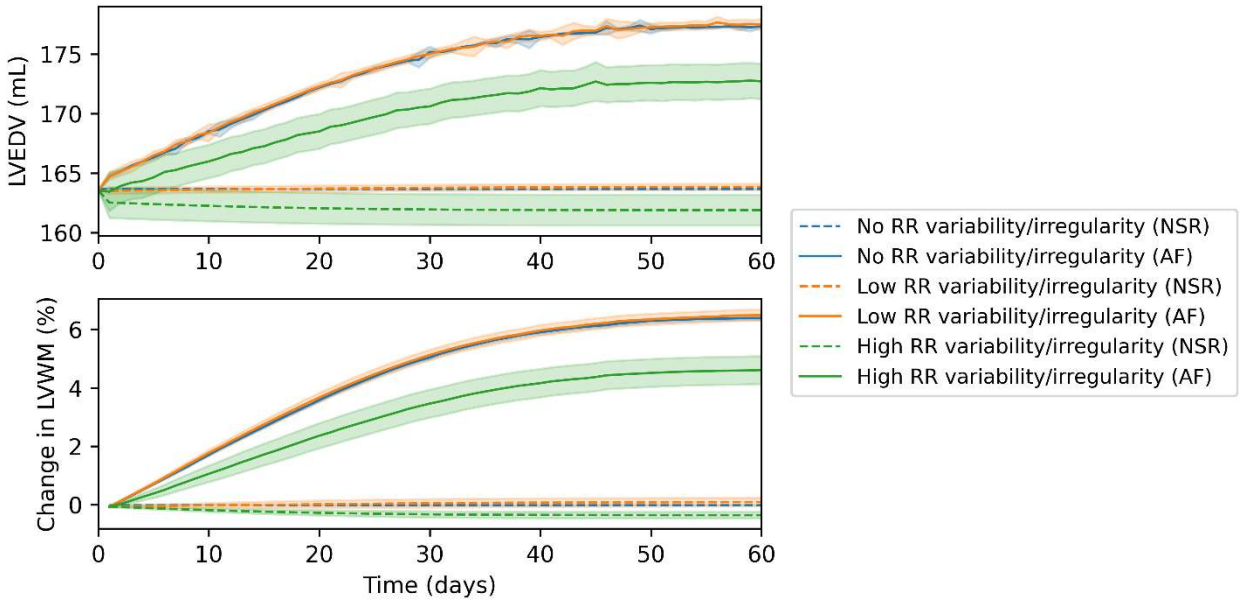
[1]University of California, Irvine, Irvine, California, United States. [2]University of Oslo, Oslo, Oslo, Norway

Introduction

Atrial fibrillation (AF) increases heart failure risk 4-5 fold, yet predicting which AF patients will develop cardiac dysfunction remains challenging. We developed a computational biophysics model to mechanistically investigate how different AF rhythm patterns drive cardiac remodeling. Unlike existing cardiac remodeling models that assume a regular rhythm represented by one heartbeat per day, AF-induced remodeling studies must account for beat-to-beat variations in the irregular rhythms characteristic of AF.

Methods

We developed a reduced-order computational model integrating cardiac mechanics, electrophysiology [1], and mechanics-driven growth [2]. Simulations compared normal sinus rhythm (NSR) with coordinated atrial contraction 120ms before ventricular activation, versus AF with uncoordinated and irregular atrial activity. For both heart rhythms, we simulated 50 heartbeats daily (96bpm average) over 60 days using three rhythm patterns: 1) regular rhythm without RR variability/irregularity, 2) low RR variability with low irregularity, 3) high RR variability with high irregularity.



Results

Left ventricular end-diastolic volume (LVEDV) and left ventricular wall mass (LVWM) increased markedly during AF across all rhythm patterns, suggesting that loss of atrial kick plays an important role in LV remodeling. Critically, the magnitude of remodeling varied with rhythm characteristics: regular rhythms and low RR variability with low irregularity produced greater cardiac growth than high RR variability with high irregularity. AF by itself leads to mild hypertrophy, and increase in cardiac hemodynamics. Interestingly, our model predictions suggest that high RR variability and irregularity mitigate AF-driven remodeling.

Discussion

Our computational model is the first of its kind that combines cardiac remodeling in response to different heart rhythms and atrial activation patterns. Our model's prediction of mild hypertrophy following AF matches with clinical data [3], thus validating our model formulation. The mitigation of AF-induced remodeling by high variability and irregularity can be explained by changes in preload: higher RR variability leads to less optimal filling of the heart, which thus mitigates the increased preload caused by AF. Our next step is to validate model predictions with patient-specific data from previously conducted clinical trials.

Introduction

Current techniques for quantifying tricuspid regurgitation (TR) based on magnetic resonance imaging (MRI) or transthoracic echocardiography (TTE) all suffer from limitations [1]. To address these, we proposed a new approach that directly quantifies tricuspid regurgitant volume (TR_V) by combining 4D Flow MRI with retrospective tracking of the tricuspid valve (TV) annulus. We assessed the reproducibility of this method and its agreement in terms of TR grading compared with standard MRI- and TTE-based strategies.

Methods

A cohort of patients (n=30) with TR was prospectively enrolled. TR_V was quantified implementing four MRI-based approaches into an in house Matlab pipeline [2]: i) indirect quantification, obtained by subtracting the total forward volume through the pulmonary valve (FV_{PV}) from the right ventricular stroke volume (SV_{RV}); direct quantification as time-integral of the regurgitant flow through the TV orifice measured from ii) 2D phase-contrast (PC) MRI on a plane positioned at the level of TV annulus (π_{TV}); iii) 4D Flow MRI using the

same static plane π_{TV} to project the TV orifice; iv) 4D Flow MRI with frame-by-frame update of π_{TV} position and direction based on the automated tracking of the TV annular landmarks.

Results

The dynamic 4D Flow MRI method showed strong correlations with all other MRI methods (r = 0.80-0.84, p<0.001), but consistently yielded higher TR_V estimates (Figure 1). Agreement in TR severity grading based on regurgitant fraction was poor across methods (kappa ≤ 0.07), with dynamic 4D Flow MRI classifying more cases as moderate or severe. Compared with TTE, dynamic 4D Flow MRI showed slight agreement (kappa = 0.17). Inter-observer reproducibility was excellent (r = 0.91, bias = 0.7ml, kappa = 0.80).

Discussion

TR_V quantification from 4D Flow MRI with dynamic update of π_{TV} demonstrated superior reproducibility; its tendency to yield larger TR_V estimates may provide a more sensitive quantification for TR_V compared with conventional MRI techniques. Although alignment with TTE remains limited, it may help overcome key imaging limitations and improve TR evaluation, especially in complex clinical scenarios.

Images (Optional)

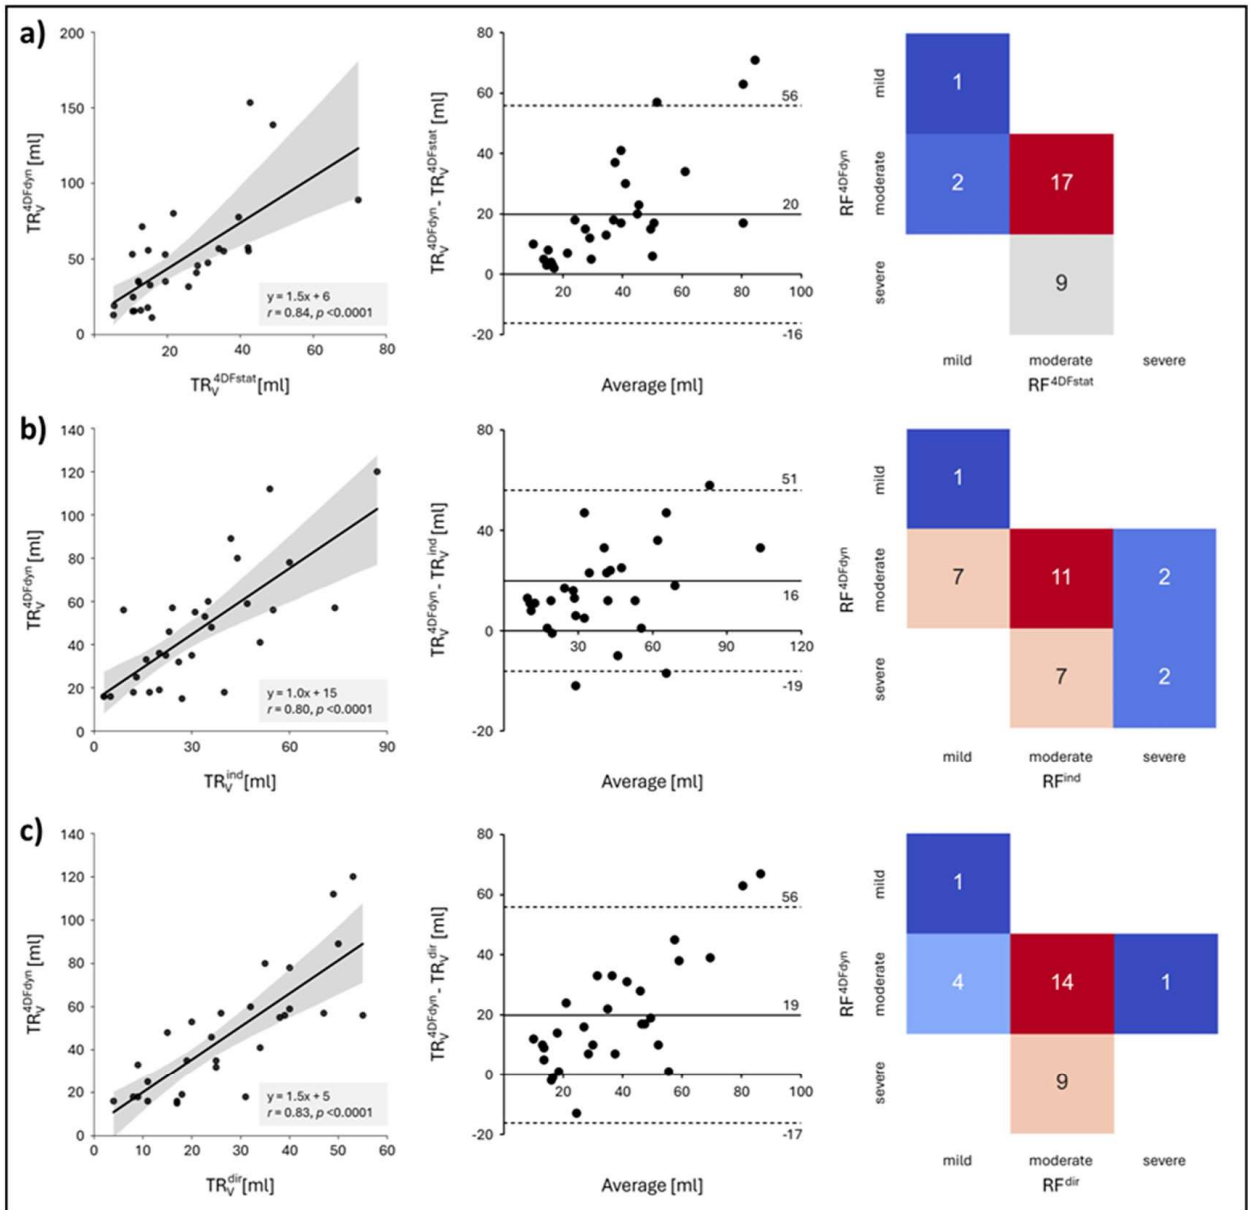

Figure 1: Comparison of 4D Flow-based TR_V with dynamic TV tracking and a) 4D Flow-based TR_V with static plane, b) indirect conventional TR_V and c) direct conventional TR_V, respectively. Linear regression plot with Spearman correlation, Bland-Altman agreement with bias and limits of agreement and confusion matrix for agreement of TR severity are reported for each comparison.

[4]UnIC@RISE, Department of Surgery and Physiology, Faculty of Medicine, University of Porto, Porto, N/A, Portugal

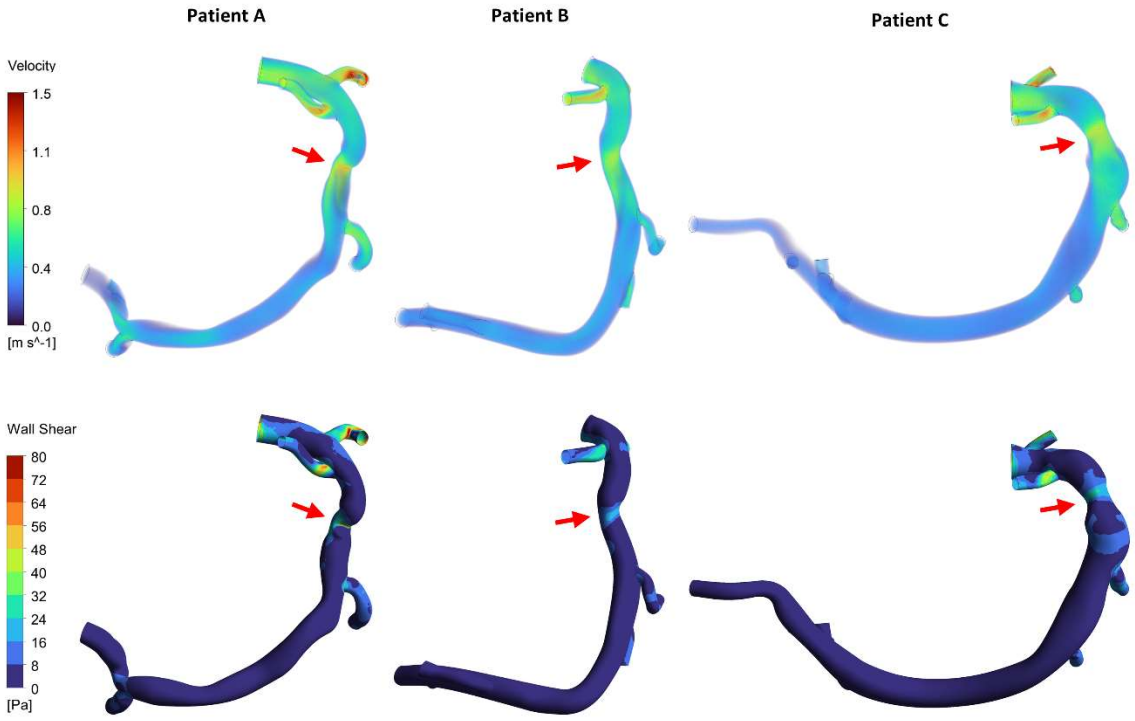
Introduction

Coronary artery disease is a major cause of morbidity, and assessing the functional impact of stenoses remains challenging. Fractional flow reserve (FFR) is the clinical reference for identifying flow-limiting lesions but offers only a single value and lacks spatial detail on hemodynamic factors such as velocity or wall shear stress (WSS) [1]. Computational fluid dynamics (CFD) based on coronary CT provides a noninvasive alternative, though many methods lack physiological realism. This study evaluates whether a physiologically grounded CFD workflow can relate patient-specific systolic velocity and WSS patterns to stenosis severity defined by invasive FFR.

Methods

Three right coronary arteries representing significant (Patient A, FFR = 0.63), non-significant (Patient B, FFR = 0.93), and borderline/significant (Patient C, FFR = 0.76) lesions were reconstructed from CT and transformed to hyperemic conditions. Unsteady CFD simulations incorporated viscoelastic blood rheology, Womersley pulsatile inflow and Windkessel outlet models. Physiological consistency was confirmed by comparing CFD-derived and invasive FFR values, yielding a mean relative error of 6.2% (SD = 4.2%).

Results



Hemodynamics differed markedly between cases. Patient A showed a pronounced systolic jet (1.45 m/s) and high focal WSS (70–75 Pa) distal to the stenosis, consistent with a flow-limiting lesion. Patient C exhibited slightly lower velocities (1.40–1.45 m/s) and WSS (65–70 Pa) but retained a concentrated high-shear band characteristic of borderline severity.

Patient B presented reduced peak velocity (0.90 m/s) and WSS (35–40 Pa), with no shear amplification, reflecting a non-significant lesion. These patterns aligned with invasive FFR and demonstrated sensitivity to anatomical and functional variation.

Discussion

Pronounced jets and focal WSS peaks reliably differentiated significant and borderline lesions from non-significant ones, supporting established mechanisms of pressure loss and shear-mediated vascular response [2,3]. The physiologically informed CFD workflow offered spatial information unavailable from FFR alone and may aid assessment of stenoses. Limitations include the small cohort, motivating future validation in larger populations and potential integration into clinical decision-support pathways.

Relationship Between Portal Vein Thrombosis and Wall Shear Stress After Hepatectomy: Computational Fluid Dynamics Analysis

Mr. Yoshiki Iijima, Dr. Mamoru Takada, Mr. Shunsuke Nakajima, Dr. Hisato Kobayashi, Dr. Isamu Hosokawa, Prof. Masayuki Ohtsuka, Prof. Gaku Tanaka

Chiba University, Chiba, Chiba, Japan

Introduction

Portal vein thrombosis (PVT) is a severe complication that can occur after hepatectomy. While the association between wall shear stress (WSS) and thrombus formation has been suggested, its relationship with post-hepatectomy PVT remains unclear. Additionally, the relationship between WSS and the portal vein bifurcation angle, which is considered a risk factor for post-hepatectomy PVT, has not been fully elucidated. In this study, we used computational fluid dynamics analysis to examine the relationship between PVT and WSS, as well as between bifurcation angle and WSS.

Methods

Hemodynamics were analyzed using patient-specific models reconstructed from CT images and simplified models with only the bifurcation angle modified. Preoperative and postoperative portal vein models were reconstructed from patients who underwent right hepatectomy. This study involved seven patients, two of whom developed postoperative portal vein thrombosis and five patients who did not. Blood flow simulations were conducted based on the continuity and Navier-Stokes equations for steady, laminar, non-Newtonian flow.

Results

The results showed that patients who developed PVT had higher WSS at the left portal vein bifurcation than those who did not. The maximum postoperative WSS at the bifurcation was 82% higher in PVT patients, and the postoperative increase in spatially averaged WSS was 3.7 times greater. Furthermore, WSS tended to increase as the bifurcation angle became more acute.

Discussion

The findings of this study provide new insights in the portal venous system, suggesting that elevated WSS postoperatively plays a crucial role in the development of post-hepatectomy PVT. Unlike typical venous thrombosis, which is generally associated with low WSS, this study demonstrated a substantial postoperative increase in WSS, with localized regions

exhibiting high WSS. This suggests that post-hepatectomy PVT may follow a different thrombus formation mechanism, driven by high rather than low WSS. Additionally, surgical planning to increase the bifurcation angle may help mitigate postoperative WSS elevation and reduce the risk of PVT.

Visualization of Transitional Flow in Nasal Cavities During a Sniff

Mr. Yasuyuki Hirai[1], Prof. Toshihiro Sera[2], Dr. Hideo Yokota[3], Prof. Gaku Tanaka[1]

[1]Chiba University, Chiba, Chiba, Japan. [2]Tokyo University of Science, Katsushika-ku, Tokyo, Japan. [3]RIKEN, Wako, Saitama, Japan

Introduction

The nasal cavity is characterized by extremely complex three-dimensional structure, and its small size and structural complexity prevents detailed in vivo airflow measurements. Airflow patterns in the nasal cavity strongly affect the uptake and deposition of inhaled pollutants, airborne particles, and odorant molecules across the nasal mucosa. The aim of this study is to investigate the airflow instability in the nasal cavity during a sniff based on the in vitro experiment.

Methods

Particle image velocimetry (PIV) was performed using a realistic bilateral nasal model that fully replicates the internal and external nasal airways. The transparent silicone nasal model was reconstructed from CT slices of a healthy male with no clinical disorders. The working fluid was an aqueous solution of glycerin with concentration adjusted to match the refractive index of the silicone model. Experiments were conducted under both steady and unsteady flow conditions using an inverter pump. Flow instability was evaluated by turbulent kinetic energy (TKE).

Results

PIV measurements confirmed that the jet through the nasal valve plays an important role in the occurrence of flow instability. It was also found that significant differences were observed between flow in the right and left cavities, indicating strong dependence on the local geometry. In the left cavity, which has larger cross-sectional area and TKE values than the right cavity, the maximum TKE during deceleration phase was 1.2 times that in steady flow at the same Reynolds number, while the TKE during acceleration phase was 0.5 times.

Discussion

The results show that the occurrence of flow instability strongly depends on the geometry of the right and left cavities, and on the flow acceleration and deceleration, rather than the Reynolds number. The TKE values in the left nasal cavity was highest near the upper nasal passages where olfactory cells exist. This unstable flow appears to be related to olfactory function.

Pre-Transcatheter Aortic Valve Replacement Prediction of Hypoattenuated Leaflet Thickening using CT-Derived Measurements

Ms. Gauri Anil Student[1], Ms. Courtney Ream Student[2], Mr. Aniket Venkatesh Student[2], Dr. Lakshmi.P Dasi Professor[2]

[1]Dublin Jerome High School, Dublin, OH, United States. [2]Georgia Institute of Technology, Atlanta, GA, United States

Introduction

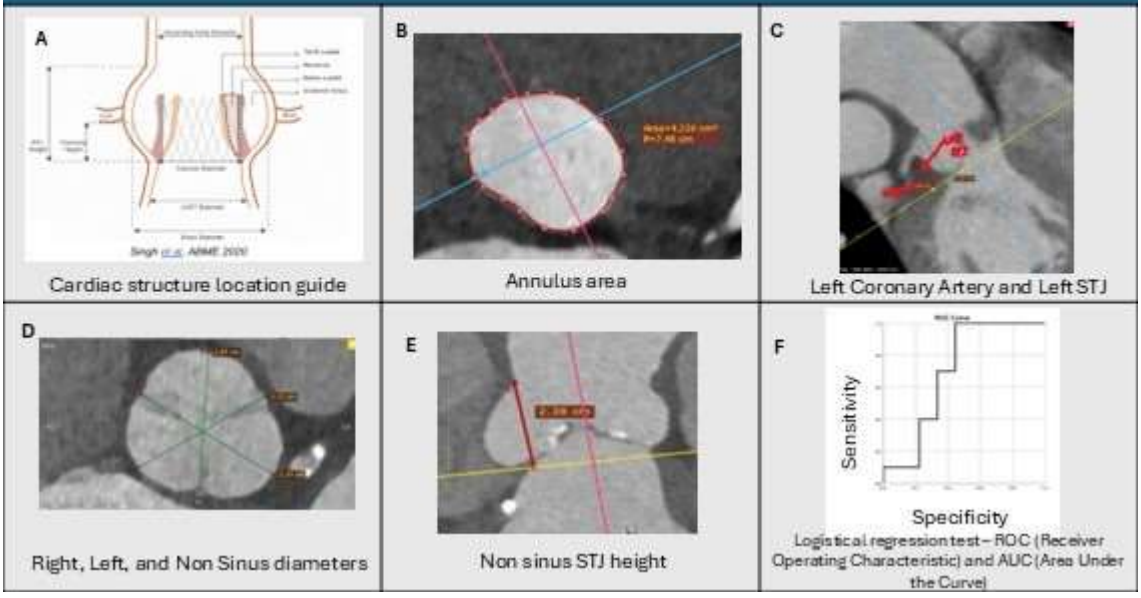
Aortic stenosis is the narrowing of the aortic valve which restricts blood flow, and the only effective treatment is aortic valve replacement. Instead of performing an open-heart Surgical Aortic Valve Replacement, the newer Transcatheter Aortic Valve Replacement (TAVR) offers a less invasive alternative for patients at high surgical risk. However, there exists a high likelihood of developing prosthetic leaflet thrombosis post-TAVR, which can reduce valve mobility, durability, and increase stroke risk. On post-procedure CT scans, this complication appears as Hypoattenuated Leaflet Thickening (HALT). In this study, we conducted a logistic regression test to investigate whether measurements taken from pre-TAVR CT scans could help detect HALT post-procedure.

Methods

A cohort of 19 patients who received the Evolut R TAV was selected from CT databases from GVM Care & Research, Palermo, Italy. The patients were recruited based on the presence of leaflet thrombosis after TAVR as scored by radiologists (n=10 HALT+, n=9 HALT-). Each patient's annulus area, average sinus diameter, left and right coronary arteries, and average sinotubular junction (STJ) height, along with other features, was measured using Radiant DICOM Viewer (Poznan, Poland), and the multiplanar reconstruction of patient CT scans were manipulated and measured with the length tool (Figure 1). These pre-TAVR anatomical dimensions were used as input parameters into a logistic regression model to identify any possible correlations indicating prediction of HALT post-TAVR.

Results

Using the selected predictors in the logistic regression analysis, we found that the AUC=0.7 (p=0.142). From a Hosmer and Lemeshow Test, we fail to reject the null hypothesis that the model is a good fit (p=0.096). Furthermore, our t-test results indicate that the most



significant variable was the average sinus diameter, with a mean difference of 0.219mm between HALT+ and – groups (p=0.26).

Discussion

Although the model does calibrate reasonably with the observations, the data failed to correctly distinguish the difference between the HALT+ and HALT- patients. However, we aim to increase sample size and add flow-related variables from echocardiography to our analysis. Such predictive capabilities could provide valuable clinical insight in identifying high risk post-TAVR thrombosis patients for whom proactive antithrombotic therapy is required.

Model-Based Methods for Characterising Kinematics Following Myocardial Infarction: Application of Mobstr3D

Mr George Harpur[1], Mr Robin Laven[1], Dr Vicky Wang[1], Dr Debbie Zhao[1], Prof Alistair Young[1,2], Dr Thiranja Prasad Babarenda Gamage[1], Prof Martyn Nash[1,3]

[1]Auckland Bioengineering Institute, University of Auckland, Auckland, Auckland, New Zealand. [2]School of Biomedical Engineering an Imaging Sciences, King's College London, London, London, United Kingdom. [3]Department of Engineering Science and Biomedical Engineering, University of Auckland, Auckland, Auckland, New Zealand

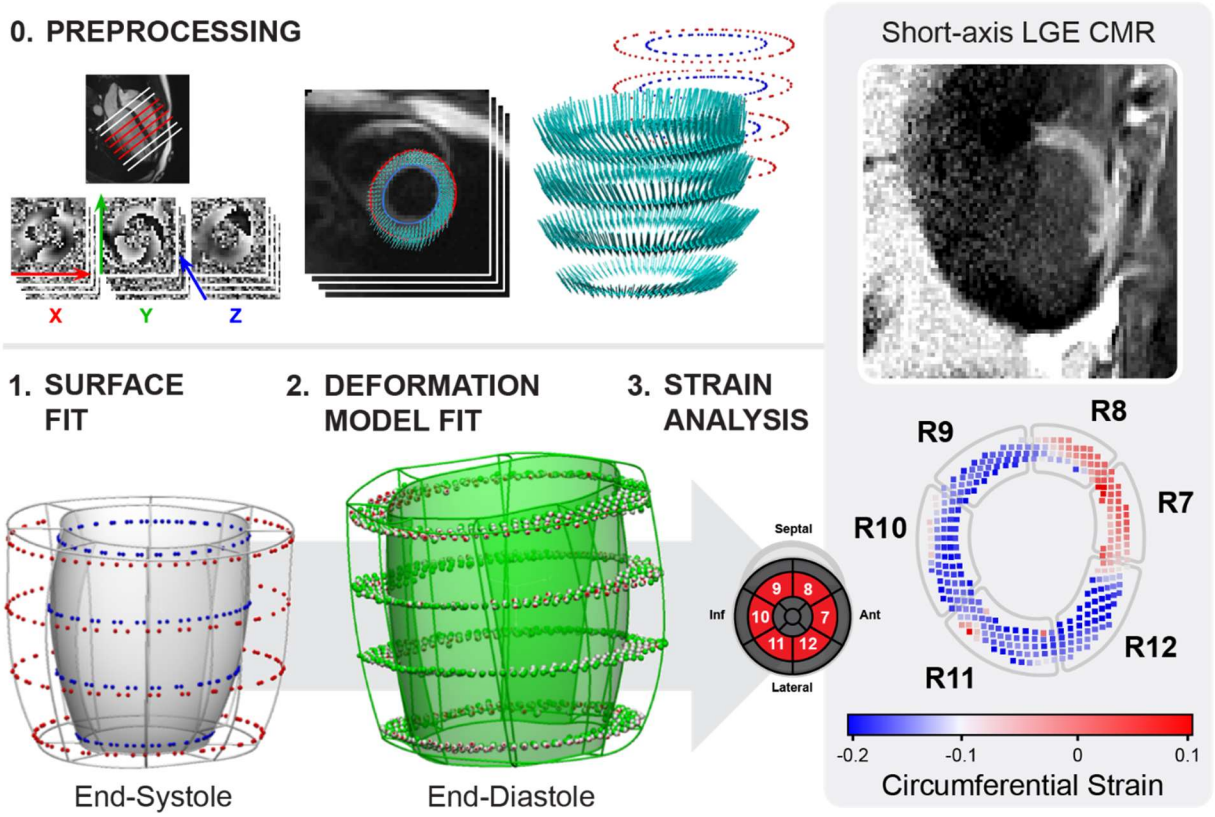
Introduction

Regional differences in left ventricular (LV) kinematics, such as strain and torsion, have been highlighted as early indicators of cardiovascular disease, particularly ischemic heart disease. Non-invasive cardiac magnetic resonance (CMR) displacement encoding with stimulated echoes (DENSE) [1] is widely considered the gold standard for intramyocardial tracking. Accurate kinematic assessment requires reliable reconstruction of 3D displacement fields; however, existing tools are generally restricted to 2D in-plane kinematic analyses. We have developed a novel, open-source software package, mobstr3D (MOdel-Based STRains in 3D, v1.0.0) for analysing cardiac geometry and 3D displacement fields by reconstructing 3D patient-specific kinematic models, from which regional strains can be estimated.

Methods

mobstr3D was used to characterise regional distributions of circumferential strains (ECC) for infarct, neighbouring and remote AHA segments in a swine with myocardial infarction (MI), and a healthy control swine as a reference. Three mid-LV short-axis DENSE with 3D displacement encoding images were preprocessed using the existing 2D analysis tool, DENSEanalysis [2]. An end-systolic model was created by fitting the surfaces of a bi-cubic Hermite quadratic Lagrange cylindrical template model (with 8 elements circumferentially) to the segmented contour data. The phase-unwrapped displacements informed a free-form deformation fit, defining the end-diastolic model. Peak systolic Lagrangian ECC was then estimated and separated into six mid-LV AHA regions (R7-R12).

Results



Late gadolinium enhancement (LGE) imaging indicated infarction in R7/R8. R9/R12, and R10/R11 were labelled as neighbouring and remote, respectively. Mean ECC was significantly smaller in the infarct regions, compared with the same regions in the control

case (-0.05±0.10 versus -0.12±0.04, p<0.001). ECC values in remote regions were similar to control (-0.16±0.06 versus -0.15±0.04, p=NS), while neighbouring regions were significantly larger than control (-0.17±0.05 versus -0.13±0.03, p<0.001). ECC differences can be attributed to variable infarct extent observed via LGE.

Discussion

Model-based mapping of regional circumferential strain can indicate infarct regions without the need for invasive contrast agents, which are contraindicated for some patients. Non-invasive kinematic characterisation can improve patient outcomes when monitoring disease progression.

Modelling Parameterised Left Atrial Appendage Morphologies Under Sinus and Atrial Fibrillation Conditions With Fluid-Structure Interaction

Mr. Matthew Tsu-En Lee[1], Dr. Giulio Musotto PhD[2], Prof. Gaetano Burriesci PhD[1,2,3], Prof. Ryo Torii PhD[1], Dr. Giorgia Maria Bosi PhD[1]

[1]UCL Mechanical Engineering, University College London, London, Greater London, United Kingdom. [2]Bioengineering Group, Ri.MED Foundation, Palermo, Sicily, Italy. [3]Department of Engineering, University of Palermo, Palermo, Sicily, Italy

Introduction

The left atrial appendage (LAA) is known for its high morphological diversity, where complex shape features contribute to increased thrombotic risk under irregular heart conditions such as atrial fibrillation (AF). While general haemodynamic trends related to LAA shape are well analysed clinically [1], the specific relationship between individual shape features and thrombotic risk remains poorly understood. This study seeks to elucidate this relationship with the development of a novel parametric morphology, where individual shape features may be deliberately adjusted within clinical ranges. The specific thrombogenicity of the chosen features is then modelled with fluid-structure interaction (FSI) under both sinus and AF conditions and categorised accordingly.

Methods

32 FSI simulations have been run on a novel LAA parametric model. The fully-adjustable morphology was built in SolidWorks, with anatomical measurements from literature [2] to generate 16 different variations. FSI boundary conditions included simulation of LAA contraction and pressure over 3 cardiac cycles of sinus rhythm and AF. Haemodynamic indices of velocity, shear strain rate (SSR), time-averaged wall shear stress (TAWSS), oscillatory shear index (OSI) and endothelial cell activation potential (ECAP) were obtained and correlated with different anatomical features.

Results

FSI results were obtained for each of the 32 simulations and compared to those of median 2-lobe morphology under sinus and AF conditions. A subset of these comparisons, focusing on the effect of morphological bending on LAA velocity, volume change, wall SSR and body SSR, is presented in Figure 1. As shown, bending in the distal LAA region, an understudied anatomical feature, leads to the lowest risk of thrombosis. Other understudied features that are evaluated by this model include trabeculae and secondary lobe distribution.

Discussion

The developed parametric FSI model can help identify the extent to which specific anatomical features lead to a higher probability of blood stagnation, thus helping clinicians better identify high thrombosis-risk patients for therapy selection. A limitation of the current setup is that blood is defined as Newtonian and single-phase. Multi-phase blood modelling will be evaluated with future collaboration.

A computational model of chemically- and mechanically-induced thrombus formation: application to hepatectomy

PhD Giulia Cardillo[1], PhD Morgane Garreau[2], Inria Research Director Irene Vignon-Clementel[2], Professor Abdul I Barakat[1]

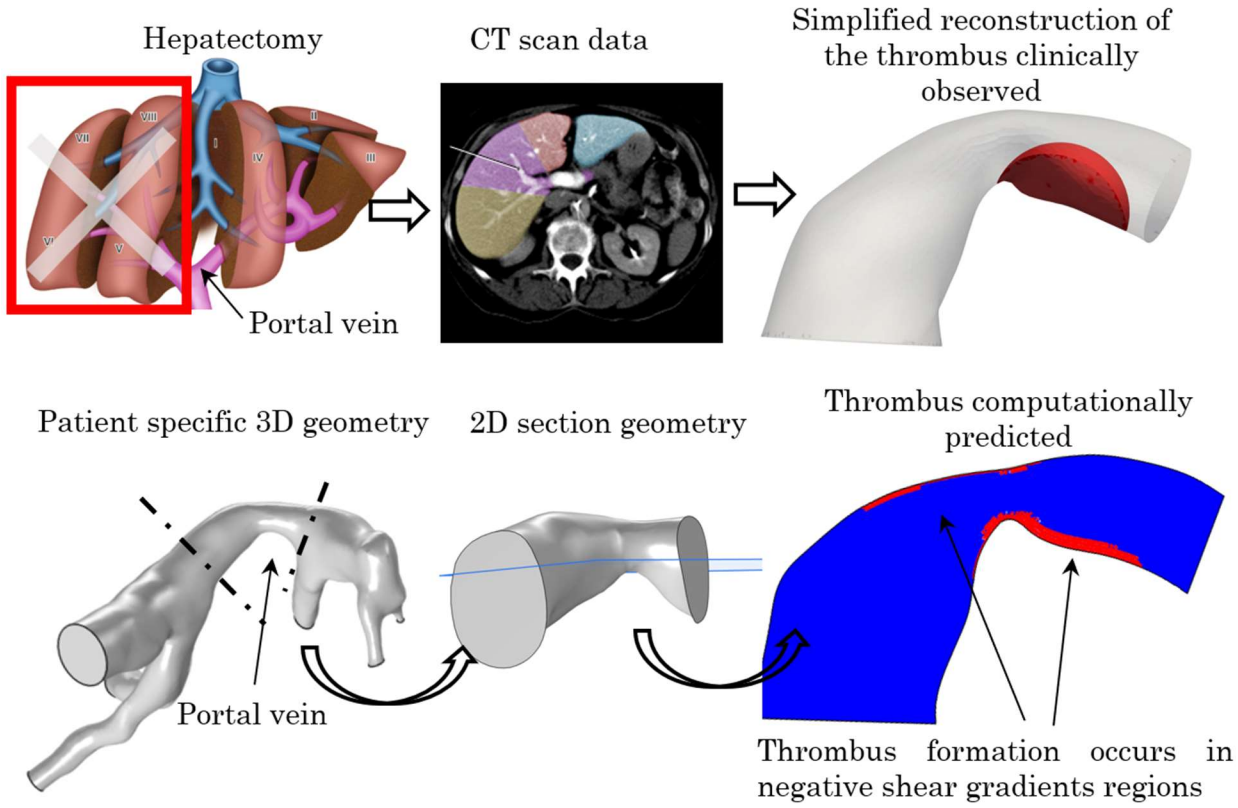
[1]École polytechnique de Paris, Palaiseau, Essonne, France. [2]Inria Saclay Île-de-France Research Center, Palaiseau, Essonne, France

Introduction

Thrombosis is a leading cause of death worldwide. Experiments have demonstrated that spatial changes in blood shear rate, i.e. shear gradients, play a dramatic role in thrombogenesis by controlling the process of platelet aggregation [1]. Our broad objective is to develop a computational model capable of reliably predicting thrombus formation in complex flow environments. The specific goal of the present work is to apply a validated computational thrombosis model that we had previously developed and that incorporates the impact of spatial shear gradients to a particular clinical scenario. The model is applied to cohort of 17 patients subjected to hepatectomy, a procedure involving the surgical resection of part of the liver and the consequent reconfiguration of the liver vasculature. One of the major complications associated with hepatectomy is thrombus formation inside the modified portal vein.

Methods

The 2D computational model represents the biochemical component of thrombosis as a set of coupled convection-diffusion-reaction equations and accounts for resting and activated platelets as well as various pro- and anti-thrombotic biochemical species. Platelet adhesion and aggregation to the blood vessel surface are modeled via different flux boundary conditions, implementing both chemical- and shear gradient-mediated platelet aggregation. The impact of thrombus growth at on the blood flow field is incorporated into the analysis. A simplified model of the coagulation cascade allows us to account for the role of fibrin fibers. Starting from computed tomography scan data, patient-specific geometries of the portal vein were reconstructed, and the thrombosis model was applied to the most relevant vascular sections.



Results

The computational predictions for thrombus formation and localization demonstrated agreement with clinical observations in different patients after hepatectomy. The results suggest that, even though the post-operative vessel inflammation plays an important role, thrombus formation is driven principally by negative shear gradients.

Discussion

Despite some limitations of the model, such as its 2D nature, it has shown promising results. The model promises to constitute a tool capable of predicting thrombus formation and evolution in different clinical scenarios, providing medical doctors with meaningful insights into disease onset and progression.

[4]Department of Biomedical Engineering, University of Cincinnati, Cincinnati, Ohio, United States

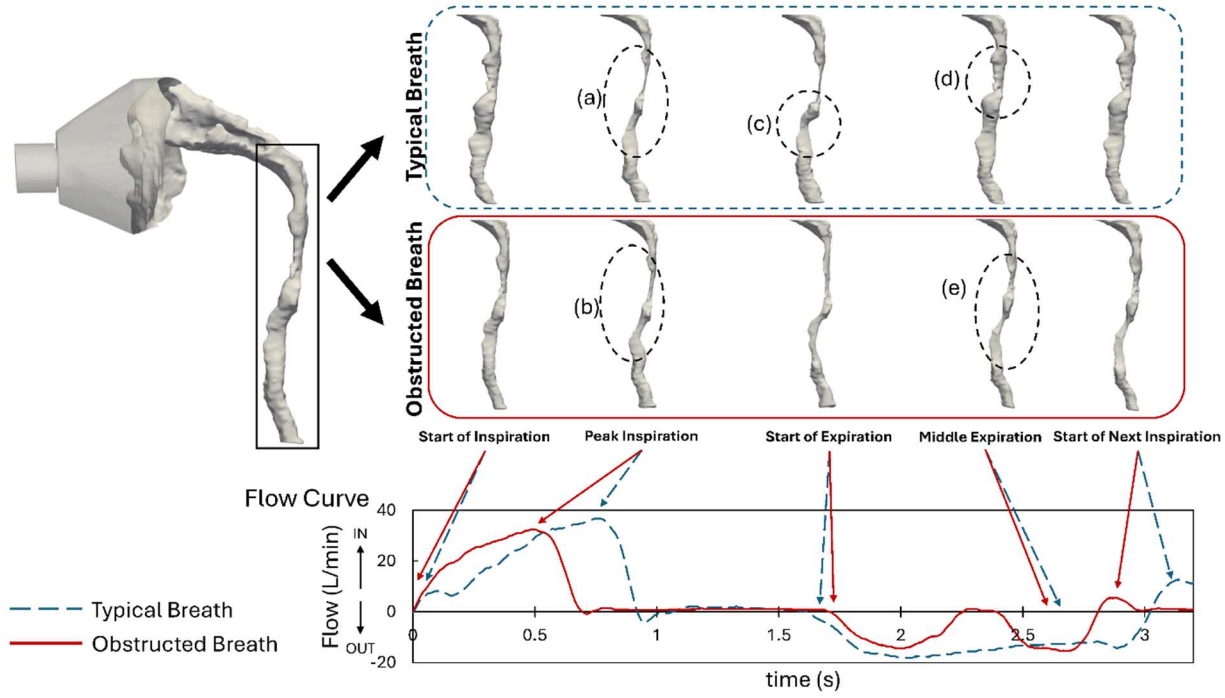
Introduction

Obstructive sleep apnea (OSA) occurs when the balance between the aerodynamic load due to airflow and the neuromuscular forces that maintain upper-airway patency fails. However, clinical metrics do not characterize the mechanisms of collapse. Even in children with severe OSA, most breaths remain stable and existing clinical metrics cannot explain why collapse occurs only intermittently. Here, we integrated cine MRI with computational fluid dynamics (CFD) to simultaneously evaluate time-resolved airway morphology, wall motion, airflow, and pressure to identify the root cause of airway collapse.

Methods

A 9-year-old with OSA (oAHI 11.9 events/hour) and trisomy 21 underwent high-resolution static MRI and cine MRI with synchronized airflow measurement. The upper airway was segmented from static MRI, then registered with cine MRI to generate dynamic airway geometry during one typical and one obstructed breath. CFD simulations quantified the power transferred between air and tissue when the airway wall moved, and distinguished between pressure and neuromuscular driven motion.

Results



Both breaths demonstrated a respiratory pattern of inspiration, pause, and expiration. However, in the obstructed breath, the expiration and following inspiration failed due to obstruction and normal breathing resumed at the third attempted breath. Airway collapse started around peak inspiration in both breaths (Fig. a, b). In the typical breath, the

larynx dilated around expiration onset (Fig. c) followed by the oropharynx by the middle of expiration (Fig. d). In the obstructed breath, however laryngeal dilation started around the middle of expiration (Fig. e) and the oropharynx did not dilate in this period. In the larynx, the ratio of neuromuscular-driven collapsing force to pressure-driven expansion force was stronger in the obstructed breath than in the typical breath during exhalation (1.3vs.0.4).

Discussion

In this patient, successful reopening after collapse during inspiration requires an initial dilation of the larynx during the post-inspiratory pause, followed by subsequent expansion of the pharynx. Power-transfer analysis suggested that the absence of this initial laryngeal dilation during the obstructed breath was associated with inappropriate neuromuscular activation, not pressure-driven. This patient-specific approach allows evaluation of OSA mechanisms alongside anatomical variability and may facilitate personalized assessment of airway collapsibility.

Integrating Statistical Shape Modelling and Finite Element Simulation to Evaluate the Effect of Anatomical Variation on Mitral Valve Mechanics

Dr Hyab Mehari Abraha[1,2,3], Dr Chris Goddard[2], Dr Rebecca Bryan[2], Dr George Hyde-Linaker[2], Dr Claire Conway[1,3]

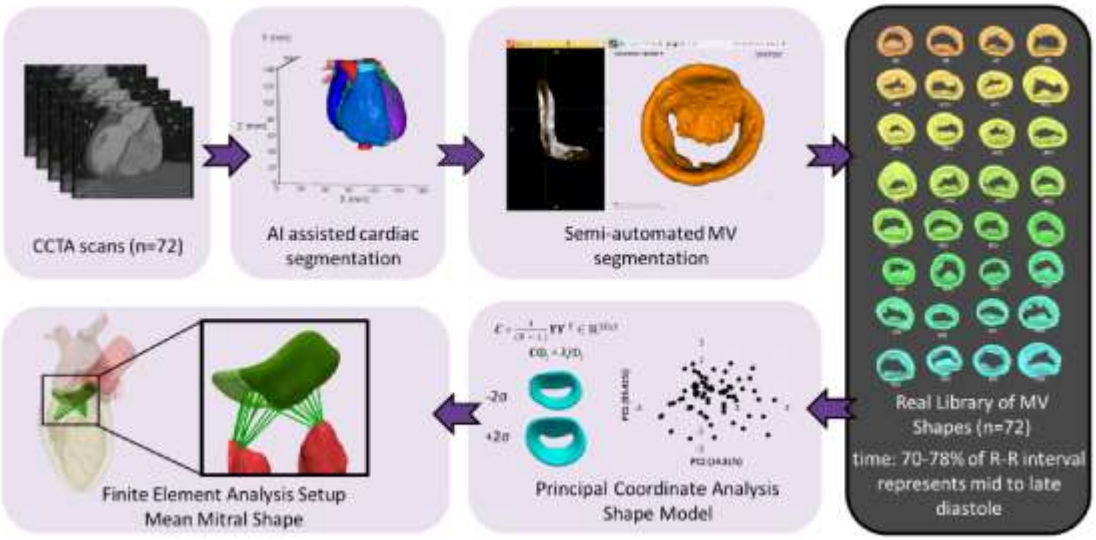
[1]Royal College of Surgeons, Dublin, Dublin, Ireland. [2]Synopsys NE Ltd, Exeter, Devon, United Kingdom. [3]Trinity Centre for Biomedical Engineering, Trinity College Dublin, Dublin, Dublin, Ireland

Introduction

Statistical shape modelling (SSM) provides a quantitative description of anatomy and enables the generation of virtual patient cohorts for in silico simulation [1] . We built a SSM of the adult mitral valve (MV) from ECG-gated coronary computed tomography angiography (CCTA) scans. Here, we extend the framework by coupling the SSM to a finite-element (FE) workflow to examine how realistic anatomical variation affects MV closure mechanics under load.

Methods

Prospectively gated CCTA volumes from 72 adults were obtained from the orCaScore dataset [2]. We used a semi-automated pipeline in Synopsys Simpleware to segment the mitral leaflets and the papillary posts. We are currently using this SSM to generate a cohort of virtual valves spanning the range of anatomical variability. Each MV will be converted to a volumetric finite element mesh for solution in Abaqus Explicit Solvers. The leaflet annulus and papillary post will be fixed against translation in all directions. Healthy pressure loads (80mmHg diastolic, 120mmHg systolic) will be applied to atrial and ventricular leaflet surfaces to approximate transvalvular pressure. Coaptation and leaflet stress/strain measures will be extracted from each virtual anatomy.



Results

The SSM of 72 CT-derived MVs captured a wide range of anatomical variation in the cohort, with the first 10 principal components describing >90% variability in annular size and shape, leaflet height and area (Fig.1). Initial statistical shape models including papillary muscle segmentations markedly restricted the spread of leaflet shapes in morpho-space, thus the SSM was re-constructed from the annulus and leaflets, and papillary tips were treated as fixed landmark points (Fig.1).

Discussion

Our created SSM results provide a compact, quantitative description of the key morphological patterns observed in the clinical dataset, and results are concordant with similar work that has been done on a paediatric transoesophageal echocardiography dataset of the mitral annulus [3]. Integrating our SSM results with the proposed FE workflow will broaden the understanding of the link between mitral mechanics and anatomical variation.

Automating FSI Simulations to Uncover the Downstream Effects of Ascending Aortic Grafts: A Prospective Analysis of 20 patients

Ms Ione Ianniruberto MSc[1,2], Mr Davide Astori MSc[1], Mr Davide Tondi MSc[1], Dr. Pablo Villar Calle[3], Prof. Emiliano Votta PhD[1], Dr. Jonathan Weinsaft[3], Prof. Alberto Redaelli PhD[1]

[1]Politecnico di Milano, Milano, Italy, Italy. [2]European Society of Biomechanics (ESB), Milano, Italy, Italy. [3]Weill Cornell College, New York, New York, United States

Introduction

Replacing the ascending aorta with a synthetic graft is a well-established surgical intervention for aortic aneurysms, yet it can lead to long-term degeneration of the descending aorta[1]. Compliance mismatch between the graft and the native aorta is one of the main risk factors, as it alters the hemodynamic in the distal regions[2]. We propose a novel fully automated FSI-based approach that incorporates comprehensive patient-specific data to evaluate the biomechanical impact of graft implantation.

Methods

For each patient, MRA, 4D flow MRI, and cine-MRI scans are collected both before and after surgery and used to set two different simulations: i) real pre-operative scenario, ii) Dacron graft implantation. The vessel geometry is reconstructed from MRA and meshed with an in-house Python code. Patient-specific inlet velocity profile is derived from 4D flow MRI, while outlet boundary conditions use a three-element Windkessel tuned to in-vivo pressures. The aortic wall is modelled as an incompressible, hyperelastic, anisotropic material with regional properties for ascending aorta, arch, and descending aorta. Regional compliance values are extracted from cine-MRI, while the material parameters are determined by fitting constitutive models from literature to the measured compliance. Two preliminary simulations, a fluid simulation to compute inner pressure and a structural simulation to determine prestress, provide initial conditions for the final FSI simulation.

Results

The workflow has been tested on 20 patients, (40 FSI simulations) each simulation requiring about two days. Significant differences in Wall Shear Stress (WSS) distributions were observed between pre- and post-operative models, with higher WSS values (~10 Pa) consistently appearing in the post-graft simulations in the isthmus region. Strain and oscillatory shear index (OSI) increased in almost all patients (~95%) post-graft implantation, in the proximal descending aorta.

Discussion

This automated framework enables large-scale patient-specific FSI analyses and highlights the significant biomechanical changes induced by aortic grafts. Because WSS values rise in nearly all post-operative cases, notably in the isthmus, these findings suggest that WSS could serve as a key metric for designing next-generation compliant grafts aimed at mitigating downstream disease progression.

A Poroelastic Model of Lymphatic Massage

Prof. James Baish[1], Prof. Timothy Padera[2], Prof. Lance Munn[2]

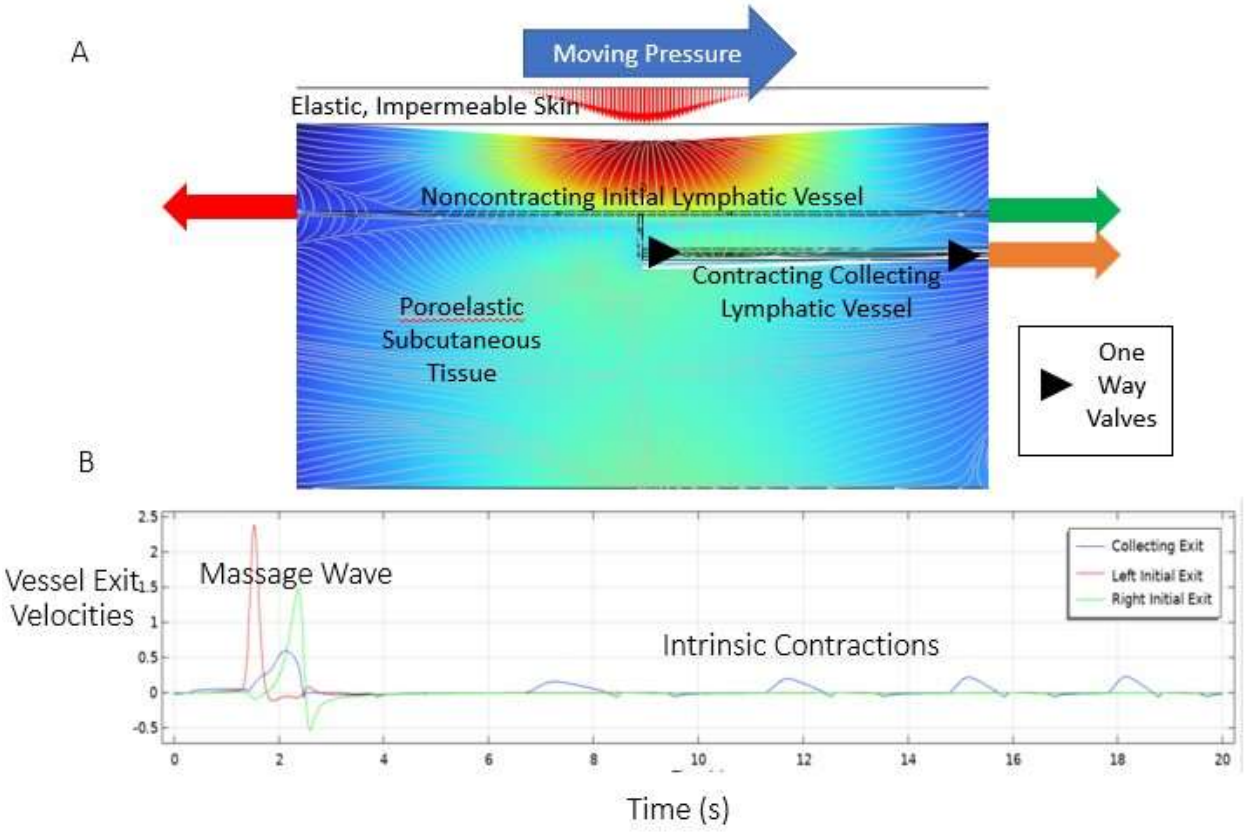
[1]Bucknell University, Lewisburg, PA, United States. [2]Massachusetts General Hospital, Boston, MA, United States

Introduction

Lymphatic massage is a common treatment for lymphedema, a condition often resulting from lymphatic dysfunction or surgical interventions. A form of lymphatic massage, called Gua Sha, is also employed in traditional Chinese medicine, self-care or cosmetic contexts. However, the precise mechanics by which massage impacts interstitial fluid flow and lymphatic vessel function remain poorly understood. Here we use a computational model to examine the relevant mechanical processes.

Methods

The computational model simulates lymphatic massage with a moving compressive pressure applied to the skin (Fig. 1A). Under the skin, interstitial fluid is driven by local pressure gradients through a poroelastic subcutaneous layer into an initial lymphatic vessel, and subsequently carried away by a collecting lymphatic vessel featuring one-way valves and contractile walls. The model incorporates extrinsic forces from the massage and intrinsic pumping by the contracting collecting lymphatic vessel that is modulated by calcium from vessel stretch and nitric oxide released from wall shear stress [1]. Solution for flow, pressure, deformation, and concentrations is obtained using COMSOL Multiphysics®. Using literature parameter values our results were found to be qualitatively similar to those obtained experimentally in mice [2].



Results

Massage transiently produces localized increases in interstitial pressure, facilitating fluid entry into the initial lymphatic vessel (Fig. 1A). The collecting lymphatic vessel then clears interstitial fluid through three primary mechanisms: (1) passive conduit flow to regions of lower pressure, (2) extrinsic pumping via massage-induced vessel wall compression, and (3) intrinsic pumping through lymphatic muscle contractions (Fig. 1B). A parametric study of the model shows that there is an optimal speed for the massage wave and that massage in the orthograde direction relative to the valves is somewhat more effective than retrograde.

Discussion

The model shows how massage can modulate intrinsic pumping. Specifically, vessel wall deformation appears to stimulate intrinsic pumping, while fluid shear stress from the massage-induced flow tends to temporarily inhibit muscle contractions. The model promises to be useful as a tool to suggest further optimization of lymphatic massage techniques, as well as for prediction of tracer and antigen movement from manual stimulation.

Discrete Fiber–Continuum Framework for Patient-Specific Modeling of Aneurysmal Wall Microstructure

Mr. Yamnesh Agrawal[1], Dr. James R. Thunes[2], Dr. Ronald N. Fortunato[1], Dr. Anne M. Robertson[1], Dr. Spandan Maiti[1,3]

[1]Department of Mechanical Engineering and Materials Science, University of Pittsburgh, Pittsburgh, PA, United States. [2]Synopsys, Waterloo, ON, Canada. [3]Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Aneurysm rupture risk assessment remains limited by biomechanical models that neglect tissue wall microstructure. Collagen fiber organization governs the mechanical integrity of aneurysmal tissue, yet the physiological representation of fiber architecture within patient-specific aneurysm geometries remains unresolved. This study introduces a discrete fiber–continuum framework that integrates microstructural architecture into finite element modeling of cerebral aneurysms which provides a fuller representation of the stress-state experienced by the wall tissue.

Methods

Patient-specific aneurysm geometries (N=2) were reconstructed from clinical angiographic data and extruded into multilayered hexahedral meshes representing the wall thickness. Fibers were stochastically seeded and chosen to be propagated conformally along the principal curvature directions (though this framework can also accommodate arbitrary fiber orientation vector fields) with angle dispersion of ±30° forming 1D embedded rod elements within continuum matrix. The matrix was modeled as neo-Hookean solid (**Eq.1**) and fibers as linear reinforced elastic elements (**Eq.2**).

$$\Psi_{matrix} = 1/2\mu(J^{-2/3}I_1 - 3) + 1/2K(J-1)^2 \qquad (1)$$

$$\Psi_{fiber}=1/2E_f(\lambda_f-1)^2 \qquad (2)$$

Results

The matrix and fiber stress for both samples using fiber-reinforced finite element (FE) method [1] are shown in **Fig.1**. FE analysis revealed that the mean Von-Mises stress for Sample 1 & 2 in the non-collagenous matrix was 38.99±11.96 kPa and 73.89±27.62 kPa, while the corresponding fiber stresses were 0.33±0.20 MPa and 0.72±0.44 MPa respectively. Furthermore, fiber stress maps demonstrated significant heterogeneity at

local scales where adjacent fibers exhibited varying load-bearing states (inset, right column of **Fig.1**) which cannot be captured by homogenized anisotropic models.

Discussion

The presented framework bridges the gap between physiological microstructural data and computational biomechanics by incorporating individual fiber-matrix level mechanics. Unlike homogenized anisotropic models, our discrete approach elucidates how different fiber architecture within the aneurysm geometry dictates local stress concentrations, offering a mechanistic explanation for wall failure distinct from averaged wall stress. Observed heterogeneities and attendant focal elevation in fiber stress can initiate sub-tissue scale tears revealing novel biomechanical pathways leading to wall rupture; Such failure mechanisms cannot be captured through continuum scale homogenized tissue models. Consequently, this methodology offers a scalable route for improving patient-specific rupture risk prediction.

[3]Department of Cardiothoracic Surgery, University of Pittsburgh, Pittsburgh, PA, United States. [4]Asheville Heart, Asheville, NC, United States. [5]Department of Chemical and Petroleum Engineering, University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Patient-specific prefailure and failure biomechanics of aorta is governed by collagen and elastin fiber network of wall tissue. Accurate biomechanical modeling requires high fidelity representation of the fiber architecture across the aortic wall. However, substantial spatial heterogeneity exists in this network (**Fig.1a**). While multiphoton microscopy (MPM) can capture fiber organization, imaging is limited to discrete locations. We propose a sparse-sampling framework to reconstruct the complete fiber architecture from limited measurements enabling spatial mapping of microstructure-induced wall stress fluctuations.

Methods

Reconstruction of aortic fiber architectures properties from limited discrete measurements was obtained by Radial Basis Function (RBF) mapping between sampling locations and the discretized geometry using Ansys System Coupling (v2025R2). To validate our sparse-sampling methodology, we constructed a synthetic “ground-truth” reference fiber direction field on a patient-specific aorta mesh with 24,502 triangle elements (**Fig.1b**) guided by the principal curvatures of the aortic surface. We sampled the field at 20 random points using Poisson disc method and reconstructed the complete fiber direction field. This process was repeated 100 times to assess reproducibility. Angular difference between the reference and reconstructed vector at each element centroid for each run was used for error estimation of the interpolation. A custom discrete embedded-fiber finite element analysis [1] was performed with the “ground-truth” and reconstructed fiber network.

Results

The average angular difference between reference and reconstructed fields was $6.6^{o}\pm8.7^{o}$ (**Fig.1c**). FE analyses using discrete fiber networks generated from the reference

and reconstructed fields (**Fig.1d,e**) showed that the fiber stress predicted from the reconstructed field (1.03±0.56 MPa) is comparable to that from the reference field (1.04±0.51 MPa).

Discussion

We demonstrated that a sparse distribution of sampling locations can approximate fiber orientation across complex aortic geometries with high fidelity. Beyond fiber orientation, this framework offers a generalized method to spatially interpolate other critical microstructural parameters such as wall thickness, fiber crimp, and material stiffness from limited local data. Future work includes optimal sampling number and placement and uncertainty quantification.

Finite Element Investigation of Mandibular Advancement and Hyoid Mechanics in Modulating Upper Airway Stability

Dr Wedad Saab[1,2], Dr Joseph Ghafari[2,3], Dr Jason Amatoury[4,1]

[1]Sleep and Upper Airway Research Group (SUARG), American Unviersity of Beirut, Beirut, Beirut, Lebanon. [2]Department of Dentofacial Medicine, American University of Beirut Medical Centre, Beirut, Beirut, Lebanon. [3]Department of Orthodontics, University of Pennsylvania, Philadelphia, Beirut, United States. [4]Biomedical Engineering Program, Maroun Semaan Faculty of Engeering and Architecture, American University of Beirut, Beirut, Beirut, Lebanon

Dr Wedad Saab

Dr Joseph Ghafari

Introduction

Mandibular advancement (MA) is used in the treatment of obstructive sleep apnea (OSA); however, it is not effective in all individuals. The hyoid bone serves as a key anchor point for multiple upper airway dilator muscles, including those connected to the mandible, and its position and mobility are therefore expected to influence airway stability under MA. Despite this, the combined biomechanical effects of natural (baseline) hyoid position, hyoid mobility, and surgical hyoid repositioning on MA-induced airway stabilization remain poorly understood. This study aimed to quantify these effects using computational modeling.

Methods

A validated two-dimensional mid-sagittal finite element model of the rabbit upper airway was used to simulate MA under a range of hyoid conditions. Simulations incorporated progressively more caudal baseline hyoid positions (OSA phenotype), a hyoid that was either free to move or mechanically fixed, and anterior–cranial surgical hyoid repositioning with fixation. For each simulated condition, upper airway collapsibility was quantified using closing pressure (Pclose). Mid-sagittal airway cross-sectional area (CSA), anterior–posterior diameter (APD), and stress/strain distributions were determined.

Results

At the initial (healthy) baseline hyoid position, MA reduced Pclose and increased CSA and APD, particularly at the hyoid region, indicating improved airway stability. A more caudal baseline hyoid position increased airway collapsibility and attenuated the mechanical benefits of MA, regardless of whether the hyoid was free to move or fixed. Hyoid fixation mostly reduced the effectiveness of MA in lowering Pclose and enlarging the airway, with the greatest regional APD increase shifted from the hyoid to the tongue region. Anterior–cranial surgical repositioning of the hyoid consistently reduced Pclose, increased CSA, and enhanced regional APDs across all baseline hyoid positions. Stress and strain distributions increased non-uniformly and varied across simulated conditions.

Discussion

Baseline hyoid position and mobility influence the biomechanical response of the upper airway to MA. A caudal and/or mechanically constrained hyoid limits MA-induced airway stabilization, whereas anterior-cranial hyoid repositioning enhances airway patency and compensates for unfavorable baseline anatomy. These findings highlight the importance of incorporating hyoid biomechanics into personalized OSA treatment planning and support the potential value of combined MA–hyoid interventions in selected anatomical phenotypes.

Biomechanical Modeling of Postnatal Growth of Large Arteries

Professor Jay Humphrey PhD[1], Professor Abhay Ramachandra PhD[2], Dr. Erica Schwarz PhD[1]

[1]Yale University, New Haven, CT, United States. [2]Iowa State University, Ames, IA, United States

Introduction

Arteries undergo dramatic changes during prenatal and postnatal development. Notwithstanding the importance of both, understanding early postnatal development is critical for it is during this period that surgeons intervene to palliate congenital defects. Although there is accumulating data on transcriptional, histological, and biomechanical changes throughout postnatal development of large arteries, detailed computational biomechanical models needed for surgical planning remain wanting.

Methods

With IACUC approval, we collected RNA-sequencing, histological, geometrical, and biomechanical data on the right pulmonary artery from 50 wild-type mice at postnatal days P2 (perinatal), P10, P21 (weaning), P42, and P84 (maturity). These data provided time-course changes in key transcripts (e.g., cell proliferation, matrix synthesis), composition (elastic and collagenous fibers), dimensions (radius, wall thickness, axial stretch), and mechanical metrics (biaxial wall stretch, stress, stiffness, and elastic energy storage). To understand how these many contributors to development work together, we formulated a novel constrained mixture model of growth (changes in mass) and remodeling (changes in microstructure) and focused on changes in elastic fibers (including deposition, compaction), fibrillar collagens (deposition, orientation, maturation), and smooth muscle cells. Applied loads included a near constant distending blood pressure following closure of the ductus arteriosus and near sigmoidal increases in blood flow and axial force.

Results

Transcriptional data revealed monotonic decreases in cell proliferation and the aggregating proteoglycans that support proliferation and migration, but transient increases in elastin and collagen production that peaked at ~P10 and ~P21 respectively. Using these data to inform a model of early genetically-driven transients in mass production/removal to augment a long-term model of mechanical homeostasis based on intramural and wall shear stresses allowed the model to capture simultaneously the measured time-course

changes (many sigmoidal) in luminal radius, axial length, biaxial wall stretch and stress, energy storage, and even mass fractions for elastin, collagen, and cells. The model similarly captured the more modest changes in wall thickness and biaxial material stiffness.

Discussion

Whereas prior computations have focused on the hemodynamics during development (often assuming rigid walls at individual ages), we submit that the present multiscale growth and remodeling model promises to enhance computer-based surgical planning by including the underlying mechano-genetics.

Towards Single-Access, Contrast-Free TAVR Guidance using PINN Hemodynamics

Mr. Jerome Gosselin[1], Professor Rosaire Mongrain[1], PhD. Frédéric Couët[2], Mr. Sébastien Lalancette[2], Dr. Renzo Cecere[1], PhD. Caroline Wagner[1]

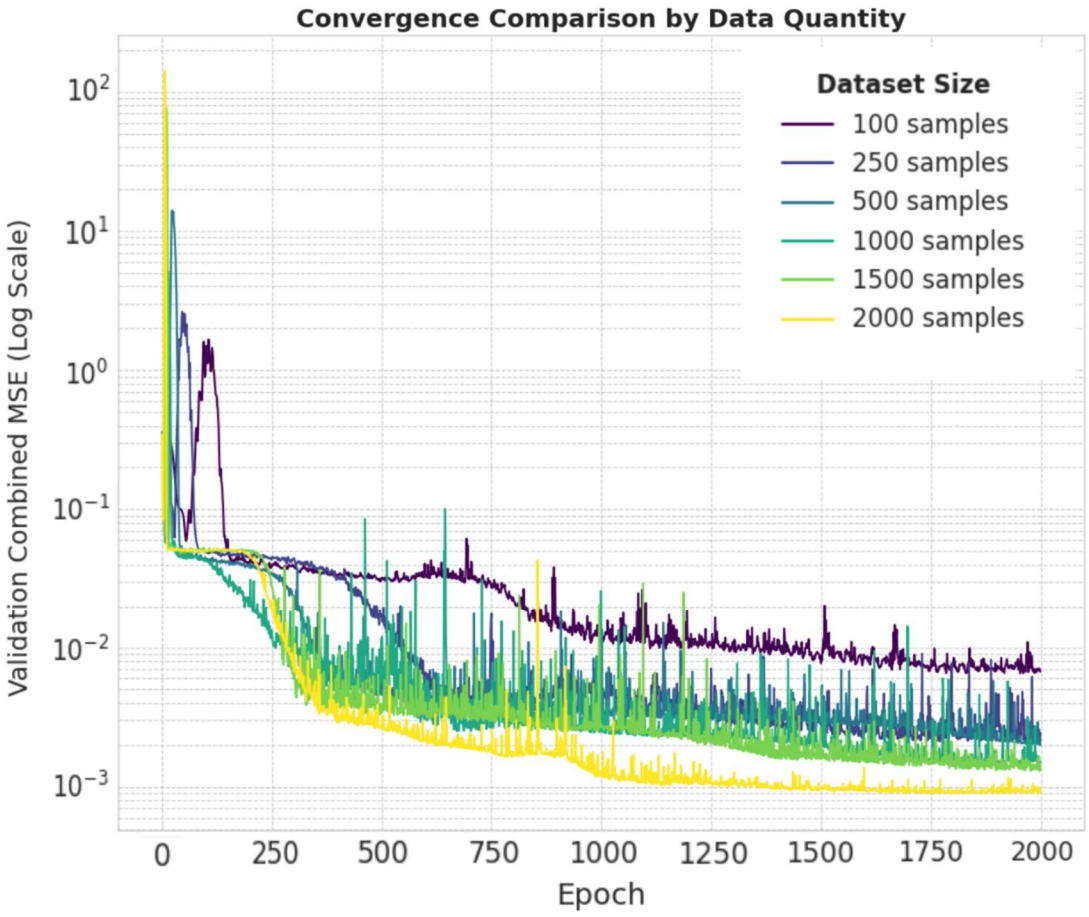
[1]McGill University, Montreal, Quebec, Canada. [2]Haemonetics, Québec, Québec, Canada

Introduction

Aortic Stenosis (AS) is the most common valvular heart disease in developed countries, typically treated with Transvalvular Aortic Valve Replacement (TAVR). Vascular access complications can lead to increased early mortality, with bleeding as a key predictor. To achieve a minimalist approach—a single-access, contrast-free procedure—we aim to generate essential physiological data, like a coplanar view, traditionally obtained invasively with a pigtail catheter. We propose using a Digital Twin (DT) based on Physics-Informed Neural Networks (PINN) to model flow hemodynamics and accurately identify the coplanar view.

Methods

The approach uses PINNs to create the core computational engine for the single-access Digital Twin (DT) procedure. Unlike traditional methods, PINNs rely on governing equations to complement existing data. We initiated with modeling steady-state, incompressible, non-viscous 1D flow (the Bernoulli equation) as a foundational step.



Results

The PINN model is an MLP that addresses three key residuals: the Momentum equation, the Continuity equation (with varying pipe diameter), and Simulation data. To establish model reliability, we focused on the impact of the quantity of upstream training data. We tested PINN's prediction accuracy across a dataset range of 100 to 2000 samples, fixing the physical complexity at a 30% stenosis severity. Model accuracy and stability were assessed using Root Mean Square Error (RMSE) for the pressure and velocity fields. Initial trials confirmed that performance was already highly robust with only 100 training samples, yielding a Mean RMSE Pressure of 7.19×10^{1} Pa. This RMSE, approximately 0.54 mmHg (0.45% of a 120 mmHg range), is comparable to the ±1 mmHg fidelity of the SavvyWire™ pressure sensor. Increasing the dataset size further dramatically reduced underfitting (as seen in the figure 1).

Discussion

The results show that PINN provides reliable predictions with physics-based residuals, depending on the quantity and diversity of training data. Initial high accuracy was achieved with a fixed architecture and training duration, indicating room for further improvement. It highlights the need for a multimodal dataset of TAVR cases to enable the Digital Twin (DT) to generate reliable pressure information for the coplanar view, thereby supporting the single-access minimalist TAVR procedure.

A Hybrid Multi-Scale 3D Computational Model to Explore the Origins of Atherosclerosis

PhD candidate Mané Sarkissian[1], Professor Vasileios Vavourakis[2], Professor Jérome Noailly[1]

[1]Pompeu Fabra University, Barcelona, Catalonia, Spain. [2]University of Cyprus, Nicosia, Nicosia, Cyprus

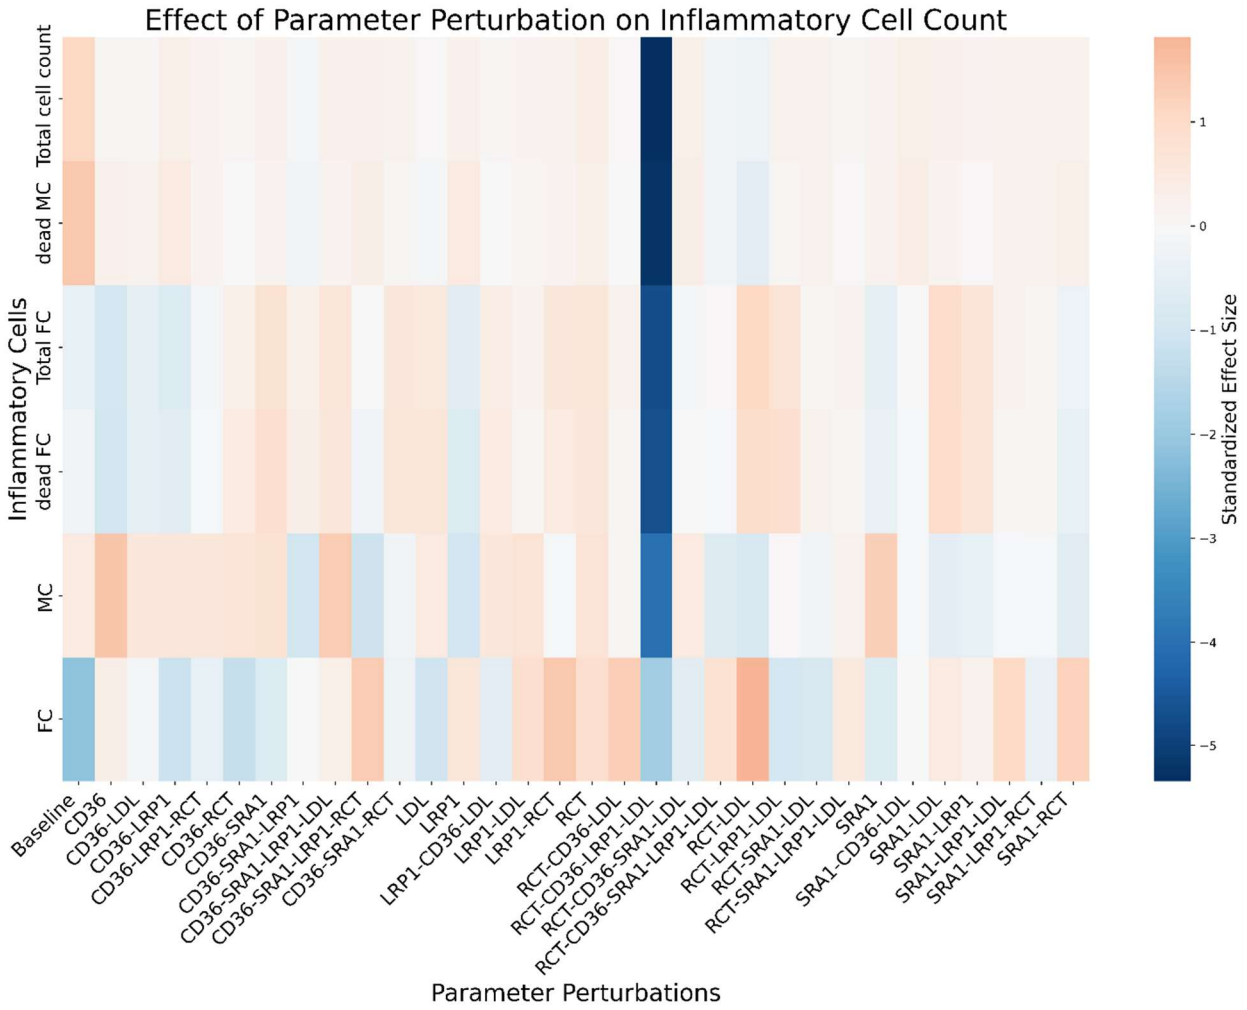
Introduction

Atherosclerosis (AS) is influenced by inflammation, biomechanics and characterized by foam cell (FC) formation. AS has no cure beyond a very early stage. New approaches are necessary for subclinical characterization. We aimed to create a model of early AS, including key atherogenic processes for early biomarker identification with mechanistic risk stratification.

Methods

A regulatory network model (RNM) was combined with an agent-based model (ABM). The RNM was solved at each time step with a set of ordinary differential equations [1]. RNM interacted with higher-level agent rules integrating oxidative stress; inflammation; LDL oxidation & aggregation; wall shear stress (WSS); reverse cholesterol transport (RCT). WSS mechanobiology activated specific endothelial cell signaling pathways: normal WSS activated ERK5-KLF2; low WSS activated NF-kB. RCT was modelled via ABCA1 kinetics in macrophages (MC) & FC. The model was implemented in BioDynaMo. 18 cases were simulated with 6 combinations of HDL and WSS levels, each for three levels of LDL: high (200 mg/dL); borderline (150 mg/dL); normal (90 mg/dL). Each simulation was repeated 10 times. A sensitivity analysis (SA) explored the effects of the: LDL uptake rate by CD36, SR-A1 & LRP1 receptors; RCT rate by ABCA1; LDL modification rate.

Results



Normal LDL and WSS with high HDL showed no atherogenesis. For the hypercholesterolemic case, the SA revealed the parameter combination resulting in lowest levels of inflammation: the simultaneous upregulation of CD36, RCT and LRP1 along with increased LDL modification rate significantly reduced MC & FC ($p_value < 0.05$). Remarkably, though, the increase of CD36 alone increased oxLDL uptake and MC accumulation. However, when this upregulation was combined with increased RCT, LRP1 &

LDL modification a strong reduction in inflammatory cell counts was observed (Fig.). These results could potentially explain controversial findings on the role of CD36 in AS [2].

Discussion

This unique AS model provided realistic simulations of key atherogenic processes in the artery. The results underscore the multifactorial nature of AS highlighting the dual role of CD36. In conclusion, functional MC with effective LDL uptake and efflux are crucial for halting AS.

CFD-Agent-Based Model Reveals Spatial Clustering of Inflammatory markers in Low Shear Arterial Regions

Dr. Veera Venkata Satya Varaprasad Jakka, PhD Candidate Mané Sarkissian, PhD Candidate Yalemzerf Motbaynor Alemu, Prof. Jérôme Noailly

Universitat Pompeu Fabra (UPF), Barcelona, Catalonia, Spain

Introduction

Atherosclerotic plaques develop preferentially in arterial regions with disturbed flow and low wall shear stress [1]. The NLRP3 inflammasome, a critical mediator of atherosclerotic inflammation, responds to shear stress [2], hypoxia [3], and oxidized lipids. However, spatial relationships between hemodynamics and inflammasome activation remain unclear. We coupled CFD and agent-based simulations to investigate monocyte inflammatory signaling regulation by arterial flow.

Methods

Blood flow through a curved iliac artery was simulated using OpenFOAM with Lagrangian tracking of 4,000 monocytes over 10 hours. BioDynaMo agent-based modeling integrated hemodynamics with monocyte processes: (i) chemokine sensing, (ii) selectin-mediated rolling, (iii) integrin-dependent adhesion, (iv) state-dependent NFκB activation, (v) NLRP3 activation by NFκB and environmental stimuli (hypoxia, oxidized LDL, low shear), and (vi) subtype-specific transmigration. Monocytes were assigned classical (85%), intermediate (5%), or non-classical (10%) phenotypes.

Results

Simulations predicted 8.0% adhesion (321/4000 cells) and 9 transmigration events. Regional NFκB (Fig 1B-C) showed state-dependence: adhered cells exhibited 5.2-fold higher activity (0.800) than rolling cells (0.155). Population NLRP3 reached 0.066, while activated cells achieved near-maximal NLRP3 (0.83-0.99). NLRP3 exhibited pronounced spatial heterogeneity (Fig 1A,C,E): the middle vessel region (lowest flow velocity 27.2 μm/s, Fig 1D) showed 2.63-fold enrichment versus inlet. The middle showed highest cell density (139 cells, Fig 1F) versus inlet (55) and outlet (127).

Discussion

This multiscale framework links arterial hemodynamics to cellular inflammatory signaling. The 2.63-fold NLRP3 clustering in low-shear regions, where flow recirculation and hypoxia co-localize, provides mechanistic insight into preferential plaque development in curved

vessels [1]. The 5.2-fold NFκB amplification upon adhesion reveals that hemodynamic forces promoting capture trigger inflammatory cascades. Population-average NLRP3 (0.066) reflects that only adhered monocytes (8%) activate inflammasomes. The framework successfully models monocyte biology, enabling testing of atherosclerosis mechanisms and interventions. This arterial simulation represents a first step toward whole-body vascular modeling. Scaling from 3D segments to body-wide vasculature enables growth from ~4,000 to ~350×10^6 agents, permitting patient-specific vascular mapping to track inflammation system-wide and support precision cardiovascular interventions.

Patient-Specific Fluid-Structure-Interaction Simulations Suggest Endothelial Cell Activation Potential (ECAP) as a Biomarker for Aortic Events in Marfan syndrome

Miss Yufan Wu[1], Dr. Krashn Dwivedi[1], Dr. Hadi Wiputra[2], Dr. Marisa Bazzi[3], Dr. Alan Braverman[4], Dr. Victor Barocas[2], Dr. Jessica Wagenseil[1]

[4]Department of Medicine, Cardiovascular Division, Washington University School of Medicine, St. Louis, Missouri, United States

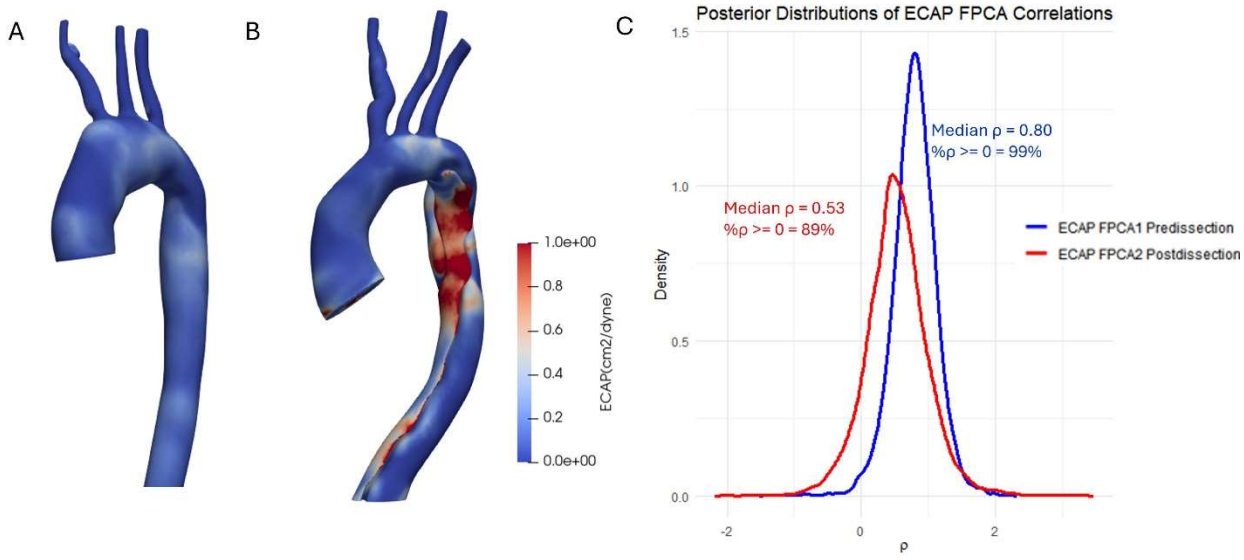
Introduction

Marfan syndrome (MFS) is a connective tissue disorder whose cardiovascular complications include thoracic aortic aneurysm and dissection. Current surgical guidelines for intervention rely on maximum aortic diameter, failing to capture patient-specific hemodynamics. We performed fluid-structure interaction (FSI) simulations on pre-dissection and post-Type B dissection MFS aortas to identify potential hemodynamic biomarkers of aortic events.

Methods

Seven MFS patients with CT imaging before and after dissection were analyzed. Aortic geometries were reconstructed and meshed in SimVascular. FSI simulations incorporated patient-specific heart rate and blood pressure, a three-element Windkessel model at the lumen outlets, and a neo-Hookean constitutive equation for the wall and dissection flap (if applicable). Hemodynamic metrics including time-averaged wall shear stress (TAWSS), oscillatory shear index (OSI), endothelial cell activation potential (ECAP), and relative residence time (RRT), were extracted from the simulation results. Functional principal component analysis (FPCA) assigned patient-level scores for each metric. Bayesian posterior and probability models assessed the likelihood and strength of the scores' association with aortic events (i.e. dissection).

Results



Compared to pre-dissection states, post-dissection aortas showed reduced TAWSS and elevated OSI, ECAP, and RRT (Fig.1 A-B). In dissected aortas, the true lumen, which is significantly smaller than the false lumen, demonstrated higher OSI, ECAP, and RRT. In pre-dissection models, ECAP peaked at the proximal descending aorta, anatomically matching

the future dissection site despite negligible dilation. Across all patients, ECAP showed the highest likelihood of positive correlation with aortic events (Fig.1 C).

Discussion

High ECAP indicates regions with low shear stress and highly oscillatory flow – conditions that promote endothelial dysfunction and degeneration of the intimal layer, where dissections originate [1]. Clinicians identified the start of the descending aorta as a highly dissection-prone site, coinciding with the location where ECAP peaks in our study [2]. For the dissection case, elevated ECAP in the true lumen suggests disturbed flow that may contribute to malperfusion of downstream vessels and organs [2]. Because ECAP can be estimated noninvasively from 4D-flow MRI, it holds potential as a biofluidic biomarker of aortic events in MFS.

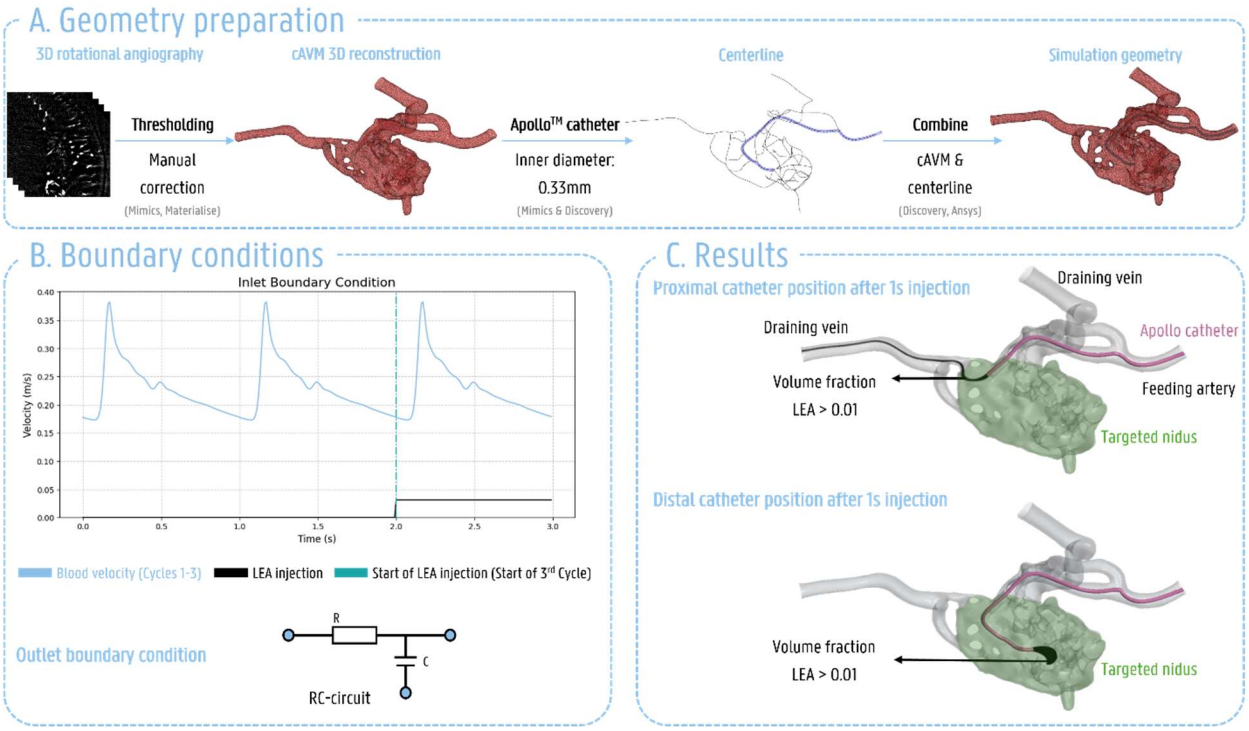
Introduction

Cerebral arteriovenous malformations (cAVMs) are high-flow vascular anomalies in the brain characterized by an abnormal tangle of blood vessels (nidus). This poses an increased risk of intracranial hemorrhage (1-4% annual rupture rates [1]). Endovascular embolization (EE) using liquid embolic agent (LEA) is a viable treatment option. The efficacy of EE is largely dependent on the LEA's interaction with the local blood flow and the treatment-related parameters including the microcatheter position. This study uses patient-specific multiphase computational fluid dynamics (CFD) to investigate how variations in catheter position influence the LEA distribution and targeted flow occlusion within the cAVM.

Methods

A patient-specific cAVM geometry was 3D-reconstructed (Mimics, Materialise) and meshed with 10.9 million tetrahedral elements (Fluent, Ansys, USA). The Apollo microcatheter (0.33mm inner diameter) was virtually inserted into the feeding artery (Discovery, Ansys; Fig. 1A). Blood flow (ρ:1060kg/m^3, μ:3.5mPa·s) and LEA injections (ρ:1104kg/m^3, μ:18mPa·s) were modeled using transient multiphase CFD. Boundary conditions included a cerebral inlet velocity profile derived from the Reymond model [2] scaled to patient data, and 2-element Windkessel models at the draining veins (Fig. 1B). LEA progression was modelled for two distinct axial catheter tip positions to quantify filling efficiency and potential reflux.



Results

Fig. 1C illustrates the LEA progression, showing the embolization extent. When the catheter tip was positioned proximally near the entrance of the feeding artery, the LEA progression was directly shunted towards the draining vein (42.97% of injected LEA volume in targeted nidus). When the catheter tip was advanced more distally in the feeding artery, it immediately targeted the nidus (100% of injected LEA volume in targeted nidus).

Discussion

The simulation results show that distal microcatheter placement maximizes targeted nidus occlusion and minimizes unintentional shunting to the draining veins. These findings suggest that a more distal catheter tip penetration into the AVM nidus may support maximizing therapeutic efficacy. Future work will focus on quantifying targeted occlusion metrics and analyzing nidus hemodynamics for multiple patients. Ultimately, these CFD-models will be extended to simulate multi-injection sequences (i.e. longer injection times, etc.).

Validation Pipeline for Subject-Specific Bone Conduction Finite Element Models

M.Sc. Johannes Niermann[1], M.Sc. Linus Taenzer[2], Dr. Ivo Dobrev[1], Dr. Bart Van Damme[2], Prof. Dr. Christof Röösli[1], Dr. Flurin Pfiffner[1]

[1]Department of Otorhinolaryngology, Head and Neck Surgery, University Hospital Zurich, University Zurich, Zurich, Zurich, Switzerland. [2]Laboratory of Acoustics/Noise Control, Empa, Dübendorf, Zurich, Switzerland

Introduction

Bone conduction (BC) hearing refers to the transmission of sound to the cochlea via skull vibrations. Individual anatomies and material properties cause variations in BC response [1,2].

Individualized full head BC models offer the potential for advancements in basic research, hearing aid development, and personalized treatment. A hierarchical experimental framework for the development and validation of these models has been formulated [3].

This study shows preliminary comparisons of experimental measurements with simulation predictions of the dynamic response of a dried bone piece.

Methods

CT and motion data were collected as described in [3]. The CT scan of the bone piece was segmented semi-manually into cortical and trabecular bone. A finite element (FE) mesh was generated using Synopsis Simpleware (Fig. A). Material properties were defined based on a combination of measurements, literature [2], and model tuning. A custom automatic registration and interpolation method was developed to align simulation with experimental data on a common grid of points. The modal assurance criterion (MAC) was used as a comparison metric.

Results

The registration method showed robust results with an average error of less than 0.45 mm across fiducials. The MAC showed agreement of simulation and experiment of over 98 % for multiple mode shapes of the dried bone piece (Fig. B).

Discussion

The presented validation methodology can be used in several scenarios within the development of individualized bone conduction models, including:

1. validation across large sample sizes within an individual as well as across multiple individuals
2. validation of bone piece conditions (wet and dry)
3. variation of model definitions for sensitivity studies or identification of material properties.

Additionally, the methodology can be extended towards validation of more complex model geometries (i.e., full heads), by using similar measurement methods. Furthermore, spatial registration of datasets from different hierarchies (e.g. pieces to heads) will allow application of identified properties.

Introduction

Cerebral arteriovenous malformations (AVMs) are vascular anomalies in the brain that increase hemorrhage risks. Endovascular embolization using catheter-based liquid embolic agent injections (e.g. Onyx) can reduce AVM flow and risks, but outcomes can be operator-dependent, influenced by parameters like injection rate and catheter position/direction. Despite an FDA-recommendation of 0.16 ml/min (with 0.30 ml/min upper limit due to angionecrosis and vasospasm in animals), flow rate is rarely monitored [1]. Hence, this study used computational fluid dynamics to assess injection rate effects on Onyx distribution and local pressure differences in an AVM.

Methods

One patient-specific AVM model was reconstructed from 3D rotational angiography in Mimics (Materialise, Belgium) and meshed in ANSYS Fluent (Ansys, USA) with ~$11 \cdot 10^6$ tetrahedral elements. Blood (density=1063 kg/m^3, viscosity=4 cP) and Onyx (density=1103.9 kg/m^3, viscosity=18 cP; mass-weighted properties of two phases of Onyx-18: 6 m% ethylene vinyl alcohol and 94 m% dimethyl sulfoxide) were modeled as incompressible, Newtonian fluids under transient conditions (time step size 0.01 s and assuming heart rate of 75 bpm) using a multiphase Volume-of-Fluid approach, with blood inlet velocity waveforms (mean 0.0920 and 0.1325 m/s for inlet 1 and 2), outlet-pressures based on patient-specific fractional outflows, and varying Onyx injection rates (0.08, 0.16, and 0.32 ml/min).

Results

Preliminary results indicate that faster injections accelerated Onyx propagation and shifted Onyx distribution from 74.35% to 39.06% of injected Onyx mass towards branch 1 over

three cardiac cycles (2.40 s) for 0.08 versus 0.32 ml/min, indicating notable Onyx spread changes, likely attributed to elevated flow resistance in branch 1 from faster delivery of viscous Onyx (Fig. 1). Maximum pressure differences over a 4 mm downstream segment rose from 3.61 Pa without Onyx to 4.47 Pa, 5.95 Pa, and 8.85 Pa at 0.08, 0.16, and 0.32 ml/min, respectively.

Discussion

Based on the AVM studied, Onyx injection rates affect embolization dynamics, suggesting need for closer clinical attention to this parameter. Future work should quantify sensitivity for various procedural parameters, as well as include larger patient cohorts, optimized boundary conditions, and experimental validation for generalizability.

Images (Optional)

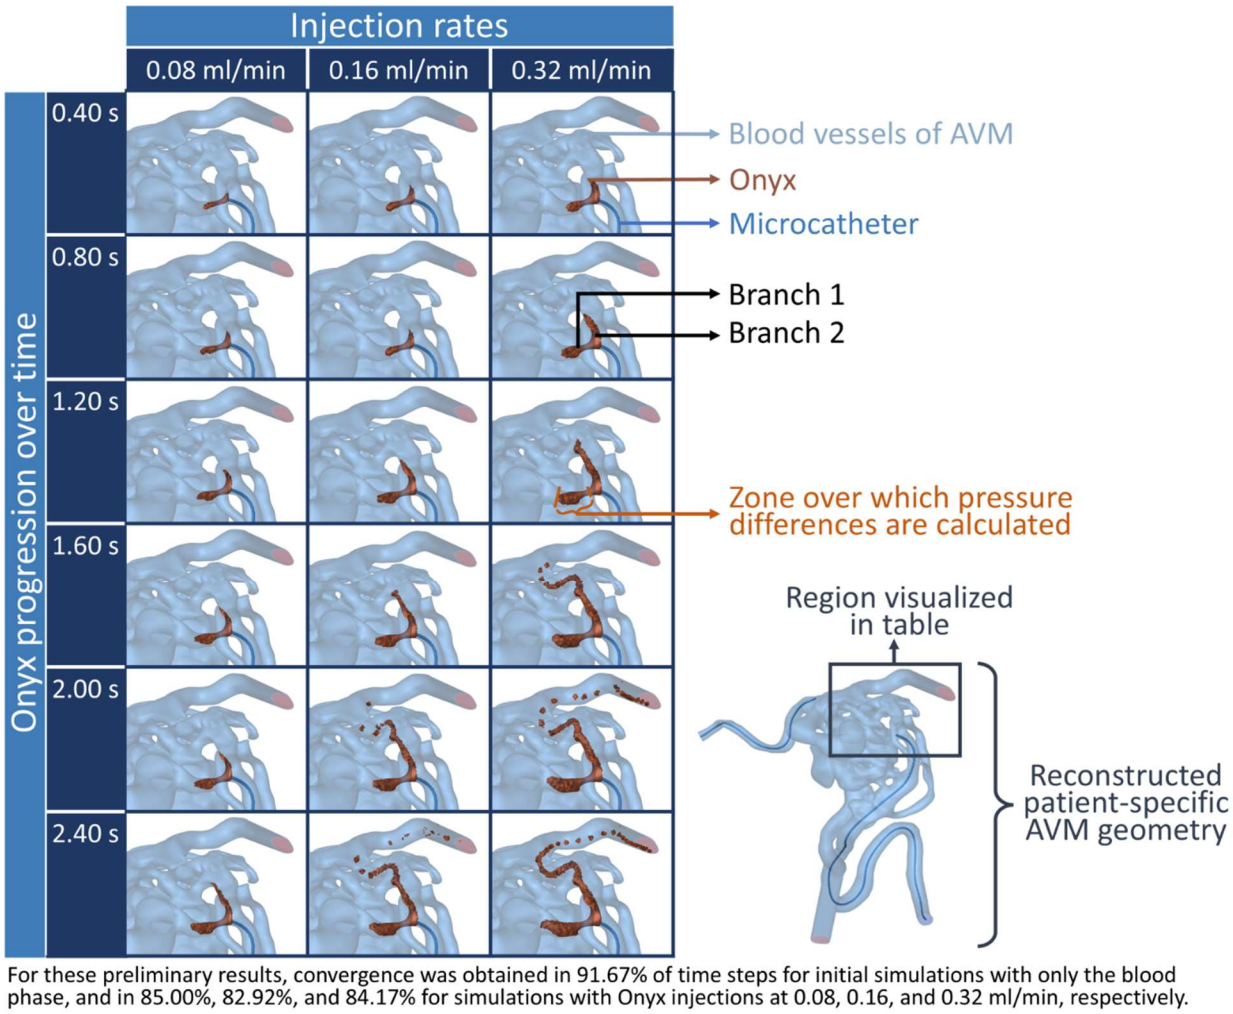

Figure 1. *Onyx progression over time (2.40 s) for various injection rates (0.08, 0.16, and 0.32 ml/min). The brown color indicates cells that contain Onyx, but are not necessarily fully filled with Onyx (criterion of volume fraction for Onyx phase > 10^{-6}).*

Investigation of Plastic Deformation and Fracture of Ischemic Stroke Clots

Ms. Kila Bein Snee[1], Ms. Alessia Ruzzier[2], Dr. Behrooz Fereidoonnezhad[2], Dr. Ray McCarthy[3], Prof. Patrick McGarry[1]

[1]Biomedical Engineering, University of Galway, Galway, Co. Galway, Ireland. [2]Biomechanical Engineering Department, TU Delft, Delft, South Holland, Netherlands. [3]Johnson & Johnson MedTech Neurovascular, Galway, Co. Galway, Ireland

Introduction

Stroke clot composition (fibrin and RBC content) strongly influences thrombectomy outcomes [1]. A deeper understanding of clot biomechanics during lodging and retrieval is critical for improving device design and clinical strategies.

This study provides the first evidence of clot permanent plastic deformation, non-linear volumetric behaviour, and composition-dependent fracture. We demonstrate that these features are key determinants for thrombectomy outcomes.

Methods

Uniaxial tension and unconfined compression tests were performed on platelet-contracted clot analogues (0-40% hematocrit). A novel hyperelastic-plastic model with non-linear volumetric stress was implemented in Abaqus (UMAT) and calibrated to axial stress-strain (σ_{axial} - ε_{axial}) and volumetric strain (ε_{vol}) data.

Benchtop tests and finite element models were developed to investigate the biomechanics of clots lodging in bifurcated vessels under physiologically relevant pressures. Friction coefficients (μ) were determined by matching lodged positions.

To evaluate clot fracture, we developed a phase field fracture model.

Results

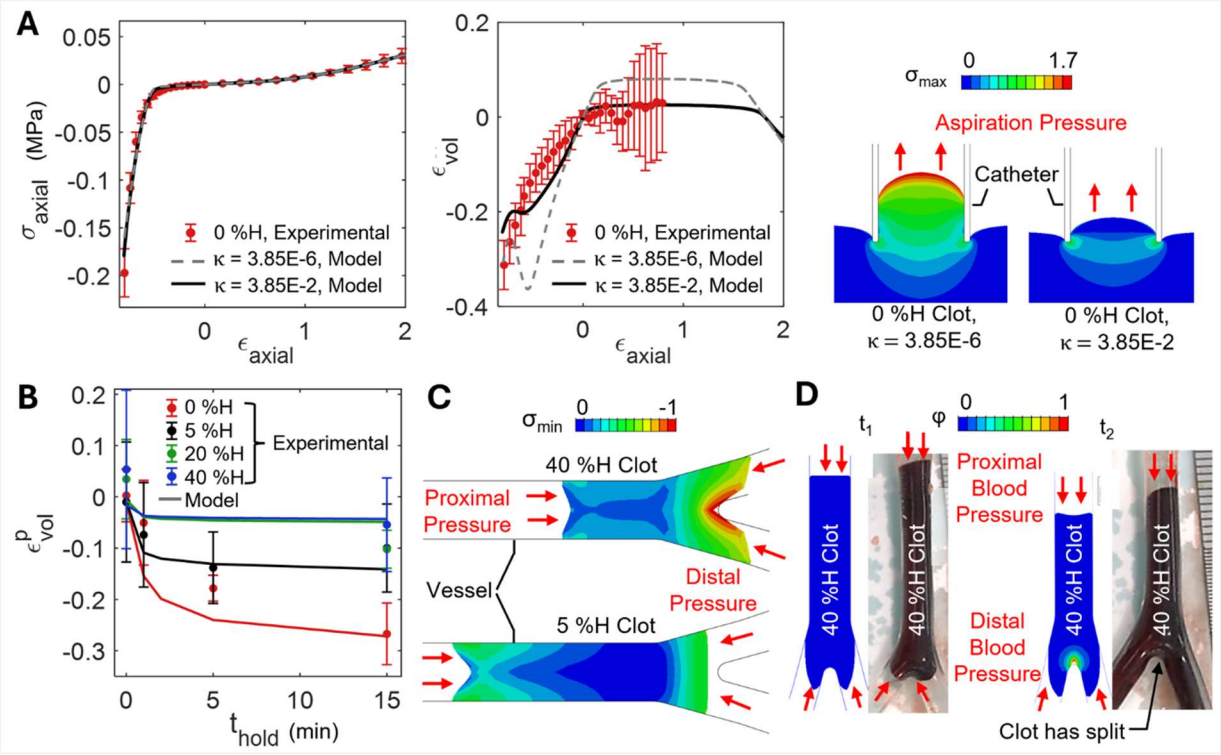
Calibration of the initial tangent bulk modulus (κ) was essential for realistic aspiration lengths and strain distributions (Fig. 1A).

Plastic volumetric (ε^p_{vol}) and isochoric (ε^p_{iso}) deformations decreased with increased %H and increased deformation duration t_{hold} (Fig. 1B).

RBC-rich 20-40 %H clots lodged more distally and exhibited shorter lodged lengths than fibrin-rich 5 %H clots (Fig. 1C). Lodging induced strains sufficient for plastic deformation

and large volumetric compaction. Purely hyperelastic material models underpredicted clot shrinkage over time, underscoring the importance of plastic deformation.

RBC-rich 20 %H and 40 %H clots showed localised fracture ($\phi>0$) due to contact with vessel bifurcations (Fig. 1D) and catheters, whereas fibrin-rich clots exhibited no fracture ($\phi=0$).



Discussion

Our findings significantly advance the understanding of clot biomechanics with implications for clinical practice and device design:

(i) Volumetric deformation significantly influences fracture in RBC-rich clots and aspiration lengths in fibrin-rich clots. Our non-linear volume change and fracture model should guide catheter tip design;

(ii) The plastic behaviour of fibrin-rich clots contrasts sharply with the predominantly hyperelastic behaviour of RBC-rich clots, motivating the development of composition specific thrombectomy devices and the advancement of imaging techniques to determine clot composition *in vivo* [2].

Left-to-Right Ventricular Interaction: Insights From an Ex-Vivo Beating Heart Model

Mr. Chenghan Cai, Dr. Lei Fan

Michigan State University, East Lansing, Michigan, United States

Introduction

Interventricular interaction, where changes in the loading condition of one ventricle affect the diastolic and systolic function of the other, is critical for overall ventricular performance. For example, unloading of the left ventricle (LV) due to left ventricular assist device implantation affects right ventricular (RV) function through the interventricular septum. Previous animal experiments using isolated hearts have shown that LV contractility is augmented with an increase in RV pressure and vice versa, indicating systolic interdependence. Similarly, LV volume is increased at a given filling pressure when the RV is unloaded, indicating diastolic interdependence. However, the effects of ventricular loading conditions (e.g., preload and afterload) remain unquantified. The ex-vivo beating heart model provides a controlled platform to study these dynamics though most existing work focus on LV function within systemic circulation, often neglecting RV function.

Methods

To address these limitations, we further developed the ex-vivo beating heart apparatus by allowing precise manipulation of preload, afterload, and coronary perfusion, as well as direct measurement of aortic function, and ventricular pressures and volumes in both LV and RV. This beating heart setup enables detailed investigation of how ventricular interdependence shapes normal and pathological biventricular function. The gain factor is used as a quantitative measure of interventricular interaction, reflecting how changes in loading or pressure in one ventricle are transmitted to the other through interventricular septum.

Results

Our results suggest that under physiological baseline condition, LV and RV developed pressures linearly vary with coronary blood flow with a steeper gradient in the LV than in the RV. When LV preload and afterload were varied in the working heart antegrade perfusion mode, the gain factor for developed pressure and ventricular systolic pressure was below 1 whereas the gain factor of ventricular diastolic pressure was close to 0.

Discussion

In this study, we developed an ex-vivo beating heart model to measure biventricular function. The results demonstrate that changes in one ventricle significantly influence the systolic function of the other whereas diastolic effects are minimal. These findings highlight the importance of considering biventricular mechanics in studies of cardiac function and interventions, particularly when modulating ventricular loading conditions.

Introduction

In renal artery and femoropopliteal artery stenotic disease, treatment decisions could be improved using pressure gradients instead of anatomic grading. However, invasive pressure measurements in peripheral arteries require equipment that is commonly not available and that demand additional lesion crossings and procedural time. An attractive alternative is the use of computational fluid dynamics (CFD). We performed two separate studies to validate the use of CFD for estimating the pressure gradient in patients with renal or femoropopliteal stenotic disease.

Methods

For study 1, fifteen patients with two or more lesions in the femoropopliteal artery (multi-segmental) scheduled for angioplasty were enrolled. For study 2, twenty patients scheduled for renal angiography were recruited. In both studies, the pressure gradient in resting condition was measured using simultaneous sheath and pressure-wire measurements. Based on pre-operative computed tomography angiography (CTA), the pressure gradient was simulated with CFD. For study 1, CFD was performed (CFD_{US}) using a patient-specific flow rate derived from Duplex ultrasound. For study 2, the CFD flow rate was set based on the distal renal artery diameter (renal, CFD_D) or the segmented kidney cortical volume (renal, CFD_C).

For statistical analysis, a Pearson's correlation and Bland-Altman analysis between the measured and CFD-simulated pressure gradient were performed.

Results

For the femoral study, the mean pressure gradient over the multi-segmental lesions was 12.8 mmHg. An example simulation is shown in Fig. 1a. CFD_{US} closely approximated the measured gradient with a 0.1 ± 3.1 mmHg difference (R^2= 0.91).

For the renal lesions, the mean pressure gradient was 13.5 mmHg. A simulation example is provided in Fig. 1b. CFD_D showed a reasonable agreement of the pressure gradient with a difference of 3.1 ± 7.5 mmHg (R^2 = 0.91). Using kidney cortex volume information, CFD_C showed an excellent agreement with a difference of 1.1 ± 5.3 mmHg (R^2 = 0.95).

Discussion

The results support the use of CFD for hemodynamic assessment of renal artery and femoropopliteal stenotic lesions. External validation studies are indicated. For femoral disease with multiple lesions, pre-intervention CFD could help prevent overtreatment. For renal artery disease, CFD can be a valuable method for deciding on the indication for endovascular treatment.

Images (Optional)

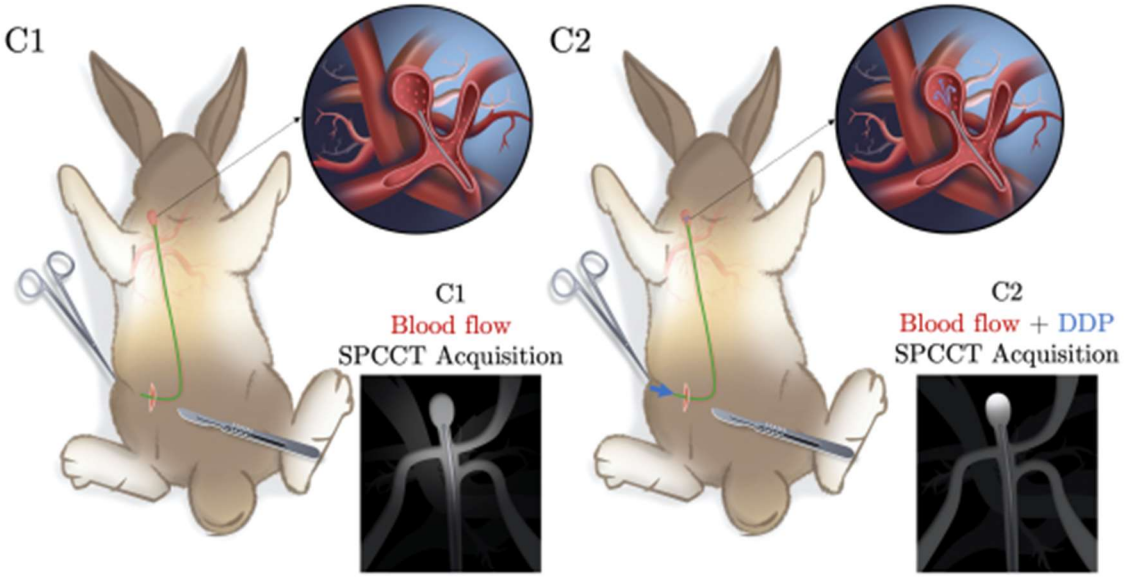
Introduction

Intracranial aneurysm (IA) is a life-threatening pathology related to arterial wall deterioration. Although these mechanical alterations are a key factor in the rupture mechanism, no reliable method currently exists to predict rupture risk using in vivo biomechanical data. Developing tools to characterise these properties non-invasively is therefore essential for improving clinical risk assessment and guiding treatment decisions. This work, conducted on an animal model of aneurysm, represents a first step towards better understanding of vascular wall rupture risk. It presents the application of a procedure based on the Coherent Point Drift (CPD) algorithm to quantify the strain fields induced by a non-destructive vascular wall deformation device (DDP), enabling the acquisition of mechanical data to build a database for IA analysis.

Methods

A saccular aneurysm was induced on the bifurcation of a rabbit carotid artery to mimic a human IA. The DDP was designed as a catheter repurposed from its original use [1]. The Spectral Photon Counting Computed Tomography prototype system (SPCCT) was used for imaging. Two configurations were considered for the images acquisition: Configuration 1 (C1) with the DDP positioned in the aneurysm without flow, and Configuration 2 (C2) with flow applied by the DDP (Figure 1). An original procedure was implemented to determine the mechanical properties of the aneurysm using the CPD algorithm, which aligns two point clouds by assuming that one is a probabilistic transformation of the other [2]. Extracting the aneurysm from SPCCT images as point clouds allows a direct comparison of the two configurations and provides mechanical characterisation of the aneurysm.



Results

Among the rabbits tested, several aneurysms were successfully created. Using the numerical procedure, it was possible to quantify the strain fields for a known mechanical loading. The average strain of aneurysms ranged from 1.5% to 3.7%.

Discussion

By combining the strain fields with material parameters representative of rabbit arteries, it would be possible to determine the corresponding stress fields, thereby pointing toward the definition of a rupture criterion.

Asymmetric Leg Blood Flow Regulation Before and After Walking in Individuals with Unilateral Transtibial Amputation

Dr. Logan Faux-Dugan PhD[1], Mr. Jose Anguiano-Hernandez MS[1], Dr. Jenna Burnett PhD[1], Dr. Colby Hansen MD[1], Dr. Rakesh Srivastava PhD[2], Dr. Song-young Park PhD[3], Dr. Kota Takahashi PhD[1]

[1]The University of Utah, Salt Lake City, Utah, United States. [2]Innovative Prosthetics & Orthotics, Omaha, Nebraska, United States. [3]University of Nebraska Omaha, Omaha, Nebraska, United States

Introduction

Leg blood flow (LBF) supplies oxygen to muscles during walking, especially in response to positive muscle work production (higher energetic demand [1]). One approach to examine how muscle work relates to LBF is by studying individuals with unilateral transtibial amputation (TTA) because their residual limb (RL) has less muscle mass overall to perform mechanical work. Individuals with TTA have less blood distributed to their RL when cycling [2], but it is unclear whether this asymmetry exists with walking. We, therefore, investigated the relationship between positive mechanical work done during walking and LBF, when accounting for the inter-limb asymmetry in TTAs. We hypothesized that the intact limb (IL) would have greater change in LBF (pre vs post walking) than the RL, and the inter-limb asymmetry in LBF will be correlated with asymmetry in positive work.

Methods

Eight TTAs (2F/6M) walked at a comfortable speed (1.0 ± 0.2 m/s) for ten minutes on an instrumented treadmill. Pre- and post-walking LBF, as well as the change in LBF, were measured via Doppler ultrasonography of the common femoral artery. Total positive work was computed on the IL (sum of foot, ankle, knee and hip) and the RL (sum of knee and hip). Inter-limb asymmetries were calculated as (IL-RL/IL+RL)*100 [2]. Two-sample t-tests compared LBF and work between limbs, and linear regression examined the correlation between inter-limb asymmetries in positive work and LBF change.

Results

The IL generated more positive work during walking ($p=0.002$, Figure 1) and received greater LBF post-walking ($p=0.034$). Differences in pre-walking LBF ($p=0.059$) and LBF change

(p=0.052) trended toward significance. Positive work asymmetry was not associated with LBF change asymmetry (p=0.374).

Discussion

Despite no correlation between asymmetries of work and LBF change, more post-walking blood was supplied to the IL. These findings are supported by the asymmetric LBF responses found during cycling in TTAs [2]. This growing knowledge may inform clinical practices aimed at preserving and improving tissue health in TTAs.

Restoring Tissue Anisotropy and Contractility Synergistically Supports Sustained Structural Repair After Myocardial Infarction

Mr. Luuk H.F. Souren[1,2], Dr. Hesam Hoursan[1,2], Dr. Tommaso Ristori[1,2], Dr. Peter H.M. Bovendeerd[1], Prof. Carlijn V.C. Bouten[1,2], Prof. Sandra Loerakker[1,2]

[1]Department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Noord-Brabant, Netherlands. [2]Institute for Complex Molecular Systems, Eindhoven University of Technology, Eindhoven, Noord-Brabant, Netherlands

Introduction

Restoring cardiac structure and function after infarction remains a central challenge in regenerative medicine. Strategies focusing solely on restoring infarct tissue composition and contractility (e.g., cardiomyocyte injections) have shown limited success, shifting attention toward a combined restoration of tissue anisotropy. An aligned extracellular matrix (ECM) may improve injected cardiomyocytes' alignment, retention, and contractile efficiency, thereby supporting restoration of anisotropic tissue properties [1]. However, it remains unclear whether therapeutically induced ECM re-alignment is sustained or altered by remodeling under infarcted heart mechanics [2]. Here, we use computational modeling to investigate how induced infarct ECM (an)isotropy adapts under mechanical loading in the acutely infarcted left ventricle, with or without injected cardiomyocytes aligned with the ECM.

Methods

A finite element (FE) model of the acutely infarcted left ventricle with opposing helical fiber alignment (reference, REF) was used to compute strains at four transmural locations (Fig. 1a) [3]. Infarct properties were varied in anisotropy, either isotropic (ISO) or anisotropic aligned with REF (ANISO), and in contractility (0% or 25%) to mimic partial restoration via cardiomyocyte injections. Computed strains served as input for a mechanobiology-informed ECM remodeling model predicting in-plane collagen alignment from uniform starting conditions (Fig. 1b) [4]. Remodeling parameters were calibrated so that, under healthy conditions (ANISO-100%), predicted collagen alignment approximated REF (Fig. 1c).

Results

Collagen in untreated infarcted tissue (ISO-0%) remodeled toward transmurally uniform longitudinal alignment (Fig. 1d). Similar alignment developed when either contractility (ISO-25%) or tissue anisotropy (ANISO-0%) alone was restored. Strikingly, combining anisotropy with partial contractility restoration (ANISO-25%) preserved the induced ventricular alignment.

Discussion

Our computational findings indicate that cardiac regenerative strategies focusing solely on restoring infarct contractility through cardiomyocyte injections do not lead to favorable infarct ECM remodeling and recovery of ventricular anisotropy. Instead, therapeutically inducing infarct ECM re-alignment in combination with modest restoration of contractility is sufficient to sustain anisotropy, critical for ventricular mechanics. Future work will expand the model's design space by including diverse infarct geometries and properties.

Introduction

Research into healthy aortic blood flow and anatomy is valuable for understanding and treating cardiovascular diseases. In many cases, general flow boundary settings are applied when studying physical or digital models of the aorta. Applying localised boundary conditions – for example, flow waveforms at the suprarenal aorta and iliac arteries – is crucial for obtaining reliable results. This study aims to obtain aortic flow boundary conditions in healthy volunteers using phase contrast four-dimensional magnetic resonance imaging (4D-flow MRI) by studying blood flow in the whole aorta and its main side branches.

Methods

4D-flow MRI scans were acquired in healthy volunteers (n=20) using a custom sequence (WIP 1106B, MAGNETOM Aera 1.5T, Siemens Healthineers) to obtain volumetric MRI data over 24 phases of the cardiac cycle. Data was acquired with a spatial resolution of 2.5x.2.5 mm^2, slice thickness of 2.5 mm, and temporal resolution of 37 ms. Separate thoracic and abdominal acquisitions were performed to capture the full aortic geometry from the ascending aorta to the iliac bifurcations, including side branches. An in-house pipeline was developed (MATLAB R2025b, MathWorks) for manually segmenting the aorta and obtaining flow velocity vectors. Flow velocity fields were visualised, and flow waveforms were plotted (Tecplot 360, Tecplot, Inc.).

Results

Preliminary results of aortic blood flow analysis in the aorta of one healthy volunteer are presented in figure 1. The segmented aortic geometry is shown (A) and four regions of interest – at the ascending aorta, descending aorta, suprarenal aorta, and left common iliac artery – are indicated. Peak systolic flow velocity magnitude and direction are shown in flow velocity fields (B). Flow waveforms are plotted to demonstrate how the flow velocity magnitude changes over the cardiac cycle, showing different flow profiles in the four regions of interest.

Discussion

4D-flow MRI was used to obtain preliminary healthy aortic blood flow boundary conditions in the aorta and its main side branches. Using the methods presented here, the effect of age and gender on aortic flow will be studied in a cohort of 70 healthy volunteers. Results will be presented as an atlas of healthy aortic flow as a base for future in-vitro and in-silico studies.

Images (Optional)

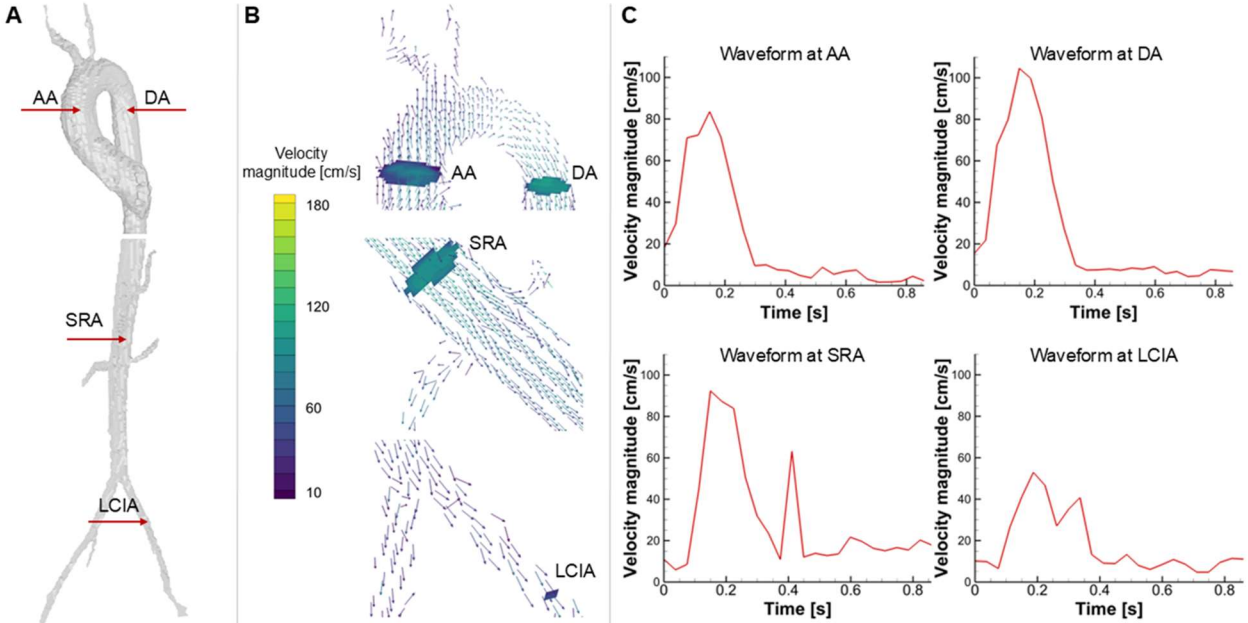

Figure 1: *Blood flow in the aorta and main side branches of a healthy volunteer studied using 4D-flow MRI. The segmented aortic geometry is shown (A). Regions of interest at the ascending aorta (AA), descending aorta (DA), suprarenal aorta (SRA), and left common iliac artery (LCIA) are indicated. Flow velocity fields (B) are shown for these regions of interest. Arrows indicate the direction of the velocity vectors, and the colour bar indicates the magnitude of the velocity vectors at peak systole. Cross-sections are drawn at the four regions of interest and flow waveforms (C) are plotted for the centre points of these cross sections.*

Characterization of Cerebral Artery Hemodynamics in a Circle of Willis Model for Optimizing Thrombectomy Outcomes

Ms. Mackenzie Moser First Year PhD Student Biomedical Engineering, Dr. Bryan Good PhD in Bioengineering

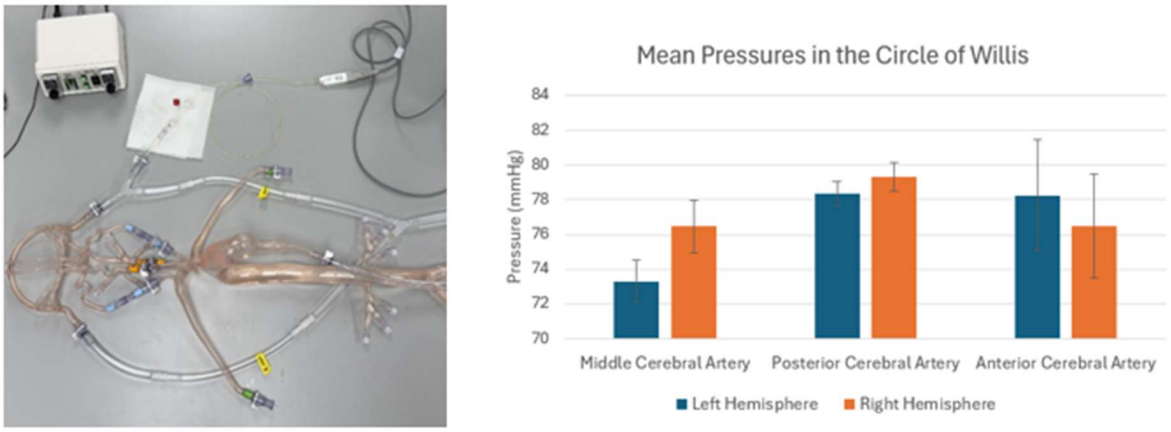
University of Tennessee, Knoxville, Tennessee, United States

Introduction

Mechanical thrombectomy (MT) outcomes vary widely, and growing evidence suggests collateral flow and pressures distal to an arterial occlusion play a critical role in clot retrieval. An overall poor understanding of downstream intracranial hemodynamics, including distal perfusion pressure and pressure gradients across an occlusive clot, has limited the ability to optimize MT strategies. Our hypothesis is that collateral flow patterns and distal pressures significantly influence clot removal forces and these parameters can be manipulated to improve MT success. To test this using a combination of novel experimental and computational models informed by patient-specific acute ischemic stroke data, a physiologically accurate benchtop platform must first be established. The objective of this study was to characterize a silicone Circle of Willis (CoW) model and pulsatile pump by measuring pulsatile pressures in the ACA, MCA, and PCA and comparing them to invasive human intracranial data.

Methods

A CoW-Neuro Test silicone model (United Biologics) was integrated into a closed-loop pulsatile flow system. Pulsatile hemodynamics were generated using a FlowTek 125 pump (United Biologics), and pressures measured with Millar Mikro-Tip catheter transducers positioned in bilateral ACA, MCA, and PCA branches. Mean pressures were analyzed over multiple cardiac cycles and compared with published human intracranial data to evaluate physiological fidelity.



Results

Model pressures closely matched in vivo intracranial measurements. MCA average pressures were 73.3 mmHg (left) and 76.46 mmHg (right), consistent with reported human data (62 ± 29 mmHg and 72.8–75.5 mmHg). Average ACA pressures measured 78.25 mmHg (left) and 76.48 mmHg (right), while average PCA pressures were 78.36 mmHg (left) and 79.32 mmHg (right). Hemispheric variation was minimal (1–5%).

Discussion

This study provides the first vessel-specific pressure characterization of the CoW-Neuro Test model under pulsatile flow conditions. The agreement with human intracranial pressure data validates the system as physiologically accurate. This characterization is essential for upcoming studies designed to investigate how collateral pathways, distal pressures, and pressure gradients across clots influence MT mechanics, areas currently lacking experimental data yet central to improving stroke outcomes.

Images (Optional)

Computational Hemodynamic Analyses of Left Ventricle Segmentation in Bicuspid Aortic Valve Patients: A Comparison with Normal Valve Morphology

Ms. Malvika Sawant, Dr. Lakshmi Dasi, Mr. Aniket Venkatesh

Georgia Institute of Technology, Atlanta, Georgia, United States

Introduction

Bicuspid aortic valve (BAV) anatomy modifies aortic flow and increases the risk of structural alterations after transcatheter aortic valve replacement (TAVR). Previous predictive models use post-TAVR imaging and don't incorporate patient specific pre-procedural hemodynamics. This study aims to compare left ventricular (LV) function in BAV patients and tricuspid aortic valve (tri-AV) patients using computational modeling based on pre-TAVR computed tomography (CT).

Methods

Pre-procedural CT images of 30 BAV and 30 tri-AV patients were segmented to assess left ventricular (LV) geometry and function, using a previously validated computational pipeline. The LV was segmented using an intensity-based approach with manual adjustment in areas of significant anatomical complexity (Figure 1A). CT images underwent the proximal process of the cardiac phase selection, conversion from DICOM to numpy, motion stabilization, blood mask generation, segmentation, and volume extraction (Figure 1B). A variety of hemodynamic parameters were calculated, and two-sample t-tests assuming unequal variances were used to compare the groups ($p<0.05$) (Figure 1C).

Results

Valve morphology was most strongly associated with higher ejection fraction in tri-AV patients (58.9% vs 19.4%, $p<0.001$), lower end-diastolic volumes in tri-AV patients (148.7 mL vs 1108.5 mL, $p<0.001$), shorter ejection times in tri-AV patients (0.35s vs 0.44s, $p<0.01$), and higher peak systolic flow rates in tri-AV patients (438.9 mL/s vs 312.9 mL/s, $p<0.05$).

Discussion

This hemodynamic study offers a strong model for differentiating cardiac function for tricuspid and bicuspid aortic valves, and consequently, predicting functional outcomes in patients with different valve variants, once validated in a larger group.

Introduction

Annually affecting 1.1 million people in Europe, stroke remains a significant health concern, with 20% of cases attributed to vulnerable carotid plaques. However, even though plaques detection is crucial for stroke prevention, current strategies often fail to identify high-risk patients [1]. A comprehensive multi-disciplinary predictive strategy for the assessment of any possible complications related to vulnerable carotid plaques, enabling any effective patient stratification and overcoming the limits of current approaches is still lacking.

Methods

From the acceptance of the ethical committee 5 patients underwent to an endarterectomy procedure in which the anatomical district affected by the pathology is substituted by a synthetic graft. The fresh harvested sample is acquired through micro-CT in order to detail the shape and the density of the different regions of the plaque. After the acquisition, the plaque is stored at -80°C. The part of the tissue characterized by the presence of the plaque is indented (Chiaro, Optics11 Life) with a fixed depth of 10 μm, using a spherical tip (diameter 103 μm, stiffness 0.53 N/m) at a speed of 5 μm/s. Finally, extracting non-invasive functional information, a completely automatic python-based numerical pipeline, is under development to perform fluid dynamic simulations for the assessment of patient-specific hemodynamic parameters.

Results

The micro-CTs show very detailed images of the carotid plaque, highlighting the morphology of high-density deposits, that consisted of an assembly of different small and detached deposits, that cannot be observed from CT data. From a mechanical point of view, healthy tissue exhibits a higher Young's modulus than non-calcified plaque tissue. Both healthy tissue and non-calcified plaque, however, show lower stiffness than calcified plaque regions. Measurements taken in its proximity suggest that early stages of calcification or the presence of nearby calcium deposits may already increase local stiffness.

Discussion

This study, based on few patients, aims to develop a sound basis for a new multi-disciplinary analysis of the characteristics of the carotid arteries in a larger cohort of patients. Moreover, any imaging-based information can be very important for radiomic or AI-based strategy.

Machine Learning Model for Predicting the Risk of Thrombotic and Haemorrhagic Complications in Patients Supported by the Impella CP Device

Prof. Marek Pawlikowski[1], Prof. Aleksandra Gąsecka[2], PhD Ewelina Błażejowska[2], PhD Zbigniew Gulbinowicz[1], PhD Janusz Domański[1]

[1]Warsaw University of Technology, Warszawa, mazowieckie, Poland. [2]Medical University of Warsaw, Warszawa, mazowieckie, Poland

Introduction

Patients supported by the Impella CP pump due to cardiogenic shock or undergoing high-risk percutaneous coronary interventions are at risk of significant bleeding and thromboembolic complications, which are among the most commonly observed adverse events in this population. Modern versions of the Impella device, equipped with the SmartAssist function, enable continuous recording of haemodynamic parameters, pressure signals, and information related to pump operation. Although these data theoretically allow for early detection of changes conducive to bleeding or thrombosis, their systematic use in risk analysis remains limited.

Methods

Retrospective data were collected from over 300 patients supported with the Impella CP pump. The following data were obtained from electronic and paper documentation: demographic data, baseline clinical characteristics, comorbidities, medications, laboratory test results (including coagulation parameters and haemolysis), haemodynamic parameters, details of the procedure (vascular access, duration and settings of support, device type), data on anticoagulation used, and occurrence of complications. The main endpoints analysed were: clinically significant haemorrhagic complications, thromboembolic complications, including device thrombosis and ischaemic stroke, and haemolysis related to pump operation. All data were anonymised prior to analysis.

Preliminary models of artificial neural networks were created and trained using data adapted for machine learning. Various neural networks (with different structures, numbers of neurons and layers, activation functions) were examined. Several machine learning algorithms of the SGD type, Adam Optimizer, or eXtreme Gradient Boosting were used for training the artificial neural networks.

Results

Discussion

The application of machine learning algorithms can be very useful for assessing the significant bleeding and thromboembolic complications in cardiovascular procedures.

Until now, no research has been carried out to thoroughly evaluate the potential of predicting haemorrhagic and thromboembolic complications in patients treated with Impella CP using machine learning algorithms. Addressing this research gap could facilitate earlier detection of high-risk patients, personalise anticoagulant therapy, and improve management of mechanical support treatment.

Coupling Pulmonary Arterial Hypertension Growth and Remodeling Models

Ms. Margaret Millar[1], Dr. Edward Manning[2], Dr. Jay Humphrey[3], Dr. Ana Estrada[4]

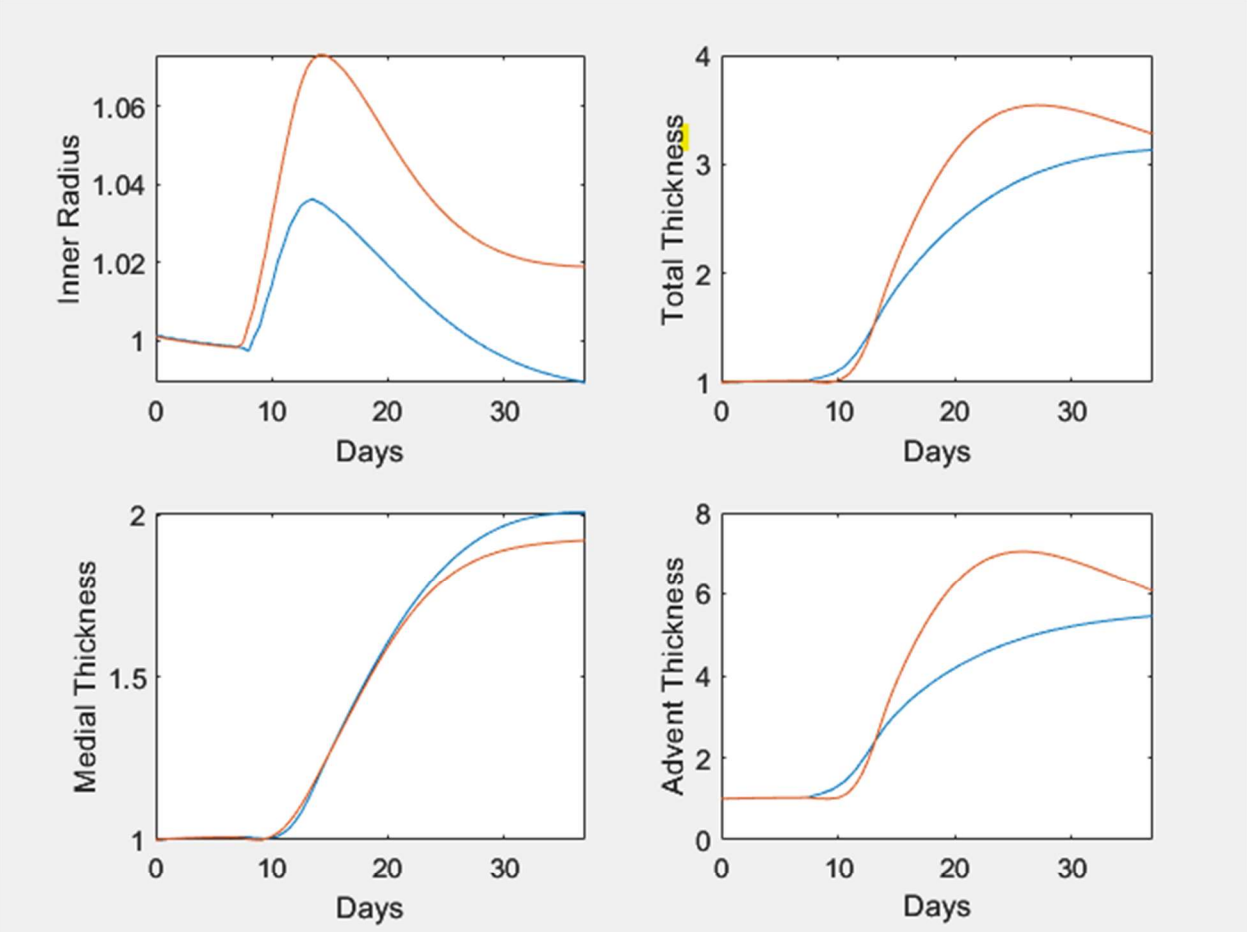
[1]Fairfield University, Fairfield, Ct., United States. [2]Yale University, New Haven, Ct., United States. [3]Yale University, New Haven, Ct, United States. [4]Fairfield University, Fairfield, Ct, United States

Introduction

When exposed to stressors, such as hypertension, the cardiovascular system goes through complex cellular and sub-cellular changes that result in the deposition, organization or removal of tissue to maintain homeostasis in response to wall and shear stress. Computational models of growth and remodeling (G&R) can be used to better understand these adaptations. In this study, we are combining G&R models of the pulmonary arteries with logic-based models of intracellular cell signaling to create a more accurate multiscale model of pulmonary artery adaptation.

Methods

We adapted a classical bilayered constrained mixture model of arterial G&R for pulmonary arterial applications, following methods established by Latorre et al. (2019). The model uses the 4-fiber family model for collagen material properties. The script utilizes data collected at two timepoints, taken 28 days apart, and interpret the G&R progression between. The material parameters were optimized using a particle swarm to find the best-matched growth model, compared to experimental data. The optimized parameters were used in a coupled multi-cell, multiscale model of vascular G&R in which individual cell-signaling network models of smooth muscle cells, fibroblasts, and macrophage drive adaptation. The G&R predicted by the coupled model was then compared to a previously published model [2] to compare differences between predictions of pulmonary vs. aortic G&R.



Results

The predictive model found the optimal values for the mass fraction of the medial layer to be 0.483886634314232 on day 0 and 0.427618001141548 on day 28. The model is optimized for AngII presence to be evaluated at 0.35 in the medial layer and 0.53 in the adventitial layer. The tissue-resident macrophage reaction weight is 0.85 and the recruited weight is 0.75.

Discussion

The circulatory system is a network of connected pieces. These pieces do not work separately but affect and are affected by each other so properly predicting adaptation requires models that can capture this biological complexity. By combining these models of tissue- and cell-level remodeling, we can create a more accurate predictive model and generate a better understanding of how the circulatory system remodels in response to stress.

[3]INSERM UMR_S 999, Université Paris Saclay, Le Plessis-Robinson, Hauts-de-seine, France

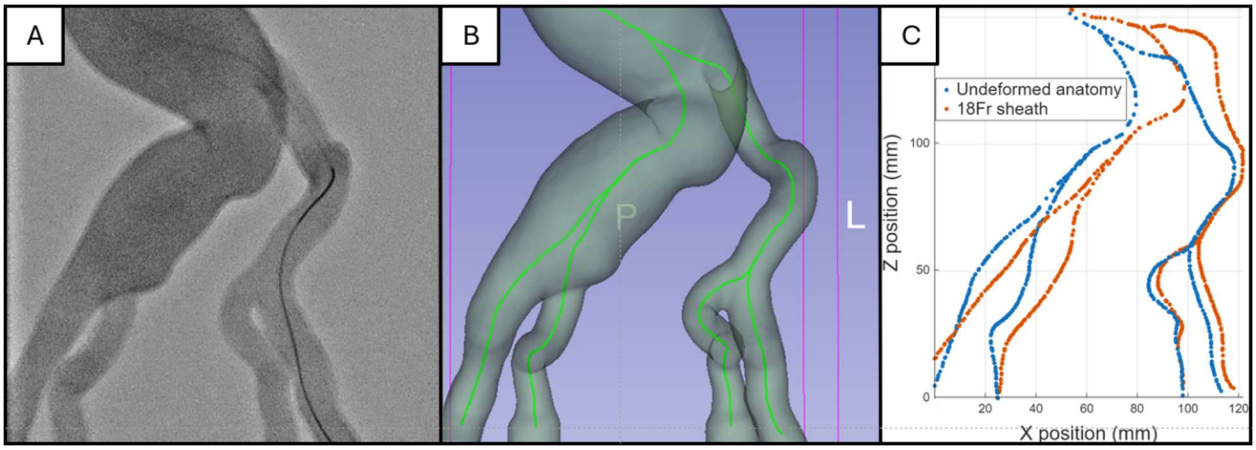
Introduction

During endovascular procedures, arteries undergo deformations induced by the insertion of devices. In tortuous anatomies, the iliac arteries are straightened by stiff guidewires and sheaths which can influence endograft positioning and adequate sizing. This work presents preliminary results from a pilot study, using flexible 3D-printed aortic aneurysm models to characterize these deformations.

Methods

Three infra-renal aortic aneurysm models, including aneurysmal and non-aneurysmal iliac arteries, were 3D-printed in silicone using Dynamic Moulding technology. The vascular geometries were derived from patient CT scans and subsequently modified to fit the experimental setup. Using a test bench including a pulsatile pump, the models were integrated into a flow loop with controlled flow rate, pressure and temperature. Endovascular devices, namely a stiff guidewire, a 16Fr sheath and an 18Fr sheath, were inserted through dedicated puncture points within the test bench. At each step, 2D fluoroscopy and 3D CT scans were acquired using a GE hybrid-room scanner (Figure 1A). DICOM data were processed using 3D slicer. Each anatomy was segmented, and centreline models were generated using the Vascular Modelling Toolkit (Figure 1B). Extracted coordinates were processed in MATLAB (Figure 1C). For the least aneurysmal common iliac artery, the iliac tortuosity index [1] (ITI) was calculated at each step. Change in ITI, along with maximal and mean Hausdorff distance [2] between steps were quantified.

Results



Initial ITI ranged between 1.02 and 1.45 (1.22 ± 0.22, N=3). In the anatomy with the lowest initial ITI, no change in ITI was detected, despite visually observable deformation, suggesting ITI change alone does not fully capture geometric changes. Across all models,

increases in device size produced larger changes in both maximal and mean Hausdorff distances.

Discussion

These early results demonstrate the feasibility of the proposed experimental and computational workflow. Further experiments are required to verify the statistical robustness of the findings. Future work will quantify post-endograft deployment deformation and compare model behavior to clinical EVAR data to evaluate the realism of the 3D-printed models.

Ovine Postnatal Venous Remodeling Informs Pediatric Tissue-Engineered Vascular Graft Design

Dr Marisa Bazzi Postdoctoral Scholar[1], Dr Cole Anderson[2], Dr. Gavin Mays[3], Prof Christopher Breuer[2], Prof. Jay Humphrey[3], Prof. Alison Marsden[1]

[1]Stanford University, Palo Alto, CA, United States. [2]Nationwide Children's Hospital, Columbus, OH, United States. [3]Yale University, New Heaven, CT, United States

Introduction

Growth and remodeling (G&R) models are increasingly used to predict medium- and long-term vascular responses to changing mechanical loads and to optimize tissue-engineered vascular grafts. Yet most model parameters and design criteria are calibrated using adult vessels, even though pediatric patients undergo rapid somatic growth, evolving cardiac output, and changes in venous return that fundamentally alter hemodynamics and wall mechanics. We aimed to quantify age-dependent changes in venous structure, mechanics, and flow to provide data-driven targets for future pediatric TEVG G&R simulations.

Methods

Postnatal ovine inferior vena cava (IVC) were studied at 3, 10, 16, and 28 weeks of age (n=3 per time point). At each age, catheterization provided angiography used to reconstruct 3D lumen geometry (Fig.1A). Intravascular ultrasound (IVUS) was used to obtain wall and lumen geometry and derive a non-uniform wall thickness map (Fig.1B). At the same time, 2D phase-contrast MRI measured through-plane flow waveforms for inflow boundary conditions (Fig.1C). Biaxial mechanical testing of excised IVC segments was performed. Linearized stiffness parameters were computed around the in vivo pressure range. Subject-specific fluid–structure interaction simulations were performed in SimVascular's svMultiPhysics solver, with wall mechanics represented by a neo-Hookean model whose elastic modulus was calibrated to match in vivo compliance (Fig.1D-E).

Results

With growth, all components of the stiffness matrix increased (Fig.1F), with the largest changes occurring in the circumferential direction. Vessel diameter and wall thickness also increased (Fig.1G-H), consistent with postnatal growth and remodeling. Simulations showed that time-averaged wall shear stress decreased with age (Fig.1I), whereas oscillatory shear index increased from 3–16 weeks and declined at 28 weeks (Fig.1J).

Endothelium activation potential, defined as the ratio of oscillatory shear index to time-averaged wall shear stress, increased monotonically with age (Fig.1K).

Discussion

These data demonstrate coupled growth-dependent changes in venous geometry, material stiffness, and hemodynamics during early life in an ovine model. The age-resolved stiffness parameters, wall thickness, and shear metrics provide mechanistically grounded targets and boundary conditions for future pediatric TEVG G&R simulations. Incorporating these growth-dependent benchmarks into TEVG design and optimization frameworks may reduce graft maladaptation and failure in children undergoing venous reconstruction.

Integrating 0D Pressure-Volume Dynamics Into Hybrid 3D-0D Cardiovascular Models in Abaqus

MSc Marta Zattoni[1,2], Dr. Annette Caenen[1,3], Prof. Patrick Segers[1], Prof. Mathias Peirlinck[2]

[1]Ghent University, Ghent, East Flanders, Belgium. [2]TU Delft, Delft, South Holland, Netherlands. [3]KU Leuven, Leuven, Flemish Brabant, Belgium

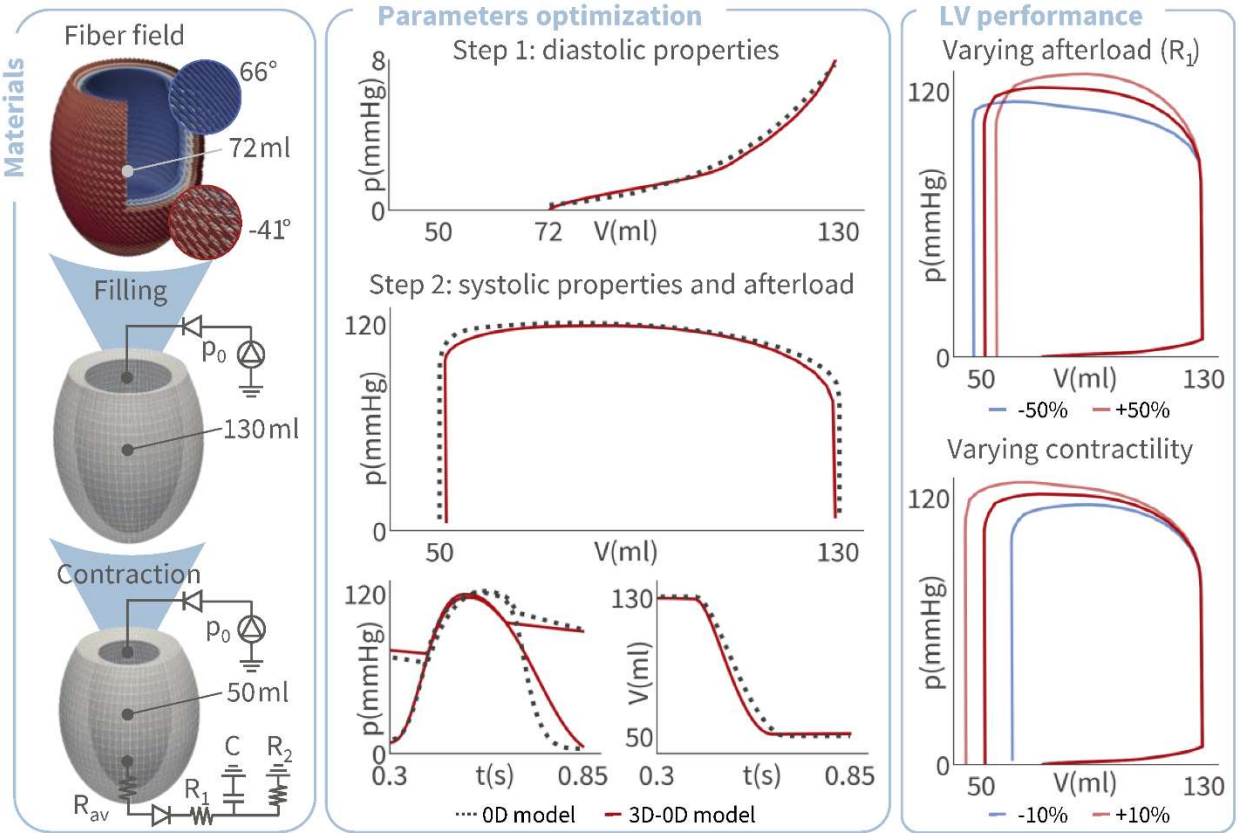
Introduction

0D cardiovascular hemodynamics models provide a computationally efficient research tool and solid basis for human virtual twin research, but lack the ability to study localized biomechanical tissue phenomena, where higher-fidelity 3D-0D hybrid models are required. Nevertheless, their implementation requires careful tuning of the underlying functional parameter set. We present a methodology to map 0D outputs to a hybrid 3D-0D left ventricular (LV) model and a two-step optimization framework to calibrate model parameters.

Methods

To demonstrate the workflow, reference 0D pressure-volume (pV) data for a healthy subject was generated in CircAdapt from vanOsta2024. For the hybrid model, a LV hexahedral mesh was parametrically designed in pyFormex. In Abaqus, passive myocardial behavior was represented by Holzapfel-Ogden (2009) constitutive law and active contraction following Guccione *et al.* (1993). Interaction with the systemic circulation was captured through a three-element Windkessel model equivalent coupled to the LV cavity. An additional proximal resistance was implemented to decouple aortic valve effects from the contribution of aortic characteristic impedance to the afterload. Two least square optimization algorithms were sequentially applied. Firstly, passive material properties were adapted against reference single-beat estimations of the end-diastolic pV relationship (Peirlinck *et al.*, 2018) (Fig-1,step-1). Then, Windkessel and contractility parameters were updated through a penalty function including LV pressure-, volume- and aortic pressure-time CircAdapt curves (Fig-1,step-2).

Results



The 3D-0D implementation incorporating aortic valve effects reproduced the behavior of the three-element Windkessel formulation. The two optimization routines yielded results consistent with reference curves for pV and volume-time, while a mismatch remained

present in the pressure-time curves in the relaxation phase. The model reproduced physiological responses: 50% variations in contractility increased stroke volume by 8.9% or reduced it by 12%, while changes in afterload resistance produced a decrease and an increase of 8.9% and 5.1%, respectively (Fig-1).

Discussion

The proposed 3D-0D modelling framework captures key features of healthy LV physiology and can be reasonably well calibrated on 0D data. Further work should include better matching for the contraction-relaxation dynamics and pressure-time data, and extend to a closed-loop formulation to simulate multiple heartbeats. Overall, our model provides a simple yet robust platform for studying spatially varying cardiac mechanical phenomena.

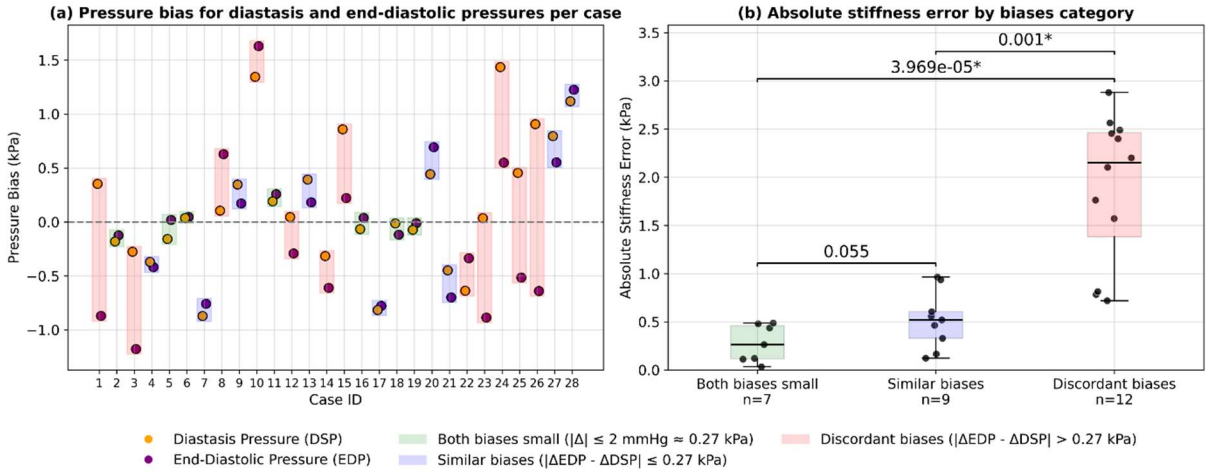
[2]School of Biomedical Engineering and Imaging Sciences, King's College London, London, Greater London, United Kingdom. [3]Department of Engineering Science and Biomedical Engineering, University of Auckland, Auckland, Auckland, New Zealand

Introduction

Personalised cardiac parameters, such as passive myocardial stiffness, are not routinely available in the clinic, despite their potential to provide a more specific understanding of myocardial properties. Passive myocardial stiffness can be estimated through modelling approaches that often rely on the availability of invasive pressure measurements. This study leverages a recent non-invasive method for estimating diastolic pressures to derive myocardial stiffness estimates and assess their accuracy.

Methods

Invasive left heart pressures and 3D echocardiography (3DE) were recorded on the same day for patients referred for coronary angiography. Patients with valve diseases and atrial fibrillation were excluded from this study. Twenty-eight patients were included. We implemented a method by Smiseth et al. [1] to non-invasively estimate diastolic pressures using data derived from 2D and 3DE. We used our local biomechanics pipeline relying on diastasis (DSP) and end-diastolic (EDP) pressures to derive passive myocardial stiffness by minimising the projection error between the measured shape from 3DE and the model-predicted shape at end-diastole using non-linear optimisation.



Results

Using the non-invasive pressure estimates to derive myocardial stiffness yielded a root mean square difference (RMSD) of 1.38 kPa compared to the estimates derived from invasive pressure measurements. Nine cases exhibited similar biases for the EDP and DSP, reflecting a consistent underestimation or overestimation of both pressures compared to the invasive reference (Figure a). The stiffness RMSD for these latter cases was 0.59 kPa, while cases with discordant biases in pressure estimation (n = 12) resulted in an RMSD of 2.03 kPa (Figure b).

Discussion

We found that consistent underestimates or overestimates of both the non-invasive diastasis and end-diastolic pressures yielded stiffness estimates that were similar to those derived from the invasive pressure measures. These preliminary results show the potential of deriving intrinsic myocardial parameters from non-invasive measures. These results also highlight the sensitivity of passive myocardial stiffness estimates to left ventricular pressure measurements. Future work will focus on refining the implementation of the non-invasive pressure estimation method, and assessing the potential for non-invasive tissue property estimates to better characterise phenotypes of heterogeneous conditions such as heart failure.

Modeling Longitudinal Adaptation of the Infarcted Left Ventricle using Cardiac Magnetic Resonance and Ex-Vivo Biomechanics

Mr. Emilio Mendiola[1], Mr. Tanmay Mukherjee[1], Mr. Rana Raza Mehdi[1], Mr. Md Ajwad Mohimin[1], Dr. Qian Xiang[2], Dr. Robia Paulter[3], Dr. Peter Vanderslice[2], Dr. Reza Avazmohammadi[1]

[1]Texas A&M University, College Station, Texas, United States. [2]Texas Heart Institute, Houston, Texas, United States. [3]Baylor College of Medicine, Houston, Texas, United States

Introduction

Regional structural, biomechanical, and functional remodeling of the left ventricle (LV) post-myocardial infarction (MI) are dynamic time-evolving processes, yet our understanding of their true longitudinal evolution remains limited. Previous studies relied on cross-sectional data to characterize the progression from acute ischemia to late-stage remodeling. These approaches fail to capture the continuous, subject-specific trajectories that guide the heart towards an adaptive state or progressive decline and heart failure (HF). To elucidate individual mechanisms and interactions that drive functional outcomes, longitudinal remodeling must be characterized on a subject-specific basis to observe the gradual shift from an adaptive to a maladaptive state.

Methods

We developed longitudinal, subject-specific finite-element models of rodent hearts pre- and post-MI. Mild and severe MI were induced in six (n=3 for each group) rodent subjects via partial and complete ligation of the left anterior descending artery. Cine cardiac magnetic resonance imaging was acquired before MI and at 1-wk and 3-wks post-MI. After sacrifice, hearts were excised and the LV free wall underwent biomechanical testing. Histological analysis was performed to characterize the fibrous architecture and delineate the infarct, border zone, and remote regions of the LV. By integrating image-based geometries with in-vivo volumetric data, ex-vivo mechanical characterization, and detailed histological analyses, we offer a multiscale, longitudinal view of the post-MI remodeling process.

Results

Substantial kinematic alterations, altered ejection fraction, and region-specific variations in tissue stiffness and architecture were observed, suggesting early kinematic decompensation may prompt late-stage maladaptation. Inverse modeling and ex-vivo results demonstrated an increase in regional stiffness within the infarct and border zone

regions, with an accelerated rate of stiffening in the severe MI group. The estimated time-course regional stiffness showed that subjects progressing to maladaptation exhibited distinct, early mechanical and structural remodeling in the border zone.

Discussion

Continuous tracking of structural, biomechanical, and functional adaptations through time-course regional inverse modeling not only enhances our mechanistic understanding of post-MI adaptation but also lays the groundwork for improved, patient-specific prognostic tools and therapeutic strategies. Ultimately, our study represents a critical step towards bridging the existing gap in longitudinal cardiac assessment, with the potential to inform more personalized approaches in assessing HF risk post-MI.

Images (Optional)

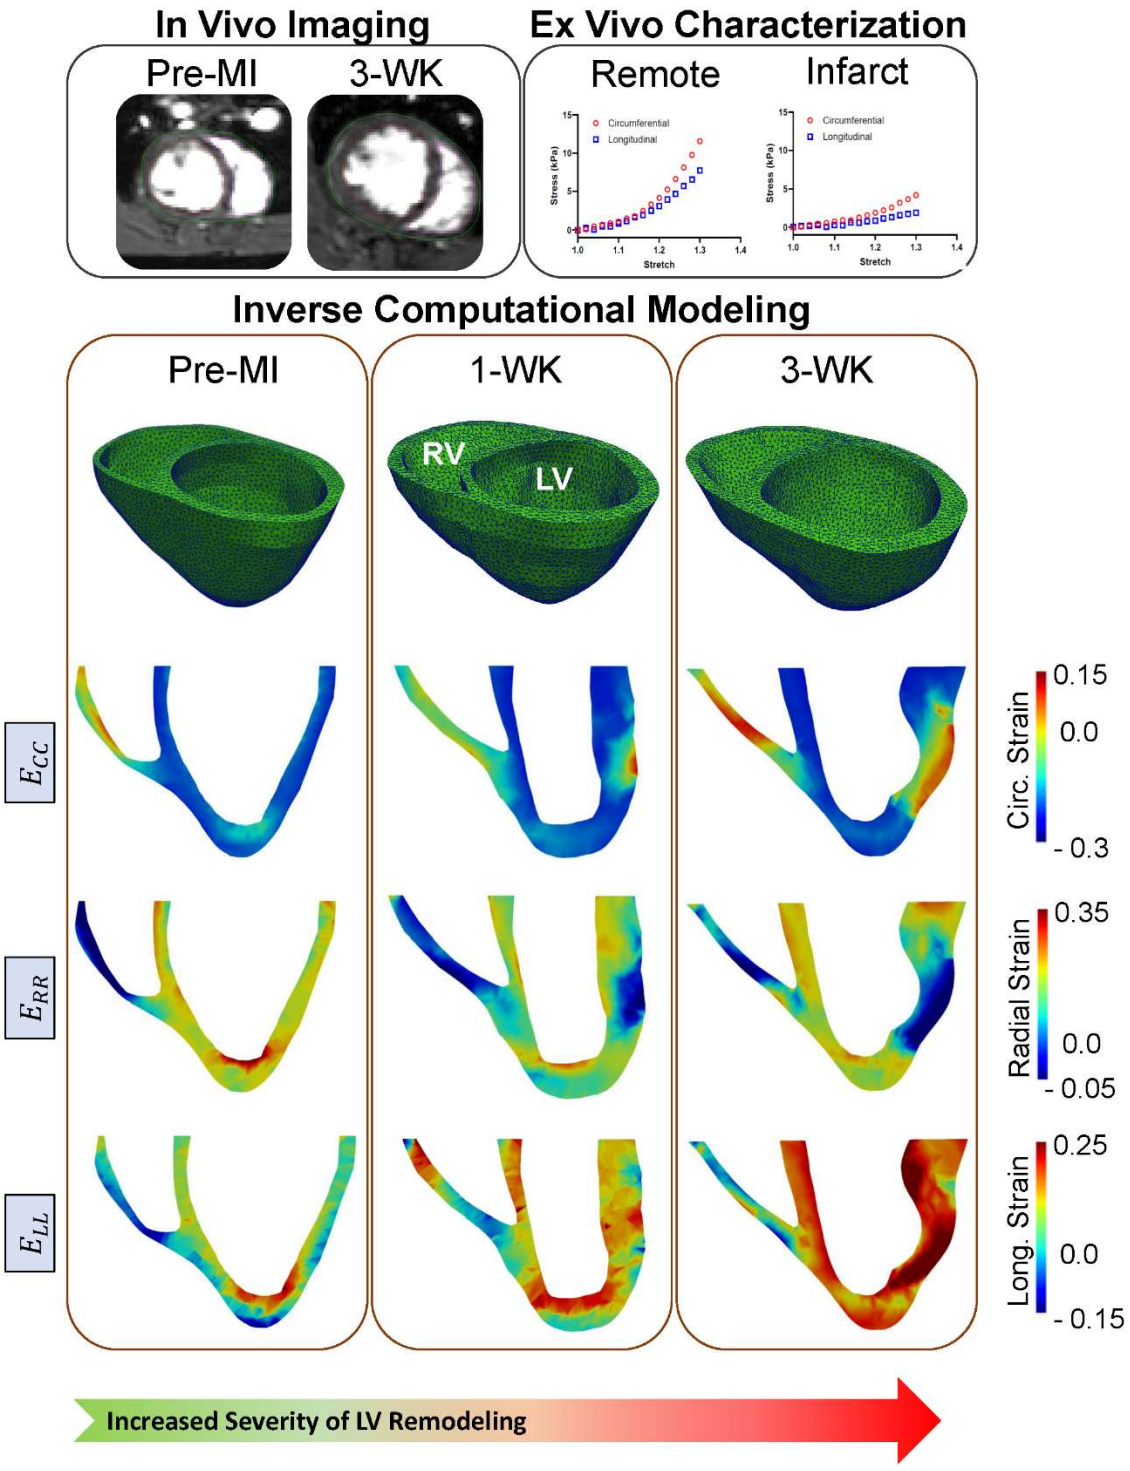

Figure 1: Longitudinal in vivo cardiac magnetic resonance imaging and ex vivo biomechanical and structural data were integrated to develop rodent computational cardiac models of a single subject at the pre-MI, 1-WK, and 3-WK post-MI timepoints. Finite-element meshes shown here are reconstructed at the end-diastolic state. Simulations revealed substantial regional alterations in end-systolic circumferential, radial, and longitudinal strain evolving over time.

Pre- and Post-Operative Hemodynamic Assessment of Mitral Valve Prolapse Using Image-Derived Moving-Wall CFD

Mr. Md Ajwad Mohimin[1], Mr. Tanmay Tanmay Mukherjee[1], Mr. Emilio Mendiola[1], Dr. Dipan Shah[2], Dr. Reza Avazmohammadi[1]

[1]Texas A&M University, College Station, TX, United States. [2]Houston Methodist DeBakey Heart and Vascular Center, Houston, TX, United States

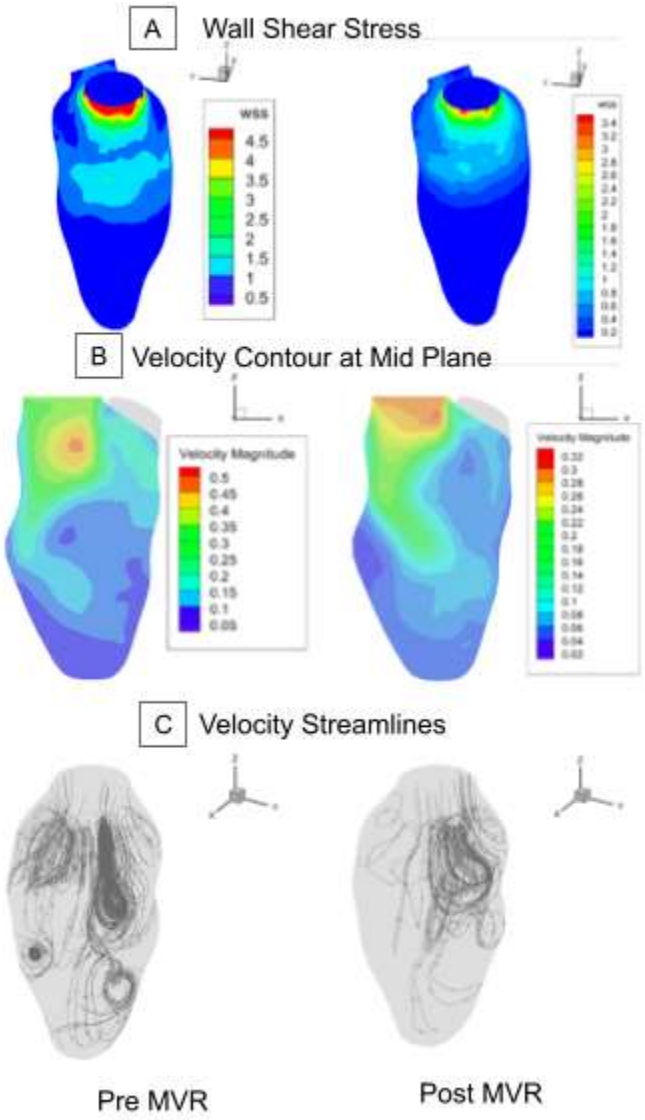
Introduction

Mitral valve prolapse (MVP) significantly disrupts intracardiac hemodynamics, creating abnormal flow patterns that may result in ventricular remodeling. Accurately characterizing these fluid dynamics is critical for evaluating surgical efficacy and predicting post-repair outcomes. However, standard imaging often lacks the resolution to fully capture complex flow structures within the left ventricle. To address this need, we employed a patient-specific moving-wall computational fluid dynamics (CFD) framework derived from standard cine cardiac magnetic resonance (CMR) and phase-contrast magnetic resonance imaging (MRI). By incorporating accurate endocardial wall motion without relying on complex tissue modeling, this study aims to investigate the changes in flow characteristics within the left ventricle pre- and post-mitral valve repair (MVR).

Methods

This project studies a cohort of eight MVP patients (n=8) pre- and post-surgery. We are developing patient-specific CFD models for all the subjects (16 models total). Standard cine CMR and phase-contrast MRI (PC-MRI) were acquired from the patient before and after mitral valve repair. We utilized a non-rigid image registration (NRIR) algorithm to extract the endocardial wall motion from cine images. This wall motion was prescribed as a moving boundary condition, eliminating the need for complex solid mechanics modeling of the endocardial wall. Patient-specific mitral inflow rates were derived from PC-MRI and used as the inlet condition for the CFD model. Finally, the three-dimensional Navier-Stokes equations were solved to simulate intracardiac blood flow under the assumption of Newtonian fluid and laminar flow.

Results



Preliminary simulations (n=1) demonstrated distinct hemodynamic alterations following mitral valve repair. Pre-operative analysis revealed elevated wall shear stress (WSS) peaking at approximately 4.5 Pa. Following repair, peak WSS decreased by 24%. Similarly, mid-plane velocity contours showed a 36% reduction in peak flow velocity, indicating a

quantitative decrease in hemodynamic parameters. In addition, a reduction in swirling motion is observed in the post-MVR case.

Discussion

The preliminary findings from our CFD study show a significant reduction in WSS and peak velocity after MVP repair. In the next phase of this study, these findings will be investigated for all the subjects in the cohort. In addition, the linkage between the structural remodeling and hemodynamic alterations will be evaluated.

Wall Shear Stress Signatures Across Pulmonary Arterial Branching Orders Reveal Mechanistic Links from Acute Pulmonary Embolism to CTEPH and Post-Endarterectomy Haemodynamics

Dr Behdad Shaarbaf Ebrahimi[1], Dr Misha Dagan[2], Professor David Kaye[2], Mr Atsuo Doi[2], Dr Timothy Joseph[2], Professor David McGiffin[2], Professor Merryn Tawhai[1]

[1]Auckland Bioengineering Institute - University of Auckland, Auckland, Auckland, New Zealand. [2]The Alfred Hospital, Melbourne, Victoria, Australia

Introduction

Acute pulmonary embolism (PE) can progress to chronic thromboembolic pulmonary hypertension (CTEPH), yet the haemodynamic mechanisms linking initial obstruction to distal microvascular remodelling remain poorly defined. In particular, how wall shear stress (WSS) changes in CTEPH across different arterial orders in non-occluded territories - and how these patterns evolve after pulmonary endarterectomy (PEA) - has not been quantified in a spatially resolved manner. Because low time-averaged WSS (TAWSS) or high oscillatory shear index (OSI) promotes endothelial dysfunction and vascular remodelling, characterising order-specific shear disturbances may help explain why microvascular disease may persist after PEA.

Methods

Using a detailed patient-specific pulmonary arterial model and a one-dimensional (1D) haemodynamic framework, we examined WSS across Horsfield orders under four key scenarios: baseline (healthy), acute PE (proximal occlusions only), CTEPH (occlusion plus fitted microvascular remodelling in non-occluded regions), and a post-PEA state (occlusions removed but distal remodelling retained in non-occluded regions). TAWSS and OSI were computed for all vessels and aggregated by order to quantify how shear signatures shift between proximal and distal branches.

Results

Relative to baseline, acute PE produced substantial reductions in TAWSS in non-occluded mid-distal orders - typically falling by ~30–60% - while OSI increased in several orders, reflecting disturbed redistributed flow. CTEPH caused a far more pronounced collapse of shear, with >70–90% reductions in TAWSS across most orders and uniformly low OSI, indicating globally diminished pulsatility due to microvascular narrowing and pruning. In

the post-PEA state, lower-order vessels showed partial TAWSS recovery (~20–40%), but proximal branches remained markedly suppressed, consistent with clinical observations that microvasculopathy drives residual pulmonary hypertension.

Discussion

Overall, the results suggest that acute PE generates abrupt shear deficits in specific non-occluded arterial generations, providing a plausible mechanobiological trigger for distal remodelling. CTEPH amplifies these disturbances into a pan-arterial low-shear environment, whereas PEA restores proximal haemodynamics but cannot reverse microvascular disease, leaving persistently abnormal shear in high-order vessels. These order-specific WSS signatures offer mechanistic insight into CTEPH progression and may help identify vascular regions most vulnerable to remodelling, incomplete postoperative recovery, and targeted future intervention.

Towards the Validation of Arteriovenous Fistula Sounds Using An in-Vitro vascular Flow Simulator

Dr Sofia Poloni[1], Dr Elia Pederzani[2], Dr Luca Soliveri[3], Eng Alessia Sofia Bolandrina[2], Prof Monica Soncini[2], Prof Gianfranco Beniamino Fiore[2], Prof. Andrea Remuzzi[3], Prof Chiara Emma Campiglio[3], Dr Michela Bozzetto[1]

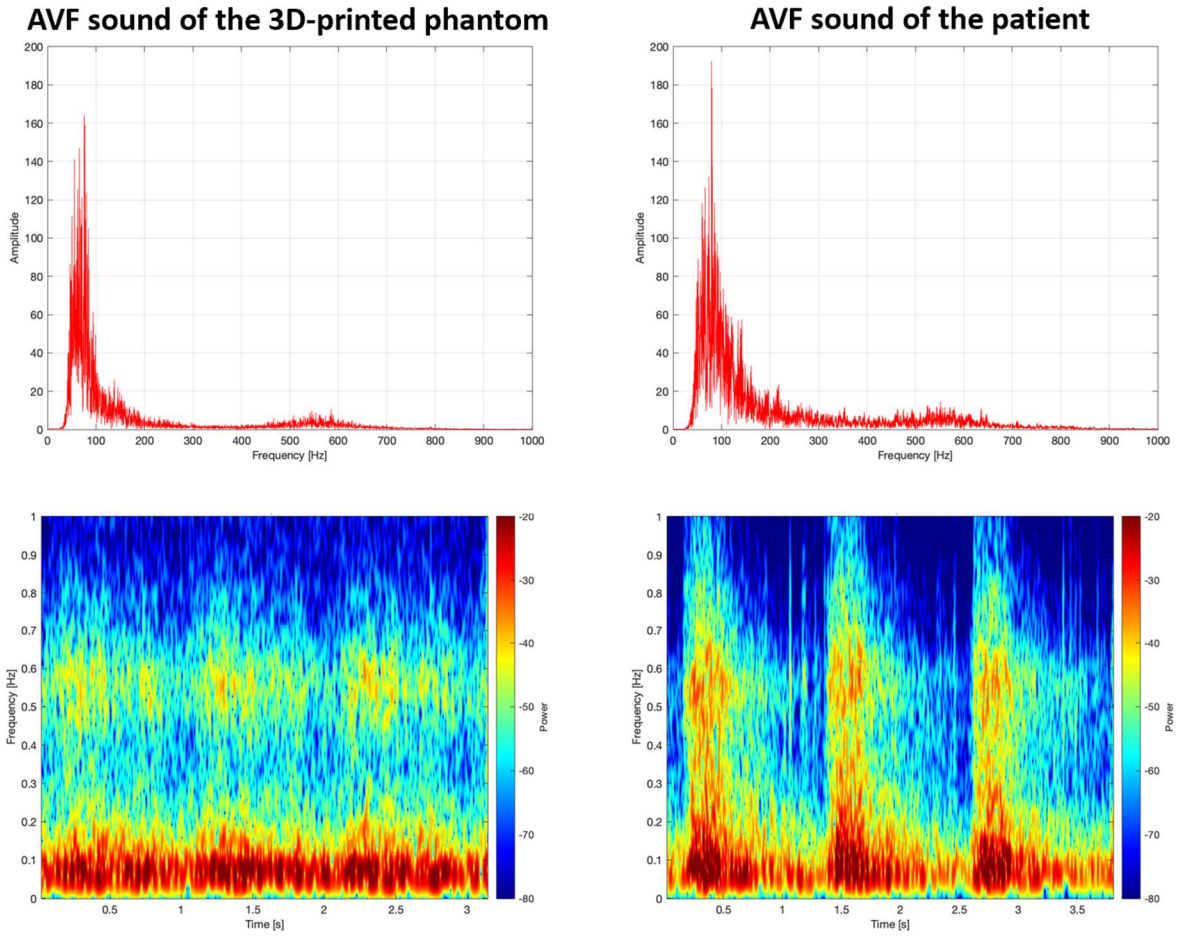
[1]Istituto di Ricerche Farmacologiche Mario Negri IRCCS, Bergamo, Italy, Italy. [2]Politecnico di Milano, Milan, Italy, Italy. [3]Università degli Studi di Bergamo, Bergamo, Italy, Italy

Introduction

The arteriovenous fistula (AVF) remains the vascular access of first choice for hemodialysis, although primary patency at one year after surgery is about 60%, largely due to maladaptive vascular remodeling. Our recent work has shown that turbulent-like flow patterns can induce vibrations of the AVF venous wall [1]. Disturbed hemodynamics is also related to AVF-generated audible sounds [2], which can be used to monitor AVF functional status. The aim of the present study was to validate the occurrence of flow-induced sounds using an *in-vitro* vascular flow simulator.

Methods

A 3D-printed silicone AVF phantom was fabricated starting from MR images of a 6-week AVF. The phantom was housed in an advanced vascular flow simulator [3] and perfused with a patient-specific flow waveform derived from Doppler Ultrasound acquired at the same timepoint. Sounds produced by the AVF phantom were recorded positioning an electronic stethoscope 3M Littmann 3200 at the anastomosis. The recorded signals were cut to three cardiac cycles and high-pass filtered at 50 Hz. Sound processing included FFT-based spectral analysis and spectrogram representation. Spectral features were then compared with those derived from a typical sound of a matured well-functioning AVF of a dialysis patient.



Results

The spectral analysis revealed strong agreement between the sounds acquired in the 3D-printed phantom and those acquired in the patient (see FFT analysis and spectrograms in Figure 1). Indeed, both experimental and clinical sound recordings exhibited a dominant low-frequency component between 50–100 Hz, along with a secondary, lower-amplitude contribution between 500-700 Hz. Interestingly, the amplitude values of the corresponding spectral peaks also fell within the same order of magnitude.

Discussion

These results represent a step forward towards the validation of the occurrence of hemodynamically induced AVF sounds. The versatility of the in-vitro vascular flow simulator allows the housing of different AVF geometries associated with distinct hemodynamic conditions, enabling a deeper understanding of the relationship between flow phenotypes and AVF sounds, ultimately improving the knowledge on the mechanisms of AVF failure.

Quantifying the Role of Vasoactivity on Arterial Hemodynamics Using a Spatially Multiscale, One-Dimensional Fluid Models

Dr. Mitchel Colebank Ph.D.

University of South Carolina, Columbia, South Carolina, United States

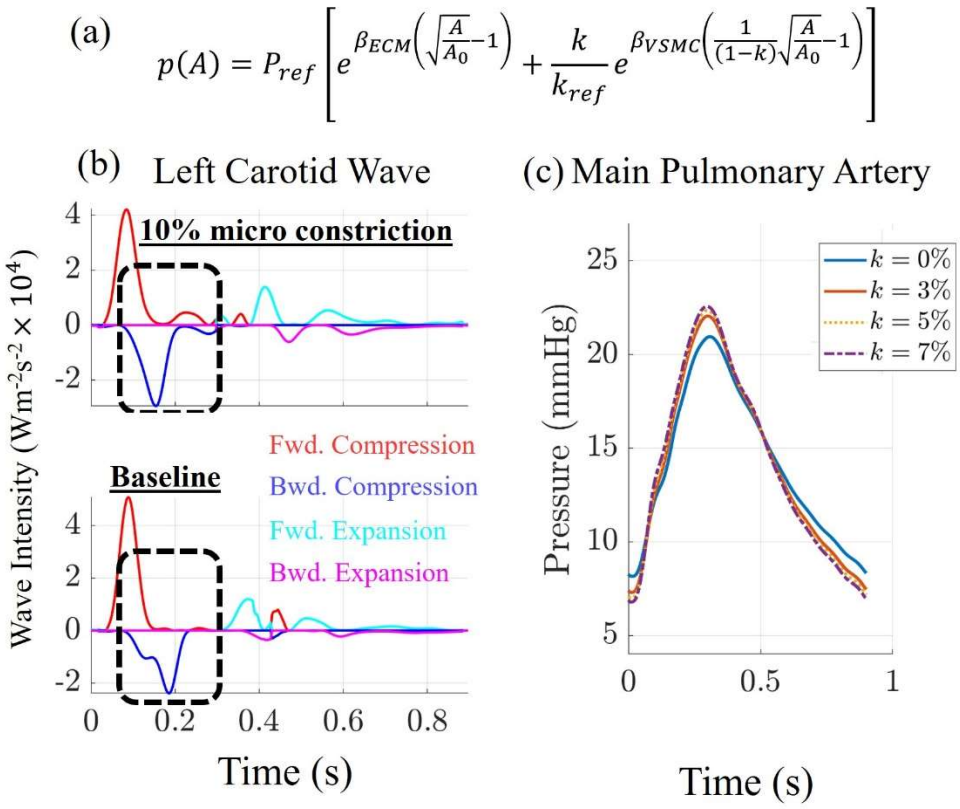
Introduction

Systemic and pulmonary arterial hemodynamics are governed by multiple factors, including ventricular function, arterial stiffness, and microvascular function. The latter two components can be modulated by the vasomotor tone of vascular smooth muscle cells (VSMCs) within the arterial walls. In particular, an imbalance between extracellular matrix (ECM) stiffness, VSMC stiffness, and vasoactivity contribute to systemic and pulmonary hypertension, and may make it difficult to identify whether treatment via vasodilators is optimal for a given patient. Computational, one-dimensional (1D), pulse-wave propagation models can help investigate these possible confounders. Here we introduce a 1D model that combines nonlinear stress-strain dynamics under vasomotor tone with a microcirculation model to identify the role of ECM and VSMC stiffness and VSMC tone on arterial wave propagation.

Methods

The 1D model is applied to a 34-vessel systemic arterial circulation and 15-vessel pulmonary circulation network. The 1D model includes a spatially averaged mass conservation and momentum balance equation. The model provides predictions of pressure, flow, and area; thus, we introduce a third equation describing the pressure-area relationship. This relationship includes ECM and VSMC stiffness, as well as VSMC tone (Fig. 1(a)). We use the structured tree model [1] to describe the downstream vasculature, allowing us alter microvascular reactivity in addition to the large vessels.

Results



Results show that vasoconstriction of the microvasculature has large impacts on wave propagation, as shown in Fig. 1(b). Left carotid backward waves amplify with a 10% reduction in microvascular radii. In the pulmonary circulation (Fig. 1(c)), vasodilation (as k goes to zero) reduces blood pressure when ECM stiffness is comparable to VSMC stiffness. In contrast, vasodilation is ineffective when ECM stiffness is substantially larger,

as the ECM of the vessel is loaded. Thus, a combination of small and large vessel vasodilation is necessary to reduce blood pressure when ECM stiffness is high.

Discussion

We developed an interpretable hemodynamic framework for quantifying the interactions between VSMC, ECM, and pulse-wave propagation in the large and small arteries. This provides a new tool for examining the mechanisms of high-blood pressure and possible avenues for subject-specific treatment.

Development of an Integrated Systemic–Coronary Closed-Loop Pulsatile Simulator with Actively Controlled Coronary Impedance

Ms. Mone Katagiri B.Eng., M.S. student[1], Dr. Kaoru Hattori MD, PhD[1,2], Mr. Katsuyoshi Suzuki[2], Prof. Kiyotaka Iwasaki PhD[3,1,2]

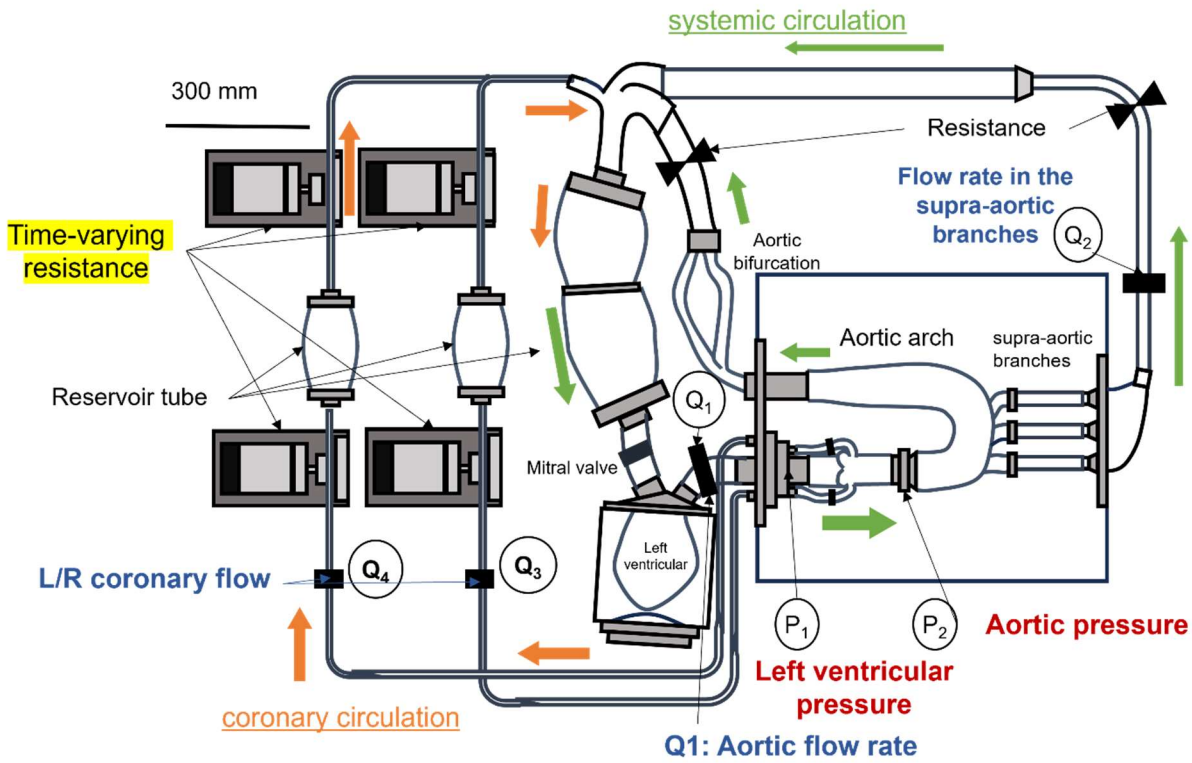
[1]Department of Integrative Bioscience and Biomedical Engineering, Graduate School of Advanced Science and Engineering, Waseda University, Shinjuku-ku, Tokyo, Japan. [2]Waseda Research Institute for Science and Engineering, Waseda University, Shinjuku-ku, Tokyo, Japan. [3]Department of Modern Mechanical Engineering, School of Creative Science and Engineering, Waseda University, Shinjuku-ku, Tokyo, Japan

Introduction

Coronary blood flow is maintained within a specific range through coronary autoregulation. However, this mechanism becomes impaired under low pressures, resulting in a pressure-dependent reduction in flow. Consequently, in conditions such as cardiogenic shock, reduced coronary prefusion pressure (CPP) causes a vicious cycle of declining flow and worsening myocardial ischemia. Coronary impedance fluctuates due to extravascular myocardial pressure, producing characteristic biphasic waveforms. This study aimed to develop a systemic-coronary integrated pulsatile simulator capable of reproducing physiological coronary pressure-flow relationships, including autoregulation, to quantitatively evaluate the effects of low cardiac output and mechanical circulatory support (MCS) on coronary hemodynamics.

Methods

We constructed a closed-loop pulsatile circulation system comprising a silicone elastic left ventricle, an aortic valve with coronary arteries, an aortic arch, and venous models. Two actuator-driven variable-resistance units were incorporated into the coronary arteries. We simulated coronary pressure–flow relationships by implementing: (i) phase-dependent impedance via beat-synchronized coronary artery compression, and (ii) feedback-controlled impedance adjustment based on measured mean coronary flow to track CPP-derived target flow. Target flow values were obtained by interpolation of the steady-state CPP–coronary flow curve reported by Mosher et al. (1964). Systemic conditions were set to aortic pressure 120/80 (90) mmHg, cardiac output 5 L/min, and left ventricular pressure 120/10 mmHg. The target autoregulation range was set to 70–140 mmHg.



Results

Under baseline conditions, physiological biphasic coronary flow waveforms (left: diastolic-dominant; right: systolic-dominant) were generated. Initial coronary flows were 88 mL/min/100g (left) and 44 mL/min/100g (right). When CPP (aortic diastolic pressure) was varied within the autoregulation range (70–140 mmHg), left coronary flow was maintained within 82–105 mL/min/100g, successfully simulating autoregulation. Conversely, in the low CPP range below the set limit (30–70 mmHg), pressure-passive characteristics were confirmed, with flow decreasing alongside pressure drops.

Discussion

We successfully developed a systemic-coronary integrated simulator capable of reproducing physiological coronary hemodynamics via active impedance control. This system uniquely simulates the dynamic transition from a pressure-passive flow during cardiogenic shock to restored autoregulation under MCS. It serves as a valuable platform for quantitative evaluation of cardiovascular devices in complex hemodynamic scenarios.

Predicting Cardiovascular Events in Turner Syndrome Patients: Validation of the Hemodynamics Digital Twin Through 4D and 2D-Flow MRI

Dr Monika Colombo[1], MD Line Balsby Valsted[2], Prof. Steffen Ringgaard[2], Prof. Claus Højbjerg Gravholt[2]

[1]Department of Mechanical and Production Engineering, Aarhus University, Aarhus, Jutland, Denmark. [2]Department of Clinical Medicine, Aarhus University Hospital, Aarhus, Jutland, Denmark

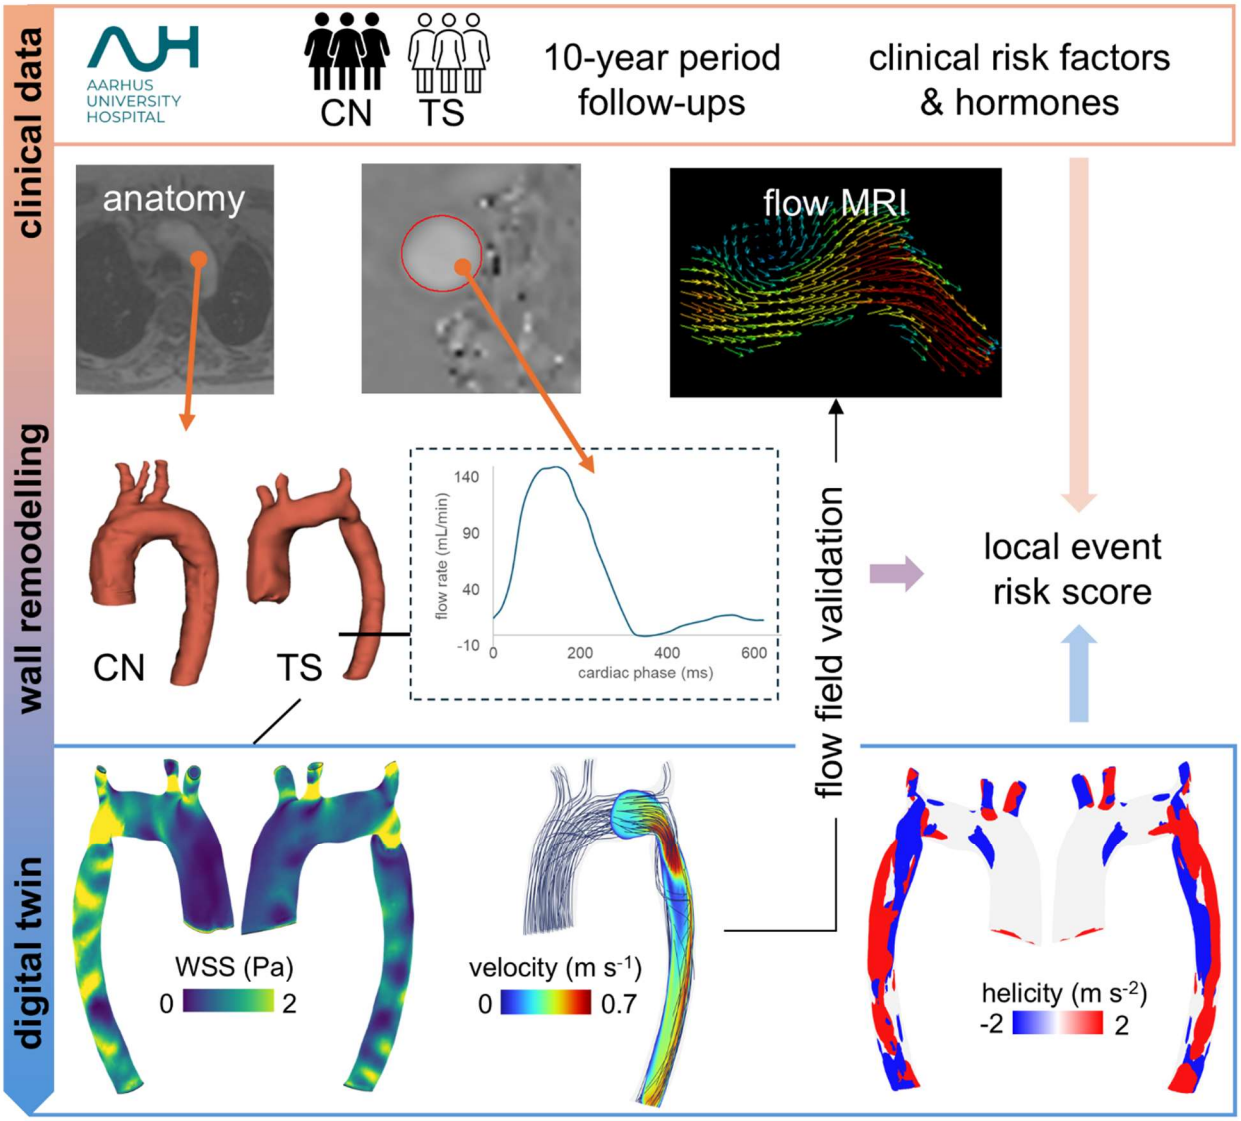
Introduction

Turner Syndrome (TS) [1] is associated with a substantially increased risk of congenital and acquired cardiovascular complications. Early identification of individuals at risk remains challenging, highlighting the need for reliable, non-invasive biomarkers derived from hemodynamic assessment. We aim to develop a predictive hemodynamic and remodelling score using clinical MRI flow data and computational modelling.

Methods

The study included 30 women with TS, 15 of which followed over a 10-year period and healthy age- and sex-matched controls (CN) examined once (Fig.1). Participants underwent 2D- and 4D-flow MRI, with 3D-flow data available for baseline assessment. These imaging datasets were used to construct personalized moving-boundary computational fluid dynamics (CFD) models. Manually segmented geometries were used for the analysis of the wall remodelling [2] and discretized for unsteady, laminar simulations. Near-wall (wall shear stress, WSS) and bulk-flow (helicity) descriptors were computed. Clinical variables, wall remodelling, and haemodynamic data were integrated into a statistical model to generate a local event risk score (LERS).

Results



MRI-derived flow measurements were used to validate the computed flow field across multiple anatomical levels of the model [3]. LERS was significantly higher in the TS group, with considerable inter-individual variability. Bicuspid aortic valve and coarctation of the aorta remained strong predictors of elevated risk. The haemodynamic burden and wall remodelling markers were consistent with their known association with adverse cardiovascular outcomes. These findings suggest that combined imaging and modelling

metrics capture clinically relevant differences in cardiovascular risk among women with TS.

Discussion

This study introduced the first integrated model in TS that combines patient-specific moving-boundary CFD-derived hemodynamics, wall remodelling, and clinical history to estimate cardiovascular risk. The results revealed substantial variability in haemodynamic burden among women with TS, reflecting heterogeneity in clinical risk. These findings demonstrate the potential of combined imaging and modelling approaches to inform future strategies for risk stratification and personalised management.

Effect of Artery and Tissue Compliance on Oscillometric Blood Pressure Measurement

Mr Muhammad Azhar[1], Dr Zia ul Rehman Tahir[2], Dr Philip Lewis[3,1], Dr Parthasarathi Mandal[1]

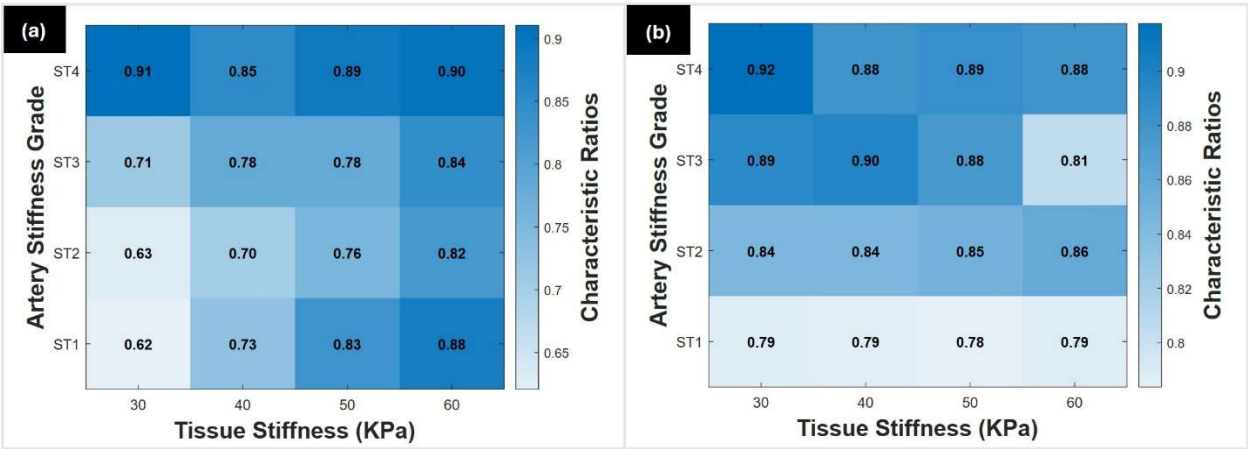
[1]The University of Manchester, Manchester, Greater Manchester, United Kingdom. [2]University of Engineering and Technology, Lahore, Punjab, Pakistan. [3]Stockport NHS Foundation Trust, Stockport, Greater Manchester, United Kingdom

Introduction

Oscillometric blood pressure (BP) measurement is a widely used non-invasive technique, but its accuracy is markedly influenced by certain biomechanical factors. Prior studies attempted at examining their influence on oscillometric BP but were limited by uniform pressure transmission assumption [1] and improper representation of arterial mechanics [2]. To address these limitations, our study develops an improved FE model that systematically investigates the effect of surrounding tissue and artery compliance on oscillometric BP.

Methods

Geometry of human upper arm and hyperelastic material properties of brachial artery were sourced from literature [1, 2]. Arterial pressure was modulated to reflect the heart rate of 1.2 Hz and BP of 120/70 mmHg. An FE model in Abaqus® simulated the oscillometric BP measurement by quick arm loading (0 to 150 mmHg) followed by 40s unloading. Oscillometric waveforms were generated by tracking brachial artery lumen area changes for unloading period. For systematic analysis the arterial stiffness was varied from compliant artery (ST1) to stiff artery (ST4) and surrounding tissue stiffness from 30 to 60 kPa [1].



Results

Evaluation of envelope profiles for baseline data showed that the stiff artery produced wide and gradual envelope while compliant artery exhibited steeper one. Maximum amplitude fell at 85.2 mmHg for compliant artery, and 84.48 mmHg for stiff artery; the values were close to MAP of 86.7 mmHg yet differences in envelope shapes indicate potential differences in SBP and DBP estimations. This is further corroborated by systematic analysis of artery and surrounding tissue stiffness that shows variation from 0.62-0.91 for SBP [Figure (a)] and 0.79-0.92 for DBP [Figure (b)] characteristic ratios.

Discussion

Our study accounts for tissue stiffness effect on pressure transmission, a factor overlooked by Ref. [1], and evaluates its effect on oscillometric BP. Further, our proposed model demonstrates the effect of arterial compliance, addressing the limitations of earlier FE model [2], providing insights aligned with clinical evidence. These findings highlight the need to improve design and calibration of BP monitoring devices, to improve clinical accuracy.

Numerical Investigation of Oscillometric Waveforms Using Non-linear Two-Way Fluid-Structure Interaction

Mr Muhammad Azhar[1], Mr Hafiz Zeeshan Ali Sardar[2], Dr Zia ul Rehman Tahir[2], Dr Philip Lewis[3,1], Dr Parthasarathi Mandal[1]

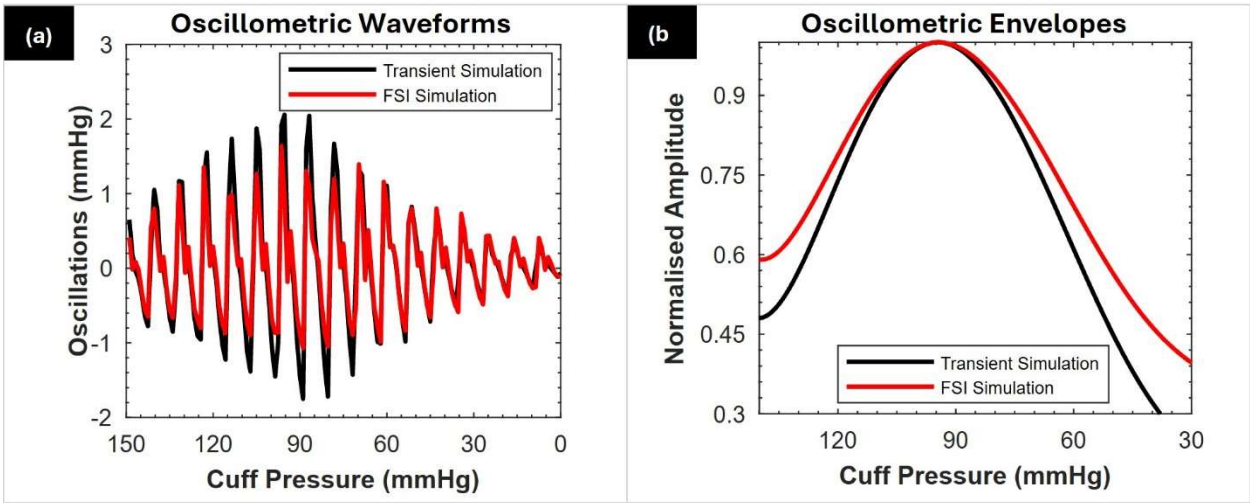
[1]The University of Manchester, Manchester, Greater Manchester, United Kingdom. [2]University of Engineering and Technology, Lahore, Punjab, Pakistan. [3]Stockport NHS Foundation Trust, Stockport, Greater Manchester, United Kingdom

Introduction

Blood pressure (BP) in oscillometric devices is estimated by detecting pressure oscillations measured by cuff during controlled deflation. Complex interaction between blood flow and arterial deformations, influences these oscillations. Flow variables, such as velocity and pressure, dynamically change as the artery deforms that affects the measured signal; traditional FE [1,2] models assume constant pulse on arterial wall, overlooking this important coupling. To simulate an oscillometric signal considering the two-way interaction of arterial wall mechanics and blood flow dynamics, this study develops a fluid-structure interaction (FSI) model.

Methods

Geometry of human upper arm and brachial artery's hyperelastic properties were selected in consistency with literature [1,2]. A two-way FSI model was implemented in ANSYS, structural deformations were solved in ANSYS Mechanical and ANSYS Fluent was used to determine fluid mechanics; Carreau constitutive model was employed to model blood. Pressure and velocity profiles for flow conditions were accessed from the data bank [3] and BP was setup at 120.5/82.2 mmHg. Arm loading representing cuff pressure was raised from 0 to 150 mmHg followed by 14s deflation; arterial wall deformations were frequently saved to generate lumen area changes and oscillometric waveform.



Results

The resulting waveform [Figure (a)] exhibits the expected pattern of gradual increases and decrease, closely resembling the realistic physiological oscillations. Its envelope [Figure (b)] follows a bell-shaped trend, yielding a mean arterial pressure (MAP) estimate of 94.30 mmHg, that is close to actual value of 94.99 mmHg. Comparison with FE model (Transient-Simulation) shows noticeable difference between two; FSI envelopes are wider with gradual transitions.

Discussion

Close agreement of estimated MAP with actual value demonstrates accuracy and reliability of the model. FE model considers constant pulse pressure applied on arterial wall; in FSI model artery's effective pressure is different as structure feedback to fluid domain that results in varied pressure on wall. This effect is not considered in reported literature [1,2]. Overall, the model provides a robust framework for future investigations of flow-related variables and their influence on oscillometric BP.

Study of Thrombus Adhesion on Fluttering Bioprosthetic Aortic Valve Leaflets

MSc Nataliya Sevryugina, Prof. Dr. Dominik Obrist

ARTORG Center for Biomedical Engineering Research, University of Bern, Bern, Bern, Switzerland

Introduction

Bioprosthetic valve thrombosis (BPVT) is a possible failure mode for bioprosthetic heart valves (BHVs). BPVT could be related to leaflet fluttering [1].

To understand the effect of leaflet fluttering on BPVT, wall shear stress (WSS) patterns are analysed in fluttering and non-fluttering BHV models, as WSS could affect thrombus adhesion.

Methods

Systolic flow in two simplified BHV models (Edwards Intuity Elite and Edwards Perimount) was simulated with a high-fidelity fluid-structure interaction solver [2].

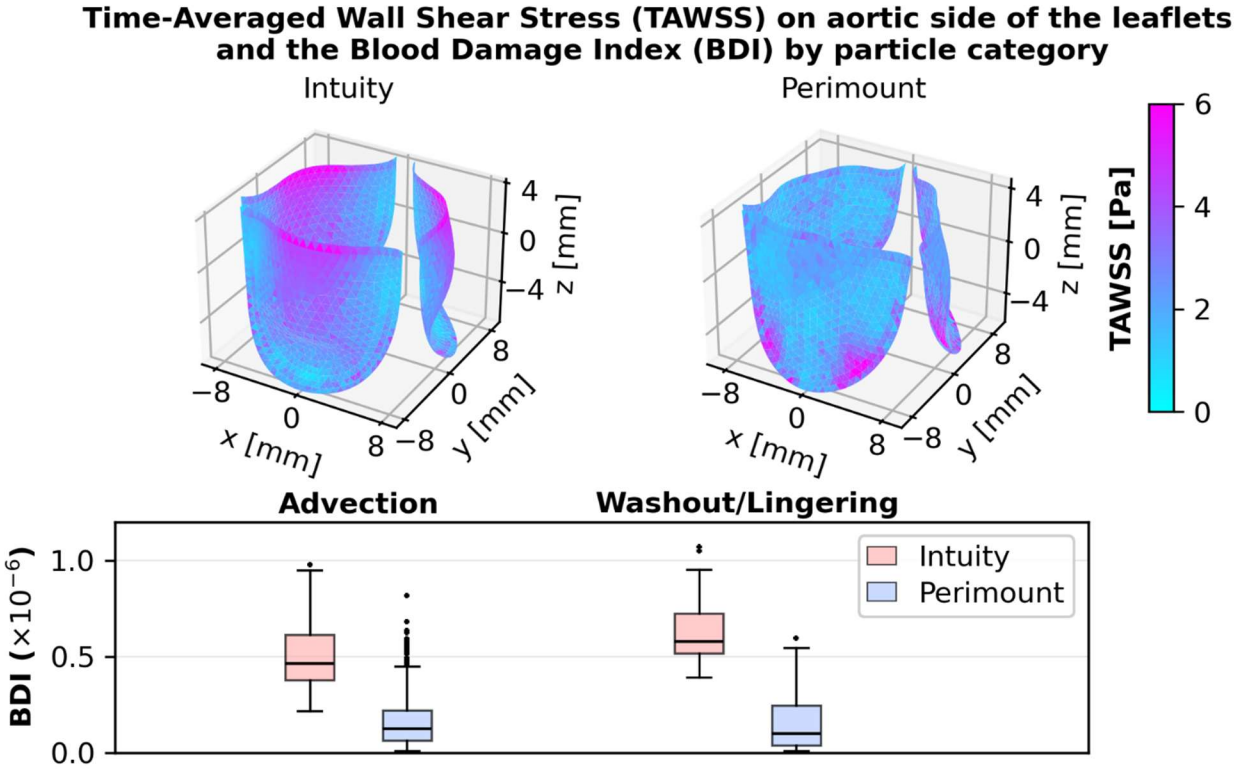
First, the flow was analysed by Lagrangian particle tracing combined with the computation of the Blood Damage Index (BDI). The particles are then categorised into advected, sinus-washout, and lingering particles that remain in the sinus at the end of the systole [1].

Second, WSS was computed on the aortic side of the leaflets. This created a map on the leaflet area indicating where the lingering particles are likely to adhere to the leaflet to form thrombi.

Results

The non-fluttering Perimount valve (<0.5mm amplitude, >200Hz vibrations of the leaflet tips) presents low amplitude WSS with a chaotic and high frequency oscillating pattern. Suggesting the existence of small-scale vortical structures that can trap the thrombi at the end of the systole.

In contrast, in the fluttering Intuity valve (40Hz leaflet fluttering) we found structured WSS with higher amplitudes, that show an oscillatory pattern aligned with the fluttering. This implies larger scale vortical structures that can promote the recirculation on the leaflet and prevent thrombus deposition.



For a single release of 1025 particles, Intuity showed 3.7x higher BDI for advection and 5.9x higher BDI for sinus-washout and lingering, indicating high shear stress experienced by particles.

Discussion

Fluttering does increase WSS, this could be linked to a lower probability of thrombus deposition on the aortic side of the leaflets.

This result makes fluttering a contradictory phenomenon: on the one hand it increases the BDI which favours BPVT, and, on the other hand, fluttering elevates WSS, possibly decreasing the thrombus deposition on the leaflets. Further research will be required to resolve this contradiction.

An Automated Method of Centerline Computation in Vascular Anatomies with Loops

Ms. Nhien Tran-Nguyen MASc[1], Dr. Stephen Fremes MD[2,3,4], Dr. Laura Jimenez-Juan MD[5,6,4], Dr. Piero Triverio PhD[1,7,8]

[1]Institute of Biomedical Engineering, University of Toronto, Toronto, Ontario, Canada. [2]Department of Surgery, University of Toronto, Toronto, Ontario, Canada. [3]Sunnybrook Health Sciences Centre, Toronto, Ontario, Canada. [4]Sunnybrook Research Institute, Toronto, Ontario, Canada. [7]Department of Electrical and Computer Engineering, University of Toronto, Toronto, Ontario, Canada. [8]Department of Mechanical and Industrial Engineering, University of Toronto, Toronto, Ontario, Canada

Introduction

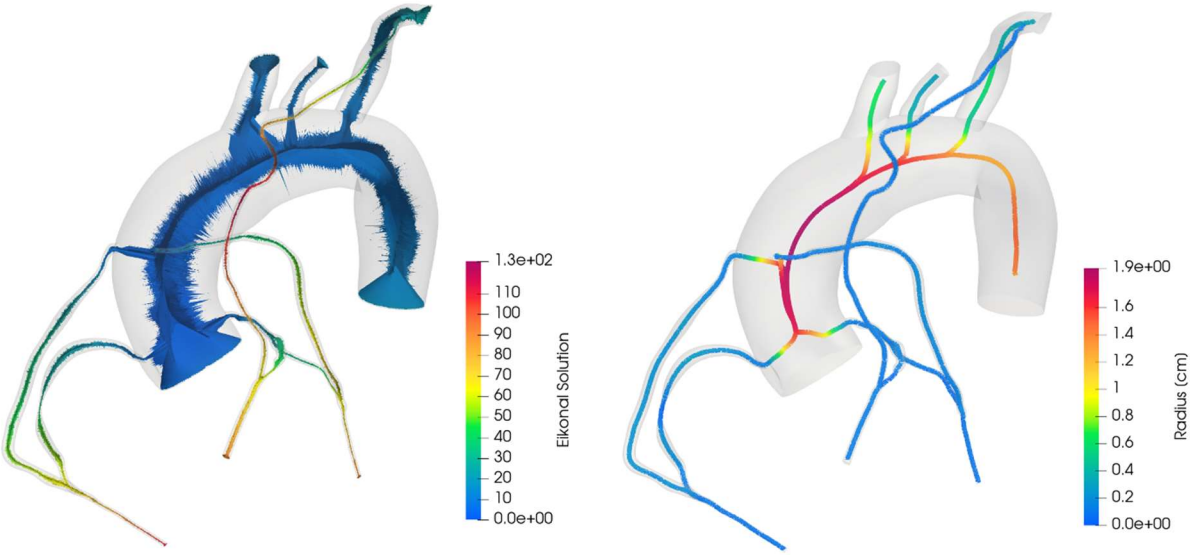
The Vascular Modeling Toolkit (VMTK) is an open-source library that enables the processing of cardiovascular models for computational fluid dynamics (CFD) simulations [1]. Crucial to the library's functionality is the computation of centerlines from a surface through the *vmtkcenterlines* method, which traces paths from target points to source points. While this method works well for vascular surfaces with a tree-like topology, it cannot identify all vessels in a loop. In such cases, manual interventions are required to clip and merge multiple centerlines generated separately, increasing the time required to process CFD models. While existing methods like *vmtknetworkextraction* can capture the topology of an arbitrary vessel network, the output is sometimes inaccurate at bifurcations and incompatible with other VMTK methods. In this work, we present an algorithm to automatically compute centerlines in vascular anatomies with loops.

Methods

The *vmtkcenterlines* method utilizes the Voronoi diagram, consisting of many points interior to the original surface. Each Voronoi point is associated with a radius derived from the largest inscribed sphere centered at that point and with a radius-weighted distance to the nearest source point, obtained by solving the Eikonal equation. This distance is used to compute the minimum-energy path from each target point to the nearest source point.

We propose a more general method to detect multiple paths from target to source. Using the centerlines and associated radii, untraced regions of the Voronoi diagram are identified, which represent vessels missing from the centerlines. Based on the Eikonal

solution, new target points are automatically selected to repeatedly compute and merge additional centerlines until the Voronoi diagram is fully traced.



Results

The algorithm was validated on multiple patient-specific models of vascular anatomies with loops, including coronary artery bypass grafts and the Circle of Willis. Centerlines were successfully traced in every vessel for all tested models.

Discussion

An algorithm is presented to compute centerlines from vascular anatomies with loops, requiring no additional user input. Significantly, the generated centerlines are compatible with other VMTK functions, enabling the direct application of state-of-the-art processing tools to a wider range of complex vascular anatomies.

Introduction

Aortic stenosis (AS) is characterized by leaflet thickening and calcification, which markedly increase stiffness and restrict cusp mobility, ultimately reducing the aortic valve area (AVA) and increasing transvalvular pressure gradients (ΔP) [1]. Preclinical evaluation of new valvular prostheses as well as the optimization of existing devices and implantation strategies, require *in vitro* benchmarking under controlled and reproducible hemodynamic conditions. We proposed a methodology to fabricate stenotic aortic root (AR) phantoms and reproduce the *in vitro* hemodynamic AS conditions.

Methods

A parametric AR model was reconstructed from averaged computed tomography angiography (CTA) measurements of 40 patients with small aortic annuli and severe AS (Fig.1a). Modular molds were designed from this geometry (Fig.1b-c), 3D-printed and filled with silicone (Fig.1d). Calcifications (50 vs. 100 mg) were reproduced by embedding calcium phosphate crystals into the leaflet during silicone casting, while the resulting fusion of leaflet free-margin was fully or partially (50%) released. Four AR phantoms (AR1-AR4) were fabricated and tested for three repeated sessions in a pulsatile mock circulatory loop (heart rate, 60 bpm; stroke volume, 70 mL; systolic/diastolic pressures, 120/80 mmHg). ΔP was measured using pressure transducers while AVA was recorded and quantified employing a downstream camera. Compression tests quantified the mechanical response of the silicone-calcium mixture.

Results

Both calcium content and free-margin incision impacted on the hemodynamic behaviour of the tested AS configurations, with the pattern of free-margin incision being the predominant factor. Phantoms AR1, AR2 and AR4 reproduced hemodynamic conditions clinically consistent with moderate to severe AS severity (mean ΔP, 33-56 mmHg; AVA, 0.6-1.9 cm) [2]. AR3 (100 mg calcium load, full-margin incision) showed decreasing ΔP and increasing AVA. The silicone-calcium composite exhibited stiffness values (0.3-2 MPa) comparable to *ex vivo* calcified leaflet tissue [3]. The overall material cost per model is inferior to € 3.

Discussion

This methodology enables reproducible and low-cost fabrication of stenotic AR phantoms that reproduce the hemodynamic of AS. Our experimental framework makes the models a valuable tool for preclinical device testing, procedural planning, and surgical training.

Computational Fluid Dynamics Aided Hemodynamic Analysis of Transarterial Radioembolization Treatment

Dr Nisanth Kumar Panneer Selvam Ph.D

University of California Davis, Davis, California, United States

Introduction

Liver cancer remains one of the leading causes of cancer-related deaths worldwide. Transarterial radioembolization (TARE) is a well-established minimally invasive procedure in which Y^{90} microspheres are injected through the hepatic artery to deliver targeted radiation to tumors. However, treatment outcomes are highly dependent on complex patient-specific hemodynamics that govern microsphere transport and deposition. High-fidelity computational fluid dynamics (CFD) simulation is a promising method to enhance TARE outcomes by pretreatment planning, yet still facing modeling and computational challenges to achieve high fidelity [1]. This study presents a CFD-based hemodynamic analysis designed to predict blood flow behaviour and microsphere transport during selective and lobar TARE injections.

Methods

The patient-specific 3D geometric model of hepatic artery tree is generated from the cone beam computed tomography (CBCT) images (Fig 1(a)). Tumor feeding artery is marked in red in Fig 1(a). The reconstructed 3D hepatic arterial tree was imported into COMSOL Multiphysics environment for meshing and blood-flow CFD analysis. The material property of the blood is considered as Newtonian incompressible fluid with density and viscosity as 1.06 g cm^{-3} and 0.04 g cm^{-1} s^{-1}, respectively [1]. The complex flow field within patient-specific hepatic artery tree was obtained by solving Navier-Stokes equations. Microsphere transport was modelled using two-way coupling (particle fluid interaction). The number of microspheres injected during selective and lobar injection was set to 547200 and 645800, respectively based on our previous patient studies [2].

Results

The results show that selective injection alters the blood flow more strongly than the lobar injection, as shown in the streamline plot of Fig 1(b). This flow disturbance develops higher

Time Averaged Wall Shear Stress (TAWSS) on the tumour feeding artery wall, as shown in Fig 1(c).

Discussion

The effects of flow disturbance created during selective injection influence the TAWSS developed on the tumour feeding artery. The results demonstrate that patient-specific hemodynamics analysis using CFD simulation could enhance the pretreatment planning of TARE by estimating the flow modifications in the tumour feeding artery after injection of microspheres.

Personalized Cerebrovascular Modeling: Comparing Generalized and Patient-Specific Boundary Condition Approaches for Sickle Cell Disease

Miss Lara Abdelmohsen, Mr. Joel Dis, Mr. Nahom Mossazghi, Miss Elizabeth Meinert-Spyker, Dr. Sossena Wood, Dr. Noelia Grande Gutiérrez

Carnegie Mellon University, Pittsburgh, PA, United States

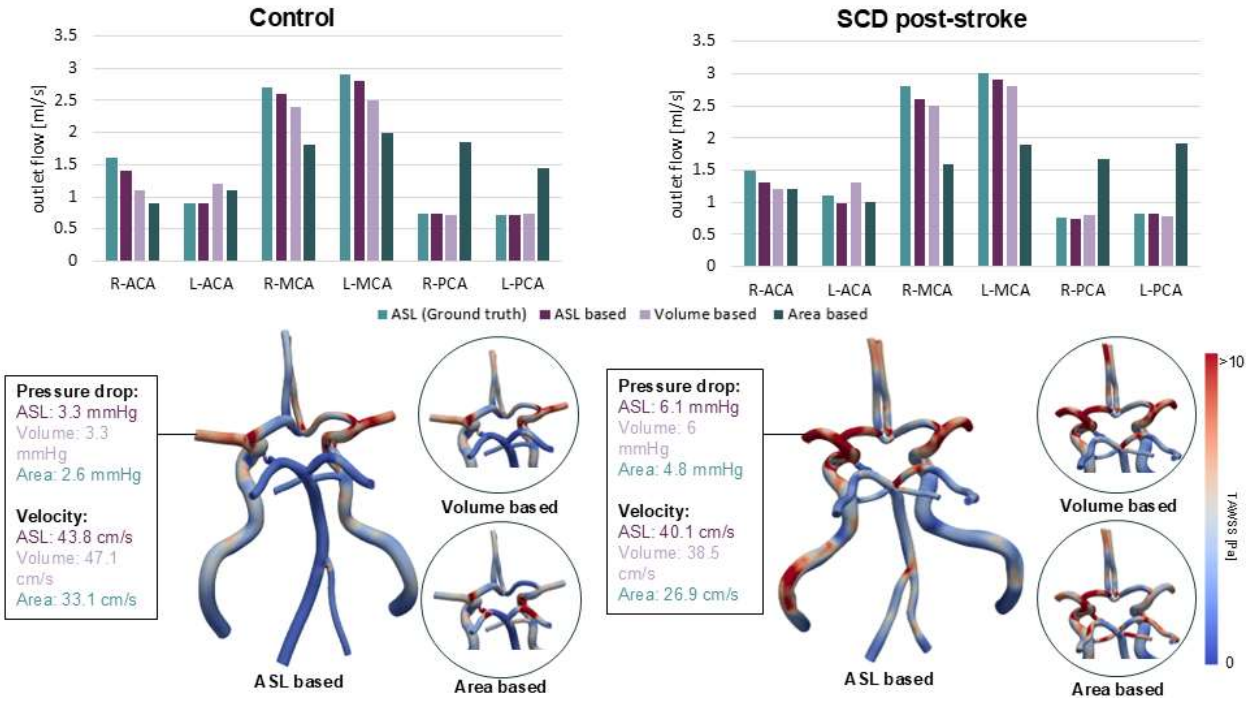
Introduction

Accurate cerebral hemodynamic modeling depends critically on physiologically realistic boundary conditions (BCs). However, many computational studies of the Circle of Willis (CoW) rely on generalized assumptions of total cerebral blood flow (CBF) distributions, or lumen-area-based flow splits, rather than patient-specific perfusion data. These simplifications may limit the accuracy and clinical relevance of predicted hemodynamics, particularly in disease cases where the microvasculature may be compromised. In this work, we evaluate how different methods for determining outlet BCs influence simulated pressure drops from inlets to outlets in different vascular territories, time-averaged mean of the maximum velocity (TAMMV), outlet mean flow, and spatially resolved time-averaged WSS (TAWSS) across patient-specific cerebrovascular models.

Methods

A healthy control and a patient with sickle cell disease (SCD) post-stroke were included in this study. For each subject, we generated 3D models of the CoW in SimVascular and ran simulations using three different methods to prescribe outlet BCs: (1) ASL-based, using territorial perfusion from arterial spin labeling (ASL); (2) area-based, distributing total CBF by outlet lumen area; and (3) volume-based, distributing CBF by the relative volume of each vascular territory using a vascular territory atlas. Flow waveforms measured using phase contrast MRI were prescribed at the inlets.

Results



Across both subjects, volume-based BCs best reproduced ASL-derived pressure drops, with errors typically within 1–14%. Area-based BCs showed much larger pressure-drop deviations, particularly in the posterior circulation (−38% to −130%). For outlet flows, volume-based BCs again closely matched ASL perfusion (<14% error), while area-based BCs produced large posterior flow errors, often exceeding 100%. TAMMV in the MCA followed the same pattern: volume-based BCs remained within ~8% of ASL values, whereas area-based BCs deviated by up to 33%. Spatially resolved TAWSS maps from

volume-based and ASL-based simulations were similar, while area-based BCs overestimated anterior TAWSS.

Discussion

These findings show that area-based BCs can substantially distort cerebrovascular hemodynamics, whereas territorial volume-based BCs provide a more accurate and practical surrogate for patient-specific perfusion when perfusion imaging is unavailable. This comparison highlights the importance of physiologic BC selection in patient-specific cerebrovascular modeling, particularly for diseases such as SCD, with altered regional perfusion.

A Closed Loop 2D Hemodynamic and Thermoregulation Model for Total Circulating Blood Volume Estimation in Circulatory Systems

Msc. Noëlle Gerards, Dr. Simona Turco, Prof. Dr. Frans van de Vosse, Dr. Marcel Rutten

Eindhoven University of Technology, Eindhoven, Noord-Brabant, Netherlands

Introduction

Accurate assessment of the total circulating blood volume (TCBV) is clinically important for managing trauma, major surgery and acute heart failure. Thermodilution is widely used for cardiac output measurement and enables TCBV estimation when both first-pass and recirculating thermodilution curves (TDCs) are captured [1]. However, this approach overestimates volumes [2], indicating that interpreting these TDCs requires models describing the spatiotemporal transport of an injected cold bolus.

Existing thermoregulation models often assume a centralized blood pool and do not represent TDC dynamics, while convection–diffusion models typically focus on small vascular segments. So, no suitable model exists for analyzing TDC measurements.

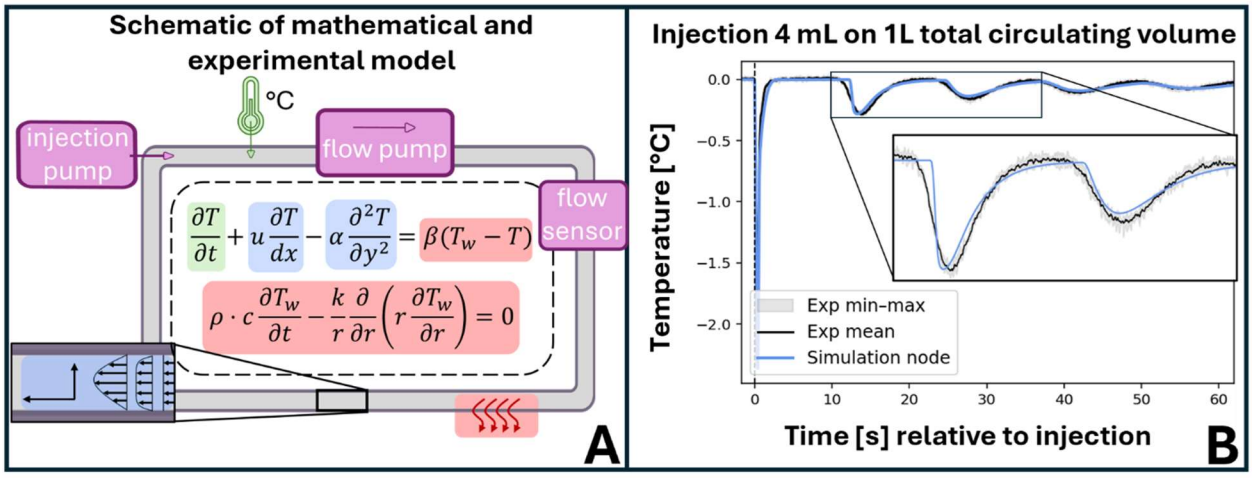
Methods

We developed a novel two-dimensional coupled circulation–thermoregulation model simulating a cold bolus traveling through a closed-loop circulation under steady flow conditions. The model describes axial convection, vessel wall heat exchange and radial diffusion while prescribing a developing velocity profile (Fig. 1a).

Model results were compared to experimental TDCs obtained from a mock circulatory loop (MCL) during cold bolus injections using a clinically accepted thermometer (Fig. 1a). The MCL consists of a centrifugal pump connected to flexible tubing. Measurements were performed at 37°C with varying total circulating volume (1-5L, 1L increments) and injection volumes.

Results

The mathematical model accurately reproduced the experimentally observed TDCs, capturing both their timing and amplitude (Fig. 1b). The model results agreed closely with the measurements. Deviations at the downslope of the TDCs were attributed to additional diffusion in the experimental setup.



The model reproduced the experimental temperature transients with a mean RMSE of 0.087°C (R=0.97). This RMSE was higher than the inter-experiment RMSE (0.045°C),

reflecting the consistency of experiments and indicating the model performed close to the reproducibility limit of the experimental measurements. This confirms that the model captures essential TDC dynamics.

Discussion

This first closed-loop model describing full thermodilution bolus dynamics including recirculation, was successfully validated in an MCL. The model provides a useful tool to interpret and optimize future thermodilution-based TCBV assessment and is a first step towards TCBV measurements in vivo.

Introduction

Carotid artery web (CaW) is an important cause of embolic stroke in young patients without traditional vascular risk factors [1]. CaW is a shelf-like projection into the proximal internal carotid artery lumen which creates a pocket region distal to the shelf where clots form [2, 3]. In this study, we quantified shear rate (SR) in 20 CaW patients with clots using computational fluid dynamics (CFD) simulations to assess thrombosis risk.

Methods

Paired CT angiography (CTA) studies from two clinical sites were acquired in 20 CaW patients (18 female, mean age 51) -- one study during initial symptomatic presentation with CTA-confirmed clot superimposed in the web pocket ("*clot*" scan) and one without superimposed clot ("*no-clot*" scan). *Clot* and *no-clot* images were co-registered non-linearly to identify the clot volume (FSL v.6.0.7). CFD simulations were performed in the *no-clot* scans for each patient (SimVascular v.2023.03.27). Segmented clot volumes from the *clot* scans were superimposed over CFD results, and the carotid wall area in direct contact with the clot volume was isolated. Within this clot-wall region, we identified the contiguous patch of 100x100 μm where peak SR over the full cardiac cycle was minimized. SR below 100 s^{-1} was chosen as our thrombogenic threshold [4].

Results

Across 20 patients, SR in the clot-wall region remained low during diastole (mean 72.5 ± 56.1, max 359.0 ± 306.7) but increased during systole (mean 155.1 ± 145.0, max 644.6 ± 563.5). In the 100x100 μm minimum SR region, SR remained below 100 s^{-1} across the cardiac cycle (mean 24.3 ± 18.7, peak systole 29.6 ± 22.9).

Discussion

Spatial correlation of SR with known clot-vessel wall contact regions allowed us to assess SR values associated with cot formation in CaW patients. We examined SR in a small region within the clot-wall with low SR values across the entire cardiac cycle to identify potential nidus regions for thrombosis initiation. SR metrics may help guide clinical intervention to prevent stroke in CaW patients.

Automated Breath Detection in Infants Using 1-Dimensional Convolutional Autoencoder

Mr Paul Bokelman, Ms Holly Olvera, Dr Erin Mannen, Dr Clare Fitzpatrick

Boise State University, Boise, Idaho, United States

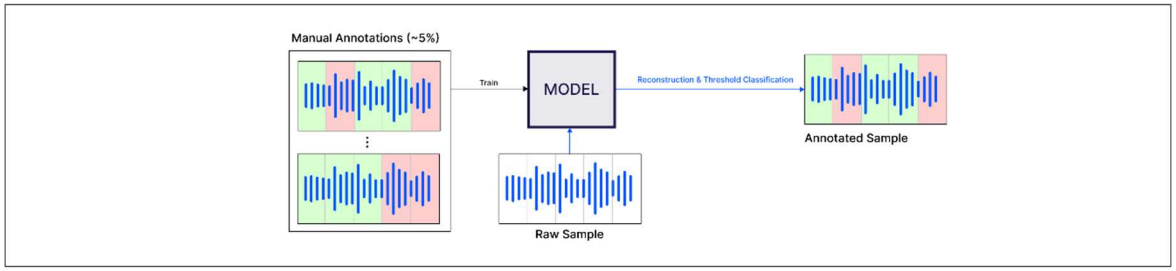
Introduction

Lack of foundational knowledge in the relationship between respiratory and biomechanical factors (e.g., body position in seated inclined products) likely contributes to avoidable deaths attributed to sudden expected infant death (SUID). Collecting biomechanics and respiratory data from infants can help elucidate these relationships. CO_2 waveforms and chest expansion biomechanics offer a rich representation of respiratory behavior. However, these studies generate large volumes of data (i.e., temporal data streams), making it time-intensive to manually annotate individual breaths. Automated techniques capable of learning and identifying normative patterns could substantially accelerate analysis and improve the reliability of infant respiratory assessment.

Methods

Five infants were placed supine in two conditions: 0° flat (baseline) and 45° thoracic flexion, representative of common infant products. For each infant we collected end-tidal carbon dioxide (EtCO2) using a Medtronic Capnostream 35 and positional chest data of 23 reflective markers using an eight-camera motion capture system during 2-5 minutes of calm breathing. A manual observer extracted “normative” breaths from the CO_2 waveform (clean peaks with sufficiently long plateaus) to generate training data. A 1-dimensional convolutional autoencoder was trained to reconstruct normative breathing patterns with a threshold-based classifier constructed from the 95^{th} percentile of validation reconstructions being used to classify future samples (Fig-1A).

Results



The model successfully identified normative CO_2 breathing patterns, with mean validation reconstruction error of 0.00262 for normal units. Using a conservative threshold-based classifier (MSE<0.00079), the model achieved 93.2% accuracy for normal units (Fig-1B) and 100% accuracy for abnormal units. Mean reconstruction error was 0.000335 for normal units and 0.033617 for abnormal units. 11.2 hours of data was classified in just 0.59 seconds.

Discussion

Our novel approach provides researchers with a tool to efficiently and reliably annotate large volumes of respiratory and biomechanics data, facilitating faster and more accurate analysis of infant respiration. We are extending this framework to automatically synchronize CO_2 waveforms with motion-capture chest expansion data, enabling data-driven investigation of relationships between respiratory and biomechanical factors. Ultimately, our objective is to generate robust, high-volume data that will support product design improvements that will reduce preventable infant mortality.

In-Silico Analysis of Tensile and Compressive Stress-Strain in Idealized Arteries

Undergraduate Student Unnathi Peri[1], Ph.D. Student Paulina Trevino[1], Postdoctoral Associate Jeremy Warren Ph.D.[2], Professor of Instruction Clark Meyer Ph.D.[1], Associate Professor Heather Hayenga Ph.D.[1]

[1]University of Texas at Dallas, Richardson, Texas, United States. [2]Yale University, New Haven, Connecticut, United States

Introduction

Atherosclerotic plaque rupture is a primary trigger of fatal cardiovascular events. Because rupture occurs in regions of high mechanical stress, characterizing arterial stress–strain patterns is essential for identifying rupture-prone regions [1]. Our laboratory previously examined arterial curvature using IVUS imaging, evaluating effective von Mises stress and Lagrange strain. However, this work did not assess how circumferential plaque location in curved arteries affects loading and rupture risk. This study aims to analyze stresses and strains in curved, idealized arteries across various curvature parameters.

Methods

The model contains two arterial layers, adventitia and media, and a homogeneous plaque layer of either necrotic core or calcium. Each layer was assigned physiologically relevant material properties [3]. A 120-mmHg load was applied to simulate blood pressure.

185 simulations were run with combinations of six percent-stenosis values, four curvature magnitudes, and nine curvature directions. For each simulation, median von Mises stress, Lagrange strain, and axial and radial tensile–compressive components were computed [4, 5].

Results

Preliminary results show that increasing percent stenosis decreases effective stress–strain in the arterial wall. Plaques on the outer curvature exhibited lower stress–strain magnitudes, while plaques on the inner curvature experienced higher loading, primarily compressive.

Discussion

The decrease in stress–strain with increasing stenosis suggests redistribution of mechanical loading into plaque regions, consistent with prior work [6]. The influence of circumferential plaque location aligns with angiography-based findings showing plaque

accumulation along the inner curvature where mechanical stresses are elevated [7]. These trends suggest that compressive loading may drive rupture mechanisms for plaques on the inner curvature, whereas tensile loading may be more relevant for plaques on the outer curvature.

Limitations include mesh density and plaque-generation variability. Future work will refine mesh resolution and plaque modeling to verify these trends.

Multi-scale Hemodynamic Finite Element and Agent-Based Modeling Framework with Estrogen-Related Factors in Atherogenesis

PhD Student Paulina Trevino[1], Postdoctoral Associate Jeremy Warren PhD[2], Undergraduate Student Unnathi Peri[1], Professor of Instruction Clark Meyer PhD[1], Associate Professor Heather Hayenga PhD[1]

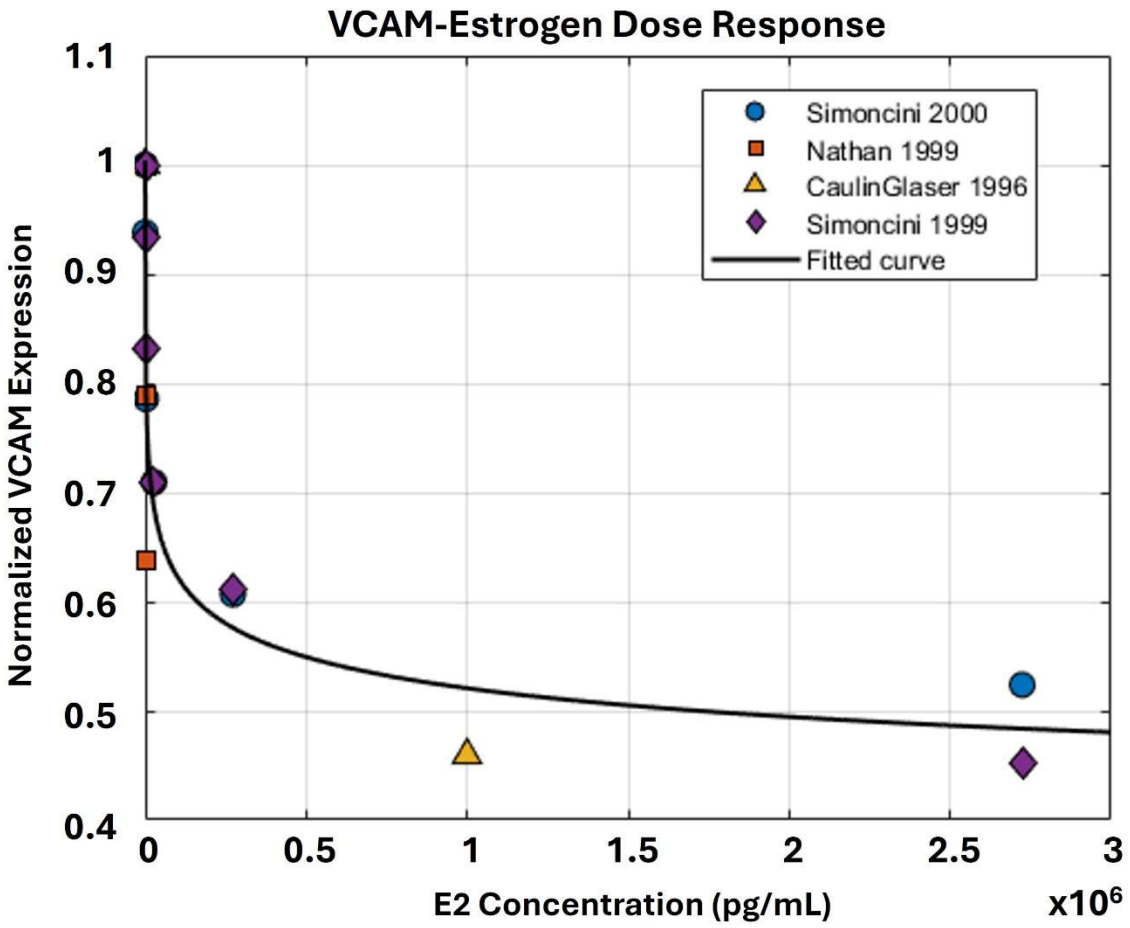
[1]The University of Texas at Dallas, Richardson, TX, United States. [2]Yale University, New Haven, CT, United States

Introduction

Cardiovascular disease remains the leading cause of mortality in the United States, largely by plaque rupture. Because plaque rupture is influenced by both mechanical and biological factors, attention has turned on molecular regulators such as the sex hormone 17β-estradiol, shown to have cardio-protective effects [1]. Although hormone replacement therapy may slow disease progression, the continued high incidence of major adverse cardiovascular events after acute coronary syndrome highlights the need for more individualized therapeutic strategies. Our laboratory developed CAFe [2], an in-silico framework integrating agent-based modeling (ABM), computational fluid dynamics, and finite element analysis. To enhance predictive power, we propose an optimized 3D-multiscale computational approach incorporating hormones to understand their impact in plaque behavior. We hypothesize that integrating sex hormone dynamics into CAFe will reveal critical mechanisms driving plaque remodeling.

Methods

We will conduct a literature review to extract quantitative relationships describing estrogen's effects on endothelial function and inflammatory signaling. Dose-response curves will be generated using candidate functional forms and selected on goodness-of-fit criteria. Fits from literature-derived in-vitro data provide quantitative equations that are implemented directly in the ABM. These biological updates then modify the mesh geometry, leading to recalculated mechanical and hemodynamical measurements.



Results

Preliminary results suggest a potential correlation, using the regression model established from the data presented in Figure 1; higher circulating estrogen levels correspond to a decrease in atherogenic processes. This relationship supports the hypothesis that estrogen exerts protective effects on vascular endothelial function, potentially by reducing inflammatory signaling or modulating leukocyte trans-endothelial migration.

Discussion

The early observations highlight a biologically plausible mechanism which estrogen may contribute to improved vascular health. A limitation is potential biological mismatch when integrating heterogenous datasets; sensitivity analyses will be used to assess robustness. Future work will extend the framework to additional sex hormones, advancing CAFe toward a comprehensive, sex-specific hormonal platform.

Small Changes in Venous Tube-Laws Significantly Alter Flow Patterns: Insights From 1D Modeling

MSc. Pauline Haulez[1], Dr. Marcel Rutten[1], Dr. Arjen van der Horst[2], Dr. Wouter Huberts[1]

[1]Eindhoven University of Technology, Eindhoven, Noord-Brabant, Netherlands. [2]Royal Philips, Eindhoven, Noord-Brabant, Netherlands

Introduction

Venous hemodynamics are strongly influenced by small perturbations in anatomy and physiologic state, making diagnosis of venous diseases difficult. Respiration induces changes in abdominal pressure, altering the cross-sectional area of abdominal veins [1], which leads to distinct flow patterns in the infrarenal inferior vena cava (IVC) of healthy volunteers: cardiac-driven, respiration-driven, and a combination of both.[2] How this respiratory–cardiac interplay exactly shapes flow patterns is still not fully understood. To address this, a 1D wave propagation model capturing venous collapse, valves, respiratory-induced transmural pressure and right atrial pressure is developed to investigate how mechanical properties influence collapse and flow patterns under respiratory pressure variations.

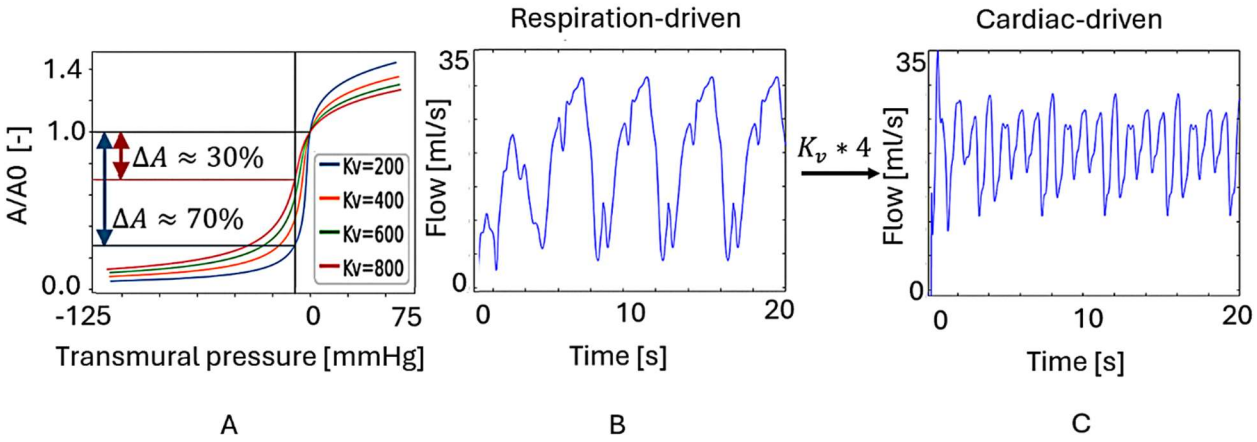
Methods

The Shapiro tube-law [3] is applied to capture the transmural pressure-area relation:

$P_{tr}=K_v(\alpha^m-\alpha^{-3/2})$, $\alpha=A/A_0$

With m, a fitting parameter, set to 10, and K_v the effective stiffness. Parameter Kv is scaled with vessel radius, resulting in stiffnesses ranging from 153 Pa (IVC) to 814 Pa (small veins).[4] Figure 1A illustrates the tube-laws for these stiffnesses, showing that increasing K_v from 200 Pa to 800 Pa decreases the amount of collapse at -10 mmHg from 70% to 30%, relative to A_0. To assess the effect of increased stiffness on flow patterns, all stiffness values in the system are increased fourfold.

Results



Increasing K_v fourfold alters the infrarenal IVC flow pattern from respiration-driven, Figure 1B, to cardiac-driven, Figure 1C. Intermediate K_v values result in a combined pattern. In

addition, simulations show that the amount of collapse decreased from 52% to 32% when shifting the respiratory pressure range from 0 to -10 mmHg towards -5 to -15 mmHg.

Discussion

These findings show that variations in transmural pressure and effective stiffness strongly influence vein collapse and flow patterns, resembling respiration-driven and cardiac-driven flow. Accurate modeling of venous hemodynamics requires improved tube-laws and quantification of respiratory-induced transmural pressures. Therefore, future work will assess the IVC tube-law and estimate transmural pressure during respiration using ultrasound.

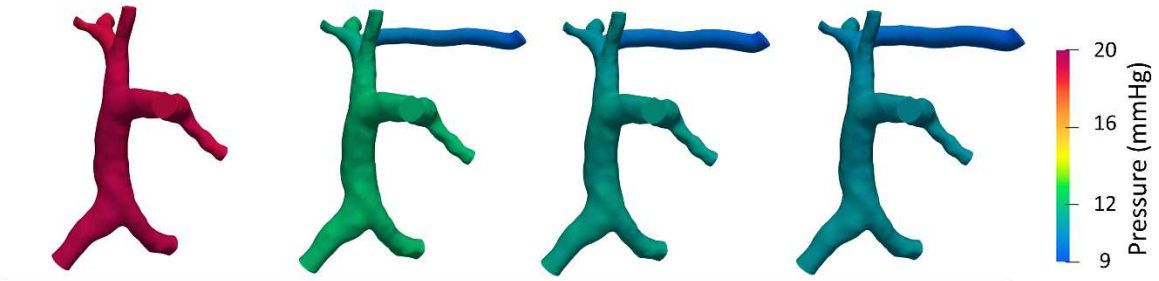
Introduction

The Transjugular Intrahepatic Portosystemic Shunt (TIPS), is a well-established treatment tool in liver cirrhosis, shown to prolong transplant-free survival. It is a stent-graft connecting the portal vein to the hepatic vein within the liver parenchyma, thus reducing the portal pressure gradient (PPG) [1]. However, excessive shunting with larger graft diameters can increase systemic ammonia levels, predisposing patients to hepatic encephalopathy (HE), and may also lead to cardiac complications such as right heart failure [2]. Computational modeling can therefore serve as a valuable predictive tool for patient selection and preprocedural planning, optimizing shunt diameter and location to assess the portosystemic pressure gradient.

Methods

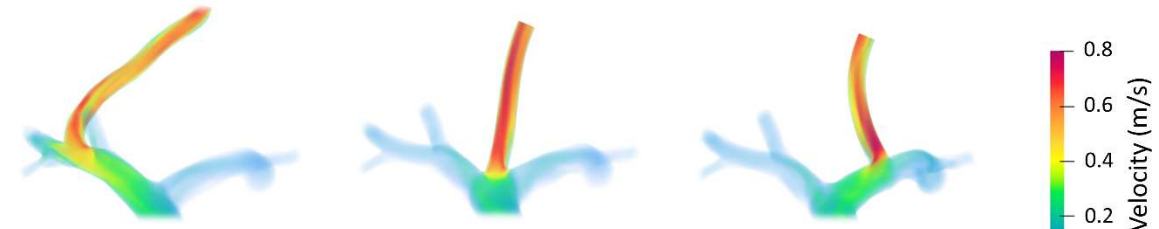
In this study, patient-specific TIPS geometries are segmented from CT images and analyzed using computational fluid dynamics with realistic boundary conditions to investigate the influence of geometrical and flow-related factors. Boundary conditions consider patient-specific liver volumetry as well as pre-TIPS catheterization for PPG measurement. This study includes variations in shunt positioning (right, left, and main portal vein) and diameter (8, 9, 10 mm). Flow investigations assess inflow-outflow variations and liver volume effects. A multiscale (3D-0D) model of the hepatic circulation is constructed to evaluate hepatofugal and -petal flow states.

Results



Larger shunt diameters reduce the PPG below the 50% clinically required threshold, and increase TIPS flow and steal (Shunt Index, see Figure). Shunt location affects flow distribution and the contribution of the ammonia-rich blood from the mesentery into the TIPS. Left portal puncture reduces the mesenteric flow in the TIPS, potentially lowering HE

risk. Hepatofugal and -petal flow patterns reflect disease severity and are governed by intrahepatic portal and hepatic vein resistances.



Discussion

It is clear that hemodynamic responses vary strongly with shunt configuration and patient-specific parameters. Future work will include portal vein flow measurements to validate predictions and extension of the model to include the heart and the rest of the circulation to asses brain ammonia levels and potential cardiac complications.

From Birth to Adulthood: Modeling Long-Term Cardiac Effects in Preterm Born Individuals

Ms. Judith Weng Zhu B.S.[1], Mr. Christian J. Andrade Herrera B.S.[1], Dr. Kara N. Goss M.D.[2], Dr. Naomi C. Chesler Ph.D.[1], Dr. Colleen Witzenburg Ph.D.[3], Dr. Pim J.A. Oomen Ph.D.[1]

[1]University of California, Irvine, Irvine, CA, United States. [2]University of Texas Southwestern Medical Center, Dallas, Texas, United States. [3]University of Wisconsin - Madison, Madison, Wisconsin, United States

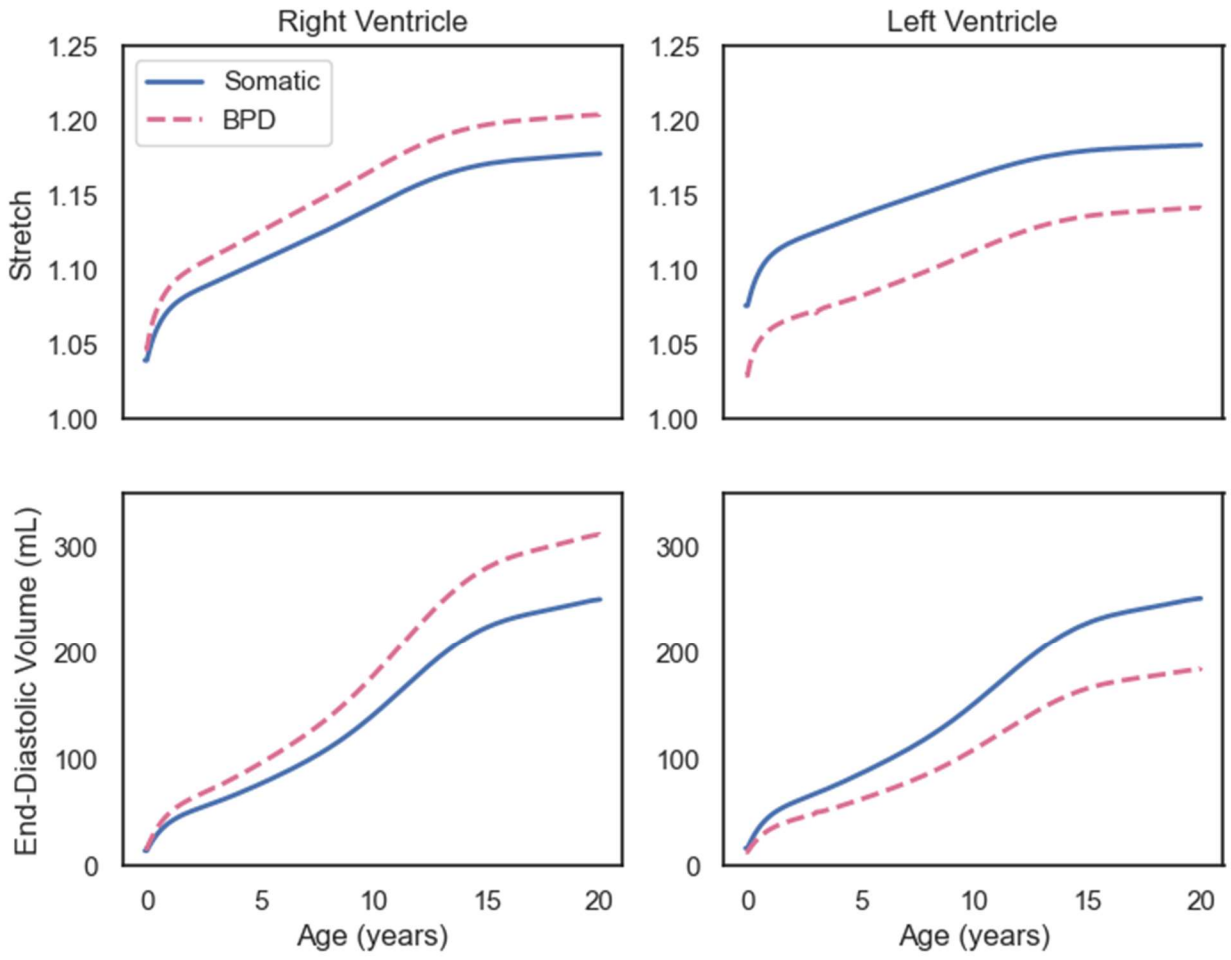
Introduction

Survival of preterm birth, defined as a delivery before 37 weeks of gestation, is a relatively recent medical advance, and those who have reached adulthood show several long-term cardiopulmonary effects. However, because the oldest preterm born individuals are just reaching their 40s, our understanding of lifelong manifestations remains limited. A well-known complication in preterm infants is bronchopulmonary dysplasia (BPD), which is a chronic lung disease that occurs following ventilator use and oxygen therapy. BPD includes worse respiratory function and pulmonary hypertension which may lead to changes in right ventricular geometry and function. However, the long-term effects on cardiac growth and function remain poorly understood. Computational modeling has emerged as a tool to address this gap, allowing researchers to simulate long-term trajectories by integrating experimental and clinical data. This study aims to model preterm long-term cardiac growth, and provide mechanistic insights on how cardiac growth differs under somatic and BPD conditions.

Methods

We used our previously published reduced-order model to simulate cardiac mechanics and hemodynamic circulation [1]. We assumed that cardiac growth from birth through adulthood in healthy females and males is purely driven through somatic processes, so this was simulated by allometrically scaling cardiac and circulation parameters based on body weight. We then simulated the lung injury in BPD by increasing the pulmonary vasculature resistance, and simulated growth by combining allometric somatic growth with a strain-driven growth model, driven by the difference in elastic strain between the healthy and BPD simulation.

Results



Our model demonstrates that BPD induces right ventricular hypertrophy via increased wall stretch, driven by elevated preload secondary to heightened pulmonary arterial resistance.

Conversely, our model shows that BPD lowers left ventricular volume compared to the healthy case.

Discussion

While several studies have measured changes in the right ventricle following BPD, less is known about the left ventricle. Our results showed contradicting growth patterns under BPD, where the right ventricle grows larger while the left ventricle smaller compared to somatic growth. Future work will focus on testing mechanisms other than, or in combination with, pulmonary resistance, such as vascular compliance and contractility.

Computational Modeling of Stent-Induced Mechanical Stimuli in Pediatric Pulmonary Vein Stenosis

Mr. R Patrick McCarthy[1], Dr. Edward Kirkpatrick DO[2,3,4], Dr. John LaDisa PhD[1,2,3,4]

[1]Biomedical Engineering, Marquette University and the Medical College of Wisconsin, Milwaukee, WI, United States. [2]Pediatric Cardiology, Medical College of Wisconsin, Milwaukee, WI, United States. [3]Cardiovascular Medicine, Medical College of Wisconsin, Milwaukee, WI, United States. [4]Herma Heart Institute, Children's Wisconsin, Milwaukee, WI, United States

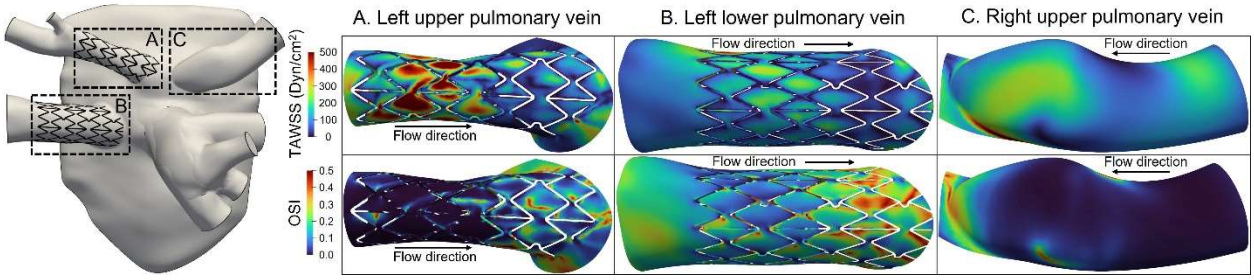
Introduction

Progressive pulmonary vein stenosis (PVS) represents ~2 cases/100,000 children under 2 years old and has a ~55% 2-year untreated survival rate[1]. Stenting is a common treatment, but restenosis occurs in >50% of cases at 6 months and 5-year survival is <50%[1]. Adverse mechanical stimuli have been implicated in restenosis[2]. Unfortunately, there are no studies including stent geometry, physiologic boundary conditions and local blood flow patterns within stented pulmonary veins (**PV**). Hence, it's unknown whether optimizing mechanical stimuli after stenting will benefit PVS outcomes. Our objective was to characterize stent-induced changes in wall shear stress (**WSS**) indices from data of patients treated for PVS.

Methods

Patient-specific stented PV geometries were reconstructed from computed tomography imaging using SimVascular. Geometries included the left atrium, PV and branches influencing local flow patterns. The make and model of stents used for each patient were then virtually implemented. PV-specific boundary layer meshes were created using Simmetrix to resolve complex flow features near stent struts. Inlet boundary conditions included multiple waveforms from clinical Doppler data. Pressure was tuned to available clinical data using Windkessel approximations. Time-average WSS (**TAWSS**) and oscillatory shear index (**OSI**) were calculated for each stented and unstented (control) PV.

Results



The accompanying figure shows a representative patient-specific stented model and WSS results with left upper and left lower PV stented (Cook Formula 418: 4x12 and 7x16 mm, respectively). TAWSS and OSI ranges align with unstented values from literature[3]. The right upper PV highlights normal values, which are PV-specific due to flow distributions and local area. Stent-induced changes in TAWSS and OSI patterns were most pronounced near

the atrial ostia. Additional quantification is underway across multiple patients for association with PV experiencing restenosis.

Discussion

To our knowledge, this is the first study of pediatric PVS to include stent-induced changes in WSS. Expanded results to be presented at WCB2026 will further serve as a foundation for ultimate use in optimizing stent selection and predicting the likelihood of restenosis for future PVS patients.

Introduction

The left atrial appendage (LAA) is a heterogeneous structure and the predominant site of thrombus formation, causing thromboembolic strokes in atrial fibrillation patients [1].

Percutaneous deployment of LAA occlusion devices (LAAODs), such as the Amplatzer Amulet (AA) and Watchman FLX (WFLX), has become a popular intervention to reduce thromboembolism and stroke risk [2]. Yet, selection criteria between these devices and their sizing still rely on clinician preference [3], even though WFLX and AA achieve sealing through different mechanisms. Moreover, the effect of LAA morphometric parameters on device deployment remains unclear. This study aims to identify quantifiable selection criteria between the most popular LAAODs by virtually implanting them into different LAA anatomies. The objectives are:

- Develop and calibrate computational models of both LAAODs
- Create an experimental pipeline to generate different LAA anatomies
- Build a physical set-up to mimic and validate the virtual procedure
- Investigate mechanical parameters (e.g., contact pressure and gap area) for deployed devices in varied anatomical configurations.

Methods

The AA and WFLX were CAD-designed via centrelines derived from micro-CT scans of the physical devices (Figure 1a). Various LAA models were CAD-generated for key parameters, including ostium diameter, eccentricity, and LAA bending angle (Figure 1b). These were 3Dprinted in Elastic 50A material on a FormLabs SLA machine. Finite Element simulations were run in Abaqus, modelling devices as Nitinol beam structures. Material properties were derived from radial compression tests performed on both devices at 37 °C (±1 °C) with the RX675 Machine Solutions. Virtual LAAs were modelled as shell elements with linear elastic behaviour.

Results

LAAODs virtual implantations were evaluated in terms of gap area between the device and the anatomy, landing zone and contact pressure, and compared qualitatively against corresponding experiments. The WFLX device generates higher local contact pressure than the AA.

Discussion

Numerical simulations of the LAAO procedures can anticipate peri- and post-procedural complications and guide a more effective device selection. Further analyses considering device orientation via the fossa ovalis are ongoing.

Rheological Comparison of Biological Fluids and Simulant Mixtures for Biomedical Flow Modeling

Mr. Rakib Hasan MS, PhD Candidate, Mr. Joby Job MS, Dr. Connor J. Evans PhD, Dr. Robert A. De Lorenzo MD, MSCI, MSM, FACEP, Dr. Alan Whitington PhD, Dr. R. Lyle Hood PhD

The University of Texas at San Antonio, San Antonio, Texas, United States

Introduction

Accurate replication of biological fluid behavior is essential for validating biomedical devices. However, many existing fluid simulants fail to capture *in vivo* rheological properties. This study compares the rheological profiles of biological fluids—including saliva, sputum, blood, and vomit—with simulant mixtures designed to emulate their flow characteristics. Benchmarking simulants against biological counterparts allows assessment of their suitability for biofluid modeling.

Methods

Rheological testing used an Anton Paar MCR 302 rheometer across 10^{-2}–10^{4} s^{-1}. Two simulant formulations were evaluated: (1) an ISO Vomit Simulant Mix composed of 10 g xanthan gum, 1000 mL distilled water, and 100 g glass beads; and (2) a Blood Phantom Mix (Akhter et al., 2019) consisting of 276 mL glycerol and 1224 mL distilled water. Reference data for saliva, sputum, and blood samples were obtained from the literature (Rantonen & Meurman 1998; Nader et al. 2019; Sturgess et al. 1971). Viscosity was plotted as a function of shear rate to assess non-Newtonian behavior and temperature sensitivity.

Results

The ISO (10079-4) vomit simulant exhibited strong shear-thinning behavior (Figure 1), with viscosity decreasing by approximately three to four orders of magnitude across 10^{-2}–10^{4} s^{-1}. Its viscosity remained far greater than sputum (10–100×) and saliva (100–10,000×). Temperature variation from 22 to 38°C produced minimal changes (<10%). The glycerol–water blood phantom showed only mild non-Newtonian behavior in 20–250 s^{-1} and displayed lower viscosity than reported whole-blood values, indicating limited physiological fidelity.

Discussion

This study presents the first known rheological characterization of the ISO vomit simulant and demonstrates its strong shear-thinning behavior across a wide shear-rate range. Here, the ISO's 1 mm glass beads were replaced with 0.1 mm beads while keeping the 100 g loading unchanged, and the simulant was tested both with and without beads (beads used only at 25°C). However, its viscosity remained far higher than saliva or sputum. The glycerol–water blood phantom mixture showed near-Newtonian behavior at shear rates >100 s^{-1} and maintained a lower viscosity than reported values for whole blood. Future studies should improve simulants to more closely reflect biological rheology.

Images (Optional)

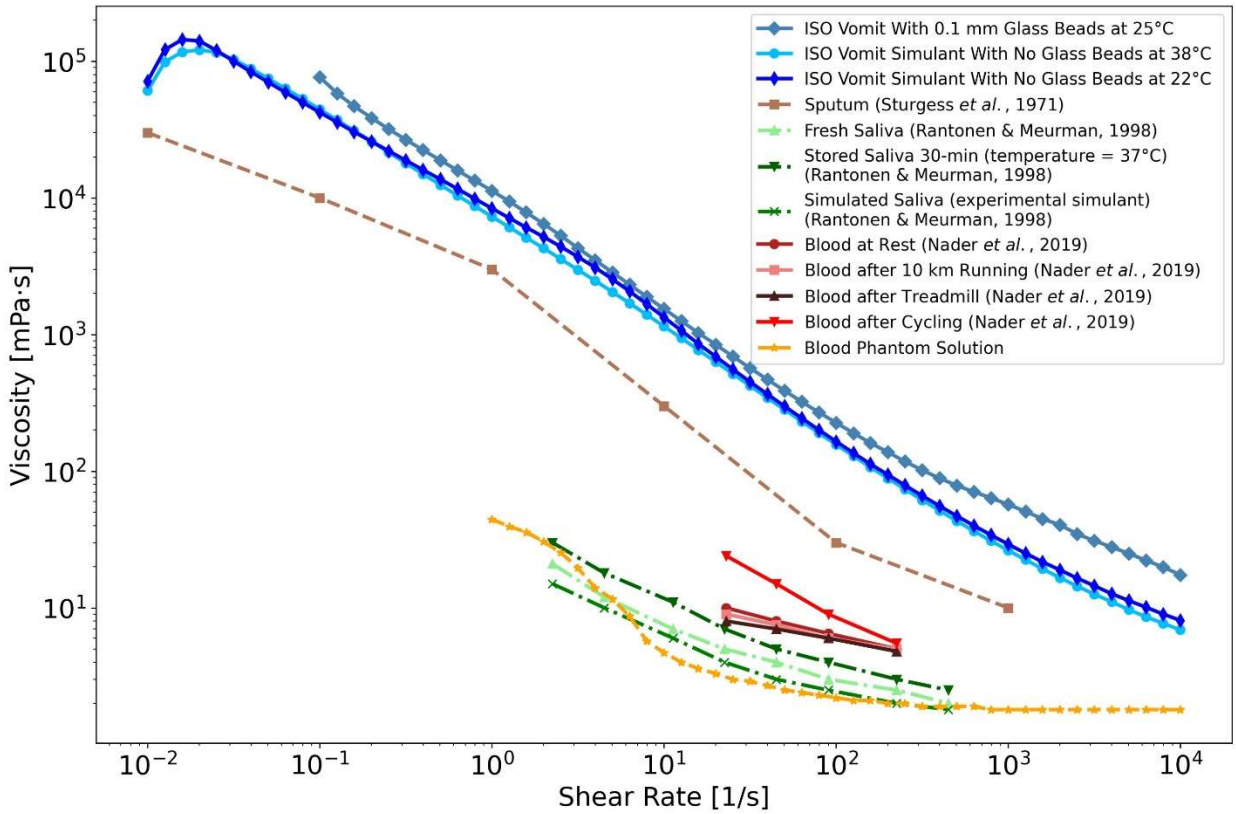

Figure 1: Comparison of Shear-rate–dependent viscosity data for multiple biological fluids (fresh saliva, stored saliva, stimulated saliva, sputum, and blood under different physiological conditions) and representative simulant materials, including ISO vomit simulants at 22 °C and 38 °C without glass beads, and a 25 °C formulation containing 0.1 mm glass beads.. Data compiled from Rantonen & Meurman (1998), Sturgess et al. (1971), Nader et al. (2019), and Akhter et al. (2019).

Optimal Transport by Gradient-Based Optimization for Synthetic Vascular Tree Generation

PhD Raoul Sallé de Chou[1,2,3], PhD irène Vignon-Clementel[2], PhD Hugues Talbot[3], PhD Laurent Najman[4,5]

[1]University of Texas at Austin, Austin, Texas, United States. [2]Inria, Palaiseau, Ile de France, France. [3]CentraleSupelec, Université Paris-Saclay, Gif sur Yvette, Ile de France, France. [4]Univ Gustave Eiffel, CNRS, LIGM, Marne la Vallée, Seine et Marne, France. [5]Khalifa University, Abou Dab, Abou Dab, United Arab Emirates

Introduction

To create useful blood-perfusion models with non-invasive diagnostic tools, it is important to generate realistic vessel networks efficiently and effectively. A widely adopted method is the Constrained Constructive Optimization (CCO) tree algorithm, which iteratively builds trees by adding new segments one by one while minimizing tree volume. We recently introduced a blood transport–based cost function for CCO, offering a more optimal and physically coherent alternative to volume minimization. For a fixed tree topology, optimizing branching point positions and vessel radii under transport cost becomes a convex problem, allowing globally-optimal solutions. Building on this, the present study develops a gradient descent–based method to generate synthetic trees from terminal nodes. We aimed to identify optimal tree topologies that minimize transport cost and improve upon limitations of traditional CCO approaches.

Methods

To facilitate comparisons between the two methods, we generated trees with 100, 200, 300, and 400 terminal nodes using the transport-constrained CCO approach. The resulting terminal node distributions were then reused as inputs for tree generation with our new terminal node–based method. We first initialized the tree topologies using the dendrograms from a single-linkage clustering of terminal nodes. Optimal branching point positions, associated with the dendrogram’s internal nodes, were determined by minimizing the transport cost. A gradient-based clustering optimization method was applied to refine dendrogram's altitudes and thus the tree topology, by minimizing altitude differences between nodes closest in Euclidean distance. After each gradient update, geometric optimization of branching point positions was performed accordingly.

Results

The gradient-based method reduced transport cost compared to volume-based CCO by 9.0%, 8.7%, 9.2%, and 9.3% for trees with 100, 200, 300, and 400 terminal nodes, respectively.

Discussion

Although simulated annealing has been used for topology optimization of CCO trees, a key novelty of our method is that it is fully differentiable. It could be integrated into deep learning frameworks for synthetic tree generation or used to solve inverse problems of identifying optimal tree topologies to better match simulated blood flow with patient-specific perfusion images. The method also enables exploration of diverse terminal node geometries. Further work should focus on enabling the method to generate multiple trees.

Validation of Diffeomorphic Image Registration for Regional Lung Biomechanics Using an In-Silico CT Phantom

Mr. Prathmesh Bhatt, Dr. Reza Avazmohammadi1, Dr. Sunder Neelakantan

Texas A&M University, College Station, Texas, United States

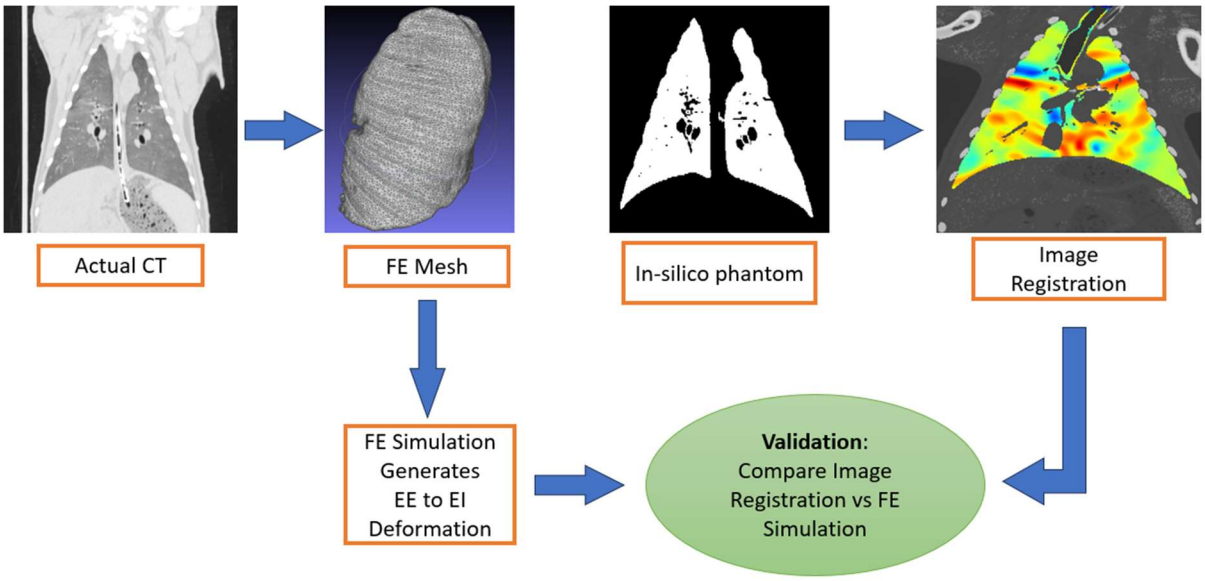
Introduction

Regional lung mechanics derived from deformable image registration provide insights into heterogeneous lung injuries. Biomechanical metrics, including the Jacobian for volume change and distortion indices for shape change, quantify local tissue deformation during respiration. However, large deformations between end-expiration and end-inspiration challenge registration accuracy, and the absence of in-vivo ground truth data limits confidence in the computed biomechanical fields. We propose validation framework combining finite-element-based computed tomography phantoms with manual landmark tracking to assess registration accuracy in lung biomechanics.

Methods

Our framework uses finite element simulations of lung parenchyma to generate in-silico CT phantoms, with nodal displacements serving as ground truth for deformation. The phantom images replicate clinical acquisition parameters and enable controlled assessment of registration algorithms. We use two different image registration algorithms to register images from end-expiration to end-inspiration. We compute the deformation gradient **F** from the displacement field, use **F** to compute the Jacobian *J*, and define the distortion index D as the ratio of the maximum to the minimum isochoric principal stretches. To extend validation beyond voxelwise comparisons, we identify anatomical landmarks, vessel bifurcations, and bronchial branch points, and track their positions in both finite element simulation and registration results. Comparison of landmark displacements between these methods quantifies registration, where imaging artifacts and anatomical complexity may influence performance.

Results



Phantom-based validation enables quantification of registration accuracy by directly comparing it with finite-element ground truth, revealing mean errors and spatial patterns of failure modes. We will compare the results for two commonly used image registration algorithms: ANTs and NiftyReg, and additionally use manual landmark tracking to provide

independent verification and further assessment. The combined approach identifies parameter regimes where registration reliably estimates regional biomechanics and reveals limitations near anatomical boundaries and regions with complex motion patterns.

Discussion

This validation framework establishes confidence in registration-derived biomechanical metrics for lung mechanics studies. By integrating computational ground truth with manual anatomical landmarks, the approach enables reliable quantification of regional deformation for applications in mechanical ventilation and lung injury assessment. The framework identifies accurate parameter regimes and limitations to inform proper use of registration for computing strain and stress fields in respiratory biomechanics.

Role of Hemodynamic Factors in the Development of Cerebral Aneurysms

Mr. Riki Kobari, Prof. Yuji Shimogonya PhD

Nihon University, Koriyama, Fukushima, Japan

Introduction

Wall shear stress (WSS) is thought to be involved in the development of cerebral aneurysms. While blood flow simulation based on actual patient vessel geometry is effective for quantifying WSS, obtaining patient vessel geometry data prior to aneurysm development is difficult. Therefore, we aimed to reproduce pre-aneurysm vascular geometry by virtually removing the aneurysm, perform blood flow simulations on the vascular geometry of 10 such cases, and investigate the relationship between WSS and cerebral aneurysm development.

Methods

For the 10 cerebral aneurysm cases provided in the Aneurisk dataset repository[1], the aneurysms were virtually removed using the Vascular Modeling Toolkit (VMTK) (Fig. 1(a)). CFX 2022 (ANSYS) was used to perform the blood flow simulations. From the obtained results, time-averaged wall shear stress (TAWSS) and Normalized transverse wall shear stress (NtransWSS)[2], an indicator of temporal disturbances of WSS, were calculated. By comparing values between the entire vessel and the aneurysm site (Fig. 1(b)), the relationship between hemodynamic factors and cerebral aneurysm development was investigated.

Results

The values shown below represent the mean and standard deviation for the 10 cases. The TAWSS for the entire vessel was 4.12 ± 0.94 Pa, while the TAWSS at the aneurysm site was 4.66 ± 2.83 Pa. In 5 of the 10 cases, the TAWSS at the aneurysm site was higher than that for the entire vessel. Meanwhile, the NtransWSS for the entire vessel was 0.0412 ± 0.0104, and the NtransWSS at the aneurysm site was 0.0544 ± 0.0220. In 9 of the 10 cases, the NtransWSS at the aneurysm site was higher than that for the entire vessel.

Discussion

The results suggest that temporal disturbances of WSS may be associated with cerebral aneurysm development. It has been reported that strong WSS disturbances induce

inflammatory responses in vascular endothelial cells[3]. Furthermore, chronic inflammation in vascular endothelial cells may trigger cerebral aneurysm development[4]. The findings obtained in this study are consistent with these previous experimental results.

CCR2+ Cells Are Critical for Normal Aortic Development

Ms Rira Choi BS, MS, Professor Jay Humphrey PhD

Yale University, New Haven, CT, United States

Introduction

Whereas it is well known that endothelial cells, smooth muscle cells, and fibroblasts contribute to the growth of the aortic wall during postnatal development, recent findings by others showed that tissue resident macrophages (Lyve1+) also contribute to normal development. In the absence of these macrophages, the aortic wall exhibits excessive stiffness, due in part to the absence of MMP-9 production by these cells. By contrast, it has been generally thought that bone marrow derived, recruited macrophages (CCR2+) contribute primarily to host defense and injury response. Here, we show that absence of CCR2+ macrophages results in unexpected aortic vulnerability.

Methods

All live animal care and use was approved by the Yale IACUC. Briefly, following euthanasia, the thoracic aorta was excised from both CCR2 null and age- and sex-matched wild-type (WT) control mice. Vessels were cleaned of loose perivascular tissue, cannulated, mounted within a custom computer-controlled biaxial testing device, and subjected to a series of isobaric-axially isometric active protocols and seven passive cyclic pressure-distension and axial force-extension protocols. The passive data were fit with a four-fiber family constitutive relation that allowed calculation of biaxial stresses and material stiffness as well as elastic energy storage. Data were collected at 6 developmental ages: P2, P10, P28, P42, P56, and P84.

Results

Amongst the many findings, three stood out. First, the rate of increase of blood pressure during development was normal despite an apparent difference in homeostatic values of multiple passive metrics. Second, aortas from CCR2 null mice exhibited a reduced vasoconstrictive capacity. Third, aortas from CCR2 null mice across age and sex exhibited an unexpected susceptibility to intramural delamination ex vivo under simulated physiological loading despite the absence of in vivo dissections or ruptures.

Discussion

CCR2+ macrophages contribute to the normal development of the structural integrity of the thoracic aorta. There is, therefore, a need for further studies of interactions between recruited macrophages and host cells and determination of the mechanisms by which these macrophages impact homeostatic targets for the mechanics of the wall.

Influence of Bifurcation Angle and Rewiring Configuration on Double Kissing Crush Performance: A Computational Study of Mechanical and Hemodynamic Outcomes

Mr Andrea Colombo[1], Dr Dario Carbonaro[2], Dr Mingzi Zhang[1], Dr Chi Shen[1], Dr Ankush Kapoor[1], A/Prof Claudio Chiastra[2], A/Prof Mark Webster[3], Mr Robert Verdoes[1], A/Prof Nigel Jepson[1], A/Prof Susann Beier[1]

[1]University of New South Wales, Sydney, NSW, Australia. [2]Politecnico di Torino, Torino, Piedmont, Italy. [3]Auckland City Hospital, Auckland, Auckland, New Zealand

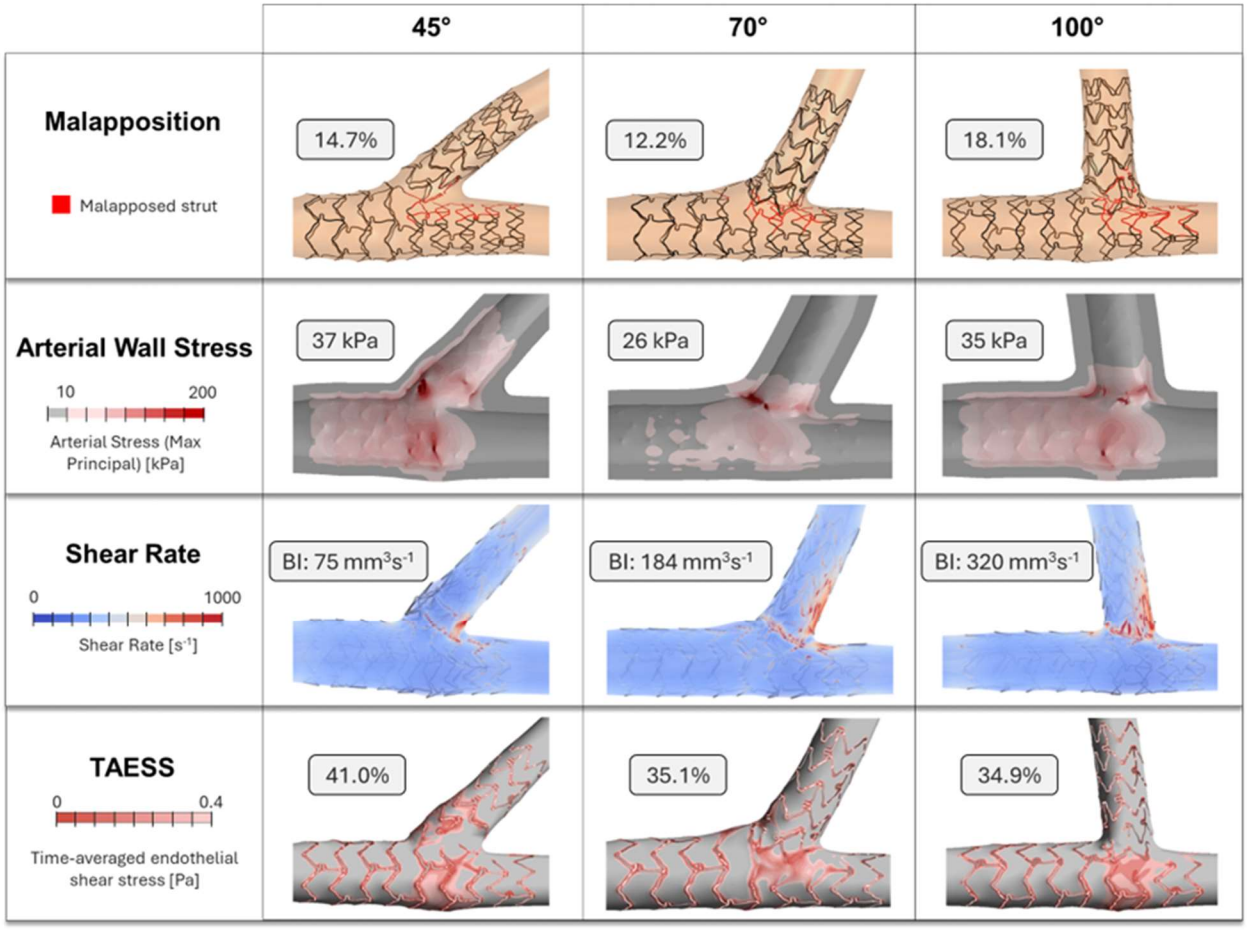
Introduction

The Double Kissing Crush (DKC) technique is widely used for complex coronary bifurcation lesions. Clinical practice favors proximal rewiring to reduce the risk of technical failure, yet the biomechanical consequences of this choice remain poorly understood. The effect of bifurcation angle on deployment quality is also unclear. This study investigates how bifurcation angle and rewiring configuration interact and influence DKC outcomes.

Methods

Twelve DKC procedures were modelled by combining three bifurcation angles (45°, 70°, 100°) with four rewiring configurations: proximal-proximal, proximal-distal, distal-proximal, and distal-distal. Finite element simulations reproduced all procedural steps, including stent crushing, two kissing balloon inflations, and proximal optimization technique, enabling quantification of malapposition, arterial wall stress, and side branch ostium clearance. Computational fluid dynamics simulations were then conducted on the final deployed geometries to evaluate regions of low endothelial shear stress and the burden of high shear rate, providing complementary insight into post procedural flow conditions.

Results



Bifurcation angle strongly affected mechanical and flow outcomes. Malapposition increased from 12.0% to 14.2% at 70° to as high as 18.1% at 100°. Side branch clearance declined with angle, from 54 to 65% at 45° to as low as 23% at 100°. High shear rate burden increased markedly in wide angles, from 75 to 140 mm^3s^{-1} at 45° up to 320 mm^3s^{-1} at 100°, driven mainly by larger high shear volumes. Average arterial wall stress varied modestly across angles, ranging between 26 and 44 kPa. Rewiring strategy influenced results in an angle-dependent manner. Proximal-proximal performed best at 70°, distal-distal at 45°,

and distal-proximal gave the most favourable balance at 100°. Low endothelial shear stress showed minimal variation and did not discriminate between strategies.

Discussion

DKC performance depended jointly on bifurcation angle and rewiring strategy. Wide bifurcations produced the worst malapposition, scaffolding, and shear conditions, indicating that DKC is not equally suited to all anatomies. No rewiring configuration was optimal across angles, and the standard proximal-proximal approach did not consistently yield the most favorable outcomes. These findings support tailoring rewiring strategy to anatomy and highlight the relevance of intravascular imaging to guide cell entry and improve procedural precision.

A Method for Generating Realistic and Demographic-Specific Populations of Synthetic Coronary Artery Models

Mr Robert Verdoes[1], Dr Mingzi Zhang[1], Dr Diogo Ferreira de Almeida[2], Mr Miro Březík[2], A/Prof Susann Beier[1]

[1]School of Mechanical and Manufacturing Engineering, University of New South Wales, Sydney, New South Wales, Australia. [2]Virtonomy GmbH, Munich, Bavaria, Germany

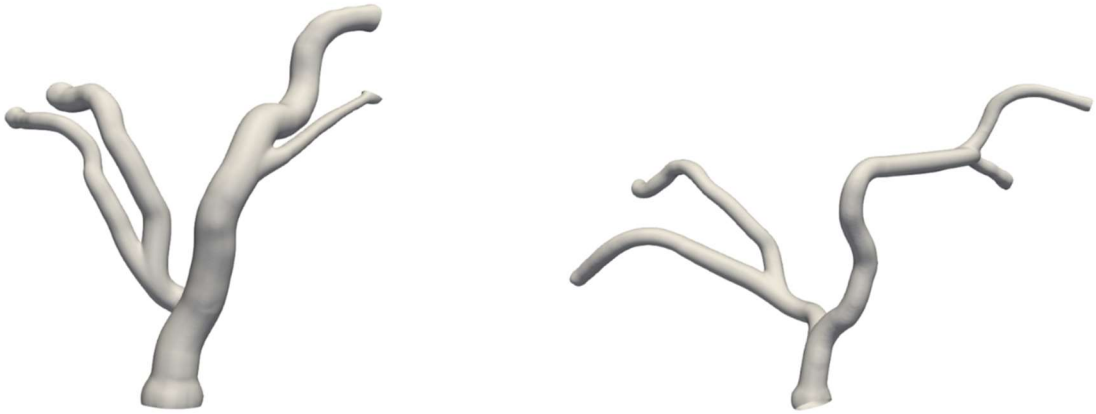
Introduction

Coronary artery disease (CAD) remains a leading cause of mortality and morbidity across all demographics, with risk and incidence varying across populations. Understanding population-specific coronary anatomy and local haemodynamics is essential for accurate CAD risk assessment, yet comprehensive patient datasets are scarce. To address this gap, this study develops and validates a method for generating synthetic artery models representative of distinct populations.

Methods

From a ground truth population of 112 bifurcating left coronary arteries, we isolated sex-specific shape modes of the first three major bifurcations by statistical shape modelling. By correlating the dimensional deviation in each of the shape modes summing to 95% explained variance, a correlation matrix between each dimension was established. Ground truth linearity was used for each non-bifurcation dimension, on a branch-specific basis, so that the matrix could encapsulate 32 dimensions, including branch-specific diameters, tortuosities, and bifurcation angles. Using these correlations, sex-specific synthetic populations were generated and evaluated against the ground truth by comparing the error of all dimensions and dimensional correlations. Additionally, using morphMan [1], we constructed a pipeline to generate synthetic left coronaries models.

Results



Based on the ground truth population, we generated a dimension set for a synthetic population of 200 left coronaries. For the 32 synthesized dimensional averages the error relative to the ground truth was 1.1% and 2.4% for male and female respectively. The average error for dimensional correlations between ground truth and synthetic populations, recorded as coefficients of determination, was 27% and 33%, whereas the

error when comparing the sex-specific ground truth populations against the entire population was 36% and 23%.

Discussion

These methods enable the realistic generation of synthetic left coronary artery datasets for distinct populations, based on their specific dimensional averages. The results demonstrate somewhat improved accuracy of anatomical correlation nuances than a less specific real dataset. Utilizing the generated coronary models, the haemodynamic significance of anatomical features can be evaluated on a population-specific basis. Furthermore, with reasonable assumptions regarding additional populations, input adjustments may allow for the study of underreported demographics.

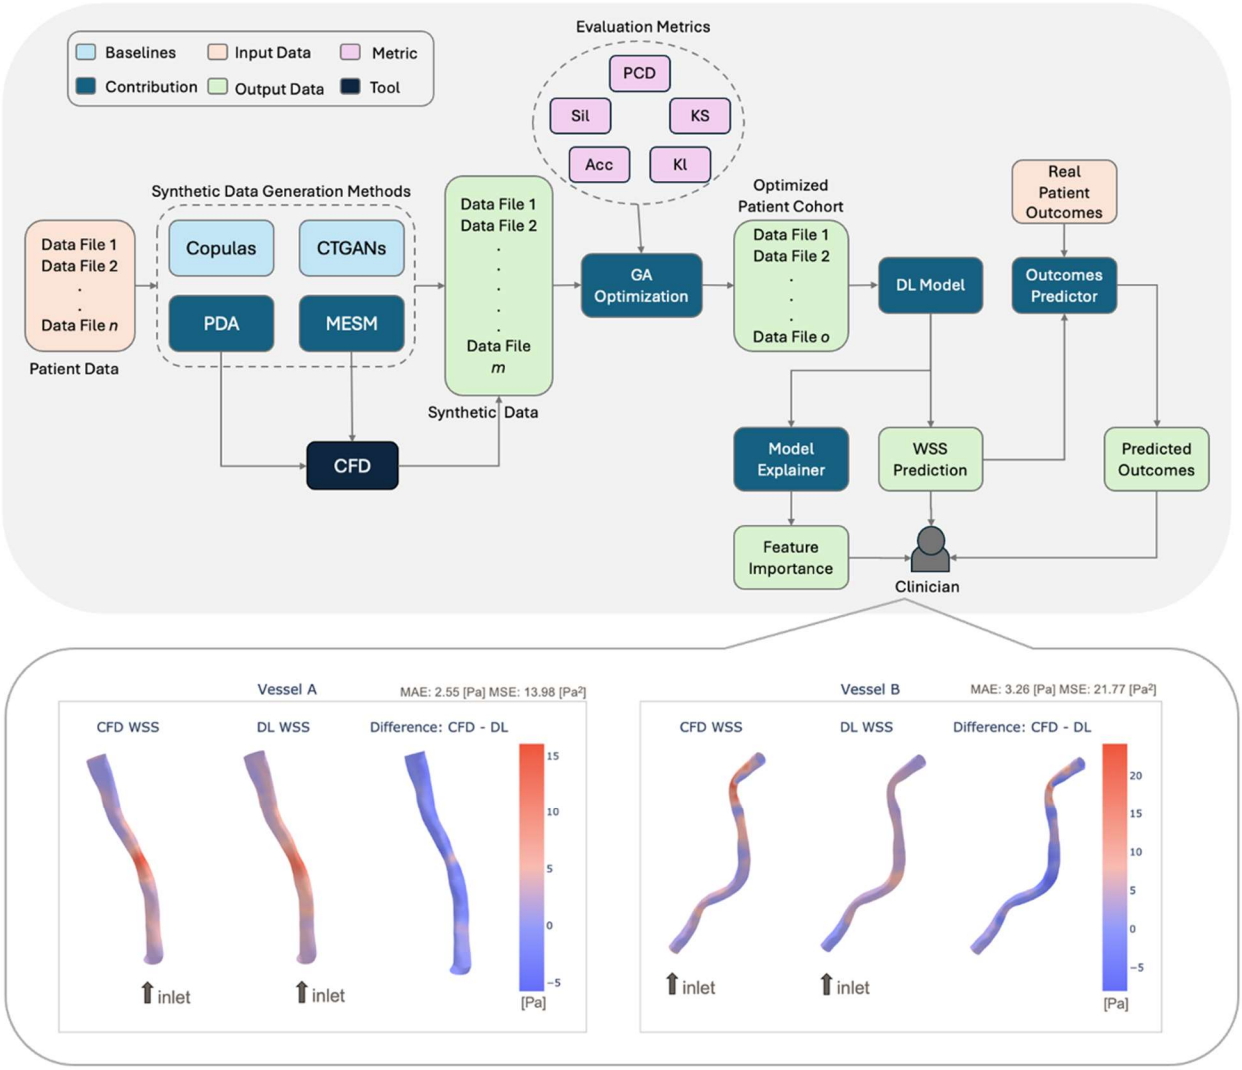
[5]Satsuma Lab, Centre for Medical Image Computing, University College London, London, London, United Kingdom. [6]UCL Respiratory, University College London, London, London, United Kingdom

Introduction

Endothelial wall shear stress (WSS) derived from computational fluid dynamics (CFD), has been shown as a promising risk stratification metric for atherosclerotic coronary arteries. The use of deep learning (DL) based surrogate models has attracted attention towards clinical adaptation, with initial successes including ours [1], but large required data sizes remain a challenge. To address this, we present an integrated framework combining synthetic coronary artery data generation and DL–based WSS prediction with validation using clinical outcomes.

Methods

Fifty patient-specific stenosed coronary geometries reconstructed from X-ray angiography and CFD-derived WSS data served as the foundation for training data. The WSS was computed with two types of synthetic vessels: (1) geometrical reorientation and inflow-velocity modification of patient data, and (2) parametrically-described fully synthetic vessel geometries. A combination of real and synthetic data (440 synthetic, 40 real) was used to train a U-net–based neural network, to predict WSS from vascular anatomy and inflow velocity. Model performance was evaluated using five-fold cross-validation and normalized mean absolute error (NMAE). For preliminary clinical validation, DL-predicted WSS values were used to identify high-risk patients, i.e. experienced cardiac death or revascularization in a long-term follow-up (57 ± 20 months) in an independent test cohort (n=10 real patients) using a 4.95 Pa WSS threshold [2].



Results

The deep learning model achieved an NMAE of 6.0% and inference times of 0.35 seconds per vessel. Synthetic data augmentation improved predictive accuracy relative to training on real-patient data alone, and synthetic data optimization using genetic algorithm achieved a 21.1% better alignment with real patient data. In the clinical test cohort, predicted mean WSS across patients ranged from 3.93–11.90 Pa, and no events occurred in the low-WSS group (<4.95 Pa), compared with four events among seven high-WSS patients (57%).

Discussion

This framework demonstrates that DL-predicted WSS correlates well with cardiac deaths and/or revascularization, and WSS prediction can be enhanced using high-fidelity synthetic data. Our framework and findings support the potential for real-time, image-based biomechanical risk stratification, via fast and reliable CFD-free WSS prediction.

Mitigating Material Uncertainty: A Framework for Fluid-Structure Interaction Simulations of Aneurysmatic Ascending Aorta

Ms. Sabrina Nocerino MSc[1], Dr. Chiara Catalano PhD[2], Dr. Sara Zambon PhD[1], Dr. Karol Calò PhD[1], Prof. Salvatore Pasta PhD[2], Prof. Umberto Morbiducci PhD[1], Prof. Diego Gallo PhD[1]

[1]Politecnico di Torino, Torino, Piemonte, Italy. [2]Università degli Studi di Palermo, Palermo, Sicilia, Italy

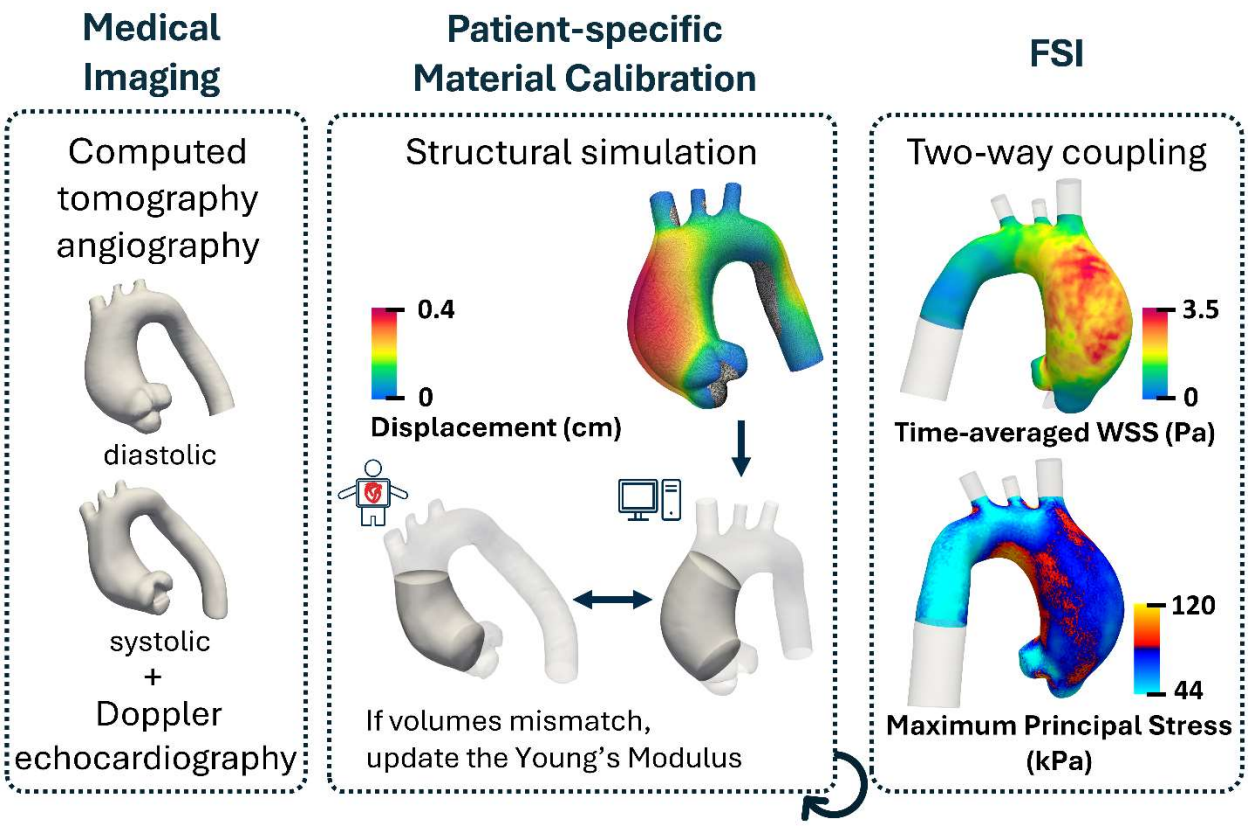
Introduction

Computational fluid-structure interaction (FSI) simulations enable to investigate biomechanical drivers of ascending thoracic aortic aneurysm (ATAA) progression [1, 2]. However, their predictive value is limited by uncertainties in the mechanical properties of the aortic wall. This study presents an FSI framework designed to mitigate this limitation via inverse identification of patient-specific wall properties.

Methods

Aortic geometries at peak systole and late diastole were reconstructed from retrospectively gated CTA [1]. The wall was modeled as a hyperelastic Neo-Hookean solid. Patient-specific material properties were estimated via an iterative inverse procedure using the CTA-measured systolic volume of the ascending aorta (AAo) as calibration target. First, finite-element structural simulations were performed to compute the diastolic stress state [3]. Then, patient-specific systolic pressure was applied, and the Young's modulus of the aortic wall was updated through a bisection method until the simulated AAo systolic volume matched the target within a 1% tolerance. Subsequently, fully coupled FSI simulations were run using the Arbitrary Lagrangian-Eulerian formulation, imposing zero displacement at ring-shaped boundaries of the solid domain. As for fluid boundary conditions, inflow waveforms were scaled using Doppler-measured transaortic jet velocities and patient-specific pressures enforced through zero-dimensional outlet models.

Results



We preliminarily applied the method to three ATAAs. Identified patient-specific Young's moduli ranged from 1.25 to 3.20 MPa, capturing the expected inter-individual variability in aortic stiffness. Peak wall stresses localized along the inner aortic curvature, with secondary foci along the outer curvature. FSI simulations captured complex

hemodynamics, including flow impingement and wall shear stress (WSS) topology associated with localized contraction/expansion dynamics—potential biomechanical markers of adverse wall remodeling [2].

Discussion

This framework enables a more accurate assessment of the interplay between hemodynamic and structural drivers of ATAA progression, reducing uncertainty about aortic material properties. Limitations include the assumption of spatially uniform wall properties and the use of a global volumetric calibration target. Ongoing studies are incorporating regional material heterogeneity and distinguishing between tricuspid and bicuspid valve morphologies, both potentially relevant for improving ATAA risk stratification.

Investigating the Impact of Balloon Post-Dilatation on Transcatheter Heart Valve Expansion after Self-Expanding TAVI in the Bicuspid Aortic Valve: A Patient-Specific Multiphysics Modelling Approach

Mr. Sam Boxwell[1], Dr. Rachel Cahalane[1,2], Mr. Dylan Armfield[3], Mr. William Hickey[4], Dr. Philip Cardiff[3], Prof. Laoise McNamara[1]

[1]University of Galway, Galway, Connacht, Ireland. [2]Harvard Medical School, Boston, MA, Ireland. [3]University College Dublin, Dublin, Leinster, Ireland. [4]Boston Scientific Corporation, Galway, Connacht, Ireland

Introduction

Transcatheter aortic valve implantation (TAVI) is increasingly utilised to treat bicuspid aortic valve (BAV) stenosis [1]. However, BAV calcification restricts transcatheter heart valve (THV) deployment causing underexpansion, which is associated with paravalvular leakage (PVL), structural degeneration and thrombosis [2]. To address suboptimal expansion and mitigate these complications, balloon post-dilatation may be conducted. In this study, we develop and validate a novel patient-specific multiphysics modelling framework to investigate the impact of balloon post-dilatation on THV expansion following self-expanding TAVI in the BAV.

Methods

A type-1 BAV patient-specific model with severe aortic stenosis was reconstructed from pre-TAVI computed tomography (CT). We simulated the complete TAVI procedure, including crimping, deployment, balloon post-dilatation (Fig. 1A) and then applied normotensive conditions to simulate post-implantation cardiac cycle loading. Models were validated against (1) post-TAVI CT (Fig. 1B) and (2) hydrodynamic testing conducted in 3D-printed patient-specific models (Fig. 1C). Next, we investigated the impact of balloon post-dilation and balloon sizing on THV expansion, ellipticity and PVL-risk at distinct regions. We assessed bioprosthetic leaflet stress at full balloon inflation, an indicator of structural degeneration.

Results

Our approach predicted frame expansion and ellipticity in excellent alignment with post-TAVI CT (within ±10% across all planes – Fig 1B). Moreover, the predicted geometric orifice area and stent deflection were comparable to hydrodynamic testing (Fig. 1C). Balloon post-

dilatation was effective at increasing frame expansion (+4%) and circularity (+16%), whilst also reducing PVL-risk (-53%) (Fig. 1D). Although balloon size did not affect THV expansion, the 23 mm balloon (labelled THV diameter) resulted in higher leaflet stresses (σ_{mean}=1.51MPa) compared to the undersized 22 mm balloon (σ_{mean}=0.38MPa) (Fig. 1E) at full balloon inflation (3 atm).

Discussion

Utilizing a novel computational framework, we predicted that balloon post-dilation improved frame expansion and reduced PVL in a challenging case of BAV stenosis. Moreover, balloon undersizing may reduce biomechanical stress-related leaflet degeneration. Ongoing work utilizes computational fluid dynamics (CFD) to assess thrombogenic risk associated with balloon post-dilatation [3], whilst also extending the analysis to a larger BAV cohort.

Mechanical and Microstructural Analysis of Human Umbilical Arteries

Ms. Sanaz Farmani BS, Mr. Bahman Kargarbahrkhazar, Dr. Sayed Ahmadreza Razian

University of Nebraska Omaha, Omaha, Nebraska, United States

Introduction

The mechanical properties of human umbilical arteries (UAs) are critical for maintaining placental perfusion and fetal health. Furthermore, vascular stiffness at birth may serve as a marker for fetal programming, potentially predisposing individuals to cardiovascular disease later in life. Despite this importance, mechanical characterizations of UAs have often relied on uniaxial testing, which may not fully capture the complex, anisotropic behavior of the vessel under physiological multiaxial loads. Consequently, the relationship between UA multiaxial mechanics and wall microstructure has not been comprehensively studied. This study provides a comprehensive analysis coupling biaxial mechanical testing with quantitative histomorphometry on the same tissue specimens.

Methods

Umbilical cords were collected from 30 term deliveries. UA segments were isolated and subjected to planar biaxial tensile testing using a Biaxial BioTester (CellScale). Specimens underwent preconditioning followed by equibiaxial loading up to 80 mN to characterize stress-stretch behavior in longitudinal and circumferential directions. Following mechanical testing, tissues were fixed and stained with Movat's Pentachrome and Masson's Trichrome. High-resolution whole-slide imaging and machine learning-based image analysis were employed to quantify the density and orientation of collagen, elastin, and smooth muscle cells in the extracellular matrix.

Results

Preliminary analysis demonstrated characteristic nonlinear, pseudo-elastic stress-stretch behavior. At 15 kPa equibiaxial stress, mean longitudinal and circumferential stretches were similar (1.25 ± 0.13 vs. 1.25 ± 0.19). While the average behavior was relatively isotropic, we saw significant variability between samples with different risk factors, and some subjects displayed significant anisotropy. Histologically, samples from pregnancies complicated by preeclampsia exhibited distinct structural remodeling, characterized by a marked increase in collagen density and a reduction in elastic fibers within the inner tunica media compared to healthy controls.

Discussion

This study establishes that human UAs exhibit complex, heterogeneous mechanical behaviors that are intrinsically linked to their microstructural composition. The structural alterations observed in pathological pregnancies suggest that adverse intrauterine environments trigger vascular remodeling, leading to stiffening. These findings provide a baseline for understanding fetal vascular development and support future studies aimed at understanding the specific roles of different risk factors on UA biomechanics and fetal cardiovascular programming.

Personalized Multiphysics Four-Chamber Heart Modeling Framework for Simulating Heart Failure and Treatments

Dr Sandra Hager[1], Dr Vahid Ziaei-Rad[1], Dr Jenny Choy[2], Dr Mengjun Wang[2], Dr Ghassan Kassab[2], Dr Lik Chuan Lee[1]

[1]Michigan State University, East Lansing, Michigan, United States. [2]California Medical Innovations Institute, San Diego, California, United States

Introduction

Computational cardiac modeling is an important tool for understanding heart function, enabling personalized therapies, and developing digital twins. While frameworks for left-ventricular and biventricular mechanics are well established, physiologically realistic four-chamber models that include the Purkinje fiber network, however, remain limited. To address this issue, we developed a computational model framework that integrates a fractal-tree-based Purkinje fiber network and a patient-specific four-chamber heart geometry coupled to a closed-loop circulatory model. The computational framework was used to simulate left-branch bundle block (LBBB) and cardiac resynchronization therapy (CRT).

Methods

A patient-specific four-chamber myocardial model was generated and subsequently used to project a fractal-tree-based Purkinje fiber network onto the endocardial surfaces [1]. Electrical propagation within both the Purkinje system and the myocardium was simulated using a modified FitzHugh–Nagumo (FHN) formulation, with a modified diffusion tensor to reflect electrophysiological activation characteristics of the heart [2-4]. Electromechanical coupling was through active and passive components of a transversely isotropic constitutive law, combined with a rule-based fiber field [5,6]. Closed-loop hemodynamic coupling was incorporated using a lumped circulatory model enabled by pressure-driven contraction [7]. LBBB was simulated by setting diffusion parameters to zero at a network junction near the His bundle. To simulate CRT, two additional activation sites, lateral LV and apical RV, were introduced, reflecting the clinically accepted gold-standard approach [8].

Results

The baseline model produced activation and deformation patterns consistent with expected ventricular physiology, with total myocardial activation after 115ms an ejection

fraction (EF) of 47% and a peak LV pressure of 147mmHg. LBBB resulted in delayed LV depolarization, reduced EF to 24% and lowered peak pressure to 104mmHg. CRT pacing partially restored synchronous activation with a 28% reduction in activation time and improved global pump function (43%), with peak LV pressure of 125mmHg.

Discussion

This preliminary model offers a foundation for studying LBBB-related activation abnormalities and evaluate CRT strategies. Although quantitative metrics such as conduction velocities may require further calibration, the qualitative activation sequence and resynchronization response align with clinical observations. Its modular structure will facilitate future integration of atrial electrophysiology and refined conduction parameters, with the long-term potential to support patient-specific predictions of CRT response.

Computational Analysis of Cerebral Hemodynamics Under Variations in Circle of Willis Anatomy and Autoregulation Capacity

Ms. Seo Yeon Kim[1], Mr. Chang Min Lee[1], Prof. Keun-Hwa Jung[2], Prof. Hyeyeon Chang[3], Prof. Hyun Jin Kim[1]

[1]Korea Advanced Institute of Science and Technology, Daejeon, Daejeon, Korea, Republic of. [2]Seoul National University Hospital, Seoul, Seoul, Korea, Republic of. [3]Konyang University Hospital, Daejeon, Daejeon, Korea, Republic of

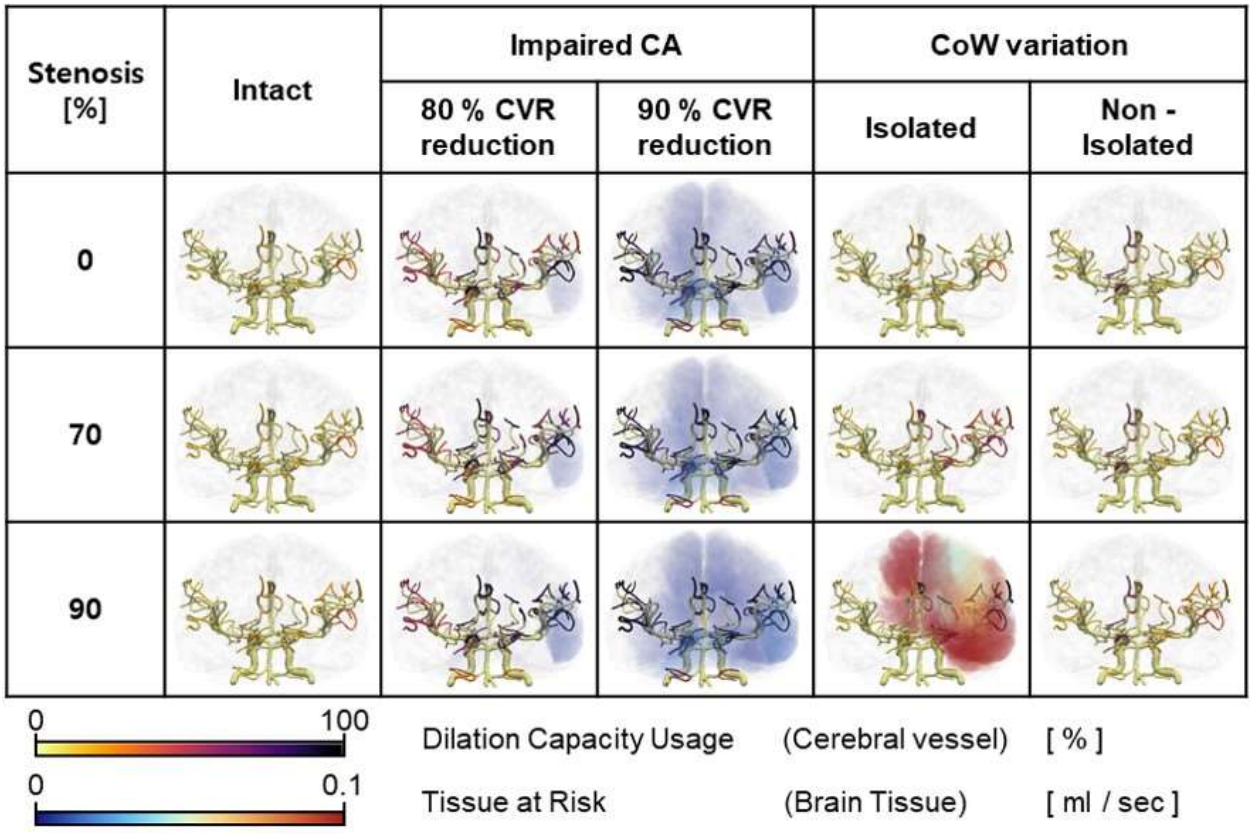
Introduction

The brain is highly sensitive to reductions in cerebral blood flow (CBF) and relies on compensatory mechanisms such as cerebral autoregulation (CA) and the Circle of Willis (CoW). CA stabilizes CBF across a range of arterial pressures by dynamically modulating arteriolar resistance, whereas the CoW provides collateral pathways for redistributing flow when primary vessels are compromised. Both mechanisms exhibit substantial inter-individual variability, which may influence disease progression and susceptibility to ischemia. This study investigates the combined impact of CoW anatomical variation and CA impairment on cerebral hemodynamics using three-dimensional vascular models with progressive stenosis on the left internal carotid artery.

Methods

A patient-specific cerebrovascular geometry was reconstructed from MRI data and multiple CoW variants were generated to examine the effect of anatomical configurations. CA was implemented by modulating downstream resistances within physiologically informed bounds, based on arterial spin labeling measurements from ten healthy subjects before and after acetazolamide administration. Blood flow was modeled as an incompressible Newtonian flow governed by the Navier–Stokes equations and solved using a stabilized finite-element formulation. Simulations were performed across increasing stenosis severities while varying both CoW anatomy and CA capacity.

Results



Under reduced cerebrovascular reserve (CVR<80%), models with a complete CoW exhibited only modest flow deficit of 0.07~1.93% across stenosis levels. In contrast, CoW variations produced substantially larger flow deficits of 2.83~33.61%, particularly in isolated configurations where perfusion territories depended on a single ipsilateral artery.

Impaired CA produced gradual increases in Dilation capacity usage (DCU) with worsening stenosis, whereas CoW variations induced abrupt spikes in DCU for isolated configurations. Even in non-isolated configurations, certain CoW configurations redistributed hemodynamic burden and created localized regions of vulnerability despite preserved global flow.

Discussion

Reduced CVR produces progressive increases in DCU, whereas the collateral pathways of CoW mitigate substantial flow loss. However, anatomical variability in the CoW can trigger sudden increases in DCU and precipitate acute hemodynamic vulnerability, particularly in isolated configurations. These findings highlight that CA impairment contributes to gradual hemodynamic instability, whereas CoW anatomical variation represents a conditional but potential risk factor capable of triggering abrupt cerebrovascular compromise.

Evaluation of Automated nnUNet Convolutional Neural Network (CNN) Segmentation of Coronary Arteries and Ascending Aorta from Coronary CT Angiography

Mr. Seraphim Fahmy, Ms. Anahita Seresti MS, Dr. M. Owais Khan PhD, P.Eng.

Toronto Metropolitan University, Toronto, Ontario, Canada

Introduction

Coronary artery segmentation from coronary computed tomography angiography (cCTA) has received increasing interest, driven primarily by non-invasive fractional flow reserve (CT-FFR) using computational fluid dynamics simulation (CFD). However, reconstructing complete coronary trees from cCTA is labor-intensive, with few open-source deep-learning coronary-specific segmentation tools, particularly for CFD. nnUNet is an open-source self-configuring convolutional neural network framework designed to automatically segment anatomical structures from various imaging modalities (e.g. CT, MRI). In this work, we evaluated the accuracy of detailed nnUNet segmentations of coronary artery trees and aorta from cCTA.

Methods

We used N=71 cCTA images. Detailed coronary arteries were segmented in SimVascular software to generate 3D label maps, which included the left/right coronary arteries and aorta. A separate dataset of N=29 test cases were used for testing with pre-existing labels. Images and coronary/aorta labels were fed into nnUNetv2 using default nnUNetTrainer, Residual Encoding Medium preset, default pre- and postprocessing, and 3d_cascade_fullres configuration. Dice scores were evaluated using nnUNetv2's built-in evaluation script. Visual Identification of true/false extensions of vasculature and disconnected regions was performed via comparison to original image.

Results

Mean Dice Scores were 0.87+-0.06 for Aorta, 0.71+-0.07 for the left coronary tree, and 0.74+-0.12 for the right coronary tree. After preliminary analysis of 6 selected cases, 14 regions were found in ground truth but disconnected, 12 regions demonstrated correct extension of vasculature, and 4 included segmentation of vasculature outside of coronaries. Mean inference time was ~10 minutes on Nvidia RTX4090. Inference dice exceeded cross-validation, indicating high model generalizability.

Discussion

nnUNet has been applied to many medical imaging tasks with high success (e.g., tumors, kidneys, liver). However, extending nnUNet to coronary arteries presents challenges due to their finer structures. Our results demonstrate that while nnUNet can segment aorta reliably, left and right coronary arteries present discontinuities and fragmentation. Post-processing techniques, including Sequential Segmentation (SeqSeg) that infer along vessel centerlines, could further improve performance. In daughter branches of epicardial coronary arteries, the segmented lumen was typically narrower than ground truth. nnUNet could provide fast initial reconstruction of coronary arteries that could be refined with post-processing, ultimately streamlining cCTA-based analysis.

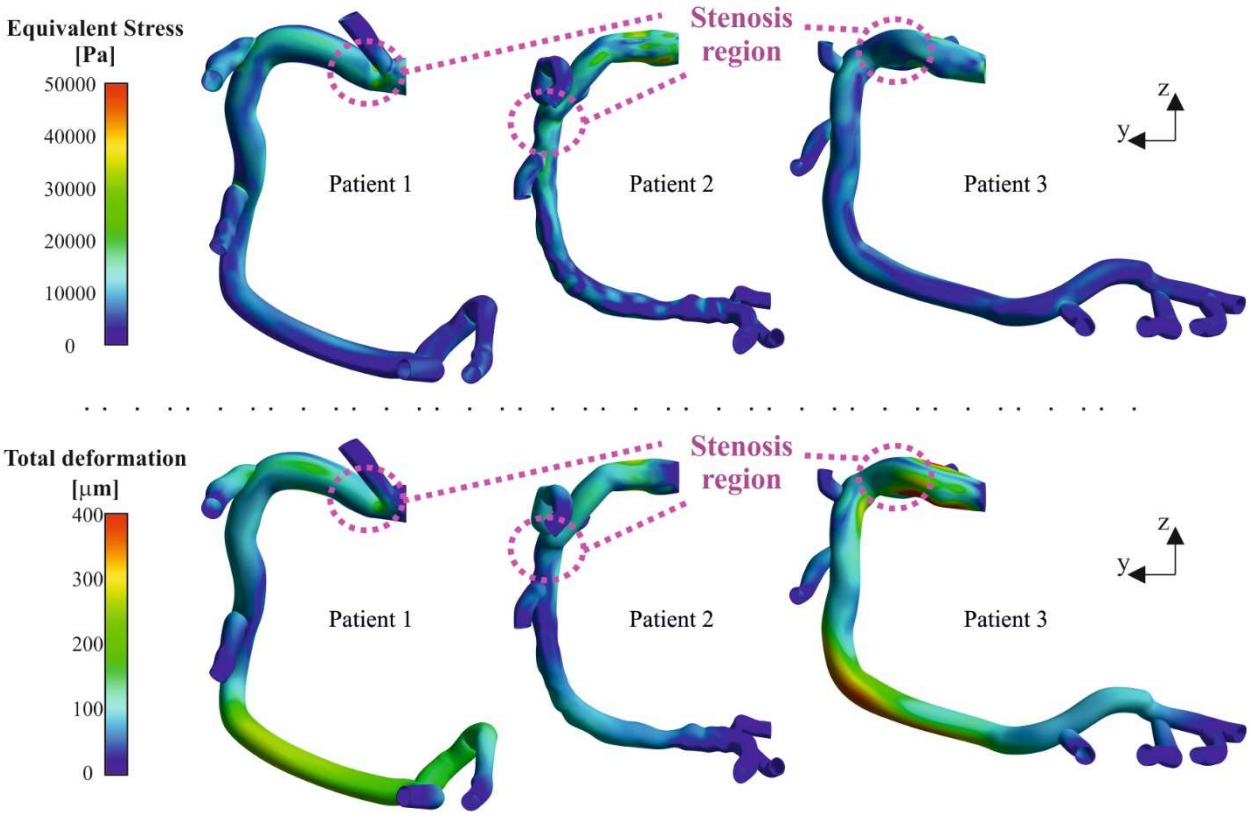
[6]UnIC@RISE, Department of Surgery and Physiology, Faculty of Medicine, University of Porto, Porto, N/A, Portugal

Introduction

Coronary artery disease remains a major cause of mortality, and current diagnostic tools struggle to describe the structural impact of stenoses. Fractional flow reserve (FFR) identifies flow-limiting lesions but provides only a global pressure index and neglects local wall mechanics [1]. Fluid–structure interaction (FSI) modelling estimates wall stress and deformation under hyperemic conditions, potentially revealing structural features linked to stenosis severity. This study examines whether patient-specific FSI-derived metrics correspond to invasive FFR classification.

Methods

Three right coronary arteries were selected to cover different lesion severities: two non-significant cases (Patients 1 and 3, FFR = 0.90 and 0.97) and one borderline/significant case (Patient 2, FFR = 0.75). Patient-specific geometries were reconstructed from CT and adapted to hyperemic anatomy. Blood was modeled as viscoelastic with Womersley pulsatile inflow and Windkessel outlets. Arterial walls were assumed linearly elastic and FSI simulations were run. The methodological consistency was confirmed by comparing FSI-derived with invasive FFR, yielding a mean relative error of 7.87% (SD 6.14%).



Results

Peak hyperemic structural responses differed across patients. In Patient 1, the stenotic region exhibited 10,000–50,000Pa of equivalent stress and 80–200 μm deformation, confined locally without downstream propagation. Patient 2 showed marked stress concentration (8,000–28,000 Pa) and deformation of 50–130 μm, forming a focal mechanical pattern aligned with borderline functional severity. Patient 3 demonstrated the lowest stress (5,000–12,000 Pa) and diffuse deformation (60–180 μm), indicating a geometrically irregular yet mechanically benign lesion. Stress increased over 200% from Patient 3 to Patient 2, whereas deformation showed no linear relationship with FFR.

Discussion

FSI-derived structural biomarkers distinguished lesions by mechanical relevance, identifying features not captured by pressure-based indices. Stress amplification was the clearest marker of severity, particularly in the borderline case, supporting evidence that local mechanical forces drive plaque evolution [2,3]. FSI therefore complements FFR by revealing wall loading patterns. Larger cohorts and refined wall models are required to assess prognostic value and enable clinical translation.

GPU-Accelerated Cardiovascular FSI in SimVascular

Dr. Sujal Dave, Dr. David Codoni, Dr. Alison Marsden

Stanford University, Stanford, CA, United States

Introduction

High–fidelity fluid-structure interaction (FSI) simulations are central to advancing cardiovascular biomechanics, however, their computational cost remains a major barrier to rapid design, uncertainty quantification, and clinical translation. In this work, we present ongoing efforts to accelerate cardiovascular FSI and CFD simulations within the *SimVascular* [1,2] framework through GPU-enabled computing and investigation of preconditioning strategies.

Methods

Using Trilinos linear algebra libraries with Kokkos for on-node GPU parallelization, we evaluate the performance of several state-of-the-art preconditioners for representative cardiovascular test cases. Our investigation focuses on comparisons between CPU-only and GPU-enabled execution, as well as behaviour of different Trilinos preconditioners at a fixed configuration of eight MPI ranks for both FSI and rigid-wall CFD simulations.

Results

GPU-accelerated solvers provide substantial reductions in wall time compared to CPU-only runs, enabling more efficient parameter sweeps and reduced turnaround times for patient-specific analyses. For a representative Abdominal Aorta Aneurysm FSI case with Diagonal preconditioning, GPU (Ampere80 architecture) execution reduced the wall time from approximately 2200 seconds on CPUs to about 700 seconds, corresponding to a reduction of roughly 65%. For a rigid-wall CFD case with a RILUK(0) preconditioner, GPU (Ampere80) execution yields speedups of 3-4x at the same rank count. Preliminary results indicate that customized preconditioners, particularly algebraic multigrid variants optimized for coupled FSI systems, yield robust convergence and significant wall-time reductions. On the rigid-wall Navier--Stokes system, algebraic multigrid (ML) reduced GPU wall time by approximately 60% compared with Diagonal or ILUT preconditioning under GMRES. For FSI runs, the difference between Diagonal and ML remains modest to a few percentage but still favorable to multigrid.

Discussion

These results indicate that GPU-enabled cardiovascular solvers, combined with carefully selected preconditioners, can deliver significant improvements in computational efficiency. The insights gained here provide a pathway towards routinely deploying large-scale FSI simulations on GPU clusters, ultimately enhancing the modeling capabilities available to the cardiovascular biomechanics community. This work builds on the established open-source ecosystem of *SimVascular* and contributes new directions for its integration with diverse HPC systems.

Biphasic Modeling of a Water-Permeable Arterial Wall Under Steady Axisymmetric Deformation

Graduate Student Takeo Fujiwara MEng student[1], Associate Professor Tomohiro Otani PhD[1], Professor Shukei Sugita PhD[2], Professor Shigeo Wada PhD[1]

[1]The University of Osaka, Toyonaka, Osaka, Japan. [2]Nagoya Institute of Technology, Nagoya, Aichi, Japan

Introduction

Arterial tissue has conventionally been treated as incompressible, while recent experiments have reported large apparent compressibility [1,2]. In vitro arterial inflation tests showed volume increases of up to 40% [1], although the mechanism underlying this behavior remain unclear. In this study, we aimed to clarify the underlying mechanism of arterial compressibility using biphasic modeling approach, in which arterial compressibility arises from interstitial fluid flow driven by pressure differences across the arterial wall.

Methods

Arterial deformation was assumed to be steady, axisymmetric, and in a plane strain state following [1]. The artery wall with permeable nature was modeled as a biphasic porous media composed of incompressible solid and fluid phases. Their mechanical behavior was formulated following [3]. The constitutive law of the solid skeleton was modeled as Fung-type strain-energy density function for distortional part [4]. For volumetric deformation, we applied Simo-type logarithmic function [4,5] in compression and an exponential function in expansion (Fig. (a)). Interstitial fluid flow was modeled using Darcy's law. The governing equations were solved with an in-house finite element solver, and pressure differences ranging from 15 to 160 mmHg were examined (Fig. (a)).

Results

The pressure-total volume relationship showed good agreement with the experimental results of [1] (Fig. (b)). Figures (c) and (d) illustrate the radial distributions of fluid volume fraction and radial Cauchy stress at the pressure differences of 100 mmHg. Fluid volume fraction increased throughout the arterial region, resulting in positive radial stress across the artery wall, with the maximum occurring near the mid-wall.

Discussion

These results demonstrated that biphasic modeling could express the large arterial compressibility observed in recent experiments. Because this behavior cannot be captured using conventional single-phase, incompressible models, the biphasic framework provides a useful basis for understanding the mechanical responses in the artery under physiological loading.

An Analytical Fluid-Structure Interaction Framework for Biomechanical Behaviour of Common Carotid Artery

Mr Muhammad Azhar[1], Mr Hafiz Zeeshan Ali Sardar[2], Mr Muhammad Sohail Ashraf[2], Mr Muhammad Shehryar Naeem[2], Mr Talha Akhtar[1], Mr Muhammad Fasih Iqbal[2], Dr Zia ul Rehman Tahir[2], Dr Parthasarathi Mandal[1]

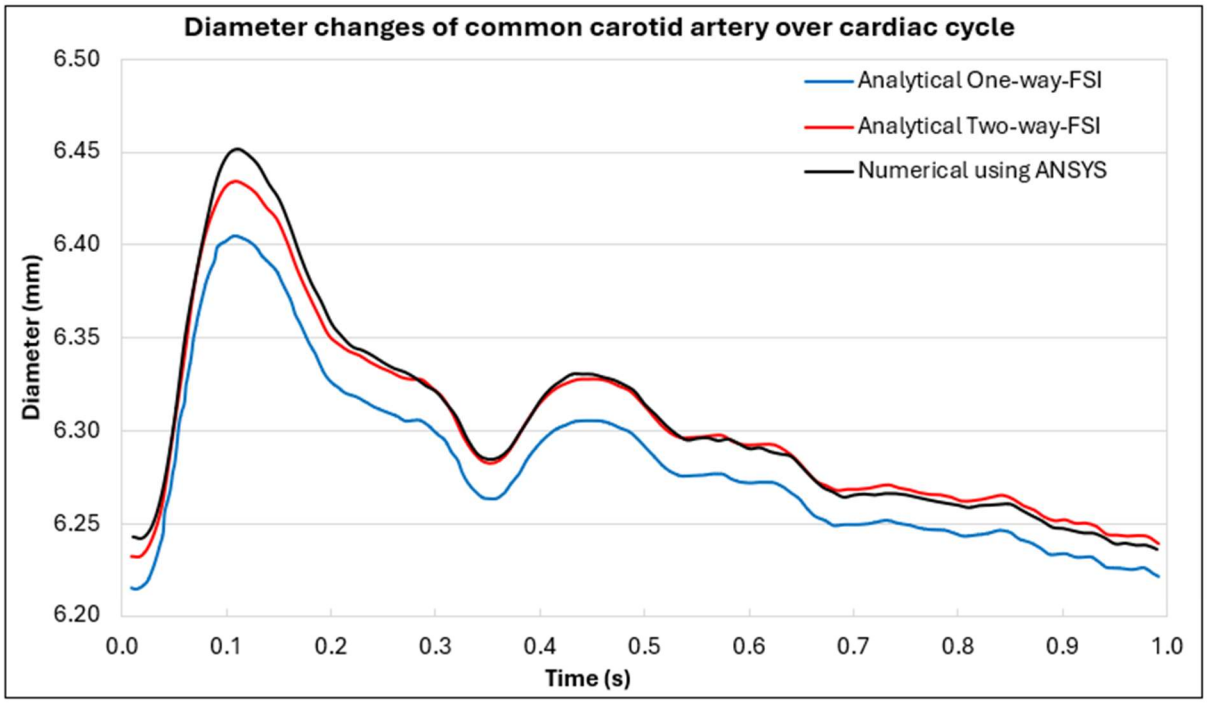
[1]School of Engineering, University of Manchester, Manchestrer, Greater Manchester, United Kingdom. [2]Department of Mechanical Engineering, University of Engineering and Technology, Lahore, Punjab, Pakistan

Introduction

Common Carotid Artery (CCA) is major vessel responsible for carrying oxygenated blood to human brain, which is susceptible to atherosclerotic plaque formation and aneurysm development, resulting in increased risk of stroke, making its analysis important for advancing clinical understanding. Previous studies on investigation of diameter changes over cardiac cycle, often assume the arterial wall as rigid, neglecting physiological compliance of the artery, limiting assessment of its biomechanical behavior. Fluid-Structure Interaction (FSI) analysis of CCA is necessary to fully understand its biomechanical behavior. Novel analytical models using one-way-FSI and two-way-FSI are developed to determine diameter changes over cardiac cycle at any location along CCA.

Methods

Experimental data for CCA were taken from [1]. Inner radius, thickness, length, and modulus of elasticity of the artery was 0.3 cm, 0.7 mm, 10 cm, and 1.0 MPa, respectively [2]. The velocity and pressure profiles of blood over cardiac cycle from Ref. [2] were used to determine diameter changes. Two novel models (one-way-FSI and two-way-FSI) were developed to determine diameter changes. Numerical analysis was performed using ANSYS, structural changes were computed in Transient Structural, whereas changes due to blood flow were computed in Fluent, and both coupled through Coupling System Module.



Results

The diameter changes over cardiac cycle using analytical models (one-way-FSI and two-way-FSI) and numerical analysis are presented in Figure. Three curves follow same physiological trend, with maximum diameter (6.41-6.45 mm) at systole and minimum diameter (6.22-6.24 mm) at diastole, except that analytical one-way-FSI underestimate diameter throughout the cycle.

Discussion

A comparison of results is presented in Table, and percentage difference with respect to experimental results is presented in parentheses. Analytical and numerical systolic diameters fall within range of experimental data, whereas diastolic diameter is slightly higher, with about 2% difference. Analytical one-way-FSI is simpler, yet its results are in close agreement with experimental data. Analytical two-way-FSI model gives similar results compared to computationally intensive numerical analysis. These results support validity of proposed analytical framework and provide real-time assessment of CCA without iterative computation, while retaining underlying physics.

Effect of Cuff Compliance on Oscillometric Blood Pressure Measurements: A Finite-Element Study

Mr Muhammad Azhar[1], Mr Muhammad Fasih Iqbal[2], Mr Muhammad Sohail Ashraf[2], Mr Talha Akhtar[1], Dr Zia ul Rehman Tahir[2], Dr Parthasarathi Mandal[1]

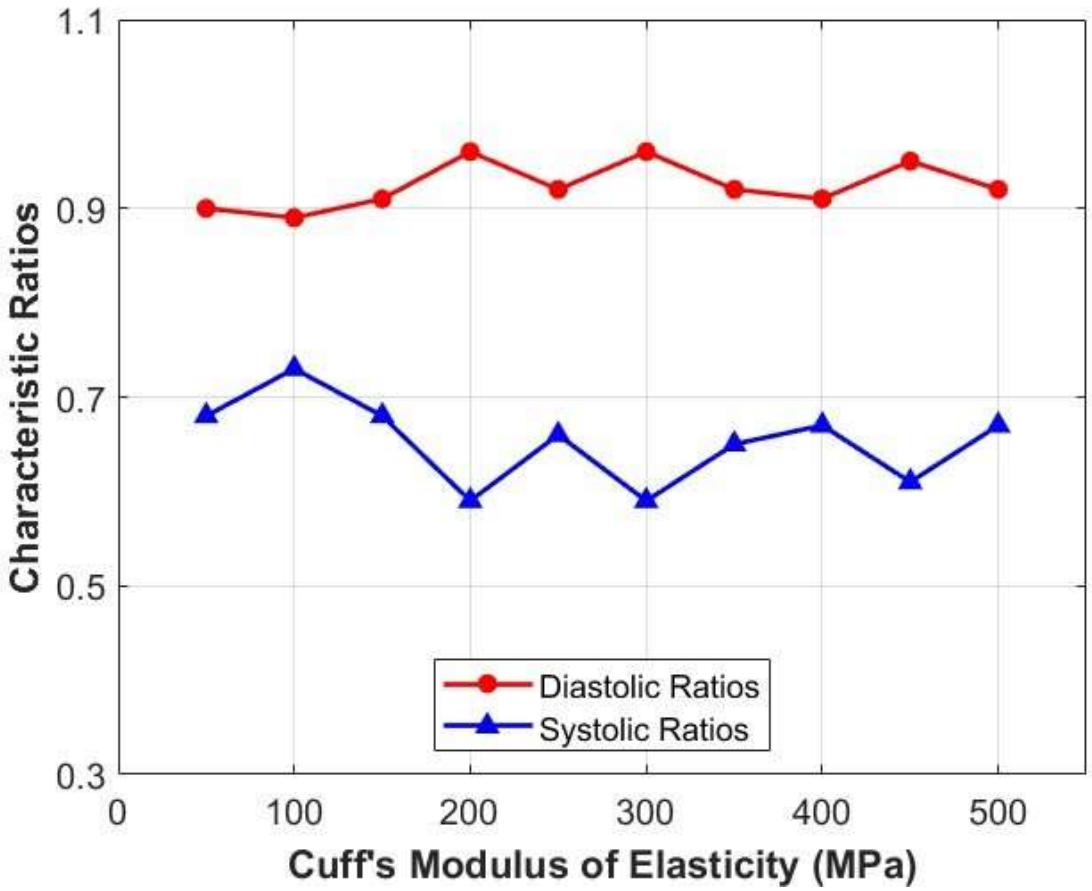
[1]School of Engineering, University of Manchester, Manchestrer, Greater Manchester, United Kingdom. [2]Department of Mechanical Engineering, University of Engineering and Technology, Lahore, Punjab, Pakistan

Introduction

Cuff-based oscillometric devices have become standard way of measuring blood pressure (BP) in clinics and at home, yet concerns regarding their accuracy persist. The cuff remains critical component of BP devices, as it is primarily responsible for pressure transmission to brachial artery, thereby influencing BP estimations. However, limited literature addresses effects of cuff on oscillometric signals. Ursino and Cristalli [1] evaluated effect of cuff elastance for oscillometric BP; however, their assumption of uniform inner wall and omission of cuff buckling constrained the study. The present study instead explicitly considers cuff buckling to systematically evaluate effect of cuff compliance on oscillometric BP using fixed ratios.

Methods

Three-dimensional model of human upper arm was developed in Abaqus CAE, with geometry, material properties, and bladder-less cuff modelling adopted in accordance with literature [2]. The model was analysed using dynamic explicit scheme; cuff was inflated to 150 mmHg over 5 seconds and deflated over 25 seconds. The cuff compliance sensitivity analysis was performed by varying modulus of elasticity from 50 to 500 MPa. For each simulation, oscillometric envelope was obtained by plotting amplitude against cuff-pressure, and characteristic ratios were obtained for respective systolic/diastolic (120/70 mmHg) values.



Results

Change in cuff compliance led to noticeable differences in characteristic ratios; these variations were not systematic, reflecting nuanced influence of cuff compliance. Diastolic ratios ranged between 0.89-0.96 and systolic ratios ranged between 0.59-0.73, as shown in Figure. These variations could be attributed to changes in cuff buckling wave around arm that result in axial redistribution of cuff-arm contact pressure.

Discussion

Ursino and Cristalli [1] reported negligible effect of cuff compliance on characteristic ratios, primarily because of uniform cuff-pressure distribution on arm did not account for cuff buckling. Present study demonstrated that cuff buckling, tends to concentrate loads near fabric folds, and is influenced by fabric compliance. Such load concentrations affect arterial deformations and resulting oscillometric signal used for BP estimations. These findings emphasise need for cuff-specific calibrations that account for cuff compliance given its influence on BP measurements.

Surgical Planning for Neonatal Pediatric Heart Surgery – Optimizing the Configuration of BTT Shunts to Prevent Post-operative Complications

Mr. Tanmay M. Khare MS[1], Dr. Mohan John MD[2], Dr. Kevin O. Maher MD[2], Dr. Subhadra Shashidharan MD[2], Dr. Lakshmi Prasad Dasi PhD[1]

[1]Georgia Institute of Technology, Atlanta, Georgia, United States. [2]Children's Healthcare of Atlanta/Emory University School of Medicine, Atlanta, Georgia, United States

Introduction

The Blalock Taussig Thomas (BTT) shunt is used in the surgical palliation of cyanotic congenital heart diseases. In 30% of the cases, post-operative complications like stenosis or thrombosis develop inside the shunt. Our initial studies on a cohort of 39 patients have identified distinct differences between patients who had complications and those who did not, based on: (a) the location and angle of attachment of the shunts, and (b) flow patterns in the shunt. Using these guidelines, we have developed an in-silico surgical planning pipeline to determine optimal shunt configurations and prevent post-operative complications.

Methods

CT scans done prior to shunt implantation are used to build a 3D patient-specific model of pre-operative geometry. Using CAD software, all surgical steps are performed virtually on this model, and a shunt is constructed to generate a post-operative geometry (Figure 1c). Multiple such geometries are created for each patient by parametrically varying quantities like the location and angle of attachment of the shunts (Figure 1e, 1g). CFD simulations are performed on these new geometries (Figure 1f, 1h) using patient-specific boundary conditions adopted from echocardiogram scans and catheterization lab data. Simulations reveal the presence/absence of a region of recirculating, thrombogenic flow patterns that may develop inside the shunt for each shunt configuration. Similarly, for each patient, CFD simulations are also performed on actual post-operative geometries (Figure 1a).

Results

First, we observed that the flow patterns in the pre-operative geometry with shunt (Figure 1d) are similar to those observed in the actual post-operative geometry (Figure 1b). This demonstrates the ability to mimic the surgical shunt insertion procedure using in silico techniques. The case shown had stenosis near the shunt inlet and flow recirculation region

was also observed near the inlet. Therefore, we demonstrate that we can generate alternative shunt configurations where the flow recirculation regions are eliminated (Figure 1f) or reduced in size (Figure 1h), thus reducing the chances of complication development.

Discussion

This pipeline can serve as a predictive modeling tool for post-surgical hemodynamics and help clinicians design more informed treatment for each patient. It can also help to improve the success rate of this procedure.

Images (Optional)

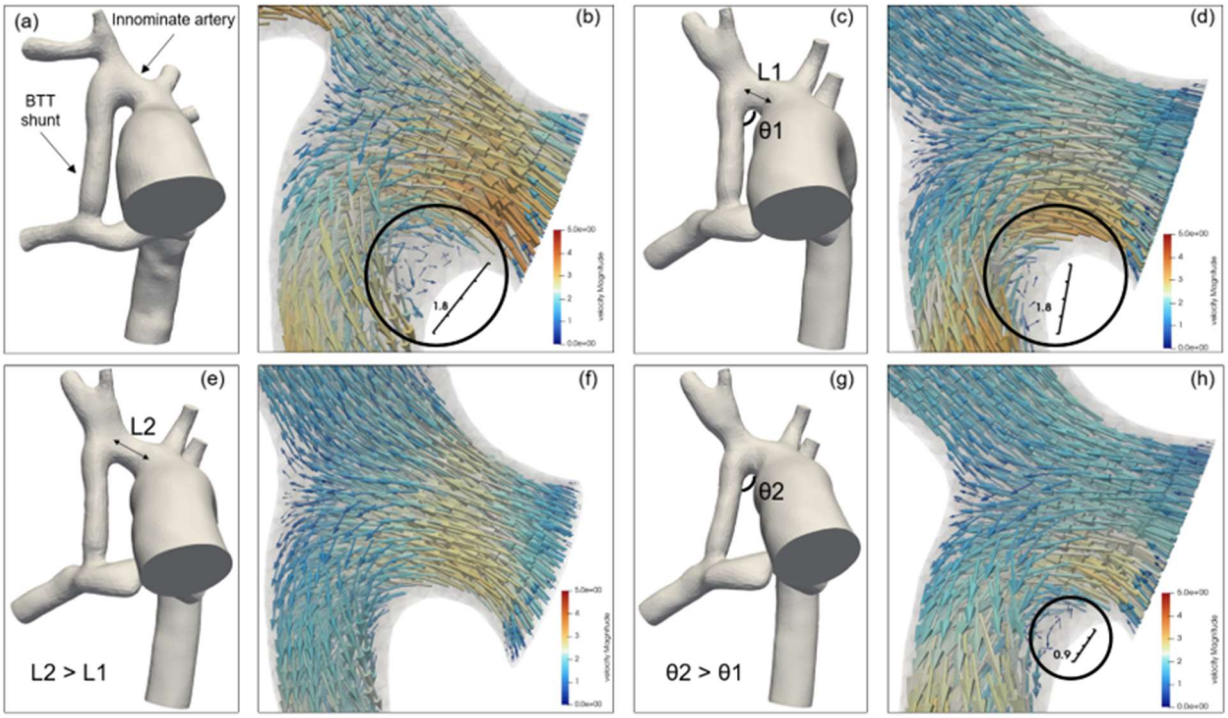

Figure 1: (a) actual post-operative geometry; (b) velocity vectors near shunt inlet of (a) – flow recirculation region highlighted by black circle; (c) shunt constructed in pre-operative geometry; (d) velocity vectors near shunt inlet in (c) – similar flow recirculation region highlighted by black circle; (e) new shunt configuration 1 where the inlet end is attached more distal along the innominate artery as compared to (c); (f) velocity vectors near shunt inlet in new configuration 1 – flow recirculation not observed; (g) new shunt configuration 2 where shunt is attached at a larger angle at the inlet end as compared to (c); (h) velocity vectors near shunt inlet in new configuration 2 – smaller flow recirculation region than original configuration (d) was observed.

Deep Learning Estimation of Pulsatile Intracranial Aneurysm Wall Shear Stress

Mr. Wenhao DING, Dr. Choon Hwai Yap

Imperial College London, London, London, United Kingdom

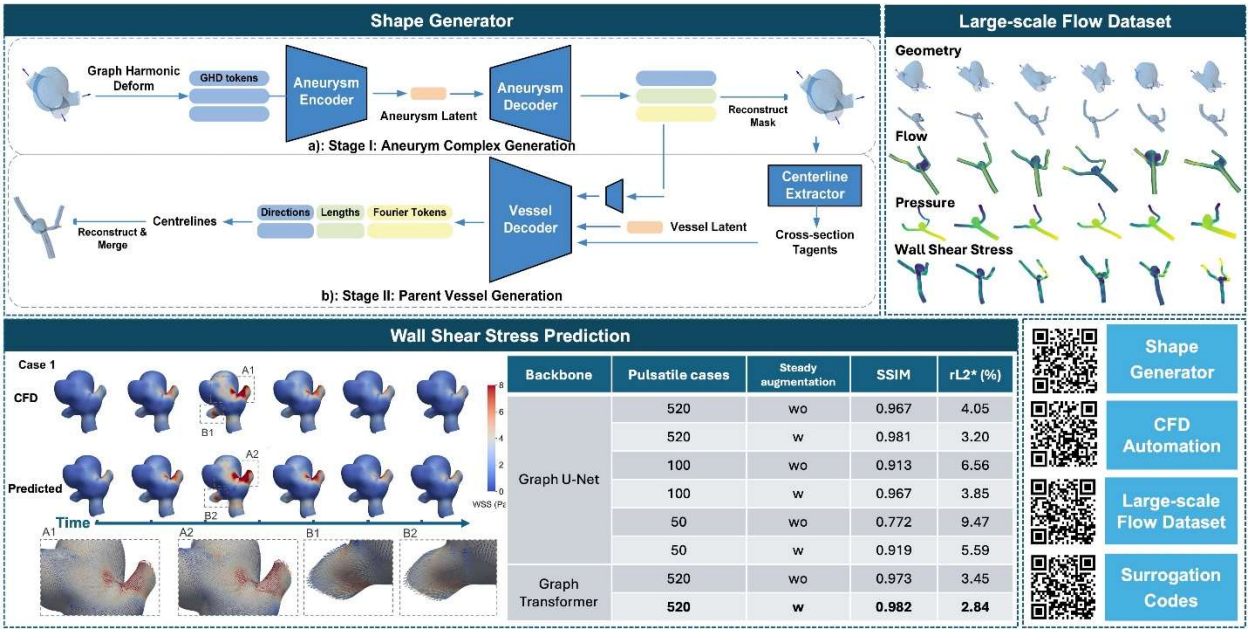
Introduction

Intracranial aneurysm (IA) involves a weakness in the cerebral arterial wall that bulges and carries a potentially lethal risk of rupture. Despite extensive biomechanics studies and meta-analysis suggesting a correlation between fluid mechanics markers and aneurysm instability, these markers have yet to be adopted by physicians, who continue to rely on simple morphological markers to assess risks, even though this is inaccurate (false-positive rates up to 56%). Key reasons for this are that computational fluid dynamics (CFD) simulations are time-consuming and require specialized expertise. So physicians are unable to obtain sufficiently large samples of fluid dynamics data to evaluate their clinical utility.

We developed a deep learning (DL) framework to address this. We built a DL aneurysm generator to overcome scarce clinical data and used it to create a large CFD dataset for training a WSS predictor, which can be used without CFD skills for real-time, high-throughput predictions.

Methods

Our DL IA shape generator is a two-stage conditional VAE trained with 109 patient-specific IA morphologies [1], producing both the aneurysm pouch and its parent vessels suitable for CFD simulations. Next, mass shape generation and CFD simulations produced a large dataset with 16,000 steady and 730 transient simulations on diverse morphologies [2]. Finally, we utilized a graph Transformer to predict WSS over a full cardiac cycle, using cotangen-Laplacian eigenvectors as positional encoding. Codes and datasets are publicly shared (figure's QR codes).



Results

Our model captures WSS pattern evolution across diverse geometries, achieving excellent spatial pattern (SSIM =0.981) and WSS magnitude accuracy (maximum-normalized relative L2 error = 2.84%). The augmentation with steady data substantially improves generalization, and allowed very few transient training data (even with <100) to achieve decent accuracy.

Discussion

We present the first DL model for pulsatile IA WSS prediction, and will also work for other parameters (OSI, pressures). Future work includes expanding boundary conditions and including IAs with different topologies.

Numerical Assessment of Collateral Circulation for Ischemic Relief in Coronary Chronic Total Occlusion

Mr. Wonjin Choi[1], Mr. Se Hyeog Kim[1], Mr. Hyeok Sul Kwon[1], Prof. Jung-Kyu Han[2], Prof. Bon-Kwon Koo[2,3], Prof. Hyun Jin Kim[1]

[1]Korea Advanced Institute of Science and Technology, Daejeon, Daejeon, Korea, Republic of. [2]Seoul National University Hospital, Seoul, Seoul, Korea, Republic of. [3]Seoul National University College of Medicine, Seoul, Seoul, Korea, Republic of

Introduction

Coronary chronic total occlusion (CTO) can lead to severe myocardial ischemia, and clinical outcome depends not only occlusion site and lesion length but also the extent and functional effectiveness of collateral circulation. However, current clinical assessments rely largely on imaging findings or coarse clinical measurements, offering limited quantitative insight into the hemodynamic contribution of collaterals. In this work, we quantify the role of collateral vessels in ischemia relief using numerical modeling applied to both idealized and patient-specific CTO configurations.

Methods

Coronary arteries were reconstructed as 1D vascular trees from clinical imaging. CTO lesions were artificially introduced in proximal, mid, and distal segments of major arteries [1]. We generated 500 collateral configurations per scenario, uniformly sampling the number of collaterals (1-20) and diameters (0.01-0.10 cm). Donor–recipient segment pairs followed clinical distributions [1], with anatomically realistic paths along ventricular epicardial surfaces. Hemodynamics was simulated using an in-house reduced-order solver for 1D vascular networks, enabling efficient evaluation of thousands of CTO-collateral combinations. Fractional flow reserve (FFR) was computed as the primary indicator of collateral efficacy. Gaussian process regression was employed for sensitivity analysis to identify key determinants of collateral performance.

Results

Collateral diameter was the dominant factor influencing FFR improvement and ischemia relief in the idealized model. When collateral diameter fell below a critical threshold, ischemic relief was minimal regardless of the number of collaterals. Beyond specific thresholds in diameter and vessel count, FFR improvements reached saturation, indicating diminishing hemodynamic benefit with further enlargement or collateral addition. In the

patient-specific model, collaterals reconstructed from angiographic data contributed only marginally to perfusion support, consistent with trends observed in idealized simulations.

Discussion

This study quantitatively demonstrates that angiographically visible collaterals provide limited perfusion support unless their diameters exceed a critical threshold. While functional variations existed across proximal, mid, and distal lesions, FFR rarely exceeded the clinical threshold, implying that collateral circulation alone does not guarantee clinically meaningful perfusion improvement. The proposed *in silico* framework enables an efficient, patient-specific evaluation of collateral function and provides a computational foundation for future decision-support tools in the management of coronary CTO.

The Influence of Viscoelasticity on the Transition to Turbulence in Blood Flow: An in Vitro Study Using Ultrasound Particle Imaging Velocimetry

Ms Ying Hu, Dr Lee Nissim, Dr Katharine Fraser

University of Bath, Bath, England, United Kingdom

Ms Ying Hu

Dr Lee Nissim

Introduction

Blood is viscoelastic, combining shear-thinning viscosity and elasticity. Experimentally a delayed transition-to-turbulence in comparison with Newtonian rheology is clear, however, the source of contribution is obscure. Studies assessing the influence of shear-thinning rheology have conflicting conclusions.

To investigate the independent influence of elasticity on the transition-to-turbulence, viscoelastic blood analogues were studied in a pipe flow rig using ultrasound particle imaging velocimetry (echo-PIV).

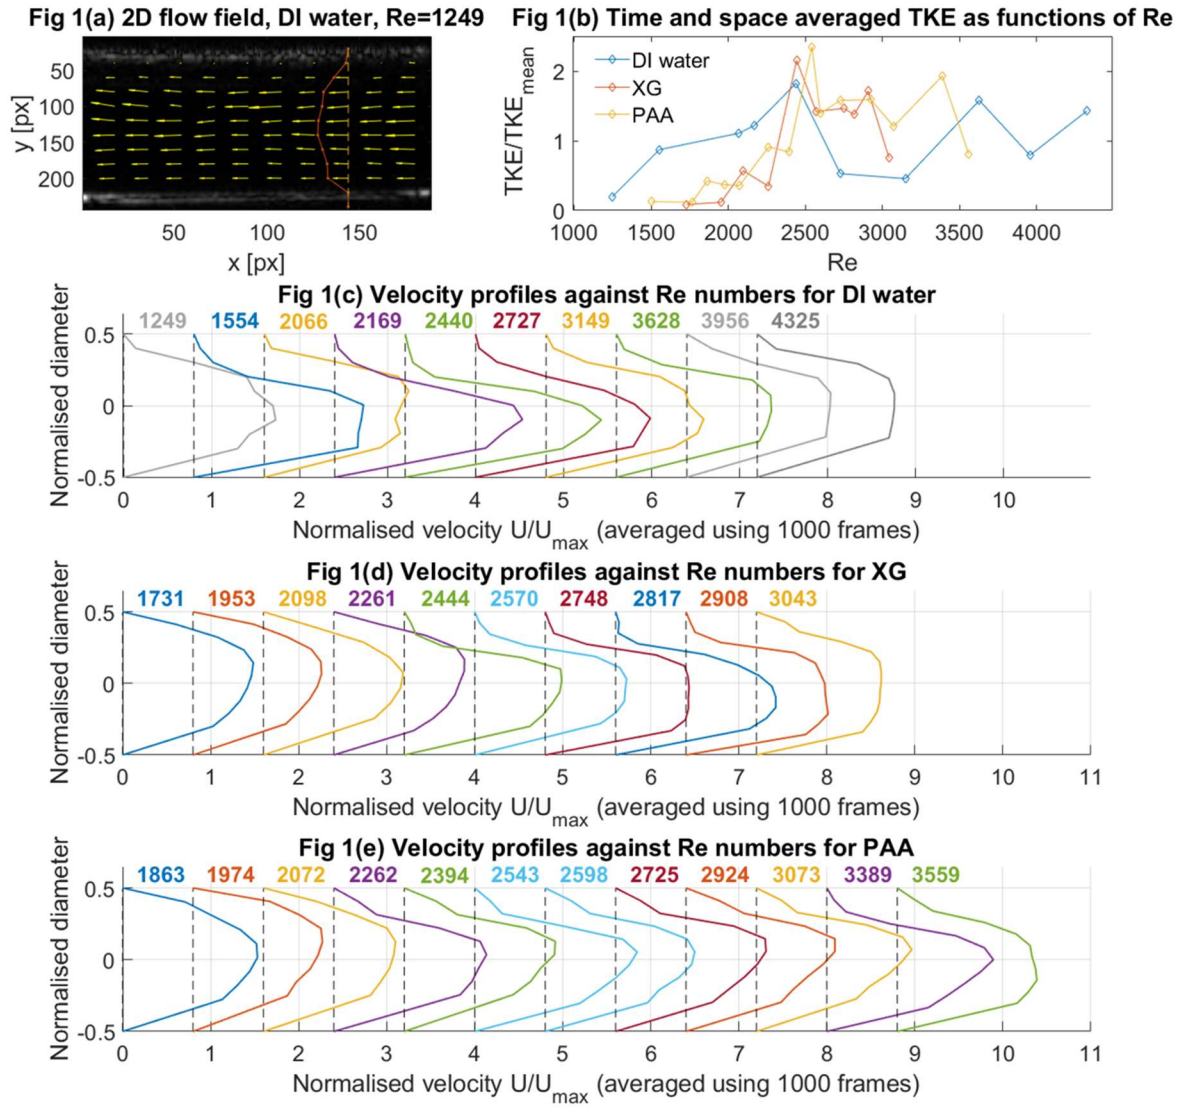
Methods

A pump supplied continuous flow through an 8 mm pipe flow geometry, measured by a flowmeter (em-tec GmbH). Two blood analogues with matched shear-thinning viscosity corresponding to real blood were prepared: xanthan gum solution (XG, 500 ppm, w/w) with a relaxation time of 3.8 ms; and polyacrylamide solution (PAA, 125 ppm, w/w) with a relaxation time of 38 ms. Deionised water was used as a Newtonian control.

An ultrasound research platform (Vantage 256, Verasonics) with linear transducer (GE Healthcare) was used for high-temporal-spatial-resolution B-mode image acquisition. A low concentration of Hollow Glass Spheres (Dantec Dynamics, 10 um) was used as contrast agent for motion tracking.

A custom iterative cross-correlation with correlation plane averaging, window size-reduction and image-deformation features was applied. The calculated 2D vector fields

have temporal resolution of 17.63 fps (Newtonian) and 8.5 fps (XG and PAA), and spatial resolution of 1.6 x 4.14 mm (depth x lateral).



Results

Transient vector fields (example Fig1(a)) were used to calculate turbulent kinetic energy (TKE), used as the marker of the transition-to-turbulence (Fig 1(b)). Peaks of TKE (Fig 1(b)) show that elastic analogue (PAA) delays transition-to-turbulence, in comparison with shear-thinning (XG) and Newtonian (water). The evolution of the velocity profiles with Re (Fig 1(c–e)) further distinguishes the behaviour of water, low-elasticity-shear-thinning, and high-elasticity-shear-thinning analogues.

Discussion

Although the elasticity of blood, caused by the deformation of blood cells and aggregation, is small compared to high-elastic polymer solutions, this study found blood's elasticity caused a measurable delay in transition-to-turbulence, consistent with the drag-reduction phenomenon found in high-elastic flows. This work contributes to the knowledge on the interaction between haemorheology and haemodynamics, which is the key to improve current design of blood contacting medical devices.

Production Of viable cardiac muscle strips From frozen tissue for Mechanical Experimentation

Mr Zisen Zhou[1,2], Prof Andrew Taberner[1,2], Dr June-Chiew Han[1,2], Dr Julia Musgrave[1,2], Associate Professor Kenneth Tran[1,2]

[1]University of Auckland, Auckland, AKL, New Zealand. [2]Auckland Bioengineering Institute, Auckland, AKL, New Zealand

Introduction

Human cardiac tissue biorepositories provide an invaluable resource for studying cardiac physiology and pathology, offering samples linked to detailed clinical records. These repositories enable retrospective, large-scale investigations of disease mechanisms. However, mechanical experiments often require homogenisation of tissues into multicellular preparations, which can be challenging to handle and manipulate for mechanical experimentation. To overcome these limitations, we propose a method for generating cardiac muscle strips from frozen tissue samples that preserves structural integrity and enables high-throughput mechanical testing.

Methods

Cardiac tissue blocks were excised from the left ventricular free wall of healthy rats (n = 6) and frozen at –80 °C. After storage, blocks were thawed in Tyrode's solution (4 °C) containing 2,3-butanedione monoxime to inhibit cross-bridge cycling. Each block was mounted in a custom vibratome oscillating at 80 Hz with 1 mm peak-to-peak amplitude to produce 300 µm-thick slices. Parallel blades spaced 1.2 mm apart cut each slice into muscle strips (1.2 mm wide, 3–4 mm long). Prior to cutting, slices were oriented so fibres were parallel to the blades. Strips were permeabilised in 1% Triton solution at 4 °C for 20 hours before mounting in our custom muscle mechanometer [1], consisting of a length motor for precise muscle length control and a force transducer. Strips were stretched to 2.2 µm sarcomere length, activated in pCa 4.5 solution, and subjected to sinusoidal length perturbations (amplitude 0.25% of muscle length) at frequencies from 0.1–200 Hz to determine complex modulus. This measurement allows quantification of actively cycling cross-bridge kinetics. Passive and active force–length relationships were also measured by varying muscle length.

Results

Frozen muscle strips exhibited force–length characteristics and complex moduli comparable to those of fresh cardiac trabeculae. The preparation method consistently produced viable strips suitable for mechanical testing.

Discussion

We developed a reliable system for producing muscle strips from frozen cardiac tissue samples, routinely available in biorepositories. This approach enables high-throughput mechanical experiments without reliance on fresh tissue, significantly expanding opportunities for large-scale studies of cardiac mechanics in health and disease and facilitating integration with clinical datasets.

The Effects of Femoral Anteversion/Retroversion on Squatting Biomechanics in a Straight and Externally Rotated Foot Position

Dr Scott Lynn PhD[1,2], Mr Logan Kaptis DPT[2], Mr Dylan Darling DPT[2], Ms Abigail Brittain MS[2], Dr Abigail Schmitt PhD[3,2]

[1]California State University, Fullerton. Center for Sport Performance., Fullerton, California, United States. [2]University of Arkansas Medical School (UAMS), Little Rock, Arkansas, United States. [3]University of Arkansas. Health, Human Performance and Recreation., Fayetteville, Arkansas, United States

Introduction

The squat is a fundamental movement pattern requiring large contributions from the hip joint. Optimal squatting technique may need to vary based on an individual's anatomical hip structure. One aspect of hip structure that should be considered is hip version, as malalignments have been associated with various pathologies of the lower extremity[1-2]. Individuals with anteverted hips may avoid squats that require significant external rotation, while those with retroverted hips may struggle with a standard squat set-up (feet pointed straight forward). This study examined the differences in squat biomechanics between a more anteverted (ANT) and retroverted (RET) group in two squatting tasks: feet forward (STR) & feet externally rotated (EXT). We hypothesized that the ANT group would squat deeper in the STR condition, and the RET group would squat deeper in the EXT condition.

Methods

46 healthy participants volunteered for this study (24 male, age: 31.1±5.5 years). Participants wore a full body marker set and performed two sets of 5 squats in two different conditions in random order: STR and EXT. Craig's Test was then performed by a single experienced clinician to determine hip version for each subject. Kinematic data was used to calculate the center of mass displacement during the squat and normalized to standing height. Participants were split into 2 groups (ANT & RET) based on their Craig's Test results. A 2x2 mixed model ANOVA (group x condition) compared squat depth.

Results

Craig's Test results for the ANT and RET group (n=23/group) were 33.7±6.3 deg and 19.0±5.2 deg, respectively. Squat depth results are shown in Table 1. The interaction effect was not significant (p=.327).

Discussion

Our hypothesis was not supported, indicating other factors need to be considered to better understand these squat patterns. Compensations such as forward trunk lean and knee valgus could be used to lower the center of mass in an unfavorable alignment condition and should be investigated. Further research should also consider using medical imaging to better quantify hip version alignments.

Images (Optional)

Table 1. Squat depth for the more anteverted and more retroverted groups in both the straight and externally rotated foot position.

Anteverted (n=23)		Retroverted (n=23)	
Straight	External	Straight	External
47.0 ±5.4%	46.8 ±5.5%	48.7 ±6.1%	49.1 ±5.3%

- All numbers presented as the maximum depth of the center of mass (CoM) during the squat presented as a percentage of standing height. Calculated as % = (CoM standing height – Lowest position achieved by the CoM during the squat)/ (CoM standing height)
- Note: No significant group (anteverted/retroverted) x squat condition (straight foot position/externally rotated foot position) interaction (p=.327).

Spatiotemporal Gait Parameters and Cancer: Preliminary Data From Clinical Patients With Cancer

Dr Abigail Schmitt PhD, Mr. Yale Hughes MS, Dr Nicholas Greene PhD

University of Arkansas, Fayetteville, AR, United States

Introduction

Despite acceptance of clinical gait assessments in some fields, including orthopaedics, widespread adoption of gait and functional assessments in oncology are lacking. Cancers and cancer treatments can negatively impact the musculoskeletal and nervous systems, yielding diminished muscular strength and physical function related to adverse outcomes and reduced overall survival. Chemotherapy-induced neurotoxicity is associated with sensory and motor symptoms leading to poorer physical function and gait and balance impairments. Collectively, these symptoms and side-effects reduce functional independence, increase fall risk, and reduce quality of life.

Clinical trials and cancer research recognize the need to evaluate physical function but debate how to best characterize impairment. Preclinical evidence suggests gait speed as a potentially viable biomarker for functional decline, but very few cancer clinical trials include a gait outcome. Thus, we developed a clinical partnership incorporating comprehensive gait assessments into the clinical workflow of a large, regional oncology center to evaluate the viability of spatiotemporal gait data to serve as a biomarker of physical function. Herein, we provide a preliminary assessment of gait data from a clinical population with cancer.

Methods

Gait assessments are available to all cancer patients at a major, local oncology clinic. Patients are recruited, consented, and subsequently administered a gait assessment on a 16’ instrumented pressure-sensing Zeno Walkway. Electronic medical records (EMR) data are used to align cancer diagnoses and stage to gait assessments.

Results

As of this report, gait data has been collected for 213 unique patients, 43 of which have complete gait and EMR data with staging available. The sample was 54% female, 68±11

years (range: 38-91), across 22 cancer types, with 27% Stage I, 17% Stage II, 15% Stage III, 33% Stage IV, 8% other/unavailable. For this initial report, patients were grouped by cancer severity (Stage I-II vs Stages III-IV) due to low staging data availability and compared using *t*-tests (Table 1, alpha= .05).

Discussion

These preliminary data demonstrate feasibility and practicality of integrated gait assessments in an oncology setting. These pilot data are collapsed across types and stages of cancer; subsequent analyses will disaggregate data for cancer type and stages as additional data allows.

Images (Optional)

Table 1. Mean ± standard deviation of spatiotemporal gait variables for Stages I-II (*n*= 20) compared to Stages III-IV (*n*= 23). Cadence differed significantly between groups; patients with more advanced disease took fewer steps per minute.

Biomechanical Evaluation of Cervical Degeneration Using Patient-Specific Finite Element Models

Mr Afonso Silva[1], Dr Fábio Fernandes[1], Dr Alfredo Calheiros[2], Dr Ricardo Alves de Sousa[1]

[1]TEMA - Centre for Mechanical Technology and Automation, University of Aveiro, Aveiro, Aveiro, Portugal. [2]CHUSA - Centro Hospitalar Universitário de Santo António, Porto, Porto, Portugal

Introduction

Cervical spondylotic myelopathy (CSM) is frequently encountered in middle-aged and elderly patients. Aging may lead to the development of bone spurs, thickened ligaments, and herniated discs, ultimately causing spinal cord compression that can progress to spinal cord injury [1]. Despite an estimated prevalence of 1 in 50 adults, fewer than 20% receive a formal diagnosis, largely due to the nonspecific presentation of early symptoms [2]. Surgery remains the only effective treatment but is generally reserved for patients with moderate-to-severe or progressive disease because of associated risks. Given these limitations, there is a need for methods that enable detailed biomechanical assessment of the spine under varying pathological conditions. This work aims to develop finite element (FE) models to improve understanding of CSM dynamics.

Methods

Two patients with different degrees of cervical degeneration were selected. Model geometries were reconstructed using CT-scans and MRIs. Each FE model included vertebrae, intervertebral discs (IVDs), facet joints, and ligaments. Isotropic linear elastic material properties were assigned to rigid structures (bone and cartilage), whereas hyperelastic formulations were applied to IVDs and ligamentous tissues to more accurately represent physiological behavior under degenerative conditions. Both models were subjected to pure moments of 1 Nm in flexion, extension, axial rotation, and lateral bending, and the range of motion (ROM) was quantified for each loading scenario.

Results

Model validations were conducted by comparing FE results with published in-vitro data [4]. Further comparison with a previously developed healthy cervical FE model [5] enabled assessment of degenerative effects. Degenerated levels demonstrated reduced ROM and increased stress in adjacent IVDs.

Discussion

Preliminary findings indicate increased stiffness in the cervical spine associated with degeneration, with elevated IVD stress likely reflecting compensatory biomechanical responses. Limitations arise from the use of healthy-subject experimental data for initial validation, an aspect currently being refined. Overall, this work establishes a promising framework for advancing computational tools that may support clinicians in optimizing treatment strategies.

Altered Organization of Muscle Synergies during Forward Bending in People with Low Back Pain and Preliminary Evidence of Exercise Efficacy for Restoring Neuromuscular Control

Assistant Professor Ahyoung Song Ph. D.[1], Post-Doctoral Research Associate John Gillilam DPT, Ph. D.[2], Associate Professor Sheri Silfies PT, Ph. D.[3]

[1]Texas State University, Round Rock, Texas, United States. [2]University of Florida, Gainesville, Florida, United States. [3]University of Delaware, Newark, Delaware, United States

Introduction

Although prior literature has identified alterations in the activation and timing of individual trunk muscles in low back pain (LBP) [1], the neuromuscular control strategies that manifest these alterations remain unclear. This study aimed to elucidate the underlying structure of trunk muscle synergies in persons with LBP during an active forward-bending task, to compare these synergies with those of healthy adults (HA), and to examine changes in neuromuscular control following an 8-week motor-learning-based lumbar stabilization program (MLB-LSP).

Methods

Surface electromyography (EMG) of 16 trunk muscles of 25 HA and 25 persons with LBP was recorded during 6 repetitions of forward bending and return to standing. EMG signals were time- and amplitude-normalized and averaged. Non-negative matrix factorization was performed to extract muscle synergies, and the best-matching scalar product of weighting coefficients was used to calculate the similarity between synergies.

Results

5 synergies explained over 95% of the variance in both groups (Figure 1). In HA, 3/5 synergies were dominated by the trunk extensors, 1 by the trunk flexors, and 1 was mixed. In the LBP group, we observed the merging of 2 synergies present in the HA into a single mixed synergy, suggesting increased co-contraction as a strategy for trunk control. While 4/5 synergies were consistent across groups, there were significant differences in weighting coefficients and temporal patterns within these synergies. The LBP group's muscle contributions were predominantly reduced in lumbar multifidus and internal oblique with a redistribution to other extensor and flexor muscles. Following the MLB-LSP, the LBP group's 5 synergies aligned more closely with those of the healthy group, including splitting

the previously merged synergy into separate and aligned trunk flexor and extensor synergies.

Discussion

These data provide evidence of altered muscle-synergy structure in persons with LBP and preliminary evidence that MLB-LSP may alter the synergies used during a common functional task. Changes in muscle synergies aligned with improvements in patient-reported symptoms and function. Data from this study moves beyond identifying individual muscle impairments to consider how movement strategies differ in the presence of pain and change with targeted treatment.

Images (Optional)

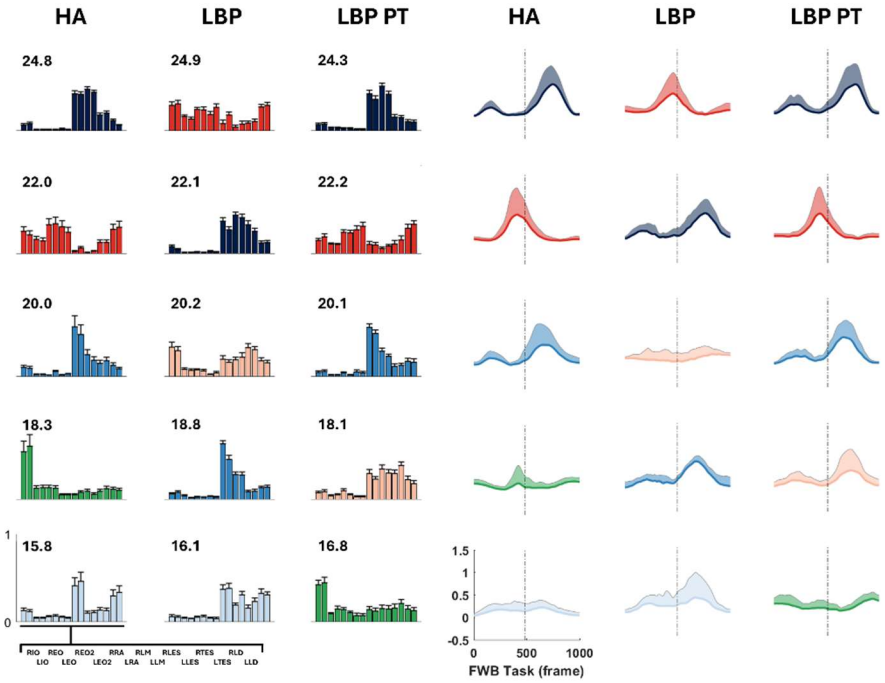

Figure 1. Summary of muscle synergy patterns of the HA and LBP groups at baseline and post-intervention (LBP PT). (Left) Group averaged weighting coefficients and standard error (+SE) of extracted muscle synergies with the same color indicating representing the same synergy (mean scalar product greater than 0.8). Averaged variance accounted for in EMG reconstruction is presented in the upper left corner of each weighting coefficient bar graph. (Right) Temporal activation patterns of extracted synergies, with group standard deviation. The vertical line separates the forward bending phase from return to standing. Extensor synergies presented in blue color scheme (dark blue, blue and light blue). Mixed synergies presented in red color scheme (dark red, light red). Flexor synergy presented in green.

Exploring the Knee Loading Variability in Parkinson's Disease With the Stochastic Modelling Approach

Mr. Alex Bersani Ph.D. candidate, Mr. Marco Viceconti Ph.D., Professor, Mr. Giorgio Davico Ph.D., Assistant professor

University of Bologna, Bologna, Italy, Italy

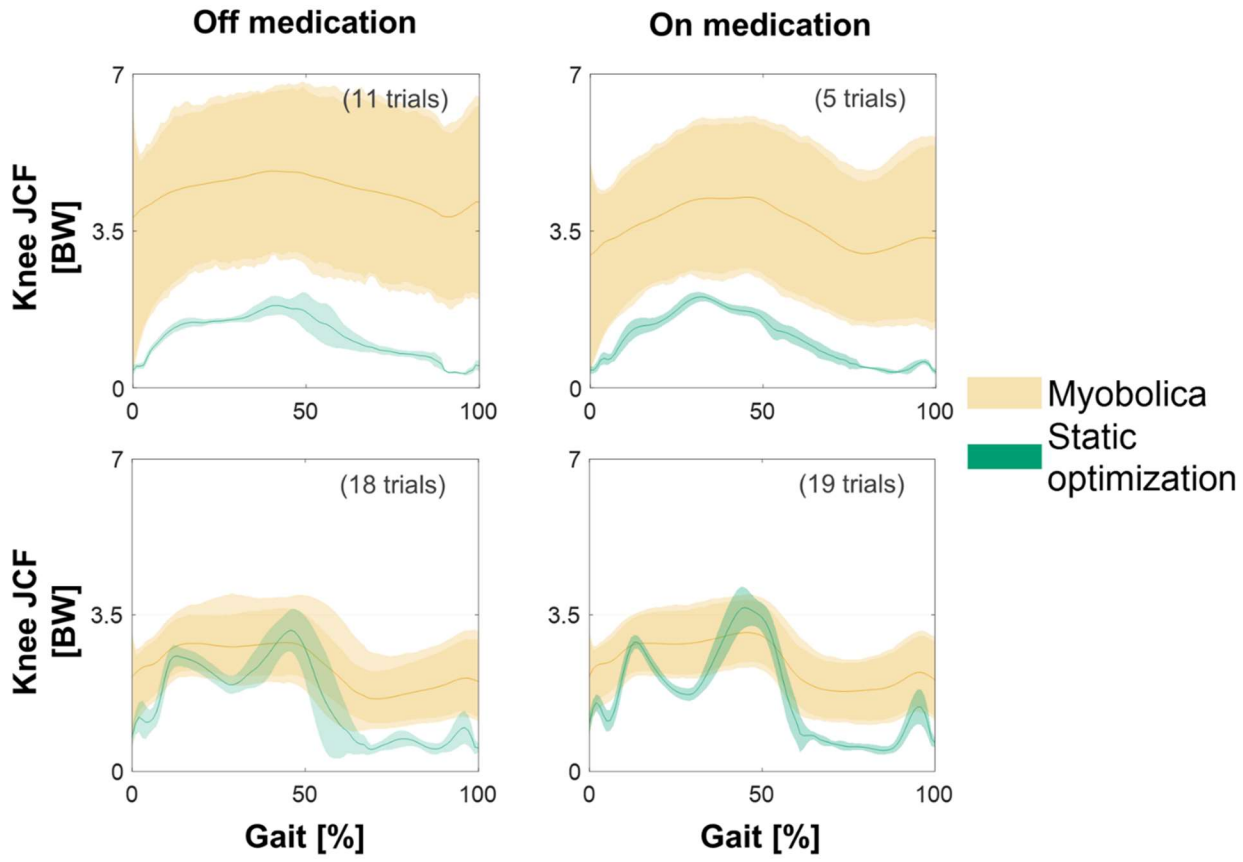
Introduction

Parkinson's disease (PD) is a neurodegenerative disorder affecting about 1-2 % of the population over the age of 65. People with PD exhibit a wide range of mobility disabilities, including tremor, rigidity, and freezing of gait. As there is no cure for PD, current treatments aim to reduce physical and functional impairments. However, novel wearable sensors allow to monitor disease status and progression, providing clinicians with objective assessments in real world conditions. In addition, computer models and simulations can provide further insights by allowing to explore how suboptimal is the motor control in people with PD. In particular, the use of stochastic approaches to estimate the effect of multiple control strategies onto muscle and joint biomechanics, may allow to study neuromuscular control in PD.

The aim of this work was to explore the effect of dopaminergic medication on the knee joint loads experienced during walking and predicted by a stochastic approach [1], in a group of people with PD.

Methods

Motion capture and force plates data from a publicly available dataset [2] were employed in this preliminary analysis on four subjects with PD (age: 46-74 year-old, Hoehn & Yahr, H&Y: I-IV). The generic "Full Body Model" [3] was scaled to match subjects' anthropometry and used to perform stochastic simulations within Myobolica to estimate 200k feasible solutions.



Results

Preliminary results showed marginally larger solution bands and higher values in the "off" medication trials, especially true for the most impaired case (Figure 1 shows results for two selected subjects compared to the static optimization solution; line 1: H&Y IV, line 2: H&Y II).

Discussion

The stochastic approach showed joint load and neuromotor control variability reduction in the preliminary subjects (Figure 1) as well as deviations from a typical healthy gait, underlining the impact of impaired kinematics on joint loading. This work provides an initial foundation for evaluating PD-related joint loading, showing that quantitative modelling of altered neuromuscular control may offer deeper insights into disease mechanisms and provide valuable information.

9-Month Test-Retest Reliability of the Shoulder 3D Kinematics in an Asymptomatic Control Group to Support RCRSP Evaluation

Dr Aliah F Shaheen Reader in Biomechanics, Miss Alexa McCloskey Medical Student, Mr Harry Ford Doctoral Researcher and Physiotherapist

Brunel University London, Uxbridge, London, United Kingdom

Introduction

Reliable shoulder motion assessment is critical for monitoring recovery and guiding return to sport decisions in individuals with rotator cuff-related shoulder pain (RCRSP). Limited standardization and reliability data restrict accurate interpretation of longitudinal outcomes. This study evaluates the test-retest reliability of a 3D shoulder motion protocol used within a larger investigation comparing healthy participants with individuals recently rehabilitated from RCRSP. The objective is to assess the reliability of the range of motion (ROM) and joint kinematic measures for control participants between sessions, separated by 9 months.

Methods

Nine healthy controls performed 30 standardized upper-limb movements, including glenohumeral abduction, glenohumeral flexion, and functional tasks. Reflective markers were placed on the upper and lower limbs to allow the construction of coordinate systems for the pelvis, thorax, scapulae, humeri, forearms, hands, the right thigh, shank, and foot. 3D motion was collected using Qualisys Track Manager and processed and analyzed in Visual3D to calculate 3D kinematics based on the ISB recommendations. Reliability metrics were computed using Excel (means, standard deviations, and calculation of minimal detectable change [MDC]) and SPSS (intraclass correlation coefficients [ICC 3,1] with 95% confidence intervals). ICC interpretation followed established thresholds (ICC >0.75 = good reliability).

Results

Most movements demonstrated excellent reliability (ICCs >0.9). Two of the computed joint angles, glenohumeral flexion and maximum hip flexion, demonstrated lower reliability (ICCs < 0.60). MDC values ranged from 0.5° to 23°, reflecting variability in measurement reliability and error across motion parameters.

Discussion

This analysis confirms excellent test-retest reliability for the majority of shoulder kinematic variables, supporting their use for longitudinal biomechanical assessment. Establishing MDC values enables differentiation between true change and measurement error, strengthening their clinical application. Movements with lower reliability suggest opportunities for refinement, such as improving marker placement or reducing movement variability by providing clearer instructions. Certain movements, such as hip flexion, were expectedly low as they are designed to assess variation in movement strategy between individuals in activities of daily living. Overall, the validated measures provide a stable reference for the broader study examining RCRSP recovery trajectories.

[3]Universidade Federal do Rio de Janeiro (UFRJ), Rio de Janeiro, Rio de Janeiro, Brazil. [4]Midwest Orthopaedics at Rush (MOR), Chicago, Ilinois, United States

Introduction

Scapular dyskinesis has been recognized as a key biomechanical factor contributing to shoulder pain and dysfunction in individuals with subacromial pain syndrome (SAPS). Among the contributors, pectoralis minor tightness has been proposed as a determinant of altered scapular kinematics, though its impact on three-dimensional scapular kinematics and shoulder strength remains unclear. The objective of this study was to investigate the influence of pectoralis minor tightness and the presence of SAPS on shoulder kinematics and strength.

Methods

A cross-sectional analysis was performed using a biokinetic database of 38 participants (24 males, 14 females; mean age 42±12 years) diagnosed with SAPS and presenting healthy contralateral shoulders. Patients were stratified according to pectoralis minor index (PMI) median (<8.24 vs. ≥8.24) and both shoulders of each patient were analyzed. Kinematic assessment included active abduction in the scapular plane (0–120°). Primary outcomes were scapulohumeral rhythm, scapular upward rotation, posterior tilt, and internal rotation across elevation. Secondary outcomes were isometric strength in flexion, internal and external rotation. Two-way ANOVA assessed the effects of pathology and PMI on kinematic and strength outcomes.

Results

When all shoulders were analyzed together using a two-way ANOVA with Pathology (SAPS vs. healthy) and PMI group (tight vs. normal) as factors, a significant main effect of PMI group was observed for scapular vertical excursion. Post-hoc analyses showed that “tight” shoulders demonstrated greater vertical excursion than “normal” shoulders during the

concentric phase of scaption—below 90° (mean difference=3.3°, p=0.03; Cohen's d=0.54) and above 90° (mean difference=5.6°, p=0.04; d=0.51) (Table 1). No significant main effects of Pathology were found for any scapular or humeral variables (p>0.05). Passive range of motion and isometric strength also did not differ significantly between groups (p>0.05).

Discussion

The results suggest that shorter muscles were associated with increased vertical scapular displacement during elevation, whereas strength and passive mobility were minimally affected. These findings suggest that altered scapular coordination may occur independently of substantial strength deficits and without consistent changes in traditional movement planes. The preserved isometric strength in this cohort indicates that scapular kinematic alterations in subacromial pain syndrome can occur without marked strength deficits, particularly in early or moderate stages.

Images (Optional)

Table 1: Two-Way ANOVA Results for the Effects of Pathological Status (Subacromial Pain Syndrome [SAPS] vs. Non-Affected Shoulder) and Pectoralis Minor Index (PMI) (Tight: <8.24 vs. Normal: ≥8.24) and interactions between Pathological Status and PMI on Shoulder Kinematics during arm elevation (scaption)

Movement	Effect	p

P4-137

Spatiotemporal Responses to Various Dual-Tasks in Children with Autism

Dr Alyssa O Vanderlinden PhD, Ms Alyssa Moreno MS

New Mexico State University, Las Cruces, NM, United States

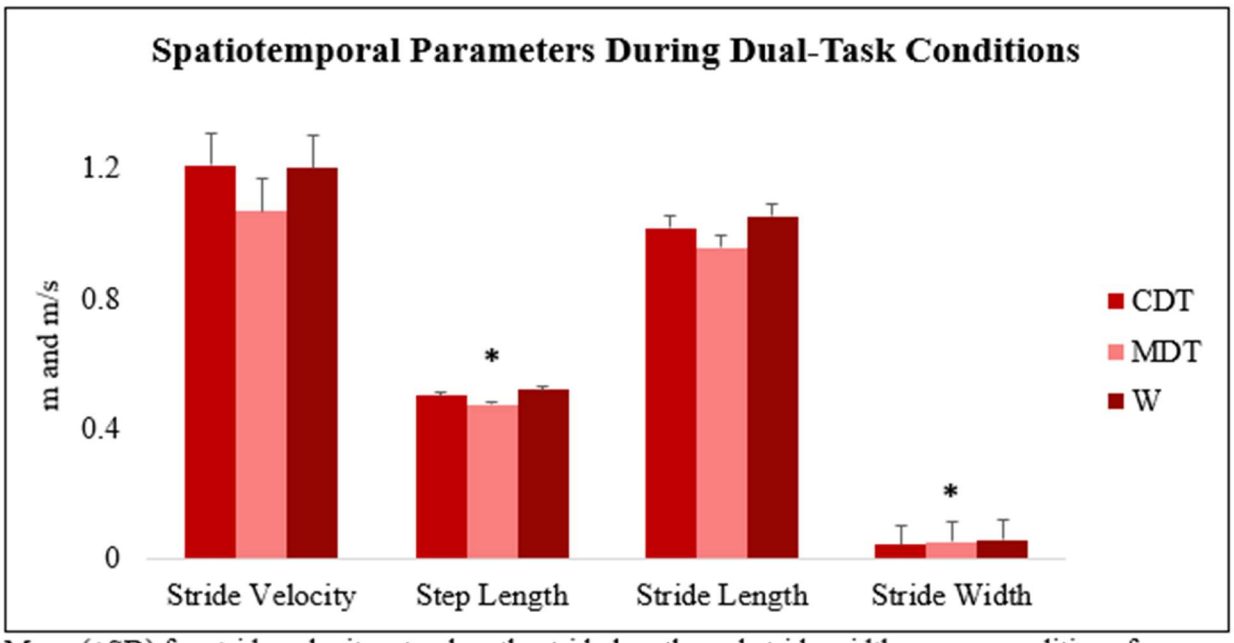
Introduction

Autism Spectrum Disorder (ASD) affects approximately 1 in 36 children in the United States and is characterized by behavioral symptoms [1]. Recent research has also identified motor, gait, and cognitive impairments associated with ASD [2,3]. Dual-task paradigms may be particularly relevant for this population, who often present with comorbid conditions that affect attentional resources [4]. Executive function and attention play key roles in gait control [5], and dual-task effects on gait are more pronounced in children with deficits in these domains [6]. However, the relationship between cognitive abilities and gait in children with ASD remains underexplored. Therefore, the purpose of this study was to examine the impact of various dual-task conditions on gait in children with ASD.

Methods

20 children (13 males, 12.35±2.49 years, 1.57±0.14 m, 52.64±14.30 kg) with ASD participated. Participants were instrumented with retroreflective markers on their lower extremities and trunk, and kinematic data was collected (10 camera; 200 Hz; Vicon Motion Systems, Ltd., Oxford, UK). Participants walked at a self-selected speed under three conditions: normal walking, a cognitive dual-task (Stroop Color Word Test), and a motor dual-task (balancing three tennis balls on a tray). Data were smoothed using a low-pass Butterworth digital filter (6Hz) using Visual3D (HAS-Motion, Kingston, Ontario). Mean and standard deviation values were calculated for step length, stride length, stride width, stride velocity. A repeated measures ANOVA ($\alpha = 0.05$) was used to examine differences across conditions, with Bonferroni-adjusted post hoc comparisons when appropriate.

Results



Analysis revealed that children with ASD displayed statistically different stride widths: $F(2,22)=3.70$, $p=0.041$, and step lengths: $F(2,22)=3.47$, $p=0.039$ among conditions. There was no statistical differences in stride velocity: $F(2,22)=1.39$, $p=0.270$, or stride length: $F(2,22)=2.21$, $p=0.134$ (Figure 1).

Discussion

These findings suggest that dual-tasking selectively impacts certain spatiotemporal gait parameters in children with ASD rather than producing a global effect. This work represents

a preliminary analysis and will be compared with an age- and sex-matched neurotypical group to further characterize dual-task gait differences. Understanding these patterns may help inform interventions aimed at improving functional mobility and independence.

Aging Adults with Hip Osteoarthritis Ambulate with Lower Joint Power During a 30-Minute Walking Task

Ms Amara Sharp MS, ATC[1], Dr. Jaimie Roper PhD[2], Dr. Aaron Fain MD[1], Dr. Stephen Duncan MD[1], Dr. Anthony Mangino PhD[1], Dr. Kate Jochimsen PhD, ATC[3,4], Dr Michael Samaan PhD[1]

[1]University of Kentucky, Lexington, Kentucky, United States. [2]Auburn University, Auburn, Alabama, United States. [3]Massachusetts General Hospital, Boston, Massachusetts, United States. [4]Harvard Medical School, Boston, Massachusetts, United States

Introduction

Approximately 25% of all adults will develop hip osteoarthritis (HOA) across the life span. During the course of healthy aging, the power required for forward propulsion shifts from the distal to proximal joints. Aging adults with HOA walk slower and with lower ankle joint power compared to aging adults without HOA, yet the impact of slower gait speeds on power production in HOA is understudied. Although aerobic exercise is used in HOA rehabilitation, the impact of prolonged walking on ankle joint power and the underlying impact of slower gait speeds on ankle joint power during aerobic exercise in HOA is understudied. Therefore, we assessed changes in lower extremity joint power in aging adults with and without HOA and the corresponding impact of gait speed on joint power during a prolonged walking task.

Methods

Fourteen asymptomatic individuals without radiographic HOA (9 females, 55.60±10.01 years, 27.10±2.50 kg•m^{-2}) and fourteen individuals with radiographic HOA (6 females, 61.40±9.75 years, 25.70±3.54 kg·m^{-2}) underwent 3D motion capture while walking at a self-selected speed on an instrument split-belt treadmill for 30 minutes. The peak total power (sum of the lower extremity joint powers) was calculated at the start and the end of the 30-minute walking task. Gait speed was compared using Welch's t-test. Changes in peak total power and the corresponding hip, knee, and ankle power at the peak total power were compared using a gait speed adjusted and non-gait speed adjusted repeated measures analysis of variance.

Results

The HOA group walked significantly slower than the control group (HOA: 0.77±0.18m·s^{-1}, Control: 0.94±0.17m·s^{-1}, p=0.02). No within-subject effects were found for any of the joint power-based parameters (ps>0.05). The HOA group exhibited significantly lower peak total power and lower knee and ankle power at the peak total power regardless of gait speed.

Discussion

Regardless of gait speed, the HOA group exhibited lower peak total power throughout the entire 30-minute walking task and was driven by lower knee and ankle joint powers. HOA-related rehabilitation should target knee and ankle joint power production to improve total lower extremity power and function during aerobic exercise.

[4]Center for X-ray Analytics, Empa - Swiss Federal Laboratories for Materials Science and Technology, Duebendorf, Zurich, Switzerland

Introduction

We introduce the application of a novel, validated high-speed dynamic biplanar radiographic imaging (DBRI) system to acquire femoro-acetabular (hip) arthrokinematrics with sub-millimetre accuracy to develop a new, dynamic metric for characterising micro-instability in patients with femoral torsion abnormalities

Methods

Two 3D-printed hip joints recreated from two patient CTs with different pathological (abnormal femoral torsion) conditions were the study objects. A DBRI system consisting of two pairs of x-ray tubes and digital flat image intensifiers along with a marker less model-based bone tracking system (DSX Suite, Has-Motion Inc., CA) was employed to capture 3D hip arthrokinematics during two defined nominal movements. "Bones" were tracked in 3D space during a nominal flexion-extension (70° ROM) and external rotation (50° ROM) recorded at 60 frames per second (fps). Three metal beads were embedded on each "bone" of one of the hips in order to validate the system and marker less model-based tracking accuracy against the gold standard radiostereometric analysis technique. Local reference frames were defined for the femur (origin at femoral head centre) and acetabulum with the femoral motion expressed relative to the acetabular reference frame. Bounding boxes for the loci of instantaneous femoral head centre (iFHC) position for each abnormal torsion condition were computed.

Results

First, the model-based marker less tracking process was validated against the bead-tracked instantaneous poses with an average accuracy of ≤ 0.83mm.

In the second step, iFHC loci of the two hips were mapped within bounding boxes, first for nominal rotation motion and then for nominal flexion-extension motion. The bounding box range for each condition and each motion varied between 1x1x1 mm^3 to 2x2x4 mm^3. Furthermore, there was no overlap between the instantaneous femoral head centre bounding boxes for the two conditions computed during the nominal rotational motion.

Discussion

iFHC bounding boxes obtained using DBRI imaging may be exploited to diagnose and quantify pathological microinstability in the hip.

Differences in Landing Strategies during a Choice Reaction Forward Hop-to-Stabilization in Individuals With and Without Chronic Ankle Instability

Dr. Amelia Bruce Leicht PhD, CSCS[1], Ms. Amelia Johnson BS[1], Dr. Phillip Gribble PhD, ATC, FNATA[1], Dr. Nicholas Heebner PhD, ATC[1], Dr. Johanna Hoch PhD, MPH, ATC[1], Dr. Kyle Kosik PhD, ATC[1], Ms. Ilana Patlan MSc[1], Dr. Ke'La Porter PhD, ATC[1], Dr. Danielle Torp PhD, ATC[1], Dr. Bridget Walsh PhD, ATC[2], Dr. Matthew Hoch PhD, ATC, FNATA[1]

[1]University of Kentucky, Lexington, KY, United States. [2]Ohio University, Athens, OH, United States

Introduction

Physical activity commonly occurs in chaotic environments and requires cognitive-loading during dynamic tasks (e.g. jump-landing). The combination of these activities can alter movement strategies, increasing the risk of injury. However, applications of dual-tasking activities in populations with chronic ankle instability (CAI), known for having biomechanical alterations during functional movements, has seen limited investigation. The choice-reaction forward hop-to-stabilization (CR-FHTS) task is a dynamic cognitive-loading task. The purpose of this study was to compare landing kinematics during a CR-FHTS in individuals with and without CAI.

Methods

Ninety-one volunteers (CAI: 19F/27M, 21.0±5.1yrs, 172.4±10.5cm, 74.9±13.1kg; Healthy: 25F/20M, 21.4±5.2yrs, 169.8±9.4cm, 68.8±13.8kg) completed the CR-FHTS. From a double-limb stance, volunteers hopped forward over a 30cm hurdle positioned at 20% of their height, to a single-limb landing in a zone beginning at 40% of their height. Volunteers were instructed to hop as quickly as possible in response to an illuminated sensor (red/green) that indicated which limb (left/right) to land on. Upon landing, volunteers balanced for 5-seconds with hands on hips. Lower extremity joint angles in the frontal and sagittal planes were collected via inertial measurement units at 100Hz from 200ms pre-initial contact (IC) to 200ms post-IC (40 frames, IC occurring at frame 20). Outcomes from the injured limb within the CAI group and dominant limb within the healthy group were compared for using statistical parametric mapping.

Results

Significant differences were observed between groups in the frontal plane across all joints in periods prior to IC (p<0.05). Significant group differences were identified at the ankle between frames 14-17 (p=0.03), at the knee between frames 0-4 and 13-18 (p=0.01, p=0.003), and at the hip between frames 12-14 (p=0.04, Figure 1). No group differences occurred in the sagittal plane across any joints (p>0.05).

Discussion

Volunteers with CAI utilized more ankle adduction, less knee adduction, and more hip abduction immediately prior to IC. The addition of cognitive-loading during a CR-HTS may elicit risky frontal plane landing strategies prior to IC. Dynamic landing tasks paired with cognitive-loading components may provide utility as an assessment tool and mimic real-world scenarios for patients with CAI to decrease re-injury.

Images (Optional)

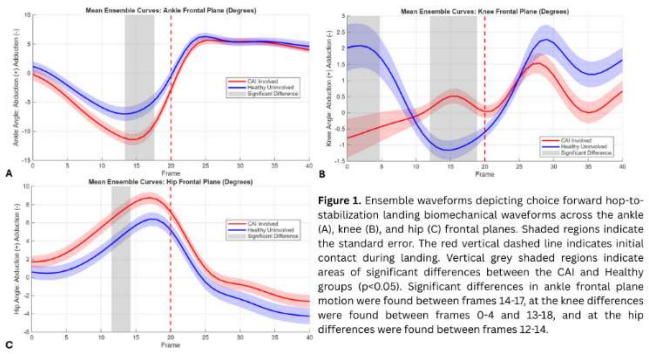

Figure 1. Ensemble waveforms depicting choice forward hop-to-stabilization landing biomechanical waveforms across the ankle (A), knee (B), and hip (C) frontal planes. Shaded regions indicate the standard error. The red vertical dashed line indicates initial contact during landing. Vertical grey shaded regions indicate areas of significant differences between the CAI and Healthy groups (p<0.05). Significant differences in ankle frontal plane motion were found between frames 14-17, at the knee differences were found between frames 0-4 and 13-18, and at the hip differences were found between frames 12-14.

Biomechanics-Informed Virtual Surgical Planning for Tongue Reconstruction

Dr. Amir Isazadeh[1], Dr. Daniel Aalto[1], Dr. Lindsey Westover[2], Dr. Hadi Seikaly[3]

[1]Faculty of Rehabilitation Medicine, University of Alberta, Edmonton, Alberta, Canada. [2]Faculty of Engineering, University of Alberta, Edmonton, Alberta, Canada. [3]Faculty of Medicine and Dentistry, University of Alberta, Edmonton, Alberta, Canada

Dr. Amir Isazadeh

Introduction

In tongue reconstruction, virtual surgical planning improves anatomical and functional outcomes. However, unified digital workflows are required to integrate virtual planning more widely into tongue reconstruction surgery. To address this, we present a patient-specific Virtual Surgical Planning (VSP) framework with a twofold objective: to bridge the gap in free flap design via biomechanical optimization and to deploy high-fidelity, high-throughput surgical simulations to transform the current intuition-driven, surgeon-dependent paradigm into data-driven decision-making.

Methods

To address the challenge of optimal flap geometry, we developed the hyperelastic inverse Finite Element Method (hiFEM), an algorithm to generate flap designs that minimize tissue stretch. Second, we established an automated, end-to-end finite element simulation pipeline, incorporating virtual reconstruction and long-term postoperative atrophy, to estimate long-term outcomes. This virtual testbed was deployed in a 120-virtual-case factorial study to systematically isolate the independent and interactive effects of two surgical decisions: donor site (Radial Forearm vs. Anterolateral Thigh) and flap overbulking on the final neotongue biomechanics.

Results

Comparative analysis demonstrated that hiFEM minimized tissue deformation, maintaining maximum area stretches between 1.10–1.12, outperforming a clinically validated geometric flattening (1.19–1.38). In the factorial study, statistical analysis quantified a mechanical trade-off: flap overbulking was the primary driver for anatomical restoration

($p<0.001$), yet it incurred a predictable penalty in imposed deformation on the native tongue ($p<0.001$). Furthermore, donor-site stiffness significantly modulated this relationship; stiffer thigh flaps imposed higher baseline strains ($p<0.001$) and exhibited diminished anatomical tunability from overbulking compared to pliable forearm flaps ($p<0.001$). This finding aligns with the clinical preference for forearm flaps in tongue reconstruction.

Discussion

This work transforms the art of surgical judgment into a data-driven science. By shifting the planning objective to biomechanical optimization, the framework enables surgeons to identify patient-specific strategies that optimally balance surgical decisions. Ultimately, the integration of active muscle contraction models will further enable function simulation for speech and swallowing, and establish a risk-aware digital ecosystem for soft-tissue reconstruction VSP.

The Effects of Neuromuscular Control Exercises Versus Strengthening on Clinical and Biomechanical Outcomes in the "Strong" Subgroup of Individuals With Patellofemoral Pain: A Randomized Controlled Trial

Ms. Ana Luiza Cabral[1], Mr. Victor Hugo V. Carrijo[2], Dr. J. Paulo Vilas-Boas[3], Dr. Jim Richards[4]

[3]Center of Research, Education, Innovation and Intervention in Sport (CIFI2D), Porto Biomechanics Laboratory (LABIOMEP), Faculty of Sport, University of Porto, Porto, Porto, Portugal. [4]Allied Health Research Unit, University of Lancashire, Preston, Lancashire, United Kingdom

Introduction

The existence of Patellofemoral Pain (PFP) subgroups has been proposed to explain inconsistencies in longitudinal studies showing high symptom recurrence after strength-focused interventions. Interestingly, one subgroup demonstrated normal strength compared to others [1], suggesting neuromuscular control may play a key role in this subgroup. This study compared the effects of two 6-week protocols based on neuromuscular control vs. strengthening on clinical and biomechanical outcomes.

Methods

Twenty-four individuals from the "strong" subgroup of PFP were randomly allocated into two groups: neuromuscular control exercises (NMC) (n = 12; 27.5 y; BMI 23.8 kg/m^2) and strengthening exercises (STG) (n = 12; 29.98 y; BMI 23.7 kg/m^2). All volunteers performed 3 sessions per week, totaling 18 sessions. The NMC group performed exercises based on proprioception and balance, and the STG group performed strengthening exercises for the quadriceps, hamstrings, hip abductors, and lateral rotators. Pain, function, kinesiophobia and biomechanics were assessed pre and post intervention. Three-dimensional kinematics were captured with a 12-camera Qualisys system (100 Hz), and kinetics were recorded during stair descent using a four-step instrumented staircase (2000 Hz). Knee angles and moments were extracted using Visual3D. Statistical analysis was conducted in SPSS version 29 (IBM, USA). A mixed-model method (two groups x two time points) was performed. Where significant main effects were seen, pairwise comparisons using LSD were performed.

Results

The table below shows the results of the clinical and biomechanical outcomes.

Discussion

Both interventions produced relevant clinical improvements, highlighting the therapeutic value for individuals in the “strong” PFP subgroup. Nevertheless, STG led to greater improvements in knee specific function and reductions in kinesiophobia, indicating a broader clinical impact even when baseline strength is not compromised. The NMC still contributed meaningful symptom relief and may target coordination and sensorimotor aspects not directly addressed by strengthening. The lack of biomechanical changes may reflect the already high baseline strength and relatively short intervention duration.

Biomechanical Impacts Of Multidisciplinary Intervention For Youth With Chronic Musculoskeletal Pain

Dr. Anna H Bailes PT, DPT, PhD[1], Dr. Samuel M Lyons PhD[2], Dr. Lauren E Harrison PhD[1], Dr. Laura E Simons PhD[1]

[1]Department of Anesthesiology, Perioperative and Pain Medicine, Stanford School of Medicine, Palo Alto, CA, United States. [2]Department of Kinesiology, Whittier College, Anaheim, CA, United States

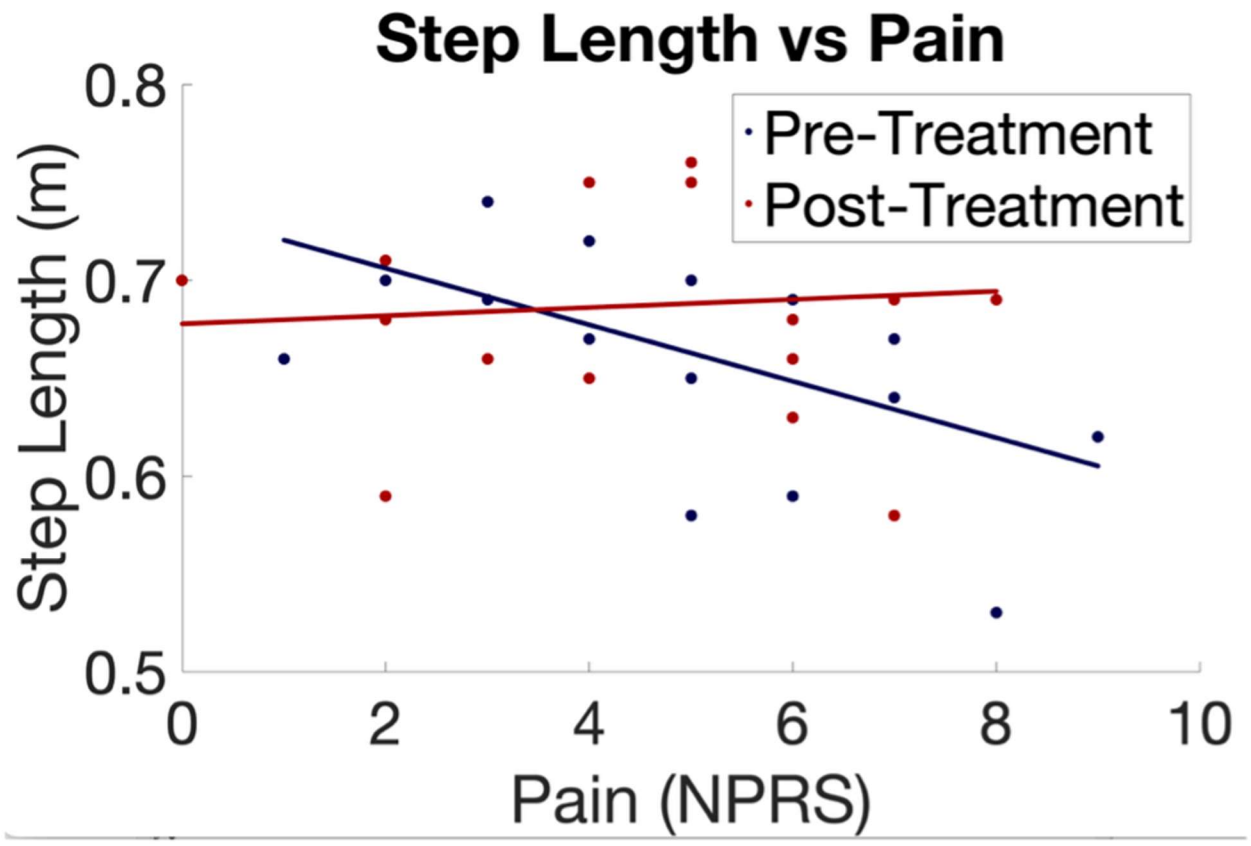
Introduction

One is four youth have chronic musculoskeletal (MSK) pain, leading to functional impairments and altered movement biomechanics. Although multidisciplinary interventions lead to improvements in self-reports of function, impacts on movement biomechanics remain unknown. Aims of this study were to 1) identify differences in movement biomechanics pre-/post-treatment and 2) determine the impact of multidisciplinary intervention on relationships between self-report measures and biomechanics.

Methods

This secondary analysis was performed ancillary to a clinical trial (1R21AR072921) in youth (8-17 y.o.) with chronic MSK pain. Youth engaged in 12 sessions of multidisciplinary treatment with a physical therapist and pain psychologist. Participants visited the motion capture laboratory for study visits pre-/post-intervention. They performed functional tasks (double leg squat, 6-minute-walk test). Optoelectronic motion capture was used to collect primary outcomes: hip/knee kinetics/kinematics, spatiotemporal gait metrics. Participants completed the Numeric Pain Rating Scale and Functional Disability Index as secondary outcomes. To address Aim 1, paired t-tests were used to compare movement biomechanics pre-/post-treatment. To address Aim 2, mixed linear regression models with ‘timepoint’ (pre-/post-treatment) interaction effects were used to determine changes in relationships between self-report and biomechanical measures pre-/post-treatment.

Results



Of the 59 youth completing the clinical trial, 21 (13.8±2.6 y.o., 18% M) participated in motion capture assessment. There were no significant differences in joint kinetics/kinematics or spatiotemporal gait metrics pre-/post-treatment ($p>.05$). Aim 2 revealed a significant pain × timepoint interaction for predicting step length ($p<0.05$). Specifically, there was a moderate negative correlation between pain and step length pre-

treatment (r = -0.54) but not post-treatment (r=0.11). Plainly, participants with more pain took shorter steps pre-treatment, but the association disappeared post-treatment. There were no other significant main or interaction effects in predicting biomechanics.

Discussion

Multidisciplinary intervention did not result in biomechanical changes in youth with chronic MSK pain. The negative association between pain and step length that was observed pre-treatment was eliminated post-treatment, suggesting that high pain was no longer associated with gait impairments (reduced step length). This 'decoupling' of pain and step length is the first biomechanical evidence to corroborate existing findings that functional restoration precedes pain reduction following multidisciplinary intervention.

Toward Adaptive and Predictive Digital Twins in Orthopedics: A Multimodal Patient-Specific Database

Dr. Annchristin Andres, Dr. Michael Roland, Dr. Kerstin Wickert, Prof.Dr.-Ing. Stefan Diebels

Applied Mechanics, Saarland University, 66123 Saarbrücken, Saarland, Germany

Introduction

The ongoing digitization of medicine is opening up new perspectives for patient-specific modeling, simulation, and prognosis of orthopedic healing processes. This study presents a unique database built up over five years that includes patients with fractures of the long bones of the upper and lower extremities. The database currently contains 100 fully documented cases, based on a standardized, specially developed workflow [1].

Methods

Each data set includes multimodal information (see Figure 1), including imaging data (CT images, X-ray), motion analyses using the Xsens™ motion capture system, and musculoskeletal simulations using AnyBody™ software. For patients with fractures of the lower extremities, the team additionally recorded ground reaction forces using instrumented soles. Andres et al. [2] describe the methodological principles and technical capabilities of these combined measurement systems.

Based on this data structure, the creation of digital twins for orthopedic-traumatological applications was established [3]. This human digital twin approach enables patient-specific mapping of biomechanical analyses and the simulation of individual stress scenarios. In addition, these models can be used to predict healing processes and provide quantitative support for therapy decisions. For example, the workflow enabled prediction of the effects of individual partial loads on mechanical stability and healing progress in tibial head fractures [4].

Results

The database presented here thus provides a basis for developing adaptive and predictive digital twins, which are highly relevant to both research and clinical decision-making. By linking imaging, motion data, and biomechanical simulation, patient-specific factors influencing fracture healing can be systematically analyzed and quantified. In addition, the database opens new possibilities for the use of machine learning and artificial intelligence methods.

Discussion

This unique data basis thus represents an important step toward data-driven, personalized orthopedics and trauma surgery. In the future, it will be continuously expanded and supplemented with additional measurement methods to further improve the precision of digital twins and open new clinical fields of application.

A Biomechanical Framework for Assessing Evidence of Joint Stability across the Symptomatic and Asymptomatic Generalized Joint Hypermobility Spectrum

Ms. Susan Burnap[1], Dr. Rebecca Abbott PT, DPT, PhD[2], Mr. Yaqoub Yusuf MS[1], Dr. Aaron Hellem[1], Dr. Arin Ellingson PhD[1]

[1]University of Minnesota, Minneapolis, MN, United States. [2]University of Colorado, Aurora, CO, United States

Introduction

Generalized joint hypermobility (GJH)—excessive joint range of motion (ROM) throughout the body—affects up to 30% of the general population, and is frequently asymptomatic (aGJH) [1–3]. Symptomatic GJH (sGHJ) describes a subset who experience severe chronic pain and debilitating functional limitations including hypermobile Ehlers-Danlos Syndrome (hEDS) and Hypermobility Spectrum Disorder (HSD). Although joint instability is proposed as the biomechanical mechanism underlying pain in sGJH, direct evidence remains lacking.

The objective herein was to synthesize the indirect evidence of joint stability in aGJH and sGJH using White & Panjabi's [4] biomechanical framework, which conceptualizes joint stability as the interaction of passive (non-contractile tissues), active (muscle), and neural (nervous system) subsystems.

Methods

In this structured narrative review, we identified peer-reviewed studies through targeted searches across multiple databases. Evidence comparing sGJH, aGJH, and non-GJH control groups was qualitatively synthesized and mapped to passive, active, and neural subsystems. The direction and consistency of findings were summarized to characterize subsystem-specific patterns of joint stability.

Results

There was a clear and consistent pattern of impairment in sGJH compared to controls across all subsystems (↑ laxity, ROM; ↓ strength, endurance, proprioception, tissue stiffness). Findings for aGJH compared to controls were more variable, though more studies reported differences mirroring the impairment patterns observed in sGJH. Direct comparisons between sGJH and aGJH were limited, with available studies generally reporting greater impairments in sGJH. **Table 1** summarizes the number of studies (n=51) and direction of reported differences.

Discussion

Taken together, these findings demonstrate consistent impairments across multiple subsystems in sGJH compared to non-GJH. Evidence in aGJH was more variable and may reflect partially preserved active and neural subsystem function. The limited comparisons between aGJH and sGJH further support the concept of a continuum, in which symptom status corresponds to subsystem impairment. Key limitations include inconsistent definitions of GJH, heterogeneity in study populations, and a lack of direct evidence linking these to true mechanical instability. The underlying drivers of subsystem impairment—and the extent to which they can be modified—remain unclear, and may reflect complex interactions among pain, connective tissue properties, and other unmeasured contributors.

Images (Optional)

Table 1. Summary of Evidence for each joint stability subsystem (active, neural, and passive) for comparisons between symptomatic GJH (sGJH), asymptomatic GJH (aGJH), and non-GJH healthy controls (control). *The number of studies reporting outcomes in each domain are listed before the symbol indicating the direction of the finding. For example, "8<" in the "sGJH vs control" column indicates that 8 studies reported that the sGJH had a significantly lower outcome than controls in the domain.*

Subsystem	Domain	sGJH vs control	aGJH vs control	sGJH vs aGJH
Active	Strength	8 < | 1 =	5 < | 6 =	1 < | 2 =
	Endurance	3 <	0	1 <
Neural	Motor Control	2 < | 1 =	1 < | 3 =	1 < | 1 =
	Proprioception	8 < | 1 =	1 < | 3 =	1 <
	CNS/Other	1 =	1 =	0
Passive	Joint Laxity	2 >	7 > | 3 =	0
	Joint ROM	3 >	3 > | 2 =	2 =
	Tissue Stiffness	3 < | 1 =	2 < | 1 =	0

Modeling First-Stage Hypoplastic Left Heart Syndrome Strategies Using a Zero-Dimensional Closed-Loop Framework

Dr. Aseem Milind Pradhan[1], Dr. Sophie Malekzadeh-Milani[2], Dr. Chiara Sacchi[2], Dr. Damien Bonnet[2,3], Dr. Irene Vignon-Clementel[1]

[1]INRIA Saclay, Palaiseau, Île-de-France, France. [2]M3C-Necker, Hôpital Necker-Enfants malades AP-HP, Paris, Île-de-France, France. [3]Université de Paris Cité, Paris, Île-de-France, France

Introduction

Hypoplastic Left Heart Syndrome (HLHS) is a complex congenital cardiac condition which needs a series of surgeries to ensure the survival of the patient. The first-stage palliation (Norwood procedure) is especially critical, as it establishes the physiological conditions necessary for both immediate survival and eligibility for subsequent surgeries. Clinicians employ a variety of surgical and interventional strategies informed by individual patient data, institutional preference, and surgeon experience. Currently morbidity and mortality remain substantial. Early reintervention rates vary with 20–40% of patients requiring additional procedures before the stage two intervention. There is, thus, an opportunity for improving outcomes with the aid of virtual human twins.

Methods

We constructed zero-dimensional (lumped parameter) computational models representing the entire HLHS circulation before and after the first-stage intervention. We evaluated four potential strategies for this stage, including the traditional Norwood procedure with either a Blalock-Thomas-Taussig or Sano shunt, Hybrid Norwood approach, and fully catheter-based interventions as practiced at Hôpital Necker-Enfants Malades, Paris. Rather than the usual time-varying elastance cardiac chamber model, we have used the single fiber heart model that is more mechanistic and capable of improved patient-specific modeling [1]. The model incorporates key cardiovascular compartments, allowing assessment of how different procedural strategies affect relevant biomarkers (shown in **Figure 1**).

Results

These virtual models enable systematic exploration of these interventions by introducing targeted modifications to each strategy, for example, the length and diameter of the cardiopulmonary shunts, the degree of banding of the pulmonary arteries, etc. By quantifying clinically meaningful biomarkers such as systemic and pulmonary flows, load on the single ventricle, coronary and cerebral perfusion, and flow to other vital organs, the

model provides insights into which approaches are most likely to produce favorable outcomes and reduce the need for reinterventions.

Discussion

This virtual human twin modeling framework could help optimize surgical and catheter-based strategies and support personalized intervention planning.

A comparison of obstacle crossing measures among older adults with and without total hip or total knee arthroplasty.

Dr. Ashlyn M. Jendro[1], Ms. Abby Brittain[2], Dr. Abigail C. Schmitt[1,2]

[1]The MOVE Lab, Exercise Science Research Center, University of Arkansas, Fayetteville, AR, United States. [2]Biomechanics Laboratory, Department of Orthopaedics, University of Arkansas for Medical Sciences, Little Rock, AR, United States

Introduction

Most falls among older adults occur due to tripping, most commonly over objects in plain sight. To successfully cross obstacles and avoid trips, sufficient clearance is needed in both the vertical (i.e., toe/heel clearance) and horizontal (i.e., approach/landing distance) directions. However, it's largely unknown how these measures might change after lower extremity total joint arthroplasty. This study sought to compare obstacle crossing measures between individuals with and without total joint arthroplasty at the hip or knee.

Methods

Fourteen older adults (7 men, 69±7 years) were included in this preliminary analysis of an ongoing study. Five older adults served as a control group and were compared to individuals with total hip (n=4) or total knee (n=5) arthroplasty. Participants completed 10 obstructed walking trials at a comfortable speed stepping over a dowel (height: 150mm) while barefoot. Participants crossed with their self-selected limb while 3D motion capture recorded marker trajectories over the 8-meter walkway.

Vertical clearance was measured as the distance between the obstacle and the toe/heel marker when directly over the obstacle. Approach and landing distance were defined as the horizontal distance between the obstacle and the toe or heel marker, respectively. Crossing step length was defined as the horizontal distance between the lead and trail heel markers during the crossing step and gait velocity was collected during the middle 4-meters of the walkway. ANOVAs were used to compare means between groups (alpha=.05).

Results

Although none of the variables examined reached significance (all $p>.08$), large effect sizes for approach distance ($p=.15$, $\eta^2=.29$), landing distance ($p=.08$, $\eta^2=.37$) and obstructed gait velocity ($p=.15$, $\eta^2=.21$) suggest meaningful group effects.

Discussion

Our findings indicate, although there were no significant differences between groups in this preliminary data, significance may be found with a larger sample, based on the large effect sizes. This would suggest individuals with total hip or total knee arthroplasty utilize different obstacle crossing strategies than older adults without joint replacements. This can help better inform fall risk and rehabilitation strategies for patients with total joint replacements. This study is ongoing, and we expect a larger sample size by the time of the conference.

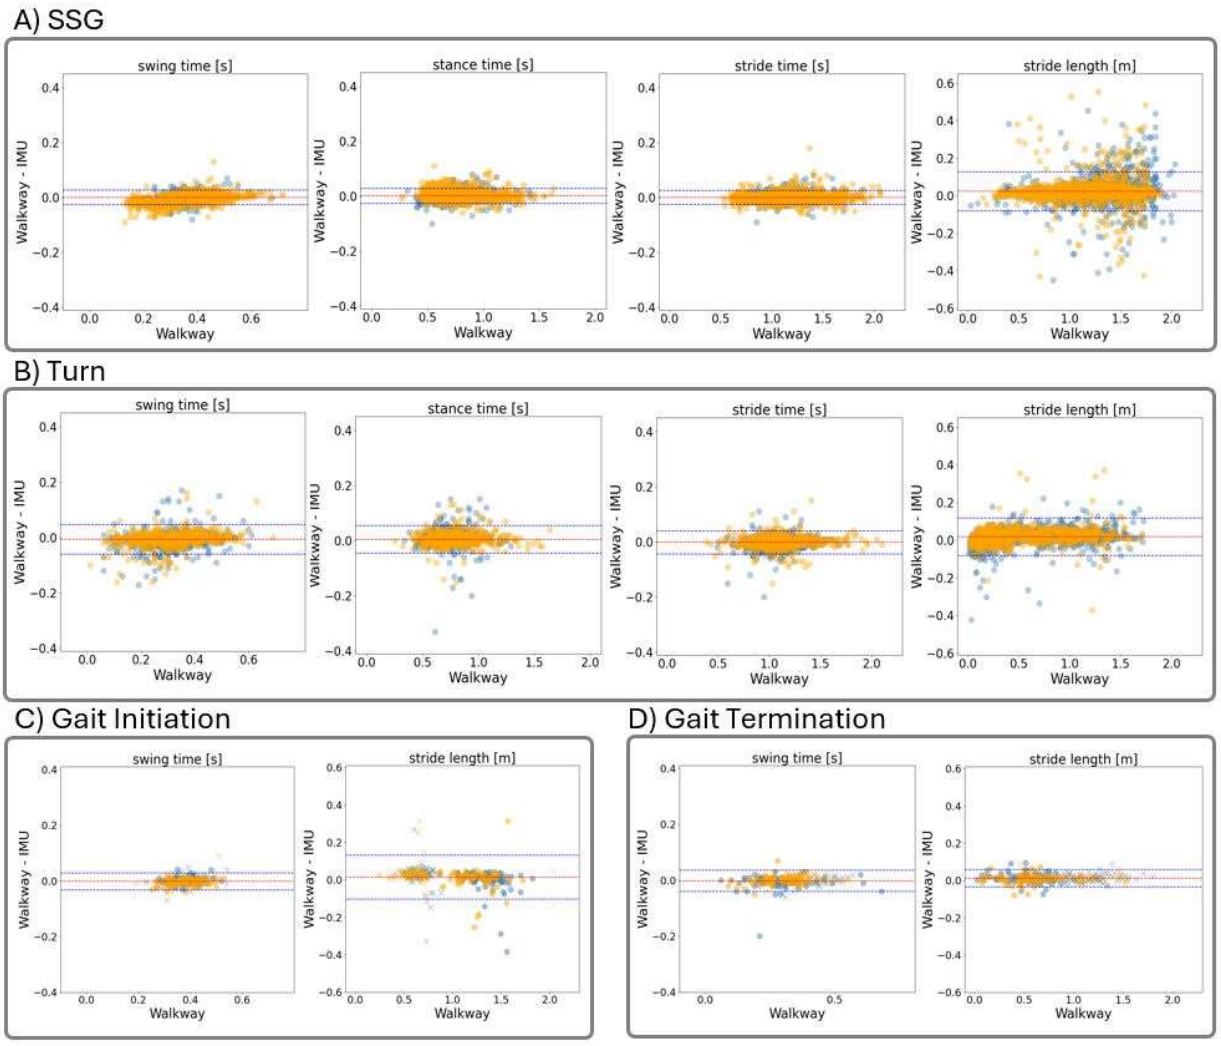
[3]University of Washington, Department of Mechanical Engineering, Seattle, Washington, United States. [4]University of Washington, Department of Neurology, Seattle, Washington, United States. [5]University of Washington, Department of Rehabilitation Medicine, Seattle, Washington, United States

Introduction

Parkinson's disease (PD) often impairs gait and balance; however, clinical assessments offer limited, subjective insight into real-world mobility. Inertial measurement units (IMUs) enable quantitative gait analysis but have mainly focused on steady-state gait (SSG), overlooking transition strides like turns, gait initiation (GI), and gait termination (GT), which are difficult to segment. Deep learning methods, particularly Temporal Convolutional Networks (TCN), show promise in identifying gait events in complex, non-cyclic movement where traditional methods are limited. The study aims to evaluate the accuracy of a pipeline combining a novel TCN-based stride segmentation algorithm and established functions for quantifying simple to complex gait tasks in people with PD.

Methods

All analyses used data from our open-access dataset, WearGait-PD, which includes recordings from gait and balance from 76 individuals with PD and 78 healthy controls. A subset of data was used for training TCN models, while the remaining data was used for analysis against a pressure walkway. Acceleration and gyroscope data from dorsal foot sensors and a lower back sensor were processed via a processing pipeline using our TCN models for stride segmentation and pre-established functions to reconstruct the stride and extract gait metrics. Bland-Altman plots and Spearman correlation were used to evaluate the performance of the IMU pipeline against the pressure walkway.



Results

For SSG strides, our method demonstrated small mean errors when calculating spatial and temporal parameters (≤ 2.3cm and ≤ 1.0ms, respectively) and strong correlation ($r \geq 0.96$) with the walkway. Performance for turns, GI, and GT was comparable, with small temporal and spatial mean errors (≤7ms and ≤2.9cm) and correlations (≥0.95).

Discussion

The IMU sensor analysis pipeline was able to effectively derive gait outcomes with high accuracy when compared to the gold standard. The outcomes are consistent with prior analyses for SSG and extend this capability to more complex tasks of gait initiation, turns, and gait terminations. Although the high accuracy of our method heavily relies on the performance of TCN models and the training data, the proposed framework is a reliable method to quantify complex walking tasks, allowing for a more complete understanding of mobility.

Inertial Sensor-Based Gait Parameters During Complex Walking Tasks in Parkinson's Disease Beyond Steady-State Walking

Research Engineer Avocet Nagle-Christensen BS[1], Regulatory Scientist Anthony Anderson PhD[2,3], Regulatory Scientist Michael Gonzalez PhD[2], Fellow Physician Siegfried Hirczy MD PhD[4], Associate Professor Valerie Kelly PT, PhD[5], Biomedical Engineer Kimberly Kontson PhD[2], Principal Investigator Brittney Muir PhD[1,3]

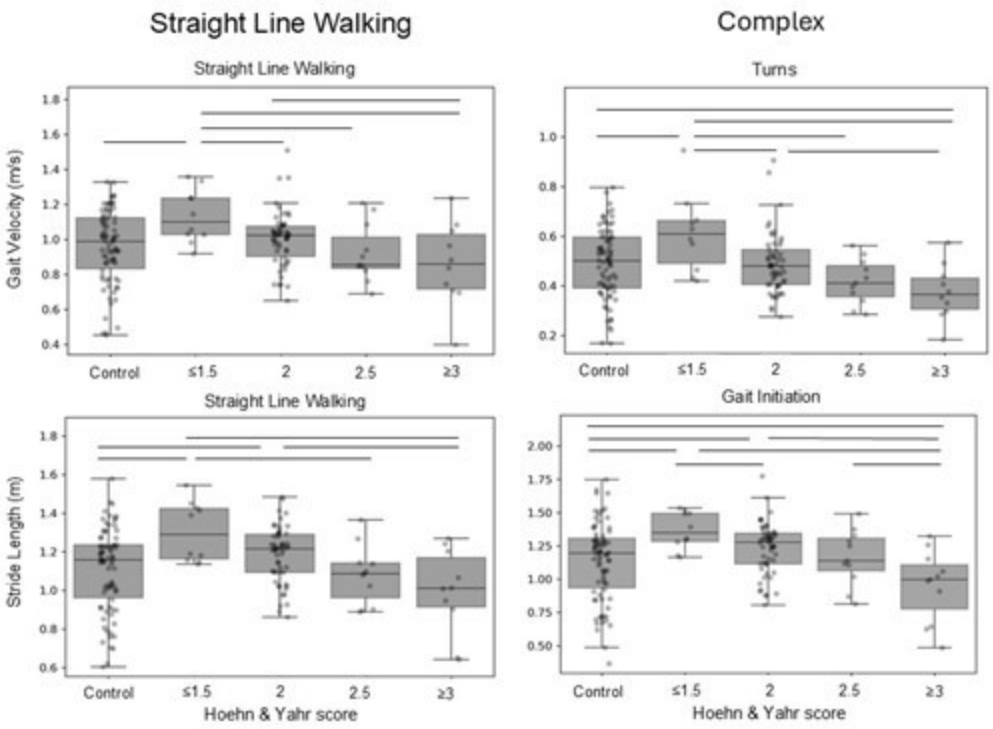
[1]VA Puget Sound Healthcare System, Seattle, Washington, United States. [2]US Food and Drug Administration, Silver Spring, Maryland, United States. [3]University of Washington, Department of Mechanical Engineering, Seattle, Washington, United States. [4]University of Washington, Department of Neurology, Seattle, Washington, United States. [5]University of Washington, Department of Rehabilitation Medicine, Seattle, Washington, United States

Introduction

Parkinson's disease (PD) is a progressive neurodegenerative disorder that often impairs gait and balance. The most common way to assess motor symptoms is through clinical examinations, however they are infrequent, subjective, and provide limited quantifiable information. Inertial measurement units (IMUs) enable quantitative gait analysis but have mainly focused on steady-state gait (SSG), overlooking transition strides such as turns, gait initiation (GI), and gait termination (GT), which potentially hold valuable clinical information. The purpose of this study is to evaluate gait metrics of simple and complex walking and their association with disease status and progression.

Methods

All analyses used data from our open-access dataset, WearGait-PD, which includes recordings from gait and balance from 76 individuals with PD and 78 healthy controls. These tasks captured gait initiation, gait termination, steady-state gait, and 180-degree turns. Acceleration and gyroscope data from dorsal foot sensors and a lower back sensor were processed via a pipeline using Temporal Convolutional Network models for stride segmentation and pre-established functions [5] to reconstruct the stride and extract gait metrics. A linear mixed-effects model was used to evaluate gait metrics across PD and control populations and Hoehn & Yahr (HY).



Results

Stride length was significantly different between HY groups 2.5 and ≥3, <2, and 2, and controls and HY ≥3 and <2 when evaluating SSG along with complex strides. Gait velocity was significantly different between HY groups <2 and 2, 2.5, and ≥3, and controls and HY ≥3 in SSG along with complex strides. Max foot height showed significant differences across several HY scores and control during all complex strides, however none during SGG.

Discussion

Several gait metrics suggest that complex strides have more sensitivity to changes in gait across disease status and progression compared to SSG. Metrics such as turn duration and number of strides taken during a turn have been associated with PD status and falls. Gait initiation and termination have also been associated with freezing, balance, and falls. However, stride-level metrics for turns, GI, and GT are often not published. This study proposes potential sensitive gait metrics that could be used to better characterize and understand movement in people with PD.

Development of a 3D Visualization and Quantification System for Dynamic Evaluation of Shoulder Joint

Ms. Aya Nakamura[1], Prof. Takeshi Shimoto[1], Prof. Satoru Ikebe[2], Ms. Ayano Maehara[1], Mr. Takumi Nakano[1], Mr. Hiroya Monji[1], Ms. Hanae Myotsuzono[3], Prof. Naoya Kozono[4], Prof. Hidehiko Higaki[3], Prof. Yasuharu Nakashima[4]

[1]Fukuoka Institute of Technology, Fukuoka, Fukuoka, Japan. [2]Yamaguchi University, Ube, Yamaguchi, Japan. [3]Kyushu Sangyo University, Fukuoka, Fukuoka, Japan. [4]Kyushu University, Fukuoka, Fukuoka, Japan

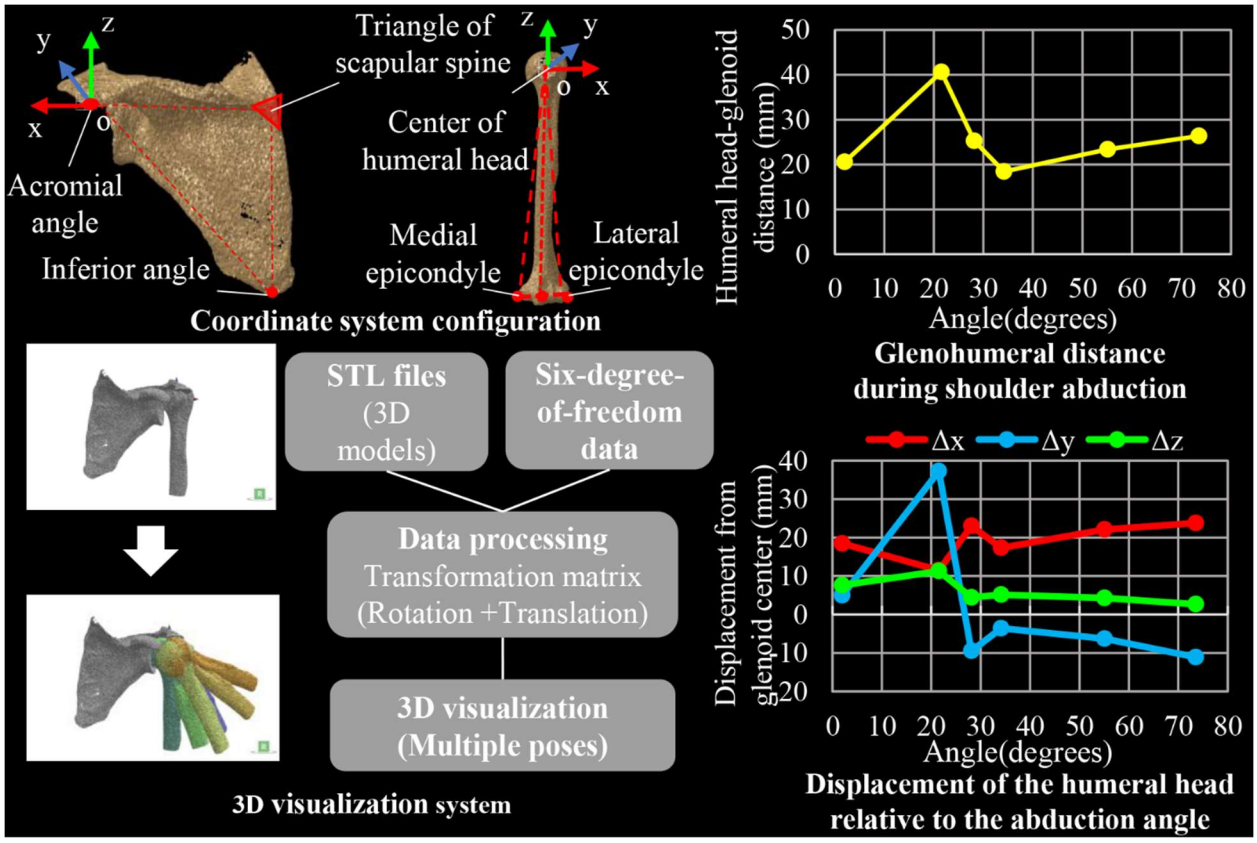
Introduction

Postoperative evaluation of arthroscopic rotator cuff repair (ARCR) has primarily relied on qualitative assessments by physicians, limiting the ability to evaluate joint dynamics in a three-dimensional and quantitative manner. Our research group has established a high-precision image-matching technique for dynamic analysis[1] and obtained novel insights through visualization.[2,3] However, visualization was performed using 3D-CAD software, restricting its application to research purposes. The aim of this study was to develop a dedicated software system that visualizes and quantitatively evaluates three-dimensional dynamics during scapular plane elevation for clinical application of these findings.

Methods

One postoperative ARCR patient performed scapular plane elevation, and continuous X-ray images were acquired using a flat-panel detector. Three-dimensional models of the scapula and humerus were reconstructed from the patient's CT scan, and six-degree-of-freedom motion data were calculated using an image-matching technique. Based on these data, we developed a dedicated software system to visualize the three-dimensional relative motion of the humerus with respect to the scapula. The system loads multiple bone models and displays multiple motion postures in different colors simultaneously. Additionally, it quantifies glenoid-humeral head distance and three-dimensional displacement of the humeral head center relative to the glenoid.

Results



The developed system visualized the three-dimensional relative motion of the humerus with respect to the scapula using six-degree-of-freedom data obtained from image-matching. Validation using data from one postoperative ARCR patient demonstrated that simultaneous color-coded display of six motion postures throughout the elevation movement enabled observation of dynamic positional changes at each elevation angle and

quantification of glenoid-humeral head distance and three-dimensional displacement of the humeral head center relative to the glenoid.

Discussion

This system demonstrated the potential to quantitatively evaluate dynamic impingement and changes in bone-to-bone distance, which were difficult with conventional qualitative assessments. This enables more objective and accurate evaluation of joint dynamics after ARCR, potentially contributing to improved postoperative assessment. Further validation using a larger patient population is necessary to establish the clinical utility of this system.

Joint Power Redistribution and Reduced Mechanical Efficiency in Adults with Knee Injury During User-Controlled Walking

Mr. Brandon Peoples MS, EP-C, Ms. Bria Smith MS, Ms. Isabella Helm, Mr. Keven Santamaria-Guzman MS, Mr. Kenneth Harrison MS, Ms. Damaris Cifuentes MS, Ms. Silvia Campos-Vargas MS, Dr. Jaimie Roper PhD

Auburn University, Auburn, Alabama, United States

Introduction

Self-selected walking (SSW) speeds are optimized to minimize energy expenditure while maximizing muscle-tendon mechanics[1,2]. However, lower extremity injuries disrupt this balance, leading to compensatory adjustments in joint mechanics that may reduce walking efficiency[3]. User-controlled treadmill technology preserves natural SSW gait patterns and offers a valuable method to study how injury affects walking efficiency[4]. Therefore, this study examines walking efficiency and lower-extremity joint power during user-controlled SSW in adults with and without knee injury.

Methods

Eight adults (5 experimental with knee injury and 3 controls, 29±11 years) performed user-controlled treadmill SSW while outfitted for motion capture and indirect calorimetry. The treadmill algorithm used real-time pelvic marker data to regulate belt speed (SSW speeds: 1.1–1.5 m/s). Walking efficiency, efficiency of positive work, is defined as the ratio of positive joint work to the sum of net metabolic power and negative joint work. Preliminary results are presented descriptively since this is part of an ongoing study with a larger sample.

Results

Preliminary evidence suggests that injured participants had lower metabolic power (2.41±0.51 W/kg) than controls (2.97±1.07 W/kg) during SSW. Positive work was reduced at the ankle (0.58±0.21 vs. 0.91±0.29 W/kg) and the knee (0.34±0.18 vs. 0.48±0.21 W/kg), with smaller differences observed at the hip (0.59±0.19 vs. 0.65±0.26 W/kg). Negative work patterns revealed greater ankle absorption in the injured group (-0.35±0.21 vs. −0.30±0.04 W/kg), reduced knee absorption (-0.44±0.10 vs. -0.60±0.14 W/kg), and slightly greater hip absorption (-0.14±0.14 vs. -0.10±0.08 W/kg). Efficiency was modestly lower in the injured group (0.45±0.05 vs. 0.52±0.15).

Discussion

In our sample, adults with knee injury exhibit altered joint power distribution and reduced efficiency, suggesting compensatory patterns may incur a metabolic penalty. Larger sample and inferential analyses will clarify the mechanisms underlying these preliminary trends and determine whether the observed effects are unlikely to occur by chance.

Physical and Behavioral Trajectories and Cognitive Outcomes: A Longitudinal Analysis of the Health and Retirement Study

Ms. Breanna Morales MS[1], Dr. Harlan Sayles PhD[2], Dr. Jennifer Yentes PhD[1]

[1]Texas A&M Univeristy, College Station, Texas, United States. [2]University of Nebraska, Omaha, Nebraska, United States

Introduction

Alzheimer's disease and related dementias (ADRD) are preceded by subtle physiological changes that may appear years before clinical diagnosis. Declines in gait speed and daily activity have been proposed as early indicators of neurodegenerative vulnerability, yet longitudinal evidence remains limited. The Health and Retirement Study (HRS) is a nationally representative cohort of U.S. older adults, aged 51 years and older, re-interviewed biennially. This dataset provides longitudinal data to examine how trajectories of physical function and lifestyle behaviors predict cognitive outcomes. This study evaluated whether longitudinal changes in gait speed and physical activity serve as early, modifiable indicators of Alzheimer's disease and dementia in a nationally representative cohort of older adults.

Methods

Data were obtained from the Health and Retirement Study (HRS). Participants with at least two assessments of gait speed or physical activity and no diagnosis of Alzheimer's disease or dementia at baseline were included. Alzheimer's and dementia status were determined through self- or proxy-reported physician diagnosis. Annual rates of change for each variable were calculated as the slope between available waves (2004–2022), with missing intervals estimated under the assumption of linear change. These slopes represented the yearly trajectory of change in gait speed and physical activity. Generalized estimating equation logistic regressions and Cox proportional hazards models were used to test associations with subsequent Alzheimer's or dementia diagnosis, adjusting for baseline age.

Results

Gait speed was a significant predictor of Alzheimer's and dementia diagnosis. Each one-second per year slowing in gait speed increased the odds of Alzheimer's by 3.7 times and dementia by 2.8 times ($p < .001$). Annual declines in physical activity were also associated with a greater risk, while maintaining higher activity levels was protective (OR = 0.95, $p < .001$).

Discussion

Findings were consistent across Cox models, indicating that steeper yearly declines were linked to earlier disease onset. Even after adjusting for age, gait speed remained the strongest predictor. These results align with prior evidence linking slower gait to cognitive decline and suggest that subtle, measurable decreases in gait and physical activity may serve as early, modifiable indicators of neurodegenerative risk.

Gait Speed Reserve of Young Adults Is Not Affected by a Sleep Extension Intervention

Ms. Bria Smith[1], Mr. Brandon Peoples[1], Mr. Kenneth Harrison[1], Dr. Meral Culver[1,2], Mr. Keven Santamaria Guzman[1], Ms. Silvia Campos Vargas[1], Dr. Austin Robinson[3], Dr. Jaimie Roper[1]

[1]Auburn University, Auburn, AL, United States. [2]Texas A&M University- Kingsville, Kingsville, Texas, United States. [3]Indiana University - Bloomington, Bloomington, Indiana, United States

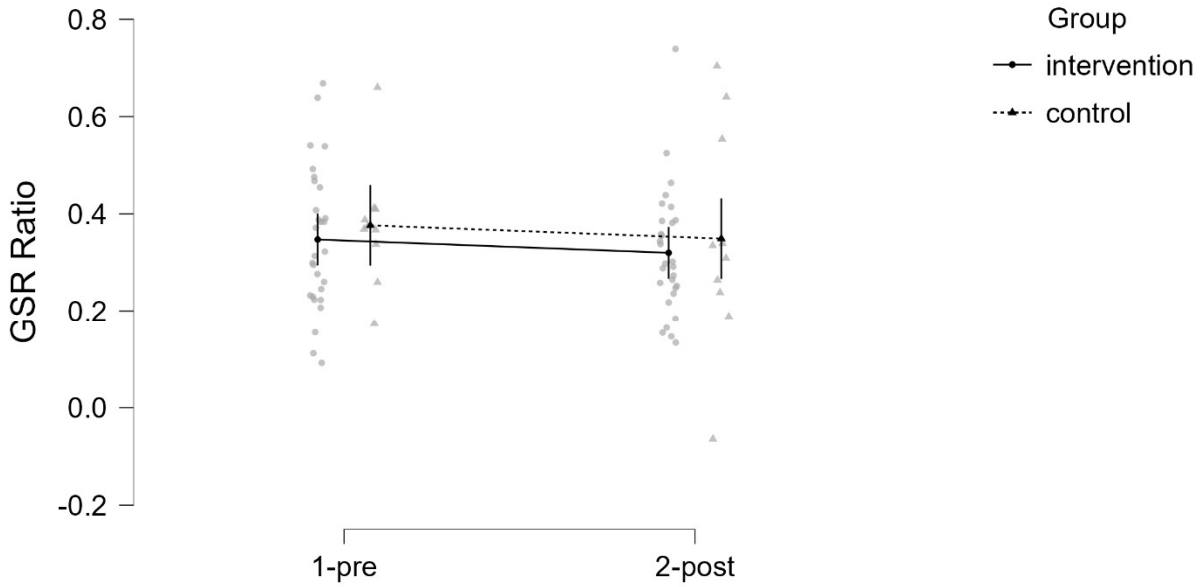
Introduction

Gait speed reserve (GSR), which describes the difference between an individual's maximum and preferred gait speeds, is regarded as an indicator of physiological reserve, cognitive reserve, and functional capacity [1,2]. Inability to increase one's gait speed is linked to decreases in mobility and cognitive functioning [2]. While sleep plays an important role in physiological and cognitive functioning, little is known about the relation between sleep and GSR. Based on recent literature demonstrating sleep extension does not affect the single-task gait speed in young adults, we hypothesized that sleep extension would not affect GSR in young adults [3].

Methods

Thirty-nine young adults (16M/23F; SD = 22±2 years) who self-reported sleeping <7 hours per night completed two lab visits. Participants were split into a control group (N=10), who maintained their typical sleep for two weeks, and an intervention group (N=29), who were instructed to extend their sleep by one hour for two weeks. The Pittsburgh Sleep Quality Index (PSQI) was used to assess self-reported sleep duration and quality. Participants completed the instrumented 2-minute walk test (i2MWT) at preferred and fast gait speeds during laboratory visits before and immediately after their respective intervention. Relative GSR capacity was calculated using the following equations: (fast speed-preferred speed)/fast speed. A linear mixed model was used to compare changes across group and visit.

Results



While the control group reported no improvements in sleep duration ($p>.05$) or quality ($p>.05$), the sleep extension intervention group reported increases in sleep duration (6.2 ± 0.9 vs. 7.3 ± 1.0 hours, $p<.001$) and improvements in sleep quality (5.4 ± 1.6 vs. 3.4 ± 1.4,

p<.001). However, no significant differences in GSR were found when comparing across groups or visits (p>.05).

Discussion

In our study, we found that sleep extension does not affect GSR in apparently healthy young adults. However, improvements in cognitive and physical performance associated with increased GSR and sleep extension may be more drastic in older adults due to age-related decreases in cognitive ability and sleep health.

Sex Differences in Running Biomechanics in Knee Injured Adults: A Systematic Review and Meta-Analysis

Mr Brody McCarthy, Ms Stephanie Tamer, Dr Danilo De Oliveira Silva, Dr Marcella Ferraz Pazzinatto, Prof Kay Crossley, Mr Matthew Savage, Dr Brooke Patterson, Ms Juanita Low, Dr Benjamin Mentiplay

La Trobe University, Melbourne, Victoria, Australia

Introduction

Running is a popular way for individuals to exercise, with female participation increasingly on the rise. Injuries are common among those who participate in running, especially at the knee joint, with female runners more likely to sustain an injury compared to their male counterparts. Altered running biomechanics (e.g., higher hip adduction) are often associated with increased knee injury risk and are more prevalent in females. To aid understanding of disease progression and prevention, it is important to consider how running biomechanics differ between males and females with knee injuries, a topic which has not been systematically reviewed. Therefore, we aimed to systematically review the literature to compare running biomechanics between males and females with knee injuries.

Methods

Six online databases were searched from inception to October 2025. We included studies that reported biomechanical running data split by males and females in individuals with knee injuries (e.g., patellofemoral pain (PFP), iliotibial band syndrome (ITBS), anterior cruciate ligament reconstruction (ACLr)) using three-dimensional motion capture and/or force plates. Variables reported in at least three studies were pooled and analysed using random-effects meta-analyses.

Results

Sixteen studies involving 517 participants (389 PFP, 78 ITBS, 50 ACLr) were included, with females representing 51% of the sample (n = 262). Meta-analyses were conducted for eight biomechanical variables (six kinematic, two kinetic). Females exhibited significantly greater peak hip adduction and hip internal rotation angles during running than males (MD = 3.84°, 95% CI = 2.82–4.86; MD = 2.88°, 95% CI = 1.35–4.41, respectively). No sex-specific

differences were found for knee joint angles (flexion, abduction, rotation), ankle eversion, or external knee joint moments (flexion, adduction).

Discussion

Our review found that females with knee injuries had higher peak hip adduction and hip internal rotation angles during running than males, while no sex-specific differences were observed for knee or ankle angles or knee joint moments. It is important to consider sex differences in running biomechanics when examining relationships with injury status and rehabilitation outcomes, and future research should account for these differences in both reporting and analysis.

[4]Porto Biomechanics Laboratory (LABIOMEP), Faculty of Sport, CIFI2D, University of Porto, Porto, Porto, Portugal

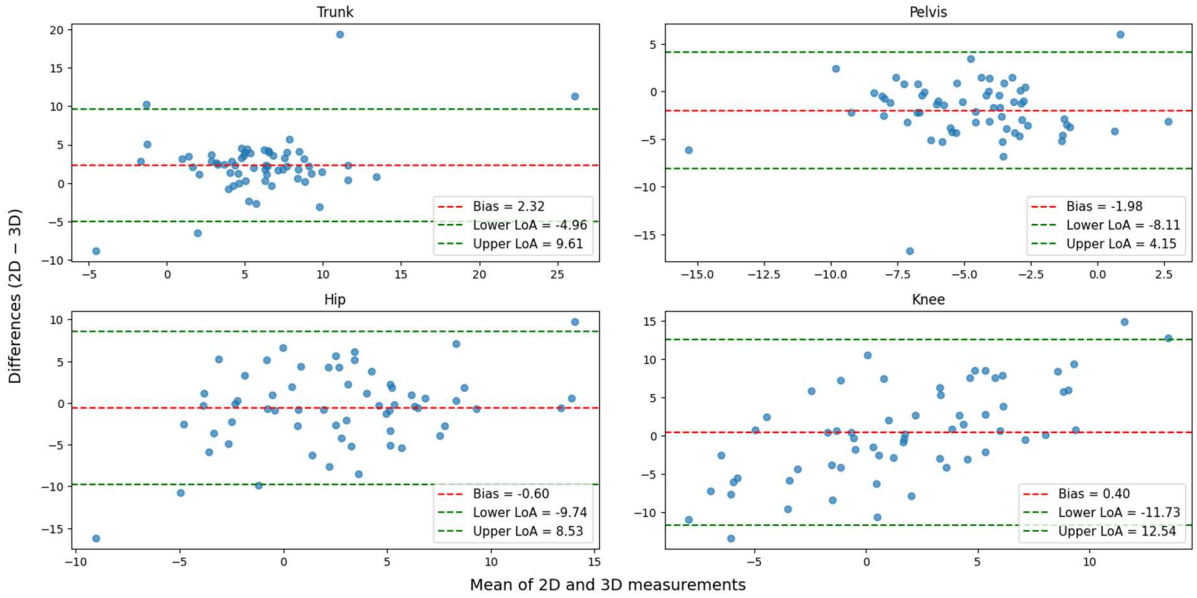
Introduction

Markerless motion capture systems are increasingly used to quantify human movement, but the validity of 2D pose-estimation approaches (e.g., MediaPipe) relative to 3D markerless systems remains unclear. This study investigated the concurrent validity of a 2D MediaPipe-based system against Theia3D in estimating frontal-plane trunk, pelvis, hip, and knee angles during a single-leg landing test.

Methods

In this study, 31 physically active adults (19 men; 29.3±8.1 years; 25.1±3.2 kg/m^2) performed single-leg landings from a 30 cm height onto a force platform. Two video datasets were simultaneously collected: an eight-camera Miqus setup processed with Theia3D (Theia, Canada) and a mobile phone frontal-plane video processed with a custom 2D pipeline based on MediaPipe pose estimation (version 0.10.14, Google, USA). Both datasets were captured at 120 Hz. Frontal-plane trunk, pelvis, hip, and knee angles at the deepest point of the landing were extracted. Both lower limbs were analyzed. Concurrent validity was assessed using Pearson correlation coefficients and Bland-Altman analysis (between-system mean differences and 95 % limits of agreement).

Results



For the trunk, the correlation between 2D and 3D measurements was strong ($r = 0.71$; $p < 0.001$). For the pelvis ($r = 0.59$; $p < 0.001$), hip ($r = 0.67$; $p < 0.001$), and knee ($r = 0.57$; $p < 0.001$), the correlation was moderate. Bland-Altman analysis revealed moderate bias for the trunk (2°; LoA: -5 to 10°) and small bias for the pelvis (-2°; LoA: -8 to 4°), hip (-1°; LoA: -10 to 9°), and knee (0°; LoA: -12 to 13°). There was a moderate correlation between the

mean values and the differences between methods for the knee (r = 0,67; p < 0,001). Bland-Altman plots are presented in Figure 1.

Discussion

Although measurements were correlated, the wide limits of agreement reveal considerable between-method variability. Even so, the excellent reliability suggests that this 2D approach may be suitable for tracking within-subject changes and standardized screening in clinical or field settings.

Is the Dynamic Knee Valgus During Single-Leg Tasks Associated With Knee Disorders? a Systematic Review With Meta-Analysis

Mr. Jean Marlon Machado[1], Ms. Kauane de Farias Andrade[1], Dr. Danilo De Oliveira Silva[2], Dr. Heiliane de Brito Fontana[3], Dr. João Paulo Vilas-Boas[4], Dr. Caroline Ruschel[1]

[1]College of Health and Sport Science, University of the State of Santa Catarina, Florianópolis, Santa Catarina, Brazil. [2]La Trobe Sport and Exercise Medicine Research Centre (LASEM), La Trobe University, Melbourne, Victoria, Australia. [3]BSiM-UFSC Musculoskeletal Biomechanics Research Group, Federal University of Santa Catarina, Florianópolis, Santa Catarina, Brazil. [4]Porto Biomechanics Laboratory (LABIOMEP), Faculty of Sport, CIFI2D, University of Porto, Porto, Porto, Portugal

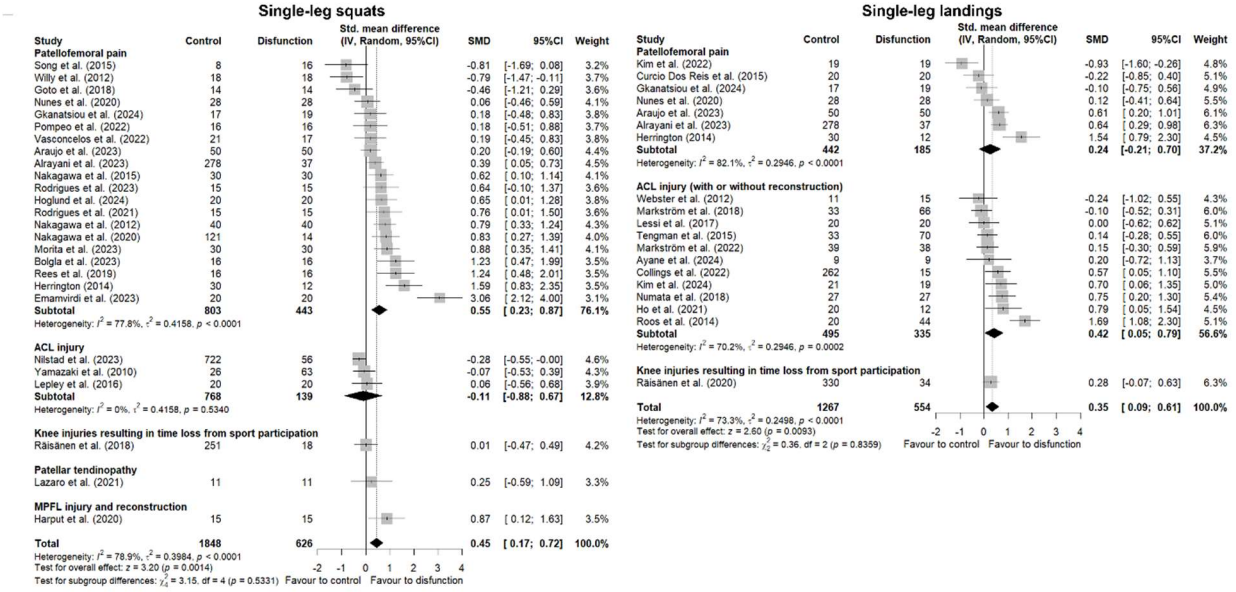
Introduction

There is conflicting evidence on the association between knee disorders and dynamic knee valgus (DKV) during functional tasks, possibly because different tasks generate different biomechanical demands. We conducted a systematic review to synthesize the evidence on whether DKV in single-leg tasks is associated with knee disorders and whether this association differs between single-leg squats and landings.

Methods

Systematic searches were conducted in Web of Science, CINAHL, Embase, PubMed, and Scopus. We included studies comparing DKV during single-leg tasks between individuals with knee disorders (or who later developed these disorders) and asymptomatic controls. We extracted data on participants, tasks, disorders, and DKV measures (type and magnitude). DKV measures were converted to standardized mean differences (SMD) and pooled in two meta-analyses: landings and squats. Subgroups were defined by disorder type. PROSPERO: CRD420251006257.

Results



Of 10204 records, 40 studies were included. The knee disorders identified were patellofemoral pain (k=22), ACL injuries with or without reconstruction (k=14), Knee injuries that resulted in time loss from sports participation (k=2), patellar tendinopathy (k=1), and medial patellofemoral ligament (MPFL) injury with reconstruction. For single-leg squats, DKV was greater in individuals with patellofemoral pain (SMD=0.55; 95%CI=0.23–0.87; p<0.001), but not different in individuals with ACL injuries compared to control, with a small overall effect (SMD=0.45; 95%CI=0.17–0.72; p<0.001). For single-leg landings, DKV was greater in individuals with ACL injuries (SMD=0.42; 95%CI=0.05–0.79; p<0.001), but

not different in individuals with patellofemoral pain compared to controls, with a small overall effect (SMD=0.35; 95%CI=0.09–0.61; p=0.009).

Discussion

The results reveal a task-specific association between knee disorders and dynamic knee valgus, suggesting that the sensitivity of DKV to differentiate disorders may depend on the biomechanical demands of the task. Individuals with patellofemoral pain exhibited greater DKV during single-leg squats, a slow and controlled task that demands proximal control and altered movement strategies commonly reported in PFP. In contrast, individuals with ACL injuries demonstrated greater DKV primarily during single-leg landings, a high-demand, impact-driven task that challenges neuromuscular control, knee stability, and trunk–hip coordination. Based on our findings clinicians should choose tasks that biomechanically challenge the clinical population they are managing.

Functional Relevance of Radiographic Alignment Measures in Reverse Total Shoulder Arthroplasty: A 3D Kinematic Analysis

Dr. João A. Bonadiman MD[1], Dr. Renato Miyadahira MD[1], Dr. Vitor La Banca MD[1], Dr. Felipe F. Gonzalez MD[2,1], Dr. Carolline P. Nunes MD[2,1], Dr. Gregory Nicholson MD[2], Dr. Brian Forsythe MD[2], Dr. Nikhil N. Verma MD[2], Dr. Jorge Chala MD[2], Dr. Leonardo Metsavaht PhD[1], Dr. Gustavo Leporace PhD[1], Dr. Grant E. Garrigues MD[2], Dr. Jonathan Gustafson PhD[2]

[1]Instituto Brasil de Tecnologias da Saúde (IBTS), Rio de Janeiro, Rio de Janeiro, Brazil. [2]Department of Orthopaedics, Rush University Medical Center, Chicago, Illinois, United States

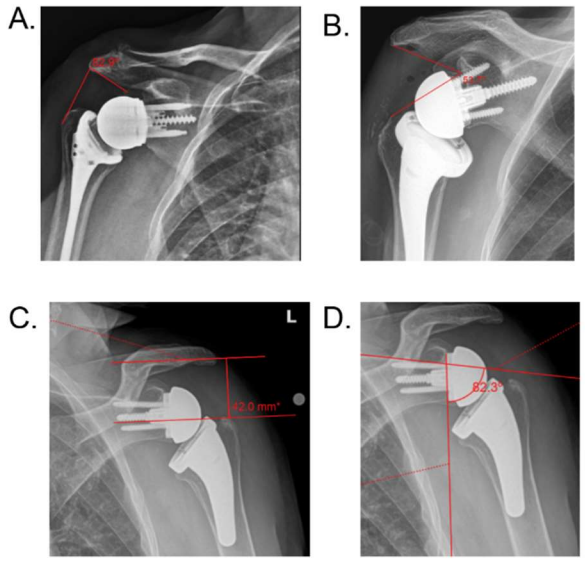
Introduction

Reverse total shoulder arthroplasty (RTSA) is widely used for cuff tear arthropathy, glenohumeral osteoarthritis, and complex proximal humerus fractures. Radiographic parameters such as the lateralization shoulder angle (LSA), distalization shoulder angle (DSA), acromiohumeral interval (AHI), and reverse shoulder arthroplasty angle (RSA beta) have been proposed as indicators of implant positioning, yet their relevance to postoperative function remains uncertain. This study evaluated associations between radiographic alignment parameters and in vivo shoulder kinematics in patients with medialized and lateralized glenosphere designs.

Methods

Twenty-five RTSA cases (11 medialized, 14 lateralized; mean age 71.0 ± 6.0 years) were analyzed. True anteroposterior radiographs were used to measure LSA, DSA, AHI, and RSA beta. Dynamic shoulder kinematics were recorded during abduction, scaption, and forward flexion. Range of motion was segmented into glenohumeral, scapulothoracic, and humerothoracic components, and scapulohumeral rhythm was calculated during scaption. Associations between radiographic parameters and kinematic outcomes were examined using Pearson or Spearman correlations and multivariable regression ($p < 0.05$).

Results



During abduction, glenohumeral abduction correlated with RSA beta ($r = 0.415$; $P = 0.049$), while glenohumeral internal/external rotation correlated with DSA ($r = 0.407$; $P = 0.054$) and AHI ($r = 0.487$; $P = 0.018$). Humerothoracic elevation and humerothoracic rotation correlated with RSA beta ($r = 0.479$; $P = 0.021$ and $r = 0.426$; $P = 0.043$). During scaption,

RSA beta correlated with humerothoracic rotation (r = 0.462; P = 0.026). During forward flexion, scapulothoracic rotation correlated with LSA (r = 0.470; P = 0.024). Regression analyses identified AHI as a predictor of glenohumeral rotation (r^2 = 0.15; P = 0.036) and LSA as a predictor of scapulothoracic rotation (r^2 = 0.17; P = 0.028).

Discussion

RSA beta showed the most consistent moderate correlations with kinematic variables, suggesting it may reflect aspects of implant positioning relevant to postoperative motion. Although these associations did not persist in multivariable models, the overall pattern indicates that RSA beta may capture alignment features related to dynamic behavior. These findings underscore the complexity of linking static radiographic measures to shoulder motion after RTSA and support the need for larger studies incorporating dynamic imaging and neuromuscular assessments.

Systematic Characterization of the Magnitude of Tremulous Joint Rotations Throughout the Upper Limb

Mr. Thomas Alley[1], Mr. Chayse Wright[1], Dr. Steven Charles PhD[1,2]

[1]Department of Mechanical Engineering, Brigham Young University, Provo, UT, United States. [2]Neuroscience, Brigham Young University, Provo, UT, United States

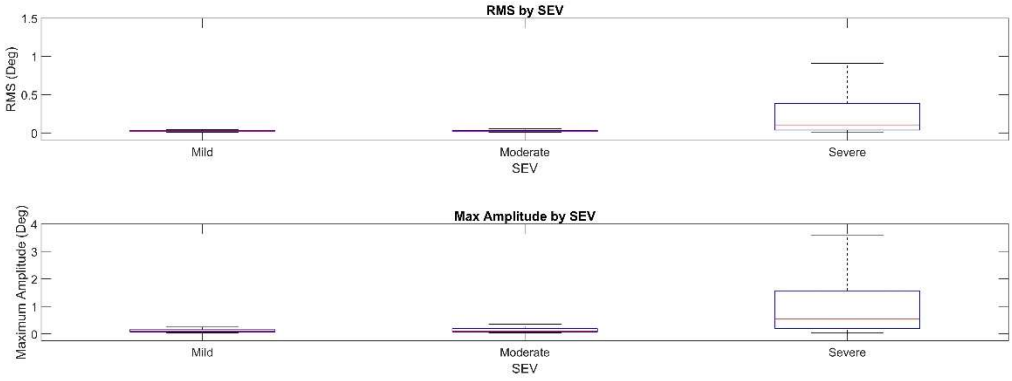
Introduction

Essential Tremor (ET) is one of the most prevalent movement disorders, affecting millions of people worldwide and often impairing activities of daily living [1]. Many efforts to improve tremor suppression methods (such as the development of tremor-suppressing orthoses) would benefit from a characterization of the magnitude of tremulous rotations in the joints of the upper limb. Although tremulous joint rotation (TJR) has been characterized in terms of power [2], a systematic characterization of the magnitude of TJR (in terms of degrees or radians) is not currently available.

Methods

Using motion capture data previously collected throughout the upper limbs of 23 participants with ET while they performed various postural and kinetic tasks [2], we calculated joint angles in the 7 main joint degrees of freedom (DOF) from the shoulder to the wrist [3], and applied a 6th order high-pass Butterworth filter with cut-off frequency at 2 Hz to remove voluntary motion. The root mean square (RMS) amplitude and the maximum amplitude, defined as the largest instantaneous deviation from the mean, were computed for each 30-second trial across all DOF and tasks.

Results



Across all participants and DOF, the mean ± SD of RMS amplitude of postural and kinetic tremor was 0.10 ± 0.33 deg and 0.53 ± 0.46 deg, and the maximum amplitude of postural and kinetic tremor was 0.42 ± 0.93 deg and 2.25 ± 1.95 deg. As expected, these magnitudes varied significantly by tremor severity (see figure) and DOF (not shown).

Discussion

This study provides the first systematic quantification of the magnitude of TJR throughout the upper limb, providing insight into where (which muscles/joints) to best intervene with peripheral tremor suppression methods. Considering the disabling nature of tremor, TJR

magnitudes were surprisingly small, especially for participants with mild and moderate tremor. The small rotation magnitudes provide partial justification for linear models of tremor propagation, which describe the effect of the peripheral neuromusculoskeletal dynamics on tremor [4].

A More Accurate Method to Quantify Tremorogenic Muscle Activity

Mr. Chayse Wright[1], Mr. Noah Francom[1], Dr. Dario Farina[2], Dr. Steven Charles[1,3]

[1]Department of Mechanical Engineering, Brigham Young University, Provo, UT, United States. [2]Bioengineering, Imperial College London, London, Greater London, United Kingdom. [3]Neuroscience, Brigham Young University, Provo, UT, United States

Introduction

Although many studies have analyzed surface electromyographic (sEMG) signals in persons with tremor, there is a lack of standardization in how tremorogenic muscle activity is quantified. Researchers commonly quantify features of peaks in the tremor band (4-8 Hz) of the power spectral density (PSD) of processed sEMG using Welch's method, but Welch's method produces many spurious peaks unrelated to tremor, especially in persons with mild and moderate tremor. We explore two methods to reduce the presence of spurious peaks, providing a more robust estimation of tremorogenic muscle power.

Methods

We previously recorded sEMG from the 15 major superficial muscles of the upper limb in 24 persons with Essential Tremor and 10 control subjects as they performed a variety of tasks [1]. In the first method (W+), after estimating the PSD of the linear envelope of sEMG using Welch's method, we identified tremor-band peaks that were both significant and consistent (peaks whose amplitude was statistically significantly different from side windows, and whose frequency was consistent across the participant's muscles and trials). In the second method (YW), we estimated the PSD of the linear envelope using an autoregressive method (Yule-Walker) known to minimize the number of PSD peaks, and then identified the tallest peak. The two estimates were optimized by finding the transform parameters that minimized the variance in peak frequency within a participant, which was assumed to be constant in similar experimental tasks.

Results

Both W+ and YW methods greatly reduced the presence of spurious peaks compared to Welch's method by itself. Furthermore, the W+ method accurately predicted clinical tremor severity. That said, the YW method resulted in 5-10 times lower variance in peak frequency that the W+ method (see table).

Discussion

Developing PSD estimation practices that are sensitive to tremor in persons with mild and moderate tremor allows more accurate quantification of tremorogenic muscle activity in all persons with tremor. This opens the door for future studies comparing tremorogenic activation patterns between muscles, tasks, persons, and tremor types, paving the way for improved tremor suppression.

Changes In Trunk Flexion During Five Times Sit-To-Stand In Post-Operative Ventral Hernia Repair Patients Measured Using Single-Camera Markerless Motion Capture

Mr. Cheikh Tandiang B.A.[1], Ms. Kiana Shannon B.S.[2], Mr. Peter Edwards B.S.[3], Dr. Benjamin Poulose MD/MPH[2], Dr. Stephanie Di Stasi PT, PhD[2], Dr. Ajit Chaudhari PhD, FACSM[2]

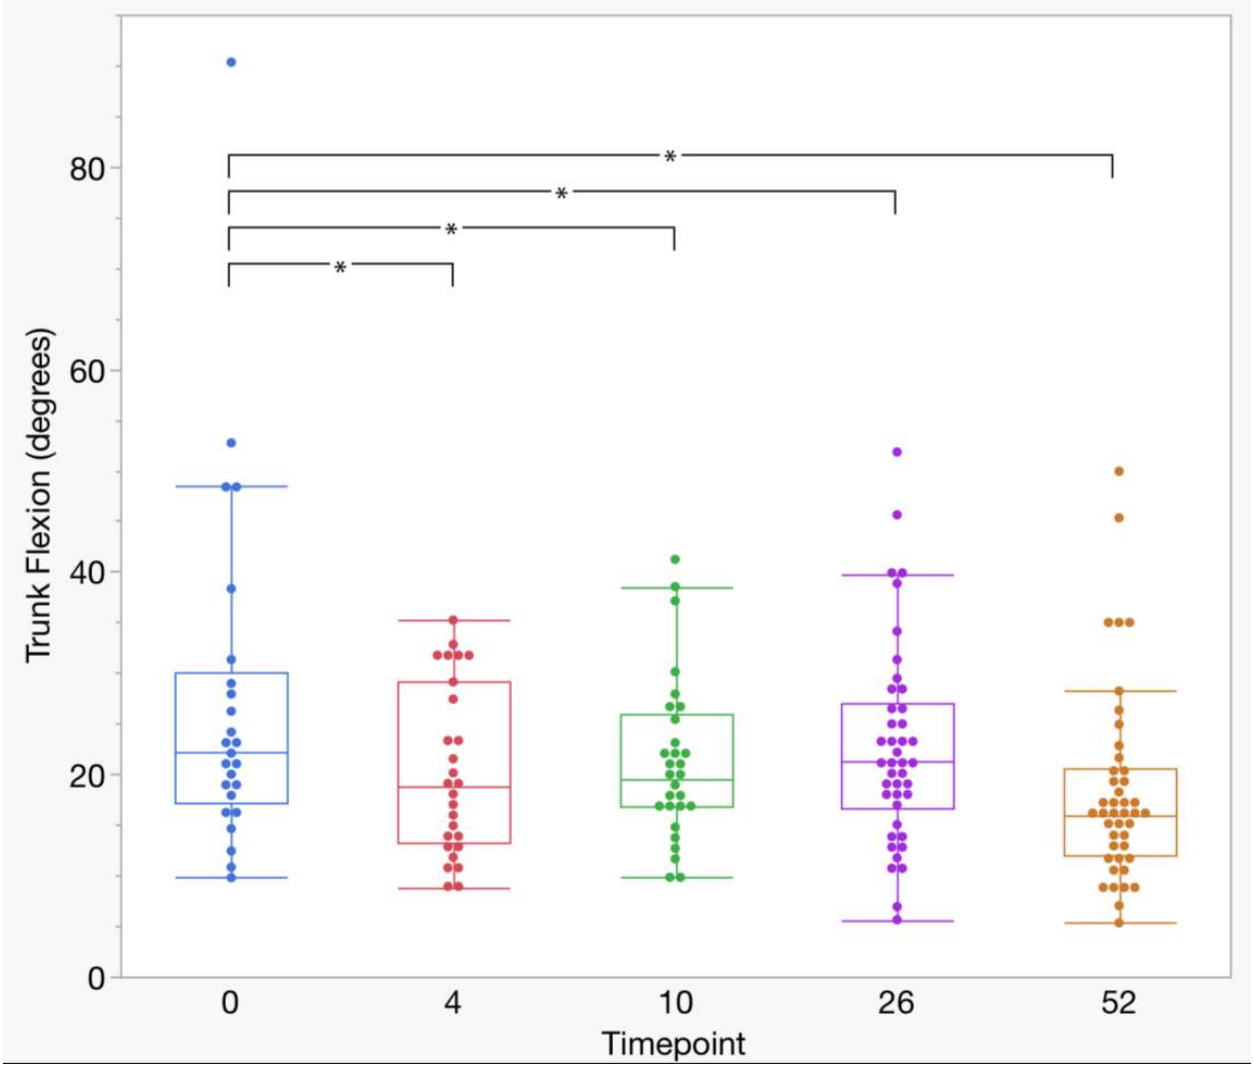
[1]Ohio State University, Columbus, OH, United States. [2]Ohio State University, Columbus, Ohio, United States. [3]Case Western Reserve University, Cleveland, Ohio, United States

Introduction

The Five Times Sit to Stand Test (5XSTS) is a widely utilized test of physical function for a range of clinical populations, with time to complete as the primary outcome [1]. Studies regarding the biomechanics of 5XSTS have focused on populations with neuromuscular and degenerative joint diseases [2] to better understand compensations to overcome weakness, lack of control, or pain. The purpose of this study was to evaluate the biomechanics of 5XSTS in a novel population of ventral hernia repair patients to assess how they move their trunk, and how this changes as they progress through recovery.

Methods

This study included 58 participants aged 18–70 enrolled from the ABVENTURE-P trial [3] (aged 18-70) scheduled for elective ventral hernia repair. De-identified video recordings of 5XSTS were uploaded to Sit2stand.ai [4] to extract peak trunk flexion and peak trunk acceleration. Video collection was initiated part way through the trial, so not all participants had videos for all timepoints. Peak values were compared across the five timepoints using a mixed-effects model with timepoint as fixed ordinal effect and participant as a random effect, with Tukey HSD post-hoc comparisons.



Results

Peak trunk flexion significantly decreased (i.e. more upright) between pre-operative baseline and the other timepoints (-9.7±2.3° @ 1y, $p<0.0001$). Peak trunk acceleration significantly increased between 4 weeks post-op and 1-year post-op (+128±45°/s^2, $p=0.03$).

Discussion

This study demonstrates that trunk biomechanics during 5XSTS change during recovery from ventral hernia repair. More work is needed to determine the trajectory of these changes, whether they are associated with perceived functional or quality-of-life improvements, and how they may be influenced by post-operative rehabilitation. These findings highlight the value of biomechanical analysis for identifying functional changes beyond just time to complete, and they identify a potential tool to guide development of more targeted rehabilitation for ventral hernia repair patients in clinical and telehealth environments.

Estimating Joint Moments with Marker-less Motion Capture and Pressure Insoles

Ms. Christina Kyriacou

University of Rochester, Rochester, NY, United States

Introduction

Joint moments are important to consider in gait characterization, supporting injury prevention and rehabilitation assessment. Marker-based motion capture and 3D force plate data form the gold standard for joint kinetic estimation, but these modalities are confined to motion analysis labs, limiting accessibility and scalability. Alternatives such as marker-less motion capture and in-shoe pressure insoles offer increased portability, enabling assessment of movement mechanics outside of a research lab. This study evaluates the feasibility of estimating joint moments using marker-less motion capture and pressure insoles.

Methods

3D marker-based and marker-less (Theia3D) motion capture, force plate, and pressure insole (XSENSOR X4) data were collected during 252 stance phases (93 walking, 67 jogging, 70 drop vertical jump landing). Sagittal plane joint moments were estimated using (1) marker-based motion capture and force plates (gold standard), (2) marker-less motion capture and force plates, and (3) marker-less motion capture and in-shoe pressure insoles. After estimation, an algorithm was developed and validated to adjust alternative method outputs to the gold standard; the training subset was extracted evenly across the dataset to avoid uneven training/validation (85%/15%) distribution across participants. Within the adjustment algorithm, dynamic time warping was used to temporally align each alternative method curve with the gold standard curve. Then, the alternative method curve was scaled in magnitude to match that of the gold standard curve. Methodological agreement was assessed before and after adjustment through discrete analysis of peaks and continuous analysis using Statistical Parametric Mapping (SPM).

Results

Before adjustment, peak moments computed by alternative methods differed from the gold standard, and incorporating insoles produced larger and more variable biases. After adjustment, continuous joint moments from the alternative methods did not significantly differ throughout the stance phase compared to the gold standard (Figure 1).

Discussion

These results demonstrate feasibility to estimate sagittal plane joint moments using 3D marker-less motion capture and pressure insoles, although an adjustment algorithm is necessary to interpret outputs alongside gold standard data. This supports the possibility of joint kinetic analysis outside of a lab environment using alternative modalities, driving community-based data collection and supporting a representative population.

Sacral Tissue Risk Under Wearable Devices: Effects of Contact Geometry and Person-Specific Tissue Mechanics

A/Prof. Daphne Weihs[1,2,3], Ms. Anastasiia Simonova[1], Dr. Aleksei Orlov[1]

[1]Technion-Israel Institute of Technology, Haifa, Haifa, Israel. [2]Gent University, Gent, Belgium, Belgium. [3]Hasselt University, Hasselt, Belgium, Belgium

Introduction

The mechanical stability of loaded human skin tissues is central to understanding thresholds that may lead to pressure injuries. Soft-tissue thickness and mechanics vary widely across individuals, affecting stress and strain development beneath wearable devices. Despite this variability, the combined influence of device geometry and tissue material properties is not fully understood. Using computational modeling, we quantify the mechanical loads generated by simple devices, e.g. sensors and cables on sacral soft tissues.

Methods

A multi-layer sacral model was developed in Abaqus/CAE 2024, incorporating epidermis, dermis, adipose tissue, and muscle with literature-based thicknesses and mechanical properties [1], [2]. Stiffness was reduced or increased to represent aging, tissue degeneration, or rigid conditions. Two device configurations were simulated: a round, flat sensor and an elongated cable. Pressures of 2-10 kPa were uniformly applied beneath each device, and stress and strain were evaluated in all tissues in a 30 mm region of interest (ROI). The top quartile of stresses and strains was evaluated within the ROI, allowing device-specific comparisons independent of externally defined strain limits.

Results

With 10 kPa loading, the two devices exhibited distinct tissue exposure to high strains. The sensor's flat contact generated smoother, more uniform strain fields without localized peaks. In contrast, the cable's narrow elongated footprint created concentrated strain regions, yielding 1.25 times greater tissue exposure in the highest strain quartile than the sensor. Softened tissues amplified these effects, increasing high-strain exposure to 1.4 times the initial level for the sensor and 1.6 times for the cable. In stiffened tissues, high-strain exposure decreased for both devices, becoming 1.1 times lower for the sensor and 1.3 times lower for the cable, indicating reduced mechanical vulnerability.

Discussion

Device geometry and tissue stiffness together influence mechanical tissue-risk in the sacral region. The cable created localized high strains, while the flat sensor produced smoother fields across most tissue layers. These effects increased with tissue softening and diminished as tissues stiffened, emphasizing importance of consideration of tissue variability in device design, application, and in assessing pressure-injury risk.

Effect of Starting Position on Shoulder Orientation Error Across Various Target Angles

Professor David Suprak PhD, Student Grace Truesdale MS, Professor Nathan Robey PhD, Professor Jun San Juan PhD

Western Washington University, Bellingham, WA, United States

Introduction

Previous research indicates that joint position sense (JPS) is affected by muscle activation and torque. Researchers have required repositioning from a single neutral starting position. Further, constant error has only considered planar errors.

This study was conducted to assess the effect of starting position on directional repositioning errors at the shoulder. It examined the effect of starting position (at side (AS) vs. 90º of abduction (ninety) vs. full elevation (FE)) on orientation error at four different target positions (50º, 70º, 90º, and 110º of scapular plane elevation).

Methods

Twenty-four healthy participants (21.79 ± 1.67 yrs, 172.10 ± 9.52 cm, 71.95 ± 14.31 kg) completed a single JPS testing session.

The Polhemus Fastrak 3Space electromagnetic tracking system (Colchester, VT), integrated with custom LABVIEW software (National Instruments, Austin, TX), collected humerothoracic kinematics.

Participants were guided to target positions via a head-mounted display, concentrated on the position, returned to start, and tried to replicate the position. Participants lay supine on a custom apparatus with back support and minimal skin contact to reduce tactile stimulation. Participants completed two trials to each target angle, from each starting position. Kinematic data were used to calculate orientation error, with 0° indicating reproduced position to the right, 90° directly above, 180° to the left, and 270° directly below the target position.

A Harrison-Kanji test was run via custom MATLAB code (CircStat Toolbox) to examine the interaction and main effects of starting position and target angle on orientation error.

Results

There was a significant starting position-by-target angle interaction effect on orientation error (p = .017). The follow-up Watson-Williams test indicated no effect of target angle on orientation error starting from the at-side position (p = .116), but a significant effect when starting at 90° (p = .0007) and from full elevation (p < .001) (Table).

Discussion

Participants overshot most, but not all, target angles. They overshot each target angle starting AS. From ninety, they overshot 70° and 90°, missed anterior at 50°, and missed high at 110°. From FE, participants undershot 50° and overshot higher angles. These results may help elucidate contributions from peripheral receptors and motor command.

Impaired Control of Whole-Body Angular Momentum During Gait in Chronic Ankle Instability

Ms. Diane Malenfant[1], Mr. Chems-eddine Hakmi[2], Dr. Charlotte Le Mouel[1], Dr. Rosemary Dubbeldam[2]

[1]Institut des Systèmes Intelligents et de Robotique (ISIR), Sorbonne Université, CNRS, Paris, Paris F-75005, France. [2]Dept. of Movement Science, University of Münster, Horstmarer Landweg 62b, Münster, North Rhine-Westphalia, Germany

Introduction

Musculoskeletal injuries can severely disrupt the motor strategies of human balance, increasing the risk of falls and health costs. Dynamic balance during walking is maintained by controlling the range of Whole-Body Angular Momentum (WBAM). This range is increased in patients with lower limb injuries and/or neural pathologies.

Chronic Ankle instability (CAI) is one of the most common and disabling balance disorders, developing in up to 40–70 of individuals after a lateral ankle sprain. It combines mechanical instability – tissue laxity and altered joint kinematics – and functional instability, including proprioceptive deficits, delayed neuromuscular response and impaired postural control. Ankle torque during gait is altered in CAI patients, and this alteration at the ankle level might affect their control of the angular momentum. Considering previous works, we expect the range of WBAM to be increased in CAI patients, reflecting impaired control of WBAM.

Methods

We recorded the kinetics and kinematics of thirteen CAI patients and thirteen healthy controls while they walked barefoot on force plates, at self-selected comfortable speed, with reflective markers for 3D motion capture. We then computed the net torque around the Center of Mass (CoM) – the WBAM being its integration over time –, the mean walking speed over each gait cycle and step length and width.

Results

The results indicate that patients walked significantly slower than controls, with shorter steps. After correcting for walking speed, patients had larger range of WBAM. This was due to a significantly increased net torque around the CoM in both the sagittal and frontal

planes only during the single stance phase of gait. In contrast, during the double stance phase, patients had significantly lower torque than controls.

Discussion

This suggests that patients regulate their WBAM more tightly than controls during double stance, possibly because both feet touching the ground simultaneously facilitates torque control. Such better regulation at the hip level in patients may then be a compensation for impaired control of the ankle due to CAI. However, double stance compensation alone does not seem to be sufficient to fully correct for impaired control, since the range of WBAM on the whole gait cycle it is still increased.

Bilateral Impairments in the Stability of Center of Pressure Control During One-Limb Stance in Chronic Ankle Instability

Mr. Chems-eddine Hakmi[1], Ms. Diane Malenfant[2], Dr. Rosemary Dubbeldam[1], Dr. Charlotte Le Mouel[2]

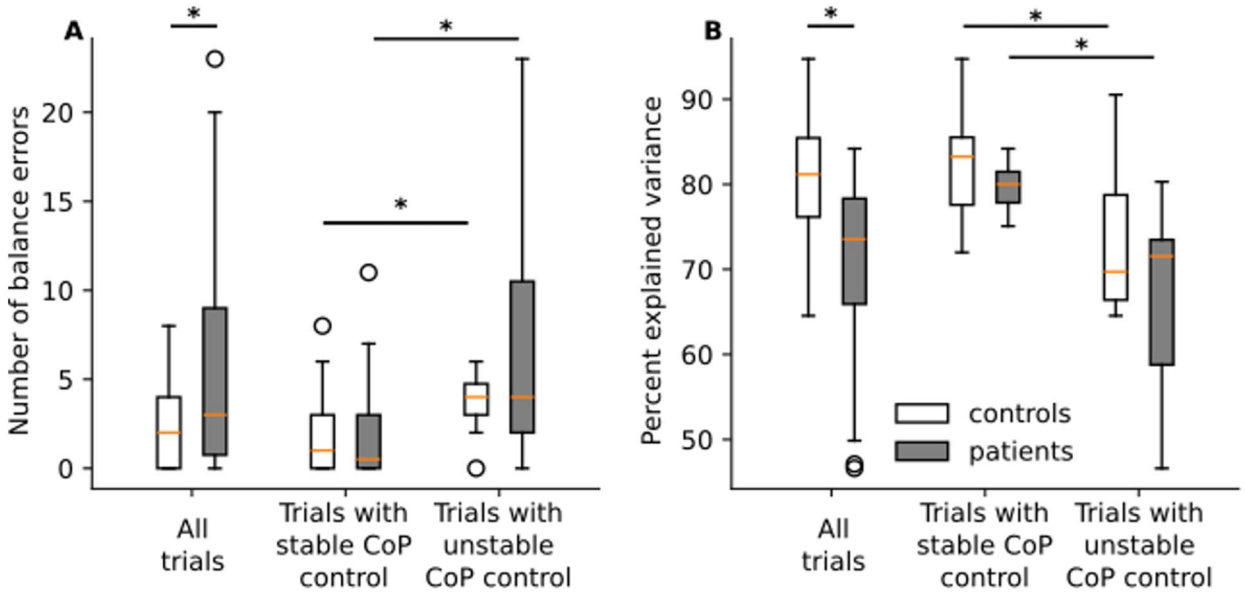
[1]Dept. of Movement Science, University of Münster, Horstmarer Landweg 62b, Münster, North Rhine-Westphalia, Germany. [2]Institut des Systèmes Intelligents et de Robotique (ISIR), Sorbonne Université, CNRS, Paris, Paris F-75005, France

Introduction

Lateral ankle sprains are amongst the most prevalent injuries in the general population. In 40 to 70% of patients, symptoms persist more than 1 year after the injury, with sensations of the ankle “giving way” and increased re-injury risk. In such Chronic Ankle Instability (CAI), bilateral alterations in the neural control of standing balance have been identified, suggesting that maladaptive neural changes play a role in the chronification of symptoms. We hypothesise that CAI patients have a bilateral deficit in the control of the Centre of Pressure (CoP), impacting their balance.

Methods

Thirteen CAI patients and thirteen matched healthy controls completed one-limb stance with eyes open and closed. The CoP was recorded using force plates. Full body kinematics were recorded using motion capture, and used to estimate the Centre of Mass (CoM) position. The CoP was reconstructed as a linear sum of the delayed CoM position and velocity in the frontal plane, yielding the proportional and derivative gains. The stability of the CoP controller on a given trial was determined analytically, depending on whether a controller with these gains can stabilise an inverted pendulum. Balance errors were detected whenever the raised foot touched the ground.



Results

There were no significant differences between the injured and uninjured limb in either balance errors or CoP control. Balance errors increased when closing the eyes for both patients and controls, and were larger in patients than controls. With eyes closed, CoP control was impaired in patients relative to controls, with a reduction of both the variance of the CoP explained by CoM state, and the proportion of trials with stable controllers. When comparing trials with stable (respectively unstable) controllers between patients and controls, we found no differences in either explained variance or balance errors.

Discussion

The ability to maintain balance on one limb with eyes closed is impaired bilaterally in CAI patients, due to a bilateral impairment in CoP control, specifically a reduction in the proportion of trials with stable CoP control. This ability to adopt a stable CoP controller seems critical for balance, as differences between patients and controls disappeared when controlling for CoP controller stability.

Images (Optional)

Influence of CoP controller stability on balance with eyes closed. Number of balance errors (A) and Percent explained variance of the CoP in the frontal plane (B). There are significant difference between controls (white) and patients (grey) when considering all trials (left), but these differences disappear when considering only trials with stable (middle) or unstable (right) CoP control.

Tibiofemoral Loading Shifts Following Combined ACL Reconstruction and Meniscus Treatment: A Weight Bearing CT Study

Mr. Tyce C. Marquez, Mr. Travis Zhang, Dr. Richard VanTienderen, Ms. Shannon Ortiz, Prof. Brian R. Wolf, Prof. Donald D. Anderson

University of Iowa, Iowa City, IA, United States

Introduction

Failure to fully restore native knee kinematics with ACL reconstruction (ACLR) is theorized to shift tibiofemoral loading to unconditioned cartilage regions, contributing to later osteoarthritis (OA) development [1]. ACL-injured knees often have concurrent meniscal injuries, with certain pathologies known to accelerate OA [2,3]. This study analyzed shifts in the tibiofemoral center of contact (CoC) in ACLR knees with concurrent meniscal injuries.

Methods

Bilateral knee weight bearing CT (WBCT) scans were acquired for 58 patients (26M/32F, Age=22.9±8.9) at 12.5±0.8 months post-ACLR in semi-flexed (~20°) and fully extended poses. 3D joint space width (JSW) distributions in the knee were computed from WBCT using semi-automated methods [4]. The CoC was defined as the centroid of the narrowest 10% of JSW values measured in each compartment. CoC location and translation between poses for patients with ACLR+meniscus treatment were compared to their intact contralateral knee and ACLR only knees. Group differences in CoC translations were assessed using one-way ANOVA with post-hoc Bonferroni correction, significance set at p=0.05.

Results

A meniscus tear was concurrently treated in 36 patients, with 22 patients receiving ACLR only. A medial meniscus tear resulted in a more medially positioned CoC in the medial compartment during full extension compared to ACLR only and intact knees (Figure 1). This resulted in a significant difference (p=0.02) in medial-lateral translation between ACLR+meniscus and ACLR only knees and a trend, although not significant (p=0.08), between ACLR+meniscus and intact knees. No significant differences were observed for anterior-posterior translations in the medial compartment or for any translations in the lateral compartment.

Discussion

As the knee moves from semi-flexed to fully extended, a medial meniscus tear, although treated, shifted medial compartment tibiofemoral loading medially. This shift in tibiofemoral loading to unconditioned cartilage regions may contribute to later OA development. Utilizing WBCT and new biomarkers, such as the CoC, may enable earlier OA risk stratification, allowing for timely intervention.

Images (Optional)

Dr. Felipe F. Gonzalez

Ms. Eleonora Cabai

Introduction

A large proportion of individuals with medial meniscus posterior root (MMPR) tears progress to knee osteoarthritis even after surgical repair. Gait analysis can help identify modifiable biomechanical risk factors to optimize knee joint loading through gait modification interventions. The objective of this study was to define gait kinematics and kinetics in patients with MMPR tears and those with MMPR repairs, compared to healthy, age-matched controls. We hypothesized that patients with MMPR tears and repairs would exhibit altered gait characteristics associated with joint degeneration.

Methods

In this cross-sectional study, 58 knees were analyzed: MMPR tear (n=20), MMPR repair (n=21), and healthy controls (n=17). MMPR repair patients underwent transtibial pullout repair performed by a single fellowship-trained surgeon. Gait analysis was conducted using a marker-based 3D motion capture system and force plates. Primary outcomes included

knee joint kinematics and kinetics. Statistical comparisons of discrete metrics and time-series data via Statistical Non-Parametric Mapping were evaluated across the gait cycle. Patient-reported outcomes were also assessed using IKDC, KOOS Jr., VR-12, and VAS pain scores. Group comparisons were performed using the Kruskal–Wallis test. The significance level was set at $p<0.05$.

Results

Both MMPR tear and repair groups exhibited increased knee varus thrust (Tear: 5.0° ± 2.1; Repair: 5.2° ± 2.0; Control: 3.3° ± 0.9; $P < 0.01$), decreased tibial internal rotation at loading response (Tear: –6.2° ± 5.3; Repair: –2.1° ± 3.6; Control: 2.2° ± 5.8; $P < 0.01$), and greater knee adduction angle (varus) at midstance (Tear: 0.1° ± 3.9; Repair: –0.1° ± 5.0; Control: –5.9° ± 4.1; $P < 0.01$) (Figure). The MMPR repair group exhibited higher functional scores (IKDC: 75.3 ± 19.9 vs. 43.6 ± 14.2; KOOS Jr.: 84.7 ± 15.4 vs. 59.7 ± 8.9; $P < 0.01$), lower pain levels (VAS: 1.5 ± 2.1 vs. 3.8 ± 2.4; $P < 0.01$), and higher tibial internal rotation compared to the tear group ($P < 0.05$; ES: 0.95).

Discussion

The repair group showed more favorable clinical and biomechanical variables than the tear group. However, both groups exhibited established biomechanical risk factors for knee OA progression, such as varus thrust. Motion analysis can be used to detect early biomechanical issues and may help identify MMPR tear and repair candidates for timely gait-modification interventions to improve long-term joint health.

Characterizing Ipsilateral Temperature Differentials in Wearable Foot Monitoring for Ulcer Prevention

Dr. Emily Matijevich PhD[1,2], Dr. Maryam Hajizadeh PhD[1], Ms. Emily Bray MBA[1], Ms. Erin Barrett MScHQ[1], Dr. Evan Minty MD[3], Dr. Breanne Everett MD[1]

[1]Orpyx Medical Technologies, Calgary, Alberta, Canada. [2]Faculty of Kinesiology, University of Calgary, Calgary, Alberta, Canada. [3]Department of Medicine, University of Calgary, Calgary, Alberta, Canada

Introduction

Since 1979, foot temperature monitoring has been used to detect tissue inflammation in individuals with neuropathy at risk of foot ulceration [1]. Guidelines recommend identifying temperature differences between corresponding plantar regions on the left and right foot that exceed a threshold (2.2°C) [2].

Contralateral differentials help reduce confounding that impacts both limbs (environmental temperatures), but cannot be used in individuals with one foot or when one foot is obscured (bandages, offloading devices). Although unilateral monitoring methods exist [3], accuracy may be enhanced by relating ipsilateral and contralateral differentials in individuals with data from both feet.

The purpose of this analysis was to compare ipsilateral (within foot) to contralateral differentials in individuals at risk for diabetic foot ulceration.

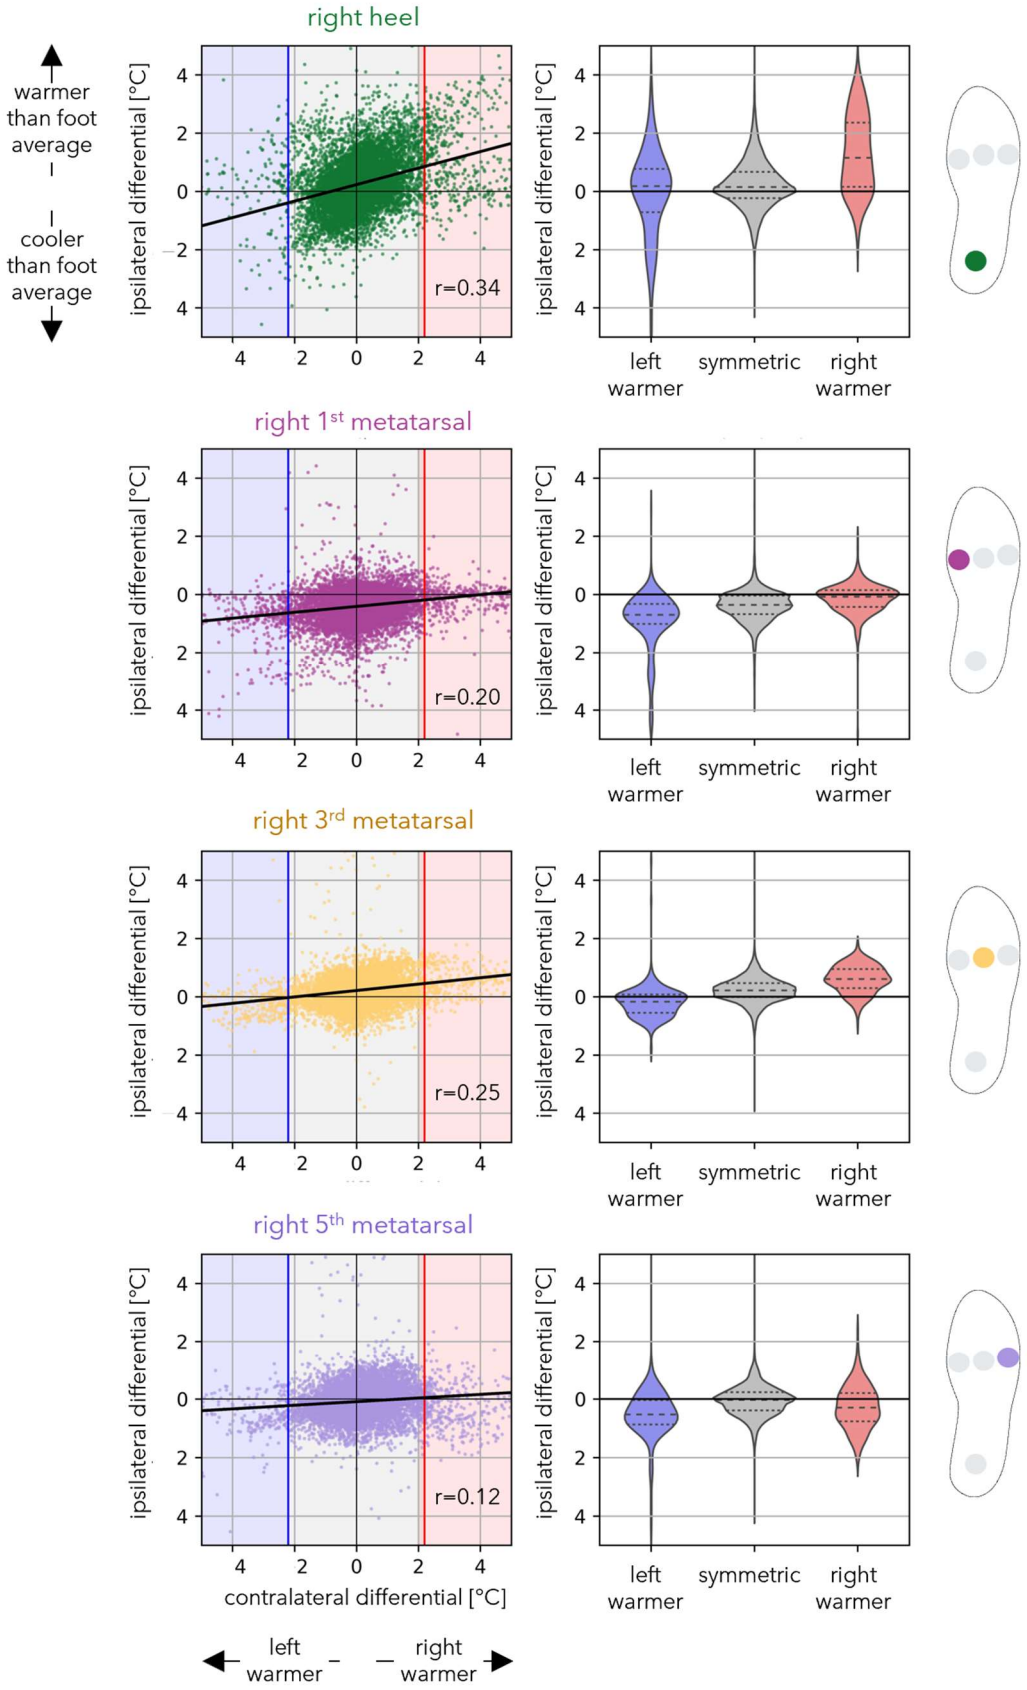
Methods

Twelve months of plantar temperature data were analyzed from patients using the Orpyx® Sensory Insole system, which monitors temperature continuously at high-risk bony prominences.

For each patient-day, contralateral differentials were computed between corresponding locations on left and right feet and ipsilateral differentials between a single location and the average temperature of that foot. Correlations were evaluated using Pearson's r.

Data were categorized as left contralaterally warm, right contralaterally warm, or contralaterally symmetric. Differences in ipsilateral differentials among groups were analyzed with Kruskal-Wallis tests, and significant results ($p<0.05$) were followed by Mann-Whitney tests with Bonferroni correction.

Results



11,165 patient-days were analyzed (Figure 1). Contralateral-ipsilateral correlations were significant for all regions except the left heel (p=0.29). Significant correlations were weak (r = 0.12 to 0.34).

Significant group-wise differences were found across all regions. Pairwise comparisons were significant except for the left heel (symmetric vs. left warmer, p=0.10) and right heel (right cooler vs. symmetric, p=0.77). Median ipsilateral differentials ranged from 0.05-0.73 °C (contralaterally cool), 0.03-0.36 °C (contralaterally symmetric), and 0.07-1.15 °C (contralaterally warmer).

Discussion

Ipsilateral differentials varied across contralateral groups, though the magnitude of difference was small. Robust unilateral monitoring may require detecting deviations from an individual's personalized temperature profile, while also considering factors such as angiosome-level perfusion and activity dependent foot loading.

Acute Cartilage Deformation Following Walking Differs With Radiographic Severity in Clinical Knee Osteoarthritis

Dr. Erin C.S. Lee PhD[1], Dr. Kendal A. Marriott PT, PhD[1], Dr. Anthony A. Gatti PhD[2], Ms. Natasha K. Ivanochko MSc[1], Dr. Jacquelyn M. Maciukiewicz PhD[1,3], Dr. Lauren Straatman PhD[1], Ms. Emily Wiebenga[1], Dr. Jonathan D. Adachi MD[4], Dr. Michael D. Noseworthy PhD[4], Mr. Paul W. Stratford MSc[4], Dr. Monica R. Maly PT, PhD[1]

[1]University of Waterloo, Waterloo, ON, Canada. [2]Stanford University, Palo Alto, CA, United States. [3]Waterloo Regional Health Network, Waterloo, ON, Canada. [4]McMaster University, Hamilton, ON, Canada

Introduction

Knee osteoarthritis (OA) severity is commonly classified by Kellgren-Lawrence (KL) grade. While KL grade indirectly accounts for cartilage loss by categorizing joint space narrowing, cartilage also varies in quality and function. Compliant cartilage may have a compromised ability to withstand loading [1] but it is unknown whether compliance differs across OA severity. The objective of this study was to compare tibiofemoral cartilage thickness, composition (T2 relaxation time), and acute deformation following walking across KL grades in adults with clinical knee OA.

Methods

89 adults aged 45-75 with clinical knee OA received an x-ray of their most symptomatic knee. KL grade was determined by a musculoskeletal radiologist. Participants underwent magnetic resonance imaging before and immediately after a 25-minute walk at a standardized speed [2]. We computed mean thickness and T2 (reflecting free-water content) in the medial and lateral tibia and weight-bearing femur. Acute deformation was the change in thickness from pre- to post-walk scans. For each region, we performed ANCOVAs and post hoc Tukey tests to compare thickness, T2, and deformation between KL grades cross-sectionally, after adjusting for covariates.

Results

15 participants were classified as normal (KL0) or doubtful (KL1), 25 as mild (KL2), 24 as moderate (KL3), and 25 as severe (KL4) OA. Thickness and acute deformation of the medial tibia, medial femur, and lateral femur varied across KL grade. In the medial regions, knees with severe OA (KL4) had thinner cartilage ($p<0.001$) and greater deformation ($p<0.01$) than

less severe knees (KL0-KL3). In the lateral femur, severe knees had thicker cartilage ($p<0.05$) and greater deformation ($p<0.05$) than mild knees (KL2). Thickness and deformation did not differ among KL0-KL3. There was no difference in T2 in any region; or in thickness or deformation in the lateral tibia.

Discussion

Compared to KL0-3, acute cartilage deformation in the medial tibia and weight-bearing femur is greater in KL4, suggesting that more compliant cartilage is a feature of severe knee OA disease. Thickness, composition, and function were highly variable in KL0-3. Future work will explore whether greater cartilage compliance and lower thickness predict future worsening in KL0-3.

Electromyography Activation Comparison of a Novel Deceleration Upper Extremity Exercise Compared to Traditional Thrower's Ten Exercises

Dr. FJ Goodwin PT, PhD, DPT, Dr. Angela Stagliano PT, DPT, PhD, OCS, GTS, CSCS, Dr. Grant Drenning PT, DPT, Dr. Davis Jackson PT, DPT, Dr. Garrett Sicard PT, DPT

Charleston Southern University, Charleston, SC, United States

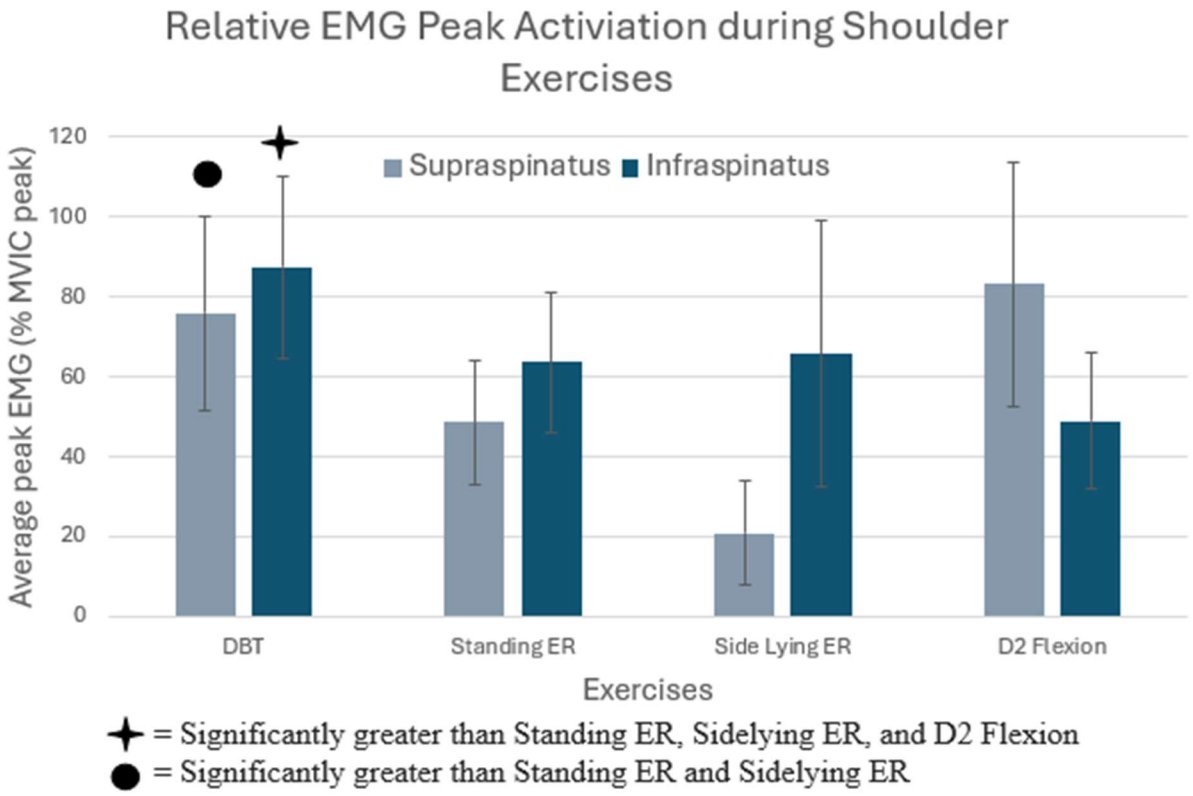
Introduction

Current throwing rehabilitation programs attempt to restore shoulder neuromuscular control and function. Deceleration training has emerged as a novel exercise to improve ball throwing velocity however it is not utilized in Throwers Ten programs. We hypothesize that a novel deceleration brake training (DBT) upper extremity exercise will demonstrate greater muscular activation levels assessed via electromyography (EMG) compared traditional Thrower's Ten exercises.

Methods

24 individuals (14 M, 10 F; 24.7±2.1 y.o; 1.73±0.06 m; 74.1±11.8 kg) free from upper extremity pathology volunteered for this study. Subjects completed dominant arm external rotation MVIC with EMG sensors placed on supraspinatus and infraspinatus with a handheld dynamometer in the 90/90 position. Peak EMG values were recorded and averaged across 3 trials. Subjects then completed 2 sets of 4 exercises via a balanced Latin Square: Sidelying ER with 5#, Standing D2 Flexion with Theraband, Standing ER with arm at side with Theraband, & Seated DBT with arm in 90/90 position. The DBT exercise involved rapidly pulling a strap attached to a 5# weighted pendulum and then catching as the pendulum swung back down. EMG was collected during each exercise and average EMG peaks were determined from 3 consecutive repetitions. These were calculated as percentages with the peak EMG values from the MVIC trials. ANOVAs were completed to determine the difference between exercises in relative peak EMG activation in the supraspinatus and infraspinatus muscles.

Results



1-way ANOVA of Infraspinatus EMG peaks was significant ($F=12.36$, $p<0.001$) with Tukey's HSD post-hoc revealing the DBT exercise (87.45±22.83%) was significantly higher than Sidelying ER (54.66±33.29%, $p<0.001$), Standing ER (63.54±17.77%, $p=0.003$), and D2 Flexion (49.0±16.87%, $p<0.001$).

1-way ANOVA of Supraspinatus EMG peaks was significant (F=39.79, p<0.001) with Tukey's HSD post-hoc revealing the DBT exercise (75.88±22.12%) was significantly higher than Sidelying ER (20.79±13.06%, p<0.001) and Standing ER (48.54±15.67%, p<0.001) but not different from D2 Flexion (83.08±30.75%)

Discussion

The DBT exercise appears to elicit greater EMG activation compared to traditional rehabilitation exercises. Clinically, DBT could be a higher skilled exercise which indicates its use for later phase rehabilitation protocols when athletes are ready for ballistic exercises.

Phase Shift of Brain Tissue and Cerebrospinal Fluid Motion in Chiari Type 1 Malformation

Bioengineering PhD Student Hannah Higgins B. S. E.[1], Bioengineering PhD Candidate Mahsa Karamzadeh M.S., B. S. E.[1], Associate Professor of Radiology Rafeeque Bhadelia D. M. R., M. B., B. S.[2], Pediatric Neurosurgeon Petra Klinge MD, PhD[3], Professor of Radiology and Imaging Sciences John Oshinski PhD[4], Associate Professor of Bioengineering and Mechanical and Industrial Engineering Rouzbeh Amini PhD[1], Professor of Bioengineering and Mechanical and Industrial Engineering Francis Loth PhD[1]

[1]Northeastern University, Boston, MA, United States. [2]Harvard University, Cambridge, MA, United States. [3]Brown University, Providence, RI, United States. [4]Emory University, Atlanta, GA, United States

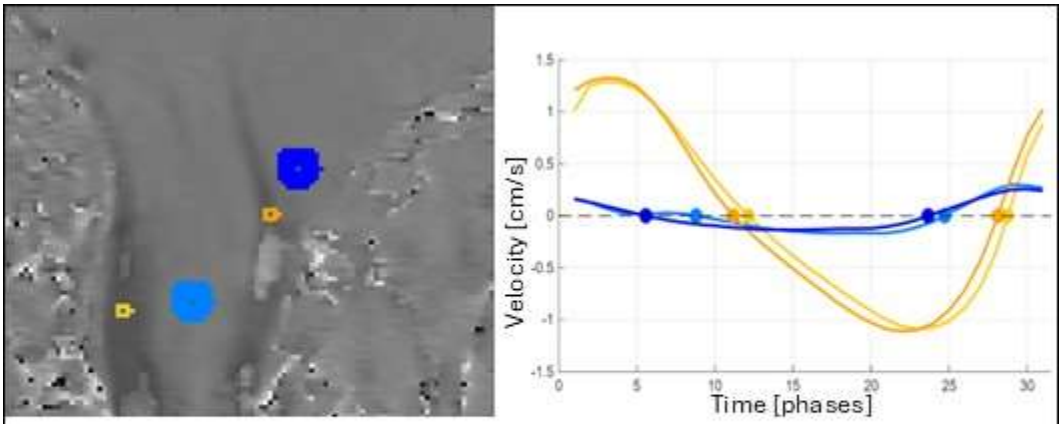
Introduction

Chiari Malformation Type I (CMI) is a neurological disease characterized by herniation of the cerebellar tonsils into the spinal canal and symptoms such as headaches, dizziness, and brain fog, with an incidence of 1/1000 patients. Researchers have been searching for measurable biomechanics that are predictive of CMI symptomatology. Studies have shown that CMI patients exhibit 52% higher compression strains in the cerebellum compared with healthy subjects. We hypothesize that there is a statistically significant difference in the timing of caudal (away from the brain) motion between brain tissue (BT) and cerebrospinal fluid (CSF) in CMI subjects. The goal of this preliminary study is to evaluate timing differences between BT and CSF using phase-contrast magnetic resonance imaging (PC-MRI) data.

Methods

10 CMI subject midsagittal-plane tissue-gated PC-MRI datasets were selected based on image resolution and non-surgical status. Four regions of interest were selected to evaluate the velocity of BT and CSF (see figure). Two regions of interest were selected on the spinal cord and cerebellum, respectively, with a five-voxel radius mask. The two remaining regions of interest were selected in the anterior and posterior CSF of the spinal canal, with a two-voxel radius mask. A paired two-tailed t-test was conducted for the beginning, end, and duration of caudal movement for the CSF and BT.

Results



The results showed an average of 94 and 84 ms delay in the beginning and ending of caudal motion in the CSF compared to the BT ($p < 0.001$). However, there was no significant

difference between the overall duration of caudal movement in the BT and CSF. The project is ongoing to evaluate if this behavior is observed in a larger CMI population.

Discussion

The findings suggest that motion in the cranial vault and spinal canal originates in the BT, most likely due to an initial influx of fluid volume into the hyper-vascularized BT during the cardiac cycle, which is then transmitted to the CSF. The findings of this preliminary study suggest that further investigation in a larger sample size should be conducted to see if delays could be a factor in CMI symptomatology.

Images (Optional)

LEFT - PC-MRI image at peak systole at the midsagittal plane showing the location of the ROIs for cerebrospinal fluid (CSF) and brain tissue (BT). RIGHT - Velocity trace over the cardiac cycle showing the difference in phase shift for caudal motion between the CSF and BT.

Damage Accumulation at the Taper of Modular Hip Revision Implants

MSc Lennart Rogoll, Prof. Sara Checa, Dr.-Ing. Gerd Huber

TUHH Hamburg University of Technology, Hamburg, Hamburg, Germany

Introduction

Modular hip revision implants separate distal fixation of the stem from proximal patient-specific intraoperative reconstruction through the neck segment. Although rare, serious fractures have been reported at this intermediate taper connection, which has the smallest diameter of the implant.

Load pattern along the implant axis significantly depend on the performed activity [1]. Thus, the taper should be placed in a low-load position with respect to all activities, bringing the length-ratio between neck segment and shaft under debate.

The aim was to combine the contribution of daily activities for damage accumulation, to determine the favorable length of neck segments.

Methods

Three mobility profiles (low, medium, high) containing different daily activities were defined. For each activity and two body weights (75 kg, 100 kg) von Mises equivalent implant stress for a taper diameter of 13 mm was calculated [1] based on in-vivo measured hip joint forces [2]. Wöhler's curve of TiAl6V4 and Miner's rule enabled to combine the activities of each profile to determine the damage accumulation and hence taper junction's fatigue life for each potential neck segment length.

Results

Stair descent and jogging impose the greatest impact on accumulated damage, while cycling, walking and other daily activities have a minimal effect. Taper fatigue life is highly sensitive to patient weight (medium activity: 100 kg / 75 kg -> 4 y / 29.5 y) and activity (75 kg: low / medium / high -> 8.4 y / 29.5 y / 116.5 y). The hereby determined favorable neck length lies between 70 mm to 90 mm.

Discussion

This study emphasizes the need to consider patient-specific factors such as activity level and body weight, when selecting implants and surgical planning.

Results are limited by not considering osseous implant support on one side and extreme events such as stumbling on the other side.

Revision implants are available in various lengths and shaft thicknesses. For compatibility reasons, a uniform tapered cone is often used at the end of the shaft. In order to be able to treat large and heavy patients, however, this uniform cone size should be questioned.

Images (Optional)

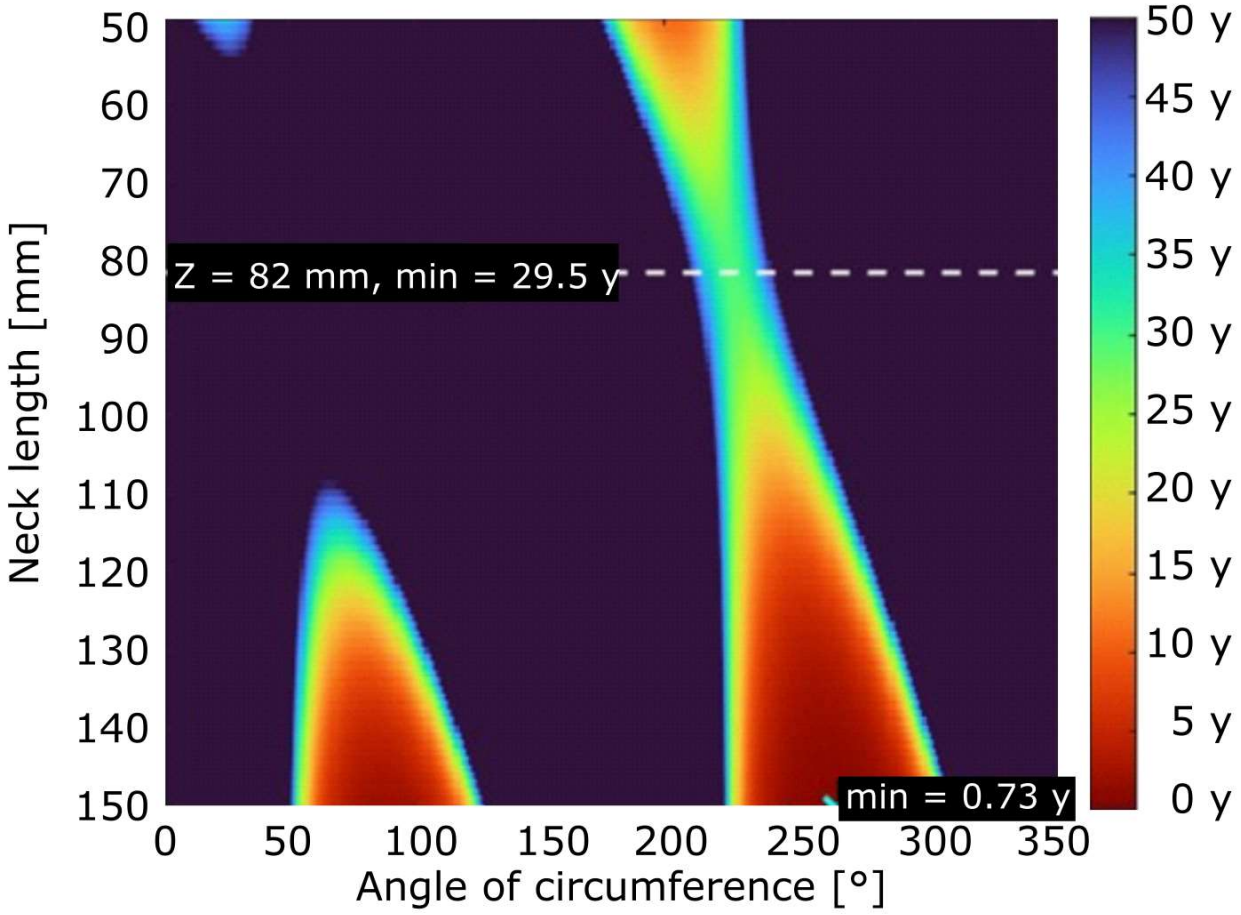

Fig. 1: Time to failure (years) based on the accumulated loading of a 75 kg person with medium activity profile. A neck segment length of 82mm reveals the highest survival time.

Test–Retest Reliability of 4DCT-Derived Wrist Kinematics in Healthy and Scapholunate-Injured Wrists

ir. Hanne Vries, Ms. Maranda Haenen MSc, Ms. Erin Teule MSc, dr. Stefan Hummelink, prof.dr. Ioannis Sechopoulos, prof. dr. Brigitte van der Heijden

Radboudumc, Nijmegen, Gelderland, Netherlands

Introduction

Four-dimensional CT (4DCT) provides quantitative in-vivo evaluation of carpal motion and is increasingly used to characterize wrist kinematics. Its ability to capture carpal bone movement throughout motion makes it a promising tool for evaluating wrist injuries, such as scapholunate (SL) instability. To support its use in both biomechanical and clinical contexts, the repeatability of 4DCT-derived kinematic parameters must be evaluated in healthy and unstable wrists. This study therefore evaluated the test–retest reliability of 4DCT-based wrist kinematics in healthy wrists and in wrists with suspected scapholunate (SL) injury.

Methods

Patients with a unilateral suspicion of scapholunate (SL) injury underwent bilateral 4DCT scanning, with the contralateral wrist used as a healthy reference. Each scan included one static acquisition and two dynamic sequences during radial–ulnar deviation (RUD) and flexion–extension (FE). To assess test–retest reliability, both dynamic sequences were repeated. An automated pipeline segmented and registered all carpal bones across time frames. Kinematic parameters of the scaphoid and lunate were extracted, including 3D scapholunate distance (SLD), 3D translation (norm of x,y,z), and 3D rotation (axis angle magnitude). Reliability was evaluated using the coefficient of multiple correlation (CMC) and root mean square difference (RMSD), and differences between motion directions were tested with a paired t-test.

Results

Dynamic 4DCT scans from eighteen patients were analyzed. Both RUD and FE showed high reliability, with median CMC values of 0.90 for scapholunate distance and above 0.90 for scaphoid and lunate translation and rotation, accompanied by low RMSD values across all parameters (Figure 1). For both movements, no significant differences were found between directions for any kinematic parameter.

Discussion

This study demonstrated high test–retest reliability of scaphoid and lunate kinematics, indicating that 4DCT can consistently quantify key motion parameters relevant to scapholunate instability. Across both FE and RUD, rotational and translational measures showed stable motion patterns on repeated scans, with no direction-dependent differences. While these findings confirm the repeatability of 4DCT-derived kinematics, further work is needed to determine whether this consistency translates into sufficient accuracy for specific clinical diagnostic tasks.

Images (Optional)

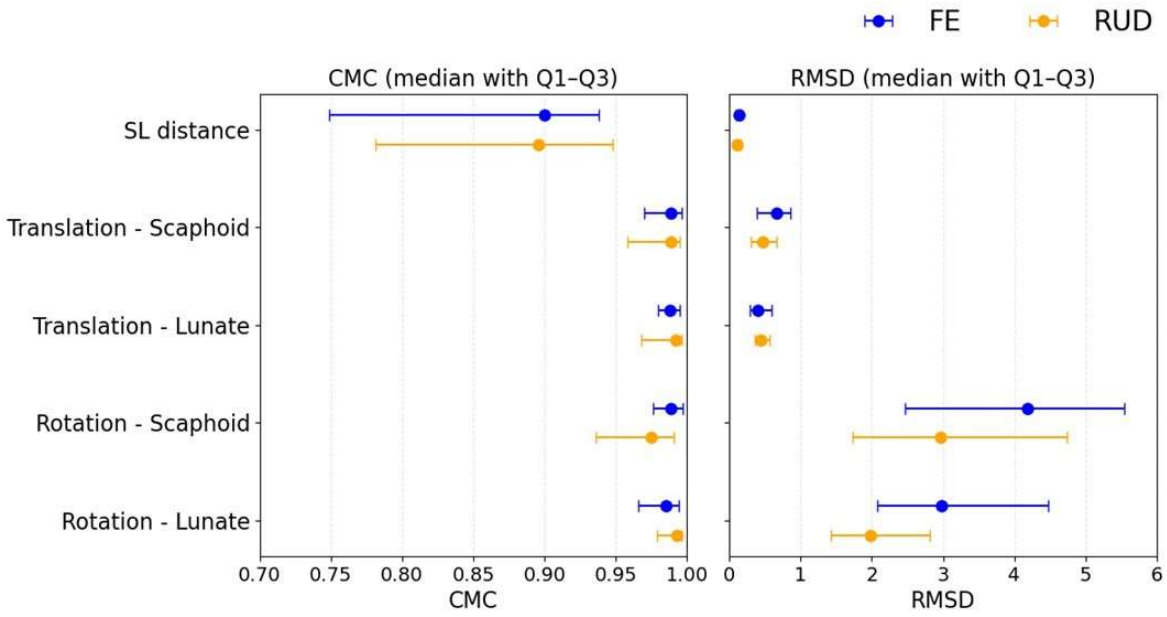

Figure 1. CMC and RMSD values (median with Q1–Q3) for SLD, scaphoid and lunate translation, and rotation during FE and RUD. Both movements show high reliability with CMC values near 1.0 and low RMSD across all parameters. RMSD is shown in millimeters for translations and SLD, and in degrees for rotations.

Hysteresis in 4DCT-Derived Wrist Kinematics: A Comparison of Healthy and Scapholunate-Injured Wrists

ir. Hanne Vries, Ms. Maranda Haenen MSc, Ms. Erin Teule MSc, dr. Stefan Hummelink, prof. dr. Ioannis Sechopoulos, prof. dr. Brigitte van der Heijden

Radboudumc, Nijmegen, Gelderland, Netherlands

Introduction

Four-dimensional CT (4DCT) enables detailed, non-invasive quantification of wrist kinematics. Despite this capability, wrist motion is often interpreted using simplified, unidirectional models that overlook direction-dependent behavior. Hysteresis, the change in carpal motion that depends on movement direction, may therefore be an important but under-recognized aspect of wrist mechanics. It is unclear whether hysteresis is different for healthy wrists and injured wrists like those with a scapholunate ligament injury. Therefore, this study aims to investigate the difference in hysteresis on dynamic CT-derived wrist kinematics between healthy and scapholunate ligament-injured wrists.

Methods

Dynamic CT scans from healthy wrists and wrists with complete scapholunate ligament rupture (arthroscopically confirmed) were analyzed. Each dataset included a static scan and two motion sequences: radial–ulnar deviation (RUD) and flexion–extension (FE Carpal bones were segmented, registered, and analyzed using a fully automated algorithm, which extracted five kinematic metrics at each wrist position: radioscaphoid (RSA), scapholunate (SLA), capitolunate (CLA), and radiolunate (RLA) angles, plus the 3D scapholunate distance (SLD). Motion curves were generated for both directions of FE and RUD, and hysteresis was calculated as the area between direction-specific curves, normalized to range of motion. Group differences were assessed using unpaired t-tests ($p < 0.05$).

Results

In FE, twenty SL4 and seventy-one healthy wrists were analyzed. Only the SLD showed a significantly greater hysteresis area in SL4 wrists (0.24 [0.17 – 0.30] deg^2; median [25^{th} percentile – 75^{th} percentile], $p < 0.001$) compared with healthy wrists (0.10 [0.07 – 0.14] deg^2). In RUD, SL4 wrists showed significantly higher hysteresis for both SLA (2.15 [1.46 – 3.43] deg^2 vs. 1.35 [1.04 – 1.78] deg^2, $p = 0.00$) and SLD (0.18 [0.10 – 0.24] deg^2 vs. 0.08 [0.05 – 0.11] deg^2, $p < 0.001$). The remaining kinematic parameters showed no significant differences during RUD (Figure 1).

Discussion

Automated motion analysis of dynamic wrist CT showed significantly greater hysteresis in scapholunate-injured wrists, particularly for scapholunate distance across both motions and for scapholunate angle during RUD. Since hysteresis captures direction-dependent carpal mechanics that are not visible in static or single-direction assessments, these results highlight its potential as a sensitive biomechanical marker for pathology like scapholunate instability.

Images (Optional)

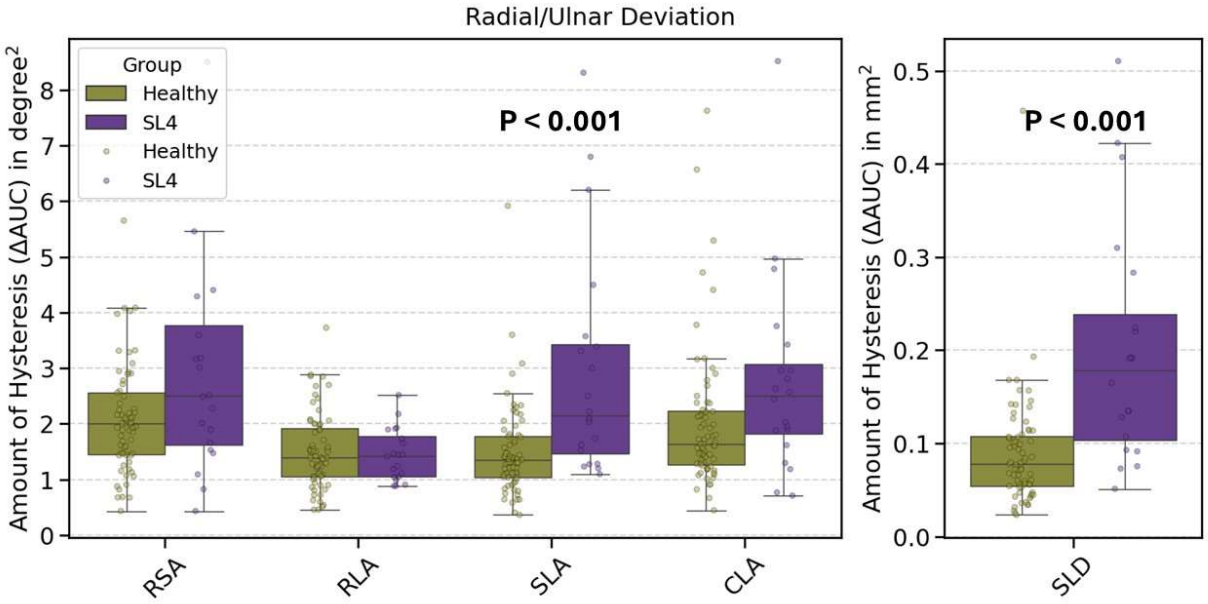

Figure 1. Hysteresis during RUD was greater in SL4 wrists across all kinematic parameters. Only the scapholunate angle and scapholunate distance showed statistically significant differences compared with healthy wrists.

Effects of Maximal 1500-m Running on Relative Stiffness of the Biceps Femoris Long Head and Semitendinosus in Trained and Untrained Individuals

Sr. Thiago de Souza da Silva[1], Sr Heinrich Leon Souza Viera[2], Dr. Fabio Juner Lanferdini[3], Dr Heiliane de Brito Fontana[1]

[1]BSiM-UFSC - Musculoskeletal Biomechanics Research Group, Federal University of Santa Catarina, Florianopolis, Santa Catarina, Brazil. [2]Federal Universiy of Santa Maria, Santa Maria, Rio Grande do Sul, Brazil. [3]Federal University of Santa Maria, Santa Maria, Rio grande do Sul, Brazil

Introduction

The hamstrings play a key role in running, particularly in generating horizontal propulsion and controlling limb deceleration during terminal swing—the phase in which hamstring strains most frequently occur. The biceps femoris long head (BFlh) is injured two to four times more often than the semitendinosus (ST). Because muscle injury risk is mechanically linked to the magnitude of fiber strain, understanding how the relative stiffness of these muscles responds to fatiguing running may help explain differential injury susceptibility. This study evaluated whether a maximal 1500-m effort alters the BFlh/ST stiffness ratio in trained and untrained individuals.

Methods

Twenty-three participants were assigned to a trained group (n=14; athletes with >1 year of running experience) or an untrained group (n=9; healthy individuals without systematic training). Muscle stiffness was assessed with shear-wave elastography (Siemens Acuson S2000) at 55% of femur length, with participants positioned prone on a dynamometer (hip 0°, knee 30°). For each muscle, three passive and three active measurements at 20% maximal voluntary contraction were obtained. Participants then completed a maximal 1500-m track run, after which stiffness and torque were reassessed. Active stiffness values were normalized to passive stiffness. Pre–post comparisons used paired tests; between-group differences used independent t-tests ($\alpha=0.05$).

Results

In untrained individuals, the BFlh/ST stiffness ratio decreased significantly (–19%; $p=0.039$; median from ~1.26 to ~1.02). In trained individuals, the ratio remained unchanged ($p=0.983$). Ratio data showed normal distribution and homogeneous variances.

Discussion

A maximal 1500-m effort reduced the relative stiffness of the BFlh only in untrained individuals. Lower BFlh stiffness may increase muscle fiber strain by reducing the contribution of series elastic components, potentially heightening susceptibility to strain injury—particularly relevant given the high incidence of BFlh injuries during running. Trained individuals maintained stiffness stability, suggesting protective neuromuscular or structural adaptations. Future studies should explore whether training interventions can modulate these stiffness responses and reduce strain risk.

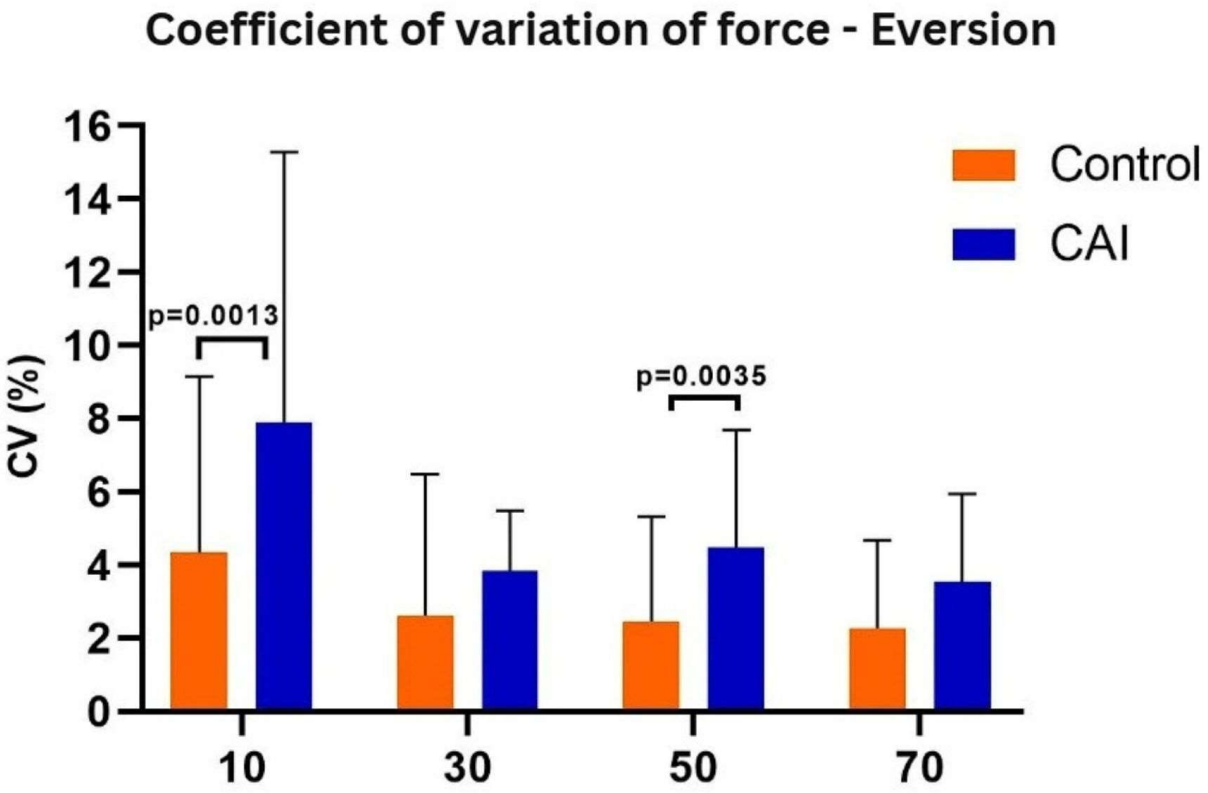
Introduction

Acute lateral ankle sprain is highly prevalent among active individuals, with an incidence of 50%[1]. One of its long-term consequences is chronic ankle instability(CAI), which affects 46% and leads to sensorimotor and mechanical deficits, episodes of giving-way, perceived

instability, pain, and reduced functional performance[2]. Considering inconsistencies in the literature on neuromuscular control, we aimed to analyze and compare the magnitude (Coefficient of variation CV, standard deviation SD) and structure (Sample Entropy, SE) of force performance during isometric tasks at different force levels (10%, 30%, 50% and 70% of MVIC), between individuals with CAI and healthy controls.

Methods

This cross-sectional study approved by the ethical committee (CAEE:80722924.7.0000.0068) included 42 adults (26 CAI; 16 controls). CAI was defined based on the International Ankle Consortium criteria[3], in addition to functional tests scores (Y-Balance Test). Participants were asked to perform three submaximal isometric tasks (eversion, inversion and plantarflexion) at four force levels. Ankle force was recorded using a dynamometer (OTBioelettronica) @2048Hz, 500x gain. Signals were digitally low-pass filtered using a zero-lag 8th order Butterworth filter (10Hz cutoff). Force CV, SD and SE were compared between groups by mixed ANOVAs followed by Newman Keuls post hoc ($p<0.05$).



Results

CAI group showed a significantly worse performance on functional tests ($p=0.010$ for YBT posteromedial direction). They also showed greater eversion force (peroneus longus) CV at 10% and 50% of MVIC (fig.1). No group differences were found for force SD or SE. However, within both groups, greater force levels resulted in reduced force CV and SD ($p<0.05$). Fig.1: CV (mean±standard deviation) of eversion force for both groups.

Discussion

The increased eversion force CV at low-level tasks in CAI indicates reduced force consistency possibly due to irregular MU recruitment, impairing ankle control and performance in precision tasks, such as Y-Balance Test. These findings may represent markers of neuromuscular impairments in CAI, which support rehabilitation emphasizing proprioception, balance, evertor strength, and submaximal isometric control.

What Strategies Do Healthy Adults Use to Alter Foot Progression Angle During Gait?

Ms. Antoinette Torsij[1], Dr. Erin Macri[2], Dr. Martin Schepers[3], Dr. Jos Runhaar[2], Dr. Ignazio Aleo[3], Dr. Selma Papegaaij[3], Dr. Eline van der Kruk[1], Prof. Jaap Harlaar[2,1], Dr. Mariska Wesseling[2]

[1]Delft University of Technology, Delft, South-Holland, Netherlands. [2]Erasmus MC University Medical Center, Rotterdam, South-Holland, Netherlands. [3]Moveshelf Labs B.V., Utrecht, Utrecht, Netherlands

Introduction

Altering foot progression angle (FPA) has been shown to reduce pain, reduce knee adduction moment, and slow down structural progression in knee osteoarthritis. It is not well understood what lower limb kinematic strategies individuals employ to achieve different FPAs. Therefore, the aim of this study was to explore how pelvic, hip, and subtalar joint kinematics differ between natural walking and walking with different FPAs among healthy adults.

Methods

Fourteen healthy participants were included (9 women, age: 57.8 ± 12.1 years; BMI: 23.7 ± 2.7 kg/m^2). We performed three-dimensional gait analysis using an instrumented treadmill while participants walked under five conditions: natural FPA (self-selected pace) and 5° and 10° toe-out and toe-in (at same speed) relative to their natural FPA. The FPA was calculated using an inertial measurement unit on the shoe. Participants received visual and audio feedback on their altered FPA every five steps. Pelvic, hip and subtalar joint angles were obtained via OpenSim using a generic musculoskeletal model. We performed statistical parametric mapping on the last 20 gait cycles of each condition, to compare joint angles throughout stance between each FPA condition and natural walking.

Results

Compared with natural walking, 10° toe-out involved ~6-8° greater hip external rotation and 5-10° more subtalar eversion (significant in late stance). Toe-out 5° showed a similar pattern but with smaller magnitudes. Toe-in conditions produced similar changes but in opposite directions, again larger with toe-in 10°. For example, subtalar inversion was significant only with toe-in 10°. Toe-in gait also involved contralateral transverse pelvic rotation (i.e. forward translation of the ipsilateral pelvis) that reached significance for 10° toe-in only (standard deviations were large for all conditions).

Discussion

Hip and subtalar joint angles were consistently and significantly altered for different FPAs, compared to natural walking. Pelvic rotation was more varied, possibly reflecting individual anatomical differences (e.g. pelvic rotation may help overcome limited hip internal rotation) or movement strategies. Investigating these adaptations may help clarify what strategies individuals employ to achieve different FPAs, which could support the development of predictive models to estimate the effects of gait modifications based on natural gait.

Comparison of Static Alignment with and without X-Ray Metrics in Pediatric Foot Deformities

Ms. Janet Le[1,2], Dr. Joseph Krzak PT, PhD, PCS[3,4], Dr. Karen Kruger PhD[1,2,4]

[1]Marquette University, Milwaukee, Wisconsin, United States. [2]Medical College of Wisconsin, Milwaukee, Wisconsin, United States. [3]Midwestern University, Downers Grove, Illinois, United States. [4]Shriners Children's, Chicago, Illinois, United States

Introduction

Segmental foot models (SFM) have been widely used in clinical gait analysis to assess foot deformities and differentiate between flexible and rigid deformities for intervention planning. The Shriners Children's Model (SCM) has been shown to be amongst the most repeatable and reproducible SFM [1]. While the SCM can be utilized with marker and goniometer-based definitions or in combination with radiographic offset inputs, prior studies have not examined the alignment differences between the two input conditions for pediatric foot deformities.

Methods

Segmental foot data was collected from 16 pediatric patients with foot deformities. The SCM was analyzed between marker-based and radiographic inputs. Deformity severity was taken from the absolute value of the radiographic offsets. Pearson's correlation coefficients (r) were calculated to test the hypothesis that greater differences between model outputs would be associated with increasing deformity.

Results

A strong correlation (r=0.89) was found between deformity severity and SCM input measure differences for the coronal hindfoot (Figure 1A). Transverse midfoot alignment (Figure 1B) showed a moderate correlation (r=0.50) between measurement differences. Sagittal hindfoot alignment measurement differences exhibited a moderate correlation (r=0.48) with hindfoot pitch (Figure 1C). A negative correlation (r=-0.19) was observed between measurement differences for sagittal forefoot alignment and pitch (Figure 1D).

Discussion

The static alignment results show that as deformity increased, there was increased disagreement between static alignment from marker/goniometer and x-ray inputs,

particularly for the coronal hindfoot. While marker-based inputs for the coronal hindfoot provide appropriate measurements for typical feet, the physical exam may underestimate the deformity compared to x-ray inputs with increased severity. Even with less differences for transverse midfoot and sagittal hindfoot alignment, it is suggested that forefoot and hindfoot progression be examined separately to determine the specific segment contributions. Sagittal forefoot alignment showed an inverse correlation, where decreased deformity displayed better agreement between input conditions. This confirms that SCM input measure differences for smaller deformities can be examined by either goniometer or x-ray inputs, but as severity increases, these differences increase, indicating x-ray inputs should be considered, especially when used for presurgical assessment.

Images (Optional)

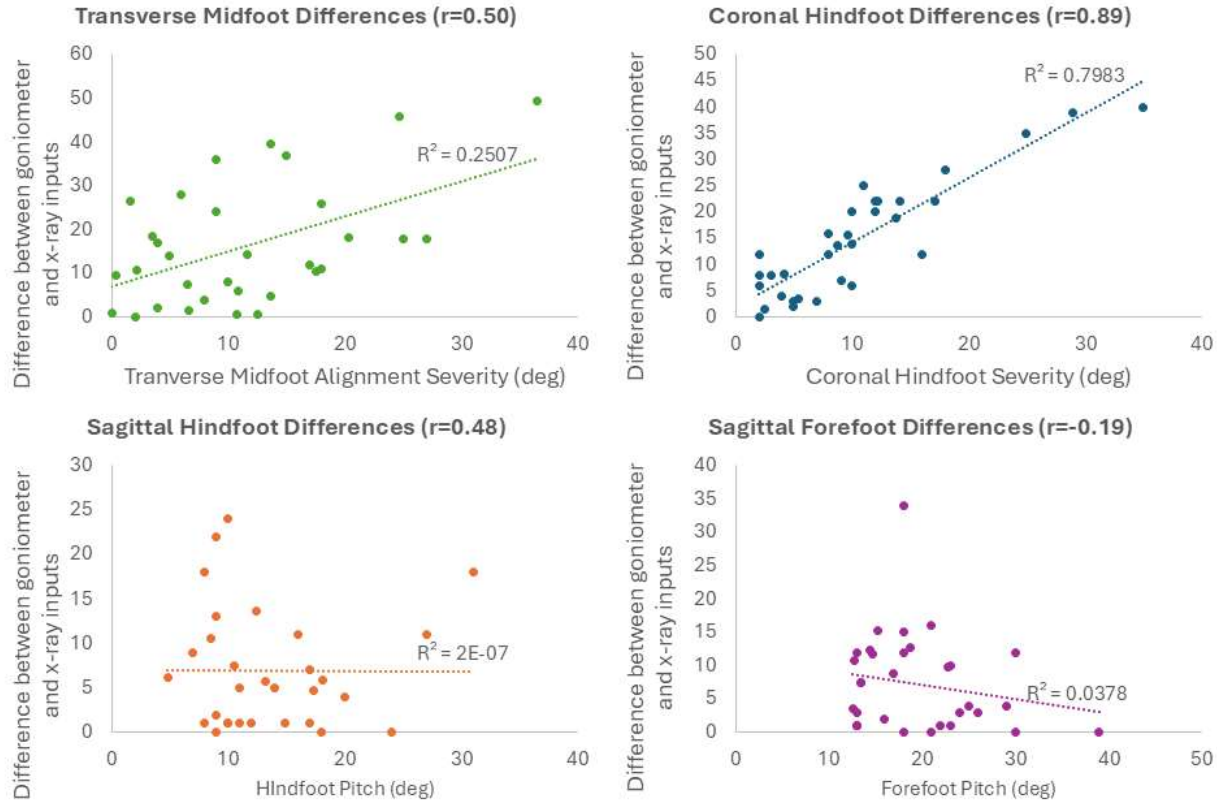

Figure 1. Measurement differences between goniometer and x-ray SCM inputs against deformity severity (deg) for A) coronal hindfoot and B) transverse midfoot. C) Sagittal hindfoot measurement differences against hindfoot pitch (deg). D) Sagittal forefoot measurement differences against forefoot pitch (deg).

Altered Relationships between Lower Limb Torques and Limb Loading during Speed Modulation after Stroke

Mr. Zekun Liu, Mr. Jason Tsai, Dr. Hao-Yuan Hsiao

The University of Texas at Austin, Austin, Texas, United States

Introduction

Individuals post-stroke commonly exhibit impaired limb loading, which is associated with reduced walking speed and mobility limitations. Limb loading during walking depends on coordinated sagittal-plane knee extension and frontal-plane hip abduction torque production. This study compared how knee extension and hip abduction torques contribute to changes in limb loading with increasing walking speed in individuals post-stroke and healthy controls.

Methods

Nine individuals more than 6 months post-stroke and nine age-matched healthy control individuals walked on an instrumented split-belt treadmill (Motek Medical, Amsterdam, Netherlands) at self-selected and maximal speeds. Kinematic data were collected using a 10-camera motion capture system (Vicon-USA, Denver, USA), and inverse dynamics was used to estimate hip abduction and knee extension torques for the paretic limb in stroke and the non-dominant limb in controls. Peak vertical ground reaction force (vGRF) during the 1st half of the stance phase was used to characterize limb loading.

Results

Compared with stroke, controls showed greater increases in speed, peak knee extension torque, and peak vGRF ($p < 0.05$). In controls, changes in peak hip abduction torque and peak knee extension torque were both positively correlated with changes in peak vGRF as walking speed increased. In contrast, only changes in peak hip abduction torque were correlated to changes in peak vGRF in individuals post-stroke. In addition, changes in peak knee extension and hip abduction torques were correlated in controls but not in stroke.

Discussion

Persons with chronic stroke and healthy controls adopted different strategies to change limb loading as walking speed increased. Specifically, healthy controls modulated both hip abduction and knee extension torques to increase limb loading. In contrast, knee extension torque did not contribute to changes in paretic limb loading in individuals post-stroke. Moreover, the strong coupling between knee extension and hip abduction torques in

controls suggests coordinated modulation of both joints. This coupling was not observed in individuals post-stroke. Therefore, knee extension torque may be an important target for improving coordinated joint torque modulation to restore limb loading after stroke.

Effect of Strut Stiffness on Peak Push-Off Powers Using Two Approaches in Carbon Fiber Custom Dynamic Orthoses

Ms. Kaitlyn deBlois[1], Dr. Kirsten Anderson PhD[1], Dr. Kota Takahashi PhD[2], Dr. Jason Wilken PT, PhD[1]

[1]The University of Iowa, Iowa City, Iowa, United States. [2]The University of Utah, Salt Lake City, Utah, United States

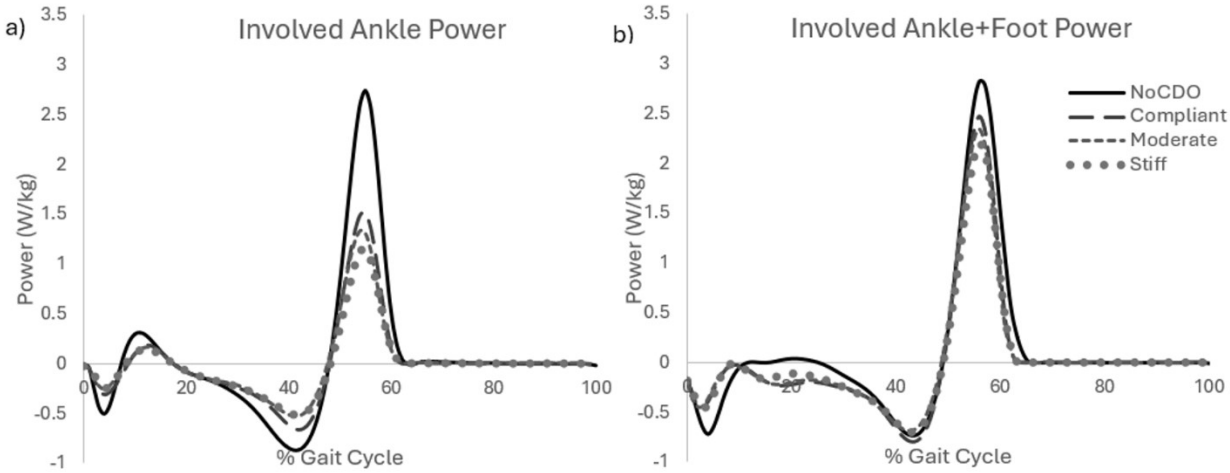
Introduction

Carbon fiber custom dynamic orthoses (CDOs) improve gait and function after limb trauma.[1] CDOs have a cuff below the knee, a footplate, and a stiff carbon fiber posterior strut. CDOs reduce pain and control limb position during gait but reduce ankle motion and peak sagittal plane ankle rotational push-off power by nearly 50%. This decrease contrasts with positive patient perceptions of energy return reported with CDO use. The unified deformable (UD) model, which quantifies contributions from all structures distal to the shank (ankle+foot),[2] is thought to better represent CDO energetics than the traditional assessment of rotational ankle power (ankle). The purpose of this study was to determine the effect of strut stiffness on ankle and ankle+foot powers.

Methods

Participants walked at a controlled speed without an orthosis (NoCDO) and with different stiffness CDOs in randomized order: Compliant 3.9(1.2)Nm/deg, Moderate 5.4(1.4)Nm/deg, Stiff 7.0(2.1)Nm/deg. Peak ankle and ankle+foot power were calculated using Visual3D (HAS Motion) and MATLAB (The MathWorks Inc.). One-way repeated measures or Friedman ANOVA were used to determine main effects. Post-hoc analysis included paired sample t-tests or Wilcoxon signed rank tests with Bonferroni Holm correction.

Results



Seven individuals with limb trauma participated (1 Female, 35.9(10.1)yrs, 1.8(0.1)m, 92.2(19.4)kg). Differences were not observed between stiffnesses for ankle or ankle+foot power. Ankle power for all stiffnesses was significantly reduced ($p<0.001$) compared to NoCDO, with reductions greater than 47% (Figure 1a). Ankle+foot power for all stiffnesses was also significantly reduced ($p<0.001$) compared to NoCDO, but differences ranged from 17-24% (Figure 1b).

Discussion

Ankle and ankle+foot powers did not differ between stiffnesses, however, both were lower with CDO use compared to NoCDO. Accounting for contributions distal to the ankle joint (ankle+foot) resulted in a 50% smaller deficit in peak power with CDOs than indicated by peak ankle power. This difference highlights the potential importance of CDO footplate energy storage and return, and importance of accounting for contributions distal to the ankle joint.

The Effects of Proximal Cuff Tightness on Hindfoot and Forefoot Forces During Gait With Carbon Fiber Custom Dynamic Orthoses

Dr. Kirsten Anderson PhD, Mr. Matthew Nachtman, Dr. Jason Wilken PT, PhD

The University of Iowa, Iowa City, Iowa, United States

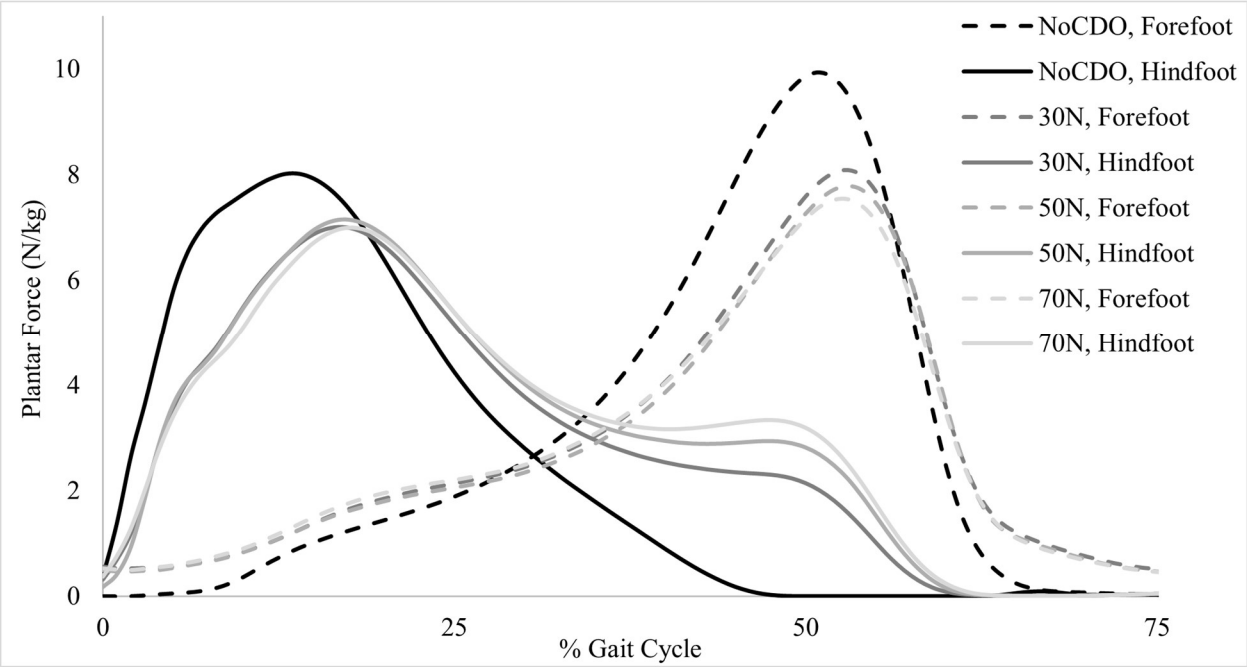
Introduction

Carbon fiber custom dynamic orthoses (CDOs) reduce pain, restore function, and alter foot loading for individuals after limb trauma.[1-4] CDOs include a proximal cuff, posterior strut, and footplate. The CDO cuff is tightened around the limb every time the CDO is donned, however, the impact of cuff tightness on foot loading is not well understood. The purpose of this study was to determine the effect of cuff tightness on foot loading during gait.

Methods

This study was institutional review board approved. 15 unimpaired individuals (9 Female, 29.6(12.6)yrs, 1.7(0.1)m, 72.5(13.3)kg) provided informed consent. Loadsol insoles were placed under the foot and loadpad sensors were placed inside the cuff to measure forces acting on the limb (Novel Electronics Inc.). Participants completed testing without an orthosis (NoCDO) and in a CDO (Biomechanical Composites Inc.) tightened to 30N, 50N, and 70N in a randomized order. Peak force and force impulse, the indefinite integral over stance, were calculated for the hindfoot and forefoot as participants walked at a controlled speed. Repeated measures or Friedman's ANOVAs were performed to determine main effects, and post-hoc paired sample t-tests or Wilcoxon signed rank tests with Bonferroni Holm correction were performed.

Results



Hindfoot impulse increased significantly in 50N and 70N compared to NoCDO (23%) and 30N (8%). Peak hindfoot force (12-13%), peak forefoot force (21-26%), and forefoot impulse (20-24%) decreased significantly with CDO use compared to NoCDO, but there was no significant effect of tightness for these measures.

Discussion

Similar to previous work[1-4] study CDO altered foot loading at each tightness compared to NoCDO. Force was redistributed from the forefoot to the hindfoot in late stance (Figure 1). While cuff tightness had a limited effect, hindfoot impulse demonstrated a trend toward increased hindfoot loading with increased cuff tightness. This may be due to the stiffer

cuff-limb interface and suggests that rather than decreasing loading, a tighter cuff may increase hindfoot foot loading.

Investigating Lower and Upper Body Shock Attenuation Across Walking Speeds in Middle-Aged Adults with Obesity

Dr. Julie Rekant PT, DPT, PhD[1,2], Dr. Odessa Addison DPT, PhD[1,2], Dr. Mark Redfern PhD[3], Dr. Jennifer Brach PhD, PT, FAPTA[3], Dr. April Chambers PhD[3]

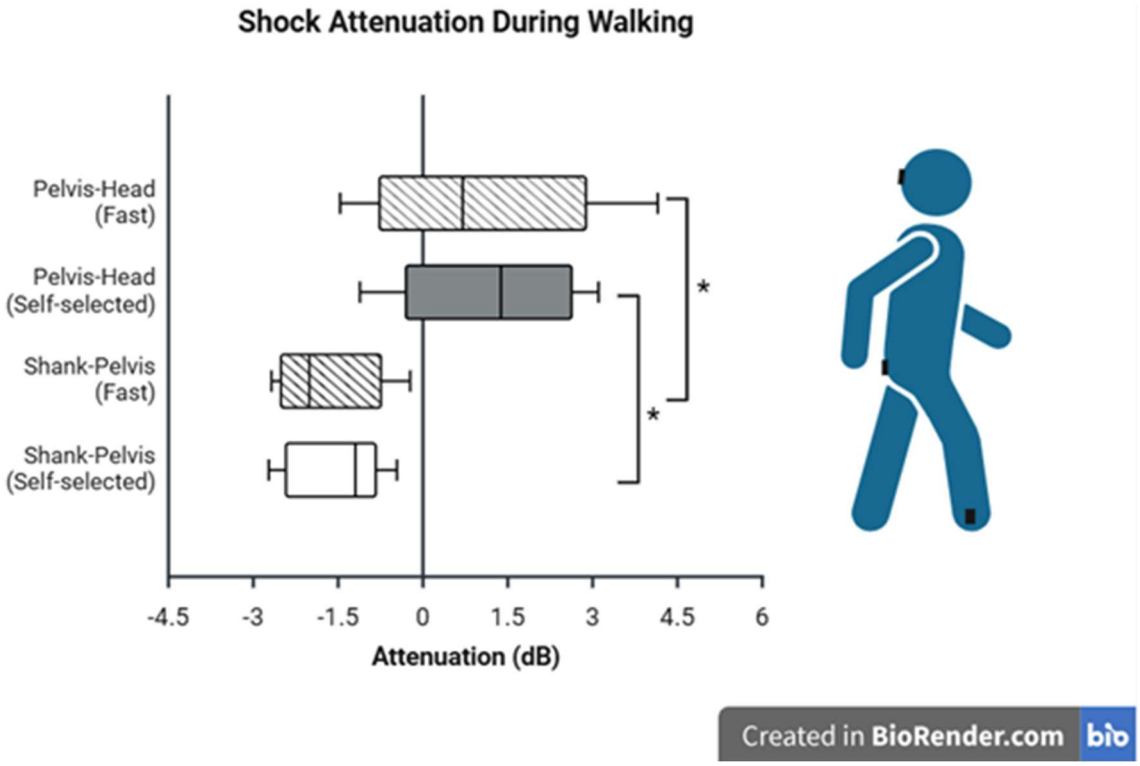
[1]University of Maryland, Baltimore, Baltimore, MD, United States. [2]Baltimore VA, Baltimore, MD, United States. [3]University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Shock attenuation – the absorption of accelerations as they propagate through the body – is linked to musculoskeletal injury risk, with greater attenuation at a segment indicating higher exposure to potentially injurious forces there. Adults with obesity walk more slowly than their normal-weight counterparts and experience higher rates of musculoskeletal injuries, likely due to greater mechanical loading and altered gait mechanics. This pilot study examined shock attenuation during walking at different gait speeds in middle-aged adults with obesity and explored relationships with temporal gait characteristics.

Methods

Six participants (3 male/3 female; age:49.7±7.1years; BMI:37.1±2.3kg/m^2) completed overground walking at self-selected and fast speeds while wearing accelerometers at the shanks, pelvis, and head. The ratio of vertical acceleration power spectral densities of the proximal to distal segment quantified shock attenuation for the shank-to-pelvis (ATT_{SP}) and pelvis-to-head (ATT_{PH}) across steps. Step timing identified from shank accelerations was used to derive temporal gait characteristics.



Results

Fast gait speeds exceeded self-selected speeds (1.9±0.2 vs. 1.2±0.0m/s,$p<0.01$), achieved through shorter step times (0.43±0.05 vs 0.54±0.03 s, $p<0.01$), higher cadence (137±12 vs. 111±8steps/min, $p<0.01$) and reduced terminal double support (0.12±0.02 vs. 0.19±0.02s,$p=0.03$). At self-selected speeds, attenuation was greater in the lower (ATT_{SP}=-1.5±1.0dB) versus upper body (ATT_{PH}=1.2±1.8dB,$p=0.03$); a similar trend was seen for fast walking ($p=0.07$). No meaningful differences in attenuation were observed across conditions for ATT_{SP} ($p=0.62$) and ATT_{PH} ($p=0.86$). ATT_{PH} was related with terminal double support time during fast walking (Rho=0.951,$p=0.01$) and inversely related with walking speed for self-selected walking (Rho=-0.97,$p=0.03$).

Discussion

Middle-aged adults with obesity demonstrate greater shock attenuation in the lower compared to upper body while walking at fast and self-selected speeds, suggesting the knees and hips may be at greater risk for injury than the back in these individuals. Walking speed and terminal double support time helped explain a large amount of variance in ATT_{SP} at self-selected and fast speeds, respectively. These preliminary findings support the feasibility of accelerometry to capture speed-dependent differences in shock attenuation and gait and suggest interventions targeting walking speed and mechanics may help reduce exposure to potentially injurious acceleration propagation in this population.

The Impact of Pregnancy on Whole Body Angular Momentum During Walking

Ms. Kaitlyn Kleeman BS, Mrs. Maryam Golmohammadi MS, Dr. Amanda Paluch PhD, Dr. Sarah Roelker PhD

University of Massachusetts Amherst, Amherst, MA, United States

Introduction

More than 25% of pregnant individuals experience a fall [1,2], most often in months 6-8 of gestation [1]. Regulation of the whole-body angular momentum (WBAM) about the body's center of mass is required to maintain dynamic balance and prevent a fall during gait [3]. Larger peak-to-peak ranges of WBAM are associated with poor balance control and increased fall risk [4]. This study aims to determine the effects of pregnancy on peak-to-peak range of WBAM during gait. For each anatomical plane, we hypothesize that 1) WBAM range will be larger in trimester 3 (P-T3) than trimester 2 (P-T2), indicating reduced balance control later in pregnancy, and 2) pregnant participants will show larger WBAM range than age-matched nulligravida individuals, reflecting poorer balance control.

Methods

12 pregnant (PREG) (n=12, 34 ± 3.8 yrs) and 8 nulligravida (NG) (n = 8, 34 ± 4.6 yrs) participants performed 5 overground walking trials at a self-selected speed, at two timepoints in PREG (P-2T and P-3T) and once in NG. Motion capture and ground reaction force data were collected to quantify WBAM in the sagittal, frontal, and transverse planes. The WBAM range in each plane was calculated as the average peak-to-peak range from all 5 trials at each time point and normalized to mass, height, and gait speed. A mixed-model ANOVA with a Bonferroni correction assessed for differences in WBAM range across groups.

Results

Compared to NG, frontal plane WBAM range was significantly lower in P-T2 ($p = 0.008$) and PT-3 ($p = 0.009$) (Fig. 1). There were no differences in WBAM range in the sagittal and transverse planes, or between trimesters.

Discussion

The lower range of WBAM in P-T2 and P-T3 indicates greater balance regulation in PREG in the frontal plane, which may indicate a more cautious mediolateral gait strategy. Future work will determine the relationship between WBAM, strength, and neuromuscular control

while walking during pregnancy, and whether physical activity levels might modulate these changes.

Images (Optional)

Metatarsal Injury Study: Hormonal, Energetic, & Activity-Related Determinants (MISHEARD)

Dr. Andrew Wilzman PhD, Ms. Julia Nicolescu, Dr. Karen Troy PhD

Worcester Polytechnic Institute, Worcester, Massachusetts, United States

Introduction

Metatarsal Bone Stress Injuries (BSI) are common in women and youth athletes, yet links among bone structure, strength, and BSI risk remain limited [1]. This study tested if metabolic and biomechanical metrics could classify recent metatarsal BSI.

Methods

Thirty-six female runners (17-40 y; >10 mi/wk) were assigned to healthy or injured groups (n=7). Questionnaires quantified past activity and RED-S risk [2,3,4]. DXA quantified lean mass and mineralization. Micro-CT measured metatarsal and tibial geometry and density [5]. Each injured runner was matched with two unique controls by running performance. We predicted injury status based on load history, foot arch, metabolism, foot strength, and bone strength. The two strongest predictors per category (Hedges' g) were pooled and the top five were entered in a Linear Discriminant Analysis, using leave-one-out cross-validation.

Results

Injury status aligned with longer metatarsals, higher RED-S risk (low energy availability and bone density), lower age of menarche, and greater activity levels, particularly when increased after age 15 (Table 1). The same three participants were misclassified between the validation and final model.

Discussion

Findings indicate elevated risk in individuals who had lower physical activity during adolescence but high bone loading in early adulthood. Mechanical loading during adolescence has a large influence on peak adult bone mass and structure [6]. Suboptimal bone adaptation may also reflect age, overuse, reduced energy availability, or genetic factors. Combined metabolic and structural markers form a risk model suitable for screening if confirmed in larger cohorts.

Introduction

Markerless motion capture has the potential to facilitate pediatric clinical gait analysis by eliminating the difficulties associated with marker placement. This study aims to evaluate markerless motion capture compared to the marker-based clinical standard for children with and without mobility impairments.

Methods

Two cohorts were recruited for this study: 26 (11 female/15 male) children with mobility impairments (20 cerebral palsy) who had been referred for clinical gait assessment and 30 (15 female/15 male) typically developing (TD) children. Participants walked barefoot while marker-based (12 Motion Analysis Eagle4 cameras with modified Helen-Hayes approach) and markerless (Theia3D with 8 Sony Cameras) data were captured concurrently. For each participant, lower body joint angles normalized to 100% of the gait cycle were statistically compared using root-mean-square-deviation (RMSD). The RMSDs for each subject were then averaged across multiple strides for each side of the body. The TD cohort values were calculated with 7 strides per individual, while the clinical cohort used 3-6 strides per individual due to factors including fatigue and marker occlusion.

Results

Table 1 shows the median and 25th-75th percentiles for the RMSD of the left side. In both groups the frontal and sagittal planes showed better agreement between marker-based and markerless approaches than the transverse plane across all joints, except for the pelvis. The clinical group had higher median RMSD values all plane-joint-side combinations except the right hip frontal plane. The largest difference between the two groups was seen at the frontal and transverse plane ankle angles.

Discussion

The transverse plane poses challenges for marker-based systems due to its higher sensitivity to soft-tissue artifacts and marker placement. The larger RMSD values in the transverse plane indicate disagreement between systems, but not which system is closer to a true measurement. The larger RMSD values in the clinical group could be caused by anatomic differences including foot deformities being underrepresented in Theia3D's training dataset or fewer strides contributing to the participant's average. These results indicate potential systematic differences between how clinical and TD individuals are measured using markerless motion capture that should be explored prior to implementation in a clinical pediatric gait laboratory.

Foot Strategies Used During Y-Balance Tests may be Influenced by Suboptimal Postural Control in Adolescents Post-Anterior Cruciate Ligament Reconstruction

Ms. Kasey Stammen BS[1,2], Dr. Elliot Greenberg DPT, PhD[3], Ms. Madeleine McCreary BS[1,4], Mr. Stone Streeter BS[3], Mr. Kevin Xu BA[3], Dr. Theodore Ganley MD[3], Dr. Valentina Graci PhD[1]

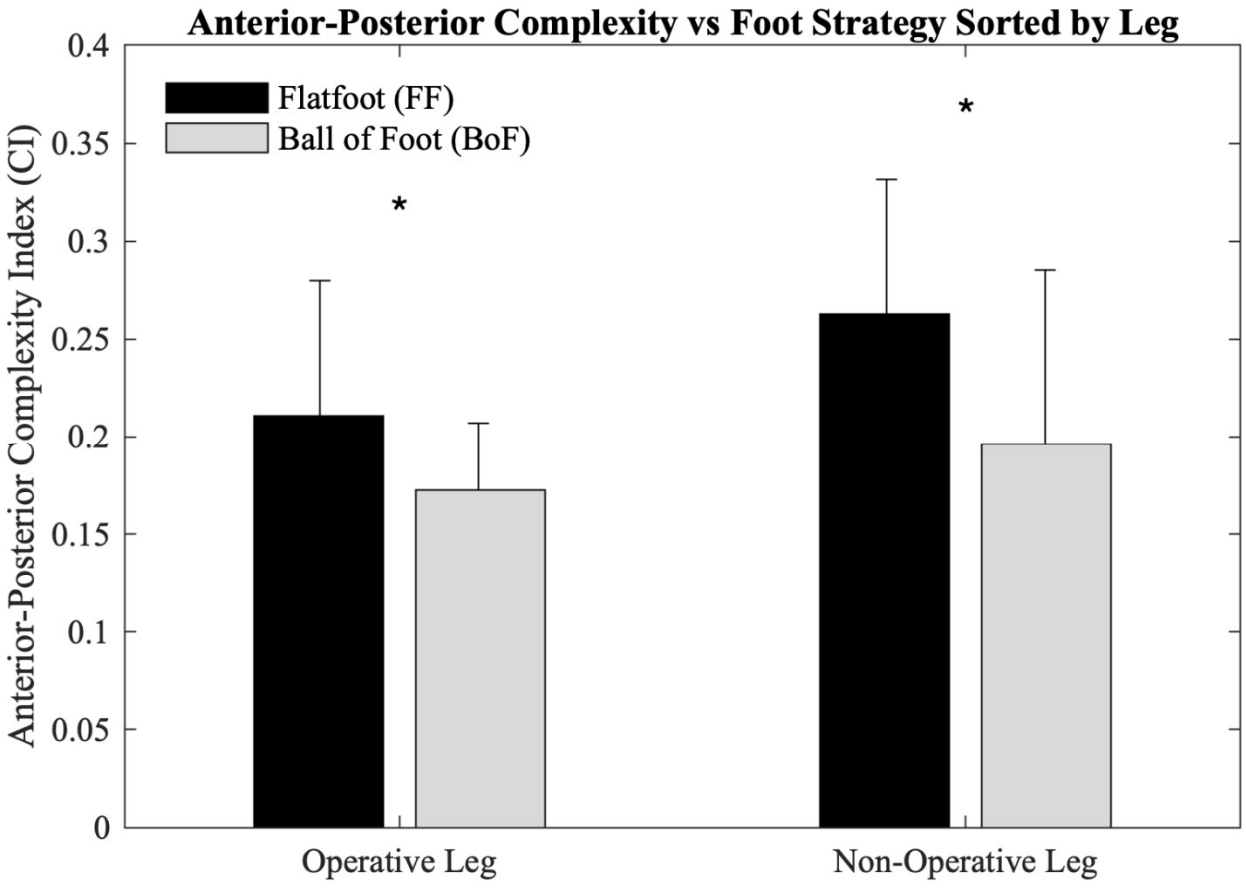
[1]Center for Injury Research and Prevention, Children's Hospital of Philadelphia, Philadelphia, PA, United States. [2]Department of Human Sciences, Ohio State University, Columbus, OH, United States. [3]Department of Orthopaedic Surgery, Children's Hospital of Philadelphia, Philadelphia, PA, United States. [4]Department of Mechanical Engineering, University of Washington, Seattle, WA, United States

Introduction

Prior research has identified that three months after anterior cruciate ligament reconstruction (ACLR), adolescents will utilize different movement strategies to perform the anterior reach portion of the Y-balance test (antYBT) by remaining more flatfooted (FF) on their operated limb (OPL) and moving onto the ball-of-foot (BoF) on the non-operative limb (NOPL). It remains unclear if the foot strategy (FS) is influenced by postural control and/or strength. Understanding which factors influence FS can help guide precise rehabilitation during recovery. This study aimed to assess how FS and leg strength impact the center-of-pressure (CoP) entropy of adolescents post-ACLR while maintaining balance during the antYBT.

Methods

Adolescent athletes three months post-ACLR, completed two trials of the antYBT, which involves balancing on one limb, reaching their opposing limb forward as far as possible, and returning to a single-leg balanced position. Video recordings on their OPL and NOPL were reviewed and classified as either FF or BoF strategy on the balancing limb. The complexity index (CI; CoP entropy measure) in the anterior-posterior (AP) and medial-lateral (ML) direction was calculated for each trial. Hamstring/quadriceps strength ratios were extracted from medical records. Wilcoxon test was used to compare strength and CI between FS ($p<=0.05$).



Results

23 patients (15.53 ± 1.98 years old, 65% female) completed 45 OPL and 46 NOPL trials. CI in the AP direction was statistically significantly lower when using BoF strategy for both OPL and NOPL (OPL: 0.21±0.06 vs 0.17±0.03 p=0.05, NOPL: 0.26±0.06 vs 0.19±0.08 p=0.03, Figure 1). There was no significant difference in CI in the ML direction between FS. There was no significant difference in hamstring/quadriceps strength ratios between FS.

Discussion

Lower AP CoP entropy in the BoF than the FF strategy suggests less refined postural control and adaptability in both legs in adolescents post-ACLR during this dynamic balance task. Patient's hamstring/quadriceps strength ratio did not show differences between FS, suggesting that FS may be more influenced by postural control than strength. Future studies should seek to better understand how CoP entropy may affect movement strategies, recovery, and reinjury risk in adolescents post-ACLR.

Passive Smartphone Gait Monitoring in Ankle Fracture Recovery: Feasibility in a Prospective Cohort of 91 Patients

Dr. Daniel Fitzpatrick MD, MS[1], Dr. Michael Hahn PhD[2], Dr. Blake Dowdle MD[1], Dr. Brandon Wilkinson MD[1], Dr. Nicholas Strasser MD[3], Ms. Tessa Kirkpatrick BS, CCRC[4], Ms. Cindy Headlee[4], Ms. Ellie DeLoretto BS[4], Ms. Leila Hollis MS[5], Dr. Kate Spitzley PhD[4]

[5]University of Nevada Reno School of Medicine, Reno, NV, United States

Introduction

Smartphone-based gait monitoring presents clinicians with a low-burden opportunity to objectively compare pre- and post-injury gait patterns and offers individualized baselines for functional recovery. This study evaluated the feasibility of passively collecting iPhone gait metrics to track functional recovery after ankle fracture in both a private orthopedic practice and university medical center setting.

Methods

A cohort of 91 patients with isolated ankle fractures was enrolled. Thirty days of pre-injury baseline gait data was captured retrospectively at enrollment, and gait data was prospectively captured for 6 months following treatment. Gait metric data was passively collected on the HealthKit app and transferred to the research team using an app designed for this study. Metrics included step count, walking distance, double support percentage, walking speed, step length, and walking asymmetry. Data completeness was determined relative to the subgroup of patients with valid preinjury baseline data for each metric.

Results

Preinjury baseline data was present in 62 of 91 patients (68.1%) for walking speed; in 45 of 91 patients (49.5%) for step count, walking distance, double support, and walking asymmetry; and in 54 of 91 patients (59.3%) for step length. Among those with valid preinjury baseline data, complete follow-up was achieved in 47 of 62 patients (75.8%) for walking speed, in 38 of 45 patients (84.4%) for step count, walking distance, and double support, in 46 of 54 patients (85.2%) for step length, and in 29 of 40 patients (72.5%) for

walking asymmetry. In contrast, among participants lacking preinjury baseline data, complete follow-up rates ranged from 0% for step length to 31.3% for step count.

Discussion

Passive collection of iPhone gait metrics is a feasible approach for monitoring functional recovery following orthopedic trauma in a subset of the patient population. Our findings demonstrate that when preinjury baseline data are available, follow-up data completeness is relatively high across multiple gait parameters. Conversely, patients without baseline data show significantly lower follow-up completeness, underscoring the necessity for researchers to confirm the availability of pre-injury measurements prior to longitudinal analysis. This study supports the broader utility of passive smartphone monitoring as a tool in clinical research and practice.

Markerless Pose Estimation to Assess Functional Mobility Before and After Focused Ultrasound Ablation in Individuals With Essential Tremor

Dr. Kavya Katugam-Dechene PhD[1,2], Mr. Ethan Simaitis[1,2], Dr. Daniel Roque MD[1], Dr. Aaron Gelinne MD[1], Dr. Vibhor Krishna MD[1], Dr. Jason Franz PhD[1,2]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States. [2]North Carolina State University, Raleigh, NC, United States

Introduction

Essential tremor (ET) is a common neurologic disorder that disproportionately impairs upper-limb control but is frequently associated with balance and gait dysfunction. Focused ultrasound ablation (FUSA) is a treatment option that targets the ventral intermediate nucleus of the thalamus to disrupt central nervous system excitatory pathways that perpetuate ET pathology. Although generally safe, FUSA can lead to post-treatment gait dysfunction or imbalance in ~33% of patients. Traditional neurological tests may miss subtle changes in locomotor function necessitating the need for more objective means to evaluate gait following FUSA. In this study, we used markerless pose estimation to assess pre-post changes in spatiotemporal gait patterns, joint kinematics, and center-of-mass (CoM) control following FUSA in people with ET.

Methods

ET patients (males and females) aged 22 years and older with moderate to severe ET refractory to at least two medications were included. Five adults with ET have completed a battery of functional and locomotor tasks immediately before and immediately after FUSA. The battery included: walking at preferred speed and fast speeds, walking with head turns, a figure-8 walking test, and a sit-to-stand task. Standard 2-camera videos were processed using OpenCap to extract 3D joint kinematics (hip, knee, ankle flexion-extension) and keypoint and CoM trajectories.

Results

Most participants adopted slower preferred (n=3/5), maximum (n=4/5), and figure-8 (n=4/5) walking speeds with shorter and wider steps and, when walking with head turns, larger path deviations (n=4/5) following FUSA. Across most tasks, participants tended to adopt smaller peak leg joint angles and lesser CoM peak jerk, the latter interpreted as a “smoother” pattern (preferred: n=4/5; fast: n=3/5; figure-8: n=3/5; walk with head-turn: n=3/5). These changes may be unique to locomotion; n=4/5 participants completed the sit-to-stand more quickly following FUSA.

Discussion

Early findings suggest that FUSA in patients with ET may promote smoother walking patterns yet precipitate a more cautious, stability-oriented gait strategy. Together, these findings demonstrate the clinical feasibility of markerless pose estimation to quantify gait and mobility after FUSA, providing an objective complement to standard neurological assessments to fully capture functional recovery.

Effectiveness of Stochastic Resonance Electrical Stimulation on the Timed Up-and-Go Test Performance in Individuals with Cerebral Palsy

Introduction

Individuals with cerebral palsy (CP) have somatosensory deficits that contribute to balance impairments and postural challenges, leading to increased fall risk and poorer quality of life. Effective sensory-motor interventions may enhance somatosensory perception and balance. Stochastic Resonance (SR) electrical stimulation improves somatosensation, standing, and walking balance, predominantly in individuals with poorer sensory perception, by utilizing sub-sensory noise to elicit the detection of weak sensory input. While SR has shown promising results in improving balance during standing and walking in individuals with CP, its effect on more complex tasks, such as the Timed Up-and-Go test (TUG), is unknown. Thirty-five percent of falls in individuals with CP occur during walking-related activities such as turning and trunk bending, which are components of the TUG. We investigated the immediate effects of SR stimulation on TUG in individuals with CP.

Methods

Twenty individuals with spastic diplegic CP performed three trials of TUG each with and without SR stimulation. The optimal SR intensity was used to simultaneously stimulate the muscles and ligaments of the ankle and hip joints. We segmented the TUG into five phases, i.e., sit-to-walk, walk forward, turn, walk back, and turn-and-sit. The time taken to complete TUG and its phases was calculated. Paired-samples T-tests were performed to

evaluate changes in the time taken to complete the TUG and its phases in individuals with CP in response to SR.

Results

SR stimulation did not shorten the time it took to complete the TUG in individuals with CP. SR stimulation similarly did not affect the time required to complete any phase of the TUG in individuals with CP (**Table)**. Although TUG performance times did not significantly differ, all time measurements showed a slight increase with the use of SR.

Discussion

SR-enhanced somatosensory information may not be immediately utilized by the central nervous system to improve performance in more complex tasks. SR may not be effective to change performance, it may initially act as a distraction, or it may require training for individuals with CP to learn to use the enhanced sensory information to change their motor performance.

Images (Optional)

Table: Mean difference in total time taken to complete the Timed-Up-and-Go test (TUG) and its phases with the use of stochastic resonance electrical stimulation (SR) for individuals with cerebral palsy (CP). Significance is Bonferroni corrected to be at $p < 0.008$.

	No-SR Mean ± SD (s)	ΔSR Mean difference (s)	p-value
Sit-to-walk	2.55 ± 0.66	0.07	0.596
Walk-forward	5.73 ± 1.54	0.07	0.772
Turn	2.50 ± 0.57	0.01	0.844
Walk-back	5.12 ± 1.37	0.05	0.727
Turn-to-sit	4.50± 1.23	0.06	0.838
Total time	19.37 ± 4.29	0.14	0.781

Dynamic Visual Acuity in A Pediatric Population: Differences between Sexes

Dr. Kiara Barrett[1], Dr. Anastasia Kyvelidou[2], Dr. Kathryn Lucas[3], Dr. Kamran Barin[1]

[1]Bertec Corporation, Columbus, OH, United States. [2]Creighton University, Omaha, NE, United States. [3]Creighton University, Phoenix, AZ, United States

Introduction

The Dynamic Visual Acuity (DVA) test is a functional measure of the vestibulo-ocular (VOR) reflex that measures visual acuity during head movements. Although the DVA test is used routinely in adults, testing in children is less popular. Normative values have been established for children using the same optotypes used for adult testing [1], however pediatric-friendly optotypes have recently become available. Normal limits for such optotypes have yet to be reported. The purpose of this study is to determine the DVA normative values and compare sex differences in developing children using child-friendly optotypes.

Methods

39 participants (M=23, F=16) under the age of 18 were tested at two Creighton University campuses; characteristics are reported in Table 1. Computerized assessments were administered using the Bertec Vision Advantage system™. During testing, participants were asked to identify pediatric optotypes with the head at rest (baseline) and with the head moving horizontally at about 100°/s (dynamic). Passive instructor-led testing was performed if the participant was unable to maintain consistent head velocities independently. Trials with different optotype sizes continued until acuity thresholds were established. Responses were tabulated then statistically analyzed using a non-parametric Kruksal-Wallis test with an alpha level of .05.

Results

No significant differences were found between sexes in Baseline Visual Acuity (BLVA) (p=.076) or between right (p=.061) and left (p=.617) directions in DVA. Means and standard deviations for each group are provided in Table 1.

Discussion

This study provides normative pediatric values for the child-specific optotypes in the DVA test. The NIH toolbox reported an average DVA score of 0.116 for children aged 3-17 [1] using a “tumbling E” optotype, which is consistent with our results; however, no comparison of sexes was made. The lack of sex differences in our findings suggests early

development of the VOR is not influenced by this variable. Future research should investigate the impact of passive and active head movements in a pediatric population to determine if a disparity in methodology influences results.

Evaluating MRI-Derived Predictors of Hamstring Strength in Facioscapulohumeral Muscular Dystrophy

Ms. Kimberly M. Steininger[1], Dr. Seth D. Friedman[2], Dr. Silvia S. Blemker[1]

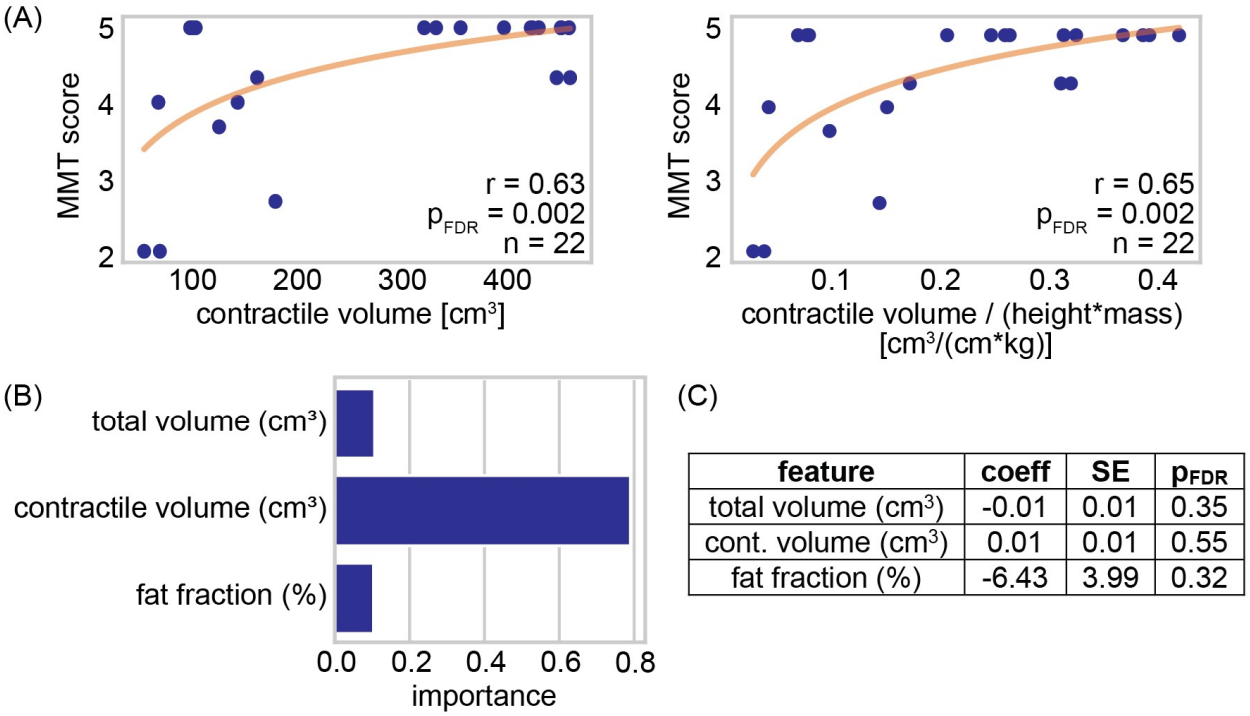
[1]University of Virginia, Charlottesville, VA, United States. [2]Seattle Children's Hospital, Seattle, WA, United States

Introduction

Facioscapulohumeral muscular dystrophy (FSHD) causes progressive muscular degeneration and intramuscular fat infiltration, reducing force-generation capacity. Muscle force depends on structure and quality, but as the heterogeneous spatial distribution of fat in FSHD impacts muscle composition, this structure-function relationship is complicated. This study aims to evaluate which MRI-derived muscle features best predict knee-flexion strength from manual muscle testing (MMT) and whether changes in contractile volume (CV) influence functional decline independently of fat fraction (FF).

Methods

We analyzed longitudinal MRI and clinical manual muscle testing (MMT) data for the biceps femoris long head (BFLH), semimembranosus (SM), and semitendinosus (ST) in FSHD patients [n=11, 7, 6 at t=1, 2, 3yrs]. For each hamstring and as a group, we calculated total volume (TV) and CV, FF, mean and max cross-sectional area (CSA), and length. Log-Pearson correlations assessed associations between absolute and normalized CV and MMT, with p-values were corrected using Benjamini–Hochberg FDR. Random forest models ranked feature importance. Longitudinal changes were evaluated via within-subject deltas (Δ) of MRI features and side-matched ΔMMT using linear regression models adjusted for timepoint and clustered by subject. P-values were FDR-corrected.



Results

Log-Pearson correlations revealed significant associations between CV and MMT scores at the first timepoint: r = 0.63, p_{FDR} = 0.0019 for abs(CV) and r = 0.65, p_{FDR} = 0.0019 for norm(CV), indicating modest improvements with normalization. Random forest models showed that CV (importance = 0.79) was the top predictor, followed by TV (0.11) and FF (0.10). Longitudinal Δ analyses indicated no MRI feature was significant after FDR correction: FF, −6.43 (3.99), p_{FDR}=0.32; TV, −0.0069 (0.0058), p_{FDR}=0.35; CV, 0.0046 (0.0076), p_{FDR}=0.55.

Discussion

Overall, CV emerged as the primary MRI determinant of strength, with secondary contributions from TV and FF. While longitudinal Δ associations were not significant, the direction of effects aligned with cross-sectional findings. Body-size normalized metrics modestly improve strength prediction and highlight CV as a key MRI biomarker. Future studies with larger cohorts are warranted to better characterize temporal relationships between MRI features and functional decline and inform objective outcome measures for FSHD clinical trials.

Effect of Carbon Fiber Custom Dynamic Orthosis Cuff Design on Foot Loading During Gait With Unimpaired Individuals

Dr. Kirsten Anderson PhD, Ms. Molly Pacha MS, ATC, Dr. Jason Wilken PT, PhD

The University of Iowa, Iowa City, Iowa, United States

Introduction

Carbon fiber custom dynamic orthoses (CDOs) include a footplate, posterior strut, and cuff that wraps around the leg under the knee. The cuff is a primary interface between CDO and patient. CDOs reduce pain, improve quality of life, and alter foot loading during gait following lower limb trauma.[1-3] Multiple cuff designs are available for clinicians to choose from, based on their patient's needs. However, the effect of cuff design on foot loading is not well understood. This study was completed to determine the effects of cuff design on foot loading in a group of unimpaired individuals.

Methods

Activities were approved by the local institutional review board and participants provided informed consent. 15 individuals with no history of injury (9 Female, 25.5 (7.1)yrs, 1.7 (0.1)m, 73.0 (13.1)kg) participated. Loadsol insoles (novel electronics inc.) measured forces acting on the foot as participants walked at a controlled speed without a CDO (NoCDO) and with a CDO using four interchangeable cuffs (Figure 1; BOA, ChiScrew, AntShell, Flex) in a random order. Peak force and force-time integral (impulse) were calculated for the hindfoot and forefoot. One-way repeated measures ANOVAs were used to test for main effects of condition and post-hoc testing included paired sample t-tests and Wilcoxon signed rank tests with Bonferroni Holm correction.

Results

Peak forefoot force (43-45%) and impulse (32-36%) decreased significantly and hindfoot impulse (47-63%) increased significantly with CDO use compared to NoCDO. There were no significant differences between cuffs. Peak hindfoot force was not significantly different between conditions.

Discussion

Similar to previous work,[1-3] CDOs in this study significantly altered foot loading compared to NoCDO. The reductions in peak forefoot force and impulse, combined with the increased hindfoot impulse, indicate that forces are redistributed from the forefoot to the hindfoot within the CDO footplate. The lack of significant differences between cuffs

indicates that cuff design plays a limited role in foot loading and that clinicians can choose from multiple cuff designs to alter foot loading during gait.

P4-193

EFFECT OF CUFF DESIGN ON HINDFOOT AND FOREFOOT LOADING DURING GAIT WITH CARBON FIBER CUSTOM DYNAMIC ORTHOSES IN INDIVIDUALS WITH ANKLE ARTHRITIS

Dr. Kirsten Anderson PhD, Ms. Molly Pacha MS, ATC, Dr. Jason Wilken PT, PhD

The University of Iowa, Iowa City, Iowa, United States

Introduction

Limb trauma often results in post-traumatic osteoarthritis (PTOA), leaving patients at risk for poor outcomes including weakness and pain with loading.[1] Carbon fiber custom dynamic orthoses (CDOs) alter foot loading, reduce pain, and address limitations associated with limb trauma and PTOA.[2-4] CDOs consist of a cuff below the knee, posterior strut, and footplate. Clinicians can choose between cuff designs to best meet the needs of their patients. However, the effect of cuff design on foot loading is not well documented. This study recruited individuals with ankle PTOA to determine the effects that cuff design has on foot loading during gait.

Methods

This study was institutional review board approved. 14 individuals with injury resulting in ankle PTOA (9 Female, 47.8 (12.3)yrs, 1.8 (0.1)m, 88.5 (21.8)kg) provided consent. Forces acting on the hindfoot and forefoot were measured using loadsol insoles (Novel Electronics Inc.). Peak force and force-time integral (impulse) were calculated as participants walked at a controlled speed without a CDO (NoCDO) then with a CDO using four interchangeable cuffs (Figure 1; AntShell, BOA, ChiScrew, Flex) in a randomized order. Main effects of condition were tested for using one-way repeated measures ANOVAs. Paired sample t-tests and Wilcoxon signed rank tests with Bonferroni Holm correction were completed for post-hoc analysis.

Results

Peak hindfoot force did not significantly differ between conditions. Hindfoot impulse significantly increased (39-50%) while peak forefoot force (32-34%) and impulse (19-22%) significantly decreased with CDO use compared to NoCDO. There were no significant differences between cuffs.

Discussion

Results indicate that all cuffs altered foot loading compared to NoCDO. Reductions in forefoot loading, combined with increased hindfoot impulse, indicate redistribution of

forces from the forefoot to hindfoot, which aligns with previous work.[2-3] There were no significant differences between cuffs, which indicates that cuff design plays a limited role in foot loading. This may allow clinicians to use multiple cuff designs to alter foot loading for individuals with ankle PTOA.

Adaptations to Unilateral Dorsiflexor Fatigue in Walking

Mr John Kerr BEng, MSc[1,2], Dr Luca Modenese PhD[1], Dr Key Nahan BPodMed, MSc, PhD[3,1,2], Dr Lucy Armitage BAppSci, BEng, MBiomedE, PhD[1], Associate Professor Lauren Kark BE (Hons), MBiomedE, PhD[1], Dr Martin Héroux BSc PT, MSc, PhD[4], Dr Kirsty McDonald BSc (Hons), PhD[5,1,2]

[1]University of New South Wales, Sydney, NSW, Australia. [2]Neuroscience Research Australia, Sydney, NSW, Australia. [3]University of Massachusetts Amherst, Amherst, MA, United States. [4]University of Sydney, Sydney, NSW, Australia. [5]Edith Cowan University, Perth, WA, Australia

Introduction

Humans without pathology walk symmetrically in stable environments to improve energetics and stability [1, 2]. We aimed to determine whether symmetric gait is conserved under conditions of unilateral dorsiflexor fatigue, given the importance of local muscle effort in dictating gait strategy [3].

Methods

The study was approved by the University of New South Wales Human Research Ethics Committee. Able-bodied adults (8M/8F; age: 28.1±5.8 years; mass: 68.4±11.2kg; mean±SD) provided informed consent. Trunk and lower limb markers were tracked (200Hz; Bonita, Vicon) as participants walked on a split-belt instrumented treadmill (1000Hz; M-Gait, Motek Medical). They performed 30s of baseline unfatigued walking, followed by maximum voluntary contractions (MVCs) and a unilateral dorsiflexor fatiguing protocol involving isometric contractions. This led to a 30.5% [26.7, 34.2] (mean [95%CI]) reduction in MVC dorsiflexor torque. Participants then completed a 30s fatigued walk and another MVC. Linear mixed-effects models were developed for step time, step length, first and second peak vertical ground reaction force (vGRF), peak swing dorsiflexion angle and peak stance dorsiflexor moment, with trial (baseline, fatigued) and limb (unfatigued, fatigued) as fixed factors, and participant as a random intercept. MVC torque was compared using paired t-tests.

Results

Fatigue recovered slightly (2.7%) during the fatigued walk ($p=0.022$). Spatiotemporal parameters showed no interaction effect ($p\geq0.602$), and main effects of trial (step time: $p=0.015$; step length: $p=0.049$) but not limb ($p\geq0.09$), indicating symmetry was conserved despite bilateral gait adaptations. First and second vGRF peaks showed no trial, limb, or

interaction effects ($p \geq 0.051$). Peak dorsiflexor moment asymmetries existed (limb effect: $p=0.012$) and persisted between baseline and fatigued trials (interaction effect: $p=0.220$; trial effect: $p=0.045$). Peak dorsiflexion angle showed an interaction effect ($p=0.025$), as the only variable asymmetrically altered.

Discussion

These findings suggest that while minor (<2°) kinematic changes occurred in the fatigued limb, high-level symmetry was maintained, possibly prioritising energetic/stability benefits over asymmetric offloading. This contrasts with recent experimental work suggesting fatigue (or local muscle effort) minimisation represents a principal locomotor objective [3].

Effective Body Stiffness Estimation During Falls Using a Customized Hand-Held Indentation Device for Hip Fracture Risk Prediction

Dr. Kitaek Lim PT, PhD, Ms. Soyeon Yoon PT, Mr. Junwoo Park PT, MSc, Dr. Seyoung Lee PT, PhD, Mr. Sungmin Chun PT, Mr. Donggeon Kim PT, Prof. Woochol Joseph Choi PT, PhD

Injury Prevention and Biomechanics Laboratory, Dept of Physical Therapy, Yonsei University, Wonju, Gangwon, Korea, Republic of

Introduction

Hip fracture risk is defined as a ratio of hip impact force to femoral strength, where the impact force (F) is given by $F = v*(m*k)\text{^}(1/2)$, with v denoting impact velocity, m effective body mass, and k effective body stiffness [1]. If k can be readily estimated, an individual's hip fracture risk during a fall can be predicted easily. To estimate the k at impact, we developed a customized hand-held indentation device designed to measure the trochanteric soft tissue stiffness.

Methods

Nine young adults mimicked older adults' falls, with different landing configurations (Figure 1a). Impact force was measured with a force plate underneath the mat, and pelvic deformation was tracked with a motion capture system. Effective body stiffness (k_b) was calculated from total stiffness (k_t) and mat stiffness (k_m) using a series spring model ($1/k_b = 1/k_t - 1/k_m$). A customized hand-held indentation device was also used to record force and deformation data under cyclic forces (>100 N) at 30 and 60 cycles per minute. Then, trochanteric soft tissue stiffness was determined as the tangent slope at maximum deformation from first and second order polynomial and exponential fits (k_{sc_30}, k_{sc_60}), and also measured with a MyotonPro (k_{sm}), which were normalized by body weight and trochanteric soft tissue thickness [2]. Linear regression analyses were used to predict k_b with trochanteric soft tissue stiffness.

Results

Descriptive statistics are summarized in Table 1. Correlation analysis indicated that normalized k_b in the knee-on-mat configuration was associated with normalized k_{sc_30} derived from both first and second order fits ($p < 0.05$). Furthermore, linear regression analysis suggested that the normalized k_b decreased 2041.9 and 777.9 for every

increase in k_{sc_30} derived from both first and second order fits, respectively (Figure 2). However, no significant correlations were found for other variables ($p > 0.05$).

Discussion

Our results suggest that the effective body stiffness can be predicted with trochanteric soft tissue stiffness measured by the customized hand-held indentation device, suggesting its potential for hip fracture risk assessment without complex laboratory experiments.

Acute Effects of Reactive Agility Training on ACL injury Risk Factors in Collegiate and Recreational Athletes

Dr Kristamarie Pratt PhD, Mr Wesley Johnson DPT, Mr Daniel Reynolds DPT, Mr Noah Ackerman DPT, Ms Julia Chapell DPT, Ms Lindsay Coffey DPT, Ms. Ashlyn Tavares DPT, Ms Victoria Jedrychowski DPT, Ms Amanda Warner DPT, Ms Aarohi Patel DPT

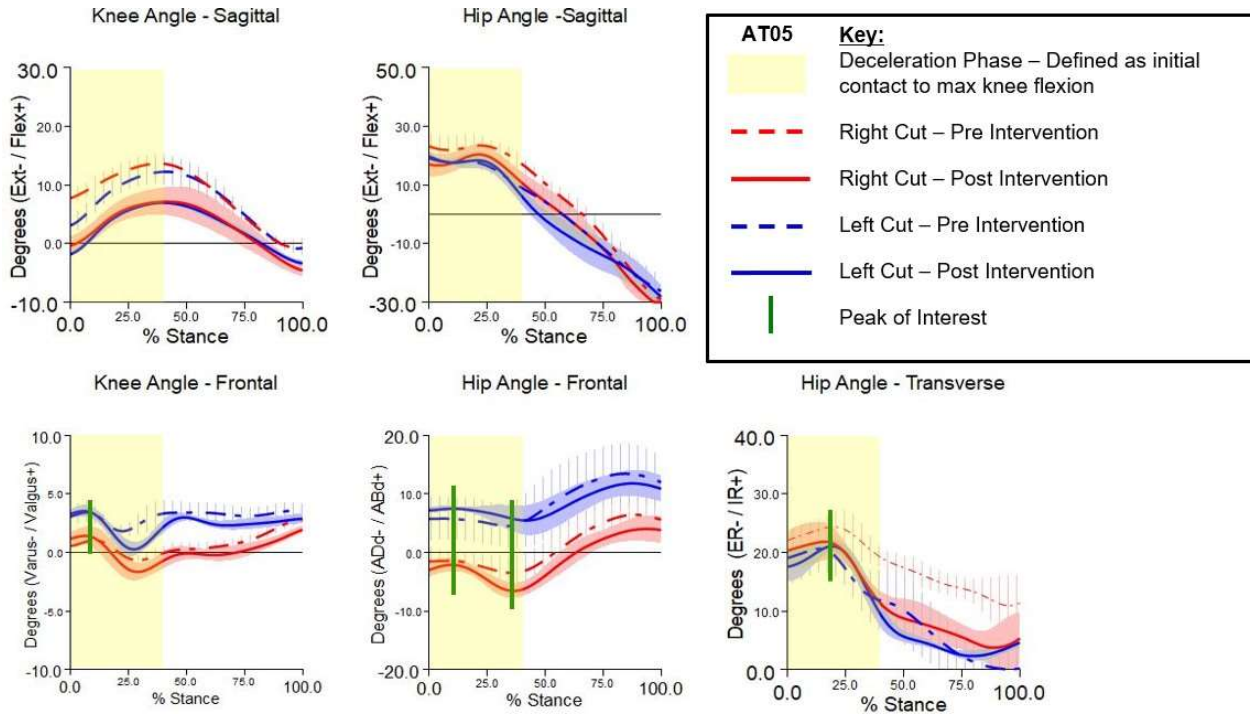
University of Hartford, West Hartford, CT, United States

Introduction

Collegiate and recreational athletes participating in sports involving reactive movements like defense cutting and sudden directional changes are susceptible to ACL-injuries. Contributing risk factors include lower neurocognitive function leading to poor knee and hip biomechanics. Research has shown that reactivity agility training (RAT) drills have notable improvements on overall performance of cutting mechanics and deceleration during game time decisions for athletes. Acute effects of RAT drills on risk factors are unknown; therefore, the purpose is to investigate the real time effects of RAT drills, ultimately providing valuable insights into how RAT drills can reduce ACL-injury risk.

Methods

18 recreational or collegiate athletes (10 offensive/10 defensive) over 18 years old with no current injuries were tested. 3D motion capture data and forces were collected during pre-training and post-training test sessions which involved an unanticipated 45° cuts on both left and right limbs; Participants completed an acute bout of RAT using a Mirror Drill in between testing sessions. Knee and hip kinematics and kinetics were recorded and calculated.



Results

Initial findings indicate athletes performed cutting with greater knee and hip flexion following an acute bout of RAT. We anticipate improvements in ACL injury risk factors for defensive player between pre-drill testing and post-drill testing, suggesting that use of reactive agility drills as a pregame warm up can reduce risk factors related to in game injuries. This result will be further supported if there is no significant change observed in offensive players ACL injury risk factors. We also expect to find a greater statistical change in ACL injury risk factors of recreational athletes compared with collegiate athletes.

Discussion

Understanding acute effects of RAT may reduce ACL-injury risk factors. Coaches, and clinicians could benefit from incorporating such functional drills into warm-up routines pre-game or pre-practice, potentially offering a more effective approach than traditional drills. Although further analysis is warranted to validate these anticipated findings, stage for a potential breakthrough in ACL-injury prevention strategies for athletes.

Relating Head Impacts to Pupillary Light Reflex Metrics and Symptom Reporting in Collegiate Rugby Players

Ms. Lauren Duma, Dr. Nicole Stark, Dr. Steve Rowson

Virginia Tech, Blacksburg, VA, United States

Introduction

Concussions are a common sports-related injury, and athletes in contact sports will also sustain several subconcussive head impacts throughout their career. Previously, studies have observed measurable changes in the pupillary light reflex (PLR) in response to concussion [1]. The objective of this study was to relate changes in PLR metrics and symptom reporting to subconcussive head impacts experienced throughout a semester of collegiate rugby games.

Methods

Twenty-one male collegiate rugby players were observed during seven 15s rugby games across a semester. Before and after each game, players completed a symptom survey and PLR measurement. The total number of reported symptoms and the Symptom Severity Score (SSS), the sum of all symptom ratings, were calculated for each survey. Pupil measurements were taken with a PLR-4000 pupillometer (NeurOptics). Players wore instrumented mouthguards (Prevent Biometrics) during each game, and the recorded head impacts were video-verified. For each player, the number of head impacts sustained in each game was counted, and the change in SSS, number of symptoms, and PLR metrics were calculated by subtracting baseline measurements from post-game measurements.

Results

Data collection and analysis is ongoing. Preliminary results show no correlation between the number of head impacts sustained in a game and change in SSS, number of symptoms, or any PLR metric (SSS: $r^2 = 0.02$, $p = 0.24$; Number of symptoms: $r^2 = 0.02$, $p = 0.22$; Average constriction velocity: $r^2 = 0.01$, $p = 0.32$; Average dilation velocity: $r^2 = 0.14$, $p < 0.01$). Further, there is no significant correlation between change in SSS and change in any PLR metric (Average constriction velocity: $r^2 = 0.02$, $p = 0.21$; Average dilation velocity: $r^2 = 0.01$, $p = 0.30$).

Discussion

In this study, we assessed the ability of the PLR to quantify the effects of repetitive subconcussive head impacts. Preliminary results show that the head impacts experienced

throughout this study were likely not severe enough to result in measurable changes in the PLR as observed in previous studies with concussed athletes. Future directions include relating head impact severity to PLR changes and including women's rugby players.

Association of Intramuscular Fat Fraction with Knee Extensor Strength in Adults with Clinical Knee Osteoarthritis

Postdoctoral Fellow Lauren Straatman PhD[1], Postdoctoral Fellow Anthony A. Gatti PhD[2], Postdoctoral Fellow Jacquelyn M. Coyne PhD[1,3], Lab Tech Braeden Cowbrough[4], Postdoctoral Fellow Kendal A. Marriott PT, PhD[1], PhD Student Natasha I. Ivanochko MSc[1], Lab Coordinator Emily Wiebenga[1], Professor Dawn E. Bowdish PhD[4], Professor Marina Mourtzakis PhD[1], Professor Monica R. Maly PT, PhD[1]

Introduction

Quadriceps weakness is a hallmark of knee osteoarthritis (KOA). While lean muscle loss contributes to weakness, accumulating evidence suggests adiposity, a metabolically active tissue, may further impair muscle function through inflammatory mechanisms [1]. In parallel, anti-inflammatory cytokines have a protective influence on muscle strength in females with KOA [2]. The purpose of this study was to determine if serum inflammatory cytokines mediate the association between quadriceps and adipose tissue volumes with knee extensor strength in adults with clinical KOA.

Methods

Forty participants (20 male-female pairs matched on age (± 3 years) and BMI (±3 kg/m^2)) with clinical KOA were included. The most symptomatic limb was examined. Knee extensor strength was the average peak torque from five maximal voluntary isometric contractions measured using an isometric dynamometer (Biodex System 4). Thigh MRIs were captured using the IDEAL sequence on a 3T magnetic resonance imaging scanner, auto-segmented using an open-source program [3], and manually edited in 3D Slicer for total volumes of quadriceps intramuscular fat (IMAT), and quadriceps lean tissue (QV). Fat fraction was calculated as IMAT divided by QV. Fasting venous blood samples were collected after 30-minutes of rest to assess C-reactive protein (CRP, proinflammatory) and interleukin-10 (IL10, anti-inflammatory). Hierarchical linear regression models assessed direct associations between tissue volumes with knee extensor strength (adjusting for age, sex, and step count); followed by mediation analyses with CRP and IL10 in separate models.

Results

After adjusting for covariates, greater fat fraction associated with lower knee extensor strength ($t = -2.21$, $p = 0.03$); and larger QV associated with greater knee extensor strength ($t = 3.7$, $p < 0.001$). Inflammatory cytokines did not mediate these associations.

Discussion

In clinical knee OA, serum cytokines did not mediate associations between thigh tissue volumes with knee extensor strength. However, quadriceps fat fraction and QV associated with lesser and greater knee extensor strength respectively, highlighting the importance of both muscle quality and quantity in knee strength. This work complements existing data showing quadriceps fat fraction associated with self-reported disability [4].

Unique Frontal Plane Gait Biomechanical Features in Lateral Knee Osteoarthritis

Dr. Kendal Marriott PT PhD, Dr. Erin Lee PhD, Mrs. Emily Wiebenga BSc, Dr. Monica Maly PT PhD, Leah Williams

University of Waterloo, Waterloo, Ontario, Canada

Introduction

Knee osteoarthritis (OA) affects the medial tibiofemoral compartment most often. OA that primarily affects the lateral compartment may reflect unique biomechanical features, but little is known. The purpose of this study was to compare hip and knee angles and moments between medial and lateral tibiofemoral OA and between sexes.

Methods

Baseline data from a longitudinal study of clinical knee OA were used. Participants completed gait analyses and knee radiographs. Biomechanical features measured included peak knee (adduction, flexion) and hip (adduction) moments and knee (adduction) and hip (adduction) angles. Standing radiographs were acquired in a standardized position. From these radiographs, joint space in the medial and lateral compartments was assessed separately using the Osteoarthritis Research Society International (OARSI) atlas; with greater joint space narrowing defining the primary OA compartment (medial or lateral). Those with equal narrowing in the medial and lateral compartments were excluded from analyses. For each of the five peak biomechanical features, a two-way (OA compartment, sex, OA compartment × sex) ANCOVA (covariates: age, BMI) was completed.

Results

Data from 92 participants (age=65.4 years, body mass index (BMI)=29.0 kg/m^2, females/males=61/31) were used. For each biomechanical feature, there was no interaction (OA compartment × sex). For both the peak knee adduction moment and peak knee adduction angle, there were main effects for OA compartment ($F=31.44$, $p<0.001$ and $F=6.59$, $p<0.02$, respectively) and sex ($F=14.87$, $p<0.001$ and $F=9.95$, $p<0.003$), with those with medial compartment disease and males demonstrating higher peak knee adduction moments and angles. For the peak hip adduction angle, there were main effects for OA compartment ($F=14.91$, $p<0.001$) and sex ($F=13.11$, $p<0.001$), with those with lateral compartment disease and females demonstrating higher peak hip adduction angle. For both the peak knee flexion moment and peak hip adduction moment, there were no main effects.

Discussion

In lateral OA, the pattern of peak knee moments and peak knee and hip angles in the frontal plane reflect greater mechanical loading of the lateral tibiofemoral compartment; and higher moments in males compared to females. These differences in frontal plane gait biomechanics may indicate different underlying biomechanical mechanisms for lateral versus medial knee OA.

Images (Optional)

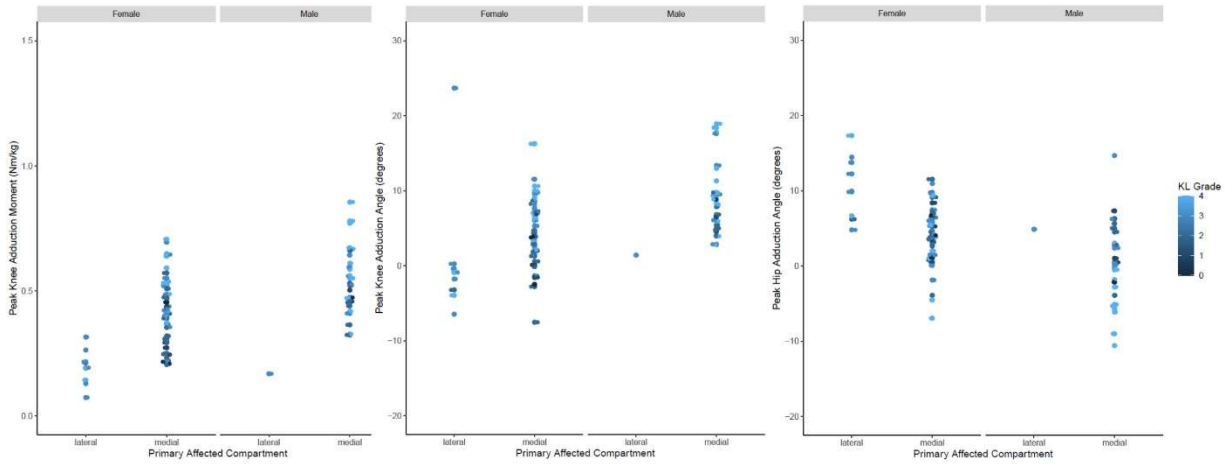

Figure 1. Distribution of peak values for knee adduction moment (Nm/kg), knee adduction angle (degrees) and hip adduction angle (degrees) across primary compartment affected by osteoarthritis (medial versus lateral) and across sex (female versus male). Osteoarthritis severity is represented by Kellgren-Lawrence (KL) grade with darker blue indicating greater disease severity (ranging from 0-4).

Markerless Motion Capture Hardware for Biomechanical Assessment in Compact Clinical Spaces

Dr. Ryan Rykhus PhD, Dr. Lisa MacFadden PhD

University of South Dakota, Sioux Falls, SD, United States

Introduction

Quantifying human movement through biomechanical assessments provides objective metrics for evaluating rehabilitation progress and assessing functional movements of patients. Traditional motion capture systems provide accurate results but have significant barriers that limit clinical integration, including high costs, space requirements, and time required to perform assessments. Recent advances in markerless motion capture methods have reduced some barriers but have yet to address all three simultaneously. Despite these advances, there remains no clinical movement assessment tool that fits into the small spaces present in existing healthcare settings.

This study presents CloseCap, a markerless motion capture system designed to enable motion capture close to the participant by integrating wide field-of-view (FOV) cameras into a calibration-driven 3D reconstruction workflow. The objective was to evaluate the feasibility of performing gait assessments in compact clinical environments while maintaining clinically interpretable kinematics.

Methods

CloseCap uses low-cost, synchronized, wide field-of-view, global-shutter cameras mounted with fixed relative geometry to enable 3D reconstruction at close proximity (approximately 1m). Camera calibration was performed using distortion-aware methods optimized for wide-angle lenses. Using Facebook Research's Sapiens pose estimation algorithm, 2D body keypoints were identified us and triangulated into 3D coordinates.

The performance of CloseCap was assessed against OpenCap using thirty simultaneously recorded treadmill walking trials for two participants. Kinematics for both methods were computed using an OpenSim inverse kinematics pipeline, and lower-limb joint angles were compared. This study was deemed not human subject research by IRB.

Results

CloseCap successfully captured full-body gait data within a substantially reduced spatial footprint. Wide FOV imaging ensured consistent visibility of lower-limb landmarks at close range, and calibration-based distortion modeling supported stable 3D triangulation.

Comparisons revealed mean joint-angle differences of 6-8 degrees, depending on the joint measured. Despite higher-than-expected differences, kinematic trajectories were temporally consistent for gait analysis.

Discussion

These results demonstrate clinical movement assessments can be performed in spaces much smaller than previously possible by prioritizing wide FOV imaging and calibration-driven processing. Although joint-angle differences exceed commonly cited benchmarks, CloseCap produces clinically interpretable kinematics in environments where traditional motion capture is infeasible. Future work will focus on formal validation, repeatability, and expansion to additional movements and clinical populations.

[5]Department of Clinical and Development Psychology, University of Amsterdam, Amsterdam, Amsterdam, Netherlands. [6]Mental Care Group, Woerden, Woerden, Netherlands

Introduction

Pressure-optimized custom-made footwear helps prevent foot ulcer recurrence in people with diabetes. This footwear protects the foot from high mechanical loads, by redistributing pressure underneath the foot. Adherence to wearing such footwear is essential for its biomechanical function to affect clinical outcome, yet is often too low. There is limited evidence for adherence-improving interventions. We assessed the effectiveness of an integrated personalized multimodal intervention on footwear adherence in people with diabetes at high risk of ulceration, aiming to reduce cumulative mechanical stress on the foot.

Methods

In a multicenter randomized controlled trial, we randomized 126 participants with diabetes, peripheral neuropathy, ulcer history and custom-made footwear to usual care or enhanced treatment. Enhanced treatment consisted of pressure-optimized custom-made footwear, provision of pressure-optimized indoor-specific custom-made footwear, foot temperature monitoring, structured education, and motivational interviewing including personalized feedback. The primary outcome was adherence, calculated as percentage of steps wearing prescribed footwear, and objectively measured using a temperature sensor in the shoe and a physical activity monitor. Adherence was measured at baseline (before intervention), at 6 and 12-months follow-up, and statistically tested using a linear mixed model. Secondary outcomes included objectively measured wearing time in hours/day,

compared before and after study events, and cumulative mechanical stress, statistically tested using (paired) t-tests.

Results

Adherence to wearing custom-made footwear was significantly higher in enhanced treatment compared to usual care (75% (SD:10) vs 56% (SD:22) at 6 months, and 58% (SD:18) vs 49% (SD:20) at 12 months, $p<0.001$), with a relative improvement of 34% at 6 months (Fig.1). Wearing time was significantly increased after the provision of indoor-specific footwear (mean 7.7 to 9.4 hours/day, $p<0.001$), and structured education (mean 7.8 to 8.2 hours/day, $p=0.049$). Cumulative mechanical stress results will be presented at WCB.

Discussion

An integrated personalized multimodal intervention significantly increased footwear adherence compared to usual care. This increased adherence in combination with pressure-optimized footwear will likely lead to decreased cumulative mechanical loads underneath the foot, currently investigated as a secondary analysis of the trial and expected to finish in due time. The results support emphasizing indoor-specific footwear and structured education in foot care, as adherence-improving interventions.

Images (Optional)

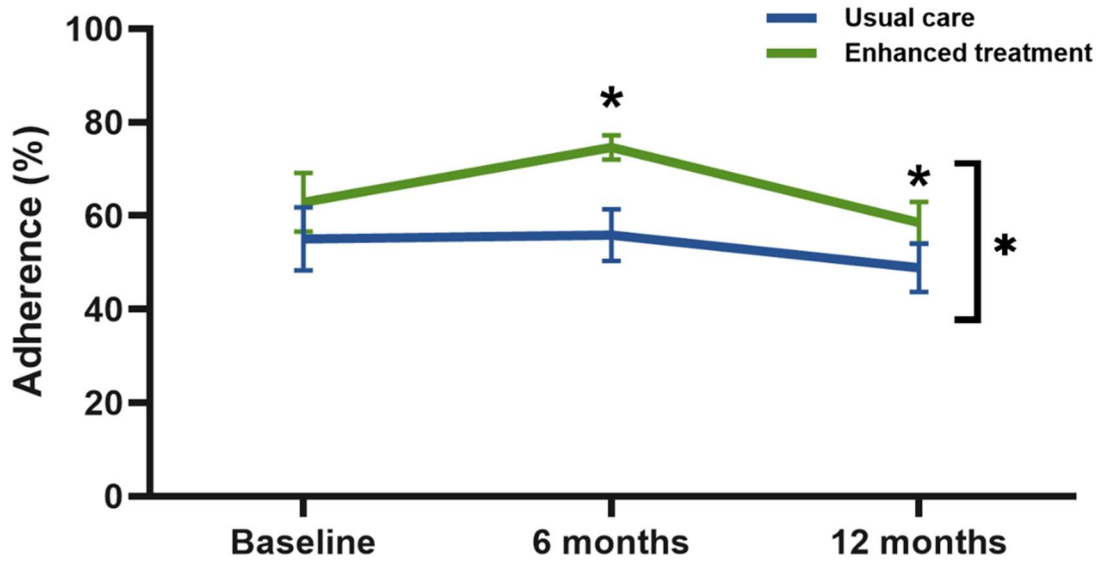

Fig.1: Adherence over the study period for usual care (blue) and enhanced treatment (green), measured at baseline (before intervention), and at 6 and 12 months after start of the multimodal intervention. Asterisks indicate significant differences between groups ($p<0.05$).

A Dynamical Model of the Pendulum Test in Stroke Patients with Quadriceps Spasticity: Parameter Identification and Correlation with Clinical Scales

Prof. Luciano Menegaldo[1], Dr. Joeana Withers[2], Dr. Veronica Silva[2], Dr. Carla Rinaldin[2], Prof. Maria Isabel Orselli[3], Prof. Elisângela Manffra[2]

[1]Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil. [2]PUC-PR, Curitiba, PR, Brazil. [3]Faculdade Israelita de Ciências da Saúde Albert Einstein, São Paulo, SP, Brazil

Introduction

Stroke often leads to muscle spasticity, characterized by velocity-dependent resistance to stretch beyond a specific threshold. The pendulum test is a simple assessment for monitoring spasticity. This study proposes a model for the knee pendulum test that incorporates nonlinear rotational springs and dampers. Model parameters were identified from kinematics of stroke patients. We hypothesized that parameters correlating with clinical scales could serve as biomarkers for spasticity.

Methods

Ten individuals with post-stroke quadriceps spasticity (51.6 ± 15.9 years; 65.9 ± 10.1 kg; 163.5 ± 8.7 cm) participated. The protocol was approved by the PUC-PR Ethics Committee. Participants underwent the Timed Up and Go test (TUG), the Modified Ashworth Scale (MAS), and the Fugl–Meyer Assessment (FMA). They performed two pendulum tests while seated on a chair, ensuring 70° hip flexion. Knee kinematics were recorded with a Vicon system.

Segment inertia was computed using regression equations. The model incorporated elastic and damping torque actuators for flexion and extension. Elastic torques used an inverse-logit formulation with parameters for maximum torque, stiffness, and threshold angle. Velocity-dependent damping was defined as the product of a damping coefficient and the normalized inverse-logit term. A linear damper acting throughout the motion simulated passive soft-tissue effects. Nine parameters were estimated.

Hybrid constrained optimization (particle swarm followed by *fmincon*) in MATLAB identified parameters by minimizing the L2 error between measured and simulated absolute leg angles. Pearson correlations were computed between parameters, clinical scales and years since stroke.

Results

For seven participants, simulations matched measured angles with a mean error of 1.9 ± 1.1°. But the model failed to reproduce kinematics for three participants, who were excluded from the analysis. Significant correlations ($p < 0.05$) between model parameters and clinical measures are shown in Table 1.

Discussion

The proposed model successfully represented the kinematics of pendulum tests in most participants. Poor fits in three cases may reflect experimental inconsistencies or patient-specific neuromuscular characteristics not captured by the model. Preliminary findings suggest that higher reflex extension stiffness and damping are associated with better clinical status, whereas increased maximum flexion torque and reflex stiffness may reflect worse impairment. Larger samples are required to validate these trends.

Images (Optional)

Table 1 – Significant ($p<0.05$) Pearson correlation between identified model's parameters and clinical scales. C – whole joint span damping; K_E – Extensors reflex stiffness; Tor_E – maximum reflex torque; Tor_F – maximum reflex flexor torque, θ_E – extensors' reflex threshold angle; θ_F-flexors' reflex threshold angle; C_E – extensors' reflex damping; K_F – flexors' reflex stiffness; TUG - Timed Up and Go Test; MAS - Modified Ashworth Scale; FMA - Fugl-Meyer Assessment. Years – years of disease at the test; (-) – not significant correlation.

Numerical Analysis of the Biomechanical Behavior of Patient-Individual Root Analogue Implants Compared With Conventional Threaded Dental Implants

Dr. Ludger Keilig, Ms. Farah Al-Obaidi, Dr. Mostafa Aldesoki, PD Dr. Istabrak Dörsam, Prof. Dr. Christoph Bourauel

Oral Technology, Medical Faculty, University of Bonn, Bonn, NRW, Germany

Introduction

Single tooth replacements with conventional threaded dental implants (CI) cannot be in inserted directly into the empty alveolus, but require a sufficiently solid bony anchorage. Root analogue implants (RAI), which mimics the shape of the root of the lost teeth, may offer an alternative if the alveolus is still intact. We investigated the biomechanical behavior of both implant types at different positions in both jaws, compare them with each other and with the natural dentition.

Methods

CT scan of a jaw with full dentition and healthy bone was used as modelling basis. Further models were generated where selected teeth were replaced by implants (one incisor, canine, premolar, molar each in the upper and lower jaw). For the CIs we filled the alveolus with spongious bone, covered with thin layers of cortical bone. RAIs were modelled from the original geometry of the alveolus, removing undercuts that might hinder the insertion. A central node on each natural crown was identified, transferred to the corresponding model with an implant, and connected to that implant using a rigid body element. Each natural tooth and each implant was then loaded separately at this node with forces between 130 N (incisor) and 500 N (molar) in vertical direction.

Results

Displacements at the loaded node differed between the implant types (e.g. at the upper canine 0.03 mm and 0.02 mm for CI and the RAI, respectively; and 0.11 mm and 0.05 mm for the same implants in the lower jaw). This was lower than the movement of the natural teeth (0.05 mm and 0.12 mm in the upper and lower jaw) due to the absence of the PDL. Stresses around the RAIs were lower than for the CIs, where sharp corners at the threads resulted in localized, increased stresses.

Discussion

The larger support of the RAIs in the alveolus as well as the absence of sharp geometric features seem to be advantages for the RAI. While this type of implant is only applicable if

the alveolus is still intact, such implants might offer a suitable alternative to the conventional threaded implants.

Ms. Madeleine McCreary

Dr. Elliot Greenberg

Mr. Kevin Landrum

Dr. Theodore Ganley

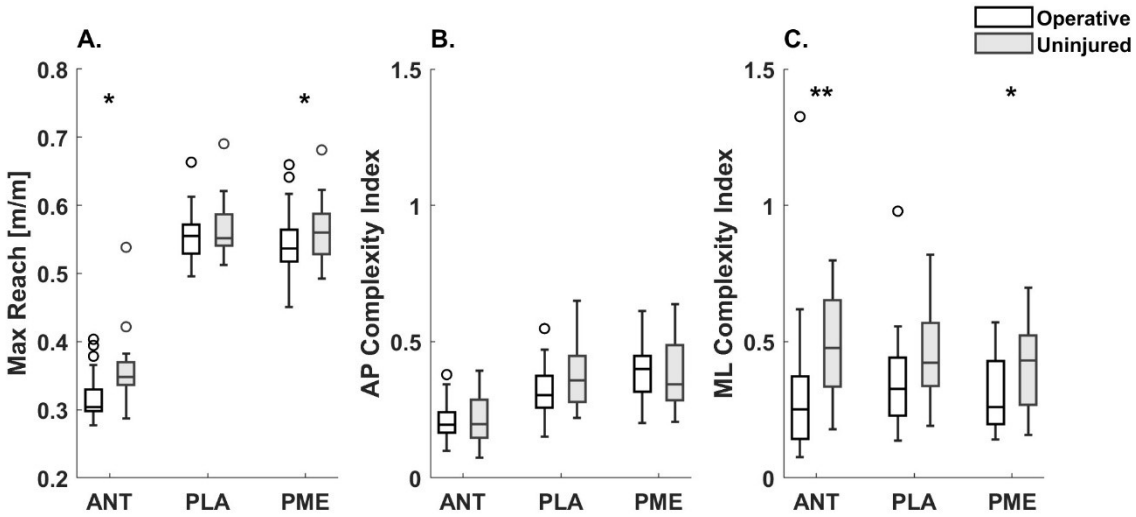
Introduction

Due to risk of re-injury after anterior cruciate ligament reconstruction (ACLR) in adolescents, return to sport decisions may need to include new metrics of dynamic postural control. Entropy is a nonlinear parameter that assesses temporal variability, looking at the overall structure found within signals such as the center of pressure (COP) by analyzing the regularity and predictability of the signal. Thus, the aim of this study was to understand if entropy of the COP while performing a Y-balance test could detect differences between the operative and uninjured limbs in adolescents three-months post-surgery.

Methods

Twenty-four adolescents completed the anterior, posterior-medial, and posterior-lateral directions of the Y-balance test on their operative and uninjured limbs while standing on a

force plate. Y-balance maximum reach distance was recorded, and entropy (*i.e.,* complexity index) of the anterior-posterior and medial-lateral COP traces was calculated for each trial. Maximum reach distance was normalized by participant height. Wilcoxon signed-rank tests evaluated differences between limbs (p<0.05) and the correlation between maximum reach distance and complexity index was calculated.



Results

Maximum reach distance and the medial-lateral COP complexity index of the operative limb were statistically significantly lower in the anterior (p=0.001, < 0.001; Effect Size = 0.81, 0.74) and posterior-medial (p=0.01, 0.006; Effect Size = 0.37, 0.59) directions of the Y-balance test, respectively. There were no significant differences in the anterior-posterior complexity index between limbs (p > 0.06; Effect Size < 0.54). The complexity index was weakly correlated with maximum reach distance (|r|<0.32).

Discussion

The results of this study suggest that COP entropy can differentiate between operative and uninjured legs three-months after ACLR in the frontal plane of motion. Decreased frontal plane COP entropy and maximum reach distance in the operative limb indicates a less adaptive postural control strategy compared to the uninjured limb. The lack of correlation between complexity index and maximum reach distance shows that these measures quantify different aspects of postural control during dynamic balance tasks post-surgery. Using the complexity index, in addition to other clinical assessments, may allow practitioners to tailor rehabilitation strategies to meet a participant's individual needs, marking an improvement towards precision medicine in ACLR recovery.

Simulated Plantarflexor Strength Differences in Osteogenesis Imperfecta Gait

Ms. Maeve McDonald MS[1,2], Dr. Rachel Lenhart MD, PhD[1], Dr. Jessica Fritz PhD[1,2]

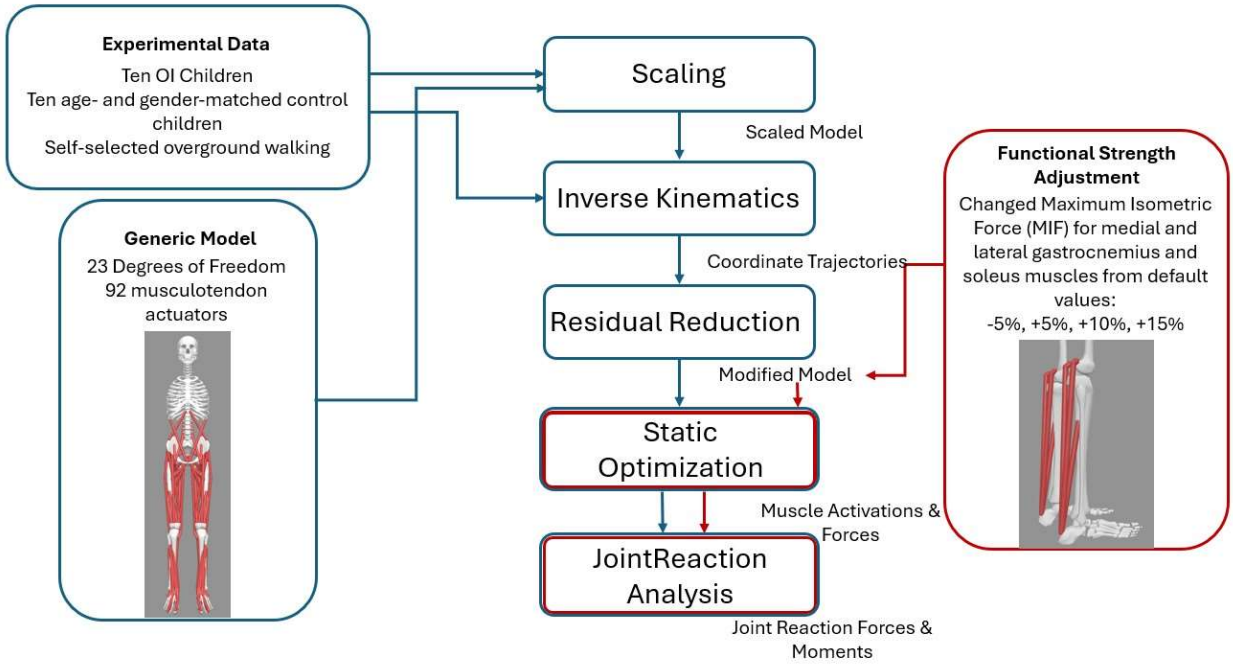
[1]Medical College of Wisconsin, Milwaukee, WI, United States. [2]Marquette University, Milwaukee, WI, United States

Introduction

Osteogenesis imperfecta (OI) is a rare genetic disorder caused by defective type I collagen production. Type I OI, the mildest and most common form, is characterized by bone fragility, mild long bone bowing, and reduced muscle mass and force generation, leading to weakness, fatigue, gait impairments, and increased fracture risk. Although strengthening programs benefit children with OI, isolated strengthening may increase fracture risk from increased tensile forces and moments applied to weakened bones and joints. The goal of this study was to simulate varying plantarflexor strength and compare resulting muscle force (MF) outputs during gait in OI and control subjects.

Methods

Deidentified motion analysis data from a previously conducted, IRB-approved study was used to create ten OI and ten age- and sex-matched control models in OpenSim. Models were scaled using anthropometric measurements and maximum isometric force (MIF) for each muscle was scaled using subject-specific body mass. Baseline kinematics, kinetics, muscle activation (MA), and MFs were simulated using subject-specific motion analysis data. MIF of the gastrocnemius and soleus muscles was adjusted from baseline (−5%, +5%, +10%, +15%) to model plantarflexor strength changes, and simulations were rerun (Figure 1). Baseline kinematics, kinetics, and MAs between the OI and control group were compared using a Student's t-test (α=0.05). Peak MFs of the lower extremities at each strength level during stance were compared within groups using one-way repeated measures ANOVA (α=0.05).



Results

When plantarflexor strength was increased, OI patients showed increased peak gastrocnemius and tibialis anterior MF ($p<0.02$). No differences were seen in controls. Differences in MF outputs between the OI and control groups may be a result of significantly increased hip flexion ($p<0.05$) in OI patients, reflective of neuromuscular strategies to compensate for muscular weakness and bone fragility.

Discussion

Though not significant, the differences seen in kinematics, kinetics, and MA in OI patients may contribute to the MF differences with varied strength. Although minimal MF differences with plantarflexor strength level were seen, fracture risk may still be affected due to the altered material properties in OI bone. Further analysis includes development of subject-specific finite element models to study how changes in plantarflexor strength affect fracture risk.

Lower Limb Proprioception Assessed in Free-Standing, Standing-Braced and Lying

Dr Martin Héroux[1], Ms Linda Wang[2], Dr. Annie Butler[1], Prof Janet Taylor[1], Mr Amin MohammadiNasrabadi[3], Prof Jean-Sébastien Blouin[3], Prof Simon Gandevia[1]

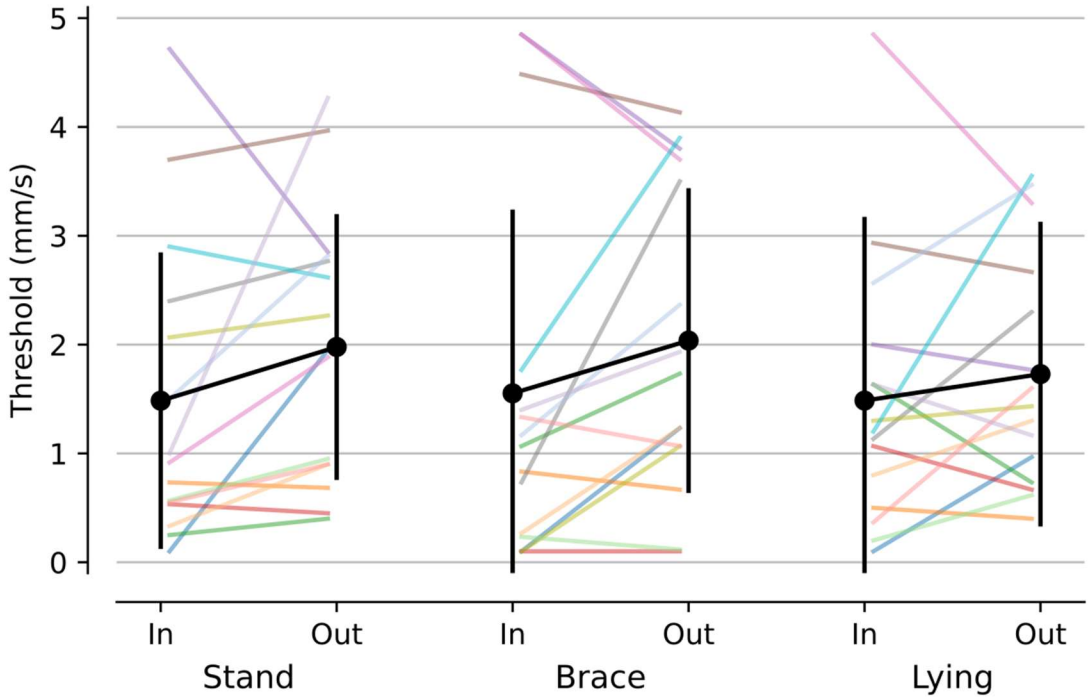
[1]Neuroscience Research Australia, Randwick, NSW, Australia. [2]University of New South Wales, Kensington, NSW, Australia. [3]University of British Columbia, Vancouver, BC, Canada

Introduction

Lower limb proprioceptive tests are typically performed unilaterally at a single joint with participants seated or supine. Such approaches do not reflect how the lower limbs are used during everyday activities like standing and walking. Preliminary evidence suggests proprioceptive acuity is better in bipedal stance than in single-joint, supine tests [1]. This study examined which factors associated with standing and balance might contribute to improved proprioceptive ability when upright.

Methods

Fifteen healthy adults (8 males, 7 females; mean age 30.1±9.1 yr) were tested in three conditions: free standing (Stand), standing with support (Braced), and lying supine (Lying). Braced reduced sway and lower-limb muscle activity; Lying further removed joint compression and most foot-sole forces. Movements were delivered using two motorised platforms: 0.8 mm inward/outward displacements at 0.1–5 mm/s. Proprioceptive velocity thresholds were obtained using a 2-alternative forced-choice protocol. Linear mixed models estimated effects of condition and direction, with mean differences reported alongside 95% CIs for planned contrasts.



Results

Across conditions and directions, thresholds ranged from 1.46–2.04 mm/s. Thresholds differed minimally between In and Out movements: Stand: –0.49 mm/s [–1.12, 0.13]; Braced: –0.48 mm/s [–1.11, 0.15]; Lying: –0.24 mm/s [–0.87, 0.39], with negative values indicating lower thresholds for In movements. Unexpectedly, condition had little influence on threshold values, and this for both In movements (Stand vs Braced: –0.07 mm/s [–0.70, 0.56]; Stand vs Lying: –0.001 mm/s [–0.63, 0.63]; Braced vs Lying: 0.07 mm/s [–0.56, 0.70]) and Out movements (Stand vs Braced: –0.06 mm/s [–0.69, 0.57]; Stand vs Lying: 0.25 mm/s [–0.38, 0.88]; Braced vs Lying: 0.31 mm/s [–0.32, 0.94]).

Discussion

Compared with published single-joint thresholds, thresholds here were approximately ten-fold better across all three conditions. Available evidence suggests this enhanced acuity likely reflects the integration proprioceptive input (muscle spindles, joint receptors, foot-sole tactile receptors) from multiple joints and body regions. These findings indicate that single-joint tests underestimate lower-limb proprioceptive ability during real-world tasks involving coordinated bilateral limb use.

Introduction

Methods

Results

Discussion

The sensorimotor synchronization of children with DS follows a similar control mechanism as TD peers. Whole-body vertical stiffness is not controlled on a cycle-by-cycle basis to maintain consistent cycle times. Moreover, children with DS responded to the external cue of the metronome by increasing the regularity of their stance time parameters.

Images (Optional)

Table 1: Mean coefficient of variation (sd) of force-time parameters during the *free* condition and the *preferred* condition. † indicates that the DS group was significantly different from the TD group. * indicates that the *preferred* condition was significantly different from the *free* condition. Note that at the *free* condition the participant hopped at their self-selected frequency without a metronome. At the *preferred* condition the participant hopped at a metronome-cued frequency which was equal to their self-selected frequency.

Investigating Neuromuscular Coordination and Adaptations from Knee-Ankle-Foot Orthosis (KAFO) Assisted Gait Training in Post-Stroke Individuals

Mr. Matthew De Guzman B.S.[1], Dr. Shuo-Hsiu Chang PhD[2], Dr. Gerard Francisco MD[2], Dr. Mohammad S. Shourijeh PhD[2]

[1]McGovern Medical School, Houston, TX, United States. [2]UTHealth Department of Physical Medicine and Rehabilitation, Houston, TX, United States

Introduction

Stroke survivors with hemiparesis often experience abnormal gait patterns and high energy cost due to impaired neuromuscular coordination. Muscle synergy analysis provides insight in pathological neuromuscular control and adaptations during and after rehabilitation. Advanced stance and swing control knee-ankle-foot orthoses (KAFOs), such as the C-Brace, improve gait mechanics and efficiency, but their effects on neuromuscular control remain poorly understood. This study will evaluate changes in muscle synergy organization following C-Brace gait training in individuals with post-stroke hemiparesis.

Methods

Five participants with chronic hemiparesis completed 12 sessions of gait training with the C-Brace KAFO. Surface EMG was collected from major lower-limb muscles before training, after training without using the KAFO (PostWO), and after training with using the KAFO (PostWT). Muscle synergy weights and activations were extracted using non-negative matrix factorization, and similarities across conditions were compared using statistical parameter mapping (SPM) and cosine similarity metrics.

Results

At baseline, the paretic limb demonstrated fewer synergies (3.6 ± 1.14) compared to the nonparetic limb (4.6 ± 0.55), consistent with impaired motor control. In the post-training, KAFO assisted trial (PostWT), synergy counts increased in the paretic limb and decreased slightly in the nonparetic limb (3.8 ± 1.10 paretic; 4.4 ± 0.55 nonparetic). In the post-training, KAFO unassisted trial (PostWO), paretic and nonparetic synergy counts were slightly lower (3.2 ± 0.84 paretic; 4.2 ± 1.10 nonparetic). Importantly, compared to baseline, the paretic limb demonstrated the emergence of 2 ± 0.8 unique synergies PostWO and 1.6 ± 0.7 unique synergies PostWT, suggesting enhanced neuromuscular organization.

Discussion

Preliminary findings suggest that C-Brace–assisted gait training may promote more complex and adaptive neuromuscular control in stroke survivors. The increase in synergy number and the emergence of unique synergies with KAFO use point to potential neural reorganization, beyond mechanical assistance alone. These results support the role of advanced KAFOs not only in improving gait mechanics but also in driving neuroplasticity. Ongoing work will expand this sample and assess how synergy changes relate to long-term functional outcomes.

Feasibility of Utilizing a Robotic System to Deliver Physical Therapy-based Exercises to Individuals with Parkinson's Disease: A Pilot Study

Dr. Meredith Wells PhD[1,2], Mr. Matthew Lamsey[3], Ms. Arielle Wallenstein[2], Mr. Jerry Feldman[4], Dr. Charles Kemp PhD[5], Dr. Madeleine Hackney PhD[2,3,6,7]

[7]Dept. of Veterans Affairs Birmingham/Atlanta Geriatric Research Education and Clinical Center, Brookhaven, GA, United States

Introduction

Parkinson's disease (PD) is the fastest growing neurodegenerative disease with approximately 10 million people living with PD worldwide [1]. Physical therapy (PT) can slow the functional decline associated with PD through cardiovascular endurance, strength, balance and flexibility training [2,3]. However, patients may not achieve the full benefits of PT due to therapist availability and time limitations. To overcome this barrier, robotic exercise systems have been introduced into PT for certain populations. This study aimed to determine if a custom-programmed robotic system could lead individuals with PD through movements at different joints.

Methods

Eleven participants with PD (7 female; age: 68.2 ± 6.2 yrs; time since diagnosis: 7.1 ± 5.1 yrs; Hoehn &Yahr stage: I-II.5) completed 6 exercises with a Stretch-with-Stretch robot (Hello Robot, Inc.). The robot-guided activities included 3 seated (calf raises, forward reach, knee extensions) and 3 standing (contra-body reach with rotation, windmills, high knees) exercises. The robot (Figure 1) was programmed to present a target at specific locations for each exercise and to provide instructions. Range of motion (ROM) was collected via inertial sensors (APDM). Participants also completed a standing forward reach immediately before and after the session to assess any immediate improvement in mobility.

Results

Participants completed all exercises with the robot. ROM was dependent upon the exercise and joint of interest. For example, hip ROM during the standing reach was 8.2±2.2 degrees, while hip ROM during high knees was 71.4±9.2 degrees. Standing forward reach improved by an average of 1.7 inches, demonstrating immediate benefits of exercising with the robot. Additionally, when asked if the robotic system would be useful in their daily exercise, 8 of the 11 participants agreed, indicating a positive experience.

Discussion

Results demonstrated potential benefits of exercising with a robotic exercise system, such as functional mobility gains. The number of sessions spent with a PT can be limited by time and availability, so this system could be a fun way to encourage individuals with PD to consistently complete their PT exercises at home.

Physiological Strain Windows as Drivers of Fracture Healing: A Simulation-Based Framework for Site-Specific Modeling

Dr Michael Roland[1], Prof. Dr.-Ing. Stefan Diebels[1], Dr. Thorsten Tjardes[2]

[1]Saarland University, Applied Mechanics, Saarbrücken, Saarland, Germany. [2]Hospital of the German armed forces Berlin, Berlin, Berlin, Germany

Introduction

Fracture healing is governed by mechanobiological regulation, in which local mechanical stimulus is the primary driver of cell differentiation, tissue formation, and remodeling in the callus. Existing mechanobioregulatory models and Frost's mechanostat define strain "windows" for healing and bone formation but thresholds mainly come from animal lower-limb data and are poorly specified across human bones and anatomical sites. Because loading and mechanosensitivity are site-specific, it is unclear whether strain ranges at one region can be transferred to others without bias. We hypothesize that the strain window for bone formation in fracture callus corresponds to Frost's physiological usage window at the same anatomical site, and that this relationship can be quantified via simulations.

Methods

We constructed subject-specific finite element models of healthy and fractured long bones (lower and upper extremity) based on clinical imaging. Physiological activities (walking, stair negotiation, and a palm-leaning task) were applied using musculoskeletal simulations based on motion capturing data to estimate joint and muscle forces. For healing scenarios, callus tissue was represented by time-varying material properties and mechanobioregulatory rules adapted from literature models [1,2]. For each site and activity, distributions of different strains were quantified. The strain-states were then compared to the corresponding physiological usage windows [3].

Results

Across all subjects and activities, the peak and median strains in the regions of bone formation were within the callus or only slightly deviated from the physiological usage window derived for the corresponding healthy bone site. In addition, for the different bones considered and the different probands, there was also an inter-individual strain variability observable.

Discussion

Our simulations support a quantitative overlap between the physiological usage window and the strain ranges that drive osteogenesis in fracture healing at matched anatomical sites. This linkage can provide a pathway to generate mechanically driven site-specific differentiation rules.

Mimicking Daily-Life Loading: A Hexapod-Driven, 6-Axis Experimental Setup for Fracture–Implant Mechanics

Dr. Michael Roland, Laboratory manager Danijel Crepulja, M.Sc. Kerstin Wickert, Prof. Dr.-Ing. Stefan Diebels

Saarland University, Applied Mechanics, Saarbrücken, Saarland, Germany

Introduction

Multi-axis physiological loading is essential for evaluating bone-implant constructs, yet most experimental setups still apply simplified uniaxial or planar loading. This limits their ability to reproduce the complex 3D force and moment patterns occurring during daily activities. We present a new hexapod-based test system capable of applying controlled six-degree-of-freedom (6-DOF) loading to long-bone fracture-implant systems while simultaneously measuring forces, moments and interfragmentary mechanics. To our best knowledge, this is one of the first systems designed to mimic daily-life loading scenarios in a biomechanically realistic way.

Methods

The testing device consists of a hexapod with flexible mold clamping system for long bones, equipped with two 6-axis force/moment sensors at the proximal and distal interfaces. A four-camera digital image correlation setup records full-field surface displacements and strains across the fracture region. Artificial composite bones and human cadaveric specimens were prepared with standardized AO-classified diaphyseal fractures and stabilized using clinically relevant implants. Hexapod motions were programmed to reproduce kinematics representative of daily-life activities and partial weight-bearing. Time-resolved interfragmentary movement, local strain distributions, and global load paths were quantified and compared to ranges reported in mechanobiological literature for fracture healing cell differentiation. In parallel, specimen-specific finite element models with identical boundary conditions were used to validate the simulations against DIC and load cell measurements.

Results

The hexapod system reproduced complex multi-axis load paths, including combined axial loading, bending, torsion, and shear, with good repeatability of boundary forces and kinematics. DIC revealed heterogeneous strain fields and interfragmentary movement patterns that were dependent on implant configuration and fracture type. For selected loading conditions, measured interfragmentary strains fell within stimulus ranges reported

in the literature, supporting the physiological relevance of the test protocols. FE predictions showed good agreement with experimental displacement and strain fields, confirming the suitability of the setup for validating numerical models.

Discussion

This new hexapod-based testing platform enables 6-DOF, activity-mimicking loading of fracture-implant systems with concurrent measurement of interfragmentary mechanics. The combination with validated FE models provides a framework for designing implants, optimizing loading protocols, and linking experimental data to mechanobiological healing models in future digital-twin applications.

Gait Kinematics of Children With Severe Motor Impairments Using Conventional Gait Trainers Versus a Motorised Robotic Rehabilitation Trainer

Miss Miray Kirollos, Dr Angela Kedgley

Imperial College London, London, Greater London, United Kingdom

Miss Miray Kirollos

Introduction

Gait trainers, also known as walkers, are conventionally used to assist the mobility of children with severe motor impairments. More recently, a novel motorised robotic rehabilitation trainer, thought to simulate gait-like patterns and help maintain musculoskeletal health, has been prescribed [1]. This study aimed to compare the kinematics of typical, walker-assisted and motorised device-simulated gaits. It was hypothesised that using the motorised device would improve lower-limb movement symmetry and produce consistent joint angle trajectories.

Methods

Participants comprised five children with severe motor impairments (aged 10.2 ± 3.9 years; three males and two females) who performed assisted walking using their walker, and five typically developing children (aged 10.4 ± 3.8 years; two males and three females) who performed unassisted walking on a level surface at a self-selected speed. Simulated gait using the motorised device (Innowalk Pro, Made for Movement GmbH) was performed by all participants. Lower-body kinematic data were acquired via eight inertial measurement units (Xsens, Movella Inc.) and analysed in the sagittal plane for five continuous gait cycles. The lower limbs were categorised into more and less flexed sides for symmetry comparison.

Results

Children with severe motor impairments showed greater gait variability than typically developing children (Figure 1). The motorised device produced increased asymmetry for typically developing children; however, improved symmetry, especially in the ankle (from 14.8° ± 8.2° to 2.7° ± 2.1°), for children with motor impairments. The motorised device

(compared to typical and walker-assisted gaits, respectively) resulted in decreased hip (62.2%; 57.0%), knee (71.21%; 59.8%,) and ankle (82.93%; 73.9%) ranges of motion.

Discussion

The motorised device did not produce gait-like patterns, instead it resulted in more constrained movement, limiting both hip and knee flexion and extension. The device reduced excessive plantarflexion and improved limb movement symmetry for children with severe motor impairments. This can assist with posture and muscle contracture management, supporting the improvements in passive joint extension after device use shown previously [2]. Walkers continue to encourage a greater range of motion, but the robotic rehabilitation trainer could form a complementary therapy to improve walker-assisted gait.

Bilateral External Knee Adduction Moment During Cycling in People With and Without Knee Pain From Osteoarthritis

Mr Dan Currie, Ms Dalia Grad, Ms Kathryn Webster, Ms Huaning Liu, Dr Stacey Acker, Dr Nikolas Knowles, Dr Monica Maly

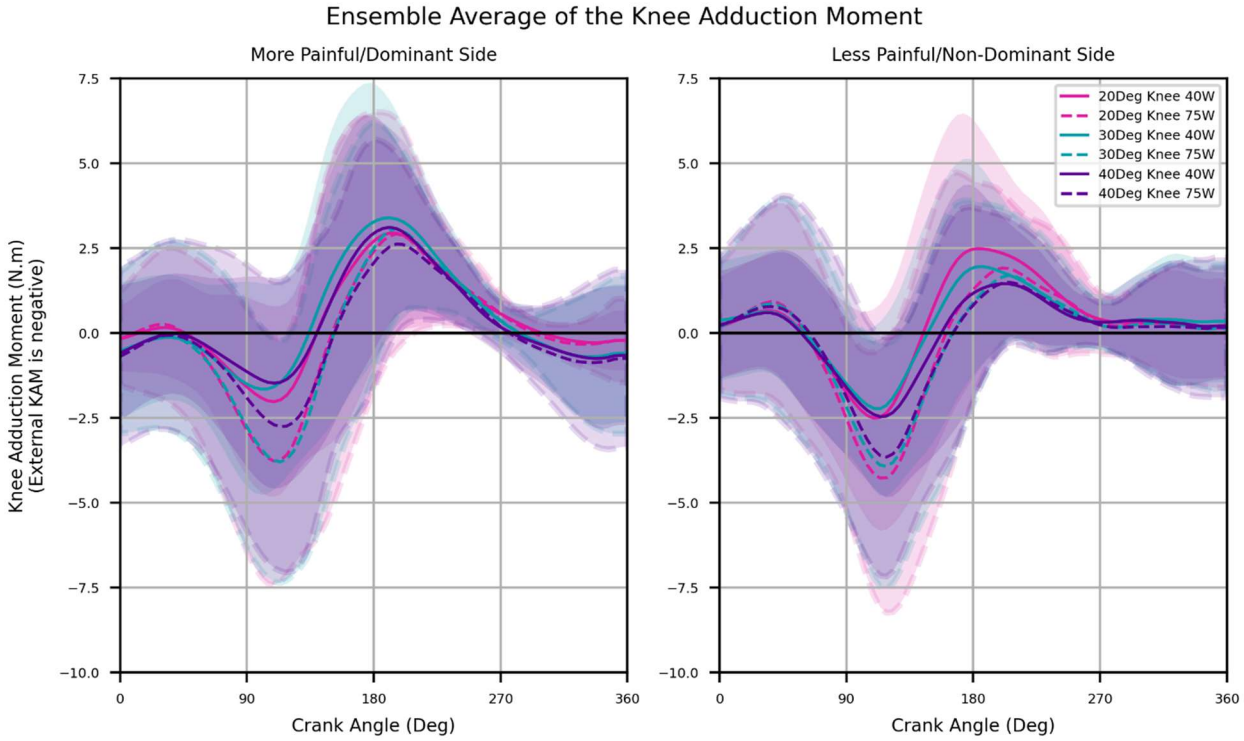
University of Waterloo, Waterloo, ON, Canada

Introduction

Knee osteoarthritis (OA) is one of the most common chronic conditions in Canada [1]. Commonly, the pain caused by knee OA is unequal between knees, which can lead to asymmetry of movement in daily activities. External knee adduction moment (KAM) is linked to the progression and severity of knee OA [2]. The effect of seat height and workload on KAM during cycling has been explored in a single leg analysis in healthy adults [3]. Bilateral analyses are rare. The objective of this secondary analysis is to compare peak KAM between seat heights, workloads and knees (more versus less painful knee; or dominant versus non-dominant when there was no knee pain or the same pain intensity in both knees) in people with and without symptomatic knee OA.

Methods

Twenty-six participants aged 45-75 years, with and without symptomatic knee OA completed six cycling bouts at three seat heights and two workloads on a commercial fit-bike (Pro 1, Purely Custom, USA). Each bout was performed for two minutes at a cadence of 60 rpm. Self-reported knee pain on the Numeric Pain Rating Scale (NPRS) was recorded before the first and after each bout. Synchronized three-dimensional kinematics and kinetics were collected with a commercial motion capture system (Optotrak Certus, NDI, Canada) and a commercial instrumented three-axis pedals (Science to Practice, Slovenia). The KAM waveform for both knees was calculated in Visual3D (HAS-Motion, Canada). From the full waveform, a one-minute portion was selected and averaged to one pedal cycle. A three-factor repeated-measures analysis of variance was used to compare the peak external KAM values.



Results

A significant effect of workload was found ($p < 0.01$) where peak KAM was greater with greater workload. No difference in peak KAM was observed between seat heights or between knees ($p > 0.05$).

Discussion

The peak KAM, on average, is the same in both knees in this bilateral task. The increase in demand from the higher workload appears to increase the external peak KAM. This result is in line with previous research [3].

Effects of Prolonged Walking on Toe Clearance and Stability Margins in Older Adults With and Without Knee Osteoarthritis

Ms. Nancy Nguyen, Ms. Fany Alvarado, Ms. Millissia Murro, Ms. Grace Kellaher, Ms. Mayumi Wagatsuma, Dr. Jocelyn Hafer, Dr. Jeremy Crenshaw

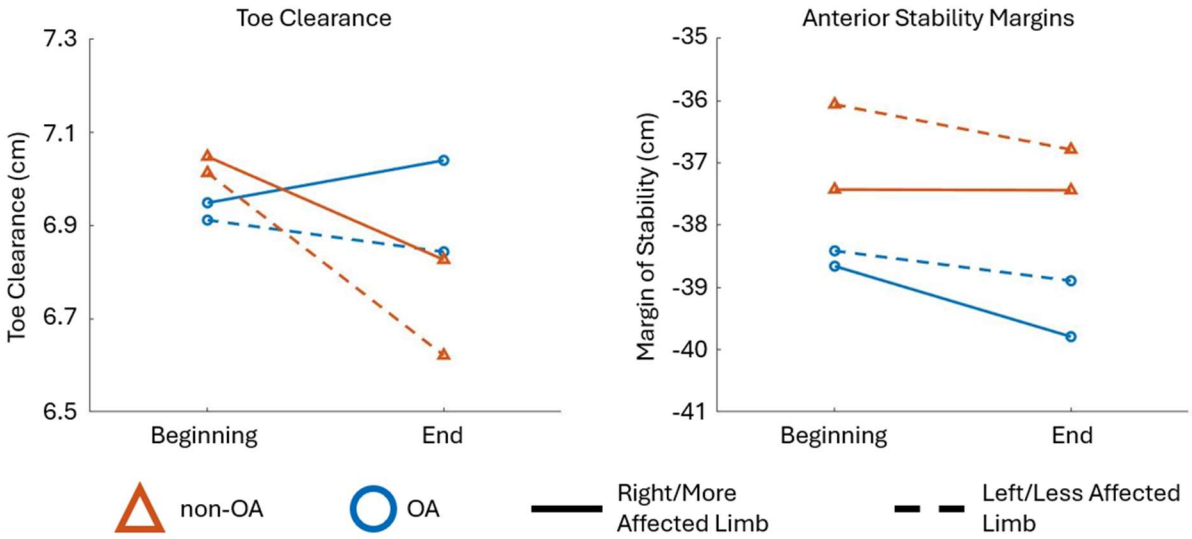
University of Delaware, Newark, DE, United States

Introduction

Fatigability, defined as an individual's susceptibility to fatigue with activity, may underlie the elevated fall risk of individuals with knee osteoarthritis (OA) because 1) those with knee OA do not always have worse balance or gait stability when unfatigued, 2) fatigue affects balance and walking mechanics, and 3) knee OA is associated with high fatigability. If prolonged walking induces disproportionate fatigue in those with knee OA, fatigue-related gait changes may explain their elevated fall risk. The purpose of this study was to determine how prolonged walking changes gait in adults with and without knee OA. Falls in this population often result from a trip during walking, so we focused on measures that characterize the likelihood of a trip (i.e., toe clearance) and the initial stability conditions should a trip occur (i.e., anterior stability margins).

Methods

Eight participants with knee OA (4F/4M, 64.3±3.0 years, 25.1±4.2 kg/m^2) and ten without knee OA (4F/6M, 63.0±3.6 years, 26.3±4.2 kg/m^2) walked on a treadmill (OA=1.38±0.08 m/s, non-OA=1.44±0.17 m/s) with full-body motion capture for 34 minutes, including three one-minute challenge periods at +50% speed. Four-minute periods were analyzed at the beginning and end of the walk. Using a 3-way ANOVA, we assessed the effects of GROUP (OA, non-OA), LIMB (more/less affected, right/left), and TIME (beginning, end) on each individual's lower quartile of minimum toe clearance and corresponding anterior stability margins.



Results

We observed a significant GROUP*TIME interaction on toe clearance ($p=0.025$). The non-OA group decreased toe clearance with prolonged walking (-0.3±0.1cm, $p=0.001$, Figure). No between-group differences were observed ($p>0.5$). No main effect or interactions containing LIMB were significant ($p>0.09$). A significant effect of TIME was observed on anterior stability margins, with margins becoming more negative with prolonged walking (-0.6±0.3cm, $p=0.048$). No main effects or interactions containing GROUP or LIMB were significant ($p>0.06$).

Discussion

We cannot conclude that OA-related fatigability affects gait in a manner that increases the risk of trip-related falls. Changes in dynamometer-measured, knee-extensor power were not different between groups (OA=-12.7±19.8%, non-OA=-2.2±20.3%), suggesting that our premise of OA-related fatigability was not supported.

Estimating Spinal Loads of Clinicians in Real-Time Using Machine Learning

Ms. Natasha Anderson[1], Mr Samuel Brost[1], Dr Cari Whyne[2], Dr Qingguo Li[1]

[1]Queen's University, Kingston, Ontario, Canada. [2]Sunnybrook Health Sciences Centre, Toronto, Ontario, Canada

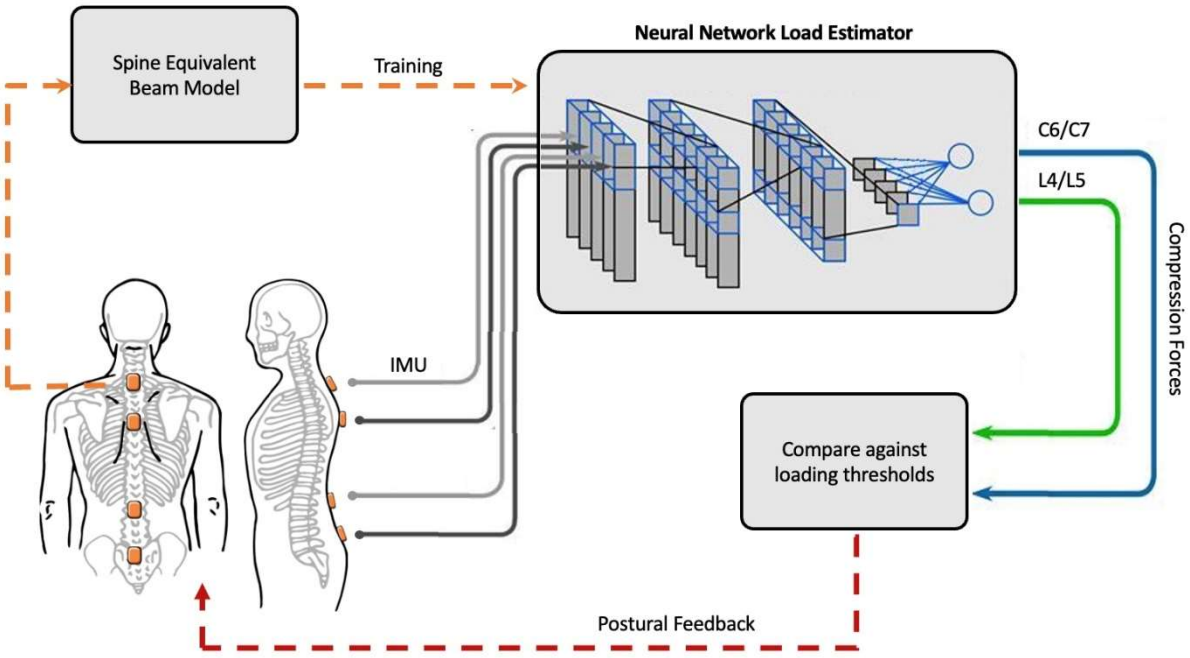
Introduction

Back-related musculoskeletal disorders are a common injury among clinicians because of the prolonged non-neutral postures they maintain in the operating room [1]. We investigate whether machine learning can be used to estimate the spinal load in real-time, as previously developed models do not have this ability, limiting their practical applications [2]. This can be integrated with wearable sensor systems to provide feedback to promote postural awareness in clinicians, thus reducing their risk of injury.

Methods

The spinal load was estimated from data collected from 4 IMUs placed along the spines of 20 participants (8F/12M) at Sunnybrook Health Sciences Centre, using the spine equivalent beam model [2]. The algorithm used was a neural network with 2 hidden layers (sizes: 128 and 64). The model had four inputs (from each IMU), and two outputs, the compressional loads at C6/C7 and L4/L5 vertebra. It was trained on 16 datasets, with 10% set aside for validation, and 4 datasets left unseen for testing.

Results



Comparison between the true and predicted compressional forces showed mean average percent errors of 25.7±5.6% and 28.5±7.3% for the C6/C7 and L4/L5 locations, respectively. Calculating the cumulative load per participant at the same locations resulted in errors of 4.3±1.9% and 6.2±2.9%. This model had an average run-time of 0.5±0.1 seconds.

Discussion

The model’s accuracy is not sufficient for estimating instantaneous loads, however, it has significantly less error when estimating cumulative load. Cumulative load has higher injury contributions since it leads to repeated stresses and overuse [3]. Therefore, the cumulative load-based algorithm is an effective method for delivering postural feedback to clinicians, as it can accurately estimate loads in real-time. The model will be further explored to compute the shear and internal moment, for a more robust loading profile. Additional inputs, such as gender and height will be added to allow the model to learn more features

that impact spinal loading thresholds, leading to future development of individualized models with reduced error margins.

Obesity Increases Muscle Capacity Utilization in Those With Clinical Knee Osteoarthritis

Ms. Natasha K. Ivanochko MSc[1], Dr. Jacquelyn M. Maciukiewicz PhD[1,2], Dr. Kendal A. Marriott PT, PhD[1], Dr. Lauren Straatman PhD[1], Ms. Kathryn F. Webster MSc[1], Mrs. Emily G. Wiebenga[1], Dr. Monica R. Maly PT, PhD[1]

[1]University of Waterloo, Waterloo, Ontario, Canada. [2]Waterloo Regional Health Network, Waterloo, Ontario, Canada

Introduction

Obesity and weakness are common features of knee osteoarthritis (OA). However, the impact of these features on demands to the musculoskeletal system during activities of daily living, and how weakness might interact with obesity, is not fully understood. The objective of our study was to investigate the association between obesity and muscle capacity utilization (MCU), which represents the proportion of maximal muscle capacity required to perform a task, in those with clinical knee OA.

Methods

Participants with clinical knee OA were recruited and the most symptomatic knee was studied. Obesity was represented by body mass index (BMI) (kg/m^2) from measured height and weight while barefoot, wearing a t-shirt and shorts. MCU was the ratio of knee flexion moment during walking and maximal knee extensor strength. Level, barefoot walking at a self-selected speed was completed. Kinematics were collected using 5 infrared camera banks at 100 Hz. Kinetics were collected with a synchronized, floor-embedded force plate at 1000 Hz. From these data, the mean peak external knee flexion moments (Nm) during stance phase from 5 trials was calculated. Maximal knee extensor strength (Nm) was the mean of the 3 largest peak values during maximal voluntary isometric contractions on a commercial dynamometer. Multiple hierarchical linear regressions (adjusted for covariates age, gait speed, accelerometry-based step count, and self-reported comorbidity) evaluated the association between BMI and MCU. Regressions were then stratified by sex.

Results

Data from 83 (57 female/26 male/0 intersex) participants were included. Mean (SD) age was 65.0 (6.2) years and mean BMI was 28.5 (4.9) kg/m^2. Obesity related with MCU (R^2 increased 0.140 from the covariate model to 0.191, p = 0.03), such that a greater

BMI related with greater MCU. For females, BMI was positively associated with knee extensor strength (R^2 increased 0.389 to 0.439, p = 0.038). No other associations were found.

Discussion

Obesity was related to greater MCU, suggesting a greater functional demand during level walking in adults with clinical knee OA. Also, contrary to previous findings, greater BMI was associated with greater knee extensor strength in females [1].

Images (Optional)

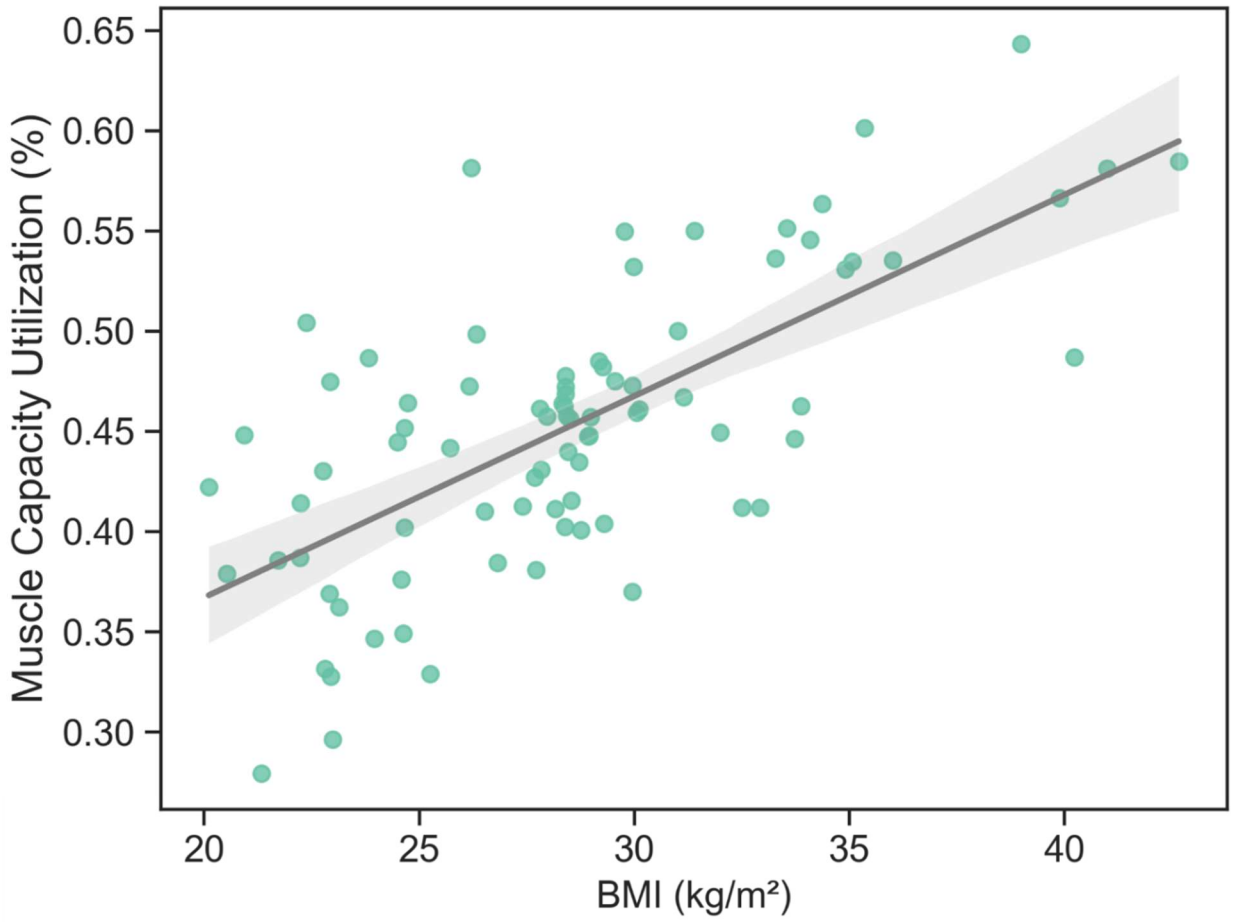

Figure 1. Scatterplot of the association between BMI (kg/m^2) and muscle capacity utilization (%) adjusted for age, gait speed, accelerometry-based step count, and self-reported comorbidity. The grey line represents the best linear fit with 95% confidence intervals.

Immediate Biomechanical and Symptomatic Effects of 3D Printed Lateral Wedge Insoles in People With Knee Osteoarthritis and Foot Pain

Ms. Natasha M. Krowchuk BSc[1], Mr. Haocheng Zhang MSc[1], Ms. Jessica M. Millan Alvarez BASc[2], Dr. Jesse M. Charlton PhD[1], Dr. Michael A. Hunt PhD, PT[1]

[1]University of British Columbia, Vancouver, BC, Canada. [2]Universidad Iberoamericana, Mexico City, Mexico, Mexico

Introduction

Lateral wedge insoles (LWIs) are shoe-worn insoles that represent an inexpensive, non-surgical approach to manage knee osteoarthritis (KOA). LWIs reduce the external knee adduction moment (KAM) – a biomarker associated with KOA disease progression – by approximately 6% on each step. Though effective at the knee, little is known about their effects at the foot – the location in which they interact with the body. Addressing this knowledge gap is especially relevant for certain subgroups, including those with KOA and concomitant foot pain given the large prevalence of this clinical presentation (25%). The purpose of this study was to examine the immediate biomechanical and clinical effects of LWIs in people with KOA and foot pain.

Methods

Individuals with foot pain and KOA in the same limb were recruited. They underwent a single gait analysis session to compare outcomes from two gait-speed matched, randomly-ordered conditions: with and without 3D printed 6-degree LWIs. Participants wore slip-resistant socks during both conditions, and the LWIs were secured underfoot with tape before donning the socks. Synchronized kinematic (120 Hz) and kinetic (1200 Hz) data were collected from five trials per condition. Participants rated pain in the foot, ankle, and knee after each condition (0 = “no pain”, 10 = “worst pain imaginable”). Commercially-available software (Orthotrak) was used to calculate joint kinematics and moments, and paired t-tests were used to test for any statistical differences between conditions.

Results

51 individuals participated (36 females, mean (sd) age: 63 (8) years; BMI: 28.6 (5.6) kg/m^2). Walking with LWIs produced significant reductions in the KAM impulse (p<0.001), knee flexion angle at initial contact (p=0.035), and knee valgus angle during midstance (p=0.003), as well as significant increases in toe-out angle (p=0.015) and peak ankle eversion moment (p<0.001). Foot pain was significantly reduced with LWIs (p=0.015).

Discussion

LWIs produce significant immediate improvements in foot pain and lower limb biomechanics relevant to KOA (i.e. knee adduction moment, knee valgus, and toe-out angles) in people with both KOA and foot pain. Though our findings are positive, future research is needed to understand the longer-term effects of LWIs in this clinical subgroup of the KOA population.

Introduction

Pediatric flatfoot can occur either idiopathically or as a secondary neurological disorder such as cerebral palsy (CP). Physiologically, idiopathic flatfoot arises from a multitude of factors while flatfoot in cerebral palsy specifically develops through impaired neuromuscular control, spasticity, and weakness.

High variability in subtalar joint alignment relating to pediatric flatfoot may be attributed to differences between idiopathic flatfeet or flatfeet secondary to CP. The objective of this work was comparing distance and coverage mapping of CP and idiopathic participants to discern potential differences within the flatfoot population.

Methods

This IRB approved study contained a CP group (n=5, mean=13.7 years, range=12-16 years) and an idiopathic group (n=10, mean=12.83 years, range=11-17 years). Weightbearing CT scans were collected, and talar/calcaneal bone segmentations were generated using BoneLogic, Mimics 25.0, and 3D Slicer v5.8.0. Joint distances and bony coverage percentage ratios were calculated using methods described by Dibbern [1]. Statistical differences were assessed with t-tests at $\alpha=0.05$.

Results

Distance and coverage mapping analysis yielded significant results in the sinus tarsi region. Distance mapping significance showed $p=0.043$ with CP sinus tarsi mean distance 6.22mm±0.47mm and idiopathic sinus tarsi mean distance 5.44mm±0.64mm. Coverage mapping significance showed $p=0.012$ with CP sinus tarsi coverage of 20.9%±4.9% and idiopathic sinus tarsi coverage of 33.6%±9.1%. Increased joint space distances and higher

uncoverage in sinus tarsi region of the CP group are indicative of subluxation. Decreased distances in the sinus tarsi region of the idiopathic group suggest impingement in the subtalar joint.

Discussion

This data reports an objective measure of CP participants having higher spacing and less coverage in the sinus tarsi region compared to the idiopathic group. All other facets were not statistically significant, but this may be due to low participant numbers. Since significance occurred at the sinus tarsi region, differences in this region may be the primary driver of subtalar joint coverage differences between these two flatfoot populations. Our ongoing work aims to increase sample sizes to confirm these findings. These improved metrics can aid in earlier, less invasive intervention recommendations targeted at specific types of flatfeet.

Images (Optional)

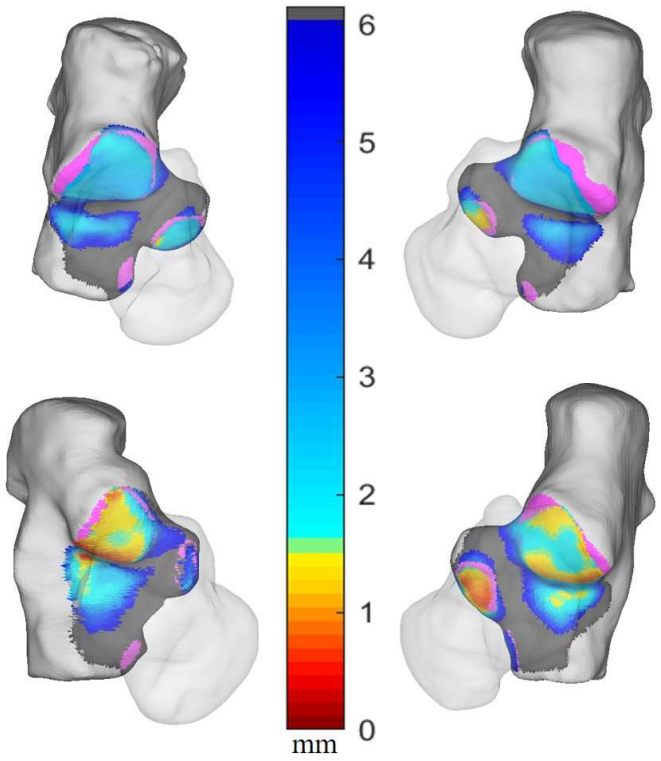

Figure. Example distance mapping on calcaneus and opaque talus overlayed. Top models are a CP participant, bottom models are an idiopathic participant. Warmer colors indicate smaller joint space (impingement) and cooler colors indicate larger joint space (subluxation).

Introduction

Hand function is impaired in rheumatoid arthritis (RA) and psoriatic arthritis (PsA), even in the absence of acute inflammation [1,2]. The contribution of muscle activity and motor control to loss of function in RA and PsA is unclear. Surface electromyography (sEMG) enables objective, non-invasive quantification of neuromuscular activity. By using machine learning, we aimed to classify RA, PsA, and healthy controls (HC) and identify the most discriminative sEMG features from forearm muscles during standardized cylinder-grasping.

Methods

RA (ACR/EULAR 2010) and PsA (CASPAR) patients (MED3 clinics Erlangen, Germany) and HC performed cylinder-grasping (four varying diameters, three repetitions each), while sEMG (Noraxon, USA, 1500Hz) was recorded using two sEMG sensors (n-electrodes, Ambu, Denmark) from flexor digitorum superficialis (flexor) and extensor digitorum communis (extensor) (Ethics #357_20B). After standard post-processing [3], signals were normalized task-specific (participant-specific peak across all grasps) or to the maximum voluntary contraction (MVC; isometric grip strength). Time- and frequency-domain features were extracted from a one-second segment around the peak sEMG and classified using Linear Discriminant Analysis (LDA), Random Forest, and Support Vector Classifier with stratified k-fold cross-validation by participant.

Results

Data from 64 HC (58% female, 46.3±18.9 years), 71 PsA (52% female, 52.1±14.4 years), and 57 RA patients (72% female, 54.4±14.5 years) were analyzed. The highest accuracy was achieved for HC vs PsA using LDA on female-only extensor sEMG signals during the largest cylinder-grasp with task-specific normalization, while binary classifications outperformed the three-class model in other comparisons. The most informative features (descending order) were: Root Mean Square, Mean/Median Frequency, Enhanced Wavelength.

Discussion

Female extensor muscle activity during the largest-cylinder grasp best distinguished PsA from HC. RA was less separable from both HC and PsA, reflecting more overlapping activation patterns. The three-class model showed poor performance due to shared EMG characteristics. Results suggest the extensor digitorum communis as the most discriminative muscle in our data set. Sex-specific activation patterns strengthen disease discrimination, supporting sEMG's potential to identify disease-specific muscle activation patterns.

Ipsi- And Contra-Lateral Neural Connectivity Among Arm MusclesIs Disrupted by Muscle Weakness: A Computational Neuromechanical Study of Force Production in the Two-Handed Tennis Backhand

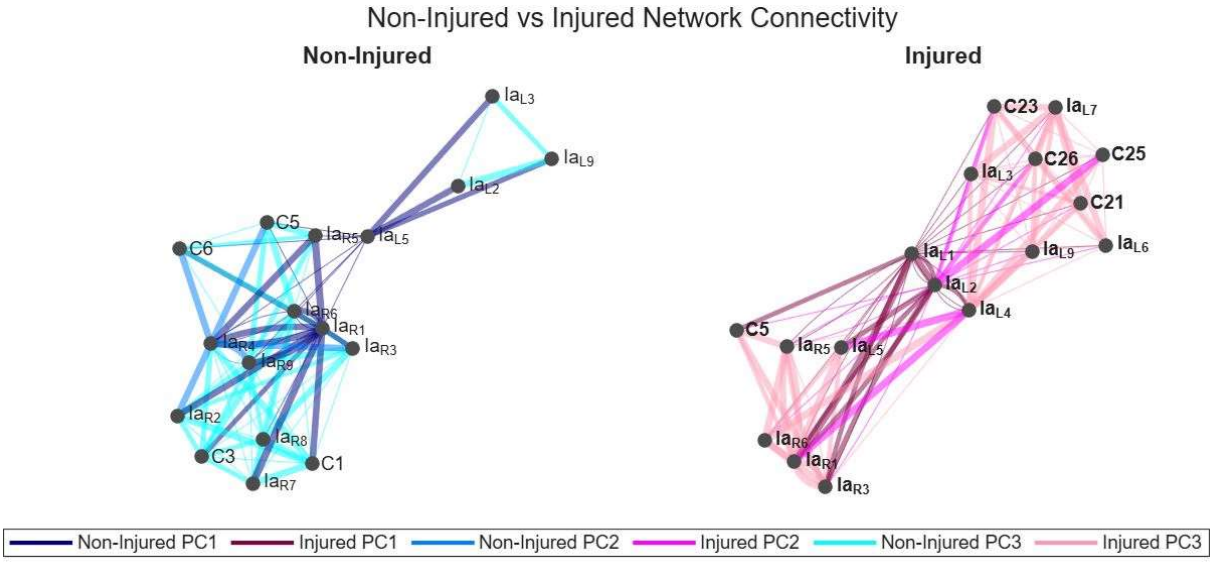
Introduction

Musculoskeletal models of limb function often assume that muscles are controlled independently of each other. However, ipsi- and contra-lateral neural interconnections among muscles are well documented by mutual inhibition/facilitation [1] and force-sharing of neural origin among fingers [2] . Here, we investigate the functional interactions between muscle connectivity and coordination in arm muscles for force production during the two-handed tennis backhand (with the left arm in the rear as the power-arm) before and after simulated injury.

Methods

A coupled neuro-muscular computational 3D model of two arms simulated instantaneous force production at the moment of ball impact. The model included 17 muscles per arm [4], plus alpha motor neurons, commissural interneurons, Ia pathways and gamma motor neurons, linked via a connectivity matrix W ([170 x 170]) representing synaptic weights between -1 and 1. Starting from a random W_0, synaptic weights and muscle activations

were iteratively adjusted via simple Hebbian plasticity to reduce the Euclidean norm between the predicted and target 3-D force at the racquet {300, 100, 200} N. Injury was implemented by reducing the maximal isometric force (F_0) of 3 left-arm muscles (*Ant. Delt, Post. Delt and Tri)* by 50%, simulating disuse atrophy from rotator cuff injury. Principal Component (PC) analysis of the converged W identified dominant connectivity patterns, Fig. 2, with a threshold of $|w_i| \geq 0.2$.



Results

For the 'un-injured' case, 40 PCs explained 80% of the variance in W, but PCs 1, 2 and 3 accounted for 38% (18%, 13%, and 7%, respectively) in a representative case shown in Fig. 2. These PCs reveal dominant interconnections from Ia pathways and commissural interneurons, underscoring the functional relevance of reflex and contralateral pathways. Results for the 'injured' case showed increased Ia and commissural interconnectivity compared to the 'un-injured' case.

Discussion

This pilot study computationally demonstrates adaptive and maladaptive neural plasticity in post-injury cross-muscle and cross-limb interconnectivity. Our results suggest rehabilitation strategies should consider neural plasticity and target possible maladaptive plasticity to optimize return-to-sport performance.

Baseline Knee Flexion Moment Is Associated With Short-Term Infrapatellar Fat Pad Volume Change After Anterior Cruciate Ligament Reconstruction

Dr. Nicholas Brisson PhD[1], Dr. Matej Skrobot[1], Dr. Stephan Oehme[2], Dr. Tobias Jung[2], Prof. Jürgen Reichenbach[3], Prof. Georg Duda[1], Dr. Martin Krämer[3]

[1]Julius Wolff Institute, Berlin Institute of Health, Charité – Universitätsmedizin Berlin, Berlin, Berlin, Germany. Introduction

Anterior cruciate ligament (ACL) injury increases post-traumatic osteoarthritis (PTOA) risk, and this risk persists after reconstruction (ACLR) due to aberrant gait mechanics. The infrapatellar fat pad (IPFP) is mechanosensitive; cyclic deformation during walking – primarily from sagittal-plane knee loading – may influence its structure and composition, which can be assessed using magnetic resonance imaging (MRI)-based volume and T1 measures. Whether sagittal-plane knee moments relate to early IPFP remodeling after ACLR is unknown. This study tested whether baseline peak knee flexion and extension moments (KFM, KEM) predicted 6-month changes in IPFP volume or T1.

Methods

Ten ACLR patients (4 women; age 34±9 y) and ten age- and sex-matched controls underwent baseline gait analysis and knee MRI; with repeat scans at 6 months. For ACLR, baseline was 6.2±0.7 months after ipsilateral four-strand semitendinosus reconstruction (9.6±1.9 months post-injury). Gait data (45 s) were collected during self-paced treadmill walking using motion capture (Vicon) and force plates (Motek). Peak external KFM and KEM were averaged across gait cycles. MRI (3T Siemens Vida) acquired ultrashort echo-time images and T1 maps ($0.6\times0.6\times1.5\ mm^3$). The IPFP was segmented to extract volume and mean global T1. Between-group differences were tested with independent t-tests; 6-month changes with paired t-tests. In ACLR, linear regression tested whether baseline KFM or KEM predicted ΔVolume or ΔT1. Significant results were followed by a multivariate model including all participants, adjusting for baseline volume. All tests were two-tailed ($\alpha=0.05$).

Results

Groups were similar in age, sex, and walking speed. Baseline KFM, KEM, and IPFP volume were comparable; T1 was higher in ACLR ($p=0.003$). IPFP volume and T1 showed no group-

level change over 6 months. In ACLR, baseline KFM predicted ΔVolume (β =–6.51, p=0.027). In the multivariate model, both KFM (β=–4.17, p=0.001) and baseline volume (β=–0.06, p=0.040) were significant predictors (Figure 1).

Discussion

Group-level IPFP volume and T1 remained stable over 6 months, yet individual ΔVolume variability allowed loading–volume associations to emerge. Baseline KFM was related to ΔVolume, suggesting sagittal-plane loading influences short-term IPFP behavior. Larger, longer-term studies should determine whether early loading-related IPFP responses are relevant to PTOA development.

Images (Optional)

Dr. Tiago Zimerman

Introduction

Medial meniscus posterior root (MMPR) tears disrupt stress transmission in the knee and may change limb coordination during bilateral functional tasks. Understanding how MMPR tears and repairs affect bilateral squat (BLS) biomechanics, a highly functional movement, could help clarify how this pathology contributes to long-term joint degeneration. The purpose of this study was to examine BLS kinematics and kinetics in patients with MMPR tears and those with MMPR repairs, compared to healthy, age-matched controls. We hypothesize that patients with MMPR tears and repairs will exhibit altered BLS biomechanics associated with knee osteoarthritis.

Methods

Our cross-sectional cohort consisted of 56 knees: MMPR tear (n=20), MMPR repair (n=20), and healthy controls (n=16). Each patient performed eight bilateral squats with standardized instructions in our Motion Analysis Lab. Lower-limb kinematics (120 Hz) were estimated using a point cluster technique, and kinetics were measured via force plates (3000 Hz). Statistical comparisons of discrete metrics and time-series data via Statistical Non-Parametric Mapping (SnPM) were evaluated across the BLS cycle. Group comparisons

were performed using the SPM1D nonparametric one-way ANOVA test, and post hoc pairwise t-tests (permutation inference), and Bonferroni correction was employed for multiple comparisons ($\alpha = 0.05$).

Results

Significant differences were observed for knee adduction throughout 0.1-16.6% (P=0.021) and 92.2-95.7% (P=0.046) of the squat cycle (%SC). Group comparisons revealed a significant main effect of group knee external rotation over 12.5-16.2% and 78.6-94.7% of the squat cycle; however, post-hoc analysis did not identify any individual pairwise group differences. The MMPR tear and repair groups displayed increased knee internal rotation moment at 0-5.7%SC (P=0.0149) compared to control (Tear: 0-9.1%SC, P=0.0015; Repair: 0-2.8%SC, P=0.0382). (Figure 1)

Discussion

Distinct group differences appeared during bilateral squats. Both MMPR tear and repair groups exhibited altered kinematics and kinetics linked with increased osteoarthritis risk. Still, the repair group showed patterns closer to those of controls, indicating partial restoration of knee biomechanics. These findings highlight the value of assessing squat mechanics to help guide targeted specific movement interventions and to identify the patients who may benefit from earlier surgical management to reduce long-term joint degeneration.

Introduction

Individuals with LBP typically show altered spinal motor behaviour [1,2], which has been associated with clinical outcomes, such as changes in pain and disability [1]. However, spinal motor behaviour assessments in clinical practice are typically based on visual evaluation [3], possibly since objective measurements are predominantly laboratory-constrained. Inertial sensors, integrated in most smartphones, allow ambulatory spinal kinematic measurements [4]. However, for smartphone-based spinal kinematic measures, reliability amongst LBP individuals and ability to differentiate between LBP and asymptomatic groups, remain unknown, and we therefore aimed to evaluate these in this study.

Methods

Spinal kinematics were collected using a custom-made smartphone application amongst eighteen LBP (female=14; age=43±17y) and seventeen asymptomatic (female=11; age=37±13y) individuals. Participants performed, at their preferred speed, eight repetitions of maximum trunk flexion, extension, left/right lateral flexion, and a natural pen-pickup movement in two sessions (5±2 days apart) while holding the smartphone against their sternum. Since spinal movement amplitude and speed are generally altered in LBP [1,2], average maximum trunk inclination and root-mean-square (RMS) angular velocity were computed across the eight repetitions for each movement task. Within- and between-

session reliability were determined using intra-class-correlation (ICC) coefficients and group discrimination using a 2x2 repeated-measures ANOVA.

Results

Within- and between-session reliability was near-excellent to excellent for both maximum inclination and RMS angular velocity across all movements (generally ICC>0.86; Table 1). Both measures yielded significant (p-value<0.05) differences between groups for all movements, indicating lower maximum inclination and RMS angular velocity in LBP. Furthermore, both reliability and discrimination outcomes suggested that similar ICCs and p-values were reached after three repetitions.

Discussion

This study demonstrates that, with a smartphone, clinically relevant spinal kinematic measures can be measured that yield near-excellent to excellent reliability in individuals with LBP and effectively discriminate them from asymptomatic individuals. This enables objective, ambulatory assessment of spinal movement and paves the way for including such assessments in longitudinal studies on LBP.

Introduction

Trunk motor control, commonly evaluated through postural tasks, is altered in individuals with low back pain (LBP), potentially reflecting clinically relevant phenotypes [1]. Conventional assessments are often laboratory-constrained. Inertial measurement units (IMUs), integrated in most smartphones, enable ambulatory assessments of trunk kinematics [2]. We examined the use of smartphone-embedded IMUs to evaluate postural control in LBP.

Methods

Eighteen LBP (female=14; age=43±17y) and seventeen asymptomatic (female=11; age=37±13y) individuals performed standing with eyes closed for 90 seconds twice, 5±2 days apart, while holding a smartphone against their sternum. Trunk kinematics were recorded using a smartphone and with an optoelectronic motion capture system (Mocap). The Centre of Pressure (CoP) was measured using a force plate. We assessed smartphone- and Mocap-based root-mean-square trunk angle and angular velocity (anterior-posterior (AP), medial-lateral (ML), and AP-ML vector norm), and root-mean-square CoP position [1,3]. We also assessed these measures' spectral content using frequency bands (<0.5Hz, 0.5-2Hz, >2Hz), based on CoP literature associating the lowest and highest band with visual/vestibular- and proprioceptive control, respectively [3]. Group differences were evaluated with a two-by-two repeated-measures ANOVA.

Results

Smartphone- and Mocap-based kinematics showed greater overall sway (vector norm) in individuals with LBP (Fig. 1A), while AP and ML sway and root-mean-square angular velocity did not differ. Smartphone-based angular velocity spectral analysis revealed group differences in AP at <0.5Hz and >2Hz (Fig. 1B) and in ML at <0.5Hz, with a reduction in high-frequency and an increase in low-frequency content in LBP. Mocap-based spectral measures and all CoP measures showed no between-group differences across both sessions.

Discussion

We found increased smartphone- and Mocap-based trunk sway in LBP, in line with previous findings [1]. Only smartphone-based angular velocity revealed spectral content differences, possibly reflecting decreased proprioceptive and increased vestibular weighting in postural control in LBP [3]. These findings suggest smartphone-embedded IMUs may detect postural control changes not captured by Mocap or CoP measures, providing insight into potential mechanisms underlying altered postural control in LBP.

Images (Optional)

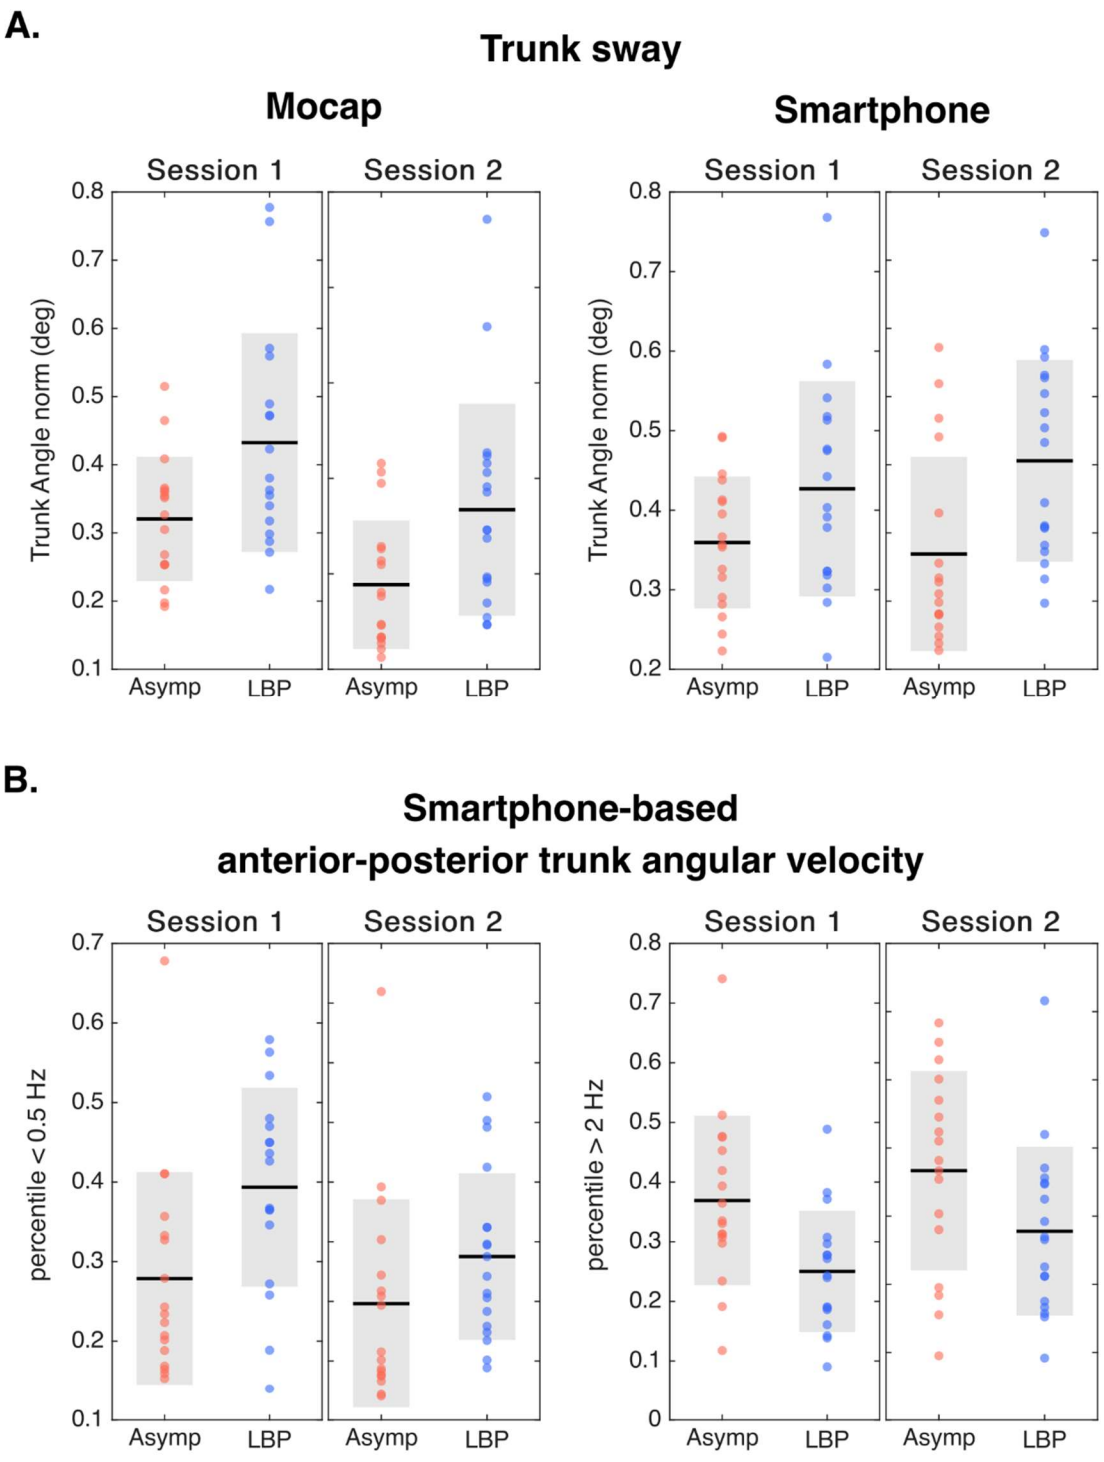

Figure 1. (A) Mocap- and IMU-based overall trunk sway (root-mean-square of vector norm) for asymptomatic (Asymp) and low back pain (LBP) individuals for both sessions. Both showed significant group differences across the two sessions (Mocap-based: *p*-value = 0.011; IMU-based: *p*-value = 0.017). (B) IMU-based spectral analysis of anterior-posterior trunk angular velocity: percentile of normalized power < 0.5 Hz and > 2 Hz. Both showed significant group differences across the two sessions (< 0.5 Hz: *p*-value = 0.037; > 2 Hz: *p*-value = 0.013). Black line: mean; grey rectangle: standard deviation.

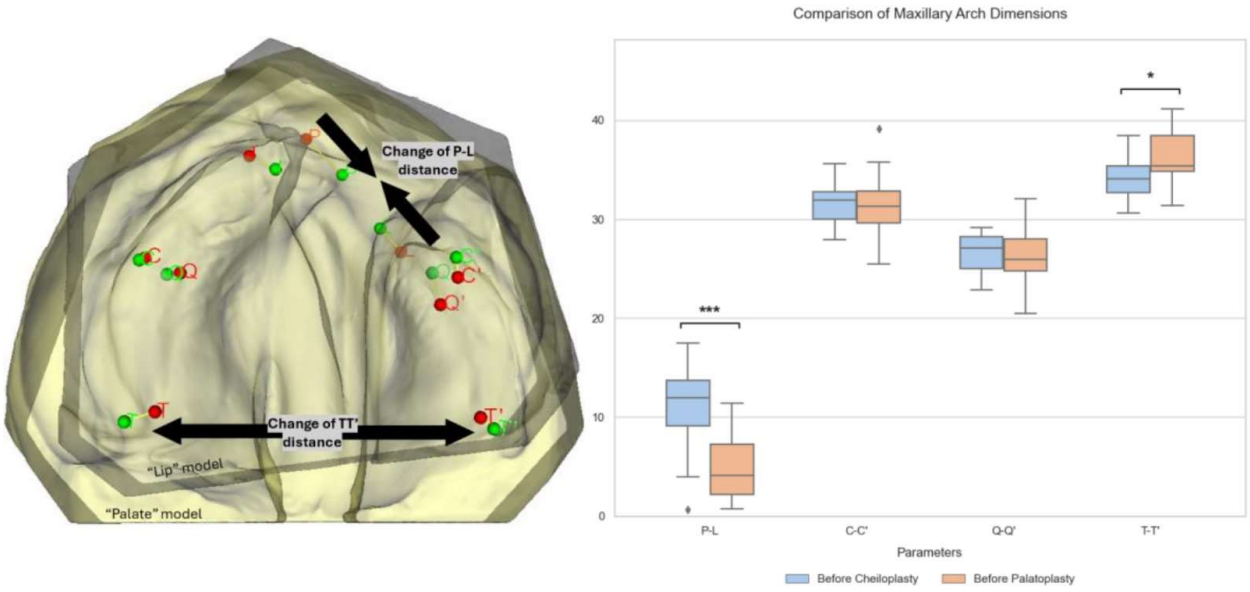
[4]Clinic of Dentistry, St. Anne's University Hospital Brno, Brno, Czech Republic, Czechia. [5]Department of Anatomy, Masaryk University, Faculty of Medicine, Brno, Czech Republic, Czechia

Introduction

The growth of the craniofacial skeleton is influenced by genetic factors and biomechanical forces (Wolff's Law). In healthy infants, a balance between tongue pressure and the containment from lips and cheeks guides the development of the maxillary arch. In newborns with cleft lip and palate, the absence of anterior muscular continuity leads to pathological displacement of alveolar segments.
Primary cheiloplasty re-establishes the anterior muscular sling, introducing new biomechanical forces that trigger bone remodeling. While this effect is recognized, its precise 3D nature remains insufficiently quantified.
This study aimed to use the 3D morphometric tool CleftPoint to quantify the vectors of bone remodeling vectors and changes in maxillary arch geometry between lip and palate surgeries. We hypothesized significant medial remodeling in anterior segments post-cheiloplasty, with posterior regions maintaining innate growth.

Methods

A retrospective study was conducted on 14 patients with non-syndromic unilateral cleft lip and palate (UCLP). All underwent modified Fischer cheiloplasty (~7 days of age) and one-stage palatoplasty (~8 months). No presurgical orthopedics were used.
Silicone impressions were taken before each surgery. 3D dental models were digitized and spatially aligned using a quaternion-based algorithm. Landmarks according to Seckel were identified on both timepoints using CleftPoint [1].
Four morphometric parameters (P-L, C-C', Q-Q', T-T') were calculated and compared using the Wilcoxon signed-rank test ($p < 0.05$).



Results

The anterior alveolar cleft width (P-L) showed a significant median decrease of 7.82 mm (from 11.94 mm to 4.11 mm; $p < 0.001$), representing a >60% reduction. Transverse dimensions (C-C', Q-Q') remained stable ($p = 0.808$ and $p = 0.670$), while the posterior width (T-T') significantly increased (from 34.05 mm to 35.42 mm; $p = 0.020$).

Discussion

Primary cheiloplasty induces significant remodeling of the maxillary arch. Reconstructing the orbicularis oris muscle restores anterior pressure, which contributes to the medial shift of anterior alveolar segments and initiates a cascade of biomechanical adaptations. The resulting remodeling pattern—anterior constriction with posterior expansion—reflects a new functional equilibrium of forces. CleftPoint enables precise quantification of these 3D morphological changes, highlighting the role of cheiloplasty as a catalyst for functional, not just aesthetic, normalization.

Unilateral Arm Restriction Affects Dynamic Balance Recovery in Response to Unanticipated External Treadmill Perturbations

Dr. Paige Paulus PT, DPT, PhD[1], Mr. Bradley Moore MS[2], Mr. Paul Hammond II MS[3], Ms. Rebecca Stine MS[3], Dr. Noah Rosenblatt PhD[4], Dr. Matthew Major PhD[1,2,3]

[1]Northwestern University Department of Physical Medicine and Rehabilitation, Chicago, IL, United States. [2]Northwestern University Department of Biomedical Engineering, Evanston, IL, United States. [3]Jesse Brown VA Medical Center, Chicago, IL, United States. [4]Rosaland Franklin University, Chicago, IL, United States

Introduction

Research suggests that unilateral arm restriction (UAR) during steady-state walking, due to upper limb casting/bracing, can increase fall risk. Less is known about how UAR affects perturbation recovery. This study aimed to (1) assess the influence of UAR on reactive balance control in healthy individuals, (2) observe the effect of UAR on muscle activation during recovery to assess motor adaptations. We hypothesized that individuals would experience greater dynamic balance disturbance during perturbation recovery with UAR.

Methods

Ten able-bodied individuals provided informed consent to participate in this IRB-approved study. Participants donned a ceiling-mounted harness and walked on an instrumented treadmill for ten randomly presented perturbation trials (5 per foot) per condition: non-dominant UAR and unbound. Kinematic data were collected by an optical motion capture system (120Hz). Wireless EMG sensors collected bilateral posterior deltoids (PD), tibialis anterior (TA), and medial gastrocnemius muscle activity (960Hz). Perturbations were defined as unexpected treadmill acceleration-deceleration (6.5m/s^2) from 1.0m/s to 3.3m/s and back. Kinematic and EMG data were processed following previous methodology using Visual3D. Whole body angular momentum (*L*) was calculated as the sum of the instantaneous angular momentum of each segment about the center of mass and normalized by treadmill speed and participant mass and height. *L* range (L_{range}) was calculated as the global range (max-min) over the first five post-perturbation strides. EMG data was integrated over the first five post-perturbation strides (*iEMG*). The effects of perturbation side and arm binding on L_{range} and *iEMG* were evaluated using a two-way repeated-measures ANOVA (α=0.05).

Results

UAR caused increased transverse plane L_{range} (p=0.05)(Fig.1A), with non-dominant side perturbations causing greater coronal-plane L_{range} (p=0.04)(Fig.1A). Participants had less non-dominant arm PD activation with UAR (p=0.04)(Fig.1B). There was an interaction effect (condition×side) on nondominant TA activation (p=0.04), and although non-significant, post hoc simple main effects analyses revealed greater TA activation with UAR in response to nondominant perturbations (p=0.08).

Discussion

Study findings suggest that UAR causes an increased challenge to regulating body spin and avoiding falls when recovering from trip-like perturbations. This provides some justification for clinicians to screen their patients' balance when access to natural arm dynamics is unilaterally absent.

Integrating Kinematic and Morphometric Data for the Functional Characterization of Lower Limb Joints in Individuals With Multiple Osteochondromas

MEng Giulia Rogati[1], PhD Marina Mordenti[1], MEng Roberto Ramaglia Amadasi[1], Eng Letizia Barbi[2], MD, PhD Luca Sangiorgi[1], PhD Zimi Sawacha[2], DPhil Leardini Alberto[1], PhD Paolo Caravaggi[1]

[1]IRCCS Istituto Ortopedico Rizzoli, Bologna, Emilia-Romagna, Italy. [2]Università di Padova, Padova, Veneto, Italy

MEng Giulia Rogati

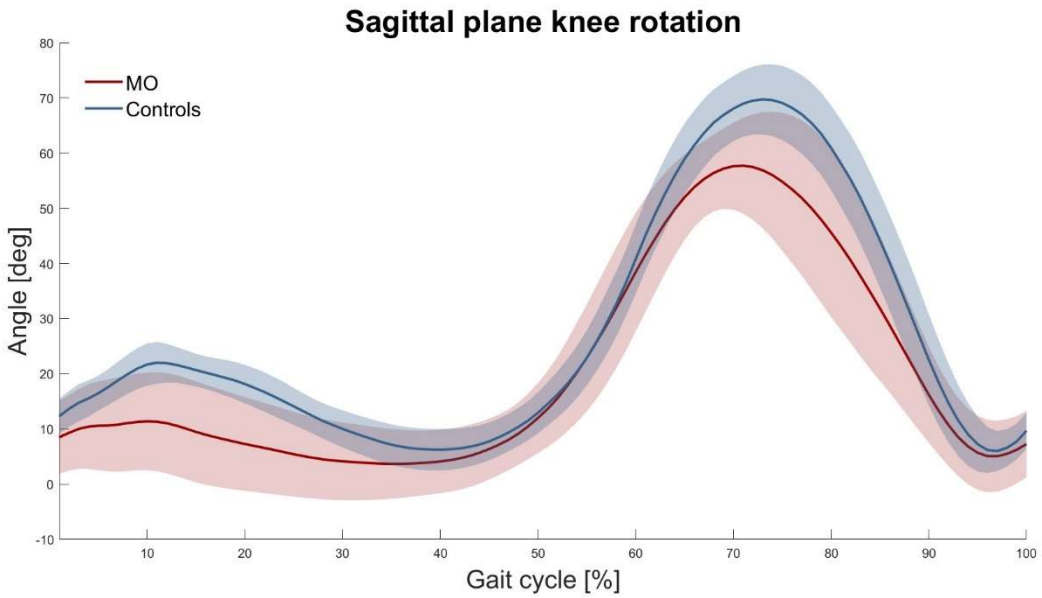
Introduction

Multiple Osteochondromas (MO) is a rare hereditary skeletal disorder characterized by benign bone tumors (osteochondromas, OCs) arising primarily from the metaphyses of long bones. These lesions can cause severe complications, such as skeletal deformities, limb length discrepancies, restricted joint motion, and functional impairments of the upper and lower limbs. This study aims to functionally characterise individuals with MO in relation to age-matched healthy populations.

Methods

Approval was obtained from the local ethics committee (333/2024/Sper/IOR) to enrol 30 young adults and children with MO and 30 age-matched healthy subjects. Lower-limb kinematics was measured during gait and in specific motor tasks (e.g. active knee and hip flexion/extension) using 8 IMUs (Ultium Motion, Noraxon). Full-body radiographic evaluation was performed using a micro-dose EOSedge (EOS imaging), and body shape was captured using 3D scanners (InBody, BeyondShape; Artec Leo, 3DZ). Spatiotemporal parameters, joint ROM, and temporal profiles of joint rotation angles were evaluated. OCs location and dimensions, as well as skeletal alignment of the spine and lower limbs, were analysed from imaging. The effect of MO on relevant spatiotemporal and kinematic parameters was investigated using the Mann–Whitney test.

Results



Sagittal plane knee joint rotations over normalized gait cycle for 7 young adults with MO (5F, 2M; 22.0±3.1 years; 22.4±4.3 kg/m^2) and 7 healthy subjects (5F, 2M; 26.6±1.7 years;

24.1±3.6 kg/m^2) are reported in Fig.1. According to the Mann–Whitney test, no statistically significant differences in ROM (deg) between the MO and controls were found in the sagittal plane for the hip (MO=47±6, CONTROL=47±3; p=1.000) or the ankle (MO=39±5, CONTROL =38±3; p=0.714), whereas a significant decrease in knee ROM was detected in the MO population (MO=59±3, CONTROL=65±2; p=0.007).

Discussion

While the recruitment of both MO and healthy individuals is still ongoing, preliminary results on lower-limb joint kinematics suggest a reduced knee ROM and a greater variability in knee kinematics for the MO population in the sagittal plane (Fig.1). These data will be combined with radiographic findings to assess possible correlations between bone deformities and functional alterations.

Achilles Subtendon Behaviour and Foot Biomechanics Following Rupture: Preliminary Findings From Heel-Rise Analysis

Dr. Andreas Brand[1,2], B.Sc. Inga Kröger[1,2], M.Sc. Honoka Ishihara[3], M.Sc. Markus Greinwald[1,2], Dr. Johannes Gabel[4], Prof. Peter Augat[1,2]

[3]Department of Sports Rehabilitation, Hiroshima University, Hiroshima, Chugoku, Japan. [4]Department of Foot and Ankle Surgery, BG Unfallklinik Murnau, Murnau am Staffelsee, Bavaria, Germany

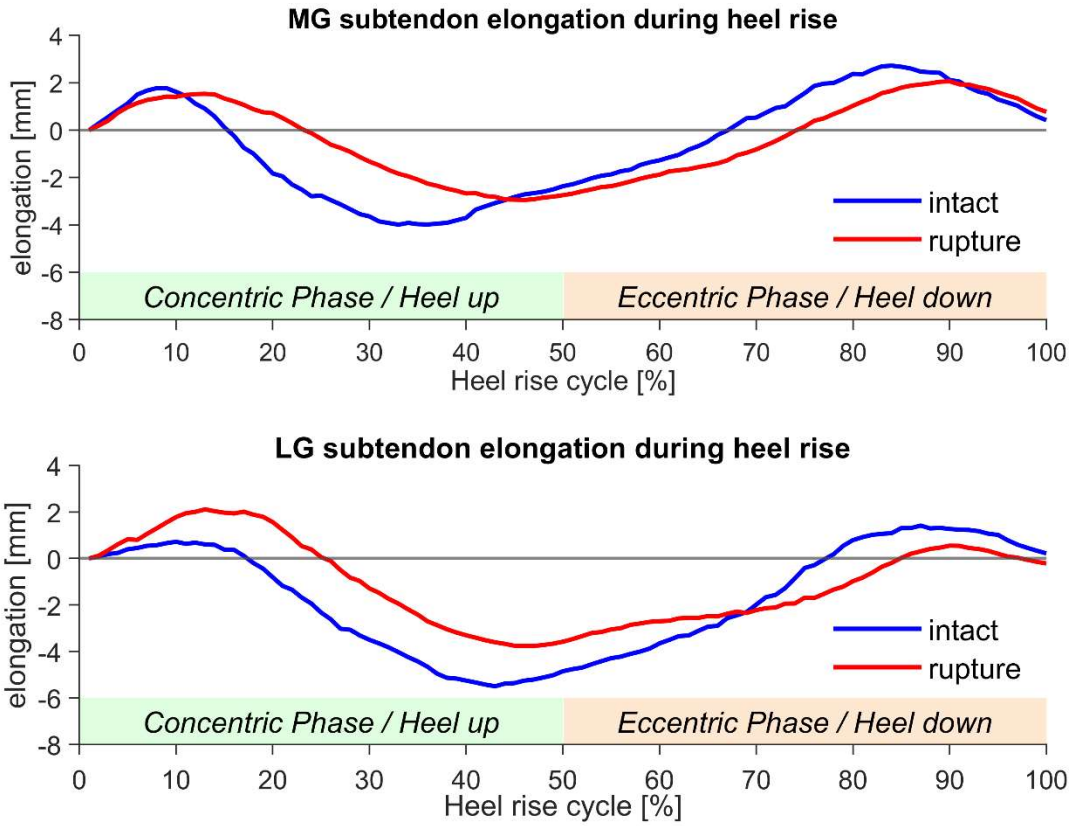
Introduction

The Achilles tendon (AT) is composed of distinct muscle-specific subtendons that enable non-uniform displacements and differential force transmission to the foot [1]. Following rupture, severe impairments of foot function are common, often accompanied by morphological and mechanical changes of the tendon [2]. Little is known about how individual subtendons adapt after rupture and surgical repair. This study aims to investigate the functional adaptations of different Achilles subtendons during dynamic plantar flexion of the foot following AT rupture.

Methods

AT movements of the medial (MG) and lateral gastrocnemius (LG) tendon portions were prospectively analysed in 13 patients with unilateral traumatic AT rupture (10M/3F; age 45±12 y; BMI:26±2 kg/m^2; AT Rupture Score: 40/100), 10-12 weeks post-surgery. Motion capture and synchronized portable ultrasound were used to analyse repetitive bipedal heel-rise performance. Subtendon elongation, sagittal ankle kinematics, weight bearing levels and local AT stiffness using tendotonometry were compared intra-individually between the ruptured and intact side. As the data are preliminary, descriptive results are reported.

Results



At the ruptured side, a prolonged LG and MG subtendon elongation during the intial phase of concentric plantar flexion was observed. Over the entire heel-rise cycle, LG subtendon elongation showed larger side-to-side differences compared to the MG subtendon (Fig. 1). Average ankle plantar flexion during bipedal heel-rise was 14° (range: 3-25°). Weight-

bearing (% bodyweight) at the foot was lower on the ruptured side (31%; range: 28–35%) compared to the intact side (66%; range: 62–69%). Local stiffness of the ruptured AT was reduced by 26% (range: 8-41%).

Discussion

Preliminary findings indicate early functional adaptations of AT subtendons following trauma and surgical repair. Altered elongation patterns of ruptured subtendons, combined with reduced weight bearing at comparable ankle kinematics, is consistent with changes of biomechanical compliance (loss of stiffness) at the entire AT. Altered elongation patterns further suggest a heterogenous AT adaptation, with the LG subtendon appearing more susceptible to functional alterations than the MG subtendon. Additional data acquisition and analysis are required to confirm these observations and their clinical significance.

Biomechanical Stability of Neonatal Cleft Lip and Palate Obturators: Effect of Thickness and Surface Roughness on Laryngoscope-Simulated Loading

Ing Petr Marcian[1], MD Olga Koskova[2,3], MD Michaela Richtrova[4,3], Ing Pavel Skacel[1], prof. Petr Stourac[4,3,5], Ing Libor Borak[1]

[4]Department of Paediatric Anaesthesiology and Intensive Care Medicine, University Hospital Brno, Brno, Czech Republic, Czechia. [5]Department of Simulation Medicine of the Faculty of Medicine, Masaryk University, Brno, Czech Republic, Czechia

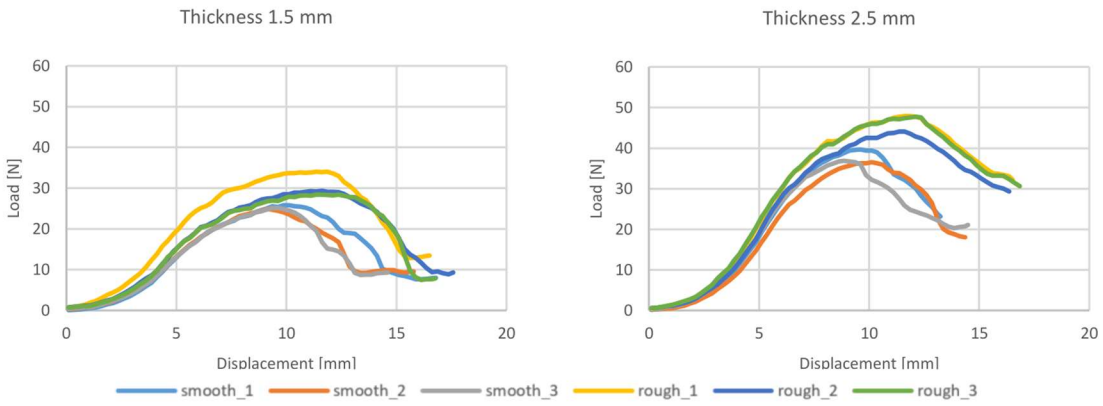
Introduction

Palatal obturators facilitate feeding and airway management in neonates with cleft lip and palate, a condition that also presents significant challenges for safe neonatal intubation. These challenges arise from a combination of typical neonatal airway anatomy and cleft-related disruptions, which together hinder visualization and increase the risk of trauma during laryngoscope manipulation. Protective obturators—silicone devices covering the cleft—may ease intubation and reduce soft tissue injury [1,2]. While digital workflows enable precise customization, the biomechanical influence of design parameters remains unclear. This study evaluated the mechanical resistance of 3D-printed silicone obturators, hypothesizing that increased thickness and surface roughness enhance load-bearing capacity under laryngoscope-simulated forces.

Methods

Patient-specific obturators (medical-grade silicone) were obtained via 3D-printed molds derived from a digital workflow. Four groups (n=3 each) were tested, varying thickness (1.5 vs. 2.5 mm) and surface finish (smooth vs. rough). A custom setup utilized a maxillary alveolus-simulating lower fixture and a laryngoscope-mimicking upper mandrel. Samples were compressed vertically until failure. Maximum load was analyzed, and Cohen's *d* was calculated to quantify effect sizes given the sample size.

Results



Thickness was the primary determinant of stability. The 2.5 mm samples withstood significantly higher loads (Smooth: 37.7±1.7 N; Rough: 46.6±2.1N) compared to 1.5 mm samples (Smooth: 25.3±0.5 N; Rough: 30.6±3.0 N). This represented an extremely strong effect size for both finishes (d=9.81 and d=6.13, respectively). Surface texture was also

critical; rough surfaces consistently outperformed smooth ones (d=2.46 for 1.5 mm; d=4.57 for 2.5 mm), increasing load capacity by approximately 20–24% and preventing premature slippage.

Discussion

The very large Cohen's d values confirm that thickness is the dominant contributor to mechanical resistance, providing essential bulk stiffness under vertical loading. However, the substantial effect of surface roughness demonstrates a complementary mechanism: friction-mediated retention. The larger effect size observed in thicker samples suggests a synergistic interaction, where enhanced structural rigidity amplifies the stabilizing influence of a textured surface. These findings strongly support incorporating controlled surface roughness into digitally designed neonatal obturators to improve safety during laryngoscope manipulation without changing material formulation.

Biomechanical Analysis of the Effect of Different Alignment Techniques in Total Knee Arthroplasty in Patients with Valgus Deformities: A Finite Element Study

Mr. Mattia Sisella[1], Mr. Fabiano Bini[2], Mr. Pietro Margheriti[2], Mr. Nicolò Monticelli[2], Mr. Franco Marinozzi[2], Mr. Bernardo Innocenti[1]

[1]BEAMS Department, Brussels, Brussels, Belgium. [2]Department of Mechanical and Aerospace Engineering, Roma, Italy, Italy

Introduction

Achieving optimal alignment in Total Knee Arthroplasty (TKA) is essential for long-term joint function and implant durability, yet the ideal alignment strategy remains debated, particularly in patients with valgus deformities. Mechanical Alignment (MA) and Kinematic Alignment (KA) are based on different concepts, raising questions about their relative biomechanical consequences. The aim of this study is to numerically compare effects of MA versus KA in valgus knees (8° and 11° deformity), aiming to identify a superior patient-specific strategy.

Methods

Patient-specific FE models were developed, following previous validated studies. A Genus FB PS (Adler Ortho, Cormano, Italy) prosthesis was virtually implanted, following the surgical guidelines. A 0°–120° squat motion was simulated under specific loading condition. Key outputs were extracted from only the flexion motion including tibio-femoral and patello-femoral joints kinematics and kinetics, polyethylene stresses and contact areas, and mean collateral ligament stresses, comparing MA and KA for each patient.

Results

For the tibio-femoral joint, polyethylene contact areas and stresses were similar between the two alignment strategies, with notable differences observed in the post-cam interaction, particularly at 60° of flexion, distinguishing the 8° and 11° valgus knees. Regarding the patello-femoral joint, KA showed reduced contact forces compared to MA in both patients, while contact areas were similar, with regional differences dictated by patellar bone anatomy. Finally, KA consistently resulted in lower mean stress values on the collateral ligaments for both patients, though the 11° valgus patient exhibited generally greater overall ligament stress.

Discussion

Despite few differences in polyethylene contact characteristics at the tibio-femoral joint, this study conclusively demonstrates that Kinematic Alignment yields a biomechanical advantage across the rest of the knee. KA consistently results in a reduction in mean collateral ligament stress and lower patello-femoral contact forces compared to Mechanical Alignment in valgus TKA patients. This evidence strongly supports KA as a superior patient-specific approach for soft tissue balancing and patellar tracking, offering a robust solution to improve functional outcomes and potentially enhance implant longevity in complex knee deformities.

Dynamic Postural Control Reveals Adaptations to Postpartum Infant Carriage

Ms. Rachel Berns BS, Dr. Kornelia Kulig PhD, PT, FAPTA, Mr. Melvin Leon BS, Dr. Kathryn Havens PhD

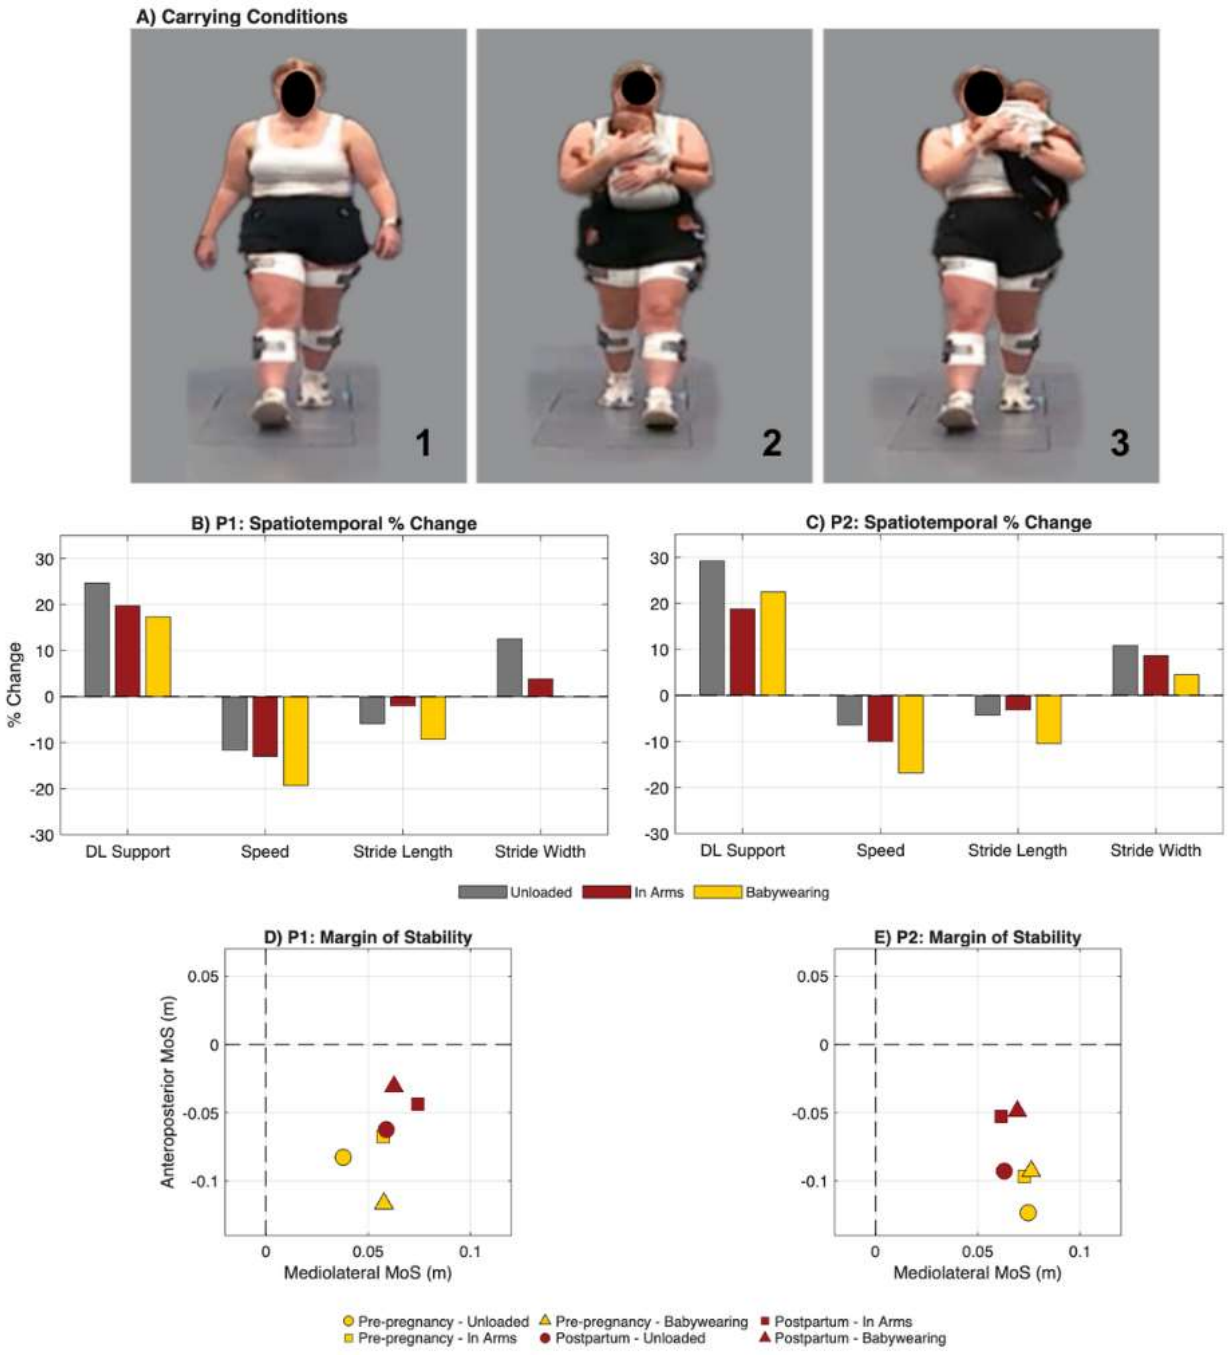
University of Southern California, Los Angeles, CA, United States

Introduction

Postpartum individuals face significant musculoskeletal pathologies and mass distribution changes that impact gait, balance, and postural control [1]. These biomechanical shifts are compounded by physical demands of infant carrying [2]. This case study followed two individuals from pre-pregnancy to early postpartum, examining changes in spatiotemporal gait and dynamic stability during various infant carriage conditions.

Methods

Two healthy women participated in data collection pre-pregnancy (32 yrs, 1.7 ± 0.018 m, 89 ± 9.3 kg), and 3-4 months postpartum (33 yrs, 1.7 m, 92 ± 9.7 kg). Participants completed self-selected speed walking trials under three carrying conditions (Fig. 1A), holding an infant mannequin (6.7 kg) pre-pregnancy, and holding their own infant (7.1 ± 1.1 kg) postpartum. Reflective markers tracked lower extremity and trunk 3D-motion and were used to compute spatiotemporal gait parameters. Dynamic postural control was assessed in the anteroposterior (AP) and mediolateral (ML) directions using margin of stability (MoS): the minimum distance between the velocity-extrapolated center of mass and base of support, defined by lateral and distal heel markers. Data were averaged across trials per condition and expressed as percent change pre-pregnancy to postpartum.



Results

Consistently across carrying conditions, increased speed and double-limb support time, with decreased stride length and width, indicated a cautious gait pattern postpartum (Fig. 1B-C). AP MoS became less negative in all conditions, suggesting greater comparative stability driven by slower postpartum walking speed. Mediolateral stability control diverged: Participant 1 experienced an 8-55% increase in lateral stability, while Participant 2 had 8-16% decreased lateral stability across all conditions (Fig. 1D-E). Interestingly, for double-limb support time, stride width, and ML MoS, the largest changes were observed walking unloaded.

Discussion

Adapted spatiotemporal gait indicates a stability-favoring strategy postpartum, consistent with AP MoS. Infant carriage either amplified or mitigated the observed changes, suggesting fundamental effects of pregnancy on gait, not solely responses to infant carriage. Notably, opposing changes in ML MoS suggest that cautious postpartum gait may mask distinct control mechanisms for lateral stability. Postpartum recovery may involve individualized compensatory strategies for dynamic stability, challenging the notion of a single postpartum gait pattern.

Estimating the Centre of the Humeral Head Using Five Humeral Anatomical Landmarks: An Exploratory Study on Dry Bones

Mr. Marc-Olivier St-Pierre PhD[1], Mr. Philippe Paquette PhD[2], Mr. Guillaume Desroches PhD[2], Mr. Rachid Aissaoui PhD[1]

[1]École de technologie supérieure, Département Génie des sytèmes, Montréal, Québec, Canada. [2]Université du Québec à Trois-Rivières, Département d'anatomie, Trois-Rivières, Québec, Canada

Introduction

Estimating the centre of the humeral head has great implications in kinematics and dynamic research as it represents the centre of rotation of the glenohumeral joint. Three-dimensional ultrasound-imaging contour-based methods have shown promising results. However, the reported 14 mm error exceeds both intracortical pins (4.2 ± 0.6 mm) and Rab equation (5.5 ± 4.0 mm). This study aimed to develop a regression-based model to predict the centre of the humeral head using five humeral landmarks.

Methods

Fifty-five dry humeri (n=55) were scanned using an Artec Eva 3D scanner (±0.1 mm). The data set was divided into training (n=35), validation (n=10), and test sets (n=10). Specimens presenting large osteophytes on the greater or lesser tubercles were excluded. The centre of the humeral head was obtained using a sphere-fitting technique. Five landmarks (lateral/medial epicondyles, lesser and greater tubercles, deltoid tuberosity) were digitized to define their centre and used as the independent variables in model (Ordinary least square (OLS) algorithm). The mean 3D Euclidean distance between the predicted and sphere-fitted humeral head centre was calculated (mm). Regression equations and errors were expressed in the ISB-recommended coordinate system.

Results

Landmark identification has shown an error of less than 1.9 ± 1.0 mm. The mean Euclidean distance between the predicted and sphere-fitted CoR was 3.4 ± 1.2 mm. The greater tubercule (GT) was the primary contributor for the superior-inferior (Y) (0.883 GT_y) and anterior-posterior (Z) (− 0.342 GT_y, + 0.879 GT_z**)** coordinates. For the X axis (latero-medial), the lesser tubercule (LT) (0.939 LT_x) influenced the position of the CoR helped with the lateral (− 0.433 LE_x) and medial (0.302 ME_x**)** epicondyles (Table 1).

Discussion

Five anatomical humeral landmarks predict the centre of the humeral head with sub-4 mm accuracy on dry bone. These findings are clinically relevant because the greater and lesser tubercules are easily accessible using ultrasound imaging. Conversely, the deltoid tuberosity contributed minimally, which may be advantageous given its less prominent bony relief and limited applicability with ultrasound. External validation of this model using 3D ultrasound-imaging is needed to quantify the error with soft tissue.

Dr Helene Follet

Introduction

Fibrous dysplasia of bone (FD) is a rare, congenital bone disease due to a post-zygotic mutation of GNAS, (guanine nucleotide-binding protein, alpha stimulating, an imprinted gene) causing bone pain, deformities and fractures. Mechanically speaking, FD lesions, which are often lytic and heterogeneous, can be compared to those of bone metastases. The assessment of mechanical strength and fracture risk in FD lesions, however, remains a significant unresolved issue for clinicians.

Methods

We have developed MEKANOS, a digital simulation tool for calculating the mechanical strength of tumor bone based on routine scans using a dedicated protocol[2,3,4,5]. Briefly, we wanted to determine whether this tool can be used to quantify bone strength in FD, with routine CT scanning? To this end, we used scanned images of patients with FD (15 patients)

obtained by the Fibrous Dysplasia National Reference Center. For each patient images, mid-length femur lengthening was done, calibration of Hounsfield Units (HU) to density was performed using (i) a patient-specific method and (ii) an asynchronous method. Femurs were automatically segmented[2], meshed using tetrahedral elements, and assigned linear elastic material properties using a model implemented in Lyon[3,6] Femurs were loaded in axial compression, and their failure load was computed using a failure criterion based on a volume of contiguous failed elements. protocol[2,3,4,5,6].

Results

We compared the fracture strength of femurs obtained numerically using the two calibration methods (n=28 from 14 patients). Both methods showed a strong correlation (R^2=0.92), but a relative bias of 12% (SD=5.56%, and IC95% [1.2 to 23%]). Between pathological bone and healthy bone, for 6 patients, both models were able to show a significant difference of bone strength between them (*resp* p=0.0278 for patient-specific method and p=0.0377 for asynchronous method).

Discussion

These preliminary results are very encouraging for the continuation of the study and to elaborate a fracture risk criterion for this type of rare disease.

Knee Joint Hyperextension is Associated with an Increased Prevalence of Knee Pain in Young Adults

Dr. Rebecca Abbott DPT, PhD[1], Ms. Susan Burnap[2], Dr. Arin Ellingson PhD[2]

[1]University of Colorado Anschutz, Aurora, Colorado, United States. [2]University of Minnesota, Minneapolis, Minnesota, United States

Introduction

Knee pain poses a major health, societal, and economic burden. Biomechanical factors, such as knee joint hypermobility, are consistently cited as potential risk factors for the development of knee pain and osteoarthritis (OA) [1]. However, there is conflicting evidence supporting [2] and refuting [3] the role of knee hyperextension in knee pain. This study investigates the relationship between knee hyperextension and pain within each individual knee in a large sample of the general population.

Methods

This data was collected as part of a larger cross-sectional study that took place at the Research Facility at the Minnesota State Fair. Participants self-reported demographics and recorded individual painful joints. Each knee was assessed for hyperextension >10 degrees as a component of the Beighton Score, a clinical measure of generalized hypermobility. Participants were dichotomized by age (young: 18-40 yrs, older: 40+ yrs) due to known effects on joint mobility. The results are stratified by individual knees, allowing us to directly link hyperextension and pain.

Results

555 participants (219 males, 336 females, age 18-86 years) were enrolled. While knee hyperextension and knee pain were more prevalent in females than males, subsequent analyses include both sexes combined because associations between hyperextension and pain were similar. The results are reported in **FIGURE 1**. Knee hyperextension was more common in young adults (28.2%) than older adults (11.6%). The association between knee hyperextension and knee pain differed by age group: in young adults, hyperextension was associated with a 2.3-fold higher prevalence of knee pain, whereas in older adults, hyperextension was associated with a 2.7-fold lower prevalence.

Discussion

Knee hyperextension is common in young adults and reflects altered biomechanical patterns associated with an increased prevalence of knee pain. Individuals with painful

knee hyperextension may lose mobility with age due to joint degeneration, leading to the inverted relationship between knee hyperextension and knee pain in older adults. Clinicians should be aware that excessive knee hyperextension in young adults may be a risk factor for knee pain.

Generalized Joint Hypermobility Modifies the Relationship Between Neck Pain Burden and Neck Function in Women

Dr. Rebecca Abbott PT, DPT, PhD[1], Dr. Andrew Leroux PhD[1], Dr. Carly Molenaar PT, DPT[2], Dr. Kyle Dalske PT, DPT, MS[2], Dr. Arin Ellingson PhD[2]

[1]University of Colorado Anschutz, Aurora, Colorado, United States. [2]University of Minnesota, Minneapolis, Minnesota, United States

Introduction

Generalized joint hypermobility (GJH; excessive joint range of motion (ROM) throughout the body) is present in up to 30% of young women and associated with increased risk of injury and joint pain [1,2]. Despite evidence that neck pain (NP) is particularly prevalent and debilitating [2], little is known about the presentation of NP in GJH, which is a barrier to effective clinical management. The objective of this study was to determine the relationships between GJH, NP burden, and neck function (ROM and strength).

Methods

Females (18+) were enrolled at the research facility at the Minnesota State Fair as part of a larger cross-sectional study. All participants were assessed for GJH with the Beighton Score (BS) and Five-Part Questionnaire [3]. A subset completed neck function measures (ROM and strength) and the Neck Disability Index (NDI). Multivariable regression models were created for each neck function outcome with predictors: GJH (BS) and NP burden (NDI), covariates: age and BMI, and an interaction term: BSxNDI.

Results

336 participants were enrolled. GJH prevalence was 23.5%. NP was more prevalent in GJH (24.1%) than non-GJH (16.0%), and most prevalent in GJH age 18-40 years (29.3%). Regression analyses were performed on 182 participants (GJH: 71, non-GJH: 111) who completed all neck function measures. Controlling for age, BMI, and NP burden, GJH was associated with increased neck ROM (flexion, extension, sidebending, rotation) and increased strength (flexion, extension, sidebending). Most outcomes showed a significant positive BS×NDI interaction (**FIGURE 1**), indicating that GJH was linked to reduced deficits in ROM and strength with increasing NP burden.

Discussion

GJH plays a role in NP, disability, and function. NP is common in women with GJH, who may present with less ROM and strength impairments than typical NP patients. These results

should be interpreted within the context of our relatively healthy and mobile study population: community members who approached the research facility at a bustling State Fair. Individuals with more severe pain and disability may not be represented.

Images (Optional)

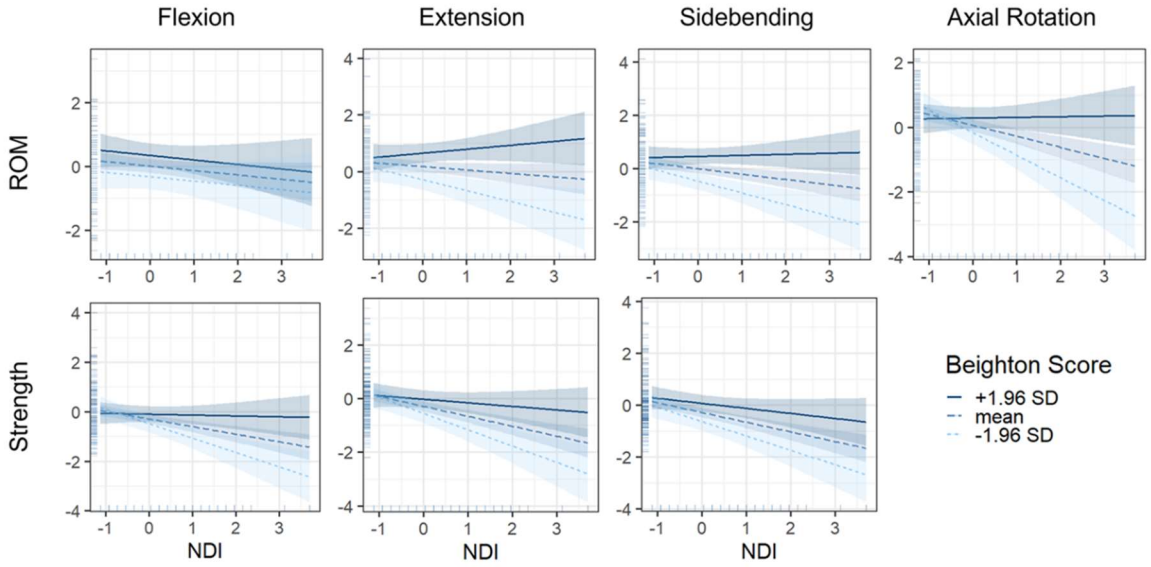

FIGURE 1: Interaction plots illustrating the interaction between Beighton Score and Neck Disability Index (NDI) as a predictor of neck range of motion (ROM) (top row) and strength (bottom row), adjusted for age and BMI. All continuous variables are centered and standardized. The interaction was significant ($p<.05$) and positive for extension, sidebending, and axial rotation ROM and neck flexion and extension strength.

Changes in Gait Kinematics and Surgical Outcomes after Proximal and Distal Femoral Derotational Osteotomy in Children with Cerebral Palsy

Dr. Reiko Hara PhD[1], Dr. Susan Rethlefsen DPT[1], Ms. Nerissa Chin[1], Ms. Alyssa Ponratana[1], Dr. Tishya Wren PhD[1,2], Dr. Robert Kay MD[1,2]

[1]Children's Hospital Los Angeles, Los Angeles, California, United States. [2]University of Southern California, Los Angeles, California, United States

Introduction

It remains unclear whether proximal or distal femoral derotational osteotomy (FDRO) is preferable for correcting excessive internal hip rotation and foot progression in children with cerebral palsy (CP). This study compares kinematic and surgical outcomes between the two types of FDRO.

Methods

Retrospective data of children with CP who underwent FDRO with pre-and post-operative gait analysis were evaluated to compare proximal and distal FDROs. Patient and surgical characteristics were compared between groups using Mann-Whitney rank sum and Fisher's exact tests. Mean hip rotation and foot progression angles during the stance phase of gait were compared between groups before and after surgery using linear mixed models accounting for repeated measures. The relationship between amount of surgical correction and change in hip rotation angle during gait was examined using Pearson's correlation.

Results

The analysis included 125 FDROs in 75 patients. 41 patients underwent proximal FDRO (25 bilateral), and 34 underwent distal FDRO (25 bilateral). Both groups improved significantly in hip rotation and foot progression angles post-operatively ($p<0.0001$). Hip rotation changed similarly between groups (Table). Foot progression changed more in the distal group because foot progression angle was more internal in the distal group pre-operatively and both groups were similar post-operatively.

The change in hip rotation angle was moderately correlated with the amount of anatomic rotation for proximal osteotomies ($r=0.44$, $p=0.0005$) but not distal osteotomies ($r=0.18$, $p=0.15$).

Total number of surgical procedures per patient was similar between groups, suggesting similar surgical complexity. Estimated blood loss was greater in the proximal group, but use of pain medication on the day after surgery measured as morphine milligram equivalents

(MME) was lower (0.42 vs. 0.65MME/kg, p=0.0003). Complication rate trended higher in the distal group (11 vs. 2%, p=0.07), mostly due to cast problems like pressure sores. Recurrence rate did not differ between groups.

Discussion

Both proximal and distal FDROs are similarly effective in reducing excessive hip internal rotation and normalizing foot progression during gait in children with CP. However, proximal rotation produces changes more consistent with the surgical correction and has a lower complication rate and reduced need for pain medication post-surgery.

Effect of Adaptive Training on Joint Coordination in Recreational Runners: A Pilot Clinical Trial

Dr. Vaibhavi Rathod PT, PhD, Mr. Scotty Hardwig MFA, Dr. Julia Basso PhD, Dr. Robin Queen PhD, FACSM, FIOR, FASB, FAIMBE

Virginia Tech, Blacksburg, VA, United States

Introduction

Running is one of the most popular recreational activities with numerous health benefits. However, it is associated with a high incidence of overuse injuries. Safe and efficient running mechanics require coordinated motion across hip, knee, and ankle joints with joint coordination playing a key role in load distribution, movement efficiency, and the ability to adapt to changing environments. Adaptive training incorporates variable, unpredictable task demands that cultivate diverse whole-body motor responses and promote neuromuscular adaptability. Therefore, the purpose of this pilot clinical trial was to examine the effects of an adaptive training movement practice on joint coordination during running and standing lunges in runners.

Methods

26 recreational runners (13F/13M; age 26.2±9.2 years; BMI 23.2±3.5 kg/m^2) completed 12 group-based movement training sessions over 4 weeks (3x/week). Training included unpredictable, game-like tasks (e.g., reaching, catching, dynamic balancing, avoiding unpredictable externally controlled obstacles) to promote diverse movement responses. Markerless motion capture (85 Hz) was used to analyze Hip-Knee (proximal) and Knee-Ankle (distal) sagittal and frontal plane coupling angles pre- and post-intervention, during running and standing lunges. A linear mixed-effects model was used to examine the effects of Time (Pre vs Post), Joint Pair (Hip–Knee vs Knee–Ankle), and their interaction on coupling angle, with participant included as a random effect.

Results

During the running task (sagittal plane), the Time × Joint Pair interaction was significant ($p< 0.001$) with a significant increase in proximal coupling ($p< 0.001$) post intervention (Table 1). Similarly, for the left-lunge task (sagittal plane), the interaction was significant ($p= 0.025$), with proximal coupling increasing post-intervention ($p= 0.017$). No significant interactions ($p= 0.856$) or main effect ($p= 0.817$) were observed for the right lunge task (sagittal plane). Additionally, no significant main effects or interaction were observed for running or lunges in the frontal plane ($p >0.05$).

Discussion

These pilot study findings suggest that adaptive training promotes greater proximal coordination during functional tasks such as running and lunging. Increased proximal engagement may indicate improved ability to control the limb using a hip-dominant strategy, important for absorbing load and stabilizing the lower extremity during dynamic movement.

Investigating How Pregnancy Weight Gain Impacts Achilles Tendon Load

Ms. Robyn de Wet, Dr. Lauren Welte PhD

University of Alberta, Edmonton, Alberta, Canada

Ms. Robyn de Wet

Introduction

Pregnant individuals undergo substantial hormonal and weight changes that impact the musculoskeletal system, leading to compensatory walking patterns such as wider stance and increased stride time [1], and larger ankle moments [2]. However, which plantarflexors are responsible for the increased moments remains unclear, as the compensatory strategies may preferentially recruit smaller plantarflexors – like the posterior tibialis – to accommodate a wider stance, instead of the larger triceps surae and Achilles tendon. This pilot study aims to simulate pregnancy weight gain to understand how these compensations alter Achilles tendon load.

Methods

To isolate the effects of increased weight from pregnancy-related hormonal fluctuations, five non-pregnant female participants were recruited (mean±SD, 24.6±4.2 y; 166.6±4.2 cm; 64.4±9.4 kg). Participants walked on a treadmill for 5 minutes at 1.0 m/s at a self-selected cadence, which was measured and kept constant with a metronome. Participants walked without added weight and with a 20 lb simulated pregnancy belly. Shear wave tensiometry, which non-invasively measures tendon wave speed [3], measured tendon loading patterns. Strides were averaged within conditions and normalized to the gait cycle.

Results

Stride times were consistent between trials; the difference between weighted and non-weighted trials was 0.006 ± 0.001 s. Four subjects experienced an average 4.7% higher peak wave speed (2.6 ± 0.8 m/s), and therefore tendon load, in weighted trials compared to non-weighted trials (Figure 1), while one subject experienced a decrease in peak tendon wave speed (3.2 m/s).

Discussion

Preliminary results suggest that simulated pregnancy may increase Achilles tendon load during walking; however, compensation responses may be subject-specific. Participants reported poorer balance and increased forefoot pressure during weighted trials, indicating compensatory gait strategies. Ongoing work includes additional subject recruitment, and collection and analysis of plantar pressure data and motion capture to quantify gait compensations and the effects on tendon load during simulated pregnancy. Understanding tendon adaptations during pregnancy could help guide exercise programming aimed at reducing lower-limb muscle and tendon strain, helping to promote healthier pregnancies.

Benchmarking AI Pose Estimators: How Well Do Markerless Pose Estimators Reproduce 3D Gait Kinematics?

Dr Romain Feigean, Mr Thomas Marques, PT Pauline Santmarty, Dr Jean-Yves Hogrel, Mr Frederic Fer

Institut de myologie, Paris, Ile de France, France

Introduction

Optical motion capture with reflective markers is a widely used and highly accurate method for assessing human movement, particularly in gait impairment analysis. However, it requires extensive setup time, technical expertise, and costly equipment, which limits its applicability in routine clinical or home settings (Rode et al., 2025). Recent advances in markerless pose estimation from a handled monocular smartphone camera offer a promising alternative for accessible gait assessment. This study aims to evaluate the accuracy of several state-of-the-art pose estimation algorithms for gait analysis.

Methods

Twenty gait trials were recorded simultaneously using a smartphone video following the participant and a 3D marker-based motion capture system (Vicon, Oxford, UK). Hip and knee flexion–extension angles were extracted from both sources. Joint angles were computed from 2D key points (MediaPipe: 33 landmarks; HRNet: 17 landmarks), and gait cycles were identified using the method by Zeni et al. (2007). Signals from video and 3D reference data were synchronized. Range of motion (RoM) and root-mean-square error (RMSE) were calculated to evaluate model accuracy. Preliminary analysis was performed on one participant and eight gait cycles as proof of concept.

Results

For the knee, the reference system reported a median range of motion (RoM) angle of 66.1°, while MediaPipe overestimated it at 94.7° (RMSE 30.4°); HRNet produced a more accurate estimate with a median of 73.4° and RMSE of 22.8°. At the hip, the reference RoM median was 42.8°; MediaPipe again overestimated (62.3°, RMSE 16.7°), while HRNet showed better alignment (35.9°, RMSE 14.0°).

Discussion

Preliminary results indicate systematic overestimation of joint angles by MediaPipe across hip and knee flexion-extension, while HRNet provides more accurate estimates. However, HRNet does not detect foot landmarks, which limits its use in full gait analysis. Given the

persistent RoM errors, interpretation should be approached with caution. Further investigation is required to determine whether these markerless methods can reliably assess gait impairments, particularly in clinical populations such as those with neuromuscular disorders.

Probabilistic detection of initial contact and toe-off from adults with impaired gait kinematics using a harmonic hidden markov model

Mr Thomas MARQUES[1], Mr Frédéric Fer[2], PT Pauline Santmarty[1], Dr Jean-Yves Hogrel[1], Dr Romain Feigean[1]

[1]Institute of Myology, Neuromuscular Exploration and Evaluation Center, Neuromuscular Physiology and Evaluation Laboratory, Paris, Île-de-France, France. [2]Institute of Myology, MyoData center, Paris, Île-de-France, France

Introduction

Precise detection of gait events such as heel strike (HS) and toe-off (TO) is crucial for evaluating gait impairments and tracking disease progression in neuromuscular disease (e.g. muscular dystrophies). Despite the wide availability of detection algorithms, some user-friendly gait analysis tools often rely on proprietary "black boxes" algorithms, limiting the interpretation and may fail in people with gait impairments. In particular, compensatory movements in neuromuscular patients can alter kinematic signals (inertial vs. optical), challenging standard detection methods. This study aims to present an innovative probabilistic approach based on harmonic Hidden Markov Models to identify HS and TO events in adults with neuromuscular gait impairment – a method not previously explored in this population.

Methods

Performances has been validated on 27 patients with neuromuscular disease (NMD) and 18 healthy controls. All completed a Two-Minute Walk Test. Kinematics were recorded using 8 sensors from IMU system (APDM Opal sensor), providing synchronized inertial signals and joint angles from which gait events were extracted. Four detection approaches were evaluated to identify HS and TO:

(1) Probabilistic joint-angle modelling, using preliminary segmentation based on knee-crossing, followed by HS and TO inference from joint-angle transitions (knee flexion–extension and hip extension patterns).

(2) Zeni's kinematic method (Zeni et al., 2008),

(3) Wavelet-based detection (Hafer et al., 2020),

(4) Ghoussayni's velocity-threshold method (Ghoussayni et al., 2004).

Comparison focused on event timing, stride variability, and spatiotemporal outcomes.

Results

Our preliminary investigation indicate that all methods can be consistently applied to IMU-derived kinematics in both healthy and neuromuscular cohorts. Notably, the probabilistic HMM-based approach successfully detected HS and TO with timing consistency comparable to or exceeding that of traditional methods, especially in NMD group. Differences in algorithm behavior led to modest variations in calculated stride time and gait speed. These findings suggest that signal modality and algorithmic strategy influence gait-cycle segmentation outcomes.

Discussion

This study demonstrates how different detection strategies and sensing modalities affect gait-event identification in heterogeneous gait patterns. Comparing our probabilistic model with standard algorithms in healthy and pathologic walkers, we highlight the impact of neuromuscular compensation on method performance and guide the development of robust segmentation pipelines across sensing technologies.

Introduction

Patellofemoral pain (PFP) is a condition whose etiology is multifactorial and poorly understood. Still, there is evidence that there are alterations in the quadriceps motor control. Given PFP unfavorable long-term prognosis[1], we aimed to investigate additional neuromuscular and motor control parameters of the quadriceps in people with PFP, based on HD-EMG and force.

Methods

This cross-sectional study, approved by the ethics committee (CAAE:80722924.7.0000.0068), included 22 adults with PFP (PFPG) and 13 controls (CG). Vastus medialis (VM) and lateralis (VL) activities were assessed by 64-electrode matrices during submaximal isometric knee extension (10%, 30%, 50% 70% of maximum force), synchronized with force data from a dynamometer (OTBioelettronica). Muscle fiber conduction velocity(MFCV) was estimated following[2]. The amount of force variability was quantified as standard deviation (SD) and coefficient of variation(CV), and the structure of variability of force and EMG was estimated by sample entropy(SaEn). Groups were compared by Generalized Estimating Equations with Bonferroni-adjusted pairwise comparisons (α=0.05).

Results

EMG SaEn and force CV were higher for PFPG across all force levels and muscles. Force SD and VM MFCV at 10% were higher for PFPG (Table 1).

Discussion

Higher force levels reduced force SaEn but increased EMG SaEn in both groups. PFPG showed greater motor control redundancy (higher EMG SaEn at 10–50% for VM and 30% and 70% for VL) despite similar force regularity, suggesting disrupted MU recruitment linked to chronic pain–related central inhibition[3]. Such inhibition[3] and cortical imprecision[4] may impair MU recruitment efficiency during sustained isometric force, requiring extra neural input to maintain force. This may explain the higher MFCV at 10% for VM due to greater control demand and poorer force maintenance in PFPG. These findings highlight PFP mechanisms that are often overlooked in guideline-oriented exercise therapies [1]. The study is ongoing, and further analyses will refine these conclusions.

Introduction

Foot muscle weakness is a frequent complication of diabetes mellitus (DM), particularly in individuals with diabetic peripheral neuropathy (DPN). These deficits contribute to altered gait biomechanics, impaired balance, and increased ulceration risk. Although changes in intrinsic foot muscles are well documented, clinical guidelines still do not include strength assessment as a marker of functional decline in people with DPN. Moreover, how DPN severity independently contributes to foot strength loss remains unclear. This study aimed to identify determinants of strength reduction in adults with DM and DPN.

Methods

This cross-sectional study approved by the local ethics committee (CAAE:63457822.0.0000.0068) included 68 healthy adults and 404 individuals with DM. Participants completed foot strength testing using the Enhanced Paper Grip Test, which measures hallux grip strength as a proxy for foot-ankle strength and function. Between-group comparisons (68 controls and 100 DM) were performed by t-tests, and differences across DPN severity levels were analyzed by one-way ANOVAs (404 DM) ($p<0.05$). Spearman correlations examined associations between strength and DPN severity, and multiple linear regression tested independent effects of DPN severity, body mass, height, and age on normalized strength (404 DM subjects).

Results

Healthy participants presented greater hallux strength than those with DM (0.51 ± 0.27N/kg vs. 0.25 ± 0.17N/kg; $p<0.0001$). In the expanded cohort, increasing DPN severity was associated with progressively lower strength (ANOVA $p<0.0001$), and the largest reduction was observed between absent and severe DPN (mean diff=0.19; $p<0.0001$). Strength correlated negatively with DPN severity ($r=-0.28$; $p<0.0001$). Regression analysis identified DPN severity as the strongest independent predictor of reduced normalized strength ($\beta=-0.0276$; $p<0.0001$), while height showed a positive association ($\beta=0.716$; $p<0.0001$). The model, including DPN severity, body mass, height, and age, explained 18% of the variance in foot strength ($R^2 = 0.18$).

Discussion

This study showed that hallux strength is reduced in individuals with DM, especially as DPN severity increases, and could be a DPN-related marker for foot-ankle function decline. These deficits are easily detected with a simple, low-cost test, supporting the inclusion of foot strength assessment in routine clinical practice.

When Neuro Meets Ortho: Assessing Knee Joint Loading Patterns during Gait in People Post-Stroke

Dr. Russell Johnson PhD[1], Ms Ria Bakshi[2], Dr. Natalia Sánchez PhD[3]

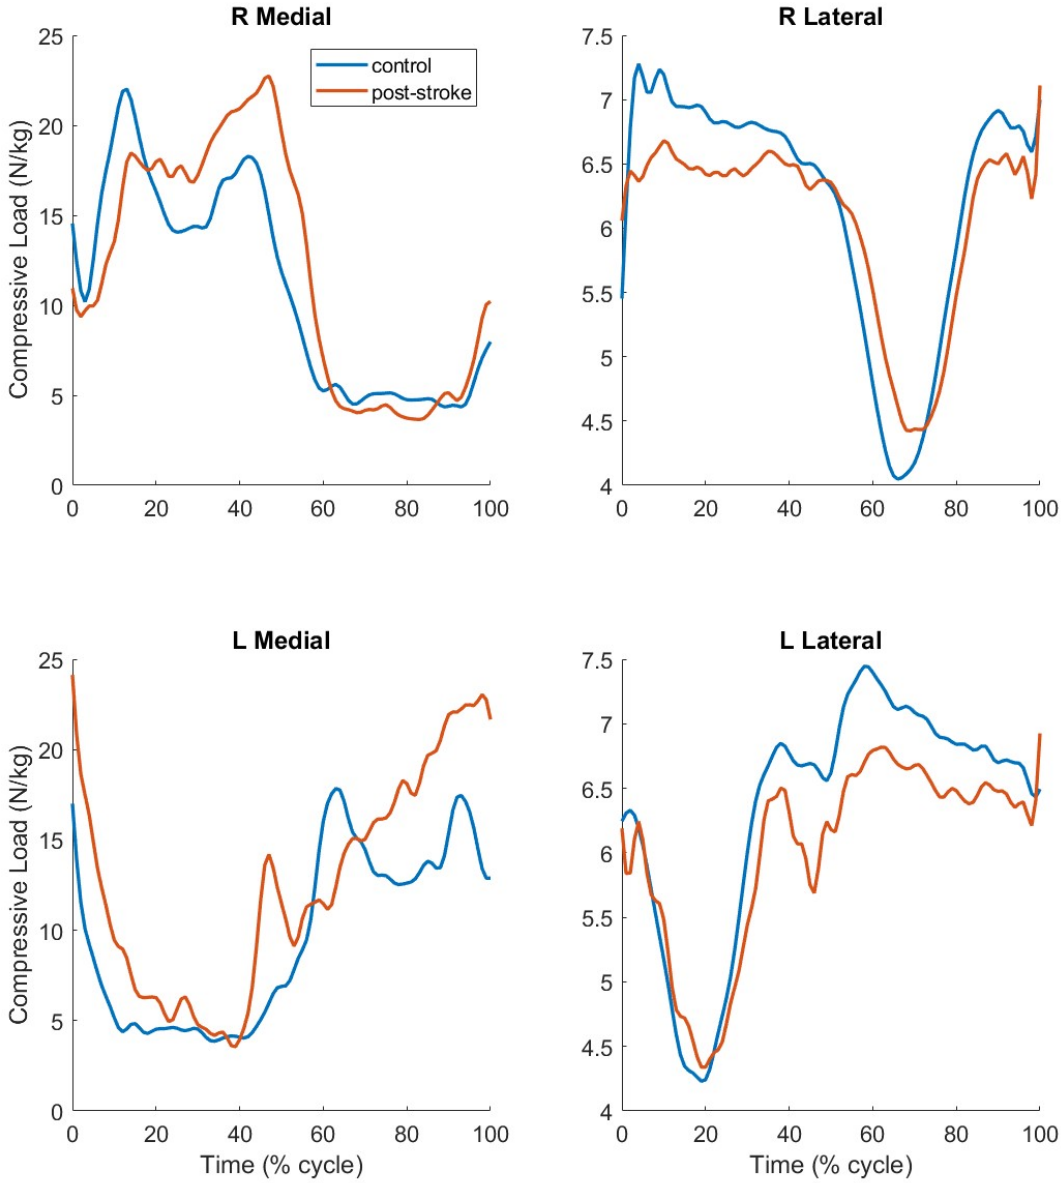
[1]Northwestern University, Chicago, IL, United States. [2]Illinois Math and Science Academy, Aurora, IL, United States. [3]Chapman University, Orange, CA, United States

Introduction

Stroke survivors experience gait impairments, including impaired muscle control and kinematic deviations [1], which likely alter knee joint loads, and may accelerate the development of knee osteoarthritis [2]. Osteoarthritis can further limit mobility for people post-stroke, compounding the burden of stroke-related disability [3]. We developed novel musculoskeletal models that use each participant's gait data to estimate knee loading during gait in people post-stroke and age-matched controls.

Methods

Fifteen people post-stroke (time post-stroke > 6 months, ability to walk independently for 5 minutes) and 12 age- and sex-matched controls participated in our study (Chapman University IRB 23-57). We recorded gait mechanics using marker-based motion capture, ground reaction forces, and electromyography while participants walked on an instrumented treadmill at their self-selected speed. A scaled 3-D model and the recorded gait data were inputs for an OpenSim Moco [4] Inverse optimization to compute muscle forces, which allow us to estimate medial- and lateral-compartment knee joint compressive forces. We compared these knee joint forces between groups and limbs.



Results

We have completed data analysis for two people post-stroke (right paresis, speeds 0.99 and 0.75 m/s) and two controls (speeds 1.5 and 1.4 m/s). Despite slower speeds, the average peak magnitude of the right (paretic) medial knee load in people post-stroke was comparable to that of controls (stroke=22.7 N/kg; control=22.0 N/kg), while the left (non-paretic) medial knee joint load was greater than that of controls (stroke=24.1 N/kg; control=17.8 N/kg). Future work will assess loading across the full sample and compare the speed dependence of knee joint loads.

Discussion

These preliminary findings suggest that knee joint loads are altered in people post-stroke, particularly on the non-paretic side. This may indicate an over-reliance on the non-paretic limb, which increases the risk of cartilage degeneration over time. Overall, this work addresses a critical gap in stroke gait rehabilitation and has the potential to reduce long-term disability and improve mobility for millions of stroke survivors.

Lower Limb Muscle Fatigue During Dry and Wet Treadmill Walking in Children with Cerebral Palsy

Mr. Sangyup Lee M.A., Mr. Joseph Harrington M.S., Dr. David Kingston Ph.d.

University of Nebraska Omaha, Omaha, Nebraska, United States

Introduction

Children with cerebral palsy (CP) experience local muscle fatigue during walking due to impaired neuromuscular control and reduced endurance[1,2]. Local muscle fatigue can be observed as a lowered surface EMG median frequency (MDF) over time[3,4]. This study compared lower-limb MDF changes across treadmill walking speeds and environments between children with CP and typically developing (TD) peers. We hypothesized that greater impairment (GMFCS II) would exhibit larger MDF decreases compared to less impaired (GMFCS I) and TD groups across walking environments.

Methods

Fifteen typically developing and 12 CP (GMFCS I = 7, II = 5) children walked for 3 minutes on a dry and wet treadmill at 75%, 100%, and 125% of their self-selected speed. Water depth was at the subject's xiphoid level. Surface EMGs were recorded from the tibialis anterior (TA), medial gastrocnemius (MG), rectus femoris (RF), and semitendinosus (ST) following SENIAM guidelines using waterproof sensors[5]. Each trial was divided into five time segments to quantify MDF changes, but segments 1 and 5 were compared here.

Results

The GMFCS II group had decreased MDF across all speeds and muscles on a dry treadmill (Left: - 4.7 Hz; Right: - 5.8 Hz; both p <.001). The TD group also had decreased MDF values, whereas GMFCS I had MDF increases in MG and ST in several conditions (Table 1). In the wet treadmill environment, the TA had decreased MDF across almost all conditions, while the left MG showed the largest change in GMFCS II at fast speeds. TD displayed minimal RF fatigue in water, whereas the CP groups showed increased left RF fatigue at both normal and fast speeds (Table 1).

Discussion

The GMFCS II group demonstrated consistent MDF declines across muscles and speeds during dry treadmill walking. This finding is similar to prior work where CP gait had a – 3.3

Hz MDF reduction at normal walking speed[6]. However, wet treadmill walking demonstrated fatigue in specific muscles likely due to aquatic modifications to gait mechanics[1-4,7]. These findings support that buoyancy and hydrodynamic resistance challenge neuromotor control and could suggest wet treadmill walking as a beneficial rehabilitation for children with CP[8].

Ertl and Non-Ertl balance strategy differences during quiet standing

Dr. Sara A. Mannello PhD, Dr. Abbie E. Ferris PhD

University of Northern Colorado, Greeley, CO, United States

Introduction

Traditional transtibial amputation methods have been associated with reduced loading of the prosthetic limb that may reduce stability. Improved loading and reduced asymmetries have been demonstrated in individuals with amputations that include a bone bridge (Ertl) compared to Non-Ertl amputations [1]. It is unknown how the Ertl method influences stability and balance. We hypothesize that postural stability measures will reveal differences between amputation techniques that exhibit reduced postural sway and improved interlimb symmetry during quiet standing in those with Ertl amputation.

Methods

Ertl (n = 11, 79.4 ± 16.7 kg, 1.77 ± 0.08 m) and Non-Ertl (n = 7, 88.3 ± 16.0 kg, 1.78 ± 0.08 m) participants stood with feet on separate force plates (AMTI, Watertown, MA) with or without a foam mat and with eyes open or closed for 20s. COP, Rambling-Trembling, and symmetry measures were calculated and compared between groups and conditions.

Results

Compared to the Non-Ertl group, the Ertl group had significantly greater overall COP RMS values (Ertl Prosthetic = 514.74 ± 213.65 mm, Intact = 485.54 ± 176.99 mm vs. Non-Ertl Prosthetic = 358.96 ± 56.12 mm, Intact = 374.02 ± 50.22 mm) for prosthetic and intact limbs. Symmetry indices indicated small prosthetic dominance in the Ertl group in the ML and RMS Rambling/Trembling mean velocities while the Non-Ertl group had greater asymmetry with preference for the intact limb especially for COP mean velocity (-11.44 ± 21.64% vs. Ertl 7.20 ± 33.13%). Examination of Rambling-Trembling measures revealed significantly increased Rambling across in the Ertl group (Table 1). Trembling only showed increases in the Ertl prosthetic limb AP velocity and RMS with more variability across individuals.

Discussion

Overall, the groups appear to use different strategies to maintain balance in quiet stance. The non-Ertl group had less postural sway and preference for the intact limb, while the Ertl

group had greater sway with a preference for the prosthetic limb. It appears that the additional manipulation of the internal structure as part of the Ertl method provides the opportunity for more loading and results in individuals utilizing different strategies for balance control.

Muscle Activation Patterns During Lifting in Individuals with Large to Massive Rotator Cuff Tears: Adaptive vs. Limited Responders

Ms. Sarah Remedios MSc[1,2], Dr. Ivan Wong MD FRCS(C), Dip. SPORTS MED, MACM, FAANA[1], Dr. Kathleen MacLean PhD[1], Dr. Janie Astephen Wilson PhD[1], Dr. Derek Rutherford PT, PhD[1]

[1]Dalhousie University, Halifax, Nova Scotia, Canada. [2]Nova Scotia Health, Halifax, Nova Scotia, Canada

Introduction

Rotator cuff tears (RCT) result in altered shoulder function, such as limited range of motion (***limiters)***. However, some adults with RCTs adapt and demonstrate full shoulder motion (***adapters)***. This study aims to determine muscle activation patterns and range of motion during a lifting task between asymptomatic older adults (ASYM) and patients with a large-to-massive RCT (***adapters***, ***limiters***).

Methods

ASYM were recruited from the community (n=20). Patients with >3cm RCT were recruited from an orthopaedic clinic (N=39). The RCT group was divided into ***adapters*** *(*n=21*)* if peak active thoracohumeral flexion measured with optoelectronics was within one standard deviation of the ASYM average. Remaining RCT were classified as ***limiters*** (n=18) (Fig1). Electromyography of six shoulder muscles and optoelectronics were collected during flexion with a 2.5% body mass load to a shoulder height target. Signals were low pass filtered, time normalized to 100% of the lift cycle, and amplitude normalized to percent peak muscle activity. Principal component analysis (PCA) was used to analyze all %peak waveforms, and principal patterns (PP) were assessed for differences between groups and interactions with muscle (2-way ANOVA, =0.05).

Results

No significant thoracohumeral angle differences were found between ***adapters*** and ***limiters*** (54.4º±19.4 vs. 48.4 º±14.3,p>0.05) and both less than ASYM (78.5º±5.2,p<0.05). Three PPs were identified to represent >95% of variance. Significant group by muscle interactions were found for all *PP-scores*. RCT groups showed greater anterior deltoid *PP1-scores* (more activity) (p<0.05), only ***limiters*** had smaller lower trapezius *PP1-scores* (less activity) (p<0.05) than ASYM. ***Limiters*** had lower infraspinatus

and lower trapezius *PP2-scores* (smaller lift phase differential) than both ***adapters*** and ASYM ($p<0.05$). Upper trapezius and supraspinatus *PP2-scores* were smaller in RCT groups than ASYM ($p<0.05$). RCT groups exhibited greater deltoid *PP3-scores* than ASYM ($p<0.05$) (bigger lower phase differential).

Discussion

Limiters consistently demonstrated restricted motion and elevated activation demands in agonist and synergist muscles. a***dapters*** often resembled ASYM patterns. Findings suggest some distinct activation strategies between RCT subgroups compared to asymptomatic individuals during lifting. Clinically, the similarity of ***adapters*** to asymptomatic patterns and the heightened demands in ***limiters*** indicate RCT patients may require subgroup-specific rehabilitation approaches.

40 Hz Transcranial Vibration Enhances CSF Hydrodynamics: A Finite Element Study of the Entire Head

Ms. Seo Hyun Lee student, Mr. Taehyun Kim student, Prof. Namkeun Kim Professor

Sogang University, Seoul, Seoul, Korea, Republic of

Introduction

Current research on Alzheimer's disease (AD) depends heavily on clinical trials. However, these trials often lack a clear explanation of the physical mechanisms. Therefore, we need a computational head model to simulate physical interactions inside the head. Specifically, modeling the hydrodynamics of cerebrospinal fluid (CSF) is critical. CSF dynamics play a key role in removing toxic proteins. This study analyzes the hydrodynamic effects of 40 Hz vibration on waste transport in CSF using a whole-head finite element model.

Methods

We constructed a whole-head finite element model and validated it using magnetic resonance elastography data.[1] We defined brain tissue as a linear viscoelastic solid. We modeled the CSF using the linearized Navier-Stokes equations to represent fluid behavior. After validation, we applied 40 Hz vibration to the skin. This replicated the parameters of the AriBio HERZION device. Our analysis was based on Taylor Dispersion Theory, which suggests that high velocity gradients help mix and remove waste.[2] We measured velocity gradients and energy intensity in the CSF to evaluate potential for waste clearance.

Results

The simulation results showed distinct velocity gradient hotspots in the lateral CSF regions under 40 Hz stimulation. We compared 40 Hz vibration with 50 Hz and 60 Hz. The 40 Hz vibration generated significantly higher energy intensity and larger velocity gradient hotspots. Also, we found a direct positive correlation between energy intensity and the size of velocity gradient hotspots. These findings confirm that external vibration creates internal velocity gradients needed for fluid mixing.

Discussion

This study is the first to quantitatively show the mechanical impact of 40 Hz vibration on CSF hydrodynamics. The main contribution is the structure of the model. Unlike other studies that simplify CSF as a solid, our model treats CSF as a fluid. This allows us to observe how substances move. Also, including the skin and skull allows accurate

simulation of vibration from the outside to the inside. Future research will build models with AD pathologies to compare them with healthy brain models.

Proposed Symptom-Avoidance Strategies in Femoroacetabular Impingement Syndrome Identified Through 3D Shape-Kinematic Correlates

Mr. Seth Kussow MS, Dr. Jared Zitnay PhD, Mr. Rich Lisonbee MS, Dr. Stephen Aoki MD, Dr. Travis Maak MD, Dr. Andrew Anderson PhD

University of Utah, Salt Lake City, Utah, United States

Introduction

Cam morphology is prevalent in femoroacetabular impingement syndrome (FAIS), yet ~35% of the general population exhibits cam morphology without symptoms [1], indicating morphology alone does not dictate pathology. Combining statistical shape modeling (SSM) with biplane fluoroscopy (BF) enables precise 3D characterization of morphology and in vivo motion, overcoming limitations of traditional methods. Herein, we aimed to identify hip shape-motion relationships underlying FAIS symptom-avoidance strategies.

Methods

Symptomatic FAIS patients (n=23) and asymptomatic individuals with (positive controls; n=14) and without (negative controls; n=11) cam morphology were recruited. CT/MRI data were segmented to reconstruct 3D femur and pelvis surfaces for SSMs (femur: 2048 particles; pelvis: 4096 particles; ShapeWorks) and to measure 3D hip and pelvis kinematics from BF data while treadmill walking. Group mean SSM principal component (PC) score contributions were compared and group kinematics differences were assessed at push-off (PO) and heel-strike (HS) using ANOVA (α=0.05). Linear regression was evaluated between groupwise different PC scores and kinematic metrics across the cohort and within groups.

Results

FAIS patient femurs exhibited a more prominent cam region and greater neck-shaft angle, reflected in higher femur PC mode 4 scores versus negative controls (**Figure 1**). Patients demonstrated greater hip external rotation at PO (3.61° ± 5.78°) and less relative posterior pelvic tilt at HS (-0.57° ± 3.25°) than negative controls (hip ext. rotation: -2.03 ± 4.59°, p=0.02; pelvic tilt: -3.39 ± 2.73°, p=0.04), but not positive controls (hip ext. rotation: 2.92 ± 5.72°; pelvic tilt: -0.39 ± 2.86°). Femur mode 4 displayed a strong, negative correlation with pelvic internal rotation at PO across positive controls (**Figure 1**) and a negative correlation with hip flexion across the cohort at HS.

Discussion

FAIS patients had distinct femoral morphology and altered hip and pelvis kinematics compared to negative controls, aligning with prior work [2]. Positive controls with patient-like femurs may avoid FAI symptoms by increasing pelvic internal rotation at PO. Findings highlight pelvic mobility as a therapeutic target in FAIS treatment and support phenotyping FAIS for patient-specific interventions.

Images (Optional)

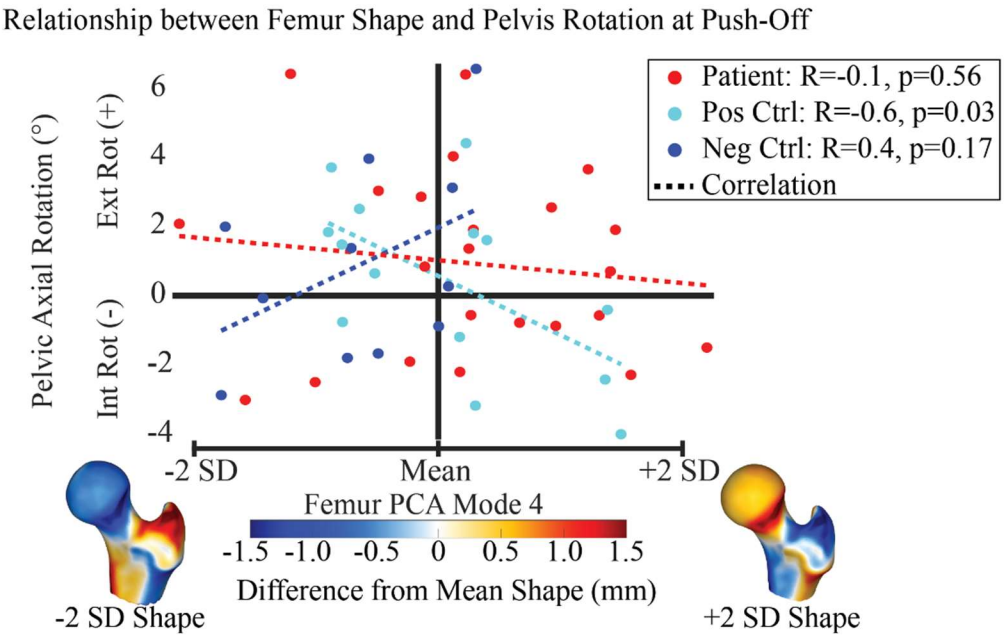

Figure 1: Positive controls with more patient-like femurs displayed a more internally rotated pelvis at push-off, as indicated by a strong correlation between PC score and internal pelvis rotation. Regression lines (top) highlight a stronger correlation for positive controls than patients. Shape variation along ±2 SD of femur PC mode 4 (bottom) that significantly differs between patients and negative controls ($p<0.05$) where patients had more positive PC scores. Red and blue in colormaps indicate regions where bone is more or less prominent compared to the population mean femur shape, respectively.

Gait Gear Shifting: Age and Perception Modulate Walking Speed

Ms. Silvia Campos-Vargas[1], PhD Kenneth Harrison[1], PhD Redden David[2], PhD Jaimie Roper[1]

[1]Auburn University, Auburn, Alabama, United States. [2]VCOM-Auburn, Auburn, Alabama, United States

Introduction

Gait speed is a crucial marker of mobility and falls risk in older adults (OA), but how individuals adjust gait speed with aging and verbal instructions remains unclear. In younger adults (YA), gait speed varied (0.91–2.16 m/s) across 24 prompts [1], showing high adaptability. Extending this to OA, verbal instructions explained 76.1% of variance, suggesting modulation strategies change with age [2]. This study examines age-related differences in gait speed adaptability, hypothesizing that YA exhibit more gait groupings while OA show reduced variability and stronger cue dependence.

Methods

49 Auburn University participants. 26 YA (21±2 years) and 23 OA (70±5 years), completed gait trials on a 5.8-meter walkway following 24 randomized walking instructions. Inclusion required no lower extremity injuries for 6+ months. K-means clustering identified gait-speed patterns with and without verbal instruction consideration. Silhouette analysis validated cluster quality, and relative instruction contributions were calculated using the distance of each instruction from its specific cluster center.

Results

Without instructions, YA exhibited 4 gait-speed clusters (average 1.1–1.4 m/s) versus 3 in OA (1.1–1.2 m/s) in the clusters, indicating reduced speed range. With instructions, cluster numbers remained stable but revealed distinct modulation patterns. YA, explaining 79% variance, showed Low Demand, Comfortable, Hustle, and Maximal (as fast as possible, 100% loading) clusters. Older adults demonstrated three clusters, accounting for 77% of the variance: Comfortable, Hustle, and Maximal (Figure 1). Critically, the "fast as possible" instruction was only in YA but was in Maximal for OA with urgency cues.

Discussion

This study highlights age-related differences in gait-speed modulation. Younger adults exhibited 4 distinct speed clusters, whereas older adults showed only 3, indicating decreased adaptability with age. Notably, the "fast as possible" instruction triggered a separate cluster solely in younger adults (100% loading). In older adults, this cluster

merged with the contextual urgency cues to form the Maximal cluster. It is worth considering whether this absence reflects an actual limitation or a decline in rarely-used reserve capacity, as meaningful comparisons should focus on real-world speeds.

Instrumented Timed Up and Go in Younger Adults: Variability of Neuromechanical and Spatiotemporal Parameters Using an 18-Sensor Inertial Measurement System

Prof. Slawomir Winiarski DSc, Associate Professor, Eng[1], Doctor Mateusz Kowal PhD in Medical Sciences, PT[2], Doctor Ewa Morgiel PhD in Medical Sciences[2]

[1]Wroclaw University of Health and Sport Sciences, Wroclaw, -, Poland. [2]Wroclaw Medical University, Wroclaw, -, Poland

Introduction

Quantifying neuromechanical control during functional mobility tasks is essential for clinical biomechanics. The instrumented Timed Up and Go (iTUG) test enables detailed assessment of movement phases relevant to balance, gait and transitional control [1]. However, normative data for younger adults remain limited [2]. This study characterises the variability of spatiotemporal and kinematic parameters of the iTUG in healthy younger adults to inform clinical interpretation and contribute reference values for research and therapeutic monitoring.

Methods

Seventy-three physically active adults (20–40 years) performed a standardised iTUG under laboratory conditions. Eighteen inertial measurement units (Noraxon MyoMotion) recorded 3-dimensional trunk and limb kinematics @200 Hz. The test was segmented into sit-to-stand, walking, turning and stand-to-sit phases. Descriptive statistics, ranges of motion (ROM) and coefficients of variation (CV) quantified variability across temporal, spatial and kinematic metrics.

Results

Total iTUG time demonstrated low variability (13.1 ± 1.9s, CV 14.8 %). Walk 1 and Walk 2 phases showed average variability (CV 20–23%), whereas Turn 1 exhibited low variability (CV 19,5%). Most gait parameters, including stride time (CV 7.7 %), stance and swing proportions (CV 3–6%), and foot pitch at foot -off (CV 12–14 %), were highly consistent across individuals. In contrast, derived asymmetry indices showed markedly elevated variability, particularly the double-support ratio (CV 271.5 %). Trunk-related variables displayed phase-dependent behaviour: ROM values presented average to high variability (eg, trunk rotation ROM CV 43.1%), while trunk velocity parameters during sitting transitions showed very high to extremely high variability (CV up to 373.6 %).

Discussion

Neuromechanical performance during the iTUG is highly consistent in younger adults for key temporal and gait-cycle parameters, supporting their use as normative biomechanical references. Elevated variability in trunk ROM and trunk speed metrics suggests individual movement strategies during transitional phases, indicating sensitivity to motor control differences. Extremely variable asymmetry indices demonstrate limited utility for normative interpretation but potential value as markers of pathology. The findings support the iTUG as a trastwothy, sensor-based assessment for clinical biomechanics and research requiring precise functional mobility characterisation[3].

Fundamental Study on a Predictive Diagnostic Method for Abdominal Aortic Aneurysm Expansion Using Thermal Expansion Analysis

Professor Sota Yamamoto[1], Mr. Ziyi Ye[1], Mr. Masayuki Kamada[1], Dr. Katsuyuki Hoshina[2], Dr. Ken Kimura[3]

[1]Shibaura Institute of Technology, Koto-ku, Tokyo, Japan. [2]The University of Tokyo Hospital, Bunkyo-ku, Tokyo, Japan. [3]Kyorin University Hospital, Mitaka, Tokyo, Japan

Introduction

Abdominal aortic aneurysms (AAAs) primarily affect older adults and require annual imaging follow-ups to monitor growth, imposing burdens on patients and healthcare systems. A predictive diagnostic method estimating future expansion could reduce these burdens by extending follow-up intervals without compromising safety. However, CT imaging provides only static geometry, posing challenges for predictive diagnosis.
We propose a novel framework combining finite element analysis (FEA) with thermal expansion modeling to predict future AAA geometry. Patient-specific CT data are used to reconstruct aneurysm geometry, inflate a cylindrical finite element model (FEM) within the lumen, and compute local expansion rates from node displacement and strain invariants. These rates are converted into thermal expansion coefficients, enabling time-dependent prediction by simulating temperature change.

Methods

AAA geometry was reconstructed from annual CT scans. A rigid wall model was generated, and a cylindrical shell-element FEM was positioned inside and inflated under controlled pressure. Local expansion rates were estimated by projecting FEM nodes onto the aneurysm wall and calculating strain invariants. Rates were translated into thermal expansion coefficients, with time modeled as temperature change. Calcified regions identified by Li et al. (2008) were assigned zero expansion. Two prediction strategies were tested: element-wise local rates and uniform average rates. Predicted third- and fourth-year geometries were compared with actual CT data using diameter and surface deviation metrics.

Results

The proposed predictive method was applied to longitudinal CT data from one AAA patient over four years. The constructed FEM consisted of 8,540 elements spanning from the renal artery bifurcation to the iliac bifurcation. The FEM-based approach successfully estimated local expansion rates between the first and second years and predicted the third-year

geometry using thermal expansion analysis. The element-wise expansion approach showed substantially higher accuracy than the uniform expansion model.

Furthermore, the fourth-year geometry predicted from second-year expansion rates closely matched the actual CT-derived geometry, especially in the regions of maximal expansion.

Discussion

This framework demonstrated feasibility for predicting AAA progression and clinically relevant indices such as maximum diameter. Incorporating spatial heterogeneity and calcification enhanced accuracy. Future work will expand patient cohorts, optimize mesh resolution.

Assessment of Fall Risks With Multi-Directional Perturbations in Young, Older Adults, and Older Adults With High Fall Risk

Ms Soyoung Lee PhD[1], Mr Wei Yin PhD[2], Mr Zongpan Li PhD[1], Ms Peiwen Fu[1], Mr Matteo Pergami-Peries PhD[1], Mr Li-Qun Zhang PhD[1]

[1]University of Mryland Baltimore, Baltimore, Maryland, United States. [2]New Jersey Institute of Technology, Newark, New Jersey, United States

Introduction

Reactive balance to perturbations is important for preventing falls, yet how multidirectional responses differ with aging and fall risk remains unclear. We compared center-of-pressure (COP) stability, COM (center of mass) acceleration, and COP trajectory orientation between young healthy (HY), healthy older (HO), and high fall-risk older (HFR) adults during multidirectional footplate perturbations.

Methods

Thirty-one adults stood on a moveable platform delivering horizontal translations in eight directions at 45° intervals under eyes-open conditions. COP trajectories were recorded by force plates and COM acceleration by an IMU at L5. For each trial we calculated COP stability index (SI), peak COM acceleration (pACC), and COP angular deviation from the perturbation direction. SI was the farthest COP distance from the base-of-support center normalized to the distance from center to boundary (range 0–1). COP angle deviation (AD) was the angle between the reversely extended perturbation line and the line from the base-of-support center to the farthest COP location. One-sample t-tests tested AD against 0° within each group and direction. One-way ANOVA with Tukey post-hoc tests compared SI and pACC across groups.

Results

Across all three groups, COP AD during four oblique perturbations was consistently deviated to the lateral direction (~10–20°, $p < 0.05$), whereas AD for anterio-posterior and left-right perturbations did not differ from 0° (Figure 1). SI showed significant group effects in lateral and posterior-oblique directions (lateral: $p = 0.03$; postero-medial: $p = 0.03$; postero-lateral: $p = 0.01$), with older groups, particularly HFR, exhibiting less COP movement than HY. pACC differed by group for anterior ($p < 0.001$) and postero-lateral ($p = 0.031$) perturbations; HY showed smaller peak accelerations than both HO and HFR, while HO and HFR were similar.

Discussion

Multidirectional perturbations revealed a common pattern of COP lateral deviation during oblique perturbations across groups, suggesting higher risk in lateral than AP directions. Aging and high fall risk showed reduced ability to change COP with perturbations and greater COM accelerations and instability in specific directions. Combining COP SI, COM acceleration, and COP AD provides a direction-resolved approach to detect lateral instability and design oblique- and lateral-focused fall-prevention training for older adults at risk of falls.

Images (Optional)

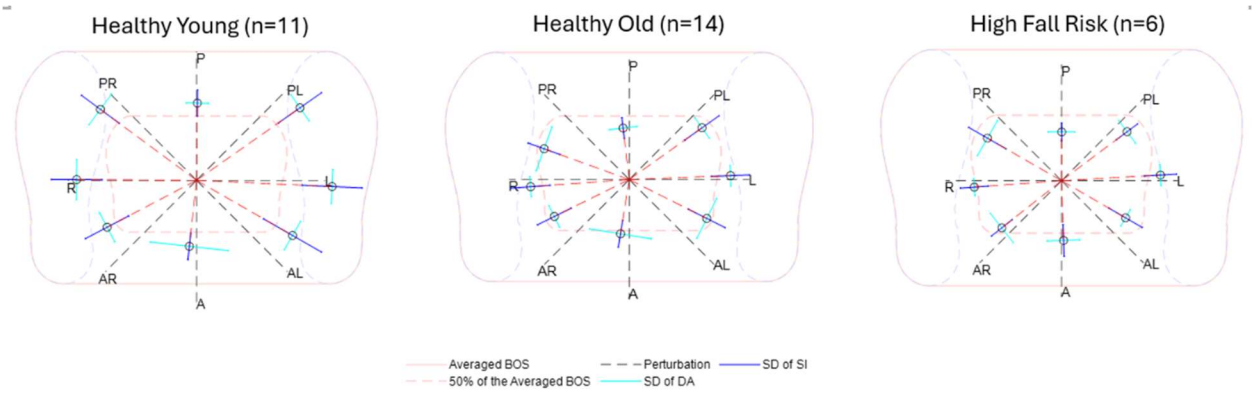

Figure 1. SI and DA across all groups during perturbations in the 8 directions. Along the radial distance, the circles and the lines show the mean and standard deviation (SD) of SI across all subjects, respectively. On the polar angle, the circles and the lines show the mean and SD of DA across all subjects, respectively. A, AR, R, PR, P, PL, L, and AL correspond to linear perturbations in Anterior, Anterior-Right, Right, Posterior-Right, Posterior, Posterior-Left, Left, and Anterior-Left directions, respectively. Participants Characteristics: Age (HY=28.7±4, HO= 73.5±3.7, HFR= 22.7±2.9), BMI (HY=23.1±3.7. HO=27.6±3.9, HFR=22.7±2.9).

Application of Lateral Pressure to the Buttocks Improves Tissue Perfusion in the Seated Patient

Miss Maegan Spiteri[1], Professor Peter Worsley[2], Professor Spyros Masouros[1]

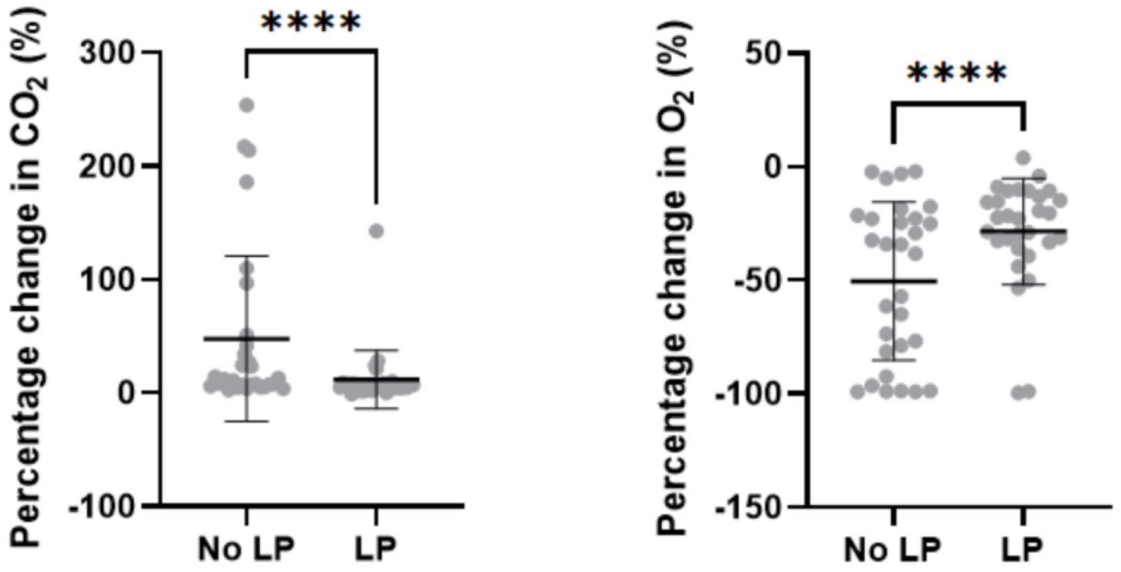
[1]Imperial College, London, London, United Kingdom. [2]University of Southampton, Southampton, Hampshire, United Kingdom

Introduction

Prolonged sitting increases pressure-ulcer (PU) risk for individuals with limited mobility such as the elderly and wheelchair users. During loading, blood vessels are occluded, O_2 is obscured, and CO_2 accumulates causing PUs [1]. Current prevention methods used in healthcare aim to reduce underbody pressure by increasing contact area through compliant surfaces, but evidence suggests that these devices don't reduce the tissue stresses deeper, at the bone-tissue interface [2]. Finite-element studies have shown that applying lateral pressure (LP) can mitigate the internal stresses [3]. Transcutaneous oximetry is commonly used in PU research as a surrogate measure of local tissue perfusion and ischaemic burden [4]. This study compares the ability of a novel LP device with a standard static foam chair to maintain baseline transcutaneous gas tensions during sitting.

Methods

Transcutaneous CO_2 and O_2 were recorded at the ischial tuberosity in 30 healthy adults using an oximeter. Participants underwent 20 minutes sitting on static-foam, 10 minutes standing to re-establish baseline, then 20 minutes sitting with the LP device. Percentage deviations from physiological baseline were determined and interpreted using Chai and Bader's classification [5]. Underbody pressure was obtained with a pressure-sensing mat. Statistical comparisons were performed using paired, one-tailed Student's t-tests.



Results

The cohort (mean age 28.9 years, 20–59; mean BMI 25.5 kg/m^2, 18.7-40.9) showed substantially improved tissue gas responses with LP. CO_2 elevations fell from +47.8% on foam to +11.9% with LP ($p < 0.0001$), while O_2 deficits improved from –50.4% to –28.5% ($p < 0.0001$). LP produced significantly lower mean and peak underbody pressures ($p < 0.0001$).

Discussion

These results suggest that lateral pressure may be more effective than static-foam in PU prevention for seated individuals. While underbody pressure decreased in every participant, the inconsistent gas-tension changes further demonstrates that pressure does not reliably represent tissue perfusion. Nonetheless, the young, healthy sample limits generalisability to higher-risk clinical populations.

Afferent feedback increases simulated upper-limb tremor but has little effect on tremor propagation patterns

Mr. Ian Syndergaard BS[1], Dr. Daniel Free PhD[1], Prof. Dario Farina PhD[2], Prof. Steven Charles PhD[1]

[1]Brigham Young University, Provo, UT, United States. [2]Imperial College London, London, Greater London, United Kingdom

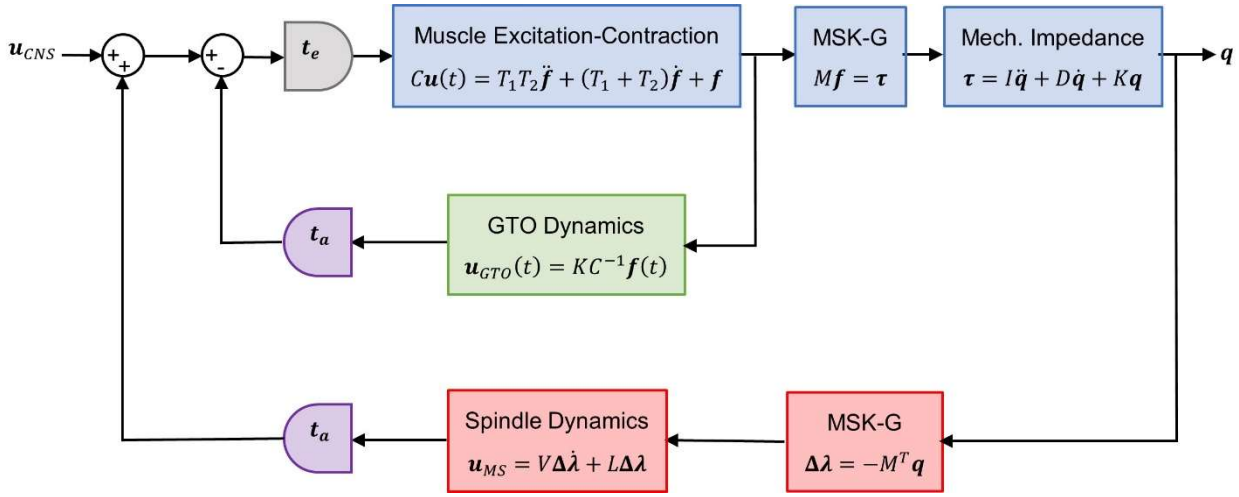
Introduction

Tremor is the most common movement disorder, often impairing daily activities [1]. Many peripheral tremor suppression techniques have been proposed, including injections of botulinum toxin, low-level electrical stimulation, and low-pass filtering orthoses. However, optimally implementing these techniques requires a deeper understanding of tremor propagation, i.e. how tremorogenic excitation to muscles creates tremor throughout the upper limb. Past simulations of tremor propagation have yielded important principles [2], but these simulations did not include afferent feedback, which may have a significant effect on tremor. The purpose of this study was to simulate the effect of short-loop afferent feedback on tremor propagation.

Methods

We used a recently developed closed-loop model of the upper limb [3] to simulate tremor propagation (see figure). Model inputs were tremorogenic excitation to the 15 major superficial muscles of the upper limb, and model outputs were tremulous rotation in the seven main joint degrees of freedom of the upper limb. Short-loop afferent feedback was modeled as homonymous feedback via Golgi tendon organs (GTO), homonymous and heteronymous feedback via muscle spindles, and neural transmission delays. Simulations across four postures and varied physiological parameters assessed tremor under different feedback conditions.

Results



Simulated GTO-mediated feedback amplified responses at tremor frequencies by 44% on average (range 11-95%). This amplification increased with transmission delay, so the greatest amplification occurred for tremor caused by distal muscles. In contrast, spindle-mediated feedback had minimal impact at tremor frequencies. Combined feedback effects were approximately additive. Tremor propagation patterns remained consistent across conditions; as without feedback, wrist muscles contributed most prominently to

simulated tremor, which appeared greatest in wrist degrees of freedom. Trends were robust across postures and physiological parameter ranges.

Discussion

According to our simulations, afferent feedback amplifies tremor by about 50% but does not significantly alter propagation patterns. Therefore, tremor propagation (how tremorogenic excitation of a given muscle creates tremor throughout the upper limb) depends primarily on mechanical coupling (multi-articular muscles and interaction torques), not neural coupling (heteronymous feedback).

Age-Dependent Biomechanical Properties of Japanese Children's Skulls: Implications for Injury Risk and Protection Strategies

A. Prof Suguru Torimitsu

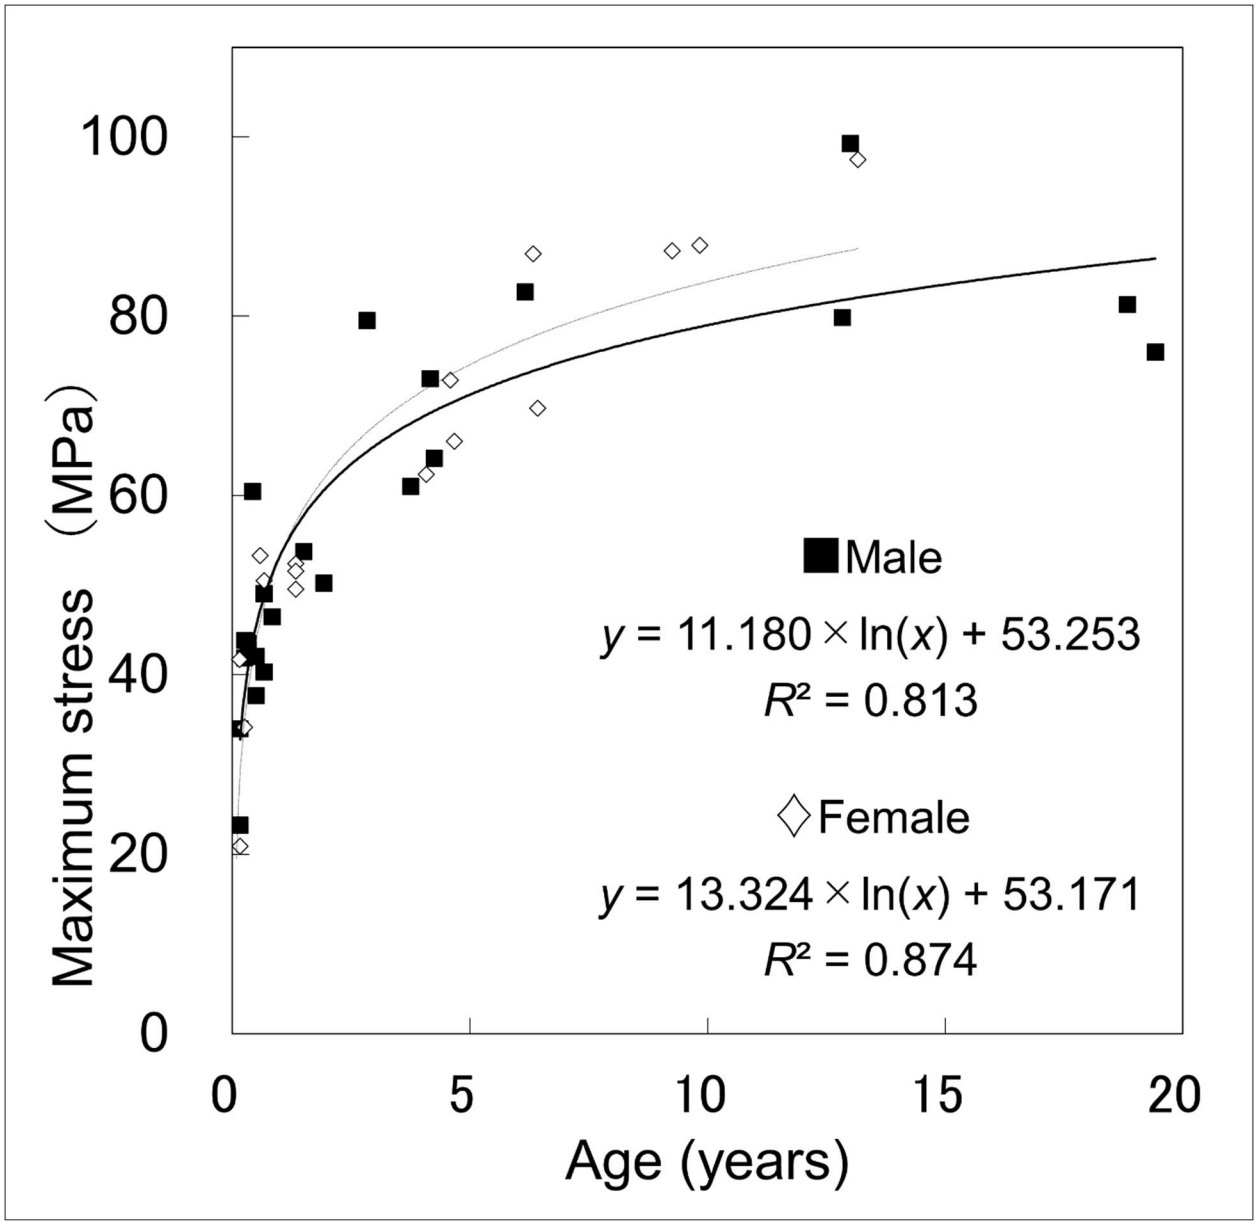
The University of Tokyo, Bunkyo-Ku, Tokyo, Japan

Introduction

Head injuries are a leading cause of death in children worldwide. Pediatric skull fractures, often resulting from falls, traffic accidents, or abuse, require accurate biomechanical understanding for forensic and clinical evaluation. However, data on skull strength and thickness in children remain limited.

Methods

Skull samples were collected from 42 Japanese deceased individuals aged 0–19 years during autopsy. Bone specimens from frontal, parietal, and occipital regions were collected using calipers. Three-point bending tests were performed to assess mechanical properties, including Young's modulus, 0.2% proof stress, and maximum stress. Linear regression analysis was conducted using age (log-transformed) as the independent variable.



Results

A total of 170 samples were analyzed. In children under 1.5 years, 34 out of 86 samples did not fracture under testing, indicating low stiffness. No significant sex differences were found in thickness or mechanical properties. All parameters—thickness, Young's modulus, 0.2% proof stress, and maximum stress—increased significantly and logarithmically with age (R^2 = 0.761–0.899).

Discussion

This study demonstrates that preschool children's skulls are thin and mechanically weak, making them highly susceptible to fractures from minor external forces. The absence of sex differences contrasts with adult skull biomechanics. These findings provide essential data for injury prevention, forensic analysis, and finite element modeling of pediatric head trauma.

A Scoping Review of the Utility of Low-Cost Markerless Motion Capture in Clinical Practice

MSc. Thiago Vidal Pereira[1,2], PT. Romina Perrotti[1,2], Dr. Guillaume Durandau[3,2], Dr. Joyce Fung[1,2]

[1]McGill University School of Physical and Occupational Therapy, Montreal, Quebec, Canada. [2]Feil/Oberfeld/CRIR Research Centre, Laval, Quebec, Canada. [3]McGill University Department of Mechanical Engineering, Montreal, Quebec, Canada

Introduction

Low-cost markerless motion capture (MMC) is emerging as a practical alternative to observational gait analysis because it is portable, inexpensive, quick to use, and requires less technical expertise than conventional marker-based systems. Although the technology is progressing rapidly, its use in clinical decision-making remains limited. This review synthesizes the current practice of MMC, its feasibility in clinical settings, and the remaining gaps that must be addressed for successful clinical integration.

Methods

We conducted a scoping review of MMC for gait analysis by searching PubMed and Ovid MEDLINE for peer-reviewed studies published in 2022 or later. Eligible studies used smartphones or other mobile devices and required minimal to no manual processing. We also screened open-source systems available through GitHub and arXiv preprints. We extracted information on the technology, study design, relevant clinical measures, factors that affect implementation, and any evidence supporting integration into clinical decision-making workflows.

Results

Nine peer-reviewed studies and one preprint were selected after critical appraisal. Four studies used single-camera smartphone systems and consistently reported small joint-angle differences compared with marker-based or multi-view systems during walking in healthy or athletic populations. The remaining studies used multi-view approaches with two or more smartphone cameras, in conjunction with open source, cloud-based applications such as OpenCap. These systems generally showed smaller or similar 3D errors than single-view systems, had a good consistency across repeated measurements and also included participants with neurological conditions.

Discussion

Most studies focus on whether MMC can replicate measurements from marker-based systems, but evidence on clinical utility remains limited. Advancing toward real-world adoption will require research conducted in close collaboration with clinicians to determine how MMC outputs can meaningfully support rehabilitation decision-making and successful integration into clinician routines. Such partnerships are essential for understanding how these technologies can meaningfully inform clinical decision-making in rehabilitation settings and for determining whether clinicians can effectively integrate MMC into their routines. Future work should evaluate alignment with clinical workflows, optimize presentation of results to guide decisions, explore integration with electronic health records, and examine whether MMC-informed assessments lead to better clinical outcomes than observational gait analysis.

Introduction

Return-to-sports (RTS) criteria after anterior cruciate ligament reconstruction (ACLR) usually focus on strength, patient-reported outcomes, and hop distance, but fail to predict outcomes accurately. Biomechanics are increasingly used to determine RTS readiness and reinjury risk. However, there is no classification that can help with RTS assessment. This study aimed to create a biomechanics-based classification using artificial intelligence to improve the RTS evaluation.

Methods

Forty-four physically active subjects, 7-9 months post-ACLR, performed a single-leg horizontal hop test. Kinematics were collected using an 8-camera motion analysis system with reflective markers. Participants also completed isometric hip and knee strength tests, the International Knee Documentation Committee (IKDC) questionnaire, and the visual analogue scale for pain. Profiles were identified using principal component analysis to extract variables from the landing phase, followed by self-organizing maps and k-means clustering. Profiles were compared using the Kruskal-Wallis test ($\alpha=0.05$). Differences were considered significant when having large effect sizes (Cohen's $d > 0.8$).

Results

Four profiles were identified (Figure 1). Profile 1 (Dynamic Valgus): good hop performance (63.4 %Ht [percentage of height) and high IKDC scores, but presented a quadriceps-dominant strategy and knee valgus (2.2°) at landing. Profile 2 (Return to Play): good hop performance (64.3 %Ht), adequate knee flexion (48.7°) and trunk flexion (31.1°), with excellent pelvic and hip control, the highest muscle strength, and mild/no pain. Profile 3 (Weak Group): adequate hop performance (59.6 %Ht), but with hip and knee weakness, moderate IKDC scores, and compensatory landing mechanics such as hip abduction (2.2°) and knee varus (3.6°) and internal rotation (-4.2°). Profile 4 (Low Performance): worst hop performance (45.3 %Ht), minimal knee (34.8°) and trunk flexion (17.1°), increased hip adduction (4.4°) and knee varus (3.4°), weak extensors, and potential kinesiophobia.

Discussion

Machine learning identified four distinct landing strategies in ACLR patients, providing a biomechanical classification to help with RTS decisions. Profile 1 has an increased risk of reinjury and requires neuromuscular training; Profile 2 is ready for RTS depending on pain management; Profile 3 needs strength training; Profile 4 must address both physical and psychological barriers. Biokinetic profiling may optimize RTS assessment and enable personalized rehabilitation strategies, potentially reducing reinjury risk.

Community-Dwelling older Adults use Different Gait Strategies During Dual-Task and Fast Gait, but Strategies Are Not Affected by Timed Up and Go Time, Handgrip Strength, or Fall History

Dr. Tiphanie E Raffegeau PhD[1], Dr. Kelly Poretti PhD[1], Ms Eter Mjavandze MS[2], Ms Dieanna C Prudholme MS[1], Mr Ahmadreza Souri MS[1], Dr. Emily S Ihara PhD, MSW, FGSA[2], Dr. Catherine J Tompkins PhD, MSW[2], Dr. Angela Miller PhD[2], Dr. Jatin Ambegaonkar PhD, ATC OT[1]

Introduction

Community fall prevention partnerships may reveal more ecologically valid results than controlled laboratory-based projects. We provided community-based health assessments via our Balance for Wellness program and examined fall-risk factors in older adults (>55 years) in a large metropolitan region. Our purpose was to determine how common clinical measures, e.g., Timed Up and Go (TUG) time (seconds, high>12, low<12), fall history in the previous 6 months (yes, no), handgrip strength (kilograms, strong > 22, weak < 22), affect gait strategies during challenging gait tasks.

Methods

In addition to common clinical tests, 129 participants (106 women, Mean(SD), Age =75.3 (7.7) years) completed three walking trials: self-paced (ST), self-paced during a verbal fluency dual-task (Dual Task-DT) (e.g. list zoo animals) and fast walking (FW) in a fixed order along a 16-foot long pressure-sensitive mat (Protokinetics, Zeno mat). We calculated DT and FW gait strategies by determining the combined percent change in step length and step time relative to ST (Length-time difference, LTD), a positive value indicates a step length dominant strategy and negative values indicate a step time dominant strategy. We used two-way mixed ANOVAs to analyze differences in LTD between clinical factors (i.e. TUG time: lower limb strength, handgrip strength, and falls history) across conditions (DT, FW) ($p<.05$).

Results

LTD differed across walking conditions ($p <.001$). During DT (LTD = 5.6 (22.1)) participants used a step length dominant strategy to accomplish the DT by taking shorter steps.

During FW (LTD = -4.3 (13.2)) participants showed a time-dominant strategy by taking faster steps. LTD did not differ between high and low lower limb function (TUG), weak or strong handgrip, or falls history (Table 1).

Discussion

Overall, older adults used a step length dominant strategy during DT, which is in contrast to previous studies showing time-dominant strategies during a DT in older adults with high lower limb strength. Contrary results may be because gait strategies differ for motoric versus verbal DTs in older adults. Dichotomizing TUG times, handgrip strength, or fall history did not explain differences in gait strategies, warranting additional research.

Using Ankle Kinematics to Differentiate Contracture as a Cause of Excessive Plantarflexion in Swing in Charcot-Marie-Tooth Disease

Dr. Tishya Wren PhD[1,2], Dr. Reiko Hara PhD[1], Dr. Eva Ciccadicola PT, DPT, PCS[1], Dr. Alison Hanson MSPT, OCS[1], Dr. Susan Rethlefsen PT, DPT[1], Dr. Emmanuelle Tiongson MD[1,2], Dr. Kristan Pierz MD[3], Dr. Jennifer Rodriguez-MacClintic PT, DPT[3], Dr. Gyula Acsadi MD, PhD[3], Ms. Sylvia Ounpuu MSc[3]

[1]Children's Hospital Los Angeles, Los Angeles, CA, United States. [2]University of Southern California, Los Angeles, CA, United States. [3]Connecticut Children's, Hartford, CT, United States

Introduction

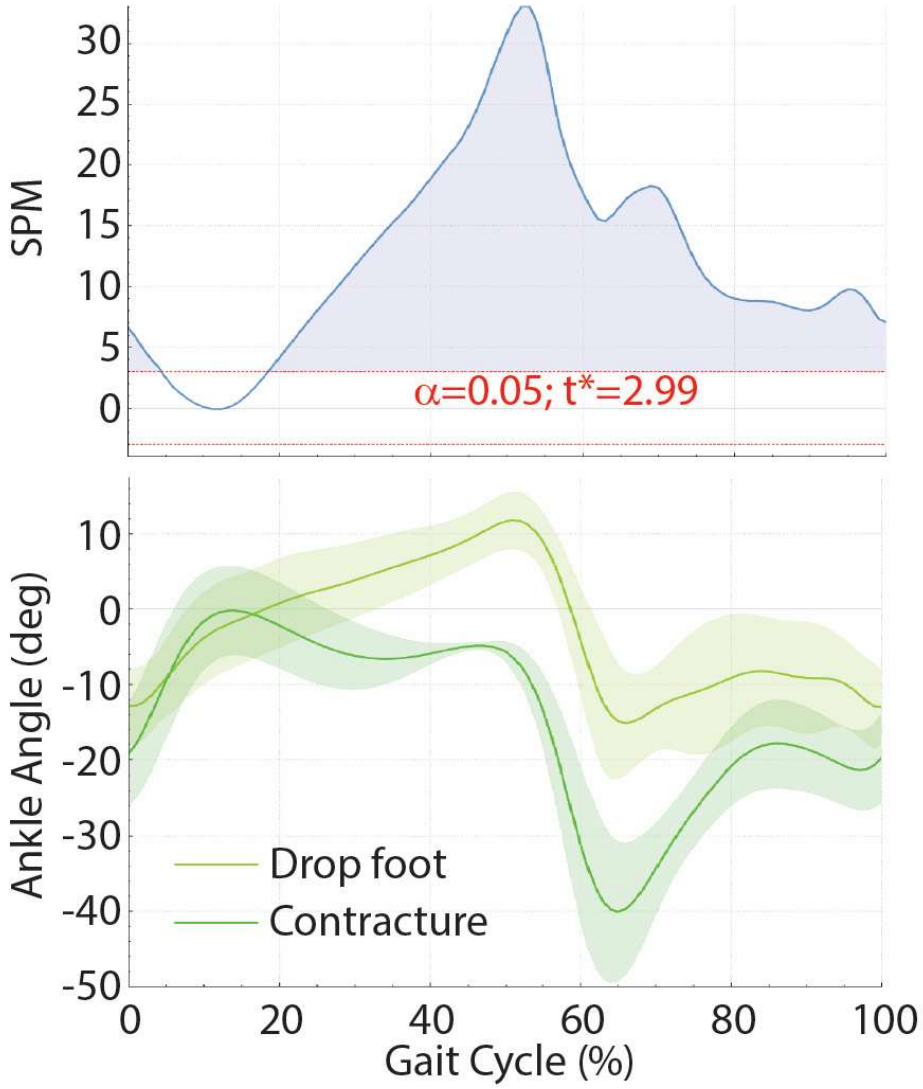
Charcot-Marie-Tooth disease (CMT) is the most common inherited neuropathy and often causes distal muscle weakness. Lack of dorsiflexion during the swing phase of gait can cause tripping and is usually attributed to weakness of the anterior tibialis. However, calf muscle tightness or contracture can also contribute to excessive plantarflexion in swing. It is important to distinguish between excessive plantarflexion in swing due to plantarflexor contracture versus anterior tibialis weakness (true drop foot) since these have different causes and warrant different treatment. This study examines differences in ankle kinematics to distinguish between excessive plantarflexion in swing due to contracture versus anterior tibialis weakness in children with CMT.

Methods

Kinematic and video data were analyzed for children with CMT who had undergone instrumented gait analysis as part of an ongoing natural history study. Walking videos were reviewed independently by three experienced gait laboratory physical therapists. Cases in which all reviewers identified excessive plantarflexion in swing of the same type (true drop foot or contracture) were included in the analysis. Ankle kinematics of the right limb were compared between groups (contracture versus true drop foot) using statistical parametric mapping.

Results

The reviewers identified 3 patients with excessive plantarflexion in swing due to contracture and 7 with true drop foot. Ankle kinematic patterns differed significantly between the two groups across almost the entire gait cycle (Figure). The drop foot group exhibited a more typical pattern of increasing ankle dorsiflexion through terminal stance, but without the first rocker. The contracture group exhibited a “double bump” pattern in stance reflecting



forefoot contact and lack of dorsiflexion in mid to terminal stance. Peak plantarflexion in initial swing was significantly greater in the contracture group although both groups showed less dorsiflexion in mid to terminal swing and at initial contact than typical.

Discussion

Ankle kinematics in stance and swing can help distinguish excessive plantarflexion in swing due to contracture from true drop foot in children with CMT. This distinction is important to identify patients whose dorsiflexion in swing will likely improve after surgical lengthening of the plantarflexors compared with those needing bracing to counteract dorsiflexor weakness.

Effects of Asymmetric Crank Arm Length Adjustments on Knee Biomechanics During Recumbent Cycling in Early Rehabilitation Following Total Knee Replacement: A Case Study

Mr. Tsung-Lin Lu MS[1], Mr. Alejandro Ovispo-Martinez MS[1], Ms. Yufei Sun MS[1], Dr. Katie Stevens DPT[2], Dr. Harold Cates MD[2], Dr. Songning Zhang PhD[1]

[1]The University of Tennessee, Knoxville, TN, United States. [2]Tennessee Orthopaedic Alliance, Knoxville, TN, United States

Introduction

Patients with total knee replacement (TKR) often exhibit biomechanical deficits in the replaced limb during upright stationary cycling in early rehabilitation [1]. Postoperative physical activity is critical for long-term recovery, but pain, swelling, and stiffness can limit adherence [2]. Shortening the crank arm on the replaced limb may accommodate reduced knee range of motion (ROM), and recumbent cycling may improve comfort, encouraging earlier pedaling. Therefore, this study investigated the biomechanical effects of shortened crank arm lengths on the replaced limb during recumbent cycling in early rehabilitation.

Methods

One male participant (71 years, 183 cm, 84 kg), 26 days post-TKR, was recruited from a local physical therapy clinic. Cycling was performed on a recumbent ergometer (RE7, Kettler, Germany) equipped with 3D Kistler force-sensing pedals and crank arm shorteners. Three crank-length conditions were tested for the replaced/non-replaced limbs: C1 (170/170 mm), C2 (155/170 mm), and C3 (140/170 mm). The participant cycled at 70 W and 70 rpm for 2 minutes and rated knee pain (0–10, VAS) and perceived exertion (RPE 6–20, Borg scale) per condition. The last 10 seconds were recorded and truncated into five consecutive crank cycles. Kinematic (240 Hz) and kinetic (1,200 Hz) data were collected using a 12-camera Vicon system and analyzed in Visual3D.

Results

Sagittal ROM in the replaced limb decreased with shorter cranks, while the non-replaced limb showed minimal reductions. Peak extension moment and power increased in the replaced limb. In the non-replaced limb, extension moment decreased from C1 to C2 with a slight rebound at C3, whereas power declined progressively across conditions. Pain in the replaced limb and RPE decreased with crank shortening (Table 1).

Discussion

Crank arm shortening of the replaced limb during recumbent cycling accommodated limited knee ROM and reduced pain and RPE, while enhancing peak extension moments and power, suggesting this intervention may support earlier engagement in cycling and improve post-TKR rehabilitation outcomes.

Frontal Plane Jerk Cost and Fluctuation Analysis for Individuals With ACL Reconstruction and Osteoarthritis

Mr. Nicholas Hunt, Dr. Tyler Brown

Boise State University, Boise, ID, United States

Introduction

Following ACL injury and subsequent reconstruction (ACL-R), altered neuromuscular function and control may accelerate knee osteoarthritis (OA) development [1]. Altered neuromuscular function following ACL injury may provoke joint instability that promotes knee OA progression. The purpose of this study is to compare jerk magnitude, cost, and fluctuation analysis between ACL-R, knee OA and healthy controls to assess smoothness of knee joint motion and provide a biomechanical measure of dynamic neuromuscular control at the joint.

Methods

Three cohorts (1: 14 ACL-R, 2: 9 knee OA, and 3: 14 healthy control) had knee biomechanics quantified during a 10-meter walk. Using filtered marker data, peak, minimum, and range (peak minus minimum) of frontal plane jerk (third time derivative of knee abduction-adduction angle during stance) and, jerk cost (area under the logarithmically transformed jerk-time curve according to [2]) were quantified during weight acceptance (initial contact to peak knee flexion angle) and full stance phase (initial contact to toe off) phases. After the jerk-time curve was submitted to a fast-Fourier transform, mean, median, and peak power frequency (PPF) as well as total signal power were calculated according to [3]. Time and frequency domain jerk measures were submitted to a one-way ANOVA to assess cohort differences.

Results

ACL-R and knee OA cohort exhibited greater range of frontal plane jerk ($p=0.002$and $p=0.035$), but smaller mean frequency ($p=0.014$ and $p=0.042$) and peak power frequency ($p=0.043$ and $p=0.029$) than controls. Knee OA also exhibited greater peak jerk than controls ($p=0.019$). No cohort differences were observed for weight acceptance or full stance jerk cost ($p=0.124$ and $p=0.107$).

Discussion

Increased jerk magnitude (peak and range) in the ACL-R and OA cohorts may indicate greater, more abrupt postural knee changes resulting in joint instability that promotes knee

OA progression. Yet, the ACL-R and knee OA cohorts may reduce fluctuation frequency in attempt to restrict frontal plane motion and protect the joint from further injury. However, this neuromuscular strategy may alter knee joint loading and may exacerbate knee OA symptoms.

Effects of Aquatic Versus Land-Based Exercise on Static Postural Sway in Older Adults With Multimorbidity: A Randomized Controlled Trial

Mr. Victor Hugo V. Carrijo[1,2], Ms. Ana Luiza Cabral[3,2], Mr. Johan Robalino[1,2], Dr. Catarina C.Santos[4], Dr. Daniel Moreira-Gonçalves[3], Dr. Mário J. Costa[1,2]

[3]Research Center for Physical Activity, Health and Leisure, CIAFEL, University of Porto, Porto, Porto, Portugal. [4]University of Trás-os-Montes and Alto Douro, Vila Real, Vila Real, Portugal

Introduction

Aging reduces balance and postural control, increasing fall risk. Physical exercise mitigates these impairments, but its usefulness for older adults with multimorbidity still requires optimization. This study aimed to verify the effects of aquatic versus land exercise programs on static postural sway in older adults with multimorbidity.

Methods

Forty-eight older adults were enrolled in a randomized controlled trial (NCT06879639), and 40 completed the 10-week intervention. The participants were allocated to a water group (n = 10; 60% women; age = 71.6 ± 5.3 years; BMI = 32.9 ± 3.5 kg/m^2), a land group (n = 15; 53% women; age = 69.8 ± 3.6 years; BMI = 31.7 ± 4.1 kg/m^2) and a control group (n = 15 66% women; age = 69.4 ± 3.1 years; BMI = 30.4 ± 3.2 kg/m^2). Both land-based and aquatic groups completed three supervised 45-minute sessions per week. Exercise intensity was monitored using heart rate (Polar®), perceived exertion (Borg scale), or a percentage of 1RM. Training load increased by 20% in weeks 3 and 7. Pre and post-test measurements of anteroposterior and mediolateral sway range (mm), total sway velocity (mm/s), and sway area (mm^2) with eyes open and closed were assessed using a force plate system by AIMT®. Statistical analysis (in SPSS 29.0) used GEEs to assess pre vs post changes across groups, with Bonferroni-adjusted post hoc tests and a significance level of $p \leq 0.05$.

Results

The comparison between groups and pre and post 10 weeks of intervention in postural sway is shown in Figure 1.

Discussion

A previous study showed that aquatic exercise improved balance in older adults using dynamic functional tasks [1]. In contrast, our static force-platform assessments revealed only small tendencies toward change, although each modality indicated distinct sensory and mechanical influences on postural control in older adults with multimorbidity. These results suggest that both interventions may have the potential to assist in managing balance in this population.

Introduction

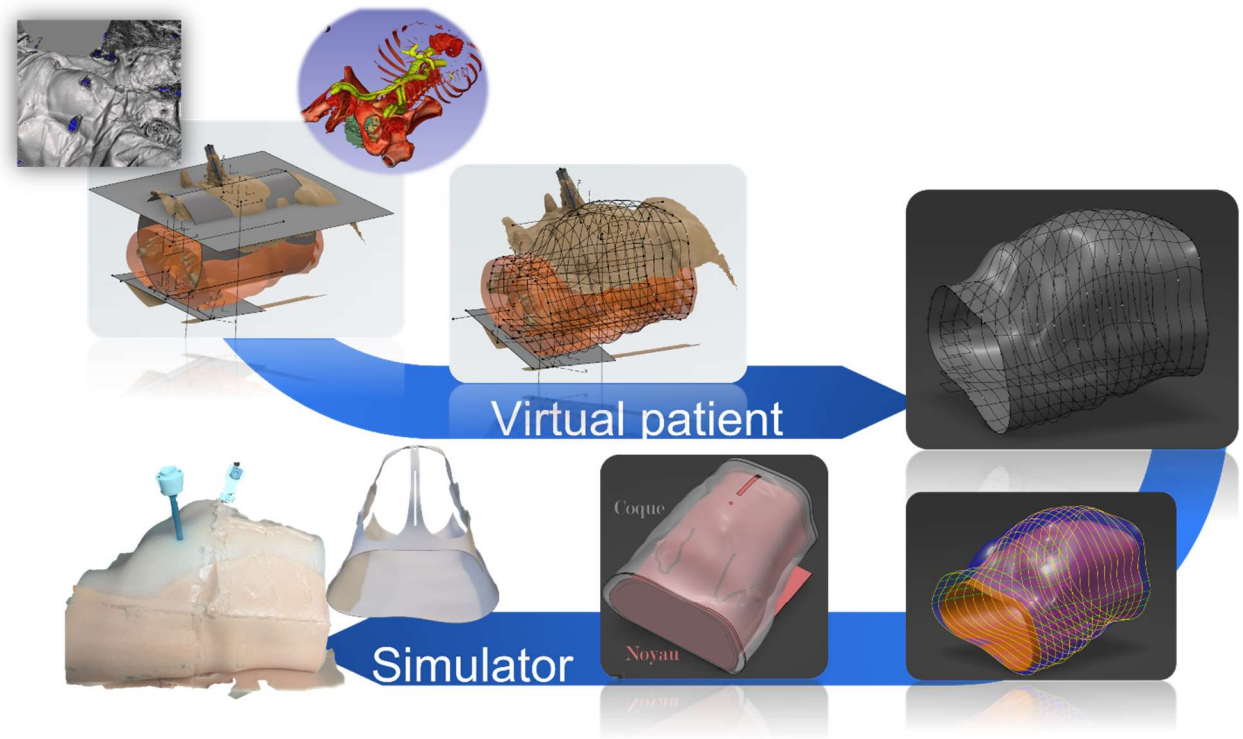
Surgical operators are among the occupational groups most susceptible to developing joint pain and musculoskeletal disorders, largely due to the adoption of constrained postures [1]. In gynecological laparoscopy, the operator's posture is shaped by interactions with operating room equipment [2], as well as by the patient's morphological characteristics. In particular, patients with a high body mass index (BMI) require adjustments of the trocar insertion site to ensure safe surgical access [3].

The aim is to develop an educational tool that incorporates the placement of secondary trocars with improved physical fidelity, achieved through the treatment of anatomical data acquired directly at the operating room.

Methods

The acquisition and processing of both internal and external anatomical data serve to account for inter-patient variability in body morphology. Internal anatomical structures are derived from preoperative computed tomography (CT) scans obtained with the patient in a supine position. External geometry is captured intraoperatively by scanning the abdominal wall under pneumoperitoneum, following prior validation of the measurement instruments.

The two resulting 3D anatomical datasets are subsequently realigned through geometric feature matching and merged into a single model. This procedure yields a virtual patient that integrates all relevant anatomical characteristics. The primary and secondary surfaces constructed to represent the envelope of the abdominal wall incorporate these fidelity parameters and constitute the basis for designing the volumes required for simulator fabrication using suitable haptic materials.



Results

A simulator for a patient with a BMI of 25 kg/m^2 was manufactured from the virtual patient, demonstrating the feasibility of the methodology based on anatomical data.

Discussion

The next step is to validate the data using an ergonomic criterion to assess the efficiency of the movements performed on the simulator. The posture data from operators using our simulator will be compared across different contextual variables (type of simulator used, participants with varying competency levels), as well as with posture data collected from surgeons in the operating room.

Explainable AI Uncovers Hidden Neuromuscular Efficiency Driving Individual Functional Performance in Complex Eccentric Hamstring Control Tasks

Mrs. Yanan YOU PhD Candidate, ACSM-EP[1], Prof. Norikazu Hirose PhD, JSPO-AT[2]

[1]Graduate School of Sport Sciences, Waseda University, Tokorozawa, Saitama-ken, Japan. [2]Faculty of Sport Sciences, Waseda University, Tokorozawa, Saitama-ken, Japan

Mrs. Yanan YOU

Introduction

Although strength testing is central to hamstring injury assessment, it does not explain why individuals with comparable strength can show markedly different eccentric control. Such discrepancies suggest that traditional models may overlook a hidden layer of neuromuscular regulation. This study used a hierarchical explainable machine learning approach (XGBoost + SHAP) to disentangle these factors. An ablation design—removing all absolute strength metrics—was implemented to isolate the independent contribution of neural coordination strategies to eccentric performance.

Methods

High-density sEMG, kinematics, and body composition data were collected from 25 healthy adults during eccentric tasks; individuals with recent lower-limb pathology were excluded. Using a comprehensive scoring system, we developed a hierarchical XGBoost–SHAP model targeting Global Hamstring Efficiency (GHE). Determinants were evaluated across three layers: global features, EMG-based neuromechanical mechanisms, and kinematic performance.

Results

Global determinants (Figure 1a)*:* Hip Smoothness was the strongest predictor of neuromuscular efficiency (35.3%, shown as relative Importance), surpassing morphological indicators such as body fat percentage. Greater semitendinosus (ST) involvement (14.0%) also characterized higher GHE.
Neuromuscular mechanisms (Figure 1b)*:* A dominant ST-driven activation strategy improved GHE (28.3%). High-efficiency performers showed stable coordination between mid-belly and distal ST regions (15.8%), emphasizing the importance of regional activation

consistency. Differential BF–ST recruitment at mid and distal sites further influenced performance (19.9%).

Kinematic characteristics (Figure 1c)*:* Greater knee range of motion and stable hip–knee coupling were shared features of high-efficiency performers, whereas compensatory hip-flexion strategies were ineffective (43.3%).

The Injury Link (Figure 1d)*:* SHAP interactions revealed that prior injury alters neuromuscular strategy. Participants without injury flexibly adopted an ST-dominant pattern that enhanced GHE, whereas previously injured individuals showed strategy rigidity, remaining locked into BF-dominant activation.

Discussion

By quantifying the neural cost–benefit relationship, this study shows that post-injury deficits arise from impaired strategy flexibility rather than weakness. Loss of ST compensatory capacity may trap individuals in a "high-cost, low-efficiency" cycle. These findings support shifting rehabilitation toward neuromuscular strategy remodeling, emphasizing BF-downregulation, ST spatial activation, and smooth movement. Limitations include modest sample size and task specificity. Future work should validate these neural signatures in larger cohorts and test targeted neuromuscular retraining.

Lower Back Strain Associated with Functional Activities in People with and People without Low Back Pain Using Motion Tape

Ms. Yasmin Velazquez MS[1], Mr. Elijah Wyckoff MS[2], Dr. Santiago Ortega DPT, MS[1], Dr. Kevin Patrick MD[2], Dr. Emilia Farcas PhD[2], Dr. Kenneth Loh PhD[2], Dr. Sara Gombatto PT, PhD[1]

[1]San Diego State University, San Diego, CA, United States. [2]University of California San Diego, San Diego, CA, United States

Introduction

Chronic low back pain (CLBP) is highly prevalent and associated with altered movement, yet existing methods for monitoring lumbar spine biomechanics are limited outside laboratory settings. Motion Tape (MT) is a flexible fabric-based device, made with multi-walled carbon nanotube piezoresistive sensors, that offers a potential solution for real-world lumbar strain monitoring. The primary purposes of this study were to: (1) determine whether MT can measure differences in lower back strains across different functional activities in a free-living environment, and (2) assess usability and acceptability of MT. A secondary purpose was to explore differences in lower back strain between people with and without CLBP.

Methods

Seventeen participants (9 with CLBP, 8 controls) completed a series of mid- and end-range functional tasks in flexion, extension, and lateral bending, and walking and stair climbing while wearing six MTs placed bilaterally on the upper, middle, and lower lumbar spine. Lumbar strain was quantified using normalized peak resistance during each task, and LBP was assessed with the Visual Analog Scale. Usability and acceptability were evaluated using the System Usability Scale (SUS) and a MT questionnaire.

Results

Significant differences in peak strain were observed across tasks ($p < .001$) and sensors ($p < .01$); significant differences in peak strain also were observed between mid- and end-range tasks for extension and lateral bending ($p < .01$), but not flexion ($p = 0.17$). Uphill walking produced greater lumbar strains than flat walking ($p < .05$). No significant differences in peak strain were observed between CLBP and control groups ($p > .05$), but the effect size for group differences was large for the mid-range lateral bending task (partial $\eta^2 = .33$). SUS ratings for usability were high (mean(SD)=77.2(14.7)), and participants reported sensors were comfortable, easy to use, and were confident in using MT.

Discussion

MT is acceptable for measuring differences in lumbar strain across functional tasks and ranges of lumbar movement and reported usability was high. MT shows promise as a wearable sensor to characterize real-world lumbar strain. MT did not distinguish between participants with CLBP and controls, but heterogeneity within the CLBP group suggests subgroup analysis may be needed.

Biomechanics of Functional Preservation in Full-Thickness Rotator Cuff Tears: A Study on Compensatory Strategies

Dr. Yi-Hsuan Weng[1], Mr. Chon-Kio Wong[1], Ms. Yang-Ting Chien[1], Ms. Kuan-Yun Liu[1], Mr. Yu-Cheng Weng[1], Dr. Chung-Hsun Chang[2], Dr. Jiu-Jenq Lin[1,3]

[1]School and Graduate Institute of Physical Therapy, College of Medicine, National Taiwan University, Taipei, Taipei, Taiwan. [2]Department of Orthopedic Surgery, College of Medicine, National Taiwan University Hospital, Taipei, Taipei, Taiwan. [3]Physical Therapy Center, National Taiwan University Hospital, Taipei, Taipei, Taiwan

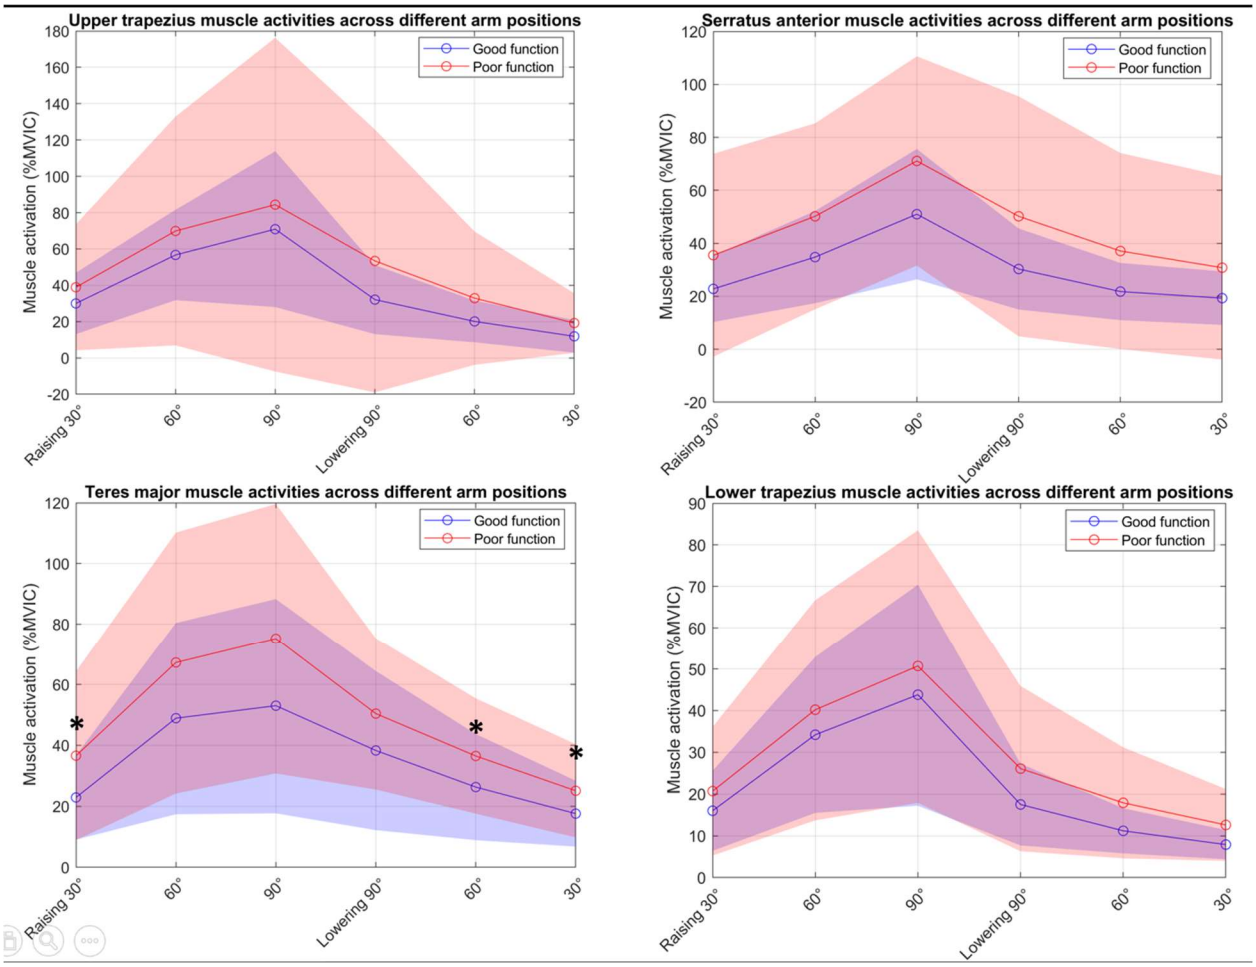
Introduction

Full-thickness rotator cuff tears (FT-RCTs) often result in pain, weakness, and limited shoulder function. However, a subset of patients remains functional and pain-free despite substantial structural damage. This study aimed to determine which clinical and biomechanical factors differentiate functional from impaired FT-RCTs, thereby providing insight into compensatory mechanisms that may preserve performance.

Methods

From the fifty-three patients with full-thickness rotator cuff tears (FT-RCTs), fourteen were selected to form the good function group (top 25% by functional score) and fourteen formed the poor function group (bottom 25% by functional score). The two groups were well-matched, showing no statistically significant differences ($p>0.05$) in most baseline demographic and clinical variables, including age, sex, height, mass, arm dominance, tear size, pain level, symptom duration, range of motion, and structural measurements. Assessments included ultrasonography to evaluate tear size and humeral head migration. Clinical outcomes measured shoulder strength, range of motion, pain intensity, and self-reported disability. Three-dimensional scapular kinematics and electromyography of the upper trapezius, lower trapezius (LT), serratus anterior (SA), and teres major (TM) were recorded during controlled arm elevation tasks.

Results



The good function group demonstrated greater shoulder flexor strength (11.2±3.2%, $p=0.001$) and lower activation of the TM (8.0-13.4%, $p=0.015$-0.028). Poor function was associated with decreased strength in the shoulder flexors ($r=0.485$, $p<0.001$) and LT ($r=0.376$, $p=0.007$), reduced humeral head migration ($r=0.311$, $p=0.028$), and increased

activation of the SA (r=-0.338 to -0.335, p=0.017) and LT (r=-0.318 to -0.347, p=0.014-0.024). Pain correlated with larger tear size (r=0.317, p=0.025), thinner coracohumeral ligaments (r=-0.365, p=0.009), narrower acromiohumeral distance (r=-0.340, p=0.016), and reduced scapular upward rotation (r=-0.308 to -0.371, p=0.008-0.029).

Discussion

This study demonstrates that functional capacity in individuals with FT-RCTs largely depends on their compensatory strategies. The primary distinction between patients with preserved and impaired function lies in muscle strength and activation profiles. Those maintaining better function exhibit stronger shoulder flexors and reduced recruitment of the TM muscle. Conversely, impaired individuals display deficits in key muscle groups and compensatory overactivation of muscles such as the SA. These findings suggest that rehabilitation could emphasize strengthening compensatory muscle groups and optimizing neuromuscular coordination, rather than focusing solely on the torn tendon.

3D-Printed Hip Protectors to Enhance User Compliance in Older Adults: Protocol of A Cluster Randomized Controlled Trial

Prof. Yijian Yang, Prof. Xu Song

The Chinese University of Hong Kong, Shatin, NT, Hong Kong

Introduction

95% of hip fractures in older adults are caused by falls. Although hip protectors have been promoted for hip fracture prevention, user compliance (acceptance and adherence) is generally low mainly due to discomfort (e.g., bulky, unbreathable, and unisize design). To address this issue, we developed and evaluated the effects of customized 3D-printed hip protectors on biomechanical performance and user compliance in older adults residing in care homes.

Methods

This study includes two stages. During stage one, we recruited 32 older adults (80.3±9, 55% females) with different body shapes from care homes and scanned their pelvis using a portable scanner. Data were used to generate 3D-printed hip protectors. Biomechanical performance of protectors was evaluated by measuring force attenuation in an impact test on a force plate. Physical performance of older adults was assessed to examine whether wearing hip protectors affect their balance and mobility. During stage two, we will conduct a 12-month cluster randomized controlled trial to evaluate user compliance with hip protectors. 300 older adults from 30 care homes will be recruited and randomly assigned to an intervention group (receiving 3D-printed hip protectors) or a control group (receiving conventional hip protectors). User compliance of wearing protectors and fall-related hip injuries (e.g., pain, bruises and fractures) will be measured over the study period. Generalized linear models will be applied to compare the acceptance, adherence and injury outcomes between the two groups.

Results

The dropping test showed that the 3D-printed hip protector attenuated 42.9% of impact forces compared to the non-protector condition. 3D-printed hip protectors did not adversely alter gait, mobility, and balance compared to no wearing of protectors ($p > 0.05$). Recruitment of older adults for the clinical trial is currently ongoing. We anticipate that participants in the intervention group will show higher acceptance and adherence to hip protectors and have a lower risk of hip injury.

Discussion

The 3D-printed hip protectors demonstrate lightweight and breathable features, with satisfied force attenuation and comfort for performing daily activities. By enhancing user compliance, our results will guide future scale-up implementation of 3D-printed hip protectors for the prevention of hip fracture in frail older adults.

Passive-Dynamic Ankle Foot Orthosis Can Offload the Achilles Tendon during Dynamic Tasks in a Patient with Achilles Tendinopathy

Ms. Zahra McKee, Dr. Stephanie Cone, Dr. Karin Grävare Silbernagel, Dr. Elisa Arch

University of Delaware, Newark, DE, United States

Introduction

Achilles tendinopathy is a common and chronic overuse injury of the Achilles tendon. Managing the load experienced in the Achilles tendon is important during rehabilitation as underloading precludes tendon remodeling and overloading induces pain and possible reinjury, but there is currently no way to control loading during daily living beyond pain monitoring [1]. Passive-dynamic ankle foot orthoses (PD-AFOs) may be able to partially offload the Achilles tendon during dynamic tasks by providing eccentric plantarflexion assistance through dorsiflexion stiffness and concentric plantarflexion assistance through energy release. PD-AFO use has previously been linked to reduced biological ankle moment and soleus activity [2,3]. This study aimed to investigate if PD-AFOs can offload the Achilles tendon for individuals with Achilles tendinopathy.

Methods

One individual with unilateral right Achilles tendinopathy (37 y.o., Female, Right VISA-A: 47, Left VISA-A: 85) was fitted for a PD-AFO, that only provided dorsiflexion resistance, on their right leg. Two PD-AFO conditions were tested: unengaged (no stiffness), and stiff (1.5 Nm/deg). Under the PD-AFO conditions, the participant performed bilateral heel raises at 60 bpm, and walking and running at self-selected speeds. Shear wave tensiometry data was collected to assess Achilles tendon loading as squared shear wave speed is a proxy for tendon loading [4]. Peak squared shear wave speed in the tendinopathic leg was averaged for each activity and compared between the PD-AFO conditions.

Results

Average peak squared shear wave speed was lower in the stiff PD-AFO condition than the unengaged condition for all three activities (Figure 1).

Discussion

The PD-AFO reduced peak Achilles tendon loading during walking, running, and bilateral heel raises in an individual with Achilles tendinopathy. If results are consistent with additional participants (being recruited), our findings may indicate that PD-AFOs enable tendinopathic patients to return to activity sooner without overloading their Achilles tendon. Future work will also explore if adjusting PD-AFO stiffness can fine-tune the level of assistance provided.

[6]Child Neurology and Clinical Neurophysiology Unit, Padova University Hospital,, Padova, ITA, Italy. [7]Department of Engineering Cybernetics, University of Science and Technology, Trondheim, Norway, Norway

Introduction

Fragile X syndrome (FXS) is a rare genetic condition and the most common monogenic cause of autism [1] characterized by two main phenotypes: Full Mutation (FXSFull) and somatic mosaicism (FXSMos). FXS children show hypotonia and joint hyperlaxity, however as the diagnosis relies on blood-based molecular testing, the impact of FMRP deficiency on muscle and connective tissues is still unclear. Recent evidence indicates preferential recruitment of fast-twitch muscle fibers [2], suggesting delayed muscular maturation. In this study, we integrated gait biomechanics and surface electromyography (sEMG) with clinical and neurocognitive assessments [1] to examine how neuromuscular patterns relate to the FXS phenotype. Unsupervised machine-learning approaches were used to identify data-driven subgroups.

Methods

FXS affects males more frequently due to their single X chromosome, therefore fifty-five FXS boys (age: 10.48 ± 3.42; BMI: 19.25 ± 4.38) and 14 age- and BMI-matched control subjects (CS) were enrolled. Markerless gait analysis was performed through GoPro Hero cameras (60 fps) and a Cometa sEMG system (2000 Hz) recording bilateral activity from Tibialis Anterior , Gastrocnemius Lateralis , Rectus Femoris , and Biceps Femoris . Spatiotemporal parameters and EMG-derived features were extracted as in [2] and used as inputs for DBSCAN, K-means, and Hierarchical Clustering. Feature subsets were evaluated

through a grid-search procedure, and the optimal configuration for each model was selected using the Silhouette score. Clusters were subsequently characterized using all biomechanical and neuropsychiatric measures and correlation analyses were performed within each cluster.

Results

K-means using muscle activation durations yielded the best performance, identifying two clusters. Children with FXS in cluster 1 showed higher Total Intelligence Quotient (TIQ) scores and biomechanical features more aligned with the CS group. Representative boxplots illustrate differences in selected EMG-based and gait parameters.

Discussion

Findings indicate that neuromuscular alterations in FXS do not fully align with blood-based diagnostic categories, suggesting that FMRP deficiency may differentially affect blood and muscle tissues. Lower anxiety scores on the Child Behavior Checklist in FXS children from Cluster 1, compared to Cluster 2, may explain why some FXS children fall into Cluster 1.

Images (Optional)

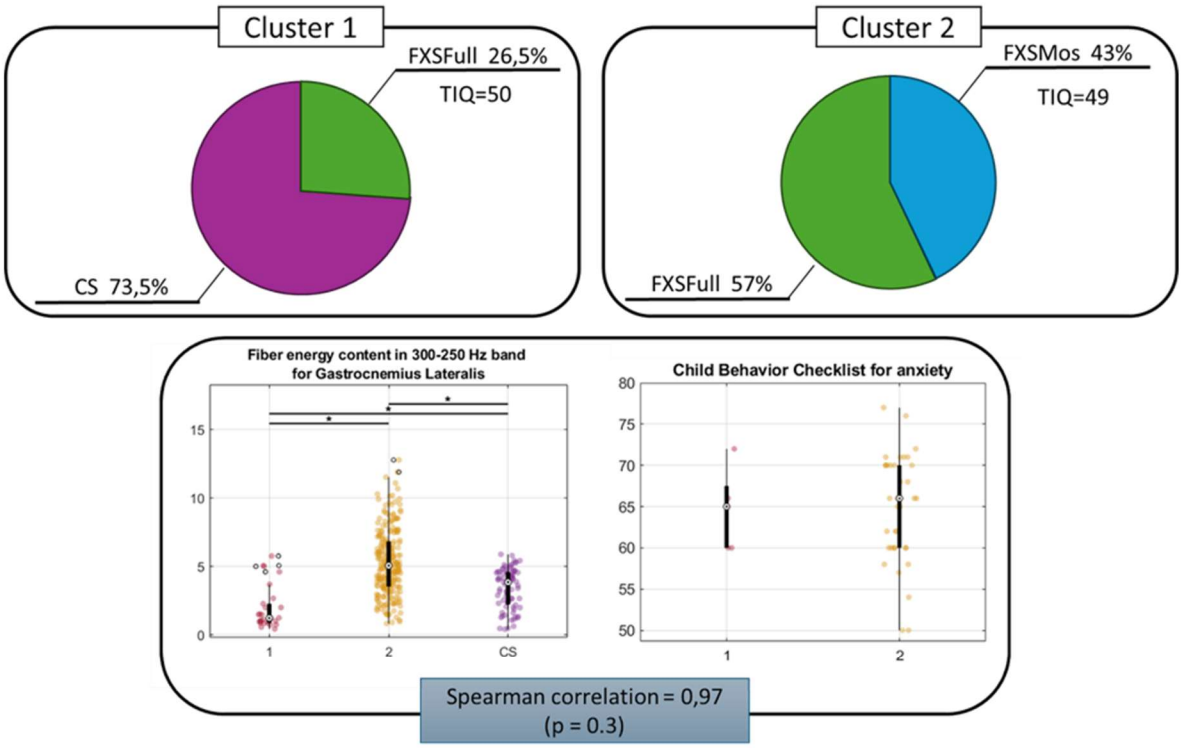

Figure 1 Top: pie charts showing the percentage composition of Cluster 1 and Cluster 2. **Bottom left**: comparison among clusters and the control group (CS) for fiber energy content in the 300–250 Hz band of the Gastrocnemius Lateralis; horizontal bars indicate statistically significant differences. **Bottom right:** Child Behavior Checklist anxiety scores for the two clusters. The lower panel reports the Spearman correlation between the two measures (ρ = 0.97, p = 0.3).

3D Printing Enables Custom-Shaped Hydrogel–Elastomer Soft Sensing Skins for Next-Generation Sensate Prosthetics

Mr. Arman Arezoomand, Dr. Heather Baltzer, Dr. Fae Azhari

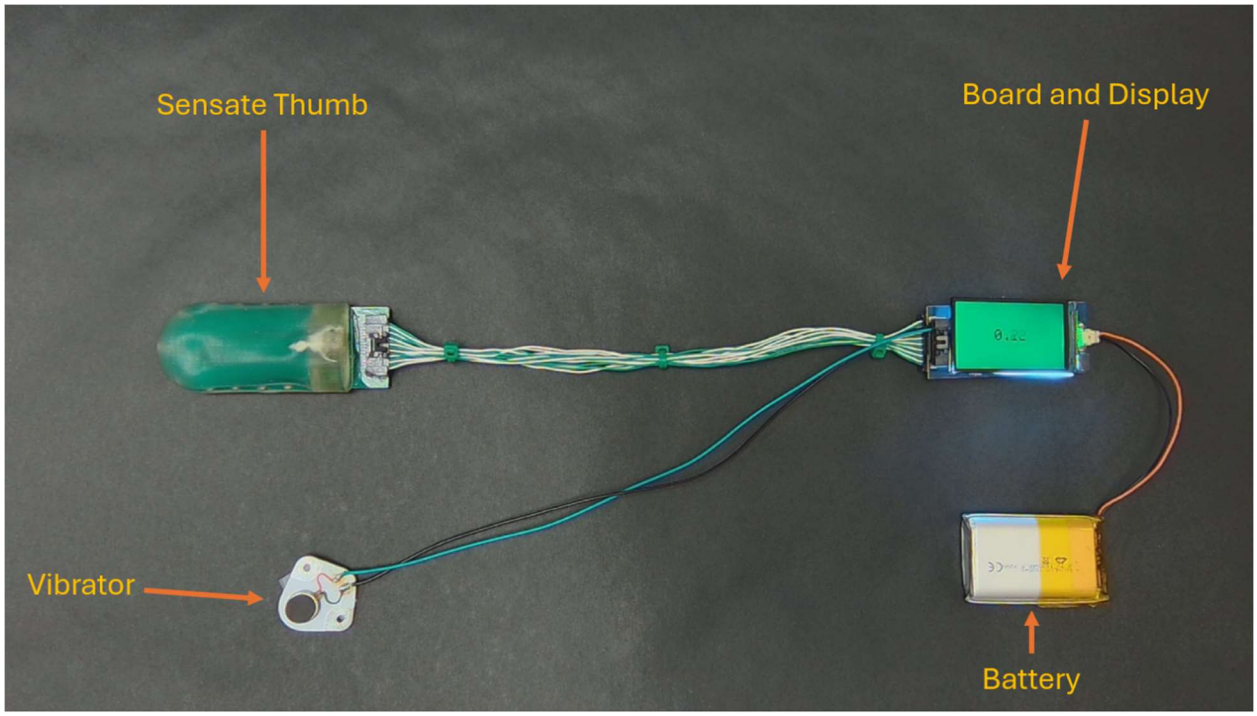
Univesity of Toronto, Toronto, ON, Canada

Introduction

Hydrogel-elastomer hybrids [1] are promising materials for soft robotic skins due to their tunable mechanical properties and inherent ionic electrical conductivity. Their mechanical compliance can be tuned to match that of soft tissues and their piezoresistive behaviour enables self-sensing by relating changes in electrical resistivity to applied pressure or strain. Despite their potential, casting the thin elastomeric layer that covers and protects the hydrogel layer is time-consuming and requires custom molds for different shapes. 3D printing can facilitate the elastomer fabrication for applications that require high flexibility and shape customization such as pressure-sensitive digits for partial hand prostheses. We propose a new fabrication method for digit-like hydrogel-elastomer hybrid sensors and demonstrate its application for tactile sensing using a customized compact impedance measurement system.

Methods

A 1-mm-thick elastomeric protective layer in the shape of a thumb was fabricated using an SLA 3D printer. A PCB that acts as the backing and houses the sensor electrodes was treated with an adhesion promoter and inserted into the elastomeric protective layer. The elastomeric cavity was then filled with the hydrogel precursor and cured with UV light. We used a custom-designed wearable impedance measurement board [2] for impedance measurements under arbitrary surface indentations. Baseline measurements were continuously compared to the latest measurements to determine the amount of applied deformation, which was then used to actuate a vibrotactile unit for feedback purposes.



Results

The resulting sensate digit has a Shore A hardness of 15±3, which is comparable to the pad of a human thumb. The hydrogel was effectively bonded to the elastomeric layer and the PCB backing. The system distinguished light (indentation<3 mm) and deep (indentation>3 mm) contact using a thresholding method applied to the sensor output and provided vibrotactile feedback.

Discussion

The sensate digit prototype demonstrates, as a proof of concept, the feasibility of integrating hydrogel-elastomer hybrid sensors into prosthetic and robotic devices with a high degree of shape customizability. Such devices can support tactile sensing architectures ranging from the simple configurations presented here to advanced, tomography-based distributed sensing.

Broadband Axial and Shear Testing Device for Heterogeneous Soft Materials

Mr. Brandon Chelstrom[1], Dr. Corinne Henak[1,2,3]

[1]Department of Biomedical Engineering, University of Wisconsin-Madison, Madison, Wisconsin, United States. [2]Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, Wisconsin, United States. [3]Department of Orthopedics and Rehabilitation, University of Wisconsin-Madison, Madison, Wisconsin, United States

Introduction

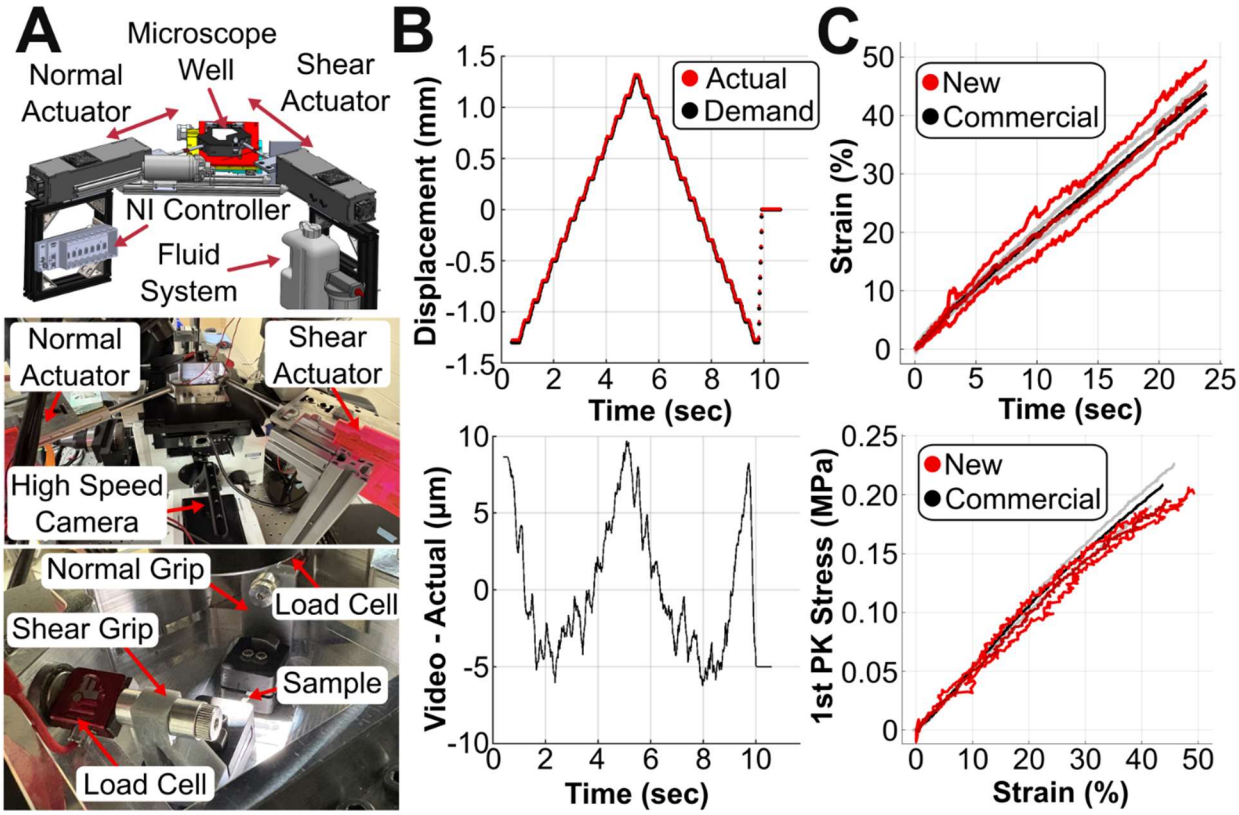
Complete mechanical characterization of soft materials remains a considerable challenge due to the local variation in mechanical properties across length scales. Heterogeneous tissue structures and material boundaries give rise to stark gradients or discontinuities often incorrectly captured using standard mechanical testing. To address these gaps, we developed a device capable of applying multi-axial loading while simultaneously capturing full-field displacements.

Methods

Two perpendicular linear actuators interface with a custom CNC machined microscope well to apply normal and shear loading to samples within the well (Fig. 1A). The well sits atop an inverted bright field microscope to visualize small scale displacement fields. Actuator displacements, loads and displacement fields are captured synchronously.

After tuning the actuators, 200μm step displacements were verified against high-speed video data across the microscope field of view (FOV). Experimental validation compared elastic properties of PDMS (1:10) in uniaxial tension and shear against an established test frame (TA Electroforce). Samples were loaded at 10 mm/min to 4 mm with a preload of 0.07 N. One batch of samples (n = 10) cured for 6 days prior to mechanical testing. Various gauge strain tracking methods, including both static and dynamic line tracking and digital image correlation (DIC), were used for each test set up due to the difference in image resolution and FOV. The average elastic modulus for each test type was compared between samples tested on both devices.

Results



Optical displacements were ±10μm of the demand position across the entire FOV (Fig. 1B). The difference in stress-strain distribution for tensile samples is within 1% across test frames (Fig. 1C). Average elastic moduli are within 5% across all tensile and shear samples.

Discussion

The proposed device can visualize local strain fields under multi axial loading using multiple strain tracking methods. Mechanical testing of PDMS samples indicates a consistent elastic response when compared to an established test device (Fig. 1B). However, mechanical analysis failed to consider out of place deformation and DIC based tracking methods were noisier due to the smaller FOV (Fig. 1C). The consistent response between standard uniaxial tests lays the foundation to further characterize local heterogeneity in soft materials.

[3]The Joint Replacement Clinic, Adelaide, South Australia, Australia. [4]Aesculap AG Research and Development, Tuttlingen, Baden-Württemberg, Germany. [5]Department of Orthopaedic and Trauma Surgery, Musculoskeletal University Center Munich (MUM), Munich, Bavaria, Germany

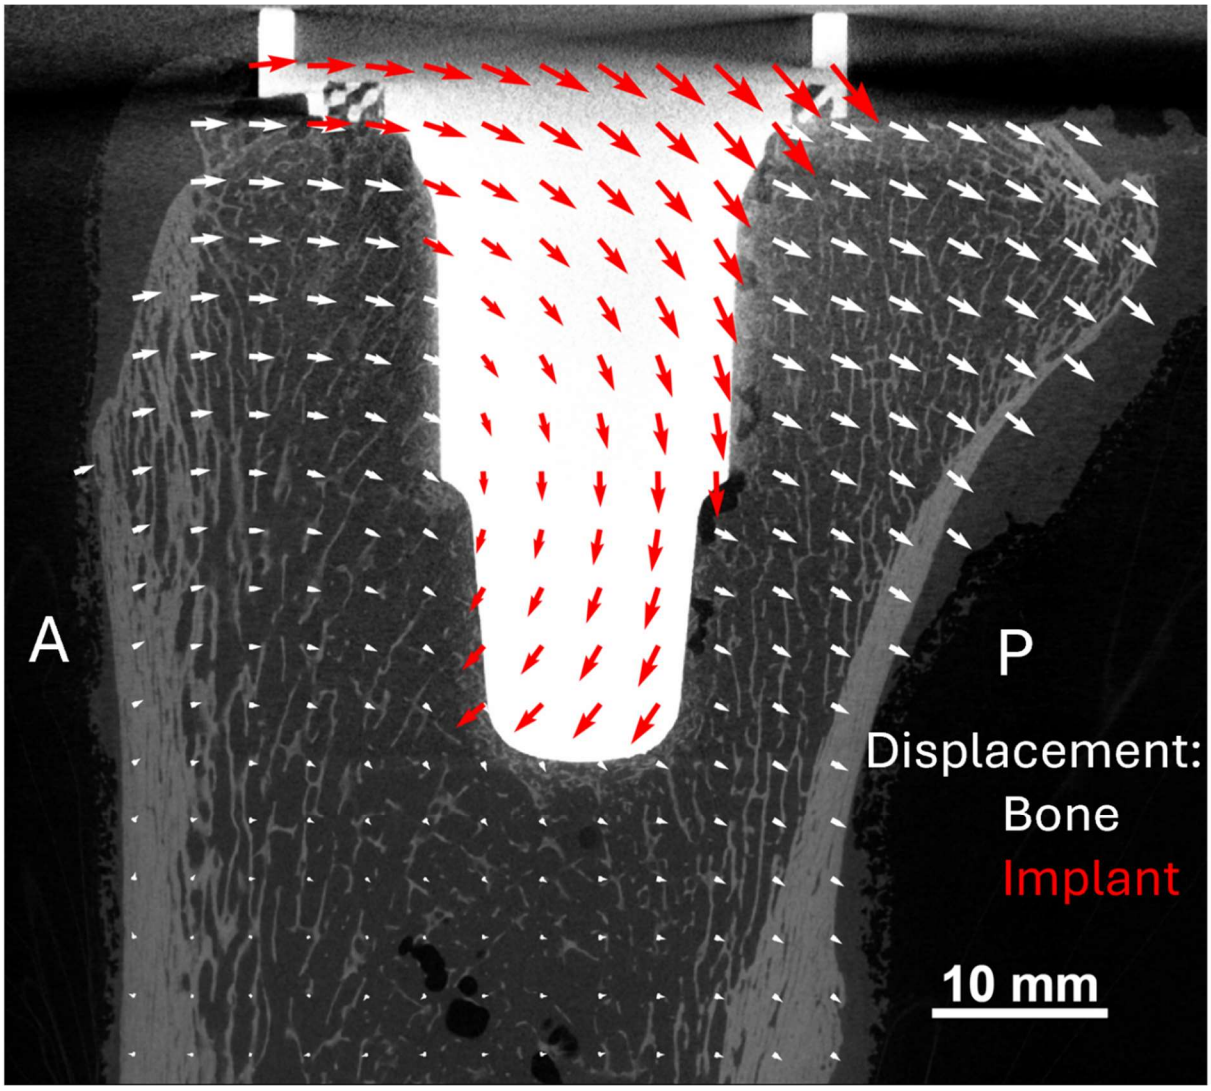
Introduction

Cementless knee implants rely on interference to achieve primary stability. Previous studies quantified the relative motion between tibial bone and implant under load using digital image correlation (DIC) [1], however, they were limited to external motion measurements. In this study, we aimed to quantify the internal relative motion between bone and implant under stair descent loads, using micro-CT imaging and digital volume correlation (DVC).

Methods

Five human cadaver proximal tibiae were implanted with in-development cementless tibial components (Aesculap AG) by an orthopaedic surgeon (ethics HREC 223.23). These tibiae were micro-CT scanned at 46 µm/pixel (Nikon XT H 225ST) [2] under increasing loads representing stair descent, from 0 to 2.5 kN. Internal bone displacements were quantified using DVC on micro-CT datasets (DaVis v8.4, subvolume side length 24 pixels, 1,104 µm), and implant displacements calculated by segmenting and aligning the implant position in each scan (MATLAB r2024b). Relative motion was determined as the difference between bone and implant displacement at the centroids of subvolumes closest to the implant, and decomposed into normal and shear motion relative to the implant surface.

Results



Relative motion increased linearly with applied load. With 2.5kN applied, maximum observed relative motion was between 78 and 295 µm, dominated by posterior bone-

implant gap closing beneath the tray baseplate (range 77-293 μm). Interestingly, in all specimens, to posterior gap closing under the tray baseplate corresponded also a gap opening on the posterior side of the keel and wings (Figure 1). Maximum gap opening was primarily observed at the most inferior and posterior point of the keel/wings (range 60-251 μm).

Discussion

The internal relative motion between implanted cementless tibial trays and bone, a measure of primary stability, has been quantified under progressive stair descent loads. Our DVC measurements around the tibial tray align with DIC measurements from literature [1], and reveal previously unreported internal relative motion at the bone-implant interface on the posterior side of internal implant geometries (keel/wings). These results improve our understanding of cementless tibial tray primary stability, informing surgical technique and implant designs.

[4]Anatomy and Regenerative Medicine Institute (REMEDI), School of Medicine, University of Galway, Galway, Connaught, Ireland

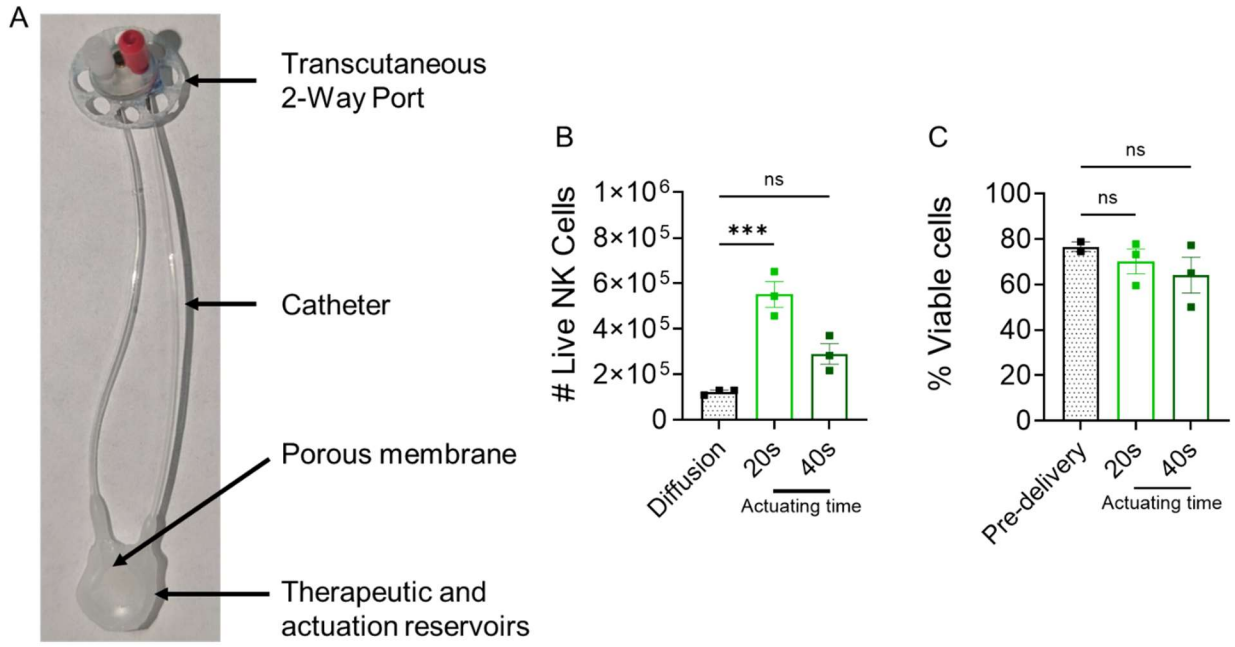
Introduction

Ovarian Cancer is the most lethal gynaecological malignancy. There is an urgent need for innovative strategies to improve therapeutic outcomes and increase patient survival. We previously described a mechanotherapeutic implant that uses actuation to modulate the foreign body response (FBR)[1,2]. Actuation significantly reduced the thickness of the fibrous capsule around subcutaneous implants[1], and improved drug transport for up to 8 weeks in immunocompetent mice[2]. More recently, we used a non-actuatable version of this implant to deliver Natural Killer (NK) cells to the peritoneal cavity in immunocompromised mice bearing OVCAR-8 tumours. Delivering NK cells through our therapeutic implant led to superior control of ovarian tumours, as compared to intraperitoneal injection of therapy[3]. We are now evaluating whether actuation of our peritoneal implant can enhance therapeutic efficacy in an ID8 immunocompetent mouse model of ovarian cancer.

Methods

We have redesigned our actuatable implant for implantation in the peritoneal space. We first assessed if actuating our implant is suitable for delivery of cell therapies. Therapeutic implants were loaded with NK cells *ex vivo* and connected to a pneumatic control system. The implants were actuated to a peak pressure of 27.57kPa for 20 or 40 seconds. Cell number and viability post-actuation were analysed using a cell counter.

Results



Actuation enhanced NK cell ejection from the therapeutic implant but did not affect cell viability, indicating that actuation can improve cell delivery efficacy without compromising cell integrity.

Ongoing work in our group is focused on establishing the ID8 mouse model of Ovarian Cancer and examining if actuation can modulate the FBR towards a peritoneal implant. Future work will use this actuatable implant to deliver immunotherapy to the peritoneal cavity and assess its ability to control tumour growth.

Discussion

Here we describe a mechanotherapeutic implant that allows for effective delivery of therapy to the peritoneal space. By combining actuation with cellular immunotherapies, our strategy has the potential to overcome the clinical challenges and shortcomings associated with intraperitoneal treatment of Ovarian Cancer.

Neonatal venoarterial extracorporeal life support: large-eddy simulations of the return cannula

MSc Hanna Hörwing[1], MD Jan Svoboda[2], Associate Professor Lars Mikael Broman[3,4], Professor Lisa Prahl Wittberg[1]

[1]Dept. of Engineering Mechanics, FLOW, KTH Royal Institute of Technology, Stockholm, Stockholm, Sweden. [2]Dept. of Pediatric Radiology, Karolinska University Hospital, Solna, Stockholm, Sweden. [3]ECMO Centre Karolinska, Pediatric Perioperative Medicine and Intensive Care, Karolinska University Hospital, Solna, Stockholm, Sweden. [4]Department of Physiology and Pharmacology, Karolinska Institute, Solna, Stockholm, Sweden

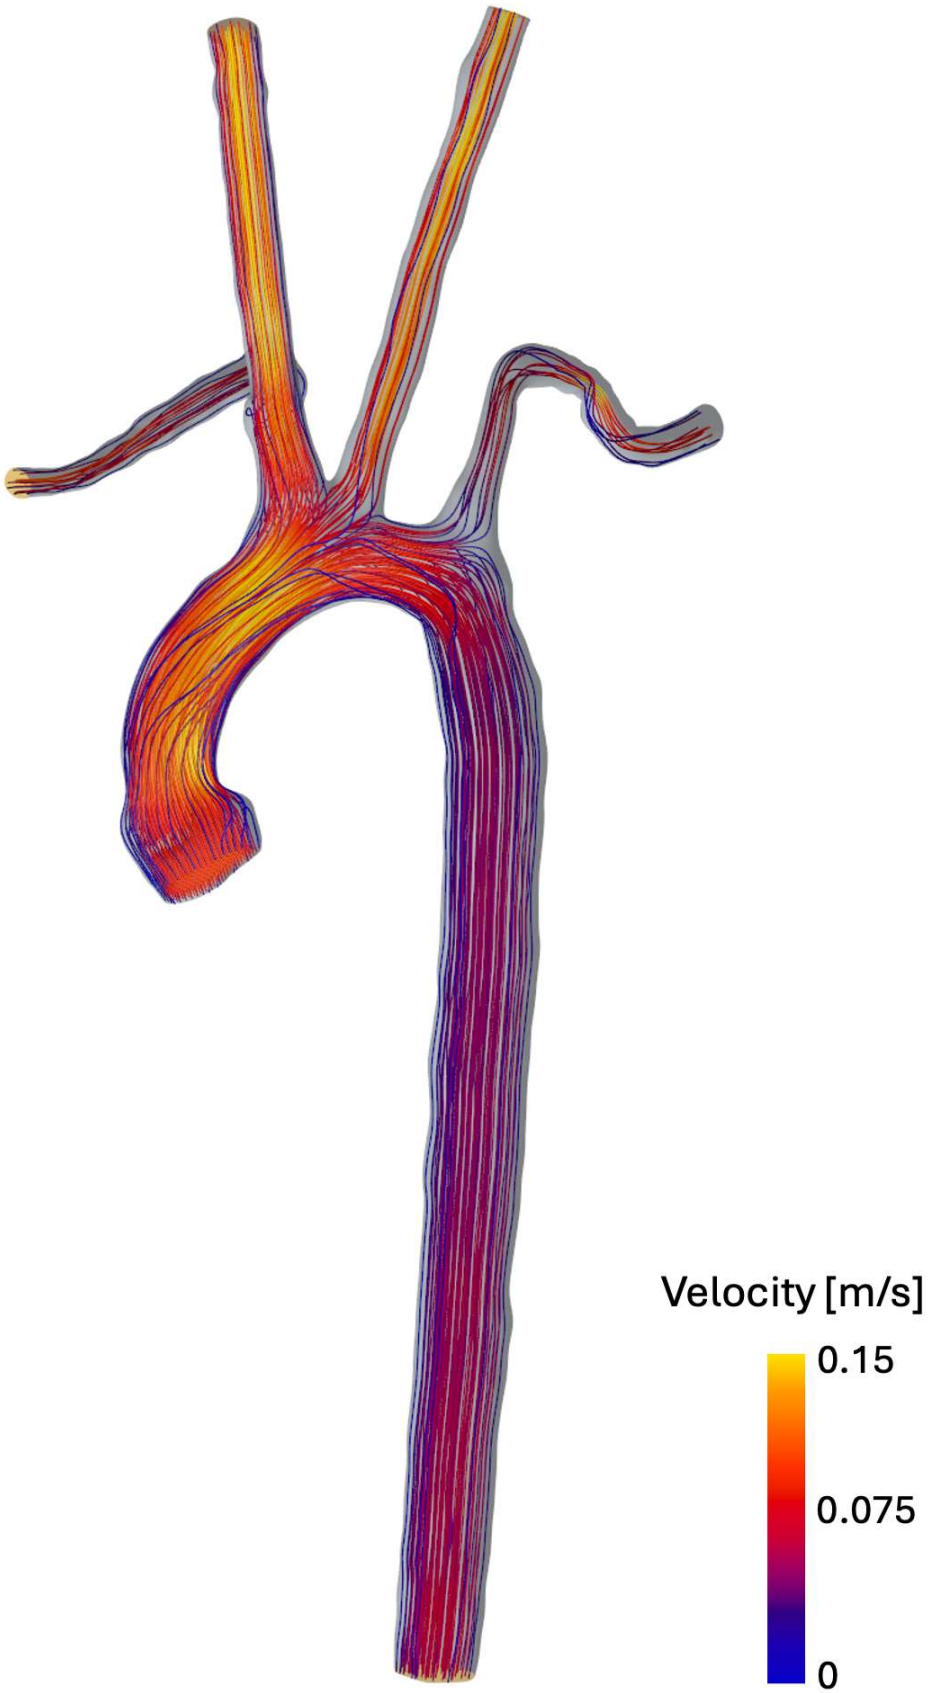
Introduction

In patients with respiratory and cardiac failure, venoarterial extracorporeal membrane oxygenation (VA ECMO) can relieve the heart and lungs of the patient, offering life support. The ECMO system drains de-oxygenated blood from the patient's venous system, pumps the blood through an oxygenator outside the body, then returns oxygenated blood to the patient's arterial system**.** In the system, blood and vessels are exposed to unphysiological conditions, promoting thrombosis and reduced oxygen delivery to the brain. In this work, CFD was used to study the return cannula in neonatal patients on VA ECMO. The aim was to investigate the effect of flow rates and cannula positioning on flow structures and stress dynamics, and thus, potentially reducing complication risks.

Methods

Computed tomography (CT) imaging of 12 neonatal patients (age 2-25 days; weight 2.5-4.5 kg) were collected during ECMO treatment (Approved by the Swedish Ethical Review Authority). 3D geometries of the aorta and major connecting vessels were reconstructed for each patient. Anatomical variations typical in neonates were identified, including a ductus in 8 out of 12 patients. A cannula was inserted into the Brachiocephalic artery according to clinical practice, applying large eddy simulations to simulate the blood flow. The Quemada (Das) viscosity model was used to account for the shear-thinning characteristic of blood. An ECMO flow rate of 90 mL/kg/min was applied as baseline, applying a pulsatile inflow profile at the aortic valve.

Results



Oxygen transport and distribution was assessed, along with flow structures linked to thrombogenicity, including shear stresses and stagnation of blood. The preliminary results indicate that the cannula return flow formed a jet colliding with the wall of the aortic arch.

Reducing the ECMO flow rate decreased wall shear stresses at the location of the impinging jet. In addition, lower ECMO flow rate decreased oxygen transport.

Discussion

While neonates represent a large group among ECMO patients, most computational fluid dynamics (CFD) studies have been centered around adult geometries. With these findings, we aim to increase knowledge on cannula flow dynamics in neonatal patients, and provide a foundation supporting clinical decision-making in neonatal practice.

Advancement in Endotracheal Intubation: Fabrication and Preliminary Characterization of An Improved Robotic Cuff System

Mr. Jacob Provencio, Mr. Orlando Favela, Mr. Mohammad Nikmehr, Dr. Connor J. Evans Ph.D., Dr. Robert A. De Lorenzo M.D., Dr. R. Lyle Hood Ph.D.

The University of Texas at San Antonio, San Antonio, Texas, United States

Introduction

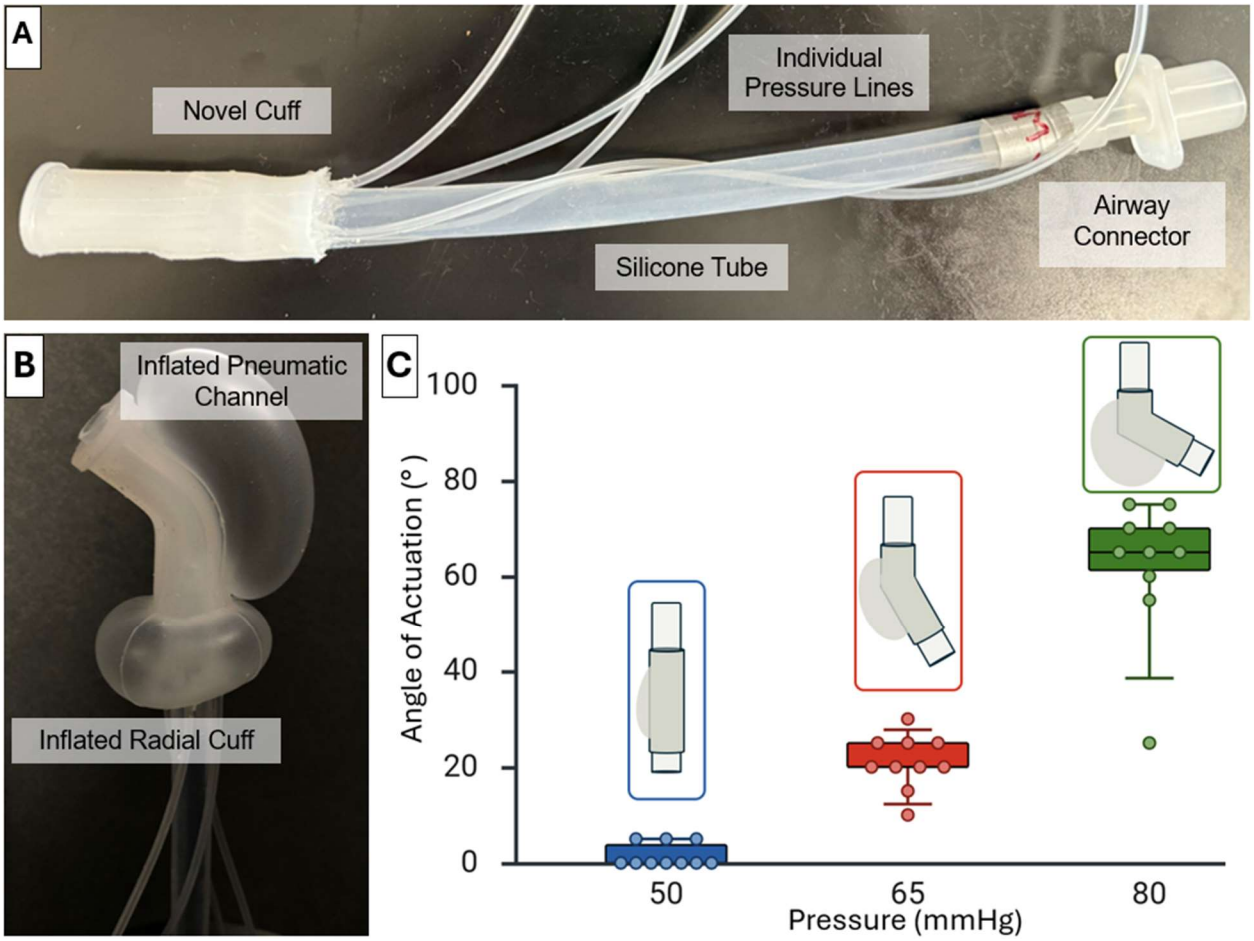
Endotracheal (ET) intubation is a common procedure, with an estimated 13–20 million cases annually in the United States. Despite its frequency, clinicians must navigate small apertures and complex anatomical curvatures. A controlled system is needed to improve ET intubation, especially in prehospital settings where first-pass success may be as low as 46.4%. This work aimed to develop and characterize a multi-channeled soft robotic steerable cuff system capable of directional actuation and radial expansion.

Methods

A soft robotic maneuverable cuff was fabricated using a multi-mold process to produce a four-channel silicone structure. Ecoflex 00-30 was mixed in equal parts and injected into 3D-printed molds designed to create pneumatic channels for steering and radial expansion. After a four-hour cure, mold components were removed, with a secondary sealing step implemented to enclose the pneumatic channels. The completed cuff was bonded to an 8 mm inner diameter silicone tube using Sil-Poxy.

Benchtop testing was performed using a lab stand with a protractor behind the tube and a stylet inserted for alignment. A 60 mL syringe—actuated via syringe pump—was connected in line with a pressure gauge and the channel being tested. Channels were pressurized and angular deflection was recorded to generate pressure–angle profiles. Four cuff prototypes were evaluated, with each channel actuated ten times.

Results



Through quality assessment, each of the fabricated tubes exhibited the ability to radially expand the pneumatic cuff channel. Across prototypes, initial angular displacement occurred between 40–50 mmHg. Three cuffs achieved anatomically relevant bending, reaching angles up to 40°, while an average tracheal tilt is approximately 20°. Three of the four cuffs produced 20° of deflection under 70 mmHg, and two tubes withstood

pressurization to 80 mmHg, achieving max bending angles of 62.5° ± 13.83° and 36.6° ± 10.6°.

Discussion

The cuff prototypes demonstrated the ability to generate both radial cuff expansion and controlled angular displacement through independent pneumatic actuation. While all prototypes produced measurable bending, further refinement is needed to achieve consistent outcomes. Future work will aim to reduce unintended channel expansion and develop a user-controlled pneumatic system for next-generation steerable cuffs.

Experimental Evaluation of the Geometry of Stepped Catheters on Backflow During Infusion into Agarose Gel

Professor Joshua Smith Ph.D., Mr. Elliott Godin, Ms. Sophia Gaysinskiy

Lafayette College, Easton, PA, United States

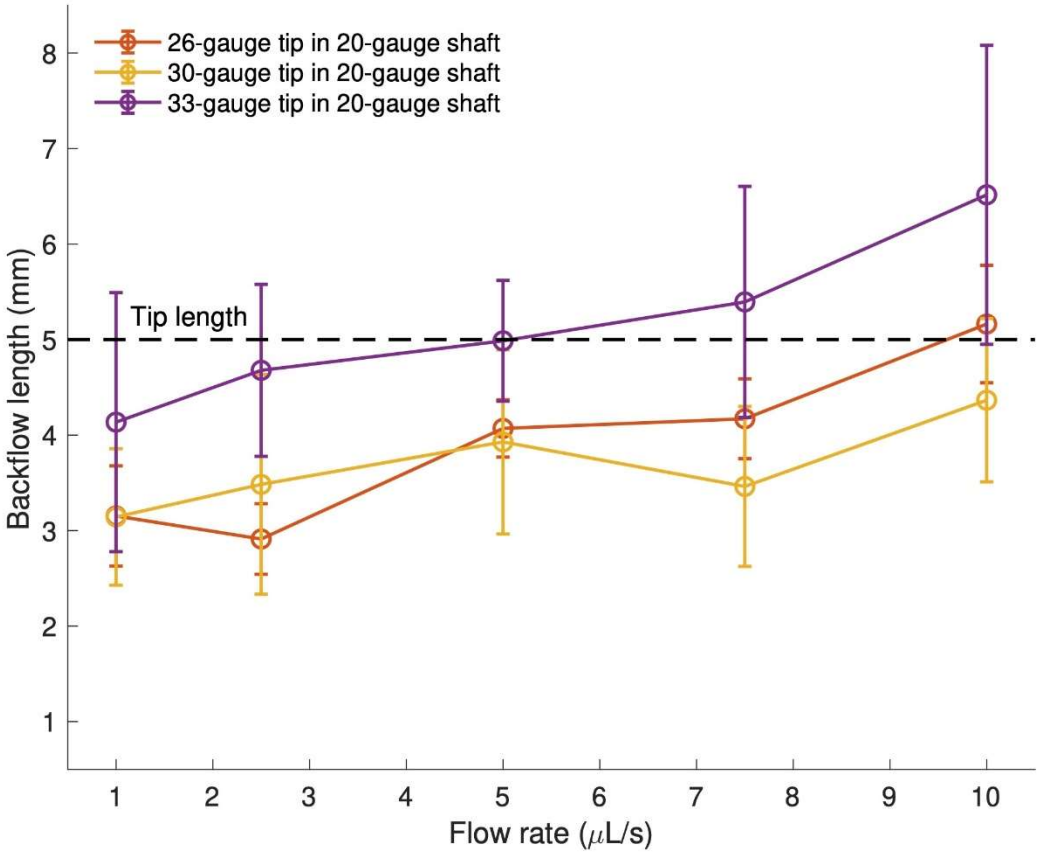
Introduction

One of the challenges of convection-enhanced delivery into brain tissue is backflow, where the infused fluid flows preferentially along the shaft of the catheter away from the targeted tissue. Stepped catheters, in which there is a sudden increase in the diameter of the shaft a few millimeters away from the tip, have been proposed as a means to minimize backflow. While a few studies have established the utility of stepped catheters, this study examines the effect of variations in the diameters of the tip and the shaft on backflow.

Methods

Stepped catheters were manufactured using 304 stainless steel needle tubing in combinations of shafts of 26, 20, and 16 gauge with 5-mm-long tips of 33, 30, and 26 gauge. Infusions were conducted with a custom-built infusion rig into 0.6% (w/v) agarose gel. Infusion flow rates from 1 to 10 μL/min were investigated and a total of 25 μL of 0.05% (w/v) bromophenol blue was infused. Backflow lengths were determined by analysis of images of the infusions. At least three infusions were conducted for each stepped catheter at each flow rate.

Results



For all catheters, it was found that lower infusion rates yielded backflow shorter than the step location, but higher flow rates for some tip/shaft combinations yielded backflow beyond the step. For stepped catheters with 30-gauge tips, it was found that the smallest shaft of 26 gauge experienced the most backflow and that the larger 20- and 18-gauge shafts did not have backflow beyond the step. For stepped catheters with 20-gauge shafts, it was found that the smallest tip of 33 gauge experienced the most backflow, with the larger 30- and 26-gauge tips not having backflow beyond the step.

Discussion

Increasing the shaft diameter for a fixed tip diameter, thereby increasing the size of the step, yielded a reduction in the backflow length. In contrast, decreasing the tip diameter for a fixed shaft diameter, which also increases the step size, yielded an increase in the

backflow length. This difference may be explained since a smaller tip diameter yields a larger infusion pressure at the tip, which may increase backflow.

Piezoelectric Peptide/Ionic Hybrid Platforms with Tunable Biodegradability for Self-Powered Biomedical Stimulation

Prof. JUHYUCK LEE

Daegu Gyeongbuk Institute of Science and Technology, Daegu, N/A, Korea, Republic of

Introduction

Diphenylalanine (FF) peptide nanotubes have recently emerged as a compelling class of bio-piezoelectric materials for implantable biomedical devices due to their strong shear piezoelectric responses, biocompatibility, and ability to self-assemble into aligned tubular architectures. Advances in meniscus-driven processing have enabled large-area, unidirectionally polarized FF nanotube films with high crystallinity, while eco-friendly ethanol–water solvent systems now allow scalable fabrication suitable for biomedical translation. Concurrently, the intrinsic rapid biodegradability of FF in physiological fluids has been addressed through incorporation of hydrophobic porphyrins, enabling controlled degradation kinetics without sacrificing piezoelectric performance. Furthermore, embedding FF nanotubes within biodegradable polymer matrices allows mechanically induced piezoelectric stimulation to directly influence cell alignment and proliferation, highlighting their potential as electromechanically active biomaterials.

Methods

Aligned FF nanotube films were fabricated using solvent-engineered self-assembly, optimizing crystallinity, orientation order, and nanotube density. Porphyrin molecules were co-assembled with FF to modulate hydrophobicity and degradation rate while retaining the non-centrosymmetric crystal phase required for piezoelectricity. To enhance mechanical robustness and biological compatibility, FF nanotubes were integrated into polymer matrices such as PLGA, PCL, PLA, and PHBV. Electromechanical outputs, degradation behavior, and cellular responses were assessed using piezoelectric measurements, biodegradation tests, FEM simulations, and in-vitro cell culture.

Results

The aligned FF nanotube scaffolds exhibited strong unidirectional polarization with shear piezoelectric coefficients exceeding 46–60 pm/V. Device platforms generated voltages in the range of 1.6–2.8 V and stable power outputs under biomechanical stimulation. Porphyrin incorporation increased hydrophobicity and extended degradation times from

minutes to beyond 15 minutes while maintaining voltage outputs above 2 V. FF–polymer nanocomposites demonstrated stable performance over more than 1000 mechanical cycles and produced local piezoelectric potentials sufficient to guide fibroblast alignment and enhance proliferation, even under cell-generated mechanical forces.

Discussion

These results establish a multifunctional platform combining aligned bio-piezoelectric nanotubes, degradation-controlled hybrid structures, and biodegradable polymer integration to create self-powered electromechanical interfaces. The ability to sustain piezoelectric output, modulate biodegradation, and regulate cellular behavior presents promising opportunities for next-generation implantable biomedical devices, including self-powered sensors, bioelectronic stimulators, and smart tissue engineering scaffolds.

Deformable Graphene-Based Electrodes That Transmit Electrical Nerve Impulses

Prof. Marek Pawlikowski, PhD Zbigniew Gulbinowicz, PhD Rafał Drobnicki, PhD Daniel Janczak

Warsaw University of Technology, Warszawa, mazowieckie, Poland

Introduction

One of the main challenges in modern neurosurgery is activating damaged nerve fibres. The complex structure and function of nervous tissue mean that materials used for nerve electrodes must meet specific requirements related to the electrical charge delivered. These emerging demands have led to the development and adoption of innovative electrode materials, along with a deeper understanding of how electrode materials influence neuron stimulation. Carbon and its allotropes are regarded as some of the best materials for neural interfaces. Their chemical inertness, biocompatibility, good electrical performance, and electrochemical stability make them superior to other materials for implantable neural electrodes.

Methods

The electrodes were produced using a screen printing method on thin, biocompatible, flexible foil with a thickness of 0.125 mm. The impulse-conducting pathway was formed from a carbon-based paste. This paste mainly comprised fine-grained graphite micropowder, conductive carbon black, and graphene.

To evaluate the basic electrical properties of the electrodes, resistance and their response to the transmission of a rectangular signal were measured. During the experiments, we applied electrical impulses to the electrodes. We tested the printed electrodes at various flexion angles to assess how different angular deformations influenced their electrical conductance. Additionally, we examined their durability and electrical stability by subjecting them to cyclic deformation.

Results

The results show that graphite- and carbon-black-based electrodes offer better electrical signal transmission, while graphene electrodes perform worse. This suggests new directions for future research on printable neural interfaces using carbon. It was also found that the electrode's electrical performance was not influenced by the flexion angle or cyclic deformation.

Discussion

In our studies, we concentrated on electrical impulse conductors printed with three types of pastes: fine-grained graphite micropowder, conductive carbon black, and graphene. The aim was to establish a correlation between the shape (length and width) of the printed electrodes and their ability to conduct electrical impulses, as measured at the different angular deformations. Since carbon and carbon-derived materials demonstrate excellent biocompatibility and low toxicity, we examined two carbon allotropes, graphite and graphene, as well as black carbon.

Utilizing Computational Models in Evaluating Exposure Risk of Implanted Medical Devices

Dr. Martin L. Tanaka PhD, PE[1], Dr. David M. Saylor PhD[2], Dr. David D. Simon PhD[2]

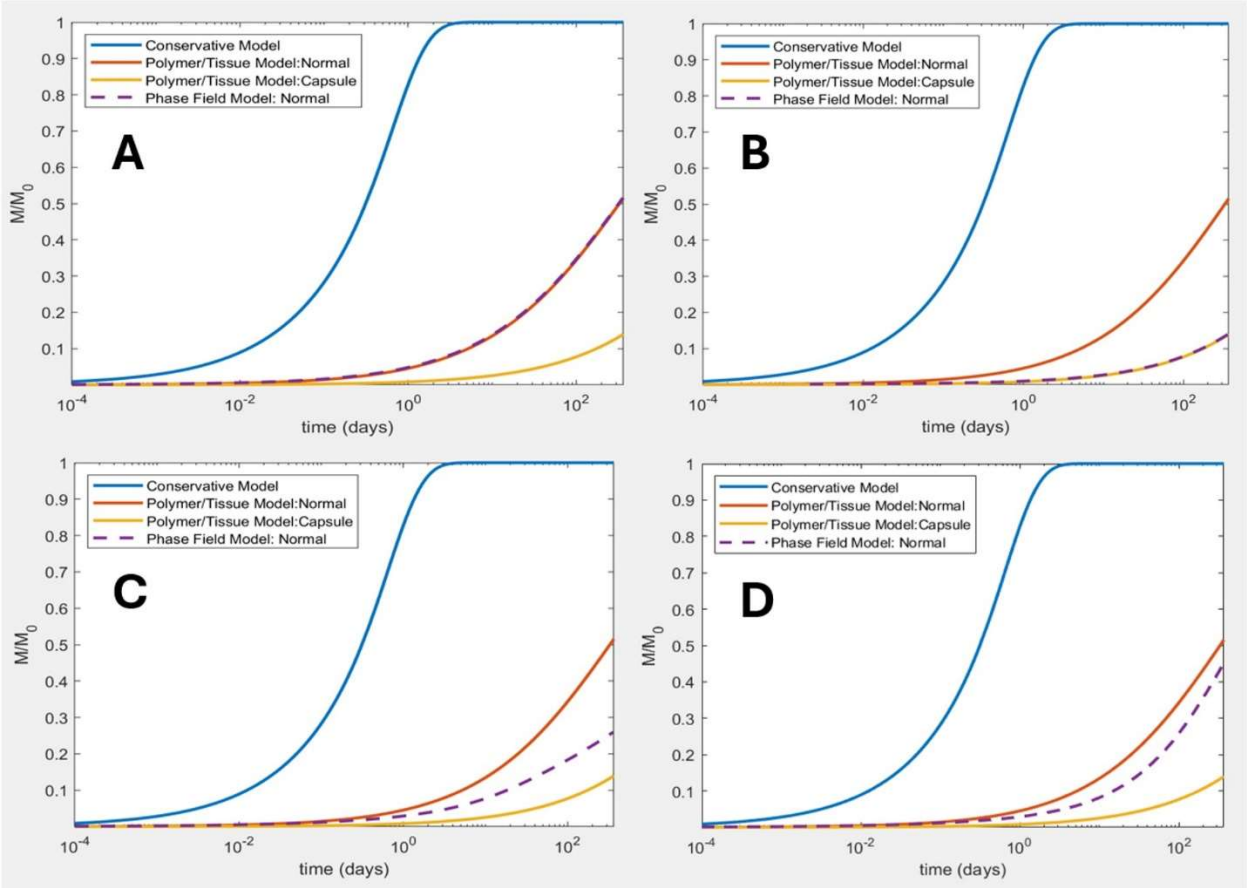
[1]Western Carolina University, Cullowhee, North Carolina, United States. [2]US Food and Drug Administration, Silver Spring, Maryland, United States

Introduction

Computational models are valuable tools often used to develop engineered products. They can be used to predict performance of a device before building the first prototype. They are particularly well suited for evaluating long term performance of a medical device because they can predict behavior spanning weeks or years in just minutes. This work examines several methods that may be used to quantify the long-term exposure and discusses the advantages of each approach.

Methods

Three methods to quantify leaching of potentially hazardous materials from implanted medical devices were examined. The **conservative model** estimates material leached from a polymeric implant by modeling diffusion of a leachable substance through the polymer matrix. The **polymer/tissue model** expands on the conservative model by also considering migration of leachable materials across the polymer tissue interface and diffusion through the tissue [1]. This enables solubility differences in the polymer and tissue to be captured. It also accounts for the influence of diffusion on leachable accumulation. The **phase field model** adds to the prior model capabilities by also considering the foreign body response, a cascade of events that can occur when medical devices are implanted.



Results

Mass release as a function of time is shown for the three models (Figure 1). The conservative model showed ~100% mass release by day four. The polymer/tissue model showed a mass release of approximately 52% in one year when set to values of normal tissue and about 14% when set to values of a capsule. The phase field model yielded results between the polymer/tissue models showing the effect of tissue transformations during wound healing.

Discussion

Performance of the three models were compared. Some are simpler to implement, while others consider more system parameters or model parameters that change over time. Each has its advantages and disadvantages. The best model to use will depend on the specific application.

Development of High-Porosity Radiopaque Shape Memory Polymer Scaffolds for Personalized Cerebral Aneurysm Therapy

Mr. Tanner Cabaniss[1], Dr. Yingtao Liu PhD[1], Dr. Chung-Hao Lee PhD[2], Dr. Bradley Bohnstedt MD[3]

[1]University of Oklahoma, Norman, Oklahoma, United States. [2]University of California, Riverside, Riverside, California, United States. [3]Indiana University School of Medicine, Indianapolis, Indiana, United States

Introduction

Cerebral aneurysms (CAs) are balloon-like protrusions of blood vessel walls in the brain, affecting approximately 4% of the population [1]. While typically harmless when unruptured, CA rupture can cause subarachnoid hemorrhage, resulting in mortality rates exceeding 50%. Current endovascular solutions, including metal coiling and flow-diverting stents, are effective in many cases but demonstrate limited efficacy for wide-necked or irregular aneurysms. To address these shortcomings, we are developing personalized shape memory polymer (SMP) scaffold-based implants with spatial and compositional tailorability to optimally treat each patient's unique aneurysm. In this study, we present an improved fabrication method for radiopaque SMP scaffolds featuring high porosity and exceptional surface area-to-volume ratios.

Methods

Polyvinyl alcohol (PVA) sacrificial templates were 3D printed and coated with a polyurethane-based SMP prepolymer mixed with powdered barium sulfate to impart radiopacity. Coated templates were shaken for uniform coverage, then centrifuged to remove excess SMP solution at varying speeds (0–100% of maximum, in 20% increments), generating g-forces up to 2500 G. Samples were subsequently cured under vacuum in a nitrogen atmosphere, and the PVA templates dissolved in a heated, circulating water bath. Cylindrical scaffolds (8 mm × 10 mm, n = 6) were evaluated both with and without barium sulfate to determine the effects of centrifugal extraction on porosity and structure.

Results

Neat (no barium sulfate) scaffold porosity increased from 83.1% to 91.5% across the centrifuge speed range, while barium sulfate–loaded scaffolds reached 87.1–94.3%. Reduced structural collapse in the barium sulfate scaffolds accounted for both higher porosity and lower surface area-to-volume ratios compared to neat scaffolds. Scaffolds

fabricated with lower infill density achieved porosities exceeding 97.5%, indicating further tunability of structural design.

Discussion

The integration of a centrifugal extraction stage substantially increased achievable scaffold porosities, enhancing compressibility, a key determinant of treatable aneurysm size. This improvement expands the potential clinical applicability of SMP scaffolds and represents a critical step toward customizable, patient-specific endovascular implants for safer and more effective cerebral aneurysm treatment.

Images (Optional)

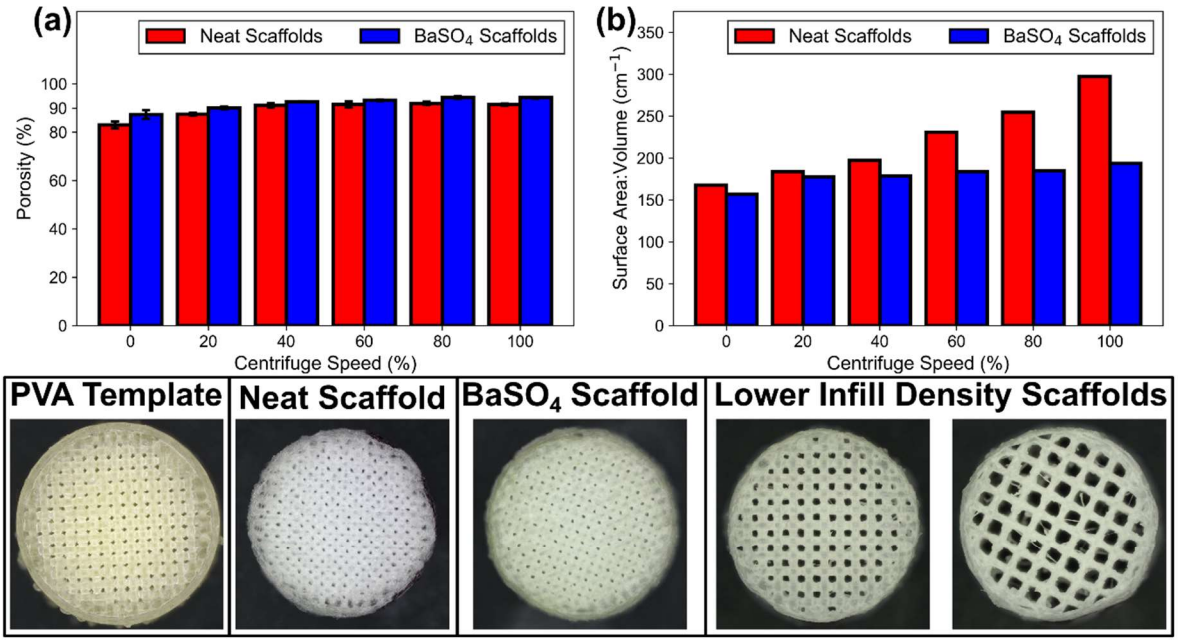

Figure 1: Bar graph summaries of (a) porosity (%) vs. centrifuge speed (%) and (b) surface area : volume ratio (cm^{-1}) vs. centrifuge speed (%). Micrographs of cylindrical (8 mm diameter, 10 mm height) PVA template and various SMP scaffolds showing 90% (left three samples), 70%, and 50% infill densities.

Toward a 3d Superelastic Corotational Beam Model for Nitinol Stents Simulations

PhD Student Thach-Hoang NGUYEN[1], Professor Mikaël Barboteu[1], Professor Serge Dumont[1], Associate Professor Francesco Bonaldi[1], Professor Franck Jourdan[2]

[1]Laboratoire de Modélisation Pluridisciplinaire et Simulations, Université de Perpignan Via-Domitia, Perpignan, Occitanie, France. [2]Laboratoire de Mécanique et Génie Civil, Université de Montpellier, Montpellier, Occitanie, France

Introduction

Flow-diverter (FD) stents have revolutionized the treatment of intracranial aneurysms, yet simulating such braided structures remains computationally demanding due to large number of wire contacts and material nonlinearity. To address the latter, we developed a 3D beam model specifically for Nitinol, one of the most widely used superelastic alloys in stent fabrication. Within the EndoBeams.jl [1] corotational framework, we developed a superelastic beam model based on Auricchio's model [2] to efficiently simulate stent wires.

Methods

The model in [2] relies on an additive strain decomposition and employs a 3D elastic constitutive law. However, for 3D beam formulation, the transverse strain and stress components (indices 22, 33, and 23) are neglected. To ensure physical consistency, the linear elastic response is defined as $\sigma_{11} = E\,\varepsilon_{11}^{e}$ for the axial component while the shear terms are governed by $\sigma_{12} = 2G\,\varepsilon_{12}^{e}$ and $\sigma_{13} = 2G\,\varepsilon_{13}^{e}$.

The superelastic model is governed by a linear evolution of the martensite fraction, updated via a return mapping algorithm. Stress and consistent tangents are evaluated at Gauss points to compute the local internal force and stiffness, which are subsequently transformed to the global system.

Results

A first simulation was conducted on a single circular beam element (radius of 0.035 mm and length of 0.1 mm) under pure tension using 27 Gauss points. Adopting material properties from [2] (E = 60000 MPa, v = 0.3, σ^{S}_{AS}=520 MPa, σ^{F}_{AS}=600 MPa , σ^{S}_{SA}=300 MPa, σ^{F}_{SA}=200 MPa), the computed Von Mises stress-strain response (Fig. 1) demonstrates initial consistency with the result in [2].

Discussion

In this study, we successfully implemented superelasticity in the EndoBeams.jl corotational framework and achieved coherent initial results. Future work focuses on validating the model with various geometries and full stents, benchmarked against commercial 3D solid solvers.

Human-in-the-Loop Optimization of Hip Exoskeleton Assistance During Incline Walking

Postdoctoral Fellow Jae-Ryeong Choi, Visiting Student Yinkai Dong, Visiting Student Catherine Rohner, Doctoral Student Anh Nguyen, Assistant Professor Patrick Slade

Harvard University, Boston, MA, United States

Introduction

Exoskeletons have the potential to substantially reduce the energetic cost of human locomotion, particularly during physically demanding tasks such as uphill walking. Although many portable exoskeletons have been developed and shown promising results, achieving substantial metabolic benefits during incline walking remains challenging. A key challenge is that providing the high assistive torques required for intensive tasks often leads to discomfort, instability, or excessive device mass.

Methods

Here, we introduce a fully portable hip exoskeleton that addresses this challenge by combining rigid structural components with a soft brace, effectively enhancing torque transmission. Using this platform, we conducted a multi-day human-in-the-loop optimization study with eight participants to identify personalized assistance profiles for incline walking.

Results

This hybrid structural component enables one of the most torque-dense portable hip exoskeletons reported to date, capable of delivering up to 45 N·m of peak hip assistance. The optimized assistance reduced the metabolic cost of 10° incline walking by an average of 21%, corresponding to a 2.1 W/kg reduction in net metabolic cost compared with walking without an exoskeleton. This absolute reduction in metabolic cost exceeds previously reported benefits across all portable exoskeletons.

Discussion

These results demonstrate that personalization combined with high-torque assistance can provide substantial metabolic benefits during uphill walking. More broadly, our findings establish a framework including exoskeleton design, optimization, and validation, which emphasizes the importance of personalizing assistance using the appropriate boundary conditions to identify optimality.

The Effect of Distributed Practice on Learning to Walk with Robotic Ankle Exoskeletons

Miss Caitlyn Baliki, Dr. Anthony Chen, Dr. Gerome A. Manson, Dr. Jessica C. Selinger

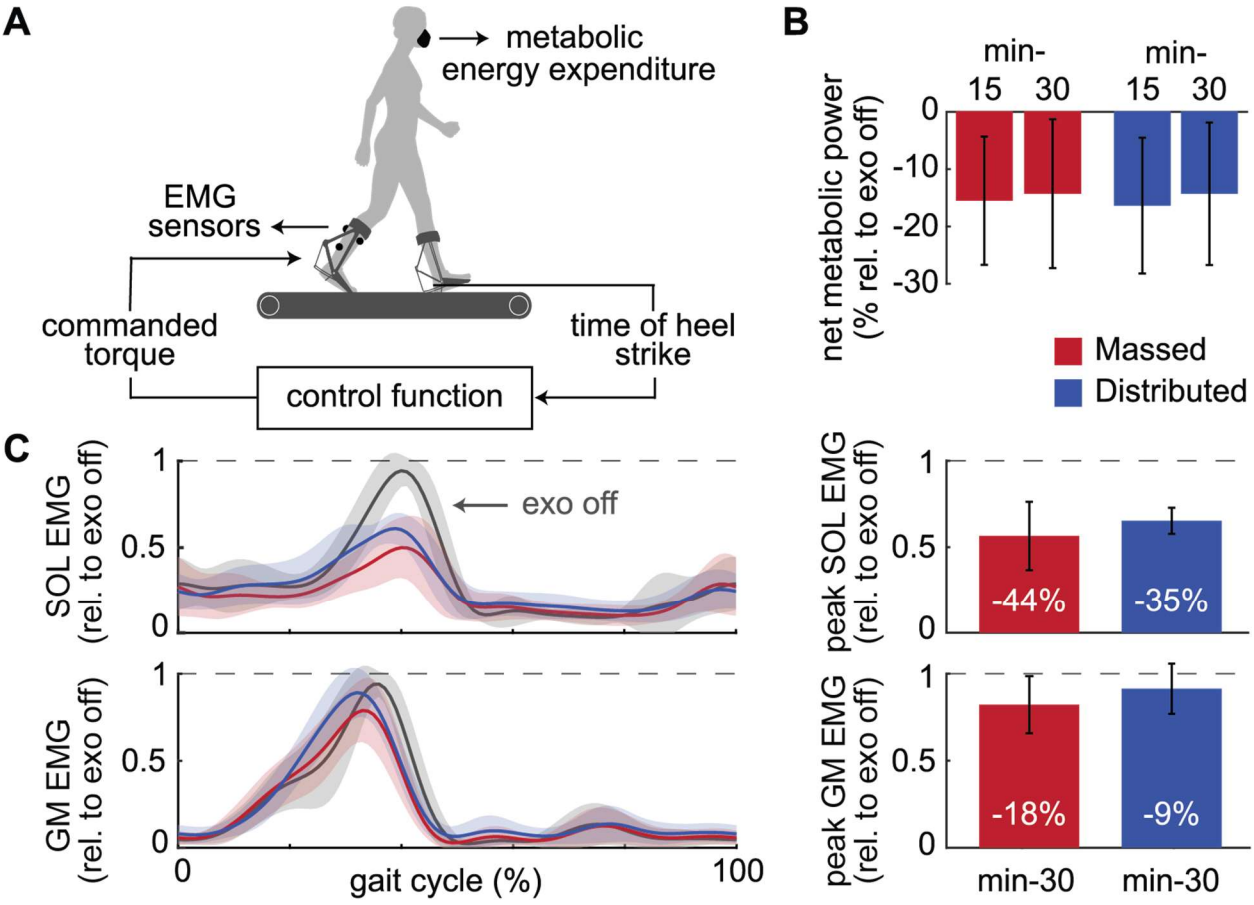
Queen's University, Kingston, Ontario, Canada

Introduction

Robotic ankle exoskeletons can reduce metabolic expenditure by decreasing the biological work required to walk. However, to achieve these savings, users must first adapt to the device, for example by reducing muscle activity [1]. This can require long and taxing periods of walking [2]. User adaptation often improves with multi-day sessions [1, 2]. This may simply be due to additional practice time, or distributed practice (where sessions are separated by extended rest periods) may offer benefits compared to massed practice (where a single, lengthy session with minimal rest occurs) [3]. Here, our aim was to test whether distributed practice better facilitates motor adaptation during exoskeleton walking compared to massed practice, when practice time is kept constant.

Methods

We instrumented participants with indirect calorimetry to measure metabolic expenditure and electromyography (EMG) sensors on the tibialis anterior, medial gastrocnemius, and soleus muscles (Fig. 1A). Participants also wore bilateral robotic ankle exoskeletons that applied assistive plantarflexion torques during the stance phase of the gait cycle. We randomized participants (n=20) into two practice groups: Massed and Distributed. The Massed group completed two 15-minute powered walking (Exo-On) trials in one day (separated by 15-minutes), while the Distributed group did so over two consecutive days (separated by 24-hours). We analyzed net metabolic expenditure and EMG peak activity using mixed ANOVAs to test for differences in adaptation magnitude for practice time and/or group.



Results

We found metabolic savings relative to the exoskeleton powered off, but no significant differences or interactions in time points (15-minute vs. 30-minute) or groups (Massed vs. Distributed) for our outcome metrics: metabolic expenditure, peak tibialis anterior, peak medial gastrocnemius, and peak soleus activity (all $p > 0.05$; Fig 1B, C).

Discussion

We were unable to determine whether distributed practice better facilitates user adaptation compared to massed practice because we observed no improvements from 15- to 30-minutes. This suggests that 15-minutes of practice is sufficient to achieve significant adaptations, but more than 30-minutes may be required to overcome an early adaptation plateau and detect further improvements.

Development of a MyoBionic Actuator for Musculoskeletal Rehabilitation

Mr. Chenghao Xing[1], Dr. Sean Thomas[2], Dr. Gregory Sawicki[3], Dr. Jonas Rubenson[1]

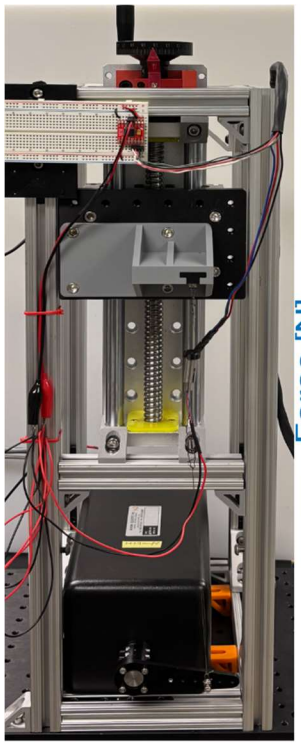
[1]The Pennsylvania State University, State College, PA, United States. [2]University of California, Los Angeles, Los Angeles, CA, United States. [3]Georgia Institute of Technology, Atlanta, GA, United States

Introduction

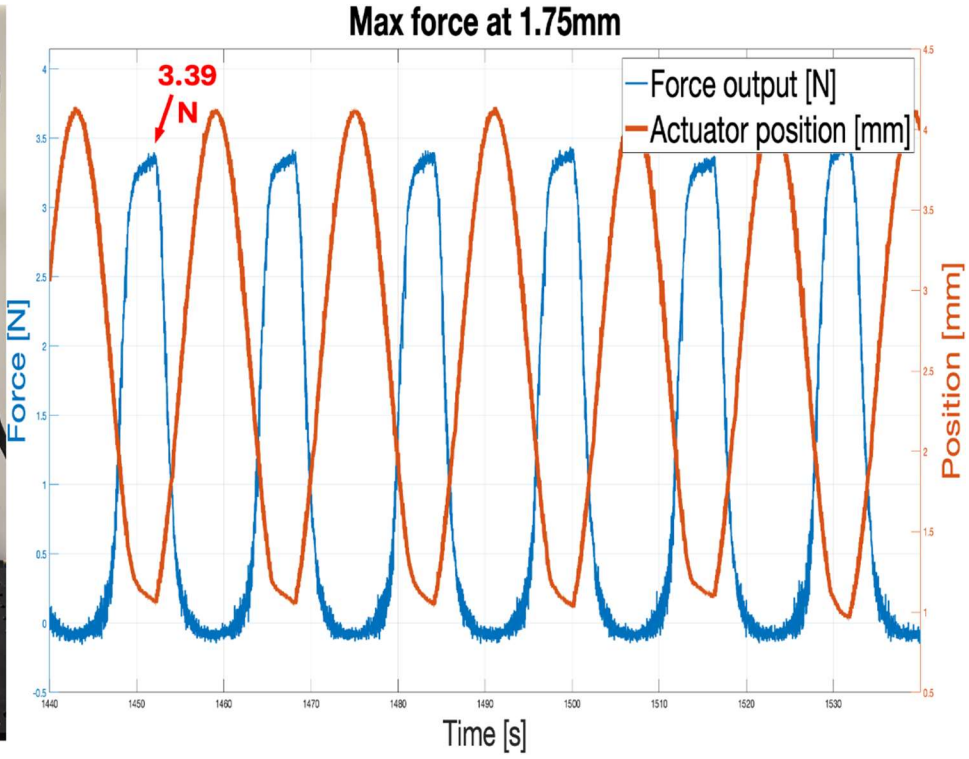
Muscle-tendon weakness is ubiquitous in aging and is common in many neuromusculoskeletal conditions. The ensuing loss of mobility is a leading cause of poor quality of life and has been linked to morbidity and even mortality (e.g., in aging [1]). Most assistive devices remain simple aids (e.g., walkers, braces, orthoses). While advanced wearable robotics are making inroads into musculoskeletal rehabilitation, both simple aids and advanced wearable devices suffer from poor user adoption, leading to the problem of non-adherence to treatment. An alternative but much less explored solution is implantable assistive devices. Here, we benchtop test a prototype assistive MyoBionic actuator aimed to be implantable in a bipedal animal model (fowl) of muscle impairment.

Methods

The Myobionic actuator was designed to provide isometric force and allow for spring elastic energy storage and return at the ankle during gait [2]. A robotic dual-mode force–length transducer was used in a linear rig to assess actuator mechanical characteristics including maximal resistance to motor back-drive (isometric force), stroke rate, and maximal contraction force. Work to simulate gait in a cadaveric preparation is ongoing.



Results



Actuator back-drive strength was estimated at over 25N, similar to the maximal in vivo ankle extensor muscle force expected during gait in fowl. Contraction strength was assessed to be 3 N, sufficient to overcome passive biological tissue resistance during length modulation. Actuator speed was assessed at 4.8 mm/sec. With these characteristics, the actuator was shown to be capable of modulating force assistance profiles for walking gait.

Discussion

Our preliminary data show that the MyoBionic actuator is suitable for meeting the functional requirements for assisting ankle torque during walking in our animal model, and for the level of assistive force to be adjustable over only a few gait cycles.

[1]University of Toronto, Toronto, Ontario, Canada. [2]University Health Network, Toronto, Ontario, Canada

Introduction

Damage to mobility devices (e.g. wheelchairs, mobility scooters) during air travel remains a surprisingly common problem that prevents many from recognizing the many benefits that air travel has to offer. There are currently no standards on how these devices should be secured when placed in aircraft cargo areas, and some of this damage has been caused by inappropriate securement. The objective of this project was to investigate current methods for securing these devices in aircraft cargo areas and develop recommendations for methods that prevent the risk of damage.

Methods

This simulation study took place in a 6 m by 6 m self-contained laboratory mounted on top of a six-degree-of-freedom motion platform. The platform was programmed to simulate 6 motions, including taxing, takeoff, turbulence, and landing, using four different aircraft. Mobility devices tested included power wheelchairs, manual wheelchairs, power scooters, strollers, and walkers, secured using different methods (Q'STRAINT self-tightening straps, conventional ratchet straps, as well as straps currently used by a major national airline). Overall, 150 different scenarios were simulated. Instrumentation included high-fidelity accelerometers and IMUs on the platform and device frames, along with calibrated load cells for measuring the tension at each strap anchor. Video recordings documented device behaviour throughout.

Results

Preliminary review of trials indicates visually stable device positioning and no evidence of slip, tip, or structural compromise across the range of test conditions, including high-vibration simulated flight. Initial results suggest that Q'STRAINT straps produced lower average loads on the devices, but slightly higher vibration transmission compared to other tie-down methods, though no failures were observed in any case.

Discussion

These early results demonstrate the feasibility and practical value of a biomechanics-informed protocol for experimentally assessing the mechanical safety of mobility devices in air travel. The protocol provides a robust foundation for future quantitative analysis and evidence-based improvement of tie-down standards, with ongoing work planned to expand data processing, evaluate load and vibration metrics in detail, and inform real-world training and policy.

Quantifying Trip Risk and Recovery Demands of Ankle-Foot Orthoses Using Pendulum Testing

Ms Elaina Van Dorp, Mr Tom Cotton, Mr Mark Roser, Dr Nataliya Rokhmanova

Motive Labs, Hebron, CT, United States

Introduction

Slips and trips are leading causes of falls, particularly among older adults and individuals with neurodegenerative conditions who rely on ankle-foot orthoses (AFOs). While AFOs provide critical gait support, their interaction with footwear can alter ground clearance and trip recovery dynamics. Standardized methods to quantify shoe-AFO performance across surface conditions are needed to guide clinical prescription and improve fall prevention strategies.

Methods

We developed an anatomically correct manikin foot-ankle system with an articulating joint mounted to a pendulum apparatus calibrated to swing at 2 m/s. Testing was conducted on smooth concrete and rocky pavement surfaces. A Converse shoe was tested alone and with three AFO designs (Blue Rocker, Semi-Rigid Leaf Spring, Adjustable Drop Foot Brace) at 0°, 5°, 10°, and 15° plantarflexion (5° increments). Minimum ground clearance was set at 1.12 mm using a gauge block. For each condition (3 trials per angle), we recorded trip occurrence and measured the peak force required to pull the shoe clear of the obstacle using a calibrated scale.

Results

At 0° plantarflexion, all configurations cleared both surfaces successfully. At 5°, only Converse tripped on smooth pavement requiring 2.39 kg clearance force, which increased to 5.16 kg on rocky terrain. The Adjustable Brace also tripped on rocky surfaces (5.50 kg). At 10°, the Converse and Adjustable Brace impacted both surfaces, with clearance force significantly higher on rocky terrain for the Brace (0.25 kg vs 5.78 kg). All configurations tripped at 15°. On smooth concrete, clearance forces were: Converse (8.85 kg), Adjustable Brace (5.85 kg), Semi-Rigid Leaf Spring (7.18 kg), and Blue Rocker (4.06 kg). On rocky pavement: Converse (13.00 kg), Adjustable Brace (12.41 kg), Semi-Rigid Leaf Spring (6.16 kg), and Blue Rocker (4.67 kg). The Blue Rocker consistently required lowest clearance forces across conditions.

Discussion

Surface texture critically influences trip recovery demands, with rigid AFO designs more vulnerable on irregular terrain. The Blue Rocker's compliant design facilitated lower clearance forces, suggesting material properties significantly affect fall risk. This pendulum method provides objective benchmarking for AFO-footwear systems. Future work should examine additional footwear styles, real-world obstacle geometries, and validation with human gait data to enhance clinical relevance.

A Powered Step Forward: Developing an Active Prosthetic Knee for Children

Mr. Elijah Birley BASc[1,2], Mr. Charles Haliburton BEng[3], Mr. Clive Mullins BASc[3], Dr. Gualtiero Guadagni PhD[3], Dr. Jan Andrysek PhD[1,2]

[1]University of Toronto, Toronto, Ontario, Canada. [2]Holland Bloorview Kids Rehabilitation Hospital, Toronto, Ontario, Canada. [3]Bionic Power, Vancouver, British Colombia, Canada

Introduction

Prosthetic knees enhance mobility, balance, and independence for individuals with above-knee amputations. Active prosthetic knees (APKs)—which use powered actuation to replicate muscle-driven movement—have demonstrated improvements in gait efficiency, symmetry, and stability in adults; however, no pediatric APK currently exists. Children with limb loss have fewer device options and unique needs due to growth, high activity levels, and size constraints. The Agilik assistive device, developed for children with cerebral palsy, features a compact, high-torque actuator. Preliminary testing suggests that this could be adapted into an APK. Considerations requiring evaluation include whether torque output and battery life are sufficient for prosthetic use.

Methods

This project will develop and evaluate the first known pediatric APK using the Agilik actuator. The five objectives are: (1) Evaluate actuator torque capacity and battery life under simulated prosthetic use, using inertial measurement units, a load cell and comparative walking trials tracking battery depletion over time and extrapolating. (2) Design and fabricate a prototype APK, through requirements definition, 3D modelling, finite element analysis, rapid prototyping, and mechanical refinement. (3) Verify safety and durability through structural testing following ISO 10328. (4) Evaluate performance using A simulated walking rig before preliminary able-bodied trials. (5) Conduct a clinical pilot study assessing gait kinematics, kinetics, spatiotemporal parameters, metabolic cost, and user satisfaction.

Results

Estimated knee torque, using able-body adult data scaled to older children, peaks at 15–21 Nm. The Agilik can be amplified up to 20 Nm; sufficient alongside the users own ability. The battery is sufficient for 1+ days use and smaller batteries, appropriate for integration, can be used. The initial 3D modelling has been completed and validated using FEA and

manufacturing has started. Assembly, structural and performance testing, and the start of pilot testing will be complete by the conference.

Discussion

This work aims to produce a functional prototype addressing a critical gap in pediatric rehabilitation technology and establish the foundation for future APK development tailored to growing users. We anticipate demonstrating that an existing assistive device can be adapted for pediatric prosthetic application, while also creating a highly controllable platform to better study pediatric gait.

Foot Progression Angle Gait Retraining: Within-Session Response to a Real-Time Feedback Algorithm in Healthy Participants

Dr. Erin Macri PT PhD[1], Dr. Mariska Wesseling[1], Dr. Martin Schepers[2], Dr. Selma Papegaaij[2], Dr. Ignazio Aleo[2], Dr.ir. Eline van der Kruk[3], Ms. Antoinette Torsij[3], Prof.dr.ir. Jaap Harlaar[1,3], Dr. Jos Runhaar[1]

[1]Erasmus MC University Medical Center Rotterdam, Rotterdam, Zuid Holland, Netherlands. [2]Moveshelf Labs BV, Utrecht, Utrecht, Netherlands. [3]Technische Universiteit Delft, Delft, Zuid Holland, Netherlands

Introduction

Altering foot progression angle (FPA) can reduce pain, reduce knee load, and slow structural progression in knee OA. Though studies have investigated FPA gait-retraining programs, it is not clear how individuals adapt to real-time feedback within a single-session. Therefore, we explored how individuals adapted their FPA in response to a single session of real-time feedback.

Methods

We developed a device with a foot-mounted sensor, and a mobile app with a previously-validated algorithm to estimate FPA and real-time audio feedback based on five-stride mean FPA. The feedback signal indicated “Good”, “Move Outward” (toe-out) or “Move Inward” (toe-in) to guide individuals towards the target FPA. We enrolled 14 healthy adults aged ≥45 years. Individuals wore the sensor on the right foot and walked on a treadmill in 3-minutes bouts, beginning with self-selected speed and natural FPA. Subsequently, individuals maintained walking speed at four target FPAs: toe-out or toe-in at 5º or 10º relative to natural FPA. To evaluate the appropriateness of a 4º feedback range (i.e., ±2º) and 5-stride feedback set-up, we calculated: FPA variance during the first and last 50 strides of each condition; overall proportion of 5-stride mean FPAs and total strides within the 4º range; and how long it took to achieve 80% adherence.

Results

Participants (57% women, mean age 59 [9.7] years, BMI 24.0[2.2] m/kg^2) naturally walked at mean 1.0 (0.2) m/s with 12.1 (6.6)º FPA, and 76% of natural strides fell within a 4º range (Table). On average, participants achieved mean FPAs close to target conditions. Variance increased substantially when learning a new FPA, but reduced during each 3-minute bout.

Most participants achieved 80% adherence within 15 feedback signals (75 strides) for each condition.

Discussion

A 4º feedback range was appropriate for this sample. Participants achieved target FPA adherence with 5-stride mean FPA feedback frequency, though this overestimated stride-by-stride performance, possibly due to regression to mean or measurement error. Adjustable feedback algorithms (range, frequency) may be useful when prescribing initial FPA targets. Some individuals may require longer walking bouts to learn a new target FPA. These findings should be confirmed in a larger, clinical population.

Physiological vs. Perceptual Exercise Intensity Targeting in Spinal Cord Injury Users: A Pilot Comparison Study

Ms Hyunji Kim[1], Ms Yoojin Choi[1], Ms Gaju Shin[1], Ms Chae Lynne Kim[1], Prof Jooeun Ahn[1,2]

[1]Seoul National University, Seoul, Seoul, Korea, Republic of. [2]Institute of Sport Science, Seoul, Seoul, Korea, Republic of

Ms Hyunji Kim

Introduction

Regular moderate-to-vigorous exercise performed for at least 20 minutes is recommended to reduce the risk of cardiovascular disease, a major secondary complication in individuals with spinal cord injury (SCI). Monitoring exercise intensity in SCI is challenging because common physiological indicators show reduced reliability due to autonomic and sensory impairments [1]. Talk-test and speed-zone approaches require substantial experience or expertise. Consequently, rating of perceived exertion (RPE) is often used for self-directed exercise. This study compared an only RPE-guided session with an individualized power-target session derived from metabolic thresholds to evaluate feasibility and differences in achieved intensity across injury levels and activity profiles.

Methods

Four SCI manual wheelchair users from a previous fitness assessment cohort (n=23) participated: tetraplegia-active, tetraplegia-inactive, paraplegia-active, and paraplegia-inactive. Participants completed two 20-minute propulsion sessions on a custom torque-sensor ergometer: (1) self-regulated using RPE 12-16 (Borg 6-20), and (2) guided to maintain individualized target power between ventilatory thresholds determined from prior assessment. Normalized peak stroke power (peak power relative to VT2 power) was computed for six 3-minute stages following a 2-minute warm-up and used to evaluate perceptual- versus physiological-based intensity targeting.

Results

Monitoring-based exercise produced more stable and target-aligned intensity profiles. Normalized peak stroke power increased across stages with relatively small between-participant variation and group means approaching the VT2 target. By contrast, RPE-only

exercise consistently underestimated the intended workload: group means remained at ~0.7-0.8 times VT2 power with greater variability, and several participants showed sustained under-target performance throughout the session. This trend was most evident among individuals with tetraplegia or lower physical activity. These patterns indicate that perceived exertion alone did not reliably reflect the physiological intensity required to reach individualized metabolic thresholds.

Discussion

Findings highlight a systematic mismatch between perceptual and physiological intensity regulation. Monitoring-based feedback improved alignment with VT-derived targets and reduced variability, suggesting enhanced feasibility for achieving prescribed intensities. Although based on a small heterogeneous cohort, the consistent underestimation clarifies the need for integrating objective workload cues into exercise prescription for SCI populations.

Towards Intelligent Assistive Aids: An Imaging-Based Rollator Walker for Posture Analysis

Ms Ivanna Kramer[1], Dr Sabine Bauer Rhineland-Palatinate[2], Prof. Dr. Dietrich Paulus[2]

[1]University of Koblenz, Koblenz, RLP, Germany. [2]University of Koblenz, Koblenz, Rhineland-Palatinate, Germany

Introduction

Poor upper-body posture during rollator use can increase discomfort and fall risk, highlighting the need for continuous and objective monitoring. This work introduces an imaging-based extension to our previously developed sensor-based rollator walker, enhancing its capability for posture classification [1].

Methods

A rollator walker was equipped with two Intel RealSense D435i RGB-D cameras, mounted using custom 3D-printed brackets to capture synchronized RGB and depth data during usage. Eight participants walked a 10-meter path twice: once with an upright posture and once with intentionally poor posture induced by lowering rollator handles. Hip joints were detected using YOLO Pose on each RGB frame to define a region of interest (RoI) in the corresponding depth map (Fig. 1). Within each RoI, multiple feature categories were extracted: (1) structural depth features using Sobel gradients to capture depth discontinuities, (2) contour-based descriptors representing shape complexity, and (3) statistical depth measures (mean depth and standard deviation). These features were used to train Support Vector Machines, Logistic Regression, Random Forest (RF), and an ensemble of XGBoost and RF (XGRF). Performance was evaluated using accuracy, precision, recall, F1-score.

Results

A total of 3,380 valid RoIs (1,787 poor and 1,593 good posture) were extracted. Using only geometric depth features resulted in moderate classification performance (accuracy 0.64–0.71), with RF and XGRF already outperforming linear models. Including statistical depth metrics enhanced separability between posture classes, increasing RF and XGRF performance to an accuracy of 0.85, precision of 0.88–0.89, recall of 0.83, and F1-score of 0.86. The SVM model showed the highest recall (0.86), indicating strong sensitivity to poor

posture, although precision was lower due to increased false alarms. Overall, ensemble approaches achieved the most stable and reliable performance across all metrics.

Discussion

Although the number of participants in this study is limited, the findings demonstrate that analyzing RGB-D data integrated into a smart rollator can reliably distinguish posture quality during walking. The accompanying RGB-D dataset further supports ongoing research in intelligent posture-aware rollator systems, showing the potential of the presented methodology.

Novel Sensor Fusion of Ultrasound and Pressure Sensing Insoles Enables Lower Limb Future Kinematic Predictions Across Ambulation Modes

Ms. Juliana Iverson, Ms. Marissa Pirritano, Mr. Finn Eagen, Dr. Nicholas Fey

The University of Texas at Austin, Austin, TX, United States

Introduction

Real-time prediction of lower limb joint kinematics can improve wearable robotics and rehabilitation. Ultrasound imaging provides spatiotemporal information on muscle tissue dynamics, indirectly measuring neuromotor processes that drive movement. Pressure-sensing insoles capture spatiotemporal patterns of foot-ground contact and are increasingly used in biomechanical research. There is minimal overlap between the spatial information each sensing modality provides making them suitable for convolutional neural networks (CNNs). This study integrates unilateral ultrasound images with bilateral insole pressure maps to predict lower-limb joint kinematics and evaluates subject-specific future prediction performance. Unlike most prior work focusing on mode-dependent gait, we also include noncyclic activities, hypothesizing that these complementary modalities enable accurate kinematic forecasts across diverse movements.

Methods

Six able-bodied adults completed trials while wearing pressure-sensing insoles and an ultrasound probe positioned across the rectus femoris of the nondominant leg. Joint kinematics were computed using markerless motion capture data. Trials included cyclic (ambulation circuit) and noncyclic tasks (non-phase-dependent activities such as pick-and-place). Subject-specific CNNs were trained on three datasets: all trials, cyclic only, or noncyclic only. Synchronized ultrasound images and pressure maps served as inputs, with CNNs predicting sagittal-plane hip, knee, and ankle angles 160 ms in the future. Performance was assessed using RMSE and Pearson correlation on held-out test sets. Permutation importance quantified each sensor's contribution.

Results

Baseline models trained on both cyclic and noncyclic trials outperformed those trained on a single trial type. Mean prediction errors (Table 1) were lower across joints for both cyclic (RMSE = 8.08°, R = 0.87) and noncyclic (RMSE = 21.56°, R = 0.35) data. Permutation

importance revealed that disrupting pressure insole data caused the largest performance drop.

Discussion

Integrating ultrasound and pressure insole data, along with including both cyclic and noncyclic movements, improves lower limb kinematic predictions. Foot-ground contact information primarily drives accuracy, while ultrasound provides complementary insight into finer muscle dynamics. Predictions for noncyclic movements remain challenging, though results across five ambulation modes in cyclic data are promising. These findings suggest that multi-sensor fusion can yield robust, subject-specific forecasts across diverse activities, extending beyond traditional mode-based models. Future work with more subjects and leave-one-subject-out validation is planned to assess generalizability.

Intraoperative Sensor-Based System for Simultaneous Dynamic Evaluation of Tibiofemoral and Patellofemoral Joint Balance in Total Knee Arthroplasty

Mr. Kosuke Tokashiki[1], Prof. Takeshi Shimoto[1], Mr. Chihiro Takaki[1], Prof. Shinya Kawahara[2], Prof. Yasuharu Nakashima[2]

[1]Fukuoka Institute of Technology, Fukuoka, Fukuoka, Japan. [2]Kyusyu University, Fukuoka, Fukuoka, Japan

Introduction

Patient dissatisfaction following Total Knee Arthroplasty (TKA) is linked to load instability in medial and lateral condyles [1]. While optimal tibiofemoral (TF) soft-tissue balance is crucial, intraoperative assessments remain largely qualitative [2]. Furthermore, despite the impact of patellofemoral (PF) complications on QOL, standardized dynamic PF evaluation is lacking [3]. We aimed to develop a surgical support system for Posterior Stabilizer (PS) prostheses that quantitatively evaluates TF-PF interaction via real-time feedback of TF load balance and PF 3D load vectors.

Methods

We developed a system for PS prostheses using a compact 2-axis moment sensor in the tibial insert and a 3-axis force sensor in the femoral trial to quantify TF balance and PF loads. Sensors were embedded in custom acrylic monomer trials; the insert featured a sliding mechanism for easy exchange. Custom software visualized real-time load vectors. Validation used a knee model with acrylic bones and artificial ligaments under a dynamic flexion/extension (0[deg]–90[deg]) protocol.

Results

PF compression from 0 N at extension to ~20 N at 10[deg], plateaued at 40-50[deg], and peaked at ~48 N at 90[deg]. Proximal-distal shear shifted distally after 20[deg], reaching -13 N at 70[deg]. TF medial-lateral load balance fluctuated with flexion angle, reversing at 40[deg] and reaching -0.5 N at 90[deg]. In contrast, TF anterior-posterior load remained negligible (~0 N), indicating high conformity and stability.

Discussion

The system successfully quantified dynamic behavior undetectable by static assessment. PF compression increase aligns with the patella engaging the trochlear groove as a biomechanical pulley. The distal shear shift reflects patellar tendon vector influence in deep flexion. Negligible TF anterior-posterior load confirms implant conformity, while

medial-lateral fluctuations relate to physiological motion. Limitations include acrylic models that do not replicate articular friction; future validation with biofidelic systems is needed. By visualizing these dynamics, the system enables intraoperative optimization of implant positioning to ensure stability throughout the range of motion, contributing to safer, more physiological dynamic stability.

Active Walking Assistive Device Considering the Anatomical Axis of Metatarsophalangeal Joint to Improve Push Off During Level Walking

Mr. Sang Woo Jung BSc, Mr. Joonsoo Kwak HS, Post Doc. Pankwon Kim PhD, Prof. Choongsoo Shin PhD

Department of Mechanical Engineering, Sogang University, Seoul, Mapo-gu, Korea, Republic of

Introduction

Anatomical axis of metatarsophalangeal (MTP) joint has not been considered in most current active walking assistive devices even though it can improve their effect on human during push off. The purpose of this study was to develop an active walking assistive device considering the anatomical axis of the MTP joint and investigate its effect on human push off performance.

Methods

The non-anatomical MTP axis was defined as a line from the first metatarsal center perpendicular to the sagittal plane, whereas the anatomical axis connected the first metatarsal center to the fifth metatarsal head. Forefoot and metatarsal segments were divided along each axis, with FSRs positioned as two on the forefoot and one on the metatarsal segment. A rear-mounted motor was adopted to emulate plantar fascia–like tensioning. A trigger-based control strategy was implemented to operate the motor by detecting heel contact, tracking the rise and peak of forefoot pressure, and determining the stance-phase duration up to toe-off. Using the normalized timing ratio extracted from these pressure events, the motor was activated so that maximal assistance was operated to the MTP joint during push-off phase.

Three healthy male subjects walked barefoot at a self-selected speed on a flat surface while ground-reaction forces were recorded using a 1200-Hz force plate synchronized with a 400-Hz motion-capture system with markers placed at anatomical landmarks. Kinematic and kinetic data were collected for a single gait cycle and processed using a fourth-order Butterworth low-pass filter frequency of 10Hz.

Results

Walking speed, device range of motion, anterior ground reaction force, and force sensing reaction value of the anatomical axis of the MTP joint rate of increase 10.33%, 30.69%,

25%, and 17.47% respectively, compared to the non-anatomical axis of the MTP joint (Table 1).

Discussion

Applying the anatomical axis brought the device behavior closer to normal MTP joint function and suggested improved human–device interaction during gait. The anatomical condition increased walking speed and anterior GRF, suggesting enhanced interaction that improved push-off. In conclusion, considering the anatomical axis in the design of walking assistive device can improve human-device interaction, ultimately improving gait performance during push off.

Quantitative Analysis of Autonomous Wheelchair Navigation Stability: A ROS2-Based Framework for Pediatric Mobility Assistance

Ms. Uchechi Ukaegbu Ph.D. Student, Mr. Jesuloluwa Zaccheus Ph.D. Student, Dr. John Andersen Professor, Dr. Mahdi Tavakoli Professor, Dr. Hossein Rouhani Professor

University of Alberta, Edmonton, Alberta, Canada

Introduction

Children with severe motor disabilities often cannot operate power wheelchairs due to an inability to use joysticks or alternative control methods. Autonomous navigation can offer safer mobility, but its effectiveness depends on tuning navigation parameters to achieve stable path tracking, minimal unnecessary rotations, and predictable behaviour in indoor clinical spaces. Without proper tuning, sudden corrections can cause postural perturbations, increasing user discomfort and anxiety. This study presents a ROS2-based autonomous pediatric wheelchair and evaluates its navigation performance following structured parameter optimization.

Methods

A conventional pediatric wheelchair (0.86 × 0.53 × 0.60 m) was equipped with an RPLidar A12, wheel encoders, and a custom ROS2 hardware interface. The ROS2 navigation stack [1] guided the wheelchair using the regulated pure pursuit controller [2] for path tracking. Baseline trials using default parameters produced excessive rotations, overshoots, and poor tracking. Five critical navigation parameters were experimentally tuned and examined individually to characterize their effects on controller stability, goal convergence, and rotation behaviour. Tuning proceeded sequentially to isolate first-order sensitivities. The resulting configuration provides a clinically practical parameter set for indoor pediatric mobility, rather than a provably global optimum. Navigation was tested using the default NavFn and the Theta star planners on a 12-meter course, followed by ten repeated trials with the optimized configuration.

Results

The optimized Theta star configuration reduced mean absolute error by 42.5% and root mean square error by 35.6% compared to baseline, as shown in Table 1. Tracking variability decreased, and the resulting paths were smoother. Across 6172 tracking points, 60% had

errors below 0.15 m. The NavFn planner performed worse, with MAE of 0.336 0.048, RMSE of 0.445 0.063 m, and spurious rotations despite parameter adjustments.

Discussion

Parameter threshold analysis showed that XY tolerances above 0.3 m and yaw tolerances above 0.785 rad produced repeated in-place rotations at navigation onset. Minimum lookahead distances below 0.25 m caused instability, while distances above 0.35 m increased overshoot. Lookahead values below 0.4 m also allowed erratic rotations. Systematic tuning improved stability, predictability, and clinical suitability, establishing validated parameters that support future user-focused trials.

Images (Optional)

Table 1: Navigation performance comparison

Parameter	Baseline parameters	Optimized parameters
rotate_to_heading_angular_vel	1.8 rad/s	1.0 rad/s
lookahead_distance	0.6 m	0.8 m
min_lookahead_distance	0.4 m	0.28 m
xy_goal_tolerance	0.25 m	0.15 m
yaw_goal_tolerance	0.25 rad	0.75 rad
Mean absolute error	0.254 ± 0.179 m	0.146 ± 0.046 m
Root mean square	0.303 ± 0.144 m	0.195 ± 0.037 m

Biomechanics of Yawning: Insights Into Cranio-Cervical Fluid Dynamics and Kinematic Consistency

Dr Adam Martinac PhD

Neuroscience Research Australia, Sydney, NSW, Australia

Introduction

Yawning is a stereotyped orofacial–respiratory behaviour whose physiological role remains uncertain. A range of hypotheses have been proposed: physiological hypotheses suggest that yawning may play a role in regulating blood oxygen/CO_2 levels and airway patency, brain thermoregulation, arousal/attentional state, and cerebral metabolic waste clearance. Because cerebrospinal fluid (CSF) movement contributes to solute transport and waste removal and is strongly influenced by respiratory pressure dynamics, this study evaluated whether yawning alters neurofluid flow relative to normal and deep breathing, and whether yawning kinematics are reproducible within individuals.

Methods

In a single MRI session in healthy adults (N = 22), real-time phase-contrast imaging at the upper cervical level (C3) was combined with mid-sagittal real-time cine imaging to quantify CSF and internal jugular venous flows during normal breathing, forceful oral inspirations (“deep breaths”), yawns, and stifled yawns, and to derive tongue-motion trajectories. The real-time PC-MRI protocol used turbo-field echo-planar imaging and was not cardiac gated. The encoding velocities were set to 10-20cm/s for CSF flow and 60-90cm/s for arterial and internal jugular flow. CSF and blood flow were measured in separate, sequential scans rather than simultaneously due to velocity encoding constraints

Results

Both deep breaths and yawns increased CSF and venous flow compared with normal breathing; despite similar flow magnitudes (Figure 1), yawns more frequently produced co-directional caudal CSF and jugular outflow during inspiration, whereas deep breaths typically showed counter-directional CSF–venous profiles. Yawning kinematics were highly reproducible within individuals across repeated events. Once triggered, yawns proved difficult to suppress completely. While participants could modify the yawn by keeping their lips closed and reducing jaw movement, they could not prevent the yawn entirely (Figure 1).

Discussion

These observations show that yawning is not simply an intensified breath but a distinct cardiorespiratory manoeuvre that reorganizes neurofluid flow. The inspiratory alignment of CSF with venous outflow during yawns suggests a transient caudal advection that could influence solute transport and heat exchange within the cranial–cervical system. In addition, yawns within individuals also exhibited highly stereotyped orofacial tongue kinematics across repeated events, compatible with, but not proof of, control by a central pattern generator.

Images (Optional)

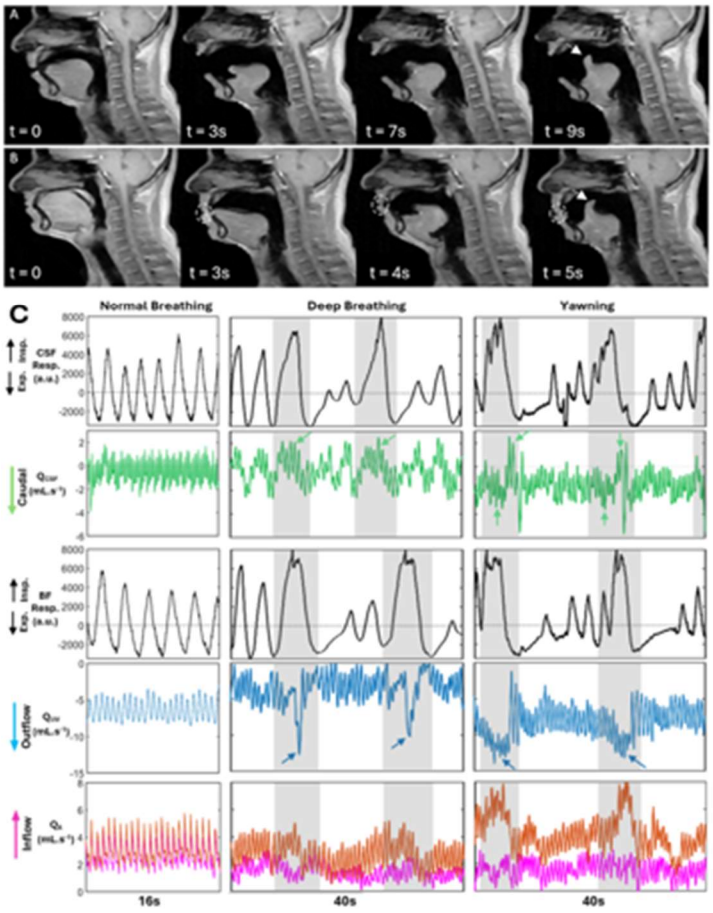

Figure 1. Yawning, stifled yawning, and associated CSF/vascular flows. **(A)** Sagittal real-time montage of a full yawn in representative participant. After inspiration, the tongue retracts and rapidly alternates between horizontal and vertical orientations at the yawn apex (white arrows), then returns to rest with expiration. **(B)** Montage of a stifled yawn in the same participant. Despite a voluntarily closed mouth (dashed white circle), tongue movements closely resemble the full yawn. **(C)** CSF (green) and vascular flows from the internal jugular vein (blue), vertebral artery (orange), and internal carotid artery (magenta) during normal breathing, deep breaths, and yawns (Q, ml·s^{-1}; positive = cranial, negative = caudal), with respiration shown in black (arbitrary units). Deep breaths produce bidirectional shifts with cranial CSF inflow and increased jugular outflow on inspiration that reverse on expiration (counter-directional); yawns produce the largest changes, often with caudal CSF flow and jugular outflow aligned during inspiration (co-directional).

Digital volume correlation at the voxel level for the study of mineralised tissues

Dr Alissa Parmenter PhD, MEng[1], Dr Elis Newham[2], Dr Aikta Sharma[1], Dr Joseph Brunet[1], Dr Nick Terrill[3], Dr Federico Bosi[1], Professor Andrew Pitsillides[4], Dr Brian Bay[5], Professor Himadri S Gupta[2], Professor Peter D Lee[1]

[4]Royal Veterinary College, London, London, United Kingdom. [5]Oregon State University, Corvallis, Oregon, United States

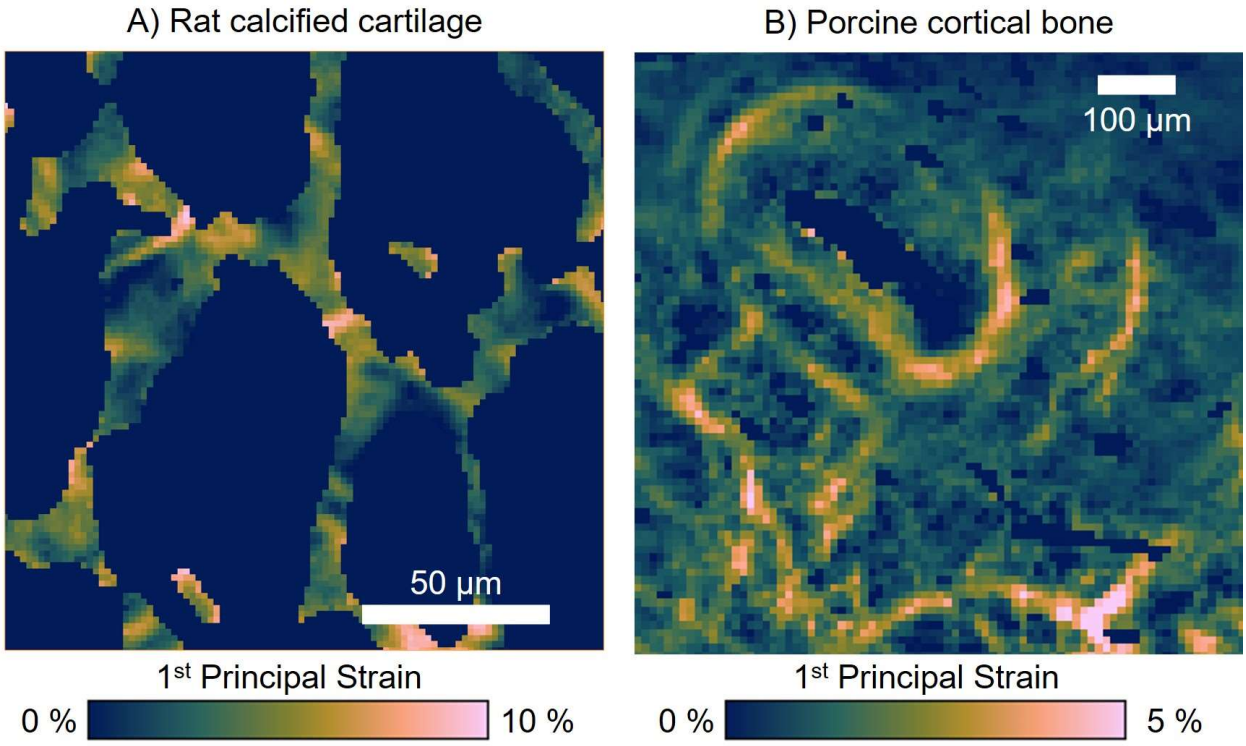
Introduction

Digital Volume Correlation (DVC) enables quantitative experimental measurements of strain in mineralised tissues. Improving spatial resolution of DVC strain fields is critical for probing microscale mechanics with lower-dose X-ray imaging and for validating finite element models. We previously showed accurate strain measurement in bone and calcified cartilage with points spaced every 4–5 voxels [1]. Here, we show that accurate voxel-wise strain measurements can be achieved in both synchrotron and lab-based microCT images of mineralised tissues.

Methods

In situ microCT datasets from multiple animal models (rat, mouse, pig, zebrafish) and imaging systems (Diamond I13-2, ESRF BM18, Skyscan 1270) with 1–10 µm voxel sizes were analysed. Mineralised tissue was segmented by thresholding. Local DVC was performed using the open-source software iDVC [2], with spherical sub-volumes (~30-voxel diameter, optimised per dataset) centred on every mineralised voxel, resulting in >90% sub-volume overlap. Lagrangian strain was derived from the displacement field via a least-squares second-order Taylor expansion.

Results



Zero-strain and virtual deformation tests showed displacement accuracy of 0.01-0.1 voxels and strain accuracy of 0.01-0.2% (image-dependent). DVC strain fields resolved tissue-level deformation in features <10 voxels thick, such as mineralised cartilage septa (Fig. A). Strain patterns generated by features smaller than the image resolution were seen, including strain around cement lines in cortical bone in images with a 10µm voxel size

(Fig.B). The presence of these features was confirmed by scans at 2µm voxel size within the same sample.

Discussion

This work substantially advances the achievable strain-measurement resolution in microCT/sCT imaging of mineralised tissues. Although smoothing means the strain field cannot fully match the underlying image resolution, we show that strain localisation driven by sub-resolution features can still be detected. This capability opens new possibilities for investigating microscale biomechanics while reducing required imaging resolution—and therefore X-ray dose—for studies of mineralised tissues. The analysis pipeline is fully open-source and we have demonstrated it's applicability across a range of synchrotron and lab-based imaging systems, as well as a range of sample types.

[4]School of Clinical Sciences, Queensland University of Technology, Brisbane, Queensland, Australia. [5]CSIRO Health and Biosecurity, Brisbane, Queensland, Australia

Introduction

Bone remodelling maintain skeletal integrity through the activity of Basic Multicellular Units (BMUs), composed of osteoclasts, osteoblasts, and progenitor cells. Synchrotron-based *in-vivo* micro-CT now enables direct 4D visualization of cortical remodeling and access to dynamic resorptive parameters such as the Longitudinal Erosion Rate (LER) [1], which previously was only measured indirectly using histology. However, current analyses rely on manual BMU identification, which is time-consuming, operator-dependent, and difficult to scale, especially within the highly interconnected cortical porosity where vascular canals form complex branching networks, often amplified under drug treatment.

To overcome these limitations, we developed a novel method integrating porosity segmentation, topological graph modeling, and scale-tensor field analysis to extract local structural features, quantify network complexity over time, disentangle branched BMUs, and track BMU progression in 4D to compute LER.

Methods

Using longitudinal *in-vivo* (t=5,10,15 days) synchrotron micro-CT (13 µm) of tibiae of New Zealand White rabbits (n = 7) treated with intermittent PTH (1–34, 30 µg/kg/day × 15 days), followed by *ex-vivo* micro-CT (t=20 days), we proposed a novel 4D analysis pipeline (Fig. 1): (1) preprocessing and segmentation of cortical porosity; (2) topological and graph-based characterization of the vascular canal network; (3) scale-tensor estimation of local anisotropy and orientation; (4) tensor-topology disentanglement to extract branched BMUs; (5) 4D tracking of BMUs to compute LER.

Results

The method enabled detailed topological characterization of the vascular canal network, revealing increased branching and complexity following PTH treatment. Scale-tensor analysis captured heterogeneous BMU orientations and morphologies. The disentanglement stage identified substantially more branched BMUs than isolated ones, consistent with the biological emergence of new BMUs from existing canals. Median LER values were 22.6 µm/day (t1–t2), 26.3 (t2–t3), 21.8 (t3–t4), and 23.1 (t1–t4). Kruskal–Wallis testing ($p = 0.138$) showed no significant temporal differences, consistent with manual measurements.

Discussion

This automated 4D method provides robust topological and structural descriptors of cortical remodeling *in-vivo*. It overcomes limitations of manual BMU identification and is adaptable to other microstructures, skeletal sites, and high-resolution imaging modalities, offering a scalable platform for studying remodelling dynamics and evaluating therapeutic interventions.

Tissue-Specific Optical Signatures: Comparing Dermis and Pancreas for Thermal Therapy Design

Ms. Anjelyka Fasci

University of Texas at San Antonio, San Antonio, Texas, United States

Introduction

Thermal therapies are minimally invasive treatments achieving effects through controlled heat delivery. A core challenge is achieving precise thermal effects while preserving surrounding structures. Dermis provides an excellent model due to its organized architecture dominated by collagen scattering, allowing reproducible measurements and predictable responses. Conversely, the pancreas presents substantial challenges: deeply situated, highly heterogeneous with irregular arrangements, and exhibiting complex optical properties due to variable lipid, fibrosis, and vascular density, particularly in pancreatic cancer with fibrotic stroma.

Methods

Optical characterization utilized a dual integrating sphere system with tungsten halogen illumination. Porcine dermis and pancreas specimens were mounted between fused silica windows for optical measurements using Inverse-Adding-Doubling analysis. Tissue thickness was measured using a dial indicator with thousandths of a millimeter precision. System calibration used a reference polyurethane phantom. This methodology enabled rigorous optical property comparison.

Results

Pancreatic tissue exhibited higher absorption coefficients, particularly near hemoglobin peaks (540-580 nm), but substantially lower scattering coefficients compared to dermis. Dermal tissue demonstrated higher baseline scattering from its dense collagen matrix. Dermal tissue's elevated scattering indicates more dramatic structural changes. These distinct signatures suggest tissue-specific calibration and predictive models are necessary for safe, effective therapy.

Discussion

This study reveals fundamental optical differences critically impacting thermal therapy design. Pancreatic tissue's higher absorption yet lower scattering demonstrates that

extrapolating protocols from superficial to deep tissues is problematic without tissue-specific characterization. These findings have implications for pancreatic cancer treatments. Future investigations should characterize optical property evolution during thermal exposure and extend this framework to diseased pancreatic tissue.

An In Silico Biomechanics Framework for Ultrasound Shear Wave Elastography to Measure Myocardial Stiffness

Dr. Eng. Annette Caenen[1,2], Eng. Marta Zattoni[3,4], Dr. Eng. Mathias Peirlinck[4], Prof. Dr. Eng. Jan D'hooge[2], Prof. Dr. Eng. Patrick Segers[1]

[1]Ghent University, Ghent, East-flanders, Belgium. [2]KU Leuven, Leuven, Flemish Brabant, Belgium. [3]Ghent University, Ghent, East Flanders, Belgium. [4]Delft University Of Technology, Delft, South Holland, Netherlands

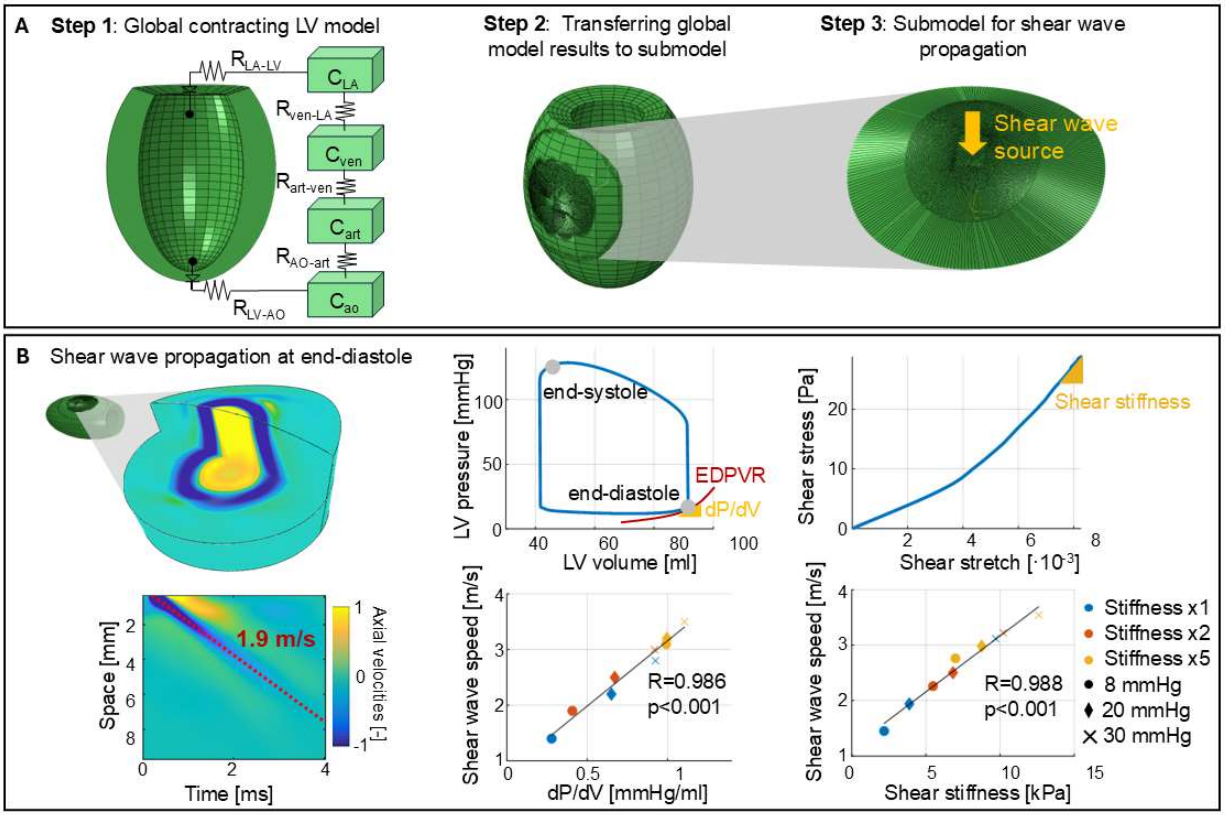
Introduction

Ultrasound shear wave elastography (SWE) can non-invasively assess myocardial stiffness by inducing shear waves with focused ultrasound and tracking their propagation in real time. Since shear wave speed reflects tissue stiffness, SWE holds promise for improving diagnosis and treatment. However, shear wave speed increase can result not only from pathology but also fiber orientation, wave-guiding, and pressurization. To address these confounders, we developed a finite element framework of the left ventricle (LV) tailored for SWE. The framework has been refined and validated in previous work through gradually increasing complexity of models and experiments. Building on this foundation, the framework was extended to incorporate myocardial contraction, enabling a more comprehensive evaluation of myocardial mechanics.

Methods

The LV was modeled as a truncated ellipsoid in Abaqus, connected to a closed-loop lumped parameter system. The passive material response followed a nonlinear, anisotropic Holzapfel-Ogden law (2009), and active response a time-varying elastance function [1]. Material parameters were tuned to obtain realistic pressure-volume response: (92ml, 12mmHg) in end-diastole and (43ml, 125mmHg) in end-systole. Operational stiffness was derived from pressure-volume and shear stress-stretch analysis. Shear waves were simulated in a refined submodel by applying a body force for 300µs at end-diastole (fig. A). Wave speeds were estimated at the mid-wall in long-axis view using Radon transform. Simulations were repeated for various LV stiffnesses (x1, x2, x5) and filling pressures (8, 20, 30mmHg).

Results



Shear wave speed increased with pressure and stiffness (fig. B). At higher stiffness levels, however, the rate of increase in speed diminished with increasing pressure (Δ1.34 vs. 0.36m/s at stiffness factor x1 and x5 for Δ22mmHg). Shear wave speed showed a strong

correlation with operational stiffness derived from pressure-volume analysis (R=0.989, p<0.001), consistent with animal experiments [2], and shear stress-stretch analysis (R=0.988, p<0.001).

Discussion

This work presents a biomechanics framework for virtual cardiac SWE measurements, enabling both validation of the technique, and mechanistic insights into the relationship between shear wave speed and myocardial stiffness. Future developments will extend the framework to end-systolic wave speed as a marker of contractility.

Anatomically Accurate Shape Correspondence for Statistical Shape Modelling of Human Bones

Dr Soheil Arastehfar, Dr Athena Jalalian

University of Twente, Enschede, Overijssel, Netherlands

Introduction

In statistical shape modelling, shape correspondence is the crucial step of establishing a mapping between structurally similar points across a population of shapes. In groupwise correspondence, these points are aligned iteratively through converging to a mean shape. Thus, the correspondence is biased to the converged mean shape. We hypothesize that the correspondence can represent the bone anatomy more accurately if the convergence criterion defines discrepancies between the shapes.

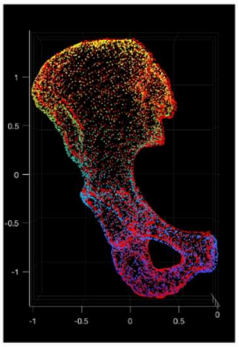
Methods

We created statistical shape models of three different bones, Femur, Tibia, and Hip. Per bone, 10 images were available. Two sets of models were produced based on iterations on mean shape and deviations of aligned shapes. We then tested these models to determine their capability of bone shape reconstruction. We did this in a leave-one-out cross validation setting. Next, the errors of the reconstructions based on the mean shape convergence and minimized alignment deviations were paired. We carried out one-way paired *t*-test at statistical significance level of 1%. The alternative hypothesis stated reduction in the mean of errors, and the null hypothesis stated the inequality in the opposite direction.

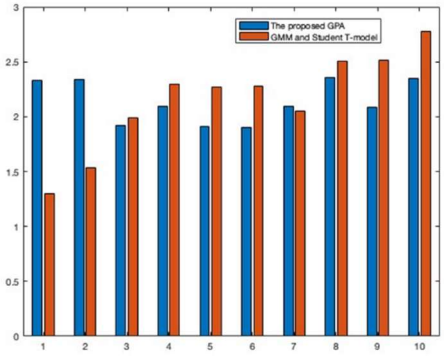
Results

The results showed error improvement from 5.5±1.3mm to 0.8±0.1mm for Femur, from 4.4±1.3mm to 0.7±0.2mm for Tibia, and from 2.2±0.5mm to 2.1±0.2mm for Hip. As for the *t*-tests, we found strong statistical evidence to reject the null hypotheses for Femur and Tibia, p=.000, while we failed to reject the null hypothesis for Hip, p=0.466. We achieved better correspondence establishment with Femur and Tibia bones, but for the hip the results were comparable.

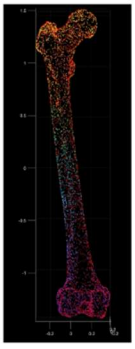
Discussion



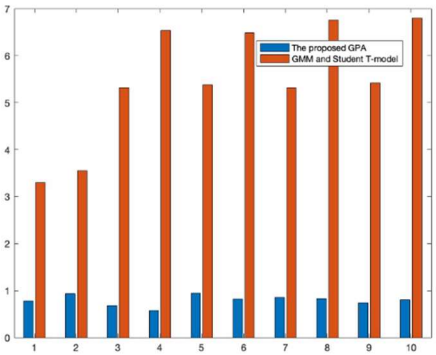
In bones with elongated shapes, the variations are mainly in the proximal and distal bones rather than in the bone shaft. For a good correspondence establishment, it is important that the two end parts are well aligned. Our approach by measuring the shape deviations



tries to minimize the discrepancies between the shapes especially in the proximal and distal bones. Whereas the groupwise approach based on mean shapes is significantly affected by the shaft because it is a big part of the point clouds of these bones, while carrying significantly less information about the bone shape.



Images (Optional)



Orange: minimization of the deviations between the shapes resulted in significantly more accurate correspondence especially for elongated bones

Regional Arterial Timing and Pulsatile Motion Signatures in the Human Brain Parenchyma

Ms. Caitlin Neher MS, Mr. Tyson Lam BSME, Dr. Fargol RezayAraghi PhD, Dr. Mehmet Kurt PhD

University of Washington, Seattle, WA, United States

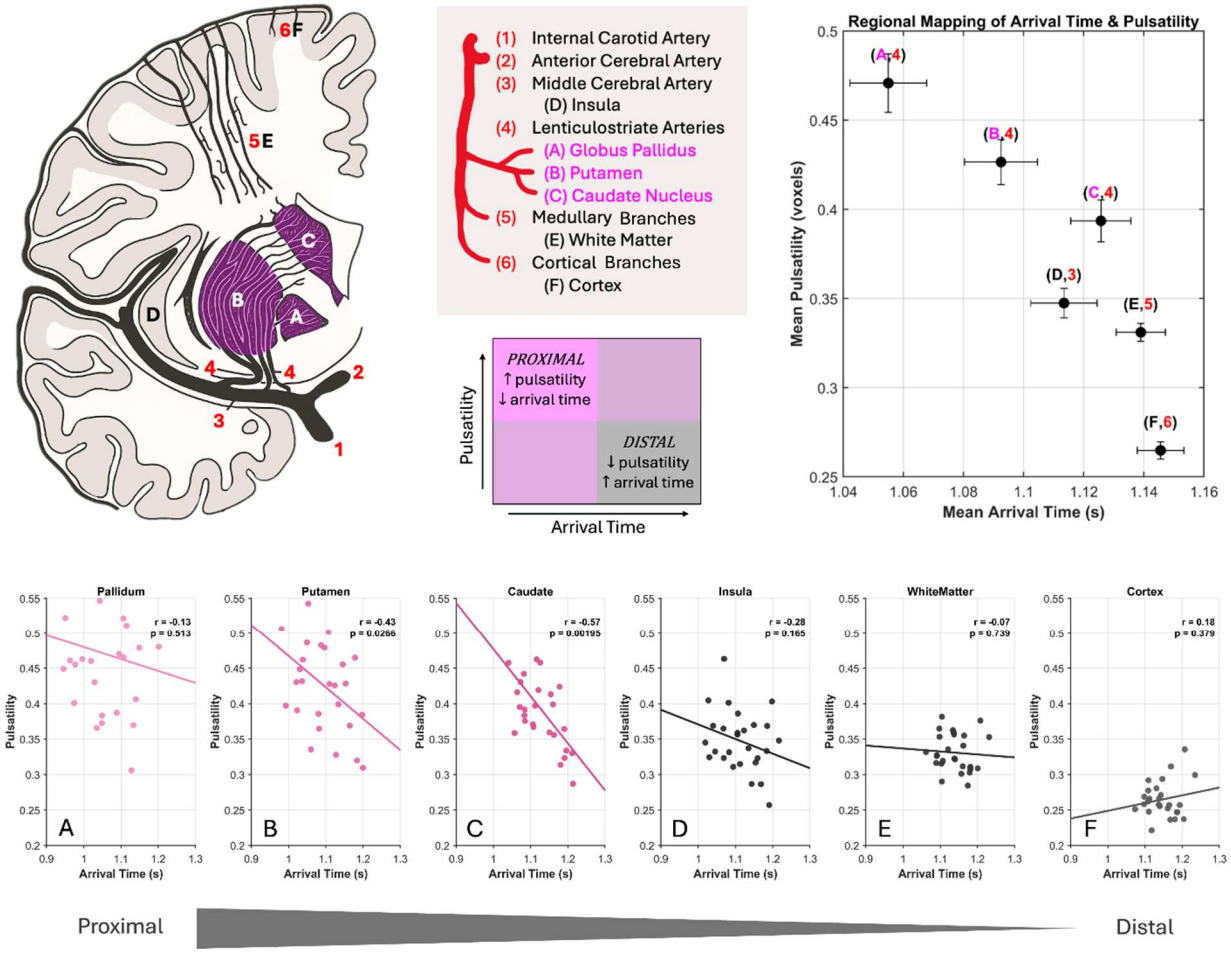
Introduction

Vascular health is crucial to the functioning human brain, with impairments leading to cognitive decline, stroke, and neurodegenerative diseases. This is due in part to the fact that precise cerebral blood flow requirements are needed to support the brain's functional activity and restful states, and that arterial pulsation drives glymphatic clearance. These essential functions motivate the ability to measure cerebrovascular function in the human brain *in vivo*, which poses challenges but has shown increased promise in aging and vascular dementia research. Here, we propose a multimodal magnetic resonance imaging (MRI) framework to measure regional arterial timing and parenchymal pulsatile motion during the cardiac cycle, and use this framework to quantify distinct vascular signatures of proximal and distal structures along the middle cerebral artery (MCA).

Methods

Thirty-one subjects (15F/16M, age 20-57) with no known neurological disorders underwent a multimodal MRI protocol including T1-weighted structural imaging, multi-delay pseudo-continuous arterial spin labeling (pCASL) and phase-contrast cine MRI. The pCASL data was postprocessed using Bayesian Inference for Arterial Spin Labeling (BASIL) to quantify perfusion and arterial transit time for each voxel of the brain; the cine MRI was postprocessed with an amplification algorithm and bandpass filter to isolate the frequency of the heartbeat. Regional segmentation of T1 images was done with FreeSurfer.

Results



A data-driven mapping of cerebrovascular dynamics emerged in the combined arterial timing and pulsatile motion 2D space, with spatial alignment to the branching MCA. Distinct vascular signatures were observed across subjects in the globus pallidus, putamen, and caudate nucleus, which are supplied by the lenticulostriate arteries, indicating a high spatiotemporal accuracy achieved by the framework. Furthermore, pulsatile motion and arterial transit time correlated across subjects in the putamen

(p<0.05) and caudate nucleus (p<0.005), potentially indicative of the known relationship between mean arterial pressure and pulse transit time in the cerebral vasculature.

Discussion

These preliminary findings introduce a noninvasive *in vivo* mapping of how arterial input propagates through the brain using multimodal MRI. Future work will investigate the framework's specificity to arterial pressure and aging, with the goal of quantifying the vascular changes which modulate the severity of cerebral small vessel disease.

A Novel Extraction and Description of Patellofemoral Joint Kinematics From the Fusion of Freehand Ultrasound and Motion Capture

Miss Caterina Vanelli Coralli[1], Dr Shihfan Jack TU[2], Prof Stephen Mellon[3,2]

[1]University of Oxford, Oxford, Oxfordshire, United Kingdom. [2]Botnar Institute for Musculoskeletal Sciences, NDORMS, University of Oxford, Oxford, Oxfordshire, United Kingdom. [3]Biomedical Engineering Centre, Department of Technology and Innovation, University of Southern Denmark, Odense, Region of Southern Denmark, Denmark

Introduction

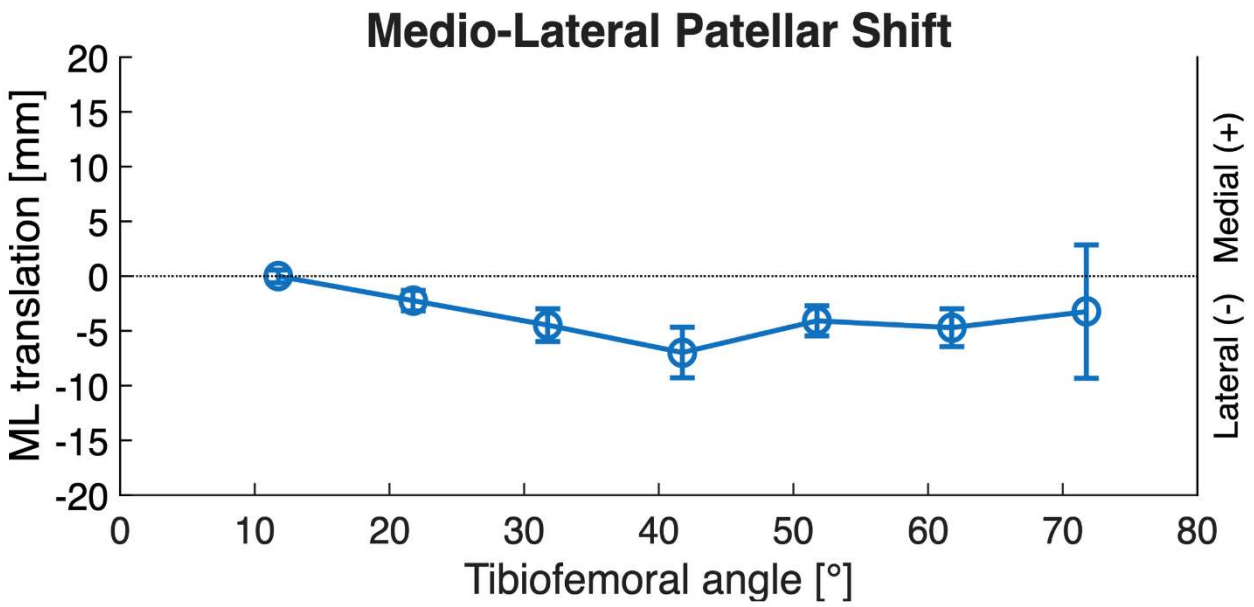
Accurate quantification of patella tracking is crucial to the clinical assessment of abnormal kinematics, such as in post-operative maltracking following total knee arthroplasty; however, current diagnostic techniques remain limited. CT and MRI provide morphological detail but inadequately describe motion, while gait analysis imprecisely tracks patellar movement due to soft tissue artefacts. This study aimed to establish the feasibility of a novel ultrasound and motion capture fusion technique for quantifying patellofemoral kinematics across loaded knee flexion.

Methods

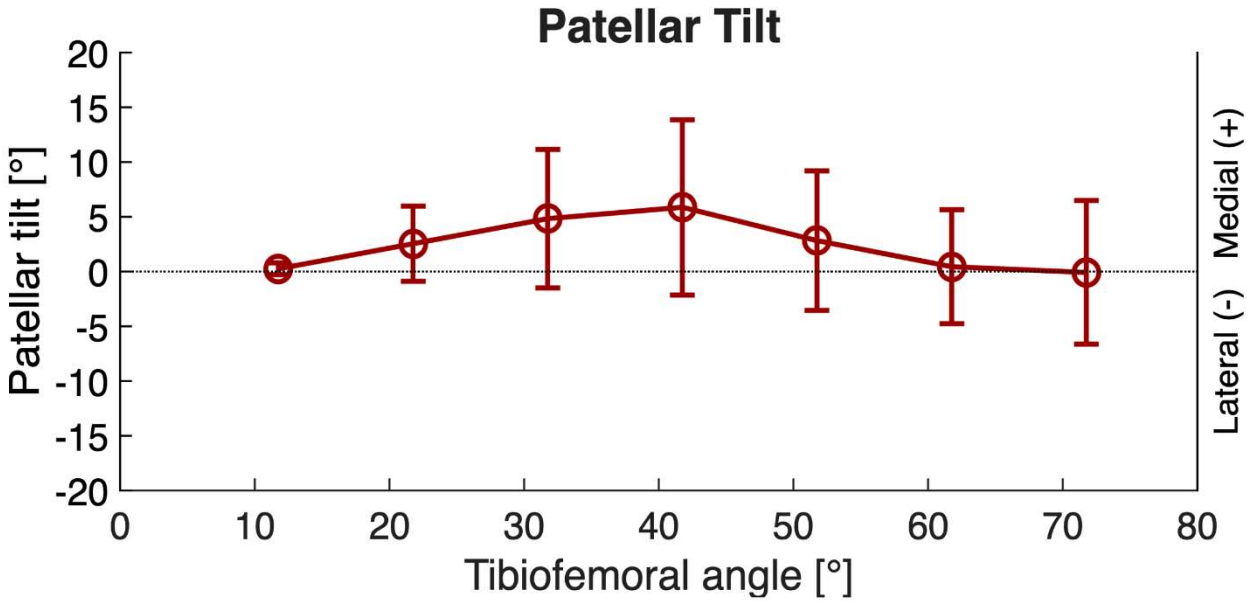
Eight healthy volunteers (22-57) participated in the study at the Oxford Gait Laboratory. Two five-marker plates were placed on the proximal thigh and distal shin of the right leg. The knee joint was scanned with a hand-held ultrasound in one reference (9 sweeps, 10 minutes) and up to five semi-dynamic positions (6 sweeps, 3 minutes). The latter represented flexion angles (10º – 75º) and loading covering the joint's range of motion during step-climbing. A Vicon motion-capture system tracked the ultrasound probe and participants' legs.

A custom segmentation algorithm extracted bony profiles from ultrasound images, creating detailed reference point-clouds and sparse semi-dynamic ones. Point-cloud registration recreated bony morphology at semi-dynamic positions. A femoral-based coordinate system enabled quantification of patellar shift and tilt.

Results



The custom algorithm was applied to a subset of participants (n = 4) for whom the scanning protocol had been optimised, yielding high-fidelity reconstructions of the bone surfaces. The point-cloud registration yielded root mean square errors of 0.47-1.41 mm, representing



the average deviation between reconstructed and reference clouds. On this basis, medio-lateral translations (-6.98 to 0 mm) and patellar tilt angles (0º to 5.87º) were extracted across the range of knee flexion. The resulting kinematic patterns were consistent with values previously reported in the literature.

Discussion

This study introduces a novel approach to patella tracking that enables extraction of clinically relevant parameters across a pseudo-dynamic range of motion, overcoming the limitations of current marker-based and imaging methods. Ongoing work aims to translate this framework into a quantitative tool for assessing patellofemoral kinematics in both healthy and pathological populations, with the longer-term objective of enabling fully dynamic assessments.

Early Subchondral Bone Remodeling after Destabilization of the Medial Meniscus (DMM) and Sham Surgery in Mice

Miss Cecilia Liberati, Prof. Harry van Lenthe

Department of Mechanical Engineering, KU Leuven, Leuven, Vlaams-Brabant, Belgium

Introduction

Osteoarthritis(OA) is characterized by progressive subchondral bone (SB) degeneration [1], yet the early alterations are not well documented. Longitudinal microCT is the gold-standard for tracking SB remodeling but detecting the pathological onset remains a challenge. Hence, this study developed an open-source, voxel-to-voxel analysis pipeline to track longitudinal SB changes in a microCT dataset of a mouse OA model to detect early pathogenic alterations.

Methods

A custom image-processing pipeline was developed in Jupyter Notebook (v7.0.8) environment to standardize processing of longitudinal microCT datasets, incorporating rigid-registration for voxel-to-voxel comparison and quantification of dynamic bone parameters in the murine tibial SB (Fig.1a). The pipeline was tested on a MicroCT dataset of C57BL/6 mice that underwent destabilization of the medial meniscus (DMM) or Sham surgery (n=10/group). Operated and contralateral limbs were imaged in vivo (Viva80, Scanco Medial AG,10.3 m, 70 kVp, 114 A) at baseline (Week 0), weekly for the first month (Weeks 1–4), and at Week 8 post-operation.

Results

Application of the pipeline revealed distinct remodeling patterns. Abnormal bone formation was primarily localized along the edges of the tibial plateaus in operated limbs across both groups. Dynamic bone morphometry showed no significant differences between DMM and Sham groups in the operated limb over the analyzed period (Fig.1b). Larger differences were observed when comparing operated and contralateral limbs within each group. Specifically, the operated limb showed increased (BV/TV), prominently in the medial compartment from 4 weeks post-operation (Fig.1c-d). The responses at the medial and lateral side appeared similar, although at two weeks a small difference in (BV/TV) was noticed.

Discussion

Using a custom, open-source pipeline, this study provided a detailed temporal and spatial visualization of SB adaptation in the early stages following DMM surgery. Analysis revealed that early post-operative changes were generally similar between DMM and Sham mice, suggesting this phase is dominated by a shared remodeling response to surgical invasiveness. Consequently, within this time window, the use of the contralateral limb as an internal control is essential to localize and quantify early site-specific pathogenic alterations characteristic of OA.

Images (Optional)

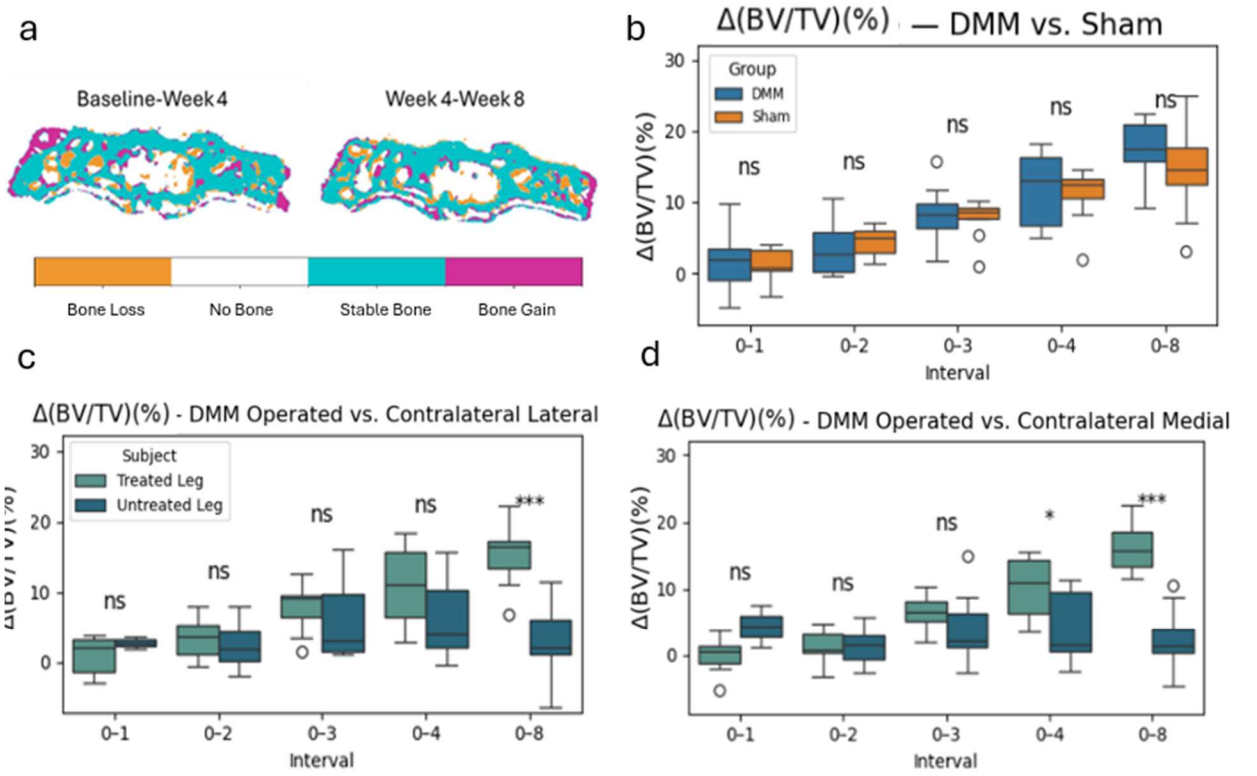

Figure 1 a) Voxel-to-voxel difference map comparing bone structure at baseline to Week 4 and comparing Week 4 and 8. Orange indicates bone loss and fuchsia bone gain localized in the tibial plateau. b) Δ(BV/TV) (%) comparison between Sham and DMM group operated limbs. c-d) Internal control comparison of Δ(BV/TV) (%) in DMM subjects comparing operated limb vs contralateral across time intervals. Lateral compartment is shown in c while Medial in d.

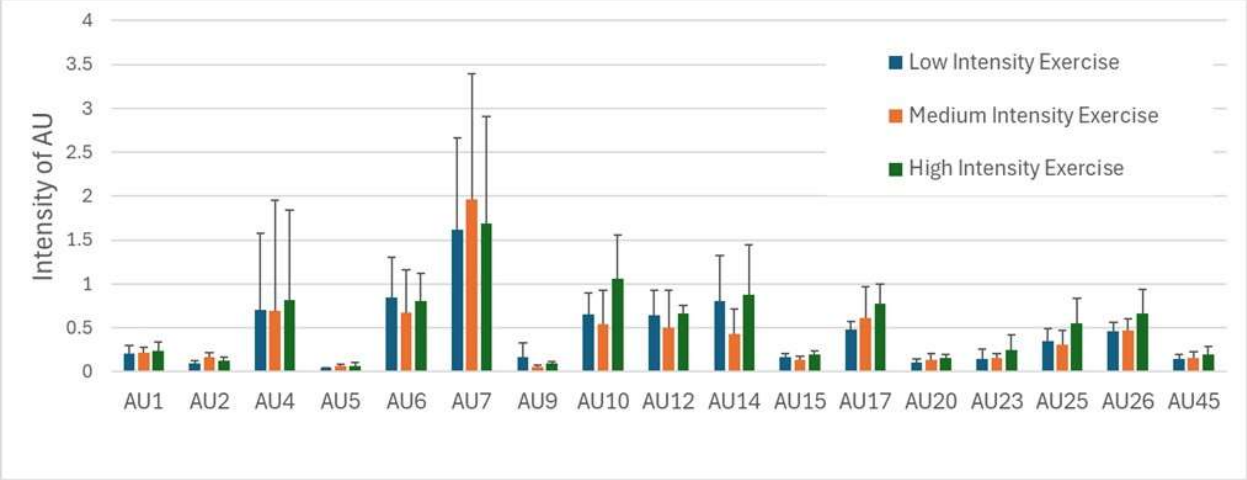
[7]Department of Mechanical Engineering, National Cheng Kung University, Tainan, Taiwan, Taiwan. [8]Medical laboratory, Medical Education and Research Center, Kaohsiung Armed Forces General Hospital, Kaohsiung, Taiwan, Taiwan

Introduction

Facial recognition technologies are increasingly used for identification and medical assessment. The Facial Action Coding System (FACS) categorizes facial movements into Action Units (AUs), but existing AU databases mostly include younger adults, and studies on AU responses to exercise or fatigue are limited. With population aging, promoting health and functional capacity in older adults has become an increasingly important priority. To address this gap, this study investigates changes in facial AUs in older adults by graded intensity exercise.

Methods

Facial expression data were collected from six older adults (68 ± 2.8 years; 1 male and 5 females) during exercise tasks. Participants completed three 7.5-minute lower-limb exercise sessions on the EIOT-ergo system[1] at predefined intensities: low (resistance level 2; 17.97 W; 40 RPM), moderate (level 5; 68.20 W; 60 RPM), and high (level 7.2; 81.64 W; 50 RPM). Video recordings were captured at 30 frames per second, resulting in a total of 243,000 frames. A YOLOv4-based model was trained and applied to detect and extract facial regions, with only frames achieving a face-detection confidence of at least 50% retained for analysis. OpenFace 2.0 was then applied to extract facial AUs.



Results

The percentage of maximum heart rate (%MHR) is widely recognized as a strong indicator of exercise intensity. In this study, the %MHR increased with graded intensity exercise, and several facial Action Units—AU10 (Upper-Lip Raiser), AU17 (Chin Raiser), AU 23 (Lip Tightener), AU 25 (Lips Part), and AU26 (Jaw Drop)—showed progressive increases across intensity levels (see Figure 1). Among these, AU 17 exhibited the most pronounced elevation.

Discussion

AU12 (Lip-Corner Puller), previously linked to fatigue in young adults, showed no significant change in this study. Musculoskeletal pain after knee replacement has been associated with increased AU10, AU17, AU25, and AU26 activation. In our findings, older adults exhibited similar patterns in the above-mentioned AUs. Notably, AU23, which emerged in our analysis, has not been previously described. These results highlight distinctive facial AU patterns in older adults during exercise, underscoring the need for larger studies to better characterize these responses and advance intelligent exercise-monitoring for aging populations.

Associations Between Head Impact Kinematics and Regional Cortical Morphometry in Collegiate Ice Hockey Athletes

Mr. Daniel Bondi[1], Mr. Alex Jaffray[1], Mr. Zaryan Masood[1], Mr. David Luke MASc[1], Dr. Rebecca Kenny PhD[1], Dr. Adam Clansey PhD[1], Dr. Paul van Donkelaar PhD[2], Dr. Songbai Ji PhD[3], Dr. Alex Rauscher PhD[1], Dr. Lyndia Wu PhD[1]

[1]University of British Columbia, Vancouver, BC, Canada. [2]University of British Columbia, Kelowna, BC, Canada. [3]Worcester Polytechnic Institute, Worcester, Massachusetts, United States

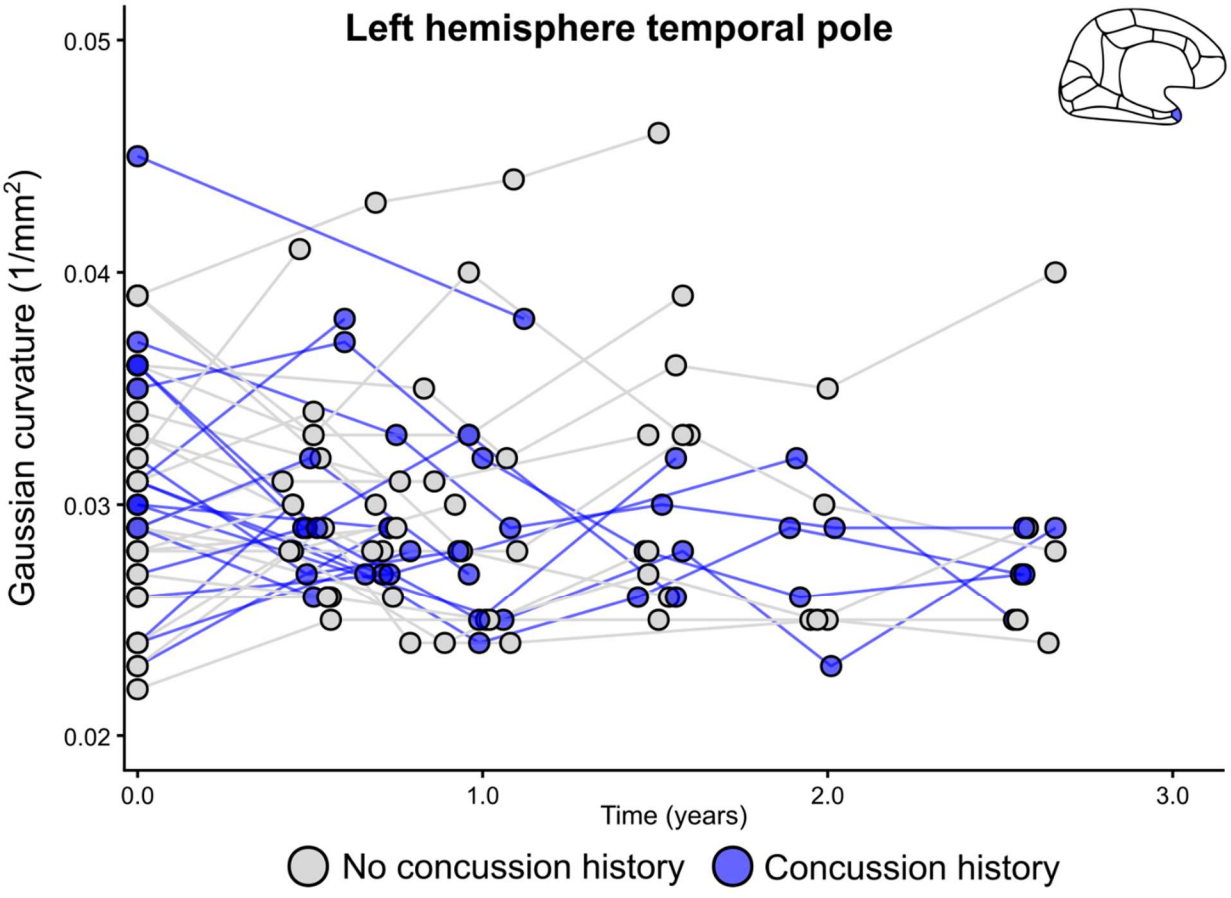
Introduction

Alterations in cortical morphometry have been correlated with head impact exposure in contact sport athletes. However, the nature and extent of these alterations remain poorly characterized due to a lack of prospective longitudinal studies linking impact biomechanics to brain structure. This study examines cortical morphometric changes using neuroimaging and associates these with cumulative head impact exposure quantified through wearable sensor technology and independent risk factors.

Methods

Collegiate male ice hockey athletes underwent pre- and post-season neuroimaging across three competitive seasons (n = 42; UBC ethics: H21-00400). Athletes wore custom-fitted instrumented mouthguards (iMGs) throughout each season, with year-one kinematic data fully verified with missing data imputed, and available for analysis (n = 26). Linear mixed-effects models examined relationships between cortical morphometric measures (cortical thickness, cortical volume, sulcal depth, mean and Gaussian curvature) and independent variables across 14 frontotemporal regions-of-interest and 4 subcortical structures. The first model tested longitudinal associations between morphometric changes and independent risk factors including prior concussion history, alcohol consumption, and cannabis use over three years. Following, cumulative kinematic values were individually added to a second model restricted to year-one data to test associations with morphometric changes over a single season. These included peak linear acceleration (PLA), peak angular acceleration (PAA), and peak angular velocity (PAV). This model also tested the association of independent risk factors with morphometric changes.

Results



Over three years, athletes with prior concussion history demonstrated decreased Gaussian curvature in the left temporal pole compared to athletes without [-2.3E-03 mm^{-2}/yr; FDR-

corrected p = 0.03]. Over a single season, no statistically significant associations (FDR-corrected p < 0.05) were observed between any independent risk factor or cumulative kinematic measure and cortical morphometry across any region examined.

Discussion

The only longitudinal change observed was progressive flattening in the left temporal pole associated with prior concussion history, defined as a clinically-diagnosed concussion sustained within three years of study entry. No significant associations emerged over a single season for any independent risk factor or kinematic measure. These findings suggest that detectable morphometric changes may require sustained exposure beyond a single competitive season, and future studies should investigate kinematic associations across multiple years.

MRI Diffusion Predicts Power Across the Lifespan

Dr. Daniel Desroches PhD, Dr. Janessa Drake PhD, Daniel Sheffield

York University, Toronto, Ontario, Canada

Introduction

Diffusion MRI Fractional anisotropy (FA) has been reported to non-invasively predict structural and functional changes such as muscular power with variable success – Scheel and colleagues [1] found a strong correlation (r=-0.85, p=0.0015) while Takao and colleagues [2] found no linear relationship (r=0.04, p=0.907). The ability to serially monitor changes over time may improve our understanding of age-related physical disability. This research evaluated the relationship between FA and ankle power output measured via countermovement jump (CMJ) with age as a crucial factor.

Methods

36 participants (23m & 13f, age 57.8 years) completed a warmup followed by three maximum effort repetitions. 3D optoelectronic motion capture (NDI 3D Investigator; 100Hz) and two 6DOF force plates (AMTI OR6-7;1200Hz) yielded ankle power. At a subsequent visit, participants underwent MRI diffusion of the soleus. Multiple linear regression was used to determine if age and FA of the soleus could predict ankle power.

Results

Age and FA of the soleus generated a statistically significant predictive model of ankle power (Figure 1; $F_{2,35} = 9.700$, $p < 0.001$, $R^2_{adj} = 0.332$). Both age and FA made significant contributions to the model age ($r_{Age} = -0.555$, $p < 0.001$; $r_{FA\ Sol} = -0.356$, $p = 0.036$). FA of the gastrocnemii and the tibialis anterior did not contribute significantly to the remaining three regression models ($p > 0.292$).

Discussion

This work is the first to demonstrate the combined effects of age and FA on ankle power. Previous work by Scheel and colleagues [1] found a strong negative correlation ($r_s = -0.85$) between FA of the soleus and ankle power measured via Biodex, likely due to their narrower and lower age range (27.2 ± 10.7 years). By comparison, our results showed a weaker effect of FA ($r_{FA\ Sol} = -0.356$) but a strong age effect on power ($r_{Age} = -0.555$) suggesting that effect of age should be a factor in future MRI diffusion investigations either in broadly-aged samples or investigations involving serial measurements.

Images (Optional)

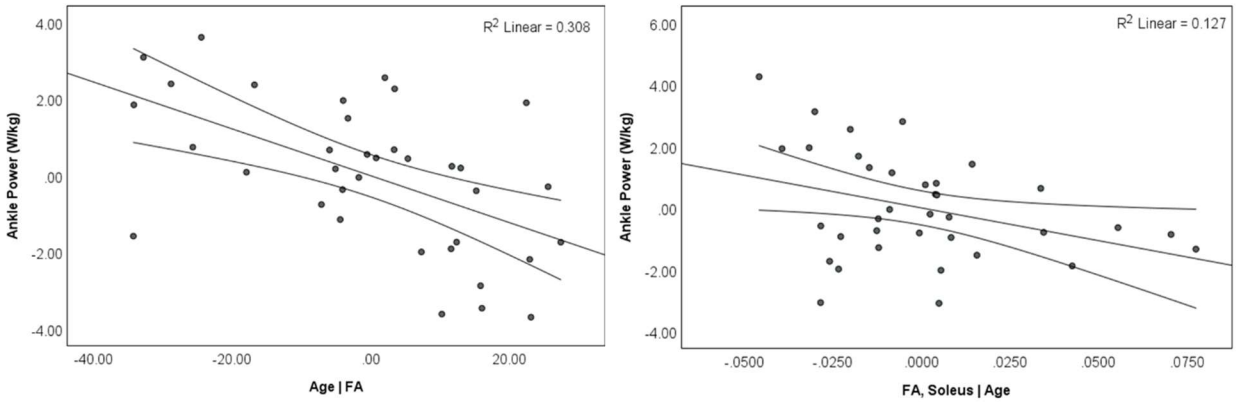

Figure 1 - The partial regressions showing the effects of age (left) and FA of the soleus muscle (right) on ankle power output during a CMJ. Age shows roughly twice the effect size in predicting ankle power, suggesting it should be included in future investigations if serial measurement or large age-spans are of interest. Error bands represent 95% confidence intervals.

Interrogating Amplified Femtosecond Laser Ablation to Induce Controlled Microvessel Rupture and Localized Bleeding in Mouse Patellar Tendon

Ms. Diane Stonestreet, Dr. Nelly Andarawis-Puri

Cornell University, Ithaca, New York, United States

Introduction

Tendinopathies are common injuries that heal ineffectively with dysregulated inflammation.[1] Dry needling is a treatment that intends to disrupt the tendon's chronic degeneration by inciting inflammation and localized bleeding, though its clinical success varies.[2] Our current work uses Amplified Femtosecond Laser (AFL) ablation to isolate damage mechanisms of cell necrosis, extracellular matrix (ECM) microdamage, and vascular rupture, mimicking dry needling. Our prior studies have optimized cell and ECM ablation. This study examines AFL ablation for microvessel rupture in mouse patellar tendon in vivo.

Methods

Under IACUC approval, animals were anesthetized and injected with FITC dextran (50µL, 1% v/v, RO) and propidium iodide (50µL, 1.5mg/mL, SQ) <1 hour prior to imaging. Imaging and ablation were conducted simultaneously using a custom two-photon microscope. Z-stacks of the targeted region were obtained immediately before and after ablation, and animals were euthanized after imaging concluded. Using ImageJ, fluorescent intensity of FITC in a 15µm radius surrounding the blood vessel was compared before versus after ablation using a paired t-test (*p<0.05, #p<0.10).

Results

Blood vessels within the peritendinous tissue ruptured at a laser energy of 50-250nJ and 1-100 pulses. Timelapse images show leakage from the targeted vessel immediately post-injury, and death of endothelial cells in the vessel wall (Fig 1A-1D). There was a trend towards decreased FITC signal surrounding the vessel after ablation (Fig 1E). No tenocytes underneath the targeted vessel exhibited increased propidium iodide signal after ablation, indicating tenocyte survival.

Discussion

This is the first study using AFL ablation to induce precise microvessel rupture in tendon in vivo. As dextran binds to blood plasma, FITC signal decreasing following ablation indicates presence of red blood cells flooding the space surrounding the vasculature. Targeted

ablation of blood vessels causes localized bleeding without inducing tenocyte necrosis or ECM microdamage, allowing precise interrogation of each damage modality. Isolating the impacts of these damage mechanisms on tendon inflammation and healing is critical in the development of precision therapies for chronic musculoskeletal disorders with dysregulated inflammatory responses.

Comparison of In-Shoe and Barefoot Plantar Pressure Maps for High-Pressure Region Identification in Diabetic Adults

Research Engineer Dylan Heino MS[1,2], Principal Investigator Scott Telfer EngD[1,2,3], Research Engineer Avocet Nagle-Christensen BS[1], Principal Investigator William Ledoux PhD[1,2,3], Principal Investigator Brittney Muir PhD[1,2]

[1]VA RR&D Center for Limb Loss and MoBility (CLiMB), Seattle, WA, United States. [2]Department of Mechanical Engineering, University of Washington, Seattle, WA, United States. [3]Department of Orthopaedic Surgery and Sports Medicine, University of Washington, Seattle, WA, United States

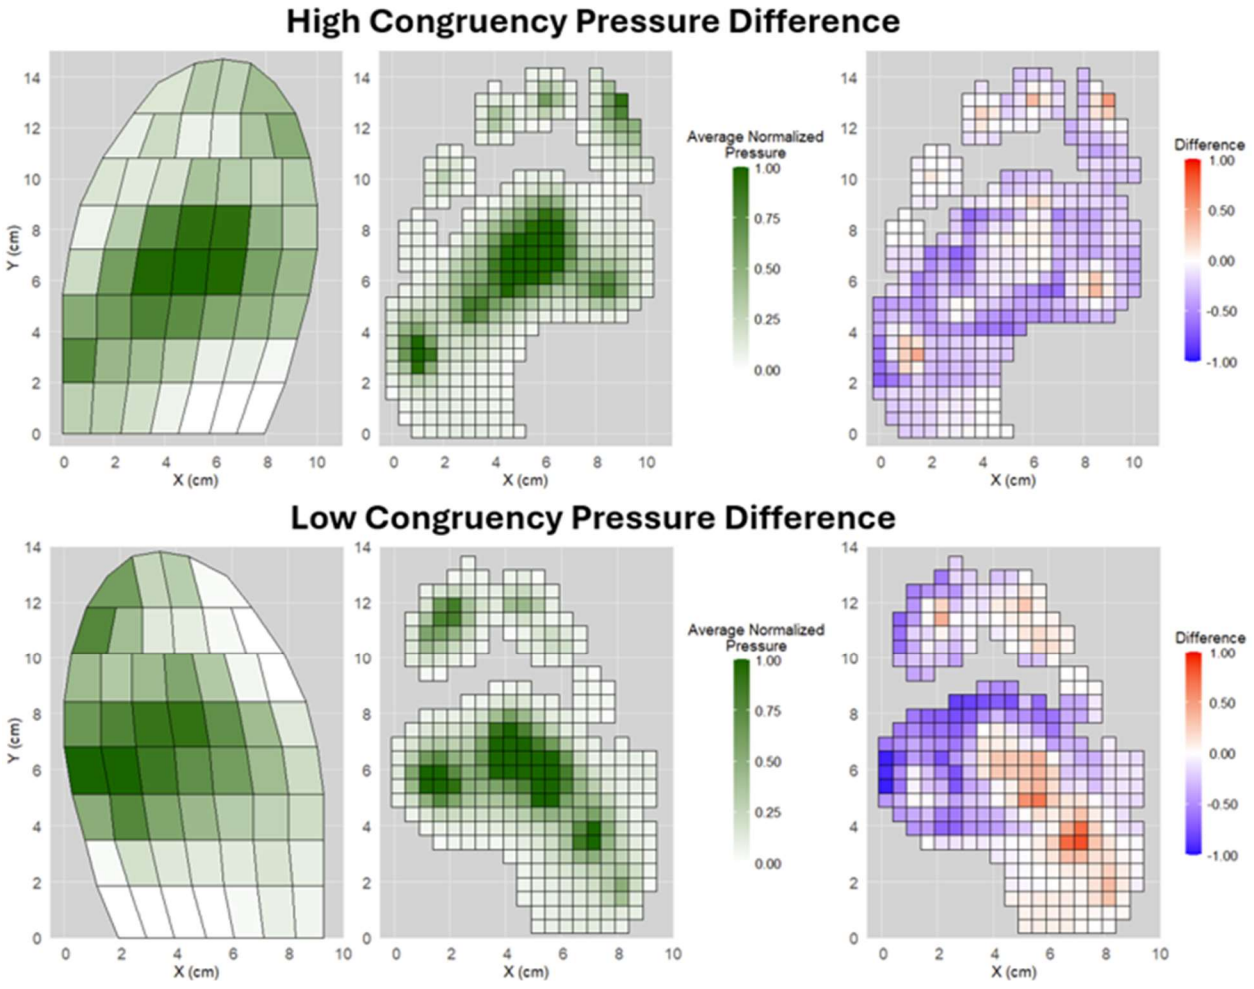
Introduction

Foot ulceration is a serious complication of diabetes, often linked to elevated forefoot pressures. Custom accommodative insoles can reduce peak plantar pressures, with greater reductions achieved when dynamic pressure data informs design. While in-shoe and barefoot pressure data are used independently to guide insole fabrication in research, their agreement in pressure distribution and location of high-pressure regions (HPRs) has not been evaluated. This study compares plantar pressure distribution and HPR mapping between in-shoe and barefoot walking in individuals with elevated forefoot pressures.

Methods

In-shoe and barefoot plantar pressures were collected during walking for 25 feet from 16 individuals with elevated forefoot peak plantar pressure (PPP). Pressures were captured using pedar-X insoles and an emed platform. In-shoe and barefoot pressure maps were averaged across trials and trimmed to the distal 50% of the foot. Barefoot trials were aligned using a global grid for averaging. Both maps were normalized by PPP thresholds (>200 kPa in-shoe; >450 kPa barefoot), overlaid at corresponding midpoints, and pressure differences for overlapping sensels were visualized. HPRs were identified, masked, and labeled by anatomical region. Barefoot HPRs within the same region but separated by one sensel were merged. For matched HPRs between systems, PPP, contact area, and centroid location were compared. Regions appearing in only one system were classified as unmatched, and PPP and contact area were averaged across trials.

Results



In-shoe high-pressure regions (>200 kPa) were typically observed in similar locations to barefoot walking, while barefoot maps often identified additional regions (>450 kPa) in the

toes and lateral forefoot. For in-shoe data, matched regions had lower peak pressures and larger contact areas. For matched regions, centroid positions differed by 0.23–0.60 cm.

Discussion

Key loading areas were spatially consistent between systems, though unmatched regions were common, particularly in barefoot data, reflecting greater sensitivity to localized pressures. Using barefoot data for insole design may help identify a broader set of high-risk regions, supporting a more conservative ulcer-prevention strategy. However, it may introduce excessive offloading that compromises performance in other regions. Future work comparing pressure offloading capabilities of insoles designed from in-shoe and barefoot plantar pressure is needed.

Dynamic In-Vivo Pulsatility Analysis for W-Stent Graft Rings in Abdominal Aortic Aneurysm Patients After Endovascular Aneurysm Repair

Miss Elke Hestermann MEng[1], Ir Marleen Krommendijk[1], dr. Hadi Mirgolbabaee[1], dr. Erik Groot Jebbink[1,2], Prof. dr. Michel M.P.J. Reijnen[1,2], Prof. dr. Robert H. Geelkerken[1,3]

[1]University of Twente, Enschede, Overijssel, Netherlands. [2]Rijnstate Hospital, Arnhem, Gelderland, Netherlands. [3]Medisch Spectrum Twente, Enschede, Overijssel, Netherlands

Introduction

Endovascular aneurysm repair (EVAR) is the preferred method to treat abdominal aortic aneurysms (AAA), although EVAR still has a reintervention rate of up to 20% due to complications such as stent migration and endoleaks. One third of the reinterventions occur because of endoleaks, with type 1 endoleaks resulting from improper sealing or fixation at the proximal or distal stent locations, exposing the aortic wall to arterial pressure and pulsatile flow. This highlights the importance of understanding the dynamic behavior of stent graft fixation to improve post-operative patient care.

Methods

Electrocardiogram (ECG)-gated computed tomography (CT), a validated method used previously for saddle-shaped stent rings, was employed in this study to analyze interactions between the aortic wall and implanted stent grafts in 10 patients at discharge, 6 months, and 12 months after receiving the E-tegra stent graft within the EASYII study. To segment the stent rings, the established algorithm was adapted to fit the W-rings of the E-tegra; allowing quantification of the proximal sealing rings' pulsatility and displacement during the cardiac cycle. Pulsatility is defined as the change in diametric distance in the anterior-posterior (AP) or left-right (LR) direction determined by fitting ellipses through the four strut levels of the W-rings.

Results

The results showed that the proximal sealing rings demonstrated no significant change over 12 months. Figure 1A shows both rings experienced a higher AP pulsatility than LR pulsatility, with values of 0.38±0.22mm, 0.40±0.18mm, 0.37±0.15mm and 0.17±0.07mm, 0.20±0.06mm, 0.20±0.07mm for Ring 1 and 0.40±0.19mm, 0.36±0.15mm, 0.35±0.15mm and 0.15±0.06mm, 0.20±0.11mm, 0.17±0.07mm for Ring 2 at discharge, 6 months, 12 months, respectively. Mean 3D displacement (Figure 1B) was 0.95±0.32mm at discharge, 0.96±0.41mm at 6 months and 1.09±0.32mm at 12 months, with overlapping data points.

Discussion

This interim analysis of 10 patients with 12-month follow-up after EVAR demonstrated minimal change in E-tegra‘s proximal sealing rings. Using stent graft segmentation, in vivo pulsatility and displacement were quantified and indicated no significant change. These results confirm limited motion within the first post-operative year and imply stable stent behavior over this period.

Images (Optional)

Longitudinal Structural Changes to Whole Knee Joint With Progression of OA Using *in Vivo* Micro Computed Tomography Imaging

Dr Han Liu PhD, Ms Emma Boersma, Dr Julia Gregory PhD, Dr Mateus Silva PhD, Dr Cathrine Davey PhD, Dr Kathryn Stok PhD

Department of Biomedical Engineering, The University of Melbourne, Melbourne, Victoria, Australia

Introduction

Structural alteration of the whole knee joint has an important role in the progression of musculoskeletal disorders [1]. Longitudinal data can provide spatial-temporal information on disease progression that can be linked to mobility and biomechanics. This proof-of-concept study aims to establish a longitudinal *in vivo* microCT imaging protocol to track mechanical alteration in whole joint structure in a mouse osteoarthritis (OA) model.

Methods

Eight nine-week-old male C57BL/10 mice were evenly assigned to control (CT) and OA groups. To induce OA, a single intra-articular injection of collagenase was administered to the right knee joints of mice in the OA group at ten-week-old. *In vivo* micro-computed tomography (microCT) scans (vivaCT80, Scanco Medical, 10.4 µm, 70 kVp, 350 ms, 114 µA, 1000 projections) were performed one day prior to collagenase injection and then weekly for eight weeks (nine scans per animal). A positioning device was used for consistent joint pose.

Lateral and medial joint space width $JSW_{L/M}$ (mm), volume $JSV_{L/M}$ (mm^3)and the orientation angle, β°, defined by the femur-tibia centre-of-mass vector relative to the animal's transverse axis, were measured [2]. To examine the differences between CT and OA group at each time point, a one-way ANCOVA was used.

Results

Representative three-dimensional visualization of joint space regions of CT and OA groups over time are shown in **Figure 1A**. Joint alignment was altered following collagenase injection in the OA group. Specifically, three weeks post OA-induction, a significantly smaller JSW was observed in the medial OA joint (**Figure 1B**). This corresponded with increasing JSW on the lateral side, and a decrease in β (**Figure 1C**).

Discussion

This study, for the first time, demonstrated the application of a longitudinal *in vivo* microCT imaging protocol for tracking structural changes in the whole knee joint in a mouse OA model. Joint malalignment, indicated by reduced JSW on the medial side and femur shifting to the animal's transverse axis, was detected three weeks post collagenase injection. Combined with future mechanical loading tests, this work has the potential to provide deeper insights into the mechanisms of musculoskeletal disorders.

Images (Optional)

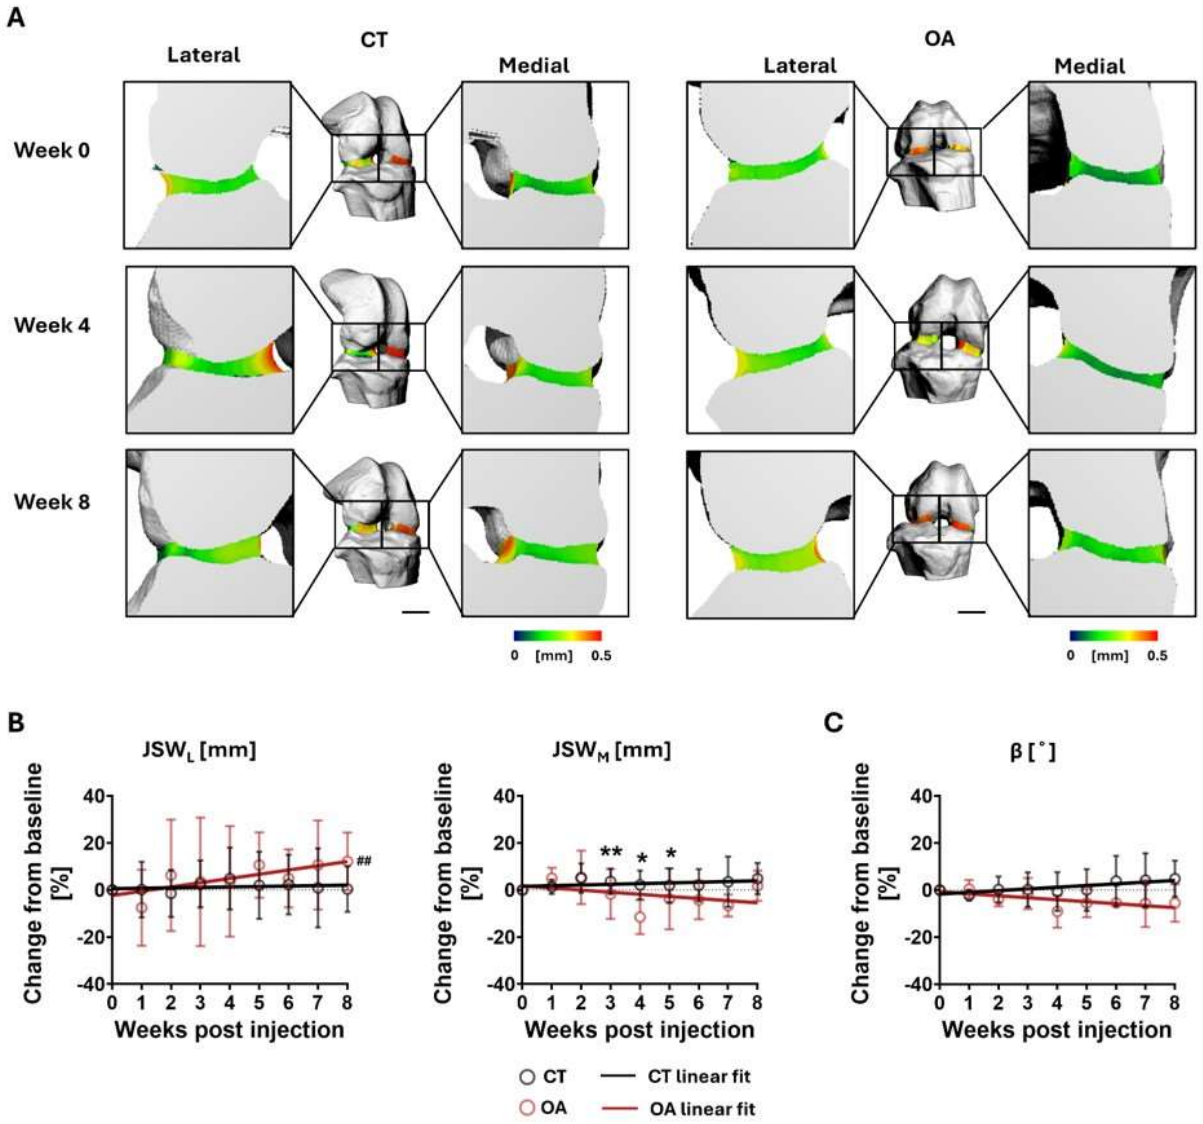

Figure 1. (A) Representative three-dimensional visualization of joint space regions of CT and OA groups at multiple time points with femur (top) and tibia (bottom). Inset: cross-sectional view of joint space region enlarged on both lateral and medial sides. (B) Joint space width measures from both lateral, JSWL, and medial, JSWM, and (C) Centre of mass measure of transverse axis alignment, β, from CT and OA groups, expressed as percent change from week 0 (baseline) with linear fits. ## indicates significant effect of time within OA group, $p < 0.01$. * indicates significant difference between CT and OA group, $p < 0.05$; **, $p < 0.01$.

Contrast-Enhanced 3D Ultrasound for Real-Time Iterative Catheter Placement During Radioembolization, A Proof of Concept

MSc. Jan van der Hoek[1], BSc. Nikita de Haan[1], MSc. Shannen Ubbink[1], Msc. Marleen Krommendijk[1], MSc. Remco Liefers[2], Dr. Erik Groot Jebbink[1]

[1]Multi-Modality Medical Imaging Group, TechMed Centre, University of Twente, Enschede, Overijssel, Netherlands. [2]Simulation Centre, TechMed Centre, University of Twente, Enschede, Overijssel, Netherlands

Introduction

Worldwide, hepatocellular carcinoma (HCC) ranks as the third leading cause of cancer-related deaths [1]. For advanced HCC palliative treatment via transarterial radioembolization (TARE) is routinely used [2]. During the procedure, radioactive microspheres are injected intra-arterially and lodge in the tumor vasculature. It was shown that patient survival improves with increasing tumor radiation-absorbed dose, however, realizing high radiation doses at the tumor is challenging as limited feedback is available during the procedure, while the microsphere injection location is of high importance [3]. Therefore, our goal is to use 3D ultrasound and contrast microbubbles as harmless precursors of the microspheres to real-time and iteratively improve the catheter position and maximize the tumor dose.

Methods

A microcatheter was advanced under fluorscopy (ARTIS Pheno, Siemens Healthineers) in the arterial system of normothermic, machine perfused, ex-vivo, non-tumorous porcine livers. A low concentration (1:40 diluted clinical dose) ultrasound contrast microbubbles (Sonovue, Bracco Suisse) was continuously injected. Simultaneously freehand, electromagnetically tracked (NDI Aurora, NDI Europe GMBH) ultrasound contrast-mode sweeps (9L4 probe, Siemens Acuson S2000, Siemens Healthineers) were recorded to obtain 3D reconstructions of the microbubble distributions in the liver, using the Plus toolbox. After several iterations, non-irradiated holmium-165 microspheres (Quirem Medical B.V.) were injected at the optimal catheter position. Thereafter, the microsphere biodistribution was visualized using a $T2^*$ multi-gradient MR scan (1.5T Aera, Siemens Healthineers) to evaluate the microbubble prediction.

Results

Fluoroscopy allowed catheter navigation (Figure 1A), followed by three iterations of contrast injections and 3D ultrasound sweeps (Figure 1B) to isolate the target location.

Subsequent MRI scanning confirmed the injected holmium-165 microspheres lodged predominantly at the target location, corresponding to the microbubble prediction (Figure 1C).

Discussion

Our proof-of-concept shows the feasibility of using 3D ultrasound sweeps to support catheter placement during TARE procedures. Future pilot patient studies should prove clinical feasibility.

Images (Optional)

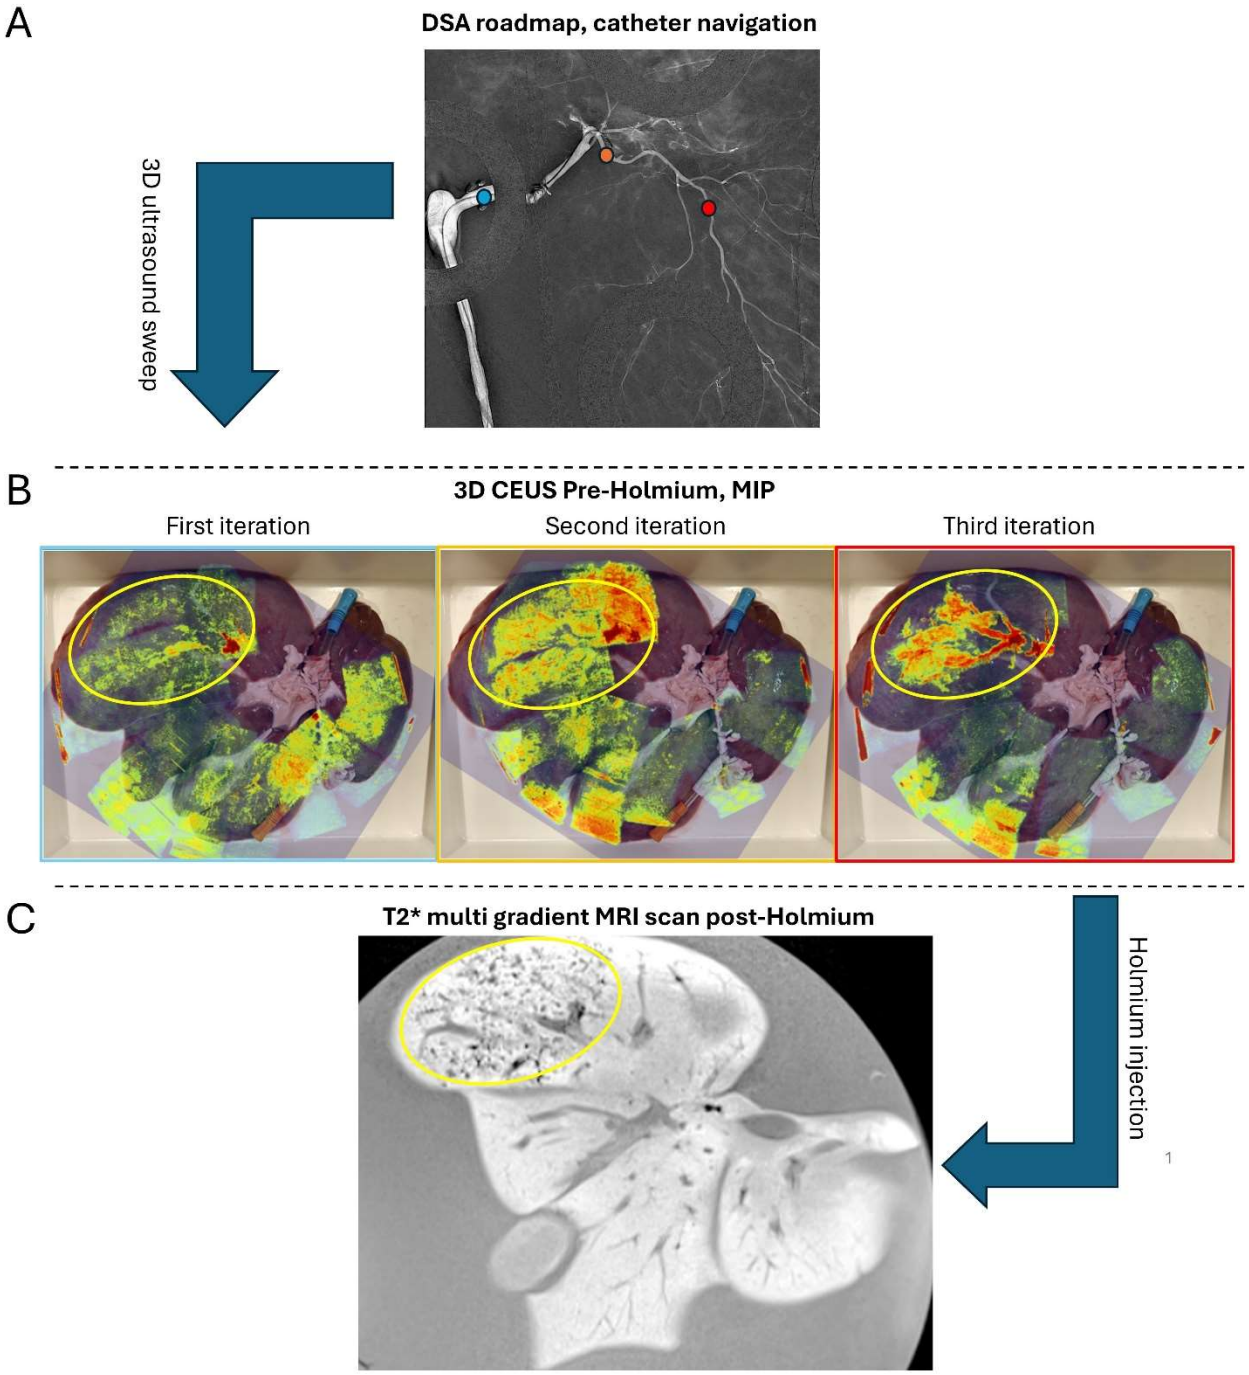

Figure 1, A. Catheter locations indicated by the blue, orange and red dots on the digital subtraction angiography (DSA) roadmap. B. Target area indicated by the yellow circle. After each catheter displacement, a contrast-enhanced 3D ultrasound sweep was performed, border color corresponds with the catheter location from A, maximum intensity projection (MIP) results are shown. Associations Between Echo Intensity and Isometric Strength in Lower Extremity Musculature in an Active Population

Dr. FJ Goodwin PT, PhD, DPT, Dr. Josie Clary PT, DPT, Dr. Hermes Gomez PT, DPT, Dr. Amanda Harris DPT, Dr. Carrie LaBonte DPT

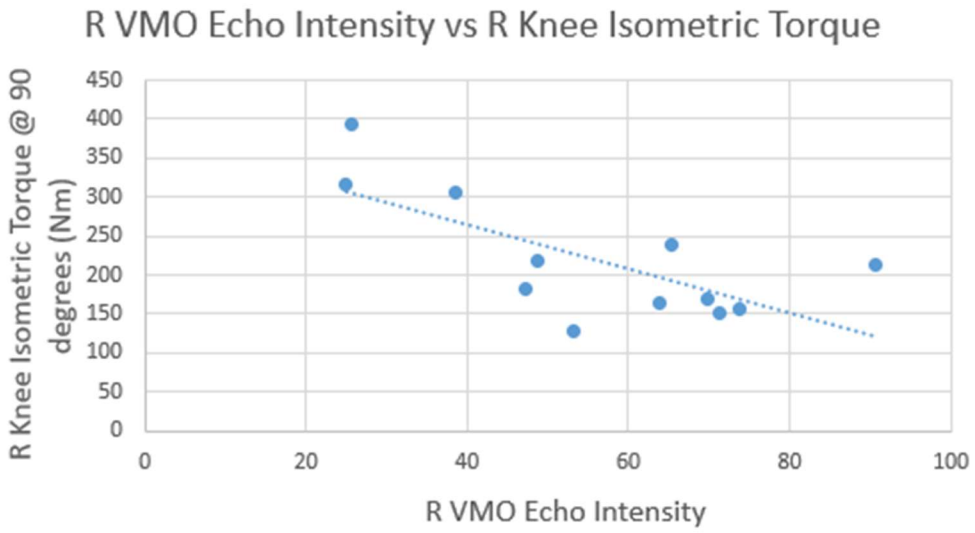
Charleston Southern University, Charleston, SC, United States

Introduction

Diagnostic ultrasound provides insight into tissue composition by using echo intensity (EI) to reflect tissue brightness. Greater EI brightness in skeletal muscle is associated with lesser contractile elements and increased intramuscular fat and connective tissue. Greater EI brightness is also associated with lesser force generating capacity. Subsequently, lower EI values are associated increased muscular force generating capability. However, these relationships are most often seen in older subjects. The purpose of this study is to observe the relationship between EI and muscular strength in young, athletic individuals. The hypothesis was that lower EI values (i.e. better muscle quality) would correlate with greater muscular performance.

Methods

Twelve active individuals (4 M, 8 F; 25.7±2.6 y.o; 1.71±0.06 m; 70.3±20.1 kg) participated in this study. Subjects were free from injury and meet the minimum level of activity per the ACSM Guidelines. Cross-sectional diagnostic ultrasound images were captured of the right vastus medialis oblique (VMO) and right lateral gastrocnemius (LG). EI was then calculated via ImageJ. Subjects then completed maximal voluntary isometric contractions via a HUMAC dynamometer seated at 90 degrees of knee flexion and prone with ankle in neutral to capture right knee and right ankle plantarflexion torque respectively. Pearson correlations were calculated for R VMO EI and average right knee isometric peak torque and time to peak torque. Correlations was repeated for R LG EI and muscular performance measures.



Results

There was a significant, negative correlation between R VMO EI (56.08±19.1) and average right knee peak isometric torque (219±77.34 Nm) ($r = -0.702$, $p=0.01$). There were no statistically significant associations with R VMO EI and time to peak ($p=0.52$). There were also no statistically significant associations with R LG EI and average right ankle plantarflexion torque ($p=0.50$) and time to peak ($p=0.69$).

Discussion

Our findings support our hypothesis that lower EI would reflect greater torque capability in a younger population in the R VMO. However, this was not reflected in the R LG or time to peak torque. These findings suggest assessments of muscular quality (EI) and muscular performance may differ across varied muscle groups in a younger population.

Diffusion MRI Method for Estimating Architecture-Based Physiological Cross-Sectional Area in Skeletal Muscle

Mr Zhenhao Liu M.S.[1], Dr Geoffrey Handsfield PhD[1,2]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States. [2]North Carolina State University, Raleigh, NC, United States

Mr Zhenhao Liu

Introduction

Physiological cross-sectional area (PCSA) is a determinant of force capacity in muscle [1] and is fundamentally defined as the combined cross-section of all fibers in parallel [2]. Presuming fibers are at optimal length, PCSA may be computed as:

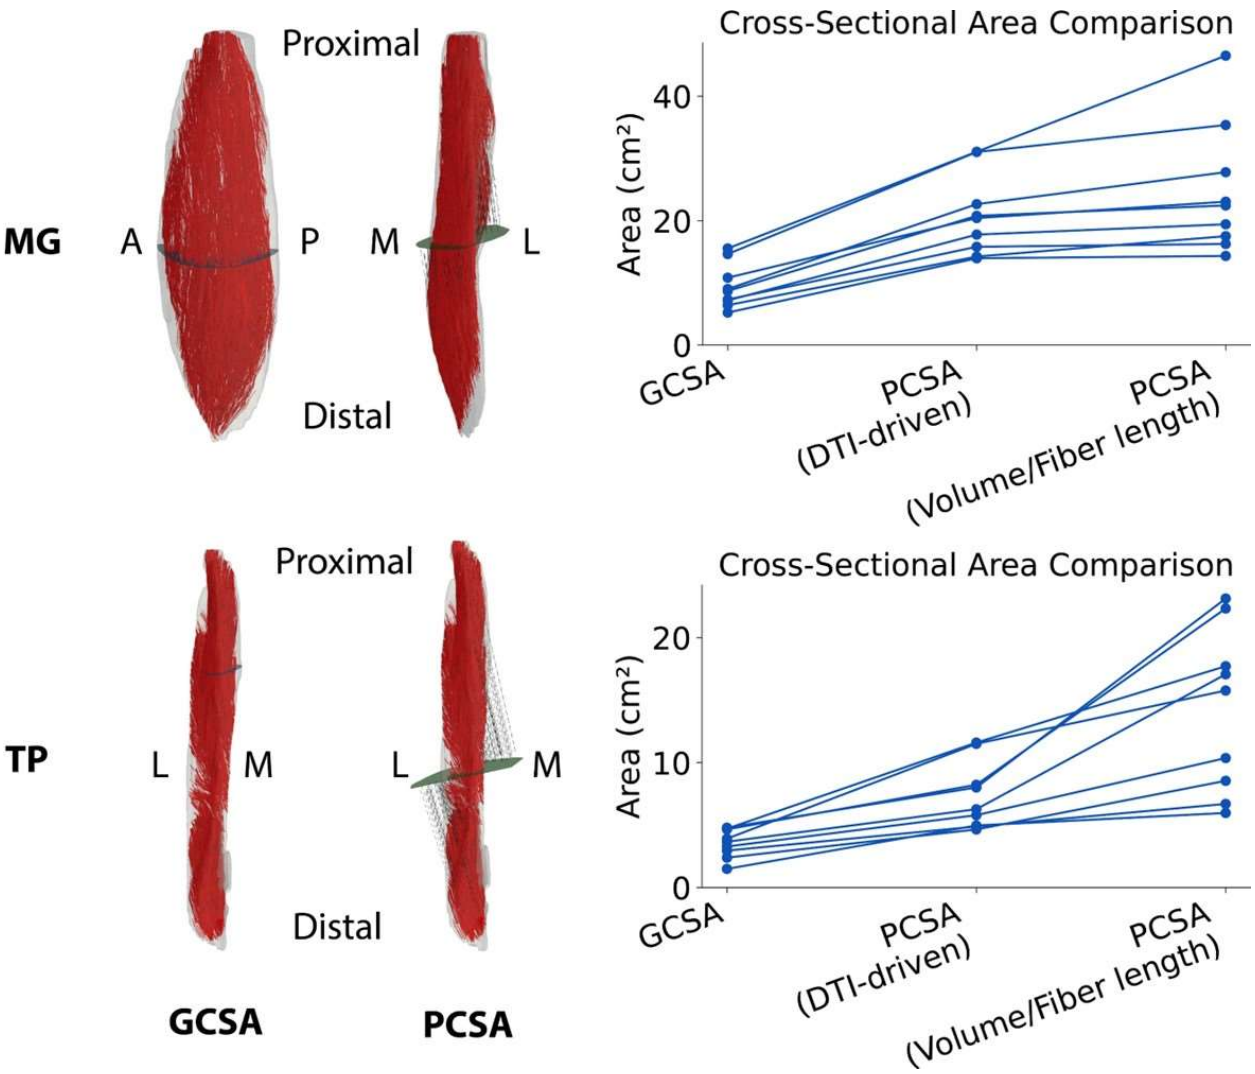
(1) PCSA = muscle volume / mean fiber length

We refer to this as the VFL equation, which is sensitive to mean fiber length measurement. While convenient, the VFL equation (1) may also not accurately capture PCSA for muscles with complex architecture. Diffusion tensor imaging (DTI) enables *in vivo* characterization of muscle architecture and allows for a more robust estimation of PCSA derived from fiber tractography [3]. Here, we present a method to compute PCSA as the combined cross-sectional area of its fibers in parallel, using DTI tractography data. Using a similar method, we compute the related geometrical cross-sectional area (GCSA) [2] and compare both metrics to PCSA computed with the VFL equation.

Methods

DTI and T1 MRI data from a previous study were used, approved by the University of Auckland Human Participant Ethics Committee [4]. Muscles were manually segmented, and fiber tractography performed with DSI Studio. We developed an algorithm that

computed PCSA by estimating the global fiber direction, projecting all fiber points onto the orthogonal plane, and calculating the convex-hull area of the projection. GCSA was calculated by estimating local fiber orientations, generating perpendicular slicing planes along each muscle, intersecting them with the segmented mesh, and identifying the maximum interior slice area.



Results

DTI-derived PCSA and GCSA were anatomically consistent and reasonable, aligning with previous literature [2]. For the medial gastrocnemius (MG), PCSA was 20.85 ± 6.50 cm^2 and GCSA was 9.42 ± 3.59 cm^2, while for the tibialis posterior (TP), PCSA was 7.33 ± 2.72 cm^2 and GCSA was 3.54 ± 1.13 cm^2. DTI-based PCSA values were lower than VFL values, with percentage differences of 12.84% for MG and 42.98% for TP (Fig. 1).

Discussion

The VFL equation may over-estimate PCSA. With increasingly accurate digital data, more sophisticated methods may be used to determine muscle architectural parameters. We plan to extend this to additional muscles and empirically measured isometric force.

Physics-Informed Anisotropic Laplacian Modeling Enables Muscle Fiber Architecture Estimation from Conventional MRI Slices

Ms Negar Mehrabi M.S., Dr. Geoffrey Handsfield PhD

University of North Carolina, Chapel Hill, NC, United States

Ms Negar Mehrabi

Introduction

Characterizing skeletal muscle fiber architecture is important for estimating force-generating capacity. Diffusion Tensor Imaging (DTI), although widely adopted, suffers from low spatial resolution, signal instability, orientation bias, and partial-volume effects [1]. Laplacian-based fiber-generation methods can estimate muscle fiber fields but are unable to capture architectural deviations, as may be seen in pathological muscle. To overcome these limitations, we present a **physics-informed neural PDE framework that learns a patient-specific anisotropic Laplacian operator directly from MRI-derived structure-tensor representations** [2]**,** providing a novel approach to infer fiber architecture from structure-tensors derived from conventional MR images.

Methods

Segmented axial T1-weighted MRI slices of the medial gastrocnemius from one adolescent with cerebral palsy (CP) were used from previous study [3]. Local image-gradient structure was quantified using Sobel derivatives and assembled into a smoothed structure tensor, yielding a spatially varying base anisotropy field We then formulated a generalized anisotropic Laplacian PDE:

$$\partial/\partial x(Dxx\ \partial\phi/\partial x + Dxy\ \partial\phi/\partial y) + \partial/\partial y(Dyy\ \partial\phi/\partial y + Dxy\ \partial\phi/\partial x) + YS(x) = 0$$

$$\text{Where: } D(x) = D_{base}(x) + \Delta D_{net}(x)$$

A physics-informed neural network (PINN) optimized the fields ΔD_{net}, Y_{net} using PDE residual as physics loss, allowing the network to **discover the differential operator best reflecting slice-specific muscle conduction anisotropy**. Fiber orientations were extracted from principal eigenvectors of learned operator field *D(x)* (Figure 1). Spatially averaged coefficients were assembled into a **patient-specific slice-wise anisotropic operator**.

Results

Our method produced smooth, continuous, and anatomically coherent [4] fiber trajectories that captured patient-specific fiber architecture (here in an adolescent with CP) when compared to DTI (Figure 1). Example coefficient values given below:

$$\partial/\partial x(0.6008\ \partial\phi/\partial x - 0.2445\ \partial\phi/\partial y) + \partial/\partial y(0.6289\ \partial\phi/\partial y - 0.2445\ \partial\phi/\partial x) + 0.0022S(x) = 0$$

Discussion

This work introduces **patient-adaptive anisotropic Laplacian operators learned from structure-tensor fields**, demonstrating that conventional MRI contains sufficient information to generate fiber directions when coupled with physics-informed learning. Extension to 3D will enable volumetric fiber continuity and establish a path toward high-resolution fiber modeling directly from standard clinical MRI.

Images (Optional)

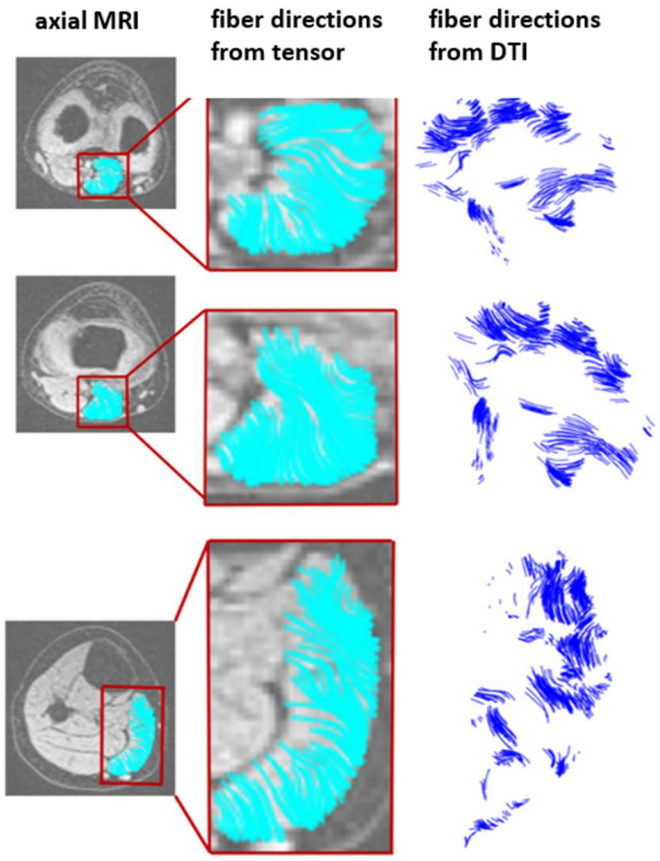

Figure 1 *Comparison of MRI-derived fiber architecture (inset) with DTI data projected into matched 2D slices. The structure-tensor method shows consistency with DTI where tracts are available in the noisy DTI dataset. Fiber directions from the structure-tensor are smoother and continuous and are consistent with fascicle patterns from the anatomical literature [4].*

µCT and HR-pQCT Texture and Finite Element Analysis as Imaging Biomarkers for Quantifying Diseases Related Bone Phentoypes: A Example in Iron-Deficiency Anemia.

MSc. BSc. Gerald Degenhart[1], MSc. Sonja Wagner[2,3], MSc. Johannes Bereiter-Payr[1], BSc. Thomas Ausserer[1], MSc. Elke Pertler[2,3], Prof. Dr. Heinz Zoller[2,3], Dr. Martina Saretto[2,3]

[1]Core Facility MicroCT Univ. Clinic. for Radiology Medical University Innsbruck, Innsbruck, Tirol, Austria. [2]Gastroenterology, Hepatology and Endocrinology, Department of Medicine I, Medical University Innsbruck, Innsbruck, Tirol, Austria. [3]Christian Doppler Laboratory on Iron and Phosphate Biology, Innsbruck, Tirol, Austria

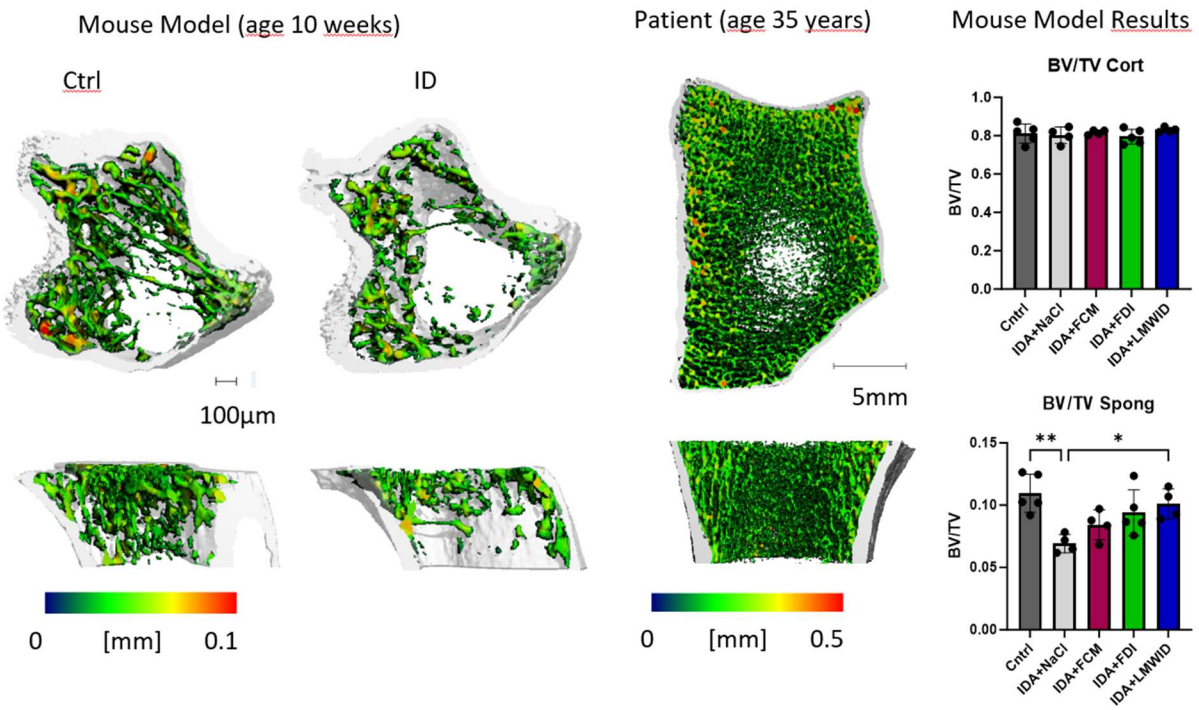
Introduction

This study investigates a characteristic bone phenotype associated with iron-deficiency anemia (ID) using micro-computed tomography (µCT) in mice and high-resolution peripheral quantitative CT (HR-pQCT) in patients. We demonstrate how texture analysis (TA) and micro finite element analysis (µFEA) can function as imaging biomarkers to detect ID-related bone alterations. In the mouse model, we additionally compare treatment effects of three iron-replacement therapies.

Methods

Tibiae from 10-week-old mice were scanned using a vivaCT 40 (Scanco Medical AG). TA was performed in an 80-slice region below the proximal tibial growth plate. Five groups (n = 5/group) were analyzed: healthy controls (Ctrl), untreated ID, and ID mice treated from week 6 onward with ferric carboxymaltose (ID+FCM), ferric derisomaltose (ID+FDI), or low-molecular-weight iron dextran (ID+LMWID). ID was induced via a reduced-iron diet.

Two male ID patients (ages 35 and 64) with a chronic clinical history of iron deficiency were scanned at the distal radius and tibia using an XCT-2 system (Scanco Medical AG). In both species, cortical and trabecular TA metrics were quantified, and µFEA simulations of axial compression were performed to estimate bone mechanical competence.



Results

In both mice and patients, cortical bone parameters showed no significant deterioration. However, the ID condition resulted in pronounced trabecular degradation compared to controls. Treatment partially restored trabecular structure, with the greatest improvement observed in ID+LMWID, followed by ID+FDI, and the smallest effect in ID+FCM. µFEA detected no statistically significant differences between mouse groups, although stiffness trends mirrored the TA findings. Patients displayed similar trabecular texture impairment but additionally reduced µFEA-derived mechanical stability.

Discussion

This study shows that TA and µFEA are suitable imaging biomarkers for detecting desease related bone phenotypes. Because ID can impair bone quality without overt structural collapse. Identifying disease-specific phenotypes is valuable beyond fracture prediction as overlooked deseases may be found. Therefore ability to non-invasively characterize bone alterations provides an opportunity to recognize and monitor metabolic and hematologic conditions with skeletal involvement at earlier stages. Moreover, the agreement between mouse and human observations supports the relevance of the ID mouse model for translational research and treatment evaluation.

Non-Invasive Cartilage Histology: A Microscopy-Informed Machine-Learning Model for MRI-Based Proteoglycan Mapping in Osteoarthritis

MSc Ikram Mohout[1], Dr. Seyed Ali Elahi[1], Dr. Shannon Helsper[1], Dr. Willy Gsell[2], Prof. Uwe Himmelreich[1], Prof. Ilse Jonkers[1]

[1]KU Leuven, Leuven, Flanders, Belgium. [2]Bruker Preclinical Imaging, Kontich, Flanders, Belgium

Introduction

Cartilage degeneration is *the* hallmark of osteoarthritis (OA), characterized in early disease stages by extracellular matrix changes, including alterations in proteoglycan (PG) concentration [1]. Quantitative MRI (qMRI) can link image parameters to tissue composition; however, the exact relationship remains unclear [2]. This *in vitro* study applies a microscopy-informed machine learning approach to predict PG content from non-invasive qMRI data of cartilage, ultimately applicable *in vivo*.

Methods

Osteochondral cylindrical plugs (1cm diameter) were harvested from 14 hip arthroplasty OA patients; one plug per subject was snap-frozen. After thawing, plugs were imaged in PBS using a 7T scanner (Bruker Biospec) with T1, T2, and T1ρ mapping sequences [3]. Samples were processed for histology: cut at the imaging plane, fixed in formaldehyde, decalcified in EDTA, embedded in paraffin, sectioned at 3µm, stained with Safranin-O, and mounted for microscopy. Brightfield microscopy (Zeiss Axio Scan.Z1) was performed, and three sections per sample were analyzed.

Microscopy data of cartilage (~9 µm/pixel) were downsampled to match MRI resolution (0.313 x 0.156 mm/pixel) and semi-automatically registered using in-house code. A bagged regression tree model was trained pixel-wise on normalized qMRI parameters (T1, T2, and T1ρ) to predict PG content, using leave-one-out cross-validation and evaluated by Pearson's r and RMSE. Three plugs were excluded due to presumed staining artefacts or limited tissue overlap. Model fitting used 3,444 training and 1,663 testing pixels, with each plug used exclusively for training or testing to avoid bias.

Results

The model showed strong training performance (r= 0.878, RMSE= 0.162) and maintained predictive ability on the independent test set (r=0.623, RMSE=0.279), as shown in Figure

1a. Predicted PG maps reproduced key spatial patterns observed in microscopy (Figure 1b).

Discussion

This MRI-based, microscopy-informed machine-learning approach predicts cartilage PG content with moderately strong correlations. It advances earlier low-field studies with limited pixel counts [2] by using high-field MRI for the first time. This non-invasive method may support future assessment of cartilage constituents in OA using clinical imaging.

Images (Optional)

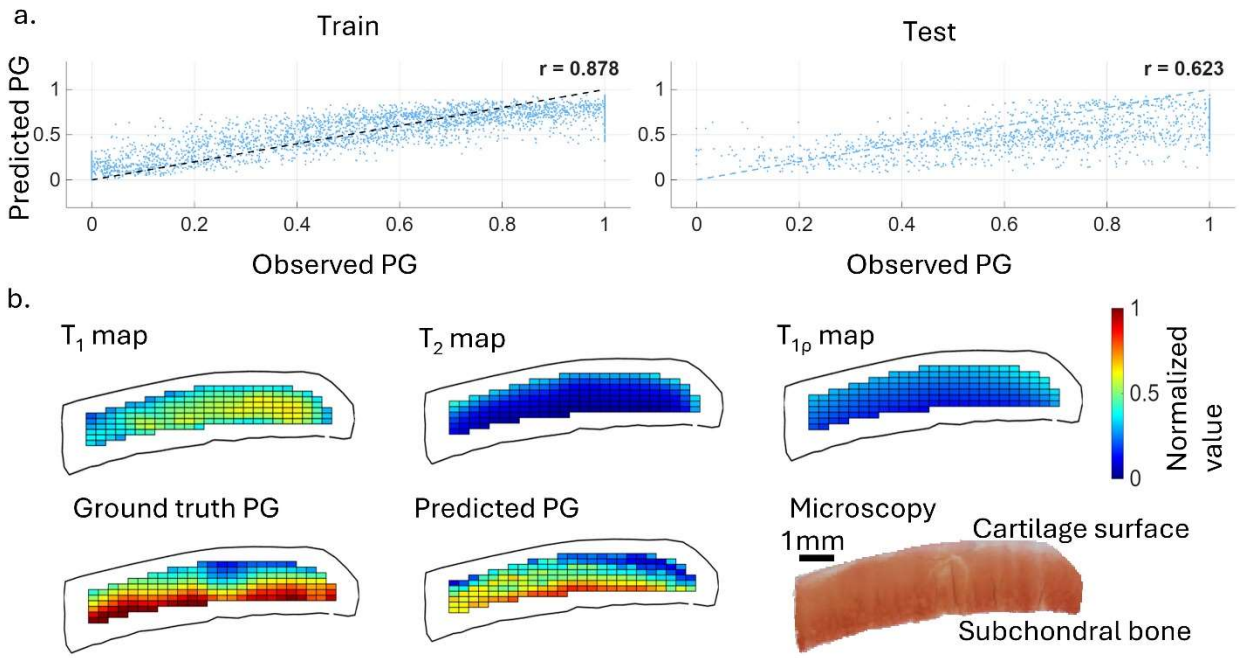

Figure 1. *(a)* Pixel-wise correlation between observed and predicted PG content for the training and independent test sets (bagged regression trees). *(b)* Example section showing normalized qMRI inputs (T1, T2, T1ρ), the corresponding Safranin-O histology, and the resulting ground-truth and predicted PG maps, illustrating spatial agreement between microscopy and model output.

Hierarchical Phase-Contrast Tomography Reveals Multi-Scale Hard-Soft Tissue Architecture in the Intact Human Spine

Miss Isla Henderson[1], Dr Aikta Sharma[1], Dr Alissa L. Parmenter[1], Dr Joseph Brunet[1,2], Dr Theresa Urban[1,2], Dr Joanna Purzycka[2], Dr Hector Dejea Velardo[2], Dr Stefan Zwingenberger[3], Dr Timothy J. P. Bray[4,5], Dr Alexandre Bellier[6], Dr Paul Tafforeau[2], Professor Peter D. Lee[1]

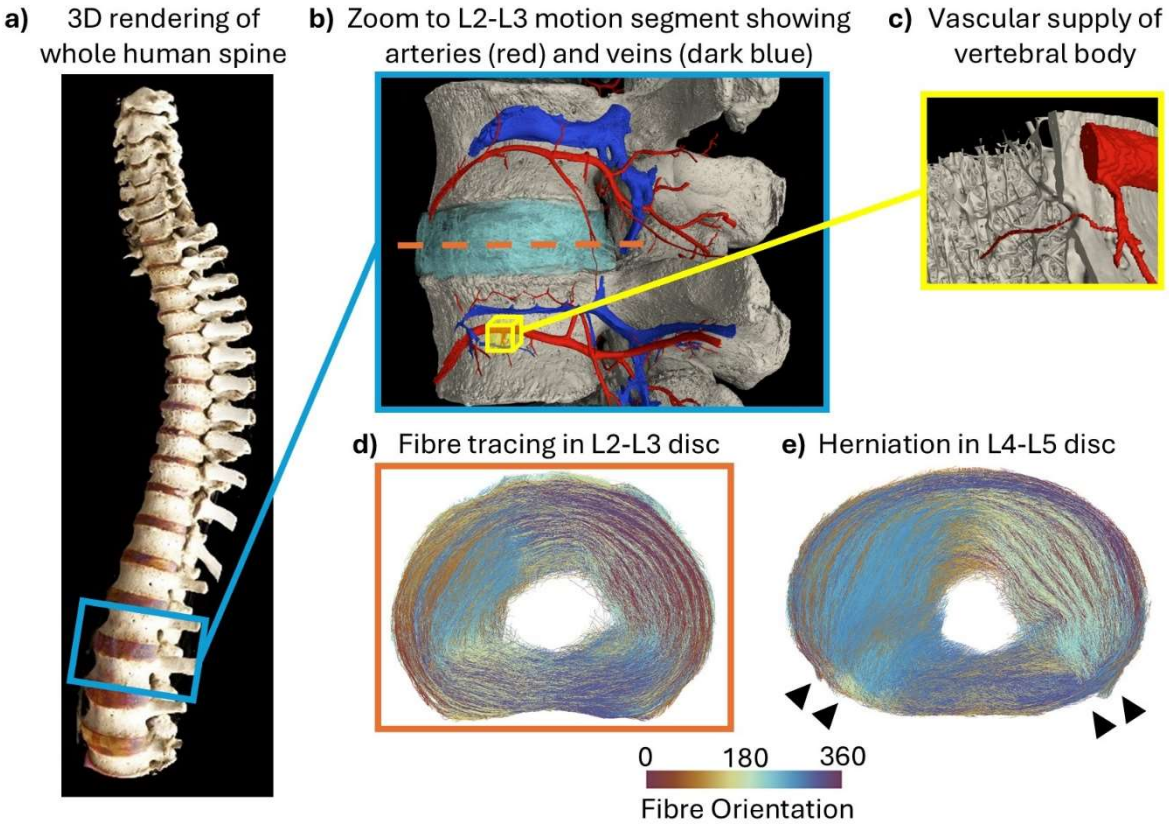
[6]University Grenoble Alpes, Department of Anatomy (LADAF), Grenoble, Auvergne-Rhône-Alpes, France

Introduction

The spine has a highly complex hierarchical structure, with its biomechanical function critically reliant upon the integrated behaviours of its bone and soft tissue components. The current understanding of the structure-function relationships between these tissues in the healthy spine is limited by the low spatial resolution of conventional imaging modalities such as MRI. Hierarchical Phase-Contrast Tomography (HiP-CT) [1] is a novel synchrotron X-ray imaging technique that is capable of resolving both hard and soft spinal tissues at unprecedented resolution and was used herein to image an intact human spine for the first time.

Methods

The spine, from a 62-year-old male donor, was chemically fixed in formalin and mounted in a formalin-agar solution. HiP-CT images were acquired at voxel size of 16.26 µm using BM18 beamline at the European Synchrotron Radiation Facility (MD1290), with local regions of interest imaged at a voxel size of 2.2 µm. Vascular networks and nerve bundles were segmented using region-growing in VG Studio Max, and collagen fibres in the intervertebral disc (IVD) were traced using the XFiber module in Avizo 3D.



Results

HiP-CT enabled high-resolution visualisation of mineralised vertebral bodies, IVDs, vasculature, and nerve bundles without exogenous contrast agents. Virtual sectioning and 3D renderings of segmented structures provide valuable insight into spinal anatomy, including vascular supply and innervation of the vertebral body and IVDs (Figure 1). Fibre tracing revealed collagen fibre orientation within the IVD (Figure 1d) and identified disruption of the lamellar architecture in herniated discs (Figure 1e).

Discussion

Our methodology resolves the multi-scale anatomy of the human spine, enabling investigation into structural changes characteristic of healthy ageing and degenerative diseases. Future work aims to perform anatomically guided microarchitectural analyses on these images which will inform the development of finite element models that better capture disease progression.

VMamba-Pose: Efficient Multiperson Pose Estimation Using Visual State Space Models

Mrs Ivanna Kramer, Dr Sabine Bauer, Mr Jan Herschel, Prof. Dr. Dietrich Paulus

University of Koblenz, Koblenz, RLP, Germany

Introduction

Accurate Human Pose Estimation (HPE) from RGB-images is essential for biomechanical research, rehabilitation technologies and the development of assistive devices, as it enables markerless kinematics. This study introduces VMamba-Pose: a novel deep learning framework for the efficient processing of RGB images in biomechanics-related environments, specifically for multiperson HPE.

Methods

The presented model is derived from VMamba visual state space architecture [1], replacing computationally expensive self-attention with state space models that enable linear-time training and constant-time inference. VMamba-Pose follows a top-down approach partitioning input images into patches and processing through hierarchical Visual State Space blocks combining normalization, selective 2D scanning (SS2D), and feed-forward layers. The SS2D module performs four-directional scanning for efficient spatial feature extraction under complex motion and occlusions. The resulting representations are decoded into 2D-joint heatmaps, producing keypoint locations.

Results

Experiments were conducted on the MS COCO dataset using AdamW optimization, and four model scales -Tiny, Tinier, Small, and Base - were trained without any pre-training.

VMamba-Pose achieved accuracy comparable to state-of-the-art transformer models requiring significantly fewer parameters and substantially reduced computational load. VMamba-Pose-S reached 77.26% AP on COCO at 576×768 resolution, matching HRFormer and ViTPose-B. The lightweight VMamba-Pose-TR (6.99M parameters) delivered 75.34% AP, outperforming YOLOv5l6-Pose and GMamba, demonstrating its suitability for real-time embedded systems (see Table 1). Importantly, the models maintained stable performance across varying image resolution. Across evaluated VMamba models (VMamba-Pose-B), increasing the input resolution resulted in an average AP improvement of approximately 1.93%. The Tiny and Tinier variants further highlight the efficiency of the

architecture: VMamba-Pose-T, with 21.05M parameters, achieved an AP of 76.89%, while the more compact VMamba-Pose-TR, using only 6.99M parameters, still reached 75.34% AP.

The implementation of VMamba-Pose, along with visual results, is available in our open-source repository : https://github.com/VisSim-UniKO/VMamba-Pose.

Discussion

The model's linear-time computation and low parameter count make it well-suited for real-time imaging systems, wearable sensors, and assistive devices, where fast inference and minimal hardware load are essential. It provides an efficient alternative to transformer-based HPE, and its computational efficiency makes it appealing for real-time clinical monitoring, sports applications, and integration with biomechanical devices.

[4]Advanced Materials and Bio Engineering Research (AMBER) Centre, Royal College of Surgeons in Ireland and Trinity College Dublin, Dublin, Leinster, Ireland

Introduction

Stroke is the second leading cause of death worldwide [1]. 87% of all strokes are ischemic [2], with 23% of these linked to large-vessel atherosclerosis, such as the carotid [3]. Recent guidelines have emphasised the importance of assessing plaque composition to inform plaque rupture risk [4]. Multi-contrast MRI is the clinical gold standard for assessing plaque composition *in-vivo;* however, it is limited by long acquisition times [5]. In this study, we assess the feasibility of running a single-sequence MR-QSM technique *in-vivo* to fully characterise carotid plaque composition and inform rupture risk [6].

Methods

Ex-vivo ME-GRE MRI (7T-Bruker-BioSpec-70/30) for QSM was acquired for excised human carotid plaques (n=4). MicroCT (μCT) was acquired to validate the presence of calcification. Histological validation of plaque composition was carried out using Movat's pentachrome (MP) and Prussian Blue (PB). *In-vivo* MRI and Computed Tomography Angiography (CTA) were acquired for a female undergoing a carotid endarterectomy. A thrive sequence was acquired on a Philips Ingenia 3.0T scanner and postprocessed to generate the QSM data.

Results

A representative *ex-vivo* QSM image is outlined in Figure.1.a, and demonstrates that calcification, the lipid-rich necrotic core (LRNC) and intraplaque hemorrhage (IPH) can be clearly distinguished. The media, intimal thickening (IT), the LRNC and calcification appeared diamagnetic, whereas IPH appeared paramagnetic, Figure.1.b. A significant difference ($P<0.05$) in susceptibility was observed for all components with the exception of

the media and IT and the LRNC and IT. *In-vivo* QSM identifies a diamagnetic region indicative of calcification that is validated by CTA, Figure.1.c and d. Heterogeneous susceptibility was observed within the calcification region, which could be due to noise artefacts or other plaque constituents, such as IPH in close proximity causing partial voluming.

Discussion

Clinical translation of MRI-QSM from *ex-vivo* to *in-vivo* was achieved. Although somewhat limited by lower resolution and motion-related artefacts, this work presents a ground-breaking first step towards using this powerful imaging for plaque risk stratification.

Images (Optional)

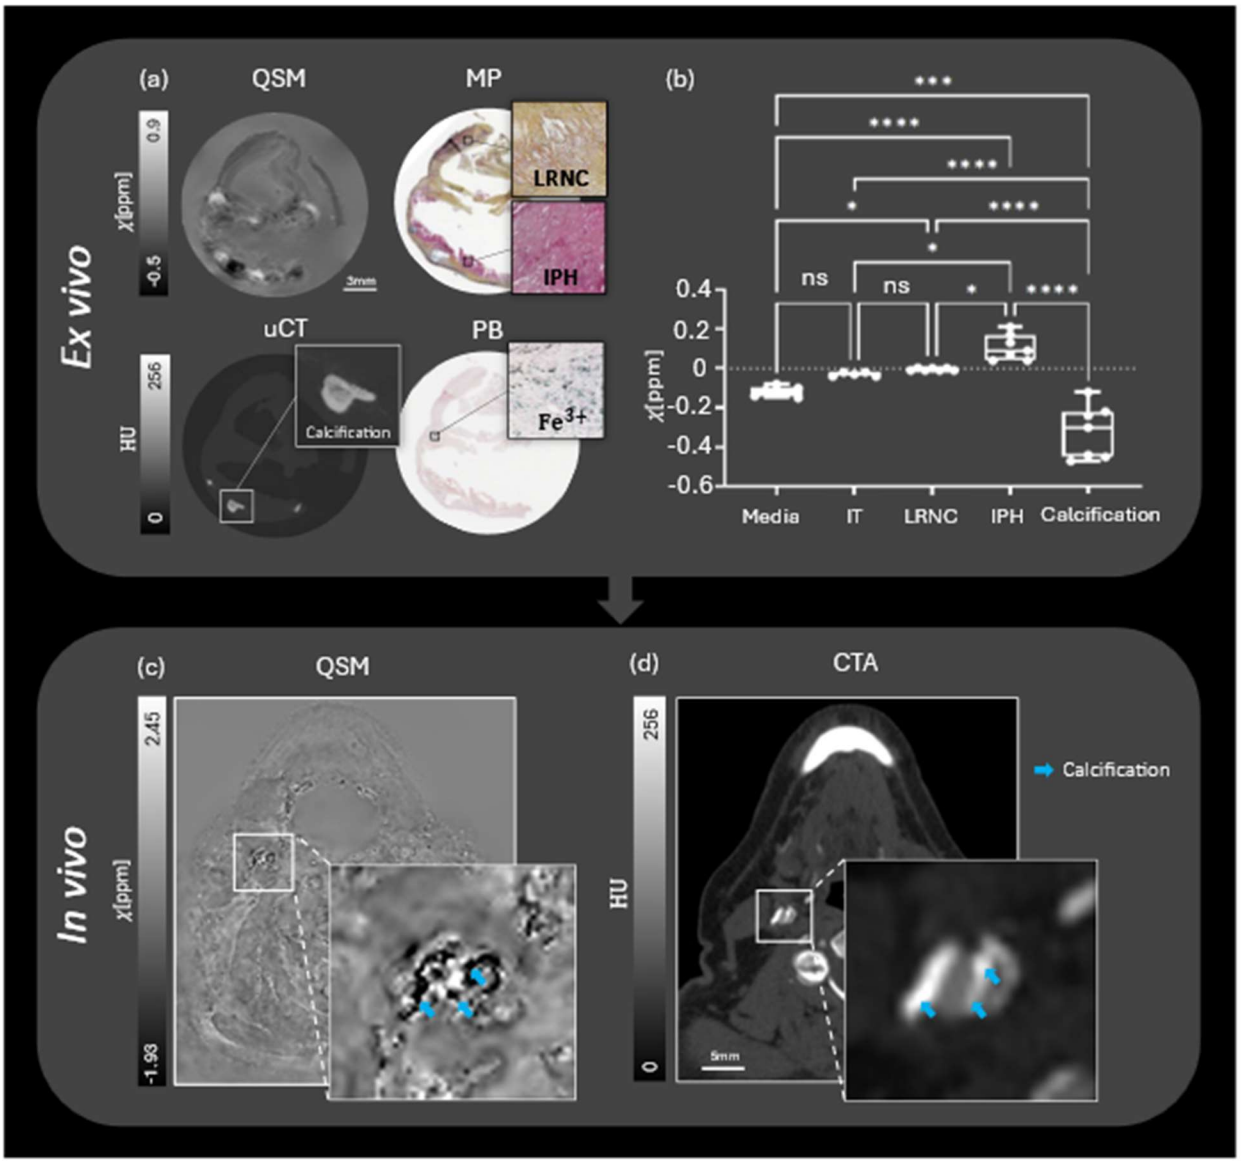

Figure 1A (a) *Ex vivo* QSM differentiates a LRNC, calcification, and chronic IPH. (b) Box and whisker plot displaying the mean, minimum, and maximum values for each plaque component (n=7). Statistical analysis was performed using one-way ANOVA (*P < .05, **P < .01, ***P < .001, ****P < .0001). **B** (a) *In vivo* QSM of a right carotid plaque identifies diamagnetic regions, indicative of calcification. (b) Registered CTA validates the presence of calcification.

Tracking Wrist Bones from Sequential 3DCT using 3DH, an Open-Source Hierarchical 3D Registration Module in SlicerAutoscoper^{M}

Ms Amy Morton[1], Ms Shelly Belsky[2], Mr John Holtgrewe[1], Mr Jean-Christophe Fillion-Robin[2], Mr Douglas Moore[1], Prof Beatriz Paniagua[2], Prof JJ Trey Crisco[1]

[1]Brown University, Providence, RI, United States. [2]Kitware, Clifton Park, NY, United States

Introduction

Kinematic tracking of *in vivo* joint and implant motion is indispensable for addressing a wide range of questions in musculoskeletal research. Projective imaging tools, such as biplane videoradiography, are established for studying the arthrokinematics of large joints. However, they can be technically challenging to implement for the small overlapping bones in the wrist and foot. In this work, we present Hierarchical 3D Registration (3DH), a 3DSlicer module for efficient, semi-automated registration of multiple bones imaged with sequential 3DCT or 4DCT.

Methods

3DH facilitates semi-automatic registration via an intelligent bone hierarchy sub-volume extraction, boundary-tests, and forward registration propagation. ITKElastix (https://elastix.dev/) is used for optimal registration between target and source sub-volumes. To validate the method, data from nine (9) hands/wrists scanned in neutral and 10 thumb ROM and task poses was used. The same dataset was previously registered via tissue-classified distance fields (TCDF) [1]. The radius, first metacarpal (MC1), and trapezium (TPM) were segmented and registered using 3DH. Bone motion was expressed as helical axis of motion rotation and translation. Bias, bias standard deviation (SD), and the 95% limits of agreement (LOA) between TCDF and 3DH motion parameters were quantified using Bland-Altman analysis.

Results

Across all subjects and tasks, the bias (SD) of the radius, MC1, and TPM rotation between TCDF and 3DH was 0.01°, -0.20°, 0.00° (0.15°, 2.30°, 0.36°), respectively, and the 95%LOA of the rotations across all bones averaged -1.87° and 1.74°. The bias (SD) of the 3DH-calculated translation for the radius, MC1, and TPM was -0.37mm, 0.01mm, and 0.00mm (1.90mm, 0.40mm, 0.91mm), respectively, and the 95%LOA for translation across all bones averaged -2.23mm and 2.00mm.

Discussion

We have developed a free, open-source software solution for musculoskeletal registration of 3D and 4DCT datasets. Our new Hierarchical 3D Registration module in 3DSlicer enables tracking of multiple small bones in 3DCT or 4DCT. The accuracy of the TCDF method was previously established as less than 0.3 mm and less than 0.4°. The agreement between TCDF and 3DH was better than 1/10 of these values. Our overarching goal is to provide a platform for sharing tracking algorithms.

P4-322

Investigation of Phase-Contrast micro-CT for Design Characterization of the Cervical Intervertebral Disc Space

Mr Jonah Leinwand, Ms Claire Thompson, Dr Stewart McLachlin

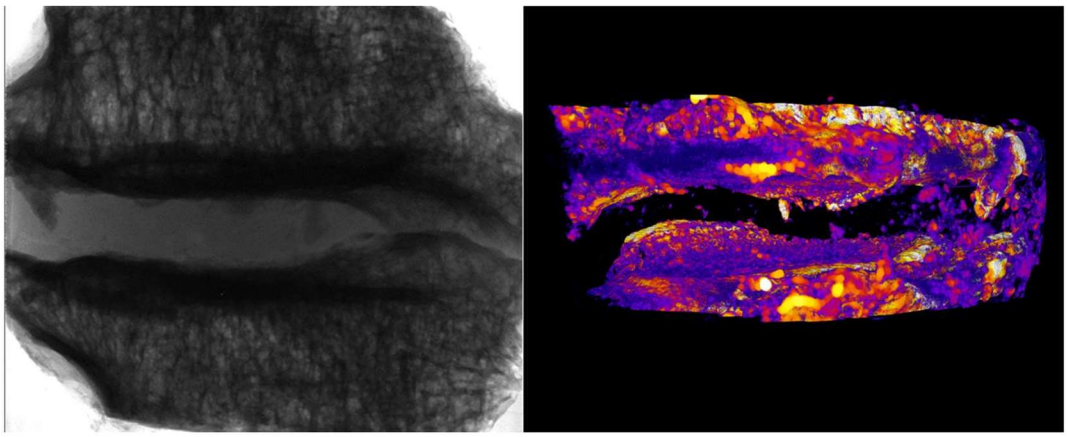
University of Waterloo, Waterloo, Ontario, Canada

Introduction

Understanding the design space is critical to spinal implant development, where knowledge of the geometry and properties of the vertebral bone and connecting soft tissues is needed to improve outcomes for devices like cervical artificial disc replacements (c-ADR). Imaging techniques, such as MRI or X-ray computed tomography (CT) are useful in characterization of these joints; however, detailed understanding of the tissue microstructure is often lacking. Use of micro-computed tomography (mCT) presents a potential option but is typically limited for understanding the intervertebral disc (IVD) space without staining [1]. The goal of this study was to investigate a phase-contrast mCT to better delineate the microstructure of the vertebral endplates towards characterization of c-ADR design constraints.

Methods

Cadaveric cervical spine motion segments were prepared for phase-contrast mCT imaging (InCiTe 3D X-ray Microscope, KA Imaging, Waterloo, Canada) by cutting through the superior and inferior vertebrae. Excess soft tissue and the posterior elements were removed. Samples were scanned at varying voltages (40-80kV), currents (100-150uA), integration times (800-2000ms), and both projection and frame count to determine optimal parameters for imaging and characterizing the IVD space and adjacent bony endplates of the vertebral joint. Scans were pre-processed with ImageJ to despeckle and normalize to an air gap measurement, then reconstructed in VGStudio (Hexagon, Sweden). Further processing was done in Fiji, an open-source image processing software, to create a volumetric thickness map of the endplates above and below the IVD.



Results

The volumetric thickness map, and the pre-processed mCT scan of the sample, with an effective pixel size of 6.15um, are shown (attached) for a representative specimen that had an overall width of 30mm and height of 22mm, with an IVD width of 25mm and height of 5mm. Scan time was approximately 5 hours.

Discussion

Further design metrics and constraints for c-ADR will be quantified based on the vertebral endplate thickness and geometric density distribution through post-processing of the 3D reconstructions. These results provide the basis for quantifying design constraints for a c-ADR to fill the envelope left by the removed IVD, while promoting attachment to the densest regions of adjacent bone.

Images (Optional)

Changes in Supraspinatus Tendon Structural and Material Properties during Manual Wheelchair Handrim Loading

Ms Jungsun Moon[1], Ms Savanna Rudy[1], Mr Dustin Tran[1], Ms Denali Hutzelmann[1], Dr. Matthew Hanks PhD, ATC[1,2,3]

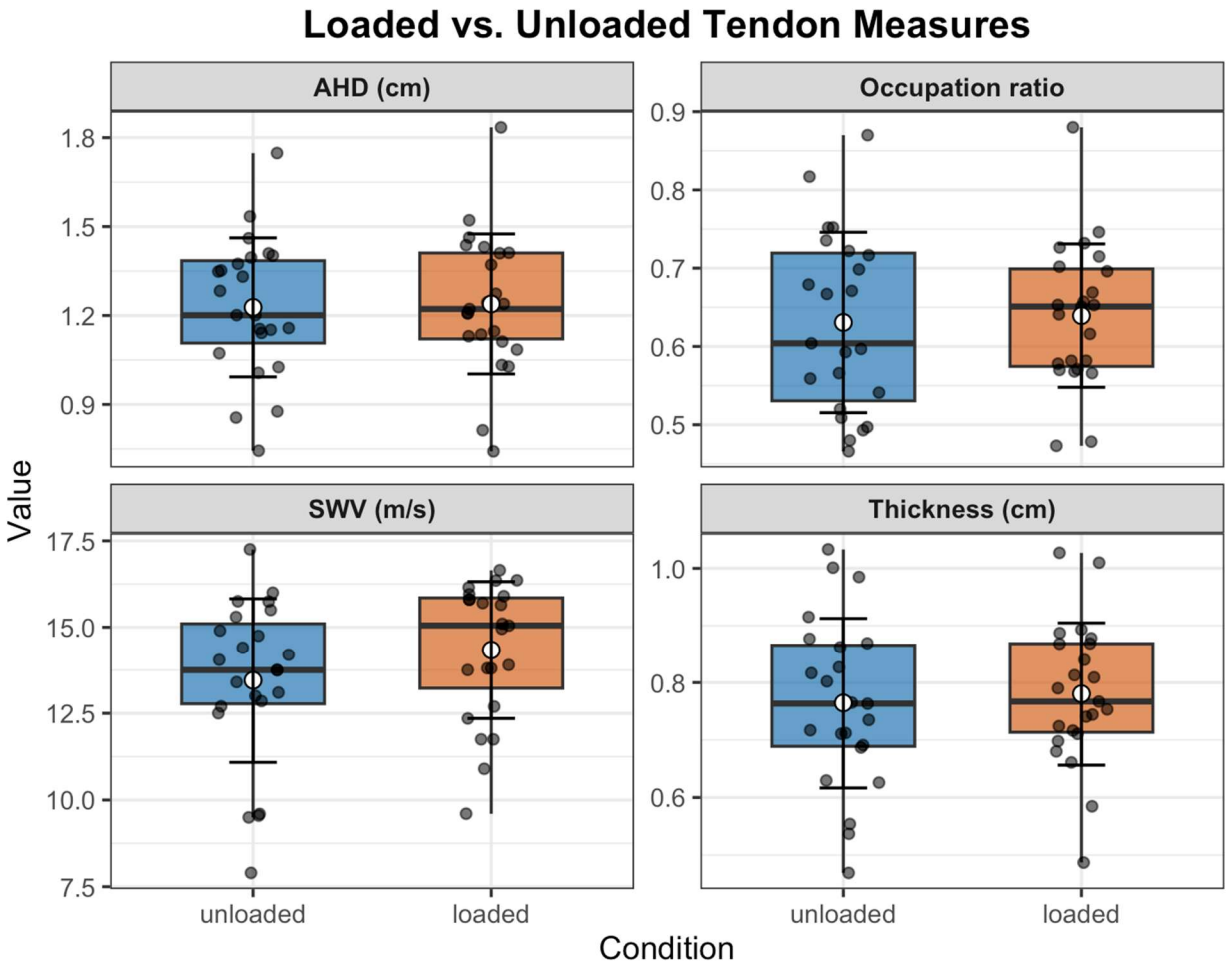
[1]Department of Health and Kinesiology, University of Illinois Urbana-Champaign, Urbana, Illinois, United States. [2]Beckman Institute for Advanced Science and Technology, University of Illinois Urbana-Champaign, Urbana, Illinois, United States. [3]Disability Resources and Educational Services, University of Illinois Urbana-Champaign, Champaign, Illinois, United States

Introduction

Manual wheelchair use places repetitive stress on the shoulder, which may contribute to shoulder pain and tendinopathy. Supraspinatus tendon properties and three-dimensional (3D) scapular kinematics are associated with these musculoskeletal conditions. However, scapular kinematics and supraspinatus tendon structural properties (e.g., cross-sectional thickness) have been evaluated independently despite their anatomical link, and studies evaluating supraspinatus tendon material properties (e.g., stiffness) among manual wheelchair users are limited. Therefore, the purpose of this study was to examine changes in supraspinatus tendon structural and material properties during two handrim loading conditions.

Methods

Twenty-three manual wheelchair users (n=23, 12M/11F, age: 21.5±3.5 years, duration of wheelchair use: 14.1±4.5 years) participated. Participants, in their personal wheelchair, assumed a natural, static position simulating propulsion with their hands atop the wheel aligned vertically with the axle. Participants then underwent shoulder musculoskeletal imaging in two conditions: (1) resting their hands on the handrim and (2) exerting a mock propulsion force on the handrim. Tendon thickness and acromiohumeral distance (AHD) were measured using B-mode ultrasound, and tendon occupation ratio (thickness divided by AHD) was computed. Tendon shear velocity, a surrogate measure of stiffness, was measured using shear wave elastography. Participants, in the same static position, were affixed with 34 passive markers on their upper body, 3D marker trajectories were tracked using motion analysis, and a biomechanical model was constructed to quantify 3D scapular kinematics. Repeated-measures MANCOVA was used to explore the effect of handrim loading condition on supraspinatus tendon properties, adjusting for scapular kinematics.



Results

No significant main effect of loading condition was observed (*Pillai's Trace*=0.036, $F_{4,19}$= 2.68, p=0.063; Figure 1), and only a small-to-moderate effect of loading condition was observed for shear velocity (η_p^2=0.05). We observed statistical significance and large effects of scapular upward/downward rotation on tendon shear velocity (p=0.017; η_p^2=0.18) and AHD (p=0.04; η_p^2=0.18) though tendon thickness was nonsignificant (η_p^2=0.17, p=0.05).

Discussion

Supraspinatus tendon structural and material properties were not different between loading conditions after controlling for scapular kinematics. However, increased scapular downward rotation was associated with smaller tendon shear velocity, thickness, and AHD. Our findings suggest that scapular kinematics may influence tendon health more than handrim loading alone.

FiberFit: A Web Application for Fiber Orientation Analysis with Comparative Assessment to Existing Software Tools

Ms. Katherine Fors, Mr. Cody Willson, Mr. Kyle Shannon, Dr. Trevor Lujan PI

Boise State University, Boise, ID, United States

Introduction

Accurate quantification of fiber network structures is essential for advancing a mechanistic understanding of biomaterials. Research groups have therefore developed software applications that quantify structural parameters from two-dimensional images, including mean fiber orientation and fiber alignment (dispersion). These applications include: OrientationJ, Directionality, CurveAlign, Cytospectre, and FiberFit, which was developed by our group [1]. However, adoption of these tools has been limited by two factors: accessibility and accuracy. Although free to use, these applications require users to download and run standalone executables, limiting accessibility. Additionally, no study has directly compared their accuracy because each program quantifies alignment using a different metric. Therefore, this study had two goals: convert FiberFit into a web-based application and objectively evaluate the accuracy of different software applications.

Methods

FiberFit's original Python code was installed on a server, and a web interface was developed in standard HTML, JavaScript, and CSS (Fig. 1A). A set of 72 unique images with known mean fiber orientations and alignments were generated using a custom MATLAB program. Each binary image was populated with line segments based on a semicircular von Mises probability function. Images were analyzed using the five software applications. The fiber angle distribution histograms produced by each tool were extracted and processed to compute the mean orientation and alignment by fitting each histogram to a von Mises distribution. Errors between known and measured parameters were computed. To ensure each program was evaluated under optimal conditions, a sensitivity analysis was conducted to identify the settings that minimized error for each application.

Results

FiberFit showed the lowest mean error for orientation (1.11°) and alignment (3.34%; $p<0.05$). Across all tools, disordered networks produced substantially greater measurement error than aligned networks (Fig. 1B-C).

Discussion

FiberFit demonstrated the highest overall accuracy among the applications analyzed, with its performance especially robust at analyzing networks of different alignments. Accuracy differences across applications reflect differences in the algorithms used to generate histograms. Importantly, this analysis was performed using optimal parameters for each specific application. FiberFit is now available as a web application providing an accurate and accessible option for fiber network analysis.

Images (Optional)

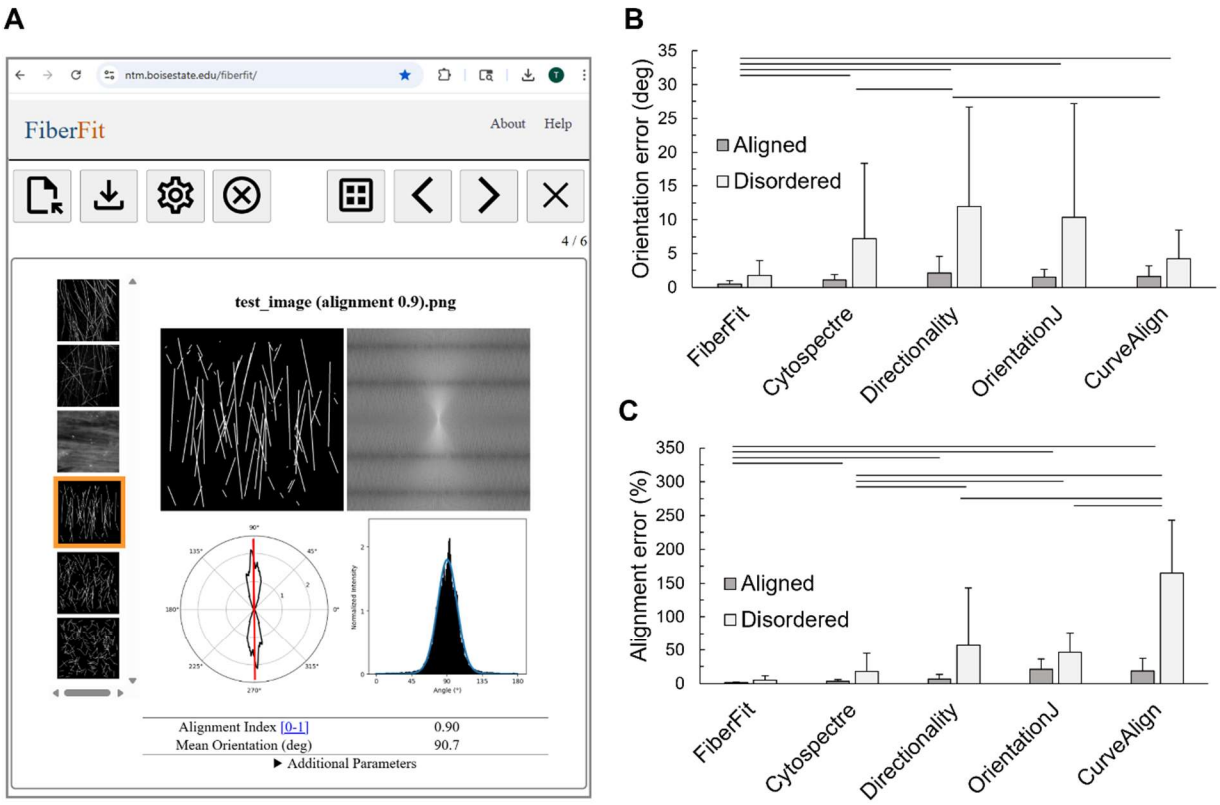

Figure 1: A) FiberFit web application. **(B-C)** Comparison of software orientation and alignment error for aligned and disordered fiber networks, where bars = ($p < 0.05$). Aligned networks had significantly lower error than disordered networks in all cases ($p < 0.05$).

Dr Geoffrey Handsfield

Dr Katherine Knaus

Dr Joe Hart

Introduction

Among the quadriceps femoris muscle group, the vastus lateralis (VL) and vastus intermedius (VI) play key roles in knee extension. The VL occupies the lateral superficial aspect of the thigh and the VI lies deep to the rectus femoris (RF). Despite these clear locations, the boundary between these muscles is not consistently identified in radiological cross-sectional studies [1]. The greatest ambiguity concerns the posterolateral inferior portion of the quadriceps, which is variably described as part of the VI in radiological studies [1] or as part of the VL in gross anatomical studies [2]. A third interpretation identifies this tissue as a distinct subdivision of the VL, termed the vastus lateralis obliquus (VLO). Despite references to the VLO in the literature [3-5], no prior study has assessed its structure in radiological cross-section and quantified its volume in a group of healthy adults.

Methods

To address this gap, we used high-resolution MRI to examine quadriceps in a group of healthy adults that included elite NCAA sprint runners (6F/4M) and non-sprinter controls

(6F/6M). Data were collected under IRB from the University of Virginia; all participants provided informed consent. We manually segmented axial images, defining the VLO as the region between the deep and superficial septum, posterolateral to the femur (Figure 1A), thus generating 3D geometries of the VLO, vastus lateralis longus (VLL), VI, vastus medialis (VM), and RF.

Results

We found that the VLO is consistently present, extends three-quarters of the femoral length, comprises 18% of the VL volume (Figure 1B), and is not significantly larger (p=0.08) in elite sprinters, though all other quadriceps heads were significantly hypertrophied in sprinters (p<0.05) (Figure 1C).

Discussion

Muscle boundary definitions impact downstream biomechanical variables such as predicted force. Our results suggest a correction factor of 18% could be applied to VL volume when comparing studies with different VL–VI definitions, offering a practical way to reconcile methodological differences without compromising internal consistency.

Images (Optional)

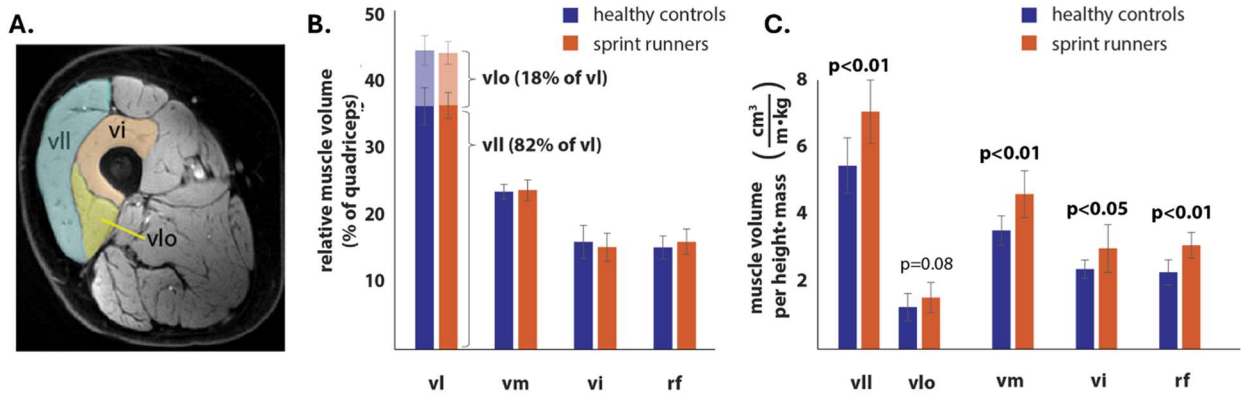

Figure 1. The vastus lateralis obliquus (VLO) was consistently identifiable across participants. (A) In axial MRI, the VLO occupied the posteromedial aspect of the vastus lateralis, superficial to the posterolateral aspect of the vastus intermedius. (B) The VLO represented 18% of the vastus lateralis, which was consistent across our population. (C) Height-mass normalized muscle volumes were higher for the sprinter group in all quadriceps heads.

Positional Accuracy Assessment of 3D Gaussian Splatting from Monocular Video for Medical Image Registration

Mr Hewamannege Sudam, Ms Kanon Sato, Prof Koich Kobayashi, Prof Makoto Sakamoto

Graduate School of Health Sciences, University of Niigata, Niigata, Niigata, Japan

Introduction

Meniscal injury diagnosis relies on both Magnetic Resonance Imaging, which suffers from limited accuracy for subtle tears, and invasive arthroscopy - the diagnostic gold standard. There is opportunity for training an AI model capable of achieving diagnostic accuracy closer to arthroscopy, by using novel 3D Gaussian Splatting (3DGS) as a generator of 3D anatomical images from knee arthroscopy video. However, accuracy of 3DGS should be assessed first.

Methods

A short video sequence, under 1 minute was captured using consumer camera of a custom-made triangular prism, in which 34 small metal balls with known coordinates were embedded (ground truth). Structure-from-Motion (Colmap) and 3DGS were employed to generate a 3D point cloud from the video frames. This is imported to CloudCompare software, and an initial scale calibration was performed using a reference distance of 120.575mm, yielding a scale factor of 0.7296. Then x,y,z coordinates of each ball was obtained. Using minimization of the least squares and by iterative translation(x,y,z); Rotation; Scaling, obtained point cloud was aligned so that it achieved the best fit with known coordinates. Aligned point cloud coordinates of each ball was compared against the ground truth, displacement (error) was recorded in each direction. 34 sets of records were obtained. Summery statistics of error was calculated.

Results

Mean three dimensional alignment error was 0.806 ± 0.337mm. The median error was 0.873mm, with a range of 0.161mm to 1.294mm. Per-axis error analysis revealed maximum single axis errors of 1.127mm (x), 0.983mm (y), and 0.978mm (z). The interquartile range was 0.072mm, indicating consistent error distribution across the reconstructed volume.

Discussion

Since metal balls are not point objects, care was taken to pick coordinates so that they represent the middle of each ball, yet there could have been human error. This pre assessment shows that monocular video derived 3D structures show acceptable

positional accuracy to be used for gross 3D-anatomy generation. Having mostly submillimeter accuracy just from an under one minute video is promising and the accuracy could be improved further by using longer videos. This validated pipeline is scheduled to be used to synthesize the 3D knee inner capsule from arthroscopy video.

Automated and Reproducible FE Patient-Specific Modeling of the TMJ Based on Medical Imaging

PhD Student Lilian Baugnon[1], Full Professor and Hospital Practitioner Romain Nicot[1,2], Research Engineer Nicolas Béthune[1], Associate Professor Pauline Lecomte-Grosbras[1], Research Engineer Jean-François Witz[1], Associate Professor Olivier Mayeur[1]

[1]Univ. Lille, CNRS, Centrale Lille, UMR 9013 LaMcube Laboratoire de Mécanique, Multiphysique, Multiéchelle, Lille, Nord, France. [2]Univ. Lille, CHU Lille, Department of Oral and Maxillofacial Surgery, Lille, Nord, France

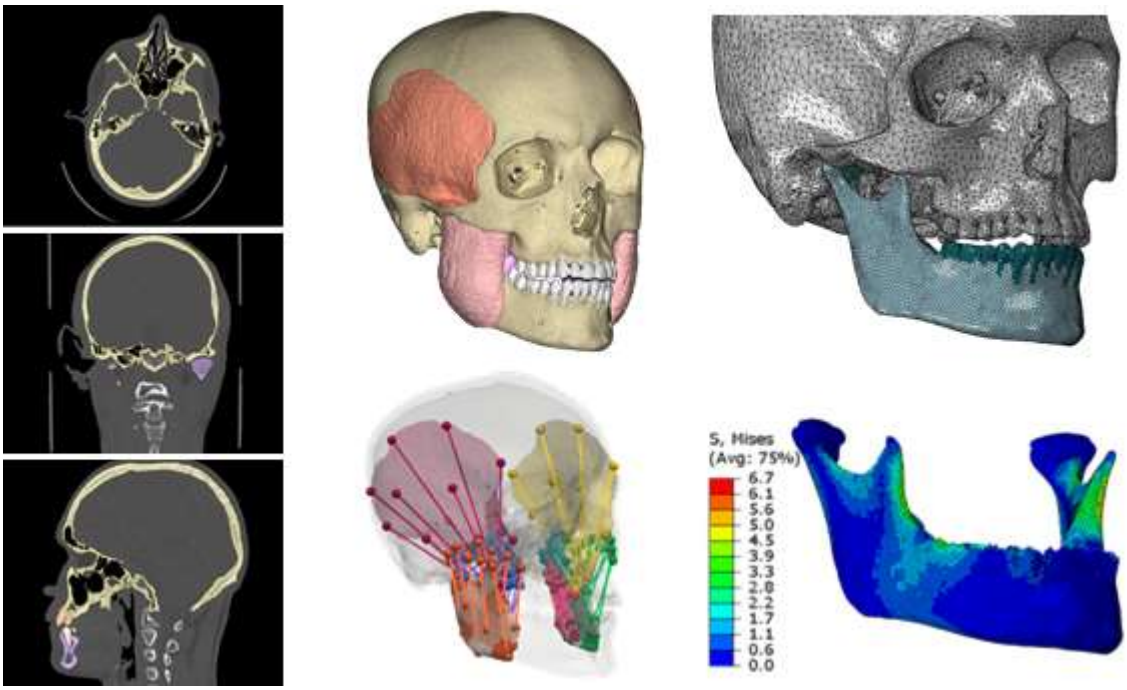
Introduction

The temporomandibular joint (TMJ) connects the mandible to the skull and enables chewing, speech, and swallowing. It is composed of a disc that separates synovial cavities. The joint combines rotation and translation to generate movements of retraction, protrusion, elevation, lowering, and lateral excursions via the temporal, masseter, and pterygoid muscles. Nearly 34% of the population shows signs of TMJ disorders according to the State Of The Art. Finite Element (FE) models driven by displacements or forces, analyze stresses and strains. The study presents a personalized model of the TMJ, automated and reproducible, that can be used for diagnostic purposes and therapeutic planning in cases of TMJ disorders and surgical correction.

Methods

The study uses algorithms for the generation of FE models, following a standardized workflow of patient-specific digital twins. The CT data in DICOM format were segmented automatically for bones and muscles, producing FE-compatible volumes. The tissues are modeled as linear elastic with generic properties or derived from medical imaging. The parametric model incorporates contacts, muscle forces according to different orientation methods, with the realistic mandibular position in inter cuspation position. This enables detailed and personalized FE simulations to analyze physiological and pathological conditions.

Results



Material assignment via HU values improves spatial resolution and mechanical consistency with the literature (mandibular Young's modulus: 11.4GPa vs 11.6GPa) and Von Mises stresses (<0.1% difference). Sensitivity analysis shows that seven cortical

classes and two trabecular classes are sufficient for convergence and highlights the limitation of assigning a single material. Increasing friction reduces overall stresses but locally doubles the stresses in the condyles, revealing a left–right asymmetry. Finally, muscle representation influences mechanical response: the multivector method provides the most accurate and stable results, with stress predictions stabilizing beyond 10 directional loads per muscles.

Discussion

This study provides a fully automatic and parameterized, patient-specific TMJ model consistent with literature, enabling diagnostic insights through stress maps, asymmetry patterns, and muscle load effects. It opens perspectives for pathological analysis and surgical planning. Future work will validate against experiments, extend to multiple patients to assess variability, and integrate automated workflows for personalized prosthesis design and evaluation.

In-vitro Investigation of Stress-Relaxation Behavior in Orthodontic Aligners

Mr. Lingyu Bu[1], Dr. Paul Major[2], Dr. Dan Romanyk[1,2,3]

[1]Department of Mechanical Engineering, University of Alberta, Edmonton, Alberta, Canada. [2]Mike Petryk School of Dentistry, University of Alberta, Edmonton, Alberta, Canada. [3]Department of Biomedical Engineering, University of Alberta, Edmonton, Alberta, Canada

Introduction

Orthodontic aligners are commonly polymeric-based, exhibiting viscoelastic behavior leading to inconsistent orthodontic forces applied to teeth over time. Previous studies have explored stress-relaxation behavior of aligner materials through mechanical tests. However, the effects of hydration are often missing in such studies. Also, most experiments were performed over planar aligner sheets, while the highly complicated 3D geometry of aligners can significantly influence their force delivery. Therefore, the present study aims to quantify the time-dependent decay of orthodontic forces in aligners using in-vitro measurements under clinically relevant tooth displacements.

Methods

In-vitro tests were performed on aligners using an Orthodontic Simulator (OSIM), which can measure the 3D forces generated by the aligner on each tooth through the connected loadcells [1]. Aligners were inserted on OSIM, and the right central incisor was displaced 0.5 mm outward to generate an initial force of ~1.5 N. Five consecutive 8-hour dry tests (DT) were performed. Hydration tests (HT) were performed after soaking the aligners for 48 hours, and aligners were tested 2 hours to avoid excessive dehydration, based on previous results showing most force decay occurs within 2 hours.

Results

A force decay of 0.15–0.38 N was observed in DT samples, with a decreasing rate of force decay over time (Test 1: 0.38 N, Test 2: 0.26 N). The averaged DT force decay was 15.40% in 8 hours and 7.67% in 2 hours. HT exhibited similar behavior but showed reduced force decay (average of 4.67% in 2 hours).

Discussion

This study bridges the gap between material and in-vitro viscoelastic behavior of orthodontic aligners. Most in-vitro studies ignored the stress-relaxation of aligner materials, which was shown to have a significant effect on force delivery. One key

limitation is that the aligners cannot be tested while immersed in fluid due to instrumentation positioning on OSIM, which limits the ability to test hydration effects. However, short-term tests showed that hydration affects the relaxation behavior. Future work will focus on developing a constitute material model based on these results to enhance FEA simulations of aligner behavior.

Images (Optional)

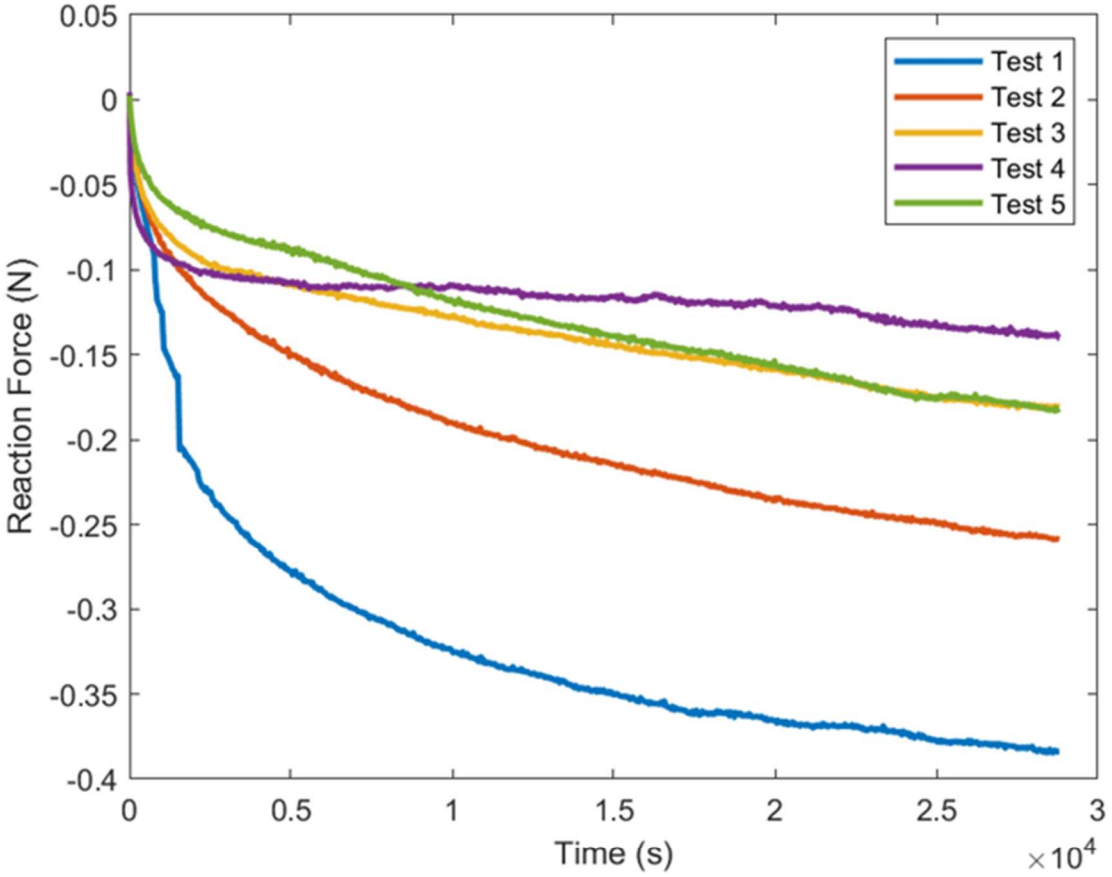

Figure 1: The force decay results from DT sample tested on OSIM with an outward displaced central incisor presented for 5 tests, where Test 1 is the first experiment and Test 5 is the final; original measurements from the loadcell were filtered by a 4th order Butterworth low-pass filter to eliminate noise, and starting points were normalized to 0 for comparison.

Design of a Dual-Probe Setup for Experimental Assessment of Multi-Mode Shear Wave Propagation in Transversely Isotropic Tissues

Ph.D. candidate Lorena Claeys[1,2], Ph.D Tim Nordenfur[1,2], Ph.D Zhongzheng Wang[1], Ph.D Ruoli Wang[1], Ph.D Matilda Larsson[1]

[1]Kungliga Tekniska högskolan, Stockholm, Stockholm, Sweden. [2]Karolinska Institutet, Stockholm, Stockholm, Sweden

Introduction

Shear wave elastography (SWE) measures tissue stiffness but is limited for transversely isotropic (TI) tissues, which require three elastic parameters for characterization. Conventional SWE captures two parameters related to shear anisotropy (SH mode), while the third, linked to tensile anisotropy (SV mode), cannot be measured directly. This study introduces a dual-probe setup allowing full parameters characterization. This design was tested on ex-vivo muscle tissue and SWE results were compared with mechanical testing.

Methods

SWE was performed on ex-vivo bovine semitendinosus tissue using a Verasonics V1 (L7-4). For shear anisotropy, a vertically positioned probe was aligned with the fiber direction (Figure 1a) and used for both pushing (5 MHz, 70 V, F#2) and imaging (5 MHz, PRF 10 kHz) every 10° over 360°. Axial velocities were computed via 2D autocorrelation and SH velocities were extracted using a Radon-sum algorithm. Rheology was performed five times on 10×10×2 mm^3 transverse and longitudinal samples using a frequency sweep (0.1–100 Hz) with 10% compressive preload. For tensile anisotropy, the vertical probe generated the push while a second, orthogonally positioned probe aligned with the fibers was used for imaging (Figure 1b); SV group velocities were manually tracked from the axial velocity maps. The extracted SH and SV velocities were fitted to a theoretical TI model to estimate the mechanical parameters (Figure 1c). Compression testing was performed on 20×20×20 mm^3 samples (transverse and longitudinal) using 1 N preload and 3 mm ramp over 2 min (±5 kN load cell), with two preconditioning cycles prior to data acquisition on the third cycle.

Results

The results demonstrate that the mechanical parameters assessed by SWE are comparable to those obtained through mechanical testing. The μ_l/μ_t ratio measured by SWE was 1.84, compared to 1.34±0.11 from mechanical testing, while the E_t/E_l ratio was 0.53 for SWE and 0.68 for mechanical testing.

Discussion

The same-range agreement between SWE-derived and mechanically measured parameters demonstrates that the dual-probe setup enables full elastic characterization of TI tissue by estimating both shear and tensile anisotropy. Future work will improve compression test robustness and extend validation to ex-vivo and in-vivo tissues.

MRI-Based Pressure Gradient Mapping in Patient-Specific Models of Aortic Coarctation

- Priya Nair[1], Dr. Lorenzo Ferrari[1], Dr. Michael Loecher[1], Dr. Charles McGrath[1], Dr. Carlos Castillo Passi[1], Dr. Doff McElhinney[1], Dr. Alison Marsden[1], Dr. Daniel Ennis[1,2]

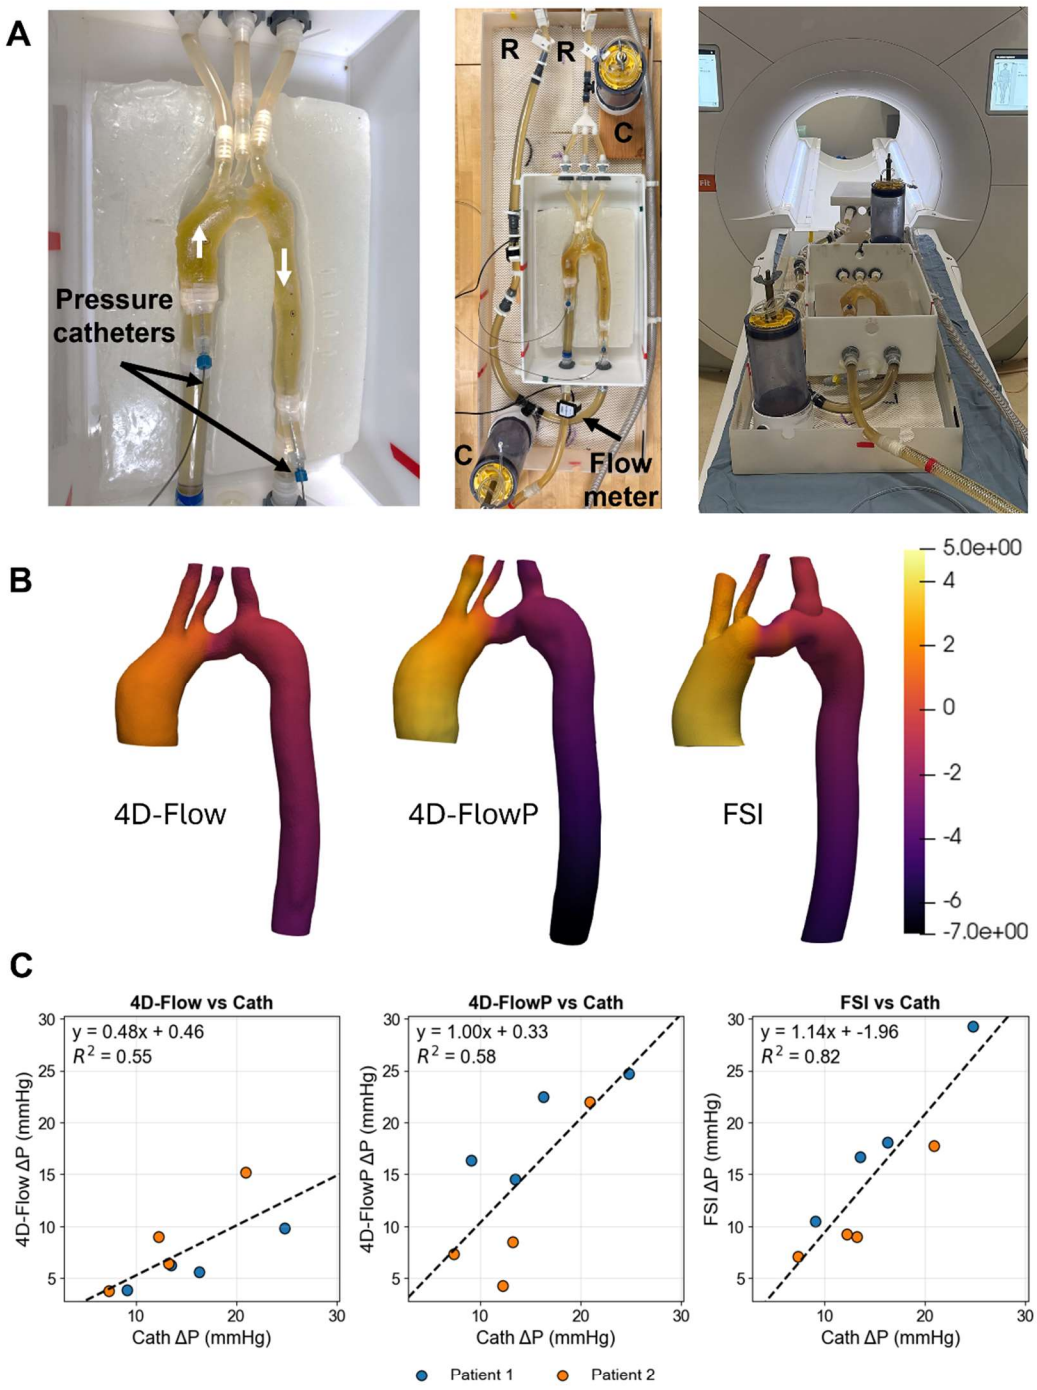
[1]Stanford University, Stanford, CA, United States. [2]VA Palo Alto Healthcare System, Palo Alto, CA, United States

Introduction

Coarctation of the aorta (CoA) is a congenital narrowing of the aorta affecting ~3 per 10,000 births [1]. Clinical decision-making relies on estimation of the pressure gradient (ΔP) across the stenosis, with invasive cardiac catheterization serving as the reference standard. Non-invasive estimation using phase-contrast MRI is feasible with 3D+time (4D) velocity-encoding methods such as 4D-Flow, where ΔP is calculated from measured velocity fields using the Navier-Stokes equations. This approach is sensitive to noise due to reliance on temporal and spatial derivatives of velocity. We developed 4D-FlowP, a novel MRI sequence that directly encodes velocity and acceleration to improve ΔP accuracy [2]. We evaluated the robustness of 4D-FlowP using *in vitro* experiments and fluid-structure interaction (FSI) simulations in patient-specific 3D-printed CoA models.

Methods

MRI and catheterization data from two patients with CoA (obtained under IRB) were retrospectively analyzed. Patient-specific aortic geometries were segmented in SimVascular, with an additional higher-severity stenosis geometry generated per patient. Compliant phantoms were 3D-printed using Agilus30 (E = 1.2 MPa) and integrated into a mock circulatory loop driven by a programmable pump (Shelley CardioFlow 5000) [3]. Pulsatile flow waveforms from clinical 4D-Flow MRI (Q1) were prescribed, with resistance and capacitance tuned to match in vivo pressures; a reduced-flow condition (Q2 = 0.5Q1) was also studied. Time-resolved 3D images (1.8 mm isotropic) were acquired on a 3T MRI (Vida Fit, Siemens) using conventional 4D-Flow and 4D-FlowP with comparable scan times. ΔP was computed via the incompressible Navier-Stokes equations, with acceleration derived from velocity gradients (4D-Flow) or directly encoded (4D-FlowP). Corresponding FSI simulations were performed using SimVascular.



Results

Conventional 4D-Flow underestimated ΔP relative to catheter measurements ($y = 0.48x + 0.46$, $R^2 = 0.55$), while 4D-FlowP demonstrated near-unity agreement with reduced bias ($y = 1.00x + 0.33$, $R^2 = 0.58$). FSI showed the strongest correspondence ($y = 1.14x + 1.96$, $R^2 = 0.82$).

Discussion

Patient-specific compliant phantoms provide a controlled framework for validating MRI-based ΔP estimation. Direct acceleration encoding with 4D-FlowP improves robustness and can enhance non-invasive hemodynamic assessment.

Images (Optional)

(A) MRI-compatible in vitro flow loop with an embedded 3D-printed compliant patient-specific CoA model instrumented for direct pressure and flow rate measures. The system includes tunable fluid capacitors and resistors to match patient-specific hemodynamics.

(B) Relative pressure fields and ΔP measures across the CoA demonstrating excellent agreement between 4D-FlowP and FSI.

(C) Comparison of 4D-Flow, 4D-FlowP, and FSI ΔP estimates to those obtained directly with a pressure catheter. Both 4D-FlowP and FSI show very good agreement with catheter-based estimates of ΔP.

Development of a 3-D Knee Joint Instability Testing System Using Image Analysis Technology

Mr. Manato Hayashi B.S.[1], Mr. Naoya Kuroyama B.S.[1], Prof. Norio Tagawa Ph.D.[1,2], Assistant Professor Yohei Okada M.D., Ph.D.[3], Prof. Atsushi Teramoto M.D., Ph.D.[3], Prof. Hiromichi Fujie Ph.D.[1,2]

[1]Graduate School of Systems Design, Tokyo Metropolitan University, Hachioji, Tokyo, Japan. [2]Research Center for Medicine-Engineering Collaboration, Tokyo Metropolitan University, Hachioji, Tokyo, Japan. [3]School of Medicine, Sapporo Medical University, Sapporo, Hokkaido, Japan

Introduction

It is important to quantitatively assess knee joint instability to improve the treatment of knee ligament injuries and total knee arthroplasty. However, commercially available knee arthrometers have several limitations: (i) the use of contact displacement sensors, which may cause errors due to skin deformation; (ii) the inability to measure the femoral three-dimensional motion, making varus–valgus testing in flexion impossible; and (iii) displacement measurement restricted to only one degree-of-freedom (DOF), although knee motion occurs in 6-DOF. To address these problems, we developed a novel knee joint instability test system using image analysis techniques.

Methods

A tibial loading device and a depth camera(RealSense D435if, Intel) were fixed in a knee-fixation plate. The accuracy of three-dimensional shape tracking with this camera using the iterative closest point (ICP) algorithm was 0.35mm in translation and 0.34° in rotation[1]. Young healthy male (n=5, age 28.8±8.2) were selected. The femoral coordinate system and tibial coordinate system were defined using bony landmarks following the ISB recommendation[2] and related to point cloud data of the patella and tibia, respectively. During the anterior drawer test and varus-valgus rotation test of the knee, the patellar and tibial surface were recorded by the camera, and the relative location between the coordinate systems was determined using the ICP with the fast point feature histograms. Finally, the 3-D knee displacement during the tests was determined with respect to the knee joint coordinate system referred from the ISB recommendation[2]. Note that a Python-based program for measurement and analysis was developed and used.

Results

At 20° of flexion, the tibial anterior displacement was 2.1 ± 1.4mm and the internal rotation was 3.7 ± 2.5° in response to 100N of anterior force. The varus–valgus rotation was 3.7 ± 2.0° in response to ±10Nm of varus–valgus moments. A good correlation between the obtained displacement and X-ray-measured true displacement was found with the intraclass correlation coefficient of 0.73-0.80.

Discussion

A novel 3-D knee instability test system was successfully developed in this study, though further accuracy improvements are needed.

Quantification of Skeletal Dissolution of Cold-Water Corals in a Changing Ocean

Dr Marta Peña Fernández[1], Dr Kristina Beck[2], Prof J. Murray Roberts[2], Dr Sebastian Hennige[2], Prof Uwe Wolfram[3]

[1]School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, Scotland, United Kingdom. [2]School of GeoSciences, University of Edinburgh, Edinburgh, Scotland, United Kingdom. [3]Institute of Materials Science and Engineering, Clausthal University of Technology, Clausthal-Zellerfeld, Lower Saxony, Germany

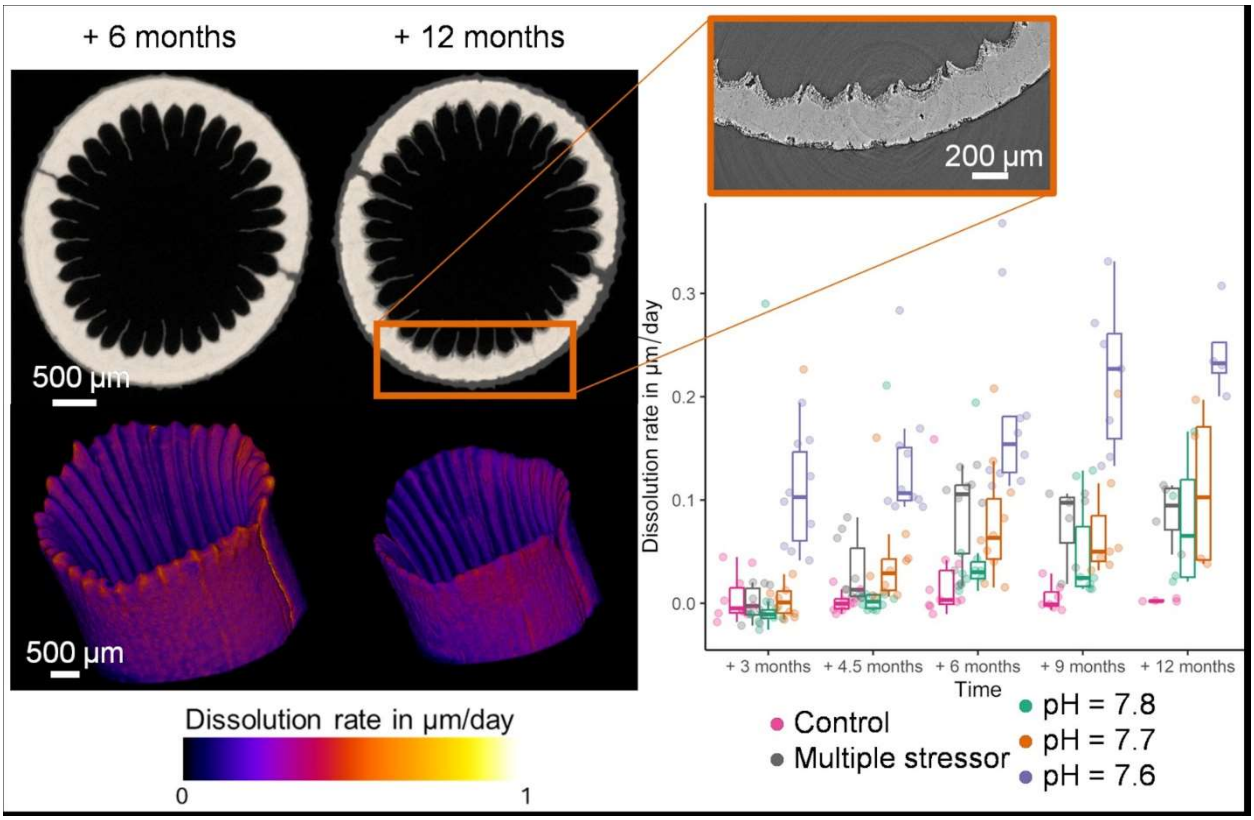
Introduction

Cold-water corals (CWCs) form complex habitats supporting high biodiversity in the deep sea [1]. Their structural complexity is at risk from ocean acidification (OA) which leads to reduction of seawater pH and aragonite saturation. While *live* corals continue to calcify under projected climate conditions, *dead* coral is prone to dissolution [2] which may result in habitat collapse and loss of biodiversity [3]. Here, we quantify the skeletal dissolution of the CWC Lophelia pertusa under projected OA conditions.

Methods

Dead skeletons were exposed for one year to (i) present-day oceanic pH (pH8.1); (ii) extreme end-of-century OA scenarios (pH7.7 and 7.8); (iii) OA projections beyond 2100 (pH7.6); and (iv) multiple stressors (high temperature, low oxygen and pH 7.7). We used time elapsed µCT (7µm) to quantify skeletal changes after 3, 4.5, 6, 9 and 12 months. Additionally, we performed high-resolution multi-scale SR-µCT (2.6µm to 0.325µm) at beamline I13-2 (Diamond Light Source) to quantify skeletal porosity.

Results



µCT images confirmed skeletal dissolution after 3 months that increased exponentially (Figure). Dissolution increased with reduced pH, with volume loss ranging from 1% to 83% for present-day pH and OA projections beyond 2100, respectively. The dissolution rate was not equal throughout the surface. Multi-scale SR-µCT images provided detailed dissolution and porosity information.

Discussion

We acquired the first µCT dataset on the dissolution process and its extent of *dead* CWC skeletons under present and projected OA scenarios. By investigating samples that have been exposed to a range of pH conditions over time, we can establish an exposure trajectory of aragonite saturation and OA-induced dissolution. This can be used to inform *in*

silico models [4,5] to investigate the increased risk of reef crumbling and consequent habitat loss under future OA projections.

In Silico Investigation of Natural Shear Wave Elastography in the Left Ventricle

MSc Marta Zattoni[1,2], Prof. Mathias Peirlinck[2], Prof. Patrick Segers[1], Dr. Annette Caenen[1,3]

[1]Ghent University, Ghent, East Flanders, Belgium. [2]TU Delft, Delft, South Holland, Netherlands. [3]KU Leuven, Leuven, Flemish Brabant, Belgium

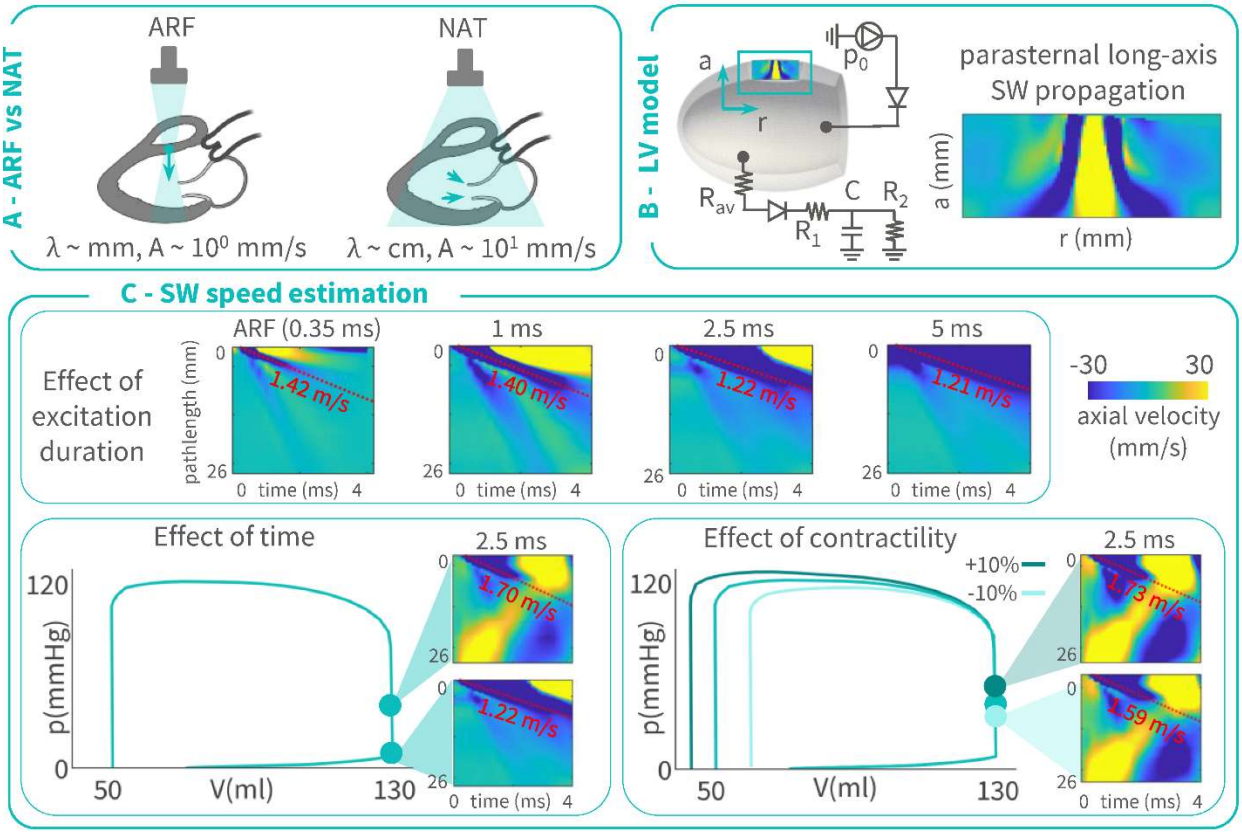
Introduction

Altered left ventricular (LV) myocardial stiffness is a hallmark of several cardiac pathologies. Shear wave elastography (SWE) provides a non-invasive tool to assess stiffness from shear wave speed (SWS) propagation. Cardiac SWs can be generated by an impulsive acoustic radiation force (ARF) or naturally (NAT) following mitral valve closure (Fig-1A). Both techniques show promise in preclinical stiffness assessment, but the physics governing NAT SW propagation remain poorly understood. We developed an *in silico* framework to investigate key mechanisms underlying NAT SW behavior: (i) excitation duration, (ii) time instant of evaluation, and (iii) LV contractility.

Methods

An idealized LV hexahedral mesh was parametrically designed using pyFormex. Myocardial mechanics were modelled in Abaqus by combining passive Holzapfel-Ogden (2009) and active Guccione *et al.* (1993) formulations. Coupling with a three-element Windkessel model equivalent allowed to reproduce healthy pressure-volume behavior. SWs were excited with an impulsive body force and their propagation was analyzed through a submodelling technique focusing on the parasternal long-axis view of the LV wall (Fig-1B). This approach has been validated for ARF SWs, and it was adapted to induce NAT-alike SWs by applying a 1-, 2.5- or 5-ms body force. Simulations were performed at end-diastole, and 30 ms after, corresponding with experimentally observed SW propagation after mitral valve closure (Papangelopoulou *et al.,* 2024). SWS was estimated using a Radon transform on the pathlength-time plot at mid-wall (Fig-1C).

Results



Longer excitation duration produced progressively longer wavelengths (λ_{ARF}=0.88mm; λ_{5ms}=6.5mm), consistent with *in vivo* reported results, and reduced SWS (-15%). NAT-alike SW assessed 30 ms after end-diastole aligned more closely with the timing of an actual SWE measurement and showed increased SWS (+39%), due to contractility effects. Averaged SWS across the wall was then 2.55±1.65 m/s, resembling averaged *in vivo* values

reported in literature. Similarly, increasing contractility resulted in higher SWS (+9%) 30 ms after end-diastole, due to pressure increase.

Discussion

Current study shows the added value of the modelling framework to study the effect of confounding factors on myocardial stiffness measurements. Ongoing work will redefine the body-force-based excitation by incorporating higher-fidelity modelling of valve closure, for a more physiological representation of NAT SW generation.

Introduction

Mechanical loading is essential for tissue health but quantifying the harm of disuse in healthy individuals is difficult. We previously showed enhanced cartilage extracellular matrix degradation after 21 days of 6° head-down-tilt (HDT) bedrest [1]. Using the validated multi-tissue Magnetic Resonance Imaging (MRI) Osteoarthritis Knee Score (MOAKS) [2], we evaluated the impact of reduced mechanical loading by three 21-day 6° head-down-tilt (HDT) bedrest periods within 1 year on knee joint structural health in young healthy adults.

Methods

Twelve healthy male participants (age 34.2 ± 8.3 years; body mass index 22.4 ± 1.7 kg/m^2) were exposed to three 21-days HDT periods within 1 year. HDT was combined with resistive vibration exercise and/or whey protein supplementation. MRI scans (3T, Siemens Trio, Erlangen, Germany) of the left knee were acquired. For this analysis, MRI scans taken

before the first (baseline, V1) and after the last HDT period (V2) were considered. Pathoanatomical features (bone marrow lesions (BML), osteophytes, meniscus damage) were assessed with MOAKS.

Results

At baseline, 8/12 participants did not have BML in the femur. After the three 21-day HDT bedrest periods, MOAKS increased. In the central medial femoral subregion, BML size decreased in one (MOAKS −0.5), and increased in two participants (MOAKS +0.5 and +2), with the latter developing an additional BML (MOAKS +1) and >66% cystic change (MOAKS +3/3). Ten participants had no abnormalities regarding the meniscus at either visit. At V1, two participants had meniscal extrusion of 2.0 to 2.9mm in the lateral and medial meniscus, respectively (MOAKS=1/3) and one of these had an abnormal lateral tear (MOAKS=4/8). These meniscal defects remained at V2. Finally, two participants had small osteophytes (MOAKS=1/3) in the femur and one participant in the tibia at both V1 and V2.

Discussion

Overall, we found very little structural change in healthy individuals in response to reduced mechanical loading during HDT immobilization. Semi-quantitative MRI assessment allows detection of pre-existent morphologic tissue damage and change over time and a complete description of joint tissue damage; quantitative assessments may be more sensitive to detect subtle longitudinal changes.

2D Bone Morphological Changes During Normal Growth at Localized Cranial Suture Sites

Dr. Michael Baggaley[1], Ms. Alexa Wingnean[2], Ms. Daelyn Page[1], Dr. Tsolmonbaatar Khurelbaatar[3], Dr. Dan Romanyk[1]

[1]University of Alberta, Edmonton, Alberta, Canada. [2]University of South Dakota, Vermillion, South Dakota, United States. [3]University of Calgary, Calgary, Alberta, Canada

Introduction

As the skull grows during infancy, the cranial sutures connecting the bones change shape to adapt to increasing pressure resulting from brain growth; suture width narrows and suture interdigitation increases [1]. However, it is unknown how these morphological changes are achieved in local regions of interest near the bone/suture interface. An image analysis pipeline was developed to quantify coronal suture morphology during normal growth in a rat model.

Methods

10 wild-type Sprague-Dawley rats received *in vivo* µCT at 7, 9, 11, and 16 weeks old. Planar images at 2% intervals between the endo- and ectocranial surfaces were created using a curved re-slicing technique to capture the entire length of the coronal suture accounting for skull curvature [1]. Three images were extracted for analysis in the endo- and ectocranial regions, located at 6%, 12%, and 18% and 86%, 92%, and 98% of skull thickness. 2D registration was performed between time-points to align the corresponding images (Figure 1A). To quantify bone addition, the younger image was subtracted from the older image; the older image was subtracted from the younger image to quantify bone removal. The number of pixels where deposition and removal occurred was counted and normalized to the suture size. Linear regression models were fit to the data; the main effect of animal age was examined using one-way ANOVA.

Results

A main effect of age was observed for bone addition ($F(1) = 49.06$; $p<0.001$) and bone removal ($F(1) = 97.23$, $p<0.001$) ratio. Bone addition decreased ($\beta = -0.034$; $t = 7.00$, $p<0.001$; Figure 1B) as the animals aged while bone removal increased ($\beta = 0.047$; $t = 9.86$, $p<0.001$; Figure 1C).

Discussion

Morphological changes are achieved through the coupled process of bone addition and removal at the bone-suture interface. Bone addition was greatest when the animal was young but decreased with aging; alternatively, bone removal was lowest when the animal was young and increased with age. Figure 1A highlights how remodeling activity differs at local suture sites; future analysis will quantify remodeling activity at specific suture features – i.e., convex, concave, and straight limb regions.

Images (Optional)

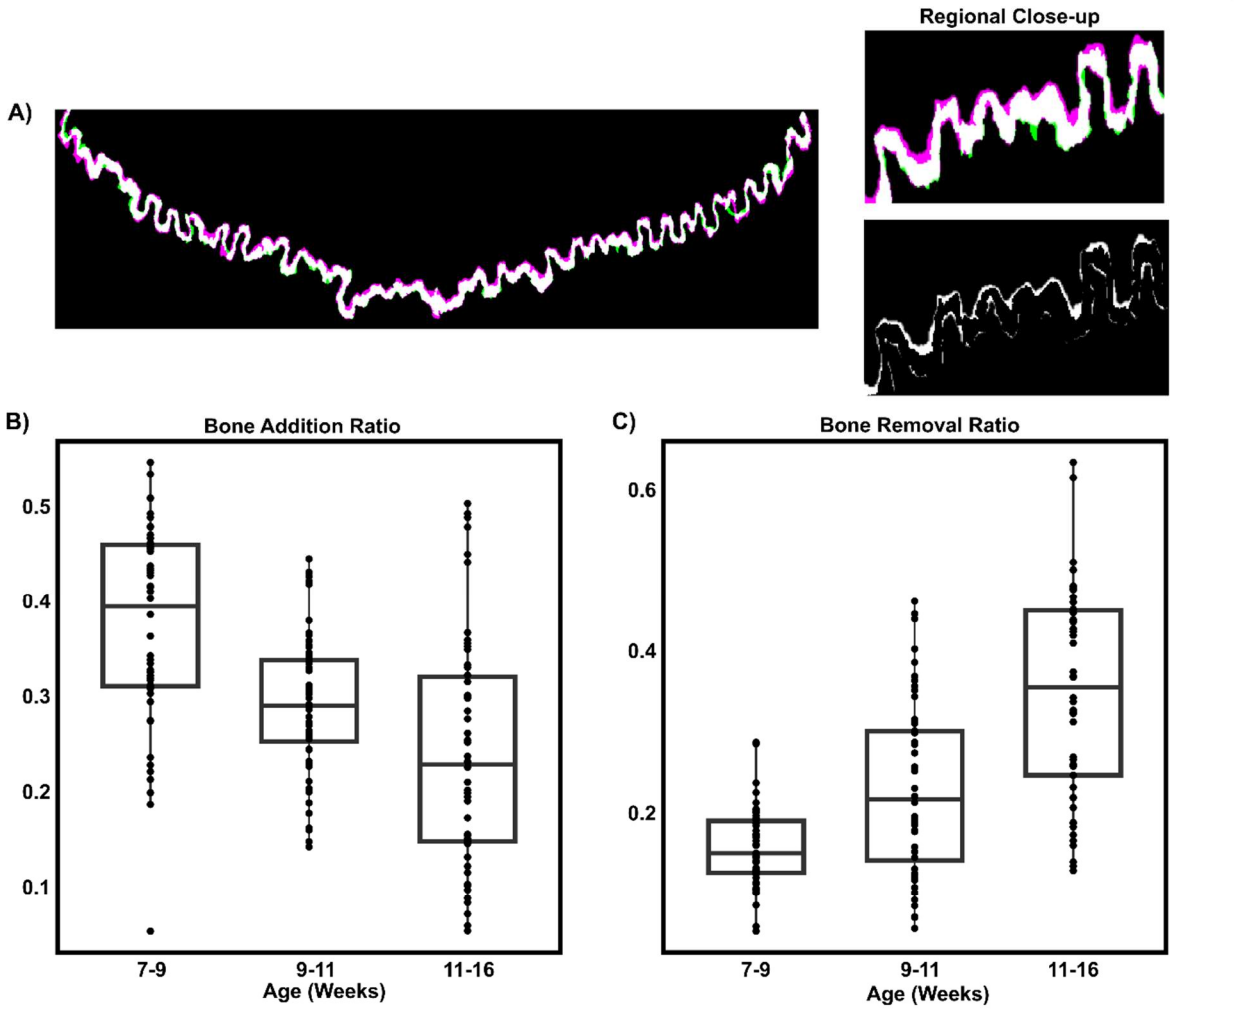

Figure 1: A) Exemplary image of the overlaid sutures. The white represents areas of mutual overlap. The pink is area unique to the older suture and green is area unique to the younger suture. The regional close up shows how changes to the suture are region specific. The black and white image indicates regions where bone addition occured. Box plots and individual data points for bone addition ratio (B) and bone removal (C) ratio vs. animal age.

Combining Raman Spectroscopy and Optical Coherence Tomography to Assess Molar–Incisor Hypomineralization: Diagnostic Support in Dentistry

Ph.D. Nelly Vanessa Padilla Bello[1], M.Sc. Capucine Tavernier[1], Ph.D. Daniel R Neuville[2], Prof. Jean-Marc Allain[3], Prof. Elsa Vennat[4], Prof. Elisabeth Dursun[1], Ph.D. Aurélie Benoit[1]

[1]Université Paris Cité, Montrouge, Ile-de-France, France. [2]Institut de Physique du Globe de Paris (IPGP), Paris, Ile-de-France, France. [3]Ecole Polytechnique, Palaiseau, Ile-de-France, France. [4]CentraleSupélec, Gif-sur-Yvette, Ile-de-France, France

Introduction

Molar-Incisor Hypomineralization (MIH) is a dental condition affecting enamel, characterized by well-defined opacities and alterations in microstructure, chemical composition, mineral density, and mechanical properties [1].

Diagnosis of MIH is typically based on visual examination and its treatment depends on lesion severity and depth, which cannot be assessed using current clinical tools. To address these limitations, we combine two non-invasive techniques: Raman spectroscopy to assess the physico-chemical alterations [2] and optical coherence tomography (OCT) to investigate lesion location [3]. The aim is to identify reliable criteria of distinction from Raman spectra and assess the OCT's ability to delineate MIH-lesions.

Methods

180 Raman spectra were collected in vitro from two cross-sections of MIH-affected teeth and pre-processed to extract band integrals of different chemical bonds (phosphate, carbonate, amide and CH). Specific regions of interest (MIH/healthy enamel, dentin) were mapped by plotting the ratio between a selected band integral and phosphate. Statistical analysis was performed using the Kruskal-Wallis test combined with Mann-Whitney post-hoc tests.

OCT acquisitions, performed on the cross-sections and a whole premolar, were analyzed to evaluate the optical attenuation coefficient (OAC) in different tissues.

Results

Raman spectroscopy revealed more pronounced amide and CH peaks for MIH than for healthy enamel. Amide/phosphate and CH/phosphate ratios were both able to discriminate MIH from healthy enamel ($p<0.001$). CH maps also revealed low variability within MIH lesions despite the tissue heterogeneity.

OCT revealed contrast in tissue architecture, with affected enamel showing stronger surface reflection and higher OAC.

Discussion

Raman spectroscopy suggested an increased protein content and a reduction in mineral density, consistent with the structural difference observed in the MIH lesions. OCT observations agreed with the reported heterogeneity of MIH lesions causing light scattering, and opened perspectives to delineate MIH lesions.

Overall, despite the low number of samples, these findings highlight the potential of integrating OCT and Raman spectroscopy for an objective quantitative, and multi-scale characterization of MIH to enhance diagnosis accuracy in both research and clinical settings.

Images (Optional)

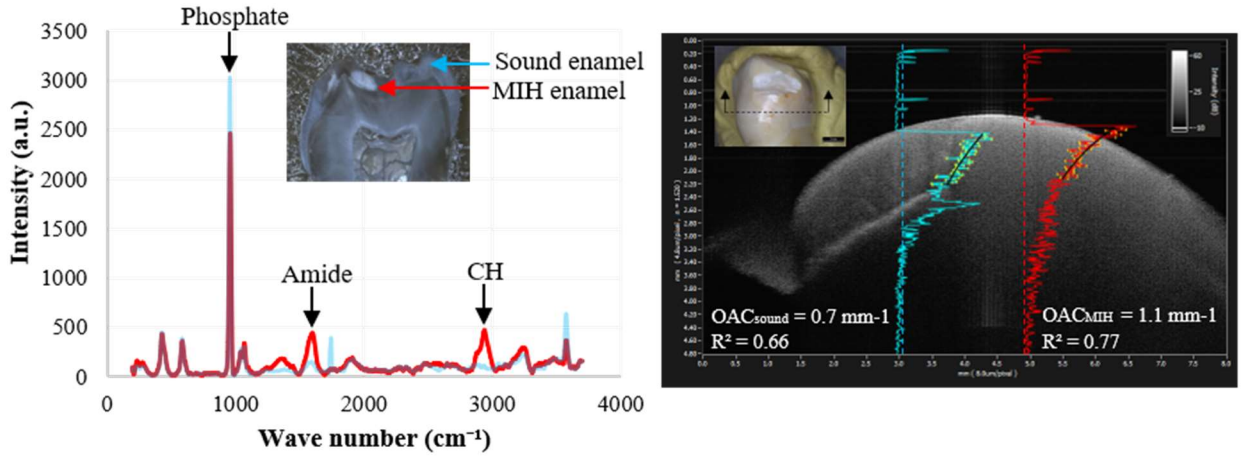

Fig. 1. Average Raman spectra of sound and MIH enamel (left) and OCT image of a premolar tooth showing the gray-level profiles with depth for sound and MIH enamel, and the regions used to calculate the optical attenuation coefficient (right).

Semi-Automated Tracking of Tissue Thickness in Ultrasound B-Mode Images During Dynamic Deformation of the Plantar Soft Tissue

Mr. Nicholas Ozanich B.S., M.S.[1,2], Dr. Scott Telfer EngD[1,2,3], Dr. William Ledoux PhD[2,3]

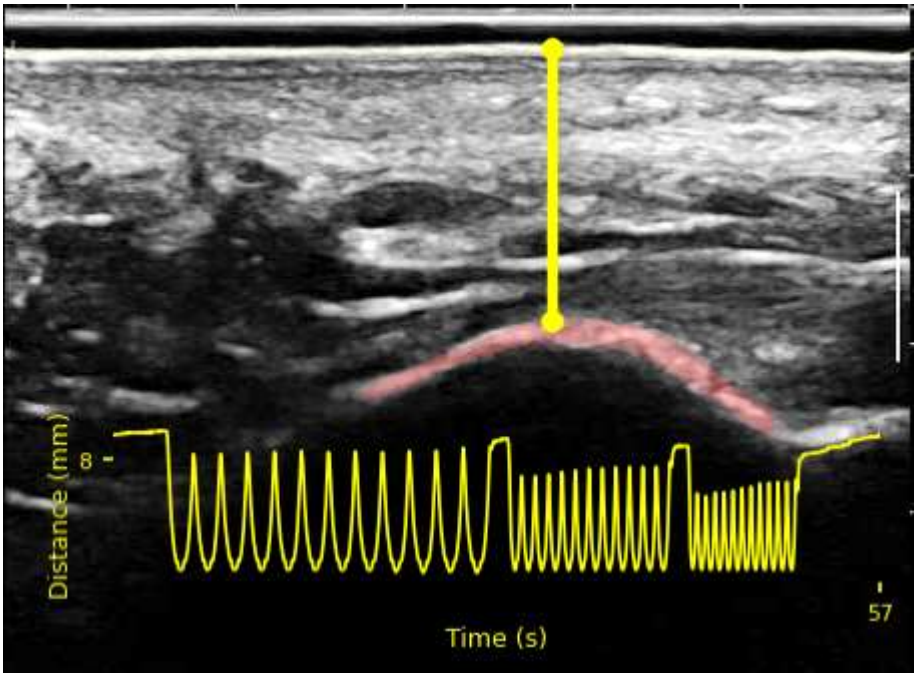
[1]University of Washington Department of Mechanical Engineering, Seattle, WA, United States. [2]Center for Limb Loss and MoBility Research (CLiMB) VA Puget Sound Health Care System, Seattle, WA, United States. [3]University of Washington Department of Orthopaedics & Sports Medicine, Seattle, WA, United States

Introduction

Tissue thickness is a fundamental metric in ultrasound analysis, but manual calculation becomes inefficient and error-prone when applied to large dynamic datasets. Although tissue thickness is straightforward to measure in a single B mode image, manual measurement across continuously deforming sequences is inefficient and susceptible to operator variability. To address this, we developed a semi-automated pipeline that requires only two operator inputs: selection of the skin and a region of interest (ROI) around the bone.

Methods

B-mode ultrasound videos of the plantar surface of a single cadaver foot at the calcaneus were collected during cyclic loading of the tibia using an Instron E3000 at 200 N across three frequencies (0.5, 1.0, 1.5 Hz), with ten cycles per frequency and three trials for various speeds of sound (1540, 1600, 1660 m/s) for a total of nine videos (n=23007 frames). Images were processed by applying a bilateral filter followed by a Gabor filter bank [1] and gamma correction to distinguish bone from soft tissue. For tracking, an ROI was drawn around the bone to initialize a kernelized correlation filter (KCF) [2], which followed the bone throughout deformation. Within the tracked ROI, Otsu's thresholding [3] was applied to each frame to segment the calcaneus, followed by morphological operations to refine the segmentation. Validation was performed through visual confirmation of tracking quality and calculation of internal metrics of tracker performance.



Results

KCF tracking was reliable with strong spatial agreement and minimal temporal variability, with no tracker failures in any video. Across all frames, mean ROI intersection over union was 0.979 ± 0.009, mask area coefficient of variation was 0.047 ± 0.012, and the temporal stability score was 0.996 ± 0.0008.

Discussion

This automated approach produced calcaneus segmentations that enabled calculation of tissue thickness. This work demonstrates an automated method for quantifying musculoskeletal tissue thickness and provides a framework for assessing tissue deformation over time without reliance on training data. Future work should extend this approach to other tissues and incorporate segmentation of skin undergoing deformation.

Ultrasound-Derived Plantar Soft Tissue Deformation Using Lucas-Kanade Tracking

Mr. Nicholas Ozanich B.S., M.S.[1,2], Dr. Scott Telfer EngD[1,2,3], Dr. William Ledoux PhD[2,3]

[1]University of Washington Department of Mechanical Engineering, Seattle, WA, United States. [2]Center for Limb Loss and MoBility Research (CLiMB) VA Puget Sound Health Care System, Seattle, WA, United States. [3]University of Washington Department of Orthopaedics & Sports Medicine, Seattle, WA, United States

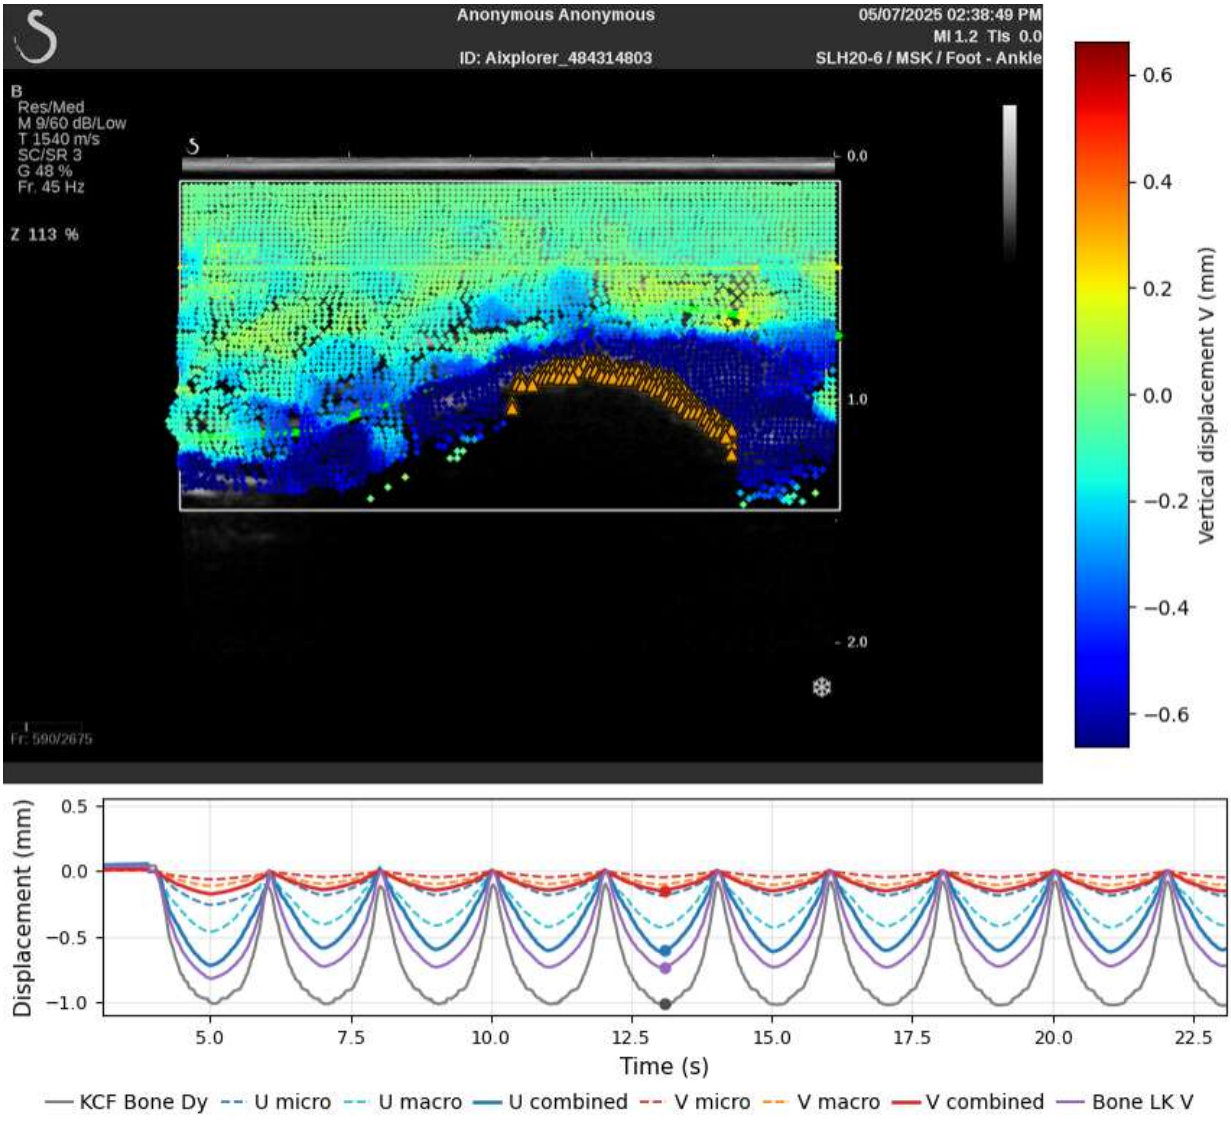
Introduction

This study introduces a grid-based pyramidal Lucas–Kanade (LK) [1] approach to quantify plantar soft-tissue displacement across the heel pad microchambers and macrochambers during cyclic compression. Quantifying full-field motion throughout the tissue area could further elucidate mechanical differences between the macrochambers and microchambers.

Methods

B-mode ultrasound videos of the plantar surface of a single cadaver foot at the calcaneus were collected during cyclic loading of the tibia using an Instron E3000 at 200 N across three frequencies (0.5, 1.0, 1.5 Hz), with ten cycles per frequency and three trials for various speeds of sound (1540, 1600, 1660 m/s) for a total of nine videos (n=23007 frames). The probe was positioned anteroposteriorly. The pyramidal LK optical flow estimates horizontal (U) and vertical (V) heel pad and bone displacements by tracking a grid of points that move with respect to localized features. The points are re-seeded after each period of unloading to prevent accumulation of drift. A horizontal line is used to roughly estimate the division between macrochambers and microchambers. Average peak vertical and horizontal displacements were calculated per-cycle. Point tracking was validated against known displacement of a bone mask and soft tissue motion was restricted to soft tissue above the bone and plantar fascia.

Results



Preliminary results showed that the LK tracking of bone underestimated peak displacement (-0.276 ± 0.069 mm when compared to known peak bone mask displacement (0.831 ± 0.141 mm), alluding to systemic underestimation of displacement (Figure 1). Average horizontal peak displacement (0.205 ± 0.052 mm) was observed to be greater than average vertical peak displacement (0.0624 ± 0.011 mm). Average horizontal peak macrochamber (0.314 ± 0.090 mm) and microchamber (0.160 ± 0.029 mm)

displacements were greater than average vertical peak macrochamber (0.079 ± 0.015 mm) and microchamber (0.045 ± 0.009 mm) displacements.

Discussion

This pipeline provides a framework for quantifying soft tissue vertical and horizontal displacement. Further analyses will seek to improve tracking performance, better discrimination between two chambers, test on larger heel pad deformations seen in gait, and test on other musculoskeletal tissues. A key limitation of this work is out of plane motion from the B-mode images.

Evaluating Sensitivity of MRI-Based Porosity Index to Acute Changes in Cortical Bone Blood Flow Following Exercise

Ms. Patricia Tran, Ms. Katie Sofko, Dr. Feliks Kogan, Dr. Olivia L Bruce

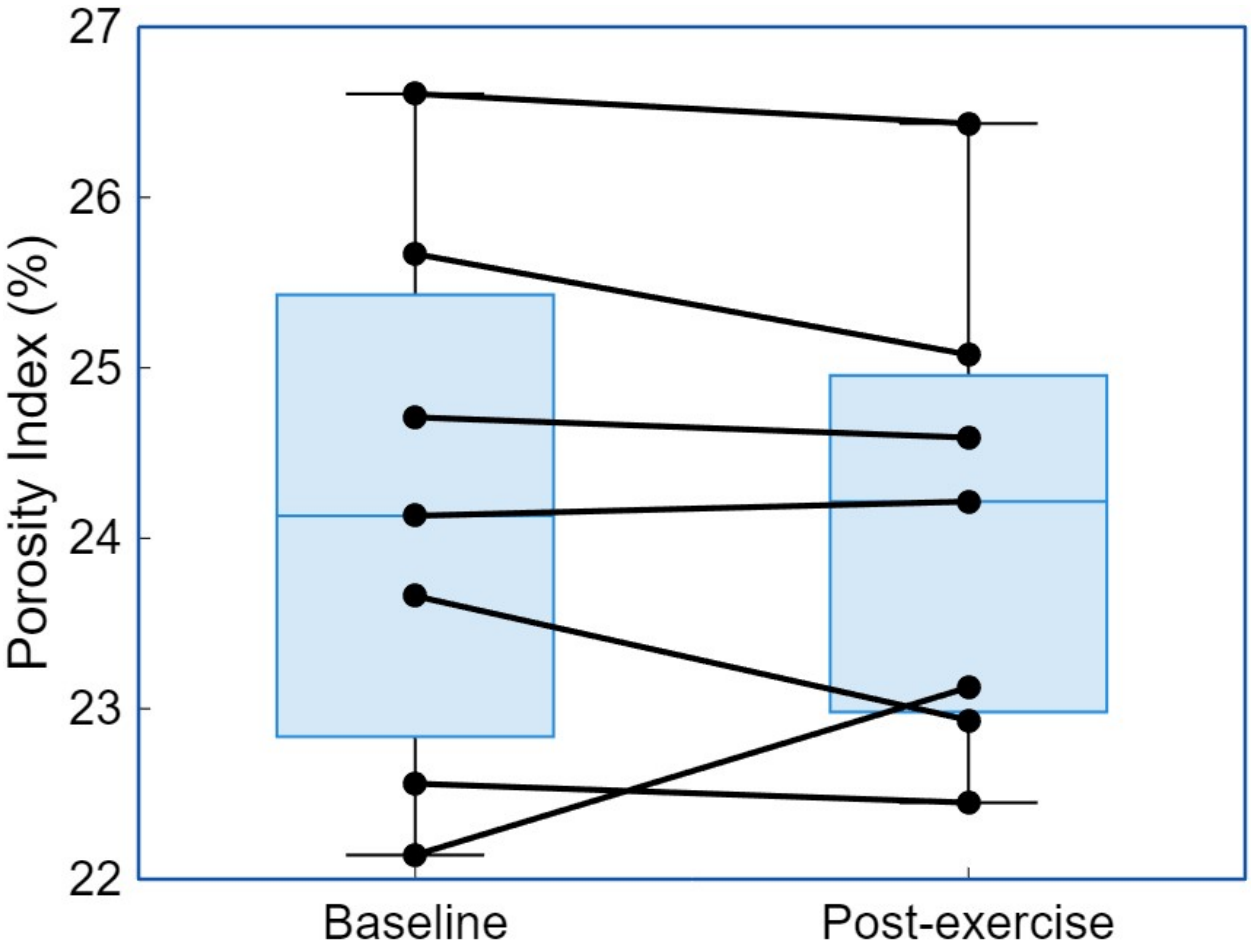
Department of Radiology, Stanford University, Stanford, California, United States

Introduction

Ultrashort echo time (UTE) magnetic resonance imaging (MRI) can detect signal from cortical bone, enabling quantitative assessment not possible with conventional MRI sequences. A UTE-derived biomarker associated with bone strength, porosity index (PI), quantifies the proportion of free water in cortical pores relative to total bone water [1]. Since pore water has a longer T2* relaxation time than water bound to the bone's collagen matrix, PI is calculated by taking the ratio of proton signal acquired at the shortest possible echo time (total water image) and a longer echo time (pore water image) [1]. Changes in blood flow in the bone could alter the long T2* components and, consequently, PI, but this has not yet been investigated. The purpose of this study was to determine whether PI is sensitive to blood flow changes in cortical bone following acute exercise.

Methods

Seven physically active participants (6 female, 1 male, 26 ± 4 years, 1.70 ± 0.03 m, 66.4 ± 10.3 kg) completed a ten minute treadmill run at preferred speed (2.7 ± 0.3 m/s). Dual-echo UTE MRI scans of the lower leg (TE = 0.028 ms and 2.2 ms; hard pulse; 2:23 min per scan) were acquired immediately following exercise and approximately 20 minutes later, which was treated as the at-rest (baseline) value. For each scan, mean cortical PI was calculated across five slices at the mid-tibia. Differences between PI values at the two timepoints were evaluated using a paired-t test.



Results

Mean PI was 24.2 ± 1.60 at baseline and 24.1 ± 1.40 immediately after exercise. PI values immediately post-exercise were not significantly different when compared to baseline (mean difference = 0.1 ± 0.6, $t = 0.543$, $p = 0.607$, Figure 1).

Discussion

PI values were within the range previously reported for tibial cortical bone [1]. Our results show that PI does not change with acute exercise. Since bone blood flow increases in response to exercise [2], this suggests that bone PI measures are not sensitive to changes in bone blood flow.

Evaluating Clinically Relevant Imaging Techniques to Assess Collagen Organisation in Ex Vivo Breast Tissue

Ms. Olivia Strong[1,2], Dr. Brooke Tornifoglio[1,2]

[1]Trinity Centre for Biomedical Engineering, Trinity College Dublin, Dublin, Ireland. [2]Discipline of Mechanical, Manufacturing and Biomedical Engineering, Trinity College Dublin, Dublin, Ireland

Introduction

Ranging from non-dense to highly fibroglandular, breast density is a major risk factor for breast cancer and correlates with increased collagen deposition[1,2]. Elevated collagen content increases cancer risk, while increased alignment links with tumour aggressiveness[3,4]. No current clinical method characterises collagen in breast tissue. MRI offers a non-invasive option and particularly, diffusion tensor imaging (DTI) has shown sensitivity to collagen orientation in other tissues[5,6]. This study aims to evaluate the sensitivity of DTI to collagen alignment within ex vivo breast tissue.

Methods

Fixed cadaveric breast tissue (N=1) was obtained from the Anatomy Department at Trinity College Dublin. Ex vivo DTI was acquired on a 7T Bruker BioSpec using a 3D-spin echo sequence with parameters based off a previous study[6]. Data was pre-processed in MRtrix3 and tensor fitted in ExploreDTI[6].

Standard histological processing was performed: Picrosirius-red (PSR) stained slides were imaged using polarised light microscopy on an Olympus-BX41. Analysis was carried out using OrientationJ in FIJI.

Results

Ex vivo DTI differentiated between the main tissue types in cadaveric breast tissue (1a). First eigenvector maps, overlayed on the MD map (1b), revealed sections of alignment within fibrous tissue. Regions of increased collagen alignment were confirmed via ground-truth PSR (1c) and the corresponding fibre orientation colour map revealed 75% of fibres were orientated along the dominant direction (1d).

Discussion

Measured MD, in this study, was comparable to previous in vivo values of normal breast tissue (0.0014 ± 0.00027 mm^2/s)[7]. Regions of high alignment were identified via the

principal eigenvector and confirmed via histology. Future work will investigate fresh breast tissue of varying densities to better assess DTI as a potential non-invasive method to quantify collagen alignment in breast tissue – potentially informing BC invasiveness.

Images (Optional)

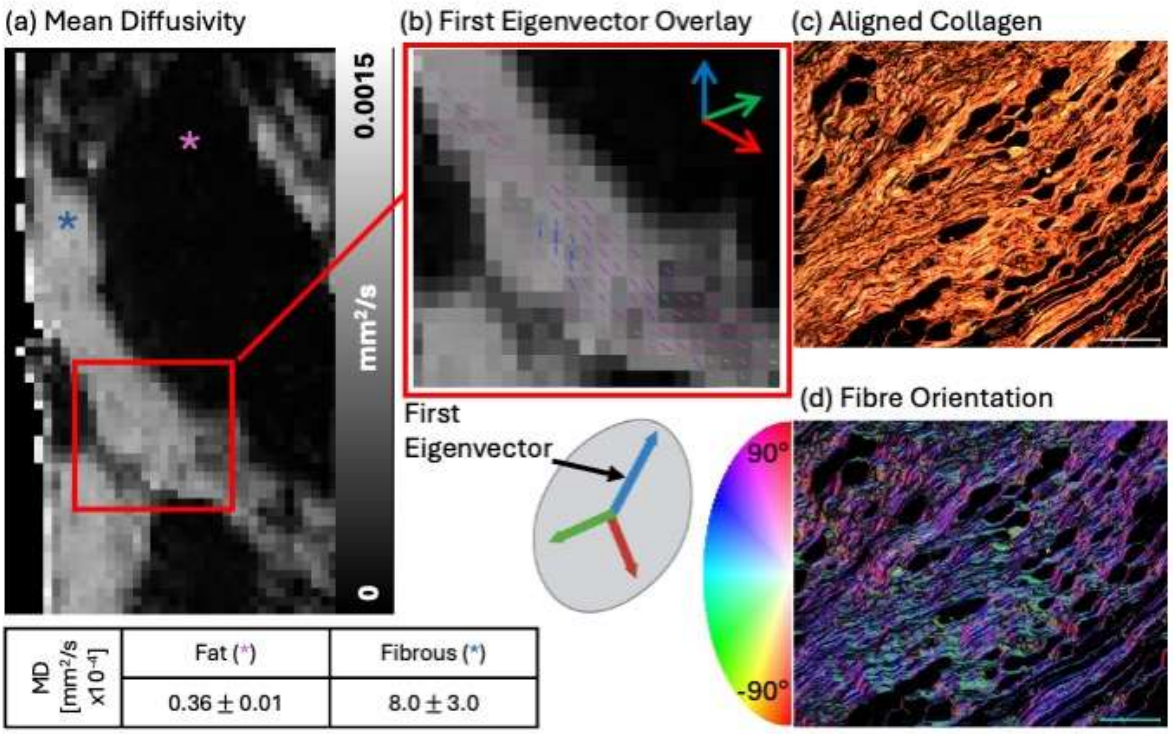

Figure 1: Ex vivo DTI metrics (a,b), PSR staining (c) and corresponding fibre orientation colour map (d) of human cadaveric breast tissue. Scale bar = 200 µm.

Age-Related Differences in Prefrontal Cortex Activation and Stance Time Modulation During Visually Cued Gait

Mr. Paul McDonnell MS, Mr. Adam B. Grimmitt MS, Mr. Jonaz Moreno Jaramillo MS, Dr. Wouter Hoogkamer PhD, Dr. Douglas N. Martini PhD

University of Massachusetts Amherst, Amherst, MA, United States

Introduction

Gait requires visually cued step adjustments, which involve modulating stride phase timing [1]. Older adults (OA) display longer stance times and larger stepping errors than young adults (YA) in visually complex environments [2,3]. OA exhibit more executive control of gait (higher prefrontal cortex [PFC] activity) [4], representing reduced gait automaticity. Reduced automaticity may limit flexible stride phase timing control when visuomotor demands increase. This study compared stance time, stepping error, and PFC activity in YA and OA during visually cued gait without (VC) and with perturbations (VCP). We hypothesized that OA would exhibit longer stance times, larger stepping errors, and higher PFC activity than YA, and that higher PFC activity would relate to longer stance times during VCP.

Methods

28 YA (21.9[3.4]yrs; 15F) and 54 OA (70.9[4.3]yrs; 32F) completed 3-minute treadmill walking trials (VC and VCP) at preferred speed. Stepping targets were presented, matching foot size, step length, and gait speed. During VCP, random targets shifted to a new position when approaching the participant. We quantified stepping error as the distance between foot and target center at midstance. Inertial measurement units computed stance time. Functional near-infrared spectroscopy quantified relative changes in oxygenated hemoglobin concentration in the PFC. Mixed ANOVAs assessed group and condition effects. Pearson's correlation assessed the relationship between PFC activity and stance time.

Results

Only YA reduced stance times from VC to VCP (p=.003). Across conditions, OA exhibited longer stance times (p=.014), larger stepping errors (p<.001), and higher PFC activity

(p<.001) than YA. Across participants, higher PFC activity was associated with longer stance times during VCP (r=0.26, p=.019).

Discussion

Consistent longer stance times and larger stepping errors across conditions in OA indicate age-related difficulty in adjusting gait to meet visuomotor demands. PFC activity was significantly higher in OA across conditions and was positively correlated with stance time during VCP, suggesting an age-related cortical compensatory gait control strategy that limits gait flexibility.

Images (Optional)

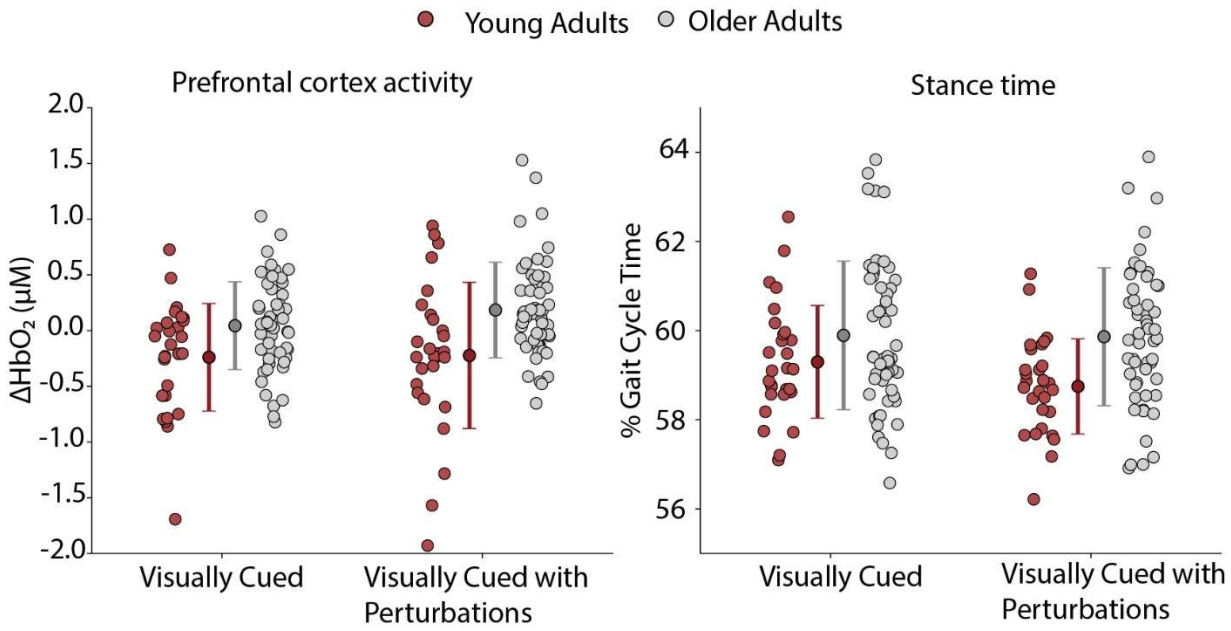

Figure: Age-related differences in PFC activity and stance time during visually cued gait and visually cued gait with perturbations. Left: individual data points represent PFC activity, measured as the relative change in oxygenated hemoglobin (ΔHbO2) concentration from baseline standing. Right: individual data points represent stance time, measured as a percentage of gait cycle time. Points with whiskers represent the mean and standard deviation for each group-condition combination.

Densitometric Correction for Appendicular Soft Tissue Artefacts Measured by Second-Generation HR-pQCT

MSc Simone Poncioni[1], BSc Alexia Pollaci[1], MSc Stefan Bracher[1], Ms Silvia Owusu[2], Prof Dr Dieter Bosshardt[2], Prof Dr Philippe Zysset[1]

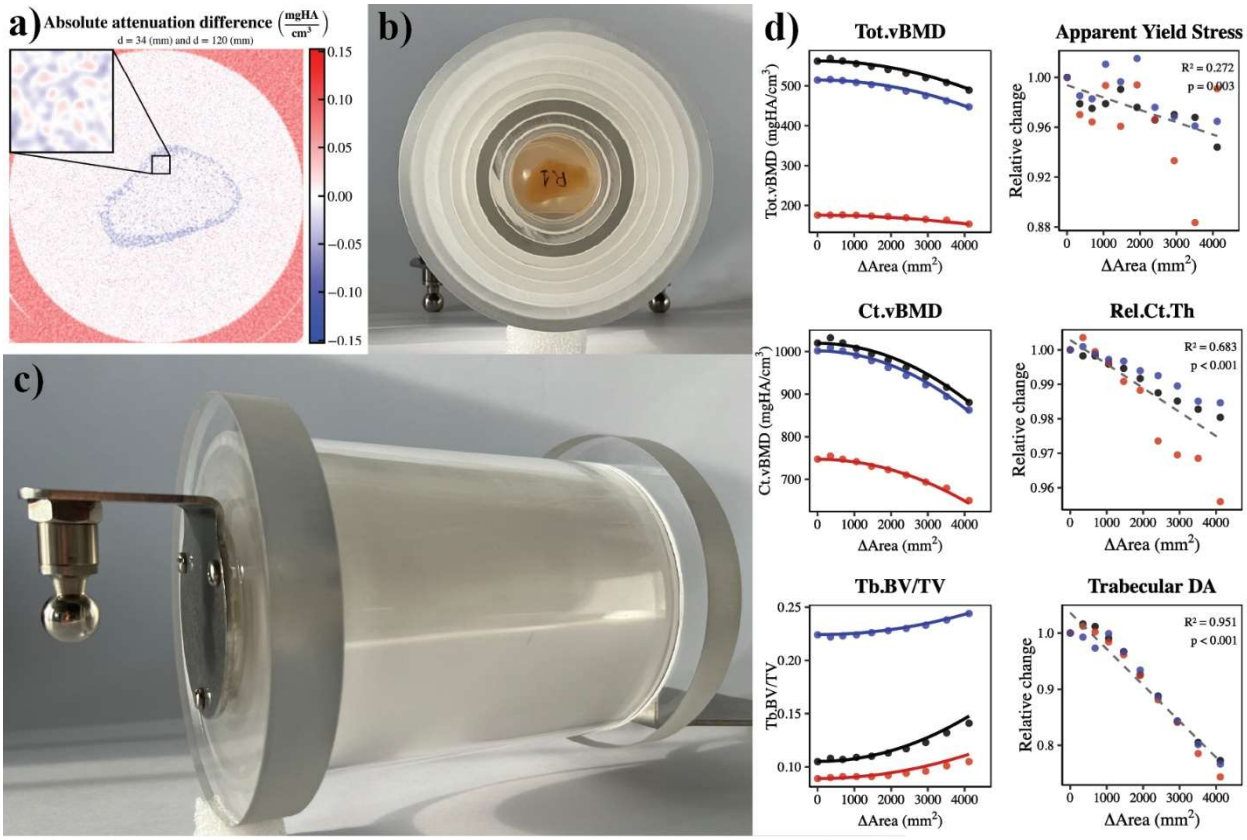
[1]ARTORG Centre for Biomedical Engineering Research, University of Bern, Bern, Bern, Switzerland. [2]Department of Periodontology, School of Dental Medicine, University of Bern, Bern, Bern, Switzerland

Introduction

Longitudinal monitoring of distal radius and tibia using high-resolution peripheral quantitative computed tomography (HR-pQCT) offers several advantages over the clinical standard DXA, including distinct evaluation of cortical and trabecular bone compartments, 3D registration, and shorter trend assessment intervals. However, CT methods suffer from beam hardening artefacts associated with the amount of soft tissues surrounding the bones, which may impair quantitative follow-up if concomitant with weight changes. Therefore, this study aimed to quantify the effects of increasing X-ray attenuation around *ex vivo* human distal radii using second-generation HR-pQCT.

Methods

A human cadaveric phantom of the appendicular skeleton was manufactured using three distal radius sections of 20 mm from distinct donors. Nine soft tissue-equivalent discs of PMMA (Ø=34-120 mm) were sequentially appositioned around the phantom to simulate the variation of soft tissue thickness (b,c). Images were acquired and evaluated using standard clinical settings and multi-stack protocol [1,2]. Densitometric variables, microstructural parameters such as trabecular degree of anisotropy (DA), relative cortical thickness (Rel.Ct.Th), and apparent yield stress were assessed at each thickness. A correction model was developed to relate Tot.vBMD, Ct.vBMD, and Tb.BV/TV attenuated to baseline values as a function of soft tissue area (A_{st}) and intercompartmental bone density ratio.



Results

The model demonstrated strong and significant relationship with A_{st} for Tot.vBMD, Ct.vBMD, and Tb.BV/TV (R^2>0.99, p<0.001). The interaction term Ct.vBMD/Tb.vBMD was significant for Tb.BV/TV (p<0.001) but not for Tot.vBMD and Ct.vBMD. Compartment-specific effects were observed, with underestimation in the cortex and overestimation in the marrow cavity for increased A_{st} (a). Geometric, microstructural, and mechanical properties decreased significantly with increasing A_{st}, strongest in Tb.DA (R^2=0.97) and Rel.Ct.Th (R^2=0.69) (d).

Discussion

These findings confirm that beam hardening artefacts in second-generation HR-pQCT cause increasing errors in bone densitometric variables as soft tissue-equivalent material increases around the bone section [3]. Future work will address generalisation by including three distal tibia sections and correction for segmented A_{st}. This will improve the accuracy of longitudinal monitoring of densitometric and biomechanical variables when substantial weight changes are involved.

[8]Mechanical Systems Engineering, Swiss Federal Laboratories for Materials Science and Technology, Empa, Dübendorf, Zurich, Switzerland

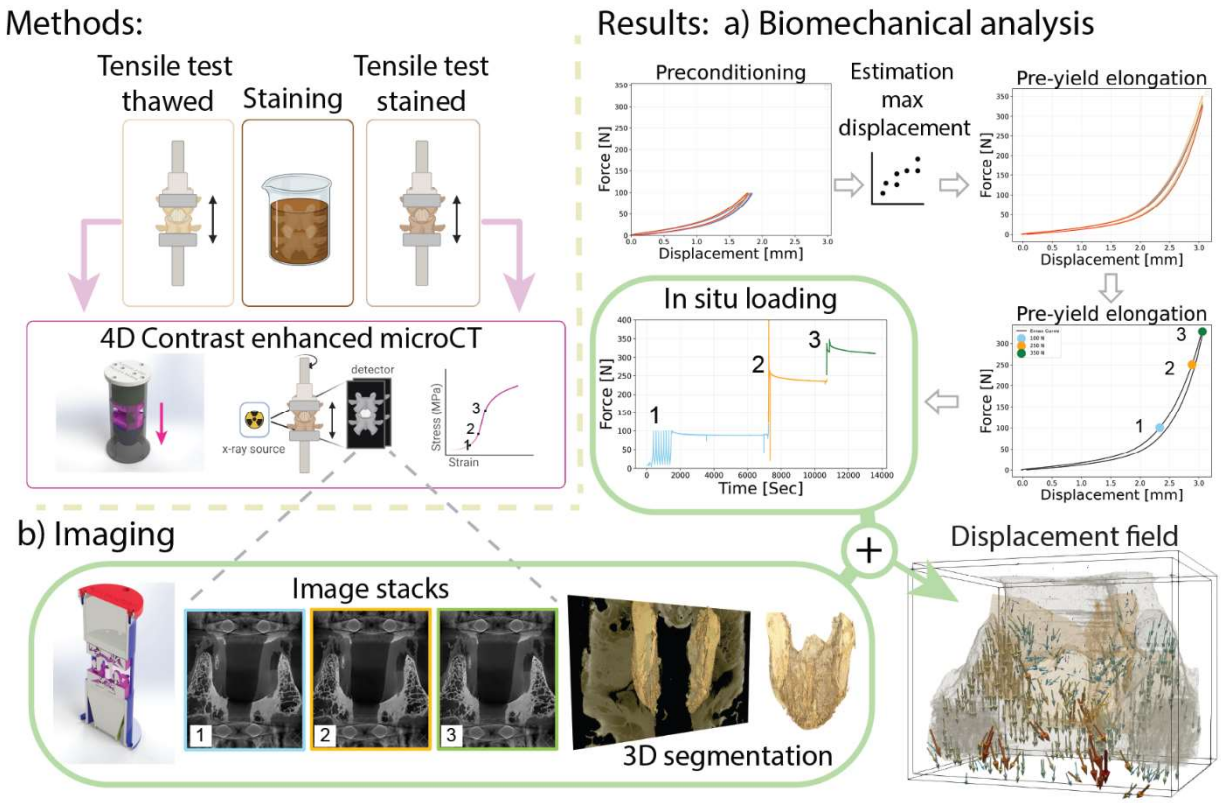
Introduction

Lumbar spinal stenosis (LSS) is the narrowing of the spinal canal compressing the spinal cord and causing low back pain. It is often related to hypertrophy of the ligamentum flavum (LF), whose altered morphology and reduced stiffness further compromise spinal stability. Existing studies are limited to LF biopsies assessed primarily with 2D histology rather than whole-ligament imaging. Control samples often come from patients with other degenerative spinal conditions, so baseline data on healthy LF physiology are lacking. This project fills this gap by developing a method that integrates non-destructive 3D imaging with in-situ loading on intact, healthy LF to relate macro-scale properties to microstructure and mechanical behaviour.

Methods

Human lumbar ligaments are biomechanically tested both fresh and after iodine staining. Tensile tests are performed using a predicted non-destructive maximum elongation, and micro-CT scans are acquired at different loading points within the linear region of the stress-strain curves. Digital volume correlation (DVC) is then used to quantify strain distribution. Staining conditions were defined through comparisons of contrast agents, concentrations, and staining durations, leading to the selection of a 10-day protocol with 3.75% buffered Lugol's iodine.

Results



Ordinary-Least-Squares regression demonstrated a strong linear relationship between displacement at 100 N and pre-yield elongation ($R^2 = 0.836$, $p < 0.0001$). This model was

estimated on 50 ramp-to-failure datasets [1] and successfully predicted non-destructive displacement for 10 preliminary specimens. For contrast enhancement, PTA and Lugol were compared; both PTA and 8% Lugol markedly increased stiffness and were discarded. Lower-concentration Lugol (3.75%) was then tested at varying immersion times, with 10 days proving sufficient. Strain distribution was computed for both label-free and contrast-enhanced samples, capturing native behaviour and fiber spatial organization (Fig:1).

Discussion

Specimen-specific prediction of pre-yielding elongation ensured repeatable non-destructive testing. Stepwise scanning enabled assessment of contrast-enhancement benefits while tracking preparation artefacts (volume shrinkage, increased stiffness). The relationship between macroscopic biomechanical behaviour and local volumetric deformations was revealed combining high-resolution micro-CT and in situ-loading, resulting in local characterization of ligament strain distribution. This multiscale approach generates valuable baseline data on healthy LF physiology and responds to a gap in current knowledge.

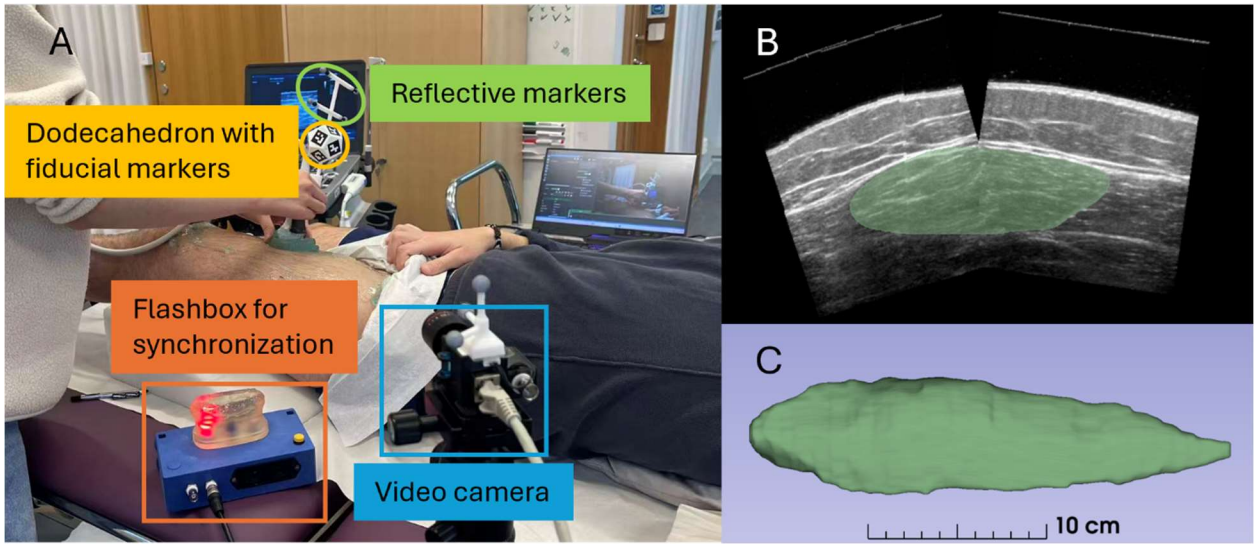
[4]Dept. of Biomedical Engineering and Health Systems, KTH Royal Institute of Technology, Stockholm, Stockholm, Sweden. [5]Division of Paediatric Neurology, Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Stockholm, Sweden

Introduction

Muscle morphological parameters, such as muscle volume (MV), fascicle length (FL) and pennation angle (PA), are key determinants of muscle function. 3D freehand ultrasound (3DfUS) enables their non-invasive quantification by reconstructing 2D ultrasound images into 3D using probe tracking. Infrared stereophotogrammetry offers high accuracy but requires specialized laboratory setups, limiting clinical applicability. Monocular tracking may enhance feasibility, yet its capability for muscle assessment remains unclear. This pilot study evaluated the reliability and validity of a fiducial marker–based monocular 3DfUS system for muscle morphology quantification.

Methods

Ten healthy participants underwent 3DfUS scanning of the rectus femoris using a linear ultrasound probe (5cm, Mindray M9, 19Hz) equipped with a 3D-printed dodecahedron housing twelve ArUco fiducial markers and a cluster of four reflective markers (Fig. 1A). Probe motion was simultaneously captured by a video camera (LUCID PHX-CS016, 60 Hz) and a motion capture system (Vicon V16, 100 Hz) as a reference. Each participant was scanned by two operators during the first session, and one operator repeated the scan in a second session within one week. Fiducial marker detection and pose estimation were performed using OpenCV's ArUco module solving a RANSAC-optimized Perspective-n-Point (PnP) problem. 3D images were reconstructed using a python library for 3DfUS (py3dfreehandus) and manually segmented using 3D slicer (Fig. 1B-C).



Results

Preliminary analysis of two participants showed a minor overestimation of MV compared with the reference (absolute difference = 4.7±4.0 mL, percentage difference = 2.8±2.4%), with slightly lower accuracy for FL (4.7 ± 2.9 mm, 5.6 ± 3.6%) and PA (1.3 ± 0.5°, 11.1 ± 4.3%). Inter-rater discrepancies were 5.0 ± 0.0 mL for MV, 3.5 ± 2.1 mm for FL and 0.0 ± 0.0° for PA, while inter-session discrepancies were 4.0 ± 1.4 mL for MV, 1.5 ± 0.7 mm for FL, and 1.0 ± 0.0° for PA.

Discussion

This pilot study demonstrates that fiducial marker–based 3DfUS can provide reliable and valid measurements of muscle morphology. The system yielded consistent estimates of MV, FL and PA, and showed good agreement with the reference. By substantially reducing hardware complexity and cost while maintaining good repeatability, this approach offers promising potential for clinical settings where accessible muscle morphology assessment is needed.

Standardized, Multi-modal Anisotropic Elastography Phantoms for the Elasticity Imaging Community

Ms Samyuktha Kolluru[1], Mr Kaden Bock[2], Ms Shruthi Srinivasan[2], Dr Kevin Eckstein[3], Dr Ned Rouze[2], Dr Juan Manuel Urueña Vargas[4], Dr Kathyrn R. Nightingale[2], Dr Philip V. Bayly[3]

[3]Department of Mechanical Engineering & Materials Science, Washington University in Saint Louis, St Louis, Missouri, United States. [4]BioPACIFIC-MIP, UC Santa Barbara, Santa Barbara, California, United States

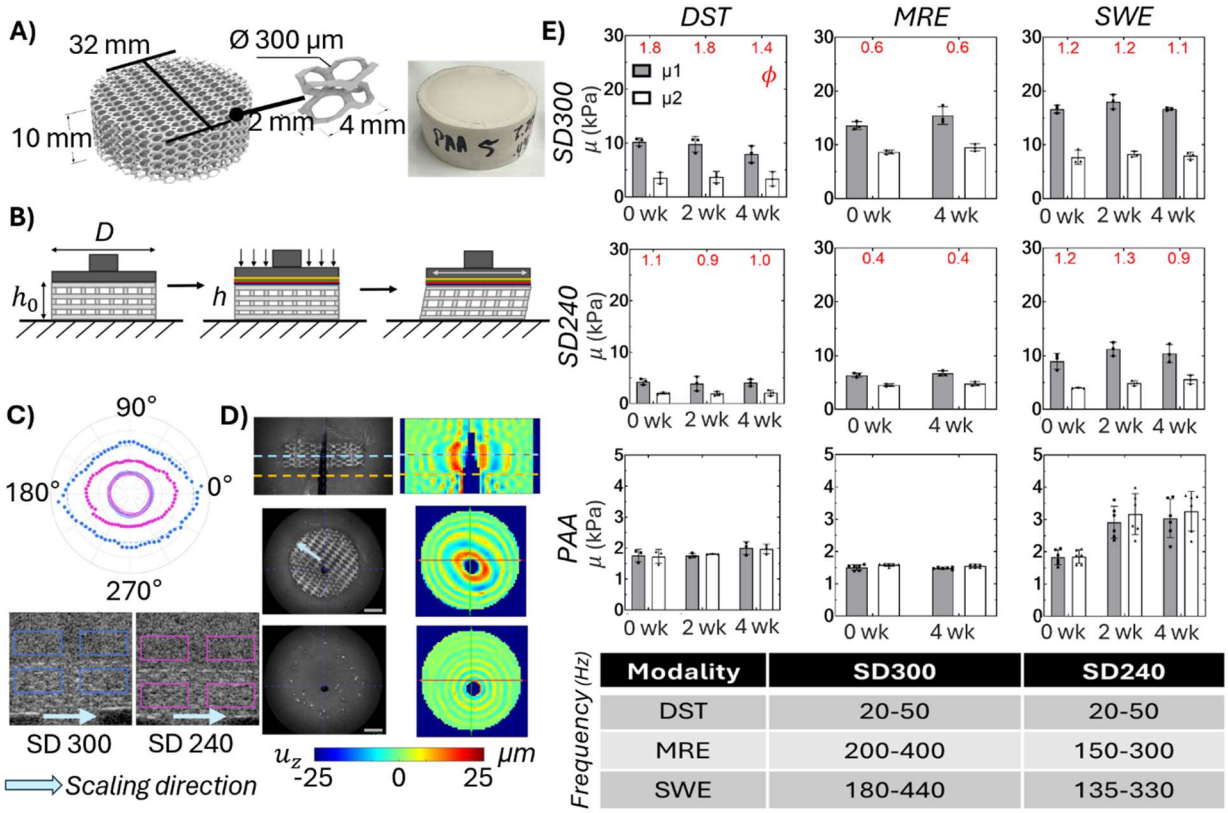
Introduction

Mechanical anisotropy is a promising biomarker for monitoring tissue health. Many tissues have organized fibrous structures that can be disrupted by injury or disease. Elastography can noninvasively characterize anisotropic properties in skeletal muscle, brain white matter, and reproductive tissues but validating elastography requires standardized phantoms that mimic anisotropic tissue behavior. To address this need, we developed a multimodal imaging phantom for both magnetic resonance elastography (MRE) and ultrasonic shear wave elasticity imaging (SWEI) and compared measurements with benchtop dynamic shear testing (DST).

Methods

Lattices were fabricated using PEGDA Start (CellInk) on a Lumen X+ 3D printer (CellInk). Two lattice types were printed: SD300 (300 μm struts, 2×2×4 mm unit cell) and SD240 (240 μm struts, same scaling). Lattices were embedded in polyacrylamide hydrogels to create composite anisotropic phantoms (Fig.1A). In DST (Fig.1B), shear moduli parallel (and perpendicular (to the lattice scaling direction were measured from shear force vs displacement ratios. In SWEI, shear moduli were estimated from shear wave speeds (Fig.1C), $\mu=\rho v_s^2$, parallel and perpendicular to the scaling direction using a Verasonics NXT scanner and GE9L-D transducer [1]. MRE experiments were performed on a Bruker 9.4T MRI, and anisotropic properties (baseline shear modulus, μ_2, shear anisotropy, $\phi=(\mu_1/\mu_2)-1$, and tensile anisotropy, $\zeta=(E_1/E_2)-1$) were estimated from displacement fields (Fig.1D) using TI-NLI inversion [2].

Results



Shear stiffness measurements from DST, SWE, and MRE agreed within 20% in both directions, while shear anisotropy values were approximately 60% lower in MRE (Fig.1E).

Across modalities, SD300 had higher shear moduli and shear anisotropy than SD240, highlighting the tunability of these anisotropic phantoms. Phantoms are reproducible (n=3) and stable for four weeks (within 15% variability).

Discussion

We developed stable, tunable, multimodal phantoms to validate elastography measurements of anisotropic mechanical behavior of soft tissues. This study extends previous work [3] by comparing modalities over time, finding consistent estimates between modalities. SWEI appears more sensitive to shear anisotropy in this material than MRE; MRE with TI-NLI also accounts for tensile anisotropy.

Time-Lapsed Micro-CT Imaging of Calcium Phosphate Scaffolds in a Mouse Model of Heterotopic Ossification

MSc Sara Lindenmann[1], MSc Nico V. Giger[2,1], MSc Farida Elharouni[3,1], Dr. Francisco Correia Marques[1], Dr. med. vet. James Tapia-Dean[2], Dr. Dr. med. vet. Stephan Zeiter[2], Dr. Neashan Mathavan[1], Dr. Gisela A. Kuhn[1], Dr. Yassine Maazouz[3], Dr. Dr. Marc Bohner[3], Dr. Esther Wehrle[2], Prof. Dr. Ralph Müller[1]

[1]Institute for Biomechanics, ETH Zürich, Zürich, Zürich, Switzerland. [2]AO Research Institute Davos, Davos Platz, Graubünden, Switzerland. [3]RMS Foundation, Bettlach, Solothurn, Switzerland

Introduction

Heterotopic ossification (HO) is a critical prerequisite for bone graft substitutes (BGS) intended to repair large bone defects. A BGS's ability to induce HO can be assessed experimentally by implanting it into soft tissue and monitoring bone formation. Granular BGS have been shown to expand in overall volume occupied by the material in the presence of HO [1]. This study aims to use time-lapsed *in vivo* micro-computed tomography (micro-CT) to assess if material-induced HO (MIHO) can be predicted with material volume and implant thickness.

Methods

15±1 mg CaP granules mixed with NaCl solution (1.36 µl/mg) were injected intermuscularly of the right quadriceps in 10-14-week-old male C57BL/6J and FVB mice (n=3/group, license: GR/27/2023). Bi-weekly time-lapsed *in vivo* micro-CT was performed over 8 weeks [2]. The full implant formed by the granules was masked using dilation and erosion of the segmented granules (threshold=350 mgHA/cm^3), registered and cropped to define a consistent field of view (FOV) (Fig. 1A). The material volume and the implant thickness within the FOV were calculated for all weeks. Endpoint H&E stained histology sections (n=32-36/animal) were evaluated for HO. Micro-CT results were analyzed using linear mixed-effects models with week and group as fixed factors and mouse ID as a random effect to account for repeated measures.

Results

96±6% of histological sections in FVB showed HO, whereas no section did in C57BL/6J. There was significantly higher material volume at week 8 (C57BL76J: 4.79±1.42, FVB: 5.65±2.65 mm^3) compared to week 0 (C57BL76J: 3.52±0.99, FVB: 4.71±0.83 mm^3, p = 0.038) within the FOV (Fig. 1B). Implant thickness showed no significant differences over

time (Fig. 1C). There were no significant effects of group or week x group interactions for either parameter.

Discussion

In vivo micro-CT allows successful time-lapsed monitoring of a partial volume of the injected granules. Even though MIHO was successfully shown in FVB, neither the material volume or implant thickness as parameters were sensitive enough to pick up on the strain dependent differences.

Images (Optional)

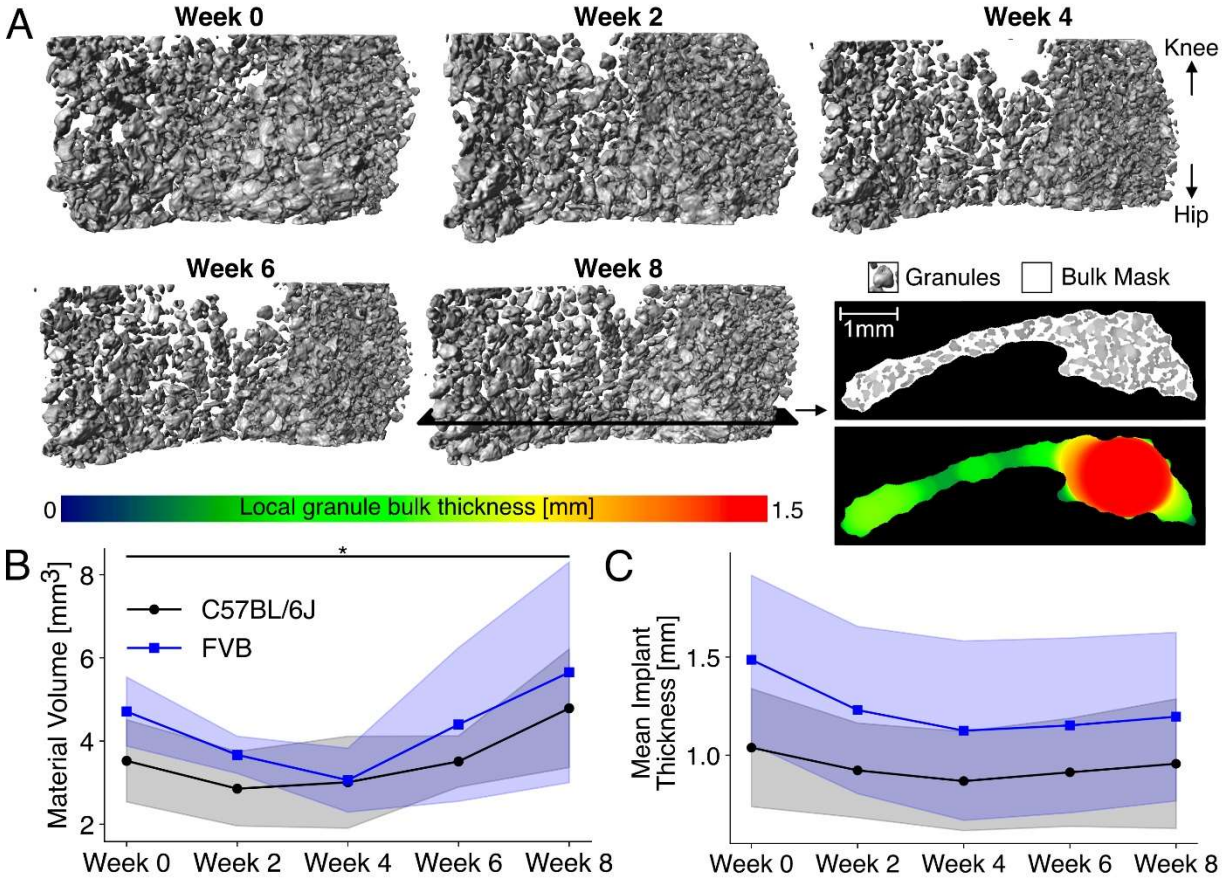

Figure 1: (A) Representative 3D visualizations of the intramuscularly implanted granules in the *in vivo* micro-CT FOV for one FVB mouse over 8 weeks. A sample 2D section at week 8 shows the granules and fitted granule bulk mask (top) and local thickness evaluation (bottom). (B) Material volume in the FOV in C57BL/6J and FVB mice presented as group mean±SD across mice. (C) Mean granule bulk thickness in the FOV in C57BL/6J and FVB presented as group mean±SD across mice. All significant differences are indicated with (*) $p<0.05$.

Reliability of 3D Scanned Breast Volume Measurements Within and Between Raters

Ms Sophia Wisotzki Bsc, Ms Ine Mylle Phd, Ms Jessica Yeoman Bsc, Mr. Christopher Napier Professor

SFU Run Lab, Department of Biomedical Physiology and Kinesiology, Simon Fraser University, Vancouver, BC, Canada

Introduction

Inadequate breast support is associated with pain and reduced physical activity participation, yet 85% of women wear an incorrect bra size [1, 2]. Accurate breast volume data are essential for designing proper-fitting bras; traditional sizing methods are limited. Three-dimensional (3D) surface scanning offers a non-invasive and reproducible alternative [1]. This study evaluated the intra- and inter-rater reliability of breast volume measurements from 3D scans to determine whether this method is reliable and usable in practice.

Methods

Healthy female participants (24.5 ± 5.7 years) underwent prone [2] 3D surface scanning (Artec Leo, Artec, Luxembourg) after breast boundaries were defined with a marker. Breast meshes were created by tracing the boundary, separating the breast from the torso, and filling the posterior chest wall in Artec Studio [1]. Volumes were calculated in cubic centimeters (cc). Two trained raters analyzed the scans of both breasts from participants to obtain volumes. Reliability was quantified using intraclass correlation coefficients (ICC; poor: <0.50, moderate: 0.50-0.75, good: 0.76-0.90, and excellent: >0.90 [3]). Precision was assessed using the standard error of measurement (SEM) and minimal detectable change (MDC; <5% considered excellent).

Results

Intra-rater (n = 35 participants/70 scans) and inter-rater (n = subset of 19 participants/38 scans) reliability analyses were performed . Intra-rater volumes ranged from 130-796 cc (left) and 108-808 cc (right). Inter-rater volumes ranged from 130-593 cc (left) and 108-596 cc (right). 3D scanning demonstrated excellent intra-rater (ICC = 0.996-0.999) and inter-rater reliability (ICC = 0.985-0.988), both with low SEM and MDC values. Mean ± SD volume, SEM, and MDC values are reported in Table 1.

Discussion

3D surface scanning demonstrated excellent reliability and high precision for breast volume measurements. Accurate breast volume data could improve bra sizing and support, addressing the high prevalence of poor bra fit and associated discomfort . Future research should evaluate the validity of 3D breast volume measurements against current sizing techniques (e.g., underband and overbust) and explore how consistent volume estimates can inform bra design, breast support, and biomechanical analyses.

Images (Optional)

Table 1. Breast volumes and reliability outcomes (Mean, ICC, SEM, MDC) for left and right breast volumes.

	Intra-rater (n = 35)			Inter-rater (n = 19)		
	Mean ± SD [cc]	SEM [cc]	MDC [cc]	Mean ± SD [cc]	SEM [cc]	MDC [cc]
Left Breast	353 ± 141	13	26	327 ± 130	10	20
Right Breast	347 ± 144	4	8	322 ± 126	7	14

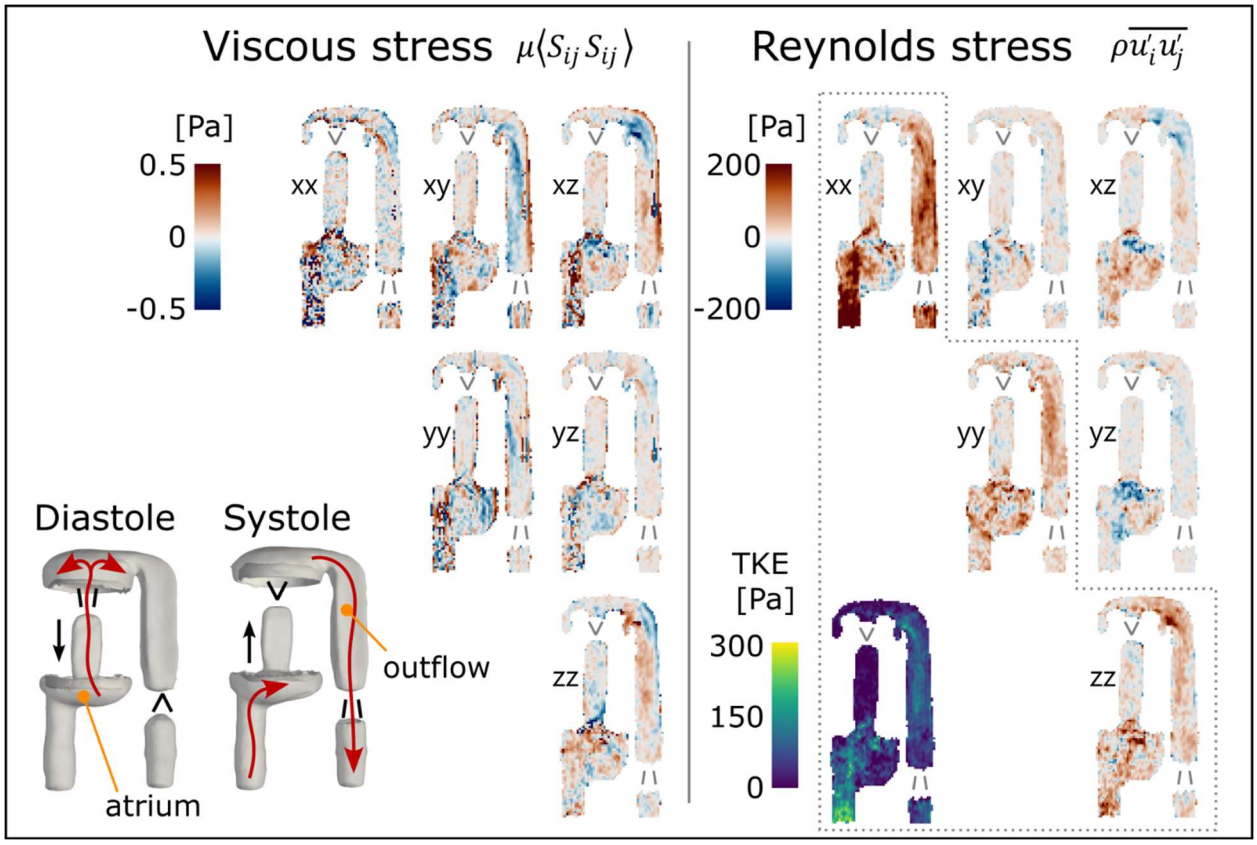
[2]Center for Medical Image Science and Visualization (CMIV), Linköping University, Linköping, Östergötland, Sweden. [3]Scandinavian Real Heart AB, Västerås, Västmanland, Sweden. [4]Science for Life Laboratory, Linköping University, Linköping, Östergötland, Sweden

Introduction

Blood constituents are believed to be relatively resistive to viscous shear stresses and turbulent normal stresses but are believed to be sensitive to the rapid fluctuations in turbulent shear stresses, potentially resulting in hemolysis and thrombosis. Measurement of turbulent shear is therefore important in the development of a total artificial heart (TAH) but has shown to be challenging. In this study, we aim to assess viscous stresses, and turbulent normal and shear stresses in a TAH using 4D flow MRI.

Methods

The Realheart pulsatile TAH was made MR-compatible and scanned with an MRI-sequence from which velocities and turbulence over time were obtained. A conventional asymmetric 4-point scheme was extended to an ICOSA6 sequence with 3 additional encoding directions. This allowed the computation of the Reynolds stress tensor, partially describing the turbulent production by velocity fluctuations. The normal stresses on the diagonal of the Reynolds stress tensor were used to derive turbulent kinetic energy (TKE), while to off-diagonal characterized the turbulent shear stresses. Viscous stresses were computed from the velocity gradients.



Results

TThe extra encodings resulted in a longer scan time (5min versus 9min) but with ICOSA6, we were able to determine the Reynolds stress tensor. TKE integrated across volumetric regions, yielded similar values as observed in the conventional 4-point method. Reynolds stresses showed more than an order of magnitude higher values than viscous stresses. In addition, the off-diagonal components revealed a non-negligible contribution to the Reynolds stress acting on the fluid in the atrium and outflow.

Discussion

We show that ICOSA6 can be used to study Reynolds stresses in a complex geometry like the TAH. ICOSA6 provided deeper insight into the turbulent stresses, specifically shear, by allowing direct computation of these components. The order of magnitude difference between turbulent and viscous stress denotes the importance of turbulence. Signal voids near the metal valves showed limitations of the 4D flow MRI technique. Noise can be reduced by extending the measurement time. ICOSA6 4D flow MRI can be a valuable tool to assess turbulent normal and shear stresses in a TAH and increase our understanding of the importance of turbulent shear stresses for blood damage.

The Lacunocanalicular Network in Subchondral Bone and the Connection Paths Between Mineralized Cartilage and Bone

Ms. Valentine Gaillard[1], Mr. Albano Malerba[1], Dr. Alexandra Tits[2], Dr. Stéphane Blouin[3], Mr. Gaëtan Lefèvre[1], Dr. Richard Weinkamer[2], Priv. Doz. Dr. Markus A. Hartmann[3], Prof. Davide Ruffoni[1]

[1]University of Liège, Liège, Wallonia, Belgium. [2]Max Planck Institute of Colloids and Interfaces, Potsdam, Brandenburg, Germany. [3]Ludwig Boltzmann Institute of Osteology, Vienna, Vienna, Austria

Introduction

The osteochondral junction transmits dynamic loads from cartilage to bone and contains mineralized cartilage, which anchors articular cartilage to the underlying subchondral bone. Both mineralized cartilage and subchondral bone maintain cells inside a mineralized extracellular matrix (ECM) where diffusion is strongly limited. In bone, osteocytes form the lacunocanalicular network (LCN), a key player in transporting matter and in regulating bone remodeling and mineralization. In mineralized cartilage, chondrocytes tend to form clusters to overcome diffusion limits. The osteochondral junction is clinically relevant, showing alterations with aging and osteoarthritis, including subchondral bone thickening and mineralization-front advancement at the tidemark. Changes in subchondral bone are driven by bone remodeling, which depends on LCN architecture. However, little is known about the organization of the LCN in subchondral bone: is it different from that of cortical bone located away from the joint? Is the LCN contributing to the possible connecting pathways between subchondral bone and mineralized cartilage? To address these gaps, we characterized the LCN in subchondral bone, comparing it with cortical bone and examining connecting pathways across the bone-cartilage interface.

Methods

We analyzed five tibiae from 10-week-old male C57Bl/6J mice, stained with rhodamine and imaged using confocal laser scanning microscopy (Stellaris 8, Leica, pixel size 0.18 µm). Network analysis was performed with the open-source software TINA [1].

Results

We found several chondrocyte lacunae reached by rhodamine, despite being surrounded by a mineralized ECM and we uncovered multiple connection patterns between chondrocyte lacunae and the underlying subchondral bone (Fig. 1f-h). The LCN in subchondral bone was disorganized, with only locally organized regions around bone

marrow and channels (Fig. 1b). Conversely, cortical bone featured larger ordered and disordered regions lying side by side (Fig. 1d). Network quantification confirmed a sparser, less connected network in subchondral bone (canalicular density Can.Dn = 0.144 ± 0.017 µm/µm^3, Fig. 1c) than in cortical bone (Can.Dn = 0.187 ± 0.022 µm/µm^3, Fig. 1e ; $p < 0.05$).

Discussion

These data provide baseline LCN metrics and highlight possible bone-cartilage connections for a widely used mouse model in pre-clinical research, enabling future comparisons of healthy, aged, and diseased states.

Diffusion MRI to Predict Hip Muscle Strength After FAI Surgery

Mr William MacDonald[1], Ms Hannah Traynor[1], Dr Ryan Degen[1,2], Dr David Wang[2], Dr Corey Baron[1], Dr Geoffrey Ng[1]

[1]Western University, London, ON, Canada. [2]London Health Sciences Centre, London, ON, Canada

Introduction

Cam femoroacetabular impingement (FAI) is a leading cause of hip pain and early osteoarthritis. While hip arthroscopy aims to restore impingement-free range of motion and function, patients may still exhibit altered muscle function, illustrating the need to further investigate hip musculature. This study uses diffusion magnetic resonance imaging, which captures how water courses through muscle, and maximal isometric voluntary contractions (MVICs) to compare the muscle microarchitecture and force output in FAI patients pre- and one-year post-operative, as well as to controls.

Methods

11 FAI patients (n=11, m:f=5:6, age=28±9 years, BMI=24±4 kg/m^2) and 11 healthy controls (n=11, m:f=5:6, age=26±9 years, BMI=23±4 kg/m^2) were included. Participants underwent 3T MRI of the lower spine and hips, including bilateral T2-weighted 3D dual-echo steady-state and diffusion-weighted sequences. Patients underwent imaging prior to and one year after surgery, with controls undergoing a single imaging session. Fifteen muscles were analyzed including the flexors, abductors, extensors, and rotators. Muscles were manually segmented (Figure 1), and apparent diffusion coefficient (ADC; lower=more restricted diffusion; higher=less restricted diffusion) and fractional anisotropy (FA; lower=less directional diffusion; higher=more directional diffusion) values were extracted. MVIC was collected via handheld dynamometer. Paired-sample (FAI_{PRE} vs FAI_{POST}) and independent-sample t-tests (FAI vs controls) compared the differences in ADC and FA, and multiple linear regressions assessed the relationship between MVIC and diffusion values.

Results

TFL ADC increased post-operatively (FAI_{PRE}=1.38x10^{-3}mm/s^2, FAI_{POST}=1.50x10^{-3}mm/s^2, p=0.004). Psoas major (R^2=45%, p=0.015) and rectus femoris (R^2=14%, p=0.13) FA predicted hip flexion strength pre-operatively, whereas iliocapsularis FA (R^2=55%, p=0.006) predicted hip flexion strength post-operatively.

Discussion

The principal findings were that FAI patients demonstrated reduced TFL microarchitectural organization one year following surgery. Persistent deficits in hip flexion, abduction, and combined flexion-abduction strength have been documented in FAI patients after surgical intervention. The reduced TFL microarchitectural organization could represent a compensatory adaptation involving suboptimal muscle activation. Interestingly, iliocapsularis proved to be crucial for post-operative hip stability during flexion. Characterizing microarchitectural adaptations of periarticular hip muscles enhances the understanding of the pathomechanical consequences of cam FAI. The post-operative changes in TFL and iliocapsularis can inform targeted rehabilitation strategies.

Preservation of Body Curvature Features in Visual Hull Reconstruction and Their Relevance to Markerless Motion Capture

Prof. Yoshimori Kiriyama Ph.D, Mr. Siyuan Hon B.S., Prof. Katsumasa Tanaka Ph.D

Kogakuin University, Shinjuku, Tokyo, Japan

Introduction

Video-based markerless motion capture is increasingly used in clinical evaluations. Although current systems can reliably capture large primary motions such as knee flexion and extension, their accuracy remains insufficient for detecting small secondary motions, including axial knee rotation. To address this limitation, we evaluated the curvature distribution of the body surface to examine the feasibility of estimating small axial knee rotations from reconstructed visual hulls.

Methods

Mean shape data of Japanese adults [1] were used as the true shape, and visual hulls were constructed from the mean model. A visual hull is composed of tangent curved surfaces defined by silhouette contours and forms a concave volume. Because curvature along the silhouettes is preserved, we examined how the curvature distribution of the shank shape depends on camera parameters, including the number and position. Curvature was assessed along both the circumferential direction of the shank and its longitudinal axis. The number of cameras ranged from three to twelve, arranged at regular intervals without any cameras directly facing one another. Camera positions were rotated around the model in 10-degree increments, and the visual hull and curvature distribution were recalculated for each configuration.

Results

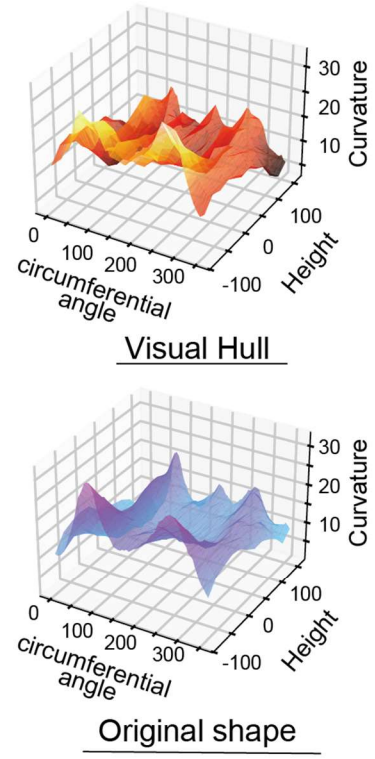

Figure 1(a) shows typical curvature distributions for the original shape and visual hulls constructed with nine cameras; the visual hull retained the characteristic curvature features of the shank. Figure 1(b) demonstrates that curvature correlation with the true shape increased as the number of cameras increased and converged near nine, with decreasing variance.

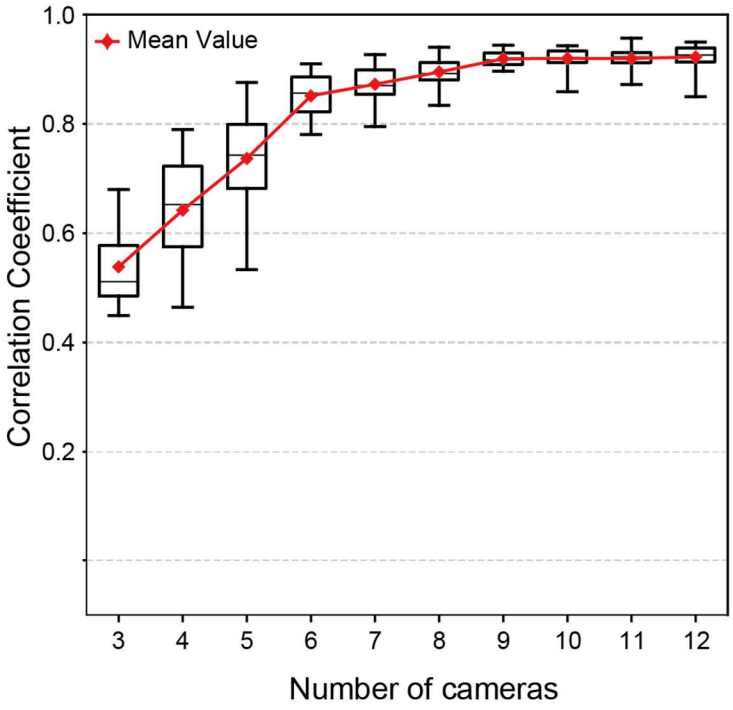
Discussion



Although a visual hull inherently contains shape errors between tangent surfaces, the curvature distribution achieved a correlation coefficient of 0.9 with the true shape, indicating substantial preservation of curvature characteristics. This study demonstrated

that nine cameras are sufficient to reconstruct shank curvature from a visual hull. Consequently, visual–hull–based markerless motion capture enables tracking of anatomical landmarks and surface deformation, allowing estimation of small shank movements while reducing skin–motion artifacts. This approach therefore provides a practical method for detailed motion analysis not inferior to marker-based systems.

Quantitative Ultrasound Characterization of Age-Related Skeletal Muscle Changes Using Multiscale Fuzzy Entropy

Mr. Yunlin Tsai MS[1], Dr. Dang Phu Ha Nguyen MD[2], Dr. Chih-Hsiu Cheng PhD[1]

[1]School of Physical Therapy and Graduate Institute of Rehabilitation Science, College of Medicine, Chang Gung University, Taoyuan City, None, Taiwan. [2]Department of Orthopedic, Nhan dan Gia Dinh Hospital, Ho Chi Minh City, None, Vietnam

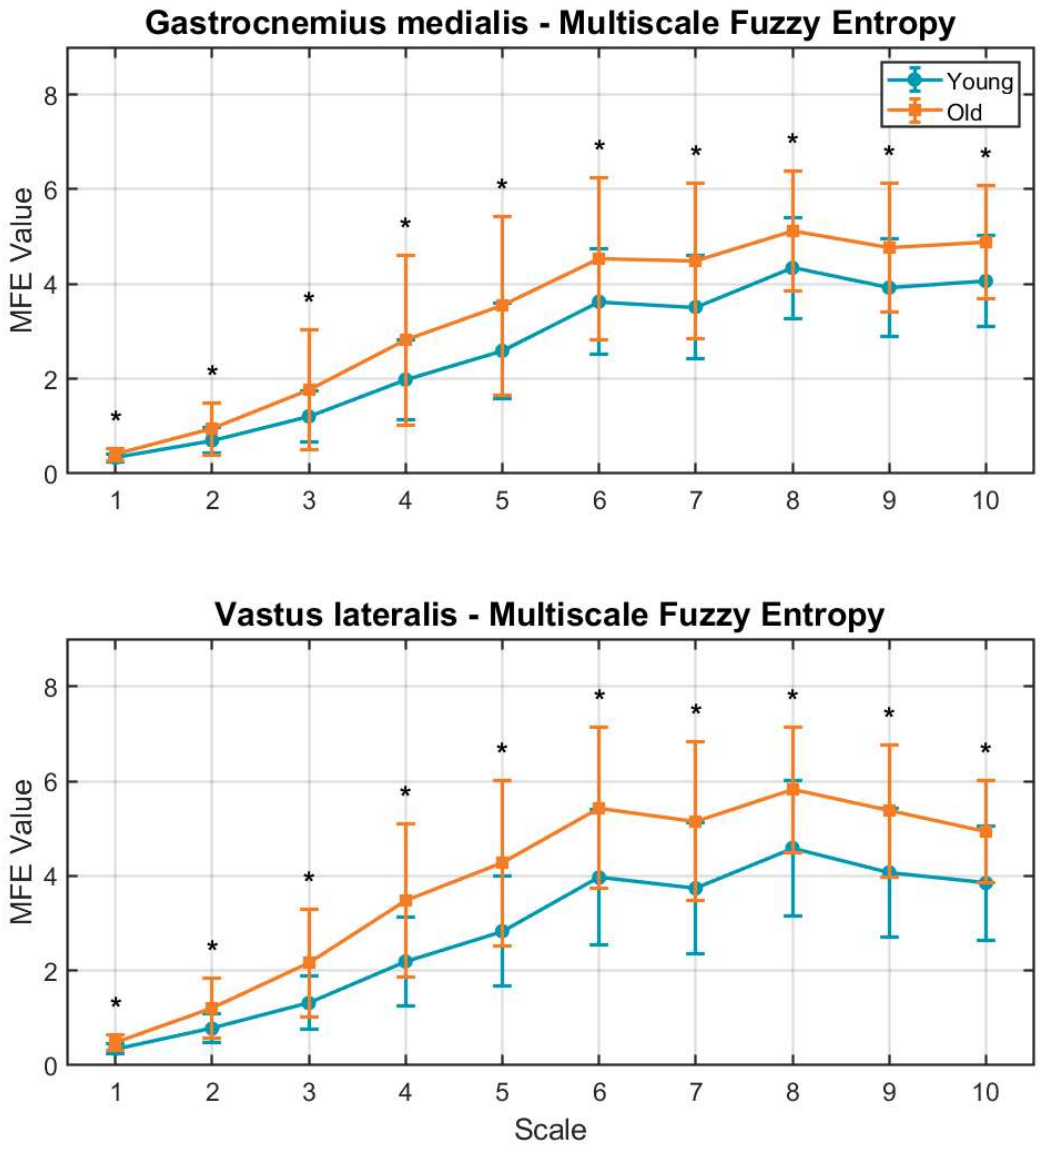
Introduction

Aging leads to skeletal muscle alterations, such as increased fat infiltration and fibrosis, which impair functional performance [1]. While these microstructural changes are difficult to detect with traditional B-mode ultrasound, raw radiofrequency (RF) ultrasound data preserve the full acoustic signature, providing superior sensitivity to tissue heterogeneity. Multiscale Fuzzy Entropy (MFE), an entropy-based measure of signal complexity, provides enhanced robustness to noise compared with conventional multiscale entropy methods [2]. This study aims to investigate whether MFE derived from RF ultrasound data can identify differences in skeletal muscle characteristics between young and older adults.

Methods

This study recruited 30 young adults (22.8 ± 2.2 years) and 23 older adults (69.0 ± 4.0 years), all capable of independent daily activities. Participants with recent musculoskeletal injuries (<3 months) or neuromuscular disorders were excluded. Raw radiofrequency (RF) ultrasound data were obtained from the gastrocnemius medialis (GM) and vastus lateralis (VL) using a 5-MHz center-frequency linear transducer (Telemed ArtUs EXT-1H) sampled at 40 MHz. Multiscale Fuzzy Entropy (MFE) was computed at scales 1–10. Group differences were examined using independent t-tests ($p < 0.05$).

Results



The overall mean MFE was significantly higher in older adults compared to young adults for both the gastrocnemius medialis (3.3 ± 1.2 vs. 2.6 ± 0.8, $p < 0.05$) and the vastus lateralis (3.8 ± 1.2 vs. 2.8 ± 1.0, $p<0.01$). Furthermore, older adults exhibited significantly higher MFE values across scales 1-10 for both muscles ($p<0.05$).

Discussion

This study reveals that MFE is consistently higher in older adults than in young adults within the gastrocnemius medialis and vastus lateralis muscles. The elevated MFE reflects increased signal irregularity and complexity, indicating greater muscle tissue heterogeneity.

These findings align with well-known age-related skeletal muscle changes, including intramuscular fat infiltration and fibrosis formation, which likely contribute to the increased entropy. These results support MFE as a sensitive tool for sub-visual muscle property alterations, providing diagnostic information beyond standard B-mode imaging analysis. Future large-scale and longitudinal research is needed to establish MFE as a predictive marker of muscle quality decline.

Evaluation of commercial visual-inertial SLAM pipelines for free-hand ultrasound-probe tracking

Mr Zohar Oddes, Dr. Dana Solav

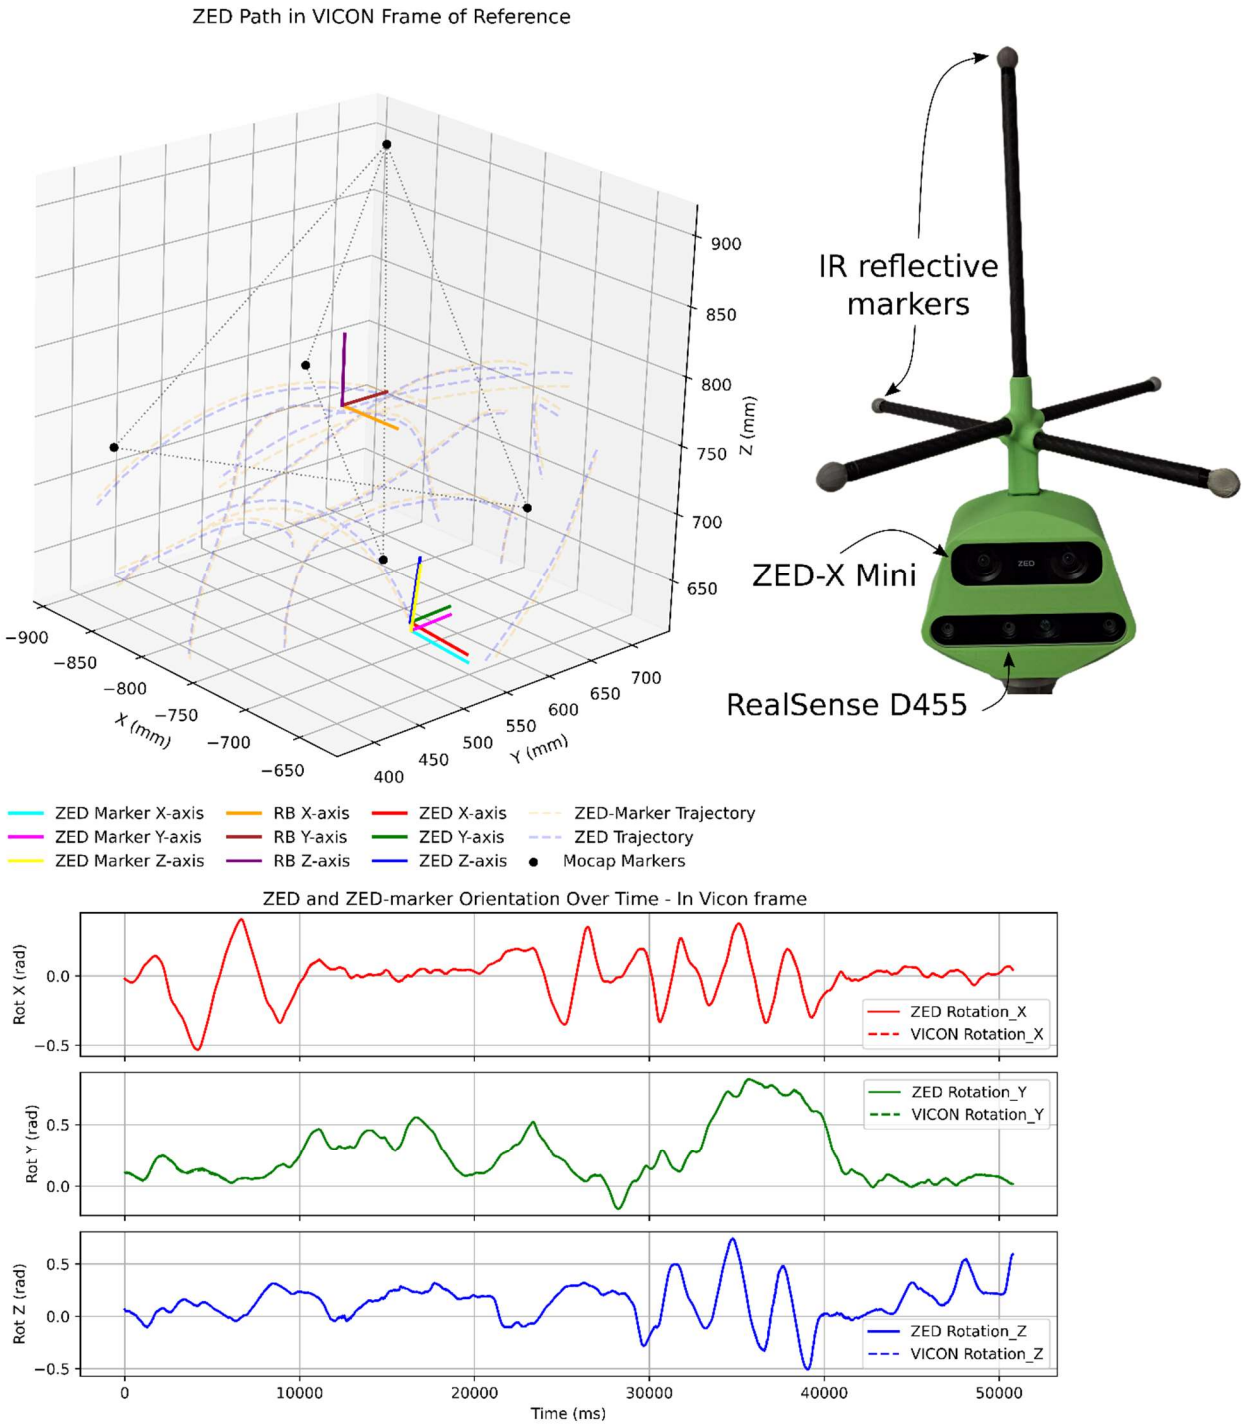
Technion – Israel Institute of Technology, Haifa, Israel, Israel

Introduction

Free-hand three-dimensional ultrasound (3D-US) relies on tracking the pose of a B-mode probe to spatially reconstruct a series of two-dimensional cross-sectional images. Outside-in optical and electromagnetic tracking systems can achieve sub-mm and sub-deg accuracy but require extensive calibration and are sensitive to line-of-sight occlusions and electromagnetic interference. Probe-mounted sensors such as stereo cameras with integrated inertial-measurement-units (IMUs) enable inside-out tracking with minimal setup. Robot-localization methods for visual-inertial odometry and visual-inertial simultaneous-localization-and-mapping (SLAM) offer robust pose-estimation, but accuracy depends strongly on both sensors and algorithms. Here, we evaluate the pose-tracking accuracy of two commercial visual-inertial SLAM pipelines based on contemporary sensors: ZED-X Mini (Stereolabs) and D455 (RealSense).

Methods

Both cameras and a set of infrared-reflective markers were rigidly mounted to a frame representing the ultrasound-probe base. Stereo and IMU data were recorded while the frame was manipulated by hand near a textured wall to mimic free-hand 3D-US scanning. A sub-mm-accuracy Vicon motion-capture system tracked the six-degree-of-freedom pose of the infrared-localizer. Visual-inertial SLAM trajectories were computed from ZED-X Mini data using ZED SDK v5.1 and from D455 data using cuVSLAM (isaac-ros v3.2). Eye-in-hand calibration was then used to derive camera trajectories in the room coordinate-frame.



Results

Treating Vicon data as ground-truth, eye-in-hand calibration residuals were used as tracking-error measures for each pipeline. Across all frames, mean translational error was 5.19 mm (SD 2.30mm) for the ZED pipeline and 4.17mm (SD 2.11mm) for the RealSense pipeline. Negligible rotational errors were measured in both pipelines.

Discussion

This study benchmarks two recent commercial visual-inertial SLAM pipelines in a 3D-US-like setting, addressing the current lack of independent accuracy data beyond vendor datasheets. Mean translation errors of 4-5mm are roughly an order of magnitude larger than typical outside-in optical tracking, so these configurations are not suitable when sub-mm accuracy is required. The RealSense pipeline showed slightly lower translation errors, whereas the ZED-X Mini pipeline provides a higher pose-update rate (60 Hz vs 30 Hz), which is especially relevant considering typical B-mode framerates. These results are preliminary; further parameter tuning and testing are planned to assess how much accuracy can be improved and in which 3D-US scenarios visual-inertial tracking is acceptable.

Prediction of Carpal Tunnel Boundary from Restricted Visibility Using Ultrasound Imaging

Ms. Mary Henderson MS, Dr. David Jordan PhD, Dr. Zong-Ming Li PhD

The University of Arizona, Tucson, Arizona, United States

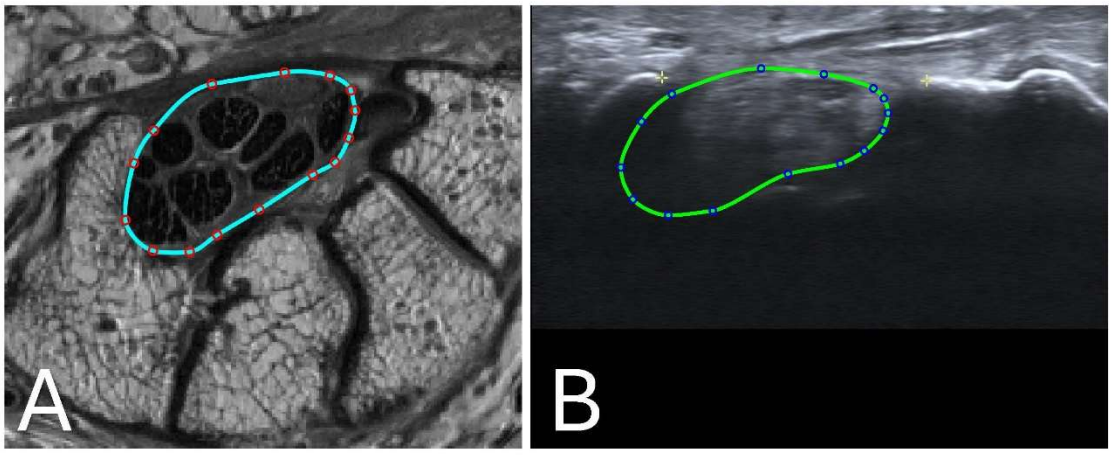
Introduction

Accurate delineation of the carpal tunnel using point-of-care ultrasound is limited due to the interference of anatomical structures, resulting in only partial visualization of the tunnel. Therefore, the purpose of this study was to (1) develop a model to predict the non-visible landmarks of the carpal tunnel in ultrasound images and (2) estimate the area and shape of the carpal tunnel.

Methods

At the distal carpal tunnel, visible carpal tunnel landmarks were identified in cadaveric hands (n=6) using ultrasound imaging. A model was created by obtaining spatial relationships between the known MRI carpal tunnel and a few internal bone landmarks, which was validated using leave-one-out analysis. The model was then used to predict the non-visible landmarks of the carpal tunnel in ultrasound images. The area and circularity (of the MRI and ultrasound tunnel boundaries were calculated and compared using paired t-tests ($\alpha = 0.05$).

Results



Based on the leave-one-out validation analysis, the average ultrasound carpal tunnel boundary was predicted within 7.90% and 9.71% error for area and circularity compared with MRI. Using the model, the predicted ultrasound carpal tunnel area was 145.1 ± 27.6 mm2 showing no significant difference from the MRI area of 144.2 ± 19.1 mm2 ($p = 0.857$) (95% CI: -10.84 to 12.56 mm2). The circularity of the predicted ultrasound tunnel (0.73 ± 0.06) also showed no significant difference compared with that from the MRI (0.79 ± 0.05, $p = 0.038$). The prediction errors averaged at 6% and 9% for area and circularity, respectively.

Discussion

Despite ultrasound's limited visualization of the carpal tunnel, the predictive model successfully reconstructed its boundary based on visible carpal tunnel landmarks. Future work will include in-vivo analysis using a larger sample size to further improve the predictive model. This model is a first step in estimating the carpal tunnel boundary from

ultrasound images, which can serve as a quick and non-invasive method for obtaining carpal tunnel area and shape for point of care use.
