The Effects of Lumbar Extensor Muscle Fatigue on Trunk Neuromuscular Control during Medio-Lateral Perturbations in Contact-Collision Athletes.

Ms. Juliana Bossom MSc., Dr. Jack Callaghan PhD.

University of Waterloo, Waterloo, Ontario, Canada

Introduction

Muscle fatigue can alter neuromuscular control in sudden-loading, yet prior research mainly examines its effects for the trunk in anterior-posterior directions with minimal between-sex comparisons. Little is known about impact responses to the torso in medio-lateral (M-L) perturbations between sexes. The purpose of this study was to investigate trunk kinematic and muscular responses to M-L sudden-loading in contact-collision athletes, with and without low-back fatigue.

Methods

Twenty-eight contact-collision athletes (14F) experienced bidirectional M-L perturbations before and after low-back fatigue, in a randomized order. Participants were positioned in a semi-seated apparatus restricting lower-extremity motion with cables connecting a chest harness to a pulley-load-supporting system with no external pre-loading. Perturbations were elicited through an unexpected drop force applied to the trunk (30% of side-bending strength) on one side. The fatigue protocol involved sets of trunk flexion-extensions on a Roman chair until the participant could no longer exert 60% of their unfatigued extensor strength. Trunk lateral flexion angles were calculated from passive 3D motion-capture data (128Hz). Peak abdominal and back electromyography (EMG) (2048Hz) response magnitudes and muscle onsets were identified, with onsets detected using a 25ms sliding window at 2 SD above baseline. Responses were evaluated within a 2-second window post perturbation (Figure 1). A two-way linear mixed-effects ANOVA was conducted on dependent variables, with condition and sex as factors.

Results

Condition-sex interactions were found for contralateral lumbar erector spinae (contra-LES) peak ($p<0.05$) and ipsilateral LES (ips-LES) onset ($p<0.05$). Pairwise comparisons with Tukey's HSD revealed males had significantly increased contra-LES peak amplitude when fatigued compared to unfatigued (20vs12.6%MVC, $p<0.05$) and significantly faster ips-LES onsets when fatigued compared to unfatigued (248vs323ms, $p<0.05$).

Discussion

Findings highlight sex-specific neuromuscular strategies in fatigue, with increased contra-LES peaks and faster ips-LES onsets in males. This demonstrates compensatory strategies to maintain stability, since angular displacements were not altered. Females' kinematics were also unaltered, yet muscular compensations were not found. A possible explanation is that female's may have compensated through contributions from muscles not measured in this analysis. Future directions could examine whole-body fatigue to determine if differences in trunk neuromuscular control exist in sport-realistic contexts.

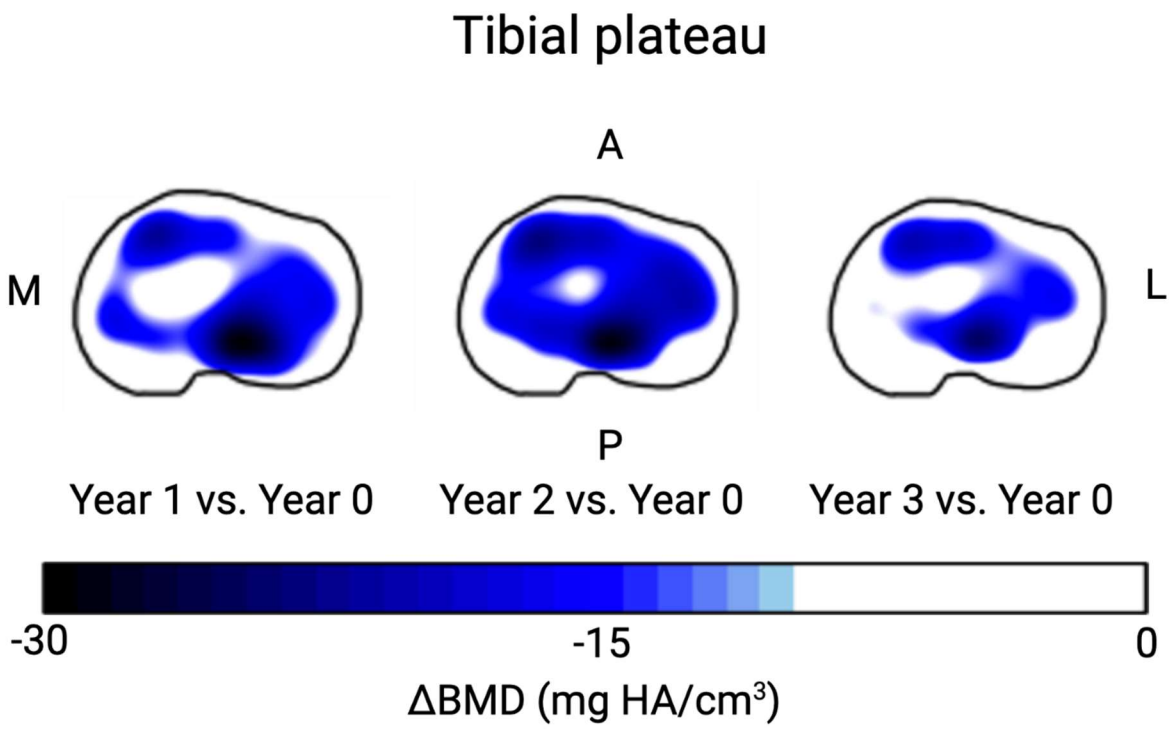
[3]Department of Radiology, School of Medicine, University of Colorado Anschutz Medical Campus, Aurora, CO, United States. [4]Department of Radiology, Cumming School of Medicine, University of Calgary, Calgary, AB, Canada

Introduction

Substantial peri-articular bone loss and structural degradation occur within the first year of anterior cruciate ligament (ACL) injury, with locations of bone marrow lesions (BMLs) experiencing accelerated bone loss relative to adjacent bone. Early peri-articular bone loss may contribute to the development of post-traumatic osteoarthritis (PTOA), yet longitudinal bone remodeling within traumatic BML regions is not well characterized beyond the post-injury period. Understanding longitudinal progression of bone adaptation is needed to inform future interventions. The objective was to quantify and visualize longitudinal peri-articular bone changes for three years following ACL injury and to examine the spatial relationship of these changes to the locations of BMLs.

Methods

Ten participants with an acute ACL injury (50% female; non-surgical management) completed knee dual-energy quantitative computed tomography (DE-QCT) and magnetic resonance imaging (MRI) scans at baseline (~6 weeks post-injury) and 1-, 2-, and 3-year follow-ups. DE-QCT scans were calibrated for bone mineral density (BMD), and bones (femur, tibia, and patella) were segmented, mirrored (if left-sided), and spatially normalized to their corresponding right-sided atlas enabling voxel-wise assessments. Mean BMD maps were created by pooling spatially normalized bones at each timepoint, with difference maps calculated by subtracting the baseline map from the follow-up maps. BMD changes greater than a previously established least-significant change were identified as plausible. Traumatic BMLs were identified on MRIs and spatially normalized to the same atlas for comparison.



Results

In the ACL-injured limb, voxel-wise BMD loss peaked by at 1 year, extended beyond the initial region at 2 years, and trended toward partial recovery by 3 years. Contralateral limbs remained stable at all timepoints. Spatial analyses revealed an overlap between the regions with the greatest early BMD loss and the locations of BMLs.

Discussion

ACL injury-related peri-articular bone adaptions are region-specific, time-dependent, and tend to align with the distribution of traumatic BMLs. Notably, regions of early BMD loss also exhibited greater BMD recovery between 1- and 2-year follow-ups compared to the surrounding bone. Given that BMLs often reflect the mechanism of injury, peri-articular bone changes following ACL injury may similarly depend on the injury mechanism, which might play a role in the development of PTOA.

Applying Load to the Wrist Reveals 3D Carpal Malalignment Following Scapholunate Interosseous Ligament Injury

Mr. Justen Saini[1,2], Dr. Brodie Ritchie[3,4], Dr. Neil White[2,3,4], Dr. Koren Roach[1,2,5,6], Dr. Sarah Manske[2,5]

[1]University of Calgary, Department of Biomedical Engineering, Calgary, Alberta, Canada. [2]University of Calgary, McCaig Institute, Calgary, Alberta, Canada. [3]University of Calgary, Department of Surgery, Calgary, Alberta, Canada. [4]South Campus Research Unit for Bone and Soft Tissue, Calgary, Alberta, Canada. [5]University of Calgary, Department of Radiology, Calgary, Alberta, Canada. [6]University of Calgary, Faculty of Kinesiology, Calgary, Alberta, Canada

Introduction

Current assessments of carpal alignment, including angular and distance relationships between carpal bones, are typically measured on two-dimensional (2D) radiographs. These 2D manual measurements are limited by projection errors, inconsistent wrist positioning, and an inability to capture multiplanar deformities. Manual measurements introduce inter-rater variability, preventing early detection of instability and limiting surgical planning for scapholunate interosseous ligament (SLIL) injuries. Automating these measurements using three-dimensional (3D) imaging techniques, such as weight-bearing computed tomography (WBCT), may help to reduce variability and provide multiplanar assessment of carpal bone position.

Objective: Develop a semi-automated pipeline to measure 3D carpal alignment from WBCT scans and evaluate these measurements in healthy and SLIL-injured wrists.

Methods

WBCT scans were acquired for ten healthy controls and ten SLIL-injured participants in non-weightbearing (NWB), weightbearing pushup bar grip (WBPUB), and weightbearing extension (WBEXT) positions. SLIL injuries were confirmed by fellowship-trained hand surgeons; participants with advanced osteoarthritis were excluded. We developed a semi-automated pipeline in Python to segment 3D carpal bones and define 3D bone axes using principal axes of inertia and curvature patterns. Carpal alignment metrics including the scapholunate interval at five locations, dorsal scaphoid translation (DST), and intercarpal

and radiocarpal angles projected onto simulated lateral and anteroposterior views were assessed (Figure 1). Differences between groups and between positions were evaluated using a mixed-effects ANOVA.

Results

In the NWB position, SLIL-injured wrists showed significantly greater DST (2.18±2.25 mm) compared to controls (0.30±0.98 mm, $p = 0.035$). DST significantly decreased in SLIL-injured wrists in the WBPUB position (1.07±1.49 mm) compared to the NWB position ($p = 0.032$). SLIL-injured wrists exhibited significantly greater scapholunate and radiolunate angles across all positions compared to controls ($p < 0.05$), indicating persistent pathological lunate extension under load.

Discussion

This open-source pipeline enables position-independent, 3D assessments of carpal alignment across multiple wrist postures, reducing reliance on manual radiographic measurements. Through evaluation of multiplanar deformities, this method supports patient-specific surgical planning and corrections. This work may also inform rehabilitation protocols, as evidenced by the reduction in DST in the WBPUB position which may help prevent increased dorsal loading.

Images (Optional)

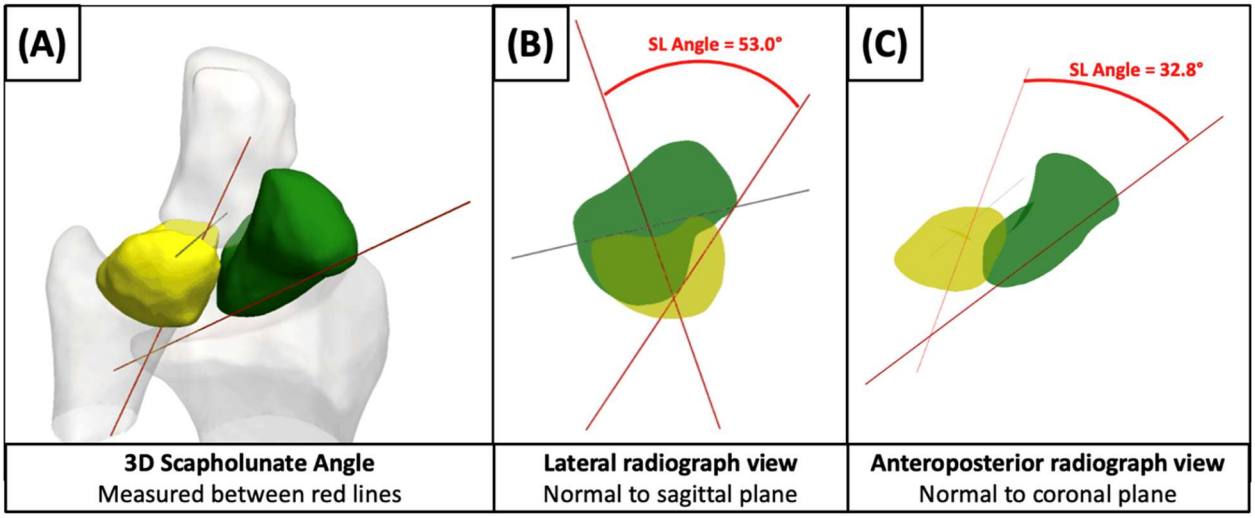

Figure 1: An example of how the three-dimensional (3D) scapholunate angle is calculated for a right-hand weight-bearing computed tomography scan. (A) The 3D representation of the angle measurement, with the axes of the scaphoid and lunate in red. (B) A 2D simulated lateral radiograph projection of the 3D axes, with the angle taken between the red lines, similar to current radiographic techniques. (C) A 2D simulated anteroposterior radiograph projection of the 3D axes, which aims to provide surgeons with additional information on the orientation of carpal bone position.

Using Biplanar Videoradiography to Quantify the Accuracy of Person-Specific Knee Models in Simulating Patellofemoral Kinematics for a Variety of Dynamic Tasks

Ms Annagh Macie[1], Dr. Anthony Gatti[2], Dr. Michael Rainbow[3], Dr. Allison Clouthier[1]

[1]University of Ottawa, Ottawa, Ontario, Canada. [2]Stanford University, Stanford, California, United States. [3]Queen's University, Kingston, Ontario, Canada

Introduction

The ability to measure patellofemoral (PF) joint function in vivo is challenging. PF kinematics can be estimated using person-specific musculoskeletal modelling, but the accuracy of these models is still unclear. Therefore, this study seeks to use biplanar videoradiography (BVR) to quantify the accuracy with which three versions of a person-specific multibody knee model can predict six DOF tibiofemoral (TF) and PF kinematics for a series of dynamic tasks.

Methods

CT scans and MRIs of the right knee of eight participants (4F/4M, 23.8+/-1.4 yrs) and BVR, optical motion capture and force plate data of a lunge ascent and hop task were used. The CT scans were segmented and converted to 3D meshes of the femur, tibia and patella. These meshes were superimposed onto the BVR capture using 3D Slicer AutoScoper which provided relative bone pose at each time frame [1]. The MRIs were segmented to produce three person-specific models of the bone and cartilage of the femur, tibia and patella (Lenhart [2], Smith No Meniscus [3]) as well as the menisci (Smith [3]). These models were then integrated into a generic musculoskeletal model and the participants' trials were simulated by each model via the COMAK routine [4]. The kinematics from the BVR data were compared to the simulated kinematics of the models.

Results

The models simulated kinematics produced relatively low RMSE, which were consistent with previous validation studies [5]; however, maximum errors indicated high between subject variability (Table 1). There was a significant effect of model on total TF rotational RMSE during the hop task
($p = 0.014$), with post-hoc holm corrections indicating the Smith model performed best. No other main effects of model were noted.

Discussion

The high maximum errors and the lack of statistical difference for model performance at the PF joint indicates personalization of other model parameters such as ligament slack length should be investigated to improve person specific performance.

Directional Dependence of Multiscale White Matter and Axonal Injury Metrics from Real-World Head Impacts

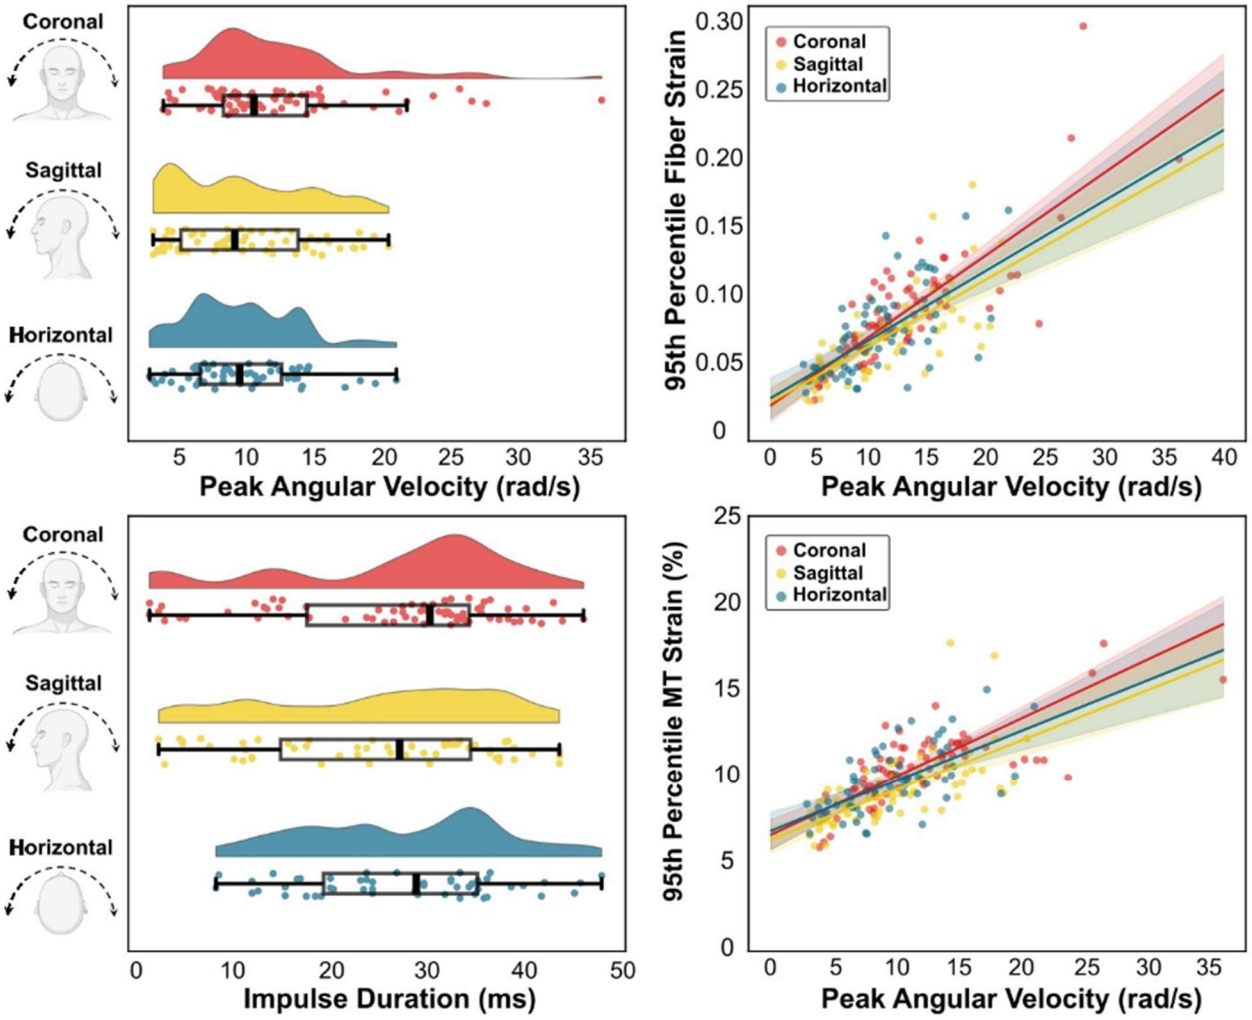
Mr. Zaryan Masood[1], Mr. Chaokai Zhang[2], Mr. Daniel Bondi[1], Mr. Alexander Jaffray[1], Mr. David Luke[1], Dr. Rebecca Kenny[1], Dr. Adam Clansey[1], Dr. Paul van Donkelaar[1], Dr. Alexander Rauscher[1], Dr. Songbai Ji[2], Dr. Lyndia Wu[1]

[1]University of British Columbia, Vancouver, British Columbia, Canada. [2]Worcester Polytechnic Institute, Worcester, Massachusetts, United States

Introduction

Traumatic axonal injury (TAI) has shown directional vulnerability in animal studies[1], but this remains less understood in humans, particularly at microstructural scales. Advances in wearable sensors, neuroimaging, and computational modeling now allow large-scale subject-specific simulations of real-world head impacts to estimate deformation from whole-brain to axonal structures. This study examined the directional dependence of white matter fiber strain and axonal substructural damage.

Methods



University men's ice hockey athletes (n = 18; UBC ethics: H21-00400) wore custom instrumented mouthguards (iMGs) over one season, and completed a structural brain MRI scan for subject-specific modeling. We simulated voxel-wise white matter fiber strains and axonal substructural deformations using a deep-learning model[2]. An impact was classified coronal-, sagittal-, or horizontal-dominant when the peak angular velocity in that plane exceeded 90% of the resultant magnitude. We used linear mixed-effects models to determine how rotational plane and peak angular velocity influence 95th percentile fiber strains and axonal substructural injury metrics, with subject ID as a random effect.

Results

We analyzed 608 impacts: 88 coronal-dominant, 86 sagittal-dominant, and 61 horizontal-dominant. Coronal-dominant impacts showed the highest median peak angular velocity (10.5 rad/s) and longest impulse durations (30.3 ms) compared with sagittal (8.4 rad/s, 26.1 ms) and horizontal (8.7 rad/s, 29.7 ms). Coronal- and horizontal-dominant impacts produced significantly higher fiber strains (coronal: $\beta = 0.0087$, $p = 0.028$; horizontal: $\beta = 0.0043$, $p = 0.313$) and microtubule strains (coronal: $\beta = 0.801$, $p = 0.004$; horizontal: $\beta = 0.290$, $p = 0.312$) compared with sagittal-dominant impacts. Neurofilament and tau failure did not differ by rotational plane. Between-subject variance was low, indicating consistent directional effects.

Discussion

Our study uniquely examined the directional dependence of microstructural injury risk using real-world head impact data and neuroimaging-enabled subject-specific multiscale modeling. Coronal- and horizontal-dominant impacts may pose a higher risk for axonal damage relative to sagittal-dominant impacts. The directional vulnerability is further compounded by higher severity coronal impacts sustained on-field, warranting protective equipment improvements and potential rule changes to mitigate high-risk impact directions.

CSB-06

Normative Modeling of Gait Biomechanics for Personalized and Multisite Clinical Assessment

Mr. Jereme Outerleys[1,2], Mr. Sachitha Wijekoon[1], Dr. Stephen Scott[1], Dr. Kevin Deluzio[1]

[1]Queen's Univeristy, Kingston, Ontario, Canada. [2]Theia, Kingston, Ontario, Canada

Introduction

Clinical gait assessment assumes that the “average” gait is an appropriate benchmark for every patient. This approach ignores variability due to factors such as age, sex, and site, limiting the precision of patient-specific measures. To address this, we apply a normative modeling framework [1] trained on a large, multisite dataset of healthy gait to model expected patterns based on individual characteristics. Applied to knee osteoarthritis (OA), this approach provides a statistical foundation for quantifying biomechanical impairment and supports patient-specific gait evaluation in clinical and multicentre contexts.

Methods

A normative modeling framework using hierarchical Bayesian regression was trained on a markerless gait dataset of healthy adults (N = 607; age 17–92), collected across six sites using Theia3D. Separate models were trained for each time point of hip, knee, and ankle waveforms and spatiotemporal outcomes (408 total). Covariates included age, sex, and site. Trained models were applied to a clinical dataset of 192 individuals with knee OA (55 moderate, 137 severe) to generate patient-specific z-scores quantifying deviations from healthy expectations. Summary deviation scores were calculated using Mahalanobis distance and standardized to a normal distribution [2]. The percentage of participants classified as high deviators ($z > +1.64$) was calculated and compared across the healthy and OA severity groups.

Results

Patient-specific z-scores revealed increasing deviation with OA severity and quantitatively identified joint- and phase-specific abnormalities across the gait cycle. Summary deviation scores classified 5.5% of healthy as high deviators, compared to 67.3% in moderate and 82.7% in severe OA, effectively separating healthy and clinical groups (Figure 1). Z-score distributions in the healthy cohort showed no systematic differences across sites, indicating minimal site effects.

Discussion

Normative modeling enables patient-specific quantification of gait deviations while accommodating demographic and site-related variability. The resulting z-scores offer interpretable, standardized metrics comparable across individuals and sites, distinguish between levels of clinical severity, and identify abnormalities throughout gait. Future work will explore federated modeling, allowing extension to new sites without sharing raw data, an advantage where privacy or resource constraints limit data pooling.

Knee and Ankle Posture Impacts Triceps Surae Muscle Neuromechanics

Mr. Sittinon Nuethong

University of Pennsylvania, Philadelphia, Pennsylvania, United States

Introduction

The three Achilles (AT) subtendons connect medial gastrocnemius (MG), lateral gastrocnemius (LG) and soleus (SOL) muscles to the calcaneus. These muscles differentially strain subtendons that causes non-uniform displacement in AT. The plantar flexor aponeuroses displace and develop internal stresses at different knee angles, foot positions, and ankle angles. This study aims to define the relationships between the joint posture and the subtendon sliding degree with the hypothesis that changing knee-ankle configuration will alter both plantar flexor muscle activation and subtendon sliding extent.

Methods

10 healthy participants (3 men, 7 women, 23 ± 3 years) were provided written informed consent and performed five maximum voluntary isometric contractions (MVICs) on a dynamometer at eight knee-ankle configurations. Surface electromyograms (sEMG) on three plantar flexor muscles and ultrasound images on AT were acquired simultaneously. The differential displacement was calculated from the difference between the deep and superficial displacements of the AT tracked by the Kanade-Lucas-Tomasi point tracking algorithm. The sEMG were normalized to the sum of the maximum sEMG of all three muscles among all configurations. ANOVA with Tukey's post-hoc was used for statistical analysis.

Results

The differential displacement differed only between inversion and dorsiflexion with extended knee (Fig 1A). MG engagement becomes less in the flexed knee position for all ankles (Fig 1B). Moreover, LG was recruited more with flexed knee and plantarflexion compared to the same ankle and both foot orientations (Fig 1C). SOL was activated more in the flexed knee position except in dorsiflexion compared to the knee extended position with the same ankle angles (Fig 1D).

Discussion

Our preliminary study demonstrated the impacts of changing knee-ankle configurations on the plantar flexion muscle activation and subtendon sliding. The higher activations of the SOL and MG muscles in the flexed knee and extended knee positions correspond to the finding of larger displacements in the SOL and MG aponeuroses in these two knee angles. However, few distinct differential displacements were found implying the participant specific quality of this metric. This project is an ongoing study with an expectation to increase statistical power to test the effect of knee-ankle configurations.

Images (Optional)

Neural Correlates of Knee Flexion-Extension after Unilateral Transtibial Limb Loss

Dr. Courtney Butowicz PhD[1,2,3], Dr. Rujirutana Srikanchana PhD[2], Dr. Brad Hendershot PhD[1,2,3], Dr. Tawnee Sparling MD[2,3], Dr. Sheri Silfies DPT, PhD[4]

[1]Defense Health Agency, Falls Church, VA, United States. [2]Walter Reed National Military Medical Center, Bethesda, MD, United States. [3]Uniformed Services University of Health Sciences, Bethesda, MD, United States. [4]University of Delaware, Newark, DE, United States

Introduction

Nearly 80% of persons with unilateral limb loss (PLL) experience chronic musculoskeletal and/or phantom limb pain, impairing function and quality of life. Amputation induces reorganization in sensorimotor brain regions as representations of the missing limb invade adjacent cortical areas, causing changes in sensory integration, motor control, and pain perception. Yet, evidence has only investigated cortical activity in response to sensory stimulation or during resting state functional magnetic resonance imaging (fMRI), failing to identify how reorganization is linked to movement. The aim of this pilot study was to identify neural correlates of voluntary limb movement among PLL.

Methods

Six participants* (4 with transtibial amputation (2 female) and 2 uninjured (CTR; 1 female)) underwent a T1-W magnetic resonance image (3T Siemens) and then completed 20 repetitions (10/side) of unilateral knee extension/flexion (5s up/5s down/10s rest) in response to visual instructions during fMRI. fMRI measured neural activation via blood oxygen level dependent signal changes. Data were pre-processed in fmriprep; first-level analysis (intact/right>rest, prosthetic/left>rest) processed using SPM in MATLAB. *Larger sample size expected by conference.

Results

Analysis revealed increased cortical activation during intact limb movement vs. rest in sensorimotor regions (primary sensory, primary motor, supplementary motor, premotor cortices) among PLL. Prosthetic vs. rest contrast revealed increased activation in the sensorimotor cortex, precuneus/paracentral lobule, supramarginal gyrus, and anterior cingulate cortex. CTR exhibited a smaller number of active voxels in sensorimotor regions compared to PLL.

Discussion

PLL use brain regions associated with motor control, sensory processing, proprioception, motor sequencing, pain appraisal, and episodic memory to move the lower limbs. Higher activations in pain appraisal and tool use regions during prosthetic side movement suggest pain history associated with prosthesis use may influence motor control. CTR demonstrated highest activations in regions linked to reward evaluation, visual, and language processing for the task.

Our findings support previous work suggesting persons with lower limb injury exhibit increased activation in sensory processing and motor planning brain regions not seen in uninjured controls when performing a voluntary movement task. Characterizing the neuroplastic changes occurring with amputation can guide motor control-based rehabilitation targets to improve sensorimotor function.

Images (Optional)

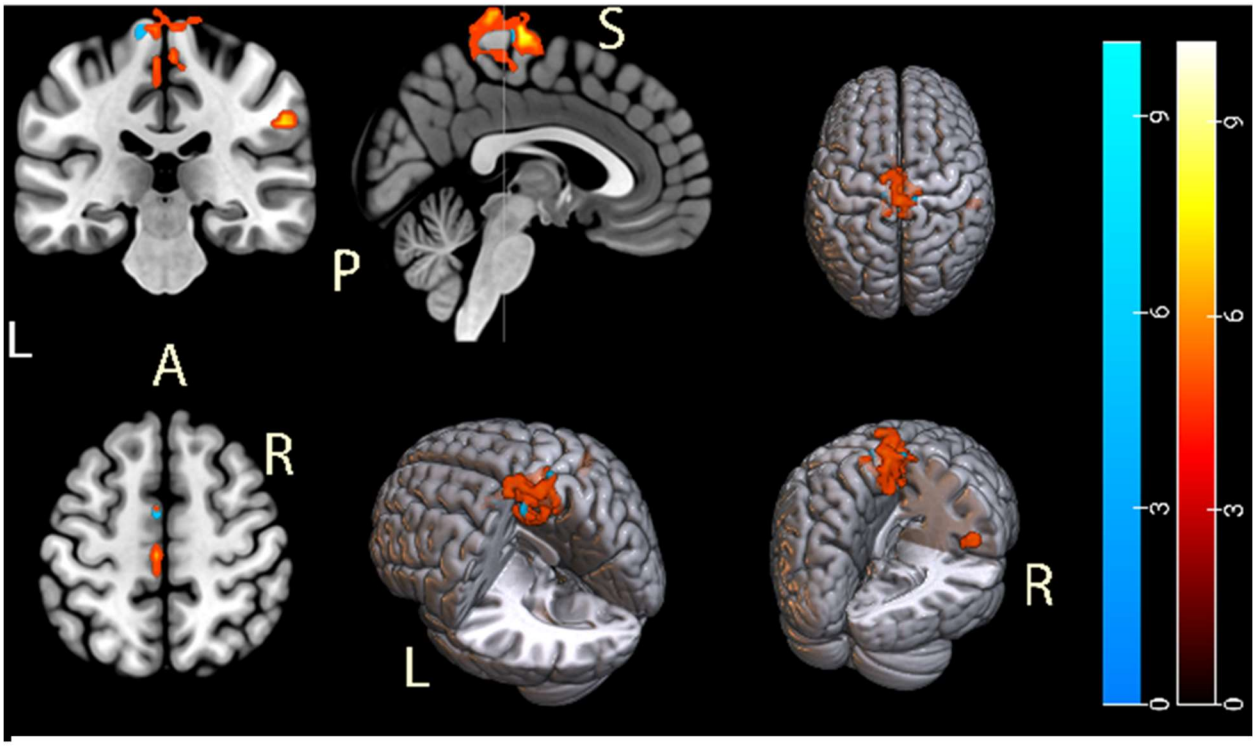

Figure 1: Regions with activation exceeding statistical threshold ($p<0.05$ with family wise error correction, $Z>3.1$, z-score indicated by heat scale) for intact (cool) and prosthetic (hot) movement greater than rest for male subject with left transtibial amputation.

Neural Control of Isometric Lower Limb Muscle Contractions in Typically Developing Children and Children with Cerebral Palsy

Mr Andrea Sgarzi[1,2], Dr Agnese Grison[3], Prof Dario Farina[3], Dr Bart Bolsterlee[1,2], Prof Nigel Lovell[1], Dr Luca Modenese[1]

[1]Graduate School of Biomedical Engineering, UNSW, Sydney, NSW, Australia. [2]Neuroscience Research Australia (NeuRA), Sydney, NSW, Australia. [3]Dept of Bioengineering, Imperial College, London, UK, United Kingdom

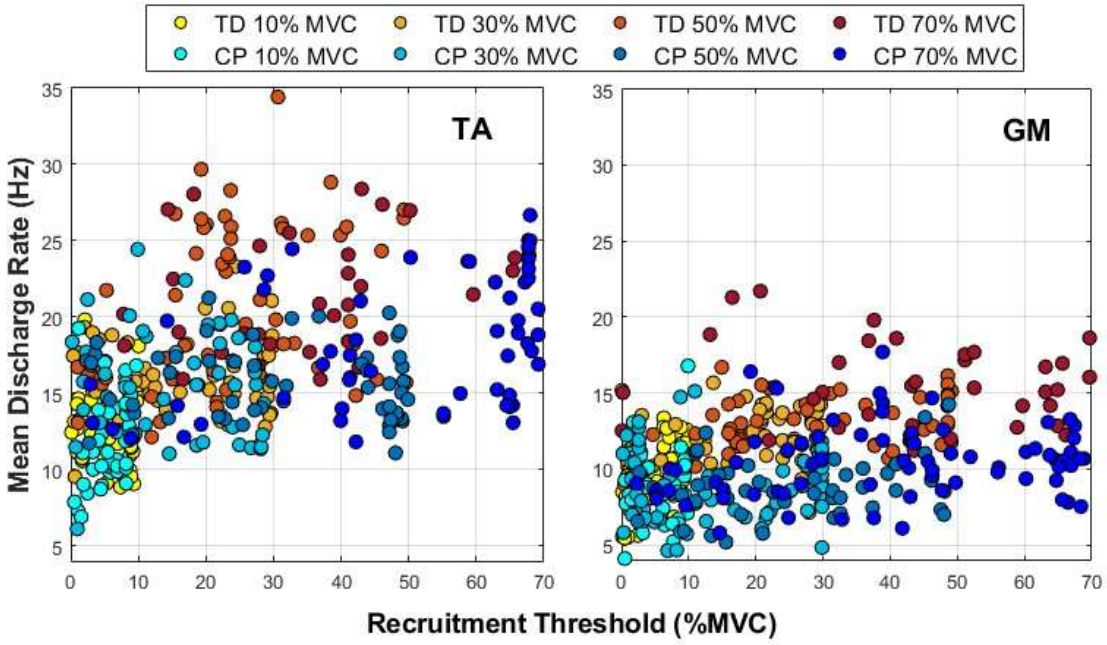
Introduction

Studying neuromuscular control in children is crucial for understanding typical development and childhood disabilities and, for ethical reasons, requires non-invasive approaches. In cerebral palsy (CP), lower limb impairments may be linked to altered motor unit (MU) activity [1]. While MU behavior has been extensively characterized in adults using high-density surface electromyography (HDsEMG) [2], it remains largely unexplored in children. This study aims to assess MU activity in lower limb muscles of typically developing (TD) children and children with CP.

Methods

To date, fourteen TD children (7 girls, 12 ± 3 years) and fourteen with spastic CP (5 girls, 12 ± 2 years) have been recruited. All procedures were approved by the UNSW Human Research Ethics Committee (iRECS6278). Participants were seated with the knee extended and the foot (dominant side for TD, most affected for CP) strapped to a dynamometer. Each participant performed a maximum isometric voluntary contraction (MVC) and four trapezoidal contractions at 10%, 30%, 50%, and 70%MVC during ankle dorsiflexion and plantarflexion. HDsEMG signals were recorded from the tibialis anterior (TA) and gastrocnemius medialis (GM) using two 64-electrode grids per muscle (4 mm interelectrode distance, OT Bioelettronica, Italy) and decomposed into MU spike trains [3]. MU firing rate (FR) and recruitment threshold (RT) were compared between groups using two-sample t-tests at each intensity.

Results



In TD children, up to 46 and 60 MUs per participant were identified in TA and GM respectively, with mean FRs and RTs of 17 ± 5 Hz and 19 ± 15%MVC (TA), and 12 ± 2 Hz and 16 ± 14%MVC (GM). In children with CP, up to 43 MUs per participant were identified in

both muscles, with mean FRs and RTs of 15 ± 4 Hz and 15 ± 15%MVC (TA), and 9 ± 2 Hz and 19 ± 17%MVC (GM). FR was lower in CP for both muscles ($p<10^{-3}$) at intensities >10%MVC. RT never differed significantly.

Discussion

These preliminary findings suggest a limited ability of children with CP to modulate force through FR, consistent with previous intramuscular observations [1].

OA1-04

The Effects of Carpometacarpal Osteoarthritis on Neuromuscular Coordination

Mr Troy Kelly Jr, Mr Benjamin Nowak, Dr Jennifer Nichols

University of Florida, Gainesville, Florida, United States

Introduction

Carpometacarpal osteoarthritis (CMC OA) is a disruptive disease that can impair hand function due to structural joint degeneration. While joint degeneration is well studied, there is a gap in knowledge regarding how muscle coordination adapts to disease progression. This study aims to examine how both co-contraction and intermuscular activation patterns differ between early- and late-stage CMC OA participants.

Methods

Data from 15 participants with CMC OA (73% female; age: 68.5±7.7 years) was analyzed. Using x-rays and the Eaton-Littler grading scale, early-stage CMC OA was classified as grades 1-2, and late-stage CMC OA was classified as grades 3-4. Intramuscular electromyography (EMG) from 8 thumb muscles during a jar grasp task were recorded. Co-contraction was determined using the Co-Contraction Index (CCI) on three thumb muscle pairs: FPL-EPL, FPB-EPB, and APL-ADD. These pairs were selected due to opposing muscle functions. Intermuscular activation patterns were quantified by calculating the Pearson correlation coefficients for all possible thumb muscle pairs (28 total). Higher CCI values indicate greater co-contraction, while higher correlation values indicate stronger synergistic coupling. Group comparisons were conducted using ANOVAs followed by Tukey's post-hoc testing for all analyses.

Results

Individuals with late-stage CMC OA had increased co-contraction relative to those with early-stage CMC OA for all three examined muscle pairs. This difference was statistically significant ($p<0.05$) for FPL-EPL and FPB-EPB (Fig. 1A). Correlation between intermuscular pairs declined in the late-stage CMC OA group across 25 of 28 muscle pairs. Across all assessed intermuscular pairs, significant ($p<0.05$) decline in correlation was found between ADD-FPB, ADD-OPP, FPB-OPP, FPB-FPL, FPL-OPP, and APL-EPL (Fig. 1B).

Discussion

These findings suggest that thumb motor control in individuals with late-stage CMC OA can be characterized as having elevated co-contraction and reduced intermuscular correlation. Increased muscle co-activation may reflect compensatory strategies to improve joint stability in response to joint degradation. In contrast, the reduced intermuscular correlation suggests altered neuromuscular control, similar to changes observed with aging, which can decrease movement efficiency and functional performance. These results suggest that CMC OA is not only associated with joint degeneration but also with altered neuromuscular control.

Sensitivity of Markerless Lower-Limb Kinematics to Camera Height and Capture-Volume Width: Implications for Camera Placement

Mr Alexander Hadwen[1], Mr Jereme Outerleys[1,2], Dr Kevin Deluzio[1]

[1]Queen's University, Kingston, Ontario, Canada. [2]Theia, Kingston, Ontario, Canada

Introduction

Markerless motion capture offers advantages over marker-based systems by eliminating marker placement errors and reducing operator-dependent variability [1]. However, the influence of camera placement on kinematic outcomes remains insufficiently understood. This study quantified the effects of camera layout on lower-limb kinematics estimated using markerless motion capture. We assessed how camera height interacts with capture-volume width to affect joint-angle waveform reliability, aiming to provide practical guidance for camera placement.

Methods

Nine participants performed overground walking trials recorded using 32 synchronized Sony RX0II cameras arranged elliptically. Cameras were organized into four height groups (0.85 m, 1.65 m, 2.45 m, and 3.30 m; eight per group). Participants repeated trials at three camera-horizontal width conditions, changed for each trial: extended (6.9 m), intermediate (5.5 m), and hallway simulation (3.3 m), with capture volume length held constant. Markerless pose estimation was performed using Theia3D (v2025.1.6) and processed in Visual3D and Python. Only strides visible in all 32 cameras were included, and a consistent region of interest ensured identical stride selection, though step count varied by width.

Results

Across all widths, the largest joint-angle difference was 4°, occurring between the 0.85 m and 3.30 m camera groups in the narrowest width condition. This camera pair accounted for the greatest difference in 64% of all joint-plane comparisons (ankle, knee, hip, pelvis; X/Y/Z planes). Peak differences occurred between 60–90% of the gait cycle, corresponding to phases with the greatest self-occlusion, as the hip and knee obscure distal segments. The narrowest width produced the largest variability, followed by the widest, then the intermediate condition.

Discussion

Differences of ≈3–4° between the highest and lowest camera positions indicate that extreme vertical angles increase occlusion and reduce tracking reliability. However, these

effects are small and below the ≈12° inter-laboratory offsets typical of marker-based systems [2], suggesting markerless kinematics remain robust with only minor height-dependent bias. Findings support positioning cameras within a mid-range vertical band, avoiding the highest and lowest placements, to improve reliability. Limitations include no ground-truth comparison and varying walking trials across widths.

Images (Optional)

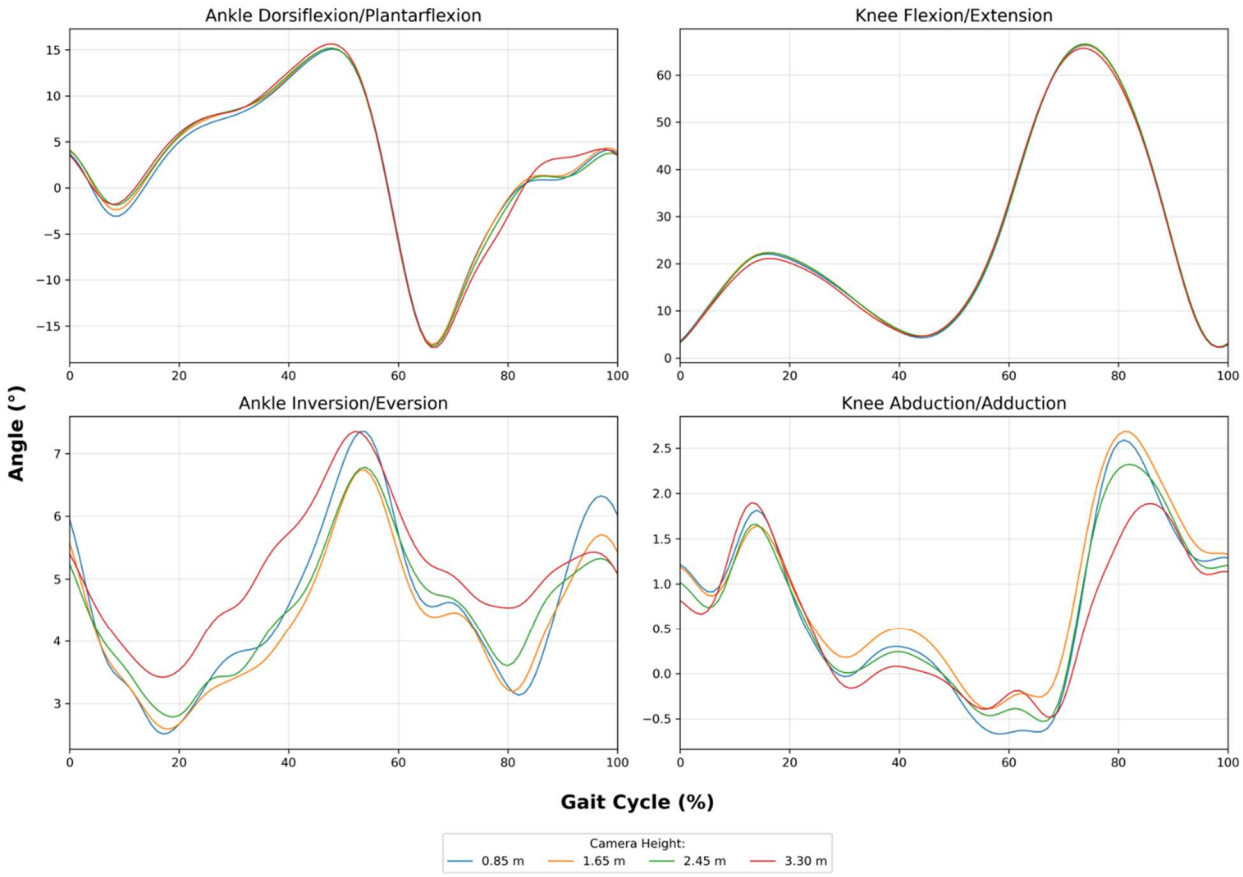

Figure 1: Ankle and knee kinematics in the sagittal and frontal planes across the full gait cycle for the intermediate width condition. Differences between camera-height groups show slight waveform variation in the ankle sagittal plane near mid-swing phase and throughout both joints in the frontal plane.

Markerless Motion Capture of Wrist Kinematics in Wheelchair Users with Spinal Cord Injury

Mr. Samuel Gillespie MS[1,2], Dr. James Cotton MD, PhD[1,2], Dr. Brooke Slavens PhD[3], Dr. Wendy Murray PhD[1,2]

[1]Northwestern University, Evanston, Illinois, United States. [2]Shirley Ryan AbilityLab, Chicago, Illinois, United States. [3]University of Wisconsin-Milwaukee, Milwaukee, Wisconsin, United States

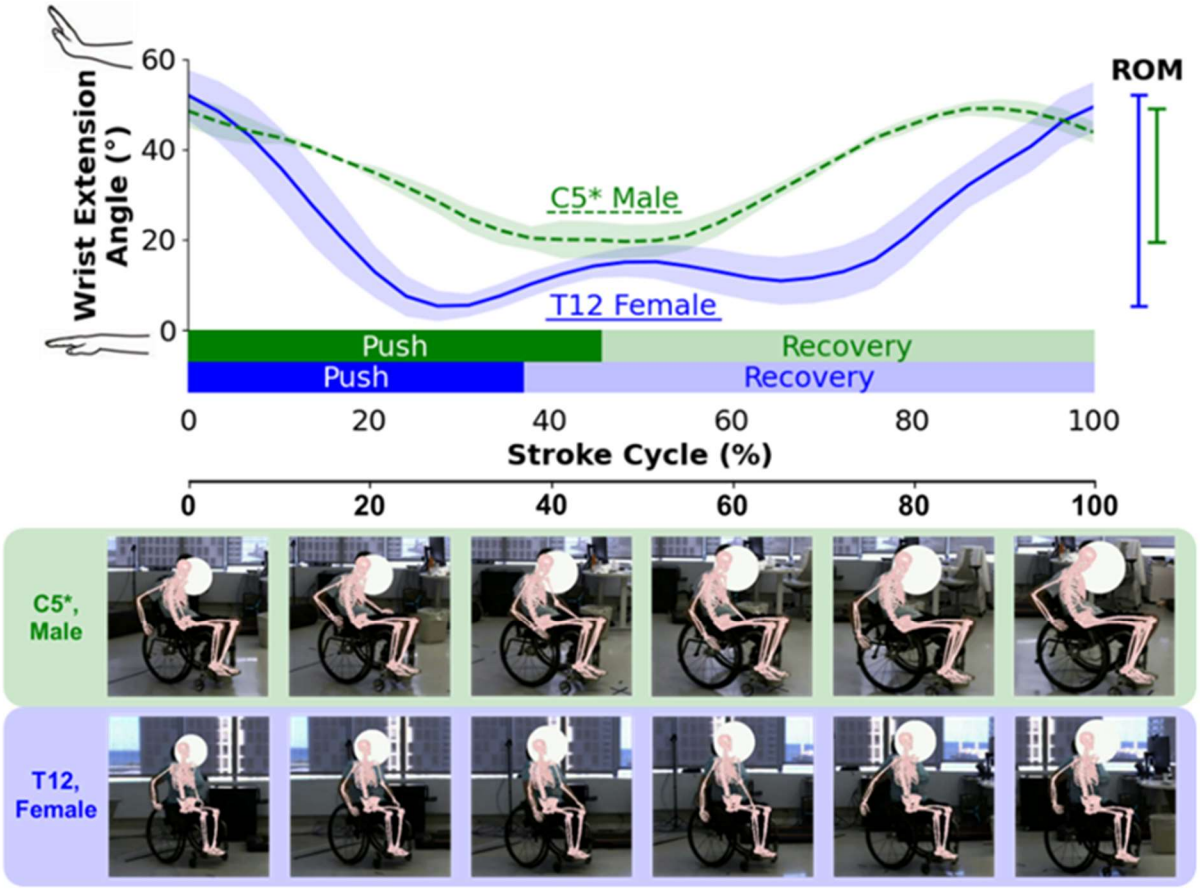
Introduction

Manual wheelchair users commonly experience upper extremity pain and pathology, particularly carpal tunnel syndrome (CTS), which is especially debilitating given their reliance on their arms for mobility and independence. Wrist kinematics provide insight into joint positions and excursions that influence carpal tunnel pressure and loading. However, quantifying distal upper limb motion is challenging: marker-based systems require complex instrumentation and lengthy setup, while markerless systems struggle with small, fast-moving segments and are typically applied for gross movements . Overcoming this barrier is critical for advancing rehabilitation research and defining best practices for CTS prevention. This work demonstrates a markerless motion capture system capable of tracking wrist kinematics during wheelchair propulsion and differentiating individuals with distinct spinal cord injury levels and functional capacities.

Methods

We implemented a multiview (12 cameras), markerless motion capture workflow using an optimization approach leveraging differentiable physics simulators accelerated on GPUs. Joint trajectories were optimized by minimizing reprojection error between a 3D kinematic model (150 DOF, including wrist and finger articulations) and 2D keypoints detected from multiple cameras. Two adults with SCI completed five 10-meter propulsion trials at self-selected speeds: one with C5 tetraplegia, characterized by limited wrist and finger control, and one with T12 paraplegia, exhibiting full distal upper limb function. Cycle-aligned joint trajectories were extracted for wrist flexion/extension, radial/ulnar deviation, and forearm pronation/supination.

Results



The markerless system successfully captured continuous wrist kinematics during propulsion. Distinct wrist extension trajectories and range of motion (C5: 29.4°; T12: 46.5°)

were observed across the stroke cycle for each participant, reflecting differences in propulsion mechanics.

Discussion

Differences in wrist trajectories observed in this study are consistent with prior marker-based findings [1], suggesting that variations in distal upper limb functional capacity associated with SCI level contribute to distinct propulsion biomechanics, which in turn could influence risk for secondary pathologies such as CTS. This end-to-end markerless approach eliminates marker placement and static calibration trials, enabling efficient, unobtrusive data collection from larger, more representative populations. Future work will leverage these methods in a larger sample to inform best practices for CTS prevention in manual wheelchair users.

Images (Optional)

Cycle-aligned wrist extension trajectories during wheelchair propulsion for two participants with spinal cord injury: one with C5 tetraplegia (green) and one with T12 paraplegia (blue). Solid lines represent mean wrist extension angle across the stroke cycle, with shaded regions indicating standard deviation across stroke cycles. Push and recovery phases are shown below the x-axis, and range of motion (ROM) differences are highlighted on the right. Bottom panels show frames from a single camera overlaid with the reconstructed 3D kinematic model at different points in the stroke cycle for each participant.

Feasibility and Reliability of OpenCap for Assessing Toddler Gait Kinematics

Dr. Ashley Collimore-Doherty PhD, Ms. Kathryn Jemas, Ms. Claire Rohleder, Dr. Jana Iverson PhD

Boston University, Boston, MA, United States

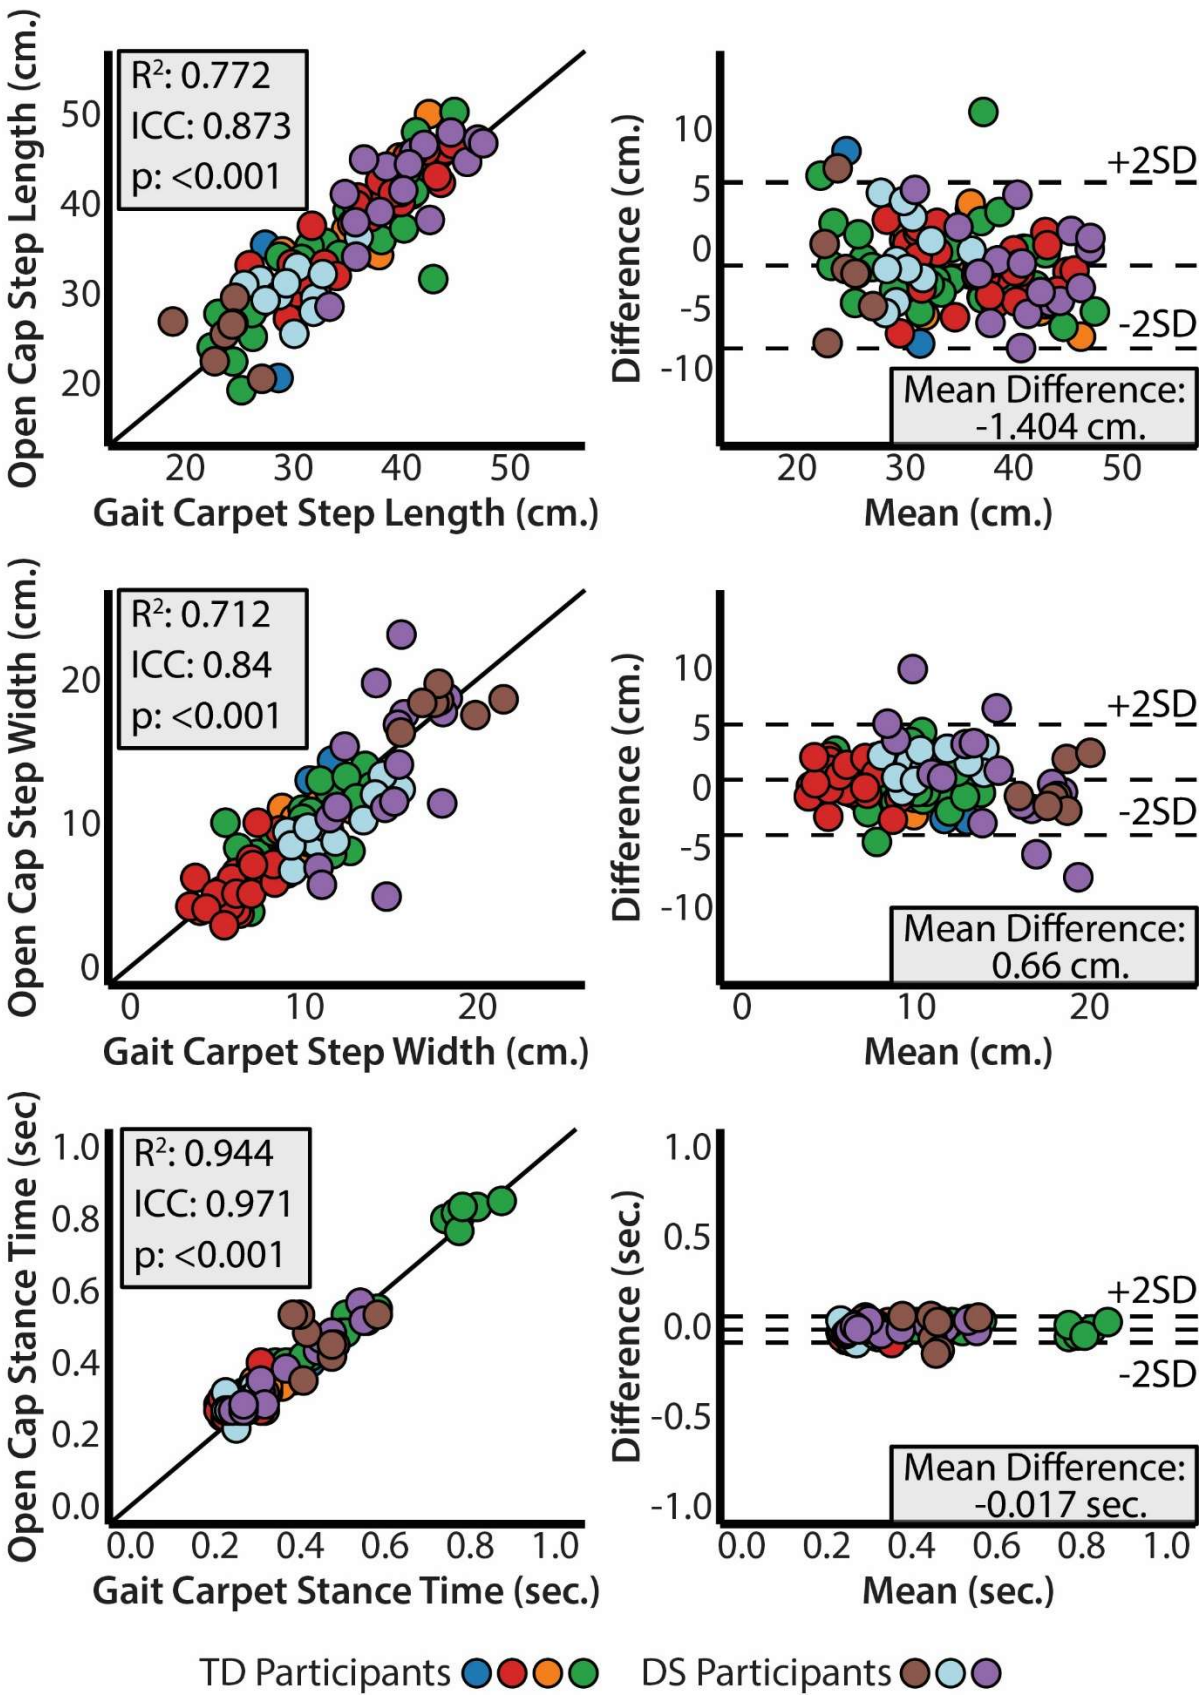
Introduction

Standardized gait assessments are critical for early identification of motor impairments and intervention evaluation for children with neurodevelopmental disabilities. However, gold-standard marker-based motion capture systems are expensive, not portable, and the markers often pose unique sensory challenges for children. Portable, pressure-sensitive walkways are a validated alternative for capturing spatiotemporal metrics but do not provide valuable insight on joint kinematics or kinetics (i.e., force) and require children walk in a straight path. OpenCap (Stanford University) has recently emerged as a portable, cost-effective, markerless motion capture system, but has not been well studied in children. The aim of this study was to determine the feasibility and validity of using OpenCap software to capture toddler walking.

Methods

Four typically developing toddlers (19-41 months) and three toddlers with Down syndrome (31-41 months) completed repeated straight path walking trials of at least 4 consecutive steps. Final data will include 10 participants per group. Spatiotemporal metrics (i.e., step length, step width, stance time) were calculated simultaneously from OpenCap and a portable, pressure-sensitive walkway (Zeno Walkway, ProtoKinetics). ICCs and Bland-Altman plots were used to compare the two systems across each variable on a step-by-step basis.

Results



53 trials were captured on the gait carpet, of which 47% were successfully processed using open-source OpenCap code. The most common reasons for unsuccessful OpenCap processing were 1) video synchronization, 2) occlusions, 3) too few matching steps identified, and 4) incorrect order of gait events (i.e., contralateral toe off before ipsilateral heelstrike; issue not found with walkway). In total, 108 steps were used in the comparison (median per participant = 11 [4-31]). Step length, step width, and stance time were all

highly correlated across OpenCap and Zeno Walkway systems (Figure 1; ICCs > 0.84, ps < 0.001).

Discussion

OpenCap may be a feasible and reliable measure of walking kinematics, that offers several advantages over pressure-sensitive walkways. However, the number of usable trials with OpenCap is significantly lower than that with the Zeno Walkway and current algorithms cannot accurately capture heelstrike and contralateral toe-off events when toddlers are close to running. Future work should explore refining OpenCap models for toddler gait and improving consistency in data usability.

Velocity-Based Strength Training: The Predictive Use of Mean Concentric Velocity Data

Prof. Silvio Lorenzetti PhD[1,2], Dr. Basil Achermann PhD[1], Mrs Rahel Heynen[3], Mrs Julia Suter[1], Dr. Martin Frey PhD[1], Mrs Naire Regazzi[2]

[1]ZHAW, Winterthur, ZH, Switzerland. [2]DHEST, Zurich, ZH, Switzerland. [3]SFISM, Magglingen, BE, Switzerland

Introduction

We examined the use of a new Velocity based Training (VBT) Framework and linear regression models for predicting the outcomes of a six-week VBT intervention in female floorball players [1].

Methods

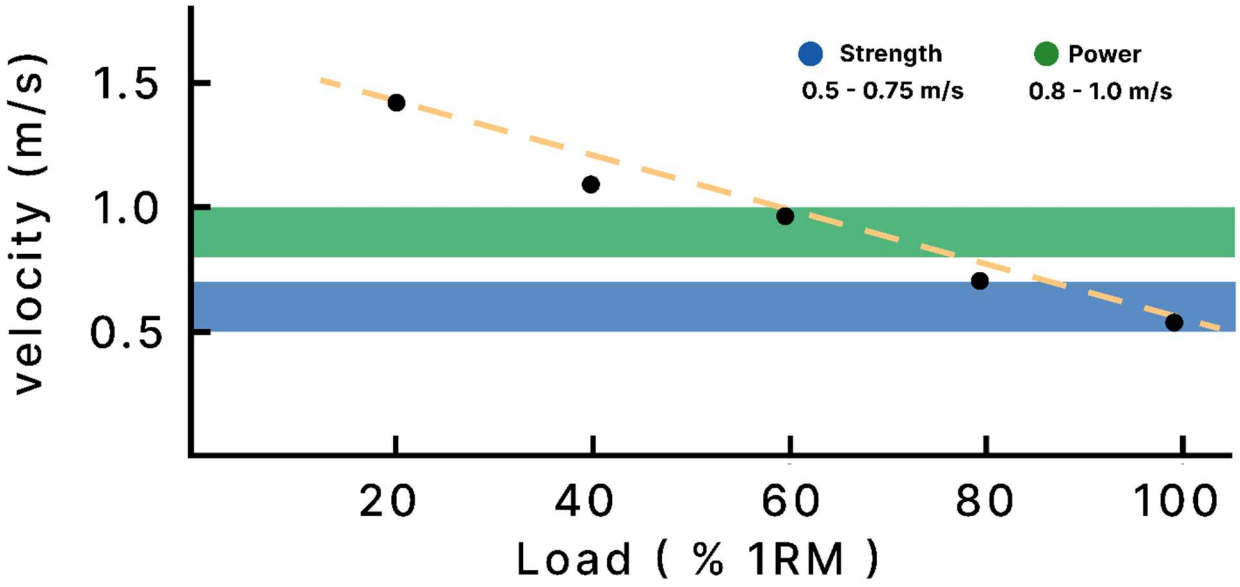
A total of 23 female participants were initially enrolled in the study, of which 17 completed the intervention. The participant characteristics at baseline were as follows: body weight = 64.5 ± 9.1 kg, height = 1.69 ± 0.06 m, and age = 22.0 ± 3.7 years.

The intervention was integrated into regular training and consisted of brief 30-min sessions focused on back squats and trap bar deadlifts. Key performance metrics included neuromuscular adaptation, sprint speed, jump performance, stop-and-go performance, and load-velocity profiles. Seventeen participants completed 12 training sessions, a strength block set (Sessions 1–6) and a power block set (Sessions 7–12).

Autoregulative VBT Framework: The intervention was divided into two distinct blocks to target specific neuromuscular adaptations (strength and power development). Velocity was the primary target for load adjustments. If three (Strength) or five (Power) repetitions fell outside the target velocity range, the load for the next set was adjusted by ±5 kg.

For the regression model the change in velocity and load was used as independent variable to predict change in movement velocity and estimated one repetition maximum.

Results



The predictive models explained 54% to 79% (R2 = 0.54–0.79) of the performance improvement in the strength-related tests. Significant gains were observed in neuromuscular metrics, including estimated one-repetition maximum and movement velocity for both exercises.

Discussion

These findings underscore the predictive potential of VBT for enhancing strength and power, while emphasizing the importance of integrating task-specific exercises to optimize sport-specific performance. The proposed VBT framework introduces a novel approach to make capturing metrics meaningful. Load and mean concentric velocity, from VBT measurements, substantially improving model accuracy. Overall, this study provides valuable insights for tailoring VBT strategies to predict performance adaptations in high-demand team sports such as floorball.

Next, we aim to extend the current methodology by applying machine-learning or deep learning models, supported and fine-tuned through the OpenSim framework, to predict anatomical adaptations over time.

[5]Departments of Biological Sciences and Biomedical Engineering, University of Southern California, Los Angeles, California, United States

Introduction

Unlike everyday manual wheelchair propulsion—where individuals contact the handrim—wheelchair basketball (WCBB) athletes contact the tire tread, altering upper-limb loading and increasing the mechanical demands needed for rapid changes in speed, direction, and intensity. Although WCBB propulsion is multifactorial and difficult to predict, upper-limb strength may be a key determinant.[1-2]

This study investigated the ability of three measures of upper-limb function - grip strength, dominant arm girth, and medicine ball throw distance - to predict performance on three common WCBB assessments: the Illinois Agility Test (IAT), a full-court sprint (FCS), and the 6-minute push test (6MPT).

Methods

Data were collected from (n=16) competitive WCBB athletes during early-season fitness screening. Upper limb strength was assessed with three measures: average grip strength (hand force), dominant arm girth (bicep size), and medicine ball put (distance) were measured. Participants then completed FCS (straight-line maximal-speed push with one 180° turn), IAT (agility-focused obstacle course), and 6MPT (endurance assessment of maximal distance covered on an oval track). The contribution of each measure to IAT, FCS, and 6MPT were assessed using backwards regression; semi-partial correlations compared predictive importance.

Results

Dominant arm girth and medicine ball throw distance were moderate predictors of FCS and IAT performance (up to 44% of variance; Table 1). 6MPT performance had weaker relationships, with grip strength and medicine ball throw distance accounting for 24–32% of variance. Due to a small sample size, models did not reach statistical significance (p = 0.09–0.39). However, effect sizes indicate task-specific associations between upper-limb strength measures and WCBB performance: power and arm size relate more to sprint/agility, whereas endurance is less influenced.

Discussion

Measures of upper-limb function had predictive value across performance assessments, although no single measure consistently predicted performance. These findings underscore the multifactorial nature of WCBB performance (including athlete impairments, propulsion techniques, equipment, and task demands) and highlight the need for targeted training strategies: prioritizing explosive strength and power training to improve agility and sprint performance, and further identifying endurance-specific factors to improve sustained mobility.

No Relation Between Maximum Hip Abductor Strength and Fatigue-Induced Changes in Hip Adduction Angles During a Near-Maximum 10 Km Run

M.Sc. Laila Sikeler, B. Eng. Mario Kanjuh, M.Sc. Luca Braun, M.Sc. Carlo von Diecken, M.Sc. Bastian Anedda, M.Sc. Sebastian Rehorst, M.Sc. Janina Helwig, Prof. Steffen Willwacher

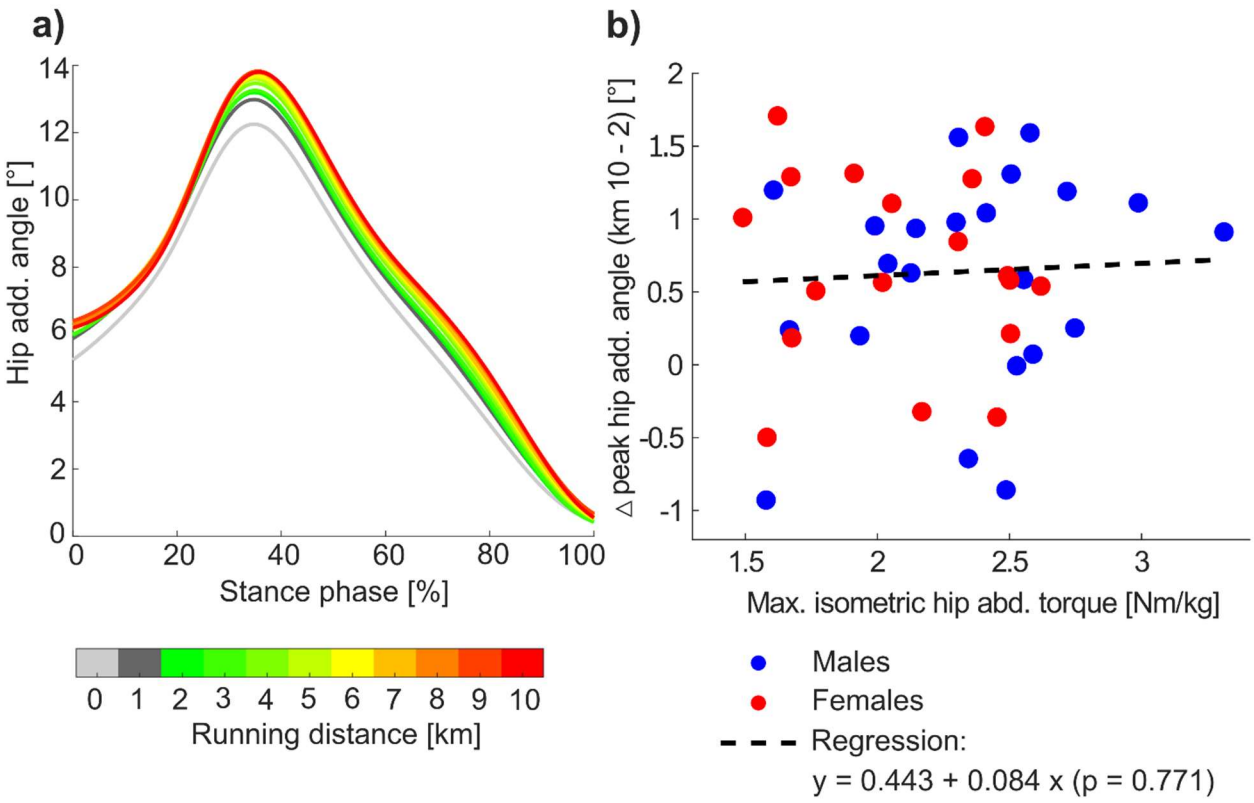
Institute for Advanced Biomechanics and Motion Studies, Offenburg, Baden-Württemberg, Germany

Introduction

Some running overuse injuries are associated with reduced hip abductor strength and increased peak hip adduction angles ($HipAdd_{peak}$) during running. However, there is no evidence supporting a consistent relationship between hip abductor strength and $HipAdd_{peak}$. Fatigue may modify this relationship, as prolonged running increases $HipAdd_{peak}$, potentially due to the inability to meet the required hip abduction force demands. Whether individuals with lower hip abductor strength exhibit larger fatigue-related increases in hip adduction angles remains unknown. Clarifying this relationship may help explain why runners differ in the magnitude of fatigue-related kinematic changes.

Methods

Marker-based kinematics of 40 healthy runners (18 females) were recorded throughout a near-maximum 10 km treadmill run (5% slower than personal 10 km best time (50:45 ± 08:16 min:s)), with 30-second measurement intervals collected at every kilometer. Perceived exertion (CR10 Borg scale) was reported every 2 kilometers. Blood lactate was sampled before and immediately after the run. Maximum isometric torque of the hip abductors (HipAbd Torque), ankle inverters, plantar flexors, and leg extensors was assessed on a separate day using an isokinetic dynamometer. A linear regression model was used to examine whether HipAbd Torque predicted fatigue-induced changes in $HipAdd_{peak}$ between kilometer 2 and 10 ($\triangle HipAdd_{peak}$) while controlling for post-run lactate, post-run perceived exertion, running speed, body weight, and sex.



Results

Fatigue was confirmed by increases in perceived exertion (2.45 ± 1.11 to 8.33 ± 1.23) and lactate concentrations (1.64 ± 0.34 to 3.85 ± 1.50 mmol/L). $HipAdd_{peak}$ increased by 0.6 ± 0.7° from kilometer 2 to 10 ($p<0.001$; Figure 1a). In the regression analysis, HipAbd Torque did not predict $\triangle HipAdd_{peak}$ after adjusting for covariates ($\beta=0.052$, $p=0.771$, adjusted $R^2=0.00$), and none of the covariates were significant predictors (all $p>0.05$; Figure 1b).

Discussion

While our results indicate a systematic and significant increase in hip adduction angles during the run, changes are small, likely not clinically relevant, and unrelated to maximum hip abductor strength. In general, investigating how the strength of other muscle groups relates to other fatigue-induced biomechanical changes (e.g., the relationship between plantar flexor strength and joint work redistribution) may clarify the interplay between muscular capacity and fatigue responses in running.

Improving an Elite-Athlete's Cutting Movement Assessment Score May Improve Their Cutting Performance in Addition to Reducing Their Risk of Injury.

Dr. Evan Dooley PhD[1], Mr. Cody M. O'Cain MS[1], Ms. Anna C. Workman BS[1], Dr. Rachel H. Teater PhD[1], Mr. W. Brody Hicks MS[1], Dr. Kristy B. Arbogast PhD[2], Dr. Laura C. Schmitt PT, PhD, FAPTA[3], Dr. Gwansik Park PhD[1]

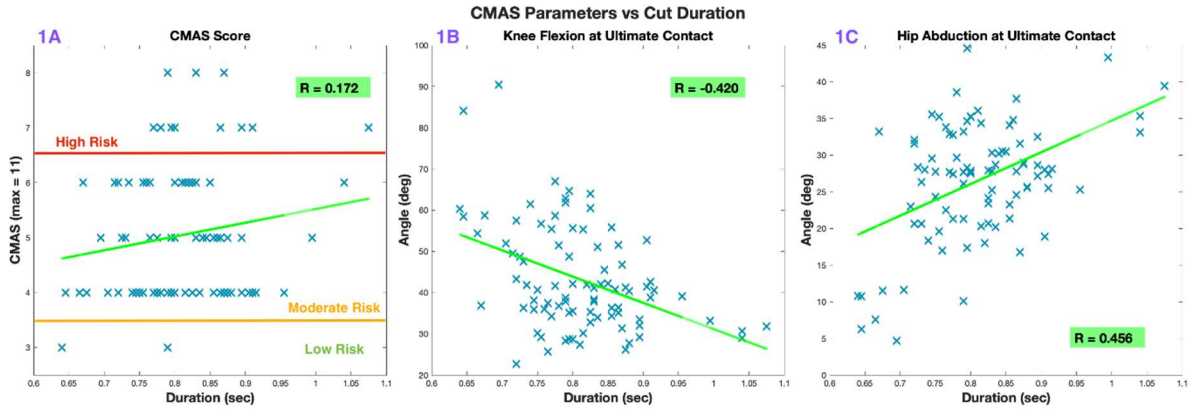
[1]Biomechanics Consulting and Research (Biocore), LLC, Charlottesville, Virginia, United States. [2]Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, United States. [3]The Ohio State University, Columbus, Ohio, United States

Introduction

The Cutting Movement Assessment Score (CMAS) is a screening tool that aims to identify movement patterns during cutting that are associated with a high-risk of injury [1]. CMAS may provide practitioners a quick and straightforward way to assess the injury risk of athletes. However, some higher-risk cutting mechanics, like a wider foot plant, may enhance the athlete's performance. Performance is paramount at the elite level, so modifications to an athlete's mechanics must enable them to execute at their highest levels. This work investigates whether performance suffers from using safer mechanics.

Methods

Fourteen elite American football players (age: 28.6 ± 4.5 years; height: 184.5 ± 6.0 cm; weight: 96.3 ± 14.1 kg) performed cutting maneuvers at game speeds [2] and were captured with marker-based motion capture (Vicon, 200 Hz). The postures included in CMAS were quantified from these cuts then scored according to literature-based thresholds, where higher scores indicate higher risk cuts. Cut performance was assessed by the total duration of the cut (time from antepenultimate foot strike to completing the ultimate stride), where faster cuts were considered better performance.



Results

Higher CMAS scores were not correlated with faster cuts (Figure 1A), indicating increased risk does not lead to increased performance. Most of the postures included in CMAS were not related to performance. There was a trend towards faster cuts being executed with a more flexed knee and less abducted hip at the ultimate foot strike (Figure 1BC), suggesting that lower-risk movements may be associated with better performance.

Discussion

These initial results in elite athletes suggest that modifying cutting mechanics may reduce injury risk without decreasing performance. Additionally, specific changes to these mechanics may improve cutting performance. For example, landing with greater knee flexion and less hip abduction on the ultimate step keeps the athlete in a safer posture, while also providing greater access to the posterior chain of muscles they need to fire to send them in their new direction of travel. This shows there are specific components of cutting mechanics that reduce injury risk while improving performance.

Preseason Functional Assessments Can Predict Ski Performance in Elite Biathletes

Ms Morgan Koskela, Mr Isaac Burgess MS, Ms Megan Peach DPT, Dr James Becker PhD

Montana State University, Bozeman, MT, United States

Introduction

Functional assessments are commonly used to identify injury risk in high caliber athletes. In paddling sports functional assessments have also been shown to be predictive of performance factors. Whether this predictive ability extends to cross-country skiing is unknown. Therefore, the purpose of this study was to determine if a preseason function assessment provides insight into performance related biomechanical factors while skiing.

Methods

Thirteen biathletes (sex: 7M, 6F, ages: 27.3 ± 3.9 years) from the U.S. National Biathlon team completed the functional assessments. Assessment included measures of dynamic balance (Y-balance test, YBT), active ankle range of motion (goniometry), and isometric hip abductor muscle strength. Following assessment participants roller skied on a treadmill while whole body kinematics were collected using markerless motion capture. Biomechanical variables describing the athlete's ability to balance on the ski and maintain a forward position on the ski were then calculated. Principal component analysis was used to reduce the multiple biomechanical variables to single surrogate variables describing balance and forward lean position and multiple regression was then used to determine whether functional assessment performance predicted the biomechanical variables during skiing.

Results

Mean mediolateral center of mass-ankle inclination angle during the gliding phase (λ = 0.874) and lateral step out distance at ski contact (λ = 0.856) both loaded highly onto the balance surrogate. The regression (R^2 = .405, p = .011) showed that both hip abduction strength (p =.038) and posterior-medial YBT reach distance (p = .008) were predictive of balance on the ski while skiing. Forward lean at pole plant (λ = 0.743) and ankle dorsiflexion at weight acceptance (λ = 0.743) both strongly loaded onto the forward position on ski surrogate. However, regression (R^2 = .055, p = .259) showed that ankle range of motion was not predictive of forward lean on the ski

Discussion

Some aspects from a functional assessment such as hip abductor strength and dynamic balance provide insight into how athletes perform while skiing while others like passive joint range of motion do not. These findings could be used as the basis for developing cross-country specific functional assessments which could be performed in any environment.

Biomechanical Predictors of Future Success Among High School Baseball Pitchers

Dr. Jonathan Slowik PhD, Dr. Glenn Fleisig PhD

American Sports Medicine Institute, Birmingham, AL, United States

Introduction

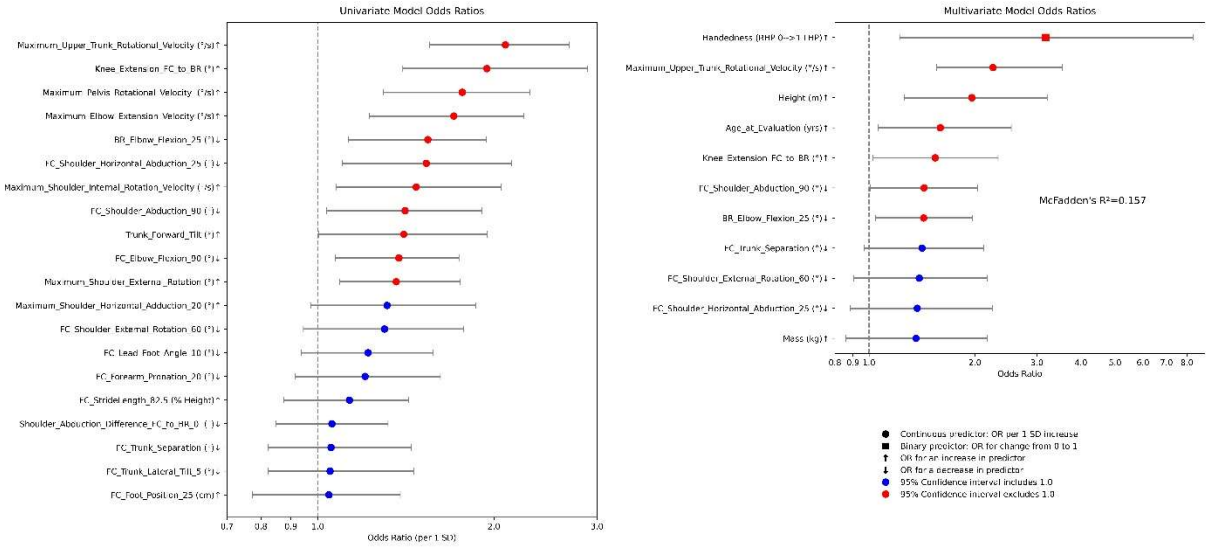
Previous studies have linked pitching biomechanics to indirect success metrics (e.g., ball velocity, reduced elbow loading) [1]; however, direct measures of long-term achievement remain largely unexplored. Thus, this study aimed to identify biomechanical factors associated with reaching the highest levels of competitive pitching.

Methods

Motion capture data from 158 high school pitchers [2] were retrospectively analyzed. Biomechanical variables (Fig. 1) commonly used in pitching evaluations were chosen as predictors, along with confounders of handedness, height, weight, and age. Some variables were raw values (e.g., maximum shoulder external rotation), while others were deviations from target values (e.g., shoulder abduction of 90° at foot contact). Follow-up data on each player's highest subsequent competition level were collected from publicly available records (e.g., league, team, and showcase websites), encompassing eight groups from high school through Major League Baseball.

Statistical analyses were conducted in Python. Continuous predictors were standardized, with binary predictors left unstandardized. Univariate associations with highest competition level (controlling for confounders) were evaluated using ordinal logistic regression with bootstrap resampling (n=500) to estimate odds ratios and 95% confidence intervals. A multivariate model was generated using predictors selected via elastic net regression (5-fold cross-validation) followed by AIC-based backward elimination. A final multivariate ordinal logistic model was fit to remaining predictors, with bootstrap resampling to estimate odds ratios and confidence intervals. Odds ratios below 1.0 were inverted for visual comparison, with relationship direction indicated.

Results



The multivariate model modestly predicted eventual competition level (McFadden's R^2 = 0.157). While the univariate analyses highlighted all four rotational velocities examined, only that of the upper trunk remained in the multivariate model, likely due to correlations across predictors. Across both analyses, maximizing knee extension between foot contact

(FC) and ball release (BR), a shoulder abduction angle 90° at FC, and an elbow flexion of 25° at BR consistently emerged as key biomechanical contributors.

Discussion

These findings highlight specific biomechanical factors that likely contribute to a pitcher reaching advanced levels of competition. Future work may incorporate injury-related follow-up.

Modeling Growth and Remodeling in Tissue-Engineered Heart Valves: Integrating Mechanobiology and Local Density of Macrophages and Tissue-Producing Cells

ir. Justina Ghebryal[1,2], ir. Willem R. Stolk[1,2], prof. dr. ir. Frank P.T. Baaijens[1,2], dr. ir. Sandra Loerakker[1,2]

[1]Department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Noord-Brabant, Netherlands. [2]Institute for Complex Molecular Systems, Eindhoven University of Technology, Eindhoven, Noord-Brabant, Netherlands

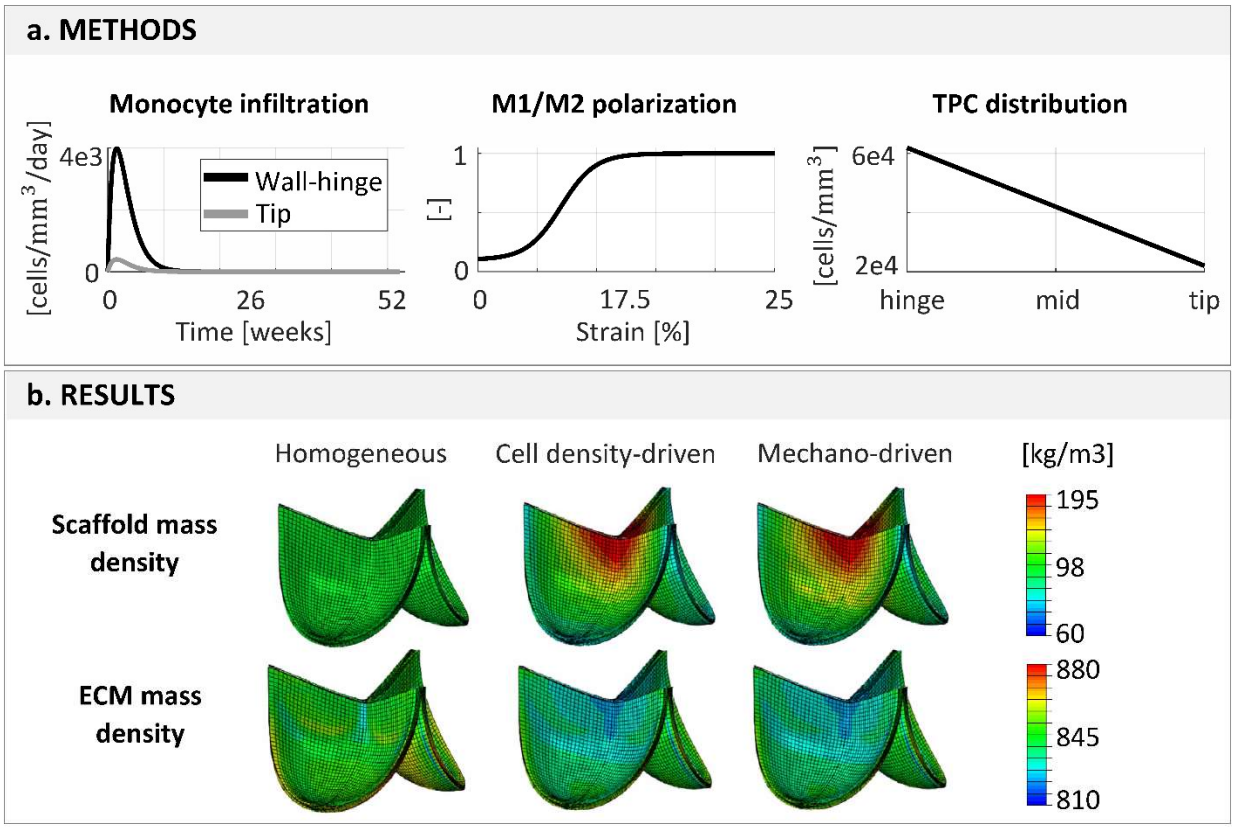
Introduction

Tissue-engineered heart valves (TEHVs) aim to overcome limitations of prosthetic valves by enabling growth and remodeling (G&R) within the patient. Successful regeneration requires balanced scaffold degradation and neo-tissue formation. Yet, long-term in vivo studies show spatial heterogeneity: hinge regions exhibit high cellularity, rapid scaffold degradation, and increased tissue deposition, whereas the tip regions show lower cellularity and slower degradation [1]. These differences lead to local mechanical variations and influence macrophage behavior, as they shift between proinflammatory M1 and anti-inflammatory M2 phenotypes in response to strain [4]. We developed a computational model to investigate how macrophage-mediated scaffold degradation affects mechano-regulated tissue production as a function of local cell density, explaining spatial heterogeneity in TEHV regeneration.

Methods

To analyze G&R of TEHVs, we developed a homogenized constrained mixture model [3,4]. A linear monocyte distribution from hinge to tip and a time-dependent gamma infiltration profile were prescribed [5,6]. Degradation model 1 assumed full M1 polarization driving scaffold loss, whereas model 2 incorporated strain-dependent M1/M2 ratios [4]. Mechano-mediated glycosaminoglycan and collagen production were scaled by spatially varying the tissue-producing cell (TPC) density [5] (Fig. 1a).

Results



The homogeneous model showed relatively uniform scaffold resorption and matrix (ECM) deposition. The cell density-driven model exhibited more degradation and ECM production in the hinge compared to the tip regions. In the mechano-driven model, strain-dependent

macrophage polarization decreased degradation in the mid-belly regions, while ECM production was similar to the cell density-driven case (Fig. 1b).

Discussion

The cell density-driven model reproduced the experimentally observed heterogeneity [1], with faster scaffold degradation and greater ECM deposition near the hinge. The mechano-driven model produced modest regional differences, yielding ECM deposition similar to the cell-driven case. Future work will examine macrophage-TPC interactions and explore different scaffold properties to understand long-term TEHV remodeling.

Introduction

Homogenized constrained mixture models (HCMMs) are widely used to simulate growth and remodeling (G&R) in soft tissues and tissue-engineered cardiovascular constructs [1,2]. Whereas most studies prescribed collagen prestretch values a priori, experimental evidence suggests that prestretch is context-dependent and driven by cellular traction forces responding to mechanical cues [3].

This limitation reduces the ability of HCMMs to generalize across different mechanical environments. To overcome this, we propose a framework that mechanistically defines cell-driven homeostatic collagen stretch and captures its dynamic adaptation to hemodynamic loading.

Methods

We extend previously developed HCMM frameworks by integrating dynamic target and deposition stress for collagen fibers, linked directly to cellular stress-fiber tension [1,2]. Cellular tension is modeled as a combination of active contractility and passive strain stiffening, giving rise to a non-monotonic stress–strain response (Fig. 1a) [4]. G&R simulations were performed in tubular constructs exposed to low (2.7 kPa) or higher (15 kPa) pressure loads, representing vascular grafts implanted in distinct hemodynamic environments.

Results

The results demonstrate a smooth and rapid convergence of G&R toward homeostatic conditions across both deformation regimes (Fig. 1b). The non-monotonic behavior of the

cellular stress led to a counterintuitive result: constructs exposed to the higher pressure experience lower cellular tension, and therefore converged to a smaller homeostatic elastic collagen stretch (λ_e). Despite this, the higher-pressure environment still led to markedly increased matrix deposition, producing thicker graft walls (Fig. 1c). This is consistent with observations that vessels exposed to higher pressures exhibit thicker walls.

Discussion

We successfully incorporated a dynamic collagen prestretch that is directly linked to cellular tension mediated by the mechanical environment. Consequently, the model predicted context-dependent remodeling, characterized by distinct equilibria in collagen stretch. Results indicate that the definition of cellular stress-strain relationships may strongly influence the G&R response, highlighting the need to further explore these relationships. Overall, the model offers a promising method to develop a more generalizable framework for studying G&R.

Distinct Remodeling Responses Emerge Across Sex and Castration Groups in Ovine Tricuspid Valve Leaflets

Dr. Colton Kostelnik PhD[1], Ms. Chien-Yu Lin MS[1], Ms. Shreya Sreedhar BS[1], Dr. Magda Piekarska MD[2], Dr. Boguslaw Gaweda MD[2], Mr. Austin Goodyke MS[2], Dr. Tomasz Timek MD[2], Dr. Manuel Rausch PhD[1]

Introduction

Tricuspid regurgitation (TR) severely impacts more than 1.6 million Americans. Most cases are deemed "functional," suggesting that dysfunction arises only from valve-extrinsic factors like right ventricular remodeling [1]. However, our prior work in pulmonary-hypertensive ovine demonstrated that tricuspid leaflets undergo fibrotic remodeling (i.e., maladapt) resulting in increased size, thickness, and stiffness [2]. Although key questions remain, valvular disease is more common in women, and prior studies have focused exclusively on males. Evidence suggests that testosterone may also influence leaflet remodeling [3]. Therefore, we hypothesized that tricuspid leaflet (mal)adaptation differs across sex and castration status.

Methods

We induced pulmonary hypertension via pulmonary artery banding (PAB) in castrated (C-Male) and non-castrated (NC-Male) males and female Dorset ovine (n = 45). After 12 weeks, leaflets were harvested for structural, mechanical, and transcriptomic analyses. Thickness maps were generated using optical profilometry (Figure 1A). Biaxial mechanical testing of the leaflet belly region was performed under equibiaxial tension. Bulk RNA sequencing was used to evaluate differential expression between PAB and control animals.

Results

Echocardiography confirmed that all groups displayed functional TR. Thickness mapping revealed a 37% increase in mean anterior leaflet thickness in C-Males ($p = 0.002$), whereas females showed a 32% increase, and NC-Males exhibited minimal thickening (Figure 1B). Radial tension–stretch curves demonstrated a stiffer response in female PAB anterior leaflets (Figure 1C). RNA-sequencing identified the largest set of differentially expressed

genes (DEGs) in NC-Males, while females and C-Males showed fewer DEG counts, displaying sex-related differences in the transcriptomic response (Figure 1D).

Discussion

All groups exhibited leaflet remodeling, but the magnitude varied across sex and castration status. The similar structural and transcriptomic remodeling observed in females and C-Males suggests a possible role for testosterone in modulating tricuspid leaflet (mal)adaptation. Ongoing integration of structural, mechanical, and transcriptomic data will help clarify mechanobiological pathways contributing to sex-related differences in TR progression. These findings underscore the importance of sex as a critical factor in understanding valve pathophysiology during TR.

Flow-Mediated Atherosclerotic Growth and Remodeling in Murine Femoral Arteries

Ms. Gloriani Sanchez Marrero[1], Mr. Jake Fernandez[2], Dr. Fujie Zhao[3,4], Dr. Rudy Gleason[1], Dr. Luke Brewster[3,4]

[1]Georgia Institute of Technology, Atlanta, Georgia, United States. [2]Duke University, Durham, North Caroline, United States. [3]Emory University, Atlanta, Georgia, United States. [4]Atlanta VA Medical Center, Decatur, Georgia, United States

Introduction

Peripheral arterial disease (PAD) is the third leading cause of atherosclerotic disease morbidity. PAD often manifests in muscular arteries such as the femoral arteries (FA) in locations of disturbed blood flow (d-flow). Taking into consideration these PAD environmental features (i.e. d-flow, muscular arteries), our research group recently proposed a murine model for PAD [1]. This model uses the partial femoral artery ligation (PFL) surgery to impose pathological blood flows by ligating 4 out of 5 arteries distal to the left FA. Arteries exposed to d-flow undergo arterial growth and remodeling (G&R). The objective of this study is to characterize flow-mediated atherosclerotic G&R in the FA following PFL surgery. Understanding PAD G&R can inform treatment options.

Methods

Five male and five female S129 mice underwent PFL surgery. One week prior, mice were injected with AAV-PCSK9 and introduced to high fat diet to impose hypercholesterolemia [2]. Doppler ultrasound was utilized to measure centerline velocity and vessel diameter at the FAs one day, two weeks, four weeks, and 6 weeks following surgery. During FA dissection, physiological stretch was measured as the ratio of *in vivo* to *ex vivo* length.

Results

Twenty-four hours following PFL surgery, velocity waveforms were dampened in the PFL side when compared to the *in situ* control side (Figure 1A,B). This was confirmed by quantifying average velocity and peak velocity (Figure 1C,D). By the two-week time point, no difference between the FA velocity profiles in the PFL and control sides were found. Atherosclerotic stenosis at the 6-week endpoint was confirmed following dissection. Physiological stretch decreased in the PFL side when compared to the control side (Figure 1E).

Discussion

This novel murine PFL surgery model acutely imposes pathological blood flows in the left FA. Furthermore, under atherogenic conditions the FAs undergo active G&R and normalize velocity profiles. Ongoing work aims to characterize temporal changes to the FA's mechanical properties utilizing biaxial testing.

Images (Optional)

Micro Finite Element Models of the Growth Plate Under Physiological Loading

Ms Camille Gardes, Dr Marta Peña Fernández

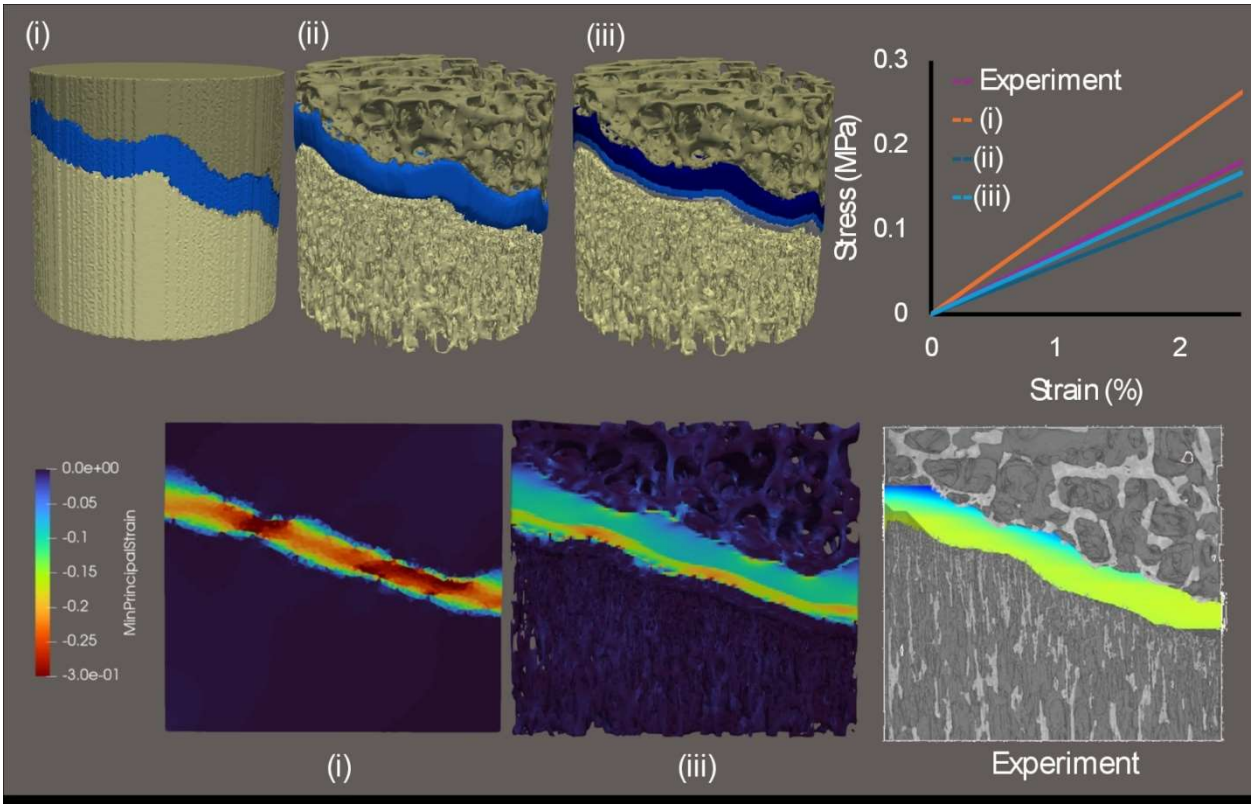
School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, Scotland, United Kingdom

Introduction

The growth plate is a thin cartilaginous layer where longitudinal growth of bone occurs. Growth is regulated by factors, including those arising from mechanical loading, with alterations in the mechanical environment associated to musculoskeletal deformities [1]. Computational models allow to investigate how changes in mechanical stimuli influence growth, however, current models fail to account for the complex microarchitecture and properties of the chondro-osseus junction at the growth plate [2,3]. Here, we develop and validate micro finite element (μFE) models of the bone-growth plate unit to investigate the influence of bone microarchitecture and growth plate cartilage heterogeneity in its mechanical response.

Methods

We performed *in situ* μCT (4μm voxel size) compression testing (2.5%) in ovine bone-growth plate units (5mm). We generated μFE models based on segmented μCT images coarsened to 25μm [4]. Three μFE models were compared: (i) homogeneous bone and cartilage, (ii) heterogenous bone and homogeneous cartilage, and (iii) heterogeneous bone and cartilage (Figure). Bone tissue was modelled as linear elastic (E_0=100MPa, v=0.3) and cartilage as both elastic (E_0= 1MPa, v=0.45) [2] and transversely isotropic poroelastic following [5]. An axial displacement corresponding to 2.5% compression was applied followed by a holding step to allow for stress relaxation.



Results

Homogeneous models resulted in high strain concentration in the growth plate cartilage and overestimation of stiffness (Figure), whereas accounting for bone microarchitecture led to better experimental agreement. Transversely isotropic properties for cartilage allow reduction of excessive transverse deformations observed with linear models. Growth plate heterogeneity improved model predictions, with proliferative and hypertrophic zones showing larger deformations than reserve zone.

Discussion

Our results highlight the importance of bone microarchitecture and heterogeneous non-elastic cartilage properties for growth plate strain predictions, which are typically neglected in bone growth simulations [2,3]. These μFE models can be exploited to provide new insight into the mechanical factors that regulate growth plate ossification, enabling predictions of local mechanical environmental under different loading conditions.

A New Isobaric Mapping Method for the Bone Vascular network.

MD Corentin Serra[1], Prof Natacha kadlub[2,3], Prof Romain Monchaux[1], Associate Professor jean boisson[1]

[1]Laboratory of Mechanics and Interfaces, ENSTA, IP-Paris, Paris, Ile de France, France. [2]Faculté de santé, Université Paris Cité, Paris, Ile de France, France. [3]Maxillofacial and Plastic Surgery, Necker Children Hospital, APHP, Paris, Ile de France, France

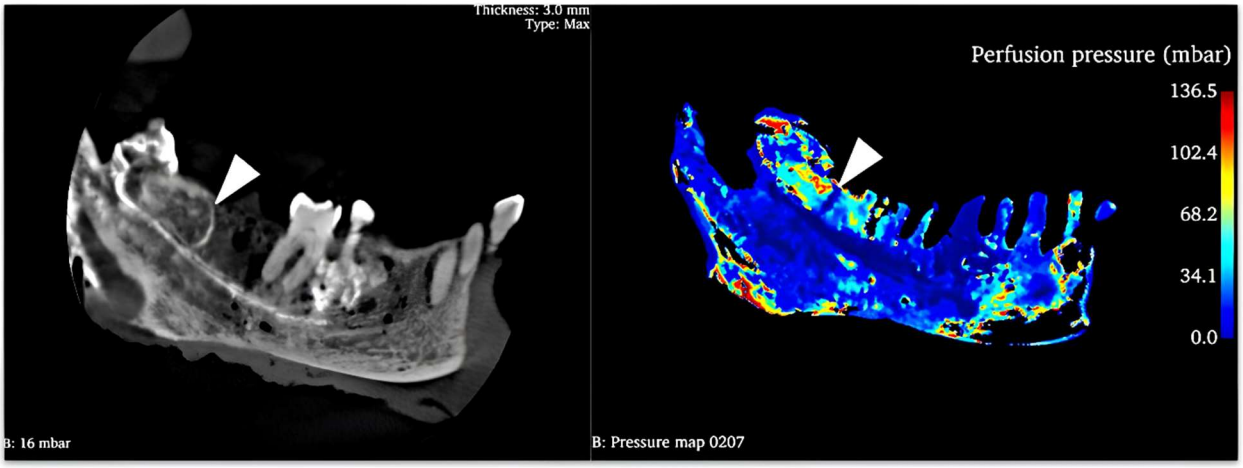
Introduction

The vascularization of bone remains largely unknown, yet it is crucial to future developments in reconstructive surgery. For example, in decellularization protocols for bone allografts, precisely tuning perfusion parameters is essential to completely remove all traces of DNA. However, traditional anatomical techniques have difficulty determining the perfusion dynamics of multiple arterial bones, such as the mandible. This study introduces a new method of examining pressure-dependent vascular territories to overcome these limitations.

Methods

We performed contrast agent perfusions on human cadaveric mandibles using an experimental setup that controlled the applied pressure with flow rate adaptation. We used cone beam computed tomography to measure the expansion of the perfused territories for each pressure increment. We identified each newly explored volume at each pressure increment using a custom segmentation pipeline that subtracted the current image from the previous increment. Ten mandibles from six French Caucasian cadaveric donors that were symmetrically dissected were studied. Then, individual pressure maps showing to perfuse different regions of the mandible were generated. An averaged map was finally reconstructed by projecting the ten maps onto a typical mandible mesh.

Results



We found that the maxillary artery consistently supplies the entire mandible, with a significant and predictable increase in perfusion volume as pressure rises. Perfusion saturation was achieved at approximately 100–125 mbar, which is consistent with physiological arterial pressures. The study confirms that regions of high bone density, such as cortical areas, require higher perfusion pressure. Additionally, the results suggest different perfusion behaviors in the retromolar area and post-extraction tooth sockets.

Within the studied pressure range, the theoretical perfusion of the mandible from the maxillary and facial arteries appears to be equivalent. However, it is limited by a bottleneck effect at the mental artery anastomosis.

Discussion

These results demonstrate that pressure-driven perfusion analysis provides valuable information about the vascularization of complex bone. Optimizing pressure parameters may enable decellularization by perfusion in massive bone allografts, thereby improving graft integration and viability. This study highlights the importance of pressure-controlled anatomical research because perfusion territories vary significantly with applied pressure, challenging traditional static angiosome models.

Neutral Pose Normalization May Misrepresent Tibiotalar Kinematics in Clinical Populations

Ms Emily Smith-Bregeda[1,2], Mr Robert Chauvet[1,2], Ms Janae Ruzicki[1,2], Dr Elizabeth Condliffe[3], Dr Koren Roach[1,2,4]

[1]Schulich School of Engineering, University of Calgary,, Calgary, Alberta, Canada. [2]McCaig Institute for Bone and Joint Health, Calgary, Alberta, Canada. [3]Alberta Children's Hospital Research Institute, Calgary, Alberta, Canada. [4]Cumming School of Medicine, University of Calgary, Calgary, Alberta, Canada

Introduction

Joint angles are often normalized to a static neutral pose to account for inter-subject anatomical variability, though this method could be detrimental to clinical interpretation. Specifically, when investigating the tibiotalar joint with dual fluoroscopy (DF), individuals who are more dorsiflexed or plantarflexed in their neutral pose may seemingly exhibit resultant joint angles with a baseline offset. This offset may misleadingly represent a joint angle as positive or negative, indicating a motion that is physiologically improbable for that individual. The purpose of this case study was to explore how neutral normalization affects tibiotalar joint angles in healthy controls and individuals with a foot deformity.

Methods

Eight typically-developed control participants (5F/3M; age: 37.9±18.9 yrs; BMI: 23.2±3.6 kg/m^2; REB19-1743), and one participant with plantarflexion contracture foot deformity (F, age: 31.1 yrs; BMI: 29.2 kg/m^2) were recruited (REB23-1432). DF data were collected for neutral (i.e., static) and walking (i.e., dynamic) trials. Computed tomography (CT) scans were acquired and segmented. CT bone models were registered to the DF data to compute tibiotalar kinematics. To assess the effect of neutral normalization, each dynamic relative transformation matrix ("raw") was normalized by post-multiplying with the inverse of the neutral relative matrix ("normalized"). Baseline offset angles were compared between raw and normalized waveforms for control participants using a paired t-test. Positive and negative waveform components for the participant were calculated as positive and negative percent of stance phase.

Results

For the controls, the normalized trials showed a greater baseline offset than raw trials ($p<0.01$). Similarly, the raw baseline offset in the contracture participant was -16°, compared to an offset of -5° when normalized. The contracture participant spent 100% of stance in plantarflexion in the raw condition, compared to only 22% of stance in plantarflexion when normalized (Fig 1).

Discussion

Although the participant had a contracture preventing dorsiflexion, normalized tibiotalar joint angles suggested they were dorsiflexed during 78% of stance. When comparing to a control population, the use of neutral normalization may misrepresent pathology. Similar results were observed in control participants offsets, other joints and planes, suggesting that neutral normalization may not be appropriate for DF analysis, especially for clinical populations.

Images (Optional)

Feasibility of MRI for Tibial Strain Estimation in Physically Active Adults

Dr Olivia L Bruce, Dr Feliks Kogan

Department of Radiology, Stanford University, Stanford, CA, United States

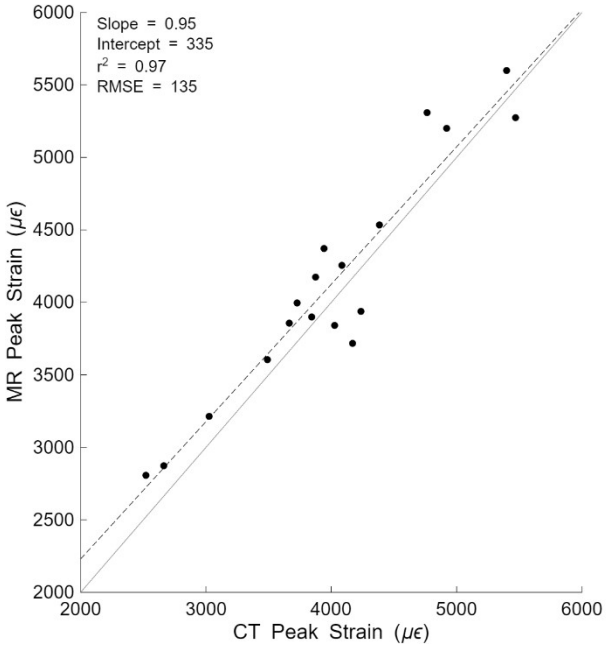
Introduction

Strain is a key factor associated with bone adaptation and the pathophysiology of bone stress injuries [1]. Finite element modelling using computed tomography (CT) is the current state-of-the-art approach to quantify strain [2]. However, CT is not always available and involves exposure to ionizing radiation. Magnetic resonance (MR) imaging is a potential alternative and would enable opportunistic studies of mechanical risk factors in patients with possible bone stress injuries. The purpose of this study was to evaluate correlations in tibial diaphysis strain measures between finite element models generated from MR and CT images.

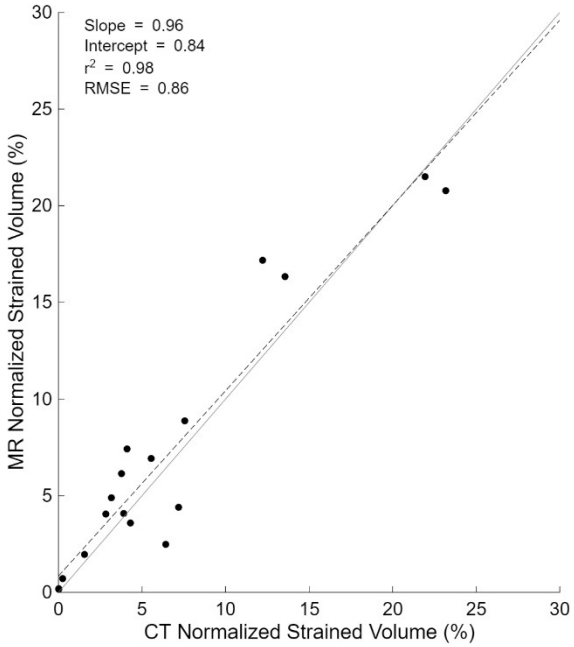
Methods

Nine physically active adults (18-56 years) underwent bilateral CT and MR scans of the lower leg. Finite element models of the left and right tibia-fibula with complex boundary conditions and generic muscle and joint contact forces representative of running were generated [2]. The CT-based models were assigned heterogeneous material properties derived from the underlying Hounsfield units and a calibration phantom placed in each scan. The MR-based models used homogeneous material properties for cortical bone, trabecular bone, and marrow regions. Peak pressure-modified von Mises strain and strained volume, defined as the volume of elements experiencing at least 4000 με, normalized to diaphysis volume, were calculated. Correlations were assessed using linear mixed models to account for non-independence of cases.

Results



Surface geometry root mean square differences were small (0.85 – 1.11 mm). Mean cortical bone mineral density across participants ranged from 1.83 – 2.00 g/cm^3. Young's modulus differences through the diaphysis were -0.2 to 1.2 GPa. Both peak strain and normalized strained volume measures were very strongly correlated between MR- and CT-based models (slope = 0.95-0.96, r^2 = 0.97-0.98, Figure 1).



Discussion

Our results suggest that MR is a feasible alternative to CT for finite element modelling of tibial bone strain in physically active adults. This may not be generalizable to studies

involving larger variations in bone density (e.g., comparing runners with and without osteopenia). Future work will investigate adding individualized material property estimates derived from quantitative MR approaches.

Laplace-Hamming Segmentation Changes Clinical Interpretation of HR-pQCT Microarchitecture and Strength Outcomes in Children With Osteogenesis Imperfecta and Healthy Controls

Dr. Seyedmahdi Hosseinitabatabaei PhD[1,2,3], Dr. Minhao Zhou PhD[4], Dr. Frank Rauch MD[1,5], Dr. Galateia Kazakia PhD[4], Dr. Bettina Willie[1,2,3,6]

[4]Department of Radiology and Biomedical Imaging, University of California, San Francisco, San Francisco, California, United States. [5]Department of Pediatrics, McGill University, Montreal, Quebec, Canada. [6]Department of Biomedical Engineering, McGill University, Montreal, Quebec, Canada

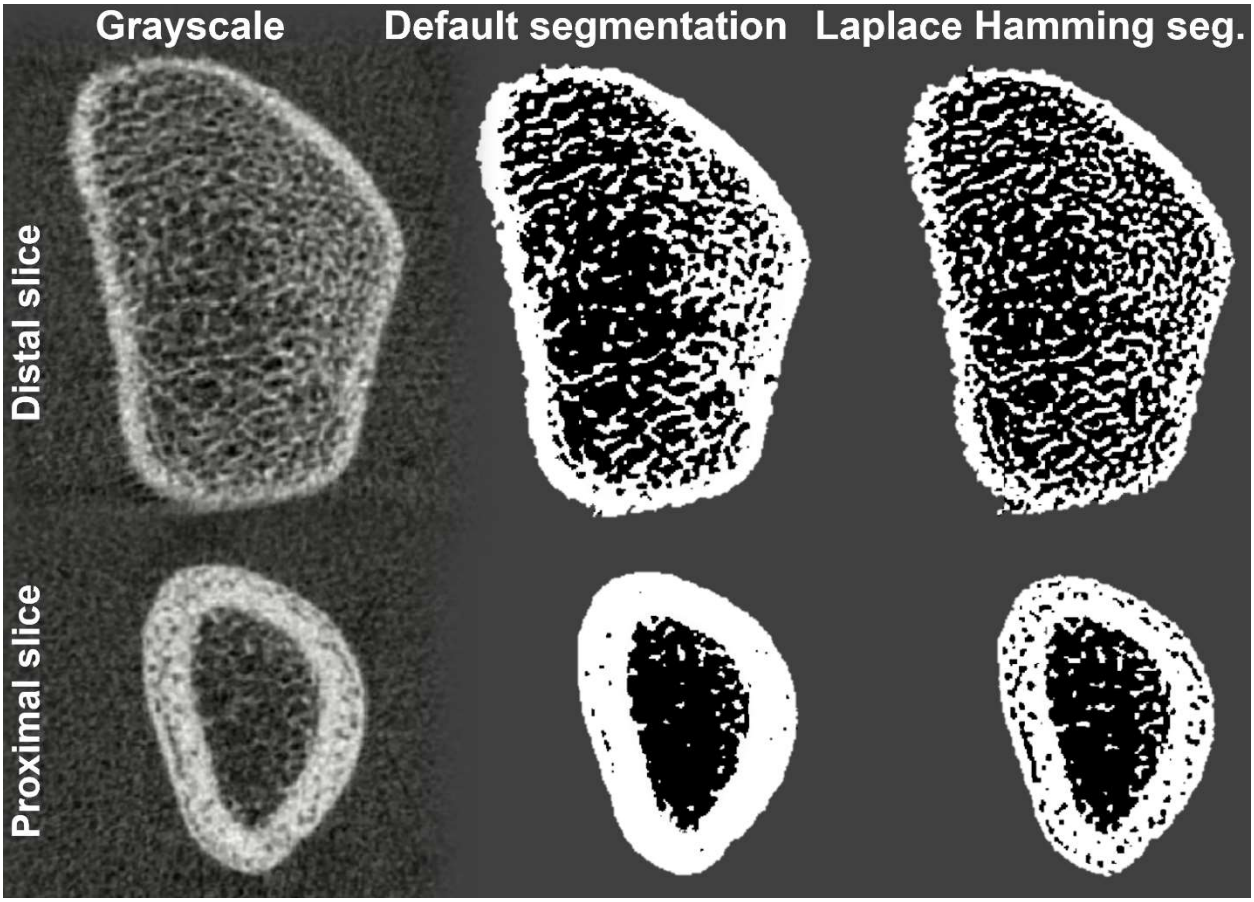
Introduction

High-resolution peripheral-quantitative CT (HR-pQCT) combined with micro-finite element (μFE) models is a powerful tool for assessing bone quality and fracture risk. A Laplace-Hamming (LH) segmentation method has improved microarchitectural accuracy in adults [1]. We investigated its impact in children with osteogenesis-imperfecta (OI) and healthy controls by comparing with data collected using standard segmentation method [2].

Methods

Radius and tibia scans from 20 children with OI and 20 age- and sex-matched controls were obtained using a second-generation HR-pQCT scanner. Microarchitectural and μFE outcomes were derived using both the default (low-pass Gaussian filter) and LH-segmentation. Absolute differences between segmentation methods were assessed using paired t-tests with Benjamini-Hochberg correction. Clinical impact was evaluated by comparing baseline OI vs control differences and 1-year changes using linear mixed-models.

Results



All HR-pQCT and μFE outcomes differed significantly between segmentation methods ($p<0.05$). Cortical porosity (Ct.Po) showed the largest discrepancy, with LH producing 700% and 1250% higher values at tibia and radius, respectively (Figure). Trabecular outcomes differed systematically: LH yielded higher trabecular bone volume fraction (Tb.BV/TV) and number (Tb.Th), and lower thickness (Tb.Th), separation (Tb.Sp), and inhomogeneity (Tb.1/N.SD), with average differences of 9–19% at both sites. Cortical thickness (Ct.Th)

decreased with LH, and estimated bone strength was 6–8% lower. Importantly, LH segmentation altered clinical interpretations. At tibia, only LH detected significant between-group differences in 1-year changes for Tb.BV/TV and Ct.Po, while baseline differences in Tb.N and Tb.Sp were no longer significant with LH. At radius, only LH detected significant group differences in 1-year changes for Tb.BV/TV, Tb.Th, and Ct.Po, and detected baseline differences in Tb.Th and Ct.Th that were not observed using the default method.

Discussion

For these second-generation HR-pQCT images, LH segmentation led to different clinical interpretations for several key outcomes compared to the default method. While strength estimates showed similar directional findings, absolute changes were noticeable. In the absence of microCT gold standards, visual assessment and prior adult data support improved segmentation using LH in children with OI and controls. These results strengthen the evidence that LH offers a more accurate alternative for clinical HR-pQCT evaluation.

Reliability of Measuring Meniscal Extrusion in Weightbearing Using Upright Open Magnetic Resonance Imaging

Dr. Jordan Broberg Ph.D., Dr. Honglin Zhang Ph.D., Dr. Parth Lodhia M.D., Dr. David Wilson D.Phil.

University of British Columbia, Vancouver, British Columbia, Canada

Introduction

Meniscal extrusion, defined as abnormal translation of the meniscus beyond the edge of the tibial plateau, is a radiological finding on magnetic resonance imaging (MRI) that suggests altered mechanical function of the meniscus, putting the knee at risk for osteoarthritis. Since menisci distribute loads across a range of knee motion, measuring extrusion in weightbearing and flexed positions would give better insight into mechanical changes caused by injury and treatment. Upright open MRI allows for knee imaging in weightbearing and flexed positions. Our goal was to assess the reliability of measuring meniscal extrusion in weightbearing and flexed positions with an upright open MRI protocol.

Methods

We recruited four healthy participants (3 female/1 male, ages 24-28) and scanned both their knees in four postures with a 0.5T upright open MRI scanner. Each participant had two identical scanning sessions for reliability analysis. Dixon sequences were used to obtain coronal images of the knee. The postures were: a) supine with knees extended; b) unloaded seated at 90° of knee flexion; c) weightbearing standing with knees extended; and d) weightbearing assisted squat with knees flexed to 90°. A MRI-compatible sloped seat supported participants in assisted squatting while still allowing for loading and muscle activation. Medial and lateral meniscal extrusions were calculated on a midcoronal slice as the distance between the edge of the tibial plateau and the external edge of the meniscus. Test-retest reliability was reported using intra-class correlation coefficients (ICC) and standard errors of measurement (SEM).

Results

Mean medial extrusion was 2.50 mm for supine, 1.87 mm for sitting, 2.86 mm for standing, and 2.05 mm for assisted squatting. Mean lateral extrusion was 0.72 mm for supine, 1.21 mm for sitting, 0.39 mm for standing, and 0.67 mm for assisted squatting. ICCs ranged from 0.75-0.96 and SEM ranged from 0.26-0.37 mm (Table 1).

Discussion

Pathological extrusion is around 1 mm greater than normal extrusion for both the medial and lateral meniscus. Our upright open MRI protocol is therefore sufficiently reliable to detect the clinically significant differences in meniscal extrusion in weightbearing and flexed knee positions, making it feasible to study effects of meniscal injury and repair techniques.

Images (Optional)

Table 1. Medial and lateral meniscal extrusion reliability.

	Medial		Lateral	
Posture	ICC	SEM (mm)	ICC	SEM (mm)

Prediction of Hip Impact Force From Video-Captured Falls Using Pose-Estimated Kinematics

Mr. Reese Michaels M.S., Dr. Yaejin Moon PhD

Syracuse University, Syracuse, NY, United States

Introduction

Falls are the leading cause of hip fractures among older adults [1,2]. Hip fracture occurs when impact forces exceed the injury threshold of bone [3], yet measuring hip impact force during laboratory falls is challenging due to safety constraints [4]. AI-based pose estimation can extract impact kinematics from video, which machine learning can use to estimate ground reaction forces [5,6]. We evaluated whether pose-estimated kinematics could predict hip impact force in older adult falls, hypothesizing that pose-based models would outperform demographic/observational features and approach IMU performance.

Methods

We analyzed 69 sideways fall trials from 11 older adults (8 male, age=62.6±3.8 years) collected using synchronized video (30 Hz), inertial measurement units (IMU), and force plates [7]. Hip impact velocity, acceleration, and knee flexion angles were extracted using OpenPose and WHAM. Four feature sets were tested: demographic + observational, pose-only, demo + obs + pose, and IMU-only. Models were trained with leave-one-participant-out cross-validation and evaluated using R^2 and mean absolute error (MAE). Prediction errors were compared with repeated-measures ANOVA (Bonferroni-corrected).

Results

The IMU-only model achieved the strongest performance (R^2=0.89; MAE=0.21±0.17 BW). Pose-only features achieved moderate accuracy (R^2=0.68; MAE=0.37±0.27 BW) and improved slightly when demographics and observational features were added (R^2=0.70; MAE=0.35±0.27 BW), outperforming demographics + observational alone (R^2=0.47; MAE=0.48±0.36 BW; p=0.02).

Discussion

This is the first study to predict hip impact forces from video-captured older adult falls. The pose-only model did not match IMU accuracy but added meaningful predictive value, improving performance over demographics and observational features. Notably, model error (MAE=0.35 BW ≈ 270 N) represents only ~4–7% of forces associated with hip fracture

risk (4050 – 6420 N) [3], supporting the potential of video-based approaches. Improving acceleration estimation remains a key target for future work.

Images (Optional)

Using Instrumented Mouthguards to Detect Concussions: Preliminary Findings in Men's Rugby League

Dr James Tooby[1], Dr Cameron Owen[1], Dr Dane Vishnubala[2], Mr Matthew Kitchin[1], Dr Gemma Phillips[3], Professor Kevin Till[1], Professor Ben Jones[1]

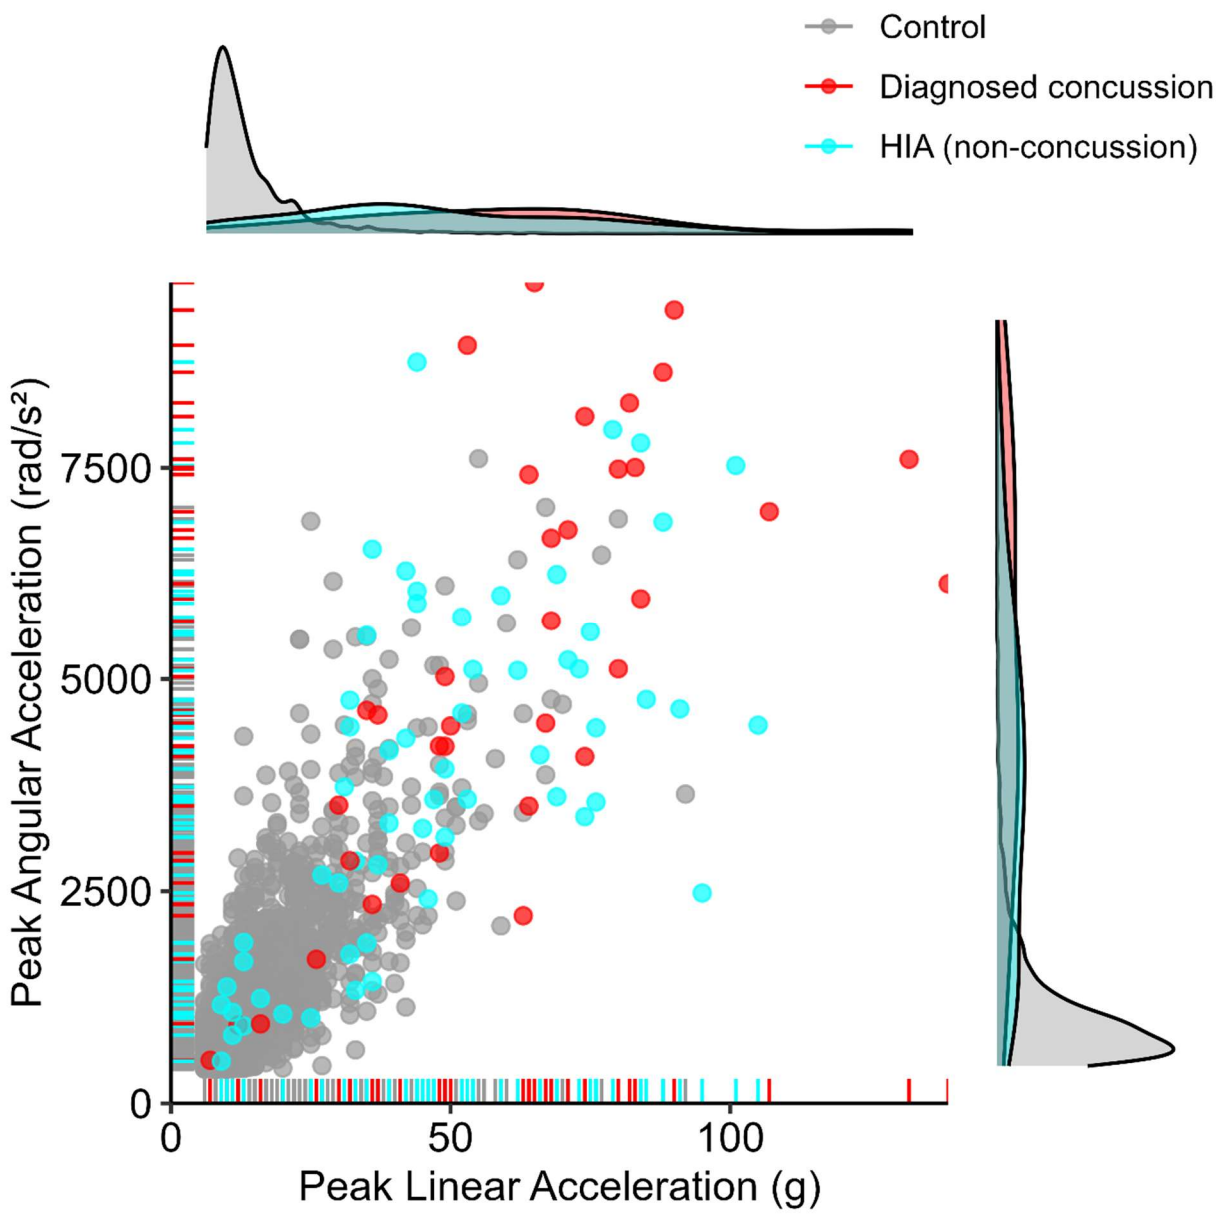
[1]Leeds Beckett University, Leeds, West Yorkshire, United Kingdom. [2]University of Leeds, Leeds, West Yorkshire, United Kingdom. [3]Rugby Football League, Manchester, Greater Manchester, United Kingdom

Introduction

The Head Injury Assessment (HIA) protocol is used in rugby league to identify and diagnose concussions. Pitchside doctors initiate the HIA process based on visible signs and symptoms of potential concussion. Instrumented mouthguards (iMGs) record head kinematics during head acceleration events (HAEs), providing objective data that may enhance this process. This study aims to evaluate how well iMG severity measures distinguish HAEs that resulted in HIAs, and further, between HIAs that led to concussion diagnoses.

Methods

A prospective observational study was conducted during the Men's Super League 2025 season, with 73.7% (n=278) of players wearing validated iMGs capturing head kinematics. HAEs linked to each HIA were identified through video analysis by a trained analyst and medical doctor. Among 199 HIAs recorded, iMG data for peak linear acceleration (PLA) and peak angular acceleration (PAA) were available for 47.7% (n=95), with 36 diagnosed concussions. HAEs not resulting in HIAs were selected from the same players and matches (n=2,644). ROC curve analysis assessed PLA and PAA diagnostic performance.



Results

Median (interquartile range [IQR]) PLA and PAA for HAEs resulting in HIA were 49*g* (33-74) and 4,301rad/s^2 (2,596-5,981) compared to 11*g* (9-16) and 885rad/s^2 (630-1,315) for HAEs not associated with HIAs. Among HAEs resulting in HIA, those with diagnosed concussion had PLA and PAA values of 64*g* (39-80) and 4,828rad/s^2 (3,226-7,452), respectively, versus 44*g* (32–69) and 3,728rad/s^2 (2,024-5,199) in non-concussion HIAs. ROC analysis showed excellent accuracy of PLA (AUC: 0.92) and PAA (AUC: 0.92) for distinguishing HAEs leading to HIAs, but poor accuracy (AUC < 0.7) for discriminating concussion diagnosis.

Discussion

Preliminary results suggest iMG-derived PLA and PAA are promising for identifying HAEs warranting medical review; however, concussion diagnosis thresholds based solely on these measures remain elusive. Some HIAs and diagnosed concussions are associated with low-magnitude HAEs (see Figure 1), indicating that detection and diagnosis should not rely exclusively on iMG data. Current analyses focus on 199 HIAs from the Men's Super League 2025 season, with ongoing work incorporating over 300 additional HIAs from other seasons and competitions, including women's leagues. Future analyses will include expanded severity metrics such as brain strain modeling.

OA6-04

Spatial and Positional Patterns of Video-Verified Head Impacts in Men's Collegiate Ice Hockey

Dr. Rebecca Kenny, Mr. Arman Mehrrostami, Dr. Adam Clansey, Mr. Daniel Bondi, Mr. Zaryan Masood, Mr. David Luke, Dr. Lyndia Wu

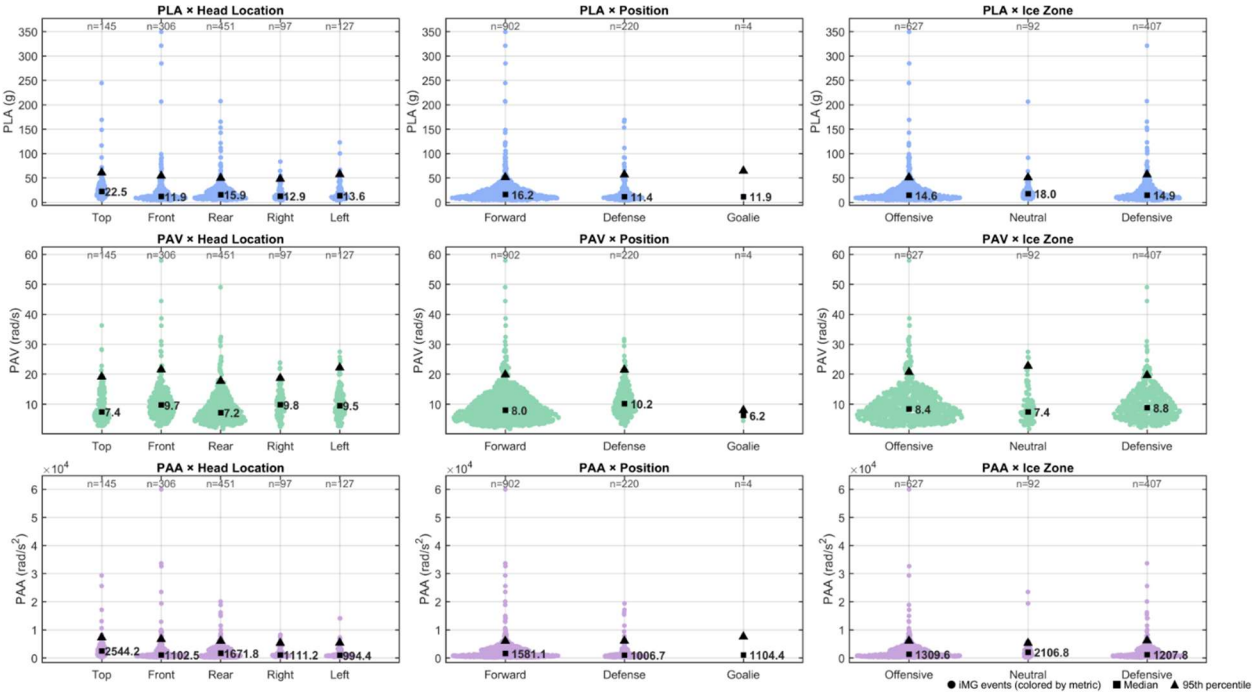
University of British Columbia, Vancouver, BC, Canada

Introduction

Head impacts in ice hockey contribute to acute concussion risk and cumulative neurological load. Instrumented mouthguards (iMGs) can quantify head kinematics but require video verification to distinguish true impacts from artifacts. This study combined iMG data with synchronized multi-angle video to characterize verified head-impact exposure across two seasons of collegiate men's ice hockey, with emphasis on positional, spatial, and head-location patterns.

Methods

Head impacts were recorded using Prevent Biometrics iMGs. All device-triggered events underwent synchronized multi-angle video review, and only well-coupled impacts—where teeth remained stably seated in the mouthguard—were included to ensure skull-coupled kinematic accuracy. Verified impacts were annotated with player identity, rink zone, and head-impact location. Peak linear acceleration (PLA), angular velocity (PAV), and angular acceleration (PAA) were summarized. Linear mixed-effects models evaluated whether impact severity differed by head-impact location, rink zone, or position.



Results

Across 28 athletes and 339 athlete-games, 1,126 well-coupled impacts were analyzed. Median (95th percentile) magnitudes were PLA 15.1 g (52.1 g), PAA 1,311 rad/s^2 (6,070 rad/s^2), and PAV 8.5 rad/s (20.5 rad/s). Impacts occurred primarily in the offensive zone (55.7%), followed by the defensive zone (36.1%) and neutral zone (8.2%). Forwards sustained most impacts (n=902), followed by defence (n=220) and goalies (n=4). Head-location analysis showed clear differences in rotational velocity: right-side (9.8 rad/s), front (9.7 rad/s), and left-side (9.5 rad/s) impacts produced the highest PAV, while top (7.4 rad/s) and rear (7.2 rad/s) impacts were lower. Mixed-effects models found no significant effects of rink zone ($p=0.84$) or position ($p=0.72$), but head-impact location was significantly associated with PAV ($p=0.0018$).

Discussion

This video-verified, well-coupled dataset provides a high-confidence profile of head-impact exposure in collegiate hockey. Lateral and frontal impacts generated the greatest rotational loads, emphasizing the importance of collision direction in impact mitigation. Despite differences in exposure frequency, impact severity remained consistent across rink zones and positions, suggesting that collision mechanics, rather than gameplay role, determine magnitude. Integrating multi-angle video with iMG data strengthens exposure modelling and supports targeted, evidence-based prevention strategies.

[4]University of Melbourne, Melbourne, Victoria, Australia. [5]Old Trinity Grammarians' Football Club, Melbourne, Victoria, Australia. [6]Vancouver Island University, Nanaimo, British Columbia, Canada

Introduction

Identifying head impacts that carry a risk of brain injury in sport remains challenging. Instrumented mouthguards have emerged as a tool to quantify head kinematics and potentially help identify high-risk impacts. Processing this kinematic data using finite element models provides a means of estimating brain tissue strain, potentially offering a more accurate prediction of injury than kinematics alone. However, studies to date have attempted to validate these biomechanical measures against subjective, binary clinical diagnoses rather than objective, biologically grounded markers of brain injury, such as blood-based biomarkers.

Methods

The analysis included 41 video-verified impacts from male amateur Australian football players: 17 resulting in concussion, five assessed but cleared, and 19 not requiring assessment. Instrumented mouthguards recorded peak linear acceleration, peak rotational acceleration, and peak rotational velocity; brain strain was estimated using the Imperial College finite element brain model; and Simoa quantified plasma concentrations of the astroglial injury biomarker glial fibrillary acidic protein (GFAP). Relationships were examined using Spearman correlations and regression.

Results

In the overall sample, plasma GFAP levels were moderately correlated with peak linear acceleration (ρ=0.46, 95% CI:0.20–0.66), peak rotational velocity (ρ=0.53, CI:0.20–0.78),

and brain strain (ρ=0.60, CI:0.32–0.80). These associations were stronger in the concussion subgroup for brain strain (ρ=0.86, CI: 0.58–0.97) and peak rotational velocity (ρ=0.64, CI:0.15–0.93). Comparing the strength of correlations with GFAP, brain strain was stronger than peak linear acceleration (Z=3.10, *P*=0.002), peak rotational acceleration (Z=3.68, *P*=2.35e-04) and peak rotational velocity (Z= 2.30, *P*=0.02) within concussion cases; it was also stronger than peak rotational acceleration for impacts overall (Z=2.60, *P*=0.009). Preliminary piecewise regression analysis identified significant breakpoints for peak rotational velocity and brain strain, above which associations with GFAP strengthened. In concussion cases, exceeding the strain breakpoint was associated with greater symptom severity.

Discussion

Finite element brain strain may better predict brain injury risk following a sport-related impact than peak acceleration metrics. Stronger associations with plasma GFAP, particularly among concussion cases, and evidence of a threshold in the association, support the use of biomarker-informed strain measures in future risk modelling and the development of brain injury screening thresholds.

OA7-02

Indentation-Based Identifiability of Anisotropic Soft Tissue Material Parameters

Mr. Amit Ashkenazi, Dr. Dana Solav

Technion - Israel Institute of Technology, Haifa, Haifa, Israel

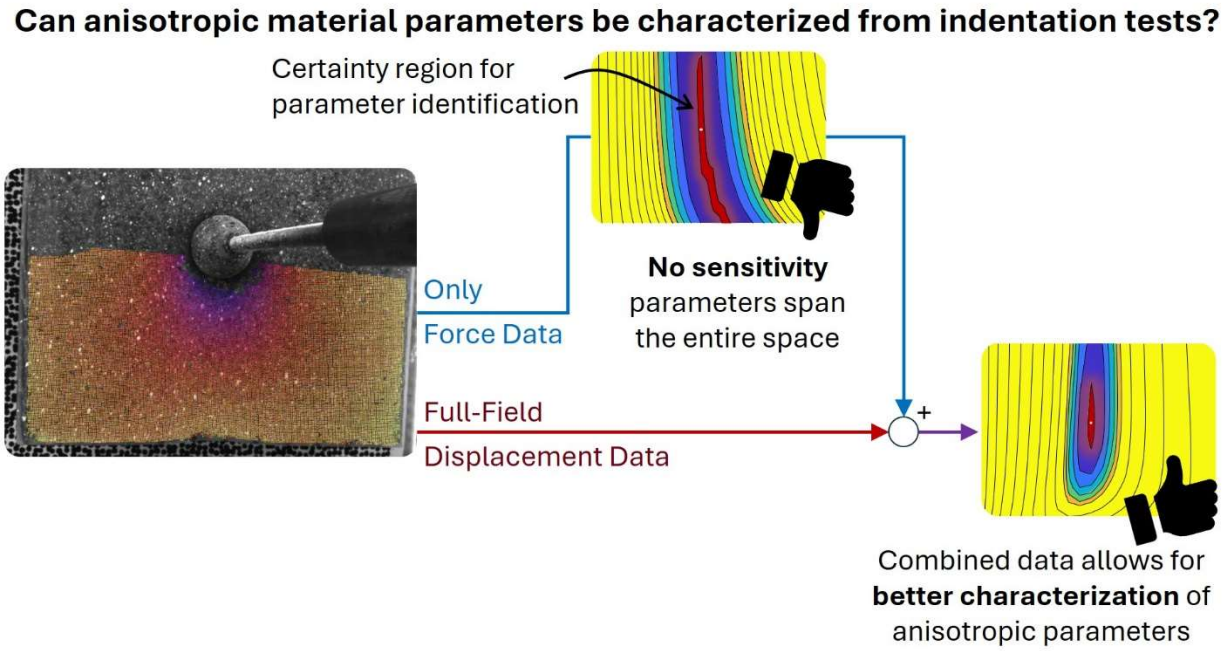
Introduction

Reliable in vivo characterization of anisotropic soft tissues is critical for patient-specific biomechanical modeling. While indentation is a preferred non-invasive testing method, deriving material parameters from force-depth data alone often creates an ill-posed inverse problem, leading to multiple parameter sets fitting the same experimental curve equally well [1]. This study investigates the added contribution of integrating full-field surface deformation measurements with standard force data, and quantifies its ability constrain the solution space and lead to reliable identification of transversely isotropic hyperelastic parameters.

Methods

We utilized a synthetic fiber-reinforced silicone phantom to validate a multimodal indentation framework. Macro-indentation experiments were conducted using spherical indenters, simultaneously recording reaction forces and 3D surface displacement fields via three-dimensional Digital Image Correlation (3D-DIC). Material behavior was described by a transversely isotropic Neo-Hookean model with isotropic (c_1) and anisotropic fiber-direction (c_5) parameters. An inverse finite element analysis (iFEA) pipeline optimized these parameters by minimizing a weighted objective function of force and displacement errors. A comprehensive sensitivity analysis quantified parameter certainty bounds [2], to determine the optimal contribution of each measurement type for maximizing identifiability [3].

Results



The sensitivity analysis demonstrated that using force data alone yielded poor identifiability, with uncertainty bounds of ±22.5% for c_1 and a massive ±210% for c_5 given a 5% measurement error. However, integrating 3D-DIC data significantly constrained the

solution space, reducing uncertainty to ±5.2% and ±28%, respectively. Experimental application of the optimized multi-modal objective function successfully identified homogenized parameters that matched validation benchmarks [3].

Discussion

The drastic reduction in uncertainty confirms that force-depth curves alone are insufficient for characterizing anisotropy, as they fail to capture directional stiffness contributions. By measuring surface deformations the optimization algorithm can decouple isotropic and fiber responses. These results confirm that surface deformation tracking is essential for reliable indentation-based anisotropic tissue characterization.

Full-Field Indentation Microscopy: Inferring Tissue Microstructure From a Single Poke

Mr. Yuvam Kulkarni M.S., Prof. Callan Luetkemeyer Ph.D.

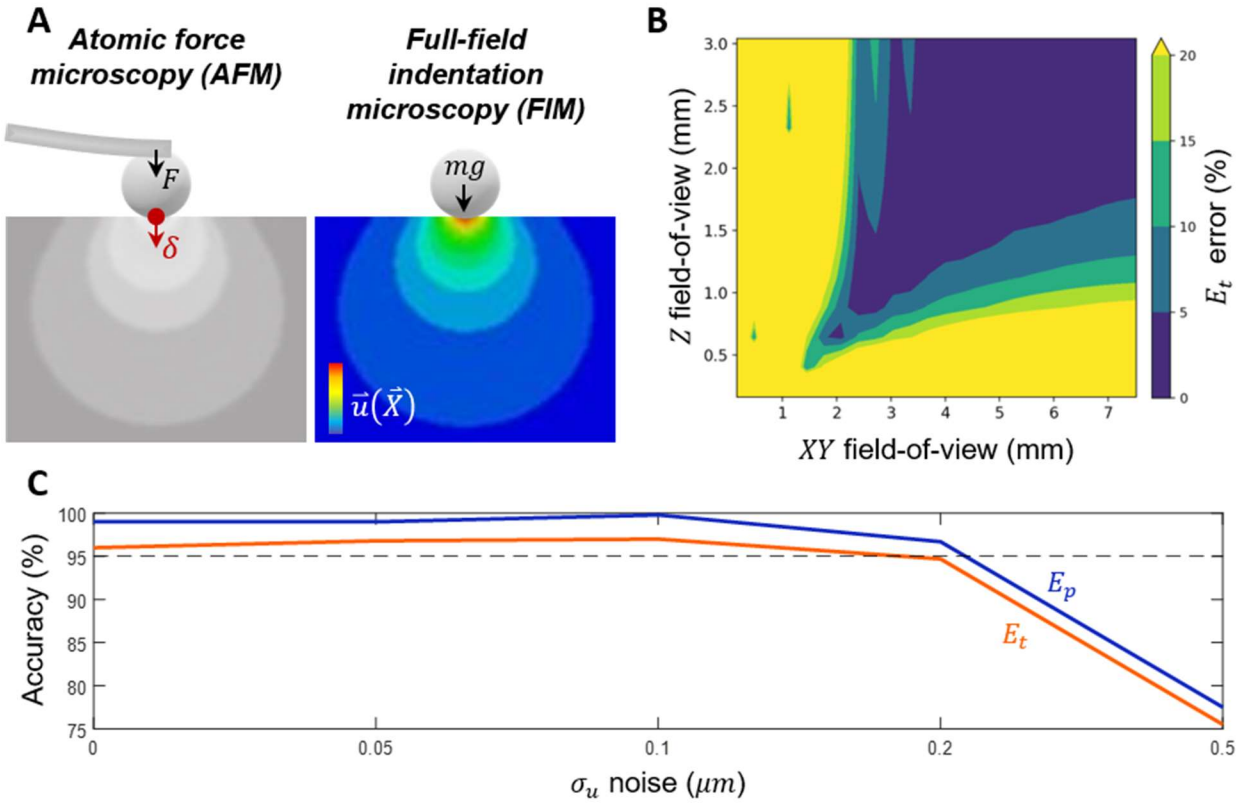
University of Illinois Urbana-Champaign, Urbana, IL, United States

Introduction

Indentation testing is non-destructive, local, and well-suited to layered, spatially heterogeneous soft tissues. Yet traditional approaches rely on unimodal force-displacement curves, which make it challenging to determine nonlinear, anisotropic properties tied to microstructure (e.g., collagen fiber architecture). Thus, we introduce **full-field indentation microscopy (FIM)**: a confocal-imaging-enabled, inverse modeling framework that leverages 3D displacement fields from a *single* spherical indent to estimate microstructure-informed constitutive parameters. Our long-term goal is to employ FIM to develop **mechano-biomarkers**: tissue- and pathology-specific, microstructurally interpretable parameters that can be non-invasively inferred via mechanical imaging.

Methods

FIM uses the weight of a glass microsphere to deform soft tissue samples and acquires 3D confocal images before/after indentation. Full-field displacement maps are computed and fed into a virtual fields method (VFM)-based inverse solver to identify anisotropic and nonlinear elastic parameters (Fig. 1A). We establish the inverse framework for linearly elastic, transversely isotropic materials and then evaluate: (1) virtual-field (VF) selection for accurate anisotropic moduli recovery, (2) extension to hyperelastic constitutive models (Neo-Hookean and Holzapfel-Gasser-Ogden), and sensitivity to (3) reduced experimental field-of-view (FOV) and (4) measurement noise. Synthetic displacement fields, generated via finite element simulations of brain tissue indented with a 1 mm sphere, were used.



Results

All tested VFs produced cost-function minima near the ground-truth moduli, and VF combinations yielded unique minima with <5% error. The best VF pair was used to assess hyperelastic models, where FIM recovered most nonlinear parameters (including bulk modulus) with ≥98% accuracy for both Neo-Hookean and HGO forms. Reducing the FOV increased error, but even with a 50% FOV reduction in both depth and lateral directions, FIM identified transversely isotropic elastic moduli with <5% error (Fig. 1B). Similarly, FIM was robust to moderate levels of synthetic measurement noise (Fig. 1C).

Discussion

FIM enables microstructure-informed constitutive characterization with a single indentation test, which is especially valuable in layered tissues (e.g., the uterus) where local properties matter. By converting full-field indentation data into parameters with microstructural meaning, FIM offers a pipeline toward in-situ development and validation of mechano-biomarkers. Ongoing work includes experimental validation and open-source software release.

OA7-04

Characterization of Human Breast Skin Mechanics for Improved Tissue Expansion in Breast Reconstruction Surgery

Ir. Nicole Ritter, MSc. Gerben Michiels, Prof. Patrick Segers, Prof. Phillip Blondeel

Ghent University, 9000, Ghent, Belgium

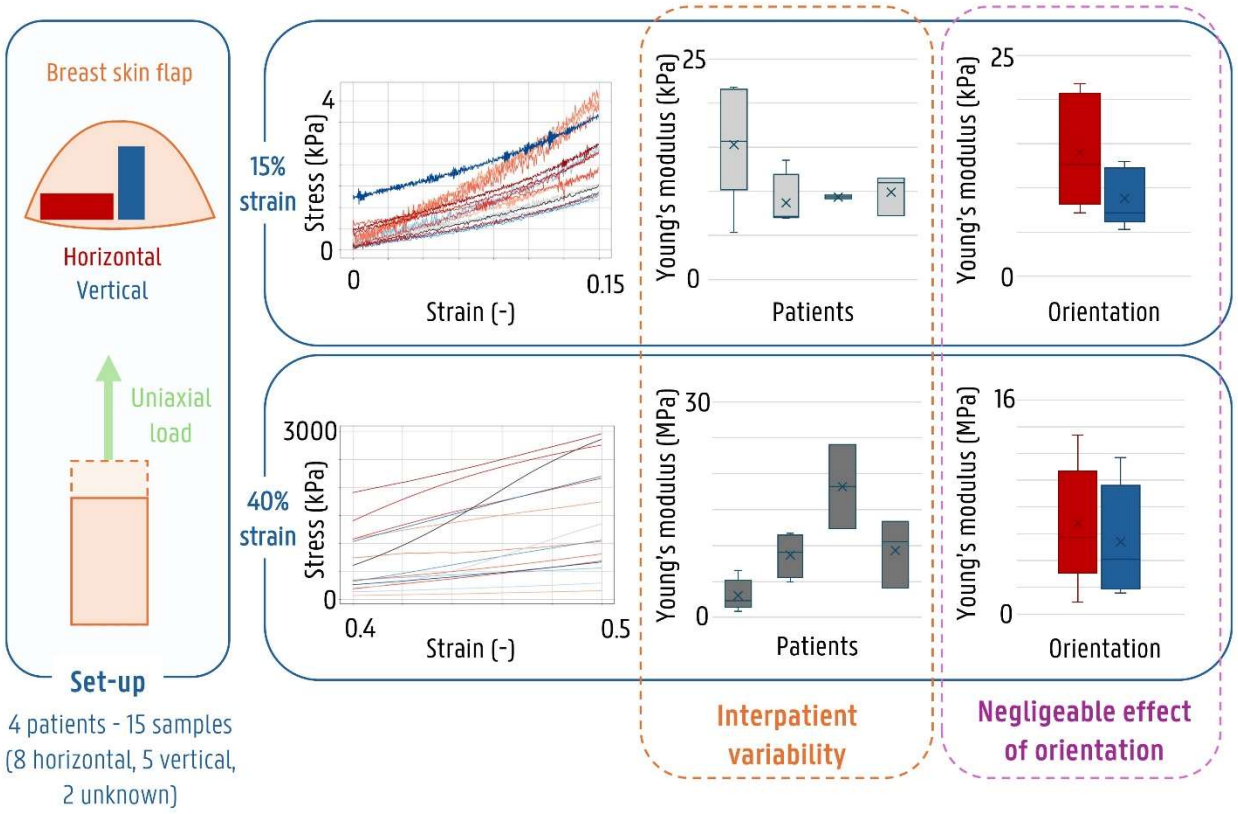
Introduction

Tissue expansion remains central to breast reconstruction, yet quantitative data describing the mechanical behavior of human breast skin are limited. Current expansion protocols used in clinics therefore rely on empirical practice rather than biomechanical evidence, restricting the optimization and safety assessment of emerging technologies. This study aims to characterize interpatient variability in breast skin stiffness and evaluate the influence of sample orientation on Young's modulus using combined suction, tensile, histological and patient data.

Methods

In this ongoing six-month study, breast skin is harvested from patients undergoing reduction mammoplasty, mastectomy, or mastopexy at Ghent University Hospital. Immediately following excision, suction testing is performed using a cutometer. After removal of hypodermal and glandular tissue, three punch biopsies per tissue flap are collected for histological analysis. Slides in all planes are stained with Verhoeff–Van Gieson to quantify collagen and elastin content and assess collagen fiber orientation. Remaining skin is sectioned into rectangular (2 × 6 cm) specimens oriented parallel or perpendicular to the longitudinal axis and square (1 × 1 cm) samples aligned with both axes. Rectangular specimens undergo uniaxial tensile testing (four cycles at 15% strain and four at 30%, strain rate 1 s^{-1}). Square specimens are snap-frozen at –80 °C for subsequent biaxial testing under matched strain conditions. Digital image correlation is applied to all tests to generate full-field strain maps. Patient characteristics, including age, weight, and cup size, will be integrated into a regression model to predict stiffness. The study on residual human tissues was approved by the medical ethics committee of the hospital.

Results



Preliminary data (Fig. 1) from 15 samples across four patients show substantial interpatient variation in Young's modulus at high strain (3–18 MPa; mean 10 ± 6 MPa) and no significant effect of specimen orientation under uniaxial loading. Ongoing collection from up to 30

patients will yield a comprehensive dataset linking ex vivo suction response, ex vivo tensile behavior, and microstructural composition.

Discussion

Improved understanding of patient-specific breast skin mechanics and predictive modeling of stiffness will support safer, individualized tissue-expansion strategies and the development of next-generation expanders that better replicate native tissue behavior.

OA8-02

Anterior Cruciate Ligament Elongation During High and Low Impact Movements Using Biplanar Videoradiography

Ms Anastasija Mihic[1], Dr. Allison Clouthier PhD[2], Dr. Michael Rainbow PhD[1]

[1]Queen's University, Kingston, Ontario, Canada. [2]University of Ottawa, Ottawa, Ontario, Canada

Introduction

1 in 3,500 people experience an anterior cruciate ligament (ACL) tear, leading to short-term disability and increasing lifetime risk of knee osteoarthritis eight-fold [1,2]. Nearly 70% of ACL injuries occur during non-contact tasks, highlighting the need to better understand knee mechanics during everyday and sport-specific movements [3]. Direct measurement of ACL strain is rarely feasible; therefore, relative elongation is commonly used as a proxy. Biplanar videoradiography (BVR) provides highly accurate arthrokinematic measurements, enabling in-vivo assessment of ligament loading during motion. This study compared ACL elongation during low-impact (lunge) and high-impact (single-leg hop) tasks. We predicted the high-impact task would produce higher elongation at the same knee flexion angle.

Methods

Five healthy participants performed a forward lunge and single-leg hop. A BVR system recorded motion. CT scans were segmented, generating bone models for tracking the femur and tibia. ACL attachment regions for the anteromedial (AMB) and posterolateral (PLB) were defined [4]. Bundle length was measured as the centroid-to-centroid distance between tibial and femoral attachments, with the maximum length across trials used as the reference for elongation.

Results

All participants exhibited greater elongation during the hop (Figure 1). The AMB showed higher elongation than the PLB. Mean hop elongation was 0.9 (AMB) and 0.9 (PLB), compared with 0.8 (AMB) and 0.7 (PLB) during the lunge. During hop trials, both bundles reached maximum elongation at max extension.

Discussion

Consistent with literature, at similar flexion angles, high-impact movements produced greater ACL elongation [5]. The magnitude of the difference varied across participants, suggesting individual kinematic strategies influence ACL loading. Because flexion alone did not account for these differences, other arthrokinematic factors such as tibial rotation,

ab/adduction, or anterior–posterior translation may contribute. These differences may reflect task-dependent neuromuscular strategies, such as increased co-activation during landing, which could alter ligament loading. These findings underscore that ACL elongation is affected by task intensity and participant-specific movement patterns. Understanding these factors may contribute to improved injury-prevention and personalized training.

Images (Optional)

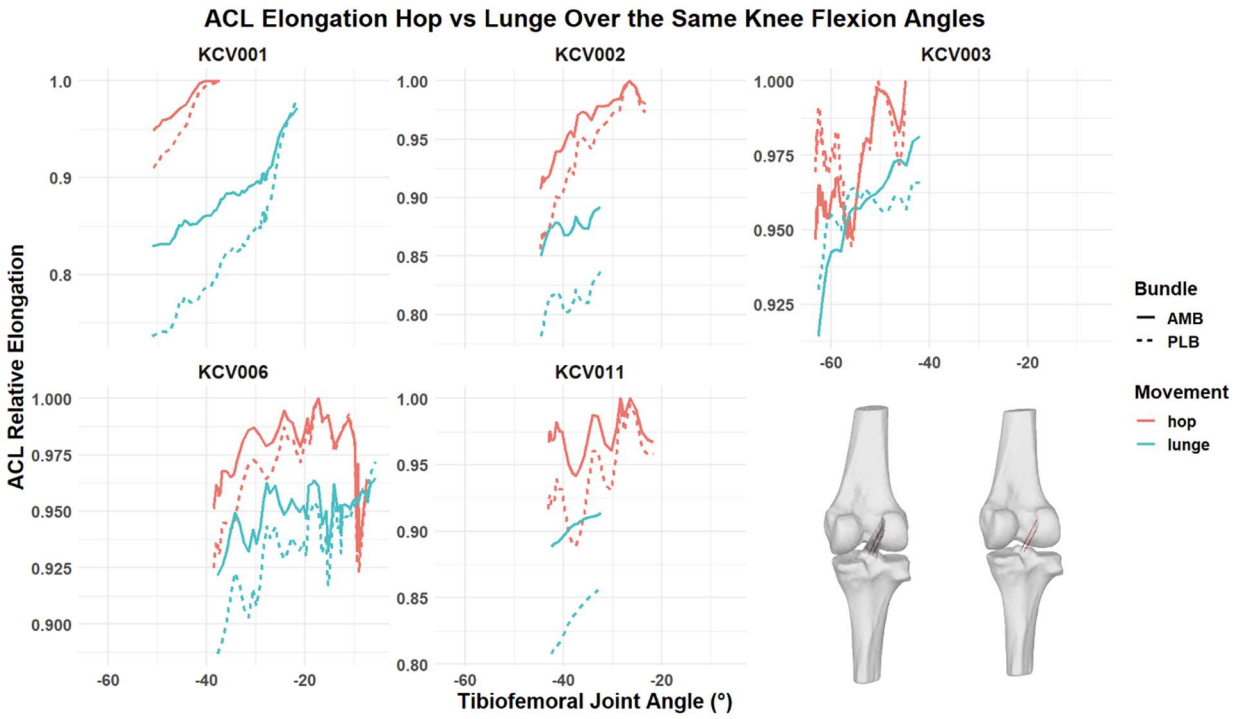

Figure 1 ACL elongation of the anteromedial bundle (AMB; solid lines) and posterolateral bundle (PLB; dashed lines) during the low-impact lunge (blue) and high-impact hop (pink) tasks, plotted over the same knee flexion angles.

A Novel Method of Quantifying Changes in Tibiofemoral Joint Stiffness after Ligament Injury via Eigendecomposition Using In Vitro Robotic Testing

Mr. David Shamritsky MEng, Dr. Reza Pourmodheji PhD, Dr. Brian Frondorf MD, Ms. Erin Berube MS, Mr. Philipp Pape, Ms. Lexie Bae, Mr. Bryce Demopoulos, Dr. Carl Imhauser PhD

Hospital for Special Surgery, New York, NY, United States

Introduction

The effect of anterior cruciate ligament (ACL) or medial collateral ligament (MCL) tears on knee stiffness has been primarily assessed via the knee's in vitro uniplanar load-displacement response. We describe a novel, complementary, method that uses eigendecomposition to quantify tibiofemoral stiffness in all three anatomic planes. Using this method, our objective was to measure changes in tibiofemoral stiffness after ACL and MCL sectioning in response to anterior and valgus loads.

Methods

Twelve cadaveric right knees (7 females; mean age: 50, range: 25-65 years) were mounted to a robotic manipulator equipped with a six-axis force-torque sensor. First, equilibrium poses were determined at 15° of flexion under 8 Nm valgus moment and at 30° of flexion under 100 N anterior force. Second, the tibia was translated and rotated by 0.3 mm and 0.3°, respectively, in each anatomic direction other than flexion/extension. Third, during each perturbation, changes in the reaction forces and moments in all directions were recorded to construct the linearized stiffness matrix. Finally, the eigenvalues of each stiffness matrix were calculated. After testing the intact state, the ACL and MCL were sectioned in two cohorts of six knees each, respectively. Steps 2-4 were then repeated at the same equilibrium poses. A system is stable if and only if all eigenvalues of the stiffness matrix are real and positive; thus, the minimum real eigenvalue was used to test our hypothesis. The difference in minimum eigenvalue between the intact and sectioned states was assessed via paired t-tests ($\alpha=0.05$).

Results

After ACL sectioning, the minimum eigenvalue decreased by a median of 11.8 ($p=0.003$) and 7.8 ($p=0.01$) under anterior force and valgus moment, respectively. After MCL sectioning, the minimum eigenvalue decreased by a median of 4.5 ($p<0.001$) and 3.6 ($p=0.02$) under anterior force and valgus moment, respectively.

Discussion

We introduce a novel method to quantify decreases in joint stiffness following ACL and MCL sectioning. Measuring changes in eigenvalues after injury may complement laxity assessments by quantifying stiffness changes simultaneously in all planes. The eigenvectors corresponding to each state's minimum eigenvalue will describe the joint's least stiff direction, which provides novel opportunity to characterize the impact of injury.

Images (Optional)

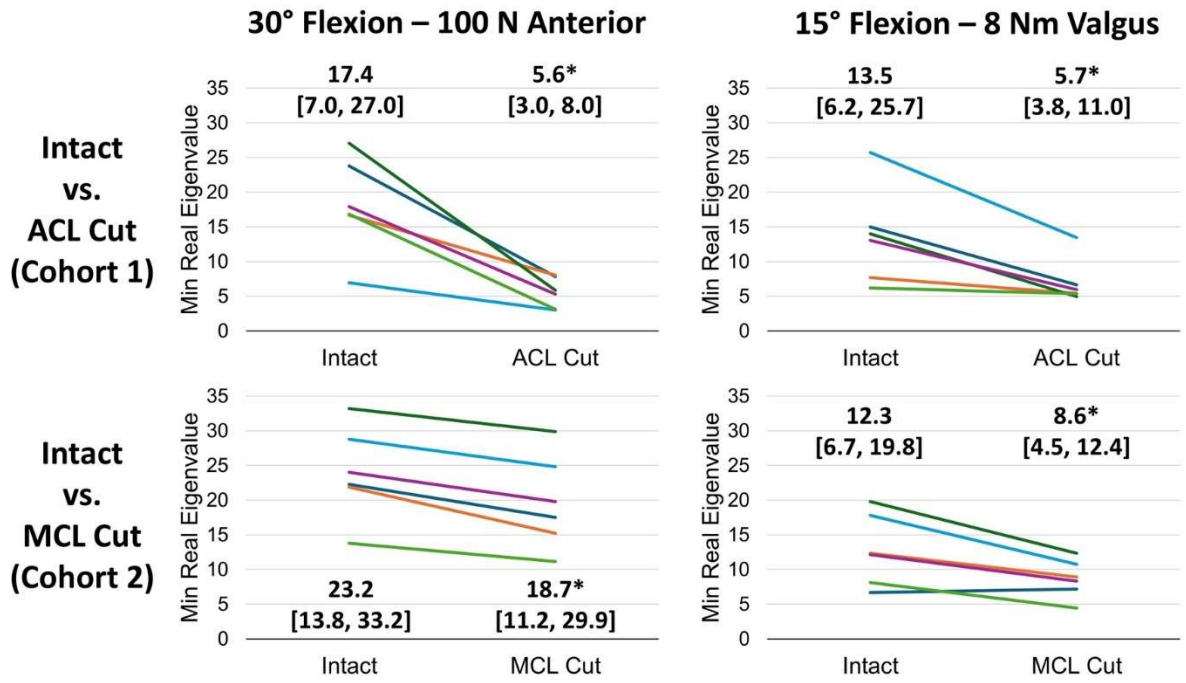

Figure 1. The minimum real eigenvalue of the linearized stiffness matrix for 12 cadaveric knees split into two cohorts. The intact and ACL- (top row) and MCL-cut (bottom row) states were tested under two loading conditions: 100 N anterior force at 30° of flexion (left column), 8 Nm valgus moment at 15° of flexion (right column). Median and range are reported for each condition and state, * indicates $p<0.05$ for the cut state relative to the intact state.

The Knee You Model is the Knee You Measure: How the Knee Model Degrees of Freedom and Range of Motion Alter the Knee Abduction Moment during Change-of-Direction

M.Sc. Marius Kindermann[1], M.Sc. Lasse Mausehund[2], Dr. Tron Krosshaug[2], Dr. Maurice Mohr[3]

[1]Department of Electrical Engineering, FAU Erlangen-Nürnberg, Erlangen, Bavaria, Germany. [2]Oslo Sports Trauma Research Center, Department of Sports Medicine, Norwegian School of Sport Science, Oslo, Oslo, Norway. [3]Department of Sport Science, University of Innsbruck, Innsbruck, Tyrol, Austria

Introduction

The peak knee abduction moment (pKAM) is a frequently investigated risk factor for non-contact injuries to the anterior cruciate ligament during landing and change-of-direction (COD) maneuvers [1]. The computation of the pKAM, however, relies on a series of analysis and modeling choices including the definition of knee joint rotational degrees of freedom (DOF) and their respective ranges of motion (ROM). The purpose of this study was to analyze the influence of modeled knee DOF and ROM on the pKAM and time to pKAM during a high-intensity 135°COD.

Methods

Twenty-two sports students completed six maximum-speed 135°CODs while their movements were captured by 3D marker-based motion capture and floor-embedded force plates. External knee moments were obtained through model scaling, inverse kinematics and inverse dynamics in OpenSim (v.4.5) and were compared between variations of a full-body biomechanical model [2]. The variations included systematic manipulation of 1) available DOFs related to knee add/abd and knee int/ext rotation and 2) ROM in knee add/abd in a 3DOF model. In a separate model variation (1D-W), secondary knee kinematics were prescribed as a function of knee flexion according to [3]. Repeated measures / Friedman ANOVAs and Spearman's rank correlations were carried out to investigate the model influence on the trial-average pKAM and time to pKAM (alpha = 0.05).

Results

A lower number of DOFs was associated with lower pKAMs ($p<0.001$) and lower time to pKAM ($p<0.001$) (Figure 1). Similarly, a lower ROM in knee add/abd was associated with

lower pKAMs (p<0.001) and lower time to pKAM (p=0.005), however, only below +/-10°. Rank correlations of above 0.8 indicated strong rank consistency among knee models.

Discussion

The magnitude of pKAM and time to pKAM should only be compared across studies if the underlying knee models are equivalent in their available DOFs and ROMs. However, the ranking of athletes according to the pKAM and time to pKAM seems largely unaffected by the modeling choice regarding DOFs and ROMs.

Images (Optional)

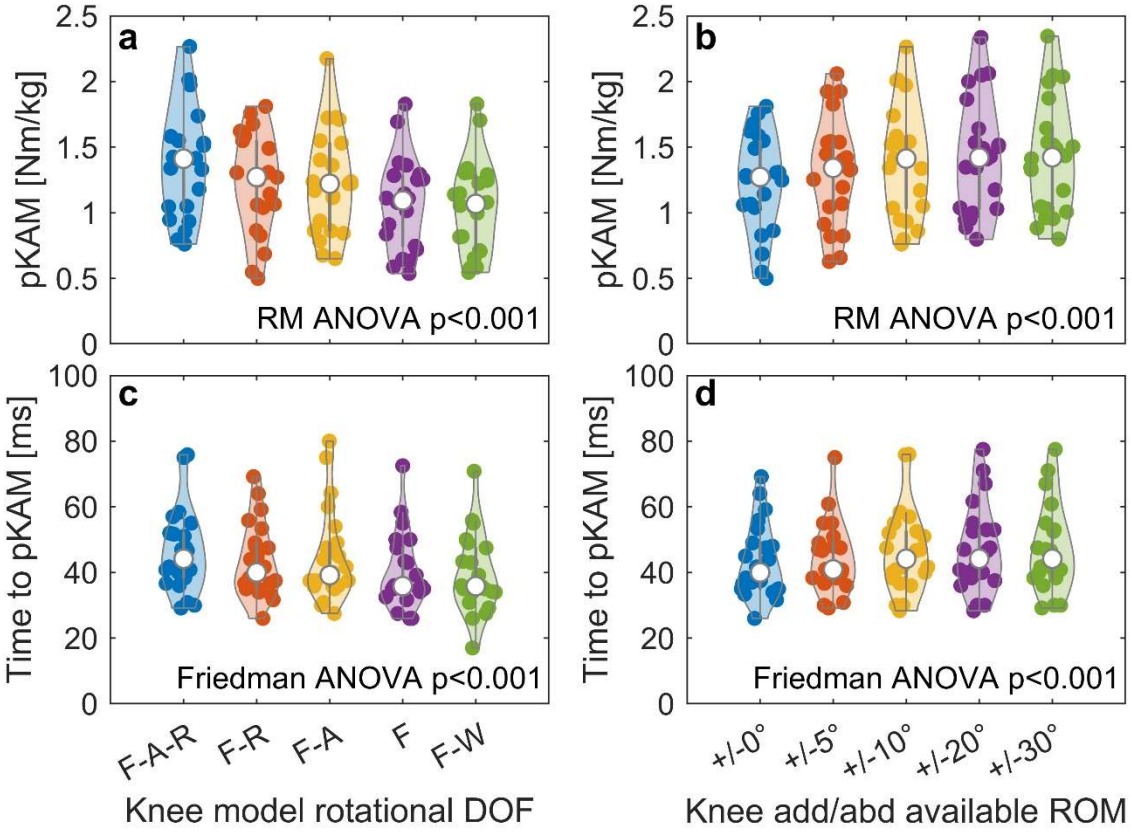

Figure 1. Peak knee abduction moment (pKAM, a&b) and time to pKAM (c&d) during a 135° change-of-direction maneuver for different knee model rotational degrees of freedom (DOFs) and available range of motion (ROM). F-Flexion, A-Add/Abd, R-Rotation, W-Walker

OA8-05

Impact of Neurocognitive Reaction Time on the Performance of an Unanticipated Sidestep Cut

Mr Cole Geschwender MS[1,2], Dr Henry Wang PhD[2], Dr Jason Avedesian PhD[3], Dr Clark Dickin PhD[2]

[1]University of Michigan, Ann Arbor, Michigan, United States. [2]Ball State University, Muncie, Indiana, United States. [3]Cleveland Cavaliers, Independence, Ohio, United States

Introduction

An unanticipated sidestep cut is a game-realistic movement commonly performed in cutting sports and is recognized as a key movement associated with non-contact anterior cruciate ligament (ACL) injuries. Neurocognitive reaction time (NCRT) measures the speed an individual responds to an external stimulus and may influence the biomechanics of an unanticipated sidestep cut, but has not been previously investigated. The purpose of this study is to elucidate how NCRT influences unanticipated sidestep cutting in performance and injury prevention.

Methods

Twenty-one right foot dominant healthy subjects (n=11 male) completed a computerized NCRT assessment (Go/No-Go, Simple RT, N-Back, and Stroop) which provided composite RT scores for both dominant and nondominant sides. NCRT was centered across the sample variation. Joint mechanics of the hip, knee, ankle, and trunk were assessed during five unanticipated sidestep cut trials to the left and right. A linear mixed model was used with NCRT, limb dominance, and sex as fixed effects.

Results

Motion capture and force plate technology was used to assess the outcome measures. When adjusting for limb dominance and sex, quicker NCRT response times were associated with less lateral trunk lean (β=0.006, SE=0.002, p =.002), faster approach speed (β=-2.75x10^{-4}, SE=1.05 x10^{-4}, p = .0128), and greater peak hip flexion moment (β=0.001, SE=1.66 x10^{-4}, p < .001). NCRT did not account for any significant differences in knee or ankle mechanics (p>.05).

Discussion

Participants with quicker NCRT scores demonstrated a more upright trunk position during unanticipated sidestep cuts, a position associated with reduced ACL loading. Additionally, NCRT performance was associated with greater hip flexion moments that are indicative of

more explosive and safer unanticipated sidestep cuts. Quicker NCRT scores also had faster approach speeds, suggesting an enhanced ability to quickly position the body during sudden changes of direction. Conversely, individuals with slower NCRT scores had a slower approach speed, potentially indicating that more time was required to perform biomechanically safe cuts, though no joint differences were reported at the knee or ankle. NCRT scores may influence the performance of an unanticipated sidestep cut and should be further considered as a factor for future unanticipated gross motor maneuvers.

Machine Learning Estimates Ground Reaction Forces with Higher Accuracy than Musculoskeletal Simulation for Anterior Cruciate Ligament Injury-Risk Screening Tasks

Ms. Janelle Kaneda MS, Dr. Julie Kolesar MS, PhD, Dr. Sam Hamner MS, PhD, Dr. Kirsten Seagers MS, PhD, Dr. Krithika Swaminathan MS, PhD, Ms. Julie Muccini MS, OTR/L, Dr. Scott Delp MS, PhD, Dr. Jennifer Hicks MS, PhD

Stanford University, Stanford, CA, United States

Introduction

Millions worldwide sustain anterior cruciate ligament (ACL) injuries, and sometimes these injuries end athletic careers. Kinetic metrics such as peak ground reaction force during drop landings have been identified as risk factors for ACL injury [1]. However, current methods to estimate forces outside of the lab are time-intensive or trained on limited motions. This work aimed to develop and test a generalizable neural network to estimate ground reaction forces during ACL injury-risk screening tasks to enable large-scale injury-risk screening.

Methods

We developed DynamicsNet, a spatiotemporal graph convolutional network that uses physics-based kinematic features to predict ground reaction forces, and trained it with 70+ hours of optical motion capture and force plate data from various activities [2]. We also used the OpenSimAD musculoskeletal simulation framework [3] to estimate ground reaction forces from measured kinematics. We evaluated both methods (DynamicsNet and simulation) on a held-out dataset of OpenCap-based kinematics [4] from adolescent female athletes performing double-leg drop jumps (58 trials, 24 participants) and single-leg squats (90 trials, 23 participants). We computed the mean absolute error of vertical ground reaction force over the region of interest for each movement, as well as at the peaks.

Results

Over the region of interest for both activities, DynamicsNet's error was lower than simulation: 0.21 ± 0.23 versus 0.33 ± 0.33 bodyweights for drop jumps, and 0.08 ± 0.06 versus 0.16 ± 0.17 bodyweights for squats (Figure 1). For peak force, DynamicsNet had about half the error of simulations for drop jumps (0.33 ± 0.24 versus 0.61 ± 0.62 bodyweights) and lower error for squats (0.12 ± 0.06 versus 0.19 ± 0.20 bodyweights).

Discussion

DynamicsNet predicted ground reaction forces with higher accuracy and less variance than physics-based simulation for both drop jumps and squats. Future work will fine-tune DynamicsNet on ACL injury-risk screening activities to ensure sufficient accuracy for detecting clinically meaningful differences in biomechanical risk factors. Our preliminary results suggest that DynamicsNet could enable rapid dynamics estimation for large-scale, effective ACL injury-risk screenings.

Neural Network Surrogates for Musculoskeletal Models: an Application to Implant Alignment in Total Knee Arthroplasty

MSc Linda ten Klooster[1,2], Dr. Ir. Periklis Tzanetis[2], Dr. Ir. Dennis Janssen[1], Dr. Ir. Thom Bitter[1], Prof. Dr. Ir. Nico Verdonschot[1,2], Dr. Jelmer Wolterink[2]

[1]Radboud University Medical Center, Nijmegen, Gelderland, Netherlands. [2]University of Twente, Enschede, Overijssel, Netherlands

Introduction

Musculoskeletal models are widely used to study human movement and simulate joint biomechanics, yet their high computational cost limits their clinical applicability. Artificial neural networks offer a promising solution as fast surrogate models for complex simulations. In this study, a neural network-based surrogate model was used to accelerate estimation of patient-specific optimal implant alignment in total knee arthroplasty (TKA), previously defined as the configuration that best replicates pre-diseased knee function [1]. Our surrogate model rapidly assesses tibiofemoral (TF) kinematics and ligament strains for candidate alignments, enabling accelerated prediction of optimal implant alignment compared to conventional simulations.

Methods

Data from eight TKA patients previously simulated with a patient-specific musculoskeletal TKA model were used [1]. This dataset contains candidate implant alignments evaluated by the root-mean-square deviation (RMSD) in TF kinematics and ligament strains relative to the pre-diseased state. The alignment with the lowest RMSD was defined as optimal. To reduce the configuration space while maintaining clinically viable positions, femoral component rotations were varied while the tibial component was fixed, yielding 125 samples per patient. For each individual patient, a multi-task multilayer perceptron (MLP) with three hidden layers, Adam optimizer, learning rate 0.005, and 80%/10%/10% train/validation/test split was trained to predict kinematics and ligament strains. A gradient-based optimization method was subsequently applied to the frozen MLP outputs to identify optimal alignments. Figure 1 illustrates the workflow.

Results

The multi-task MLP achieved a normalized mean absolute error of ~0.5% between predicted and simulated outputs when trained on the full dataset. On average, ~35

samples per patient were sufficient to keep the error below 1%. Simulation time dropped from 3h to ~50min for musculoskeletal data generation, with subsequent multi-task MLP training taking 2s and optimization less than 1s.

Discussion

Employing a multi-task MLP substantially reduces computational time while maintaining an error below 1% compared to musculoskeletal simulations. Future research will incorporate the implant translations and tibial rotations, as well as data from more patients. This approach represents a critical step toward using biomechanical modeling to determine patient-specific optimal implant alignment during TKA in a clinical setting.

Images (Optional)

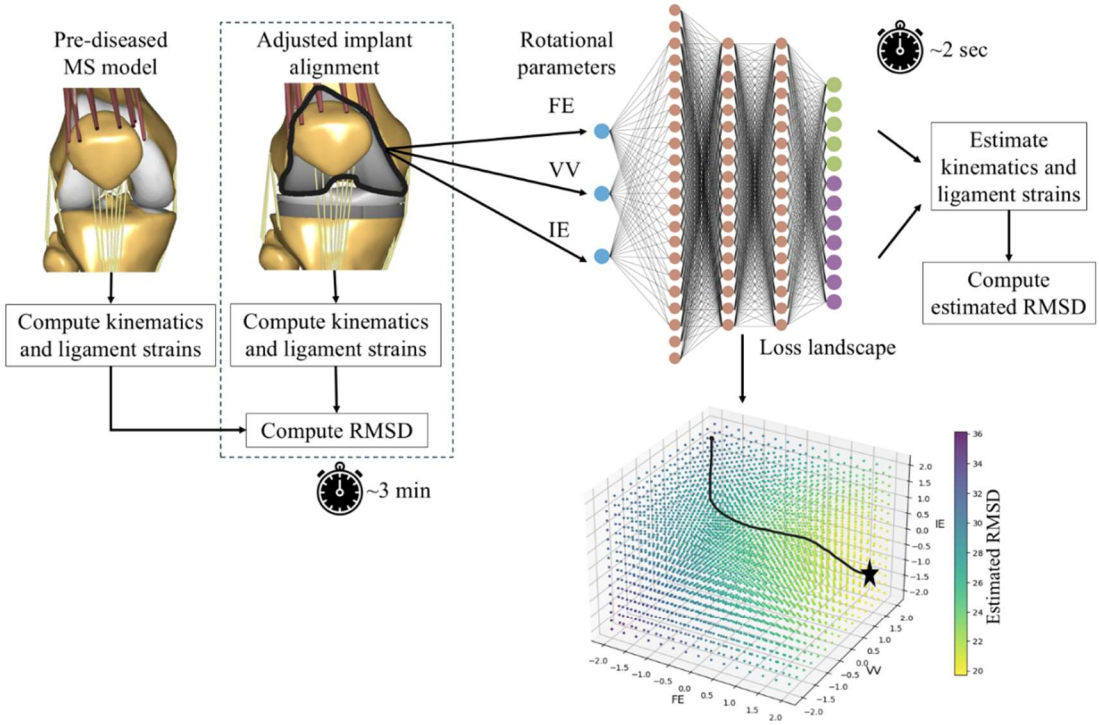

Figure 1 caption: Schematic overview of the methods as applied to one single patient. Training and validation data were obtained using an existing patient-specific musculoskeletal (MS) model that simulates knee kinematics and ligament strains for the pre-diseased state, as well as an implant-aligned femoral and tibial rotation and location. Implant alignment quality is defined by the root-mean-square deviation (RMSD) between these two simulations. We trained a neural network with three hidden layers containing 30, 20, and 20 units, respectively, to predict kinematics, ligament strains, and subsequently RMSD. The frozen trained neural network is then used for gradient-based optimization to identify the optimal implant position for this patient. Sit-to-Stand Biomechanical Subgroups Identified from A Large Dataset of Clinically Accessible Smartphone Video Recordings

Ms. Kathryn Blessinger[1], Dr. Manoj Srinivasan[1], Dr. Sarah Roelker[2], Dr. Laura Schmitt[1], Dr. Ajit Chaudhari[1], Dr. Robert Siston[1]

[1]The Ohio State University, Columbus, OH, United States. [2]University of Massachusetts Amherst, Amherst, MA, United States

Introduction

Proposed clinical phenotypes, or subgroups, for common musculoskeletal conditions help tailor physical therapy and exercise recommendations but often overlook task performance factors, such as how individuals leverage available muscle strength to meet task demands, i.e., the potential of muscles to accelerate the center of mass (COM). This study aimed to identify biomechanical subgroups during sit-to-stand (STS), based on patterns in demographics, performance, kinematics, and muscle potentials.

Methods

Seventy participants, a subset of [1], performed five-times STS recorded via smartphone video. Three-dimensional kinematics were predicted from each video, using methods developed by [2]. Sagittal plane kinematics and an induced potential analysis [3] determined muscle potentials to sagittal plane COM accelerations for lower extremity muscles during STS. K-means clustering identified STS subgroups, where participants' age, body mass index (BMI), sex, STS time to completion (TTC), and sagittal plane kinematics and muscle potentials during STS were used as clustering inputs. Kruskal-Wallis or Chi-squared and appropriate post-hoc testing compared demographic, performance and osteoarthritis (OA) prevalence data between resulting subgroups. Descriptive statistics qualitatively compared kinematic and muscle potential data between subgroups.

Results

We identified 3 STS subgroups (Table 1), each of which had similar performance (TTC). Group FEM was older, had a higher proportion of females and higher OA prevalence, the largest BMI, and demonstrated more dorsiflexion, hip flexion, and knee flexion, less lumbar flexion, and smaller plantarflexor and quadriceps muscle potential magnitudes, compared both other groups. The two remaining groups demonstrated similar demographics, performance, and OA prevalence, but Group Q demonstrated less dorsiflexion, compared to both other subgroups. Groups Q and PF showed the largest quadriceps or plantarflexor muscle potential magnitudes, respectively.

Discussion

This pilot analysis suggests that an OA-dominant subgroup characterized by older females with greater BMI (Group FEM), uses a kinematic strategy that yields smaller potentials from muscles that are key for accelerating the COM up (quadriceps and plantarflexors) and forward (plantarflexors) during STS. Our findings may inform future custom kinematic cueing interventions during STS for groups of patients with OA, like many in Group FEM.

Bridging OpenCap Outputs to Clinically Useful Gait Reports

Dr. Joseph Mahoney Ph.D.[1], Ms. Keiana Morris[2], Mr. Steve Tello[1], Dr. Allison Altman-Singles Ph.D.[2]

[1]Alvernia University, Reading, PA, United States. [2]Penn State Berks, Reading, PA, United States

Introduction

Quantitative gait measures support clinical decisions, yet traditional motion-analysis labs are costly and require dedicated space and staff. Markerless, open source systems such as OpenCap estimate kinematics and dynamics from smartphone video in small spaces with minimal hardware and training [1]. However, OpenCap typically returns zipped data and raw video or brief web-portal summaries, not a concise report. We developed and tested a low-cost pipeline that lets non-programmers turn OpenCap treadmill sessions into clinician-oriented gait summaries.

Methods

A MATLAB program was developed that ingests the zipped output from an OpenCap treadmill session, unpacks the files, and extracts joint kinematics and marker trajectories from all trials [2]. The code computes stride-averaged kinematics, basic spatiotemporal variables, and symmetry metrics, then compiles subject-level and condition-level tables and plots. To run the analysis, the user downloads the OpenCap zip file from the web portal, selects it in a simple graphical interface, and allows the program to complete all processing automatically. Modular configuration files let developers choose which joints, planes, and metrics appear so that report layouts can be tailored to specific clinical or research needs.

Results

On an initial test dataset of treadmill walking, the pipeline processed OpenCap exports and produced subject-level reports; no additional coding from the user was needed. Each report contained joint-motion plots, stride-averaged spatiotemporal parameters, and symmetry metrics formatted for quick review. From downloading the OpenCap zip file to opening the summarized report, the workflow required only a few simple user actions.

Discussion

These results demonstrate a feasible pathway from smartphone-based markerless motion capture to clinician-ready gait reports that use low-cost hardware and require minimal programming expertise. The pipeline converts high-dimensional OpenCap output into compact, configurable summaries that may support clinical decision-making and remote monitoring. Limitations include reliance on treadmill walking, the quality of video capture, and OpenCap pose estimation. Future work will validate output against gait-lab standards, expand to overground tasks and additional gait metrics, and implement a web-based Python interface that delivers the same customizable reports through a browser.

Exploring Carotid Plaque Rupture Risk Using Non-Invasive MRI-Quantitative Susceptibility Mapping Validated by Comprehensive Multimodal Imaging

Mr Francesco Digeronimo[1,2,3], Ms Jessica Bagnall[1,2], Asst. Prof. Brooke Tornifoglio[1,2], Prof. Karin Shmueli[4], Prof. Caitríona Lally[1,2,3]

[1]Trinity Centre for Biomedical Engineering, Trinity College Dublin, Dublin, Co. Dublin, Ireland. [4]Department of Medical Physics and Biomedical Engineering, University College London, London, England, United Kingdom

Introduction

Carotid Artery Disease (CAD) manifests as atherosclerotic plaque formation, with vulnerable plaque rupture causing ~20% of ischaemic strokes [1]. Identifying plaques vulnerable to rupture is vital for effective patient selection for Carotid Endarterectomy (CEA) surgery, with current approaches, based on arterial narrowing (percentage stenosis), offering limited insights into rupture vulnerability. MRI-Quantitative Susceptibility Mapping (QSM) quantifies tissue magnetic susceptibility (χ), providing deeper compositional insights than conventional MRI [2]. QSM is sensitive to arterial collagen [3], a key determinant of plaque stability [4]. This study investigates QSM's potential to identify rupture-prone plaques in CAD using multi-modal imaging validation and mechanical testing of human plaque tissue.

Methods

Plaques (N=4) from CEAs (Galway Clinic, Ireland) were fixed, mounted in custom-made holders and imaged using multiple modalities: Multi-Echo Gradient Echo MRI (7T-Bruker-BioSpec-70/30) for QSM, and for validation: Micro-CT (μCT), Contrast-Enhanced (CE)-μCT (Nikon-XTH225) and brightfield microscopy. QS-Maps were calculated with a two-pass masking pipeline [5]. QS-Maps were co-registered with CT volumes, and microscopy images aligned for comparison. Fresh plaques (N=7) underwent QSM and uniaxial tensile testing to failure (2-mm-width circumferential strips). Strips were grouped based on QSM features and mechanical differences assessed.

Results

Combined imaging confirmed QSM contrasts and enabled detailed assessment of plaque composition. Heavily diamagnetic ($\chi \ll 0$) and paramagnetic ($\chi \gg 0$) regions corresponded to calcification and intraplaque haemorrhage, aligning with prior work [2]. CE-µCT highlighted highly fibrous regions aligning with QS-Maps diamagnetism, enabling identification of fibrous tissue (Fig.1A, arrows). Based on QSM-groupings (Fig.1B), Group-A showed significantly higher force and strain at failure (Fig.1C), supporting that dense fibrous tissue confers greater plaque stability.

Discussion

By combining imaging and mechanical testing, this study clarifies the compositional basis of QSM contrast and demonstrates its value for assessing plaque mechanical integrity. We have also confirmed QSM feasibility in-vivo, from scanning to post-processing, demonstrating the translational potential of QSM for delivering key insights into plaque composition and vulnerability, supporting improved CEA patient selection.

Steps Toward Understanding Stent Thrombosis

Dr. Hadi Mirgolbabaee[1,2], BSc Karlijn Leussink[1], MSc Yu-Tung Yang[1], MSc Marleen Krommendijk[1], MSc Jan van de Hoek[1], Prof. dr. Bob Geelkerken[1,3], Prof. dr. Michel Reijnen[1,4], Dr. Erik Groot Jebbink[1,4]

[1]Multi-Modality Medical Imaging group, TechMed Centre, University of Twente, Enschede, Overijssel, Netherlands. [2]Physics of Fluids group, TechMed Centre, University of Twente, Enschede, Overijssel, Netherlands. [3]Department of Vascular Surgery, Medisch Spectrum Twente, Enschede, Overijssel, Netherlands. [4]Department of Vascular Surgery, Rijnstate Hospital, Arnhem, Gelderland, Netherlands

Introduction

Stent thrombosis (ST) is a potentially hazardous complication after an endovascular procedure, impacting patients' quality of life. Because ST usually develops abruptly without detectable precursors, its occurrence in clinical practice cannot be predicted, limiting understanding of the thrombus growth mechanism and its relation to local hemodynamics. Existing microfluidic studies provide partial insights but cannot reproduce physiological boundary conditions, realistic stent geometries, or complex vascular anatomy. Hence, current literature is lacking methods for quantifying unfavorable hemodynamics such as blood stasis and recirculation zones, which are known to increase the platelet activation potential and promote ST. To address these gaps, we developed an in-vitro framework to investigate thrombus initiation and progression from hemodynamic and stent-related perspectives.

Methods

3D-printed phantoms were integrated into a closed-loop setup using heparinized (3.5 IU/mL) porcine blood. Ultrasound particle image velocimetry (echoPIV) was used to monitor thrombus formation and obtain time-resolved 2D velocity fields using high frame rate (~2000 fps) ultrasound imaging. In phase one, we evaluated the influence of unfavorable hemodynamic regions on thrombus formation potential by fabricating a step-stenosis phantom to generate regions of stasis and recirculation. In phase two, the repeatability of our experimental setup was evaluated and compared to prior video-microscopy studies. This was done using symmetric 50–75% stenosis phantoms, creating high-shear (>5000 s^{-1}) jets to induce arterial thrombosis. In phase three, stent-grafts were deployed in phantoms to examine graft-dependent effects and dynamics of ST formation.

In all phases, residence time (RT) and vector complexity (VC) were calculated to quantify unfavorable hemodynamics and relate them to thrombus growth.

Results

Step-stenosis experiments showed elevated RT and VC in stasis and recirculation zones, where thrombus formation was observed (Fig 1a–c). Symmetric stenosis phantoms exhibited high-shear jet formation, downstream recirculation, and thrombus formation at their narrowest part (Fig 1d–f). Preliminary stented-phantom results demonstrated thrombus accumulation at the stent's proximal region (Fig 1g,h).

Discussion

These preliminary findings provide valuable insights into the role of unfavorable hemodynamic parameters in predicting thrombus growth potential. Future work will quantify correlations between stent-graft configurations, hemodynamic parameters, and ST to develop a prediction model, which will be validated using in-vivo data.

[4]European Synchrotron Radiation Facility, Grenoble, Auvergne-Rhône-Alpes, France. [5]Grenoble Alps University, Grenoble, Auvergne-Rhône-Alpes, France

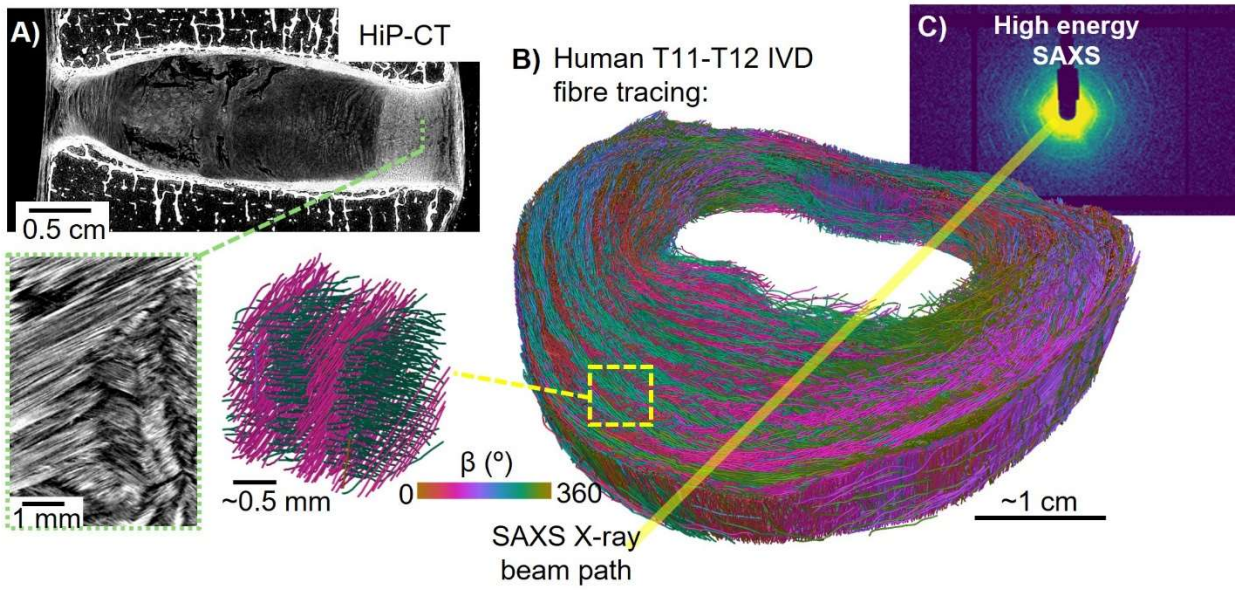
Introduction

Multiscale characterisation of fibre organisation and deformation is essential for understanding the load-bearing behaviour of the intervertebral disc (IVD), yet conventional imaging approaches cannot simultaneously capture nanoscale fibrillar mechanics and tissue-scale architecture in intact specimens. We have recently developed *TomoSAXS* – a combined small angle X-ray scattering (SAXS) and phase contrast computed tomography (CT) approach that enables 3D mapping of micro- to nanoscale collagen structure and mechanics [1]. Here, we reconstruct nano- to microscale properties of collagen fibres across intact human IVD.

Methods

Human IVDs (n=3) were imaged with hierarchical phase contrast tomography (HiP-CT) [2] (4-10µm voxel size, Fig.A) at the European Synchrotron (ESRF) beamline BM18, and correlatively with high energy (75keV) tomographic SAXS (beam size 100µm, Fig.C) at ESRF beamline ID31. Fibre tracing of IVD collagen fibres was performed using Avizo 2024.1, and orientation and curvature calculated. Fibre orientation was fed into the *TomoSAXS* reconstruction pipeline, enabling per-fibre reconstruction of collagen nanoscale properties including D-period and fibril diameter using 3D diffraction modelling and single value decomposition.

Results



HiP-CT enabled imaging of intact IVD with cellular resolution (Fig.A). Fibre tracing of the annulus fibrosus (Fig.B) provided quantification of orientation and curvature, showing areas of disruption due degenerative changes. *TomoSAXS* enabled per-fibre reconstruction of collagen fibril parameters including fibril diameter and D-period, a measure of fibrillar

pre-strain. The results show gradients in fibril diameter and pre-strain across the IVD, and that these are disrupted around degenerative features such as osteophytes and neovascularisation.

Discussion

This study is the first application of TomoSAXS to human organs, demonstrating the feasibility of the technique to study other systems such as the heart and lungs. We have previously shown that fibre curvature and fibril pre-strain are key determinants of a fibre's response to load [1], so the gradients in nano- to microscale collagen properties observed here likely support the overall mechanical function of the IVD, and could be used to improve computational models. Changes in these properties and their spatial gradients could be a key early indicator of IVD degeneration.

Structural Disease Patterns of Early Osteoarthritis in a DMM Mouse Model Relating to Mechanical Changes Revealed Using Time-Lapse *In Vivo* Contrast-Enhanced Micro-Computed Tomography

Dr Jemima E Schadow[1], Ms Emma C Boersma[1], Ms Annunzia M Cagnoni[1], Dr Pholpat Durongbhan[1], Dr Han Liu[1], Prof Rachel E Davey[2], Prof Kathryn S Stok[1]

[1]Department of Biomedical Engineering, The University of Melbourne, Parkville, Victoria, Australia. [2]Department of Medicine, Austin Health, The University of Melbourne, Heidelberg, Victoria, Australia

Introduction

The sequence of early structural tissue changes in the destabilised medial meniscus (DMM) mouse model of osteoarthritis (OA) is undefined. This study aimed to explore structural disease patterns of early OA in the DMM mouse model using time-lapse *in vivo* contrast-enhanced micro-computed tomography (CECT) at high temporal resolution.

Methods

DMM or sham surgery was performed on ten-week-old C57Bl/6 mice (n=22/group). Three mice/group were euthanised weekly until 28-days post-surgery and an additional 3 mice/group were euthanised at 10 weeks-old without surgery for histology. The remaining 10 mice/group underwent weekly microCT scans (10.4 µm, 70 kVp, 114 µA; vivaCT80, Scanco Medical AG) until day 28 and again at day 56 post-surgery. Three mice/group were euthanised for histology. All procedures approved by University of Melbourne, ethics approval #24339. Safranin-O staining and OARSI scoring were used to assess joint pathology. MicroCT images were analysed for cartilage attenuation, joint alignment, joint space and bone morphometry, and osteophyte formation. Effects of OA, time, and laterality were assessed with a mixed-effects model.

Results

OARSI score and mean attenuation were increased on the medial side of DMM mice, which is indicative of glycosaminoglycan depletion (Fig 1A). The number of voxels in the thinnest joint space layer increased on the medial side of DMM mice post-surgery and there was increased variability in dorsal axis and midsagittal axis angles of DMM mice at 14-, 21-, and 28-days post-surgery, indicative of joint space narrowing and increased laxity. Osteophyte formation was visually observed on both sides of the tibia and femur in DMM mice. Cortical porosity and trabecular thickness of medial tibia in DMM mice increased over time before decreasing at 56-days post-surgery (Fig 1B).

Discussion

Non-linear subchondral bone changes were observed in early stages following DMM surgery, likely reflecting altered mechanical loading. Initially, mechanical loading likely increased as joint space narrowed, and joint laxity increased but later decreased as osteophytes matured. These temporal fluctuations in structural disease development, highlight the importance of further research into OA phenotypes and their connection to features such as pain. Furthermore, it could provide indications for disease management, such as targeting joint laxity with physiotherapy.

The Matrix Reintegrated: Engineering Extracellular Matrix Mechanics in Organ-on-Chips

M.Sc. Hazal Kutluk[1,2], Prof. Dr. Iordania Constantinou[1,2]

[1]Institute of Microtechnology (IMT), Technische Universität Braunschweig, Braunschweig, Lower Saxony, Germany. [2]Center of Pharmaceutical Engineering (PVZ), Technische Universität Braunschweig, Braunschweig, Lower Saxony, Germany

Introduction

Mechanical properties of the extracellular matrix (ECM), including stiffness, thickness, and porosity, critically regulate cell proliferation, differentiation, and gene expression; yet current organ-on-chip (OoC) platforms mainly rely on simple protein coatings that poorly recapitulate this complexity. [1] This lack of mechanically tunable ECM analogues constrains the use of OoCs in mechanobiology research. To address this limitation, we present a novel strategy to integrate well-defined polyacrylamide hydrogels, widely used ECM-mimics, onto porous polyethylene terephthalate (PET) membranes commonly employed in OoCs.

Methods

PET membranes were amine-functionalized using different chemistries, concentrations, and treatment times, and functionalization efficacy was assessed via fluorescence labeling. Polyacrylamide gels with tunable stiffness and mesh size were covalently attached to activated PET, with stiffness measured by shear rheology and mesh size inferred from swelling behavior. The functionalized membranes were assembled into multilayer OoC devices, where hydrogel thickness was adjusted via gel precursor volume and quantified by fluorescence microscopy, while porosity was introduced by emulsion templating and visualized by scanning electron microscopy.

Results

Two membrane activation protocols yielded stable attachment of polyacrylamide hydrogels to porous PET membranes for at least 21 days in three different culture media under standard incubator conditions. The method translated to the OoC format, enabling integration of hydrogels with stiffness in the range of 3–30 kPa and tunable internal mesh size at comparable stiffness. Hydrogel thicknesses down to about 40 µm were achieved, with the maximum thickness set by the adjustable microchannel height. Emulsion

templating produced gels with around 50% porosity and mean pore sizes near 0.4 µm, with the potential for further tuning of both parameters. The resulting OoC platform is highly modular, supports thermoplastic or glass sealing, and allows optional electrode integration for non-invasive, real-time readouts.

Discussion

For the first time, our platform introduces tunable, well-defined ECM-mimicking polyacrylamide hydrogels into OoCs. Establishing precise control over hydrogel mechanics overcomes a key limitation of existing OoC systems, expands biological questions addressable on chip, and supports future work connecting ECM mechanics with disease modelling and drug-response profiling.

A Microfluidic Platform for Perfused Culture of Organoid Units With Engineered Vascular Networks

Ms. Ayaka Kadotani[1], Dr. Gen Hayase[2], Prof. Daisuke Yoshino[1]

[1]Tokyo University of Agriculture and Technology, Koganei, Tokyo, Japan. [2]National Institute for Materials Science, Tsukuba, Ibaraki, Japan

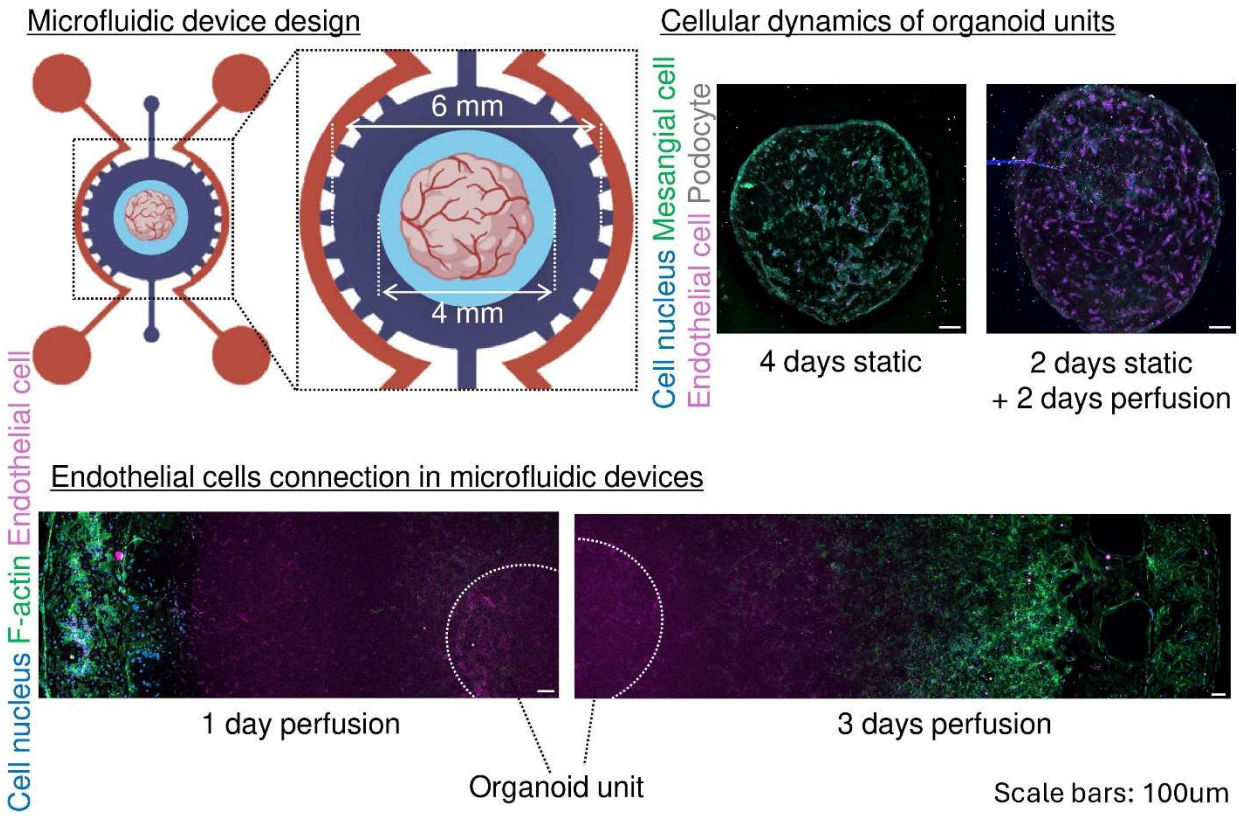
Introduction

Organoids have attracted considerable interest due to their potential to serve as alternatives to donor organs. These organoids express certain higher-order functions; however, their current size is limited to a few millimeters due to the absence of control over developmental processes and nutrient diffusion. To address these problems, we previously proposed a modular assembly approach, and we have developed the method to fabricate organoid units that replicate the kidney glomerulus rapidly and assemble them in three dimensions [1]. Nevertheless, the absence of vasculature resulted in cell death in organoid units during prolonged culture, thereby limiting the expression of higher-order functions. In this study, we developed a microfluidic device designed to culture units under perfused, physiologically relevant conditions and to analyze their cellular dynamics when combined with hierarchical vascular networks.

Methods

Microfluidic devices were fabricated by casting polydimethylsiloxane (PDMS) onto master molds and bonding PDMS layers to glass coverslips. Organoid units were prepared as previously described [1], and cultured in the designated medium fortwo days. The hydrogel containing human umbilical vein endothelial cells (HUVECs) and pericytes was dispensed into the device's gel channel, and organoid units were embedded within it. Following the incubation period, HUVECs were seeded on media channels. Subsequent to a six-hour static culture, the devices were perfused at a rate of 0.02 milliliters per minute for three days.

Results



When the organoid units were embedded within the microfluidic device and cultured under perfusion, a confluent endothelial monolayer formed along the media channel within the first day. Furthermore, the endothelial cells lining the channels have been shown to form direct connections with those residing within the organoid units.

A comparison of cellular dynamics between organoid units cultured under static conditions and those embedded in the microfluidic device revealed that the perfused units exhibited markedly improved cell survival, particularly among endothelial populations.

Discussion

The present findings suggest that integrating engineered vascular networks with organoid units supports their long-term culture. Subsequent studies must ascertain whether physiological mechanical stimuli facilitate the development of these higher-order functions, which are essential for fabricating transplantable organoids through the modular approach.

Introduction

Subcutaneous implants trigger immune reactions mediated by macrophages, making effective tissue repair essential to re-establish the native dermal environment. Three-dimensional (3D) *in vitro* microstructured scaffolds represent valuable platforms for studying these processes, as they enable the reconstruction of microvascular networks. Upon proper modulation of their physicochemical features, they can play a key role in directing macrophage behavior.

Methods

3D scaffolds were fabricated by two-photon polymerization of the biocompatible photoresist SZ2080 and presented small (15×15×15 μm^3)[1] and large (50×50×20 μm^3)[2] pores. Human dermal fibroblasts (HDF) and HUVEC were cultured in 50×50 scaffolds integrated into a Miniaturized Optically Accessible Bioreactor (MOAB, Figure 1A), perfused at 5µl/min, and administered with VEGF (50ng/mL) and TGF-β1 (5ng/mL). RAW264.7 macrophages were polarized with lipopolysaccharide (M1) or interleukin-4 (M2) in both scaffolds (Figure 1B). Co-cultures were stained for collagen I and CD31 at day 7, inducible nitric oxide synthase (iNOS, M1, Figure 1C), and arginase 1 (Arg1, M2) and acquired by confocal laser scanning microscopy (CLSM). Cytoskeletal changes and metabolic activity of macrophages were analyzed.

Results

The perfused setup provided a robust model of dermal regeneration with the development of early tubular formations (128.1±8.6 µm) and increased deposition of collagen I upon VEGF administration. Both scaffolds markedly influenced macrophage shape,

organization, and metabolic activity in static conditions. In the presence of chemical stimuli, 50×50 pores produced a modest increase in Arg1 expression (+5%), suggesting a shift toward an anti-inflammatory phenotype. Conversely, 15×15 pores strongly enhanced iNOS levels (+121%), promoting a marked pro-inflammatory response.

Discussion

The integration of the 3D scaffolds into the MOAB enabled the generation of a dermal perivascular microenvironment that closely resembles physiological conditions. Thanks to their adjustable architectural features, the scaffolds allowed precise modulation of macrophage functions. Upcoming studies will further explore macrophage dynamics within the perfused bioreactor, in presence of chemical cues.

Bending Stiffness Recovery of the Functional Spinal Unit Repaired With Human iPS Cell-Derived Cartilaginous Tissue

Prof. Hiromichi Fujie[1,2,3], Mr. Masaki Nakane[1], Mr. Yuto Noma[1], Mr. Naoto Kuroyama[1], Prof. Takashi Kaito[4], Prof. Noriyuki Tsumaki[5]

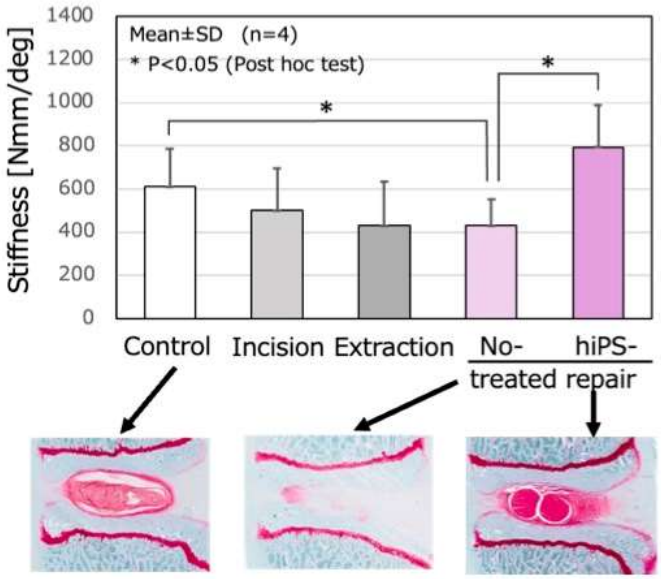
[5]Department of Tissue Biochemistry, Graduate School of Medicine, Osaka University, Suita, Osaka, Japan

Introduction

The loss of nucleus pulposus (NP) induces intervertebral disk (IVD) degeneration, which causes back pain. Conservative treatments for IVD may alleviate symptoms but do not restore the degenerated IVD to its healthy state. Yamashita and Tsumaki developed human iPS cell-derived cartilaginous tissue particles (hiPS-Cart). The present authors have performed single-cell RNA sequencing analyses and indicated that hiPS-Cart is a candidate implant for regenerating NP, and preventing IVD degeneration in a rat model. Therefore, the objectives of the present study are to implant hiPS-Cart into NP-removed IVD and assess its bending stiffness recovery in a porcine model.

Methods

hiPS cells, generated from the Center for iPS Cell Research and Application, Kyoto University [1], were chondrogenically differentiated to produce hiPS-Cart following a previously described method [2]. The vertebrae between L2 and L5 from 10-month-old mini pigs were exposed, followed by the removal of the whole NP through the longitudinal, lateral portal of the IVD. Nine hiPS-Cart particles with a diameter of 1.5 mm were inserted into the nuclectomized space. The annulus fibrosus and skin were sutured, and then the operated side was immobilized with surgical tapes. At 3 months after surgery, the vertebral samples were harvested and osteotomized into three vertebra-IVD-vertebra complexes. Histological examination was performed for the complex using safranin-O staining. The remaining complexes were subjected to the bending test using a robotic joint test system [3]. For comparison, the intact complex, sham operation-treated complex, and the non-treated, repaired complex were tested.



Results

Histological observation indicated that the NP was repaired well with remaining hiPS-Cart particles in the iPS-Cart treated group, although such tissues were not found in the non-treated group. The bending stiffness of the complex was recovered to the control level in the iPS-Cart treated group, with a significant increase compared to the non-treated group.

Discussion

It is suggested that the implantation of hiPS-Cart maintained the potential of cartilaginous tissue formation in the NP and restored the resulting bending stiffness of the vertebra-IVD-vertebra complex.

Extracellular Matrix Shape Change Contributes to Skeletal Muscle Passive Force Production

Ms Emily McParland MS, Professor Thomas Roberts PhD

Brown University, Providence, Rhode Island, United States

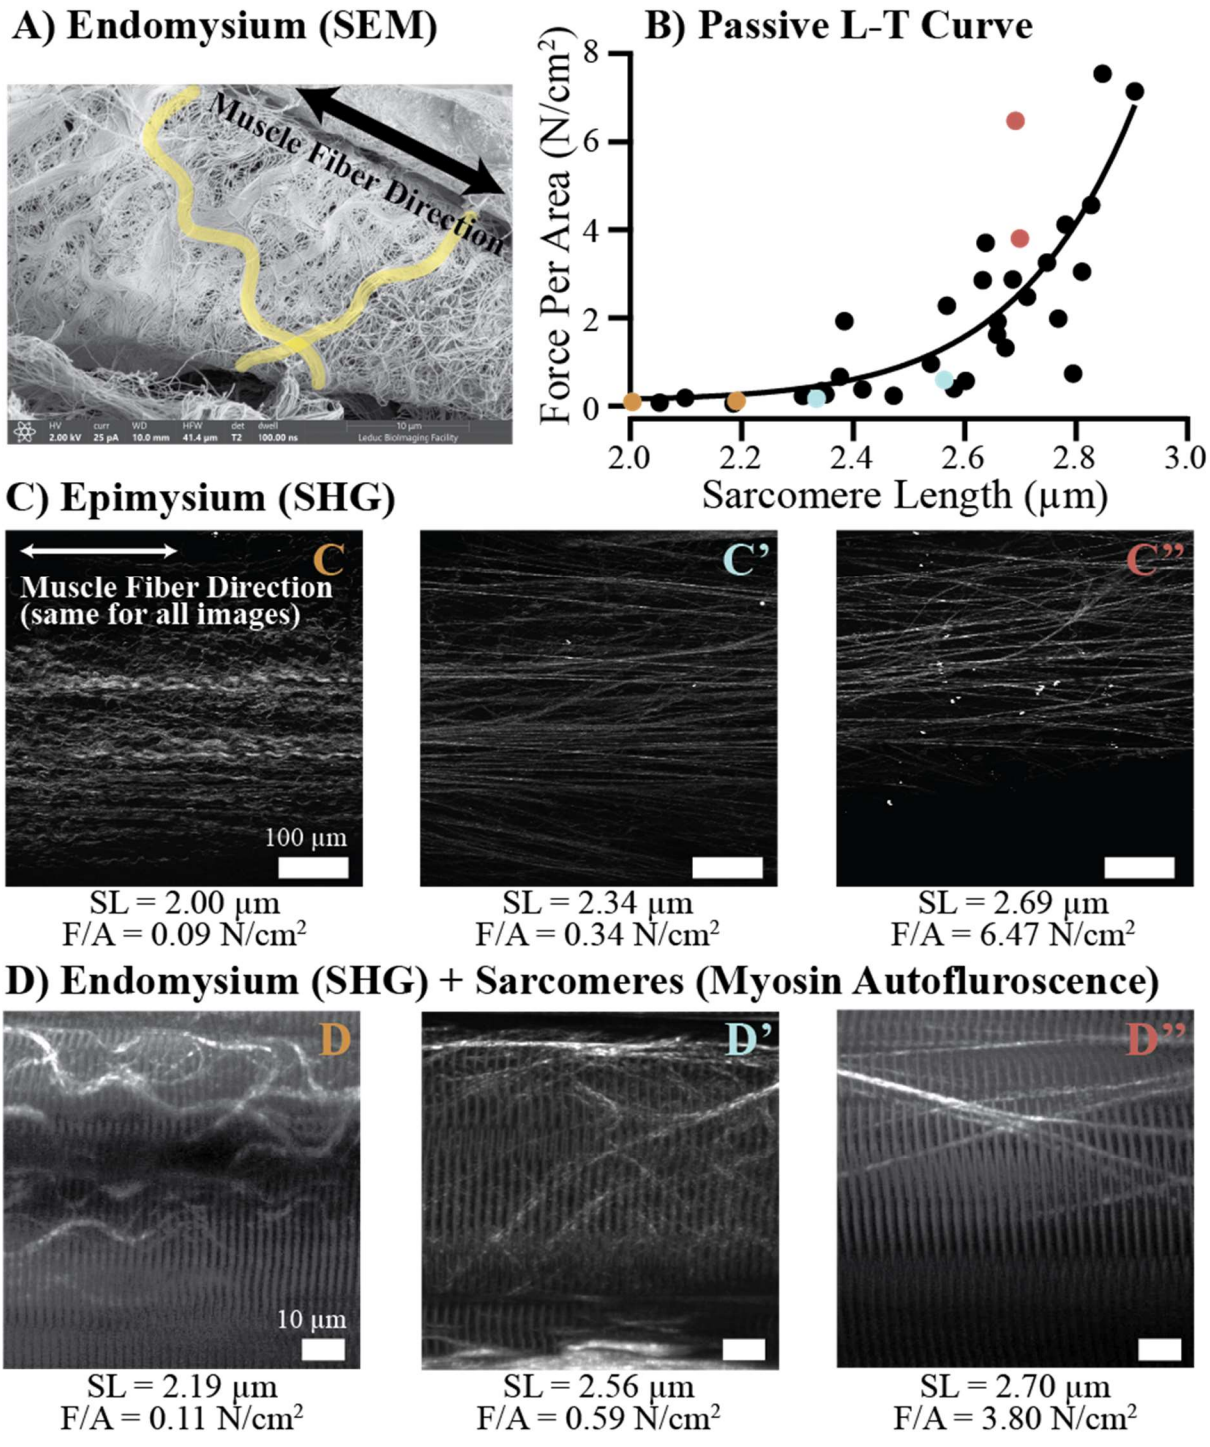
Introduction

Skeletal muscle is a hierarchically organized composite structure that contains a collagenous extracellular matrix (ECM). Each layer of ECM corresponds and interacts with the scaled layers of the muscle. Epimysium wraps around the whole muscle with large, aligned cables, acting as the most superficial layer of connective tissue. Perimysium encapsulates muscle fascicles and endomysium surrounds and interacts with individual muscle fibers [1] and has obliquely-oriented cables (Figure 1A). Previous work has indicated that ECM undergoes architectural changes during muscle lengthening [2], however, no work has correlated ECM architectural dynamics with passive force production.

Methods

Frog sartorius, trout levator operculi, and mouse soleus muscles were isolated and secured into a custom 3D printed apparatus filled with Ringer's solution. The muscle was fixed to the apparatus and connected to a force transducer secured to an adjustable stage that changed muscle length. Epimysium and endomysium collagen were visualized through second harmonic generation (SHG) using a multiphoton laser scanning microscope (Olympus, Tokyo, Japan). Sarcomere lengths in the same preparation were quantified through visualization of autofluorescent myosin.

Tortuosity was quantified (straight line distance / total collagen fiber length) for both epimysial and endomysial cables [3]. In endomysium, once tortuosity reached a value >0.99, angle relative to the long axis on the muscle was measured. Each of these metrics were compared to force and muscle length.



Results

As force rose exponentially during sarcomere lengthening (Figure 1B), epimysial cables uncrimped immediately (Figure 1C-C') and remained uncrimped throughout the muscle stretch (Figure 1C''). As muscles lengthened and force increased, endomysial cables uncrimped (Figure 1D-D'). Once straightened, endomysial cable angle relative to the muscle's long axis decreased (Figure 1D'-D'').

Discussion

Changes in frog, fish, and mouse skeletal muscle collagen architecture correlate with an increase in passive force, indicating that ECM bears some portion of the load during passive force production. Future work will assess how ECM-related pathologies, like fibrosis, impact ECM dynamics.

Scaling Work and Stability: How Two Distal Muscles Partition Propulsion and Landing Control in Guinea Fowl

Dr. Caitlin Bemis, Dr. Monica Daley

University of California, Irvine, Irvine, CA, United States

Introduction

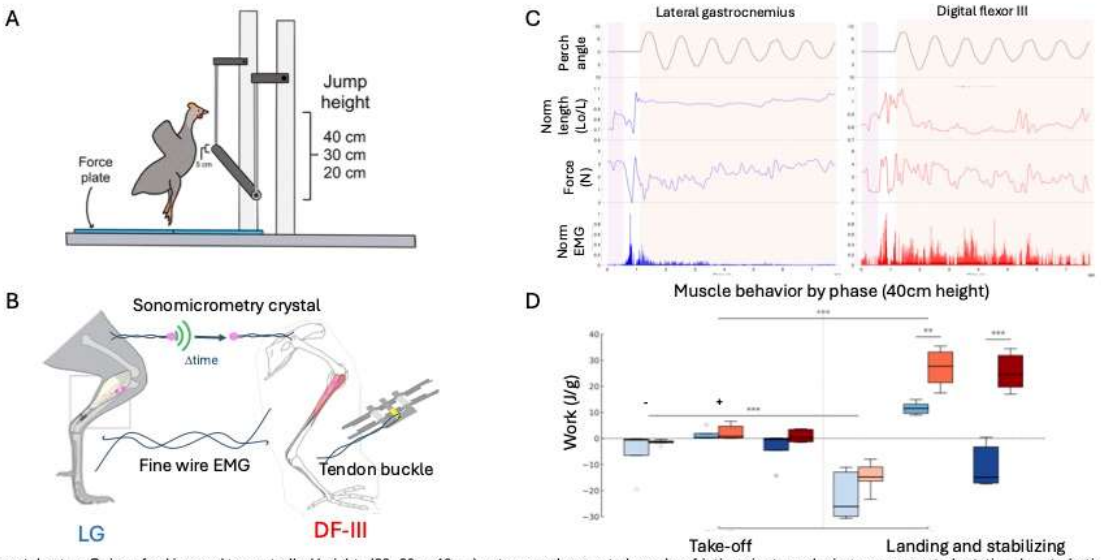
Locomotion on unstable substrates challenges animals to rapidly modulate force and energy, yet how individual muscles contribute to non-steady behaviors remains unclear. Distal muscles, with architecture that favors rapid mechanical responses, are poised to mediate stability at the limb-substrate interface. However, whether different distal muscles perform distinct roles during perturbed movement is unknown.

We investigate *in vivo* dynamics of the lateral gastrocnemius (LG) and digital flexor III (DF) in Guinea fowl (*Numida meleagris*) during jumping and landing on an unstable perch, a task that requires transition from propulsion to reactive stabilization. We hypothesized that LG and DF would exhibit muscle–specific mechanical roles. Specifically, we predicted: (1) LG would produce positive work during take-off; (2) DF would increase activation, force, and positive work during landing; and (3) DF activation would be temporally linked to substrate rotation and amplified at higher jump heights, reflecting increased perturbation magnitude.

Methods

Six adult guinea fowl performed multiple jumps to perches at three heights (20, 30, 40 cm). We recorded muscle force, fascicle length, activation, ground reaction force, and perch motion during landing and stabilization. We quantified muscle work (J/g) from force-length trajectories to compare phase specific mechanical contributions of LG and DF-III. Two-way ANOVAs were performed with muscle and phase as fixed factors on work. Additionally, we used linear mixed-effects models with individual as a random factor to account for repeated measures within birds.

Results



LG produced substantially greater positive work during take-off, confirming a propulsive role. In contrast, DF-III generated significantly greater positive and net work during landing ($p < 0.05$), with activation aligned to perch rotation. DF-III work scaled with jump height, indicating increased energetic contributions under larger perturbations. Both muscles absorbed energy during landing, but only DF-III produced positive work during perch

stabilization, demonstrating a neuromechanical division of labor: LG powers propulsion, whereas DF-III provides stability.

Discussion

Distal muscles do not scale work uniformly under unsteady conditions but adopt complementary strategies shaped by their architecture and mechanical context. This study provides rare *in vivo* evidence that distal muscles partition propulsive and stabilizing functions.

Images (Optional)

A). Experimental setup. Guinea fowl jumped to controlled heights (20, 30 or 40cm) onto a perch mounted on a low friction pivot, producing an unexpected rotational perturbation upon landing. Ground reaction forces were recorded with a force plate. B). *In vivo* muscle recordings. Lateral gastrocnemius (LG; blue) and digital flexor III (DF-III; red) fascicle length (via sonomicrometry), muscle activation (fine-wire EMG), and tendon force (E-buckle transducer) were collected simultaneously during each jump. C) Representative muscle mechanics from a 40cm jump. Perch rotation induces oscillatory perturbation during stabilization. LG and DF-II exhibit distinct mechanical signatures across standing to landing and stabilizing, including fascicle length trajectories (Lo/L), force output and EMG activity. Shaded regions denote the standing and landing responses. D). Muscle work (negative, positive, and net) portioned by movement phase. LG and DF-III perform opposing mechanical roles across take-off and landing/stabilization. Bars show median + interquartile rang; individual trials overlaid. Statistical different across muscles phases indicated (** $p < 0.01$; ****$p < 0.0001$)

Extreme Heat Production and Thermal Gradients in the Flight Muscles of Bombycoid Moths

Dr Ethan Wold[1], Dr Leo Wood[2], Dr Yash Sondhi[3], Dr Pablo Allen[4], Dr Akito Kawahara[5], Dr Simon Sponberg[6]

[1]University of Chicago, Chicago, IL, United States. [2]Princeton University, Princeton, NJ, United States. [3]Case Western Reserve University, Cleveland, OH, United States. [4]Council on International Educational Exchange, Monteverde, Puntarenas, Costa Rica. [5]University of Florida, Gainesville, FL, United States. [6]Georgia Institute of Technology, Atlanta, GA, United States

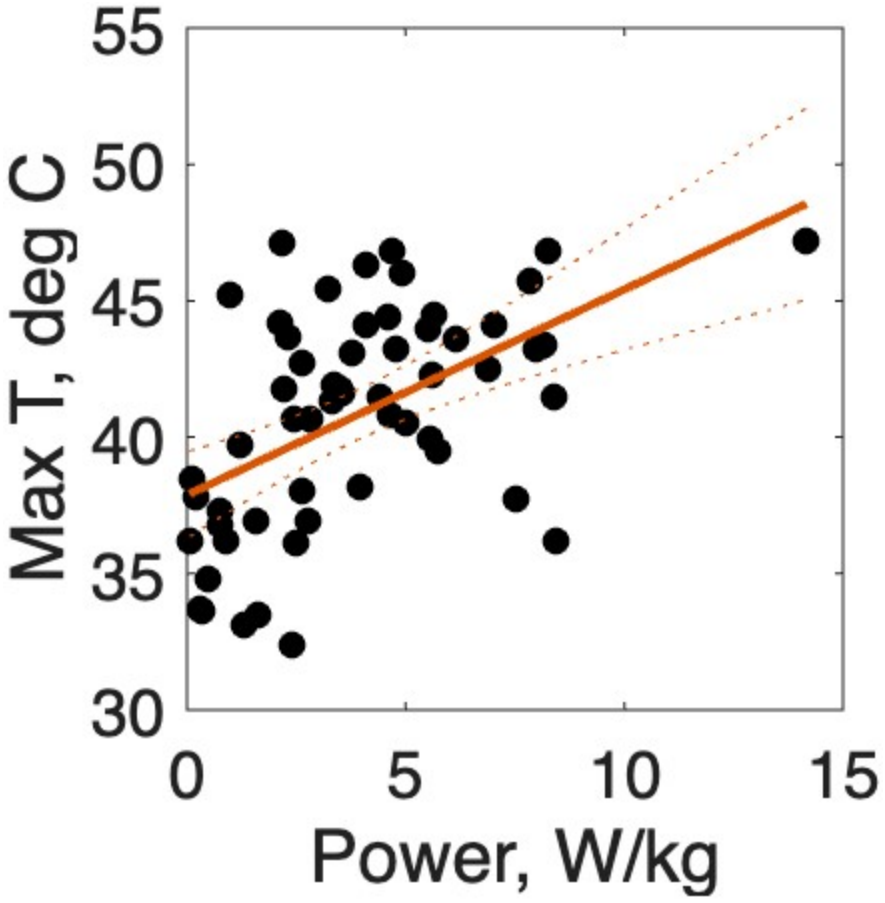
Introduction

Skeletal muscle emits heat as a byproduct of force production, but the processes that generate force are temperature dependent. Hawkmoths, for instance, use muscular heat to maintain thoracic temperatures above 40 ºC, enhancing muscle output. Consequently, the thermal gradient between the innermost and outermost fibers causes regional differences in power production. However, across species, it remains unclear whether high temperatures and associated gradients follow from flight power requirements or represent excess heat that boosts muscle function. We performed a field study on Bombycoid moths, extreme animal athletes that produce enough heat to be functional endotherms during flight. We measured depth-resolved intramuscular temperature and tested whether power demands explain variation in temperature and thermal gradient using predictions from a thermodynamic model.

Methods

Light-trapped moths were collected at Monteverde Research Station in Costa Rica. Moths were tethered beneath a high-speed video camera capturing stroke-plane kinematics. During flapping, temperatures were taken progressively deeper into their downstroke muscle. After experiments, photos quantified wing morphology and thoraxes were massed. Wingbeat frequency and amplitude were extracted from videos and flight power costs associated with aerodynamic drag and wing acceleration were estimated using standard formulae.

Results



Peak intramuscular flight temperature was 40.7 ± 4.1 ºC, with some moths reaching 47.2 ºC during sustained flapping. Thermal gradients were 0.83 ± 0.26 ºC/mm. Wingbeat frequency and thorax length predicted variation in peak temperature, but not thermal

gradient. Flight power predicted surface and peak muscle temperature, but not gradient. Assuming a spherical thorax and applying the heat equation, we predicted the relationship between power demands and both maximum temperature and thermal gradient. Measured temperatures and gradients were significantly larger than expected scaling.

Discussion

Peak temperatures exceeded model predictions based upon locomotor power costs, suggesting flight muscles produce excess heat that supports muscle function. In contrast, lack of correlation between thermal gradients and power supports that gradients themselves are not important for power production. They may stem from deep elevated temperatures or thermoregulatory responses to overheating. Further comparative tests relating in-vitro optimal muscle temperatures with these data may clarify how high intramuscular temperatures enhance muscle performance.

The Effect of Sensory Loss on Jaw Kinematics and Muscle Activation During Mastication

Dr. Jing-Sheng Li, Dr. Fritzie Arce-McShane

University of Washington, Seattle, WA, United States

Introduction

Masticatory behavior involves coordination of sensory and motor systems. Oral sensation can modify and fine-tune jaw movements. In this study, we aimed to investigate the effect of sensory loss on jaw motion and muscle activation. We hypothesized that muscles in the sensory-loss condition have reduced activation and delayed peak timing, and the jaw shows slower opening and a smaller range of motion (ROM) during chewing.

Methods

We collected jaw position and muscle activity while an adult male rhesus macaque (Macaca mulatta, weight: 11.5 kg, age: 8 years) performed a feeding task. In the simulated sensory-loss condition, a temporary anesthetic block was applied to the sensory branches of the trigeminal nerve prior to the experiment. Jaw motions were captured using marker-based biplanar videoradiography at 200Hz. Fine-wire electromyography (EMG) was used to record the activity from temporalis, masseter, and digastricus at 10kHz. Gape cycles identified as chews were included in the analysis. Jaw ROM and duration were evaluated for each chew cycle from maximum gape to the minimum gape. Raw EMG signals were filtered, rectified, and then applied to a moving-average window of 50ms. To quantitatively evaluate the effect of sensory loss, we compared the jaw ROM, gape close phase duration, EMG peak intensity, and time between the EMG peak from the maximum gape and to the minimum gape, with control condition.

Results

In the control condition, the jaw ROM was ~15° with a gape close phase duration of ~191.1ms. EMG peak intensity varies between muscles. Under nerve block, jaw ROM decreased by 11%, gape close phase duration increased by 14%, EMG peak intensity decreased by 7-52%, delayed EMG occurrence by 12-28%, and longer time from EMG peak to minimum gape in most muscles (Table 1).

Discussion

Our study demonstrates that sensory feedback is critical during chewing. Sensory loss changes both kinematics and EMG features. These may further change the loading

mechanics in the oral cavity and TMJ joint. Abnormal loading mechanics have been considered a source of early degenerative changes in the joint. However, the EMG intensity decrease in the nerve block condition may be a potential compensatory mechanism to reduce excessive force generation.

Images (Optional)

Table 1. Jaw kinematics and EMG features

		Nerve block (n= 426 gape cycles) mean (SD)	Control (n = 841 gape cycles) mean (SD)	P-value
ROM (Max gape to Min gape, °)		13.1 (5.6)	14.7 (3.9)	<0.001

Can Concomitant Meniscus Injury Modify Jumping Characteristics in Female Adolescents After Acl Reconstruction?

Dr. Karine Velasques Stoelben[1], Dr. Allison Clouthier[2], Dr. Alicia Kerrigan[1], Dr. Daniel Benoit[3], Dr. Sasha Carsen[1]

[1]CHEO Research Institute, Ottawa, Ontario, Canada. [2]University of Ottawa, Ottawa, Ontario, Canada. [3]Lund Univerisity, Lund, Scania, Sweden

Introduction

Meniscal injury often presents as part of initial anterior cruciate ligament (ACL) injury or emerges due to chronic ACL-deficiency. Meniscus injuries can impact joint load absorption, potentially leading to different landing strategies. Ten months after surgery, adult patients with concomitant meniscus and ACL injury and isolated ACL injury presented no differences in jump performance. However, the impact of concomitant injury on jumping strategies and whether it is replicated in adolescent patients is still unclear. Considering that young females are among the highest risk for poor landing mechanics and associated ACL injury, we investigated whether jump outcomes differ between female adolescents who had a concomitant meniscus injury versus an isolated ACL injury after return to activity clearance (RTA).

Methods

We conducted a cross-sectional analysis of 30 female adolescent patients who underwent ACL reconstruction surgery (ACLR) classified into two groups: concomitant (meniscus and ACL injuries) or isolated group (ACL-only injury). All participants were released to RTA and completed five trials of countermovement jump on two force plates. Outcomes measured were: ground reaction force peak (GRFp) and impulse during propulsion phase; GRFp and absorption rate (GRFp/time to peak) during landing phase; and jump height (normalized to participant's body weight or height). Mann-Whitney U, Independent t-tests, or chi-square tests compared demographic characteristics and MANOVA was used to identify group effect.

Results

Seventy-seven percent of patients presented a concomitant meniscus and ACL injury. There was no difference between groups for demographic characteristics, autograft type, or time since surgery. The concomitant injury group presented lower GRFp and higher time

to GRFp in the injured leg than the isolated injury group (Figure 1A-B). The absorption rate was lower in both legs for the concomitant injury group (Figure 1C-D).

Discussion

Female adolescents with concomitant meniscus and ACL injury present a worse strategy in jump landing than those with isolated ACL injury 9 months post-ACLR. Concomitant injury leads to longer landing compensations, which suggests a protective mechanism in favour of the injured leg. Therefore, rehabilitation process and RTA clearance may take longer and require special attention to the landing strategy for patients who have undergone surgery for concomitant injuries.

Stretch-Shortening Cycle Force-Time and Power-Time SPM Waveform Analysis Indicates Limitations of the Contralateral Limb Benchmark in Athletes After ACLR

Ms. Shadan Al-Saket[1], Mr. Zachary McClean[1], Dr. Nathan Boon-van Mossel[1], Dr. Tanita Botha[2], Dr. Helen Bayne[3,4], Mrs. Cassidy de França[5], Dr. Kati Pasanen[1], Dr. Matthew Jordan[1]

[1]University of Calgary, Calgary, AB, Canada. [2]Deakin University, Geelong, Victoria, Australia. [3]The University of Western Australia, Perth, WA, Australia. [4]Western Australian Institute of Sport, Perth, WA, Australia. [5]University of Pretoria, Pretoria, Gauteng, South Africa

Introduction

Unilateral countermovement jump (CMJ_{SL}) testing is commonly used after anterior cruciate ligament reconstruction (ACLR) to assess stretch-shortening cycle (SSC) function, neuromuscular deficits and return-to-sport (RTS) readiness. However, the impact of ACLR on contralateral limb SSC function is poorly understood and whether the unaffected contralateral limb benchmark overestimates rehabilitation status compared to an objective benchmark from sport- and sex-matched athletes remains unclear. Moving beyond discrete performance, statistical parametric mapping (SPM) may reveal additional regional deficits in CMJ_{SL} biomechanics in athletes after ACLR. This study employed SPM to compare interlimb force- and power-time CMJ_{SL} curves of (i) athletes after ACLR and (ii) healthy athletes with better ($GOOD_{SFI}$) and worse ($POOR_{SFI}$) perceived-limb function, evaluated using the Sport Fitness Index (SFI); and (iii) compare affected & unaffected limbs in ACLR athletes to an enhanced benchmark established from the $GOOD_{SFI}$ group (i.e. the $Control^{+}$ benchmark).

Methods

Canadian university athletes post-ACLR (*n*=20; 11 female; 14±5 months post-op) cleared for RTS and healthy controls (*n*=464; 192 female) performed maximal CMJ_{SL} testing on a force plate. SFI assessed perceived-limb function, and healthy control participants were divided into upper ($GOOD_{SFI}$) and lower ($POOR_{SFI}$) tertiles. The top-ranked jumpers with $GOOD_{SFI}$ were sex- and sport-matched to ACLR athletes to obtain the CMJ_{SL} $Control^{+}$ (enhanced) benchmark. CMJ_{SL} curves were compared within and between-groups using SPM.

Results

No interlimb differences were found in healthy athletes with $GOOD_{SFI}$, whereas healthy control athletes with $POOR_{SFI}$ demonstrated interlimb force and power deficits over 13% and 4% of the CMJ_{SL} movement, respectively ($p<0.001$). Compared to the unaffected limb, the affected limb of ACLR athletes showed reduced force and power over 8% ($p<0.001$) of the CMJ_{SL} propulsive phase. Reflecting greater regions of impairment, the affected limb generated less force over 14% and less power over 25% ($p<0.001$) of propulsion compared to the Control^{+} benchmark.

Discussion

An enhanced biomechanical benchmark provided a better indication of persistent SSC impairments than the contralateral limb benchmark in athletes who had returned to sport post-ACLR. Further, healthy athletes with worse perceived-limb function demonstrated interlimb force and power impairments similar to the ACLR group, highlighting the value of combining biomechanical testing with psychosocial measures in university athletes.

[3]Escola Paulista de Medicina, Universidade Federal de São Paulo (UNIFESP), São Paulo, São Paulo, Brazil. [4]Instituto Brasil de Tecnologia da Saude, Rio de Janeiro, RJ, United States

Dr. Renato Miyadahira

Introduction

Bankart repair and the Latarjet procedure are commonly used to treat recurrent anterior shoulder instability. Loss of external rotation (ER) has been seen after the Latarjet procedure, and Bankart repair may also alter muscular control of the shoulder. However, the specific neuromuscular strategies adopted after each procedure remain poorly understood, particularly during positions of high mechanical demand, such as ER with abduction. Our goal was to compare active ER range of motion and neuromuscular activation patterns after Bankart repair and Latarjet procedures, using healthy shoulders as controls.

Methods

Thirty participants (n=30) were enrolled and assigned to three equal groups (n=10 each group): arthroscopic Bankart repair, Bristow–Latarjet–Patte procedure, and healthy controls. Shoulder motion was captured using a 3D optical tracking system, and surface electromyography recorded activity from the deltoid, trapezius, pectoralis major, infraspinatus, teres minor, and serratus anterior. Participants performed ER at 90º of abduction in both weighted and unweighted conditions. Non-normally distributed variables were analyzed using the Kruskal–Wallis test with Dunn post-hoc analysis ($\alpha = 0.05$).

Results

Compared to healthy controls, the Bankart group showed greater humerothoracic flexion–extension during weighted ER (14.6º±6.0º vs 5.5º±8.2º; P=0.04) (Figure). [JG1] Both surgical groups trended (P=0.07) towards increased Scapulothoracic upward rotation during unweighted ER compared with controls (P=0.07). The Bankart repair group demonstrated greater activation of the pectoralis major (sternal head) compared with the Latarjet procedure only in the weighted condition (34.6%±17.1% vs 14.2%±11.3%; P=0.03). The Latarjet group trended towards greater infraspinatus activation in the unweighted condition (43.8%±14.5% vs 33.3%±6.1%; P=0.09).

Discussion

Although total active ER range of motion was similar across groups, Bankart shoulders demonstrated greater humerothoracic flexion–extension and increased activation of the pectoralis major (sternal head) during weighted ER. In contrast, Latarjet shoulders exhibited higher activation of the infraspinatus, indicating more posterior stabilization. The greater anterior recruitment observed in Bankart shoulders under load may be clinically relevant for postoperative rehabilitation planning to prevent potential anterior impingement problems**.**

Dr. Renato Miyadahira

Introduction

Both Bankart and Latarjet procedures are well-established techniques for surgically treating anterior shoulder instability. However, their effects on shoulder biomechanics during flexion remain poorly understood. Understanding postoperative adaptations in muscle activation and biomechanical motion can help explain how stability is restored postoperatively. We aimed to compare in vivo glenohumeral and scapulothoracic kinematics, as well as surface electromyographic (EMG) activation during forward flexion, among patients who underwent arthroscopic Bankart repair, open Latarjet procedure, and healthy controls.

Methods

Thirty participants were enrolled and divided into three groups (n=10 each group): Bankart, Latarjet, and healthy controls. Participants conducted active shoulder forward flexion tests without and with weights (1.4 kg in each hand) in our motion analysis lab. Three-dimensional glenohumeral and scapulothoracic kinematics was recorded using an optical motion-capture system synchronized with surface EMG of the deltoid (anterior, middle, posterior portions), pectoralis major (clavicular and sternal heads), trapezius (upper, middle, lower portions), serratus anterior, infraspinatus, and teres minor. Non-normally

distributed variables were compared using the Kruskal–Wallis test with Dunn's post-hoc analysis (α=0.05).

Results

Significant differences (Figure 1) between groups were observed in EMG activation during unweighted, ascending phase of flexion for the middle trapezius (ε^2=0.21, P=0.05), pectoralis major sternal head (ε^2=0.21, P=0.05), infraspinatus (ε^2=0.24, P=0.03), and teres minor (ε^2=0.22, P=0.04). Shoulders with Bankart repair showed greater activation of the middle trapezius and pectoralis major than Latarjet (P=0.04) and higher teres minor activation than healthy controls (P=0.04). Conversely, the Latarjet group presented higher infraspinatus activation than the Bankart group during unweighted ascending (P=0.03) phases and both unweighted (P=0.01) and weighted (P=0.03) descending phases. Kinematic analysis revealed greater scapulothoracic internal/external rotation in the unweighted descending phase in Bankart compared to Latarjet shoulders (ε^2=0.30, P=0.01). No significant differences were found for the glenohumeral joint.

Discussion

Latarjet patients showed increased infraspinatus activity and greater scapular external rotation during the descending phase of flexion, indicating increased stabilization of the shoulder to improve joint compression. These findings suggest that Latarjet patients demonstrate a more mechanically efficient and neuromuscularly balanced shoulder function, which may improve long-term stability compared with isolated soft-tissue repair.

Association Between Glenoid Deformity Correction and Functional Humeral Head Subluxation in Anatomic Total Shoulder Arthroplasty

Dr. Nazanin Daneshvarhashjin[1], Ms. Line Ven[1], Prof. Philippe Debeer[2], Prof. Michael S Andersen[3], Prof. Filip Verhaegen[1,4], Prof. Lennart Scheys[1,4]

Introduction

Recentering the humeral head by correcting glenoid deformity is a key goal of anatomic total shoulder arthroplasty (aTSA) in the treatment of shoulder osteoarthritis. Postoperative humeral head subluxation (HHS) causes eccentric loading and increases the risk of implant loosening. Understanding how intra-operative glenoid correction relates to HHS correction is, therefore, important for reducing implant failure. Previous studies using CT images in supine positions have reported inconsistent findings, and the relationship in upright, functional positions remains largely unexplored. This study aims to address this gap.

Methods

Pre- and postoperative biplanar radiographs in six upright functional arm positions and supine CT images were collected for patients undergoing aTSA (n=28). Radiographs were obtained in relaxed standing (RS), extension (45EX), 45 and 90 degrees of flexion (45F and 90F), and abduction (45AB and 90AB). 3D bone models were reconstructed from CT (Fig1.A-B) and registered to their corresponding 2D biplanar radiographs (Fig1.C). 3D glenoid component models were also registered to CT images. To measure HHS, the (implanted) humeral head center offsets from the native/implanted glenoid center in the anteroposterior (AP) and superior-inferior (SI) directions were measured in each pose and normalized to the (implanted) humeral head diameter (Fig1.D). A stepwise linear regression analysis was conducted to quantify the effects of pre- to post-op glenoid correction—including version, inclination, and center translation — on correction of HHS.

Results

HHS-AP was predicted by glenoid version correction in the supine position ($\beta = 0.46$, $p = 0.03$), but not during functional arm positions. HHS-SI was predicted by inclination correction in supine ($\beta = 0.43$, $p = 0.04$) and several functional positions (45AB, 90AB, 90F, 45F with $\beta > 0.35$ and $p<0.05$). Glenoid center translation in the SI direction was also a

predictor of HHS-SI in functional arm poses (45AB, 90AB, 45F). Additionally, glenoid translation in the ML direction predicted HHS-AP at EX, while glenoid version correction predicted HHS-SI at 90F.

Discussion

Correction of glenoid inclination and superior implant positioning can play a significant role in correcting HHS-SI, whereas glenoid version correction does not predict HHS-AP in functional poses. This lack of surgical control may explain the underlying mechanism behind glenoid component loosening.

Introduction

Loss of active external rotation is frequent in rotator cuff arthropathy and a key indication for reverse total shoulder arthroplasty (RTSA). Implant design, especially medialized versus lateralized glenospheres, may alter biomechanics and muscle recruitment, although in vivo comparisons are limited. This study aimed to compare humerothoracic external rotation between RTSA designs and to assess the related electromyographic activity.

Methods

This cross-sectional study included 22 RTSAs with either a medialized (n=12, mean age 71.2 ± 6.1 years, mean follow-up 47 ± 22 weeks) or lateralized design (n=10, mean age 70.8 ± 6.5 years, mean follow-up 68 ± 56 weeks). Three-dimensional optoelectronic motion capture and surface EMG were used to record standardized external rotation tasks with the arm at the side (ER1) and at 90 degrees abduction (ER2). Outcomes included humerothoracic range of motion (ROM), scapulohumeral rhythm, and EMG activity of the deltoid, pectoralis major, infraspinatus, teres minor, trapezius, and serratus anterior. EMG values were normalized to maximal voluntary isometric contraction. Between-group comparisons were performed using Mann-Whitney U-tests, and effect sizes were reported.

Results

In ER2, the medialized group demonstrated greater humerothoracic ROM compared with the lateralized group (16.7°± 10.3° vs. 5.8° ± 7.2°, P = 0.020, r = 0.485) (Table 1-A). No significant difference was observed in ER1 (18.2° ± 10.8° vs. 25.8° ± 8.9° , P = 0.088). Medialized implants demonstrated higher anterior deltoid activation (ER1: 11.0% ± 9.1%

vs. 5.0% ± 4.7%, P = 0.017; ER2: 34.2%± 11.2% vs. 22.0% ± 10.2%, P = 0.038), greater middle deltoid recruitment across tasks, and increased middle trapezius activity (ER1: 33.2% ± 10.8% vs. 20.0% ± 15.0%, P = 0.017) (Table 1-B). Lateralized designs showed lower overall activation of deltoid and trapezius muscles, with more balanced activity across scapular stabilizers.

Discussion

Medialized and lateralized glenospheres influence distinct biomechanical strategies during external rotation. Lateralized implants provided greater ROM in neutral with lower muscular demand, whereas medialized designs enhanced ROM at 90 degrees of abduction but required greater deltoid and trapezius recruitment. These position-specific trade-offs highlight the influence of implant design on motion and neuromuscular load and support individualized implant selection and rehabilitation planning.

Muscle-Tendon Recovery Trajectories Relate to Shoulder Disability in Rotator Cuff Tendinopathy

Dr. Kayla Seymore PhD[1], Dr. Oscar Vila-Dieguez PT, PhD[2], Dr. Matthew Heindel PT, DPT, PhD[1], Dr. Lori Michener PT, ATC, PhD[1]

[1]University of Southern California, Los Angeles, CA, United States. [2]University of California San Diego, San Diego, CA, United States

Introduction

Rotator cuff (RC) tendinopathy is a leading cause of shoulder disability, with up to half of patients experiencing persistent symptoms despite receiving gold-standard exercise treatment. Variability in shoulder disability outcomes following resistance exercise may be driven by distinct responses of common tendon structural and neuromuscular deficits to exercise treatment. However, mechanisms of muscle-tendon recovery for RC tendinopathy are not well understood and remain poorly linked to patient-centered outcomes. This study evaluated the association and contribution of shoulder neuromuscular function and tendon structure to shoulder disability outcomes during an 8-week resistance exercise program in individuals with RC tendinopathy.

Methods

Adults with RC tendinopathy (n=63, 23F/40M) underwent an 8-week standard-of-care resistance exercise program with measures taken at baseline and 8-weeks. Rate of force development from 50-100ms (RFD50-100) and 100-200ms (RFD100-200) during maximal external rotation isometric contraction was recorded with a load cell. Supraspinatus tendon thickness was measured via B-mode ultrasound. The Penn Shoulder Score assessed shoulder disability (0-100,100=no disability). Linear mixed-effect models tested the association of tendon structure and neuromuscular function, as well as contribution of change in neuromuscular function and tendon structure to shoulder disability, over 8 weeks of resistance exercise treatment.

Results

Tendon thickness was positively related to RFD100-200 over 8-weeks of treatment (b(SE)=7.97(3.86), p=0.042;Fig.1A). The main effects of change in tendon thickness and RFD100-200 were not related to shoulder disability, though their interaction with shoulder disability differed over time ($p<0.003$). Greater RFD100-200 at baseline related to less shoulder disability (b(SE)= -0.294(0.91), p=0.002) while reduction in tendon thickness at 8-

weeks related to improved shoulder disability (b(SE)=35.45(6.23), p<0.001;Fig.1B-C). No significant relationship or interactions were observed for RFD50-100.

Discussion

This study took an innovative approach to understand recovery for RC tendinopathy by linking tendon structure and neuromuscular function to shoulder disability outcomes with resistance exercise treatment. Findings provide critical insight into RC muscle-tendon recovery trajectories and identify tendon structural improvement as a key contributor to shoulder disability following resistance exercise treatment. Future work will integrate RC muscle activation and tendon stiffness to define the tendon loading response that drives structural remodeling and improved recovery.

OA14-06

Exploratory Kinematic Analysis for Identifying Humeral Elevation Control Strategies in Rotator Cuff Tendinopathy

Mr Chethan Reddy, Mr Daniel McPherson DPT, Dr. Kayla Seymore, Dr. Lori Michener PhD, PT, ATC, FAPTA, FNATA

University of Southern California, Los Angeles, CA, United States

Introduction

Shoulder pain affects up to 25% of the general population, with rotator cuff (RC) tendinopathy accounting for up to 90% of diagnoses. Individuals with RC tendinopathy demonstrate altered kinematics that may modify tissue-loading mechanics and contribute to maladaptive tendon stress. How these altered movement patterns reflect underlying motor control strategies remains unclear. Studies have examined kinematics in discrete and interval differences, which may obscure meaningful temporal features. Continuous-time analysis offers a more complete representation of motor control strategies. In this study, we identify kinematic patterns that may indicate motor control differences in individuals with RC tendinopathy.

Methods

52 participants diagnosed with RC tendinopathy (32M/20F; age 29.0 ± 8.6) and 52 matched controls were examined. Participants performed a standardized bilateral humeral elevation task holding dumbbells, in a constrained scapular-plane motion, following a 75-beats-per-minute verbal cadence. Humeral kinematics for the affected side were collected using a Polhemus Liberty electromagnetic tracking system (240 Hz). Humeral elevation was computed using ISB-recommended Euler angle conventions and filtered with a 6 Hz Butterworth filter. Elevation cycles were extracted using standardized boundaries around each peak corresponding to the duration of movement, and velocity and acceleration profiles were calculated by numerical differentiation. Statistical Parametric Mapping two-sample t-tests were applied to position, velocity, and acceleration waveforms.

Results

Two significant regions of interest emerged for velocity during the eccentric phase: a mid-range (100-75°) interval ($p < 0.001$) and a late-range (30-20°) interval ($p = 0.002$). Patients exhibited higher magnitude velocities during the mid-range interval, but lower magnitude

velocities during the late-range interval. No significant group differences were identified for humeral elevation position or acceleration.

Discussion

Individuals with RC tendinopathy exhibited altered eccentric control strategies characterized by phase-specific modulation of humeral angular velocity. Higher mid-range velocity may reflect reduced active resistance to gravity when the external moment arm is largest, whereas lower late-range velocity may reflect a compensatory slowing strategy near the resting position. This suggests altered regulation of eccentric torque, which may contribute to abnormal tendon loading. These findings indicate that deficits in dynamic eccentric control, rather than positional limitations, may characterize RC tendinopathy.

Images (Optional)

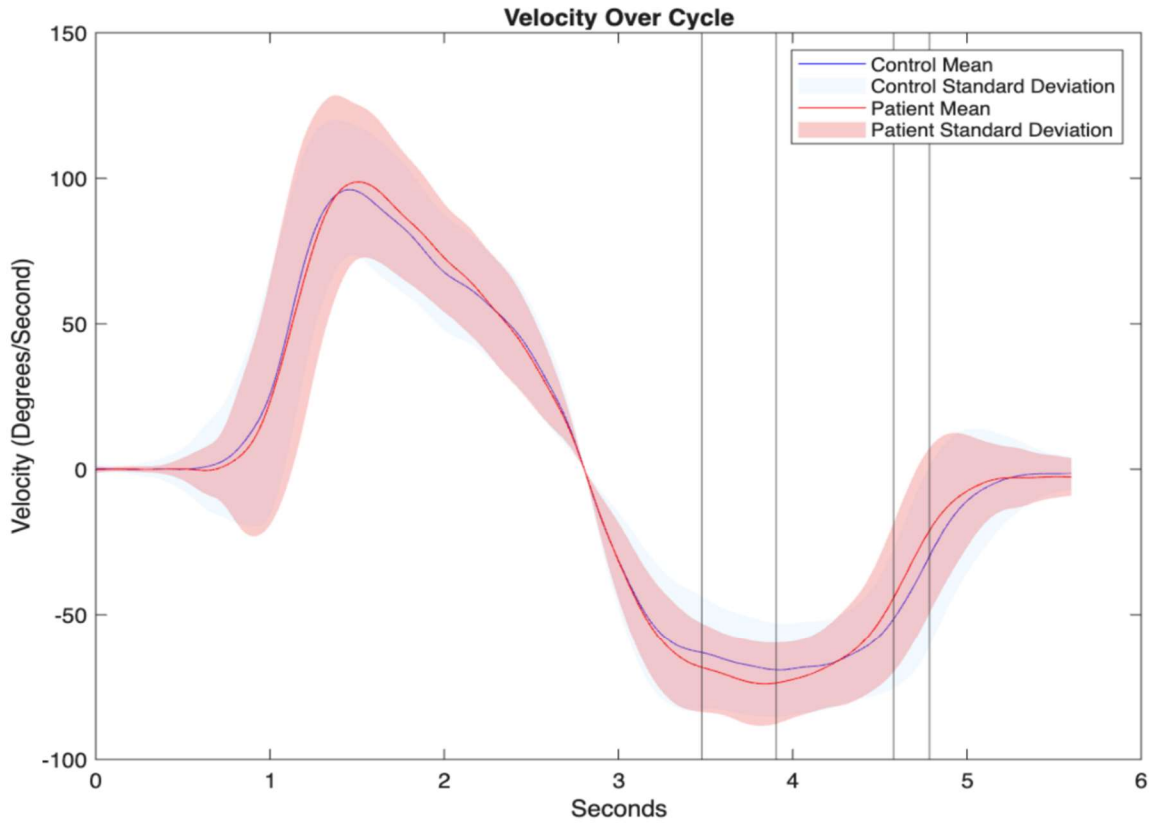

Figure 1. Mean (solid lines) and standard deviation (shaded regions) of humeral elevation angular velocity across the standardized arm-elevation cycle for participants with RC tendinopathy (red) and matched controls (blue). Vertical black lines denote the significant regions of interest identified by the SPM two-sample t-test.

Full-Body Gait Reconstruction from Arbitrarily Sparse Wearable Sensors via Diffusion Models with Transfer from Healthy to Pathological Populations

PhD Candidate Run Lin[1], Dr. Pavlos E. Evangelidis,[2], Dr. Dong Wang[1], Prof. Helen Dawes[2], Dr. Xijin Hua[1]

[1]Department of Engineering, Faculty of Environment, Science and Economy, University of Exeter, Exeter, Devon, United Kingdom. [2]NIHR Exeter BRC, University of Exeter Medical School, Exeter, Devon, United Kingdom

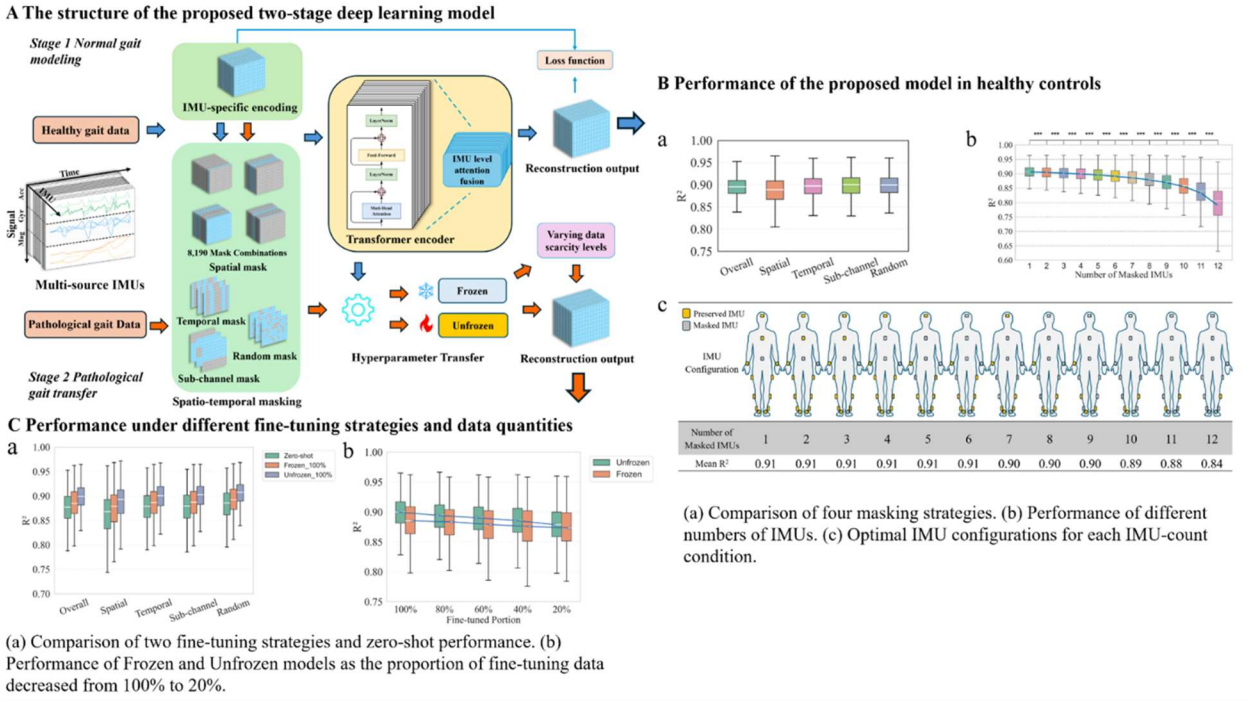
Introduction

Human motion analysis is essential for monitoring daily activities, tracking disease progression, and guiding rehabilitation. Conventional optical motion capture systems deliver high-fidelity measurements but are expensive, infrastructure-heavy and operationally demanding. Wearable inertial measurement units (IMUs) offer a practical alternative; however, existing approaches remain highly vulnerable to sparse or missing sensor signals and show limited adaptability to pathological gait. This study aimed to develop a unified diffusion-based generative model that reconstructs full-body motion from sparse or arbitrarily positioned IMUs and transfers this capability from healthy to pathological gait.

Methods

We proposed a two-stage diffusion-based framework operating on multichannel IMU data (Fig.1A). In the first stage, the model was trained on data from healthy controls to learn spatiotemporal dependencies across sensors and body segments, enabling reconstruction of complete motion signals under varying degrees of signal sparsity. In the second stage, a transfer-learning procedure fine-tuned the pretrained model using a small dataset of Parkinson's patient to adapt reconstruction to pathological gait patterns. Model performance was evaluated across diverse IMU configurations using R^2. Interpretability analyses were performed to gain a more comprehensive understanding of how different sensors and channels influence both healthy and pathological models.

Results



Trained on healthy data, the model accurately reconstructed full-body motion from sparse IMU configurations (mean $R^2 = 0.90$), despite severe signal degradation (Fig. 1B). Zero-shot evaluation on pathological gait showed a reduced R^2 of 0.86. After transfer learning on patient cohorts, the adapted model restored high-fidelity pathological gait reconstruction,

with a best-case R^2 of 0.89 (Fig 1C). Performance remained robust to different IMU placements and missing-sensor configurations.

Discussion

This is the first study to apply diffusion-based modelling to wearable gait analysis, enabling reconstruction of full-body IMU signals from sparse, arbitrarily placed sensors and transfer from healthy to pathological gait. Compared with prior methods relying on fixed configurations, the framework enables consistent biomechanical analyses across heterogeneous sensor configurations, greatly improving flexibility, robustness to missing data, and compatibility with downstream simulations. This has important implications for the design of portable wearables and exoskeletons, and future work will include validation in larger, more diverse populations and development of pathology-informed adaptive training and real-time deployment.

IMU-Derived Impact Metrics From an Outdoor Run Are Correlated to Motion Capture-Calculated Joint Kinetics

Ms. Tatiana Djafar[1], Dr. Nicholas Heebner[1], Mr. Tyler Cardinale[1], Dr. Benjamin Cuddy[1], Dr. Jeremy Ross[1], Mr. Andrejs Zalaiskalns[2], Dr. Joshua Winters[1]

[1]University of Kentucky, Lexington, KY, United States. [2]United States Marine Forces Special Operations Command, Camp Lejeune, NC, United States

Introduction

In-depth motion capture assessments of running have been used to identify movement patterns and loading strategies indicative of elevated musculoskeletal (MSK) injury risk. However, in the military, barriers such as available resources and time constraints due to occupational demands can prevent their feasibility within active training environments. Utilizing commercially available inertial measurement units (IMUs) and their outputs may provide a viable option for "invisible monitoring." This study examined the relationship between metrics derived from motion capture and automated outputs from IMUs during overground running.

Methods

15 (4 female) Marine Forces Special Operations Command personnel who were cleared for full, unrestricted duty completed an in-depth running mechanics evaluation using markerless motion capture and integrated force plates as well as a 15-minute outdoor run with tibia-mounted IMUs across separate testing sessions. The middle 10 minutes of the outdoor session were used for analysis. Pearson correlation coefficients (α=0.05) were calculated to examine the relationships between system outputs.

Results

Pearson correlation coefficients can be found in Table 1. Cumulative impact load as calculated by the commercial IMU software was negatively correlated to peak knee extension moments and positively correlated to peak ankle plantarflexion moments, ankle power absorption (dominant limb only), and ankle negative work. Average intensity as calculated by the commercial IMU software was also positively correlated to peak ankle plantarflexion moment, ankle power absorption, and ankle negative work on the dominant limb while the non-dominant limb only exhibited a correlation with peak ankle plantarflexion moment.

Discussion

Outputs determined by commercially available devices worn during the outdoor run demonstrated moderate relationships with joint kinetics calculated from markerless motion capture. These results suggest a potential capability for minimally invasive monitoring during military training that can provide clinically meaningful insights of lower extremity loading, particularly at the ankle. Differences in impact intensity relationships with joint kinetics between the dominant and non-dominant limb may be due to underlying neuromuscular mechanisms and could have training implications. Regular monitoring of impact load metrics may allow for earlier intervention from both a strength and conditioning and clinical perspective to mitigate MSK injury risk while maintaining operational readiness.

Detection of Gait Events during Aquatic Treadmill Walking using Shank Angular Velocity

Mr. Joseph Harrington MS, Dr. David Kingston PhD

University of Nebraska at Omaha, Omaha, NE, United States

Introduction

Time normalization of the gait cycle is essential to quantify walking biomechanics and motor control strategies[1]. Shank angular velocity can identify gait events in various populations on land[2,3]; but it is unknown if this approach translates to aquatic environments. Therefore, this study investigated shank angular velocity characteristics during dry and aquatic treadmill walking in typically developing (TD) and children with cerebral palsy (CP).

Methods

Fifteen TD and 14 children with CP completed three 3-minute walking trials on a dry and aquatic treadmill (9 minutes of walking per environment) at modified self-selected speeds (Slow or 75%, Normal or 100%, and Fast or 125%)[4]. Each participant had seven waterproof intertial measurement untis (WaveTrack IMU, Cometa, Milian, Italy) secured bilaterally to the foot, shank, thigh, and one on the pelvis. A custom algorithm identified gait events using shank angular velocity and was compared to marker-based gait event detection during dry treadmill walking[5]. Dynamic time warping (DTW) assessed morphological similarities of shank angular velocity across environments by matching indices of one signal with one or more indices of the other (Figure 1B), and quantified differences. Statistical parametric mapping (SPM) evaluated magnitude differences pre and post-warping.

Results

Conventional time normalization to 101 data points revealed differences in shank angular velocity between treadmill environments (Figure 1A). However, no normalized differences occurred after DTW (Figure 1C).

Discussion

Conventional time normalization assumes uniform stride structure; however, aquatic walking has altered stride mechanics due to buoyant and hydrodynamic effects[6]. Our results demonstrate that linear time normalization introduces discrepancies between dry and wet treadmill walking, particularly during the swing phase where speed-dependent

hydrodynamic effects would be largest. However, DTW characterizes and demonstrates that while water immersion modifies the temporal structure of the shank angular velocity signal, the signal morphology is unchanged. Overall, these findings suggest that features of shank angular velocity needed to identify gait periods are preserved in water, suggesting the same detection framework developed for dry environments can be used in aquatic environments without additional adjustments.

Images (Optional)

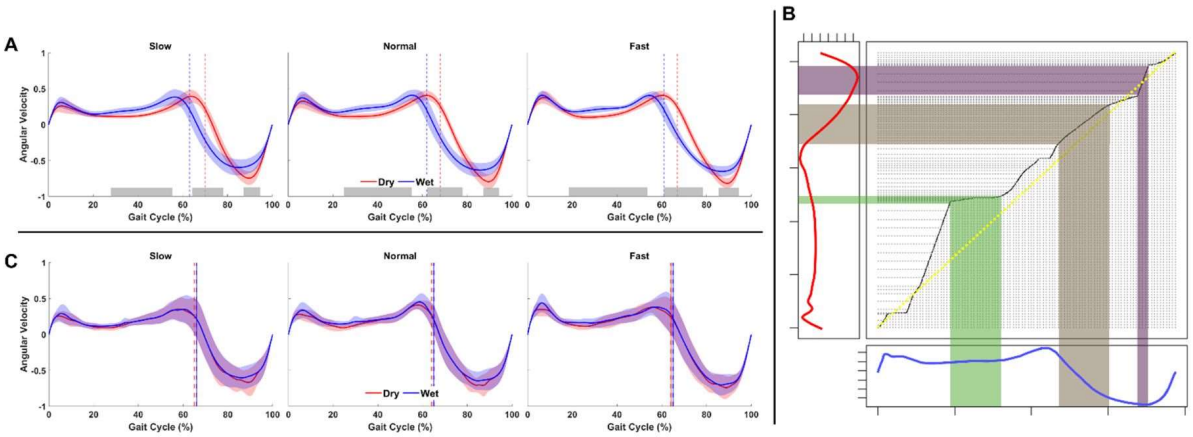

Figure 1: Statistical parametric mapping results of representative shank angular velocity waveforms during Dry (red) and Aquatic (Wet, blue) treadmill walking after normalizing to 101 data points (A) pre- and (C) post- dynamic time warping. Shaded grey areas in A indicate significant differences at α = 0.05. Vertical dashed lines correspond to toe-off. Lower Limb Joint Kinematics in Older Adults During Walking in the Home Setting

Mr Mohammad Yavari, Dr Zhou Fang PhD, Dr Yiqun Chen Dr, Dr Davood Shojaei PhD, Prof Abbas Rajabifard PhD, Prof Peter Lee PhD, Prof David Ackland PhD

University of Melbourne, Parkville, VIC, Australia

Introduction

Older adults most commonly experience falls in the home setting [1], yet gait in the home, which is known to differ substantially to that in a controlled laboratory environment [2], is seldom evaluated. The extent to which age-related changes influence gait in the home setting also remains poorly understood. The aim of this study was to evaluate lower limb joint kinematics and spatiotemporal gait parameters during habitual walking throughout a home setting in both younger and older adults.

Methods

Ten healthy young adults (age: 27.7±1.8 years) and ten older adults (age: 74.7±7.0 years) performed nineteen diverse daily activities of daily living over a 2-hour duration throughout a fully furnished single-bedroom apartment that included a kitchen, bathroom, bedroom and living room. Each participant's lower limb joint kinematics and spatiotemporal gait parameters were measured using inertial measurement units (IMUs), and their spatial location throughout the apartment captured using an ultra-wide band system. A mixed-design analysis of variance (ANOVA) was conducted to assess the effects of participant age and living space (room) on peak joint angles and spatiotemporal parameters during walking.

Results

Compared with young adults, older adults exhibited a smaller range of ankle ($p = 0.002$, $\eta^2 = 0.52$) and knee ($p = 0.040$, $\eta^2 = 0.36$) joint flexion angles. Maximum knee flexion in older adults was most significantly smaller to that of younger adults when walking in the bathroom (mean difference: 13.0°, 95% CI = [7.0°, 18.9°], $p < 0.001$). Older age was significantly associated with slower walking speed ($p = 0.006$, $\eta^2_p = 0.74$), and walking speed did not vary significantly between living spaces ($p > 0.05$).

Discussion

Lower limb gait kinematics during walking in the home setting is governed by the internal environment and its associated spatial constraints, which has a substantial impact on the mobility of older adults. The findings have implications for interior design, ergonomics, rehabilitation and fall risk assessment in the home setting.

Do Shoulder and Elbow Kinetics and Pitching Kinematics Differ Between Pitching On Dirt Surface and Turf Surface Pitching Mounds?

Dr Rafael Escamilla PhD, PT, CSCS, FACSM[1], Dr Jonathan Slowik PhD[2], Dr Rodney Imamura PhD[1], Dr Irwin Thompson EdD, PT[1], Dr Robert Asuncion DPT, PT[1], Dr Arnel Aguinaldo PhD, ATC, CSCS[3], Dr Glenn Fleisig PhD[2]

[1]California State University, Sacramento, Sacramento, CA, United States. [2]American Sports Medicine Institute, Birmingham, AL, United States. [3]Point Loma Nazarene University, San Diego, CA, United States

Introduction

While most baseball fields have dirt pitching mounds, some have turf mounds. Pitching on dirt mounds permits metal cleats, which are discouraged on turf mounds due to turf damage. However, it's unknown if pitching biomechanics differ between dirt and turf mound pitching. Therefore, the purpose was to assess differences in shoulder and elbow kinetics and pitching kinematics in college pitchers between pitching on a dirt mound versus pitching on a turf mound.

Methods

Eighteen college pitchers pitched on both a dirt mound with metal cleats and a turf mound with turf shoes. All pitchers were tested using a 240-Hz, 12-camera motion analysis system, and 28 kinematic and 7 kinetic parameters were calculated. Differences in kinematic and kinetic parameters between dirt and turf mound pitching were assessed with paired t-tests with p-values adjusted (Benjamini-Hochberg method) for multiple comparisons ($p<0.05$).

Results

Significant differences are shown in Table 1. Maximum elbow varus torque, maximum shoulder internal rotation torque, maximum lead knee height, elbow flexion, knee flexion, rotational separation between upper trunk and pelvis, maximum shoulder external rotation, and forward trunk tilt were significantly greater pitching on a dirt mound than a turf mound. Pelvic drift at maximum lead knee height and arm slot angle were significantly greater pitching on a turf mound than a dirt mound.

Discussion

Of the 35 biomechanical comparisons, 10 were significantly different between dirt and turf mound pitching. This implies that pitching mechanics are more similar than different

between dirt and turf mound pitching. However, given several pitching biomechanical differences were found, pitchers who pitch on a dirt mound in-season should only pitch on a turf mound in the off-season and not during pre-season or in-season. Kinematic differences only involved body segment and joint positions and not angular velocity magnitudes or timings. Kinetic differences demonstrated that elbow and shoulder joint torques were overall slightly less pitching on a turf mound than pitching on a dirt mound. Therefore, pitching on a turf mound may decrease throwing elbow and shoulder joint tissue stress and injury risk compared to pitching on a dirt mound, although more research is needed to fully assess injury risk.

The Influence of Soft Tissue Glenohumeral Internal Rotation Deficit (ST-GIRD) on Proprioceptive Feedback, Cortical Activity, and Pitching Performance in Baseball Players

Master Student Zong-Han Hsieh, PhD Yi-Hsuan Weng, Professor Jiu-Jenq Lin

School and Graduate Institute of Physical Therapy, College of Medicine, National Taiwan University, Taipei City, Taipei City, Taiwan

Introduction

The traditional Glenohumeral Internal Rotation Deficit (GIRD) overlooks soft tissue changes, whereas Soft Tissue Glenohumeral Internal Rotation Deficit (ST-GIRD) reflects injury mechanisms more comprehensively. GIRD adaptations may lead to proprioceptive deficits at both peripheral and central levels and affect pitching performance. This study aimed to investigate the relationship between ST-GIRD and cortical activity (central level), proprioceptive error (peripheral level), and functional performance, and to compare these measures between groups with and without internal rotation deficit.

Methods

Fifty eight high school baseball players were divided into a deficit (ST-GIRD > 5°, n=32) and no deficit groups (soft tissue glenohumeral internal rotation gain > 5°, n=26). Outcome measurements included proprioceptive error of glenohumeral joint by electromagnetic-based motion analysis system; cortical activity at F3/4 and P3/4 (alpha and beta frequencies) by electroencephalography; and functional performance (muscle strength, pitching velocity and constant error).

Results

In the no deficit group, increased soft tissue glenohumeral internal rotation gain moderately correlated with decreased pitching constant error on the x-axis and y-axis ($r = -0.356$, $p=0.074$ and $r=0.345$, $p=0.084$, respectively) and lower absolute beta frequency power in frontal lobe during the cocking phase ($r = -0.337$, $p=0.093$). There were no significant correlations among measurements in the deficit group ($r= -0113 - 0.201$, $p>0.05$). Compared to no deficit group, the deficit group exhibited significantly weaker strength in middle trapezius (9.4 kg, $p = 0.001$) and lower trapezius (5.9 kg, $p = 0.001$), and slower ball velocity (5.0 km/h, $p = 0.020$). Furthermore, the deficit group demonstrated

significantly lower amplitude of beta frequency in parietal lobe during the ball release phase (8.1%, p = 0.041) relative to no deficit group.

Discussion

ST-GIRD is not solely a problem of soft tissue tightness but is fundamentally linked to broader neuromuscular deficits and central sensorimotor alterations, as evidenced by changes in muscle strength, pitching performance, and cortical activity. This underscores the critical importance of intervention programs that move beyond passive stretching to comprehensively target soft tissue mobility, dynamic scapular control, and significantly sensorimotor retraining.

Images (Optional)

OA16-03

Intersegmental Coordination in Baseball Pitching: Identifying Skill Level Differences

Mr. Michael Jensen BS, CSCS, Dr. Katherine Boyer PhD

University of Massachusetts Amherst, Amherst, MA, United States

Introduction

In baseball, pitching performance is paramount for success among skill levels. Extensive work on the kinematic sequence has shown that the proximal-to-distal timing of peak joint angular velocities is closely related to pitching performance[1]. However, peak velocities alone do not capture how segments interact throughout the pitching motion. Intersegmental coordination provides a framework for quantifying these interactions. Here, we examined pelvis–torso and torso–arm coordination patterns across skill levels.

Methods

Full-body marker trajectories from 21 baseball pitchers (high-school, collegiate, professional; n=7/group) were obtained from Driveline Baseball's OpenBiomechanics dataset [2]. Three-dimensional pelvis, torso and arm segment angles were calculated in Visual3D. Data were time-normalized from peak leg lift to ball release and separated into three pitch phases: peak leg lift to front-foot contact, front-foot contact to maximum shoulder external rotation (ER), and maximum ER to ball release. Pelvis–torso and torso–arm coordination was quantified using vector coding to obtain coupling angles during each pitch phase [3]. Coupling angles were classified into four coordination patterns; proximal-dominant, distal-dominant, in-phase and anti-phase; across the three pitch phases. Groupwise differences in coordination distributions for each pitch phase were assessed using one-way ANOVAs with post-hoc tests and effect sizes (Cohen's d).

Results

There were no differences in coordination state distributions between groups during early pitching (peak leg lift to front-foot contact; all $p>0.16$), However, professional pitchers exhibited more pelvis-dominant coordination than high school pitchers ($d=0.41$, $p=0.08$).From front-foot contact to maximum external rotation, no coordination pattern differed (all $p>0.38$). From max ER to ball release, moderate effects for trunk and arm dominance was observed between high school and higher skill levels (p=0.08-0.13, d=0.34-0,40).

Discussion

Intersegmental coordination patterns were not significantly different between skill levels. Moderate effect sizes suggest subtle changes in coordination during early and late pitching as skill progresses. These findings suggest coordination strategies are largely conserved, with small refinements at higher levels. Future work should examine whether these refinements can be targeted through coaching and relate to performance.

Images (Optional)

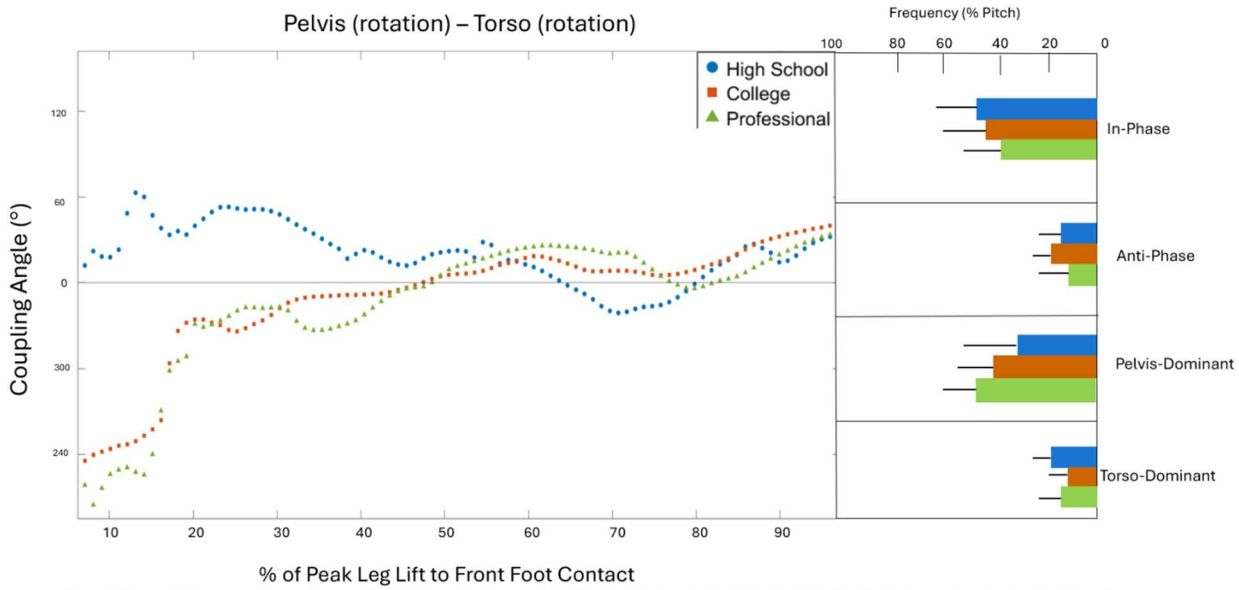

Figure 1. Mean pelvis–torso coupling angle across the pitching motion from peak leg lift to front-foot contact for high school (blue), collegiate (orange), and professional (green) pitchers (left). Horizontal bar charts (right) show the percentage of time spent in each coordination pattern (in-phase, anti-phase, pelvis-dominant, and torso-dominant) over the same phase of the pitch.

Field Performance of Modern Collegiate Baseball Bats

Prof JJ Trey Crisco[1], Prof Kristen Nicholson[2], Mr Ethan Yoon[1], Prof Richard Greenwald[3]

[1]Brown University, Providence, RI, United States. [2]Wake Forest University, Winston-Salem, NC, United States. [3]Dartmouth College, Hanover, NH, United States

Introduction

The performance of baseball bats has been an intriguing question since the first reports of wood bats being doctored or "corked" by players. Currently, non-wood bats are used almost exclusively in collegiate play, but their field performance has not been previously reported. With the advent of markerless-tracking systems now installed in many baseball stadiums that capture both pitcher and batter kinematic data, we sought to investigate if the data from these systems could be used to determine baseball bat performance.

Methods

Throughout the 2024 collegiate season at one institution, 3,170 hits were analyzed with the markerless KinaTrax motion tracking system. For each hit, pitched ball speed, impact location measured from the tip of the bat, bat speed at the impact location, and batted ball speed were computed. Player performance was intentionally excluded from the calculations. Data analysis was limited to descriptive statistics and graphical evaluation. Units are reported in mph and inches reflecting their historical use in baseball.

Results

Mean bat speed was 64 mph (29 m/s). Mean impact location was 4.3 inches (0.11 m) from the tip of the bat. These bat swings resulted in a mean batted ball speed of 83.5 mph (37.3 m/s). At a bat speed of 63.6±2.5 mph (28.4±1.1 m/s), the top 2% batted ball speeds were 102.1 mph (45.6 m/s), as compared to 92.9 mph (41.5 m/s) with wood baseball bats. The sweet spot for non-wood bats was located 2" to 10.5" (0.05 to 0.27 m) from the bat tip. This sweet spot width for the non-wood bats was substantially greater than the sweet spot for wood bats, located from 3" to 7.5" (0.08 to 0.19 m) from the bat tip (Figure 1).

Discussion

These findings provide a new reference for investigators and governing bodies as to the current field performance of modern collegiate non-wood baseball bats. This field study found that modern non-wood bats used at the collegiate level substantially outperformed wood baseball bats in terms of batted ball speeds at a given bat speed and the width of the sweet spot.

Images (Optional)

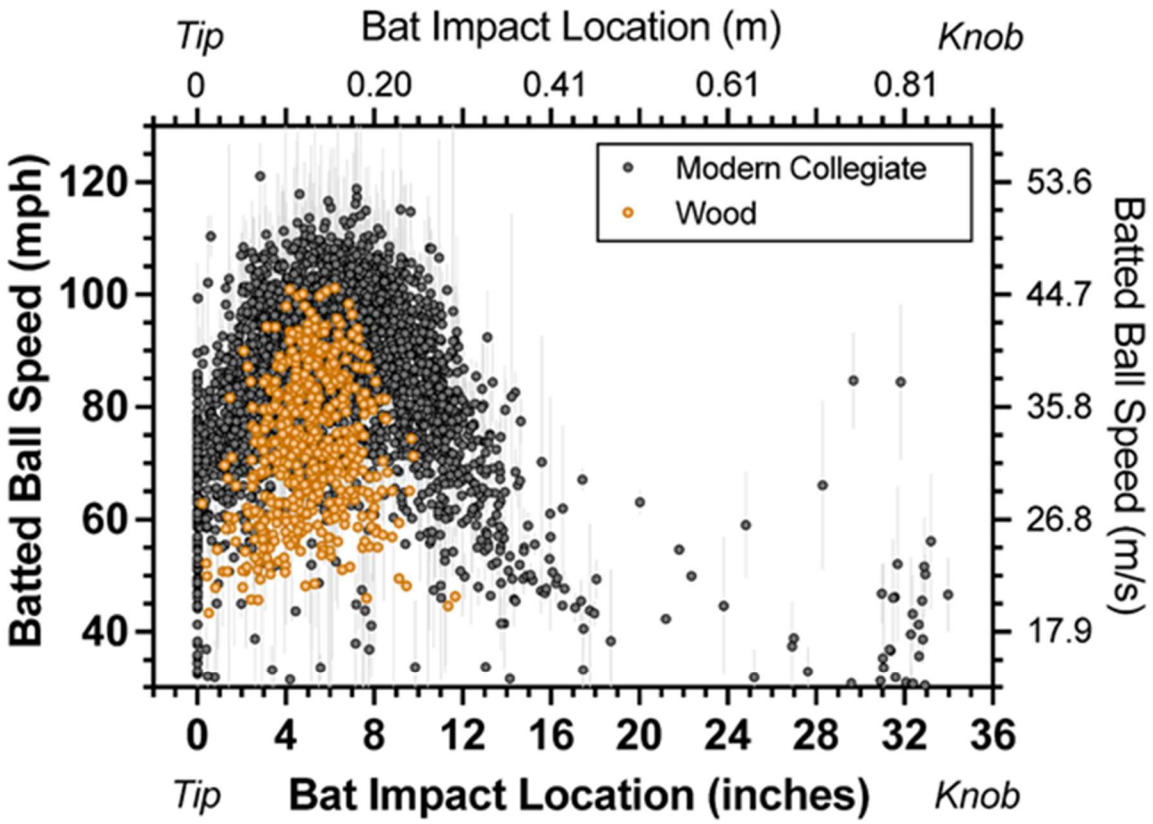

Figure 1. Batted ball speed as a function of impact location on the bat for the modern collegiate non-wood baseball bats and wood bats. The vertical error bars are the SD of the batted ball speeds computed across the six frames of captured ball data for the collegiate non-wood dataset.

OA16-05

Stride Phase Pelvis Momentum Influences Throwing Arm Load in Collegiate Baseball Pitchers

Mr. Adam Barrack MS, CSCS, TSAC-F

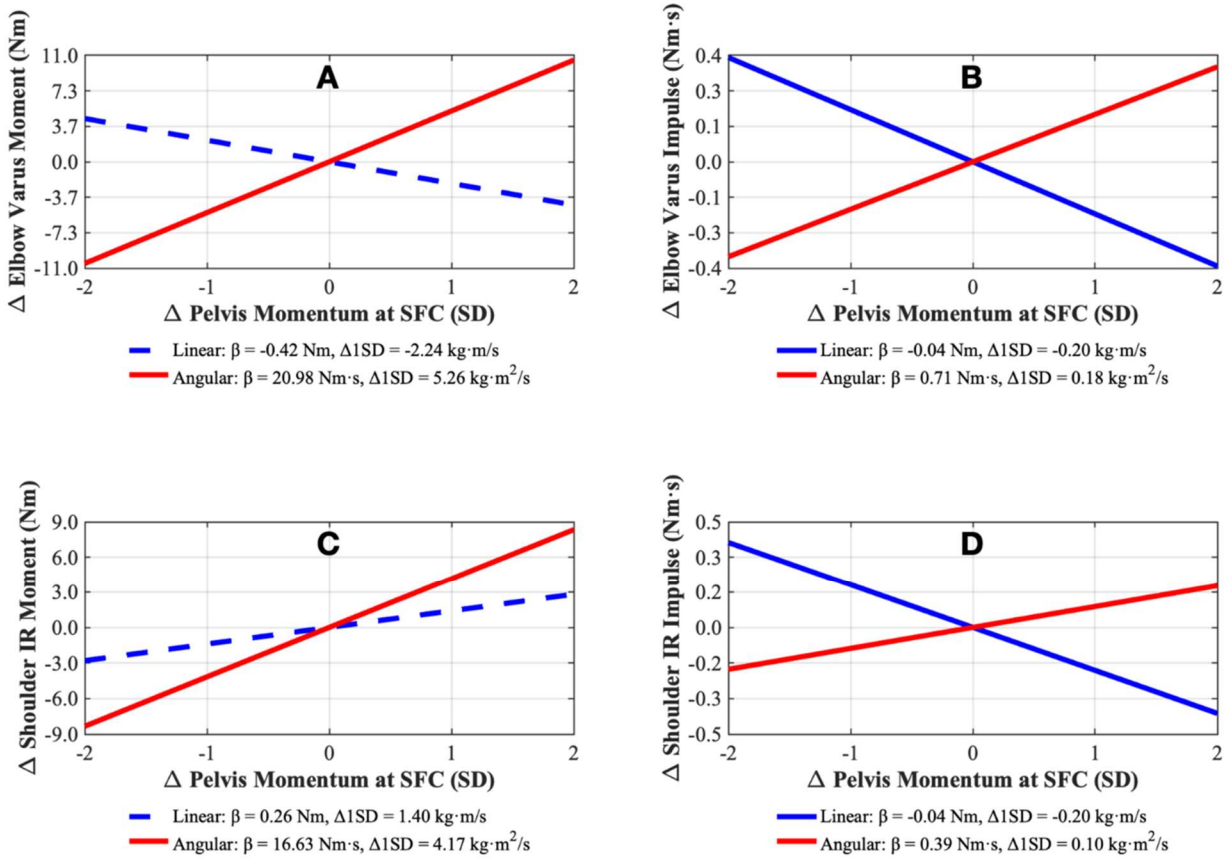
University of Southern California, Los Angeles, CA, United States

Introduction

Introduction: Pitching requires coordinated generation and transfer of energy from the lower extremities to the throwing arm. During the stride phase, the trail leg produces propulsion through home-plate-directed linear momentum and axial angular momentum, reflecting distinct mechanical strategies. Pitchers relying more on angular momentum may generate less linear momentum, equating ball velocity through greater reliance on rotational trunk mechanics. As a result, these strategies may differentially influence throwing arm kinetics. The purpose of this study was to determine how pelvis linear and angular momentum at stride foot contact (SFC) relate to shoulder and elbow joint loading. We hypothesized that pitchers exhibiting greater pelvis angular momentum at SFC would demonstrate higher peak shoulder internal rotator and elbow varus moments and moment impulses, independent of ball velocity and pelvis linear momentum.

Methods

Methods: Thirty-seven healthy collegiate pitchers executed fifteen full-effort fastballs on an instrumented mound while 3-D kinematics (300Hz) and ground reaction forces (1200Hz) were collected. Pelvis momentum was quantified at SFC, with home-plate-directed linear momentum defined in the global +X direction and axial angular momentum defined about the global vertical axis. Peak shoulder internal rotator and elbow varus moments and moment impulses were quantified using inverse dynamics and extracted from SFC to ball release. The ten fastest pitches were analyzed for each pitcher. Linear mixed-effects models with subject-level random intercepts estimated the concurrent effects of pelvis linear and angular momenta on each kinetic outcome, controlling for ball velocity



Results

Results: Greater pelvis angular momentum at SFC was significantly associated with increased peak elbow varus (β:21.0Nm,p=0.008) and shoulder internal rotator (β:16.6Nm,p=0.008) moments, and elbow varus (β:0.71Nm·s,p<0.001) and shoulder internal rotator (β:0.39Nm·s,p<0.001) impulses. In contrast, greater pelvis linear momentum was associated with reduced elbow varus (β:–0.04Nm·s,p<0.001) and shoulder internal rotator (β:–0.04Nm·s,p<0.001) impulses. Marginal R^2 values ranged from 15.6%-22.4% across models, while conditional R^2 values ranged from 64.7%-96.1%.

Discussion

Discussion: Pitchers generating greater stride axial pelvis angular momentum experienced greater throwing arm loading, whereas greater linear pelvis momentum attenuated cumulative loading. These findings highlight how trail leg propulsion influences upper-extremity kinetics and may inform performance-enhancing and injury-prevention efforts in baseball pitching.

The Influence of Shoulder Range-of-Motion on Elbow Valgus Torque Throughout a Baseball Pitch

Dr. Jonathan Slowik PhD, Dr. Glenn Fleisig PhD

American Sports Medicine Insititute, Birmingham, AL, United States

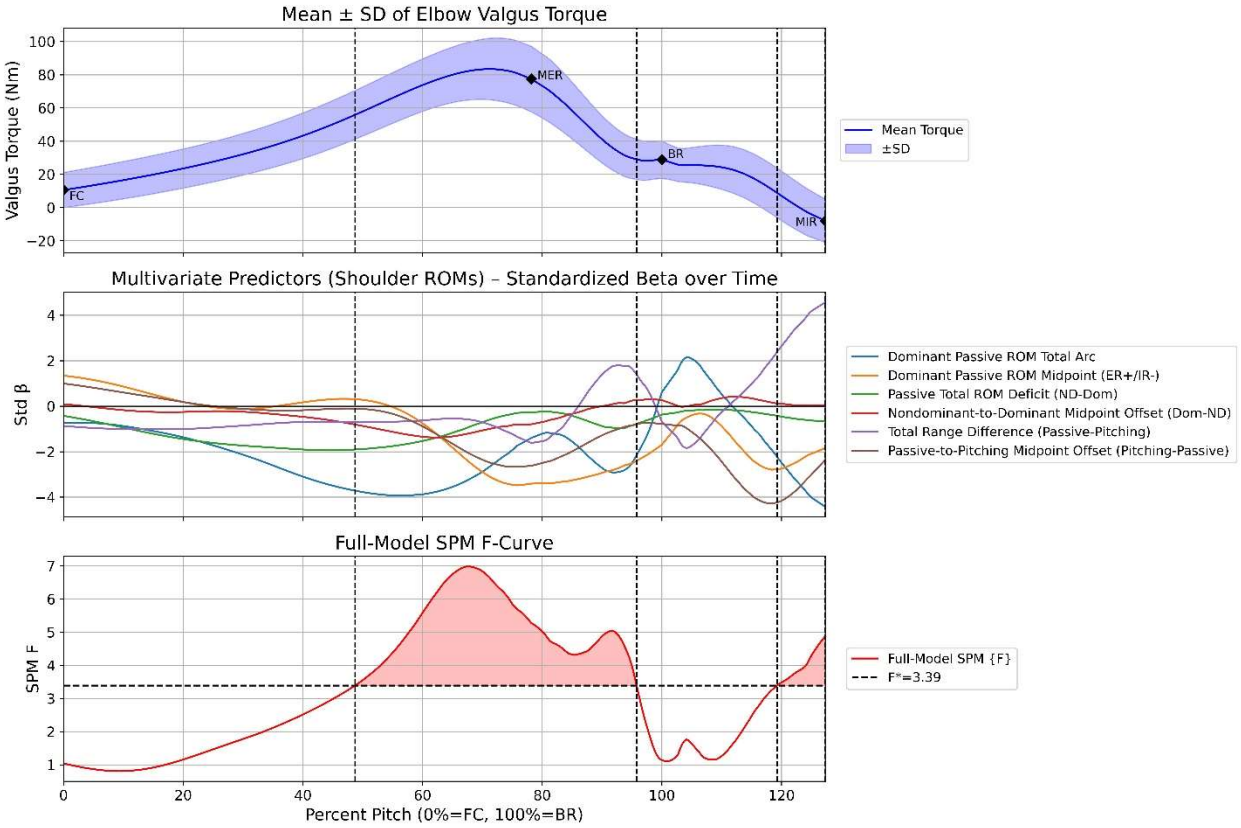
Introduction

Shoulder rotation range-of-motion (ROM) has long been thought to influence pitching biomechanics and elbow loading [1], yet it remains unclear which specific aspects of shoulder ROM are most relevant. The purpose of this study was to determine which ROM-related factors are the most strongly related to elbow valgus loading and how their individual effects may change throughout the phases of a baseball pitch.

Methods

Motion capture data from 267 healthy amateur baseball pitchers (18.7±1.9 yrs) throwing fastball pitches [2] were retrospectively analyzed, along with their shoulder passive ROM measurements. Elbow valgus torque was calculated using inverse dynamics and splined into three 100-point segments spanning foot contact (FC), maximum shoulder external rotation (MER), ball release (BR), and maximum internal rotation (MIR), then expressed as percent pitch (0%=FC, 100%=BR).

We used statistical parametric mapping (SPM) multivariate regression to examine the relationships between time histories of elbow valgus torque and six independent metrics (Variance Inflation Factors<2.5) related to shoulder external/internal ROM (passive non-dominant, ND, passive dominant, Dom, as well as shoulder rotation values reached during pitching). The model included age, height, mass, competition level, and handedness as confounders. Standardized beta curves quantified the independent effect of each metric while holding the others constant, and full-model F-curves identified statistically significant time intervals.



Results

Two significant clusters were identified, with the first occurring during the late arm cocking and arm acceleration phases (48.7-95.8% of the pitch, peak F=6.98), and the second occurring as the shoulder approached maximum internal rotation (119.3-127.3% of the pitch, peak F=4.88). Detailed time histories are provided in Fig. 1.

Discussion

Pitchers with larger total rotation arcs, and shifts towards greater external rotation experienced lower elbow valgus torque, especially around the time of MER, when the torque was near its peak. However, the combined ROM parameters also became significant near the time of MIR, led by the parameter that quantified how much of his full ROM a pitcher may be utilizing. Future work should investigate this often-ignored phase of the baseball pitch.

Disturbed Flow, Cytokine Signaling, and Plaque Growth: Insights from Sensitivity and Flow-Disturbance Analyses Using a Multiscale, Multiphysics Model of Coronary Atherosclerosis

Dr. Jeremy Warren Ph.D.[1,2], Dr. Clark Meyer Ph.D.[1], Dr. Anna Corti Ph.D.[3], Dr. Heather Hayenga Ph.D.[1]

[1]The University of Texas at Dallas, Richardson, Texas, United States. [2]Yale University, New Haven, CT, United States. [3]Politecnico Di Milano, Milan, Italy, Italy

Introduction

Coronary artery disease arises from dysregulated biochemical, biomechanical, and hemodynamic interactions that drive plaque formation. Existing multiscale models couple ABM with either CFD or FEA separately. We developed CAFe, a unified CFD-ABM-FEA framework that simulates hemodynamics, cell–cytokine signaling, and structural mechanics [Figure 1A] [1]. To assess biological robustness, we incorporated results from a sensitivity analysis of ABM rules and mechanistic studies on disturbed flow and pre-existing inflammation.

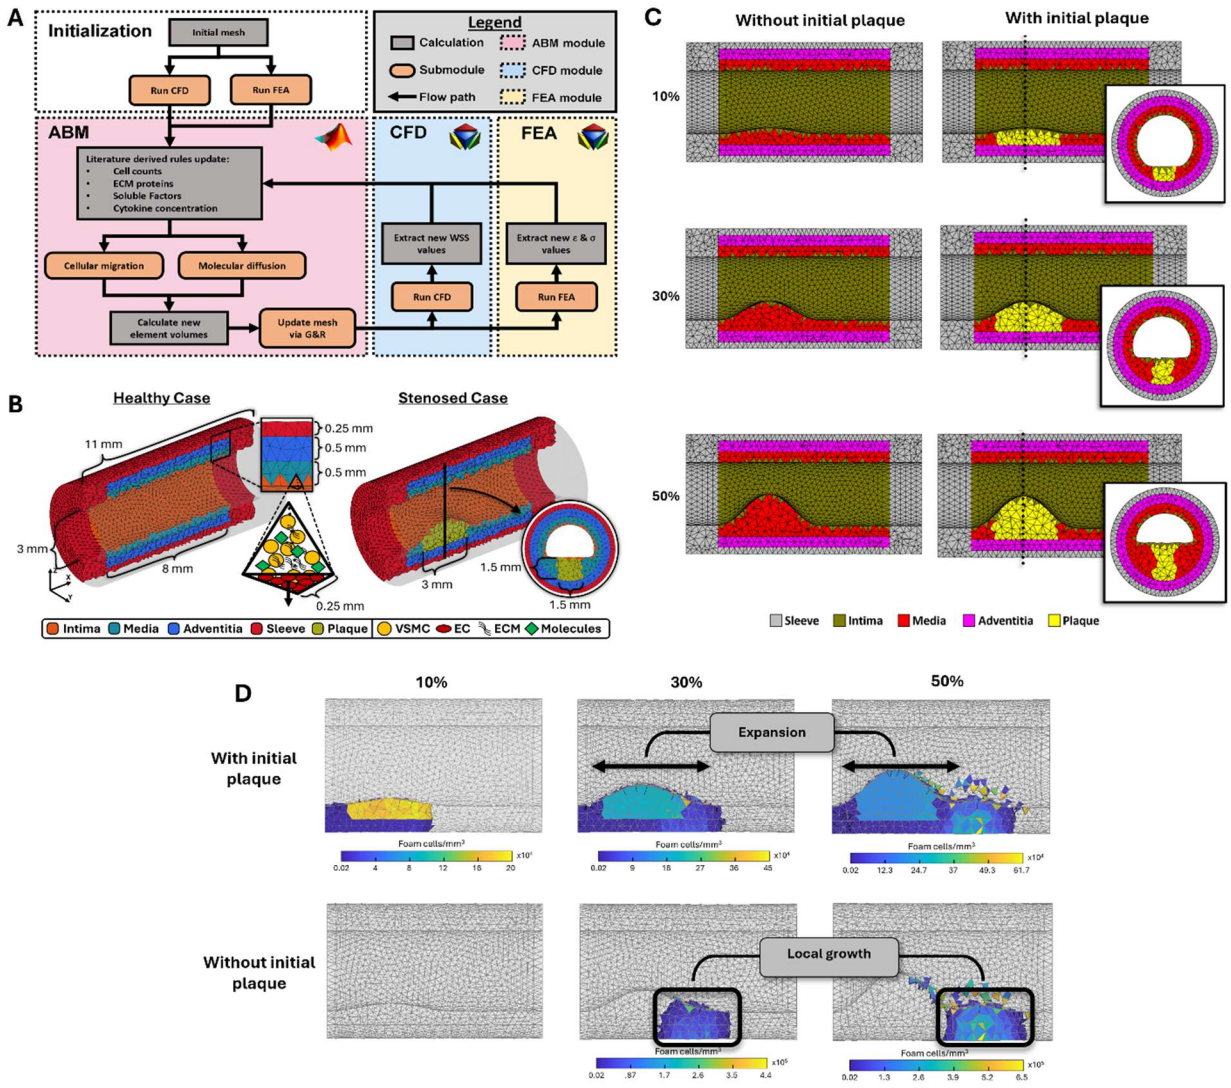
Methods

Idealized healthy and stenotic arteries were meshed [Figure 1B] and simulated for 6 months. The ABM updated cytokines, leukocytes, ECM, and growth every 6 hours; FEA computed stresses; CFD computed WSS. In the sensitivity analyses, production rates (e.g. TNFα, IL-1, IL-10, TGFβ, and PDGFαβ) were scaled by ×0.1 or ×10. Additional mechanistic studies tested whether disturbed flow alone (10–50% occlusions) or pre-existing plaque cytokines can initiate remodeling [Figure 1C].

Results

Sensitivity analysis: The model was most sensitive to PDGFαβ ×0.1, which reduced multiple cell types and caused 12–15% regional volume loss due to compounded VSMC apoptosis. TNFα ×0.1 and IL-1 ×0.1 markedly reduced leukocytes; IL-1 ×10 increased inflammatory cell numbers. Most ×10 increases produced minimal effects, and IL-10/TGFβ scaling had little impact.

Flow-disturbance study: Disturbed flow alone could initiate plaque formation starting at ≥30% occlusion, enabling leukocyte infiltration and foam-cell formation [Figure 1D]. Severe



narrowing (50%) generated a secondary downstream stenosis with orders-of-magnitude higher leukocyte counts and foam-cell accumulation.

Pre-existing plaque study: Pre-existing cytokines and foam cells enabled plaque initiation even at 10% occlusion. Unique growth patterns arose; pre-existing plaque expanded whereas plaques initiated from flow disturbance exhibited local growth [Figure 1D]. Remodeling distributions also shifted: simulations with initial plaques showed greater leukocyte buildup in transition regions but reduced downstream accumulation compared to plaque-free cases. Volume patterns reflected these shifts.

Discussion

CAFe captures how growth-factor signaling, inflammation, and hemodynamic disturbances jointly shape plaque progression. PDGFαβ, TNFα, and IL-1 emerged as dominant regulators of model stability. Flow disturbances were sufficient to initiate plaque, while pre-existing cytokines altered spatial remodeling trajectories. Together, these results demonstrate CAFe's ability to resolve nonlinear mechanobiological interactions underlying CAD progression.

A Longitudinal Study on the Association Between Haemodynamics and Early Plaque Formation in Female Coronary Arteries

Dr. Chi Shen[1], Dr. Mingzi Zhang[1,2], A/Prof. Susann Beier[1]

[1]The University of New South Wales, Sydney, NSW, Australia. [2]Torrens University, Sydney, NSW, Australia

Introduction

Haemodynamics play an important role in the development of coronary artery disease (CAD), with evidence indicating different disease presentations in females and males. However, previous work has only focused on haemodynamic effects after disease onset, due to the lack of longitudinal imaging datasets starting from the healthy state. In this study, we investigated the relationship between endothelial shear stress (ESS) and plaque formation in females, using the retrospective GeoCAD dataset featuring 387 patients with at least two longitudinal imaging follow-ups.

Methods

Plaque formation was identified by comparing per-segment CAD-RADS scores of the left coronaries between baseline and follow-up CTCA images. Patients who had no plaque in any segment at baseline and developed plaque in at least one segment at follow-up formed the formation group (21 patients, including 64 diseased segments). Each patient from the formation group was randomly matched with a control (21 patients, including 158 healthy segments), defined as those without plaque across all segments at both baseline and follow-up, after accounting for their age and diabetes status. Eleven haemodynamic factors, including (ESS), were extracted from computational transient simulations on the left coronary trees to evaluate their associations with early plaque formation.

Results

The segments with formation showed lower mean ESS (0.660 [0.505-0.969] vs. 1.055 [0.747-1.547], $p = 0.002$) and ESS gradient (0.251 [0.197-0.506] vs. 0.427 [0.280-0.724], $p = 0.006$). Subsequently, the segments with formation showed a larger percentage area exposed to low ESS <0.5 Pa (33 [14-61] vs. 11 [2-23], $p = 0.002$). In addition, segments with formation exhibited lower helical flow intensity (0.773 [0.298-1.566] vs. 1.883 [0.942-3.976], $p = 0.002$). All other haemodynamic factors showed no statistically significant differences between formation and non-formation segments.

Discussion

This is the first longitudinal study into the blood flow's effects on plaque formation using images taken prior to disease onset. ESS-based haemodynamic factors were associated with early plaque development, while higher helical flow intensity had a protective effect. Overall, haemodynamics were associated with early disease development in females, underscoring their potential for sex-specific risk assessment.

Plaque Material Stiffness as a Biomechanical Marker Distinguishing ACS from Stable Coronary Lesions

Dr. Jack Wang Ph.D.[1], Mr. Christos Georgiadis B.S.[1], Dr. Caleb Berggren Ph.D.[2], Dr. Steve Maas Ph.D.[2], Dr. Edward Hsu Ph.D.[2], Prof. Jeffrey Weiss Ph.D.[2], Dr. Lucas Timmins Ph.D.[1,2]

[1]Texas A&M University, Houston, TX, United States. [2]University of Utah, Salt Lake City, UT, United States

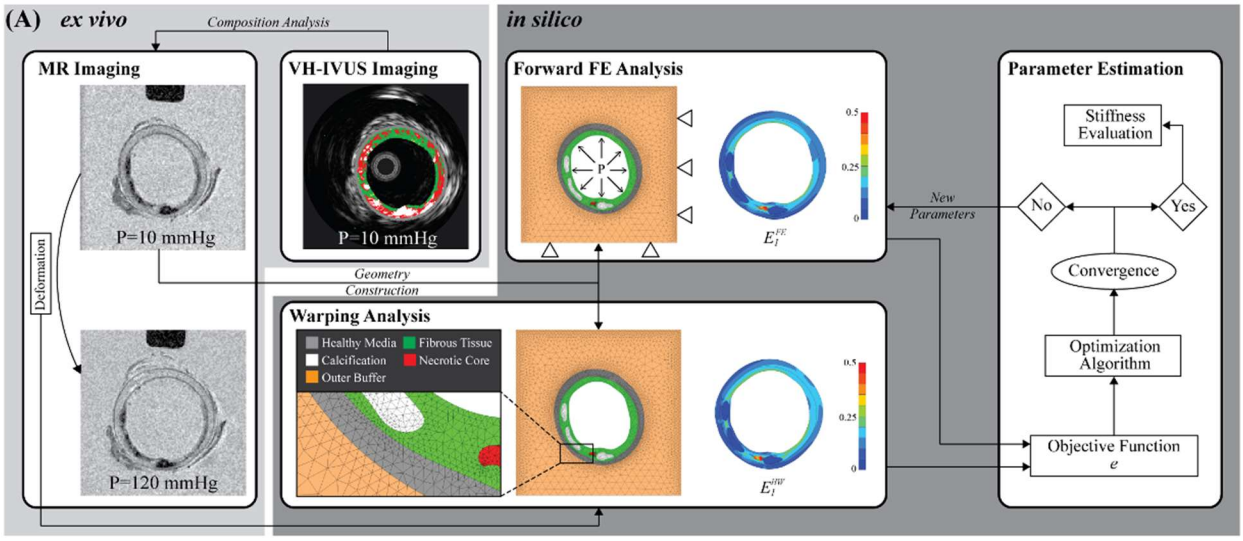
Introduction

Atherosclerotic plaque rupture remains the leading cause of acute coronary syndromes (ACS), accounting for >1 million heart attacks annually in the US. Stratifying rupture risk remains a diagnostic challenge. Because rupture is a mechanical failure in which tissue stresses exceed material strength, material stiffness may serve as a surrogate marker for rupture risk assessment. This study quantified component-wise material stiffness of diseased human coronary tissue and evaluated its ability to distinguish rupture-prone from stable plaques.

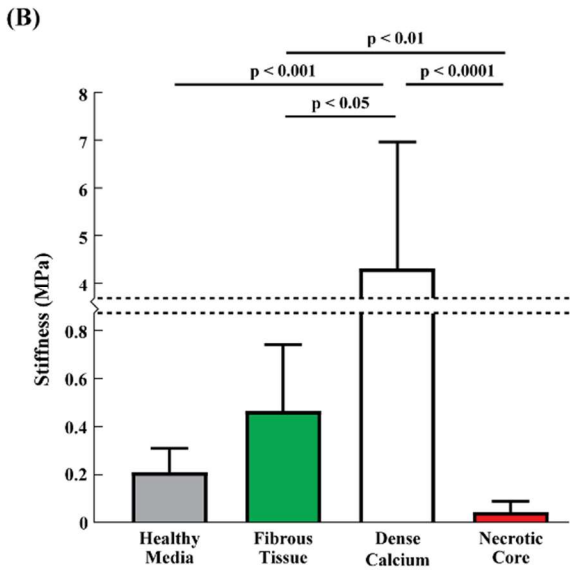
Methods

Coronary arteries (n=3) were dissected from unfixed hearts of individuals who died of non-cardiac causes. Samples were mounted in a custom MR-compatible device enabling acquisition of MR images at 7T under lumen pressures of 10 and 120 mmHg, and subsequently VH-IVUS images at the same loads (Fig. 1A). Material parameters were estimated using our established inverse finite element framework, which incorporates deformable image registration via Hyperelastic Warping. Stiffness values were calculated for VH-IVUS-defined components: fibrous tissue (FT), necrotic core (NC), dense calcium (DC), and healthy media. Stiffness values were used to examine the predictive value of local material stiffness for lesions responsible for an ACS event (n=20) compared with stable controls (n=17) from a prospective clinical dataset.

Results



Warping-derived strain magnitudes varied across plaque components, with the highest strains in the NC (0.34±0.24) and the lowest in DC (0.04±0.05). The material optimization scheme achieved strong agreement between Warping-derived and forward FE strains (RMSE=0.03±0.01, mean bias <0.1%), confirming convergence. Stress-stretch curves generated from the estimated parameters demonstrated non-linear behaviors across tissue types. Tangent moduli at 120 mmHg confirmed differences with stiffness values of 0.46±0.28, 0.04±0.04, 4.34±2.65, and 0.21±0.10 MPa for FT, NC (softest), DC (stiffest), and



media, respectively (Fig. 1B). Local material stiffness values significantly differed between lesions responsible for an ACS event compared to stable controls with values of 0.63±0.39 and 0.55±0.32 MPa, respectively ($p<0.05$).

Discussion

In conclusion, we implemented an integrated experimental-computational framework to characterize component-wise material stiffness of diseased human coronary arteries and demonstrated its clinical utility. These results support the relevance of plaque material stiffness for advancing ACS risk stratification.

Graph-Derived Mechanochemical Simulations Capture Patient-Specific and Population-Level Variability in Atherosclerosis Progression

Mr Alessandro Mastrofini[1], Dr Aikaterini Tziotziou[2], Prof Daniel Bos[3], Prof Ali C. Akyildiz[3,4], Prof Michele Marino[1]

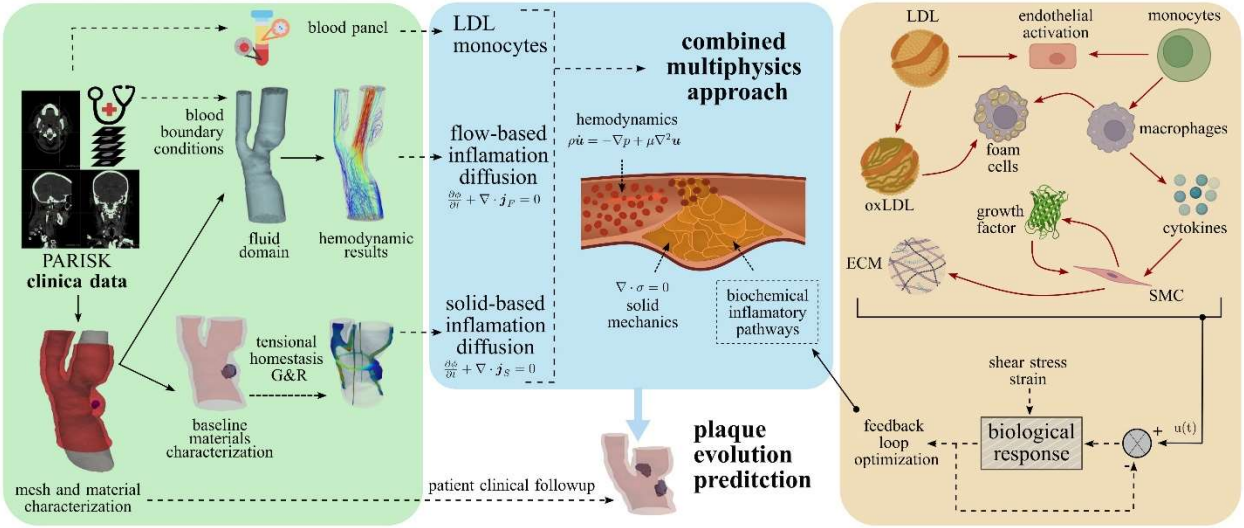
[1]Multiscale and Multiphysics Mechanics Group (M2M), Department of Civil Engineering and Computer Science Engineering, University of Rome Tor Vergata, Rome, Italy, Italy. [4]Department of Biomechanical Engineering, Delft University of Technology, Delft, Netherlands, Netherlands

Introduction

Atherosclerosis progression reflects nonlinear interactions among lipid metabolism, inflammatory signaling, cellular phenotype transitions, and arterial biomechanics. Most computational models rely on simplified pathways or large, weakly constrained parameter sets, limiting their ability to reproduce clinically observed heterogeneity [1,2]. We present an application of a graph-derived mechanochemical framework that couples ODE-based phenotype controllers with transport-reaction PDEs and finite-element biomechanics to simulate plaque evolution across both synthetic and patient-specific geometries.

Methods

A curated biological interaction graph, encompassing lipid species, cytokines, macrophage and SMC phenotypes, extracellular matrix turnover, oxidative and osteogenic cues, and mechanical drivers (strain, shear stress), was mapped to a coupled mechanochemical model using standardized operators. A magnitude-based weighting scheme assigned low/medium/high influence levels to pathway edges, ensuring biologically interpretable regulation without excessive parameterization. Phenotype transitions (e.g., M1/M2 macrophages, contractile/synthetic SMCs) were represented using bistable controller ODEs. Biochemical and cellular species were simulated via diffusion-reaction PDEs dynamically coupled to finite-element structural mechanics. Initial and boundary conditions incorporated patient-specific blood biomarkers. Simulations were performed on (i) reduced-order synthetic geometries derived from PARISK population descriptors, and (ii) two patient-specific carotid bifurcations from the PARISK longitudinal study [3].



Results

In synthetic geometries, controlled activation or suppression of graph pathways produced a wide spectrum of progression phenotypes, including lipid-dominant plaques, inflammatory amplification loops, and diverging calcification–resorption trajectories. These simulation families qualitatively reproduced patterns of variability observed in PARISK. Patient-specific simulations demonstrated numerical stability and biological interpretability. Differences in LDL levels, monocyte counts, or inflammatory markers translated into distinct spatial distributions of lipid accumulation, macrophage phenotype shifts, and calcification progression. Local predictions of calcification growth or resorption aligned with two-year follow-up imaging, supporting the framework's ability to capture inter-patient variability.

Discussion

The graph-derived mechanochemical framework successfully generated clinically consistent progression scenarios at both population and individual levels. Its ability to integrate blood-derived inputs, reproduce distinct plaque evolution trajectories, and maintain biological interpretability positions it as a promising tool for future risk stratification and personalized simulation of vascular disease.

Introduction

Hip fragility fractures represent one of the most severe manifestations of osteoporosis, associated with increased morbidity, mortality, and significant healthcare burden worldwide [1]. Although aBMD derived from dual-energy X-ray absorptiometry (DXA) is the clinical gold standard for diagnosing osteoporosis, nearly half of patients classified as non-osteoporotic experience fragility fractures [2]. Finite Element (FE) models have emerged as promising tools for improving fracture risk assessment. Within this context, the Bologna Biomechanical Computed Tomography (BBCT)-hip model was developed, which calculates an absolute risk of hip fracture (ARF0) for a subject by coupling a mathematical-stochastic model of the fall used to compute possible subject-specific impact loads with a subject-specific FE model of the femur to estimate its failure load in sideways fall conditions.

Methods

This study assessed the stratification accuracy of BBCT-hip *in vivo* compared to DXA-derived aBMD across multiple clinical cohorts of post-menopausal women, comprising 63 fractured (age: 76.5±8.1; height: 159±6.4; weight: 62.9±13.4) and 293 non-fractured (age: 71.7±7.5; height: 159.6±6.2; weight: 64.5±11.5) subjects. Specifically, three distinct cohorts with CT scans and aBMD available were combined: a retrospective cohort of 94 British women [3]; a retro-prospective cohort of 101 Italian women [4] and a cohort of 161 Italian women collected within an ongoing clinical study at the Rizzoli Orthopaedic Institute. Thanks to the availability of CT scans, weight and height information for each

subject, BBCT-hip pipeline was implemented, and the ARF0 values computed. BBCT-hip stratification accuracy was assessed through a ROC analysis and compared to the stratification accuracy of aBMD.

Results

BBCT-hip showed an AUC of 0.79 (95% CI: 0.73-0.85), which turned out to be statistically significantly higher than the AUC of aBMD, equal to 0.64 (95% CI: 0.55-0.72) (Figure 1).

Discussion

This study demonstrated an improved accuracy of BBCT-hip in separating fractured from non-fractured subjects compared to aBMD. Such a result provides evidence supporting more extensive clinical validation studies to pave the way towards BBCT-hip clinical implementation.

Associations Between Spinal Parameters and Loads During Gait in Patients With Lumbar Spinal Stenosis: A Combined Clinical and Musculoskeletal Modeling Study

Ms. Alice Caimi[1], Mr. Nicholas Fischlin[1], Mr. David Koch[2,3], Prof. Dr. med. Cordula Netzer[2,3], Dr. Corina Nüesch[2,3], Prof. Dr. Annegret Mündermann[3,4], Prof. Dr. Stephen J. Ferguson[1], Dr. Dominika Ignasiak[1]

[1]ETH Zurich, Zurich, Switzerland, Switzerland. [2]University Hospital Basel, Basel, Switzerland, Switzerland. [3]University of Basel, Basel, Switzerland, Switzerland. [4]Schulthess Clinic, Zurich, Switzerland, Switzerland

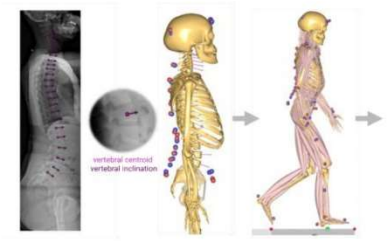
Introduction

To alleviate symptoms, patients with lumbar spinal stenosis (LSS) adopt compensatory strategies such as forward trunk inclination and pelvic retroversion [1,2]. While these postural adjustments reduce nerve root compression and provide temporary relief, they may require greater muscular effort and thereby increase spinal loading. Identifying the spinopelvic parameters associated with spinal loads is critical for developing strategies to reduce biomechanical stress and mitigate disease progression. The study aimed to investigate spinal loads in patients with LSS during gait in relation to their spinal parameters, by combining musculoskeletal modeling with motion-capture and radiographic data.

Methods

A full-body musculoskeletal (AnyBody) model was applied to 103 patients with LSS (72.7years±9.6, 52 female, 51 male). Vertebral positions and orientations were extracted from radiographs to reconstruct patient-specific spinal alignment. Inverse-dynamics simulations driven by motion-capture marker trajectories were performed to estimate spinal loads during gait (Figure 1, left). Compressive and shear forces were computed at all lumbar levels, with analyses focused on the predominantly stenotic segment (L4-L5). Associations between sagittal alignment parameters and loads were assessed with Spearman's correlation and corrected for multiple comparisons using the Benjamini-Hochberg method.

Results



Weak-to-moderate associations were found between maximum L4-L5 spinal loads and spinopelvic alignment parameters during gait (Figure 1, right). Moderate negative associations were observed between compressive loads and T2-T12 kyphosis (ρ=-0.54), and between shear forces and lumbar lordosis (ρ=-0.42) as well as T2-T12 and T5-T12

kyphosis (ρ=-0.41 and -0.40, respectively). Weak but significant positive associations were found between both compressive and shear forces and pelvic tilt, as well as L4-L5 segmental flexion.

Discussion

Spinal loads during gait were estimated for patient-specific full spinal alignment profiles in a large cohort of patients with LSS. Both compressive and shear forces at L4-L5 were associated with spinal alignment parameters, indicating that posture-dependent loading patterns are related to mechanical stress at commonly stenotic levels and may contribute to segmental degeneration over time. Future work should investigate whether spinal loads provide a mechanistic explanation for symptom progression and stenosis recurrence in LSS, supporting targeted clinical decision-making.

Evaluation of Bicycle Delivery Workers' Load With the 3D-Musculoskeletal Computermodel "Myonardo"

Mag. Norbert Lechner[1], PhD Maarten Van den Heuvel[2], Ing. Harald Bruckner[3], Prof. Heiko Wagner[2], Prof. William H.M. Castro[2], PhD Franziska Mally[1]

[1]AUVA - Austrian Workers Compensation Board, Vienna, Austria, Austria. [2]Predimo GmbH, Münster, Germany, Germany. [3]Chamber of Labour, Vienna, Austria, Austria

Introduction

Recent reports indicate that the physical strain experienced by bicycle delivery workers is excessively high. This study aimed to investigate the load on the riders' joints during cycling in comparison to standing, walking and squat lifting.

Methods

20 healthy male subjects volunteered for the study (184.6 ± 7.1 cm, 79.8 ± 10.9 kg, 27.86 ± 8.18 years). Each subject had to perform cycling in two postures (upright and forward) with and without a loaded delivery backpack (5, 10, 15 kg). Additionally, subjects performed three reference tasks (standing, walking, lifting).

Kinematics were captured using an Xsens Awinda system (Movella, Enschede). External forces were recorded using strain gauges at the handlebar and cranks. Joint loads were calculated with the musculoskeletal model Myonardo (v.7.5.9, Predimo GmbH, Münster, Germany).

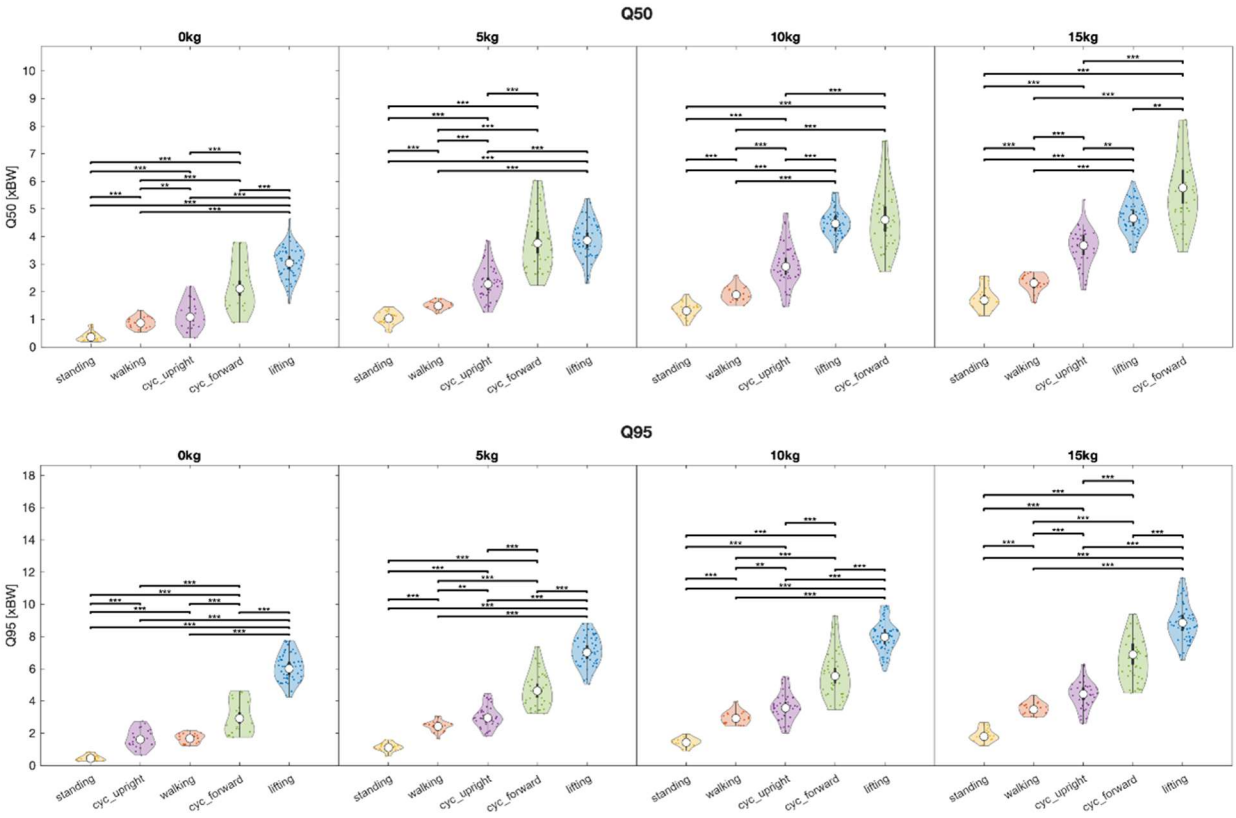
Total joint forces were normalized for body weight. 50th and 95th percentile were calculated over 20-30 s of stable cycling, 5-10 s of stable standing/walking and three repetitions of lifting. A generalized linear model analysis was used to determine statistical significance.

Results

The results show that under all weight conditions cycling in an upright position leads to lower joint forces than cycling in forward bent position. In the lower extremities standing, walking and lifting often resulted in higher loads than the cycling tasks. The influence of additional weight during cycling is less in the lower extremities, especially during upright

cycling. The highest loads were found at the L5/S1 segment, which is often an important indicator for occupational risk assessment (Figure 1).

Figure 1: Median (Q50) and peak (Q95) loads at L5/S1 segment (* $p<0.05$, ** $p < 0.01$, *** $p < 0.001$).



Discussion

To improve the safety and health of delivery riders, future regulations should focus on the reduction the physical stress by technical and personal measures. Additional weight should not be carried on the back and riders should be trained to cycle in good posture.

Next steps could be the analysis and interpretation of

- Remaining joints (i.e. ankle, elbow)
- Shear forces and peak forces
- Forces during sub-tasks (e.g. getting on/off the bike)
- Comparison between computermyography and conventional biomechanical assessment
- Derive measures to improve occupational safety and health of bike delivery riders

The Influence of Subject-Specific Musculoskeletal Modeling on Contact Stress Predictions in Dysplastic Hips

Dr. Molly Shepherd PhD[1], Dr. Jessica Goetz PhD[2], Dr. Holly Aitken PhD[2], Dr. Michael Harris PhD[1]

[1]Washington University in St. Louis, St. Louis, Missouri, United States. [2]University of Iowa, Iowa City, Iowa, United States

Introduction

Developmental dysplasia of the hip (DDH) is a condition characterized by insufficient acetabular coverage of the femoral head. Discrete element analysis (DEA), a rapidly executing computational technique to quantify joint contact mechanics, has demonstrated higher contact stresses in DDH [1]. However, previous work has focused only on individualized anatomy, despite contact stresses also depending on loading conditions, such as kinematics and joint reaction forces. The objective of this study was to determine the influence of individualized DDH loading conditions from subject-specific musculoskeletal models on DEA-computed contact stresses compared to literature-based loading conditions.

Methods

DEA models were created for 10 individuals with DDH and used to calculate hip contact stresses using two different sets of loading conditions: (1) literature-based average DDH gait kinematics and joint reaction forces [2], and (2) kinematics and forces from individualized gait analysis and musculoskeletal models created by incorporating subject-specific three-dimensional reconstructions of the pelvis and femurs and updating muscle origins and insertions. For both sets of loading conditions, the stance phase of gait was discretized into 13 quasi-static positions for analysis [1].

Results

Subject-specific joint reaction forces and kinematics strongly affected the variability in cartilage contact stresses (Figure 1). While the literature-based model was an average “pusher” loading pattern (larger second peak), subject-specific loading patterns revealed “pusher”, “hard hitters” (larger first peak), “balanced” (similar first and second peaks), and “unimodal” (no distinctive loading peaks) variations. On average, subject-specific mean stresses were significantly higher during early- to mid-stance than literature-based stresses, while there were no significant differences in late stance.

Discussion

These results highlight the importance of incorporating the variability of individualized loading conditions when estimating contact stresses. The individual variations affect not only contact stress magnitudes, but also locations within the hip joint. The larger contact stresses during early stance suggest that this component of gait may contribute more to joint damage than previously assumed. Incorporating individualized loading patterns may improve the accuracy of contact stress predictions and therefore our understanding of patient-specific degenerative risk factors.

Images (Optional)

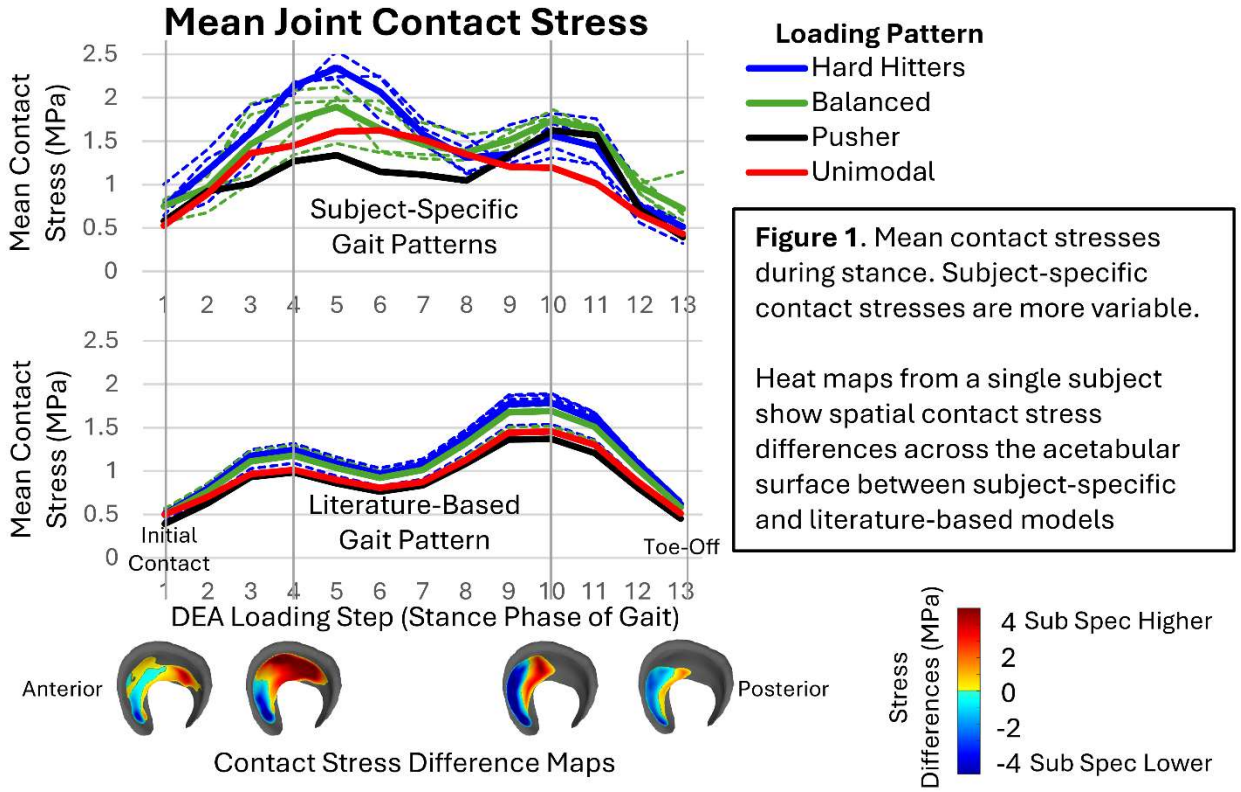

Figure 1. Mean contact stresses during stance. Subject-specific contact stresses are more variable.

Heat maps from a single subject show spatial contact stress differences across the acetabular surface between subject-specific and literature-based models

OA18-05

Biomechanical Predictors of Self-Contamination During Medical Gown Doffing: A Motion-Capture Analysis of Hand–Gown Interaction

Dr. Jingeng Li PhD[1], Professor Li-Shan Chou PhD[2]

[1]Iowa State University, Ames, Iowa, United States. [2]Purdue University, West Lafayette, Indiana, United States

Introduction

Proper removal of personal protective equipment (PPE) is essential for preventing self-contamination among healthcare workers. Although previous research has examined gown design and removal techniques, movement behaviors that contribute to contamination during medical gown doffing remain insufficiently understood. This study developed a motion-analysis–based framework to characterize dynamic gown deformation, hand trajectories, and their relationship to contamination during standardized gown removal.

Methods

Eighteen healthy adults performed medical gown doffing following the CDC guidelines. Each participant completed three trials after receiving standardized video and verbal instructions. A consistent amount of fluorescent solution was sprayed onto the gown surface before each trial to simulate contamination. A 12-camera optical motion capture system (240Hz, Qualisys AB, Sweden) recorded three-dimensional trajectories of ten reflective markers placed on the gown and two markers placed on the index finger of each hand. Marker trajectories were used to reconstruct a dynamic 3D contour of the gown and compute two interaction-based variables during the doffing process: hand-to-gown distance and hand-gown contact time. A 12 Hz 4th-order Butterworth low-pass filter was used to remove noise. UV-A inspection identified contaminated body regions post-doffing. Spearman correlations and stepwise regression were used to determine associations and predictors of contamination risk.

Results

Participants averaged 2.04 ± 1.07 contaminated regions per trial, with the dominant hand exhibiting more contamination than the non-dominant hand. Hand-gown distance showed strong negative correlations with contamination across both hands ($r_s = -0.786$ to -0.873, $p < .001$), while hand-gown contact time showed strong positive correlations ($r_s = 0.556$–0.711). Stepwise regression identified dominant hand-to-gown distance and contact time

as significant predictors of dominant-hand contamination (R^2 = .701), while total hand-to-gown distance explained 72.7% of variance in overall contamination risk.

Discussion

This study provides the first quantitative biomechanical evidence that closer hand proximity to the gown and longer contact duration are substantially associated with contamination risk during medical gown doffing. The novel approach enables identification of high-risk movement patterns that may not be detectable through visual observation alone. Future work should validate these findings in clinical populations, examine variations across different gown types, and contamination sources.

Integrating Models and Muscle-Tendon Function to Understand Sex-Specific Responses to Different Footwear Stiffness during Running

Ms. Vivian Nguyen MSc, BSc[1], Ms. Banin Al-Shimari MSc, BSc[1], Mr. Marco Perizzolo BSc[2], Dr. Jared Fletcher PhD[2], Dr. Brent Edwards PhD[1], Dr. Michael Asmussen PhD[3]

[1]University of Calgary, Calgary, Alberta, Canada. [2]Mount Royal University, Calgary, Alberta, Canada. [3]Vancouver Island University, Nanaimo, British Columbia, Canada

Introduction

Footwear longitudinal bending stiffness (LBS) influences running biomechanics by altering joint energetics [1] and lower-limb muscle-tendon behaviour. However, most studies primarily focus on male participants, despite known sex differences in muscle strength, tendon morphology, and hormonal regulation that may affect muscle-tendon dynamics and how males and females respond to changes in footwear stiffness [2]. Dynamic optimization enables estimation of muscle fiber lengths, velocities, and forces, providing insight into how LBS affects musculotendon dynamics. This study investigated how footwear LBS affects muscle-tendon dynamics between sexes during running using electromyography (EMG)-constrained dynamic optimization.

Methods

Twenty participants (10 male, 10 female) ran at 3.5 m/s on a force-instrumented treadmill in minimalist footwear with three stiffness conditions: no plate (0.05 Nm/deg), 1 mm carbon fiber plate (0.14 Nm/deg), and 1.5 mm carbon fiber plate (0.30 Nm/deg). Motion capture, ground reaction forces, and EMG from the lateral gastrocnemius (LG) and soleus (SOL) were collected. Medial gastrocnemius (MG) fascicle behaviour was recorded using ultrasound. Achilles tendon stiffness and moment arms were measured using ultrasound and dynamometry. A musculoskeletal model [3] was used to perform inverse kinematics and dynamics and an EMG-constrained optimization was used to estimate muscle-tendon dynamics.

Results

A significant interaction effect ($p<0.05$) was found for peak-to-peak normalized MG muscle fiber length, where males exhibited higher values than females in the 1 mm and 1.5 mm footwear conditions. Increased LBS decreased SOL muscle-tendon length and reduced

SOL tendon force. Males showed higher MG and SOL fiber lengths, velocities, and tendon forces, whereas mean normalized fiber velocities were higher in females.

Discussion

These findings indicate that biological sex differences resulted in changes in muscle-tendon behaviour during running. The results reinforce the importance of considering sex when evaluating how LBS influences muscle-tendon dynamics or when designing stiffness-modified footwear. Collected ultrasound fascicle data will validate dynamic optimization outputs and assess how well model estimates reflect *in vivo* behaviour, supporting more accurate, sex-specific predictive modeling.

Images (Optional)

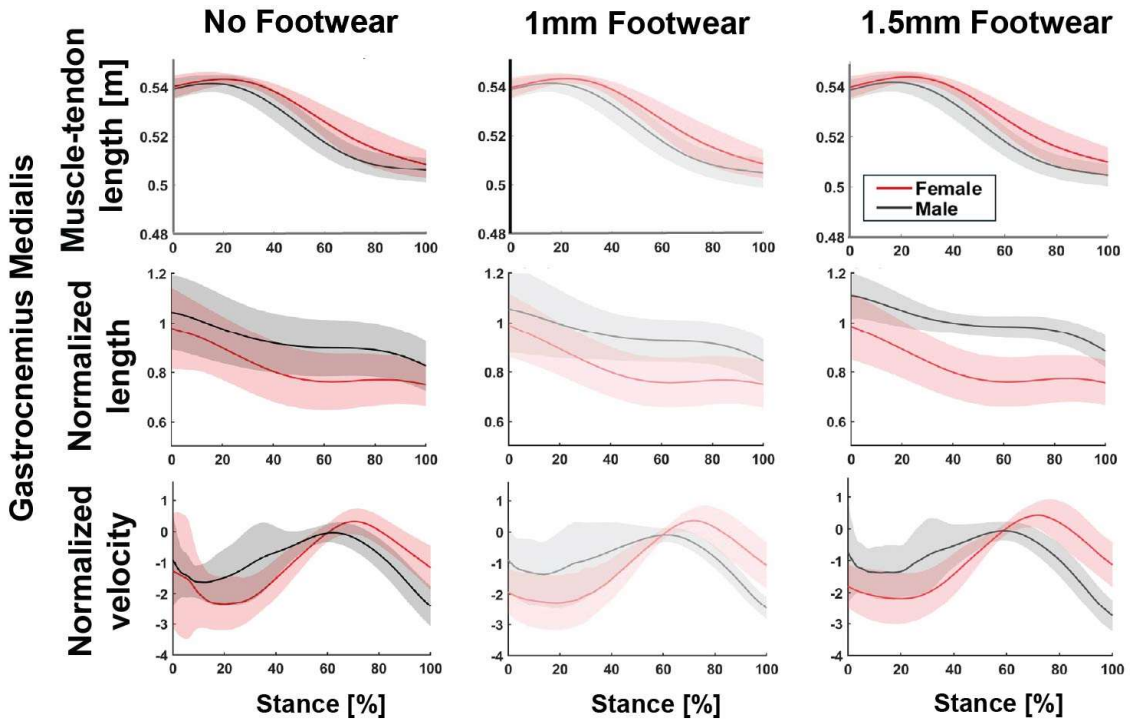

Figure 1: Mean gastrocnemius medialis (MG) muscle-tendon length, normalized muscle fiber length, and normalized muscle fiber velocity during stance across three footwear conditions (n0, 1mm, 1.5mm) and two sexes (male, female). Neck Muscle Activation during Inverted Freefalls in Human Subjects

Dr. Loay Al-Salehi[1], Dr. Peter A. Cripton[1], Dr. Gunter P. Siegmund[2]

[1]The University of British Columbia, Vancouver, BC, Canada. [2]MEA Forensic Engineers & Scientists, Laguna Hills, CA, United States

Introduction

Understanding the underlying neck injury mechanics of cervical spine fractures and dislocations in headfirst impacts is a prerequisite for potential prevention strategies. Although posture-related injury factors are well studied, the effect of active muscle has received less attention. We therefore quantified the timing and amplitude of neck muscle activation during headfirst freefalls.

Methods

Human subjects (9F/2M) were exposed to 2 initially relaxed and 2 initially braced headfirst freefalls (312.5 ms/0.479 m) on a custom-built freefall device (Fig.1). In relaxed trials, subjects maintained a horizontal head position before freefall without further instructions, while in braced trials, they were instructed to voluntarily brace for an anticipated headfirst impact immediately before freefall. Unilateral neck muscle electromyography (EMG) was recorded using indwelling electrodes which were inserted into seven superficial and deep posterior neck muscles (Fig 1). Surface electrodes were used for the sternohyoid muscle and as reference electrodes on the mid clavicle. Muscle onsets were defined as the time when each muscle's activation reached 10% of its maximum value, and was only quantified in the relaxed condition. Muscle activation levels were calculated as the root-mean square (RMS) and normalized by maximum voluntary isometric contractions. Muscle activation levels were analyzed using linear mixed models to assess the effects of time (before/after freefall start) and condition (relaxed/braced).

Results

Muscle onset times (mean (95% confidence interval)) ranged between 53.7 (49.3; 58.1) ms for STH and 93.6 (80.0; 107.2) ms for SSCAP. Muscle activation levels varied widely between subjects and muscles, and were significantly larger during freefall that before freefall ($p<0.0001$). Bracing increased muscle activation levels in 5 of 8 muscles before freefall ($p\leq0.0298$), but in only 2 muscles (LS and SSCAP) during freefall ($p\leq0.0161$).

Discussion

Muscle activation levels were larger during freefall than before freefall in both conditions, highlighting that an inverted freefall is a strong and robust sensory stimulus, even when braced. The short muscle onset times are consistent with reflex muscle activation, and thus muscle activation would likely precede head contact in many impact scenarios. Therefore, muscles should be included during headfirst impact testing in both cadaveric experiments and computational models.

Lesion Angle and Length Correlate in High-Energy Injuries of Articular Cartilage Explants

Dr. Alexander Paz Carvajal PhD.[1,2], Mr. Adnan Tahir MSc.[1], Dr. Atte Eskelinen PhD.[1], Prof. Alan Grodzinsky PhD.[3], Prof. Rami Korhonen PhD.[1], Dr. Mimmi Liukkonen PhD.[2], Assoc. Prof. Petri Tanska PhD.[1,2]

[1]University of Eastern Finland, Kuopio, North Savo, Finland. [2]Kuopio University Hospital, Kuopio, North Savo, Finland. [3]Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

Introduction

Fast loading can injure articular cartilage and trigger a cascade of degenerative changes leading to post-traumatic osteoarthritis. In previous studies, we focused on how degradative changes progress in tissue constituents following high-energy injury and periodic loading with and without exogenous inflammation. Here, the aim was to study whether cartilage structure provides a mechanistic explanation for the initiation and progression of the lesions, which could influence the speed and severity of the subsequent degeneration.

Methods

We harvested 23 cartilage explants (thickness: 1 mm, diameter: 3 mm) from the patellofemoral grooves of 1-to 2-week-old bovines. The explants were subjected to a single high-energy injury (50% strain at 100%/s) in unconfined compression. After the injurious loading, samples were fixed in formalin, dehydrated, and embedded in paraffin. Safranin-O and unstained sections were prepared. Stained sections were imaged with digital densitometry to characterize proteoglycan content and lesion/crack shape and size, while unstained sections underwent polarized light microscopy to evaluate collagen network structure. A custom MATLAB script was used to characterize crack angle with respect to the explant surface (θ, Fig. 1a), the crack length (c), and the crack distance from the explant edge (d).

Results

The protocol fully cracked 4 samples (17%), left 4 visually intact (17%), and induced lesions in 15 samples (66%). From the 30 cracks we observed, the average ([95% confidence interval]) crack length was c = 0.12 [0.09, 0.14] mm occurring at d = 0.62 [0.50, 0.74] mm

from the edge at an angle θ = 56.36 [49.43, 63.28] degrees with respect to the articular surface. In addition, we observed a clear association between a smaller crack angle and longer crack length (Pearson r = – 0.78, r^2 = 0.61; Fig. 1b).

Discussion

Discussion. Longer cracks tended to align more closely with the articular surface. The crack shape and size may be explained by the local collagen arrangement, suggesting that the damage initially develops along the fibers (breaking fiber-to-fiber bonds) rather than transverse to the collagen fibers. This hypothesis needs to be validated by further quantifying the dominant orientation of the collagen fibers in (im)mature cartilage.

Fall Detection in Extreme Class Imbalance: A Cascade Architecture for Real-World Deployment

Mr. Ethan Henley[1], Dr. Nicole Stark PhD[1], Ms. Brianna Reilly[1], Dr. Katherine Mayes MD, PhD[2,3], Dr. Damon Kuehl MD[2,3], Dr. Steve Rowson PhD[1]

[1]Virginia Tech, Blacksburg, VA, United States. [2]Virginia Tech Carilion School of Medicine, Roanoke, VA, United States. [3]Carilion Roanoke Memorial Hospital, Roanoke, VA, United States

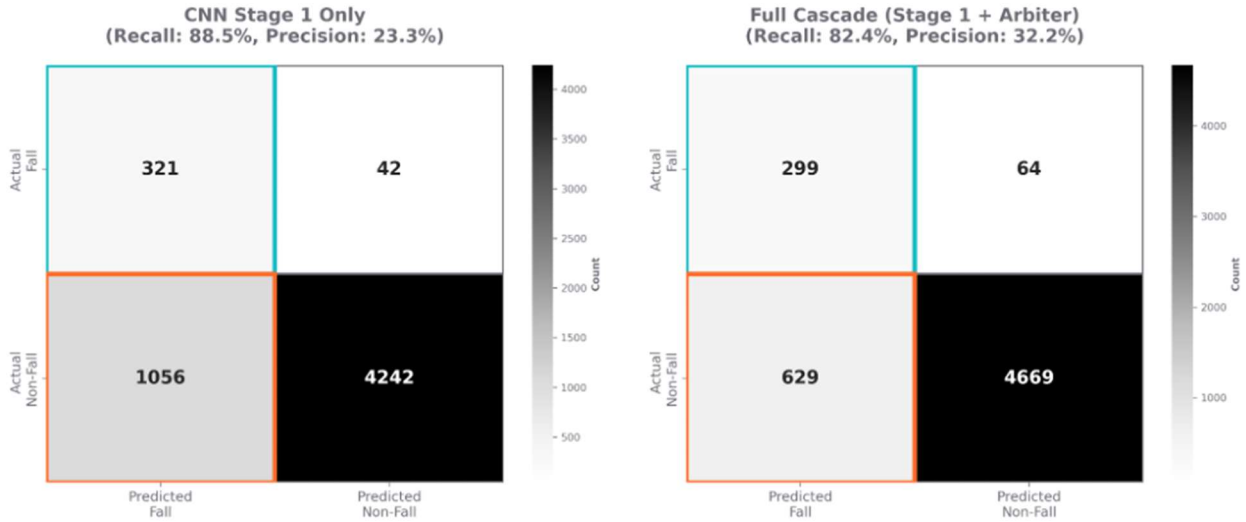
Introduction

Falls among older adults (≥65 years) result in over 3 million emergency department visits and 32,000 deaths annually in the U.S., generating more than $50 billion in medical costs [1–4]. In long-term care(LTC) settings, many falls are unwitnessed, creating significant challenges for accurately assessing injury Automated fall detection systems offer promise but face a fundamental barrier: extreme class imbalance in continuous monitoring, where falls comprise <2% of recorded footage, leading to high false-positive rates and alarm fatigue [5,6].

Methods

We developed a cascade architecture that decomposes fall detection into two sequential stages optimized for complementary objectives. Stage 1 uses a lightweight 3D convolutional neural network trained via curriculum learning with adaptive focal loss to maximize recall on the minority fall class. Stage 2 implements a feature-based arbiter that evaluates internal CNN representations to validate candidate events, aiming to reduce false positives while preserving sensitivity. The system was validated using 190 videos of simulated falls from the LE2I dataset [7] and 300 spontaneous falls from LTC residents in the Robinovitch dataset [8].

Results



The proposed cascade achieved 82.4% recall and 32.2% precision, yielding a 38% relative improvement in precision over a single-stage CNN baseline (88.5% recall, 23.3% precision). The approach reduced false positives by 40.5% while maintaining sensitivity above 80%.

Discussion

Our findings demonstrate that a two-stage cascade substantially improves the clinical viability of automated fall detection under severe class-imbalance conditions. By

maximizing recall early and applying a discriminative arbiter for refinement, the framework reduces false alarms without compromising sensitivity. This architecture provides a scalable foundation for real-world deployment in LTC environments, where accurate detection is essential yet data constraints remain significant.

OA19-05

Translating Ballet Landing Mechanics to ACL Injury Prevention: A Biomechanical Comparison of Landing Strategies Between Female Dancers and Non-Dancers

Ms. Annabelle Sung Min Kang BS

Yonsei University, Seoul, Seoul, Korea, Republic of

Introduction

Females exhibit a disproportionately high risk of anterior cruciate ligament (ACL) injury, yet female ballet dancers, despite performing frequent jumps, show lower knee injury rates per exposure hour. This study examined whether dancers adopt unique landing strategies that reduce ACL loading and whether these mechanics can inform injury prevention protocols for the general female population.

Methods

10 female ballet dancers (24.88 ± 4.12 yrs; 162.98 ± 3.4 cm; 49.16 ± 5.5 kg) and 10 non-dancers (26.8 ± 3.41 yrs; 161.72 ± 5.4 cm; 57.65 ± 4.93 kg) performed three single-leg hop trials. Kinetic variables (peak vertical ground reaction force [vGRF], time-to-peak vGRF [TTP], loading rate) and sagittal-plane kinematics at initial contact (IC) and peak vGRF were compared using independent t-tests ($\alpha = .05$) and effect sizes.

Results

Dancers showed significantly prolonged TTP vGRF (0.57 ± 0.06 s) compared to non-dancers (0.44 ± 0.16 s; $p = .038$, d = 1.08), indicating slower impact loading. Although loading rate differences were non-significant ($p = .055$), a large effect size (d = -0.98) suggested a notable trend toward reduced impact loading in dancers. Significant kinematic differences emerged only at the ankle. At IC, dancers landed with greater plantar flexion (−17.24 ± 6.70°) than non-dancers (−6.50 ± 9.45°; $p = .009$, d = −1.31), reflecting a forefoot landing strategy. Crucially, no significant differences were observed in kinematics at peak vGRF, revealing a ~1.5-fold greater total ankle excursion (~34° vs. ~22°) in dancers.

Discussion

Lack of kinematic differences at the knee, contrasted with significant ankle excursion, suggests that dancers employ a distal absorption strategy. In this mechanism, the foot and ankle complex acts as the primary shock absorber, filtering impact forces before knee transmission. However, this strategy positions the ankle in a mechanically unstable, open-

packed configuration, consistent with the high incidence of ankle sprains in dancers. Consequently, understanding the muscular control of this mechanism is vital; future research should utilize electromyography (EMG) to quantify the damping role of the triceps surae and the co-activation of the tibialis anterior. For general population application, injury prevention protocols must combine ROM enhancement with neuromuscular training to secure joint stability while leveraging the biomechanical benefits of this soft landing strategy.

Phase-Specific Neuromechanical Effects of Virtual and Augmented Reality–enhanced Robotic Gait Training After Stroke

Mr. Chaesu Kim M.Sc., Mr. Joshua Sung You Ph.D.

Yonsei university, Wonju, Gangwondo, Korea, Republic of

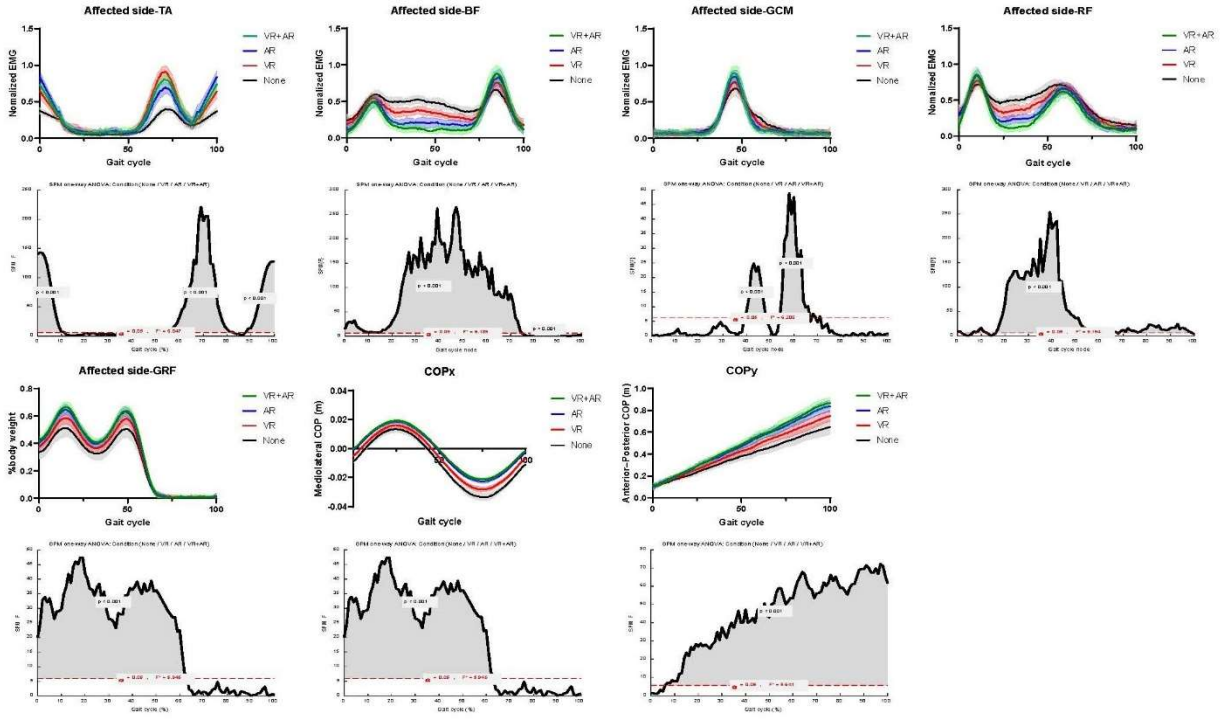
Introduction

Robotic-assisted gait training (RAGT) is widely used after stroke, but its neuromechanical effects are inconsistent and usually quantified by discrete spatiotemporal measures, so it remains unclear which phases of the gait cycle are modified by RAGT. Virtual reality (VR) and augmented reality (AR) can provide task-oriented visual feedback during RAGT and may differentially modulate impaired phases such as swing foot clearance, initial contact, and paretic propulsion.

Methods

Twenty individuals with chronic hemiparetic stroke trained on a robotic gait system (Walkbot) under four randomized, within-subject conditions: (1) RAGT alone without visual feedback (None), (2) VR-enhanced RAGT with a game-like kicking task emphasizing swing dorsiflexion, (3) AR-enhanced RAGT presenting overground walking scenes aligned with treadmill motion, and (4) VR+AR-enhanced RAGT, in which VR and AR were delivered sequentially (15+15 min) in random order. Robotic parameters (speed, body-weight support, guidance force) were held constant. During the 10–20-min steady-state window of each 30-min session, paretic-side EMG (tibialis anterior, medial gastrocnemius, rectus femoris, biceps femoris), vertical/anterior–posterior ground reaction forces, and COPx/COPy were recorded, time-normalized to 0–100% gait, and analyzed using one-way repeated-measures SPM-ANOVA with Bonferroni-corrected post-hoc SPM t-tests.

Results



Despite identical robotic assistance, the VR/AR conditions produced phase-specific changes in paretic neuromechanics. VR-enhanced RAGT showed the largest mid-swing tibialis anterior burst (60–80%), consistent with increased dorsiflexor recruitment for toe clearance. AR- and VR+AR-enhanced RAGT increased tibialis anterior activity around initial contact (90–10%), enhanced late-stance gastrocnemius propulsion, and improved heel-to-toe COPy progression with reduced medio-lateral COPx sway. Rectus femoris/biceps

femoris co-contraction during stance was highest with RAGT alone and progressively decreased in VR-, AR-, and VR+AR-enhanced RAGT, indicating more selective knee control.

Discussion

By keeping robotic gait parameters fixed and manipulating only VR/AR visual feedback, this study shows that sensory context can modulate paretic neuromuscular control in a phase-specific manner. VR-enhanced RAGT improves swing-phase dorsiflexor control, whereas AR- and VR+AR-enhanced RAGT better restore loading and propulsion mechanics and reduce maladaptive stiffening. These findings suggest that VR/AR-augmented RAGT can be configured to target specific gait-phase deficits after stroke, rather than simply increasing training intensity.

Sonified-Biofeedback Training to Improve Postural Control in Older Adults

Ms. Zahava Hirsch, Ms. Erin Kreis, Dr. Antonia Zaferiou

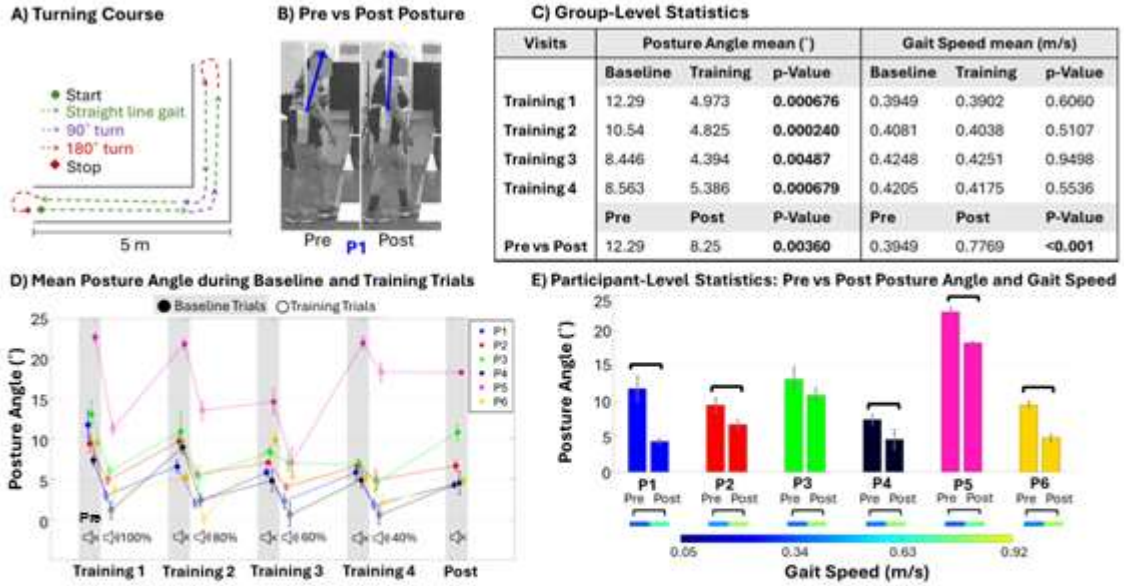
Stevens Institute of Technology, Hoboken, NJ, United States

Introduction

Varied populations have improved their balance and gait using sonified-biofeedback, which conveys biomechanical measures through precise sound cues [1]. Our goal is to understand if sonified-biofeedback training can improve postural control in older adults [2]. We hypothesized that posture angle will improve during training trials versus baseline trials and be retained during a post-evaluation.

Methods

Six older adults (5 f, 74.5 ± 4.55 years) completed an initial assessment visit, four training visits across two weeks, and a one-week post visit. A 13-segment whole-body kinematic model was built using optical motion capture data (OptiTrack USA) [3]. A physical therapist balance guarded as participants completed a walking and turning course (Fig. 1A) at a preferred speed. During the initial assessment visit, participants completed assessments and were familiarized with the turning course. Each training visit consisted of five baseline trials without sonified-biofeedback followed by 10 training trials with sonified-biofeedback, fading by 20% each visit. Posture angle was determined by a vector from the pelvis to the head, using the pelvis anteroposterior axis to determine the sagittal plane. The target posture angle was determined by the participant's baseline trials. When posture approached the target, a low-pitched musical sound played. As the angle increased the pitch increased, informing the participant to self-correct their posture. Participant-level statistics used the Mann Whitney U test. Group-level statistics used the paired t-test.



Results

A sample of pre versus post posture is seen in Figure 1B. At the group level, posture angle significantly improved during training versus baseline and pre versus post. There was no significant difference in gait speed during training versus baseline, but gait speed significantly improved pre versus post (Figure 1C). Participants' mean posture angle for each visit's baseline and training can be seen in Figure 1D. Within-participant results revealed five of six participants significantly improved their posture angle and all participants significantly increased gait speed pre versus post (Figure 1E).

Discussion

Results support sonified-biofeedback as a promising approach to help older adults improve dynamic postural control.

People With Unilateral Transtibial Amputation Reorganize Muscle Coordination Patterns When Walking With Visual Feedback Targeting Increased Peak Propulsive Horizontal Force

Ms. Ziting Liz Li[1], Prof. Chris Fink[2], Prof. Vincent CK Cheung[3], Dr. Caelyn Hirschman[4], Prof. Alena M. Grabowski[4,5], Prof. Janet Zhang-Lea[1]

[1]Human Biomechanics Lab, University of Oregon, Eugene, Oregon, United States. [2]Department of Physics, Gonzaga University, Spokane, Washington, United States. [4]Department of Integrative Physiology, University of Colorado Boulder, Boulder, Colorado, United States. [5]Department of Veterans Affairs Eastern Colorado Healthcare System, Denver, Colorado, United States

Introduction

People with unilateral transtibial amputation (UTTA) walk using a passive-elastic prosthesis and apply less peak horizontal propulsive force (PPF) from their affected leg (AL) than their unaffected leg (UL). We previously found that when given visual feedback (VF) to increase AL-PPF by 20%, 3 out of 12 participants with UTTA met the target (≥20% increase), and 6 participants increased AL-PPF <15% compared to baseline. In this study, we used muscle synergy analysis to characterize how groups of muscles were coordinated during walking between high responders (≥20% increase) versus low responders (<15% increase), and hypothesized that high responders would reorganize UL muscle coordination when presented with VF.

Methods

Twelve people with UTTA walked with a passive-elastic prosthesis on a treadmill for 5 minutes at 1.25 m/s in two conditions, without VF as a baseline, and with VF of AL-PPF 20% (20VF) higher than baseline. We recorded surface EMG from lower-limb muscles on both legs, and applied non-negative matrix factorization on the UL EMG signals to extract synergy weightings to describe muscle coordination patterns during the baseline and 20VF trials. We used k-means clustering to identify muscle synergy clusters across participants, which automatically sorts the synergy weightings into a chosen number of clusters so that muscle coordination patterns within the same cluster are as similar as possible.

Results

Participants presented 3 clusters of UL synergies during baseline and 5 clusters during 20VF trials. During baseline, we observed a cluster characterized as a co-activation of the two measured ankle dorsiflexors (Lateral Gastrocnemius and Soleus), and this cluster was regrouped into a co-activation between one of the two measured ankle dorsiflexors and one of the measured hip extensors (Bicep Femoris or Gluteus Maximus) for the 20VF trial . Such reorganization in muscle synergies was observed in all high responders, but not in low responders. Low responders continued to present a synergy cluster with co-activation of both ankle dorsiflexors.

Discussion

People with UTTA using a passive-elastic prosthesis who increased AL-PPF when given VF reorganized their UL muscle synergies to achieve the VF target. A VF-based training program targeting specific synergy profiles may be useful for post-amputation rehabilitation.

Musical Feedback for Medial Knee Load Reduction: Translational Evidence

MS, PT Luisa Cedin, MS Camilla Antognini, PhD Christopher Knowlton, PT, PhD Christopher Ferrigno, PhD Markus Wimmer

Rush University Medical Center, Chicago, IL, United States

Introduction

Medial knee joint overload is a key biomechanical driver of knee osteoarthritis (OA), however existing gait retraining strategies often face barriers in engagement and implementation. We developed a musical feedback system designed to medialize the center of pressure (CoP) and reduce knee adduction moment (KAM) through intuitive, engaging auditory cues [1]. Following initial validation in healthy adults, this study examined feasibility, acceptability, and biomechanical responses in individuals with chronic knee pain as a translational step toward an OA therapeutic tool.

Methods

Healthy (n=12) and chronic knee pain participants (n=10) completed a musical-feedback protocol designed to medialized CoP. Real-time plantar pressure was measured using wireless insoles (Moticon ReGo) and integrated with a low-pass filter that muffled a self-selected playlist whenever lateral CoP exceeded 25% of baseline. Gait analysis was performed using 3D motion capture and force plates. The knee pain cohort also completed the NASA TLX and a custom acceptability questionnaire. Biomechanical analyses focused on responders, those who medialized CoP. Spatiotemporal parameters, CoP, and KAM peaks were compared using paired t-tests.

Results

All healthy participants significantly medialized CoP (average peak -11%) and showed reductions in both KAM peaks without altering speed, cadence, or step width (Table 1). Kinematic adaptations included increased hip and ankle external rotation and reduced inversion/eversion motion. In the knee pain cohort, seven out of ten participants responded and medialized CoP. Those responders reduced their 1st KAM peak without altering spatiotemporal parameters. Interestingly, two non-responders also showed KAM reductions. Participants with knee pain reported high engagement, willingness to use the system, and moderate cognitive workload. Three reported reduced balance confidence and mild arch discomfort from the insole battery position.

Discussion

Across both cohorts, musical feedback successfully cued users to medialize their gait line and reduce knee loading without slowdown. Unloading responses varied with knee pain, likely reflecting heterogeneous gait strategies in symptomatic populations. High acceptability and moderate cognitive load support the system feasibility. Minor comfort or balance concerns indicate improvement opportunities. Together, these findings indicate real-time musical feedback is feasible, acceptable, and effective in COP change, supporting further studies in populations with knee OA.

Insole-Delivered Forefoot Plantar Force Biofeedback Improves Propulsion in Individuals with Post-Stroke Hemiparesis

Dr. Nicole K. Rendos PhD, LAT, ATC, CSCS, FACSM[1,2], Ms. Jorjie M. Wilson MS[3], Mr. Zahin Alam[4], Dr. Trisha M. Kesar PT, PhD[3]

[1]Florida Institute for Human and Machine Cognition, Pensacola, FL, United States. [2]University of West Florida, Pensacola, FL, United States. [3]Emory University, Atlanta, GA, United States. [4]Hackensack Meridian School of Medicine, Nutley, NJ, United States

Introduction

Individuals with post-stroke hemiparesis exhibit reduced propulsive force from the paretic limb, reflected by decreased anterior ground reaction force (AGRF). This propulsion deficit contributes to slower gait speed, gait asymmetry, and reduced functional mobility. Propulsion biofeedback can improve AGRF but is traditionally limited to laboratory environments. This study examined whether a wearable insole system delivering forefoot plantar force biofeedback could serve as a practical surrogate for propulsion biofeedback.

Methods

Kinematic and kinetic data were recorded as twelve participants with chronic post-stroke hemiparesis (6 male; age=57.0±12.0y; 70.0±57.2 months post-stroke) walked on a split-belt instrumented treadmill wearing 3-sensor loadsol-ACP® insoles. After a baseline walking trial, insoles provided either auditory or haptic biofeedback with a 3-10% target increase in forefoot plantar force in the hemiparetic limb. Gait data were normalized to 100% and root mean square errors (RMSE) were calculated for AGRF, ankle angle, ankle moment, and ankle power to quantify waveform similarity across conditions. Repeated-measures ANOVAs assessed differences in peak values.

Results

AGRF RMSE were 14.006±8.656 N (Baseline-Auditory), 12.819±8.570 N (Baseline-Haptic), and 5.826±3.567 N (Audio-Haptic). Ankle angle RMSE were 3.910±3.224°, 3.631±2.957°, and 1.135±0.531°, respectively. Ankle moment RMSE were .279±3.061 Nm/kg, 1.186±3.097 Nm/kg, and 0.159±0.205 Nm/kg, respectively. Ankle power RMSE were 0.182±0.125 W/kg, 0.188±0.139 W/kg, and 0.064 ± 0.045 W/kg, respectively. Peak AGRF increased significantly across conditions (p=.023), with improvements during auditory (M_{diff}=14.42±5.69 N, p=.032) and haptic (M_{diff}=10.85±6.02 N, p=.096) biofeedback. Peak ankle angle decreased with both auditory (M_{diff}=2.73±0.89°, p=0.014) and haptic

(M_{diff}=3.45±0.96°, p=.006) biofeedback compared to baseline. No differences were observed in peak ankle moment or power.

Discussion

Auditory and haptic forefoot plantar force biofeedback produced similar gait waveform patterns and effectively increased propulsion post-stroke, as reflected by greater peak AGRF without corresponding increases in joint loading. Reductions in peak ankle angle during biofeedback suggest altered limb positioning that may facilitate improved propulsive force generation. The comparable RMSE between auditory and haptic conditions indicates both modalities elicit highly consistent gait responses, supporting their potential utility as propulsion-training strategies in post-stroke rehabilitation.

Effectiveness of Wearable Device-Assisted Gait Retraining in Female Runners with Patellofemoral Pain: A Randomized Controlled Trial

Dr. Hao-Nan Wang PT, PhD, CSCS[1,2], Dr. Pei Luo[3], Prof. Jian Li[1]

[1]Sports Medicine Center, West China Hospital, Sichuan University, Chengdu, Sichuan, China. [2]Department of Orthopedics and Orthopedic Research Institute, West China Hospital, Sichuan University, Chengdu, Sichuan, China. [3]School of Sport Science, Beijing Sport University, Beijing, Beijing, China

Introduction

Patellofemoral pain (PFP) is a common overuse injury among female runners, often impairing running performance and daily activities. Gait retraining has emerged as a potential intervention, and wearable devices with real-time feedback may enhance its efficacy. This study aimed to evaluate the effectiveness of a 6-week wearable watch-assisted gait retraining intervention, which provides real-time cadence feedback to increase step frequency by 10%, in female runners with PFP.

Methods

A randomized controlled trial was conducted between March 2023 and June 2023, recruiting 30 female runners with PFP from running clubs and sports medicine centers in Beijing (15 in each group). Inclusion criteria included age 18-40 years, unilateral or bilateral anterior knee pain for ≥4 weeks (VAS ≥3/10), and insidious symptom onset. Exclusion criteria included traumatic injury history, knee surgery, and other confounding musculoskeletal or systemic diseases. The gait retraining group received 12 sessions of intervention using a wearable watch that provided real-time cadence feedback, with the target of increasing step frequency by 10%. Training duration gradually increased from 15 to 30 minutes per session. The control group received health education. Outcome measures included Visual Analogue Scale (VAS) for pain, AKPS score, and patellofemoral joint (PFJ) stress assessed at baseline and after 6 weeks. Statistical analyses included an independent *T* test, with significance set at $p < 0.05$.

Results

Among a total of 30 participants enrolled and randomized. There were no significant differences in baseline characteristics between the groups. At 6-week follow-up, the intervention group had greater improvements in AKPS compared to the control group (between-group difference, 4.31 [95%CI, 0.53 to 8.10]; P = 0.03). The intervention group showed a larger reduction in VAS pain scores (between-group difference, 5.80 [95%CI, 2.71

to 8.89]; P < 0.01) and more favorable changes in PFJ stress (between-group difference, 1.56 [95%CI, 1.26 to 1.86]; P < 0.01) than the control group. No adverse events were reported during the intervention period.

Discussion

A wearable watch-assisted gait retraining intervention with real-time cadence feedback (targeting a 10% increase in step frequency) significantly reduces pain, improves functional status, and optimizes patellofemoral joint biomechanics in female runners with PFP, demonstrating clinically meaningful effects.

Evaluating Automated Correspondence Approaches for the Scapula using Ground Truth Homologous Landmarks

Dr. Michael Rainbow PhD[1], Dr. Erin Lee PhD[2]

[1]Queen's University, Kingston, ON, Canada. [2]University of Waterloo, Waterloo, ON, Canada

Introduction

3D scapula shape is relevant for injury risk and shoulder biomechanics [1]. An essential step in analyzing shape with statistical shape modelling is to establish point-to-point correspondences that maintain homology (i.e., corresponding points having the same anatomical meaning across bone meshes). Automated methods, such as coherent point drift (CPD), are an attractive alternative to manual landmarking methods because they incorporate the entire 3D surface and capture rich details, like articular curvature, that may be relevant for joint mechanics. Automated correspondence of the scapula is notoriously challenging due to the scapula's branching morphology, but newer CPD algorithms look promising for handling complex geometries. Here, we evaluate two CPD methods for establishing homologous node correspondence in the scapula.

Methods

Eight human scapulae were segmented from CT scans (*Mimics 25*) and landmarked using 29 points that capture scapula morphology (*Stratovan*). To generate meshes with ground-truth correspondences ("warps"), we warped a reference mean mesh to match the landmarks of each participant's scapula using Thin-Plate Spline. This process ensures that the anatomical locations of the warped mesh coordinates are homologous with those of the mean mesh. To evaluate CPD approaches, we generated corresponding meshes for each warped mesh using the mean mesh as the reference. We computed the distance between the ground-truth landmark locations and those produced by the Classic [1] and Bayesian [2] CPD methods.

Results

Both CPD approaches performed well. Within each participant, inter-landmark distances between actual and CPD landmarks were smaller (2 mm) than distances across participants (6 mm). Bayesian CPD had fewer outliers and yielded a smoother mesh. It was also faster, solving in minutes per bone vs. 2 hours without GPU acceleration.

Discussion

CPD approaches can identify homologous landmarks on the scapula, with Bayesian CPD performing better and faster than classic CPD. Our approach of using a thin-plate spline to create homologous landmarks provides a new framework for testing automated correspondence approaches. Future work will investigate how well the CPD approaches reconstruct the geometry of the participant's original bone meshes.

Robot-Assisted Active Shoulder Simulator

Ms. Alina Albert MSc[1], Ms. Julia Sußiek Dr. med.[1], Mr. Willi Engelmann[1], Ms. Jane Gehling BSc[2], Mr. Jens Wermers Prof. Dr.[2], Mr. Michael J. Raschke Univ.-Prof. Dr. med.[1], Mr. J. Christoph Katthagen Prof. Dr. med.[1]

[1]Department of Trauma, Hand and Reconstructive Surgery, University Hospital Münster, Münster, NRW, Germany. [2]Department of Engineering Physics, Münster University of Applied Sciences, Münster, NRW, Germany

Introduction

Accurate evaluation of shoulder biomechanics requires systems that perform muscle driven physiological motion, but also implement clinical test protocols under controlled conditions. Existing simulators provide kinematic and muscle force data but lack integrated kinetic measurements and the capability to apply external loads. A robot-assisted active shoulder simulator is introduced to perform physiological shoulder motion in combination with standardized diagnostic tests, supporting biomechanical research.

Methods

The experimental setup (Fig. 1) integrated a six-degree-of-freedom (DoF) robotic arm equipped with SimVitro-software for measurement of joint kinetics and kinematics, and an active simulator for muscle force application. Actuators applied controlled forces to the rotator cuff and deltoid muscles via steel cables routed along anatomical paths. Tendons were reinforced with FiberWire; infraspinatus and teres minor were combined, and deltoid cables passed over frictionless pulleys. The long head of the biceps was loaded with 22 N, and arm weight simulated as 3.2% of body mass [1]. A LabVIEW-based closed-loop PID controller maintained muscle force accuracy within ±1 N. A load cell mounted on the humerus recorded applied muscle forces, which were transformed into the joint coordinate system for robotic motion. Muscle-induced glenohumeral abduction was performed in 19 cadaveric specimens using EMG and physiological cross-sectional area-based force ratios [2], adjusted every 20°. Internal rotation and horizontal abduction were fixed at 0°, with 25 N compressive force and anterior and superior forces set to 0 N.

Results

Torque compensation enabled abduction from 3° to 60°. Total muscle force increased from 81 ± 36 N/kg arm weight at 20° to 106 ± 28 N/kg. Integrated sensors provided data on joint reaction forces, translations, and muscle forces.

Discussion

Abduction forces were comparable to prior studies [3], validating the approach. The robot-assisted setup offers distinct advantages: application of clinical tests, selective in force- or displacement-controlled DoF, the ability to apply external loads or lock specific motions. Nevertheless, full closed-loop control between the robotic arm and muscle actuators remains challenging. Future work will target adaptive control and machine learning to improve responsiveness and enable more complex motion.

Muscle Loading Ratios for Scapular Plane Elevation: Preliminary Results of an In-Vitro Active Shoulder Motion Simulator

Mrs. Inês Santos[1], Ms. Lea-Marie Ocker[1], Mr. Daniel Ritter[1], Mrs. Maxi Tengler MD[1], Mr. Patrick Raiss MD[2]

[1]Arthrex Department of Orthopedic Research, Munich, Bavaria, Germany. [2]OCM, Munich, Bavaria, Germany

Mrs. Inês Santos

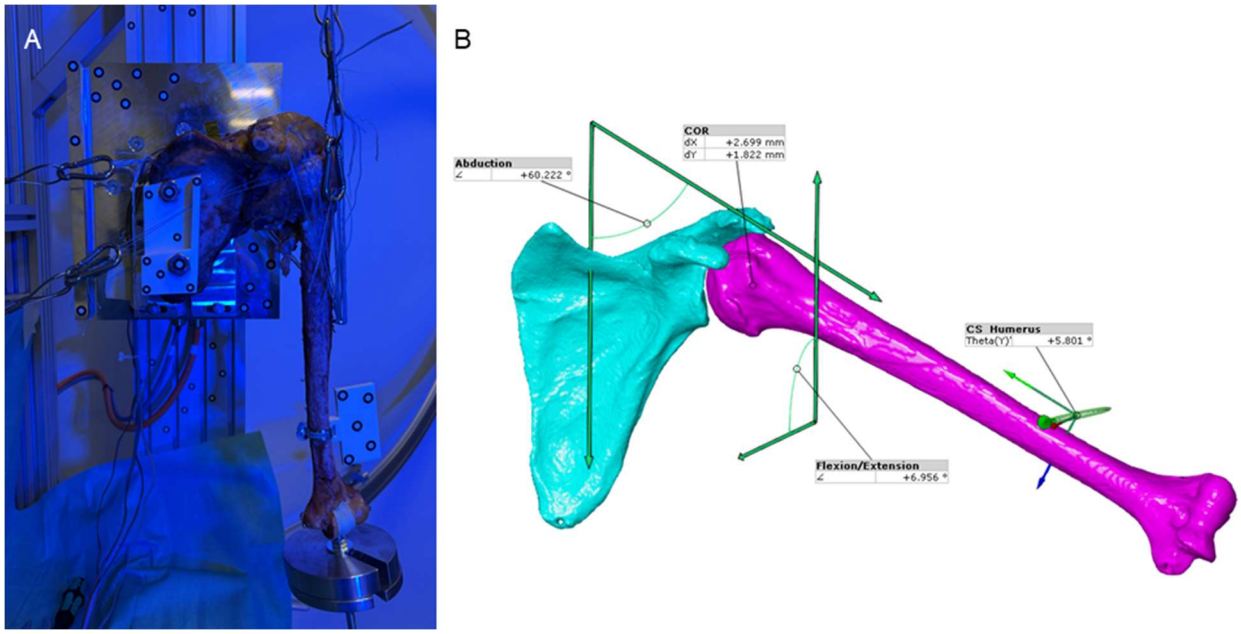
Ms. Lea-Marie Ocker

Introduction

Various muscle loading ratio datasets describing glenohumeral motion exist in the literature. Kedgley et al.[1] concluded that combining physiological cross-sectional area with electromyographic signals [2] that vary throughout motion better mimics the in vivo case. These variable muscle loading ratios, however, describe frontal plane abduction, while most shoulder simulators replicate scapular plane abduction. This ongoing study aims to analyze shoulder joint kinematics achieved with this set of muscle loading ratios and experimentally assess adjustments to achieve true scapular plane abduction.

Methods

Two fresh-frozen cadaveric shoulders were assembled in a rotary table using a custom-designed scapula fixation. The anatomic lines of action of the three portions of the deltoid, supraspinatus, subscapularis, and infraspinatus/teres minor, were routed using frictionless pulleys to six electric linear actuators (Fig.1A). Muscle forces were measured with force transducers positioned in line with each actuator. Optical tracking markers were attached to the humerus and scapula, and anatomical landmarks were digitized to create bone-fixed coordinate systems [3], allowing for the acquisition of physiological kinematic data (Fig. 1B). Scapulothoracic rhythm was simulated by rotating the scapula in a 2:1 ratio to the glenohumeral abduction angle. Abduction angles of 7°, 20°, 40°, 60°, and 90° were simulated by applying the literature muscle loading ratios [1], followed by adjusting the ratios to correct the abduction plane.



Results

The muscle ratios taken from literature resulted in an abduction plane 12.48±4.99° posterior to the scapular plane. To achieve scapular plane abduction, the middle deltoid force had to be reduced by an average of 12.93±1.03N, while the anterior deltoid had to increase 9.91±2.60N. The main discrepancies between deltoid muscle ratios were observed above 60° of abduction.

Discussion

Scapular plane abduction was not achieved with the muscle loading ratios proposed in literature; instead, they led to an abduction plane closer to the coronal plane. More specimens are being tested to better understand which ratios achieve scapular plane abduction, thereby enabling more accurate motion simulation and accounting for variability in specimen anatomy.

Dynamic Imaging of the Wrist: Anatomical Shape Variations Do Not Affect Kinematic Parameter Extraction

Drs. Maranda Haenen[1,2], Dr. Stefan Hummelink[1], Prof. Ioannis Sechopoulos[1,3,4], Prof. Brigitte Van der Heijden[1,2]

[1]Radboud University Medical Center, Nijmegen, Gelderland, Netherlands. [2]Jeroen Bosch Ziekenhuis, 's Hertogenbosch, Noord - Brabant, Netherlands. [3]University of Twente, Enschede, Overijssel, Netherlands. [4]Dutch Expert Center for Screening, Nijmegen, Gelderland, Netherlands

Introduction

Four-Dimensional Computed Tomography (4DCT) shows promise in diagnosing wrist pathologies such as scapholunate ligament lesions (SLL). Two parameters indicative of SLL lesions in these scans, the scapholunate angle (SLA) and the capitolunate angle (CLA), might be affected by anatomical shape variations. Therefore, this study characterizes the impact of anatomical shape variations on SLA and CLA estimates from 4DCT scans.

Methods

3D CT images retrieved from 4DCT scans of healthy wrists were used. Scans were segmented using a trained nnU-net and were stored as surface meshes. Meshes were re-meshed and downsampled and then registered to a reference bone using a rigid coherent point drift (CPD) algorithm. The statistical shape model (SSM) was created by performing a principal component (PC) analysis to identify main variation modes, expressing each shape as a linear combination of PCs. The quality of each SSM was evaluated using a leave-one-out approach by calculating the root mean squared error (RMSE) when fitting the SSM to each sample. New bone shapes were generated by adjusting PCs from -2σ to +2σ in 0.2σ increments, yielding 21 variations per PC. A random subset of 3000 new shapes was selected for further analysis. Next, local coordinate systems (LCSs) were assigned to the new shapes. The rotational deviation of the LCSs was calculated by a combined rotation around the three axes. Finally, the SLAs and CLAs were calculated for all new shapes.

Results

The SSM was created using 106 scans with an RMSE of 0.38 mm. The 95th percentile of the rotational deviations of the LCSs was below 5°. The resulting ranges due to anatomical variations in the calculation of the SLA and CLA were 5.7 ° and 6.8°, respectively (Figure 1).

Discussion

Bone shape variations have minimal influence on the determination of LCSs and, consequently, on the resulting SLA and CLA estimates. Based on the naturally occurring variability of carpal angles reported in the literature, the ranges of variation in the SLA and CLA are probably not clinically relevant but should be taken into account when performing inter-subject comparisons.

Images (Optional)

Designing Biomimetic Scaffolds for Bone Tissue Engineering through Machine Learning and Computational Simulation

Miss Yujie Zhang, Prof. Min Wang

The University of Hong Kong, Hong Kong, Hong Kong, Hong Kong

Miss Yujie Zhang

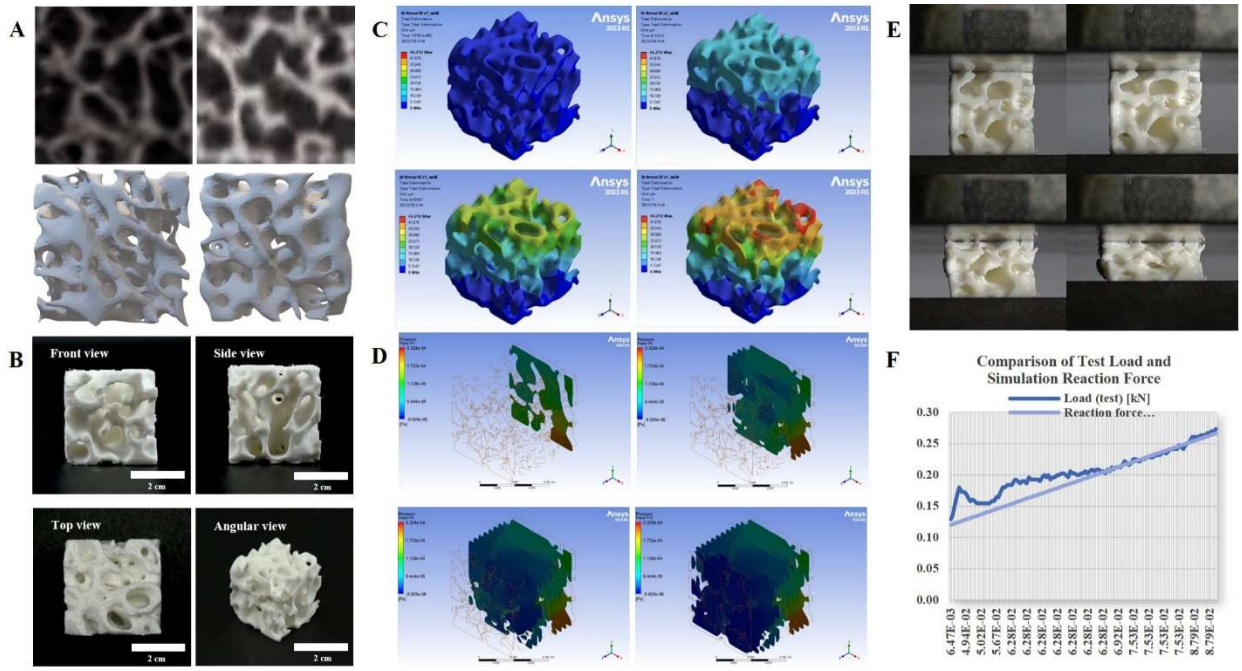
Introduction

In scaffold-based bone tissue engineering (BTE), scaffolds must be porous and mechanically robust. Trabecular bone provides a good template for BTE scaffolds owing to its mechanically resilient structure. Structural parameters such as trabecular thickness (Tb.Th), separation (Tb.Sp) and ellipsoid factor (EF) are key indicators of bone quality. Recent advances in artificial intelligence/machine learning (ML) make it possible to design patient-specific, biomimetic scaffolds. Through designing trabecular bone structure-based scaffolds using a specific region of human femoral head, this study established a framework for designing personalized BTE scaffolds.

Methods

Publicly available medical image datasets of human proximal femur were used for trabecular morphologies across gender and age. Trabecular parameters (Tb.Th, Tb.Sp, EF) were calculated for trabecular characteristics. Image data were processed and augmented using generative adversarial networks (GANs) and variational autoencoders (VAEs) to generate artificial images mimicking trabecular bone. They were converted into 3D BTE scaffold models. Finite element analysis (FEA) using ANSYS Workbench evaluated deformation, stress distribution, and stiffness of these scaffolds. Fluid dynamics simulation (CFD) using ANSYS CFX analyzed mass transport in scaffolds. Biomimetic BTE scaffolds with high structural fidelity were fabricated via fused deposition modeling (FDM) 3D printing using poly(lactic acid) (PLA) and tested under compression.

Results



ML-generated synthetic data effectively reproduced trabecular morphologies. FEA simulations revealed heterogeneous but continuous stress distributions in scaffolds similarly found in trabecular bone. Load transfer in scaffolds occurred via interconnected

struts, with stress concentrations in curved and transitional regions. The scaffolds exhibited mechanical responses closely matching experimental results. CFD simulations showed scaffolds supported uniform fluid perfusion. Computed permeability and pressure drop profiles suggested efficient nutrient exchange and metabolite cleaning. In compression tests, biomimetic scaffolds exhibited characteristic porous structure stress-strain behaviour. Reaction force-displacement curves from simulations correlated linearly with experimental data, indicating good predictivity of computational model.

Discussion

The integrated process, which combined medical images, ML-driven data synthesis/augmentation, and computational simulations, enabled creation of biomimetic BTE scaffolds that mimicked both mechanical and mass transport characteristics of trabecular bone. ML for data generation and utilization and FEA and CFD for predictive modeling provide a powerful platform for developing patient-specific, biomimetic BTE scaffolds.

CEINMS-WEB: A Web-based Application for Ultra Rapid Calibration of Neuromusculoskeletal Models

Mr Matthew Hambly BEng Elec & Biomed (Hons), MMedRes, Dr Alastair Quinn PhD, BE(Mechatronic), Dr Claudio Pizzolato BEng, MEng, PhD

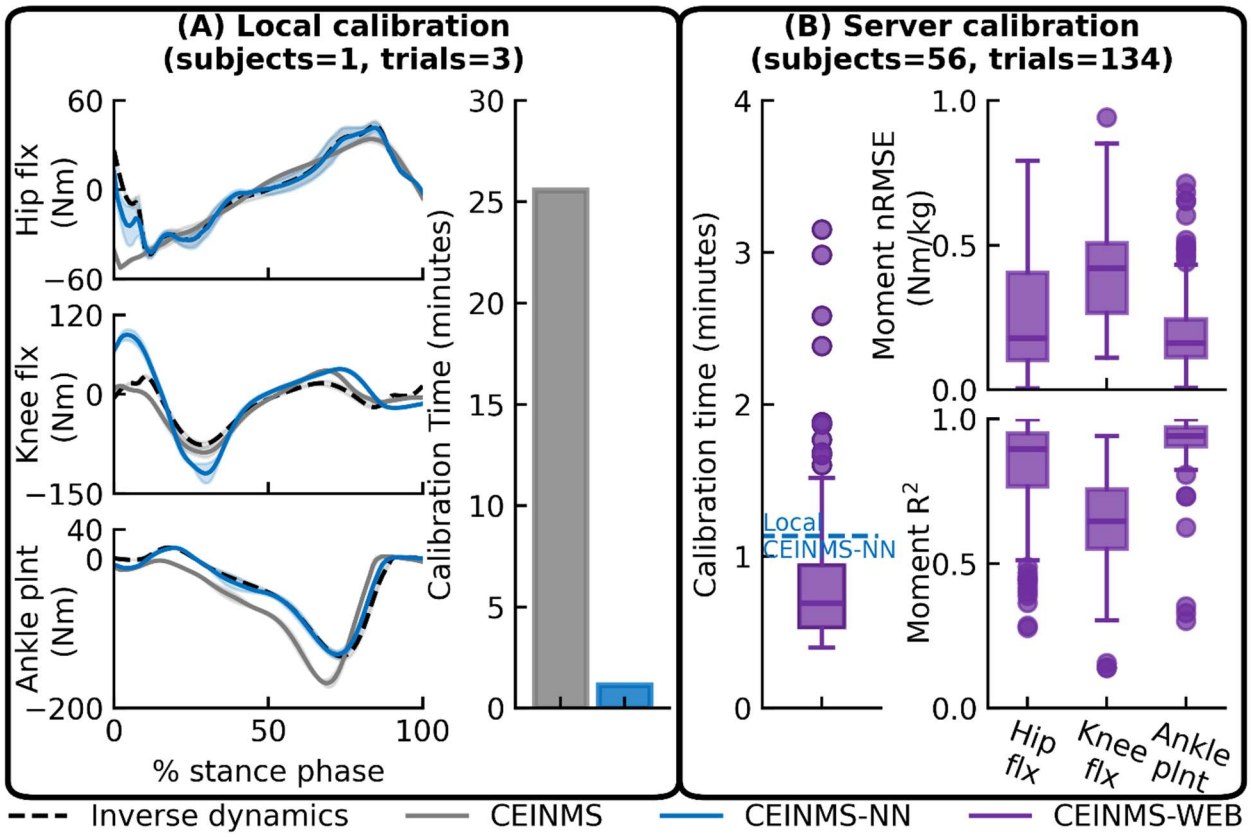
Australian Centre for Precision Health and Technology (PRECISE), Griffith University, Gold Coast, Queensland, Australia

Introduction

Electromyography (EMG)-informed neuromusculoskeletal (NMS) models predict physiologically plausible muscle and joint forces, useful for biomechanical analyses and personalized rehabilitation. However, NMS models require calibration to accurately represent the individual, traditionally taking potentially hours, limiting real-time applicability. Our recent work uses differentiable physics and muscle synergies to calibrate NMS models in minutes while synthesizing unrecorded excitations (CEINMS-NN) [1]. Here, we present a web-based application for ultra rapid NMS model calibration (CEINMS-WEB), providing easy access to users without hardware or software dependencies.

Methods

CEINMS-NN was deployed within a Docker container restricted to 1 CPU core and 1GB of memory with the host having an AMD 5975WX processor. Invited users uploaded datasets consisting of EMG, musculotendon unit kinematics, and inverse dynamics, then calibrated their NMS models. To test CEINMS-WEB, lower limb data from 56 subjects were processed, containing EMG acquired from 8 muscles, driving a model with 40 muscles and 3 degrees of freedom (hip flexion/extension, knee flexion/extension and ankle plantar/dorsiflexion). For comparison, a single-subject calibration was performed using simulated annealing in the CEINMS toolbox [2] and the synergy-hybrid CEINMS-NN calibration, both on a local Windows PC with an Intel Ultra 5 125H processor and 16 GB of memory.



Results

On the local machine, CEINMS-NN showed better overall moment tracking than CEINMS and reduced calibration time from >25 minutes to ~1 minute (figure 1A). Across 56 subjects, CEINMS-WEB reduced calibration time to typically <1 minute, while maintaining good moment prediction accuracy (figure 1B).

Discussion

We developed CEINMS-WEB, allowing users to upload data to a secure server and calibrate NMS models without requiring complex installation or high-performance hardware. By running calibration within minutes, CEINMS-WEB facilitates real-time applications and rapid testing of different modeling configurations, supporting more efficient workflows. Future updates will introduce synergy-based execution, enhanced usability, repeatability, data sharing, automated preprocessing, and results verification, ultimately creating a robust NMS modeling pipeline for the community. This streamlined process makes NMS modeling more accessible, particularly for inexperienced users, while minimizing errors linked to local setups or user error.

[5]National Taiwan University Hospital, Taipei City, Taiwan, Taiwan

Mr. Cheng-Hao Yu

Dr. Shiuan-Huei Lu

Prof. Ting-Ming Wang

Introduction

Measuring bilateral ground reaction forces and moments (GRF&Ms) is fundamental in gait analysis, requiring subjects to step each foot onto separate forceplates. This requirement often causes multiple trial attempts and alters walking mechanics, particularly in individuals with neuromusculoskeletal disorders. This study introduces a physics-informed federated learning (FL) approach that accurately predicts bilateral GRF&Ms from a single forceplate.

Methods

Retrospective gait analysis data from 4,800 trials across four groups (60 healthy young adults, 60 healthy older adults, 60 healthy children, and 60 individuals with cerebral palsy), each stored at a separate institution, were used. Each participant wore 41 markers and walked without targeted foot placement. Bilateral GRF&Ms were measured using four forceplates (OR6-7-1000, AMTI, USA), and marker trajectories were recorded using a motion capture system (MX-T40, Vicon, UK). These data were used to train and evaluate a physics-informed neural network [1] for predicting bilateral GRF&Ms from a forceplate.

Using FL, each institution trained its model locally using data from 45 participants, periodically sending model-parameter updates to the central server for aggregation into a global model. To accommodate heterogeneity in data and computational resources, a regularisation term was added to local training, and an adaptive normalisation method was applied during aggregation. The global model updated each institution's model at every iteration, enabling large-scale training while maintaining data privacy.

For trials excluded from training, model-predicted GRF&Ms were used to derive the centre of pressure (COP) and to calculate lower-limb intersegmental forces and moments via inverse dynamics. These variables were compared with gold-standard results using root-mean-square errors (RMSE) for COP and relative RMSE (rRMSE) for all other variables.

Results

Model-predicted results showed high consistency with the gold standard, given mean rRMSEs of 0.5%, 0.9%, and 1.2% for GRF, intersegmental forces and moments, respectively, and a mean RMSE of 3.1 mm for COP. No significant differences in prediction errors were observed between groups.

Discussion

The FL-trained model demonstrated strong potential to eliminate the need for step targeting in gait analysis. This approach is promising for developing large-scale AI models across gait laboratories while maintaining privacy.

OA23-02

Kinematic Constraints Fail to Capture In Vivo Intervertebral Motion Patterns in Adult Spinal Deformity and Healthy Individuals

Mr Tom Leppens MSc[1], Ms Birgitt Peeters MSc[1], Prof Sebastiaan Schelfaut PhD[2], Prof Lieven Moke PhD[2], Prof Lennart Scheys PhD[1]

[1]KU Leuven, Leuven, Vlaams Brabant, Belgium. [2]UZ Leuven, Leuven, Vlaams Brabant, Belgium

Introduction

Musculoskeletal models commonly employ kinematic constraints to reduce computational complexity by limiting intervertebral joint degrees of freedom. These constraints are based on ratios of intervertebral motions derived from limited in vivo datasets [1]. If these ratios misrepresent actual spinal motion, downstream predictions of joint loads and muscle forces may be biased. This study compares coordinate-optimization (CO) ratios against commonly applied kinematic constraint (KC) ratios.

Methods

Three participants performed seated trunk forward flexion and bilateral lateral bending using validated motion capture protocols: one adult spinal deformity patient (64 years), one healthy control (63 years), and one individual with sacralization (28 years). Subject-specific models were created using CT-like MRI for bone geometry, intervertebral joint, and motion-capture marker definition. Recorded motions were simulated using a coordinate-optimization (CO) approach to inversely compute intervertebral kinematics. [2]. CO intervertebral ranges of motion (RoM) were expressed as ratios relative to the total trunk RoM. These CO ratios were compared with KC ratios from the literature [1].

Results

During flexion, CO ratios deviated substantially from KC ratios (Figure 1). KC ratios systematically overestimated lumbar contributions and underestimated thoracic contributions with maximum deviations at L4-L5 (KC: 15.5%, CO: 0-8.4%). Upper thoracic levels showed 2-3 fold higher CO ratios than KC ratios. Lateral bending showed smaller deviations but still failed to capture compensatory patterns. The participant with sacralization exhibited zero L5-S1 contribution in CO ratios, while KC ratios predicted

13.2% in flexion and 3.7% in lateral bending. Consequently, KC ratios failed to capture the adjacent-level compensation at L4-L5, where CO ratios were 60% higher than KC ratios.

Discussion

Widely-adopted KC ratios could misrepresent segmental contributions to overall trunk motion, with error magnitude varying by movement type. Failure to account for anatomical variation highlights the inability of population-derived KC ratios to adapt to individual anatomy. These biases are problematic for applications requiring accurate segmental motion estimates, particularly for predicting joint loads and muscle forces in patients. Future modeling should prioritize patient-specific kinematic characterization over population-derived KC ratios.

Images (Optional)

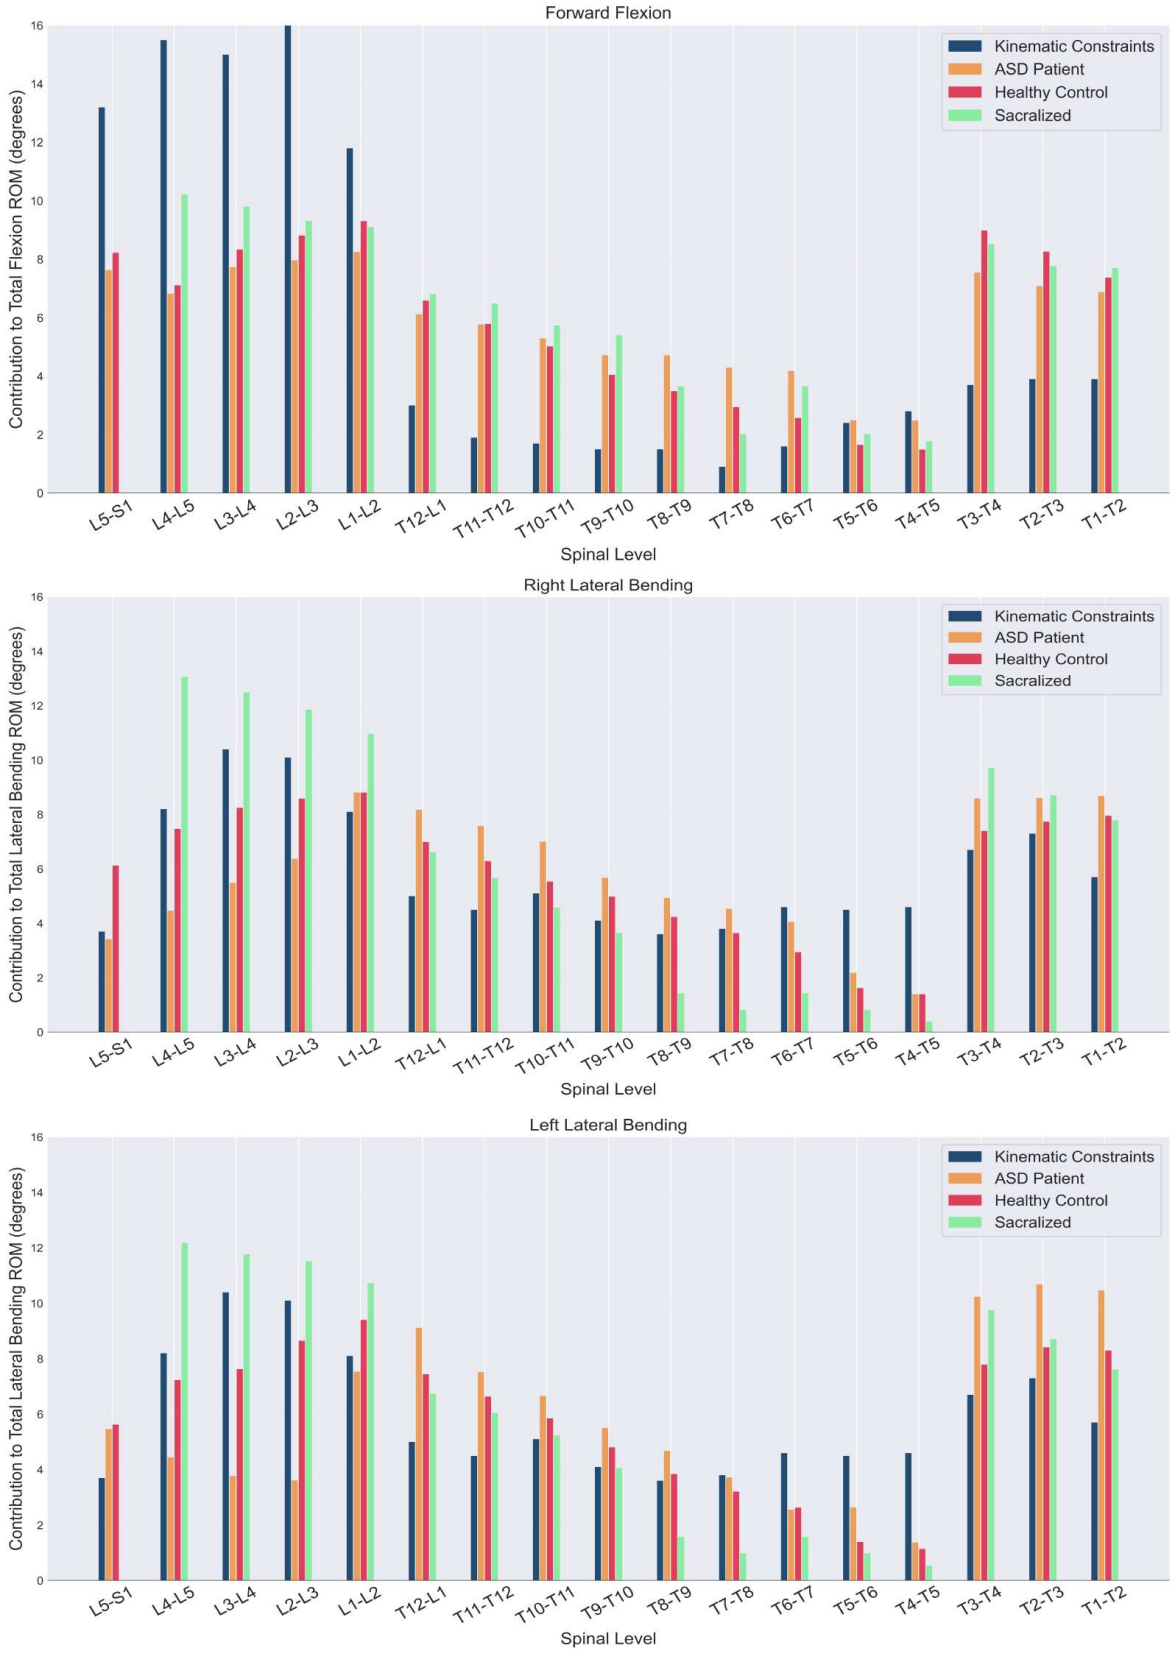

Figure 1. Comparison of intervertebral contribution ratios between coordinate-optimization (CO) and kinematic constraint (KC) approaches across three movement types.

Using Lumbar Spine Intervertebral Motion Sharing as a Kinematics Biomarker for Classifying Individuals with Chronic Low Back Pain

Mrs. Clarissa LeVasseur MS[1,2], Mr. Tom Gale MS[1], Ms. Sabreen Megherhi MPH[1], Dr. Gina McKernan PhD[1], Dr. Nam Vo PhD[1,2], Dr. Gwendolyn Sowa MD, PhD[1,2], Dr. William Anderst PhD[1]

[1]University of Pittsburgh, Pittsburgh, PA, United States. [2]Bethel Musculoskeletal Research Center, Pittsburgh, PA, United States

Introduction

Dynamic assessment of lumbar spine intervertebral kinematics may help identify subgroups of patients with chronic low back pain (cLBP) who may preferentially benefit from specific interventions. One kinematics biomarker to classify individuals with cLBP is motion sharing among intervertebral motion segments. This analysis aimed to classify individuals with cLBP by their dynamic motion sharing, and to evaluate differences in pain, disability, and age between those groupings.

Methods

Individuals fitting the NIH definition of cLBP provided written consent to participate in this IRB-approved study. Participants performed three trials each of maximal lateral bending bilaterally and flexion/extension. Synchronized biplane radiographs of the lumbar spine were captured at 20Hz for each 3s movement trial. Lumbar bone tissues were segmented from CT scans to create subject-specific 3D bone models. Vertebral motion was tracked in the biplane radiographs using a validated tracking process that matched digitally reconstructed radiographs created from the CT-based bones to the biplane radiographs. The percent contribution of each motion segment to the change in L1-S1 angle was computed at each 1° increment of L1-S1 rotation and averaged over corresponding movement trials. Segmental contributions to L1-S1 rotation were concatenated into a single waveform and then clustered using MATLAB's k-means clustering algorithm. Unpaired t-tests compared age, disability (Oswestry Disability Index (ODI)) and pain (10-point VAS in the last 7 days) between clusters.

Results

179 participants were included (86M, 93F; age: 54.7+/-16.5 yrs.; BMI: 26.4+/-3.8kg/m^2). Two clusters of motion sharing were identified for lateral bending and two for flexion/extension (Figure 1). During lateral bending, those with more evenly distributed motion sharing (Group 1) had higher ODI scores (25.5+/-11.9 vs. 21.9+/-10.6, p=0.037) compared to those

with more unequal motion sharing (Group 2). During flexion/extension, age was greater in those with greater contributions from L1-L2 and L2-L3 (Group 3), compared to those with greater contributions from L4-L5 (Group 4) (60.1+/-13.1 vs. 49.6+/-17.0 years, p<0.001).

Discussion

These results suggest individuals with cLBP cluster into two patterns of lumbar spine motion sharing in lateral bending and flexion/extension, with bending motion sharing group associated with disability and flexion/extension motion sharing group associated with age.

Images (Optional)

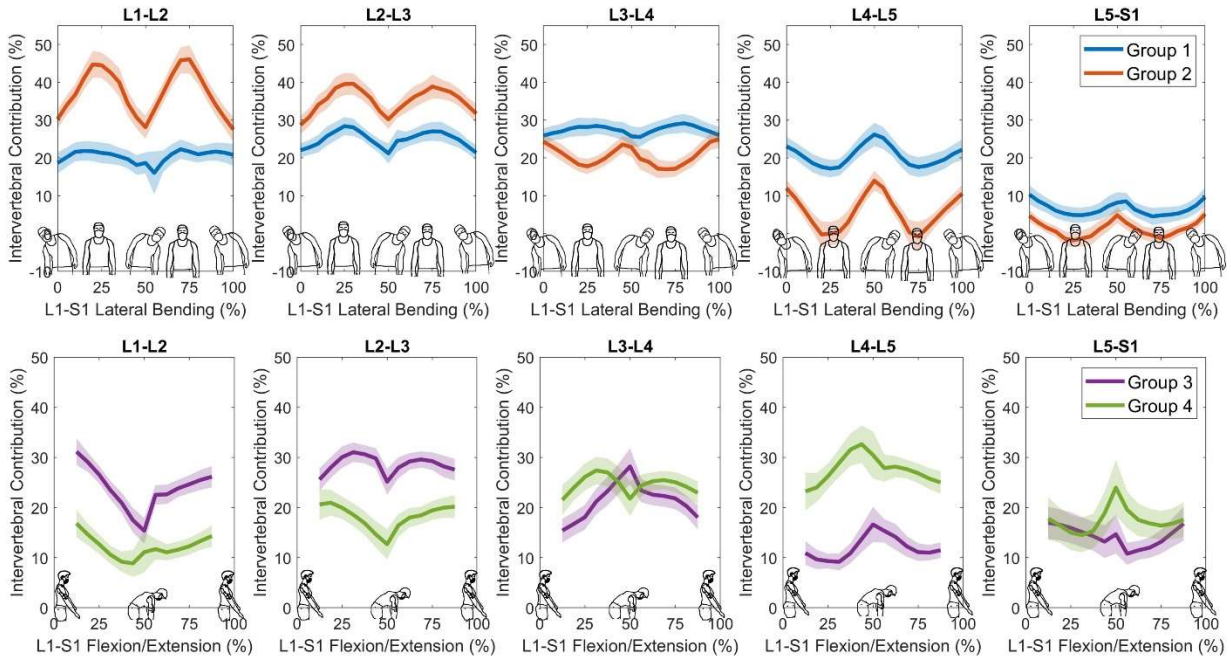

Figure 1: *Kinematics clusters at each motion segment during lateral bending (top) and flexion/extension (bottom). Each color represents a subgroup of participants with similar motion sharing across the entire lumbar spine (a cluster). The mean of each cluster (solid line) and 95% CI within the cluster (shaded region) is shown.*

Guiding Spine Flexion and Restricting Pelvic Movement During Flexion and Extension Tasks Has the Potential to Affect Lumbopelvic Kinematics

Dr Mona Frey[1], Dr Alex Breen[2], Dr Diana DeCarvalho[1]

[1]Memorial Univeristy of Newfoundland, St. John's, NL, Canada. [2]Usono B.V., Eindhoven, Noord Brabant, Netherlands

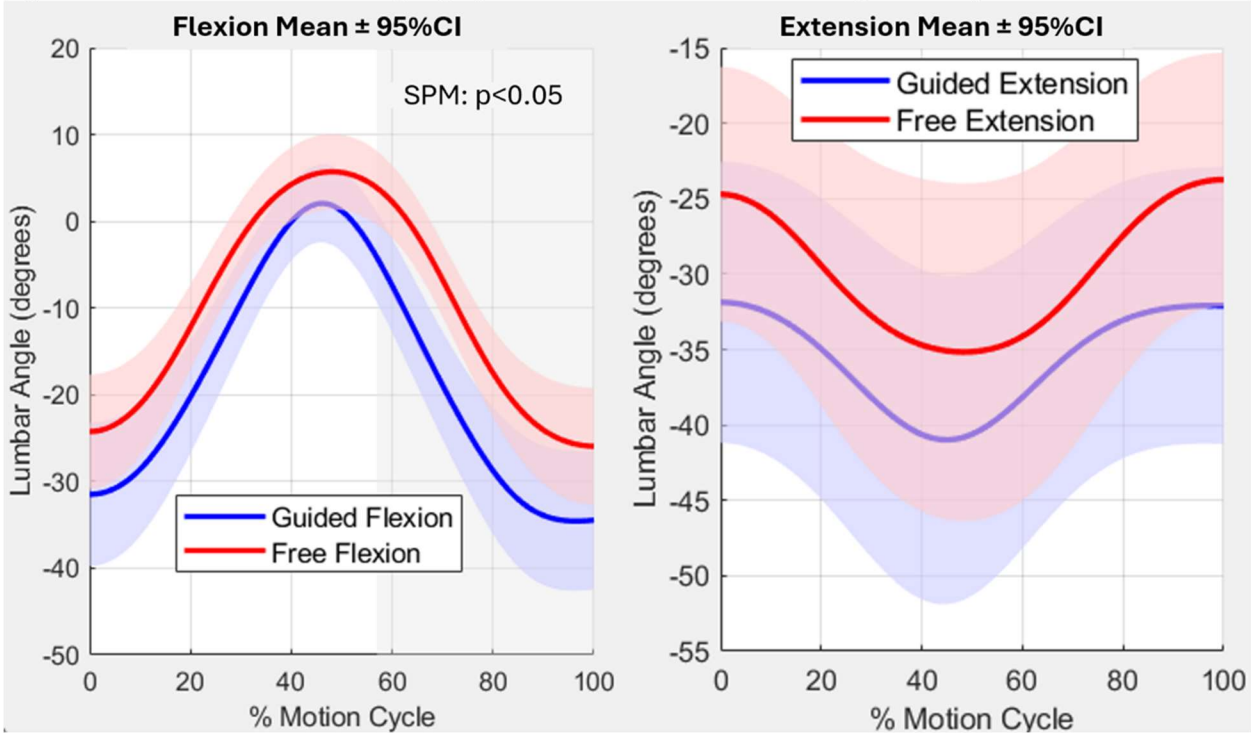
Introduction

Lumbopelvic kinematics are commonly assessed during spine flexion and extension tasks in people with low back pain [1]. However, the movements themselves often vary, reducing comparability. Some methods restrict pelvic movement to isolate lumbar kinematics or pace or guide participants through the movement to reduce variability, but it is unclear if these approaches affect lumbopelvic kinematics. **We compared lumbar and pelvic kinematics through dynamic spine flexion and extension between a free-standing (straight legs) and a guided condition.**

Methods

20 females completed a flexion and extension movement of each condition (free-standing vs guided). Guided motion involved a jig that secured participants' pelvises and used an arm rest to guide them through the motion [2]. Accelerometers (ADXL335, Analog Devices, Norwood, MA, USA) overlaid L2 and S1 spinous processes from which we calculated lumbar (L2-S1) and pelvic (S1) angles. Paired sample t-tests were used to compare lumbar and pelvic angles at standing and peak range of motion (RoM); and statistical parametric mapping (SPM) to compare angles throughout the dynamic movement.

Results



At upright standing, lumbar and pelvic angles were similar between guided (-26.49±24.36° & 17.28±9.11°) and free-standing (-21.05±19.84° & 22.30±15.96°) conditions (p=0.073; p=0.136). Similarly, lumbar and pelvic peak flexion RoM were similar between guided (3.52±9.88°; 29.63±8.23°) and free-standing (6.18±7.75° & 28.87±12.83°) conditions (p=0.807; 0.319). However, while pelvic peak extension RoM was similar between conditions (24.18±14.73° vs 17.64±7.88°; p=0.128), lumbar peak extension RoM was significantly greater in the guided condition (-35.23±27.96° vs -27.72±33.58°; p=0.028). SPM, mean and 95% confidence intervals (Figure 1) show significant differences in lumbar angle during the second half of flexion.

Discussion

Our findings suggest that our guided spine flexion task did not change peak RoM but changed lumbar kinematics during the dynamic range. Conversely, for extension, differences in peak lumbar RoM were observed. Pelvic angle was similar between conditions and its change from standing to full flexion/extension was small (<10°). When comparing studies, methodological differences should be considered as they may impact lumbopelvic kinematics.

Images (Optional)

Time-Dependent In Vivo Changes in Spinal Motion After Nucleotomy: Hypermobility or Hypomobility?

Mr. Marcel Simon Reich, Mr. Maxim Bashkuev, Ms. Nicole Bormann, Univ.- Prof. Dr. biol. hum. Hendrik Schmidt, Dr. med. vet. Sandra Reitmaier

Julius-Wolff-Institute, Berlin Institute of Health at Charité – Universitätsmedizin Berlin, Berlin, Berlin, Germany

Introduction

Nucleotomy is among the most common spinal surgeries. While in vitro studies consistently show segmental destabilization and increased range of motion after nucleotomy, in vivo animal studies have reported increased postoperative stiffness [1]. This study investigated the time-dependent in vivo kinematic response to nucleotomy in a controlled large-animal model over 10 weeks to help reconcile these conflicting findings.

Methods

Five female Merino-mix sheep underwent nucleotomy at L3–L4 with removal of approximately 0.2 g nucleus tissue. Flexion-extension kinematics were measured using two cutaneous sensor strips with integrated accelerometers and gyroscopes capturing segmental motion across the lumbar spine. Each animal was assessed twice preoperatively, on postoperative days 1 and 3, and weekly thereafter for 10 weeks. Analyses focused on (1) the index level (L3–L4), (2) the cranial and caudal adjacent segments, and (3) the overall lumbar spine. For all movement parameters, paired two-sided t-tests ($\alpha = 0.05$) were performed comparing preoperative values with week-10 measurements.

Results

At the index level, motion progressively shifted toward smaller excursion ranges over time (Fig. 1). The frequency of 2–4° movements increased above baseline by week 10 (+43.7% flexion, +51% extension), following an early postoperative peak and transient decline. In contrast, large-amplitude excursions (>8°) decreased sharply immediately after surgery and remained markedly reduced through week 10 (e.g., 10-12°: flexion –86.7%, 8-10°: extension –89.1%). Caudal adjacent segments showed a comparable reduction in large-scale motion (extension –59.8%, p=0.0067; flexion –76.7%, p=0.007).

Discussion

Although nucleotomy reduces intrinsic passive stability, the in vivo response was characterized by reduced large-amplitude motion and increased fine-scale adjustments.

This pattern is consistent with a neuromuscular compensation strategy involving increased co-contraction and elevated baseline segmental stiffness. The adaptations at both the index and adjacent segments suggest rapid re-establishment of functional stability rather than hypermobility. These findings help reconcile discrepancies between in vitro destabilization and in vivo reports of increased postoperative stiffness and provide new insight into active stabilization following disc interventions.

Images (Optional)

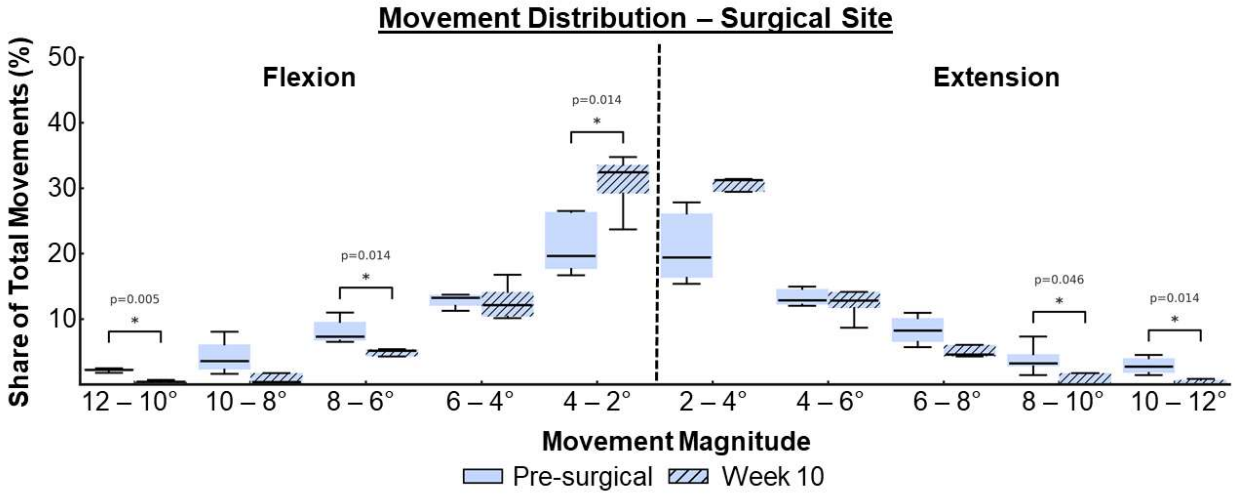

Fig. 1 Flexion and Extension movements prior to and after nucleotomy at the surgical site: After nucleotomy, movement distribution shifted from large-amplitude movements toward smaller movements: larger flexion (12-10° and 8-6°) and extension (8-10° and 10-12°) occurred less frequently, whereas smaller flexion (4-2°) increased significantly at Week 10. Pre-surgical boxes are solid; Week-10 boxes are black-hatched. The y-axis depicts movement distribution (percentage). The x-axis depicts sagittal movement sizes, with flexion to the left of the dotted line and extension to the right. Brackets with a star indicate significant differences (paired, two-sided t-test, $n = 5$, $p < 0.05$).

Finite Element Analysis of the Biomechanical Interaction Between the Thumb and Carpal Tunnel

Dr. David Jordan PhD, Dr. C. Kent Kwoh MD, Dr. Zong-Ming Li PhD

The University of Arizona, Tucson, Arizona, United States

Introduction

The transverse carpal ligament (TCL) and thumb share an anatomical connection through the thenar muscles which insert along the thumb and originate along the TCL. The biomechanics of these two structures has the potential to become disrupted in the presence of common musculoskeletal disorders, such as trapeziometacarpal (TMC) osteoarthritis. The purpose of this study was to simulate the biomechanical response of the TMC joint and TCL during pinching and the changes to the biomechanical response due to variation of TMC ligamentous stiffness.

Methods

A finite element model of the thumb and distal carpal tunnel was created (Figure 1) from the CT scan of a cadaveric hand. The model included the TCL, articular surface cartilage of the TMC joint, 4 TMC ligaments (dorsal radial ligament, dorsal central ligament, anterior oblique ligament and posterior oblique ligament), five extrinsic muscles represented as nodal forces and three intrinsic muscles represented as a collection of linear springs. A pinching simulation was performed driven by the five extrinsic muscles. First metacarpal rotation and translation, as well as TCL translation during pinching was simulated with percentage variation of TMC ligament stiffness from 100%, 75%, 50% and 25% of the maximum value.

Results

Variation of dorsal radial and anterior oblique ligament stiffness produced the greatest movement changes. A magnitude of 25% dorsal radial ligament stiffness increased metacarpal radial translation, metacarpal internal rotation, and TCL volar translation by 1.3%, 36.9% and 23.8%. A magnitude of 25% anterior oblique ligament stiffness increased metacarpal volar translation, metacarpal internal rotation, and TCL volar translation by 38.7%, 46.3% and 8.1%.

Discussion

TMC ligamentous laxity can alter the biomechanical response of the TCL during common hand activity. Motion changes were the largest for reductions in dorsal radial and anterior oblique ligament stiffness. This observation is supported by previous research which identifies the dorsal radial ligament as the primary ligamentous stabilizer of the TMC joint. Understanding how the biomechanical interaction of the thumb and TCL is altered due to the presence of TMC ligamentous laxity can aid in understanding the potential mechanisms which can alter the interaction and possible implications.

Personalized Shoulder Musculoskeletal Modeling: A Novel Workflow for Investigations of Glenohumeral Osteoarthritis and Post-Arthroplasty Joint Reaction Loads

Ir. Line Ven[1], Dr. Ir. Nazanin Daneshvarhashjin[1], Prof. Dr. Philippe Debeer[1,2], Prof. Dr. Filip Verhaegen[1,2], Prof. Dr. Ir. Lennart Scheys[1,2]

[1]Institute for Orthopaedic Research and Training, KU Leuven, Leuven, Flanders, Belgium. [2]Division of Orthopaedics, University Hospitals Leuven, Leuven, Flanders, Belgium

Introduction

Glenoid component loosening is a critical complication following anatomic shoulder arthroplasty (aTSA), with the rocking-horse effect considered as primary loosening mechanism. Although musculoskeletal modeling and simulation provide insight into joint loading, personalization of these models for glenohumeral osteoarthritis (OA) and post-aTSA patients remains poorly investigated. This study aimed to develop a workflow for generating personalized shoulder models by uniquely integrating patient-specific geometry and humeral head (HH) translations, as an initial step towards loosening investigations.

Methods

Four OA patients from our prospective clinical study with computed tomography scans and biplanar radiographs (EOS) in multiple flexion and abduction positions were selected for workflow creation. The generic thoracoscapular OpenSim model was enhanced with a detailed scapular mesh, enabling selection of closest nodes to muscle insertions and wrapping surface edges for later personalization. The scapula coordinate frame was updated to align with geometry-defined frames used during EOS-processing, whereafter glenohumeral translations were inserted as additional degrees-of-freedom (DOF).

The automated personalization workflow, built in Python, consisted of: (1) scaling the generic model towards patient-specific HH dimensions, (2) non-rigid morphing of the generic scapula to the segmented patient scapula using MeshMonk, (3) updating muscle insertions based on corresponding nodes on the morphed scapula, and (4) fitting personalized wrapping surfaces to corresponding nodes through Gauss–Newton optimization.

Following personalization, both generic and EOS-derived patient-specific 6DOF-positions were applied to the generic and personalized models, respectively. Muscle forces were

computed using static optimization, joint reaction loads were obtained with OpenSim's JointReactionTool.

Results

Personalized joint reaction forces followed the expected upward trend (Fig.1), but showed considerable variations compared to generic outcomes. Inter-patient HH translation variability seemed associated with differences in out-of-plane glenoid moments, while generic moments remained zero. Translations and moments showed directional shifts between 0-45° and 45-90° elevation.

Discussion

These preliminary findings demonstrate feasibility of the novel workflow for model personalization and joint reaction estimation. By uniquely incorporating HH translations, this workflow achieves more accurate and individualized loading predictions. While preoperative geometry variations appear to affect loading, post-aTSA models remain unexplored. Future work will include additional patients and post-aTSA configurations up to 120° elevation to assess whether loading shifts (rocking-horse effect) persist postoperatively.

Images (Optional)

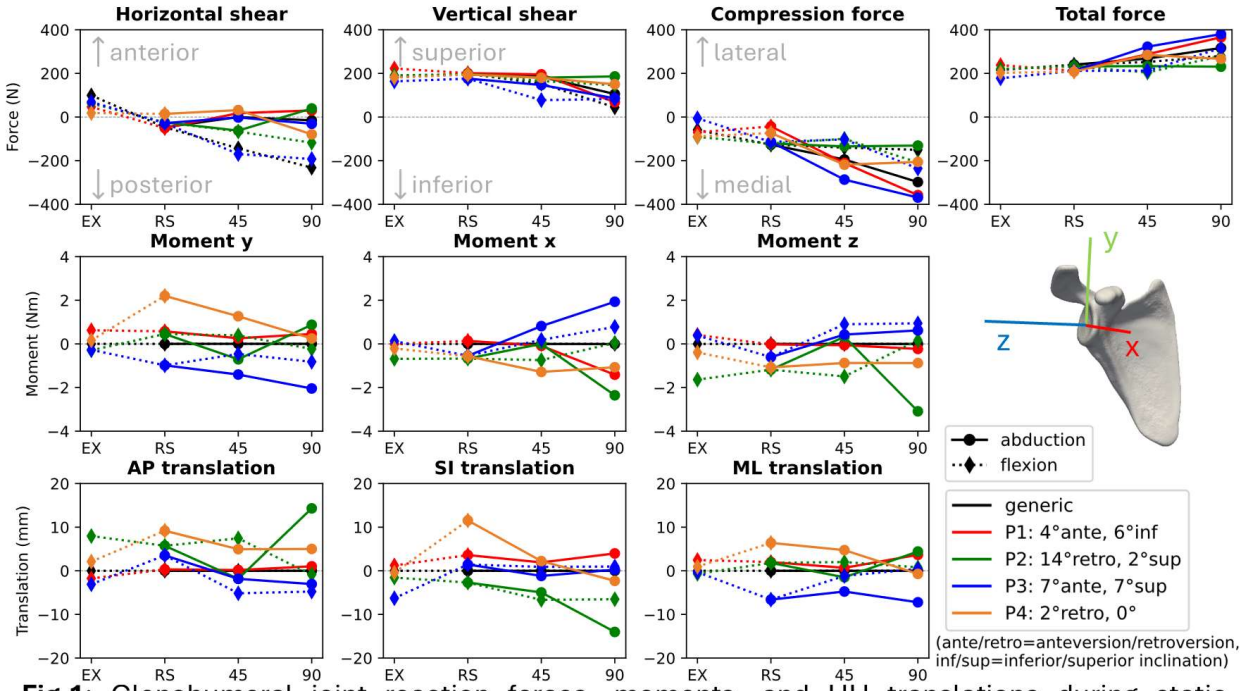

Fig.1: Glenohumeral joint reaction forces, moments, and HH translations during static extension (EX), relaxed standing (RS), 45° (45AB/F) and 90° abduction/flexion (90AB/F). Moments and translations were normalized by the ratio of the generic to the patient HH radius. PAT1+4 didn't perform flexion due to pain. For each scapula, X- and Y-axis were orthogonal to the scapular and transverse plane, respectively. Z-axis was mutually orthogonal.

Relationships between Pain and Glenohumeral Joint Motion and Loading Across Pediatric and Adult Manual Wheelchair Users

Dr. Alyssa Schnorenberg PhD[1], Dr. Amee Seitz PhD, PT[2], Dr. Shubhra Mukherjee MD[3], Dr. Karin Goodfriend MD[4], Dr. Brooke Slavens PhD[1]

[1]University of Wisconsin-Milwaukee, Milwaukee, WI, United States. [2]Northwestern University, Chicago, IL, United States. [3]Shriners Children's Chicago, Chicago, IL, United States. [4]Medical College of Wisconsin, Milwaukee, WI, United States

Introduction

Manual wheelchair propulsion is demanding on the upper extremities (UE), contributing to shoulder pain and pathology that reduce quality of life for individuals with spinal cord injury/dysfunction (SCI/D). Quantitative analyses linking propulsion biomechanics to shoulder pain may help identify injury risk factors and inform prevention strategies. This study examined associations between shoulder pain and glenohumeral (GH) joint dynamics during propulsion in wheelchair users across the lifespan.

Methods

Fifty-nine manual wheelchair users with SCI/D participated: pediatric (n=19, 13.1 ± 3.4 yr), adult pediatric-onset (n=21, 30.0 ± 11.6 yr), and adult adult-onset (n=19, 43.1 ± 13.2 yr). Participants completed the wheelchair users shoulder pain index (WUSPI) and PROMIS Pain Interference (PI) assessments, then propelled their wheelchair while a Vicon system captured their motion. A validated inverse dynamics model quantified GH flexion-extension ROM, peak superior force, and peak extension moment; each metric and its coefficient of variation (CV) were averaged across cycles.

Results

Pediatric users reported significantly less pain interference than adults with adult-onset SCI/D. Biomechanical–pain associations were group-specific. In the adult pediatric-onset group, higher GH extension moment was associated with more pain and pain interference, while children showed the opposite trend with pain interference, suggesting more efficient or protective loading patterns. Additionally, within the adult pediatric-onset group, higher GH superior force and lower superior force variability were associated with less pain interference, indicating possible adaptive propulsion strategies. Across participants, higher pain interference was associated with reduced GH flexion-extension ROM and greater ROM variability, though not significantly different across groups.

Discussion

Overall, disability onset influenced relationships between propulsion biomechanics and pain interference: pediatric users and lifelong adult users demonstrated opposite patterns, while adults with adult-onset SCI/D showed no consistent associations. These findings suggest that propulsion mechanics may have different functional consequences depending on developmental history and years of wheelchair use. Because it remains unclear whether certain loading patterns protect against pain or emerge as compensatory responses, longitudinal studies are needed to clarify their bidirectional links with shoulder pain. Such knowledge will support evidence-based propulsion training and early intervention strategies aimed at reducing overuse-related pain across the lifespan for individuals with SCI/D.

Bi-Fluoroscopy-Informed Machine Learning for Scapula Tracking in Reverse Shoulder Arthroplasty

Dr Maxence Lavaill PhD[1,2], Prof Peter Pivonka PhD[1], Dr Ehsan Sarshari PhD[2]

[1]Queensland University of Technoogy, Brisbane, QLD, Australia. [2]Stryker GmbH, Selzach, Solothurn, Switzerland

Introduction

Accurate assessment of scapular kinematics remains a major challenge in shoulder biomechanics due to substantial soft-tissue artefacts affecting skin-marker–based motion capture (Mocap). Our previous work [1] demonstrated that machine-learning (ML) models trained on concurrent Mocap and bi-fluoroscopy (BF) data from healthy adults can reduce scapular tracking errors by half. However, translating these advances to reverse shoulder arthroplasty (RSA) is essential, as RSA profoundly alters glenohumeral mechanics, increases scapulothoracic compensation, and introduces atypical movement patterns that amplify Mocap errors [2]. This study extends our scapula-tracking BF-informed ML framework to RSA, assessing whether a ML model previously trained on healthy BF and Mocap data [3] could also be applied to RSA patients.

Methods

Newly published concurrent Mocap and BF recordings from nineteen RSA patients performing standard clinical shoulder motions were leveraged [4]. Scapular (AC, AA, AI, TS), thorax and upper-limb Mocap markers served as inputs to the healthy-trained BF-informed ML model, using the same predictor structure and temporal window as originally developed [1]. The model was applied directly to RSA trajectories without retraining. RMS errors were computed against BF ground truth for both raw Mocap and ML-corrected scapular trajectories.

Results

Across all RSA patients and tasks, Mocap scapular landmark errors ranged from 10–30 mm (Figure 1), confirming substantial soft-tissue artefacts. Applying the healthy-trained ML model systematically increased these errors rather than reducing them. The most severe increase occurred for the AI landmark in the Y-direction, with ML-predicted errors reaching ~130 mm, far exceeding the corresponding Mocap error (20 mm). Similar error amplification was observed across all scapular landmarks.

Discussion

The healthy-trained BF-informed ML model did not generalise to RSA shoulders. Instead of correcting soft-tissue artefacts, it produced substantially larger errors and anatomically implausible scapular trajectories. These findings underscore the biomechanical differences between healthy and RSA shoulders, i.e., altered kinematics, compensation patterns and soft-tissue behaviour, and demonstrate that ML models trained solely on healthy data are unsuitable for arthroplasty populations. Future work will focus on developing BF-informed ML models trained on RSA datasets.

Event-Based Image Velocimetry as Alternative to Particle Image Velocimetry for the Experimental Fluid Dynamic Evaluation of Mitral Valve Prostheses

Dr. Elena Torta PhD[1], Mr. Manuel Zannone[1], Mr. Enrico Amico[1], Mr. Girolamo Mastronuzzi[1], Mrs. Emma Giaccone[1], Mr. Daniele Pecchio[2], Dr. Jacopo Serpieri PhD[1], Prof. Gioacchino Cafiero PhD[1], Prof. Diego Gallo PhD[1], Prof. Umberto Morbiducci PhD[1]

[1]Politecnico di Torino, Turin, Piedmont, Italy. [2]Affluent Medical, Colleretto Giacosa, Piedmont, Italy

Introduction

In vitro fluid-mechanics experiments are essential for understanding cardiovascular flows and for design, optimization and characterization of cardiovascular devices, particularly prosthetic heart valves[1,2]. Particle Image Velocimetry (PIV) remains the reference technique but is limited by frame-rate constraints, large data volumes, and complex and expensive setups. Event-Based Imaging Velocimetry[3] (EBIV), a neuromorphic, event-driven imaging technology, offers high temporal resolution and extended dynamic range at reduced costs. Nonetheless, EBIV has never been applied to cardiovascular flows. This study presents the first EBIV investigation of intraventricular dynamics in a left-ventricle (LV) phantom with a transcatheter mitral valve (MV), comparing EBIV to PIV measurements, considered as the reference technique.

Methods

Experiments were performed in a left-heart pulse duplicator (Vivitro System) with a simplified silicone LV phantom and a transcatheter MV prosthesis (Epygon, Affluent Medical), under two flow regimes (3.5 and 5 L/min, 35% systole, 70 BPM). A saline solution seeded with polyamide particles (100 μm diameter) served as working fluid. EBIV and PIV measurements were conducted on the aortomitral plane. The measurement plane was illuminated using a dual-cavity Nd:YAG laser (15 Hz, 200 mJ/pulse). Phase-locked image acquisition was performed simultaneously by two cameras: Prophesee EVK-4 event-based camera (Sony IMX636, 1280×720 pixels^2) and Andor Zyla 5.5 sCMOS camera (2560×2160 px^2). Proper Orthogonal Decomposition (POD) was applied to reduce noise.

Results

Results show that EBIV accurately reproduces PIV-measured valve-related hemodynamic features, including phase-averaged velocity fields (Figure 1), vortex structures (λ_2, Figure 1), circulation, Lagrangian trajectories, and pulsatile kinetic energy, while producing markedly compact datasets and benefiting from an extended dynamic range. A POD-based analysis

further confirms a strong agreement between EBIV and PIV measurements, revealing nearly identical dominant spatial modes.

Discussion

The event-based approach allowed investigating the topology and the temporal evolution of the LV fluid dynamics. These findings establish EBIV as a promising, data-efficient, and real-time capable alternative to PIV. This first biomedical application underscores EBIV's potential for device assessment, intraventricular flow analysis, and broader application in experimental cardiovascular research.

Images (Optional)

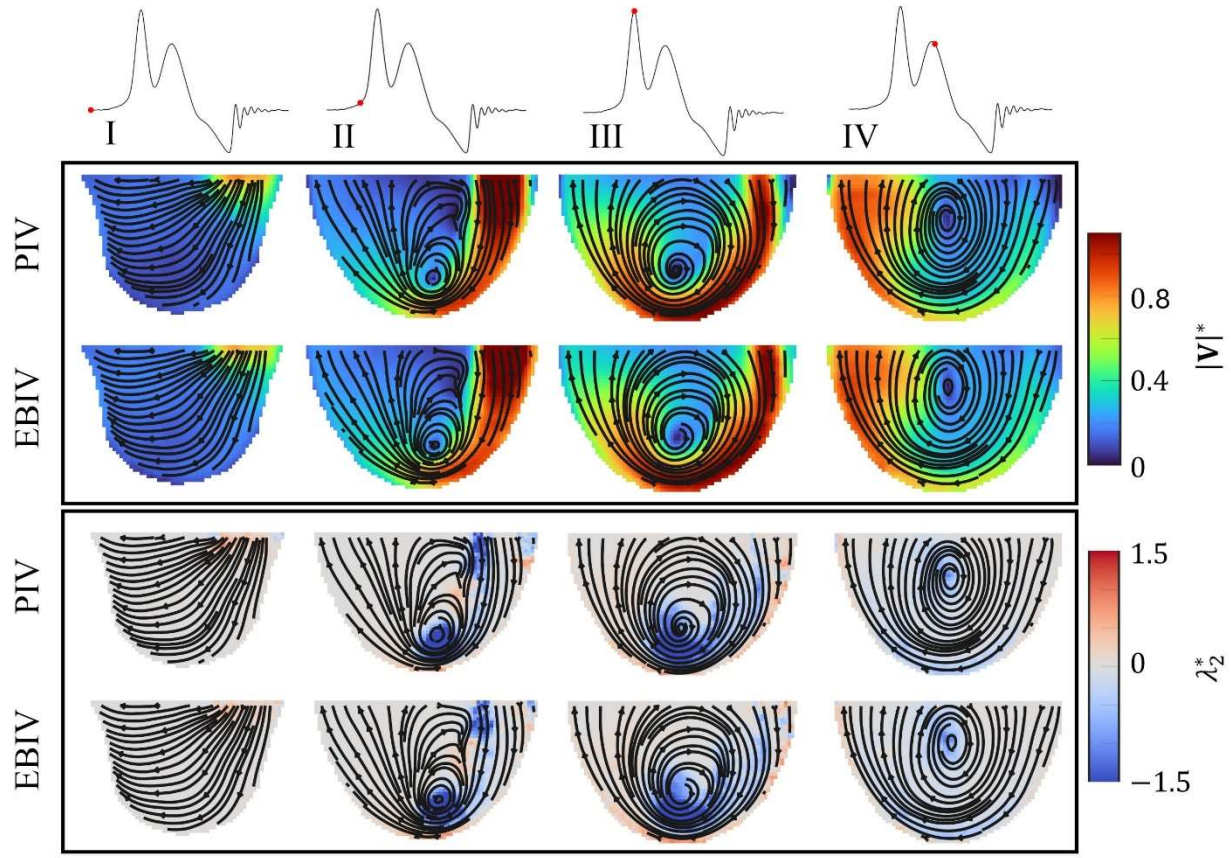

Figure 1: Normalized velocity magnitude $|\boldsymbol{V}|^*$ (top panel) and normalized λ_2^* (bottom panel) maps with streamlines resulting from PIV and EBIV for representative diastolic phases at CO= 5 L/min: early diastole (I), early acceleration (II), E-wave peak (III), A-wave peak (IV). For each phase (ϕ_{ref}), the normalized quantities are obtained by dividing the velocity magnitude and λ_2 fields by a reference quantity, obtained as the 95th percentile of the pooled distribution (respectively $|\boldsymbol{V}_{ref}| = Q_{95}(|\boldsymbol{V}|(\phi_{ref}))$ and $\lambda_{2,ref} = Q_{95}(\lambda_2(\phi_{ref}))$).

A Validated PIV–CFD Framework for Quantifying Hemodynamic Changes Induced by Left Atrial Appendage Occlusion

PhD Emanuele Gasparotti[1], Eng Ilaria Verdirame[1], PhD Emanuele Vignali[1], PhD Benigno Marco Fanni[1], PhD Francesca Berti[2], Prof Giancarlo Pennati[2], Prof Lorenza Petrini[3], Prof Simona Celi[1]

[1]BioCardioLab, Bioenegineering Unit, Fondazione Monasterio, Massa, Tuscany, Italy. [2]Department of Chemistry, Materials and Chemical Engineering, Politecnico di Milano, Milano, Lombardy, Italy. [3]Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Lombardy, Italy

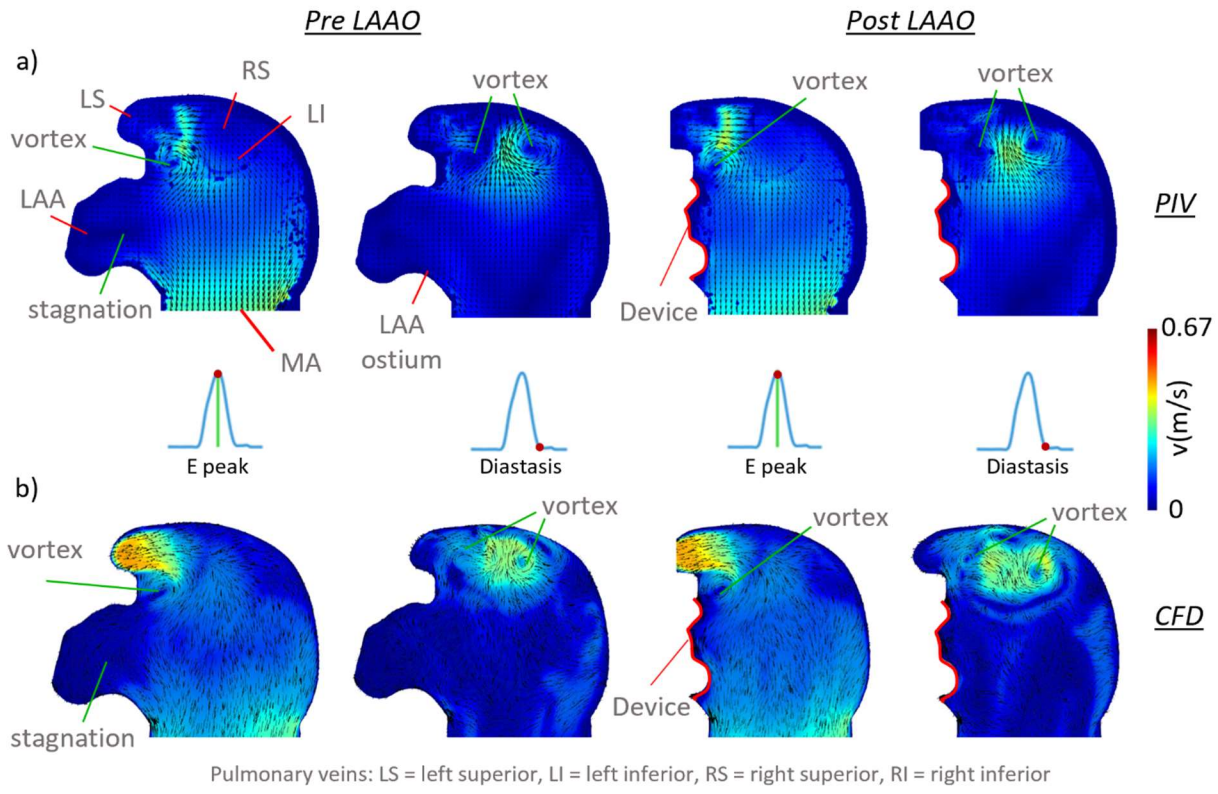
Introduction

Left atrial appendage occlusion (LAAO) is used to reduce thromboembolic risk in atrial fibrillation, yet its hemodynamic consequences remain insufficiently quantified and experimentally validated [1]. This study integrates high-resolution Particle Image Velocimetry (PIV) and Computational Fluid-Dynamics (CFD) to characterize pre- and post-LAAO Fluid-Dynamic and evaluate the consistency of numerical predictions against controlled in-vitro measurements.

Methods

Two patient-specific silicone phantoms representing pre- and post-LAAO anatomies were reconstructed from contrast-enhanced CT. The pre-LAAO model was fabricated in PDMS using a Brush–Spin-Coating technique, whereas the post-LAAO chamber incorporated a PDMS model of the device derived from finite-element simulation of LAAO procedure [2]. Phantoms were integrated into a hybrid mock circulatory loop [3] imposing patient-specific boundary conditions. Longitudinal and perpendicular planar velocity fields were acquired with a LED-based PIV system. In parallel, CFD simulations were setup with the same geometries and boundary conditions. PIV velocity fields were computed via double-frame cross-correlation and compared with corresponding CFD slices.

Results



PIV (Fig_a) revealed dominant recirculation within the LAA during peak mitral flow, with velocities decreasing below 0.1 m/s from ostium toward the distal region and coherent vortices forming near LA roof during diastasis. CFD (Fig_b) reproduced these macrostructures, matching vortex location, low-speed distribution, and velocity direction. After occlusion, both PIV and CFD showed a redirected, more coherent mitral jet and a 20% velocity increase in the region formerly occupied by the appendage, eliminating the

dominant intra-LAA recirculation. A confined near-wall recirculation emerged at the device head, consistently captured by both modalities.

Discussion

The combined experimental–numerical investigation demonstrated that LAAO reorganizes atrial hemodynamics, suppressing the large recirculation area in the appendage and reducing low-velocity zones associated with stasis in atrial fibrillation. CFD and PIV reliably reproduced key flow features, supporting its use for patient-specific evaluation of LAAO performance. High inter-cycle repeatability confirmed that observed differences stemmed from anatomical modification rather than measurement variability. The dataset offers robust benchmarks for validating computational LAAO models and strengthens the hemodynamic implications of LAAO.

Patient-Specific Pediatric Right Heart Simulator for Pulmonary Valve Assessment Using MRI

Dr. Lorenzo Ferrari, Dr. Yellappa Palagani, Ms. Elena S. Martinez, Dr. Alison L. Marsden, Dr. Michael R. Ma, Dr. Doff McElhinney, Dr. Daniel B. Ennis

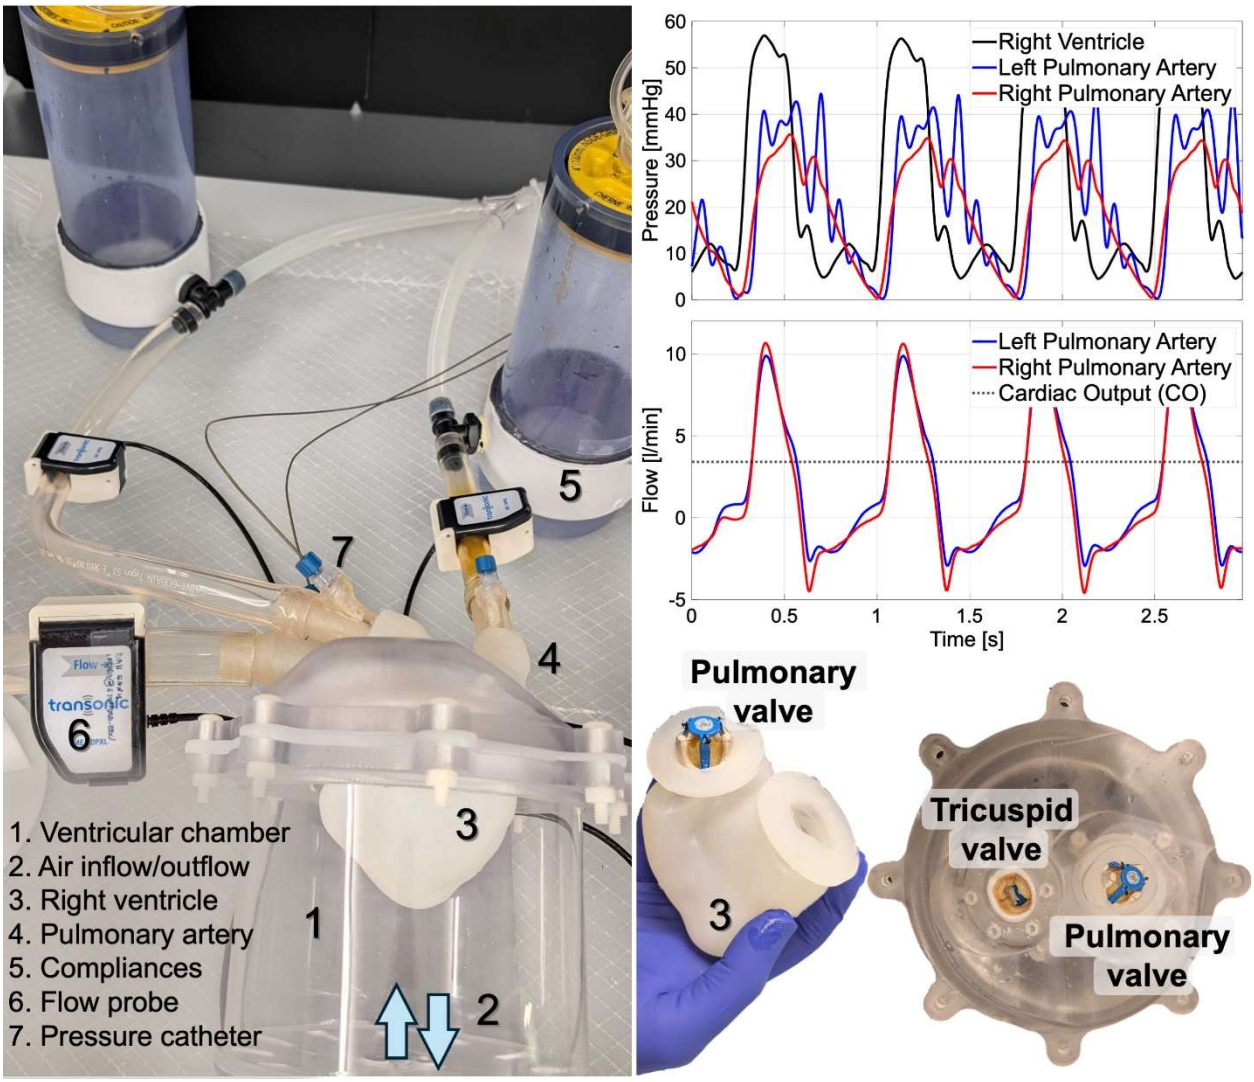
Stanford University, Stanford, California, United States

Introduction

Early deterioration of pulmonary valve replacements (PVRs) is a critical, yet poorly understood, complication in pediatric patients with repaired congenital heart disease. Existing bench-top flow-driving solutions are unable to replicate the broad range of pulsatile pressure and flow conditions typical of this heterogeneous group. It is also difficult to do so within the MRI environment, which limits the effectiveness of *in vitro* evaluations using this imaging technique. To overcome these challenges and to investigate the underlying valve failure mechanisms, we developed an *in vitro* platform designed to systematically reproduce patient-specific right heart geometries and hemodynamics derived from clinical examinations. Both clinical decision-making and future valve design will benefit from insights gained from our MRI-compatible simulator.

Methods

CT scans from a 10-year-old male subject with pulmonary atresia and an intact ventricular septum were used to create a silicone model of the right heart via 3D-printing and mold casting. Bioprosthetic valves were used in the tricuspid and pulmonary valve anatomical positions. Our computer-controlled pneumatic circuit modulated air inflow and outflow to externally compress and relax the flexible right ventricle, thereby inducing ventricular wall motion and cardiovascular-like flow. Flow sensors and pressure probes monitored the pediatric right heart conditions, which were tuned by adjusting the resistances and compliances downstream of the pulmonary artery. We used a 40% glycerol-based solution, mimicking blood rheological properties, which circulated to a reservoir-like right atrium before returning to the ventricle. The entire circuit is MRI-compatible and amenable to evaluation with advanced flow imaging methods.



Results

Our right heart simulator reproduced physiological flow and pressure values typically reported for the patient's age group. The computer-controlled pneumatic circuit can control heart rates, right ventricular ejection fraction, diastolic and systolic pressures, and flow profiles.

Discussion

Our *in vitro* setup is the first MRI-compatible right heart simulator for pediatric applications. It reproduces physiological pediatric hemodynamics in patient-specific geometries while incorporating ventricular contraction. Coupled with 4D-Flow MRI, our *in vitro* platform is a powerful and versatile tool for analyzing hemodynamics to assess mechanisms explaining early PVR failure and to identify strategies for enhancing valve durability in pediatric patients.

[8]ORSI Academy, Melle, Flanders, Belgium. [9]Department of Radiology and Nuclear Medicine, Ghent University Hospital, Ghent, Flanders, Belgium

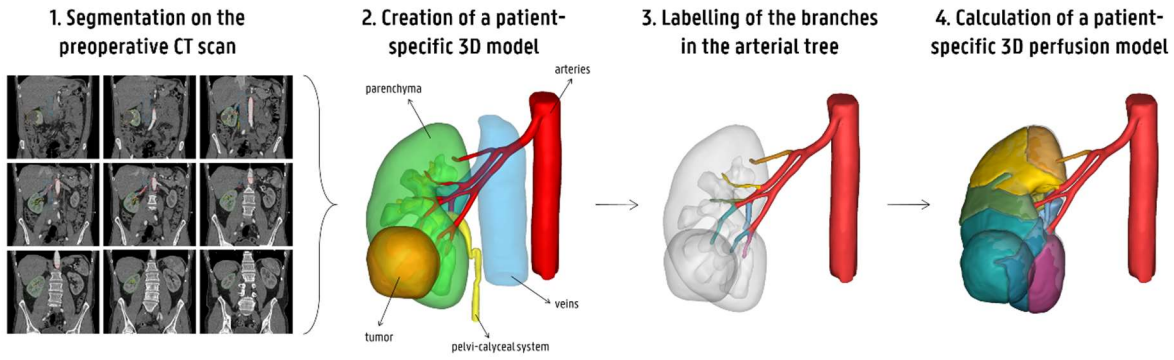
Introduction

Performing successful selective arterial clamping during partial nephrectomy for kidney tumor removal depends on the surgeon's understanding of the patient-specific vascular anatomy, which is often limited by the quality and interpretability of preoperative imaging. To overcome these limitations, we developed the DIPLANN tool [1], a Class IIa medical device that utilizes 3D modelling and in-house developed algorithms to provide the surgeon with a patient-specific perfusion model (Fig. 1). The device's safety, performance, and clinical efficacy is currently investigated through a randomized controlled trial (RCT): PODRACING [2].

Methods

This ongoing multi-centric, prospective, parallel-group RCT will enroll 235 adult patients with a cT1-2 kidney tumor. Participants are randomized 1:1 to receive either the standard of care (preoperative CT scan) or an additional perfusion model. The primary endpoint includes planned selective clamping success with secondary endpoints addressing clinical outcomes, usability and patients' insight. Data collection occurs at different stages during the one-year follow-up. The study was approved by the Belgian Federal Agency for

Medicines and Health Products and is supported by the Foundation against Cancer and FWO (Flemish Research Foundation) [3-4]. For the interim analysis, the primary endpoint was analyzed in a subgroup of patients where selective clamping was deemed feasible, using a Chi-Squared test.



Results

Recruitment and data collection are ongoing (129/235). For the interim analysis, 107 patients who underwent surgery between July 2024 and October 2025 were investigated. In 103 patients, selective clamping was deemed feasible, out of which 50 patients got a perfusion model. In 43 of these 50 patients (86%), selective clamping was performed successfully as preoperatively planned. In the 53 patients in the control group, only 22 patients (41.5%) got successful selective clamping ($p < 0.00001$).

Discussion

The interim analysis of our ongoing PODRACING trial shows that the use of perfusion models is strongly correlated with performing more accurate and more frequent SC during partial nephrectomy. More secondary and exploratory endpoints –including renal function, surgical time and quality of life– are currently being studied.

OA26-01

Nonlinear Phenomena in Bacterial Turbulence Under Imposed Background Flows

Assoc. Kenji Kikuchi Doctor of Engineering

Tohoku University, Sendai, Miyagi, Japan

Introduction

Dense suspensions of motile bacteria spontaneously generate chaotic mesoscale flows known as bacterial turbulence. While many studies have focused on unconfined or weakly confined systems, how such active turbulence interacts nonlinearly with externally imposed background flows remains poorly quantified. Here we investigate how steady and oscillatory background flows reorganise collective bacterial motion, effective transport and apparent rheology.

Methods

We combine microfluidic experiments in straight and corrugated channels containing concentrated suspensions of rod-shaped bacteria with numerical simulations of an active nematic / active Brownian particle model subjected to imposed Poiseuille and shear flows. Velocity fields are quantified using particle image velocimetry and decomposed into background and active components. By tuning pressure drop and driving frequency, we span regimes from steady weak shear to strong oscillatory forcing, and use cavity depths comparable to the intrinsic vortex size to probe wall trapping and de-trapping of bacteria.

Results

We identify three robust regimes: (i) vortex-dominated bacterial turbulence under weak background flow, (ii) shear-aligned streaming with suppressed vortices under strong background flow, and (iii) an intermediate symmetry-broken state with travelling vortex bands locked to the mean flow. In corrugated channels, bacteria accumulate in wall cavities, where trapped vortices create persistent high-density pockets. Tracer analyses show that axial dispersion and transverse mixing are strongly enhanced in the turbulent and banded states, but are markedly reduced in the shear-aligned regime. The occupancy of individual cavities exhibits intermittent switching between low- and high-density configurations, indicating stochastic transitions between trapped and flushed states driven by the competition of self-propulsion, collective vortices and imposed shear.

Discussion

Our results demonstrate that bacterial turbulence and background flows interact through strongly nonlinear mode competition, leading to bistability and history-dependent transport and mixing properties. These findings provide a physical basis for controlling dispersion in active fluids via externally imposed flows, and suggest design principles for microfluidic devices that harness bacterial turbulence and wall trapping rather than suppress them.

Measurement of bending stiffness of *Salmonella* flagella

Dr. Hossein Moghimifam[1], Dr. Jamel Ali[2], Mr. Haoxin Huang[1], Dr. Min Jun Kim[3], Dr. Henry Fu[1]

[1]University of Utah, Salt Lake City, UT, United States. [2]FAMU-FSU College of Engineering, Tallahassee, FL, United States. [3]Southern Methodist University, Dallas, TX, United States

Introduction

Bacteria swim by rotating helical flagella like propellers. These flagella are rigid enough to withstand viscous loads during much of swimming, but deform during reorientation events and certain swimming modes. Thus, flagellar stiffness has an important impact on bacterial motility. Earlier efforts to measure the bending stiffness have assumed constant stiffness along the length of the flagellum. We investigate flagella attached at one end to a slide and stretched by an imposed flow in a microfluidic channel, using 3D reconstruction of images and Kirchhoff rod models that enable enough precision to determine strain-dependent bending stiffnesses of flagella.

Methods

Fluorescently labeled flagella from Salmonella typhimurium were bound tightly by one end to a microchannel surface. Imposed flows through the channel were sufficient to deform the filaments, which were observed using fluorescence microscopy. Images of deformed flagella were analyzed by simulating expected images for varying flagellum geometries, using point spread functions that depend on the displacement of flagellum segments from the focal plane. In this way, we could determine the 3D geometry whose image most closely matches experimental observations. We used a numerical method which combines hydrodynamic forces determined using the method of regularized Stokeslets with Kirchhoff rod models of deformation to model the deformations of flagella in the microchannel flow. An input to these models is the bending stiffness of the flagellum. Comparing the results of models with varying bending stiffnesses to experimental observations enables determination of the bending stiffness.

Results

Bending stiffnesses that depend on the deformation or strain in the filament can be incorporated into the Kirchhoff rod model. Model results for bending stiffness that increase as strain increases tend to better reproduce experimental results, suggesting that that these bacterial flagella are strain-stiffening.

Discussion

Strain stiffening behavior of bacterial flagella may have important implications for bacterial swimming and microrobotic propulsion. Our results compare models with and without simple linear models of bending stiffness as a function of flagella deformation. Additional experiments may more precisely quantify the bending stiffness as a function of deformation.

Ciliary Pumping in the Choanocyte Chambers of Sponges

Dr Takumi Ogawa[1], Mr. Shuji Koyama[1], Prof. Toshihiro Omori[1], Prof. Kenji Kikuchi[1], Dr. Hélène de Maleprade[2], Prof. Raymond E. Goldstein[3], Prof. Takuji Ishikawa[1]

[1]Tohoku University, Sendai, 980-8579, Japan. [2]Sorbonne Université, Paris, F-75005, France. [3]University of Cambridge, Cambridge, CB3 0WA, United Kingdom

Introduction

Sponges, the basalmost members of the animal kingdom, exhibit a range of complex architectures in which microfluidic channels connect multitudes of spherical chambers lined with choanocytes, flagellated filter-feeding cells. Choanocyte chambers can possess scores or even hundreds of such cells, which drive complex flows entering through porous walls and exiting into the sponge channels. One of the mysteries of the choanocyte chamber is its spherical shape, as it seems inappropriate for inducing directional transport since many choanocyte flagella beat in opposition to such a flow.

Methods

We combine direct imaging of choanocyte chambers in living sponges with computational studies of many-flagella models to understand the connection between chamber architecture and directional flow.

Results

We find that those flagella that beat against the flow play a key role in raising the pressure inside the choanocyte chamber, with the result that the flow rate and mechanical pumping efficiency reach a maximum at a small outlet opening angle. Comparison between experimental observations and the results of numerical simulations reveal that the chamber diameter, flagellar wave number, and the outlet opening angle of the freshwater sponge Ephydatia muelleri, as well as several other species, are related in a manner that maximizes the mechanical pumping functions.

Discussion

The obtained results indicate the subtle balances at play during morphogenesis of choanocyte chambers, and give insights into the physiology and body design of sponges.

Introduction

Hearing loss (HL) is a major risk factor for dementia [1]. Impaired cerebrospinal fluid (CSF) clearance of metabolic waste has been associated with both HL and cognitive impairment. Although cochlear fluids communicate with CSF through narrow aqueducts in the temporal subarachnoid space (SAS), their fluid-dynamic properties and their role in solute exchange remain poorly characterized. To address this gap, the EAR2BRAIN project is developing patient-specific in silico and in vitro models of the inner-ear/brain fluidic interface. Here, we present a first multiparametric and multiphysics in silico analysis of the acustofluidics and molecular exchange across the cochlear (CA) and vestibular aqueducts (VA) (Figure 1) towards personalized fully biomimetic model of cochlear–brain communication relevant to HL and neurodegeneration.

Methods

Ranges of width, length and orifice aperture have been collected from human μ-CT scanning and MRI to build 3D geometries of CA and VA to be imported in ANSYS fluent. Physiological and pathological scala tympani pressure (STP) and intracranial pressure (ICP) conditions were imposed at aqueduct inlets and outlets for multiparametric CFD and mass-transport simulations.

Results

Input parameters collection led to an initial idealized CA geometry with a length of 12mm, narrowest diameter of 0.14 mm, and a 3mm opening into the SAS. Three human-observed luminal states will be modeled: patent, connective-tissue filled, and obliterated. STP inputs

from 0–100 dB reproduce acoustic stimuli from 20 Hz to 20 kHz, while ICP ranges from 7 mmHg at rest to 25 mmHg to model hypertension, with oscillatory components mimicking cardiac, respiratory, and sleep–wake contributions.

Discussion

To our knowledge, no biomimetic models comprehensively capture pressure and solute exchange across both aqueducts. This first idealized analysis will reveal how anatomical variability and pressure dynamics influence cochlear–CSF communication relevant for subjects with malformations, HL, or altered intracranial pressures. Ongoing work will extend these models to patient-specific geometries, enabling a broad multiparametric characterization of inner ear–brain fluid dynamics in health and disease.

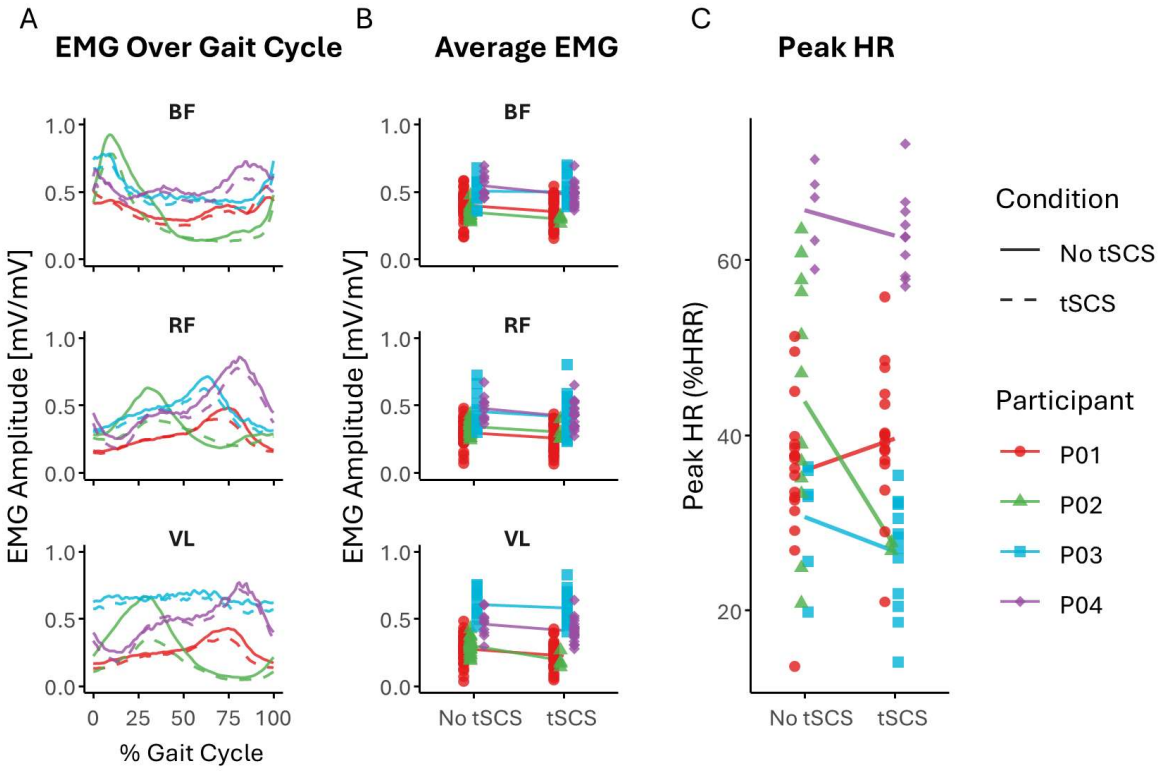
Introduction

Children with cerebral palsy (CP) often exhibit muscle weakness and impaired motor control, limiting mobility [1]. The Trexo is a robotic exoskeleton that provides hip and knee actuation to generate walking patterns, which may improve walking function and support rehabilitation [2]. Transcutaneous spinal cord stimulation (tSCS) may further enhance motor output during rehabilitation [3], though its impact during Trexo-assisted walking remains unknown. This case series examined muscle activity and cardiovascular responses during Trexo use with and without tSCS in children with CP.

Methods

Four children with non-ambulatory CP (1M/3F, 32 ± 8.0 months) completed Trexo-assisted walking trials with and without tSCS. Trial duration and device settings were individualized for comfort and engagement. Surface electromyography (EMG) data were recorded bilaterally from the biceps femoris (BF), vastus lateralis (VL), and rectus femoris (RF) and filtered, rectified, and normalized to the 95th percentile maximum of each visit. Heart rate (HR) was collected continuously with an optical HR sensor

Results



All participants displayed cyclic muscle activity during Trexo use, similar to gait. Heart rate increased with Trexo use by 36.3% (23.1 to 65.3%) compared to resting. Peak heart rate

decreased by 11.2% (-37.9 to +10.2%) for three participants during trials with tSCS. Muscle activity also slightly decreased by 10.1%, 12.1%, and 17.6% for the BF, RF, VL, respectively with tSCS.

Discussion

Muscles were active and heart rate was elevated during Trexo use in young, non-ambulatory children with CP. Adding tSCS may modulate muscle activity and cardiovascular response. Reductions in muscle activation and HR with tSCS may suggest decreased effort or altered control. Prior studies with tSCS and children with CP [3,4] demonstrated decreased co-contraction with tSCS, though we observed minimal changes in our cohort. The Trexo may have provided more constraints on limb movement that altered muscle response. Understanding these physiological responses can guide clinicians in optimizing treatment protocols for children with CP.

OA27-02

Comparing Split Belt Treadmill Adaptation Rates Between Children with Cerebral Palsy and Typically Developing Peers Using Bayesian Models

Ms. Mackenzie Pitts MS[1], Dr. Alyssa Spomer PhD[2], Dr. Andrew Ries PhD[2,3], Dr. Michael Schwartz PhD[2,3], Dr. Katherine Steele PhD[1]

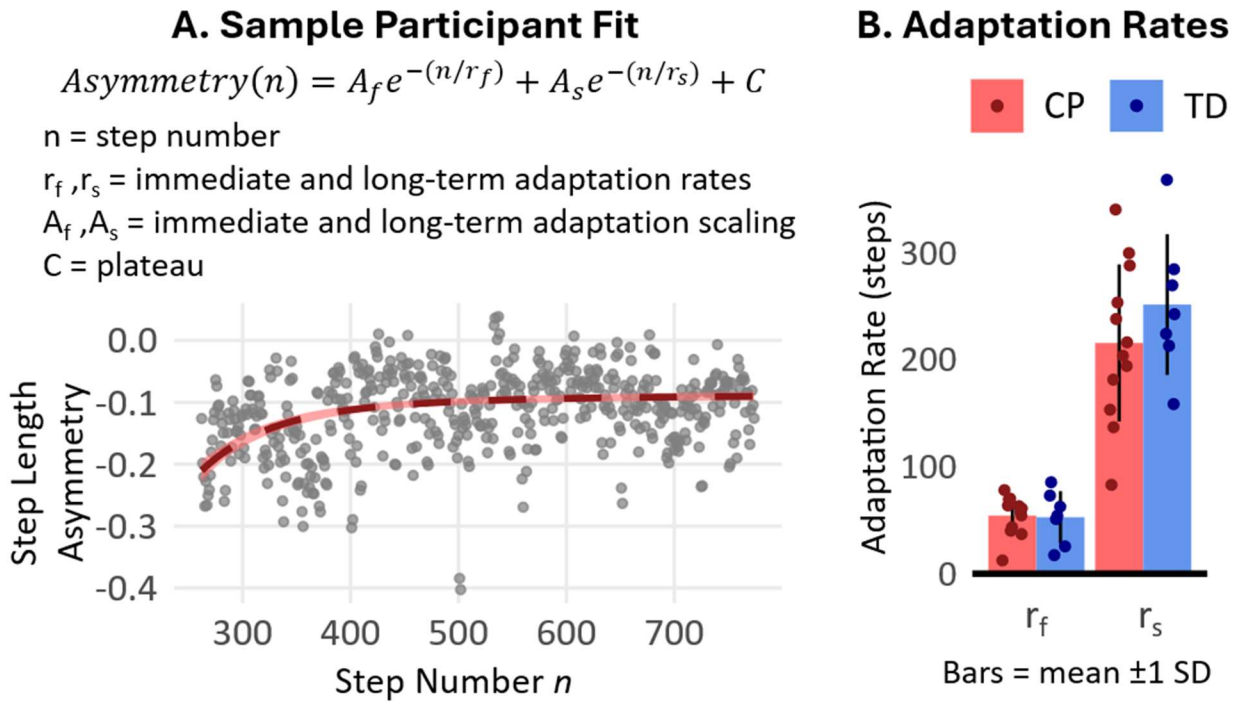
[1]University of Washington, Seattle, WA, United States. [2]Gillette Children's Hospital, St. Paul, MN, United States. [3]University of Minnesota, Minneapolis, MN, United States

Introduction

Split belt treadmill walking – a paradigm in which individuals adjust step length in response to belts moving at different speeds – has been used to understand coordination and adaptation of gait after stroke [1]. Children with cerebral palsy (CP) also have altered gait due to neurologic injury, and split belt walking may provide insight on adaptation capacity. Particularly, the rate of adaptation is significant as it could be used to identify patient-specific differences in adaptation capacity. The goal of this study was to compare split belt adaptation rates for children with CP and typically developing (TD) peers.

Methods

Twelve children with diplegic CP and seven TD children completed a six-minute split belt protocol following three minutes of treadmill acclimation. TD participants' nondominant limb and CP participants' more-affected limb were subjected to the fast belt, which operated at 1.65-1.8 times self-selected speed (slow belt). Step length asymmetry was computed as the difference between fast and slow limb step lengths divided by stride length. We evaluated step length asymmetry during the first and last 10 gait cycles. We used a Bayesian approach to fit a dual-exponential model to full trial asymmetry, capturing individualized rates for immediate (r_f) and long-term (r_s) responses to adaptation. Coefficient priors were informed by literature [2].



Results

Examining the first and last 10 steps, both cohorts exhibited asymmetry early (average: CP=-0.16; TD=-0.10) and adapted toward symmetry after six minutes (CP=-0.06; TD=-0.04). The immediate adaptation was similar between groups, with a rate of 54±18 (average±SD) steps for CP and 52±24 for TD. The long-term adaptation was smaller (faster) for children with CP at 216±73 steps compared to 252±66 steps for TD.

Discussion

Children with CP adapted similarly to TD peers, with slightly smaller long-term rates. Prior work postulated that having high energetic demands prompts a need to adapt quickly [3], which may explain the smaller rates observed for CP. The Bayesian approach provides a framework to model individualized responses that can inform personalized rehabilitation.

Examining the Effects of Selective Dorsal Rhizotomy on Kinematics and Synergistic Muscle Activity During Gait in Individuals with Cerebral Palsy

Ms. Amanda L. Vinson MS[1], Mrs. Jessica L. Stockhausen MS[2,1], Dr. James J. Carollo PhD, PE[1,2], Dr. Joyce Oleszek MD[1], Dr. Jason T. Rhodes MD[2,1], Dr. Sayan De MD[2,1], Dr. Kellen T. Krajewski PhD[2,1]

Introduction

Spastic cerebral palsy (CP) is characterized by muscle reflex hyperactivity and impaired gait. Selective dorsal rhizotomy (SDR) is a neurosurgical intervention to reduce spasticity that may indirectly improve gait. The purpose was to examine changes in kinematics and muscle activity in individuals with spastic cerebral palsy pre- and post-SDR during overground walking.

Methods

Eight patients with CP who underwent SDR (6M, 2F; 7.6±1.0y/o at SDR) completed overground walking at self-selected speeds. Kinematics (Fs=120Hz) and electromyography (Fs=2160Hz) were collected for six bilateral lower extremity muscles. Dynamic sagittal joint excursions and timing of peak muscle activity were extracted for stance and swing gait periods. Non-negative matrix factorization (NNMF) was used to assess muscle synergies, and total Variance Accounted For (VAF) for one synergy were calculated. Differences pre- and post-SDR were assessed using random effects linear mixed models ($\alpha \leq 0.05$).

Results

See **Figure 1** for kinematics with EMG and NNMF results. Peak hip extension decreased during stance post-SDR ($p=0.043$, 95% CI:-11.06º – -0.50º). Peak knee flexion increased during swing post-SDR ($p=0.002$, 95% CI:3.86 – 14.0). Peak ankle dorsiflexion increased post-SDR during stance ($p<0.001$, 95% CI:9.60º – 27.3º) and swing ($p<0.001$, 95% CI:10.2º – 23.72º). Peak ankle plantarflexion increased post-SDR during stance ($p<0.001$, 95% CI:11.7º – 30.1º) and swing ($p<0.001$, 95% CI:10.6º – 27.8º). Knee and hip excursion increased post-SDR during stance (Knee: $p=0.009$, 95% CI:1.06º – 6.65º; $p<0.001$, 95% CI:4.41º – 9.63º) and swing (Knee: $p<0.001$, 95% CI:7.03º – 13.7º; Hip: $p<0.001$, 95% CI:-3.15º – 7.97º). Peroneal longus and gastrocnemius peak timing during stance occurred

later post-SDR (Peroneal longus: p=0.029, 95% CI:1.52% – 17.4%; Gastrocnemius: p=0.008, 95% CI:2.37% – 12.0%). VAF increased post-SDR (p=0.014, 95% CI:0.007–0.050).

Discussion

Changes in kinematics post-SDR improved gait patterns as patients had larger knee and ankle excursions to better achieve critical events recognized in typically developed gait patterns, such as increased clearance for swing limb advancement. The small changes in muscle activity post-SDR indicate a slight reduction in neuromuscular control complexity potentially due to reduced somatosensory input from the procedure. While a more simplified neuromuscular control system continues to deviate from patterns identified in typically developed individuals, the reduction in muscle tone for this population improved ambulation.

Children with Unilateral Spastic Cerebral Palsy Have Smaller and Weaker Distal Tibias in the Spastic Limb Compared to the Non-Spastic Limb Independent of Physical Activity Habits

Dr Kellen Krajewski PhD[1,2], Mrs Jessica Stockhausen MS[1,2], Dr Julio Carballido-Gamio PhD[1], Dr Jason Rhodes MD[2,1], Dr David Howell PhD[1,2], Dr Sayan De MD[2,1], Dr Patrick Carry PhD[1,2], Dr Christine Swanson MD, MCR[1,3]

Introduction

Cerebral palsy (CP) is a neurological condition associated with increased fracture risk even in ambulatory individuals with mild CP (gross motor function classification system (GMFCS) levels I-II). Bone microarchitecture, referred to as bone quality, is believed to reflect mechanical loading history and deficient microarchitecture has been implicated in fracture risk. It is unknown if microarchitecture differs in the area affected by spasticity and whether microarchitecture is associated with physical activity habits in the CP population. The purpose was to examine the difference in tibial microarchitecture between the spastic and non-spastic limbs in children with CP and to examine the association between physical activity habits with spastic limb tibial microarchitecture.

Methods

Ambulatory children with unilateral spastic CP (GMFCS I-II) affecting muscles crossing the ankle completed bilateral high-resolution peripheral quantitative computed tomography (HR-pQCT) scans of the distal tibia metaphysis (4% site) to assess microarchitecture metrics. Metrics were then used to conduct a finite element analysis, modeling a uniaxial compression stress test yielding stiffness and failure load estimates. To assess physical activity habits, participants completed the bone specific physical activity questionnaire (BPAQ) which estimates osteogenic potential based on cumulative mechanical loading exposure. Paired t-test were used to assess tibial microarchitecture metrics between limbs. Linear regressions were conducted to assess the association between BPAQ and tibial microarchitecture. Alpha set $p \leq 0.05$.

Results

18 participants (6 males, 12 females; 7.6±1.5years; 124.8±14.2cm; 26.7±7.7kg) had usable scans for both limbs and were included. See **Table 1** for tibial microarchitecture metrics

stratified by limb and results of between-limb comparisons. Total area, trabecular area, cortical area, cortical perimeter, cortical thickness, stiffness, and failure load were less in the spastic limb than the non-spastic limb. There were no significant associations between BPAQ scores and tibial microarchitecture.

Discussion

The distal tibia metaphysis of the spastic limb had similar bone density but was smaller and weaker compared to the non-spastic limb. Differences in bone quality likely accounted for between-limb differences in estimated bone strength. Altered mechanical loading patterns specific to the spastic limb may explain lack of association between microarchitecture and BPAQ, but prospective research is needed to confirm this mechanism.

Mediolateral Forces and Walking Stability in Children with Cerebral Palsy

Ms. Allyson Clarke[1], Dr. Andrew Ries[2], Dr. Michael Schwartz[2], Dr. Katherine Steele[1]

[1]University of Washington, Seattle, WA, United States. [2]Gillette Children's, St. Paul, MN, United States

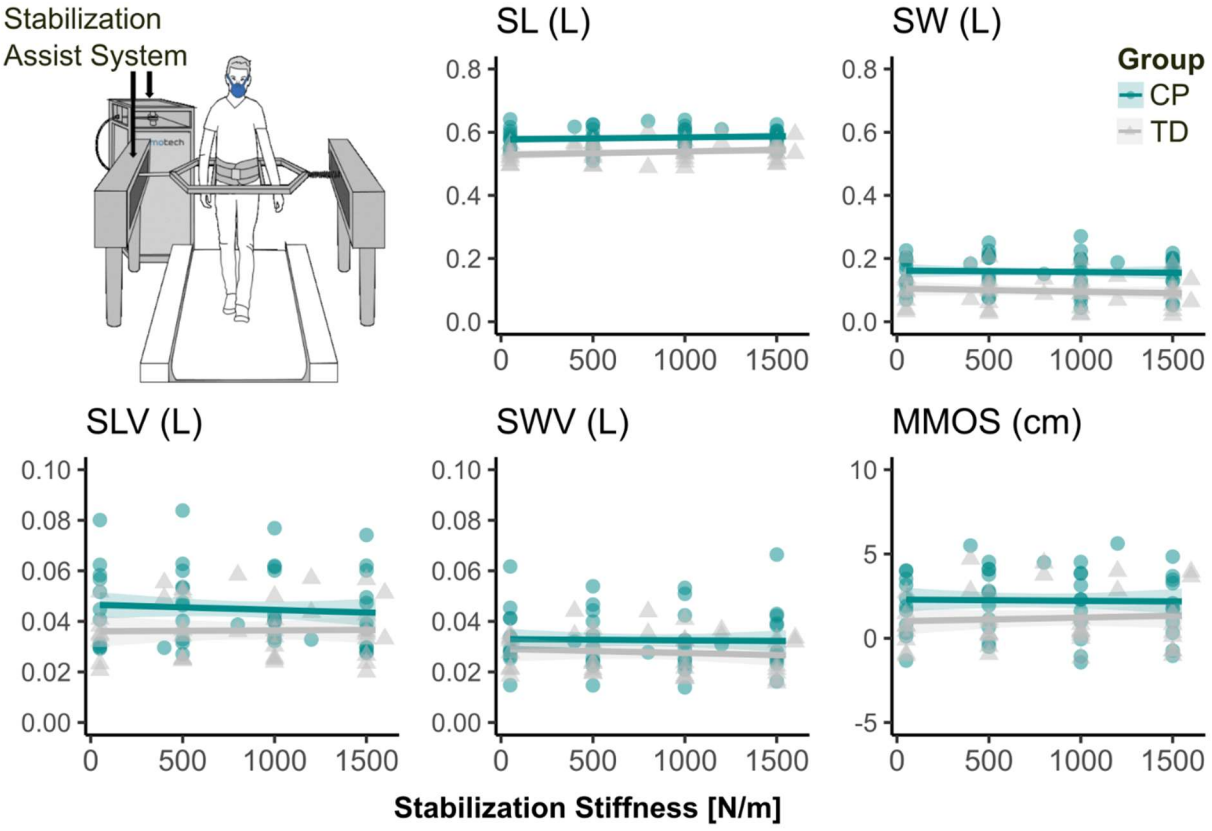
Introduction

Children with cerebral palsy (CP) experience greater gait instability compared to typically developing (TD) peers when walking, increasing energetic costs and fall risk [1]. Children with CP often walk with increased step width (SW), minimum margin of stability (MMOS), and gait variability- indicating challenges with stability [2]. Applying mediolateral forces can improve gait stability for aging and poststroke individuals, and may promote stability for children with CP [3, 4]. The aim of this study was to evaluate how gait stability changes with mediolateral forces for children with CP and TD peers.

Methods

Twelve individuals with CP and 10 age-matched TD peers were recruited. Participants walked on a treadmill with mediolateral forces applied by a mechatronic system (Humotech) to mimic a hysteretic spring. Four spring stiffnesses between 50-1500 N/m were evaluated during 5-minute trials in randomized order. SW, MMOS, step length (SL), step width variability (SWV), and step length variability (SLV) were computed from motion capture, normalized to leg length (L), and assessed with Bayesian multilevel linear models.

Results



Across all conditions, the CP group had higher SW (average = 0.16L) and MMOS (average= 2.2cm) compared to TD peers (SW= 0.10L, MMOS= 1.0 cm). However, there were negligible changes in SW, SWV, SL, SLV, or MMOS with increasing stabilization stiffness for either group.

Discussion

Mediolateral forces mimicking a hysteretic spring applied via a mechatronic system did not impact biomechanical measures of stability for either group. These findings contrast prior literature, where SW, SWV, and MMOS decrease with mediolateral forces for nondisabled adults, aging adults, and individuals after stroke. Prior work has used linear springs in experimental design, but our use of a hysteretic spring may have affected responses. As we did not observe changes for the TD group, children may also be less responsive to mediolateral forces. Our use of Bayesian statistical methods, rather than typical

frequentist methods, allows for robust analysis of small datasets and a framework for analyses of null results.

Active and Passive Force Variability Between Gracilis and Adductor Longus Muscle Fibres From Children With Cerebral Palsy

Mr. Faizan Syed[1], Mr. Latif Omerkhil[1], Ms. Sunnie Vuong[1], Ms. Ruth-Anne Seerattan[1], Dr. Jason Howard[2], Dr. Tim Leonard[1], Dr. Venus Joumaa[1], Dr. Walter Herzog[1]

[1]University of Calgary, Calgary, AB, Canada. [2]IWK Health Centre, Halifax, NS, Canada

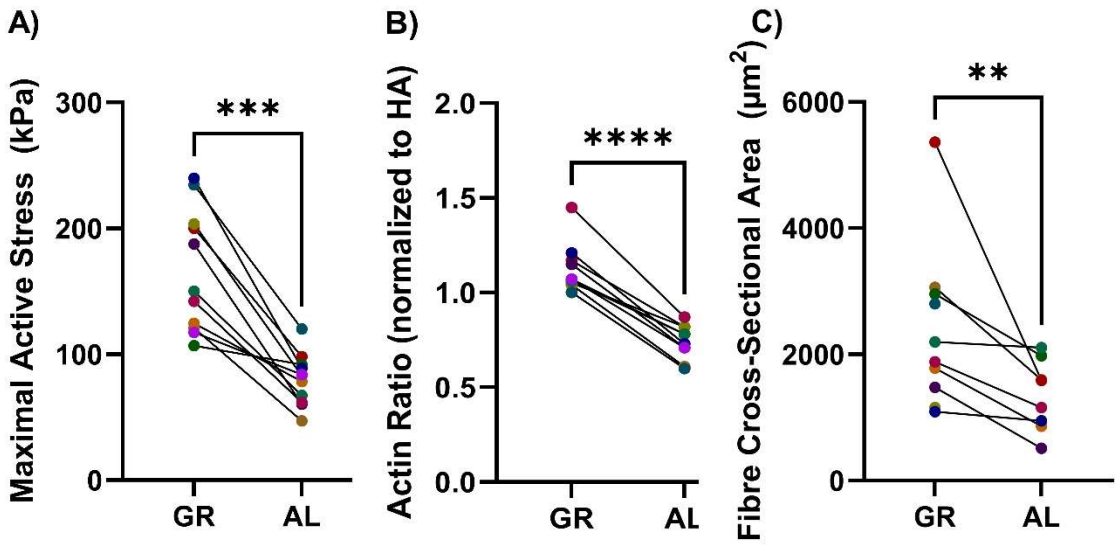
Introduction

Cerebral palsy (CP) is associated with impaired muscle growth, contractures, and spasticity. Whole muscle and single fibre studies have shown variable passive stiffness, altered sarcomere lengths, fat infiltration and fibrosis in spastic muscles, but these investigations typically examined a single muscle. However, it remains unknown whether different spastic muscles within the same child demonstrate similar fibre mechanical properties or exhibit heterogeneous adaptations.

Methods

Biopsies of the GR and AL were obtained from 11 children with CP (Gross Motor Function Classification System levels IV–V). Skinned fibres (3–5 per biopsy) were mounted between a length controller and force transducer. Maximal active stress and instantaneous stiffness (rapid, short stretch) were measured at an average sarcomere length (SL) of 2.4μm, and passive steady-state stress was measured during stepwise stretches from SL 2.6–3.4μm.

Actin, myosin, titin, and nebulin content were quantified using SDS-PAGE. Collagen, fat, and fibre size were quantified using Picrosirius Red, Oil-Red-O, laminin staining, respectively.



Results

Compared to GR, AL fibres produced significantly less maximal active stress (80 ± 20 vs. 166 ± 49 kPa, p=0.001), had lower instantaneous stiffness (5.5 ± 1.8 vs. 9.9 ± 3.0 MPa, p=0.003) and smaller fibres (1344 ± 564 vs. 2477 ± 1349 μm^2, p=0.008). Passive stress was significantly lower in AL at SLs of 3.0–3.4μm (p<0.05). Actin and nebulin content were approximately 35% (p<0.001) and 47% (p<0.01) lower, respectively, in AL than in GR. Myosin, titin, collagen, and fat content did not differ between muscles.

Discussion

Our results demonstrate muscle-specific heterogeneity in fibre properties in children with CP. Compared with GR, AL fibres are significantly smaller and weaker, possibly due to reduced actin content. Future work should explore the molecular mechanisms underlying these deficits and determine whether similar patterns occur in other spastic muscles of children with CP, so that particularly vulnerable muscles can be identified and considered when planning surgical and rehabilitative interventions.

Introduction

Musculoskeletal injuries account for over two million medical visits annually among military personnel, with Achilles tendinopathies representing a leading cause.[1] The physical demands of military service, including marching, running, and load carriage, contribute substantially to these injuries.[2] Previous studies have examined load carriage effects on Achilles tendon loading during walking.[3,4] This study investigated load carriage during running and assessed sex-based adaptations.

Methods

Physically active adults completed treadmill trials under four conditions: walking (1.34 m/s) and running (3.13 m/s) with and without an additional 30 percent body-weight load. Achilles tendon loading was measured using a shear-wave tensiometer.[5] Tendon wave speed measurements captured with tensiometry were used to derive force via a previously established calibration technique.[5] Data were processed in MATLAB to time normalize each gait cycle and extract peak tendon force and impulse normalized to participant body weight. Differences in loading variables were analyzed with repeated measures linear mixed effects models ($p<0.05$); locomotion condition and sex were included as fixed effects.

Results

Fourteen adults participated in this study (7/7 males/females, age: 23.5±1.3 years, height: 1.78±0.09 m, mass: 74.0±11.8 kg). Peak force increased from walking without load carriage to walking with load carriage, as expected, but not between running without and with load carriage (Fig. 1A-B). However, impulse increased when load carriage was added within both walking and running (Fig 1A,C). Significant interactions ($p<0.001$) between sex and condition were observed across both variables, indicating that the response to load carriage and speed differed between sexes (Fig. 1B-C). This sex-based

difference was observed in tendon force during running without and with load carriage, and in impulse across all conditions (Fig. 1B-C).

Discussion

These findings suggest females employ different ankle strategies than men when running with and without load carriage, as indicated by reduced force. Differences in force and impulse will be compared with kinematics to better understand these adaptations. This insight may help guide training programs that reduce injury risk in military populations.

Images (Optional)

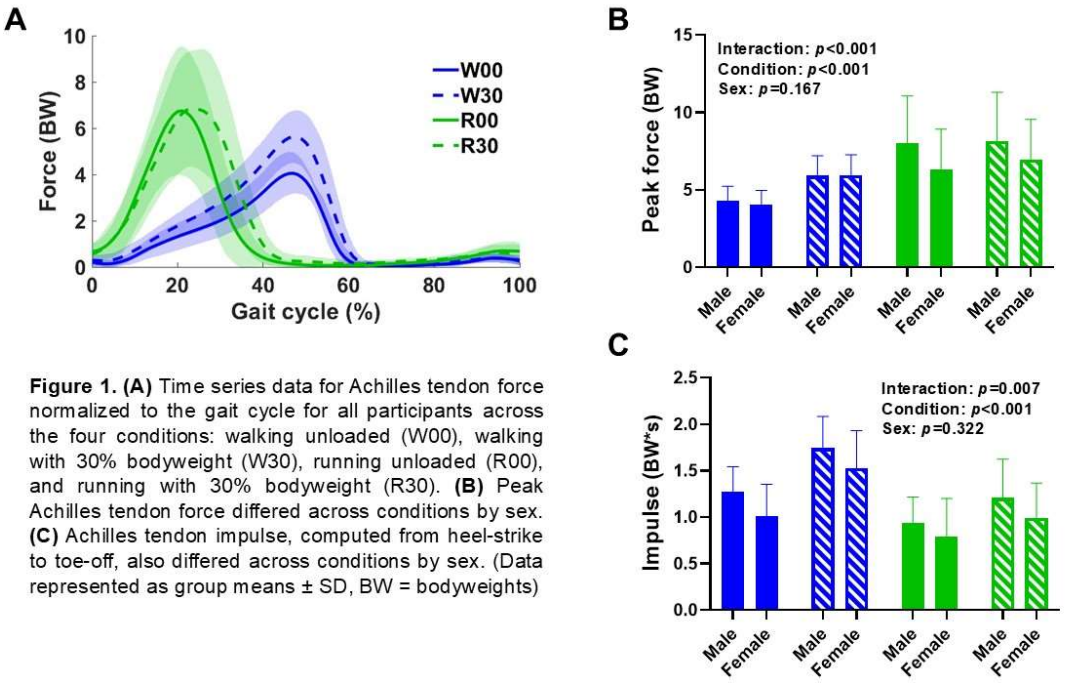

Figure 1. (A) Time series data for Achilles tendon force normalized to the gait cycle for all participants across the four conditions: walking unloaded (W00), walking with 30% bodyweight (W30), running unloaded (R00), and running with 30% bodyweight (R30). **(B)** Peak Achilles tendon force differed across conditions by sex. **(C)** Achilles tendon impulse, computed from heel-strike to toe-off, also differed across conditions by sex. (Data represented as group means ± SD, BW = bodyweights)

Effect of an Ankle Assistive Device With Printed Textile-Based Motion Sensing Suit on Muscle Activation During Walking: A Pilot Study

Ms. Minyoung D. Cho, Dr. Pankwon Kim, Mr. Yundong Kim, Mr. Hyun Seong Shin, Mr. Eun Seong Jeon, Mr. Min Soo Park, Prof. Namkeun Kim, Prof. Sang Yup Kim, Prof. Seokhwan Jeong, Prof. Choongsoo S. Shin

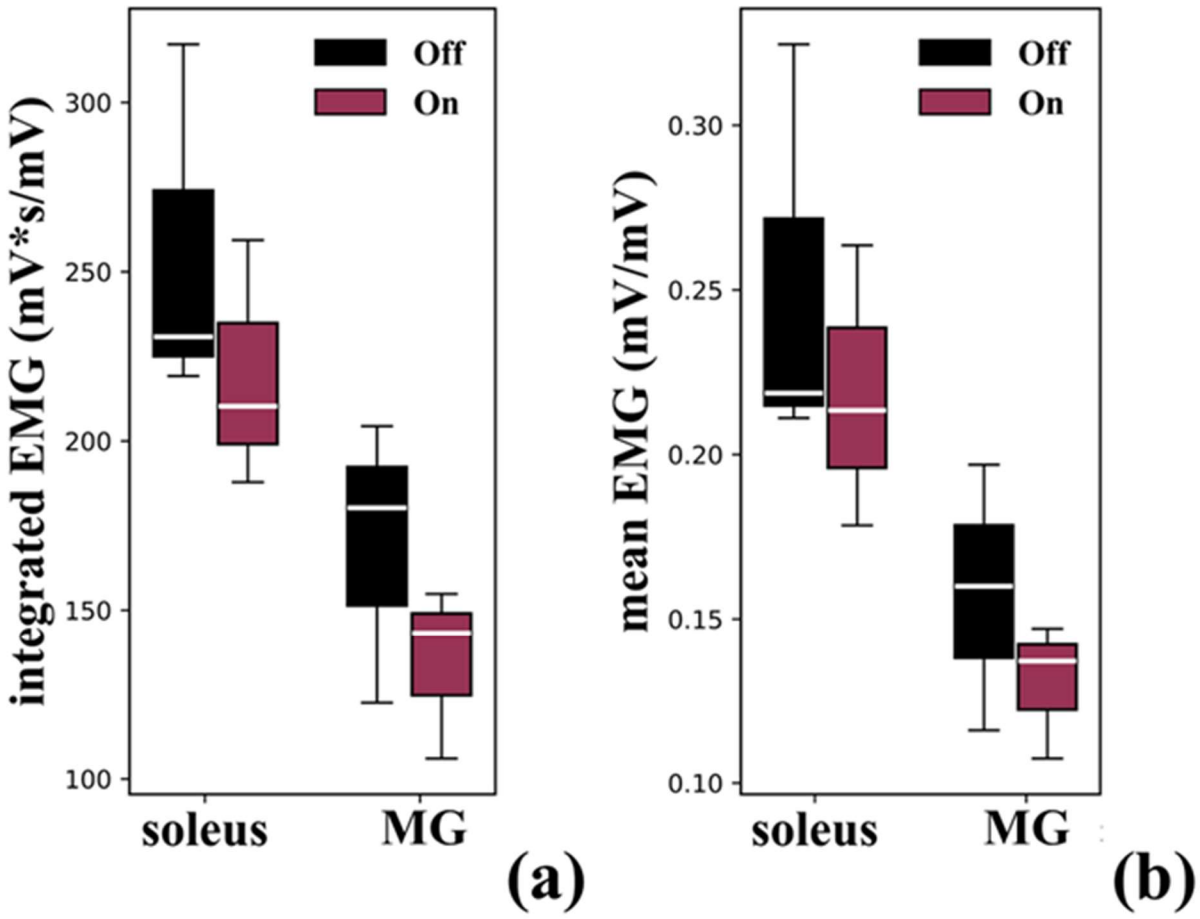
Department of Mechanical Engineering, Sogang University, Seoul, Mapo-gu, Korea, Republic of

Introduction

Active ankle assistive devices can improve human walking performance with supporting plantarflexion[1]. The gastrocnemius and soleus play important roles as ankle plantarflexors[2], which generate propulsive power during late stance of walking[3]. Many conventional ankle assistive devices have relied on inertial measurement units or pressure type sensors[4] for gait event detection. However, kinematics can be inferred by strain of skin[5]. We developed an ankle assistive device with strain sensors printed directly onto the suit to control the device, eliminating the need for extra sensors. The purpose of this pilot study was to evaluate the effects of the developed ankle assistive device on selected muscle activation during walking.

Methods

Strain sensors were printed on the following locations: the middle of the anterior thigh, the medial side of the ankle, the Achilles tendon, and the patella. To control the device, a learning-based control algorithm was developed using synchronized sensor signals, joint kinematics of lower extremity, and ankle moment obtained from experimental trials. To assess the effect of the developed device, the electromyography (EMG) data of soleus and medial gastrocnemius (MG) were obtained from three healthy male participants during walked on treadmill at a speed of 3.5 km/h. The participants completed the tasks wearing the device under power-on and power-off conditions. The integrated EMG (iEMG) and the mean EMG during stance phase were compared between two conditions.



Results

During the stance phase, both mean EMG and iEMG of soleus and MG showed reduction under the power-on condition compared to power-off condition (mean EMG: soleus -13%, MG -18%; iEMG: soleus -14%, MG -20%).

Discussion

The observed reductions in ankle plantarflexor EMG activation suggest that the assistive torque generated by the ankle assistive device successfully supported the biological torque of ankle. In conclusion, our new developed ankle assistive device effectively reduced the muscular demand required for ankle plantarflexion during walking while maintaining the walking speed.

Determinants of Enhanced Propulsive Capacity When Walking With Powered Ankle Exoskeleton Assistance

Mr. Ethan Simaitis[1,2], Mr. Oluranti Olatosi[1,2], Dr. Michael Lewek PT, PhD[1,2], Dr. Jason Franz PhD[1,2]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States. [2]North Carolina State University, Raleigh, NC, United States

Introduction

Human plantarflexor muscles are vulnerable to age- and disease-related decline, and conventional interventions fail to restore sufficient ankle push-off power in walking. Adaptive torque assistance via ankle exoskeletons (EXOs) offers a promising strategy to replace, or even supplement plantarflexor function during habitual walking to enhance *propulsive capacity* and community accessibility. Despite previously confirming this premise [1], the mechanistic determinants of EXO-enhanced propulsive capacity remain unclear. We hypothesized EXO assistance would increase propulsive capacity proportional to: (i) trailing limb angle (TLA) and (ii) total (Biological + EXO) ankle moment (AMOM) – mirroring known determinants of walking propulsion [2]. We also used invariant soleus excitation to confirm that participants maximized plantarflexor engagement, independent of EXO assistance.

Methods

Fifteen younger adults (age: 22.4 ± 3.0 yrs) walked at preferred speed on a treadmill wearing a powered ankle EXO (Biomotum) under four randomized assistance levels (0, 5, 15, 25% body weight [BW], peaks scaled to biological AMOM). At each assistance level, participants performed a 'biomechanical stress test' where an impeding force at the waist increased linearly at +1 %BW/s. The test terminated following an inexorable 0.5-m posterior displacement of the sacrum. We analyzed the stride immediately preceding termination.

Results

12 of 15 participants increased propulsive capacity (i.e., test duration and propulsive impulse, $p \leq 0.013$) without changes in soleus excitation when walking with assistance. Among those 12, the top-performing EXO condition had no effect on peak anterior ground reaction force (AGRF), peak TLA (**Fig 1A**), or peak AMOM (**Fig 1B**). Performance improvements correlated with changes in AGRF ($r^2=0.50$, $p=0.010$) but not in TLA nor AMOM. However, between-condition differences in AGRF correlated significantly with AMOM and TLA (multivariate $r^2=0.78$, $p<0.001$).

Discussion

EXO assistance preserved soleus muscle excitation while enhancing propulsive capacity during walking, but without concomitant changes in peak ankle joint moment or trailing limb posture. Significant between-condition correlations between propulsive capacity and biomechanical determinants suggest a common but unaccounted factor. The next step is to extend this approach to individuals with insufficient push-off (i.e., older adults).

Images (Optional)

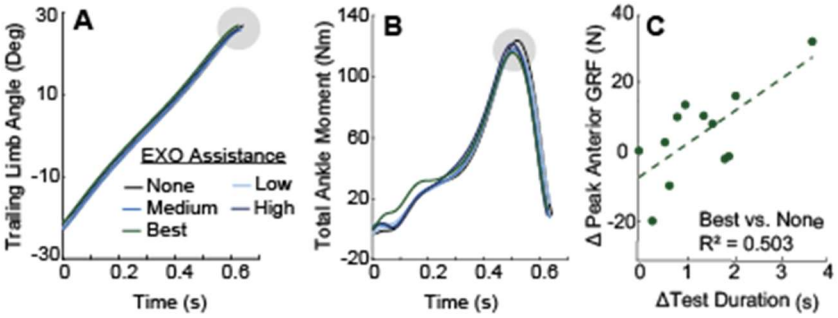

Figure 1. Determinants of walking propulsion - (A) trailing limb angle and (B) total peak ankle moment - across all exoskeleton assistance conditions (None, Low, Medium, High, and each participant's Best-performing condition, defined as the assistance level at which they achieved maximum propulsive capacity). EXO-related changes in trailing limb angle (A) and total peak ankle moment (B) together correlate with those in peak anterior GRF, which itself is positively correlated with those in propulsive capacity (C).

Running With an Exotendon: Biomechanical Insights Into Metabolic Savings Across Running Speeds

Ms. Olivia Felton, Mr. Chadwick Healy, Mrs. Alaa Ahmed, Ms. Cara Gonzalez Welker

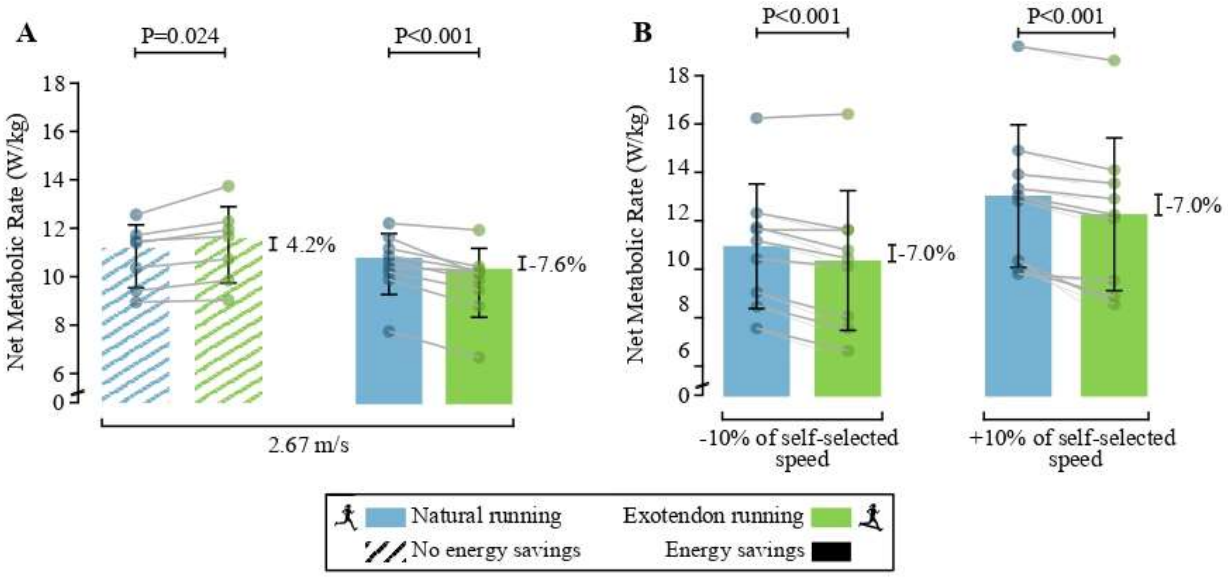
University of Colorado Boulder, Boulder, CO, United States

Introduction

Passive assistive devices can influence metabolic rate and alter running mechanics. Previously, the exotendon, a spring connecting a runner's legs, was shown to reduce metabolic rate by an average of 6.4% when running at 2.67 m/s [1]. Here, we examine individual biomechanical adaptations that influence these reductions and test whether the metabolic benefits of the exotendon persist across additional speeds.

Methods

Sixteen recreational runners completed treadmill running trials with and without the exotendon at 2.67 m/s. Participants that reduced metabolic rate with the exotendon subsequently completed trials at ±10% of their self-selected speeds. Metabolic rate was measured using indirect calorimetry, and joint kinematics were estimated using OpenCap [2]. Spatiotemporal parameters, joint angles, and ground reaction forces were analyzed to identify gait adaptations associated with metabolic changes when running with the exotendon at all speeds.



Results

Nine of sixteen participants reduced metabolic rate when running with the exotendon. Reductions in responders were associated with specific biomechanical adaptations, including increased stride frequency ($P<0.001$); decreased peak knee flexion angles ($P=0.04$); decreased peak hip flexion and extension angles ($P=0.01$, $P=0.004$, respectively); and lower peak vertical and horizontal ground reaction forces ($P<0.001$, $P<0.001$, respectively). For the participants who benefited at 2.67 m/s, metabolic reductions were consistent across speeds (see figure). The biomechanical patterns associated with metabolic savings at 2.67 m/s were consistent across speeds, suggesting that these gait adaptations influence metabolic benefits.

Discussion

This study demonstrates that the metabolic benefits of running with an exotendon generalize across speeds, but are selective for runners who adopt specific gait strategies. By promoting gait patterns associated with reduced peak joint angles and lower peak ground reaction forces, the exotendon may also offer additional benefits, such as reduced injury risk. A key limitation is the use of markerless motion capture, which may introduce small kinematic errors. These findings emphasize the importance of designing assistive devices that account for both metabolic efficiency and individual human adaptability. Future work should investigate long-term adaptation and real-world conditions to maximize the effectiveness of passive assistive technologies.

Wrist Biomechanics During Handstands: Effect of Wrist Position on the Soft Tissues

Ms Mercedes Aramayo Gomes Rezende, Dr Angela Kedgley

Department of Bioengineering, Imperial College London, London, Greater London, United Kingdom

Ms Mercedes Aramayo Gomes Rezende

Introduction

Up to 88% of gymnasts experience wrist pain [1]. It is believed that this is related to the use of the upper extremities for weight bearing, where the wrist can reach extreme extension angles [1], subjecting the joint's soft tissues to high passive moments. It was hypothesised that doing handstands on parallettes, rather than on the floor, would decrease wrist extension, thereby decreasing the passive moments at the joint and protecting the soft tissues.

Methods

Ten participants (four females and six males, 29.3 ± 9.6 years) volunteered. Wrist extension [2] was measured with an optical motion capture system (Qualisys AB, Gothenburg, Sweden) during four 10 seconds assisted handstand tasks (two on the floor and two on parallettes). Passive moments were calculated from the wrist angles [3].

Based on Shapiro-Wilk tests for normality, paired t-tests or Wilcoxon Signed-Rank tests were used to compare maximum wrist extension angles and corresponding passive moments as a function of wrist position. Significance was defined as $p < 0.05$.

Results

No differences were found due to hand dominance; therefore, averages of right and left hands across the four trials were taken. Handstands on the floor had greater wrist extension angles (by 12.7°) and passive moments (by 280 N.mm) compared to those on the parallettes ($p \leq 0.005$, Figure 1).

Discussion

Handstands on the floor had a wider range of passive moments than those on the parallettes (Figure 1C). This was because passive moments exponentially increased when

approaching the maximum range of motion [3] (Figure 1A). At extreme extension angles the palmar ligaments' lengths can increase by up to 25% [4]. By performing handstands on parallettes, wrist extension angles decrease, potentially decreasing wrist pain prevalence as the ligaments are be subjected to less elongation.

Images (Optional)

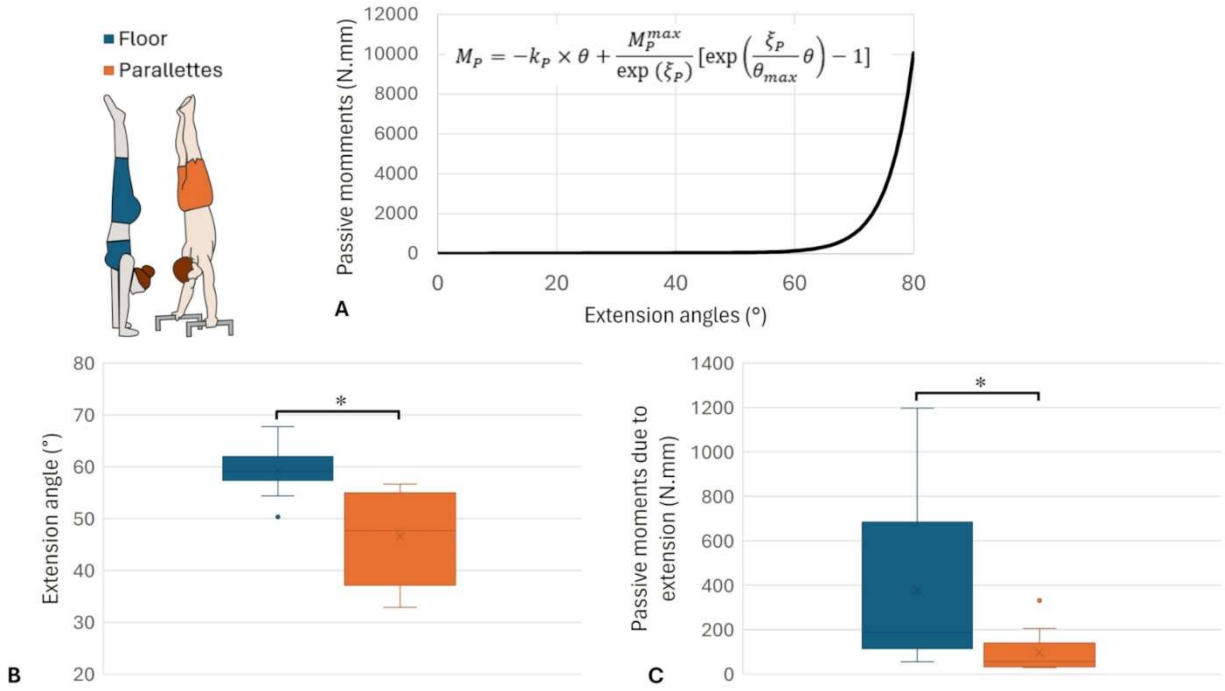

Figure 1: (A) Passive moments (M_P) as a function of wrist extension angle (θ), where M_P^{max} is the maximal passive moment, θ_{max} is the joint angle at which the maximal passive moment occurs, k_P is the linear stiffness and ξ_P is the shape parameter for the non-linear elastic component [3]. (B) Wrist extension angle and (C) passive moments compared between handstand on the floor and parallettes. * indicates p ≤ 0.005.

Scapulo- and Humerothoracic Kinematics of a Simulated Volleyball Spike Using Biplane Videoradiography

Dr. Aaron Hellem DPT, PhD, Dr. Arin Ellingson PhD, Dr. Paula Ludewig PT, PhD

University of Minnesota, Minneapolis, MN, United States

Introduction

Kinematics literature for the shoulder in overhead sports is dominated by optical surface motion capture despite significant limitations associated with skin motion artifact [1,2]. The purpose of this analysis was to describe scapulothoracic (ST) and humerothoracic (HT) kinematics of a simulated volleyball spike minimizing the limitation of skin motion artifact associated with surface motion capture.

Methods

17 volleyball players (8M, 14R, mean age 24.1) without play-limiting shoulder pain were included in this cross-sectional, descriptive analysis. Biplanar videoradiography (BVR) captured subject-specific kinematics of a simulated volleyball spike. CT scans of the scapula and humerus were obtained and semi-automated 2D/3D shape matching performed to align digitally reconstructed radiographs to BVR images. Kinematics Toolbox [3] was employed to extract and describe (mean ± 1SD) ST and HT kinematics relative to the trunk using YX'Z'' and XZ'Y'' rotation sequences. Rotations are expressed using the R-hand rule.

Results

Mean ST initial position was 36.1° ± 12.85 internal rotation; -2.1° ± 6.93 upward rotation; and -8.8° ± 7.55 of anterior tilt. Mean HT initial position was -6.3° ± 7.3 elevation; 2.3° ± 8.1 anterior to the scapular plane; and -51.1° ± 19.6 of external rotation (ER). The scapula achieved mean maximum external rotation of -25.7° ± 20.3, upward rotation of -49.5° ± 5.9, and a peak of posterior tilt (~22°) just prior to arm cocking (i.e. maximum ER). This was followed by rapid IR, downward rotation, and anterior tilt of the scapula during arm acceleration. The humerus reached mean maximum elevation of -149.6° ± 19.0 posterior to the plane of the scapula (-44.3° ± 17.6) and a mean maximum ER of -118.4° ± 21.5.

Discussion

This is the first study to describe ST and HT kinematics of a dynamic sporting task minimizing skin motion artifact. Qualitative comparison of these results with previous surface motion capture of the volleyball spike demonstrates similar HT elevation magnitudes and substantially smaller HT ER magnitudes suggesting that surface motion capture may overestimate HT ER [4]. This may be attributed to known skin motion artifact that is amplified in HT elevation angles greater than 120° and may grow with increasing movement velocity [1,5].

Images (Optional)

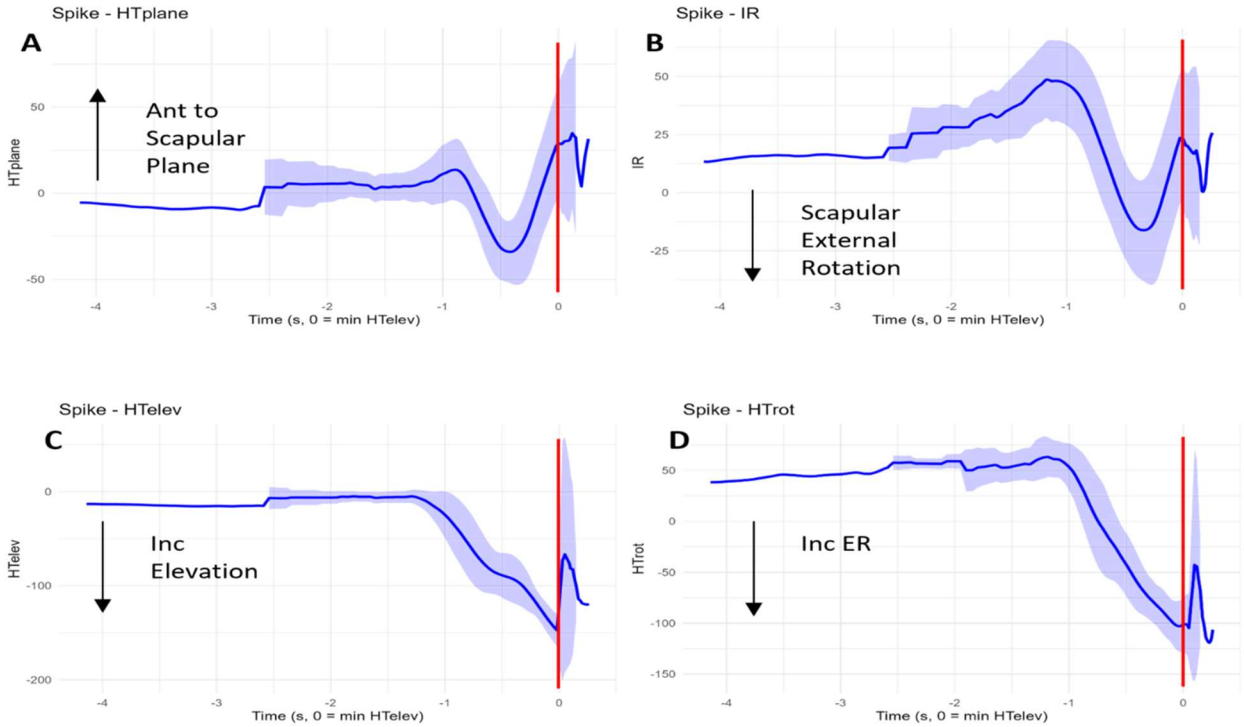

Figure 1. Scapulothoracic (left) and Humerothoracic (right) kinematics (mean ± 1 SD) of the Simulated Volleyball Spike centered at maximum elevation (t = 0, red line). Temporally, HT horizontal abduction peaked (A) just prior to ST ER (B), followed by maximum HT elevation (C) and ER (D) which occur almost simultaneously.

OA29-04

Modulation of Rein Tension and Rider's Elbow Joint Angle in Show Jumping

PhD student Nolwenn Regnault[1], PhD Nicolas Bideau[1], PhD Agnès Olivier[2]

[1]M2S Laboratory, Bruz, Bretagne, France. [2]Institut Français du cheval et de l'équitation, Saumur, Pays de la Loire, France

Introduction

In show jumping, horse–rider pairs continually adapt to clear obstacles and manage varying constraints. Rider–horse dynamics have been examined through rein tension, which is naturally asymmetrical at the canter due to the gait itself [1]. Postural adjustments enable riders to modulate forces and compensate for these inherent imbalances [2]. This study therefore investigates how the presence of an obstacle influences dynamic variables of the rider–horse interaction.

Methods

Twelve amateur riders performed a canter jumping task on the same horse, equipped with IMUs (XSens MVN). Rein tension was recorded using instrumented strain-gauge reins (Shimmer Sensing). Riders completed six straight-line (SL) canters and four straight lines including an obstacle. Elbow flexion–extension and rein tension were analysed on straight lines and during the approach phase (AP). Right–left asymmetries were tested separately for right- and left-lead canter, and for inside vs. outside rein, using paired t-tests ($\alpha = 0.05$). Pearson correlations between rein tension and elbow angle were computed for each rider and condition.

Results

No significant right–left rein tension differences were found for SL right-lead, AP right-lead or AP left-lead canter. In SL left-lead canter, however, right-rein tension was higher (RR: 21.9 ± 5.4 N vs. LR: 18.3 ± 5.3 N, $p = 0.034$). Inside–outside comparisons showed no significant effects (table 1).

In SL, most riders showed significant negative correlations between rein tension and elbow angle ($r = –0.20$ to $–0.53$, $p < 0.05$). In AP, these correlations became more heterogeneous, with both positive and negative relationships observed among riders.

Discussion

These findings result partly support previously reported natural canter asymmetries [3]. The significant asymmetry found only in left-lead canter (RR > LR), together with the tendency for higher right-rein tension when cantering right, may reflect horses' lateral preferences. This asymmetry disappears in the approach phase, suggesting that riders standardise their rein aids before the jump. The increased variability in rein–elbow coordination during AP highlights individual adaptation strategies, potentially reflecting different technical approaches.

Introduction

In adaptive sport, how an athlete's control strategy affects performance and injury risk remains poorly understood. For wheelchair tennis athletes, effective overhead serve mechanics are essential for improving performance and distributing upper-extremity loading [1-3]. This study examined trunk and arm contribution during the wheelchair tennis serve, hypothesizing that athletes with limited trunk control would display different control patterns than those with greater trunk control.

Methods

A convenience sample of wheelchair tennis athletes at different career stages performed serves during a practice session on an outdoor court. As part of a larger protocol assessing upper body strength (dominant arm girth, grip strength), power (medicine ball throw), and ROM (multidirectional reach), calibrated inertial measurement units (Equilibrium, Vayu Tech, 100 Hz) were secured to the wheelchair back and the lumbar, trunk, head, and bilateral upper arm and forearm segments to capture kinematics during the serve. Data from the Ball Toss, Execution, and Follow-Through phases were analyzed.

Results

Muscle strength and playing experience influenced serve kinematics (Table 1, exemplar athletes). Athlete 1, with reduced upper body power, showed limited trunk motion (13–25° max) across phases and used an arm-driven Ball Toss strategy (mean shoulder external rotation [ER]: 11°; max: −48°) with minimal ER during Execution (mean: 24°, max: 28°). Athlete 2, with impaired passive ROM and power, used a trunk–arm strategy, rotating the trunk away from the racket arm during Ball Toss (max: 24°), maintaining this trunk position during Execution (max: 22°) while externally rotating to −61°. Athlete 3, with full function, showed extensive trunk rotation during Toss and Execution (max: −73° and −43°, respectively), with reduced ER at Follow-Through. Peak shoulder ER occurred during Execution (max: −176°), indicating strong trunk–shoulder coupling to enhance serve performance.

Discussion

This exploratory series of case studies illustrates distinct serving strategies among wheelchair tennis athletes with varied impairment profiles. These results emphasize the need to consider an individual's trunk-shoulder coordination when designing training interventions to improve serve effectiveness and manage shoulder loading.

Personalized Cardiac Mechanics: Evaluating Diffusion Tensor Imaging and Rule-Based Methods for Cardiomyocyte Orientation

Mr. Devin Seyler[1], Dr. Aaron Brown PhD[1], Dr. Tyler Cork PhD[1], Dr. Javiera Jilberto PhD[1], Dr. Luigi Perotti PhD[2], Dr. Daniel Ennis PhD[1], Dr. Alison Marsden PhD[1]

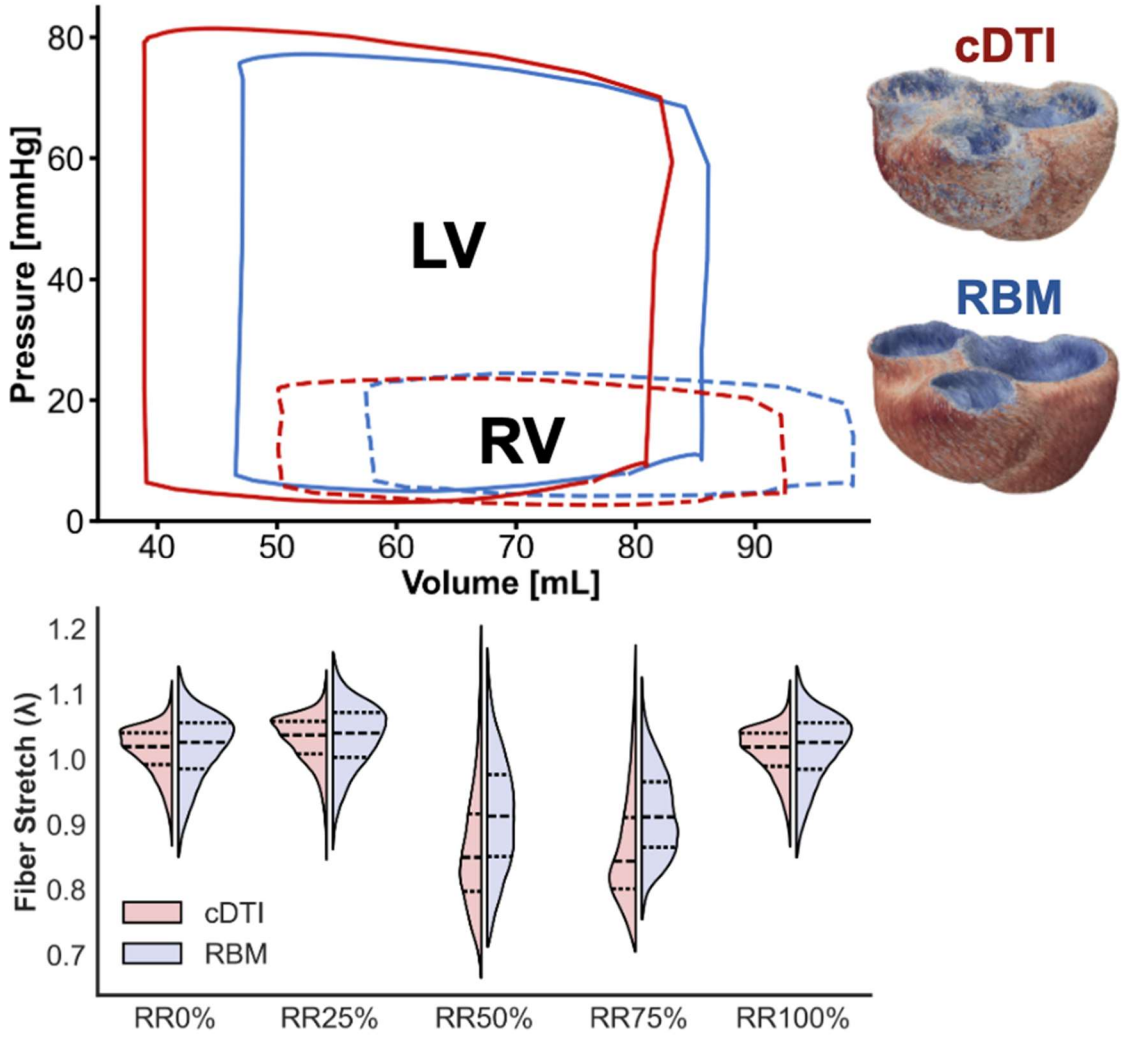
[1]Stanford University, Stanford, California, United States. [2]University of Central Florida, Orlando, Florida, United States

Introduction

Achieving clinically relevant accuracy for personalized cardiac biomechanics models requires assimilating extensive patient-specific data, including the complex, highly organized architecture of the myocardium. Cardiac diffusion tensor imaging (cDTI) can estimate aggregate cardiomyocyte orientation but is limited by physiological motion and low resolution *in vivo*. Consequently, Laplace-Dirichlet rule-based methods (LDRBMs) are widely used to algorithmically assign cardiomyocyte orientations but lack patient specificity [1]. Here, we present a method for tuning personalized cardiac models incorporating either ex vivo cDTI or LDRBM-derived cardiomyocyte orientations and investigate how this choice influences simulated ventricular function.

Methods

A biventricular model was generated from cine MRI of a healthy adult pig with corresponding LV pressure measurements and *ex vivo* cDTI [2]. Cardiac mechanics were simulated for both cDTI and LDRBM cardiomyocyte orientations using the open-source svMultiPhysics solver from SimVascular. The 3D model was coupled to a 0D lumped-parameter network tuned to match LV pressure and chamber volumes. Material parameters and an unloaded configuration were obtained via an inverse finite element method fitting the observed passive inflation [3]. A periodic active stress was prescribed using a double Hill model. Kinematics, pressures, and volumes were compared between simulations using cDTI-derived or LDRBM-derived cardiomyocytes.



Results

Significant discrepancies exist between cDTI and LDRBM aggregate cardiomyocyte orientations, particularly near the apex (~45°) and within the RV (~40°). After tuning the LPN, all pressures and chamber volumes were within 10% of their *in vivo* targets. Preliminary simulation results demonstrate a greater LV ejection fraction using cDTI (53.2% vs 45.9%) and more homogenous fiber-stretch distribution.

Discussion

This work demonstrates a method for constructing subject-specific cardiac mechanics models and evaluating the impact of cardiomyocyte orientation. Observed kinematic differences between cDTI and LDRBM models indicate the need for RBMs with greater spatial variation. Future work will extend to congenital heart disease patients for whom deviations between LDRBMs and anatomy are likely more pronounced.

Images (Optional)

Top: Pressure-volume loops for cDTI and RBM models. cDTI exhibits a higher LV ejection fraction.
Bottom: Fiber stretch over the cardiac cycle. cDTI shows more uniform stretch during systole (RR50%).

4D-Flow MRI Measurements and Computational Analyses of Pulsatile Cerebrospinal Fluid Flow in the Human Third Ventricle

Mr. Fuga USHIO[1], Assoc. Prof. Tomohiro OTANI PhD[1], Mr. Atsuhito TAISHAKU[2], Assoc. Prof. Shigeki YAMADA MD[2], Prof. Yoshiyuki WATANABE PhD[3], Prof. Shigeo WADA PhD[1]

[1]The University of Osaka, Toyonaka, Osaka, Japan. [2]Nagoya City University, Nagoya, Aichi, Japan. [3]Shiga University of Medical Science, Otsu, Shiga, Japan

Introduction

Cerebrospinal fluid (CSF) in the ventricular system exhibits bidirectional motion synchronized with cardiac pulsation and contributes to the transport of hormones and waste products, particularly within the third ventricle (3V) [1]. However, detailed flow patterns and their driving mechanisms remain unclear due to anatomical and physiological complexities. This study aimed to characterize 3V CSF flow and identify underlying mechanical factors by computational fluid dynamics (CFD) simulation based on four-dimensional flow magnetic resonance imaging (4D flow MRI).

Methods

CFD simulations of 3V CSF flow were performed following our previous study [2] using subject-specific MRI data (Fig. 1(a)). MRI-derived flow rate was imposed at cerebral aqueduct (CA), traction free was applied at foramen of Monro, and no-slip wall conditions were assigned on the ventricle surface (Fig. 1(b)). First, rigid walls were assumed and the total CSF flow rate through the 3V cross-section was compared between MRI and CFD. Next, prescribed wall motion was applied to the 3V superior-posterior region, which is anatomically formed by a thin membrane (velum interpositum) [3], to match the MRI-derived 3V total flow rate balance.

Results

Figure 1(c) shows time courses of the CSF flow rate through the 3V cross-section in MRI and CFD, and representative snapshots of CSF flow velocity on the midsagittal plane at cardiac systole. CFD results with rigid-wall assumptions markedly underestimated the 3V flow rate compared with MRI (Fig. 1(c)). Although the moving-wall assumption produced flow rates closer to MRI, local CSF flow velocity was still underestimated, particularly on the 3V inferior side.

Discussion

These results suggest that the 3V does not behave as a rigid conduit driven solely by the CA flow rate, and that pulsatile wall motion plays an essential role in forming actual CSF flow pattern. Further investigation of the wall motion to better reproduce local CSF flow distributions may provide new insights into 3V physiological functions.

School of Mechanical and Materials Engineering, University College Dublin, Belfield, Dublin, Ireland

Dr. Chanikya Valeti

Dr. Sairam Pamulaparthi Venkata

Introduction

Cardiac transplants are widely used to treat patients with critical heart conditions. However, donor availability is a major limitation for the life-saving treatment. The University of Maryland School of Medicine recently demonstrated the potential of cardiac xenotransplantation: nonetheless, long-term success requires a deeper understanding of the physiological and biomechanical challenges introduced by anatomically dissimilar xenotransplants [1]. The present computational fluid dynamics study establishes numerical simulations for the analysis and comparison of the blood flow structures in human and porcine heart models.

Methods

Computational fluid dynamics is a powerful tool for analysing complex haemodynamics in the human circulatory system. Significant progress has been made in both computational and experimental analysis of the haemodynamics of the human heart: nonetheless, detailed cross-species examination of cardiac haemodynamics remains unexplored. Human and pig hearts are reconstructed from the CT data. The left atria and aortas are assumed rigid, whereas the left ventricles expands and contracts according to prescribed mesh movements over the cardiac cycle. A moving ventricle solver is developed in OpenFOAM to facilitate the dynamic mesh movements. Pressure conditions are specified at the pulmonary veins (inlets) and mass flowrates are prescribed at the aortas (outlet).

Results

Transient flow analyses are performed on both human and porcine left heart models. A custom left ventricle mesh motion procedure has been developed to approximate physiological chamber expansion and contraction. A stroke volume of 78 ml, and an ejection fraction of 56% are assumed for the human left ventricle. Blood is taken as the Newtonian, and wall-compliance effects are ignored. Various hemodynamic and biomechanical features, such as vortical structures, Q-criteria, Wall Shear Stresses (WSS), Oscillatory Shear Indices (OSI), Relative Residence Time (RRT), are compared between the porcine and human heart models.

Discussion

The genetically modified porcine model is a promising donor for xenotransplantation. Nonetheless the hemodynamic and biomechanical compatibility needs to be investigated considering significant anatomical dissimilarities between two heart models. The key anatomical difference is pigs have only two pulmonary veins, while human heart has four, which results in different flow partitioning into left atrium.

Simulation of Purkinje-Mediated Left Bundle Branch Block and Cardiac Resynchronization Therapy

Dr Sandra Hager[1], Dr Vahid Ziaei-Rad[1], Dr Jenny Choy[2], Dr Mengjun Wang[2], Dr Ghassan Kassab[2], Dr Lik Chuan Lee[1]

[1]Michigan State University, East Lansing, Michigan, United States. [2]California Medical Innovations Institute, San Diego, California, United States

Introduction

Synchronized ventricular contraction is maintained by rapid electrical conduction through the Purkinje fiber network. Disruption of this conduction pathway, such as in left bundle branch block (LBBB), often associated with cardiomyopathy or valvular disease, leads to delayed ventricular excitation, mechanical dyssynchrony, and reduced cardiac performance. Understanding these conduction abnormalities and predicting the response of therapeutic interventions such as cardiac resynchronization therapy (CRT), requires a unified electromechanical modeling framework. In this work, we present a multiphysics model that couples cardiac electrophysiology, ventricular mechanics, and closed-loop hemodynamics in a biventricular (BiV) finite element modeling framework.

Methods

An idealized BiV geometry with rule-based fiber architecture was utilized [1]. A fractal-tree–based Purkinje network was generated using a modification of an existing algorithm and mapped onto the endocardial surfaces of both ventricles. Electrical activation was initiated at the His bundle and propagated within the Purkinje system and myocardium employing a modified FitzHugh–Nagumo (FHN) formulation with an anisotropic diffusion tensor, adapted to match physiological conduction properties in both tissues [2-4]. A transversely isotropic constitutive law was used to model time-varying active and passive myocardial stress [5]. Systemic and pulmonary hemodynamics were represented using a closed-loop circulatory model [6]. Left bundle branch block (LBBB) was introduced by setting diffusion in the left bundle branch to zero immediately after bifurcation from the His bundle. Cardiac resynchronization therapy (CRT) was simulated with a lateral left-ventricular epicardial pacing site.

Results

Baseline simulations reproduced physiological activation patterns, strain profiles, and pressure–volume dynamics (Figure 1). In the LBBB case, the myocardial wall was activated after 165ms, accompanied by reduced peak circumferential (Ecc) and

longitudinal (Ell) strains of -0.17 and –0.15, respectively. Standard CRT pacing improved ventricular synchrony, where the myocardium was activated after 100.5ms and peak strains were restored with Ecc = -0.18 and Ell = -0.16.

Discussion

This computational model provides a focused framework for examining the effects of LBBB and CRT pacing on ventricular electromechanics. Based on the modular model design, the framework can be extended to incorporate ischemic regions and alternative pacing strategies, such as His-bundle or left bundle branch pacing, and can be adapted for patient-specific simulations.

OA31-01

Integrating Paediatric Statistical Shape and Density Model Prediction to *in Silico* Finite Element Modelling of the Femur and Tibia

Miss Yidan Xu, Dr. Laura Carman, Professor Thor Besier, Dr. Julie Choisne

The University of Auckland, Auckland, Auckland, New Zealand

Introduction

Subject-specific Finite Element (FE) models have demonstrated high accuracy in biomechanical computations; however, they are limited by cost and time. Generic models are inaccurate for paediatric populations. To overcome these limitations, statistical shape-density models (SSDM) have shown promising results in predicting bone geometry and bone mineral densities (BMD) for FE analysis. The aim was to evaluate the accuracy of stress and strain distribution in personalised femoral and tibial FE models derived from paediatric SSDMs using different predictive inputs and algorithms.

Methods

SSDMs of the paediatric femur and tibia were built from 330 paediatric calibrated CT scans (136F, 12 ±5 y.o., N=657 femora and 652 tibiae)[1]. These SSDMs were used to predict femoral and tibial geometry and BMD in a leave-one-out analysis from the following inputs: 1) full medical imaging, 2) partial medical imaging (15% proximal and distal bone) and 3) no medical imaging. Three predicting algorithms were compared: 1) shape only fitting (bone geometry as input), 2) shape and density fitting (bone shape and BMD as input) and 3) Partial Least Squares Regression (from demographics). SSDM-based FE models were built based on each SSDM geometry and BMD prediction. Subject-specific FE models were built based on CT information. For each FE model, boundary conditions were applied to represent single-leg standing. Von Mises stress and 1st and 3rd principal strain from each SSDM-based model were compared to the subject-specific FE Model using element-wise normalised root-mean-square error (NRMSE).

Results

Femoral average NRMSEs for stress, 1st and 3rd principal strain were below 6%, 1% and 2% respectively, for all SSDM-based FE models. Tibial NRMSEs were higher (8%, 2%, and 5%, respectively). Adding medical imaging as input, compared to PLSR, reduced the average NRMSE for stress. Shape and density fitting further reduced stress errors and decreased

NRMSEs in the 1st and 3rd principal strains compared to shape-only fitting. Shape-only fitting with partial imaging produced similar errors to full shape-only fitting (Figure 1).

Discussion

Our SSDM-based FE models can accurately reproduce stress and strain distributions, approaching the gold standard. This is valuable in paediatric clinical settings where imaging is limited.

Images (Optional)

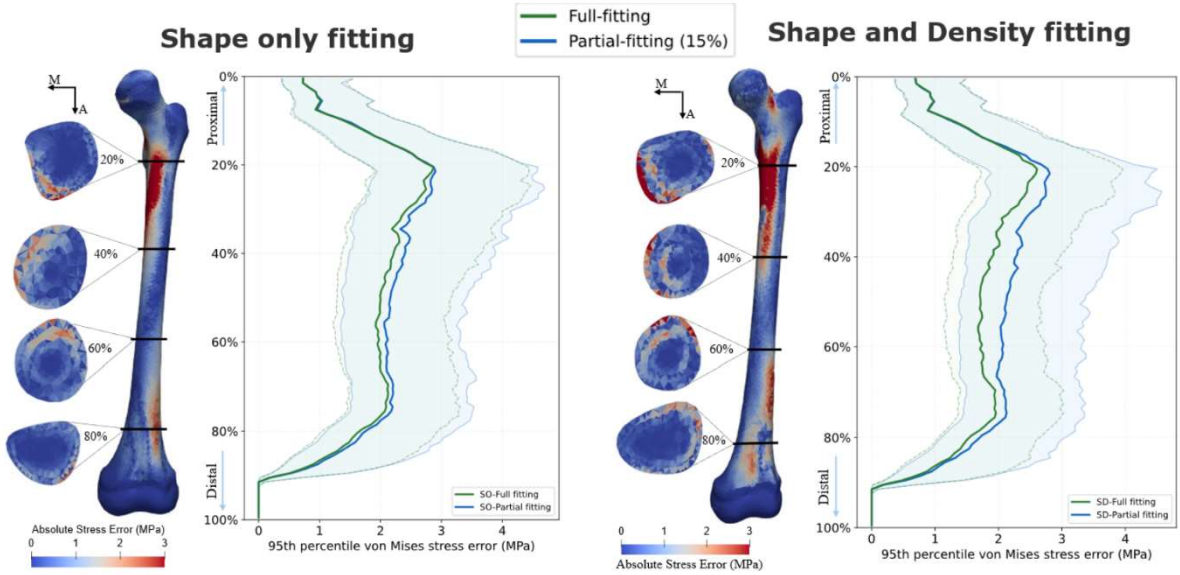

Figure 1: Slice-wise 95th percentile von Mises stress error (MPa) along the femoral axis. For each a) shape only fitting and b) shape and density fitting algorithm: left image is a representative median femur in frontal view with cross-sectional slices at 20%, 40%, 60%, and 80% of total length. Slice maps display element-wise absolute stress error relative to the subject-specific reference; A (anterior) and M (medial). The right image represent the population profiles of the 95th percentile stress error versus normalised femoral length. Curves represent the group median (solid line) and 5th - 95th percentile range (shaded area) for the Full fitting in green and Partial fitting in blue.

An Automated Pipeline for Paediatric Musculoskeletal Model Development Utilising Articulated Statistical Shape Modelling and OpenSim

Dr Laura Carman, Dr Julie Choisne, Dr Thor Besier

Auckland Bioengineering Institute, Auckland, Auckland, New Zealand

Introduction

Children are not small adults, bone morphology changes significantly throughout growth. Traditional linear scaling of adult musculoskeletal models to represent children yields large inaccuracies. Accurate paediatric musculoskeletal modelling is crucial for clinical applications such as surgical planning, and orthotic design. Statistical shape modelling has emerged as an effective tool for predicting paediatric lower limb bone geometries [1]. The aim of this study was to develop and implement an automated pipeline to generate personalised paediatric musculoskeletal models directly from motion capture data.

Methods

A dataset of 327 paediatric CT scans (4-18years (12±5years), 137F) were used to develop an articulated shape model (ASM) of the pelvis, femora, and tibiae/fibulae. Bone geometries were predicted using twelve common skin surface landmarks (ASIS, PSIS, femoral epicondyles, and tibial malleoli). These skin markers were obtained by projection from bony landmarks to the skin surface on the CT scans. The articulated shape model predicts individualized bone geometry by optimizing principal component analysis (PCA) weights and joint articulations. Model accuracy was evaluated using leave-one-out cross-validation, quantifying bone surface reconstruction error, clinical measurement error, and anatomical landmark error. The performance of the new 2-sided-ASM was compared to our previously developed shape models (1-sided-ASM, and single bone shape models (SSM)) and linear scaling of adult bone (LSA). The generated bone geometries and landmarks were used to create subject-specific musculoskeletal models via the OpenSim Python API, enabling inverse kinematic and kinetic analyses.

Results

The average RMSE for bone surface reconstructions were 2.64±0.99mm, 1.91±0.59mm, and 1.69±0.55mm in the pelvis, femur, and tibia/fibula respectively. The 2-sided-ASM performed similarly to the 1-sided-ASM and produced on average significantly lower bone surface errors compared to the SSM models and LSA, indicating the importance of personalised bone geometry in paediatric populations. Additionally, clinical bone

measurements showed low errors. The automated pipeline successfully generated OpenSim models and performed kinematic and kinetic analyses.

Discussion

This study presents a novel, fully automated workflow for paediatric musculoskeletal model generation using sparse skin surface landmarks, eliminating the need for medical imaging and enabling accurate, personalised gait analysis in clinical and research settings.

Images (Optional)

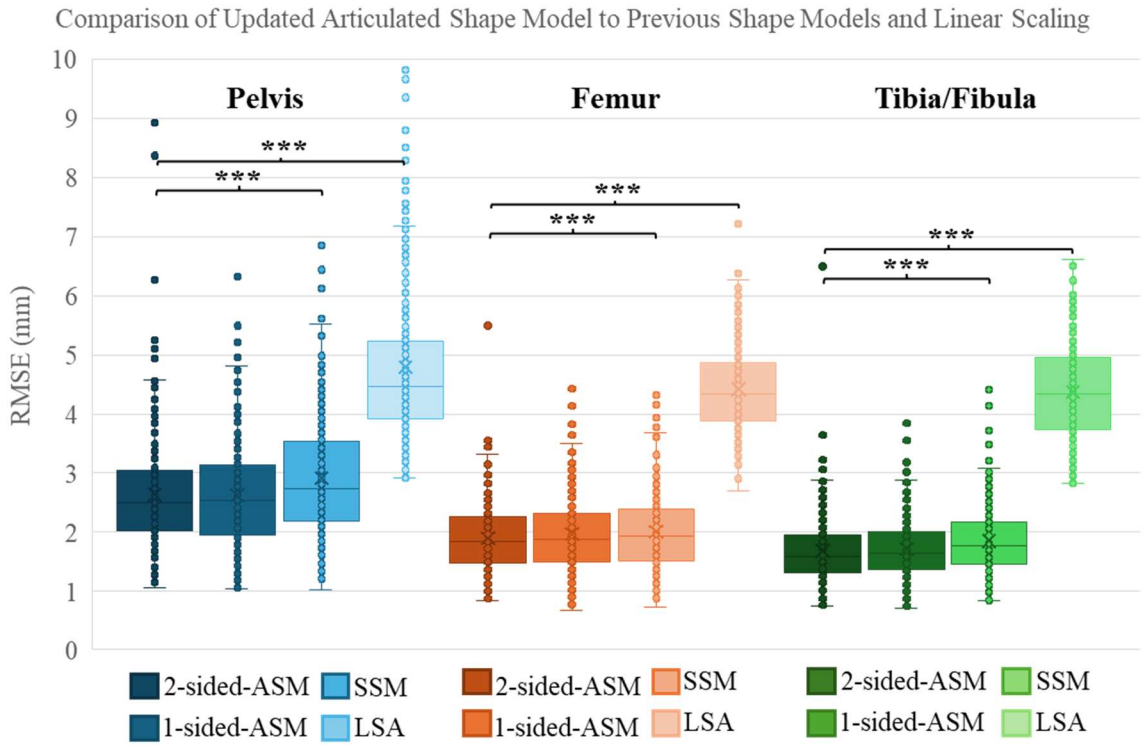

Figure 1: Box plot of bone surface geometry errors for the pelvis, femur, and tibia/fibula predicted from skin surface landmarks using the new articulated shape model (2-sided-ASM), compared to errors when predicted from bone surface landmarks using an articulated shape model (1-sided-ASM), errors when predicted using PLSR in single bone shape models (SSM), and errors when performing linear scaling of adult bone geometry from the opensim gait2392 model (LSA).

OA31-03

Automated Statistical Shape Modelling of the L4-L5 Functional Spinal Unit for Population-based Computational Studies

Dr Sherif Zantiba PhD, Dr Gavin Day PhD

University of Leeds, Leeds, West Yorkshire, United Kingdom

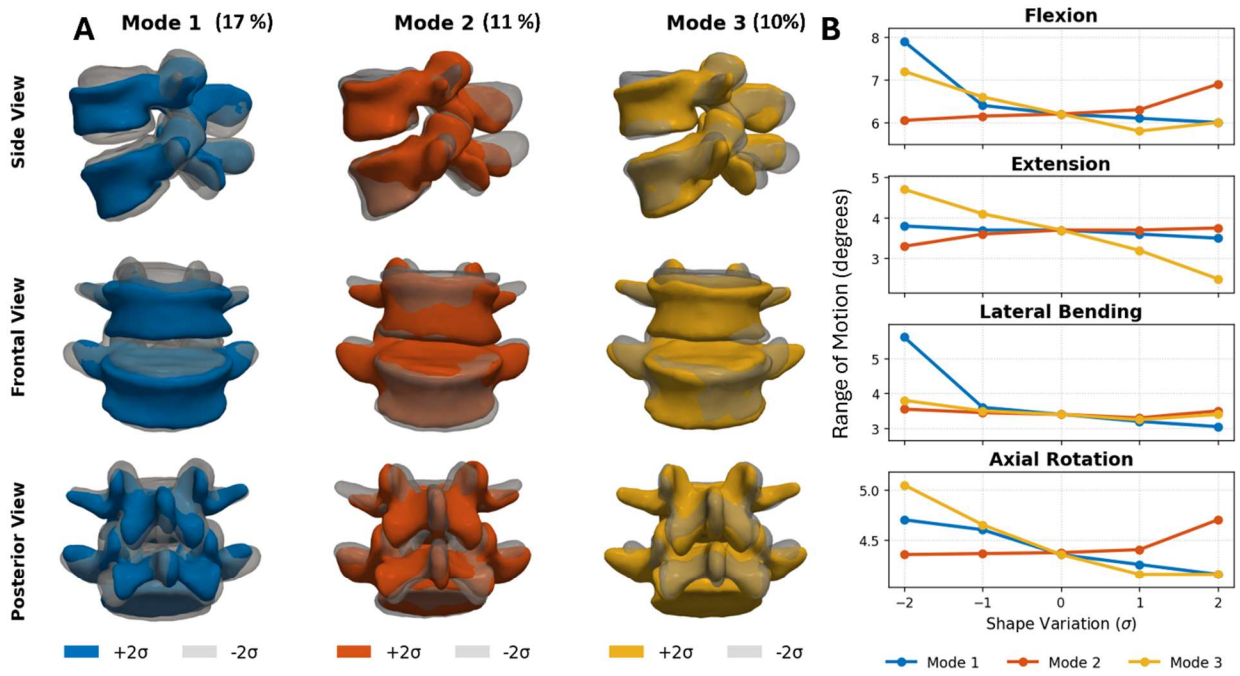
Introduction

Vertebral geometry is a critical determinant of load transfer and fusion outcomes at the L4-L5 functional spinal unit (FSU). However, current computational studies largely rely on generic models, neglecting population-level variability. In this study a Statistical Shape Model (SSM) of the L4-L5 FSU is used to quantify how specific anatomic variations drive spinal mechanics.

Methods

L4 and L5 surface meshes were derived from 25 segmented lumbar CT scans [1]. A fully-automated Python-based automated workflow utilised Coherent Point Drift [2] to non-rigidly register all specimens to a common template, ensuring nodal correspondence. Principal Component Analysis identified dominant modes of shape variation. FE models were automatically reconstructed for the mean shape and ±1/±2σ of the first three modes (13 models), crucially, this included procedural generation of the nucleus and annulus, and ligament attachment mapping via nodal correspondence. A Young's modulus distribution, derived from the population mean intensity, was mapped onto all shape variants. Range of Motion (ROM) was assessed under a 400 N follower load and 10 Nm moments.

Results



The pipeline achieved a symmetric mean surface error of 0.83±0.07 mm, with leave-one-out generalisation errors of 2.0±0.4 mm. The first three modes captured 38.7% of geometric variance. Broadly, Mode 1 captured vertical scaling (17% variation in body height), Mode 2 characterised posterior element morphology, and Mode 3 represented sagittal wedging. The models reproduced experimental ROM ranges from the literature. Finite element sensitivity analysis revealed distinct kinematic drivers: Mode 1 (-2σ; increased body) caused a twofold increase in lateral bending ROM. Conversely, Mode 3 (wedging) was the dominant sensitivity factor for extension and axial rotation stiffness.

Discussion

This study demonstrates an automated, scalable workflow for generating FE-ready spinal models with high geometric fidelity. The mechanical sensitivity analysis highlights that

specific morphological features, specifically vertical aspect ratio and sagittal wedging, drive distinct kinematic responses. These differences underscore the limitations of single-geometry models for device evaluation. While the current dataset validated the pipeline, the framework is designed for application to large-scale medical imaging databases to robustly evaluate implant–geometry interactions.

Images (Optional)

Geometric characterisation and mechanical sensitivity of the L4-L5 statistical shape model. (A) Visualisation of the first three principal component modes (capturing 38% of total variance). Solid coloured meshes represent the +2 σ geometry overlaid on the -2 σ geometry (transparent grey). Mode 1 (blue) captures vertical scaling, Mode 2 (orange) posterior element morphology, and Mode 3 (yellow) sagittal wedging. **(B)** Finite element predicted Range of Motion (ROM) sensitivity to geometric variation under 10 Nm pure moments. Key results are the non-linear, twofold increase in Lateral Bending ROM associated with Mode 1 geometry at -2 σ (increased vertebral height), and the influence of Mode 3 (wedging) on Extension and Axial Rotation stiffness.

OA31-04

Effect of Shoulder Bone Shape on Glenohumeral Joint Forces: A Population-Based Analysis

Mr Francois Bruyer-Monteleone, Dr Maxence Lavaill

Queensland University of Technology, Brisbane, Queensland, Australia

Mr Francois Bruyer-Monteleone

Introduction

Shoulder anatomy varies between individuals, affecting the glenohumeral joint (GHJ) mechanics. Musculoskeletal (MSK) models can study these internal loadings across anatomies. Medical image-based models require resources and detailed anatomy, limiting result generalizability. Population-based modelling can use statistical shape models (SSMs) derived from principal component analysis (PCA) to capture anatomical variability across a population. These models can automatically generate large cohorts, for instance, to clarify how anatomy relates to joint loading at a population level. Despite this potential, population-based MSK models remain underexplored - an important gap this study seeks to address.

Methods

Shoulder girdle bones - humerus, scapula, clavicle – were 3D modelled from 61 healthy subjects. Bones and patient height were used to build a multi-segmented SSM via PCA. The SSM was then leveraged to develop 500 instances to non-uniformly scale a generic MSK model's segments [1], with randomized body mass following a normal distribution from underweight (> 18) to overweight (< 30). Overhead scaption and flexion motions were analyzed with an optimization solver which constrains the GHJ force within the glenoid's border [2]. Simulations were run with and without a 3-kg weight in hand. GHJ forces were normalized over body weight (BW) and distribution across models were reported.

Results

During flexion, GHJ force rose from 30% to 100%BW, and tripled with the weight (100% to 300%BW; Fig.A). During scaption, the unweighted pattern was similar to flexion, but with the weight the force doubled at the start and tripled by the end (Fig.B). Overall, patterns were comparable with and without the weight.

Discussion

The population-based MSK model integrates shape variability and reproduces forces comparable to the published weighted and unweighted data -from in vivo [3], in vitro [4] and in silico [5] studies- though sometimes lower in our models. Population-based models can help elucidate loading patterns in patients whose anatomies deviate from the population average, potentially explaining the limited success of certain surgical procedures and supporting more personalized treatment strategies.

Images (Optional)

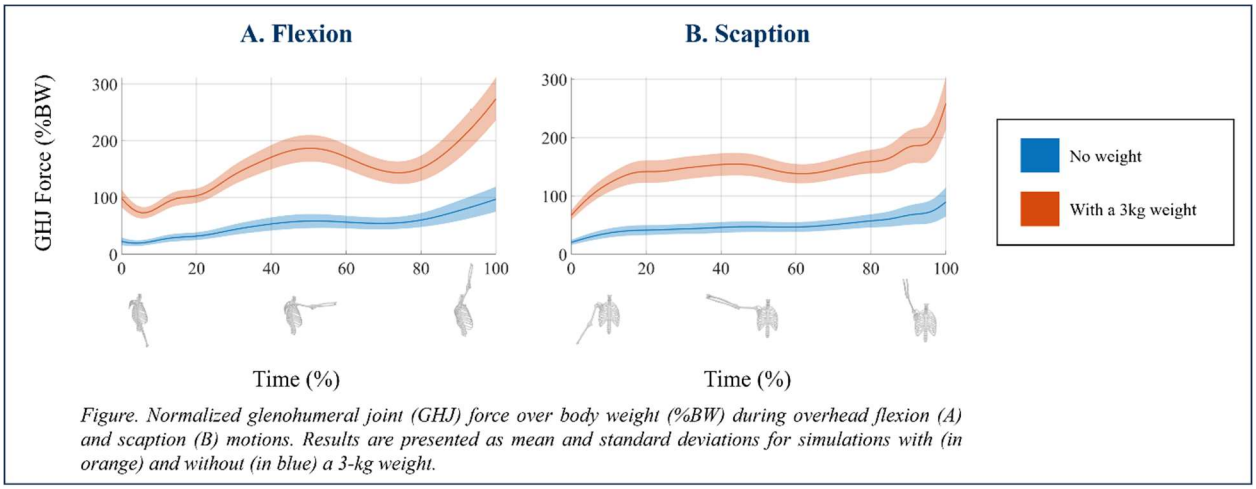

Figure. Normalized glenohumeral joint (GHJ) force over body weight (%BW) during overhead flexion (A) and scaption (B) motions. Results are presented as mean and standard deviations for simulations with (in orange) and without (in blue) a 3-kg weight.

OA31-05

Sensitivity of Knee Contact Mechanics to Statistical Cartilage Thickness Models Derived From a Single and Multiple Imaging Modalities

Dr Roberto Leonardo Diaz, Prof Sophie Williams, Prof Ruth Wilcox

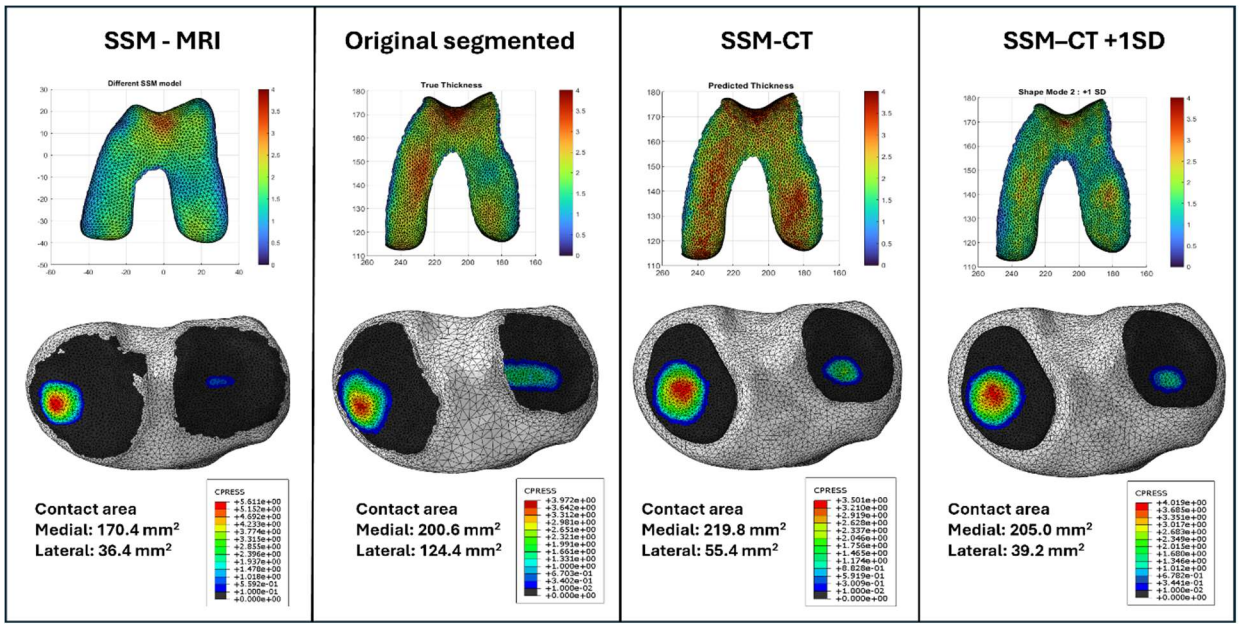
University of Leeds, Leeds, West Yorkshire, United Kingdom

Introduction

Accurate cartilage thickness distribution is essential for realistic contact mechanics simulations [1]; however, obtaining bone and cartilage surfaces from the same imaging source is not always possible. Statistical shape models (SSMs) offer the potential to apply cartilage layers to bone models derived from radiographic imaging that does not capture the soft tissue, however SSMs often combine data from different imaging modalities. The aim of this study was to compare contact mechanics predictions from models with different SSM-derived cartilage layers.

Methods

A SSM, based on a single imaging source, was developed in which the subject-specific cartilage thickness was derived from the bone geometry. Bone and cartilage masks of tibiofemoral joints (n=8) were first segmented from high-resolution CT scans (voxel size 82μm). Articular cartilage surfaces were extracted (bone shape), resampled for node correspondence and assigned with a cartilage thickness value per node. Training samples were aligned and scaled to a template for a subsequent Principal Component Analysis (PCA), applied independently to bone shape and cartilage thickness distribution. The predictive model was verified with a control sample. Contact mechanics were compared using FE models with the (original) segmented cartilage and with cartilage derived using the above SSM (‘SSM-CT’), a 1 SD shift of this model (‘SSM-CT-1SD'), and a SSM derived from MRI data (‘SSM-MRI’)[2].



Results

The predicted mean cartilage thickness distribution of SSM-CT was consistent with the segmented case but 20% larger in volume, while the SSM-CT-1SD shifted case reduced the volume error to 11%. The contact mechanics simulation showed that, compared to the segmented case, the SSM-CT case had lower peak stress (−11.9%) and contact area (−15.3%), the SSM-CT+1SD case had similar peak stress (+1.2%) but reduced contact area (−24.8%), and the MRI-derived SSM had larger errors.

Discussion

The SSM-CT model produced cartilage thickness with a systematic overestimation but maintained a similar distribution. Crucially, better results were achieved when both cartilage and bone models were derived from a single, consistent imaging modality like µCT. Despite the limited sample size to train the model, this method demonstrates strong potential for adding cartilage to image-derived bone models for contact biomechanics research.

OA31-06

Sex Differences in Ankle Muscle Morphology Revealed Through MRI-Derived Statistical Shape Models

Mr. Mario E. Garcia, Dr. Silvia S. Blemker

University of Virginia, Charlottesville, Virginia, United States

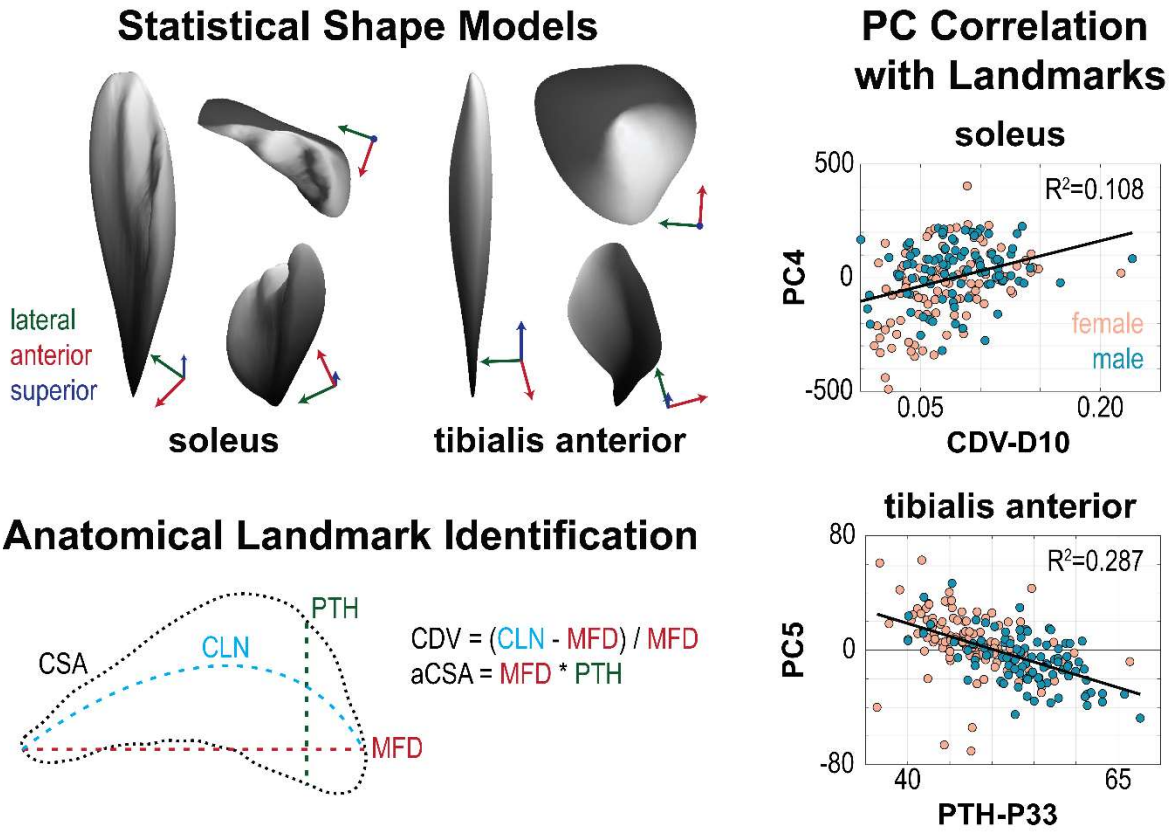
Introduction

Despite established sex-related and architectural variability, muscle morphology remains under explored. As such, this study leverages our large dataset of MRI-derived lower-limb muscle volumes and paired functional assessments to develop statistical shape models for the ankle's plantar and dorsiflexor muscles. These models reduce geometries into principal components (PC) that capture morphology features, enabling comparison across landmarks, functional capacity, and sex.

Methods

Participants (n=103, female:55, male:48) of representative heights (average:1.70±0.08m, female:1.64±0.05m, male:1.76±0.06m) and masses (average:71.52±13.92kg, female:64.32±10.72kg, male:79.78±12.59kg) were recruited. The study was approved by the University of Virginia Institutional Review Board and conducted in accordance with the Declaration of Helsinki. Participants underwent MRI scans and the ankle's functional capacity was evaluated isometrically, using a Biodex System 4. Muscle volumes were identified using automated segmentation with manual vetting (Springbok Analytics, Charlottesville, VA). Shape models for plantar and dorsiflexors (n=206, female:110, male:96) were generated using Generalized Procrustes Analysis and screened using leave-one-out cross-validation with Mahalanobis distances. Selected morphology landmarks included CSA, curvature length, maximum Feret diameter, perpendicular thickness (PTH), curvature deviation (CDV), and axial-CSA proxy. Principal component analysis was performed and related to landmarks and torque capacity using linear regressions. PC sex differences were analyzed using Welch's t-test. Reported results focused on PC1-5 for the soleus (SOL) and tibialis anterior (TA) for brevity.

Results



For SOL, PC4 was significantly greater in males and positively correlated with CDV in the distal-tenth (R^2=0.11, $p<0.05$). This PC indicated greater distal curvature in female participants. For TA, PC5 was significantly greater in females and negatively correlated with

PTH in the distal-third (R^2=0.29, $p<0.05$). This PC indicated that females' higher values correspond to reduced distal thickness.

Discussion

Utilizing our dataset, we found sex differences across multiple PCs in our shape models. These results suggest that sex differences in muscle morphology are most apparent in the distal regions of the SOL and TA, near the muscle-tendon junction, where tapering, curvature, and transitions are most pronounced. These models enable targeted investigation of morphological differences driving these differences and their links to functional capacity, and future work will compare pooled, female, and male models to further delineate variation.

OA32-01

Fall Experiments from Stepladders Using a Hybrid III Pedestrian Dummy

Dr. HIROKI TAKAHASHI Researcher, Dr. HAEYOUNG KIM Researcher, Mr. YASUMICHI HINO Researcher, Dr. KATSUTOSHI OHDO Researcher

National Institute of Occupational Safety and Health, Japan, Kiyose, Tokyo, Japan

Introduction

Falls from low heights, particularly from stepladders, remain a major cause of fatal and severe occupational injuries in the construction industry. In Japan, falls account for approximately 40% of all fatal construction accidents, and incidents involving stepladders have shown an increasing trend. Understanding head impact mechanisms during short-distance falls is essential for developing effective prevention strategies. This study experimentally investigates head acceleration responses during stepladder falls using the Hybrid III Pedestrian dummy.

Methods

Experiments were conducted in the fall-testing facility at the National Institute of Occupational Safety and Health, Japan. A stepladder was placed on a 50-cm-high platform, and female and male Hybrid III Pedestrian dummies were positioned on the ladder. A release mechanism initiated controlled falls at three inclination angles relative to the ground surface: 10°, 20°, and 30°. Dummy posture was varied between a straight-torso configuration and a flexed-waist configuration. A tri-axial accelerometer mounted at the dummy's head measured impact accelerations. Helmet and non-helmet conditions were also tested to evaluate protective effects.

Results

Greater inclination angles consistently produced higher peak head accelerations. For the female dummy at a 10° inclination, the straight-torso posture generated approximately 550 G, while the flexed-waist posture generated about 400 G. The flexed posture allowed the hip, back, and shoulders to contact the ground before the head, enabling partial energy absorption. Helmet use substantially decreased measured head acceleration compared with non-helmet conditions, reinforcing the importance of protective equipment.

Discussion

The findings indicate that even low-height falls can produce severe head impacts when the head directly contacts the ground. Fall posture strongly influences injury severity, and preventing direct head impact—together with consistent helmet use—is essential for

reducing risk. These results provide fundamental data for improving fall-prevention strategies and will be extended using biomechanical injury indices such as **HIC（Head Injury Criterion）** and **BRIC（Brain Injury Criterion）** to enable more quantitative injury assessment.

Novel Direct Assessment of Bulk Fracture Propagation Speed in Bone

Mr Souren Moradi Undergraduate Student[1], Mr Samuil Miah Undergraduate student[1], Mr Heytham Mohilldeen BS[1], Mr Charles Bass BS[2], Dr. Cameron Bass PhD[1]

[1]Wayne State University, Detroit, MI, United States. [2]Virginia Commonwealth University, Richmond, VA, United States

Introduction

Rib fractures remain common traumatic injuries, yet the mechanics of fracture propagation in bulk is poorly understood, particularly the speed of crack propagation under dynamic loading. Most existing studies investigate slow fatigue cracking at microscale. Modern Lagrangean finite element model (FEM) injury biomechanics models are is fundamentally compromised by sub-element level bony failure, often partially addressed using nonbiofidelic heuristic element deletion procedures. However, the stress-strain behavior in bulk relies sensitively on crack propagation speed. To rectify this deficiency, this study introduces and validates a novel three-point bone breaking apparatus to directly track high-speed dynamic fractures in bulk bone.

Methods

A three-point bending apparatus was constructed using a large-stroke, 10-ton hydraulic cylinder mounted in a rigid frame. The cylinder was attached to a transparent, acrylic indentor that provided access for overhead illumination of the rib specimen (30,000 lumen backlighting across ~625 mm^2). The outer margin of dry bovine rib specimens (n=11) were placed on cylindrical supports. Fracture propagation was recorded using a high-speed camera (Phantom V711) at 210,000-390,000 frames/sec. Crack tip positions from video were tracked using Tracker (v.6.2.0). Fracture velocity was calculated by differentiation of the displacement data.

Results

Crack propagation illuminated through bulk bone was successfully tracked for 3-6 frames (~400 um/pixel at 390,000 f/s). Typical fracture profiles were linear during the time tracked with an average R^2 of 99±0.8%. Mean fracture velocity was assessed as 1370±200 m/s, with no statistically significant difference in assessed velocities between the datasets with the smaller number of frames (3) and larger number of frames (4-6) ($p=0.05$).

Discussion

Fracture propagation speed is an essential input into biofidelic human FEMs that include fracture. This study demonstrated a novel and effective methodology to accurately track bulk fracture propagation in whole bone for use in improved bone injury models. Crack propagation speed in dried bovine bone is comparable to Rayleigh wave speed in dry cortical bone. Novel aspects of this study include high intensity backlighting through the indentor. With this approach, bone cracks at > 3000 m/s can be seen propagating on both sides of the rib specimens used in this study.

In-Vivo Imaging of Harmonic Brain Motion Correlates Head Rotation With Increased Mechanical Vulnerability of the Adolescent and Adult Human Brain

Dr. Ruth Okamoto[1], Dr. Jordan Escarcega[1], Dr. Curtis Johnson[2], Dr. Ahmed Alshareef[3], Dr. Philip Bayly[1]

[1]Washington University, St. Louis, MO, United States. [2]University of Delaware, Newark, Delaware, United States. [3]University of South Carolina, Columbia, South Carolina, United States

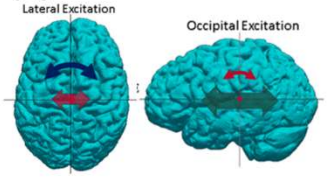
Introduction

Cadaver studies and in-silico models have linked the location and direction of head impacts to the relative risk of brain injury [1, 2]. Non-injurious experimental studies are needed to confirm these findings in living humans [3]. We used magnetic resonance elastography (MRE) to measure the response of the brain to occipital and lateral excitations and characterize contributions of rotational and translational motion to the non-dimensional strain energy - kinetic energy ratio, SE/KE [4].

Methods

96 participants in 4 age cohorts underwent an MRI exam including standard anatomical imaging and MRE with harmonic skull excitation in the lateral or occipital direction at [20, 30,50] Hz (Fig. 1). Image volume were aligned to an MNI-152 template, then processed to obtain bulk motion, dynamic deformation fields, strain fields, brain mass, m, and moment of inertia tensor, $\boldsymbol{I}$. The ratio of rotational kinetic energy to translational kinetic energy, RKE/TKE was computed at each frequency f using bulk angular displacement ($\boldsymbol{\theta}$) and centroid translation ($\boldsymbol{u_0}$) vectors. Strain energy was computed using frequency-dependent shear storage moduli for each age cohort. We used a linear, mixed-effects model (LMEM) to fit power-law relationships between SE/KE and RKE/TKE as functions of frequency for each cohort.

Results



RKE/TKE and SE/KE were highly correlated for all cohorts using the LMEM: $\log_{10}(SE/KE) = -1.4 + 0.74 \log_{10}(RKE/TKE) + 0.74*\log10(f)$. Including age cohorts and excitation direction improved the fits modestly (Fig 1E).

Discussion

RKE/TKE was larger for lateral excitation than for occipital excitation and decreased with frequency. Variations in RKE/TKE within cohorts may occur due to differences in head positioning and head shape during imaging, and explain the variability of SE/KE within cohorts. Higher SE/KE ratios for low frequency motions with large RKE/TKE suggest that longer-duration impacts lead to proportionally higher values of shear strain and possibly higher likelihood of injury across all age cohorts studied.

Apparent Shear Softening Present in *Ex Vivo* Bovine Brain Tissue Captured with MR Elastography

Ms Olivia Bailey[1], Ms Alexa Diano[1], Dr. L. Tyler Williams[1,2], Mr Ali Lateef[1], Dr. Kshitiz Upadhyay[3], Dr. Elise Corbin[1,4], Dr. Curtis Johnson[1,4]

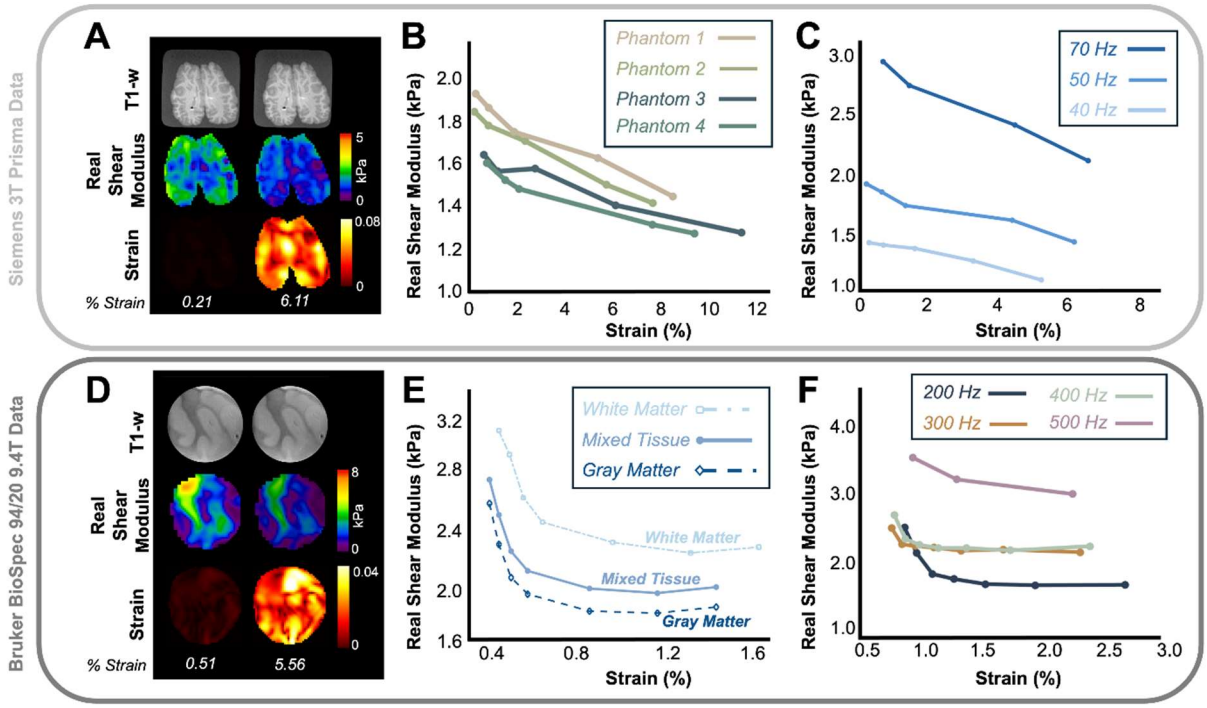
[1]University of Delaware, Newark, DE, United States. [2]Children's Hospital of Philadelphia, Philadelphia, PA, United States. [3]University of Minnesota, Minneapolis, MN, United States. [4]Nemours Children's Hospital, Wilmington, DE, United States

Introduction

Traumatic brain injury (TBI) models require advanced experimental data on brain mechanical properties, potentially acquired using magnetic resonance elastography (MRE). Traditional *in vivo* MRE is limited to capturing linear mechanical properties within the small-strain regime. However, modeling high-strain and strain-rate injuries should consider nonlinear mechanical tissue behavior. Here, we modify our MRE experiment to induce large strain in *ex vivo* tissue to capture mechanical nonlinearity.

Methods

Bovine brains were encapsulated in agarose (0.75wt.%) to create phantoms and were scanned with a custom EPI-MRE sequence on either Siemens 3T (2.5 mm isotropic resolution, 30-100 Hz) or Bruker 9.4T (0.5 mm isotropic resolution, 200-500 Hz) MRI scanners. Octahedral shear strain and maps of shear modulus, estimated with a nonlinear inversion [1], were calculated. Typically, micron-level displacements induce minor shear strain; however, here we maximize applied displacement to increase the strain induced into tissue-agar phantoms.



Results

In larger samples tested on the 3T clinical scanner, we induced 6.11% strain into the tissue, causing a 25.1% decrease (1.93 to 1.45 kPa) in shear modulus. This trend remained consistent across multiple phantoms and frequencies (Figure 1A-C). In smaller samples on the 9.4T high-resolution scanner, we induced 5.56% strain, causing a 38.16% decrease (3.15 to 1.95 kPa) in shear modulus. Comparison between tissues showed a 28.7% decrease in gray matter (2.58 to 1.84 kPa) and a 26.9% decrease (3.10 to 2.27 kPa) in white matter (Figure 1D-E). Figure 1C,F demonstrates that data collected at lower frequencies typically achieves higher strain and results in higher percent modulus change.

Discussion

Results indicate success in achieving large strain using MRE and match similar nonlinear strain softening behavior previously identified in bovine brain under shear stress [2]. We achieved peak strains of approximately 6-12%, whereas typical *in vivo* brain MRE experiments induce strains less than 0.05% [3]. Future work will assess strain-softening in fresh tissue and further investigate the influence of frequency and tissue-type. Experimental data will be incorporated into computational models to capture the large-strain nonlinear tissue response relevant to TBI.

Dr Pawel Kudzia

Ms Gabrielle R. Booth

Dr. Kristen Reynier

Dr. Matthew Panzer

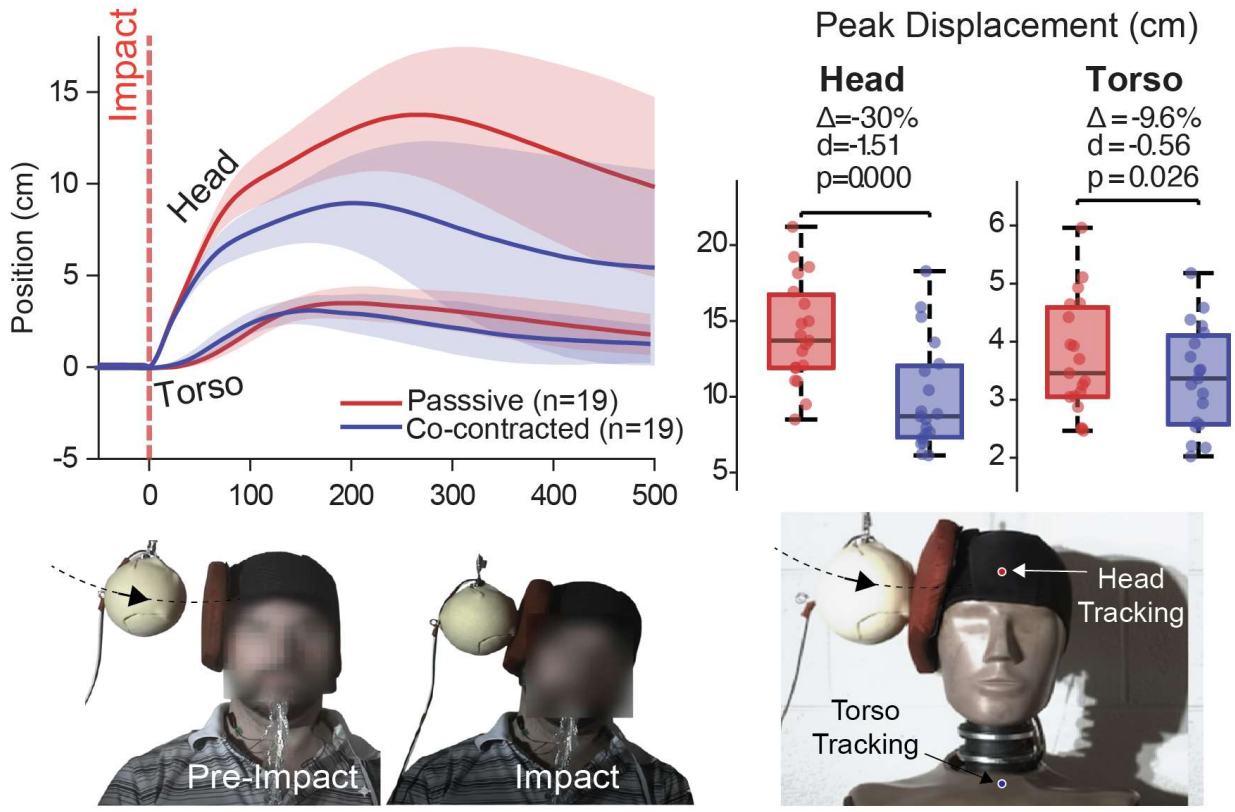
Introduction

Anthropomorphic test devices (ATDs) and human body models require empirical head and torso kinematic data to better predict injury risk. Reynier et al. (2020) characterized head kinematics during non-injurious lateral impacts under different muscle activation conditions, but their analysis focused exclusively on head motion [1]. We performed secondary analysis of their high-speed video data to quantify simultaneous head and torso kinematics for ATD biofidelity assessment.

Methods

We digitized high-speed video recordings from 19 male participants who received standardized lateral head impacts under passive and co-contracted muscle conditions. A 3.7 kg padded impactor struck participants at 2 m/s while cameras captured motion at 500 Hz. We tracked head and torso positions from video and computed velocity and

acceleration metrics. We detected impact onset using a velocity threshold and compared conditions using paired t-tests with effect sizes.



Results

Muscle co-contraction reduced peak head displacement by 30% (passive: 14.2 ± 3.4 cm; co-contracted: 10.0 ± 3.6 cm; $p < 0.001$, $d = 1.51$). Peak head velocity decreased by 6.4% ($p = 0.003$, $d = 0.78$). Torso velocity and acceleration showed no significant differences between conditions ($p > 0.05$). Head excursion relative to torso decreased 36% with co-contraction (passive: 11.3 ± 3.3 cm; co-contracted: 7.2 ± 3.2 cm; $p < 0.001$, $d = 1.35$). Individual displacement responses demonstrated consistent proportional reductions across conditions (slope = 0.70, $R^2 = 0.46$).

Discussion

While peak acceleration remained unchanged, muscle co-contraction reduced head displacement and excursion relative to the torso following lateral impact. Our video-based approach captured displacement trajectories that can be tricky to capture using accelerometer-only methods. The time-series data and head excursion metrics address a need for developing more biofidelic ATDs used in automotive safety and sports injury research. The consistent proportional reduction in head displacement across participants supports development of scalable muscle activation factors.

Poroelastic Inversion of the Human Brain at 3T Using Amplified MRI

Mr. Tyson Lam M. S.[1], Dr. Patrick Fillingham Ph. D.[1], Dr. Matthew McGarry Ph. D.[2], Ms. Caitlin Neher M. S.[1], Dr. Em Triolo Ph. D.[3], Dr. Fargol Rezayaraghi Ph. D.[1], Dr. Mehmet Kurt Ph. D.[1]

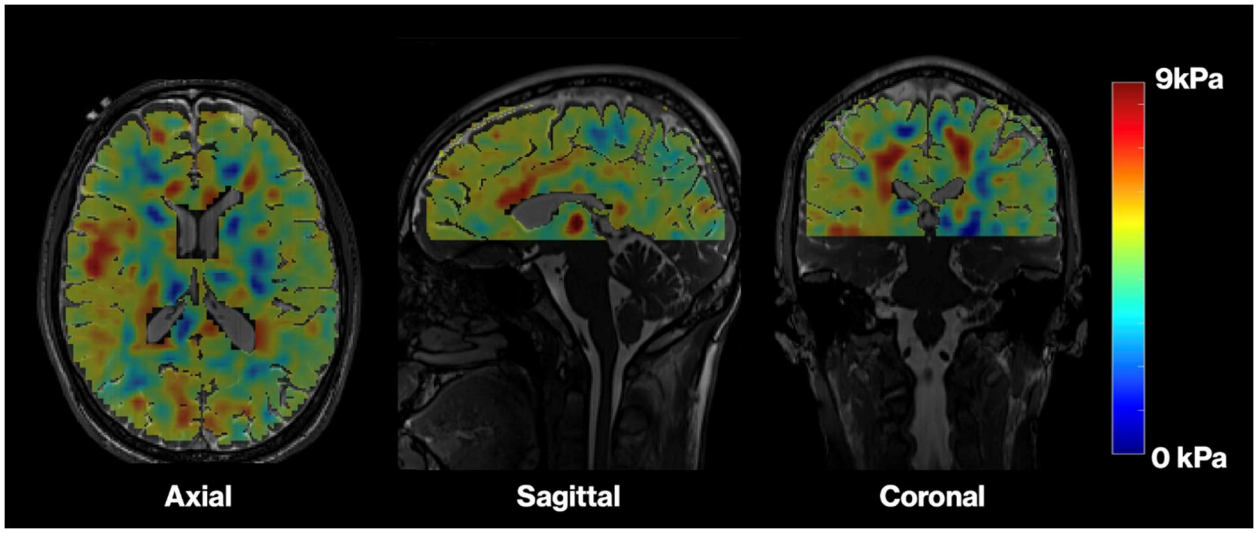
[1]University of Washington, Seattle, Washington, United States. [2]Dartmouth College, Hanover, New Hampshire, United States. [3]Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, United States

Introduction

Cardiac pulsations drive subtle, measurable brain deformations on the order of ~100 μm [1], observable with cine-MRI and amplified-MRI (aMRI) [2, 3], which amplifies subtle motion for quantification. Harnessing natural actuation offers a unique opportunity to probe low-frequency mechanics and enable elastography without external drivers. These motions serve as inputs to poroelastic nonlinear inversion (peNLI), a fluid-solid coupled iterative mesh framework [4]. The objective is to demonstrate the feasibility of aMRI-peNLI at 3T by estimating stiffness maps of the human brain at cardiac frequencies.

Methods

Healthy adults (n=18) were scanned at 3T using a 16-channel head coil and a cardiac-gated balanced steady-state free precession sequence ($1.0\times1.0\times1.0 mm^3$). 3D-aMRI was applied to the cine-MRI data, followed by Demons-based registration to obtain voxel-wise displacements across the cardiac cycle [2, 3], later served as inputs to the peNLI solver modeling poroelastic behavior with Darcy-type fluid transport by estimating the real component of the shear modulus. Soft-prior regularization [5] was applied to CSF, and ventricular regions were masked out to mitigate numerical instability and non-uniqueness.



Results

Preliminary stiffness maps/elastograms from peNLI were able to differentiate gray matter (GM) from white matter (WM) regions and yielded ratios similar to typical 50Hz magnetic resonance elastography (MRE) ranges. Since absolute stiffness values are not physically meaningful for ~1 Hz MRE, regional ratios (e.g., GM/WM) were reported for performance comparison. Residual "hotspot" clusters appeared near tissue boundaries and regions limited by registration confidence.

Discussion

Results showcase feasibility of 3D-aMRI driven peNLI at 3T, with stiffness maps broadly consistent with prior MRE studies. Deviations (e.g. thalamus softer relative to WM, -0.79±0.17 vs +0.06±0.16 literature) may reflect CSF shielding around deep GM nuclei or anisotropic fiber organization in WM. Residual hotspots likely reflect interstitial fluid forces not yet captured. Future work will incorporate poroviscoelastic models to better capture clinically relevant changes in compliance and pulsatility.

OA33-01

Multi-day Co-adaptation of Ankle Exoskeleton Assistance for Poststroke Gait

Ms Tara Kimiavi, Dr. Santiago Canete PhD, Dr. Conor Walsh PhD, Dr. Patrick Slade PhD

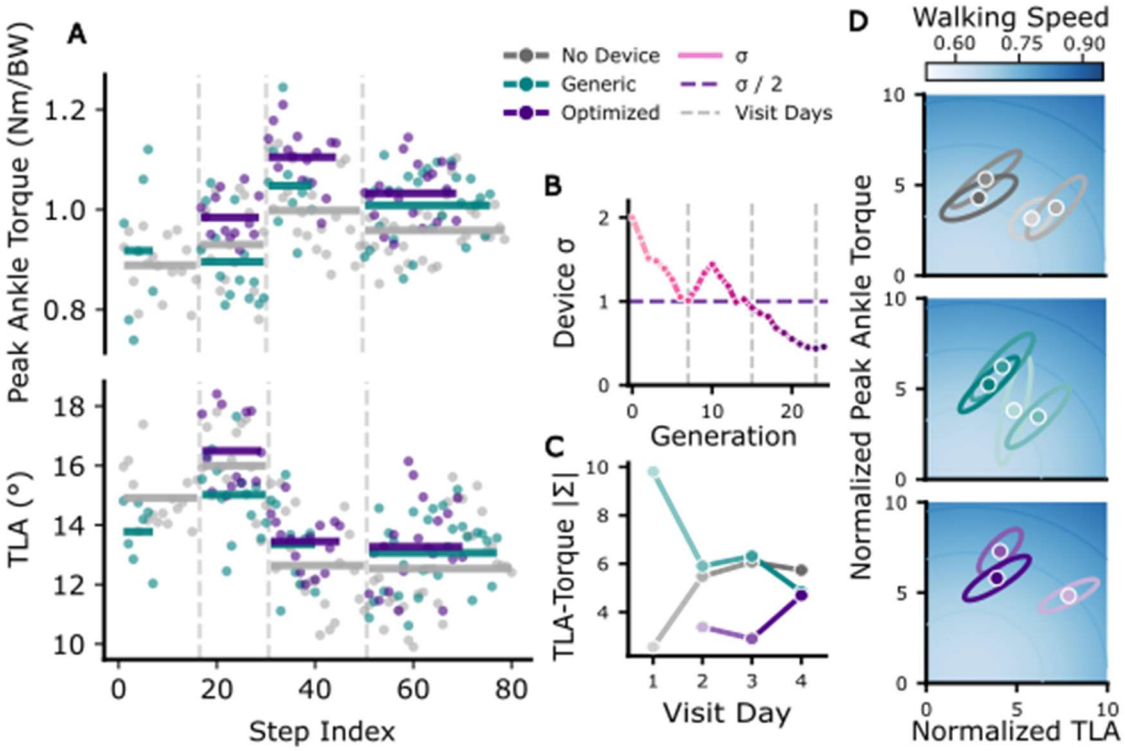
Harvard University, Cambridge, MA, United States

Introduction

Ankle exoskeletons can enhance poststroke mobility [1], but effectiveness depends on user adaptation [2] and assistance personalization [3]. Poststroke users often show reduced adaptability and endurance [4], limiting co-adaptation. Hemiparetic compensation shifts power to the hip or non-paretic limb [5], so leveraging ankle assistance may require gait readaptation. We personalized ankle assistance across multiple days to characterize poststroke human-robot co-adaptation and test how training time and continuous exoskeleton personalization influence device efficacy. We hypothesized that with increasing training, the human-exoskeleton system converges: device parameters approach an optimum while the user converges to an internal gait pattern that better exploits ankle push-off.

Methods

Two chronic poststroke adults completed four overground walking visits with an ankle exoskeleton at a comfortable speed. We measured kinematics, kinetics, cost of transport, and spatiotemporal metrics during validation trials comparing no exoskeleton, generic assistance, and optimized assistance. After each day's validations, assistance was personalized online using CMA-ES [3] to maximize overground walking speed. On the final visit, we performed a double-reversal validation of the three conditions. The generic condition was periodically retested during optimization to track adaptation.



Results

For one participant, the exoskeleton converged to an optimal assistance profile after 160 minutes of training (1B). Walking speed improved with exoskeleton assistance compared to no device on all days, with greater differences observed between the optimized controller (0.78 ± 0.1, 0.75 ± 0.1 m/s) and the generic (0.67 ± 0.1,0.73 ± 0.1 m/s) after visits 1 and 2. Covariance between paretic TLA and peak ankle torque across all validation steps (1A, 1D) indicates convergence towards a gait pattern that increases walking speed relative to the no device condition. Covariance decreased in the generic condition but remained stable in the optimized condition, indicating the participant did not adopt a strategy that better leveraged optimized assistance.

Discussion

This study will provide insights into better training protocols for people post-stroke to move towards community device use.

Effects of Backpack Loads on Bone Mechanical Stimulus in Persons with Spinal Cord Injury during Exoskeletal-assisted Walking: A Simulation Study

Ms. Gabriela B. De Carvalho[1], Dr. Ann M. Spungen[2], Dr. William A. Bauman[3], Dr. Saikat Pal[1,2]

[1]New Jersey Institute of Technology, Newark, NJ, United States. [2]James J. Peters Veterans Affairs Medical Center, Bronx, NY, United States. [3]Icahn School of Medicine at Mount Sinai, New York, NY, United States

Introduction

Severe osteoporosis is a secondary consequence of spinal cord injury (SCI). Exoskeletal-assisted walking (EAW) offers a promising approach to mitigate bone loss by providing sustained loading of bones in an upright position. However, knowledge of EAW dosing to improve bone health is non-existent. The **goals** of this study were (1) to quantify exercise dose using Bone Density Index (BDI), an established metric to quantify mechanical stimulus [1], and (2) evaluate the effects of backpack loads during EAW from persons with SCI.

Methods

We recorded the 3-D motion of three persons with SCI during EAW in the ReWalk P6.0. A generic OpenSim musculoskeletal model was scaled to match each participant's anthropometry. Human-robot interaction forces were applied to regions of exoskeletal support cuffs/bands. Knee joint forces were computed during EAW using muscle-driven simulations with muscle control signals constrained to a maximum value of zero to simulate muscle inactivity in SCI. We calculated BDI (Equation 1) for EAW steps ranging from 10 to 2000, where $\beta=1$ and $m=6$. Next, we simulated backpack loads ranging from 10 to 40lbs and calculated BDI for the range of EAW steps.

$$BDI = [\sum n * (\beta * F)^m]^{1/2m} \quad \text{(Equation 1)}$$

Results

Average peak knee joint forces during EAW with no added backpack loads were 0.88 BW, which is substantially lower than a previously defined osteogenic threshold [2]. Adding backpack loads increased average peak knee forces to up to 1.09 BW, resulting in linear increases in BDI (Fig.1A-C). More interestingly, adding a backpack load of just 10lbs reduced the number of EAW steps per day by 64%, from ~1,400 to ~500 steps to maintain a

BDI of 1.75 (Fig.1C-D). These results are exciting because many persons with SCI cannot take several thousands of EAW steps per day.

Discussion

The results from this simulation study suggest that addition of modest backpack loads during EAW may greatly improve bone mechanical stimulus in persons with SCI.

Images (Optional)

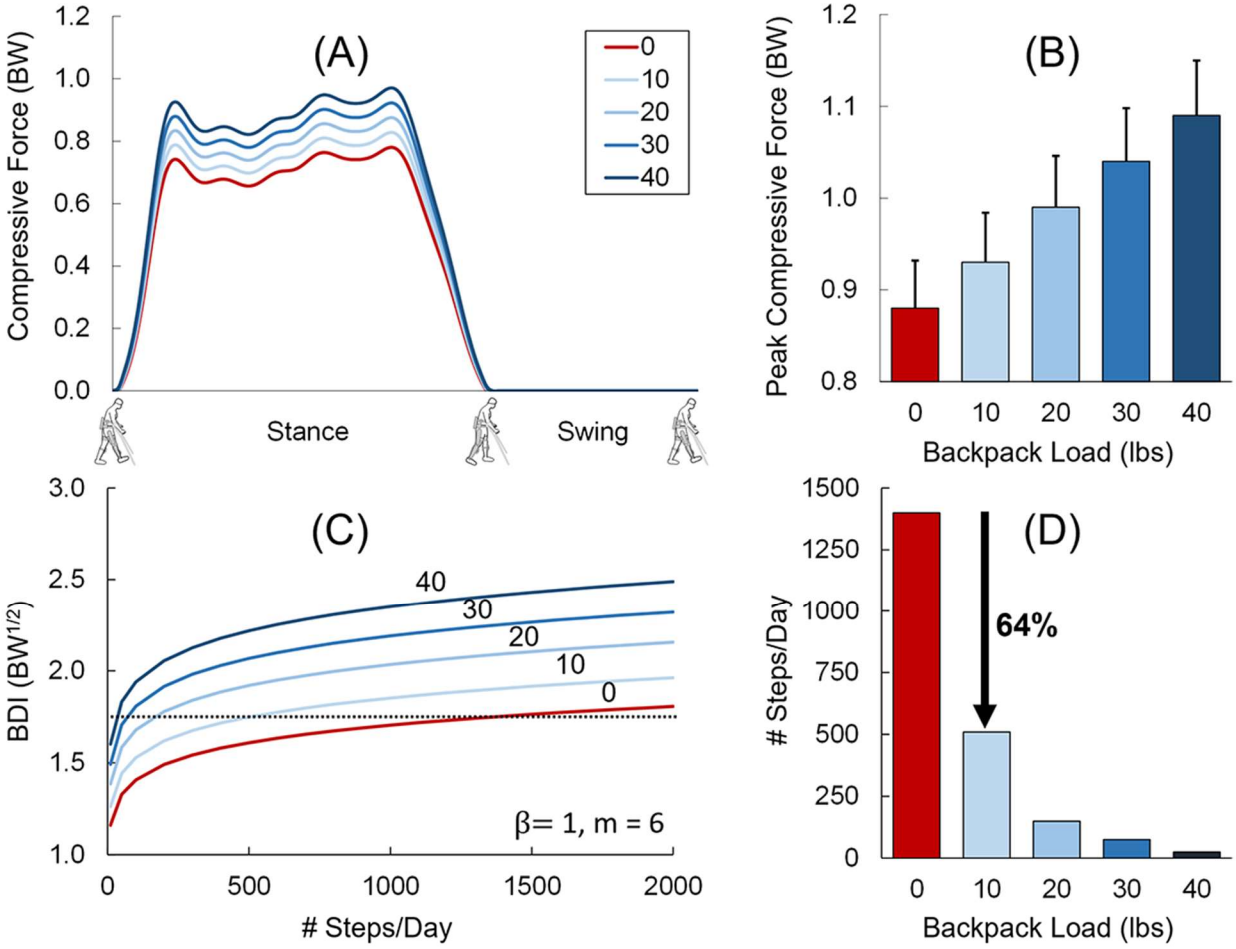

Figure 1. (A-B) Average knee compressive forces from 3 participants with SCI were computed during EAW with 0 to 40lbs backpack loads. The error bars represent +1 SD. (C) BDI was calculated from the peak knee compressive forces and number of steps of EAW per day for each backpack load condition. The horizontal dotted line denotes a representative BDI of 1.75. (D) Number of steps per day to maintain a BDI of 1.75 for each backpack load condition was highly non-linear. Our results show a 64% decrease in the number of steps required per day with a 10lb backpack load.

OA33-03

Biological Ankle Mechanics During Walking with an Ankle Exoskeleton and Limb Angle Feedback in Individuals with Chronic Stroke

Mr. Steven Thompson BS[1,2], Dr. Jason Franz PhD[1,2], Dr. Gregory Sawicki PhD[3], Dr. John Baratta MD, MBA[1], Dr. Michael Lewek PT, PhD[1]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States. [2]North Carolina State University, Raleigh, NC, United States. [3]Georgia Institute of Technology, Atlanta, GA, United States

Introduction

Following stroke, reduced paretic ankle plantarflexor moment and trailing limb angle (TLA) contribute to decreased paretic propulsion. Ankle exoskeletons (EXOs) address reduced ankle moment by supplying torque in parallel with weakened plantarflexor muscles. EXO assistance, however, does not reliably increase paretic propulsion due to concurrent reductions in TLA [1]. We addressed reduced TLA with visual feedback, but found that only TLA feedback, not EXO assistance, improved propulsion in those with and without stroke [2,3]. Here, to ascertain why EXO assistance did not improve propulsion, we investigated the role of human "motor slacking," in which users reduce their biological output, as a potential explanation. We predicted that as EXO assistance increased, biological ankle moment would decrease, resulting in no change in total mechanical output from the ankle during walking.

Methods

To date, seven individuals post-stroke walked at their comfortable speed while wearing an ankle EXO (Biomotum) providing paretic plantarflexor assistance (0%-,15%-,25%-body weight [BW]). Participants walked with each combination of EXO assistance and either no TLA feedback, feedback of typical TLA, or feedback of typical+5° TLA. We used inverse dynamics to obtain total ankle moment (peak and impulse). We subtracted EXO torque from the total to obtain the underlying biological contribution for comparison between conditions.

Results

Data from five participants are reported. Total peak ankle moment remained unchanged as EXO assistance increased (1.29±0.16, 1.30±0.15, 1.29±0.14 $Nmkg^{-1}$ for the 0%-,15%-,25%-BW EXO conditions), while peak biological moment appeared to decrease (1.29±0.16,

1.20±0.15, 1.17±0.13 $Nmkg^{-1}$, respectively) (**Fig. 1A**). Similarly, total ankle angular impulse remained largely unchanged while biological impulse appeared to decrease with EXO assistance (**Fig. 1B**).

Discussion

Here, EXO assistance did not enhance total ankle moment because of a reduction in biological ankle moment comparable to the prescribed EXO assistance. For some goals (e.g., reducing metabolic cost) motor slacking is a positive outcome. Conversely, to assist stroke survivors in augmenting gait capacity, preventing motor slacking is desired. Future work will instruct users to maintain biological ankle function while walking with an EXO to improve paretic propulsion and walking speed.

Back Exosuits Enhance Physical Therapy Outcomes Improving Recovery From LBP

Dr. D. Adam Quirk PhD[1], Dr. Diane Dalton DPT[2], Dr. Conor Walsh PhD[1], Dr. Lou Awad PhD[2]

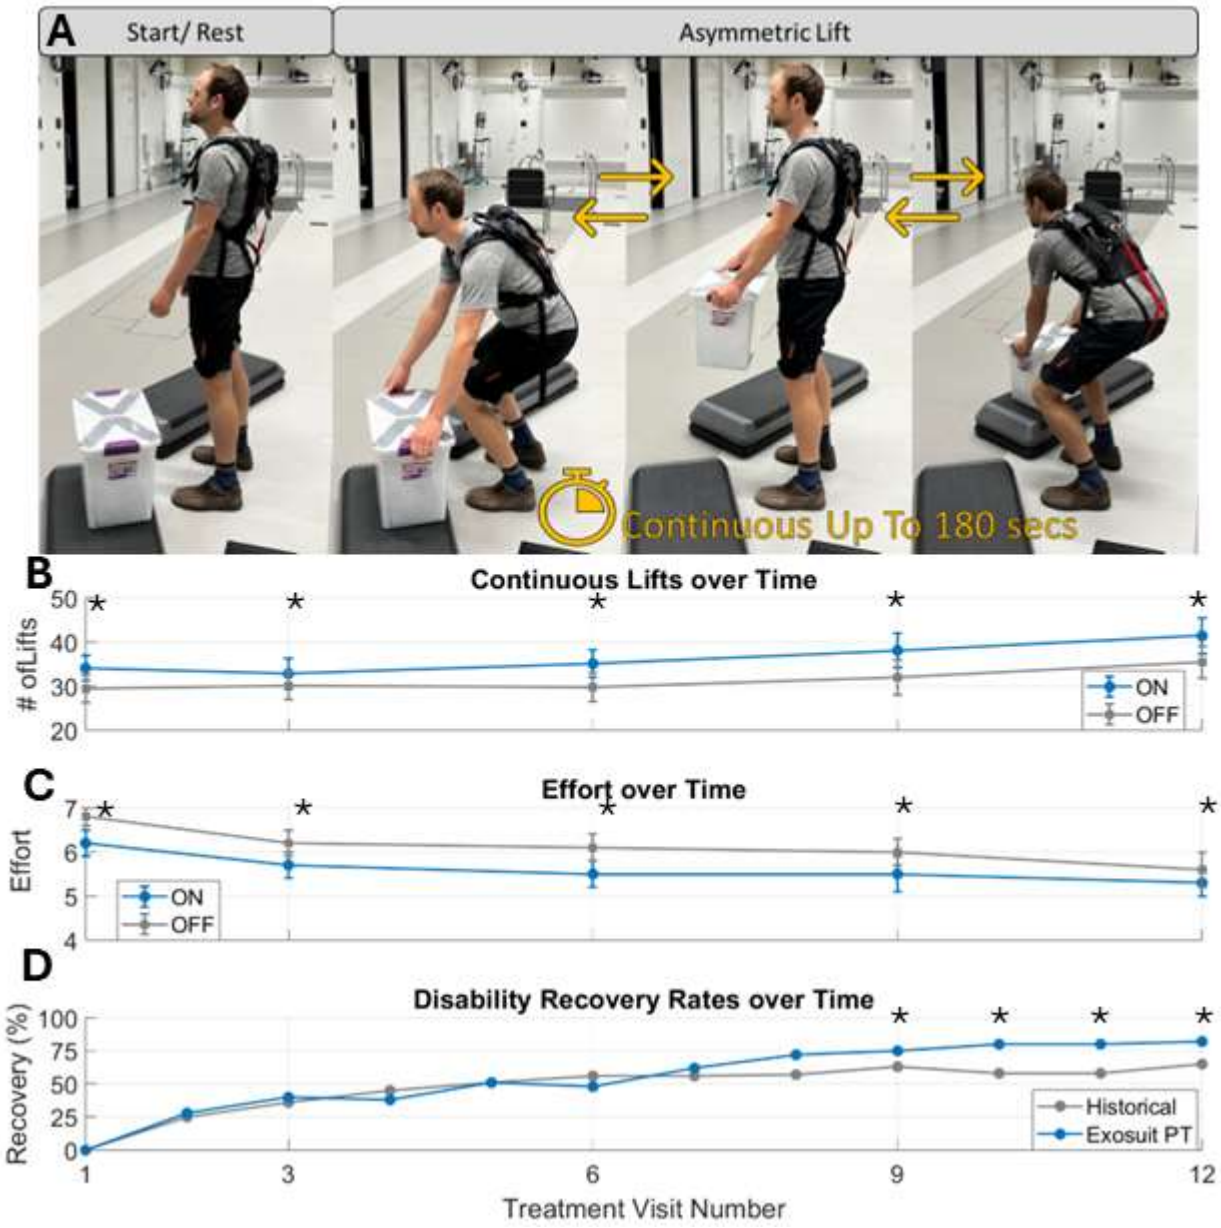
[1]Harvard University, Cambridge, MA, United States. [2]Boston University, Boston, MA, United States

Introduction

Low back pain (LBP) is a costly condition. With physical therapy (PT), one in three individuals with LBP will fail to recover, in part, due to pain and fear during exercise [1]. Wearable exosuits offload back muscles, making lifting tasks easier [2]. This study sought to determine whether a back exosuit could augment PT, hypothesizing that the device would enable individuals to complete functional activities with less effort, thereby improving recovery rates.

Methods

This single-arm clinical trial (CT) evaluated participants completing up to 12 PT visits, including the use of an exosuit [2]. On visits 1, 3, 6, 9, and 12, patient function was appraised using a 2.5-minute asymmetric lifting task performed with assistance ON and OFF (A). At each visit, modified disability questionnaires tracked recovery rates, defined as a 30% reduction in disability [1]. Recovery was compared with a historical control dataset of individuals who received PT at the same clinic without an exosuit, matched for LBP type, and selected to span a comparable age range, baseline disability, and pain-visit frequency to our CT. To assess effectiveness, generalized estimating equations were used to examine whether device assistance could change the number of lifts performed and perceived effort, and whether those in the CT would have a higher % recovery.



Results

44 participants completed 431 visits with the exosuit. Across all time points, compared to lifting with assistance OFF, individuals can complete 16% more repetitions (B) with a 9-10% reduction in perceived effort (C) with assistance ON ($p<0.001$). Compared with 300 matched control patients, group-by-visit interactions ($p=0.047$) showed higher recovery rates (13-22%) when PT is performed with an exosuit (D).

Discussion

We show that an exosuit can enable patients to complete more repetitions of functional activities with less effort over multiple PT visits. While recovery rates in our historical control group were consistent with the literature [1], we found that our clinical trial participants were more likely to recover from LBP, suggesting that exosuits may augment PT. However, these results will need to be confirmed in parallel randomized clinical trials.

3D-Printed Tunable Stiffness Chain-Mail Fabric With a Data-Driven Model Enabling Inverse Design for Rehabilitation and Assistive Devices

Mr Jiawen Xu PhD, Prof Ghita Oana Professor, Prof Evans Ken Professor, Mr Xijin Hua Dr

University of exeter, Exeter, Devon, United Kingdom

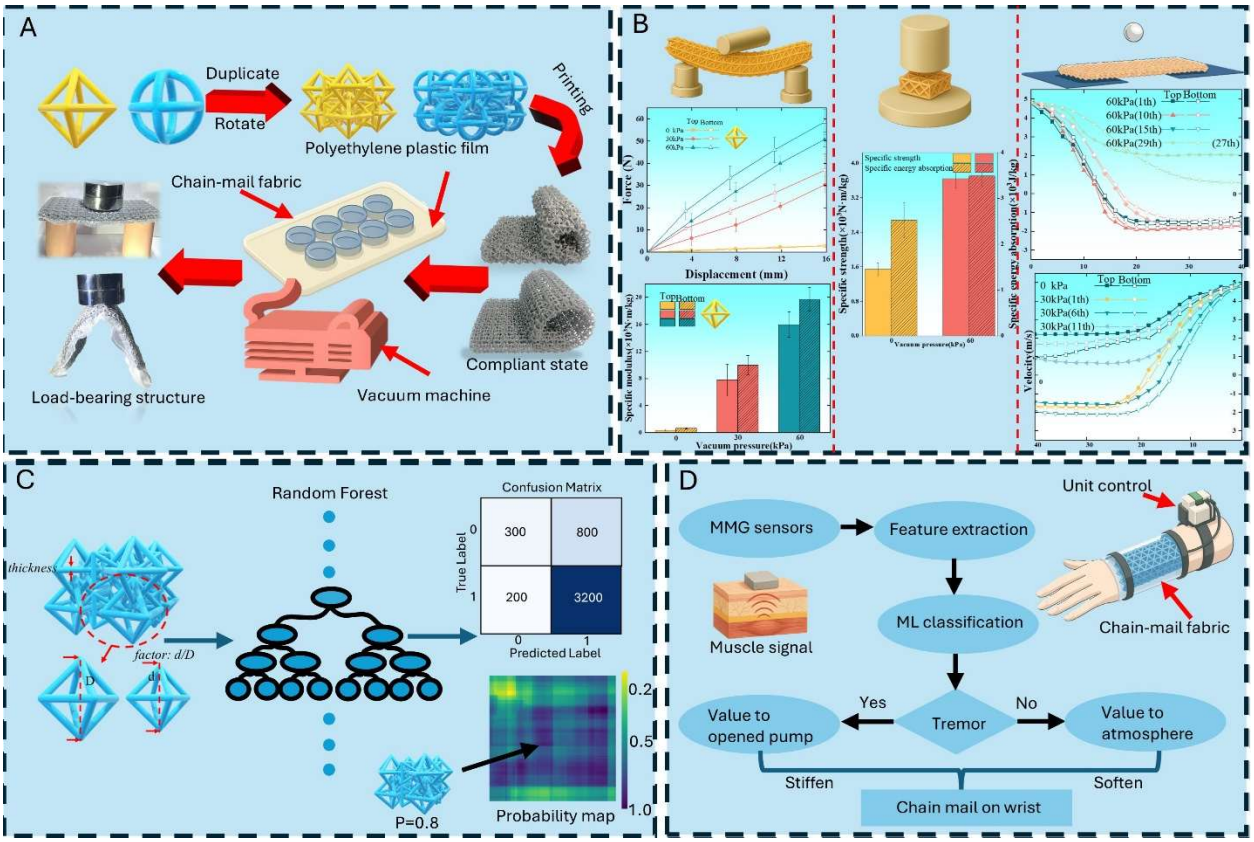
Introduction

Rehabilitation and occupational tasks require devices that stay compliant during natural motion yet rapidly stiffen to stabilize joints or support loads when needed[1]. Existing stiffness-modulation methods lack the mechanical robustness and adaptive performance required for applications such as tremor suppression in Parkinson's disease. We develop an interlocked chain-mail-inspired fabric that provides tunable, reversible, pressure-controlled stiffness for wearable rehabilitation devices via 3D printing, together with a data-driven inverse-design framework that enables application-specific customization of its mechanical response[2].

Methods

We 3D-printed hollow interlocking chain-mail particles and encapsulated them in a thin elastomeric membrane to form pressure-tunable fabrics (Fig. 1A). Compression, three-point bending, and low-velocity impact tests were performed to characterise stiffness modulation and energy absorption (Fig. 1B). A validated finite-element model was used to generate a stiffness–pressure database, on which a Random Forest classifier enabled inverse design of geometries within prescribed stiffness bands; the workflow and a conceptual wrist-support integration are shown in Fig. 1C–D.

Results



The chain-mail fabric exhibits more than an eight-fold increase in bending modulus upon vacuum-induced jamming. Pressure-dependent compression and impact tests further confirm that increasing confinement enhances load-bearing capacity and specific energy absorption, while maintaining reversible, repeatable stiffness over multiple cycles (Fig. 1B).Using the FE-generated stiffness–pressure dataset, the Random Forest surrogate achieved strong classification performance (F1 ≈ 0.84) and separated designs that do and do not meet the target stiffness band (Fig. 1C). Compared with surrogate GA and CMA-ES,

the RF-based inverse design reached >85% success after two FE evaluations and 100% after three, with improved robustness and design diversity.

Discussion

The experimental and computational results indicate that the inverse-designed tunable-stiffness chain-mail structures combine rapid stiffness activation with high flexibility in the unjammed state under loading and confinement levels relevant to wearable devices. These characteristics suggest that such fabrics are promising building blocks for future wrist and upper limb supports in rehabilitation and occupational settings, where the level of mechanical assistance can be tailored to individual needs, for example in tremor management and repetitive manual tasks.

Hip Exoskeleton Contributions to Leg Swing Initiation During Walking for Individuals Post-Stroke

Ms. Kristen Stewart[1], Dr. Gregory Sawicki[2], Dr. Aaron Young[2], Dr. Richard Neptune[1]

[1]The University of Texas at Austin, Austin, Texas, United States. [2]Georgia Institute of Technology, Atlanta, Georgia, United States

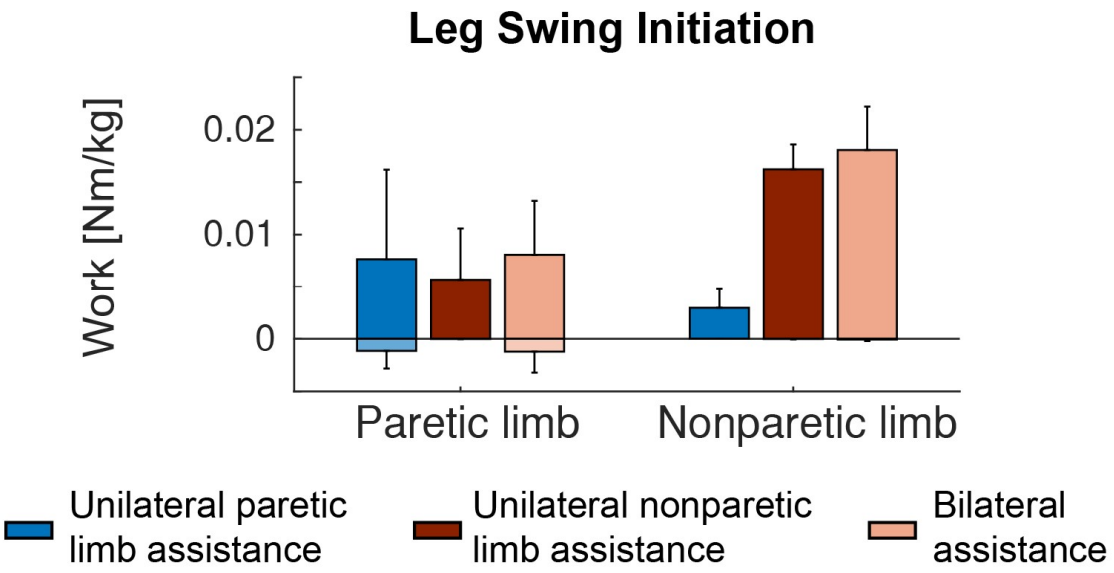
Introduction

Individuals post-stroke with hemiparesis often have asymmetric gait patterns, impaired paretic leg swing initiation [1] and reduced walking speed [2]. Bilateral hip exoskeleton assistance has been shown to improve walking speed [3], but such net measures may not fully reflect the exoskeleton's role in improving gait. Modeling and simulation can be used to determine the direct impact of exoskeleton assistance on gait mechanics. Further, it is unclear which limb assistance strategy most effectively improves walking performance given post-stroke inter-limb differences. The purpose of this study was to determine how a powered hip exoskeleton with different assistance strategies (unilateral versus bilateral) contributes to leg swing initiation during walking for individuals post-stroke. We expect that unilateral assistance will be more effective in directly providing swing initiation due to limb asymmetry.

Methods

Five individuals with chronic post-stroke hemiparesis walked on an instrumented treadmill with a powered Samsung hip exoskeleton with flexion-extension assistance in four conditions: unassisted (UN), unilateral paretic limb (P), unilateral nonparetic limb (NP) and bilateral (BI) assistance [3]. A 23 degrees-of-freedom model with 92 musculotendon actuators was scaled for each subject and simulations were performed in OpenSim [4]. A torque actuator with the exoskeleton controller was applied to the hip. Contributions to leg swing initiation were quantified by calculating the exoskeleton work delivered to the leg during pre-swing.

Results



P and BI assistance provided the greatest paretic leg swing initiation (0.0078 Nm/kg), while NP and BI assistance provided greater nonparetic leg swing initiation (0.017 Nm/kg) (Fig. 1).

Discussion

Individuals post-stroke have reduced pre-swing contributions from the paretic limb iliopsoas [1]. Thus, hip exoskeleton assistance acting with the hip flexors can increase

power for swing initiation. For the same assistance magnitude, more power was delivered to the nonparetic limb, which may help explain why only BI assistance improved walking speed [3]. These results begin to elucidate how exoskeleton assistance directly impacts walking performance, which cannot be measured experimentally. Next steps include investigating other biomechanical functions of walking.

CT-Based Workflow to Generate Subject-Specific Articular Cartilage Models

Ms Nancy Kim[1], Mr Marco Schneider[2], Ms Vickie Shim[1], Mr Thor Besier[1]

[1]Auckland Bioengineering Institute, Auckland, Auckland, New Zealand. [2]FormusLabs, Auckland, Auckland, New Zealand

Introduction

Computational models of the knee have promising clinical applications, but their uptake is limited by challenges in accurately segmenting and reconstructing patient-specific articular cartilage. Failure to capture cartilage surfaces, thickness, and edge boundaries can result in non-physiological stress concentrations and simulation convergence issues [1]. We present an approach to predict articular cartilage geometry using information from bone morphology. The advantage of this approach is that it is applicable to CT scans, which are less costly and more amenable to automated segmentation approaches than MR imaging.

Methods

Our workflow integrates bone point clouds (from segmented CT scans), cartilage thickness measurements (from population models), and subchondral bone surface normal of the femur, tibia, and patella (from fitted statistical shape models). Using these data, we performed a principal component analysis to predict cartilage geometry solely from bone morphology and validated the approach with leave one out analysis using manually segmented MR images from 51 participants.

Results

Fitting bone shape models to segmented geometries resulted in discrepancies below 0.3 mm across the femur, tibia, and patella (Figure 1). For cartilage, the median differences between predicted and segmented point clouds were 0.4 mm for the patella, 0.37 mm for the femur, 0.36 mm for the lateral tibial cartilage, and 0.34 mm for the medial tibial cartilage.

Discussion

Considering MRI voxel sizes of 0.3 × 0.3 × 1.0 mm and manual segmentation errors ranging from 0.1 to 0.5 mm, these results indicate prediction within expected error margins [2]. Our new approach accurately predicted femoral and tibial cartilage, particularly in the central region of the joint. Patellar cartilage predictions were not as good, but further refinement with larger datasets might improve these predictions. Extending cartilage boundaries could

help to reduce stress concentrations by providing smoother transitions at cartilage margins. The comparison between cartilage predicted from articulated bones and from individual bones is currently in progress, along with mesh generation from the predicted cartilage point clouds.

A Biomechanical Assessment of a Two-Foot Vertical Jump at Baseline, 6-month and 12-month following Return to Play from ACL Reconstruction

Mr. Pratham Singh, Dr. Timothy Burkhart

University of Toronto, Toronto, ON, Canada

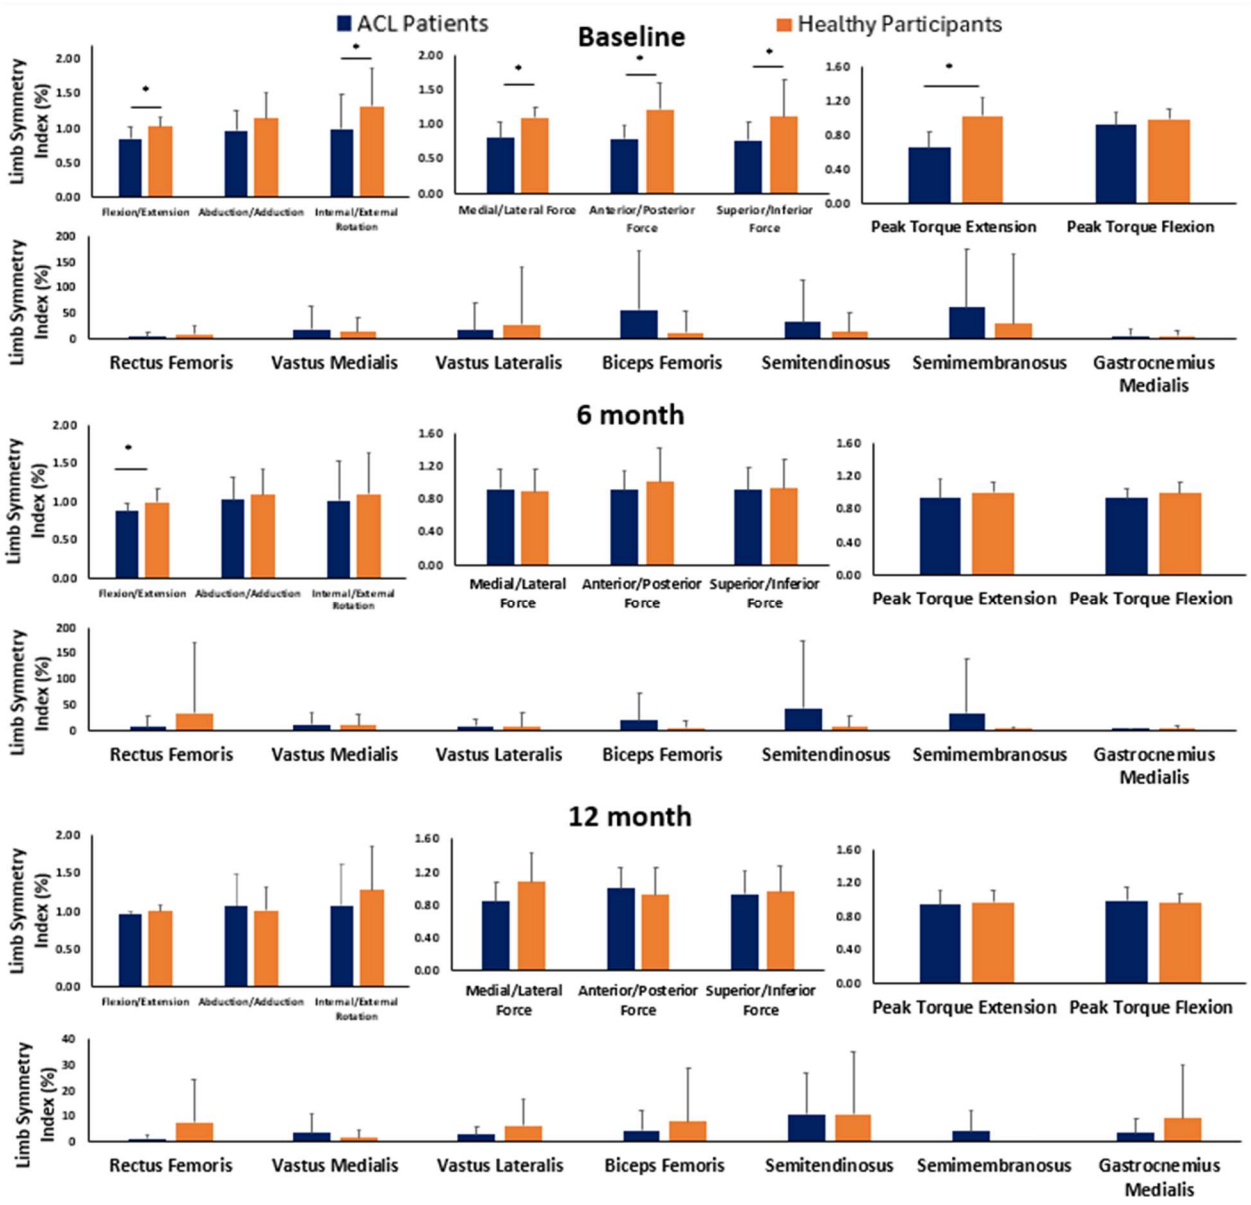
Introduction

Approximately 3% - 30% of ACL reconstruction patients experience re-injury following return-to-play (RTP) [1]. Current RTP tests do not assess the neuromuscular strategies that a patient may adopt. Therefore, the purpose was to quantify knee biomechanics in ACLR patients in response to a two-foot vertical jump.

Methods

Data was collected on 27 ACLR patients who had been cleared to return to sport (M:14; F:13; Age: 24.92 [5.14]) and 27 recreationally active healthy participants (M:17; F:10; Age: 24.44 [3.27]). Motion data, ground reaction forces (GRFs) and muscle activations were collected while a two-foot vertical jump was performed. Data were analyzed from landing to 200ms after landing. Each patient also performed resisted knee extension/flexion on a dynamometer. Limb symmetry index (LSI = involved limb/uninvolved limb) was quantified for all variables.

Results



At baseline, the ACL patients had a significantly lower LSI than the healthy participants for knee flexion/extension (0.85 vs 1.02) as well as knee internal/external rotation (0.98 vs 1.32) angles. The ACL patients also had significantly smaller LSI values for GRFs in the AP (0.80 vs 1.10), ML (0.78 vs 1.21) and SI (0.76 vs 1.10) direction. The ACL patients also had significantly smaller LSI values for peak torque extension (0.66 vs 1.03) on the dynamometer. There was no significant difference in LSI values of muscle activation patterns. After 6 months, ACL patients had significantly lower LSI for knee flexion/extension (0.87 vs 0.99) angles. After 12 months, there was no significant difference in LSI values for knee joint kinematics, GRFs, muscle activation patterns or peak torque values.

Discussion

Despite greater peak muscle activation being observed, strength deficits in the involved limb persisted up to 12 months post RTP (baseline). This may indicate that neuromuscular contributions are adapting to injury where increased neural drive is required to achieve similar or less output. This may indicate that these patients were not yet ready to RTP

despite passing a commonly used vertical jump test. Understanding neuromuscular contributions during dynamic movements may provide a better indication of when patients are ready to RTP following ACLR.

Walking With Enhanced Ankle Plantarflexor Muscle Leverage Modulates Muscle Neuromechanics in Older Adults

Dr. Daniel Davis[1], Mr. Andrew Peterson[1], Dr. Jason Franz[2], Dr. Kota Takahashi[1]

[1]University of Utah, Salt Lake City, UT, United States. [2]UNC Chapel Hill and NC State, Chapel Hill, NC, United States

Introduction

Musculoskeletal impairment reduces quality of life and longevity. Deficits in the ankle plantarflexor musculature with age are particularly impactful [1], given these muscles' importance to walking function. Changes in plantarflexor muscle operating condition in younger adults - slower fascicle shortening and increased force - have been demonstrated when walking with greater ankle muscle leverage via increased footwear longitudinal bending stiffness [2]. Improvements to muscle force-velocity behaviour position footwear stiffening as a potentially useful intervention for improving plantarflexor muscle function and overall walking performance in older adults. Thus, the purpose of the present study was to examine plantarflexor muscle operating conditions in older adults when walking with greater footwear bending stiffness.

Methods

Twenty older adults (9F; 70±6 yrs) walked at 1.2 m/s in three different footwear stiffness conditions (termed Low, Medium, and High stiffness). We employed cine B-mode ultrasonography and motion capture to characterize stance-phase medial gastrocnemius (MG) and soleus fascicle dynamics and surface electromyography to quantify stance-phase muscle excitation. We compared variables across conditions using one-way repeated measures ANOVA and post-hoc pairwise comparisons.

Results

Ultrasound data for three participants were excluded due to image quality issues. Enhancing plantarflexor muscle leverage via increased footwear stiffness slowed the average stance-phase fascicle velocity for the MG ($p=0.02$) and soleus ($p<0.01$) (Figure 1A&D). Stance-phase integrated excitation increased with greater stiffness for the MG ($p=0.02$; Figure 1B) but not the soleus ($p=0.79$; Figure 1E). Lastly, greater footwear stiffness increased average estimated MG and soleus muscle forces (both $p<0.001$; Figure 1C&F).

Discussion

Older adult ankle plantarflexor muscle operating conditions, specifically shortening velocity and estimated force, were improved when walking with greater plantarflexor muscle leverage via footwear stiffening. Acutely, improving plantarflexor muscle function may enhance older adult's capacity for meeting the propulsive demands of everyday walking. Used as a longer-term intervention, the increase in muscle force and medial gastrocnemius excitation could serve as useful stimuli to address age-related ankle muscle atrophy and subsequent walking performance deficits.

Images (Optional)

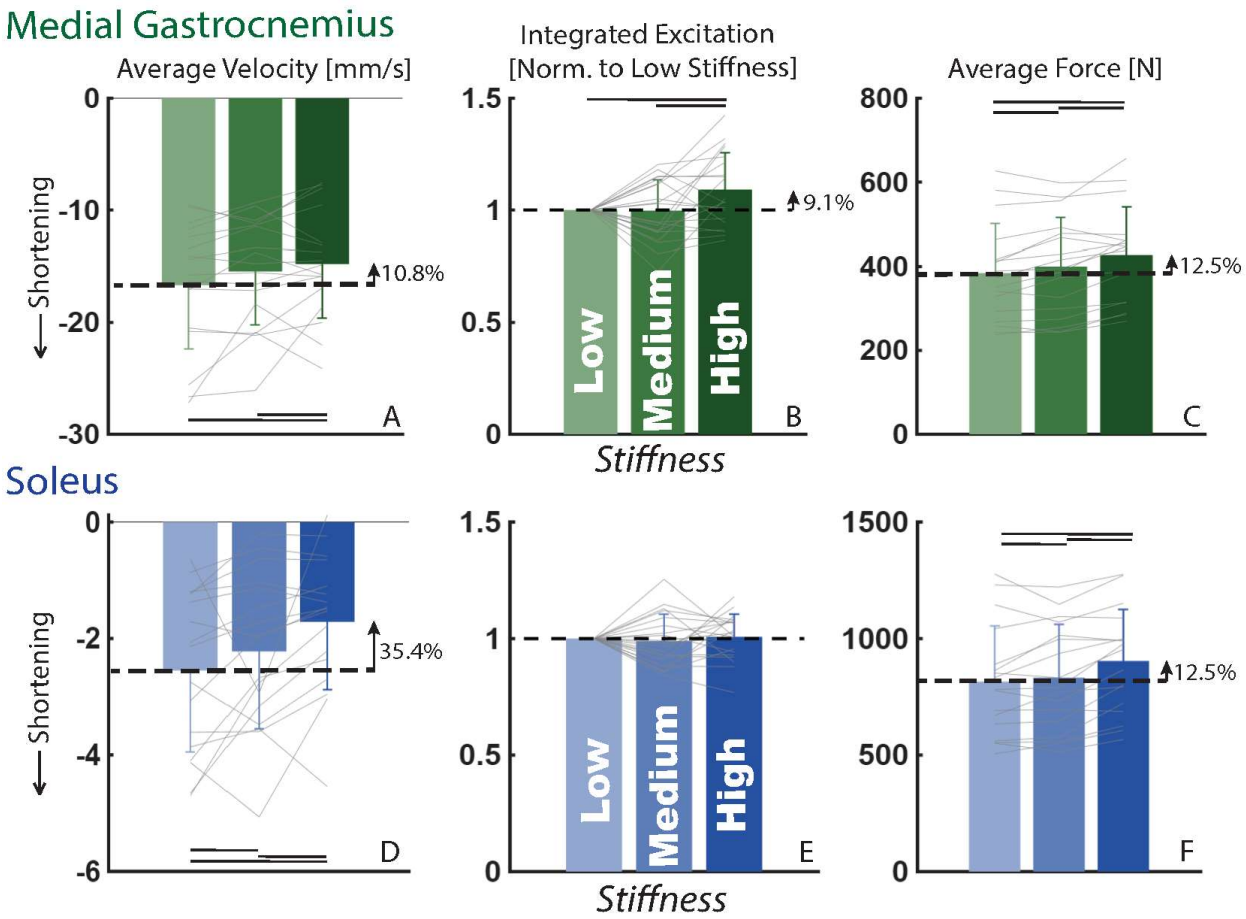

Figure 1: Medial gastrocnemius (top row) and soleus (bottom row) stance-phase average velocity (panels A & D), integrated excitation normalized to the Low stiffness condition (B & E), and stance-phase average force along the fascicle (C & F). Increasing footwear stiffness is represented by darkening color from left to right. Horizontal bars indicate statistically significant pairwise differences ($p < 0.05$).

Longitudinal Analysis of Hip Joint Contact Pressure in Growing Children using Subject-Specific Multi-Scale In-Silico Simulations

Dipl.-Ing. Kevin Kitir[1], Dr. Alexander Synek[2], Univ.-Prof. Dieter Pahr[2], Assoc.-Prof. Hans Kainz[1]

[1]University of Vienna, Vienna, Vienna, Austria. [2]Technical University of Vienna, Vienna, Vienna, Austria

Introduction

Mechanical loading plays a central role in skeletal development during childhood. While bone adaptation has been widely studied [1,2], considerably less is known about how articular cartilage responds to loading during growth. Finite Element (FE) studies in pediatric hip dysplasia have shown abnormally high peak contact pressures [3], but investigations in typically developing children are scarce and mostly cross-sectional. Understanding longitudinal changes in physiological hip joint loading is essential for establishing normative reference data and identifying early deviations preceding orthopedic disorders. **We hypothesized that growth-related increase in body weight is compensated by increased contact area due to bone growth, maintaining relatively stable cartilage contact pressures over time** [4].

Methods

Typically developing children underwent MRI-based anatomical imaging and gait analysis at two time points approximately two years apart. Subject-specific 3D models of pelvis, femur, and hip cartilage were reconstructed from MRI using manual segmentation for bone and parametric extrusion for cartilage. Musculoskeletal simulations based on MRI-informed models were used to calculate joint kinematics and joint contact forces, which served as boundary and loading conditions for FE simulations. For both time points, peak contact pressures (95th percentile) were computed throughout the stance phase of a representative gait trial.

Results

Data of three from nine available participants was analysed so far. Contrary to our hypothesis, preliminary results indicate an increase in cartilage contact pressure between time points in both qualitative and quantitative comparisons (Figure 1). However, given the

small preliminary sample and marked inter-subject variability, paired t-tests did not reach conventional statistical significance ($\alpha = 0.05$).

Discussion

Although preliminary and limited by sample size, these results suggest that hip cartilage loading may increase during growth despite structural adaptation. The proposed longitudinal pipeline demonstrates the feasibility of combining MRI, motion analysis, musculoskeletal modeling, and FE simulation in pediatric cohorts. The emerging normative data will support future comparisons with orthopedic pathologies and may help identify early indicators of abnormal joint loading.

Graph Neural Network Surrogates for Finite Element Modeling of Femur Mechanics: A Comparative Study

Ms Sikha O K[1], Mr Morteza Rasouligandomani[1], Ms Elham Alizadeh[1], Mr Jakka Prasad[1], Mr Sai Natarajan[1], Mr Miguel A González Ballester[1,2], Mr Ludovic Humbert[3], Mr Jérôme Noailly[1], [4]

[1]Universitat Pompeu Fabra, Barcelona, Barcelona, Spain. [2]Icrea, Barcelona, Barcelona, Spain. [3]3D-Shaper Medical, Barcelona, Barcelona, Spain. [4]

Introduction

Finite Element analysis is the standard for femur biomechanics but is computationally expensive.Machine-learning surrogates—especially Graph Neural Networks (GNNs)—provide a faster alternative by modeling FE meshes as graphs (nodes ↔ mesh-nodes, edges ↔ connectivity) and predicting node-level stress/strain [1,2]. This study compares hybrid deep-GNNs to find models that best balance accuracy, speed, and generalizability for femur biomechanics.

Methods

Figure.1 illustrates the surrogate-modelling workflow. We analyzed 128 FE femur models (64 controls, 64 fractures) with lateral-fall simulations, generating mechanical fields at 132,120 nodes and 126,800 hexahedral elements. FE meshes were converted to graphs, with nodes representing FE nodes and edges encoding connectivity. Each node included geometric labels, femoral parameters, density-derived stiffness, and spatial coordinates, and the model predicted six node level stress values. Graphs were normalized and trained using a DeepHybridGNN combining GIN(MLP-aggregation), GraphSAGE(stabilizes neighbor propagation), and GAT(weights neighbors via attention) within residual blocks (prevent overfitting). Training used neighborhood sampling, Adam optimizer with Smooth L1 loss,LR 0.0005, gradient accumulation, mixed precision, and a plateau-based LR scheduler, with all graph splits and normalization statistics verified beforehand.

Results

The results in Table.1 show that incorporating richer anatomical and mechanical features substantially improves surrogate performance. Models using only density and spatial coordinates (GIN–SAGE–GAT) achieve moderate accuracy, with $R^2 \approx 0.36$-0.44 and MAE ≈ 3.6–4.5. Increasing hidden dimensions does not improve performance, suggesting limited

benefit from scaling depth alone. In contrast, the SAGE–GAT model using geometric labels, femoral parameters, and nodal stiffness achieves a much higher R^2 (0.85–0.87) and markedly lower MAE, indicating that feature quality—rather than architecture size—is the dominant factor in accurately predicting node-level stress fields.

Discussion

GNNs can effectively surrogate finite-element femur models, predicting node-level stress with much lower computation time. Models using detailed biomechanical features outperform those with only density and coordinates, highlighting the importance of informative inputs. The DeepHybridGNN, combining GIN, GraphSAGE, and GAT, captures both local and global structure, offering a fast and accurate framework for clinically scalable fracture risk assessment.

OA35-03

Sensor-less Prediction of Posture-Specific Peak Interface Pressures from Anthropometry Using Machine Learning

Ms. Seohyun Lee M.S. Candidate, Ms. Seoyoung Kim Undergraduate Student, Prof. Taeyong Lee Ph.D.

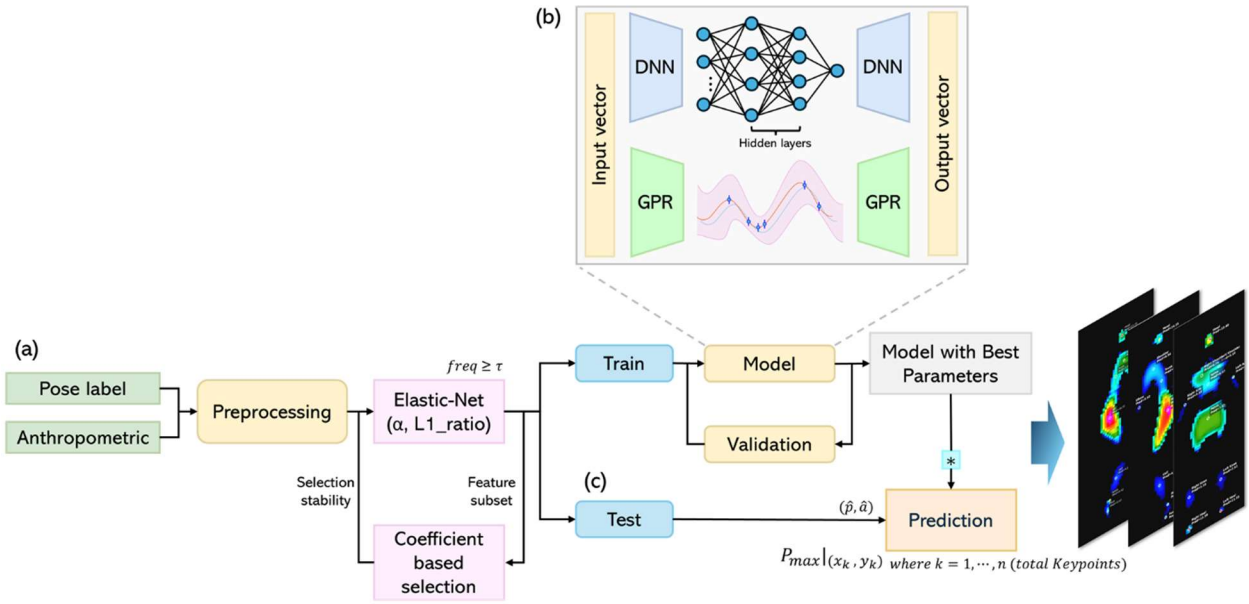
Ewha Womans University, Seoul, Seoul, Korea, Republic of

Introduction

Pressure ulcers are a major complication in immobilized patients, yet most predictive systems either stratify patient-level risk from electronic health records or reconstruct pressure maps using dedicated sensors, with few models directly estimating posture-specific interface pressures from anthropometry alone. This study proposes a sensor-less, machine learning–based framework that predicts peak interface pressures at ulcer-prone regions using a minimal set of anthropometric variables.

Methods

Interface pressure and overhead RGB data were collected from 81 adults in standardized supine, left-lateral, and right-lateral postures. Peak pressures were extracted by reconstructing 32 × 64 pressure maps, detecting local maxima, and mapping these to ulcer-prone regions via MediaPipe-based skeletal landmarks. Using BMI, body weight, waist circumference, and hip circumference as inputs, region-wise deep neural network (DNN) and Gaussian process regression (GPR) models were trained with 5-fold GroupKFold cross-validation, Elastic-Net–based stable feature selection, and permutation importance analysis. To evaluate usability, test samples were categorized as intra-range or extra-range depending on whether all anthropometric values lay within or outside the training bounds.



Results

Cross-validated performance across 27 posture–region combinations was high, with R^2 values of approximately 0.82–0.98 (grand mean ≈ 0.93) and MAE values of 0.06–0.59 kPa (mean ≈ 0.22). The DNN slightly outperformed the GPR overall (R^2 ≈ 0.94 vs. 0.93; MAE ≈ 0.21 vs. 0.24). In intra-range tests using inputs within the training anthropometric bounds, the DNN achieved R^2 ≈ 0.93 with MAE ≈ 0.29 kPa, whereas the GPR achieved R^2 ≈ 0.89 with MAE ≈ 0.36 kPa. Under extra-range conditions, the DNN and GPR attained R^2 ≈ 0.85/0.77 and MAE ≈ 0.44/0.65 kPa, respectively.

Discussion

These findings show that posture-specific peak interface pressures can be estimated from a compact anthropometric feature set without pressure sensing at prediction time, enabling low-cost, sensor-less, individualized pressure-risk estimation that is agnostic to bed hardware or camera availability. However, the current framework is limited to static posture snapshots and does not model temporal changes in pressure during repositioning. As a next step, the model will be extended to predict how interface pressures decrease as the bed or trunk angle is gradually adjusted, enabling angle-specific guidance for pressure-relief maneuvers.

OA35-04

Generating Physically Realistic Footwear Contact Pressure Distributions with Diffusion Models

Mr. Gerard Aristizábal Pla, Prof. Kurt Beschorner

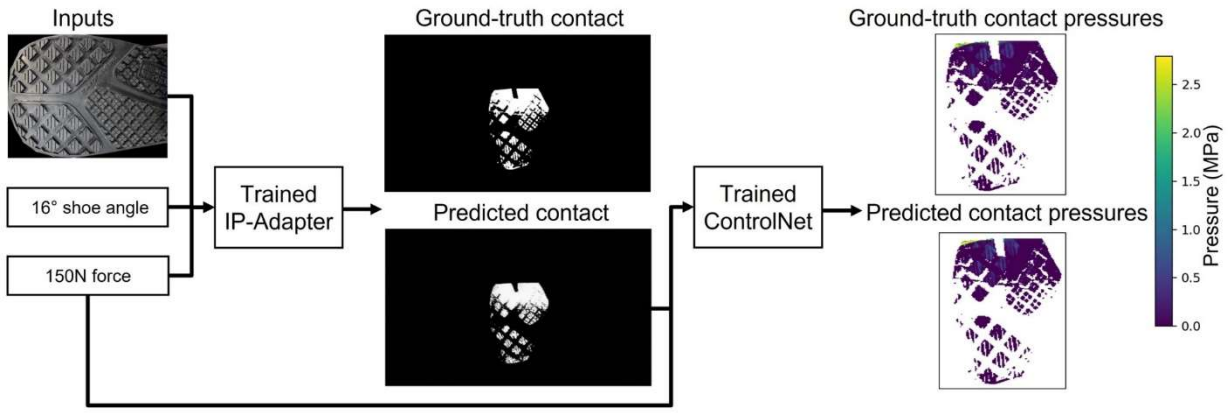
University of Pittsburgh, Pittsburgh, Pennsylvania, United States

Introduction

Diffusion models excel at image generation with flexible input prompts. Their use in biomechanics, where outputs must be realistic, remains underexplored. Shoe-ground contact mechanics are a biomechanical metric relevant to user performance and safety that may be predicted by diffusion models. We evaluated diffusion models for predicting shoe-tread contact pressure distributions trained from frustrated total internal reflection (FTIR) data.

Methods

A method that calibrates and converts pixel intensities from FTIR to vertical force was used to capture pressure maps for 10 shoes at varying shoe angles and force levels (using ~1500 frames of data). For generative modeling, we fine-tuned two large Stable Diffusion–based models (≈860M parameters each), ControlNet and IP-Adapter (Figure 1). IP-Adapter [1] predicted contact masks from smartphone outsole images, foot angles, and vertical forces (evaluated using Dice score). ControlNet [2] generated pressure distributions from contact masks and force inputs (evaluated using mean absolute error, MAE). During fine-tuning, only LoRA adapters attached to the U-Net attention layers were trained (≈5–8M trainable parameters), while the base diffusion weights and the VAE remained frozen. All models were trained and evaluated using leave-one-shoe-out cross-validation to assess generalization to unseen footwear and variability in loading conditions, with each fold trained for 30 epochs (~20,000 optimization steps). To incorporate biomechanical inputs, the U-Net was conditioned on force and foot-angle scalars via positional encodings.



Results

The FTIR intensity-to-force calibration achieved an average R^2 of 0.97. Across ten folds, ControlNet produced pressure maps with a mean MAE of 2 kPa, and IP-Adapter generated contact masks with a mean Dice score of 0.61.

Discussion

A sequence of diffusion models was developed and was able to accurately predict contact regions and pressures within these regions. ControlNet produced pressure distributions that learned physics, whereas the IP-Adapter generated contact regions from readily available visual and biomechanical inputs. Together, these findings show that diffusion models can generate physically realistic pressure distributions across diverse footwear conditions. Future work can extend generalizability of this model and integrate it within footwear digital twins.

Development of a Novel Neural Network-Based Approach for Estimating Ground Reaction Forces From Kinematic Data in Gait Analysis

Mr. Giulio Rigoni[1], Ms. Maria Dalle Vacche[1], Mr. Oier Zazpe[1,2], Ms. Federica Beghetti[1], Ms. Fabiola Spolaor[1], Prof. Damiano Varagnolo[1], Prof. Zimi Sawacha[1]

[1]University of Padova, Padova, Veneto, Italy. [2]Mondragon Unibertsitatea, Mondragòn, Basque country, Spain

Introduction

Kinematic and kinetic data (i.e., ground reaction forces, GRFs) are pivotal to human movement analysis. The growing need for real-world applications requires gathering these data out of laboratories. Even though this has been partially covered by markerless motion analysis, the provision of GRFs in absence of force plates is still an open challenge.

The present study aims to present a novel Spatio-Temporal Graph Convolutional Network (ST-GCN) based approach to predict GRF from solely kinematics input and seeks to assess its accuracy in regards to different state of the art GRF estimation methods.

Methods

A ST-GCN to predict the 3 GRF components during gait was developed based on 19 marker trajectories (IORgait protocol) maximizing informativeness through Partial Least Squares regression. Graph neural network approach was applied to implement awareness of markers spatial connections. 401 complete gait cylces were collected (8 Vicon cameras, 2 Bertec force plates) from 39 healthy (45.40 ± 20.47 years; 24.58 ± 3.57 kg/m^2) and 26 Parkinson's Disease individuals (70.74 ± 7.56 years; 25.78 ± 3.39 kg/m^2) and used as training dataset. The resultant GRFs were compared with 3 state of the art GRF estimators: OpenGRF [1]; GaitDynamics [2]; an image-based NN [3] re-trained on the same proprietary dataset. The validation of all four solutions was performed by comparing the predicted GRFs with the experimental one of 10 healthy individuals (22.70 ± 2.60 years; 21.16 ± 2.59 kg/m^2) not included in the training; RMS, coefficient of multiple correlation (CMC), and SPM [4] were used as comparison metrics.

Results

The ST-GCN training phase achieved an overall root mean square error (RMS) of 0.633 N/m.

Both GaitDynamics and the image-based NN reported the highest correlation (CMC > 0.81) and the lowest RMS (**Figure 1**). Among the three GRF components, the mediolateral direction revealed the lowest agreement.

Discussion

In this study, NN demonstrated a potential for on the field GRFs estimation. Future developments will focus on expanding the training dataset, including additional tasks as well as pathologies.

OA36-01

An Experimental Framework for Measuring Trabecular Bone Strains Surrounding Pedicle Screws

Ms Léa Slive, Ms Ye Young Shin, Prof Martine McGregor PhD, Prof Stewart McLachlin PhD, Prof Jonathan Kusins PhD

University of Waterloo, Waterloo, Ontario, Canada

Introduction

Pedicle screws are essential for postoperative construct stability in spinal fusion surgeries. However, screw loosening remains a common clinical complication, with a reported prevalence of ~13% at 6 months postoperatively [1], often linked to excessive loading that induces damaging trabecular bone strains at the screw–bone interface. This study aims to enhance pre-clinical assessment of pedicle screw fixation by establishing the feasibility of combining microCT imaging with digital volume correlation (DVC) techniques to directly characterize internal trabecular bone strains at the screw–bone interface.

Methods

Pedicle screws were surgically implanted into human lumbar vertebrae specimens (n=6). Each specimen underwent microCT imaging (225 kV, 150 µA, 37.5 µm voxel size) (Figure 1). For three specimens, paired unloaded scans were analyzed using a standard DVC uncertainty workflow. To mitigate local bone–metal artifacts, bone segmentation was performed using a deep learning convolutional neural network with a U-net architecture, trained on 90 independently annotated slices from the six vertebrae (training: 48 slices, validation: 12 slices, testing: 30 slices). Segmentation accuracy was quantified using the Sørensen-Dice similarity coefficient. DVC trabecular bone strain measurement accuracy and precision was evaluated within peri-screw volumes of interest (VOIs) defined as proximal, middle, and distal along the screw trajectory. VOI differences were analyzed using the Friedman test (α=0.05).

Results

The deep learning model reproduced manual segmentations with high fidelity (Dice=0.90). DVC accuracy and precision depended on the spatial resolution of strain measurement; at a spatial resolution of 2.4 mm, strain estimates were reliable with low error across all peri-screw bone VOIs (accuracy: 316±82 µε; precision: 195±78 µε). No significant differences in strain errors were observed between VOIs along the screw trajectory (p=0.052).

Discussion

This study established a DVC workflow for quantifying experimental strains surrounding pedicle screws. Coupling deep learning segmentation with DVC enabled spatially resolved strain measurements along the bone–screw interface which can complement traditional pullout tests by revealing how load is transferred into surrounding bone. This workflow provides a foundation for future studies involving loaded tests, further optimization of imaging/segmentation to suppress artifacts, and validation across larger cohorts and implant designs.

Images (Optional)

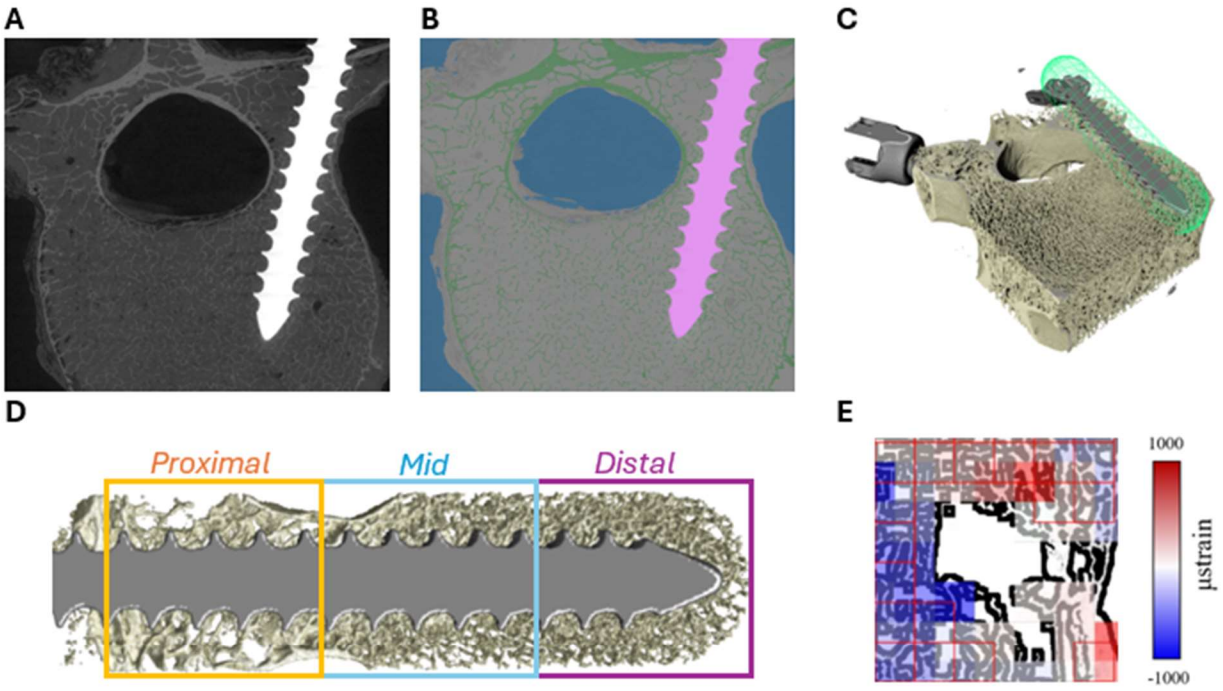

Figure 1 : *MicroCT images (A) were acquired of vertebrae samples implanted with pedicle screws. Annotation (B) was performed to generate training data for deep learning–based segmentation of the bone–implant region. An isometric three-dimensional rendering of the bone–implant interface (C) is shown, with varying volumes of interest (VOIs) defined and analyzed (D). These VOIs were subsequently used for volumetric trabecular bone strain analysis (E).*

Pre-Clinical Mechanical Evaluation of Anatomically and Mechanically Conforming Patient-Specific Spinal Fusion Cages Designed by Full-Scale Topology Optimization

Dr. Xiaoyu Du, Dr. Thijs Smit, Mr. Charles Cheruparambil, Prof. Stephen Ferguson

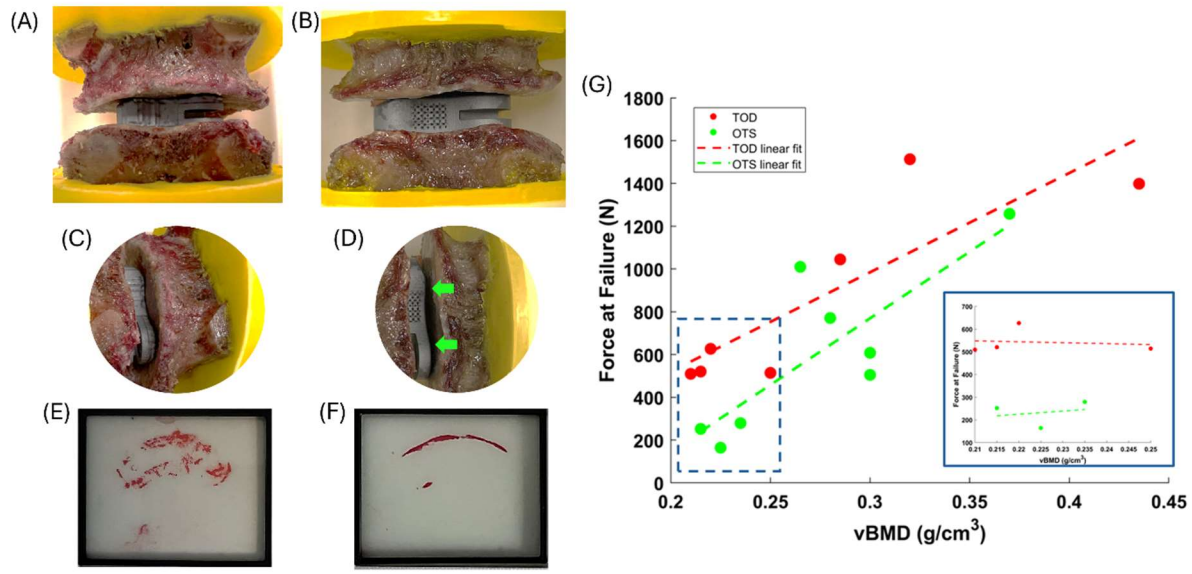
ETH Zurich, Zurich, Zurich, Switzerland

Introduction

Lumbar disc herniation often necessitates fusion surgery when conservative care fails. However, subsidence remains a concern due to the stiffness mismatch between the cages and the vertebral bone. Although porous and lattice architectures aim to reduce stress, they overlook patient-specific variation. Topology optimization offers individualized implant design to improve load distribution and minimize local stress peaks within the underlying bone [1]. This pre-clinical mechanical evaluation study aims to clarify the potential of anatomically and mechanically conforming patient-specific implants to reduce stress in the endplates and vertebral bodies, thereby mitigating subsidence.

Methods

Six human lumbar spines yielded sixteen functional spinal units (FSUs), which were allocated by bone density to topology-optimized (TOD) or off-the-shelf (OTS) groups. Each FSU underwent micro-CT imaging, potting, and implantation according to standard surgical methods. TOD and OTS cages were 3D-printed using titanium alloy and evaluated using pressure film to visualize endplate contact. Compression testing to failure (1 mm/min) was performed on a dynamic testing machine (Instron E10000) with optical displacement tracking (Epsilon). After testing, a force-displacement curve was generated, and the force at subsidence/failure was determined by the first local maximum of the force measurement for each FSU.



Results

The pressure film measurements illustrate that the TOD implants produced broader, more uniform endplate contact, whereas OTS implants showed concentrated edge loading. Mean subsidence force was higher with TOD (875 N; range 510–1513 N) than OTS (606 N; range 164–1258 N). Both groups showed increasing subsidence force with higher vBMD (integral volumetric bone mineral density), though correlations were weak. In low-vBMD FSUs, TOD implants performed significantly better (552 ± 65 N vs. 232 ± 60 N).

Discussion

These findings suggest that subsidence risk can be meaningfully reduced through implant topology optimization rather than material changes. The personalized TOD design improved endplate conformity and contact distribution, which has been shown to reduce local stress peaks while mimicking bone-like mechanical behavior with minimal material use. TOD implants showed higher forces at subsidence than OTS, especially in low-vBMD spines, highlighting their advantage for fragile bone. Limitations include small sample size and cadaveric specimens.

Hyperhydration and Endplate-Annulus Disintegrity Provoke Cervical Disc Herniation - An In Vitro Study

M.Eng. Ann-Kathrin Greiner-Perth, PhD Morten Vogt, PhD Christian Liebsch, Prof. Dr. Hans-Joachim Wilke

Ulm University Medical Center, Ulm, Baden-Wuerttemberg, Germany

Introduction

Mechanisms underlying cervical disc herniation remain poorly understood. Particularly, astronauts show a 21-fold higher risk compared to the standard population, potentially due to excessive disc swelling [1]. This study explored swelling-induced alterations in intradiscal pressure (IDP), range of motion (ROM), and neutral zone (NZ), and examined whether hyperhydration combined with compromised endplate-annulus integrity under complex loading contributes to disc herniation.

Methods

Six fresh frozen human cervical spinal motion segments (1x C3-C4, 3x C5-C6, 2x C6-C7; 17–42 years; 2 female / 4 male) were hydrated in distilled water for 14 h, with IDP being measured via fiberoptic pressure transducers. A standardized posterior defect between cranial endplate and annulus fibrosus was created paramedially under x-ray control. Specimens underwent complex loading for 3,000 cycles at 1 Hz in a dynamic disc-loading simulator [2], combining 100 N compression with flexion/extension (FE), lateral bending (LB), and axial rotation (AR) according to physiological ROM values [3]. Flexibility was assessed before and after hydration and loading using pure moments of 2.5 Nm. Data was analyzed using the Friedman test with Bonferroni correction in SPSS29.

Results

Hyperhydration increased intrinsic IDP by 243% ($p<0.05$) and reduced NZ (FE: -46%, LB: -56%; $p<0.05$). Complex loading immediately provoked herniation in one disc, showing posterior extrusion of nucleus pulposus material into the spinal canal paramedially from the cranial endplate defect site (Fig. 1). Following complex loading, ROM and NZ increased compared to the hyperhydrated condition ($p<0.05$; ROM: FE: +36%, LB: +56%, AR: +31%; NZ: FE: +148%, LB: +216%, AR: +138%).

Discussion

Hyperhydration increases IDP, thus reflecting amplified mechanical stress on annulus structures. Combined with complex loading, excessive hydration was shown to contribute to cervical disc herniation. However, induction of a paramedian defect at the upper endplate–annulus transition did not consistently provoke herniations, indicating that defects do not further augment their risk of occurrence.

Mechanical Loading Affects the Swelling Behavior of the Intervertebral Disc - An In Vitro Study

M.Eng. Ann-Kathrin Greiner-Perth, Ms. Hanna Unseld, Prof. Dr. Hans-Joachim Wilke, PhD Christian Liebsch

Ulm University Medical Center, Ulm, Baden-Wuerttemberg, Germany

Introduction

Intervertebral discs are known to undergo daily fluctuations in water content, dehydrating under daily loading and rehydrating overnight via osmotic processes [1]. While being of major importance for model validation and data interpretation, effects of constant hydration and mechanical loading on disc swelling and consequent motion segment flexibility remain insufficiently explored. This study therefore investigated the effects of disc loading on intradiscal pressure (IDP), range of motion (ROM), neutral zone (NZ) and disc height (DH).

Methods

18 fresh ovine lumbar motion segments (6x L1-L2, 6x L3-L4, 6x L5-L6) were hydrated for 24 h in 0.9% saline solution and randomized regarding segmental level into three groups (each n=6) using different axial compressive loading: 0 N (unloading), 58 N (loading during recovery phase), 130 N (loading during active phase) [2]. ROM and NZ were determined using pure moments of 7.5 Nm [3] at baseline, after 2 h, 4 h, 8 h, and 24 h. IDP was measured using fiberoptic pressure sensors. Statistical analysis was performed using Friedman's test with Dunn-Bonferroni post-hoc correction in SPSS29.

Results

Unloaded discs showed increased IDP after 8 h and 24 h of hydration ($p<0.05$) and elevated DH after all hydration intervals ($p<0.05$). Flexibility testing revealed increased IDP in all motion directions after 8 h (except flexion) and 24 h ($p<0.05$, Fig. 1). ROM decreased in lateral bending after 8 h and 24 h, and NZ in flexion/extension after 24 h ($p<0.05$). At 58 N, IDP increased during extension after 8 h and 24 h ($p<0.05$). At 130 N, no significant changes were observed ($p>0.05$).

Discussion

Lumbar ovine discs exhibit limited hydration capacity under low or recovery loads, while no fluid uptake was measurable under active load, suggesting that sustained loading reduces rehydration. In contrast, unloaded discs undergo osmotic swelling, leading to increased IDP and reduced flexibility. These effects might affect the transferability of experimental data to in vivo conditions. Future studies will verify these findings in human discs.

Post-fusion Facet Biomechanics are Influenced by Disc Degeneration and Facet Anatomy: Insights from Experimental and Computational Modelling of Cadaveric Human Lumbar Segments

Dr Shambo Bhattacharya, Dr Sophie Hutchinson, Ms. Sophie Clark, Dr Sherif Zantiba, Dr V. Nagitha Wijayathunga, Dr James Warren, Dr Marlene Mengoni

Institute of Medical and Biological Engineering, School of Mechanical Engineering, University of Leeds, Leeds, West Yorkshire, United Kingdom

Introduction

Despite Facet Joints' (FJ) critical role in governing spine biomechanical function, their biomechanics is understudied, with limited facet-specific data to evaluate their mechanical contribution or effects of interventions. Further, this hinders validation of FJ forces, often used as key outputs in computational models. The present study aimed to experimentally assess the effect of spinal fusion on FJ biomechanics, to calibrate and validate a FJ contact model, and comparing outcomes to imaging features.

Methods

Following ethical review (Yorkshire and the Humber REC15/YH/0096), human lumbar functional spinal units (FSUs) (N=7, three donors) were prepared after 3T MR imaging (Siemens-Vida), followed by a mock fusion procedure. Posteriorly off-axis compression experiments were carried out, with FJ local displacements and normal loads measured through respective motion capture and pressure-sensitive wafer-sensors. Micro-CT image-based finite element (FE) models of fused FSUs (N=4, substantial modic changes excluded) were developed. FJs were modelled as a pressure-overclosure contact defined with parameters calibrated against force-displacement curves. Validation was performed by comparing local FJ displacements. Outcomes were correlated with imaging features.

Results

Mock fusion significantly reduced FJ relative motion ($p=0.032$) with some FSUs shifting from extension to flexion. Changes in FJ normal force and motion following mock fusion negatively correlated with IVD Griffith grades ($R^2=0.42$ and $R^2=0.87$). Post fusion, relative FJ motion correlated negatively with facet space ($R^2=0.36$). Calibration yielded a good agreement between experimental and FE FJ displacements (CCC=0.92). Computational parameters for maximum contact pressure correlated positively with FJ Weishaupt grades ($R^2=0.71$), and parameter for contact initial clearance correlated positively with facet space ($R^2=0.78$), with the latter showing high variability (CoV=42%).

Discussion

This study provides the first experimental evaluation of post-fusion FJ biomechanics and development of an experimentally validated FJ contact model. Findings demonstrate IVD degeneration is a key determinant for changes in FJ kinematics and load transfer, while facet anatomy governs post-fusion kinematics. With mock fusion eliminating confounding factors of IVD modelling, findings showed FJ contact models were highly specimen-specific with dependence of facet space and facet grades. Albeit, small sample size, outcomes demonstrate high variability in FJ kinematics and role in load transfer overlooked in other spine FE models.

Process-Driven Mechanical Tuning of 3D Printed Foaming Thermoplastic Polyurethane for Age-Specific Cervical Intervertebral Disc Modelling

Mr Rajan S. Vraitch[1], Dr Xianghong Ma[1], Dr Francesco Giorgio-Serchi[2], Dr Eirini Theodosiou[1], Prof Adrian Gardner[1,3], Dr Jean-Baptiste R.G. Souppez[4]

[1]Aston University, Birmingham, West Midlands, United Kingdom. [2]University of Edinburgh, Edinburgh, Scotland, United Kingdom. [3]Royal Orthopaedic Hospital, Birmingham, West Midlands, United Kingdom. [4]Birmingham City University, Birmingham, West Midlands, United Kingdom

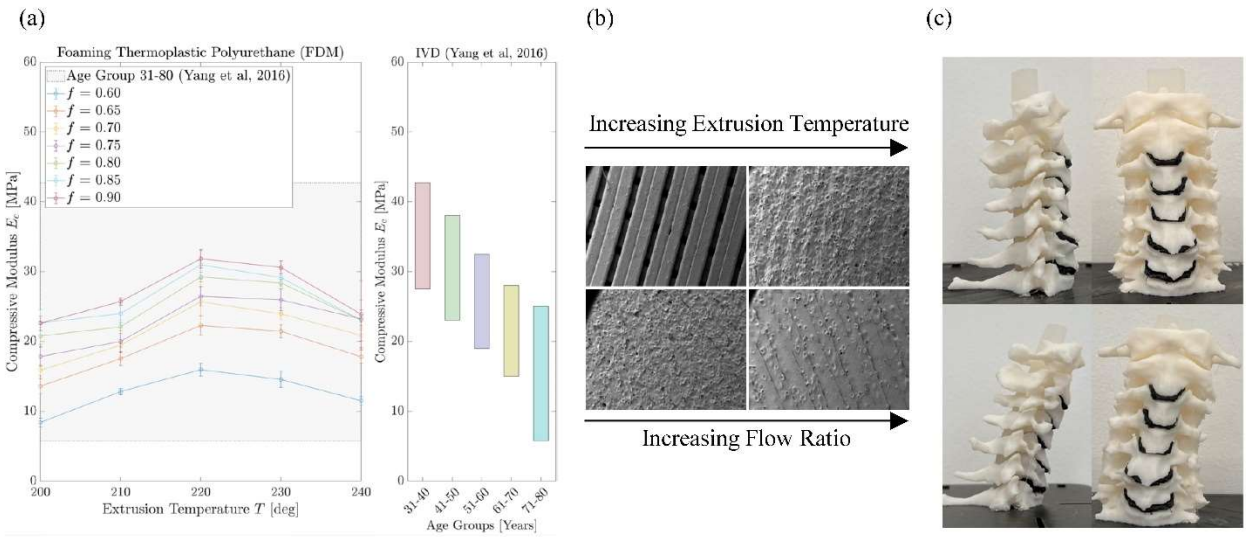
Introduction

Additive Manufacturing (AM) enables patient-specific cervical spinal models, however, while anatomical accuracy is derived from medical imaging, achieving physiologically relevant intervertebral discs (IVDs) mechanics that account for age and disease variations in mechanical behaviour remains challenging. Previous work demonstrated feasibility of modulating compressive properties using material selection and AM parameters [1], however limited understanding remains regarding how extrusion conditions govern microstructural foaming, and mechanical performance of foaming thermoplastic polyurethane (TPU). Consequently, this study investigates the process-structure-property relationship of 3D printed foaming TPU, enabling age-specific IVDs within anatomically accurate geometries.

Methods

Foaming TPU samples were manufactured with variations of extrusion temperature T (200-240°C), flow ratio f (0.60-0.90), layer height L_H (0.12-0.28 mm), and print speed S_P (40-60 mm s^{-1}). Compression tests were conducted following ISO 604:2003, with compressive modulus E_C determined using least-squares regression. For density and microstructural analysis, cubic samples were produced, with density used to characterise foaming behaviour and scanning electron microscopy (SEM) to analyse pore morphology.

Results



T and f were identified as the dominant variables governing foaming behaviour and compressive mechanical response. Increased T and lower f resulted in lower density and E_C. Conversely, conditions that restricted foaming yielded stiffer samples, representative of younger IVDs [2] (Figure 1a). In contrast, changes in L_H and S_P produced

no statistically significant changes in E_C. SEM revealed microstructural changes, with increasing T and decreasing f producing greater expansion of the foaming agent, while higher E_C was attributed to denser filament packing with few pores and overlapping of filament tracks (Figure 1b).

Discussion

These findings demonstrate that foaming TPU enables controllable replication of age-specific IVDs through extrusion-driven changes of foaming behaviour. The relationship between processing parameters, pore morphology, density, and E_C enables predictive control of mechanical behaviour. Importantly, stiffness tuning was achieved without changing geometry or material, enabling models to exhibit physiologically relevant behaviour (Figure 1c). This approach enhances the biomechanical accuracy of spinal models used for surgical simulation, thereby improving their value in clinical training and decision-making for personalised treatment.

Defining New Carpal Bone Anatomical Reference Systems Optimized for Kinematic Description

Mr. Daniel McDermott Sc.B.[1], Dr. Nicola Sancisi Ph.D.[2], Dr. Michael Rainbow Ph.D.[3], Dr. Michele Conconi Ph.D.[2]

[1]Harvard Medical School, Boston, MA, United States. [2]University of Bologna, Bologna, BO, Italy. [3]Queen's University, Kingston, ON, Canada

Introduction

Previous carpal bone reference systems definitions follow two main approaches: one defines all reference systems as parallel to the radius's in a neutral wrist [1]; another relies on carpal bones' principal axes of inertia [2]. Parallel axes do not distinguish healthy from pathological individuals, and joint angles derived from inertial axes are difficult to interpret. Based on the method developed for the foot [3], we propose a new definition of anatomical reference systems (ARS) from the articular surface shape and bone morphology, optimized for kinematic description while remaining clinically interpretable.

Methods

The proposed approach fits geometrical primitives on the articular surfaces, approximating them with elementary kinematic pairs. It was hypothesized that these features allow the definition of ARS that incorporate elements of articular coupling, such as the relative center of spherical motion. To test the effectiveness of the approach, we reconstructed wrist kinematics from CT scans of 9 wrists in 11 postures [4]; the instantaneous helical axes of all the articular pairs were computed between adjacent wrist poses, together with mean helical axis (MHA), mean pivot point (MPP), mean dispersion angle and mean axis-to-MPP distance of the IHA's. These data were used to identify the principal joint motions and their correspondence with the ARS axes.

Results

Motion occurs primarily between the scaphoid-radius, lunate-radius, and capitate-scaphoid joints, resembling spherical motion, as demonstrated by the small axis-to-MPP distance (2.7±1.1, 2.6±0.92, and 3.4±1.4mm) and large mean dispersion angles (18.9±4.1, 29.1±1.2, and 21.8±2.2°). The small distances between the MPP and the ARS's centers (4.1±1.8, 3.7±0.78, and 2.8±1.3mm) demonstrate the alignment of our ARS with the

kinematic pairs (Fig. 1, top row). Qualitatively, the distribution of the ARS is clinically sound, for instance following the natural curvature of the carpal tunnel.

Discussion

Our ARS method effectively captures joint kinematics, is clinically relevant, and will allow for more accurate principal component analysis.

Images (Optional)

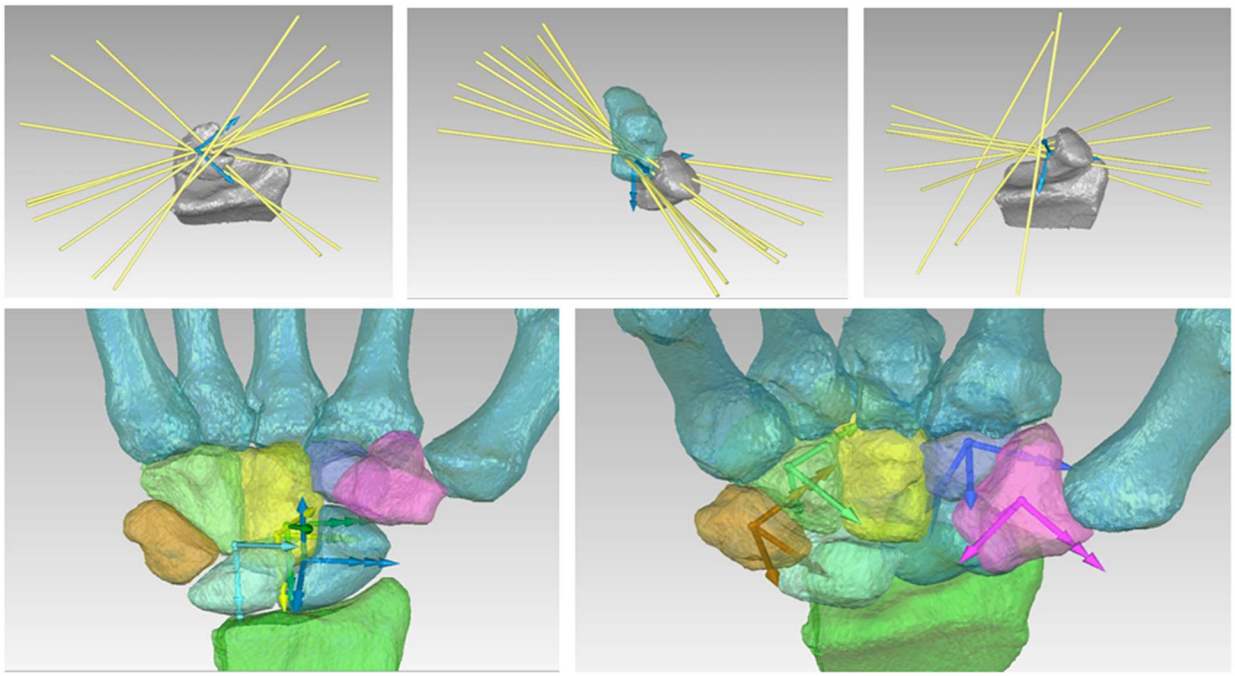

Figure 1: Distribution of the IHA for: the radius-lunate motion in the lunate ARS (top row, left); the scaphoid-capitate motion in the capitate ARS (top row, middle); the radius-scaphoid motion in the scaphoid ARS (top row, right). Dual Dysfunction: Central and Peripheral Factors of Recovery in Rotator Cuff Tendinopathy

Dr. Matthew Heindel PT, DPT[1], Dr. Oscar Vila-Dieguez PT, PhD[2], Dr. Jason Kutch PhD[1], Dr. Lori Michener PT, ATC, PhD[1]

[1]University of Southern California, Los Angeles, CA, United States. [2]University of California - San Diego, San Diego, CA, United States

Introduction

Rotator cuff (RC) tendinopathy is the most common cause of shoulder pain. Resistance exercise is effective, but outcomes are highly variable, with 40-50% developing recurrent or chronic pain. Deficits in tendon structure incompletely explain the variability in outcomes. Understanding the contribution of central factors – specifically, brain network activity – has not been explored. Other chronic pain conditions have shown decreased within-network connectivity of the default mode network (DMN), which is responsible for self-referential thought, mind wandering, and assists in descending pain modulation. No study has assessed the role of DMN connectivity in the presence or recovery with resistance exercise in RC tendinopathy. Defining the role of central and peripheral factors contributing to RC tendinopathy will aid in identifying intervention targets for personalized treatment approaches.

Methods

Adults with RC tendinopathy (n=58) completed an 8-week progressive resistance exercise program. Supraspinatus tendon structure of thickness and collagen disorganization (via peak spatial frequency radius–PSFR) were measured on ultrasound tendon images at baseline, 2, 4, and 8 weeks. DMN connectivity was measured with resting-state fMRI at baseline and 8 weeks. Shoulder disability was assessed with the Penn Shoulder Score. A linear mixed effects model was used to determine if change in tendon structure from baseline to 2, 2 to 4, and 4 to 8 weeks predicted change in shoulder disability. A general linear model was used to determine if a change in DMN connectivity, controlled for tendon structure, predicted shoulder disability change.

Results

Decreased supraspinatus tendon thickness over baseline to 2 weeks were associated with improved shoulder disability at 8 weeks, but later changes in thickness and PSFR were not. Increased medial prefrontal cortex connectivity to the DMN from baseline to 8 weeks was related to improved disability.

Discussion

Both tendon structure and central factors contribute to recovery, but brain connectivity better explains outcomes following resistance exercise. Early tendon adaptation marks the initial peripheral response to loading, but increased DMN connectivity is related to better shoulder disability, independent of tendon structure. This may indicate improved descending pain modulation. This central biomarker could be a therapeutic target for future interventions for those who do not respond to resistance exercise.

Co-Contraction Patterns of Forearm Muscles During Cylindrical Grasp Differ Between People With Hand Osteoarthritis and Healthy Individuals

Mr. Mahdi Mohseni[1], Dr. Verónica Gracia-Ibáñez[2], Dr. Angela Kedgley[1]

[1]Department of Bioengineering, Imperial College London, London, Greater London, United Kingdom. [2]Department of Mechanical Engineering and Construction, Universitat Jaume I, Castelló de la Plana, Valencian Community, Spain

Introduction

Muscle coordination analysis provides valuable information about the neuromuscular system function and may lead to improved rehabilitation strategies [1]. This study aimed to quantify forearm muscle synergy patterns for healthy individuals and participants with hand osteoarthritis (HOA) during cylindrical grasp, one of the most frequently used grasps in activities of daily living. Grasp activates most forearm muscles to generate strength and stability. We hypothesised that HOA would change forearm muscle coordination.

Methods

Seven electromyography (EMG) sensors were placed on the forearm to acquire muscle activation signals during grasp (Figure 1) [2]. EMG signals were collected while performing maximum painless cylindrical grasp from 21 healthy women and 20 women with HOA [3]. Signals were filtered and normalised to maximum voluntary contraction values. Non-negative matrix factorisation was recruited to extract synergy modules for each trial. The consistency of these synergy patterns across both groups was examined using the k-means method.

Results

Three synergy patterns (S1-S3) were extracted from EMG signals of each participant group (variance accounted for: 99.62 ± 0.07 % and 99.63 ± 0.11 % for healthy and HOA groups, respectively). In both groups, the S1 module was associated with the generation of grip force, S2 with wrist posture in extension and radial-deviation, and S3 with wrist flexion and ulnar-deviation (Figure 1).

Discussion

Participants with HOA primarily used their finger flexor muscles to apply grip force, while healthy participants used their thumb muscles as well. Both groups used almost the same

pattern for controlling wrist posture in flexion and ulnar-deviation; however, to control wrist posture in extension and radial-deviation, participants with HOA used finger extensor muscles instead of wrist extensor/radial-deviator muscles. These differences could be due to pain around the thumb and radial side of the wrist in participants with HOA. These results can be used to develop rehabilitation protocols based on the changes in forearm muscle coordination patterns and to distinguish HOA patients from healthy people using non-invasive EMG signals.

Images (Optional)

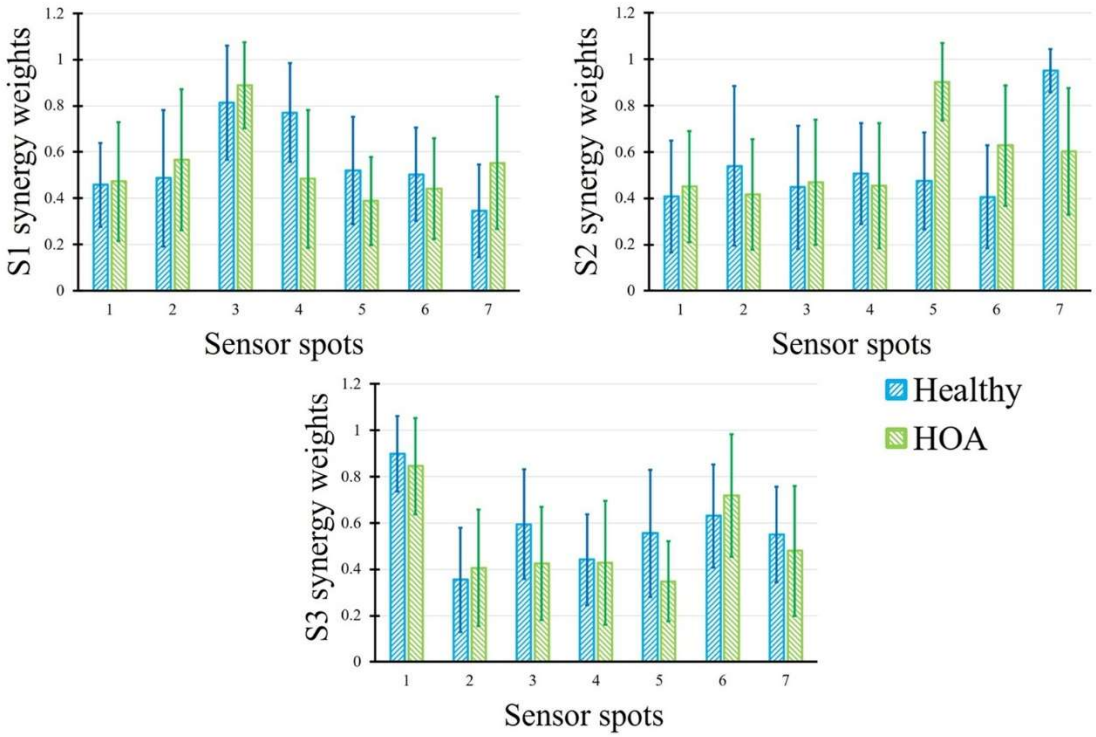

Figure 1: Synergy patterns for seven electromyography sensors collecting signals that represented muscle activity during: 1: wrist flexion/ulnar-deviation, 2: wrist flexion/radial-deviation, 3: thumb and finger flexion, 4: thumb extension/abduction/adduction, 5: finger extension, 6: wrist extension/ulnar-deviation, and 7: wrist extension/radial-deviation [2] for both healthy and hand osteoarthritis (HOA) groups.

Assessing Shoulder Pain-Related Range of Motion Limitations with Markerless Motion Capture

Ms. Vienna Liu, Ms. Belzora Lovett, Dr. David Lipps Ph.D.

University of Michigan, Ann Arbor, MI, United States

Introduction

Shoulder pain affects one in five adults, diminishing quality of life and independence by limiting shoulder mobility and hindering the ability to perform daily tasks [1]. Quantifying shoulder kinematics is vital for informing rehabilitation treatment plans to improve functional shoulder movements. Markerless motion capture is both highly valid [2] and more clinically accessible than marker-based systems; however, its application in upper-extremity assessments remains limited. We hypothesized that individuals with chronic shoulder pain would exhibit reduced shoulder range of motion as measured by markerless motion capture.

Methods

15 individuals with chronic shoulder pain (≥3 months, SPADI ≥20, pain on ≥ 3/8 clinical tests) were compared to 15 age- and sex-matched controls (14 M, 16 F, mean age 60 yr, 172 cm, 80 kg). Participants completed four shoulder range-of-motion tasks with kinematics derived using Theia markerless motion capture (16 Qualisys Miqus cameras): flexion/extension, abduction/adduction, internal/external rotation at 90° flexion, and internal/external rotation at 90° abduction. Visual3D was used to compute joint angles (YXZ rotation). Cohen's d effect sizes and independent t-tests examined the effect of shoulder pain on shoulder kinematics.

Results

Individuals with shoulder pain exhibited reduced range of motion in abduction ($d = 0.89$, $p = 0.02$), external rotation with 90° elbow flexion ($d = 1.07$, $p = 0.007$), and internal rotation in 90° shoulder abduction ($d = 0.95$, $p = 0.01$) (Figure 1). No other shoulder kinematics reached significance.

Discussion

This study highlights that individuals with shoulder pain exhibit reduced internal/external rotation and abduction range-of-motion tasks measured by markerless motion capture. Markerless motion capture has shown shoulder kinematic patterns similar to those of marker-based systems [3]. This study further suggests that markerless motion capture is

useful for distinguishing shoulder kinematics between individuals with and without pain. Future research should examine a wider range of activities of daily living and develop standardized protocols for markerless motion capture to improve reproducibility and expand clinical applications.

Images (Optional)

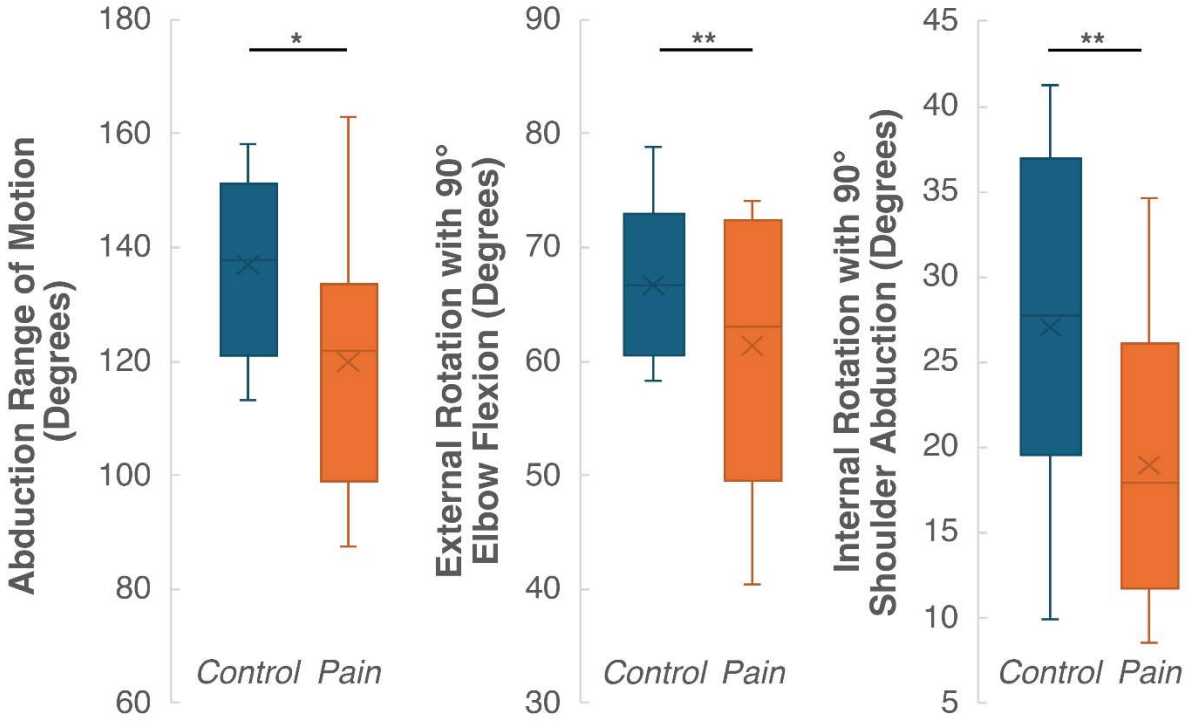

Figure 1: Abduction range of motion, external rotation with 90° elbow flexion, and internal rotation with 90° shoulder abduction in individuals with and without shoulder pain. Asterisks indicate significant between-group differences ($p < 0.05$ = *, $p < 0.01$ = **).

An Actuated Encapsulation Implant for Cell Therapy

Dr. Eimear Dolan[1], Ms Parand Shokrani[1], Dr. Lesley Trask[1], Dr. Niamh Ward[1], Dr. Hannah Prendeville[1], Dr. Aoibhin Sheedy[1], Dr. Ellen T. Roche[2], Dr. Garry P. Duffy[1]

[1]University of Glaway, Galway, Galway, Ireland. [2]Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

Introduction

Medical implants encapsulating therapeutic cells are being developed for chronic diseases[1]. However, many have limited long-term performance due to the foreign body response (FBR) impeding vital transport[2]. Our group previously demonstrated that cyclically actuating (inflating and deflating) an implant can reduce the FBR in rodents and improve drug delivery[3]. However, previous designs were not suitable for cell encapsulation. The actuatable cell encapsulation (ACE) implant, was designed (Fig 1A) and validated *in vivo* as described herein.

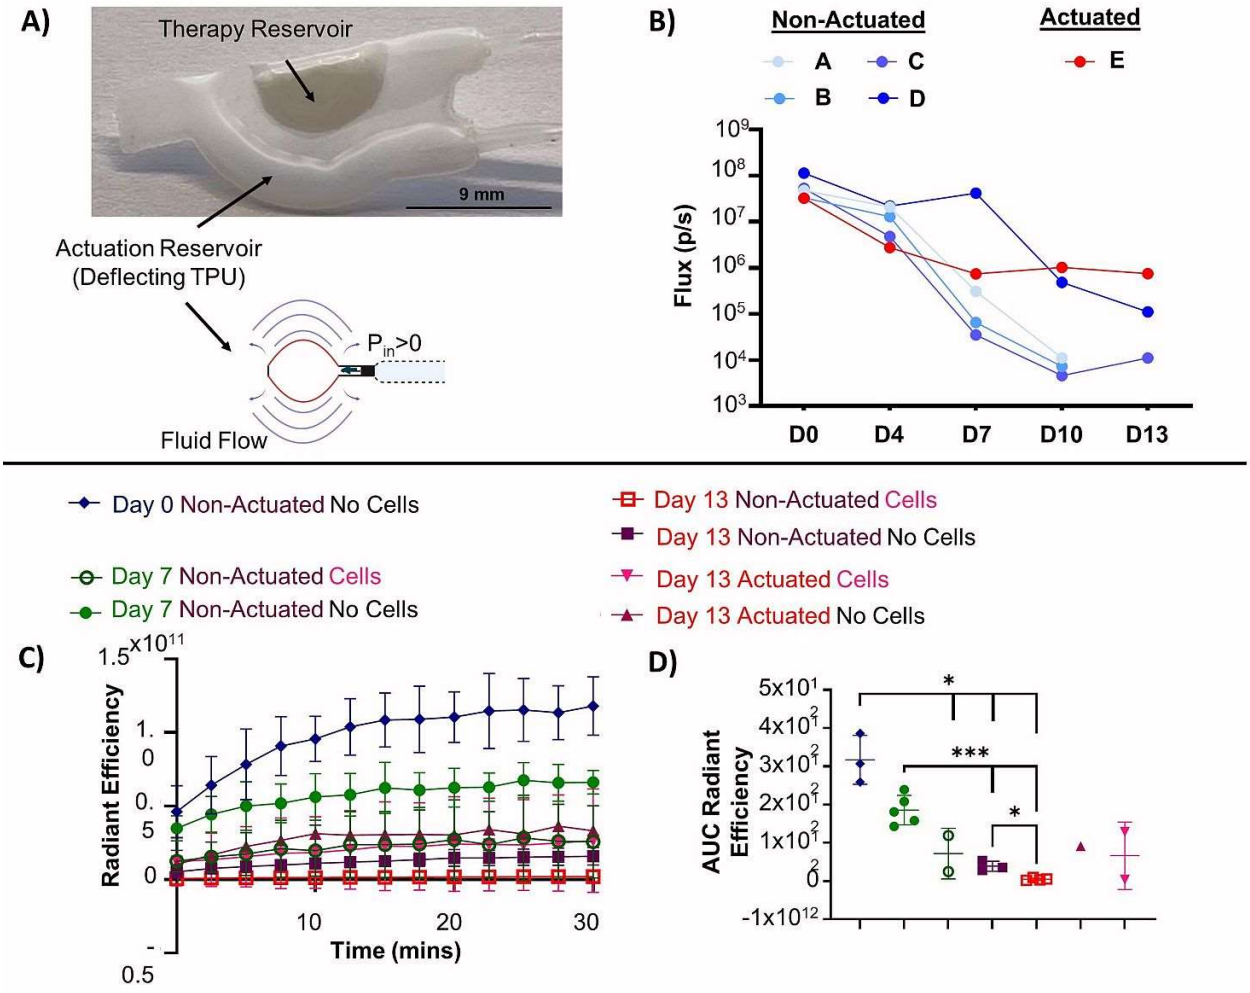
Methods

Implants were manufactured using variations of previously published techniques[3] and delivered subcutaneously to C57BL6 mice. Actuation (13.8kPa, triangular, 1Hz) occurred 10 minutes daily using an Elveflow OB1 controller. Mouse mesenchymal stem cells transfected with firefly luciferase (F-cells, $0.5x10^6$) and a fluorescent therapy analog (Genhance, 30µL), were delivered via transcutaneous port at key times. Cell viability and therapy spread were quantified via Spectrum In Vivo Imaging System (IVIS®).

Results

Preliminary *in vivo* results are shown in Fig 1. Progressive cell death, indicated by loss of bioluminescent signal (>90%), was observed in all implants (**Fig 1B**). However, the actuated implant demonstrated a plateau in bioluminescent signal beginning at Day 7, in contrast to the non-actuated controls.

The ability of the ACE implant to deliver a therapy analog was evaluated. Significant drops in the therapy's raw fluorescent signal and the area under the curve (AUC) were observed over time in all groups (**Fig 1C,D**). However, early data indicates that actuated implants show improving trends compared to non-actuated controls at Day 13.



(Figure 1 here)

Figure 1 **A**) ACE implant in the inflated state. **B**) F-cell viability Day 0 (D0) to Day 13 (D13). **C**) Fluorescent intensity of therapy analog 30 minutes following delivery. **D**) AUC fluorescent intensity of therapy analog.

Discussion

This study is ongoing. These preliminary trends show promise for actuated implants to support cell viability up to 13 days in the challenging subcutaneous space, and improve therapy delivery compared to non-actuated controls.

Experimental Validation of a Mechanically Intelligent Bone Anchor

Dr Sean Thomas, Ms Sachi Bansal, Dr Ophelie M. Herve, Dr David R. McAllister, Dr Tyler R. Clites

University of California, Los Angeles, Los Angeles, CA, United States

Dr Sean Thomas

Ms Sachi Bansal

Dr Ophelie M. Herve

Dr David R. McAllister

Introduction

Secure fixation is central to the success of orthopaedic implants, particularly in applications where implants remain in the body for extended periods. Conventional bone anchors typically rely on uniform thread engagement [1], which may not adequately adapt to bone morphology and can permit micro-motion that impedes osseointegration leading to aseptic loosening [2]. In this study, we present a mechanically intelligent bone anchor that adapts passively to the surrounding bone architecture without the use of sensors, electronics, or active control. The design leverages compliant mechanisms and force-gated mechanical fuses to achieve sequential engagement of cortical and cancellous bone while maintaining stability for osseointegration and long term implantation.

Methods

The anchor, centred around a mechanical fuse, was parametrised according to key geometric features (blade thickness, width, length, etc.). A design of experiments was conducted to sweep through the parameter space and >2000 finite element analysis (FEA) simulations were conducted to predict the buckling load and Poisson ratio of the fuse.

Using a random forest regressor [3], the partial dependence of each parameter on the two output parameters is estimated. Prototypes were fabricated using wax casting (Fig1A) and assessed through experimental validation. Motion capture was used to confirm the intended sequence of mechanical engagement.

Results

Predictions from the FEA were used to design a fuse that buckles allowing the two stages of the bone anchor to be activated sequentially (Fig1B). While blade thickness and length had opposing effects on the buckling load, the number of blades in the fuse showed a pathway to increase the required buckling loads without any effect on the Poisson ratio, critical to prevent radial expansion against the surrounding bone. Upon contact with a simulated cortical layer, the compliant fins achieved immediate fixation, followed by controlled deployment of the mechanical fuse (Fig1C).

Discussion

This study provides the first experimental validation of a mechanically intelligent bone anchor capable of passive, morphology-responsive fixation. By integrating compliant mechanisms tailored to bone anatomy, the anchor minimises micro-motion and offers a promising architecture for long-term orthopaedic implantation and future translational testing.

[5]Department of Diagnostic, Interventional and Paediatric Radiology (DIPR), Inselspital, University Hospital, Bern, Bern, Switzerland

Introduction

Dynamic 3D in vitro culture systems are essential for evaluating engineered scaffolds under physiologically relevant conditions, providing mechanical and biochemical cues that 2D cultures cannot replicate [1]. They enable realistic modeling of nutrient transport, shear stress, and mechanotransduction, all critical in bone tissue engineering [2]. We present a dynamic bioreactor capable of delivering controlled perfusion and axial compression to scaffolds from 2.3 to 14 mm in height, supporting both small-scale and clinically relevant testing. The system replicates key mechanical and metabolic features of the bone microenvironment while enabling long-term culture.

Methods

The polycarbonate bioreactor chamber was designed to enable simultaneous perfusion and compression. CFD simulations using a 50% porous, 400 µm scaffold assessed flow uniformity, shear stress, and stagnant regions. Mechanical behavior was evaluated through in situ microCT compression tests, and material stability through chemical and mechanical degradation studies on polycaprolactone scaffolds. Biological validation included 14-day cell cultures, sterility checks, and viability assays to confirm compatibility and lack of cytotoxicity.

Results

CFD simulations demonstrated uniform perfusion flow across scaffold heights from 3–10 mm, with <0.1% stagnant regions, confirming efficient internal circulation. The chamber

maintained mechanical stability under repeated compression cycles, with microCT analyses showing no structural deformation of the chamber or scaffold mounts. Biological assays indicated no contamination or cytotoxic effects during 14 days of continuous dynamic culture, validating biocompatibility of the system.

Discussion

The system was validated for fluid dynamics, mechanical performance, and biocompatibility. A perfusion rate of 0.1 mL/min provided homogeneous flow without excessive shear in 10 mm scaffolds. The bioreactor offers a versatile, scalable platform that bridges static assays and in vivo models. Its capacity to support various scaffold sizes with controlled mechanical stimulation makes it a strong tool for mechanobiology, biomaterial testing, and preclinical evaluation. Future work will extend culture duration, vary loading and flow conditions, and integrate sensors for real-time monitoring. Overall, the system enables more reproducible, physiologically relevant in vitro models and may reduce reliance on animal studies in bone tissue engineering.

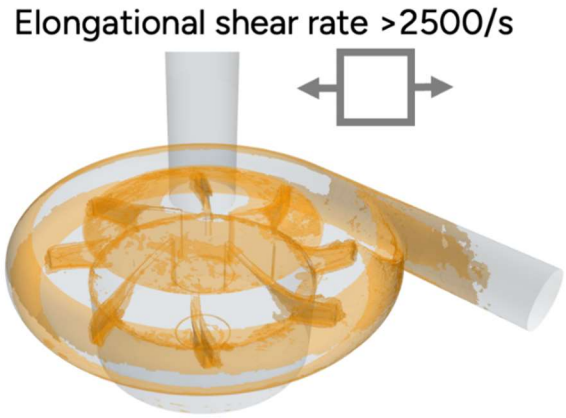
Fiber and polymer technology, Stockholm, N/A, Sweden

Introduction

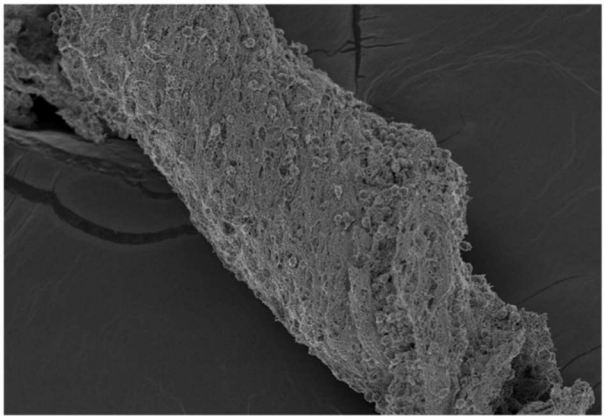
Extracorporeal membrane oxygenation (ECMO) is a lifesaving support where the patient's blood is oxygenated outside the body via a membrane lung. Besides the membrane lung, the ECMO circuit consists of a blood pump, cannulae, tubing and several connectors. It is well-known that the flow in these medical devices exposes the blood to supraphysiological stress conditions generated by the highly unsteady flow. Today, common indicators used to assess risk of thrombogenicity are time-averaged where the stress tensor is represented in a scalar form. To improve these indicators, increased knowledge of the detailed flow structures and their effect on thrombus formation is needed.

Methods

In this work, a combined analysis of human thrombi was applied. Small angle x-ray scattering (SAXS) and scanning electron microscopy (SEM) was used to characterize structure and morphology of thrombi collected from used ECMO circuit components (pump, cannula and membrane lung). Large eddy simulation (LES) was applied to obtain detailed understanding of the flow structures developing in the different components of the ECMO circuit.



Results



The flow in both pump and the membrane lung showed shear rates and elongational shear exceeding levels know to initiate von Willebrand factor unfolding, platelet activation, and hemolysis. All thrombi displayed a fibrin matrix with an outer fibrin alignment resembling the large-scale flow structures. Moreover, the fibrin matrix density varied between the different locations and samples. Besides fibrin, red blood cells (normal, echinocytes, and hemolyzed), activated platelets, and leukocytes were observed.

Discussion

Taylor-Couette-like systems used to provide data to form platelet activation and hemolysis models offer repeatability. However, they significantly differ from the fluid dynamical conditions in life supporting devices as in ECMO. An ECMO circuit exposes the blood to multidirectional and elongational flow characterized by strong shear layers, highly fluctuating, and stagnant flow regions. Our results highlight the importance of coupling knowledge of complex flow fields with the morphological characteristics of thrombi, pinpointing details in the flow promoting thrombus formation. This in turn may enable improved models for risk assessment and provide knowledge regarding parts of the different components that may benefit from re-design.

Numerical-Experimental Estimation Spanning Single Red Blood Cell Dynamics to Bulk Suspension Rheology

Dr Naoki Takeishi Associate Professor[1], Prof Naoto Yokoyama Professor[2], Prof Masako Sugihara-Seki Professor[3]

[1]Kyushu University, Fukuoka, Fukuoka, Japan. [2]Tokyo Denki University, Adachi-ku, Tokyo, Japan. [3]Kansai University, Suita, Osaka, Japan

Introduction

The deformability of human red blood cells (RBCs), which comprise almost 99% of the cells in whole blood, is largely related not only to pathophysiological blood flow but also to the levels of intracellular compounds. Therefore, statistical estimates of the deformability of individual RBCs are of paramount importance in the clinical diagnosis of blood diseases. However, there is no established method to estimate individual RBC deformability from the rheological data of RBC suspensions, and the possibility of this estimation has not been proven.

Methods

To address this issue, we conducted an integrated analysis of a model of the rheology of RBC suspensions, coupled with macrorheological data of human RBCs suspended in plasma. The contribution of the individual deformed RBC to the bulk suspension rheology is quantified by the stresslet tensor [1].

Results

Assuming a nonlinear curve of the relative viscosity of the suspensions as a function of the cell volume fraction, the statistical average of the membrane shear elasticity was estimated for individual intact RBCs or hardened RBCs. Both estimated values reproduced well the experimentally observed shear-thinning non-Newtonian behavior in these suspensions.

Discussion

We hereby conclude that our complementary approach makes it possible to estimate the statistical average of individual RBC deformability from macrorheological data obtained with usual rheometric tests [2].

The Effect of Vessel Curvature on Flow Patterns of Red Blood Cells

Mr. Yu Terada[1], Dr. Tomoaki Watamura[1], Dr. Satoshi Ii[2], Dr. Shu Takagi[1]

[1]The University of Tokyo, Tokyo, Kanto, Japan. [2]Institute of science tokyo, Tokyo, Kanto, Japan

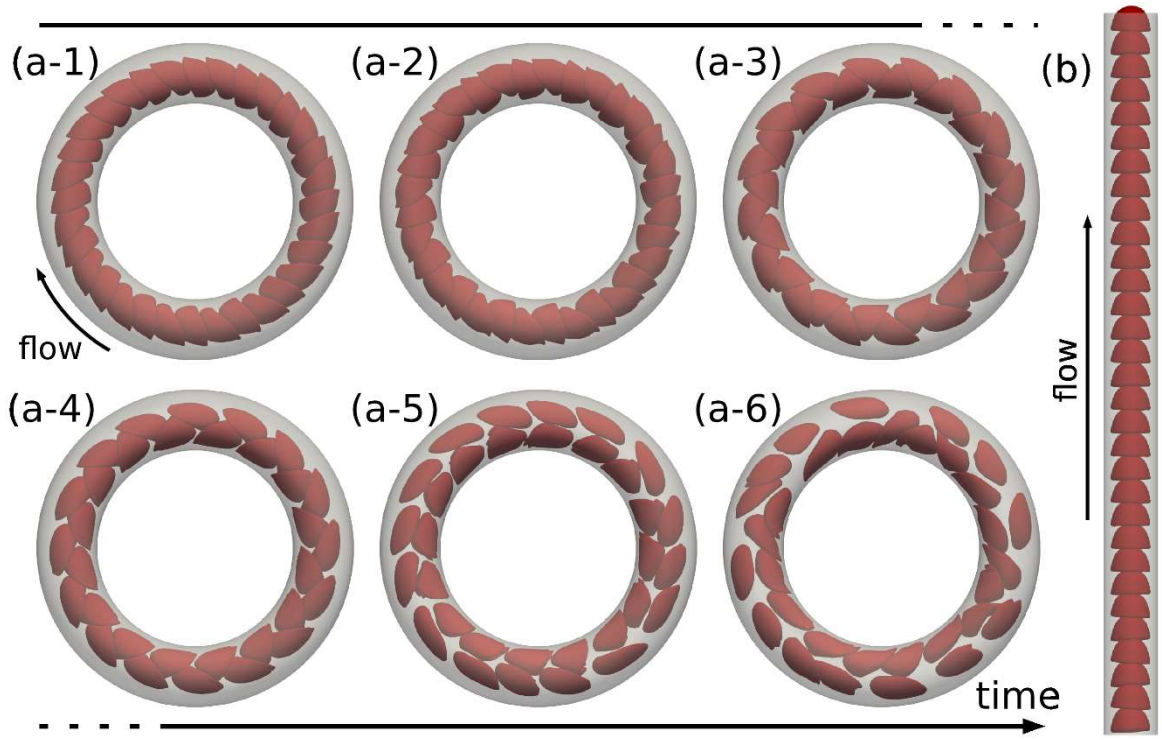
Introduction

Distinct flow patterns of red blood cells (RBCs) emerge in micrometer-scale capillary vessels depending on the vessel radius [1]. A single-file flow, in which RBCs align in a line, develops in narrow vessels whereas a double-file flow, characterized by alternating RBC alignment, appears within slightly wider vessels. These previous findings are based on straight vessels, even though curved vessels are frequently observed. In this study, we aim to clarify the transition conditions between single-file and double-file flow in curved vessels.

Methods

We performed direct numerical simulations to examine flow including RBCs in toroidal vessels with constant vessel curvature. Navier-stokes equations were solved. Red blood cells were modeled as Newtonian fluid covered by an elastic membrane with infinite small thickness. Immersed boundary method [2] was employed to exert RBCs' membrane force to fluid. No-slip boundary conditions were imposed on the surface of the toroidal vessel. The Reynolds number was on the order of 10^{-2}.

Results



We investigated the effect of vessel curvature on the flow patterns at the quasi-steady state. Although single-file flow was observed in a straight vessel with a vessel radius of $R_d=4.75 \mu m$, in a toroidal vessel with an identical radius and with a curvature radius of $R_c=20 \mu m$, double-file flow emerged as indicated in the Figure. We mapped a transition diagram in radius and curvature radius space. Double-file flow was observed for larger vessel radii and smaller vessel curvature radii.

Discussion

The effect of vessel radius on these flow patterns is primarily attributed to whether sufficient space exists. To understand the influence of vessel curvature radius, we first consider the velocity field of single-phase flow in toroidal vessels. Although the maximum mainstream velocity is located at the vessel center in straight vessels, it shifts toward the inner wall of toroidal vessels [3]. Consequently, the shear rate profile in toroidal vessels

becomes asymmetric. Since a capsule migrates towards zero shear rate position, the asymmetric profile promotes the formation of double-file flow.

Beyond Blood Flow: Combined Use of CFD and DOE to Predict Microsphere Distribution

Ms. Marta Gutiérrez de San Miguel, Dr. Jorge Aramburu, Professor Raúl Antón

Tecnun, Universidad de Navarra, San Sebastián, Guipúzcoa, Spain

Introduction

Hepatic radioembolization (RE) delivers Yttrium-90-labeled microspheres through the hepatic artery to irradiate liver tumors. Treatment efficacy depends on intrahepatic microsphere distribution, which is influenced by potentially physician-controlled parameters such as catheter axial and radial positioning. Although low Stokes number suggests microspheres follow blood streamlines and distribute proportionally to branch flow [1], clinical and computational evidence shows that small variations in catheter placement or flow conditions can significantly alter delivery, highlighting the need for personalized modeling [1,2]. Computational fluid dynamics (CFD) can simulate hepatic hemodynamics and microsphere transport, while Design of Experiments (DOE) identifies influential parameters and reduces computational cost. This work quantifies how catheter position affects microsphere distribution at the first bifurcation in three scenarios by combining CFD with DOE.

Methods

Three idealized hepatic artery bifurcations were created, with a catheter located at the parent vessel. Catheter-tip position was defined by axial (x_c) and radial (y_c, z_c) coordinates relative to the inlet plane. DOE was conducted to evaluate the influence of these three parameters under fixed geometry and flow conditions. Each parameter was set at three levels (low, medium, high), and a central composite design with 15 CFD simulations was executed per scenario. Microsphere trajectories were computed, and the response variable was the percentage of microspheres exiting a target daughter branch. Response surface models (RSM) were fitted and statistically evaluated.

Results

RSMs exhibited excellent fit and significance (R^2>0.96; ANOVA, p<0.05). Pareto charts identified dominant effects and interactions. Contour plots revealed how microsphere distribution varies with lateral (y_c) and vertical (z_c) catheter offsets for each axial position, highlighting regions highly sensitive to positional changes and others with stable, low-variability responses.

Discussion

Case-specific contour maps provide an intuitive and rapid tool to identify optimal catheter positions to achieve a desired microsphere distribution, while minimizing sensitivity to operator variability. Findings confirm that microsphere transport at the first bifurcation is a multifactorial process strongly influenced by both patient-specific and operator-controlled parameters. These DOE-CFD framework supports personalized RE planning and may contribute to more predictable dose delivery.

In Vitro and *In Silico* Study of Red Blood Cell Deformation in a Microfluidic Sudden Expansion

Ms Hannah Palahnuk, Dr. Nicolas Tobin, Dr. Keefe Manning

Pennsylvania State University, University Park, PA, United States

Introduction

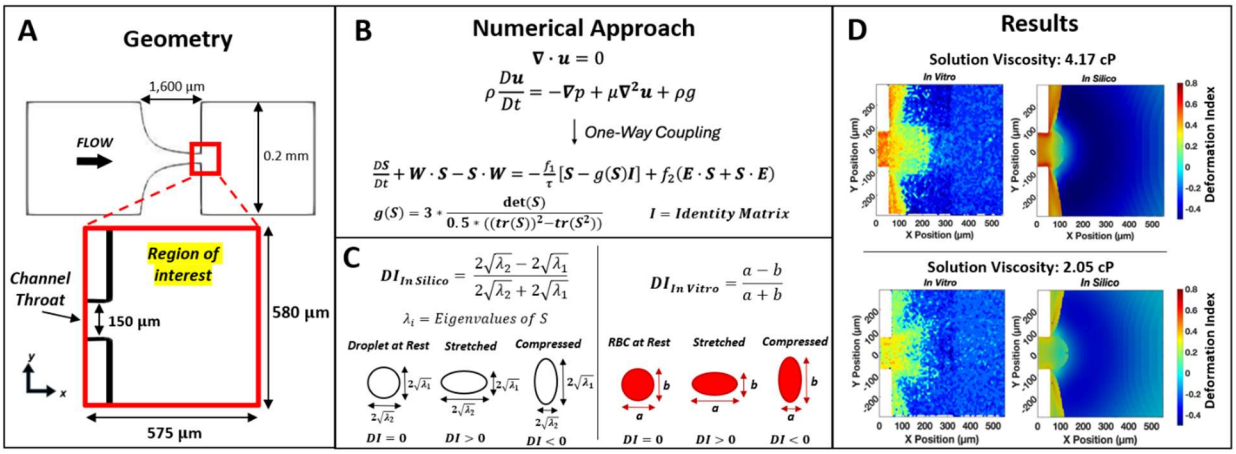
Hemolysis occurs in mechanical circulatory support devices (MCSDs) at a rate of 5-18%[1]. Strain-based hemolysis models, those governed by red blood cell (RBC) deformation, may aid in the design of MCSDs to decrease the hemolytic rate. In this study, we modify a droplet deformation-based numerical approach to capture RBC behavior in a microfluidic channel and validate *in silico* results using *in vitro* data.

Methods

In silico droplet and *in vitro* RBC deformation were quantified in a 575x580 μm area in a microfluidic sudden expansion (**Figure 1A**). The region of interest produces spatially varying strain rates with shear, rotational, and extensional components at supraphysiological magnitudes (>2,000 s^{-1}) to emulate MCSD flows. The deformation model, an evolution equation for a morphology tensor (***S***), was coupled to steady flow in the microchannel using OpenFOAM (**Figure 1B**). The symmetric (***E***) and antisymmetric (***W***) components of the velocity gradient tensor govern deformation along with constitutive parameters τ, f_1, and f_2, which were tuned to represent RBCs. The eigenvalues of ***S*** (λ_i) represent the droplet's principal axes' lengths and were used to quantify deformation (**Figure 1C**). For the *in vitro* experiments, human RBCs were suspended at 0.5% hematocrit in Hanks balanced salt solution with 13.5 or 6.5 wt.% Dextran-40,000 (viscosity of 4.17 or 2.05 cP, respectively). The channel was mounted to an inverted microscope stage and perfused with either suspension at 100 μL/min; images were captured in the region of interest (**Figure 1A**). RBC and droplet deformation indices (DIs) were compared for model validation (**Figure 1C**).

Results

The model reproduces spatially varying RBC deformation: high magnitude DI in the channel throat and the shear-dominant regions along the channel walls (DI ~0.5 or ~0.25 for 4.17 cP and 2.05 cP, respectively), and DI<0 for x>150 μm as RBCs compress when flow



decelerates (**Figure 1D**). Further, the magnitude of *in vitro* deformation increases with higher viscosity, as reflected in the *in silico* data (**Figure 1D**).

Discussion

The model reproduces RBC deformation in a heterogeneous environment akin to MCSDs. The model will be extended to capture RBC lysis in future studies.

Effect of Aging and Beta-Amyloid Deposition on Movement Variability during Single- and Dual-Task Walking

Dr. Lisa Zukowski PhD[1], Dr. Katherine Hsieh PhD[2], Dr. Samuel Lockhart PhD[3,4], Dr. Christina Hugenschmidt PhD[3], Dr. Jamie Kronenberg PT, DPT, PhD, SCS[1]

[1]High Point University, High Point, NC, United States. [2]Georgia State University, Atlanta, GA, United States. [3]Wake Forest University School of Medicine, Winston-Salem, NC, United States. [4]Perceptive Inc., Burlington, MA, United States

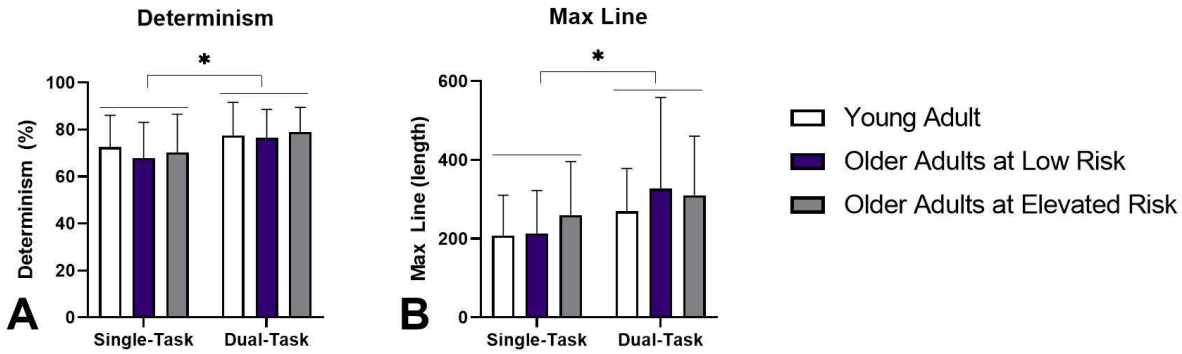
Introduction

Alzheimer's disease (AD), a progressive neurodegenerative disease characterized by beta-amyloid deposition (Aβ), negatively impacts cognition, mobility and quality of life. Aβ deposition may therefore alter healthy movement variability, which is characterized by having variable, yet stable movement solutions to accommodate multifactorial environmental demands. We sought to determine if movement variability as characterized by recurrence quantification analysis (RQA) variables of interest, differed between older adults at elevated risk of developing AD (OAer), older adults at low risk of developing AD (OAlr), and young adults (YA) during single- and dual-task walking.

Methods

Twenty-one OAer (78.6±5.0 years, 9 females, 55.0±33.2 Aβ-PET Centiloid), 31 OAlr (78.0±4.6 years, 14 females, -2.1±5.9 Aβ-PET Centiloid), and 28 YA (30.6±3.5 years, 17 females, no Aβ-PET) completed two 2-minute trials: single-task fast walking (ST) and dual-task fast walking while completing an auditory working memory task (DT). Linear acceleration in the anterior/posterior direction was recorded with an APDM opal sensor worn on the lower back. Predictability (percent determinism; %DET) and stability (max line; MaxL) were calculated using RQA of anterior/posterior linear acceleration to characterize movement variability during each task. A 2x2 mixed ANOVA assessed group (OAer/OAlr/YA) and task (ST/DT) effects on %DET and MaxL.

Results



There were no significant interactions of group and task on %DET ($p=0.349$; $h^2=0.027$) or MaxL ($p=0.170$; $h^2=0.045$). There was no main effect of group on %DET ($p=0.638$) or MaxL ($p=0.455$), but there was a main effect of task on %DET ($p<0.001$) and MaxL ($p<0.001$), with participants demonstrating greater predictability and stability during DT compared to ST (Figure 1).

Discussion

While there was no interaction of group and task on %DET or MaxL, main effects of task suggest that movement variability changes when responding to DT walking conditions independent of group. The increase in predictability and stability from ST to DT may indicate altered movement variability, suggesting increased automaticity of the gait task during DT performance to attend to the cognitive task. Future directions should include more complex gait tasks and different types of cognitive tasks to further assess the impact of aging and Aβ deposition on movement variability.

OA40-02

Longitudinal Changes in Walking Speed Reserve May Be an Indicator of pTau and Amyloid Beta Changes: A Pilot Study

Mr. John Tebbetts MS, Ms. Breanna Morales MS, Dr. Jack Manning PhD, Dr Jennifer Yentes PhD

Texas A&M University, College Station, Texas, United States

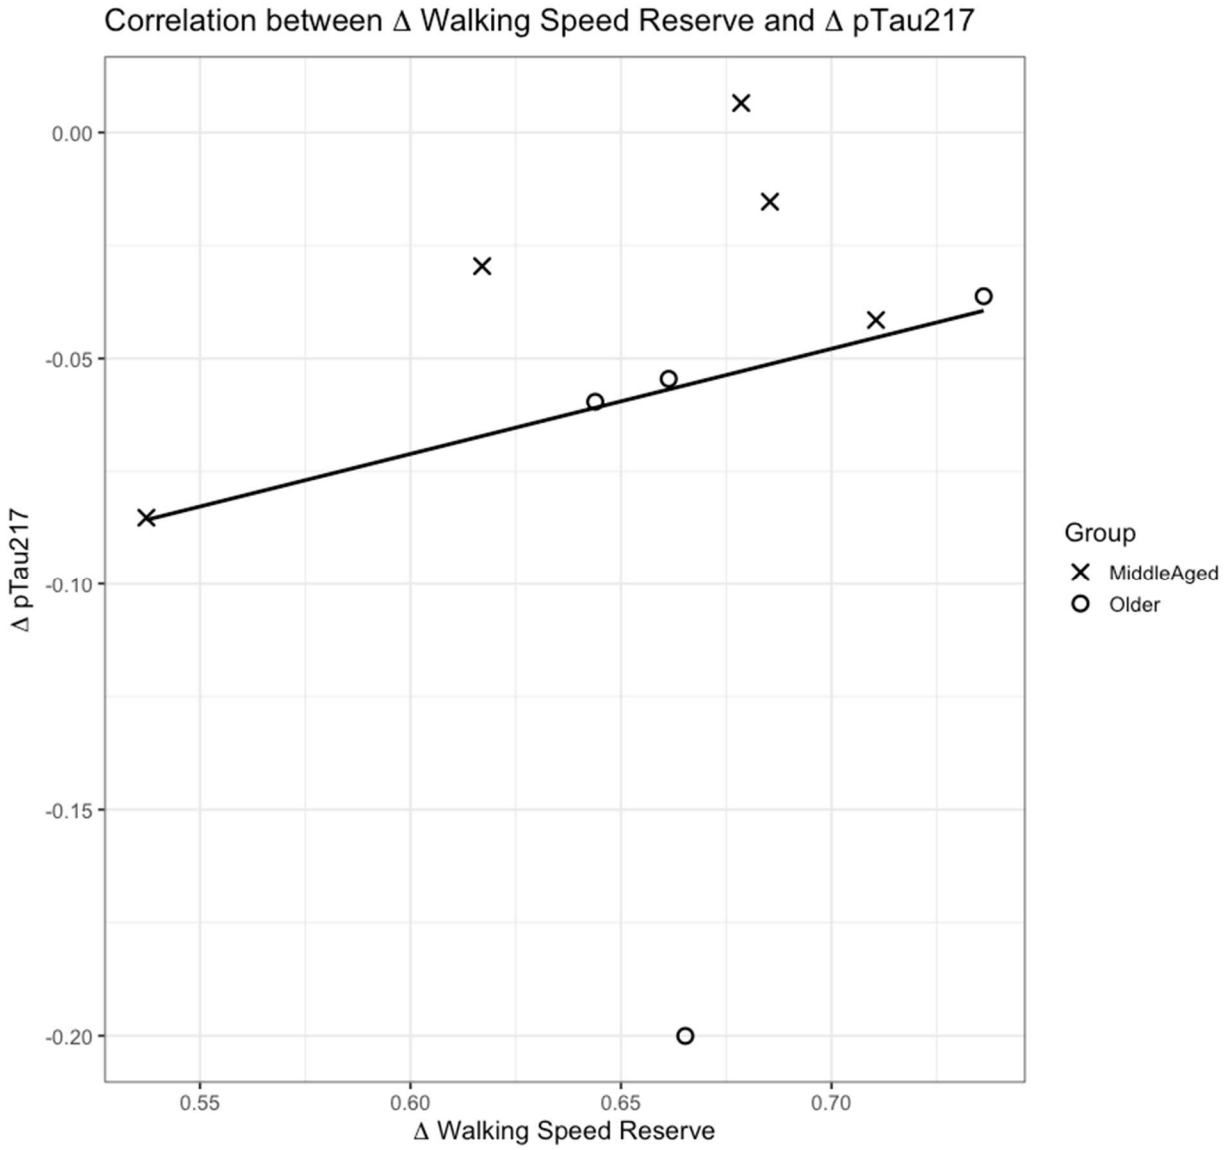
Introduction

Functional reserve is related to resilience. Resilience is defined as the ability to recover from a stressor while reserve is the capacity. An individual's functional reserve is the difference between baseline and maximal function, representative of their capacity to respond to perturbations. Reserve narrows with age through decrease in maximal capacity and/or increase in baseline requirements to maintain function. If reserve decreases over time, this may be an indicator of accelerated cognitive decline (measured by Plasma phosphorylated Tau (pTau) and Amyloid-Beta (AB)) and increased vulnerability to disease and injury. It is currently unknown if walking speed reserve may be indicative of a change in these markers of dementia risk.

Methods

Five middle aged (60.4±3.2yrs) and 4 older (67.8±2.6yrs) individuals underwent gait assessments and a blood draw twice, one year apart. Walking speed reserve (WSR) was quantified by subtracting preferred walking speed from their maximum walking speed. Levels of pTau181, pTau217, total pTau, AB 40, and AB 42 were quantified. pTau ratios to total Tau and AB42/40 were calculated for both years. Longitudinal changes were calculated by subtracting year one from year two. Spearman correlations between WSR and markers of dementia were run.

Results



Longitudinal change in WSR was moderately correlated with pTau217 ($r=0.42$, $p=0.27$), although not significant. WSR had non-significant weak relationships with pTau181 ($r=-0.13$, $p=0.74$) and AB ($r=0.28$, $p=0.46$).

Discussion

At this sample size, longitudinal change in WSR was associated with pTau217, and weakly with AB. Indicating that greater changes in WSR were associated with greater changes in blood biomarkers of dementia. Changes in walking speed are indicative of mobility and

mortality. These results provide some evidence that WSR may be an early indicator of cognitive decline and should be investigated in studies with larger samples.

Dementia with Lewy Bodies Worsens Reactive Responses to Walking Balance Perturbations Compared to Older Adult Controls

Dr. Emily Eichenlaub[1], Dr. Andrea Bozoki MD[2], Dr. Jason Franz PhD[1]

[1]University of North Carolina at Chapel Hill and North Carolina State University, Chapel Hill, NC, United States. [2]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

Introduction

As our aging population continues to grow, the prevalence of dementia is expected rise. Specifically, Dementia with Lewy Bodies (DLB) affects memory, executive function, and motor planning, making individuals nearly two-times more likely to fall than age-matched controls. When faced with an oncoming threat to balance, cognitive impairments may reduce DLB patients' ability to make proactive adjustments; when responding to a threat to balance, motor impairments may reduce their ability to effectively deploy reactive responses. To our knowledge, no studies have deployed ecologically relevant lab-based perturbations to understand changes in proactive and reactive balance control caused by DLB. We hypothesized that DLB patients would exhibit smaller proactive adjustments (via whole-body angular momentum, WBAM) for anticipated perturbations and larger reactive responses (via WBAM), particularly for unanticipated perturbations, compared to controls.

Methods

11 older adult controls (Controls; 6F; age: 71.4±4.8 years; walking speed: 1.38±0.16 m/s) and 11 older adults diagnosed with DLB (DLB; 2F; age: 71.6±4.4 years; walking speed: 1.04±0.24 m/s) were age- (±2 years) and BMI- (±2.5 pts) matched. Participants responded to treadmill-induced perturbations delivered at the instant of heel-strike in which the belt accelerated or decelerated over 200ms at 6m/s^2 delivered either unexpectedly (unanticipated) or after a 3-s verbal countdown (anticipated). We calculated WBAM and WBAM ranges ($WBAM_{range}$) in all three planes of motion during the preceding, perturbed, and recovery strides to determine the effects of cognition, anticipation, and their interaction effect on proactive adjustments and reactive responses.

Results

Preceding a perturbation, DLB did not exhibit any differences in proactive adjustments compared to controls. When responding to accelerations, DLB exhibited greater $WBAM_{range}$ in the transverse and frontal planes (perturbed stride) compared to Controls (**Fig.** 1A). When responding to decelerations, DLB exhibited greater $WBAM_{range}$ in

the sagittal (perturbed stride) and frontal planes (perturbed and recovery strides) compared to Controls (**Fig.** 1B).

Discussion

These results suggest that DLB negatively affects reactive responses to balance perturbations, independent of anticipation. Our findings have significant implications for understanding the effects of cognitive decline on balance control to inform the design of rehabilitation programs and assistive devices to mitigate patients' risk of falling.

Images (Optional)

The Effects of Mild Cognitive Impairment on Kinematic and Neuromuscular Responses to Novel Slip-Like and Trip-Like Perturbations During Walking

Ms. Jessica Pitts, Dr. Tanvi Bhatt

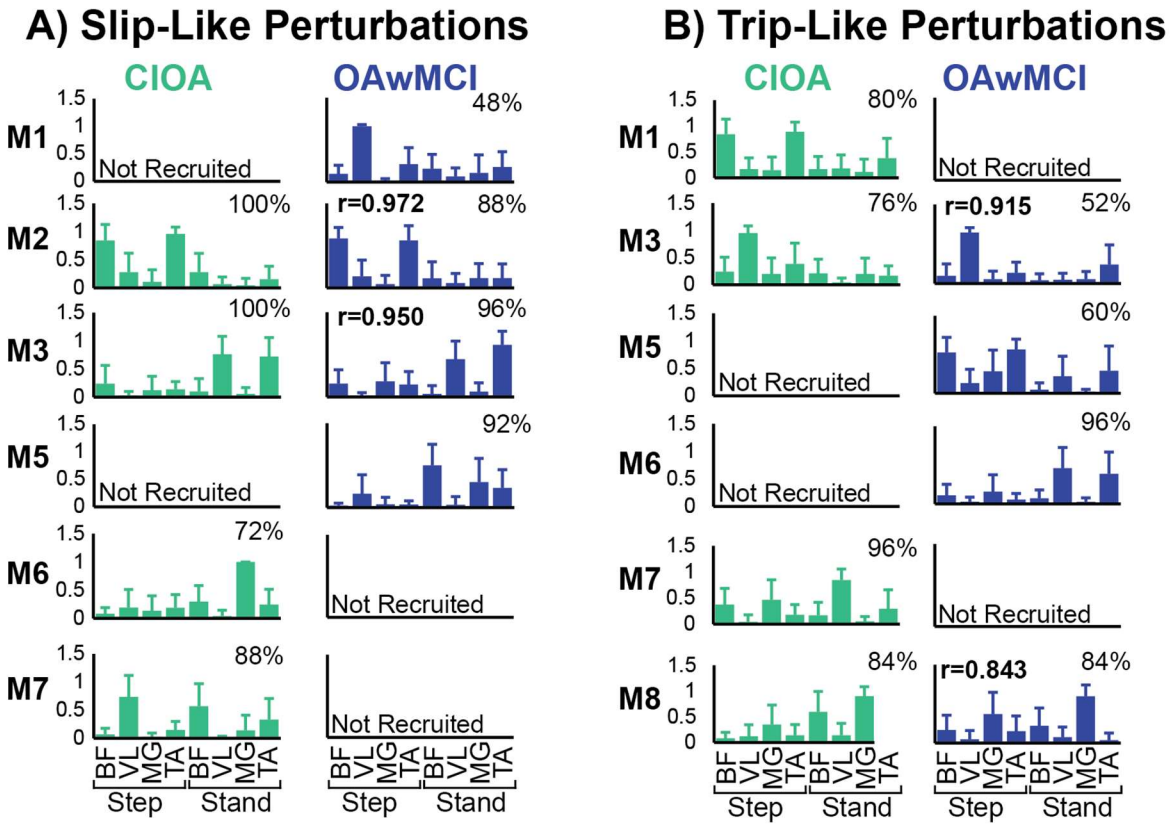
University of Illinois at Chicago, Chicago, IL, United States

Introduction

Older adults with mild cognitive impairment (OAwMCI) fall 2x more than cognitively intact older adults (CIOA) and show impaired reactive balance responses to unexpected perturbations. However, most studies in OAwMCI have delivered unidirectional stance-perturbations, whereas most real-life falls are caused by multi-directional gait-perturbations (e.g., slips and trips). This study compared kinematic and neuromuscular responses to both slip-like (backward balance loss) and trip-like (forward balance loss) gait-perturbations in OAwMCI vs. CIOA.

Methods

25 OAwMCI (Montreal Cognitive Assessment (MoCA): 18-25) and 25 CIOA (MoCA: 26-30) experienced a novel slip and trip during treadmill walking, caused by sudden belt deceleration (-6 m/s^2) or acceleration (5 m/s^2). An overhead load cell detected falls (>30% body weight), and Chi-Square tests assessed group differences in fall rate. 2x3 ANOVAs examined the effect of group and time (pre-perturbation touchdown (TD), recovery TD1, recovery TD2) on margin of stability (MOS). Muscle synergies were extracted from bilateral EMG (biceps femoris (BF), vastus lateralis (VL), medial gastrocnemius (MG), tibialis anterior (TA)) from perturbation onset to recovery TD2. Synergy structures (M) were compared between groups using Pearson's correlations.



Results

Fall rates were not significantly different between groups ($p \geq 0.123$), although OAwMCI showed 16-20% higher fall rate for both slips (64% vs. 44%) and trips (92% vs. 76%). OAwMCI showed significantly lower MOS during slip recovery (recovery TD1, $p=0.004$), although no group differences in MOS were found for trips ($p>0.05$). For both perturbations, 2-3 muscle synergies were highly similar between groups ($r>0.843$), although each group also recruited 2-3 unique synergies. For example, M7 (slips) was only recruited by CIOA (*mostly VL step, BF stand*), which could reflect greater interlimb coordination, whereas M5 (trips) was only recruited by OAwMCI (*mostly BF & MG step, bilateral TAs*) and could indicate defensive co-contraction/stiffening.

Discussion

OAwMCI showed lower reactive COM stability than CIOA during slip recovery, although not trip recovery. Trips may have posed a higher biomechanical challenge than slips (given ~30% higher fall rate) and been difficult for all older adults, regardless of cognition. However, OAwMCI still recruited distinct muscle synergies during both slips and trips, suggesting the use of different neuromuscular strategies to implement reactive stepping.

Predictive Neuromechanical Simulation Explains Gait Biomechanics in Obesity

Dr. Chi-Whan Choi PT, PhD, MPH[1], Mr. Vincent Ton MS[2], Dr. Simone V. Gill PhD, OTR, FAOTA[1], Dr. Seungmoon Song PhD[2]

[1]Boston University, Boston, MA, United States. [2]Northeastern University, Boston, MA, United States

Introduction

Individuals with obesity exhibit characteristic gait adaptations, including reduced early-stance knee flexion, altered muscle activation, and slower walking speeds. Although these patterns are well documented experimentally, the mechanisms driving them remain unclear because inverse-dynamics and tracking-based approaches cannot determine why specific gait strategies emerge. This study used predictive neuromechanical simulation to identify how obesity-related changes and gait-related objectives shape walking biomechanics.

Methods

We investigated baseline and obese models using predictive neuromechanical simulations. The baseline model represented a 1.8 m, 80 kg adult. We adapted segmental inertia properties and muscle strength according to the literature to represent a nominal obese model (1.8 m, 140 kg), as well as more apple-like and more pear-like variants with identical height and mass. Control parameters were optimized using CMA-ES to generate stable, steady walking. The cost function combined muscle effort and knee loading, and we identified optimal weightings by matching early-stance knee kinematics, one of the key gait changes observed in individuals with obesity. Using these weights, we simulated gait across walking speeds for baseline and obese models and evaluated resulting kinematics, kinetics, and muscle activations.

Results

The baseline model achieved its best match to experimental knee kinematics using the muscle effort cost alone, while the obese model required a combination of muscle effort and knee loading costs (w_{effort}=0.6 & w_{load}=0.4). With this weighting, the obese model reproduced experimentally observed gait features, including reduced early-stance knee flexion and increased muscle demand, as well as a shift toward slower preferred walking speeds. Differences in body-mass distribution produced modest but consistent variations:

the more apple-like model showed slightly greater knee flexion and vastii activation, whereas the more pear-like model exhibited slightly higher gastrocnemius activation.

Discussion

Predictive neuromechanical simulation provided mechanistic explanations for gait adaptations associated with obesity. The combination of altered physiology and an objective that penalizes knee loading reproduced stiff-knee gait features, and elevated muscle effort at faster speeds explained the emergence of slower speeds. Although the effects of mass distribution were modest, they demonstrated how morphological variation can influence knee mechanics and muscle demand. These findings highlight the value of predictive simulation for probing gait mechanisms relevant to obesity.

Images (Optional)

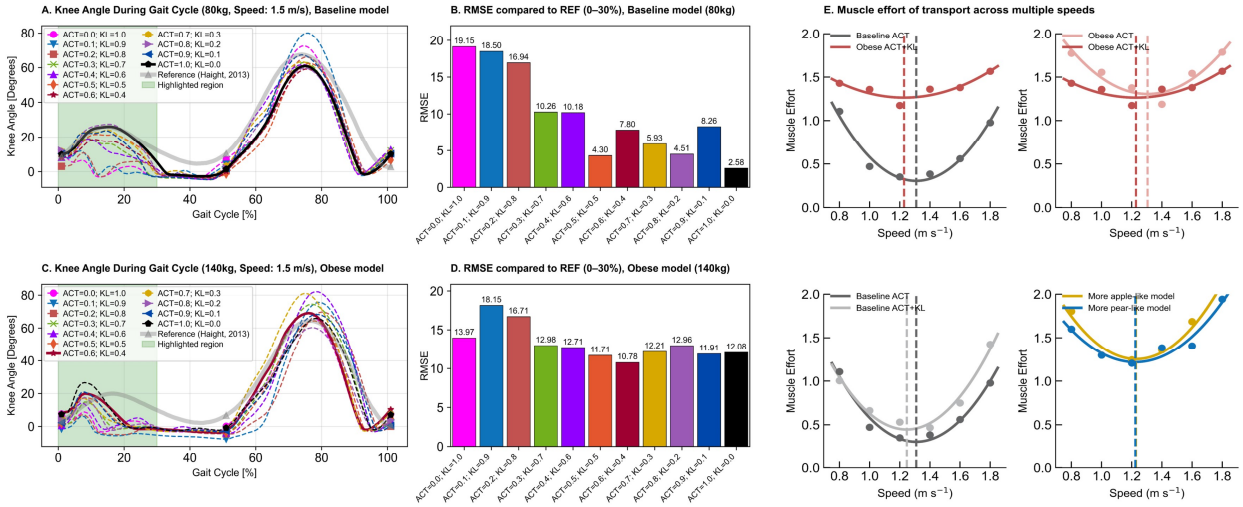

Figure 1 (A) Baseline (80kg) model: The black solid line represents the knee angle from the best weight combination based on Root Mean Square Error (RMSE) compared to knee angle (bold gray line) in individuals without obesity from the reference (REF, Haight 2014) when optimized for different costs with each weight combination of weight for muscle activation (w_{effort}: ACT) and weight for knee loading (w_{load}: KL). (B) RMSE compared to REF (0–30% during gait cycle) in Baseline model. (C) Nominal obese (Obese, 140kg) model: The dark red solid line represents the knee angle from the best weight combination based on RMSE. Bold gray line represents knee angle in individuals with obesity from REF. (D) RMSE compared to REF (0–30% during gait cycle) in Obese model. (E) Muscle effort of transport during walking simulations at each speed using the Baseline model (80kg, gray line: Baseline ACT) with the best weight combination (ACT=1.0, KL=0.0) and Nominal obese model (140kg, red line: Obese ACT+KL) with the best weight combination (ACT=0.6, KL=0.4), Nominal obese model (140kg, light red line: Obese ACT) with the weight combination (ACT=1.0, KL=0.0), Baseline model (80kg, light gray line: Baseline ACT+KL) with weight combination (ACT=0.6, KL=0.4), more apple like model (140kg, yellow line), and more pear like model (140kg, blue line) with the weight combination (ACT=0.6, KL=0.4). A Neuromusculoskeletal Digital Twin for Personalized Stroke Gait Rehabilitation

Dr. Liangliang Xiang[1], A/Prof. Ruoli Wang[1,2], Prof. Elena Gutierrez-Farewik[1,2]

[1]KTH Royal Institute of Technology, Stockholm, Stockholm, Sweden. [2]Karolinska Institute, Stockholm, Stockholm, Sweden

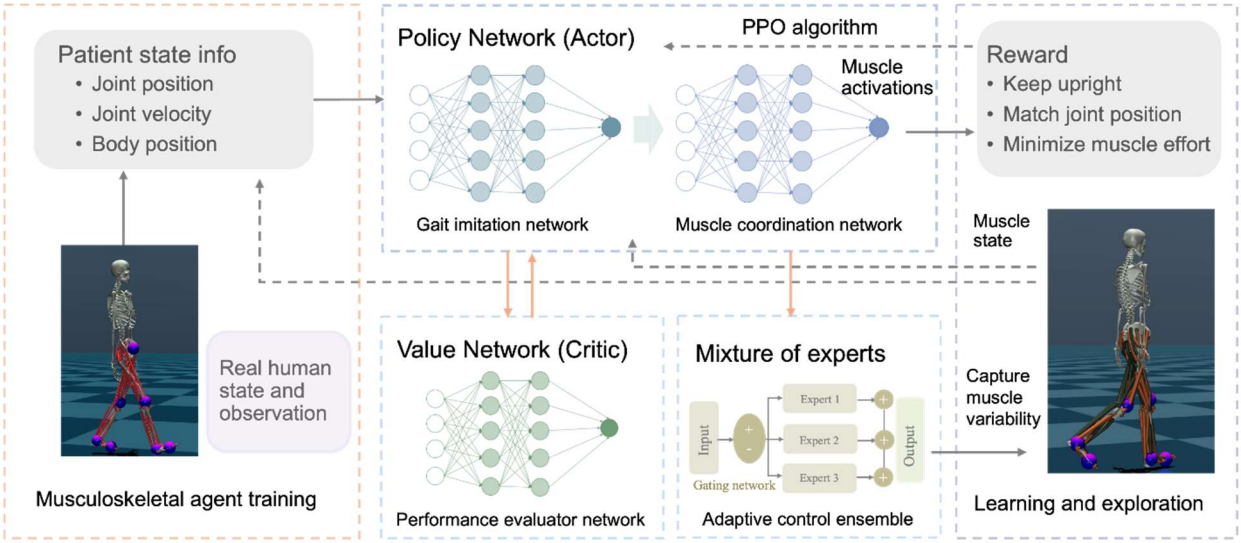
Introduction

Stroke commonly leads to muscle weakness, spasticity, and abnormal gait, substantially limiting mobility and increasing fall risk. Conventional biomechanical approaches, such as optimization-based estimators, cannot adapt to individual neuromuscular deficits. Deep reinforcement learning (DRL) offers a promising alternative, having demonstrated the ability to learn physiologically plausible control strategies, model neuromechanical interactions, and assist in locomotion and exoskeleton control [1]. Its capacity to discover individualized motor policies makes it suitable for modeling heterogeneous stroke gait impairments. We propose a neuromusculoskeletal digital-twin framework that combines personalized musculoskeletal modeling with DRL to simulate and analyze muscle coordination in stroke gait.

Methods

A public dataset of 48 stroke participants (age 64 ± 14 yr; body mass 72 ± 14 kg; height 1.70 ± 0.08 m) was used for training and evaluation. Forty-five subjects were used for training and three for testing [2]. Subject-specific kinematics were used to generate individualized anatomical constraints, and a DRL controller was trained to reproduce gait patterns through muscle excitations. The RL state included joint angles and velocities (37 dimensions), body positions and orientations (49 dimensions), and segment velocities (21 dimensions). Stroke severity (mild, moderate, and severe) was modeled by adjusting activation/deactivation delays, muscle force capacity, and passive stiffness [3]. A Mixture-of-Experts (MoE) architecture trained three severity-specific expert policies, and Proximal Policy Optimization (PPO) optimized muscle-driven control. The reward combined joint tracking, pelvis stabilization, and metabolic cost minimization.

Results



The framework reproduced subject-specific joint trajectories with low error (<10°) and generated muscle activation patterns resembling EMG references. The severe-stroke expert captured reduced plantarflexor activity and delayed quadriceps activation, while the

mild expert produced more physiological profiles. The MoE gating network appropriately selected policies across intermediate impairment levels according to Functional Ambulation Categories scores of 2.67 ± 1.07 (severe), 3.05 ± 1.08 (moderate), and 3.79 ± 0.88 (mild).

Discussion

This digital-twin approach provides adaptive, physiologically grounded insights into impaired muscle coordination and supports "what-if" analyses for weakness, spasticity, or exoskeleton assistance. It offers a scalable foundation for personalized rehabilitation and assistive-device design in stroke gait.

Revisiting How We Model Psoas Geometry in Musculoskeletal Models - Implications for Simulating Walking in Duchenne Muscular Dystrophy

Dr. Ines Vandekerckhove[1], Mr. Lars D'Hondt[2], Prof. Kaat Desloovere[1,3], Prof. Friedl De Groote[2]

[1]Department of Rehabilitation Sciences, KU Leuven, Leuven, Vlaams-Brabant, Belgium. [2]Department of Movement Sciences, KU Leuven, Leuven, Vlaams-Brabant, Belgium. [3]Clinical Motion Analysis Laboratory, University Hospital Leuven, Pellenberg, Vlaams-Brabant, Belgium

Introduction

Predictive simulations in Duchenne muscular dystrophy (DMD) fail to capture increased hip flexion, anterior pelvic tilt and posterior trunk lean. The psoas muscle is often contracted in DMD and is thought to contribute to these gait features. However, in most lower-limb musculoskeletal models, the psoas incorrectly attaches to the pelvis rather than the lumbar spine. This study corrects psoas geometry and tests its impact on predictive DMD gait simulations.

Methods

We previously generated predictive gait simulations of three DMD gait patterns (DMD1: mild, DMD2: tiptoeing, DMD3: flexion pattern), identified from a longitudinal dataset of 137 measurements in 30 boys with DMD. Simulations were based on an extended version of OpenSim's 2392 model scaled to the average dimensions of boys with the corresponding gait pattern. DMD impairments were incorporated by estimating average muscle weakness from fixed dynamometry and contractures from goniometry and clinical scales.

Here, we replaced the simplified psoas geometry with a detailed, anatomically accurate psoas derived from the Anderson lumbar-spine model and repeated all simulations with the updated model. The differences between the DMD models and the TD model with simplified psoas (original simulations) were compared to the differences between DMD models and TD model with complex psoas, and to the differences between DMD and TD experimental data.

Results

The effect of the adapted psoas geometry was minimal for lumbar and pelvic joints but slightly larger for the hip joint. The updated psoas improved agreement between

experimental and simulated differences in hip flexion during terminal stance in DMD1 and during swing in DMD3 although it reduced agreement during terminal swing and early stance (Figure 1).

Discussion

Overall, improving anatomical realism of the psoas had modest effects on the predicted gait pattern. A possible reason is that we underestimated psoas contracture. Indeed, increasing psoas contracture improved the agreement between experimental and simulated differences between DMD3 and TD gait patterns. In addition, alterations in the gait pattern might be the consequence of interactions between lower limb muscle contractures and increased spine mobility. We believe that refining trunk-hip mechanics is critical for using simulations to guide targeted interventions aimed at prolonging ambulation in DMD.

Practical Inter-Laboratory Variations in Motion Capture Measurements and Implications for Personalized Musculoskeletal Modeling

MSc. Parham Sadeghinia[1], BSc. Leendert Schaake[2], Dr. Vera Kooiman[3], BSc. Lise Wilders[4], Prof. dr. Nico Verdonschot[1,3], Dr. Periklis Tzanetis[1]

[1]Department of Biomechanical Engineering, University of Twente, Enschede, Overijssel, Netherlands. [2]Roessingh Research and Development, Enschede, Overijssel, Netherlands. [3]Orthopaedic Research Laboratory, Radboud University Medical Center, Nijmegen, Gelderland, Netherlands. [4]Department of Rehabilitation, Sint Maartenskliniek, Nijmegen, Gelderland, Netherlands

Introduction

Gait analysis is essential for understanding human movement, yet reproducibility across laboratories remains challenging due to examiner- and lab-specific factors, especially marker placement [1]. This study aimed first to determine how inter-laboratory variations in protocol-execution, including marker placement or execution of an activity, affect knee joint angles and net moments; and second, to assess whether a personalized musculoskeletal model mitigates these effects through its marker optimization process.

Methods

A healthy subject performed walking and step-down activities at three independent gait laboratories following a standardized protocol. All laboratories used the Vicon motion-capture system (Nexus v2.12) and the Conventional-Gait-Model 2.4 (CGM2.4) marker set. Knee joint angles and net moments were computed based on marker-trajectories and ground reaction forces. A subject-specific musculoskeletal model was subsequently developed in the Anybody Modeling System (AnyBody Technology A/S, Denmark) driven by the motion capture data. Marker positioning optimization and then kinematic analysis was performed to calculate joint angles, and inverse dynamics analysis to evaluate the resulting net joint moments. Inter-laboratory differences were quantified using absolute differences (Δ) in peak knee flexion angle and net moment.

Results

Table 1 summarizes absolute differences in knee joint angles and net moments across the three laboratories using the CGM2.4 and the musculoskeletal model. By utilizing the personalized musculoskeletal model, the differences in knee joint angles decreased by

maximally 38.4% and 77.9% for walking and step-down trials, respectively; the corresponding decrease in net joint moments was 74.9% and 77.6%.

Discussion

This study showed that inter-laboratory differences in kinematics and kinetics are affected by examiner-dependent marker placement and task execution, which is more variable if the task is more complex. Greater variability during step-down further reflected factors such as foot placement and balance. Multi-site studies therefore require consistent marker placement and step-by-step instructed task execution. Using a personalized musculoskeletal model can reduce both kinematic and kinetic differences through marker positioning optimization, thereby supporting a more reliable interpretation of gait analysis outcomes.

Images (Optional)

Table 1. Inter-laboratory differences in peak knee joint flexion angle and net moment computed using the CGM2.4 and personalized musculoskeletal model.

Analysis Method	Parameter	Activity	Δ Lab1 VS. Lab2	Δ Lab1 VS. Lab3	Δ Lab2 VS. Lab3
CGM2.4	Knee joint Flexion angles (°)	Walk	2.6	6	3.7
		Step-Down	5.8	8.6	3.7
	Knee joint Flexion net moments (Nm)	Walk	16.9	24.1	41
		Step-Down	32.3	25	7.3
Musculoskeletal Model	Knee joint Flexion angles (°)	Walk	1.6	5.4	3.7
		Step-Down	1.6	1.9	3.6
	Knee joint Flexion net moments (Nm)	Walk	4.2	23.6	27.9
		Step-Down	7.2	13.5	6.3

[4]Department of Biomedical and Neuromotor Sciences, University of Bologna, Bologna, Emilia Romagna, Italy

Introduction

Anterior cruciate ligament (ACL) injuries are common in handball, mostly occurring during non-contact cutting maneuvers [1]. While lab-based studies have identified biomechanical risk factors, on-court duels remain unexplored [1]. Wearable technologies (IMUs) allow on-field assessments during dynamic tasks. This study compared ACL-reconstructed (ACLR) and healthy handball players using IMUs during on-field sport-specific injury-related tasks.

Methods

Twenty-five professional handball players (23.7±3.9 years; 14 males), including 7 ACLR players (RTS>24 months), performed two high-dynamic cutting tasks: a change of direction with a passive opponent and a response to an active, real-game opponent (n=300 trials collected, Figure1). Based on dominant hand and movement direction, trials were classified as sidestep cuts (SSC) or crossover cuts (XOVER). Lower-limb and trunk kinematics were recorded using eight IMUs (100Hz, MTw Awinda, Movella), validated for high-dynamic movements. Joint kinematics was assessed in the three anatomical planes at initial contact (IC), peak knee flexion (pKF), and range of motion (ROM). Speed and acceleration/deceleration during approach/exit phases were evaluated. A linear mixed-effects model tested effects of injury (ACLR vs. healthy), opponent (passive vs. active), and their interaction effect (injury×opponent) on kinematics.

Results

Significant injury×opponent interactions indicated altered kinematics in ACLR players. Active-opponent conditions amplified kinematic differences between ACLR and healthy players (SSC: 9 vs. 2 significant variables). In SSC ($p<0.001$-0.042), ACLR showed greater

trunk sagittal ROM and ipsilateral rotation at pKF, increased contralateral pelvic rotation at IC, higher hip flexion, larger frontal-plane knee ROM, and greater ankle eversion, more pronounced with active opponent. In XOVER ($p<0.006$-0.048), ACLR demonstrated increased trunk rotation and flexion, greater pelvic flexion, higher hip flexion, reduced knee internal rotation with more varus, and increased ankle ROM with greater external rotation. ACLR players showed significant differences in performance, including higher lateral exit velocity in SSC ($p=0.023$), and lower approach velocities and higher peak accelerations in XOVER ($p\leq0.048$).

Discussion

ACLR handball players adopted altered cutting techniques compared to healthy controls, especially against active opponents. These findings highlight the need for sport-specific ecological assessment of players' motion to detect residual impairments and promote data-driven return-to-play decisions.

OA42-02

Concurrent Validation of Markerless Motion Capture Systems for Measuring Player Kinematics During Ice Hockey Skating Starts

Mr. Minori Iizuka[1], Ms. Kelsey Klug[1], Mr. Philippe Renaud[1], Dr. Glenn Fleisig[2], Dr. Philippe Dixon[1], Dr Shawn Robbins[1]

[1]McGill University, Montreal, Quebec, Canada. [2]American Sports Medicine Institute, Birmingham, Alabama, United States

Introduction

Ice hockey biomechanics has focused on marker-based motion capture systems to measure player kinematics, but these technologies are subject to skin motion artifact, and marker-placement biases. Thus, markerless motion capture systems offer a potential alternative to measuring biomechanics. However, this technology has not been validated for ice hockey tasks. This study aims to validate the kinematic measurements of a commercial markerless against a marker-based motion capture system during ice hockey skating starts.

Methods

Ten participants (six males, four females) were fitted with an adapted cluster-based marker set and performed five "V-Starts" for this cross-sectional study. A 10-camera Vicon marker-based system (240 Hz) and an eight-camera Qualisys video system (120 Hz, 720p resolution) with Theia Markerless software measured kinematics. Marker and video data were filtered using a 10Hz low-pass Butterworth filter and a 10Hz Generalized Cross-Validation Spline Filter, respectively. Lower extremity joint angles were compared using root mean squared error (RMSE) and coefficient of multiple correlations (CMC). Joints sides were categorized as lead (side that steps forward first) or push (back leg that pushes off at the start).

Results

The mean and standard deviation players' ages were 24 ± 4 years old. Table 1 highlights each joint's RMSE and CMC. The sagittal plane (flexion/extension, plantar/dorsi-flexion) joints measures had very good to excellent agreement; frontal (ab-/ad-duction, pronation/supination) and transverse plane (internal/external rotation) measures had poor to moderate agreement. The mean RMSE values for the sagittal, frontal, and transverse plane were 7.95°, 9.34°, and 11.75 °.

Discussion

The sagittal plane measures had highest agreement and lowest differences. Each biomechanical model's segment coordinate system definition likely impacted observed differences as these definitions alter joint angles calculations in secondary/tertiary segment axes [1]. Additionally, the skating start's explosive, dynamic movement may explain the results as previous markerless validation studies found larger errors with increased running speeds [2]. Angle measurements were different between systems, thus, researchers should use caution when comparing markerless and marker-based studies. Future validation studies should investigate other hockey shooting and skating tasks.

[5]Club d'athlétisme de l'Université Laval, Quebec, Qc, Canada

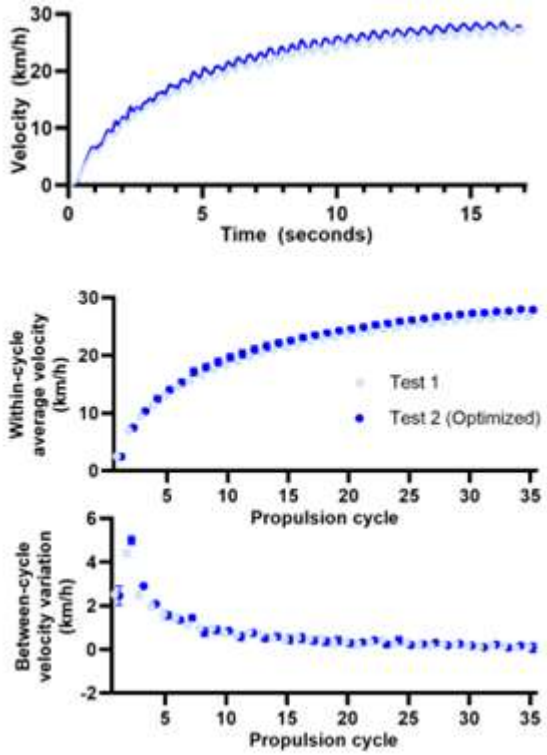
Introduction

Wearable sensors are widely used in both recreational and elite sports to monitor performance and prevent injuries. Recent studies have demonstrated that wearable sensors, when paired with appropriate analytical algorithms, can yield reliable data in wheelchair sports [1,2]. Yet, tailored feedback systems for para-athletes and their coaches remain limited [1]. This study aims to develop a real-time feedback system specifically designed for wheelchair racing athletes and their coaches.

Methods

An iterative design thinking methodology was employed, beginning with focus group interviews involving five wheelchair racing para-athletes and three coaches to identify key needs and preferences. Based on these insights, a wheelchair velocity measurement system was developed using inertial motion units (IMUs). The system underwent multiple field-testing iterations, involving up to three para-athletes, one coach, and twelve able-bodied individuals. Usability was assessed through participatory observations and semi-structured interviews, while validity was evaluated by comparing the system's output with a Lidar-based reference system and by following the evolution in performance of an elite athlete over a six-month period.

Results



The current prototype (4th iteration) calculates wheelchair velocity at 20 Hz using a gyroscope mounted on the wheel. It also communicates with a smartphone via Bluetooth for data collection control and includes onboard data storage. The system provides

sufficient spatiotemporal resolution to capture intracycle velocity variations, a key requirement identified by athletes and coaches. Longitudinal data collected during 100 m races over six months with an elite athlete demonstrated the system's sensitivity to detect a 3.9% gain in maximal velocity ($p<0.001$) following a wheelchair optimization intervention. Notably, velocity gains during the initial propulsion cycles (Figure 1) aligned with the athlete's perceived improvements in start performance.

Discussion

This project highlights the value of a participatory approach involving engineers, motor performance researchers, athletes, and coaches. The resulting system is both robust and valid for short-distance wheelchair racing. Future iterations will focus on enhancing the software interface to promote greater autonomy for users and facilitate integration into training routines.

Dr. Francisco García-Muro San José

Dr. Néstor Pérez Mallada

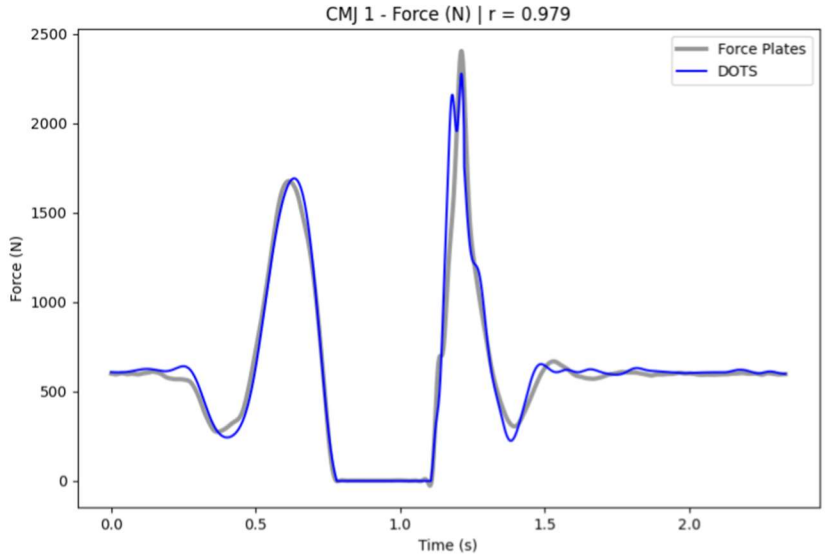
Prof. Daniel Iordanov López

Introduction

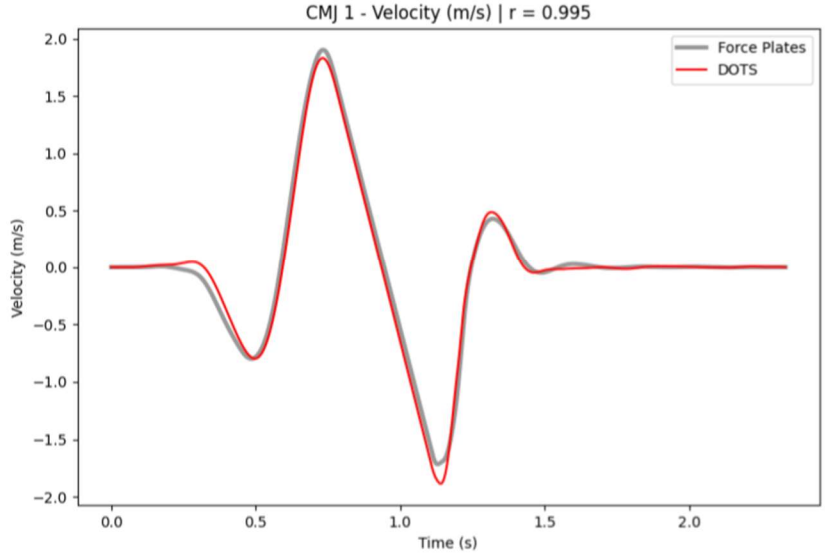
Monitoring jump kinetics is vital for assessing performance, neuromuscular fatigue, and injury risk factors in basketball, as landing dynamics and asymmetries are critical predictors [1, 2]. While force plates represent the gold standard, their high-cost limits daily application. Low-cost inertial measurement units (IMUs) could offer a feasible, reliable field-based alternative [3]. This study wants to validate DOTS IMUs against Hawkin Dynamics force plates during countermovement and drop jumps, assessing their accuracy in measuring key biomechanical variables for practical player monitoring.

Methods

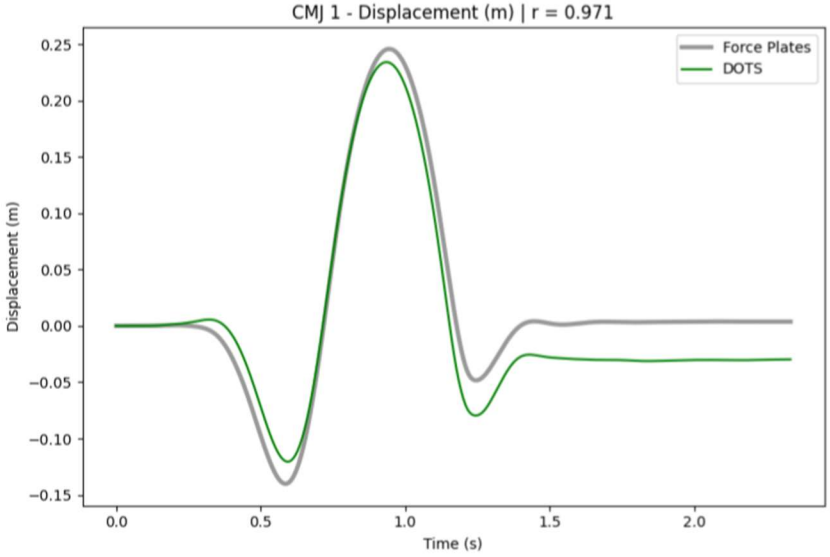
In this study 47 healthy athletes of both sexes participated (age: 26.42 ± 5.01 years; mass: 77.55 ± 24.47 kg; height: 1.77 ± 0.11 m). The technologies used were inertial movement units (IMUs) DOTS (120Hz, Movella Technologies B.V.) and force plates (Hawkin Dynamics, 1000Hz) were used to evaluate 2 repetitions of each of the following jump tests: counter-movement jump (CMJ) and drop jump (DJ). Data processing was performed in Python (v 3.7). SPSS (v 31) was used for statistical analysis (p-value < 0.05).



Results



Signal correlation between DOTS and force plates was strong (r>0.9) for both CMJ and DJ (View Figure 1). Bland-Altman analysis indicated good agreement, with the majority of data points falling within the limits of agreement across variables. SPM revealed significant differences only during the initial (0–13%) and final (75–100%) phases, attributed to IMU sensitivity to non-essential movement noise. Despite mean differences in some of the variables IMU system tracked performance metrics consistently.



Discussion

The findings validate DOTS as a practical alternative to force plates for monitoring basketball players. High correlations in key metrics support their use for performance profiling, neuromuscular fatigue, and return-to-play assessments. While IMUs showed sensitivity to noise during stabilization phases (start/end of the signal), the critical force-production phases remained accurate. Consequently, DOTS provides a valid, portable and low-cost solution for daily field monitoring of variables like peak propulsive force and RSImod, overcoming the logistical limitations of stationary force plates in team sports settings.

[6]Rehabilitation Engineering, Rancho Los Amigos National Rehabilitation Center, Downy, CA, United States

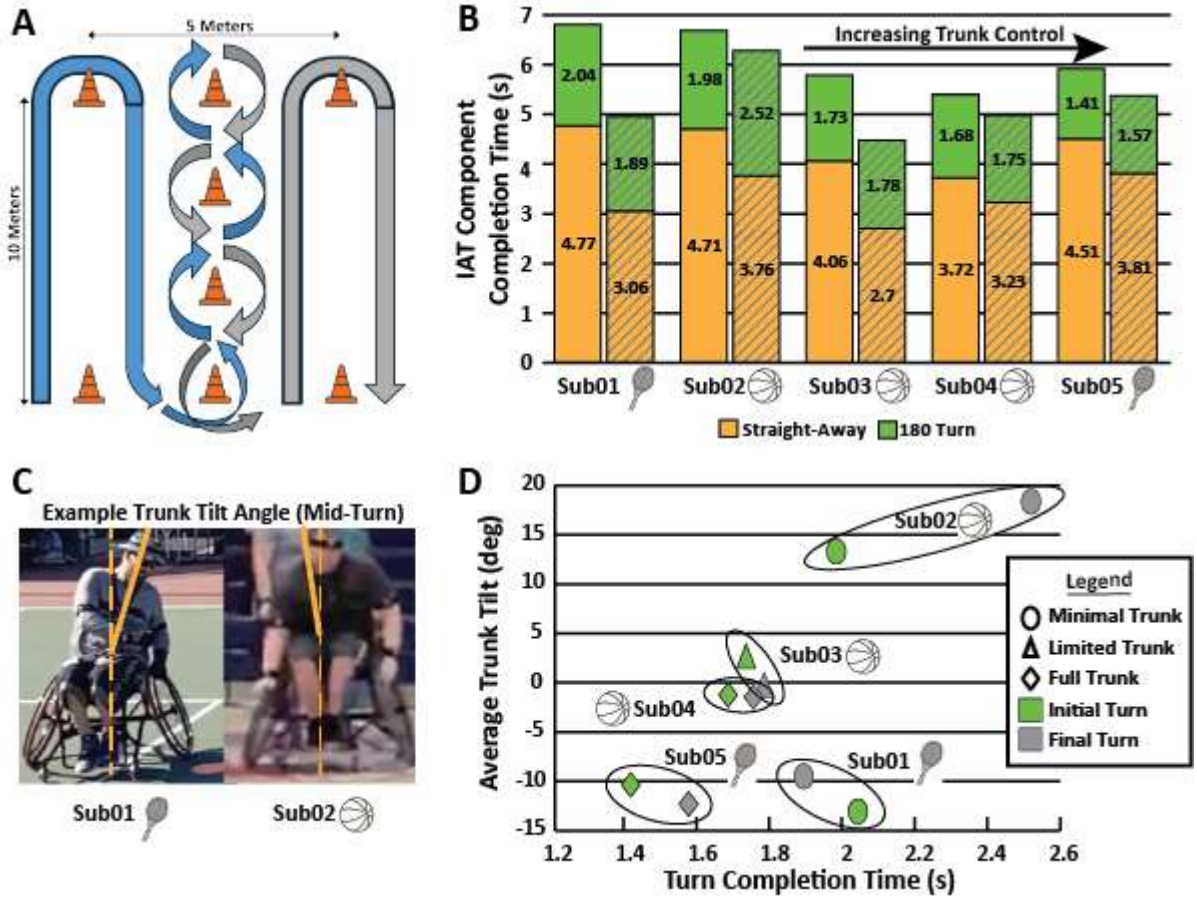
Introduction

Recent work demonstrated that an adaptation of the Illinois Agility Test (IAT) for wheelchair athletes is a reliable measure [1]. The IAT measures how quickly athletes navigate an obstacle course using straight-line and weaving movements (Figure 1A). Beyond execution time, biomechanical tools (e.g., video recordings, wearable sensors) can reveal additional movement insights. This study aimed to understand how an athlete's capacity for trunk control (CTC) influences IAT execution and performance.

Methods

Five competitive wheelchair athletes (3 basketball, 2 tennis) with varying impairments performed the IAT using their own sport chair. Spatiotemporal parameters and upper extremity joint kinematics were collected using high speed video and inertial measurement units (Equilibrium, Vayu Technology, USA). CTC was estimated through sport classification or self-report. IAT phases (e.g., straight-line, turning) were defined, and relationships between performance (i.e., phase completion times), movement technique (e.g. trunk angle), and CTC were investigated.

Results



IAT completion times were between 29.8-35.6 seconds. Analysis of the first and third straight-aways and subsequent turns (Fig 1A, bold outline) revealed strategy differences: athletes with less CTC took longer times to prepare and execute turns (Fig 1B). Surprisingly, the participants with similar CTC used different turn techniques as evidenced

by differences in average trunk side-to-side tilt: those with minimal CTC used opposite tilts (Fig 1C-D). These findings highlight that athletes with similar CTC can use varying strategies to achieve the same objective; emphasizing the need for training protocols tailored for individual capacities.

Discussion

This pilot study demonstrates that biomechanics tools are easily integrated into sport activities, providing wheelchair athletes and coaches with additional, sport-relevant insights into IAT performance. Evaluating straight line (speed) and turning (agility) IAT components, alongside trunk kinematics such as trunk tilt, revealed multiple viable performance approaches, suggesting optimal technique is influenced by CTC. Although IAT is widely used by parasport coaches and athletes, additional work is needed to contextualize the rich biomechanical data available during execution of the IAT [2,3].

Field-Based Biomechanical Analysis of Ski Mountaineering Using Smartphone Video and Open-Source Pose Estimation Methods

Dr. Pawel Kudzia PhD, Ms Naomi Clements, Dr. Peter A. Cripton PhD

University of British Columbia, Vancouver, BC, Canada

Dr. Pawel Kudzia

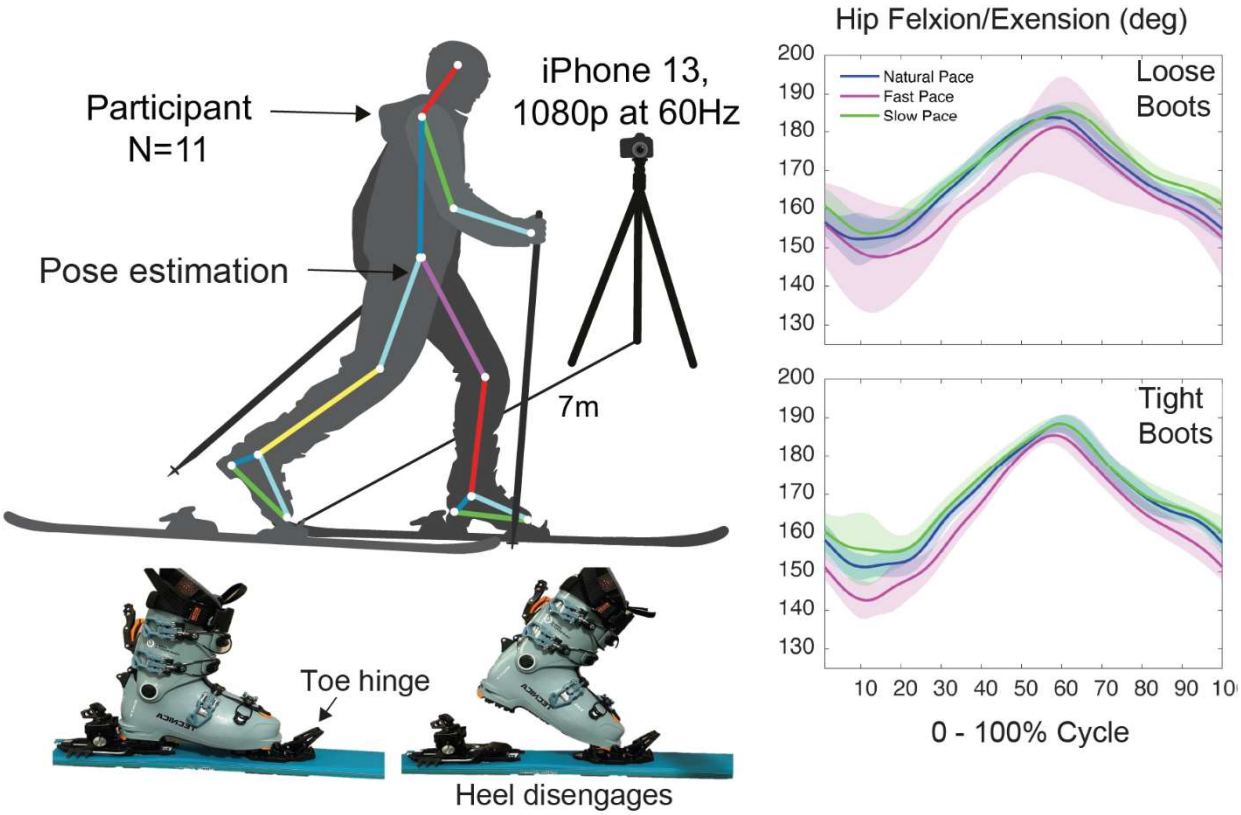
Ms Naomi Clements

Introduction

Ski mountaineering debuts at the 2026 Milano-Cortina Winter Olympics, yet we know remarkably little about how athletes actually move in mountain environments. Unlike downhill skiing, ski mountaineers spend most of their time ski touring: walking uphill with skis attached, using specialized bindings that release the heel and skins that grip the snow to prevent backward sliding [1]. During ski touring, athletes also loosen their boots to allow greater ankle mobility. This ascending phase is physically demanding and technically complex, yet nearly all biomechanical research relies on laboratory treadmills and roller skis that cannot replicate snow properties or glide characteristics. We used smartphone video and open-source pose estimation to demonstrate that meaningful kinematic analysis of ski touring is feasible in natural mountain environments.

Methods

We recruited 11 participants (ages 22-54, intermediate to expert) and recorded video using an iPhone 13 (1080p, 60 Hz) in the mountains of Sḵwx̱wú7mesh (Squamish), British Columbia, Canada. Participants ski toured under six conditions varying speed (slow, natural, fast) and boot configuration (loose touring mode vs. tight skiing mode). We extracted body landmarks using a general pose estimation algorithm (BlazePose) and then estimated hip, knee, and ankle joint angles, trunk inclination, and ski stride rate across segmented ski strides.



Results

Using this free, and easily implemented method, we found consistent hip and knee joint angle patterns across the ski stride cycle. Boot configuration altered how participants moved: tight boots reduced hip range of motion (both $p < 0.001$) but increased knee range of motion ($p \leq 0.025$), suggesting participants compensated for restricted ankle mobility through greater knee flexion. Participants also leaned further forward as stride rate increased. However, our pose estimation algorithm struggled to well track ski boot landmarks, producing inconsistent ankle angles.

Discussion

To our knowledge, this represents the largest in-field ski touring biomechanics dataset collected to date. We demonstrate that smartphone-based pose estimation can detect meaningful kinematic patterns and condition differences in natural environments. Future work will focus on improving landmark tracking on ski equipment and validate results against wearable systems such as inertial measurement units.

Patient-Specific Multiphysics Modeling for Accurate Recapitulation of Patent Ductus Arteriosus Stenting Interventions

Mr. Luis Rene Mata Quinonez ME, MS[1,2], Dr. Thangam Natarajan PhD[1], Mr. Leon Cheng B.S.[1], Ms. Emma Chang B.S.[1], Mr. Burke Thompson B.S.[3], Dr. Lakshmi Prasad Dasi PhD[1,2], Dr. Holly Bauser MD, PhD[4]

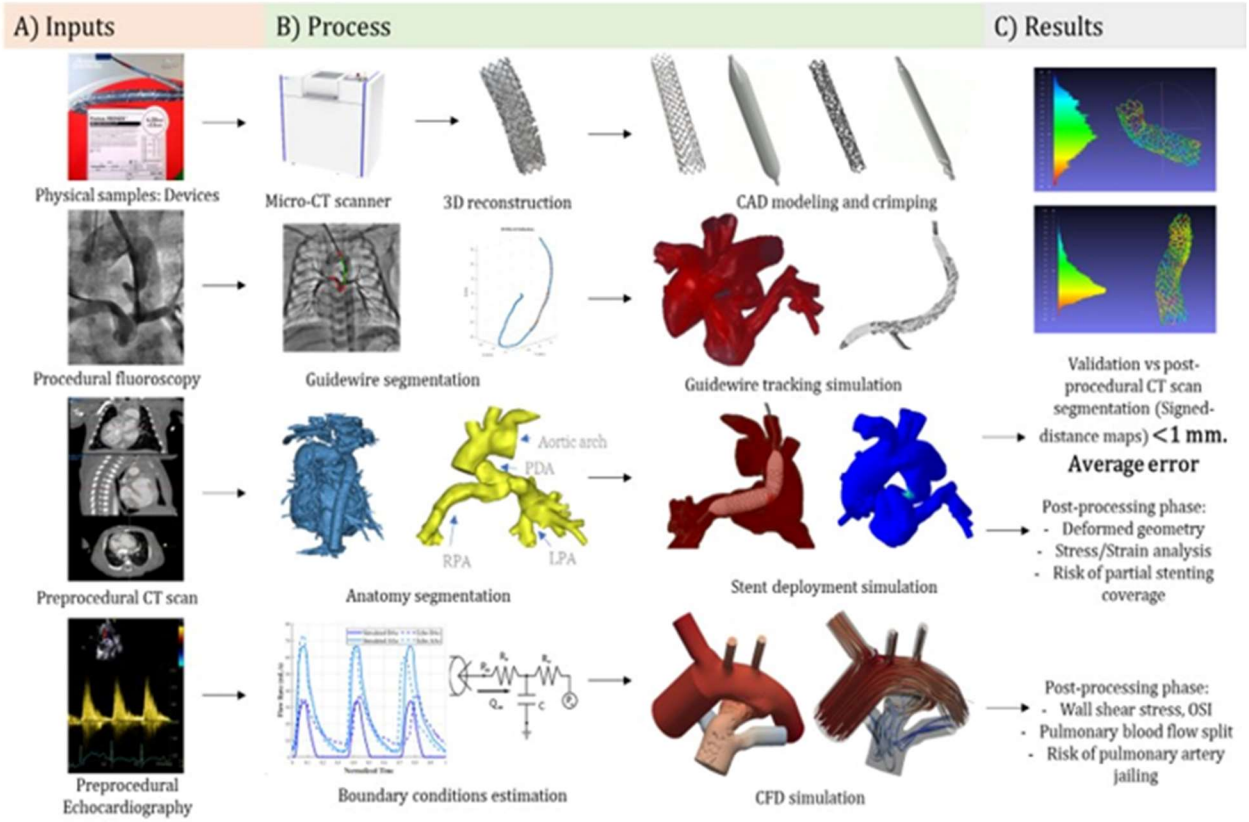
[1]Georgia Institute of Technology, Atlanta, Georgia, United States. [2]Emory University, Atlanta, Georgia, United States. [3]Georgia Institute of Technology, Atlanta, Georgia, Norway. [4]University of Texas Health Science Center at Houston, Houston, Texas, United States

Introduction

In patients with cyanotic congenital heart diseases, a common treatment is Patent Ductus Arteriosus (PDA) stenting, a minimally invasive palliative procedure that keeps the ductus open, improves oxygen saturation, and provides a more stable source of pulmonary blood flow (PBF). Even though the mortality of this procedure is low, some of the complications associated to proper stent length selection are: partial PDA coverage and risk of pulmonary artery jailing. In the former case, an implanted stent that is too short may leave segments of the PDA uncovered, accelerating ductal stenosis resulting in cyanosis, and the second issue occurs when a long stent obstructs the blood flow of the side branch pulmonary artery (PA), which often results in PBF imbalance and asymmetric PA growth.

Methods

Physical samples of the stent, angioplasty balloon, and guidewires, were micro-CT scanned to enable computational reconstruction, CAD modeling, meshing, and crimping to generate their undeployed configurations. Patient-specific PDA anatomy was reconstructed from pre-procedural CT scans. We simulated the guidewire tracking by first segmenting and 3D reconstructing the guidewire from procedural fluoroscopy videos and then deforming a PDA centerline to this configuration. The pre-deployment stent and balloon geometries, pre-bent to the guidewire path, were then positioned within the PDA model, and stent deployment was simulated through balloon inflation and deflation. For the fluid dynamics analysis, echocardiography-derived velocity waveforms were applied as boundary conditions to the post-deployment geometry, and CFD simulations were conducted to evaluate local hemodynamics. (Fig. 1A-B)



Results

We applied the pipeline to ten patients with varying PDA tortuosity. The deformed PDA and stent geometries from our FEA simulations were validated against post-procedural segmentations, yielding a mean signed-distance error below 1 mm. We developed semi-automatic tools to identify regions of elevated stress/strain and to estimate areas at risk of partial coverage. For CFD post-processing, we quantified wall shear stress, OSI, pulmonary blood-flow split, and introduced metrics to assess the risk of pulmonary artery jailing. (Fig. 1C)

Discussion

In this retrospective work, we showed a multi-physics FEA-CFD simulation pipeline to recapitulate the outcomes of PDA stenting procedures and predicted the risks of partial stenting coverage and pulmonary artery jailing.

Influence of Inherent and Exercise-Induced Aerobic Capacity on Cardiac Structure and Function in a Rat Obesity Model

Mr. Dhairya Desai, Mrs. Jeannine Turnbull, Mr. Griffin Wong, Mr. Abel Mebrahtu, Mr. Darsh Tripathi, Mr. Mauricio Delgado, Dr. Walter Herzog PhD

University of Calgary, Calgary, Alberta, Canada

Introduction

Obesity is now the leading global risk factor for early cardiovascular (CV) death and contributes to heart dysfunction through metabolic and endothelial damage [1]. Aerobic capacity is a measure of metabolic processes using maximal oxygen uptake rate and serves as a protective factor against CV degeneration. Differences between inherent (genetic) and acquired (exercise-based) aerobic capacity in the context of obesity remain unclear. Therefore, studying animal models selectively bred for high aerobic capacity (HAC) and low aerobic capacity (LAC) can help further our understanding of protective mechanisms and pathways that aerobic capacity has against the effects of obesity on the heart. We hypothesize that high inherent aerobic capacity and increased acquired aerobic capacity will lessen the negative cardiac effects of diet-induced obesity.

Methods

Forty-seven male N:NIH rats , comprised of 24 HAC and 23 LAC underwent a 12-week exercise intervention, and then were split into four groups; HAC/LAC rats undergoing a12-week diet intervention (high-fat, high-sucrose - HFS - or control chow). The primary outcome of this study is the measurement of cardiac function obtained using echocardiography taken longitudinally throughout the intervention periods every 4 weeks.

Results

Cardiac output (CO) increased during the exercise phase in both HAC and LAC rats. During the diet intervention, CO generally declined in HAC and LAC rats. LAC rats on the HFS diet showed an earlier drop in CO, though the chow-fed LAC rats converged to a similar CO level by Week 24.

Discussion

Our results suggest that inherent aerobic capacity influences cardiac resilience during metabolic stress, as reflected in literature. While both HAC and LAC rats maintained or improved CO during the exercise phase, strain differences emerged once the diet intervention began. LAC rats, especially those on the HFS diet, showed an earlier and more

pronounced decline in CO, indicating greater vulnerability to diet-induced cardiac dysfunction. In contrast, HAC rats generally preserved CO regardless of diet, suggesting intrinsic protective mechanisms linked to higher aerobic capacity.

However, interpretation is limited by the small sample size and incomplete dataset, and additional HAC and LAC rats will be incorporated as analyses continue.

Computational Framework for Studying myocardial Bridging

Dr. Giuseppe De Nisco[1], Dr. Sara Zambon[1], Mr. Stefano Elia , MD[2], Prof. Fabrizio D'Ascenzo , MD[3], Prof. Giuseppe Patti , MD[2], Prof. Diego Gallo[1], Prof. Domenico D'Amario , MD[2], Prof. Umberto Morbiducci[1]

[1]PolitoBIOMed Lab, DIMEAS, Politecnico di Torino, Turin, Piedmont, Italy. [2]Department of Translational Medicine, University of Eastern Piedmont, Novara, Piedmont, Italy. [3]Hemodynamic Laboratory, Department of Medical Sciences, University of Turin, Turin, Piedmont, Italy

Introduction

Myocardial bridging (MB) is a congenital anomaly in which a segment of a coronary artery tunnels within the myocardium. Traditionally regarded as benign, MB has been recently associated with ischemia, arrhythmias, and sudden cardiac death [1], possible consequences of systolic compression and alterations in wall shear stress (WSS). This study proposes a personalized computational framework to characterize MB morphology and hemodynamics and demonstrates its feasibility in three patients.

Methods

The workflow (Figure 1) used segmentation of dynamic cardiac Computed Tomography images acquired over multiple cardiac phases to reconstruct patient-specific MB geometries on patients P1, P2 and P3—in P1 covering the diastolic phase; in P2 and P3 the entire cardiac cycle. Each phase-specific geometry was meshed and registered using the Coherent Point Drift algorithm to reproduce vessel motion [2]. Computational fluid dynamics simulations were performed by prescribing personalized velocity and pressure data at the inflow and outflow boundaries, respectively [3]. A *Moving Boundary* condition was imposed to the wall. Anatomical features were assessed in terms of local luminal surface area, shape index, curvature, and torsion [4]. Hemodynamics was evaluated in terms of WSS-based quantities: TAWSS, OSI, RRT and TSVI.

Results

In all patients, MB segment showed marked lumen reduction (up to 70%, Figure 1C) across systole and diastole (e.g., in P2 mean MB luminal area was 5.02 mm^2 in systole and 5.64 mm^2 in diastole). MB modestly affected lumen eccentricity, with negligible changes in

curvature and torsion. MB consistently altered WSS, with higher shear disturbances in the proximal segment than bridged tract (Figure 1D).

Discussion

This pilot study proposes a patient-specific framework for morphological and hemodynamic assessment of MB. Ongoing extension to ten cases will confirm the observation,first reported here, that MB lumen reduction persists across the entire cardiac cycle (not only in systole). The proposed framework candidates as a tool to identify higher-risk MB patients who may benefit from closer surveillance or targeted management.

[5]Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

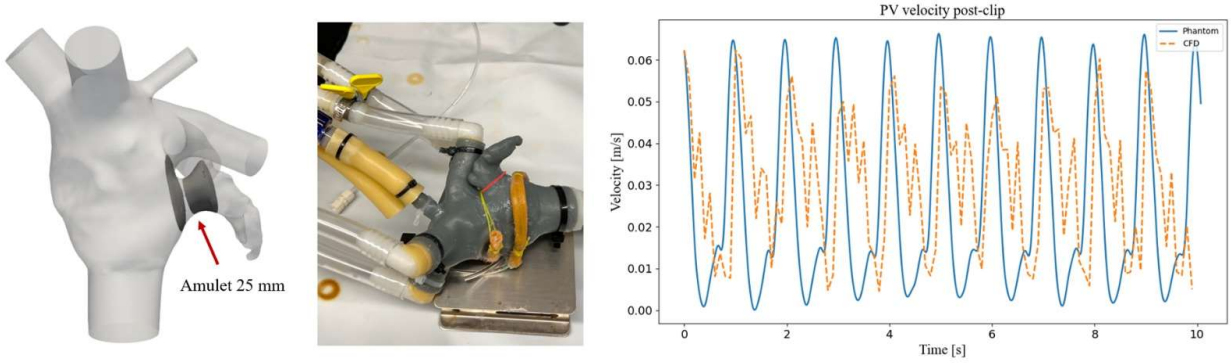
Introduction

Computational fluid dynamics (CFD) is increasingly used to study left atrial (LA) hemodynamics in atrial fibrillation (AF) and to support evaluation of left atrial appendage occlusion (LAAO) devices. However, validation of patient-specific CFD models, particularly those incorporating physiological wall motion and implanted devices, remains limited. To address this gap, this work introduces a validation framework integrating CFD with a soft-robotic dynamic atrial phantom capable of reproducing patient-specific atrial contractility in AF and post-LAAO conditions.

Methods

A patient-specific LA was reconstructed from pre-LAAO computed tomography (CT) images. This geometry was used to create a soft-robotic phantom whose actuation reproduced atrial wall motion via CT-derived displacement fields. Integrated within a closed-loop mock circulatory system, the phantom enabled pressure and flow measurements at the pulmonary veins (PVs) and mitral valve (MV) [1]. To extend validation to device-implanted conditions, the same LA was adapted to a post-LAAO configuration by virtually implanting a 25 mm Amplatzer Amulet device and reproducing the occlusion with a mechanical clip at the LAA ostium (Figure 1a: LA with virtual implanted device and phantom with mechanical LAA occlusion.). Corresponding CFD simulations were performed in ANSYS Fluent 2021R2 using the virtually cut LA geometry. Atrial wall motion was prescribed through CT-derived displacement fields, while PVs pressure and MV flow

waveforms measured in the phantom were applied as boundary conditions. Ten cardiac cycles were simulated and compared with the in-vitro recordings.



Results

CFD analysis reproduced the global features of the PV velocity waveforms measured in the phantom, capturing peak timing and waveform morphology in both pre- and post-LAAO configurations. Simulated velocities were generally lower near peak inflow and showed higher-frequency fluctuations, attributed to geometric fidelity near the PV inlets and differences between soft-robotic actuation and numerical motion mapping (Figure 1b: Phantom and CFD PV velocity waveforms in the post-LAAO scenario).

Discussion

This study provides the first validation of LA CFD under dynamic wall motion and device-implanted conditions. The agreement in global hemodynamics supports the use of CFD for benchmarking studies covering wall mechanics and LAAO devices, while remaining discrepancies motivate improvements in geometric fidelity and motion transfer methods.

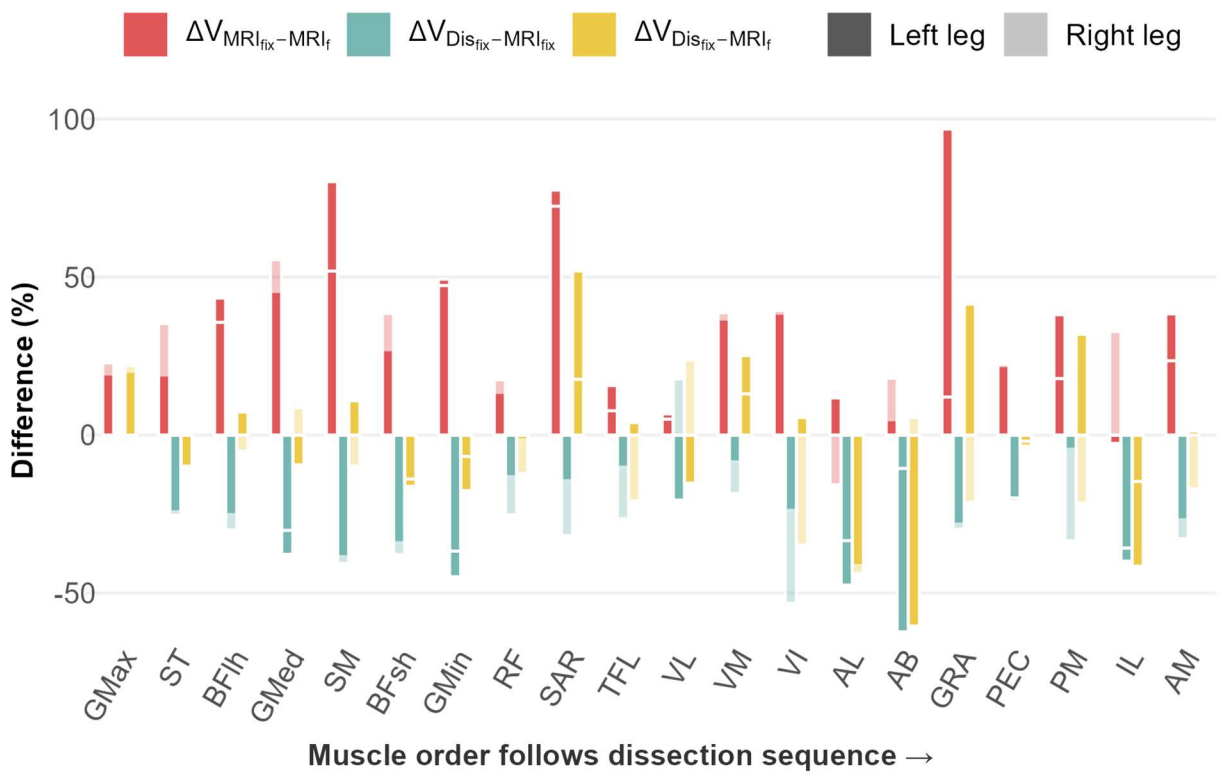
[4]Skills & InnovationLab Healthcare, Erasmus University Medical Center, Rotterdam, Zuid-Holland, Netherlands. [5]Department of Neuroscience-Anatomy, Erasmus University Medical Center, Rotterdam, Zuid-Holland, Netherlands

Introduction

Muscle parameters in generic musculoskeletal models are typically derived from combined datasets that include in-vivo, ex-vivo, and in-vitro measurements from limited studies [1]. Magnetic resonance imaging (MRI) could provide larger in-vivo datasets for a subset of these muscle parameters. However, validating MRI against anatomical-dissection is methodologically challenging. Fixation prevents decay during dissection but possibly introduces artifacts, while dissection causes dehydration that alters muscle volume. This study aimed to quantify ex-vivo volumetric differences across three stages within the same donor: MRI of fresh tissue, MRI of fixated tissue, and physical dissection.

Methods

MRI scans of the lower extremities in a fresh-frozen human were acquired before, and one week after AnubiFIX fixation [2]. Three-dimensional models were generated from manual segmentations of 20 muscles bilaterally (n=2) to calculate fresh ($V_{MRI,f}$) and fixated ($V_{MRI,fix}$) muscle volumes. Subsequently, these same muscles were dissected, and their physical volumes ($V_{Dis,fix}$) measured via water displacement. We compared: (1) the volumetric effect of fixation ($V_{MRI,f}$ vs. $V_{MRI,fix}$), (2) the methodological consistency between imaging ($V_{MRI,fix}$) and dissection ($V_{Dis,fix}$) and (3) total volumetric change ($V_{MRI,f}$ vs. $V_{Dis,fix}$).



Results

The mean percentage change between $V_{MRI,f}$ and $V_{MRI,fix}$ was +31.5% (SD 23.3%). The high SD indicates variable swelling between muscles. Transitioning from fixated MRI to physical dissection revealed a mean volume change of −26.5% (SD 15.4%).

Discussion

Results demonstrate substantial volumetric alterations between fresh, fixed, and dissected muscle tissue, varying inconsistently across muscles. While the volume increase aligns with post-fixation swelling, the high variability implies fixation effects are nonuniform, likely influenced by muscle hydration, fat content, and anatomy. This is an important finding for the accuracy of musculoskeletal simulations [1]. Furthermore, the average volume loss between fixated MRI and dissection indicates significant tissue dehydration occurred. This was time-dependent: muscles dissected later in the sequence - and thus exposed longer - exhibited greater volume deviations. Quantifying these effects on a larger scale is important to ensure that the combined data from dissection and MRI are reliable for musculoskeletal modeling.

An “Uplifting” Exploration: What Global or Local Anthropometry Best Predicts Pelvic Floor Muscle Volume?

Ms. Amanda Knizley[1], Mr. Brendan S. Shea[1], Dr. Lara Riem[2], Mr. Mario E. Garcia[1], Dr. Neha Yadu[3], Dr. Silvia Blemker[1]

[1]University of Virginia, Charlottesville, Virginia, United States. [2]Springbok Analytics, Charlottesville, Virginia, United States. [3]University of Texas at Southwestern, Dallas, Texas, United States

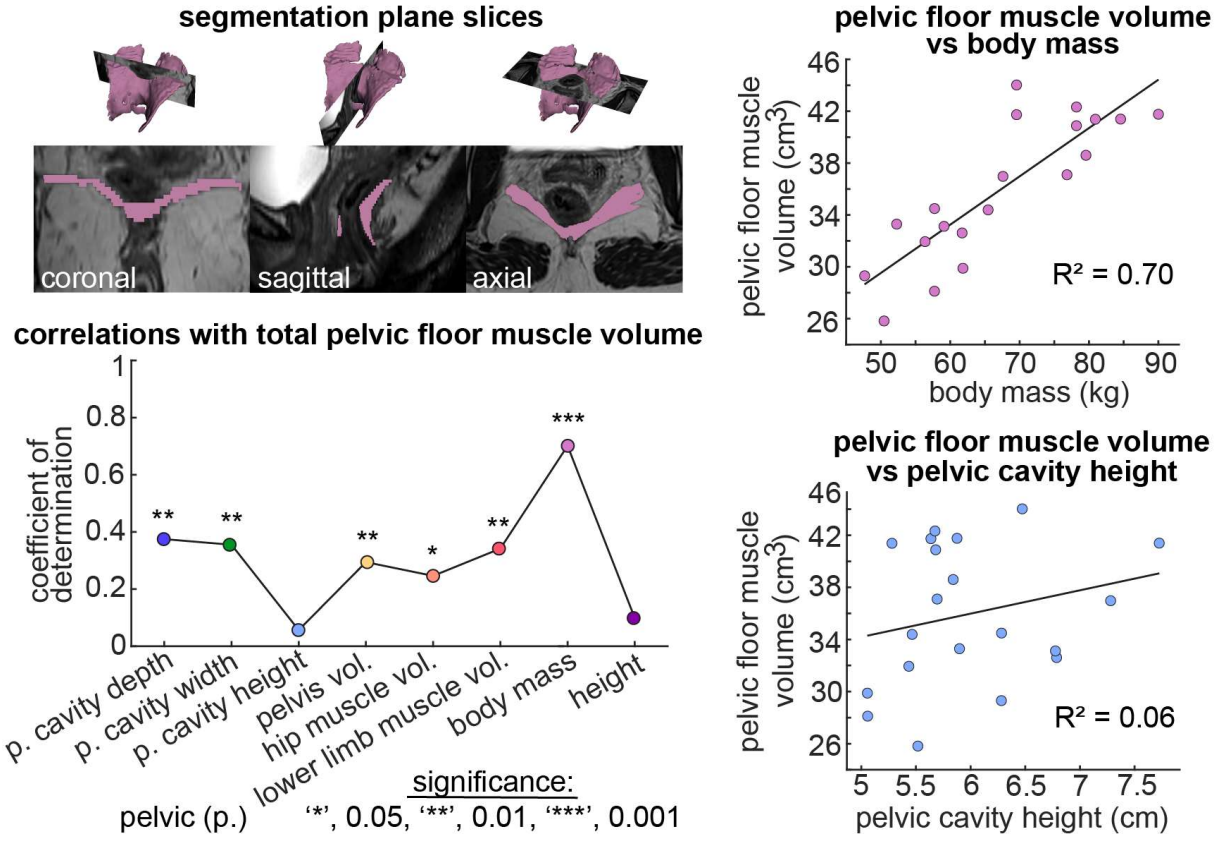
Introduction

Pelvic floor dysfunction (PFD), experienced by up to 46.50% of females worldwide, results in one or more of the following symptoms: urinary incontinence, fecal incontinence, and prolapse [1]. Even with state-of-the-art current treatments, up to 50% of females still experience dysfunction with risk increasing with age [2], greatly limiting quality of life. Little is known about what geometrical pelvic floor muscle (PFM) features may predispose individuals to PFD, limiting early intervention and preventing more tailored treatment. A quantitative framework describing anatomical predictors relative to normal PFM variability is needed to contextualize PFD. The goal of this work is to measure the variability in PFM volume and examine how this variability relates to mass, height, bone geometry, and other muscle volumes.

Methods

Static high-resolution MRI scans of the pelvic floor were collected from (n=20) female subjects between the ages of 20 and 49 with no history of musculoskeletal injury. The PFM, lower limb muscles, and lower limb bones were segmented through a combination of a trained AI system and manual editing. PFM volume was measured in 3D Slicer and related as a linear regression with measurements of pelvic cavity (including the lesser pelvis space only) depth, width, and height; pelvis volume; hip and lower limb muscle volumes; and body mass and height measurements.

Results



Across all predictors, PFM volume varied most strongly with body mass ($R^2 = 0.70$, model p-value < 0.001). The weakest predictors were pelvic cavity height ($R^2 = 0.06$, model p-value > 0.05) and body height ($R^2 = 0.10$, model p-value > 0.05). The remaining predictors (pelvic

cavity depth and width, pelvis volume, and hip and lower limb muscle volumes), all showed similar low-to-moderate correlations (R^2 = 0.37, 0.36, 0.29, 0.24, 0.34 respectively).

Discussion

PFM volume scaled most strongly with body mass, suggesting functional adaptation to support demands associated with whole-body loading and intra-abdominal pressure, rather than being primarily constrained by pelvic bony dimensions. Future studies will investigate PFMs in dysfunctional cases and see if deviation occurs in relation to healthy relationship trends.

Influence of Pelvis and Femur Morphology on Hip and Knee Joint Loading

Dr. Ekaterina Stansfield[1], Ing. Dr. Andreas Kranzl[2], OA Priv.-Doz. Dr. Jochen Hofsädter[2], Dr. Basilio Gonçalves[1], Dr. Hans Kainz[1]

[1]University of Vienna, Vienna, Vienna, Austria. [2]Speising Orthopaedic Hospital, Vienna, Vienna, Austria

Introduction

Hip and knee joint contact forces (JCF) during daily activities are central to orthopedics and sports science. Although implanted force gauges in joint-replacement patients provide gold-standard measurements (1), most estimates rely on musculoskeletal models. Here, we investigate how individual morphology of the lower girdle (pelvis, femora, tibiae) influences hip and knee JCF.

Methods

MRI images and 3D gait data of 25 women and 22 men was collected and used to create highly personalized musculoskeletal models (2). Morphology of the pelvis, femora, patellae, tibiae and fibulae was quantified using homologous anatomical landmarks. Muscle paths were wrapped onto skeletal structures using non-linear functions and refined with MRI views. Muscle forces were obtained through static optimization, and hip and knee joint contact forces were consequently calculated.

Principal components summarized skeletal shape variation. These components, combined with foot-position measures and pelvis, hip and knee kinematics, were used to predict JCF. Peak JCF during early- and late-stance phase were analyzed, yielding four dependent variables (HipPeak1, HipPeak2, KneePeak1, KneePeak2). In total, 36 independent variables were included in the regression model.

LASSO regressions were run for each dependent variable using three predictor sets: (a) speed+shape+foot position+kinematics; (b) speed+shape+kinematics; (c) speed+shape. LASSO selected up to five predictors, and Ridge regression with cross-validation assessed over-fitting and coefficient significance.

Results

HipPeak1 depended strongly on pelvic and femoral morphology and hip flexion (Fig. 1). HipPeak2 was driven mainly by speed. Knee JCF was primarily determined by knee and hip flexion, with KneePeak2 additionally influenced by foot position.

Discussion

Previous work based on generic-scaled models showed that JCF can be predicted from kinematics and anthropometry (3). This study presents the first statistical analysis using highly personalized MRI-based models with morphology-specific lower-girdle bones and muscle paths. The results underscore the importance of pelvis and femur morphology for early-stance hip JCF and confirm the overarching influence of joint kinematics and speed on hip and knee loading.

OA44-04

An Anatomy Based Technique For Predicting Knee Natural Motion

Dr. Lorenzo Capetta, Professor Nicola Sancisi, Professor Michele Conconi

University of Bologna, Bologna, Emilia Romagna, Italy

Introduction

Quantifying subject-specific kinematics is essential for identifying articular pathologies, planning treatments, and developing musculoskeletal models [1]. Accurate in-vivo measurements remain challenging, necessitating the development of predictive joint motion models. We propose a method that directly predicts subject-specific knee kinematics from joint anatomy, using only a description of articular surfaces and ligament insertions from medical images. This approach fulfils the experimentally observed reciprocity between natural motion and articular constraints: ligament fibres remain nearly isometric, while ligaments and articular contact lines of action intersect the instantaneous helical axis (IHA) throughout the entire range of motion [2]. Results were validated against experimental measurements [3], and the RMSE values were compared with those reported in the literature [4].

Methods

Six fresh-frozen leg specimens were analysed. Joint anatomy was manually segmented in MITK from CT and MRI scans. Insertions of 7 ligaments (ACL, PCL, LCL, ALL, deep MCL, proximal anterior MCL, proximal posterior MCL) were identified, and 5 fibres per ligament were extracted (35 total). Two contact lines of action were derived at each predicted pose as the weighted average of the normals of the condylar contact surfaces applied to their geometrical centroid, yielding 37 total constraints. Joint kinematics was obtained by minimising, for each flexion step, ligament length variation and the line-to-line distance between each constraint line of action and the IHA [2].

Results

Rotational and translational RMSE across subjects were 3.57 ± 3.93° and 2.70 ± 3.18 *mm*, with the highest errors observed in IE rotation and AP translation [Figure 1].

Discussion

The proposed model, based on standard CT and MRI, showed good results without requiring any calibration to experimental kinematics. Its RMSE values were lower than

those reported for calibrated predictive models of the literature (4.60° and 3.54 mm) [6], making it a promising tool for subject-specific knee motion prediction.

Images (Optional)

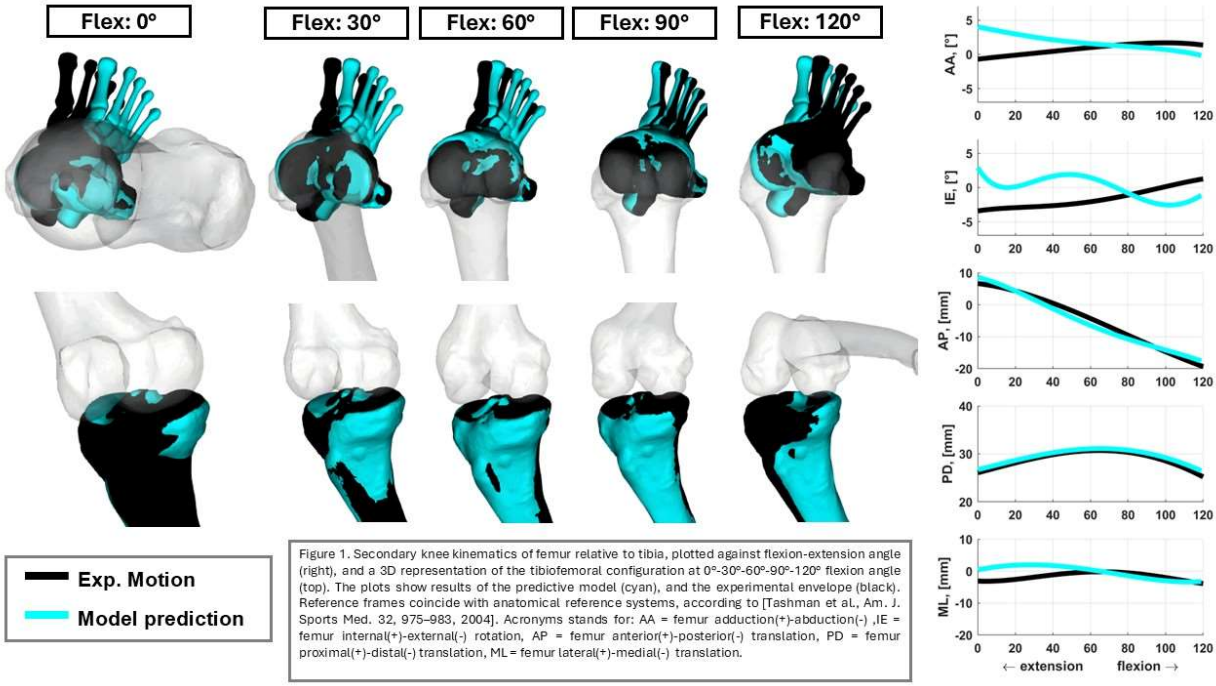

Figure 1. Secondary knee kinematics of femur relative to tibia, plotted against flexion-extension angle (right), and a 3D representation of the tibiofemoral configuration at 0°-30°-60°-90°-120° flexion angle (top). The plots show results of the predictive model (cyan), and the experimental envelope (black). Reference frames coincide with anatomical reference systems, according to [Tashman et al., Am. J. Sports Med. 32, 975–983, 2004]. Acronyms stands for: AA = femur adduction(+)-abduction(-) ,IE = femur internal(+)-external(-) rotation, AP = femur anterior(+)-posterior(-) translation, PD = femur proximal(+)-distal(-) translation, ML = femur lateral(+)-medial(-) translation.

Estimating the Patient-Specific Gravitational Loads Acting on the Spine

Dr. Benedikt Schlager[1], Dr. Peter Stauffert[1], Mr. Robert Graf[2], Mr. Hendrik Möller[2], Prof. Jan Kirschke[2], Prof. Hans-Joachim Wilke[1]

[1]Institute of Orthopaedic Research and Biomechanics, Centre for Trauma Research Ulm, Ulm, BW, Germany. [2]Department of Diagnostic and Interventional Neuroradiology, School of Medicine, TUM University Hospital, Technical University of Munich, Munich, Bayern, Germany

Introduction

A key challenge for the biomechanical analysis of patient-specific orthopedic treatment is identifying the loads which act within the individual patient.

Goal of this study was to quantify the gravitational loads and load distribution which act on the individual spine, as well as correlate these loads with the individual spinal shape.

Methods

Full body MRI images from a random retrospective subset of 270 patients (121 female, 149 male, age 21-72 years, BMI 17.4-50.6) of the German National Cohort (NAKO) were analyzed. 112 anatomical structures within the torso including the abdominal organs, lung, heart, spine and muscles were segmented using the DL-tools VibeSegmentator [1], SPINEPS [2] and MuscleMap [3]. The extracted parameters included the volume and center position of each anatomical structure, as well as the morphological parameters of the spinal shape (Fig). Density values for each anatomical structure was obtained from literature. The coordinates were transformed to a subject-specific coordinate system and the moments were calculated by the lever arm relative to the spinal vertebra L5. The data was evaluated statistically, and compared with literature and metric data of the patients.

Results

The estimated weight of the torso correlated significantly with the measured weight of the subjects (R2=0.9). The overall induced mean moment within the sagittal plane was 0.17 +/- 0.27 Nm, while the structures positioned anterior of the spine induced a mean moment of 0.3 +/-0.2 Nm and the posterior structures -0.16 +/-0.05 Nm. The subcutaneous fat induced a mean moment of 0.06 +/-0.09 Nm. No significant correlations between the shape of the spine and the weight or moments were obtained.

Discussion

Using segmented organs within the torso appears to be a promising approach for quantifying the distribution of gravitational loads acting on the individual spine. Limitations include the lying posture during MRI acquisition and the general methodological challenges of measuring and validating in-vivo loads. Nevertheless, the findings represent an important step toward individualized biomechanical analysis and orthopedic treatment.

Prediction of Adult Foot Bones Through Statistical Shape Modelling

Mr. Michael Oborn[1], Prof. Thor Besier[1,2]

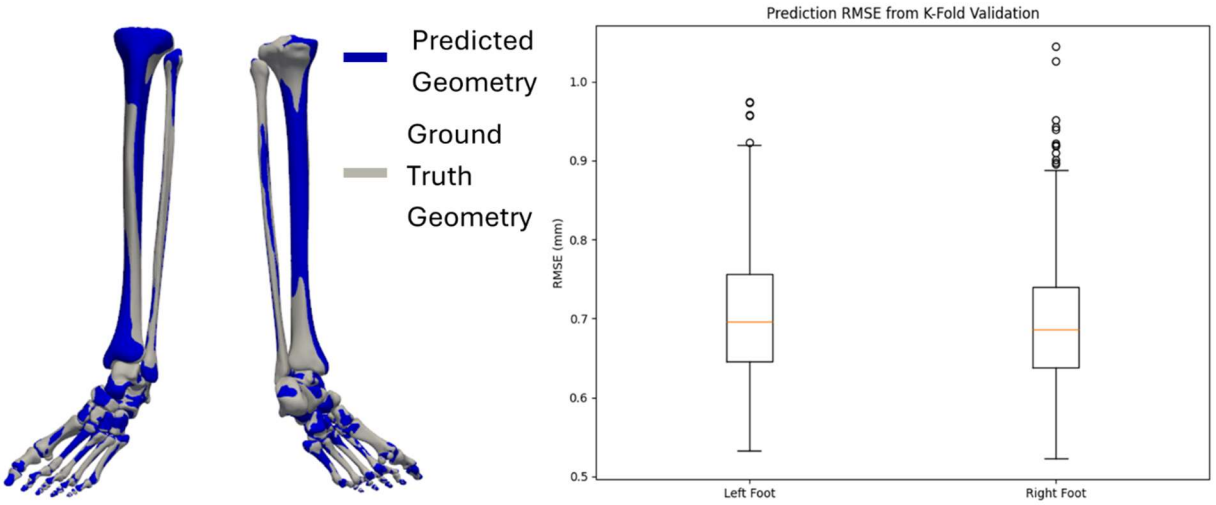
[1]Auckland Bioengineering Institute, University of Auckland, Auckland, New Zealand. [2]Department of Engineering Science and Biomedical Engineering, Faculty of Engineering, University of Auckland, Auckland, New Zealand

Introduction

Statistical shape modelling provides a means to predict personalised geometry with a greater accuracy than generic model scaling, with application to musculoskeletal modelling. Statistical shape models have effectively described the coupled relationship between the pelvis, femur, tibia and fibula geometries. However, prior models have not included the foot geometry. A coupled shape model of the foot bones would enable accurate prediction of personalised foot geometry using physiological constraints. This study describes the coupled relationship of bone shape and size variation in an adult foot population, and evaluates the performance of a combined shape model of the foot to predict bone morphology.

Methods

The tibia, fibula, and all 28 bones of the foot were automatically segmented from 418, and 368 CT scans of adults for the left and right foot, respectively. Variation in combined bone geometries was determined through principal component analysis. Separate shape models were created to predict the combined geometry of the left and right feet, through partial least squares regression, from demographic and linear bone measurements. Predictions were validated through k-fold validation, comparing RMSE and dice scores between predicted and ground truth segmentations.



Results

The first 5 principal components of the dataset described 81 % of variation in the left foot, and 85 % of variation in the right foot. These principal components described variation in overall bone size and shape, along with bone variations such as tibial torsion. K-fold validation of combined geometry prediction produced average prediction RMSE of 0.7 ± 0.4 mm for both the left and right foot. Dice scores of the predicted geometries were 0.9 ± 0.1 for the left and right foot.

Discussion

Our combined shape model of the foot provides a novel method to accurately scale all the foot bones, consistent with the lower limb anatomy, from anthropometric measurements. These patient specific models can be used in future musculoskeletal modelling workflows or clinical analysis of morphological variation.

OA45-02

A Support Vector Machine Regression Model for Rapid Predictions of ACL Forces Based on Finite-Element Knee Simulations.

PhD-student Maximilian Ebenbichler, Dr. Robert Eberle, Dr. Dieter Heinrich, PhD Maurice Mohr

University of Innsbruck, Innsbruck, Tirol, Austria

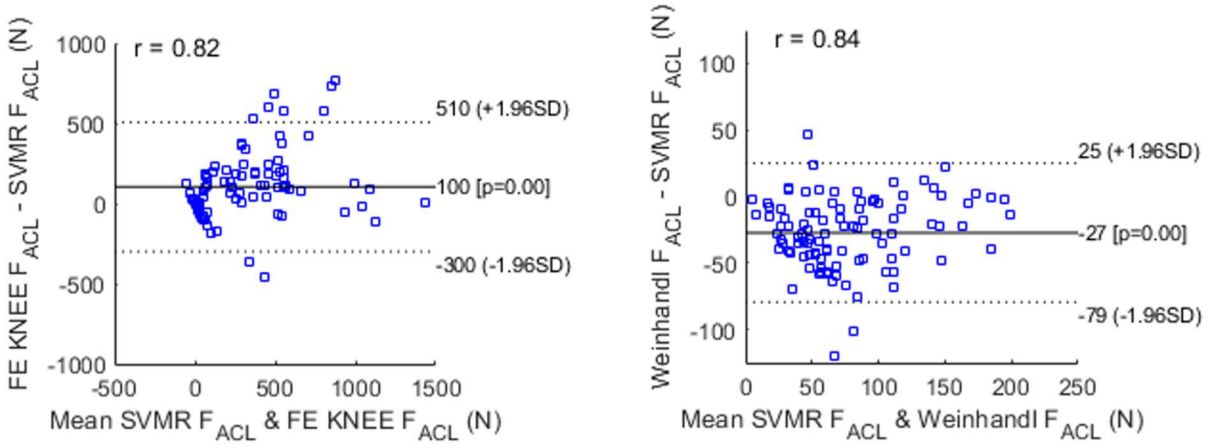
Introduction

Anterior cruciate ligament (ACL) force (F_{ACL}) is commonly estimated using FE knee models and regression models. FE models allow a wide range of loading conditions but are computationally expensive, whereas regression models offer rapid predictions. However, most existing regression models are derived from in-vitro testing [1], which is typically restricted to low-loading conditions and thus limits their application to high-loading scenarios.

The objectives of this work were to 1) train and test a support vector machine regression (SVMR) model to predict FE model-based F_{ACL} under high-loading conditions with reduced computation time, and 2) compare the SVMR model-based F_{ACL} to an existing regression model [1].

Methods

A modified version [2] of the OpenKnee(s) OKS008 FE knee model [3] was used. The FE simulations were performed by fixing the femur and applying 600 random combinations of forces and rotations to the tibia: three forces (100N < compression force < 5000N, -500N < posterior force < 500N, -500N < medial force < 500N) and three path-controlled angles (0° < flexion angle < 60°, -15° < adduction angle < 15°, -25° < internal rotation angle < 25°). From these simulations, 6000 data points were extracted to train and test the SVMR model using a second order polynomial kernel function. SVMR model-based F_{ACL} were compared to 1) the FE model and 2) the regression model by Weinhandl et al. [1] using Bland-Altman plots.



Results

The SVMR model reduced the computation time to predict F_{ACL} under high-loading conditions from 3h to 0.3s. However, the SVMR model poorly predicted FE model-based F_{ACL} in some loading conditions (Figure 1(a)), while overestimating the regression model-based F_{ACL} (Figure 1(b)). Nevertheless, there was a strong correlation between the models.

Discussion

In its current form, the SVMR model was not accurate enough for some loading conditions. However, rapid machine learning algorithms based on FE simulation generated data could be a promising method. Future work will test a reinforcement learning approach to improve the SVMR model's accuracy in predicting F_{ACL} for different loading scenarios.

Images (Optional)

(a) (b)

Figure 1 Two Bland-Altman plots are shown to compare the ACL force predicting models (a) FE knee testing data to SVMR model in high loading conditions and (b) Weinhandl model to SVMR model in low loading conditions, as the cadaver testing data in Weinhandl et al. [1]. Additionally the Pearson r-value (r) is shown for each comparison.

Computational Model Distinguishes Mechanical Injury- and Inflammation-Driven Temporal Protease Activity Underlying Collagen and Aggrecan Loss in Cartilage

Mr. Moustafa Hamada MSc[1], Dr. Atte S.A. Eskelinen PhD[1], Dr. Joonas P. Kosonen PhD[1], Dr. Cristina Florea PhD[1], Prof. Alan J. Grodzinsky PhD[2], Dr. Petri Tanska PhD[1,3], Prof. Rami K. Korhonen PhD[1]

[1]University of Eastern Finland, Kuopio, North Savo, Finland. [2]Massachusetts Institute of Technology, Cambridge, Massachusetts, United States. [3]Kuopio University Hospital, Kuopio, North Savo, Finland

Introduction

Cartilage collagen and aggrecan loss are key hallmarks of post-traumatic osteoarthritis (PTOA) [1]. However, the underlying mechanobiological pathways governing their temporal dynamics following mechanical injurious overloading of cartilage versus exogeneous inflammation remain unclear. We present a finite element model simulating post-injury cartilage degeneration that disentangles the respective temporal contributions of injury (INJ)- and interleukin-1 (IL-1)-induced catabolic cell activity to protease-mediated collagen and aggrecan loss.

Methods

Experiment: Cartilage explants from calf knee joints were cultured for 3 and 12 days in free-swelling conditions and under combination of single injurious loading and continuous IL-1α treatment [2] (fig. 1A). Aggrecan and collagen contents were quantified depth-dependently using digital densitometry and infrared microspectroscopy.

Computational model: A 2-D finite element model simulated cartilage response to injurious loading at day 0, followed by 12-day IL-1 diffusion. Excessive shear strain triggered cell catabolism, followed by release of collagen-degrading matrix metalloproteinases (MMPs) and aggrecan degrading aggrecanases. Similarly, IL-1 induced release of MMPs and aggrecanases via IL-receptor binding [3]. Model results were compared to experiments on days 3 and 12. Relative contributions of injurious loading and IL-1 to total protease activity over time in the model were analyzed.

Results

On day 3, INJ+IL model and experiment showed negligible bulk aggrecan loss versus control. Collagen loss remained negligible in the model but reached 9% in the experiment within 20%–60% tissue depth. On day 12, model predicted 14% collagen and 25% aggrecan loss, matching experimental losses (12% and 20%, respectively; Fig.1C–D). Injurious loading accounted for 70% of collagen- and 57% of aggrecan-targeting protease activity by day 2 (Fig.1E). By day 12, the IL-1-diffusion dominated, contributing 90% and 97% of protease activity against collagen and aggrecan, respectively.

Discussion

Our model reproduced the experimentally observed depth-dependent collagen and aggrecan losses following injury and inflammation. It quantified the distinct temporal contributions of injury- and IL-1-mediated protease activity, revealing an early burst of injury-mediated enzymatic degradation followed by sustained IL-1-mediated degradation. This framework provides a novel basis for examining therapeutic time windows for protease-inhibitor drugs at PTOA onset.

Combined Experimental-Computational Framework for Assessing Traction Forces and Fetal Brain Deformation in Vacuum-Assisted Delivery

PhD candidate Estelle Pitti[1,2], Assistant Professor, MD Lotta Herling[2,3], Associate professor, MD Gunilla Ajne[2,3], Professor Matilda Larsson[1], Associate professor Xiaogai Li[1]

[1]KTH Royal Institute of Technology, Stockholm, Stockholm, Sweden. [2]Karolinska Institutet, Stockholm, Stockholm, Sweden. [3]Karolinska University Hospital, Stockholm, Stockholm, Sweden

Introduction

Vacuum-assisted delivery (VAD) facilitates complicated vaginal deliveries by applying traction to the fetal head. Excessive traction may increase neonatal morbidity risk, but the underlying injury mechanisms remain poorly understood, partly due to the lack of robust experimental and computational models of fetal head biomechanics during VAD [1]. This study aims to develop a combined experimental-computational framework to allow for investigation of the impact of traction on fetal brain deformation during VAD.

Methods

The fetal head geometry for both experimental and computational models was derived from CT segmentation of a newborn [2]. The experimental setup [3] included a 3D-printed skull phantom (Fig. 1a) and a brain phantom of composite hydrogel (6% PVA, 0.85% Gellan Gum) (Fig. 1b). Six sonomicrometry crystals were embedded in the phantom to estimate brain strain and traction of 30–110 N was applied in the VAD experimental setup (Fig.1c). The computational fetal head model was obtained by morphing the baseline 2-month Infant PIPER head model [4] to the target geometry (segmented CT images) using Demons registration. The dice coefficient was computed to quantify the accuracy of the morphed model with respect to the target fetal head geometry used for the phantom.

Results

Crystal motion followed traction direction, confirming the feasibility of the experimental VAD setup with traction up to 112 N and brain strains up to 4% which correlated significantly with traction ($p < 0.05$) (Fig. 1d). The computational model presented a morphed fetal head model (Fig. 1e, 1f) with a dice coefficient of 0.75 (skull and sutures) and 0.92 (intracranial structures).

Discussion

The high dice coefficients confirm the computational model's fidelity to the patient-specific phantom, while its complexity supports ongoing work for deeper investigation of traction effects on fetal brain deformation. Framework validation is provided by the experimental framework, offering direct biomechanical measurements despite practical limitations. This integrated experimental–computational framework could help identify injury risk factors and promote safer clinical use of VAD.

Effects of Agonist-Antagonist Myoneural Interface on Whole-Body Angular Momentum During Perturbed Walking Among Individuals With Transtibial Limb Loss

Mr. Kiichi Ash MS[1,2], Dr. Courtney Butowicz PhD[2,3,4], Dr. Brad Hendershot PhD[2,3,4], Dr. Paolo Bonato PhD[5], Dr. Pawel Golyski PhD[2,3]

[5]Harvard Medical School, Boston, MA, United States

Introduction

Traditional lower limb amputation anchors transected muscles to bone, removing some proprioceptive feedback which may have detrimental effects on walking stability. The agonist-antagonist myoneural interface (AMI) procedure reestablishes agonist-antagonist muscle pairs, restoring proprioceptive feedback and muscle dynamics which are in turn leveraged by a neuroprosthesis. However, the effect of AMI on stability during walking in patients who use conventional prostheses is unknown. Thus, we evaluated stability during perturbed walking using sagittal whole-body angular momentum (WBAM) among individuals with unilateral transtibial limb loss (UTTLL) with and without AMI using a conventional prosthesis. We hypothesized patients with AMI vs. a traditional amputation would have improved stability, as evidenced by 1) a smaller WBAM range during unperturbed walking and 2) a smaller WBAM range during the perturbed (S0) and recovery steps (S+1).

Methods

7 service members with UTTLL, 2 with AMI (37.0 ± 2.8 y) and 5 without (38 ± 11.1 y), completed a full-body gait evaluation on a split-belt treadmill at a controlled velocity (1.0 m/s) with unexpected perturbations occurring every 20-35 steps. Perturbations were created with brief (200 ms duration), rapid (10 m/s^2 acceleration/deceleration) increases (“slip”) or decreases (“trip”) in unilateral treadmill velocity targeted to begin at 40% of the stance. Ten trials were collected for each condition. WBAM was calculated using OpenSim (v4.4) and custom MATLAB (2024b) scripts. Group differences were assessed with independent-samples t-tests (α=0.05).

Results

Sagittal WBAM ranges were similar between patients with AMI and those with traditional amputations during unperturbed walking ($p>0.159$), during the perturbed step ($p>0.327$), and during the first recovery step after a perturbation ($p>0.085$), across both slips and trips.

Discussion

In this work, we investigated sagittal WBAM ranges during unperturbed and perturbed walking in patients with UTTLL with and without AMI when donning a conventional prosthesis. Our findings suggest that sagittal walking mechanics before, during, and after sagittal plane perturbations are not influenced by AMI, indicating a neuroprosthesis may be necessary to obtain walking stability benefits from AMI. However, given the small sample size and modest magnitude of WBAM differences observed, definitive conclusions are premature. The study remains ongoing, with continued enrollment to strengthen future analyses.

Images (Optional)

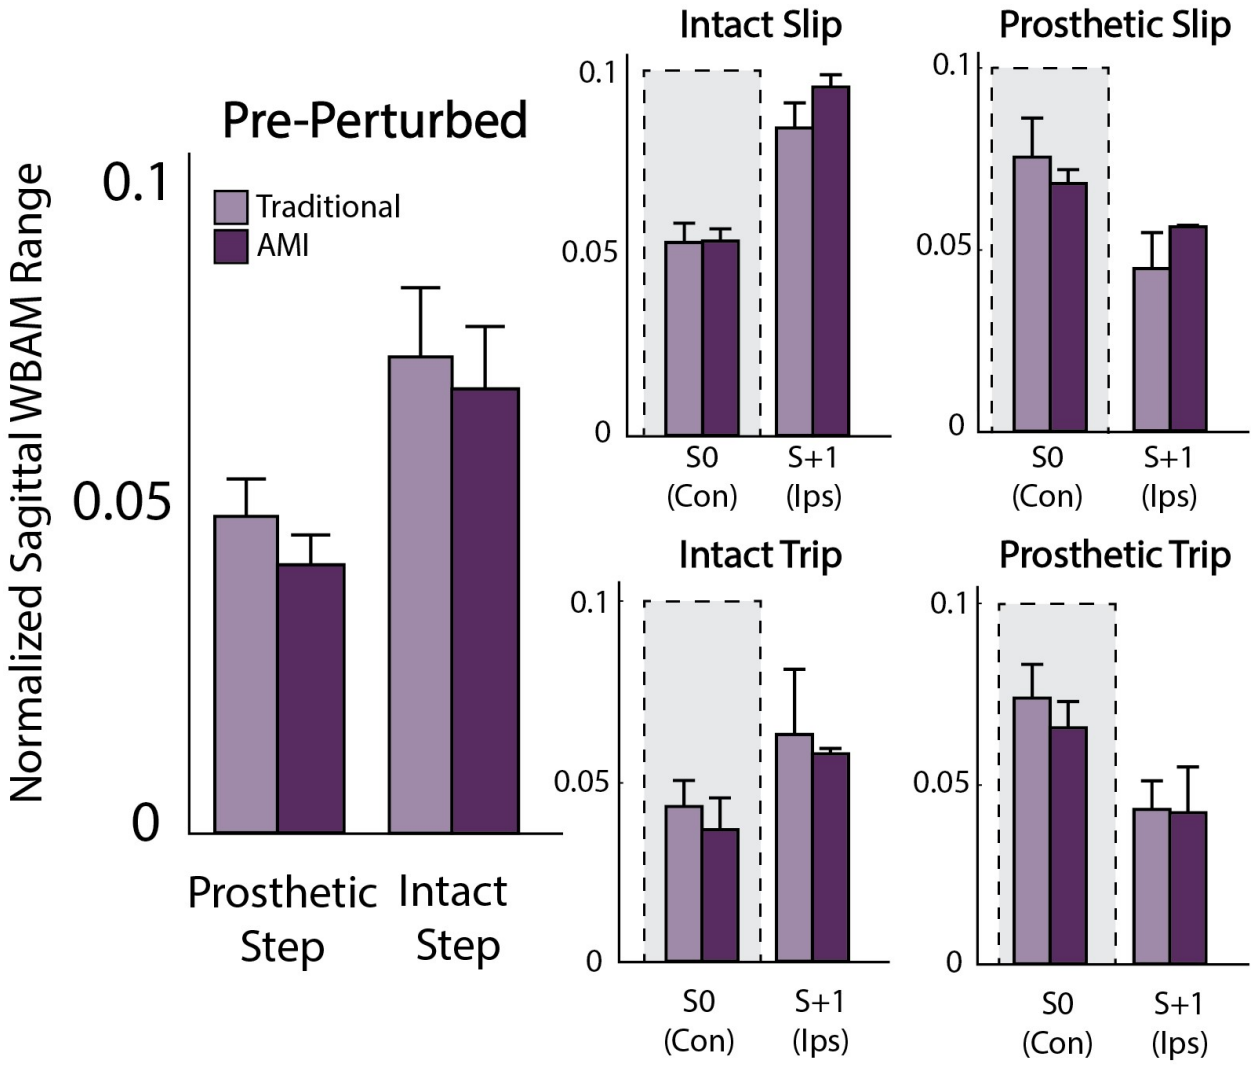

Figure 1: Sagittal whole-body angular momentum (WBAM) ranges before (Pre-Perturbed), during (S0), and after (S+1) treadmill perturbations in patients with UTTLL with and without AMI. WBAM was normalized to body mass. "Con/Ips" indicates step side relative to the perturbed side (i.e., the effect of the perturbation is first apparent at the contralateral heelstrike). S0 (gray-shaded box): Perturbed step. S+1: Recovery step

Minimally Invasive Muscle Implant Captures Greater Muscle Activation Complexity Than Surface EMG

Ms. Paige Dzenutis, Dr. Jennifer Leestma Ph.D., Ms. Kristín Helga Jónsdóttir, Mr. Alexander Madinger M.S., Dr. Shriya Srinivasan Ph.D.

Harvard University, Cambridge, MA, United States

Introduction

Electromyography (EMG) is commonly used to decode human intent. Minimally invasive, high-density EMG can improve myoelectric control, compared to low-density and surface EMG (sEMG), while avoiding invasive surgery, a benefit over traditional intramuscular EMG [1]. We have designed a minimally invasive neural implant (MINI) to provide precise and high-density EMG via ~1cm incision. We hypothesized that MINI provides greater muscle activation complexity in dynamic tasks compared to sEMG.

Methods

Under a protocol approved by the Harvard Institutional Animal Care and Use Committee, we placed 36 electrodes into a rat's hind limb, targeting superficial and deep compartments in anterior and posterior regions. For comparison, we covered the surface of the hind limb with 8 sEMG sensors. We recorded all sEMG and either anterior or posterior MINI channels (due to a 32-channel acquisition limit) while the rat locomoted through a custom 'jungle-gym' (Figure 1). We used principal component analysis (PCA) during movement periods, sectioned by laps around the 'jungle gym', to evaluate data complexity captured by the MINI and sEMG.

Results

To match channel count, we randomly subsampled 30 combinations of 8 MINI channels. For each subsample, we computed the number of principal components (PCs) required to explain 95 percent of the variance. In the anterior compartment, MINI exhibited higher dimensionality than sEMG (6.5 ± 0.7 PCs vs. 5.0 ± 0.0 PCs; $p = 0.0955$). In the posterior compartment, MINI also showed greater dimensionality than sEMG (5.5 ± 0.7 PCs vs. 4.0 ± 1.4 PCs; $p = 0.3118$).

Discussion

The MINI captured greater complexity than sEMG in both the posterior and anterior regions, given its improved access to non-superficial muscles and detection of varying activation levels throughout a single muscle due to higher spatial density [2]. Such improved motor intent signal capture will enable enhanced control of prostheses and other assistive robots, especially for dextrous movements or those elicited by smaller or deeper muscles that are classically inaccessible by sEMG.

Bone-Anchored vs. Socket-Suspended Transfemoral Prosthesis Users Do Not Differ in Intact Limb Knee Mechanics

Mr. John Pope CPO[1], Mr Ross Miller PhD[1], Garui Desai[2]

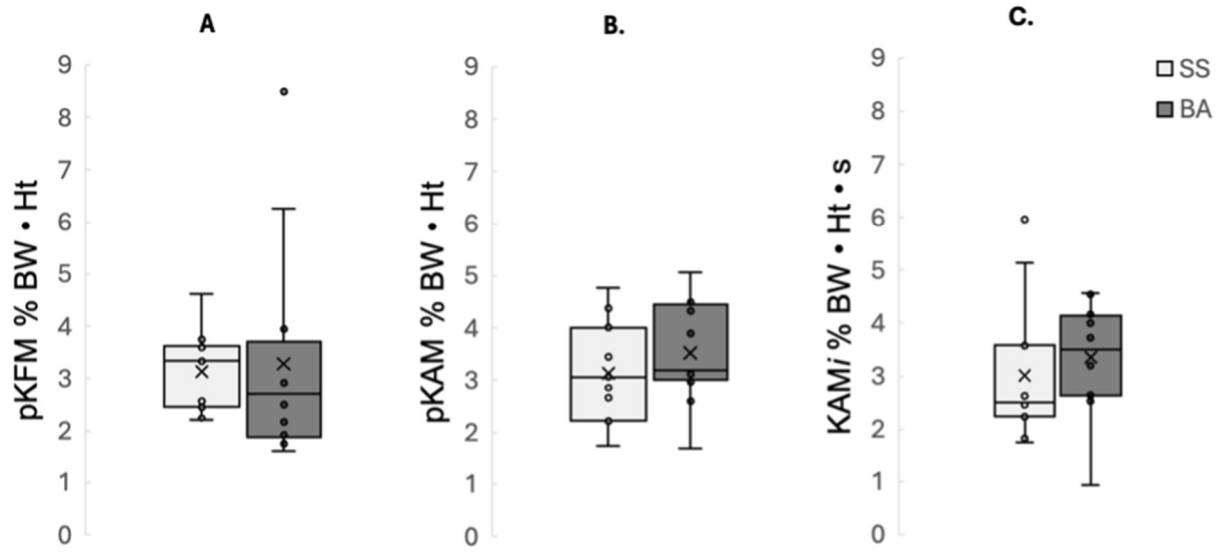
[1]University of Maryland, College Park, MD, United States. [2]Standford University, Stanford, CA, United States

Introduction

Transfemoral prosthetic users (TFPU) have high rates of knee osteoarthritis partly attributed to mechanical loading on the intact limb[1]. Peak knee flexion moments (pKFM), adductor moments (pKAM) and impulses (KAM*i*) are indicators of medial knee loading and associated with knee osteoarthritis[2]. Fit issues with traditional socket-suspended prostheses can impair gait and affect loading of the intact-limb[3]. Bone-anchored prostheses lack the fit-related issues of socket-suspension, but their effect on mechanical loads in the intact-limb is unclear. The purpose of this study is to examine differences in knee joint biomechanics during walking between physically fit TFPU with bone-anchoring versus socket-suspension. Because bone-anchoring minimizes uncontrolled movement between the prosthetic socket and the residual-limb, it may promote more symmetric weight bearing and lower intact limb knee joint loads. Therefore, we hypothesized that TFPU with bone-anchoring vs. socket-suspension would exhibit lower pKFM, pKAM and KAM*i* during walking.

Methods

Twelve bone-anchored (49±9years, 75.6±19.9kg) and twelve socketed (40±14years, 80.01±15.2kg) TFPU walked across a 15-meter walkway at a target speed (~1m/s). Participants all had K3/K4 mobility and participated in a variety of sports and exercise more demanding than walking. Knee moments were determined by inverse dynamics and scaled by total body weight and height. Comparisons between groups of pKAM, KAMi, and pKFM were made using independent Student's t-tests with a Bonferroni-adjustment (threshold $p<0.017$).



Results

There was no significant difference in knee moments found in either the sagittal or frontal plane for bone-anchored vs. socketed TFPU (Fig.1): pKFM p=0.50; pKAM p=0.34; KAMi p=0.50.

Discussion

Compared to physically fit socketed TFPU, bone-anchored revision appears to allow TFPU who previously had low function with sockets to achieve knee mechanics that do not differ from high-functioning socketed users. The cross-sectional study design can help isolate the mechanical effects of bone-anchored prostheses on intact limb loads, complementing longitudinal data where baseline mobility is low. Future studies should examine how prosthesis mechanics interact with bone-anchored suspension to affect gait and intact-limb loading.

Images (Optional)

Peak external knee flexion moment (pKFM, A.), adduction moment (pKAM, B.) and knee adduction moment impulse (KAM*i*, C.) during stance on the intact limb side of socket-suspended (SS) and bone-anchored (BA) TFPU. Joint moments are normalized to BW *Ht (m) and presented as %.

Increasing Prosthetic Limb Torque Decreases User Effort at the Cost of Symmetry in Individuals with Above-Knee Amputation during Stair Ascent

Ms. Clare Severe[1], Dr. Lukas Gabert[1], Dr. Tommaso Lenzi[1,2]

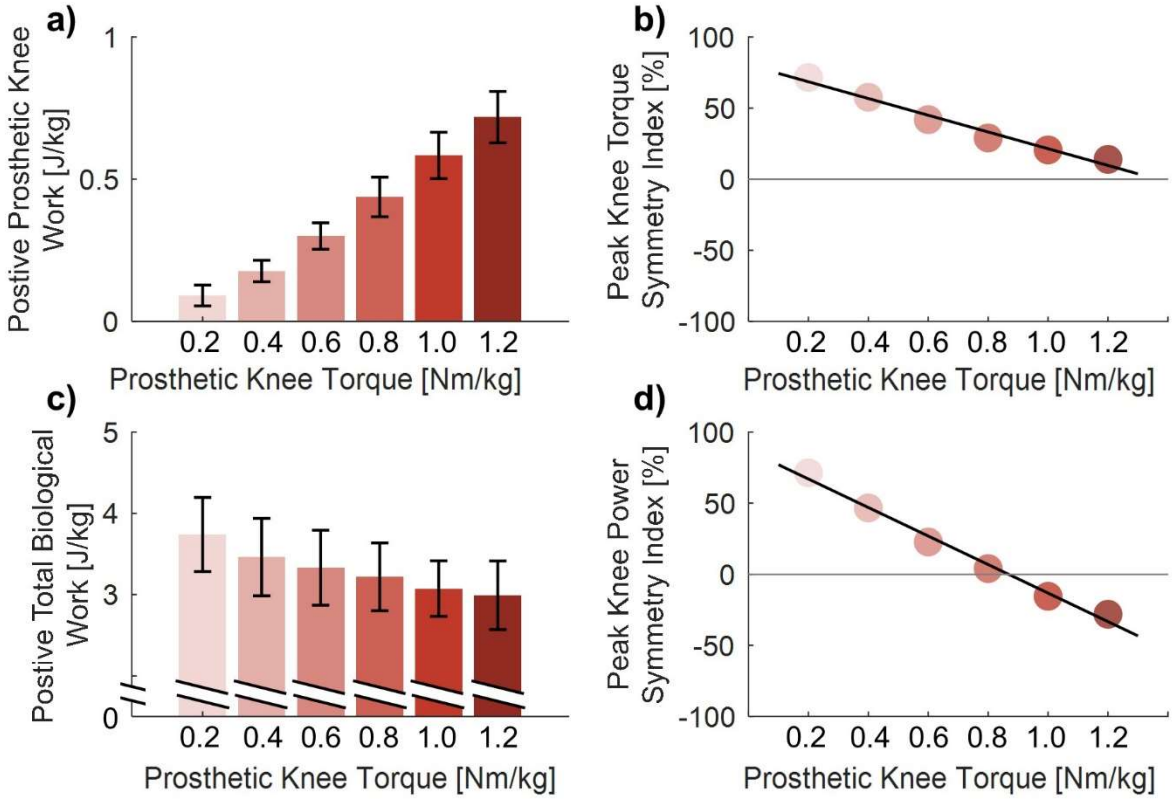
[1]University of Utah, Salt Lake City, UT, United States. [2]Rocky Mountain Center for Occupational and Environmental Health, Salt Lake City, UT, United States

Introduction

Stair ascent is biomechanically demanding, requiring substantial positive power that conventional passive prostheses cannot provide. Consequently, amputees must rely entirely on their sound side and residual limb to generate the energy needed for stair ascent. Previous research shows that active prostheses can reduce users' effort by generating positive power through their electrical motors. However, their energy contribution has yet to match the physiological energy contribution [1-3]. Therefore, reliance on biological joints remains an ongoing challenge. This study aims to assess the user's effort, measured by positive biological work, as an active knee prosthesis delivers increasing levels of extension torque. We hypothesize that increasing prosthesis extension torque will increase positive mechanical work, thereby reducing energy demands on biological joints.

Methods

Eight individuals with above-knee amputation ascended a seven-step instrumented staircase using an active knee-ankle prosthesis controlled to provide six randomized levels of knee extension torque (0.20-1.20 Nm/kg, Figure 1a). Full-body motion capture was recorded. We calculated total positive biological joint work by integrating positive joint power over stance, then summing the positive work at the residual hip and the sound hip, knee, and ankle. We also assessed symmetry by calculating the peak knee torque and power symmetry indexes.



Results

Positive biological joint work varied inversely with prosthetic knee torque, achieving its lowest level (3.0+/-0.4 J/kg) at the highest torque level (Figure 1a,c). This highest torque level resulted in the best peak torque symmetry (13.9+/-1.0%, Figure 1b). However, peak power symmetry did not follow this trend, with best results at intermediate levels of knee torque (0.80 Nm/kg) and worsening at maximum torque (Figure 1d).

Discussion

Increasing extension knee torque successfully offloads the biological joints, decreasing the user's effort. However, results indicate a trade-off: higher torque improves torque symmetry, but it degrades power symmetry, suggesting that high torque levels result in excessive, uncontrolled knee velocity. Therefore, increasing prosthesis torque is not always biomechanically advantageous. Proper device tuning requires balancing effort reduction with movement control to ensure users can comfortably climb stairs.

Bioinspired peptide therapy to augment skin mechanics in lower limb amputees

Dr Jack Hayes PhD[1], Miss Ella Beattie-Edwards[1], Miss Min Waye Chew[1], Miss Ireen James[1], Dr Summik Limbu PhD[1], Mr Jia Jun Lee[1], Miss Anna Rhodes[1], Mr Charles Sawyer[2], Dr David Gaboriau PhD[1], Dr Marc Masen PhD[1], Dr Claire Higgins PhD[1]

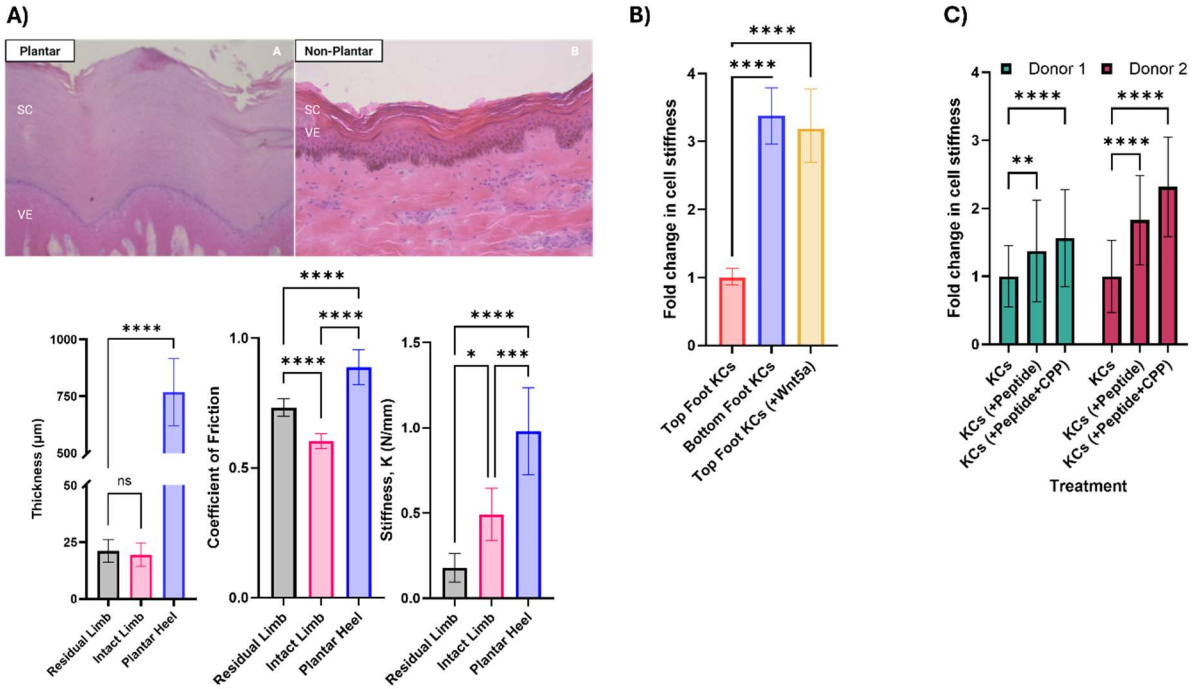
[1]Imperial College London, London, UK, United Kingdom. [2]University of Florida, Gainesville, Florida, United States

Introduction

Following lower limb amputation, an individual's life changes forever. However, despite significant advances in artificial limb function, 1 in 5 individuals with limb difference abandon their device before 1 year citing skin injury from device use (a problem that affects 75% of amputees). We hypothesise that the biomechanics of amputee skin make it unable to sustain the shear present during ambulation. This is in contrast to skin on the soles of our feet, which is designed to be load bearing. Our previous research has shown that despite 27 years of prosthesis use amputee skin is softer, has higher friction, shows minimal increase in skin thickness and has higher inflammation compared to the intact limb. Overall, prosthetic use does not transition skin to a load bearing identity, like that seen on the foot (figure 1a). Here we demonstrate how a bioinspired peptide can augment skin mechanics to that of plantar skin.

Methods

To investigate the role reprogramming plays at a cell scale, nanoindentation was utilised to characterise changes primary human keratinocyte monolayers.



Results

Our results highlight differences in mechanical properties between plantar and non-plantar skin observed in vivo (figure 1a) are retained by keratinocytes in culture (figure 1b). Nanoindentation of patient matched plantar and non-plantar keratinocytes reveals that plantar keratinocytes are 3.4-fold stiffer that non-plantar keratinocytes (figure 1b). Addition of a plantar fibroblast derived protein, Wnt5a, to non-plantar keratinocytes increases indentation stiffness by 3.2-fold (figure 1b). Use of a novel peptide inspired by plantar skin led to 1.4-fold and 1.8-fold increase in cell stiffness, for donors 1 and 2 respectively and was further increased to 1.6-fold and 2.3-fold when conjugated with a cell-penetrating-peptide (CPP) (figure 1c).

Discussion

The results presented show how a peptide treatment can augment skin mechanics, increasing the stiffness of non-plantar keratinocytes in vitro. We envisage use of a such a therapy to improve skin resilience at medical device interfaces, a currently clinically unmet need, by reengineering skin on the residuum to a load bearing identity. We are currently evaluating the effect peptide treatment has on the resistance to frictional shear of human keratinocytes both in vitro and ex vivo.

[6]Schroeder Arthritis Institute, Division of Plastic, Reconstructive and Hand Surgery, University Health Network, Toronto, ON, Canada

Introduction

Current partial hand (PH) prostheses provide adequate grip and cosmesis but are often abandoned due to lack of sensory feedback [1], which can limit rehabilitation and return-to-work. Previous work has identified tactile sensation as a design priority for thumb prostheses [2]. Vibrotactile feedback has been shown to improve grip strength and reduce cognitive workload in trans-radial prostheses but has not been incorporated in PH prostheses [3,4]. This study aimed to assess the effect of vibrotactile feedback on task performance across different levels of PH amputation.

Methods

A vibrotactile feedback system was developed, comprising a 3D-printed wristband connected to a force-sensing resistor on the volar pad of the thumb and a linear resonating actuator within the prosthetic socket for haptic feedback. Three participants with varying levels of PH amputation completed a Foraging Task Test, sorting blocks of three stiffnesses with and without vibrotactile feedback. Visual and auditory cues were blocked with frosted goggles and noise-cancelling headphones, ensuring participants relied solely on tactile cues. Task performance was evaluated using accuracy (percent correct) and efficiency (search time and accuracy per second). Results were compared between conditions (vibrotactile feedback on/off for stiffness levels 1-3) for each participant, and semi-structured interviews assessed user experience and impact.

Results

Participants with more extensive amputation saw the most significant improvement with vibrotactile feedback. Accuracy rose from 31.4% to 50.0% in the participant with D1-5 amputations and from 61.4% to 81.4% in the participant with a proximal D2 amputation. Accuracy remained stable in the participant with a distal D1 amputation, however they demonstrated improved efficiency with faster average search times when the feedback was on (4.78s) compared to when it was off (5.12s). Overall, participants reported greater object awareness, confidence, and control with vibrotactile feedback, and all requested to continue using the vibrotactile feedback system at home.

Discussion

Integration of vibrotactile sensory feedback improved task performance in individuals with more extensive PH amputation. These findings highlight the potential of vibrotactile feedback to improve rehabilitation outcomes, task efficiency, and prosthesis embodiment.

The Effect of Alignment Variability on the Primary Fixation of Cementless Femoral TKA

MSc. Verena Helgers[1], Dr. Periklis Tzanetis[2], Dr. Thom Bitter[1], Dr. Adam Briscoe[3], Prof.Dr. Nico Verdonschot[1,2], Dr. Dennis Janssen[1]

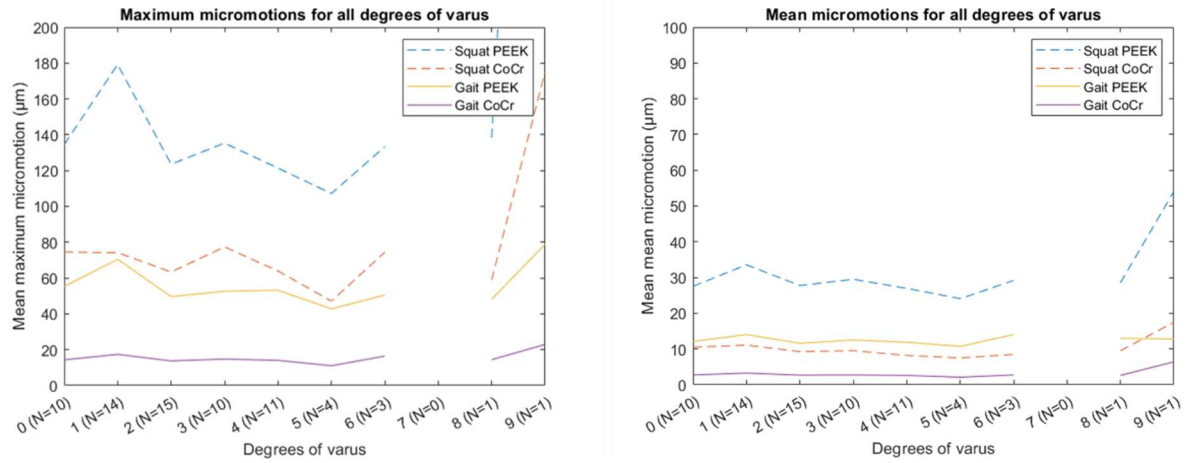
[1]Radboud University Medical Center, Nijmegen, Gelderland, Netherlands. [2]University of Twente, Enschede, Overijssel, Netherlands. [3]Invibio Ltd, Thornton Cleveleys, Lancashire, United Kingdom

Introduction

Ensuring a proper primary fixation is essential for long-term fixation and total knee arthroplasty (TKA) survival. It is, however, poorly understood how differences in surgical alignment techniques impact implant fixation and TKA survival. The aim of mechanical alignment is to obtain a neutral knee joint alignment, while in kinematic alignment the native joint alignment defines the post-operative alignment, which may have implications for fixation. The aim of this computational study was therefore to investigate the effect of variations in coronal knee alignment on the primary fixation of femoral cementless polyetheretherketone (PEEK-OPTIMA™) and cobalt-chrome (CoCr) TKA in a patient population.

Methods

Patient-specific finite element (FE) models were created using 295 pre-operative CT images of TKA patients. The natural knee alignment of these patients was determined automatically using CPAK classification. 276 FE models of kinematically aligned femoral reconstructions of 69 varus patients were created, varying the implant material (CoCr and PEEK) and applying patient-specific gait and squat loading determined from musculoskeletal models. The primary fixation of the implant was quantified by the peak and median (99th and 50th percentile) values of the resulting micromotions on the bone-implant surface.



Results

Micromotions remained stable across different degrees of varus for both PEEK and CoCr models. Overall, PEEK models generated larger micromotions than CoCr models for the various degrees of varus. However, both CoCr (6 μm) and PEEK (21 μm) displayed mean micromotions that remained below the threshold of 112 μm for osseointegration (Figure 1).

Discussion

This study presents the results of a novel workflow investigating the effect of implant material and kinematic alignment on primary fixation of TKA reconstructions in varus patients. The current results do not suggest an effect of varus alignment on primary fixation, although the number of cases with larger varus angles was relatively low. We intend to further expand the number of cases and to compare these outcomes with mechanical alignment applied to the same cohort. Differences in fixation between different alignment strategies (i.e. kinematic vs. mechanical) may become more pronounced at larger native varus angles.

How Closely Mechanical Alignment in Total Knee Arthroplasty Reproduces Normal Biomechanics: A Cohort-Based in Silico Study

BSc. Andrés Álvarez Gual de Torrella[1], Prof.dr. Nico Verdonschot[1,2], Prof.dr. Sara Checa[3], Dr. Periklis Tzanetis[1]

[1]Department of Biomechanical Engineering, University of Twente, Enschede, Overijssel, Netherlands. [2]Orthopaedic Research Laboratory, Radboud University Medical Center, Nijmegen, Gelderland, Netherlands. [3]Institute of Biomechanics, Hamburg University of Technology, Hamburg, Hamburg, Germany

Introduction

Surgeons continue to widely use the traditional mechanical alignment (MA) technique in total knee arthroplasty (TKA) to achieve a neutral lower-limb mechanical axis. It remains unclear, however, how closely MA can reproduce osteophyte-free knee biomechanics on a population level. This study compared osteophyte-free musculoskeletal knee models with MA-TKA models to quantify the extent to which MA alters tibiofemoral kinematics and ligament strains.

Methods

We used a database of 53 TKA patients, including osteophyte-free reconstructed knee bones, cartilage, and anatomical landmarks required to virtually plan MA. Utilizing this information, we generated patient-specific musculoskeletal models for both osteophyte-free and MA-TKA configurations using a previously established modeling workflow [1]. All models simulated a flexion-extension movement from 0° to 90°. Differences between osteophyte-free and MA-TKA models were quantified by calculating the root-mean-square-deviation (RMSD) in kinematics, in terms of tibial rotations and translations relative to the femur, as well as ligament strains. We defined thresholds for “close to osteophyte-free” biomechanics as ±1° and ±1 mm, consistent with the reported accuracy of validated models in predicting tibiofemoral kinematics [2]. Ligament strains were evaluated using a 3% RMSD threshold, selected as a conservative boundary below the onset of fiber micro-damage, occurring approximately at 5% strain [3].

Results

Across all 53 patients, MA-TKA models consistently exhibited deviations larger than the specified thresholds of ±1° and ±1 mm for at least one kinematic parameter, and 3% for at least one of the ligaments relative to the osteophyte-free state. The average differences

between osteophyte-free and MA-TKA models across the patients peaked at 4.4° and 5.3 mm, with ligament strain differences peaking at 8.7% (Table 1).

Discussion

In this cohort, MA resulted in substantial changes in both kinematics and ligament strains relative to the osteophyte-free state, supporting the need for more personalized alignment strategies such as kinematic or restricted kinematic alignment. The selected thresholds for "close to osteophyte-free" restoration are necessarily estimates that may be relatively restrictive; further investigation is therefore necessary to determine their appropriate values and clinical relevance.

Images (Optional)

Table 1. Average root mean-square-deviation (RMSD) in tibiofemoral kinematics and ligament strains between osteophyte-free and MA-TKA musculoskeletal models across all patients

Quantifying the Influence of Patellar Morphology on Patellofemoral Kinematics During Active Knee Extension in Healthy Knees

Ms. Erin Teule[1], Dr.ing. Sebastiaan van de Groes[1], Prof.dr.ir. Nico Verdonschot[1,2], Dr.ir. Dennis Janssen[1]

[1]Radboudumc, Nijmegen, Gelderland, Netherlands. [2]University of Twente, Enschede, Overijssel, Netherlands

Introduction

Understanding how knee morphology influences patellofemoral (PF) kinematics is essential for advancing patient-specific assessment of PF disorders. While femoral morphology has been studied, the role of patellar morphology remains underexplored. This study investigated how patellar morphology contributes to variation in PF kinematics during knee extension in healthy participants.

Methods

Six degrees-of-freedom (DOF) PF kinematics were derived from dynamic CT data from 100 healthy participants during active knee extension. Four patellar morphology features (height , width, Wiberg index, and Wiberg angle) were automatically extracted from a static CT scan. Mixed-effects models were fitted for each DOF, with patella features and knee angle as fixed effects and random intercepts and slopes per participant. Univariable analyses identified significant predictors ($p < 0.05$), which were entered into multivariable models. Due to collinearity ($r = 0.80$), patella width was retained over height when both were significant.

Results

After excluding 20 dynamic scans, unilateral data from 80 participants (78% female, mean age 24.3 ± 3.4 years, 60% right knees) were analysed. Knee angle explained most variance across all DOFs (R2=0.938-0.997). After controlling for knee angle, patellar morphology features contributed significantly to PF flexion, AP and PD position. Univariable models showed that patella height, width and Wiberg angle significantly predicted PF flexion and AP position, and that patella height and width predicted PD position. No morphology features contributed to PF rotation, tilt, or ML position. Multivariable models for PF flexion and AP position indicated that patella width (β=-0.23, 95%CI [-0.41,-0.05]; β=-0.50, 95%CI [-0.65,-0.35], respectively) and Wiberg angle (β=-0.21, 95%CI [-0.34,-0.08]; β=-0.12, 95%CI

[-0.23,-0.01], respectively) were independent significant predictors. For PD position, patella width was the only significant predictor (β=0.34, 95%CI [0.17,0.50]).

Discussion

Patellar morphology modestly but significantly influenced PF flexion, AP, and PD position, whereas other PF DOFs were unaffected. Larger patellae and greater Wiberg angles (i.e., a flatter patella) were associated with slightly reduced flexion and a more anterior and, for larger patellae, more distal position. Flatter patellae may exhibit reduced trochlear-patellar congruence, potentially leading to a more anterior patellar position and reduced PF flexion. Overall, knee angle remained the dominant determinant of PF kinematics.

Total Knee Arthroplasty Implications on the Patellofemoral Joint Contact Forces

Dr. Mounir Boudali[1,2], Mr. Jobe Shatrov[1,3], Dr. Koki Abe[4], Dr. David Parker[1,3], Prof. William Walter[1,5], A/Prof. Elizabeth Clarke[1,2,6]

[1]The University of Sydney, Sydney, NSW, Australia. [2]The Kolling Institute Sydney MSK Health, St. Leonards, NSW, Australia. [3]Landmarks Orthopaedics, St. Leonards, NSW, Australia. [4]Yokohama City University, Yokohama, Yokohama, Japan. [5]The Royal North shore Hospital, St. Leonards, NSW, Australia. [6]The Murray Maxwell Biomechanics Laboratory, St. Leonards, NSW, Australia

Introduction

Total knee arthroplasty (TKA) is an effective intervention for end-stage knee osteoarthritis, yet some patients remain dissatisfied. Persistent pain is a leading cause of revision (7.2%), including patellofemoral-related pain (6%) according to the Australian Orthopaedic Association Annual Report 24/25 [1].

Contemporary surgical philosophy emphasises restoration of native anatomy, including articular geometry, joint line, and patellar thickness. However, standard implants often fail to replicate the individual patient morphology, potentially altering joint mechanics and soft tissue tension.

This study quantifies differences in patellofemoral biomechanics between the native and the reconstructed knee following robotically assisted TKA in a cadaveric model.

Methods

Eleven fresh-frozen pelvis-to-toes specimens were prepared and mounted on the simVITRO® Universal Musculoskeletal Simulator (Jupiter 3000, Cleveland Clinic, Cleveland, OH) following the protocol described in [2].

Each specimen was tested under three conditions: **Native** (intact knee – only skin and subcutaneous fat removed), **Neutral** (patella resurfaced after a medial parapatellar incision), and **TKA** (after completion of TKA). Passive knee flexion from 0° to 100° was simulated for all conditions replicating what a surgeon would perform intraoperatively to assess the knee joint. Patellofemoral joint forces were measured with a custom patella force sensor.

All surgical procedures were performed by a single senior surgeon using the CORI robotic system (Smith & Nephew, Memphis, TN) to ensure consistency and precision across specimens.

Results

Results show a significant increase in forces between **Neutral** and **TKA** conditions. On average, we saw a 43% increase in the resultant load in the patellofemoral joint.

The lateral side of the patella saw a larger increase in the load compared to the medial side.

Discussion

The forces increased after TKA across all specimens in a non-uniform fashion. The lateral loading increase could imply the trochlear is not ideally placed and therefor the use of femoral components with lateralised trochlear groove should be prioritised over the centrally aligned designs, which could help reduce the loading of the patella and hence help mitigate abnormal soft tissue strain.

In the absence of navigation systems, surgeons could still compensate for the potential increase of the articular forces by lateralising the placement of the patellar implant.

Can a Behavioral Foundation Model Predict Human Locomotion?

Dr. Jeonghwan Lee, Dr. Nidhi Seethapathi

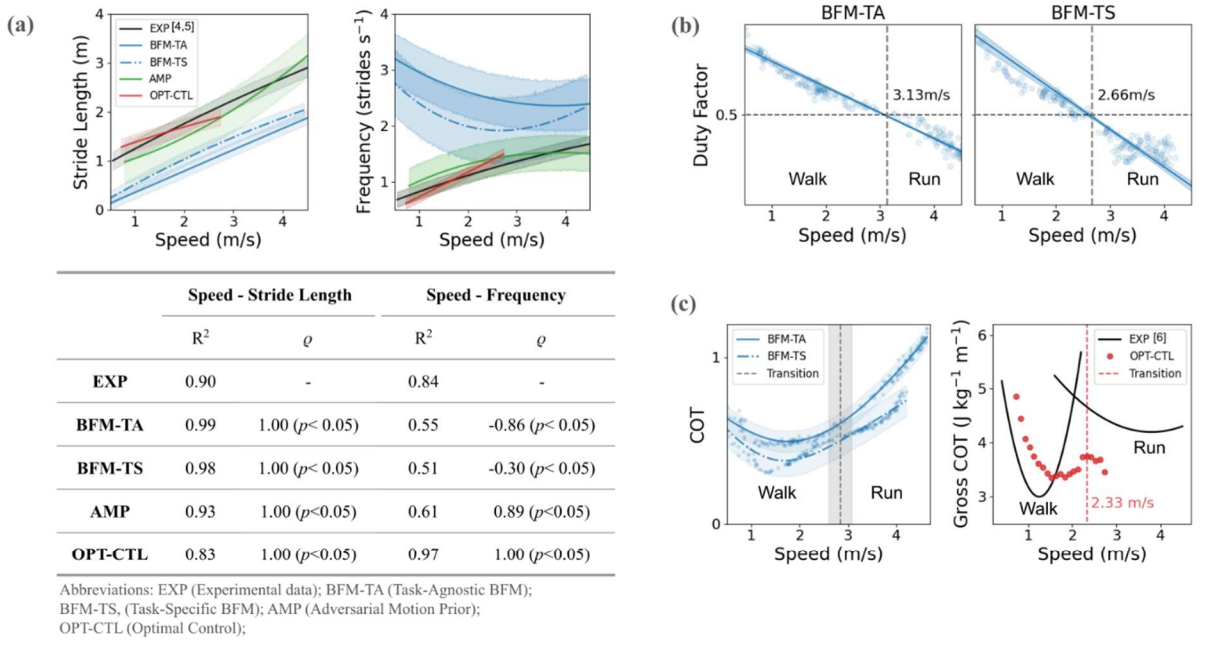
Massachusetts Institute of Technology, Cambridge, MA, United States

Introduction

Building predictive models of human biomechanics remains challenging. Traditional optimal control models provide key insights but are limited to restricted behaviors such as steady-state locomotion. Behavioral Foundation Models (BFMs) now generate complex whole-body motions from large-scale data [1], yet it is unclear whether they learn fundamental biomechanical principles such as speed-dependent gait and energy minimization. This study evaluates the biomechanical fidelity of BFMs against optimal control, imitation learning, and experimental data.

Methods

We trained two BFMs with Forward-Backward representations with Conditional Policy Regularization [1]: a “Task-Agnostic” model (BFM-TA; 8,902 motions including non-locomotor tasks) and a “Task-specific” model (BFM-TS; 1,107 locomotion-only motions). We generated 200 straight-line motions (0.5–5 m/s) in MuJoCo and compared them with an imitation learning model, Adversarial Motion Prior (AMP) [2], an optimal control model (OPT-CTL) [3], and experimental data (EXP) [4–6]. Speed-dependent manifolds for stride length, frequency, and cost of transport were fitted using generalized additive models, and transition speeds were identified from duty factor. Agreement with experimental manifolds was quantified using Spearman’s rank correlation.



Results

Both BFM variants reproduced the speed–stride length manifold (ρ=1.00, p<0.05) found in human data. However, they failed to capture the speed–stride frequency manifold (BFM-TA: ρ=-0.86; BFM-TS: ρ=-0.30, p<0.05 for both). In contrast, AMP and the optimal control model matched human trends for both manifolds (ρ=~0.90, p<0.05). BFMs overestimated the walk-to-run speed (BFM-TA: 2.66 and BFM-TS: 3.13) compared to the optimal control model (2.33) and failed to replicate the energetic landscape of human locomotion.

Discussion

Our findings reveal a distinction between the ability of BFMs to generate visually plausible locomotion and their ability to capture the underlying biomechanical principles; although BFMs captured the speed–dependent manifold, they failed to reproduce the temporal manifold and energetic landscape. These findings underscore the need to integrate the generative capacity of BFMs with fundamental biomechanical principles to advance next-generation predictive models for biomechanics.

Smartphone Video–based Estimates of the Knee Extension Moment During Chair Rise Relate to MRI Measures of Muscle Function

Mr. R. Daniel Magruder[1], Dr. Mary Hall[2], Ms. Yael Vainberg[2], Ms. Jessica L. Asay[2], Dr. Jennifer L. Hicks[2], Dr. Scott L. Delp[2], Dr. Garry E. Gold[2], Dr. Valentina Mazzoli[3], Dr. Scott D. Uhlrich[1]

[1]University of Utah, Salt Lake City, Utah, United States. [2]Stanford University, Stanford, California, United States. [3]New York University Langone Health, New York City, New York, United States

Introduction

Preserving muscle function is critical for maintaining mobility, balance, and independence as we age [1]. However, muscle function is not routinely assessed clinically due to a lack of accessible, sensitive tools. Muscle volume and quality both contribute to its force-generating capacity [2]. MRI provides high-fidelity measures of muscle volume and quality, while dynamometry quantifies maximum voluntary joint torque production. Both modalities are costly, so low-fidelity tests, like the five times sit-to-stand [5xSTS], are used in clinical studies instead [3]. Here we evaluate whether OpenCap, a scalable smartphone video–based tool for estimating musculoskeletal dynamics [4], during 5xSTS is sensitive to muscle volume and microstructure from MRI.

Methods

We collected MRI of the quadriceps, isometric and isokinetic dynamometry, and 5xSTS time with concurrent OpenCap from healthy adults across the lifespan (n=19, 30–78 y). We computed quadriceps volume and radial diffusivity (relates to fiber size) from MRI. We computed the peak knee extension moment from OpenCap during chair rise, and from isometric and isokinetic (120°/s, concentric) dynamometry. We compared OpenCap, 5xSTS time, and dynamometry to MRI measures of muscle function using linear regression.

Results

The OpenCap-derived knee extension moment correlated with quadriceps volume (r=.63, p=.004), radial diffusivity (r=.61, p=.005), and a combined metric ($volume_{standardized} \cdot$ radial $diffusivity_{standardized}$; r=.77, p<.001). Isokinetic torque correlated with volume (r=.66, p=.002), radial diffusivity (r=.52, p=.023), and the combined metric (r=.73, p<.001); isometric torque correlated with volume (r=.75, p<.001), but not radial diffusivity (r=.04, p=.862). 5xSTS time and a kinematic compensation for quadriceps weakness (torso orientation) were not correlated with MRI features (r=-.16–.35, p=.14–.97).

Discussion

Joint moments—measured with OpenCap or isokinetic dynamometry—predict aspects of muscle size and microstructure, unlike time or kinematic features. OpenCap smartphone video–based kinetics are a scalable assessment of muscle force-generating capacity that can be conducted rapidly without specialized equipment. This enables assessment of muscle function in the clinic and large-scale studies where imaging and dynamometry are impractical.

Images (Optional)

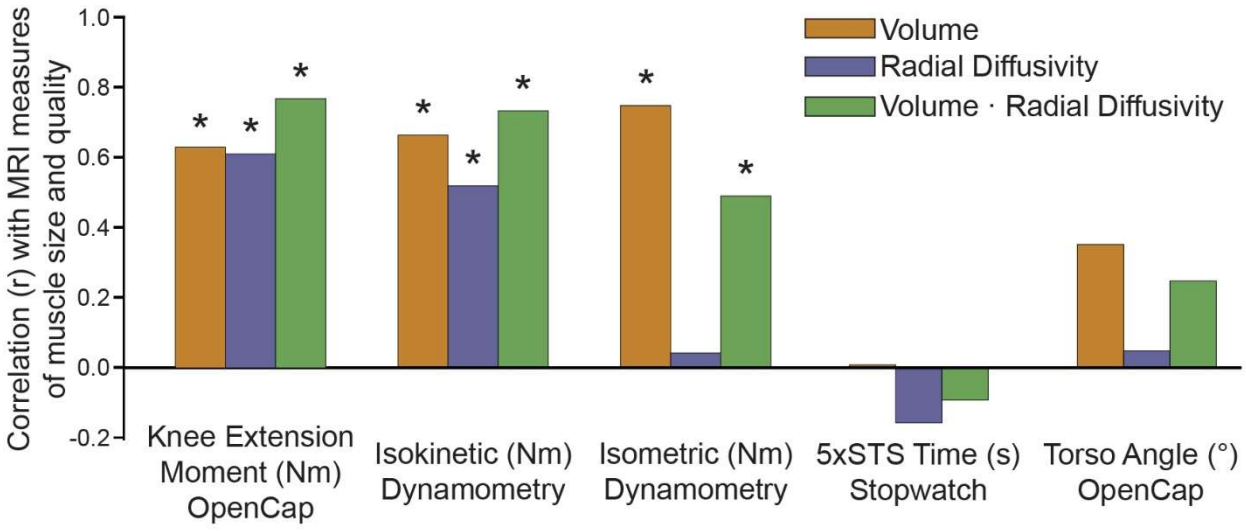

Figure 1: Pearson correlation coefficients relating biomechanical measures of quadriceps function to MRI measures of muscle force-generating capacity. The sit-to-stand knee extension moment (KEM) estimated by OpenCap correlates with quadriceps volume, radial diffusivity, and a combined metric ($volume_{standardized}$ · $radial\ diffusivity_{standardized}$). Isokinetic dynamometry has similar relationships to MRI, while the clinical standard five times sit-to-stand time did not correlate with any MRI measures. * denotes $p<.05$

Mind the Gaps: Robustness of DNN Ankle Joint Angle Prediction Models to Unexpected Sensor Flatlines

Mr. Ryan Pollard, Ms. Jacquelyn Brokamp, Mr. Matheus Ferreira-Shornack, Dr. Roberto Molinari, Dr. Ivan Nail-Ulloa, Dr. Michael Zabala

Auburn University, Auburn, AL, United States

Introduction

Despite promising results for deep neural network (DNN)-based lower-limb kinematic prediction, these models' robustness to sensor loss during deployment is unclear, raising uncertainty about the effectiveness and safety of their use in real-world exoskeleton control. In real-time settings, wearable sensor disconnection or detachment often manifests as data flatlined at the last known value. Thus, this study investigates the effect of flatlined wearable sensor data on DNN model performance and proposes a simple, sensor-agnostic training modification to mitigate the effect of erroneous sensor input on ankle joint angle prediction.

Methods

Data from eleven lower-limb biomechanical sensors (three accelerometers, three gyroscopes, three electromyography sensors, and two goniometers) from 21 participants performing five unique actions (walking, ramp ascent/descent, and stair ascent/descent) were extracted from a *Journal of Biomechanics* open-source dataset [1]. Nine Long Short-Term Memory (LSTM) models were trained to predict sagittal-plane ankle angles at a t_{hzn} = 200 ms prediction horizon, each model being informed by a unique subset of the eleven wearable sensors. Each LSTM model was trained while intermittently simulating that $0 \leq N_{dropped,train} \leq 3$ random sensors were flatlined for each input window (i.e., sensor data replaced by a random constant value within the sensor's recorded range). Model performance was then evaluated on a held-out dataset where $0 \leq N_{dropped,test} \leq 3$ sensors were randomly simulated as flatlined.

Results

No matter the number of sensors flatlined during training (i.e. $N_{dropped,train}$), LSTM model performance degraded as the number of flatlined sensors during testing (i.e. $N_{dropped,test}$) increased ($p < 0.001$). However, performance robustness to flatlined sensor data during testing improved as the number of flatlined sensors increased during training ($p < 0.001$).

Discussion

The results indicate that, during model testing, flatlined sensor data is significantly detrimental to model performance, posing a limitation to LSTM-based model implementation in practice. However, purposeful intermittently flatlined sensor data during LSTM model training ($N_{dropped,train} > 0$) was shown to improve model performance robustness during flatlined sensor test. Thus, LSTM joint angle prediction models may benefit from intermittently flatlining sensor data during training to ensure robustness to sensor failure during deployment.

Large Movement Models: Transformer-Based Models of Individual Movement in the Real World Using Data From Consumer Headphones

Dr. Alexandra Hammerberg[1,2], Dr. Samuel Grunblatt[3,1], Dr. Patricia Kramer[4]

[1]hominin labs, Seattle, WA, United States. [2]European Society of Biomechanics, London, London, United Kingdom. [3]University of Alabama, Tuscaloosa, AL, United States. [4]University of Washington, Seattle, WA, United States

Dr. Alexandra Hammerberg

Dr. Samuel Grunblatt

Introduction

Developing AI solutions that leverage existing wearable technology such as Apple AirPods or other body-worn devices to understand unconstrained walking mechanics in individuals has been a goal since this data became available, but few models address the hierarchical nature of real-world motion data and even fewer incorporate data that contextualize real-world gait mechanics such as environmental conditions. In this work we propose a novel foundation model for human movement - a Large Movement Model (LMM): a nested hierarchical and flexibly multimodal transformer-based model of individual human movement in the real world.

Methods

We utilize data from existing inertial measurement unit (IMU) sensors embedded in spatial audio-enabled headphones. Like genetic sequencing, the individual's gait pattern can be discerned by decomposing the movement signal into its fundamental features in each coordinate direction, forming the backbone of the LMM. At each layer, multimodal features (e.g., environmental conditions) are fused prior to passing through the transformer. Each layer of the model builds upon the outputs from the prior layer as initial embeddings, following a characters -> words -> sentences convention. We evaluate the LMM using a previously collected dataset consisting of AirPod Pro IMU data from 17 adults (age: 18 - 67 years, 11F) without known pathology walking outside normally and while wearing orthopaedic braces to simulate gait pathology.

Results

We found that our model outperformed a basic multilayer perceptron (MLP) neural net in identifying normal vs non-normal walking at the level of the individual (MLP: 62.4%, LMM: 76.7%). The individual-level model also outperformed the population-level model (Population: 73.6%).

Discussion

By 2050, 22% of the global population will be over the age of 60 with greater than 40% risk of developing life-altering neuromusculoskeletal pathologies. The potential of wearables to provide personalized preventative and predictive health monitoring outside of the clinic is nascent, but large quantities of open-ended data that capture movement in the physical world now exist. We demonstrate that by designing an AI model with architecture informed by the structure of the system, LMMs have the potential to expand on-body monitoring at scale.

Age-Related Changes in Spinal Load Distribution: Predictive Simulation of Active Spine Movements

Dr. Maria Hammer[1], apl. Prof. Dr. Patrick Strube[2], Prof. Dr. Matthias Woiczinski[1]

[1]Experimental Orthopedics, University Hospital Jena, Campus Eisenberg, Jena/ Eisenberg, Thüringen, Germany. [2]Spine Department, University Hospital Jena, Campus Eisenberg, Jena/ Eisenberg, Thüringen, Germany

Introduction

Age-related changes in the spine often lead to instability, altered movement patterns, and degenerative conditions, whose mechanical origins remain partly unclear. At the same time, surgical interventions in older adults show limited success, with revision rates reaching up to 30%. Biomechanical simulations could support preoperative planning but currently poorly capture the complex, age-dependent load distributions - particularly during dynamic active movements. Therefore, we developed an aged spine model to quantify changes in spinal load distribution in elderly people using predictive, muscle-driven simulations.

Methods

A population-based multibody spine model of a healthy young male, which is fully articulated and includes detailed musculature and ligament structures, was further enhanced based on [1,2]. Age-related biomechanical alterations in the intervertebral discs, ligaments, muscles, and facet joints were implemented using reported data by adjusting soft tissue stiffnesses, muscle cross-sectional areas, prestrains, and other geometric and mechanical parameters to correspond to a biological age of 60 years. By varying spinopelvic parameters, four anatomical variations were derived. For each model, muscle, ligament, disc, and facet joint forces were quantified in predictive simulations [1] of flexion–extension, lateral bending, and axial rotation, and subsequently compared with corresponding values obtained from young spine models.

Results

The results indicate a reduced stiffness of the lumbar segments and increased global instability in the upright posture when considering aging effects in all soft tissue compartments including muscle atrophy. We observe increased disc forces during active forward bending, as well as elevated facet joint forces, particularly during lateral bending.

Considering degeneration of isolated tissue elements shows the counteracting mechanism of ligament stiffening (see Fig. 1) leading to a reduced flexibility and range of motion. In general, the magnitude and location of these effects vary substantially with individual spinal curvature.

Discussion

The simulation results are consistent with experimental and clinical findings and provide deeper insight into the biomechanical load distribution in aged spines during daily-life movements. The large impact of spinopelvic parameters highlights the importance of a patient-specific assessment. Predictive simulations could therefore assist in identifying individual mechanical risk factors.

Images (Optional)

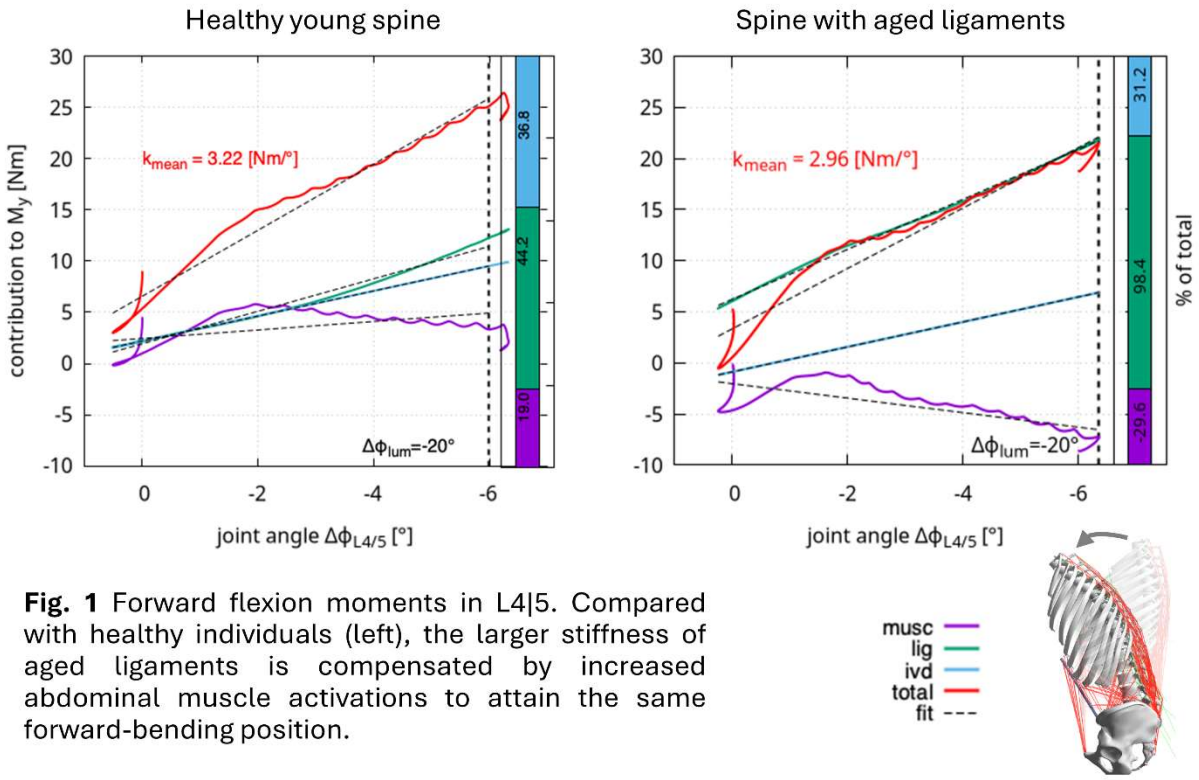

Fig. 1 Forward flexion moments in L4|5. Compared with healthy individuals (left), the larger stiffness of aged ligaments is compensated by increased abdominal muscle activations to attain the same forward-bending position.

[4]TUM-Neuroimaging Center, TUM Klinikum Rechts der Isar, Technical University of Munich, Munich, Bavaria, Germany. [5]Department of Diagnostic and Interventional Radiology, University Hospital Ulm, Ulm, Baden-Württemberg, Germany. [6]Department of Nuclear Medicine, University Hospital Ulm, Ulm, Baden-Württemberg, Germany

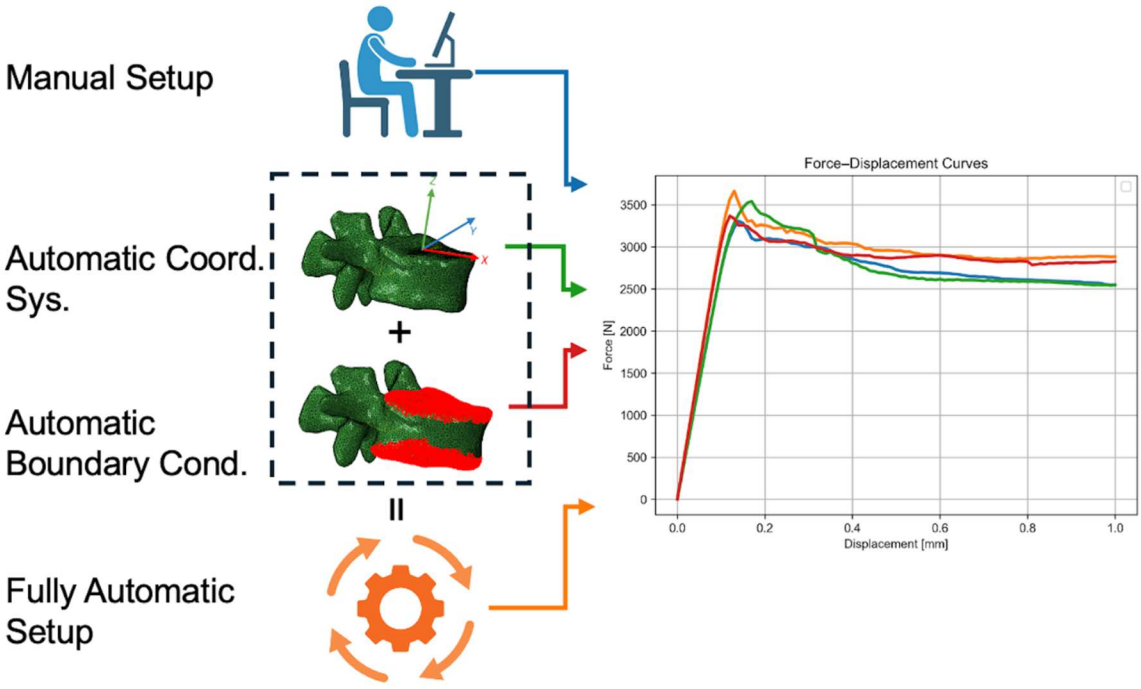
Introduction

Patient-specific finite element (FE) models derived from clinical CT can support vertebral fracture risk assessment, but their translation into routine care remains limited by the time-consuming manual tasks, including the definition of vertebral coordinate systems (CYS) and boundary conditions (BC). Because, loading direction and BC specification can substantially influence output [1], robust automation is needed. This study evaluated whether an automatic, standardized CYS and BC setup yields vertebral fracture load predictions comparable to those defined by experts.

Methods

Twenty vertebrae (10 thoracic, 10 lumbar) from an ongoing clinical study were used to generate CT-based FE models and applied density–elasticity material mapping. In the reference condition, an experienced operator manually defined the vertebral CYS and applied compression BC. The automatic pipeline [2] determined vertebral axes from geometric extreme points and extracted superior and inferior endplates using normal vectors of the elements, applying Gaussian and median filtering. From these, standardized compression BC was applied.

Three configurations were compared with the manual reference: (1) automated BC only (BC), (2) automated CYS only (CYS), and (3) fully automated CYS+BC (Auto). Agreement in FL was evaluated using linear regression (R^2) and Bland–Altman bias.



Results

All automated configurations showed excellent correlation with the manual reference ($R^2 >$ 0.97; BC: 0.98; CYS: 0.978; Auto: 0.971). Bland-Altman analysis revealed the smallest mean bias for CYS (31 N), followed by BC (230 N) and Auto (308 N).

Discussion

Both partially and fully automated setups preserved vertebral FL predictions with high agreement with manual expert models. However the automated setup was approximately 20 times faster than the manual process. The smallest bias observed for CYS suggests that modest variations in loading direction exerted a limited influence on FL in this cohort, whereas BC definition contributed more substantially to deviations. Ongoing work will expand the dataset and quantify how specific CYS and BC discrepancies propagate to FL, with the goal of establishing clinically robust and scalable automation strategies.

How Treatment Therapies Shape Mechanics in Osteoporotic Vertebral Fracture Repair: A Computational Study

Dr Robert Johnston[1], Dr Ciara Murphy[1,2,3]

[1]Tissue Engineering Research Group, Department of Anatomy & Regenerative Medicine, Royal College of Surgeons (RCSI), Dublin, Ireland, Ireland. [2]Trinity Centre for Biomedical Engineering, Trinity College Dublin, Dublin, Ireland, Ireland. [3]Advanced Materials and Bioengineering Research Centre (AMBER), RCSI and TCD, Dublin, Ireland, Ireland

Introduction

Osteoporotic vertebral fractures are the most common complication of osteoporosis and are often treated with PMMA-based vertebroplasty or kyphoplasty, but PMMA's stiffness mismatch can alter spinal biomechanics, causing stress shielding and adjacent fractures. Tunable hydrogels may offer a stabilization and regenerative alternative. This study uses finite element analysis to evaluate how PMMA and hydrogels influence lumbar stress distribution under biomechanically realistic loading conditions, aiming to guide improved treatment strategies.

Methods

T2-weighted spine MRI scans were segmented in 3D Slicer to isolate the L2–L4 vertebrae and discs using intensity-based thresholding, followed by smoothing, see Fig. 1A. The segmented geometry was exported to Abaqus as an IGES file, partitioned, and meshed in Abaqus CAE with C3D8H hexahedral elements. Material sections were assigned for healthy, osteoporotic, PMMA-treated, and hydrogel-treated models, see Fig.1B. Six biomechanical movements were simulated (flexion, lateral flexion, compression, lateral bending, extension, rotation) by constraining L4 and applying displacement or rotation to L2. Loads were 500N, 1000N, 500N, 10Nm, 20Nm, and 10Nm, with penalty contact (μ=0.1), see Fig.1C.

Results

Across all simulated loading conditions, osteoporotic vertebrae showed higher peak von Mises stresses (57.37, 33.06, 35.97, 30.06, 79.12, 58.45 MPa) and a greater bone volume exposed to elevated stress than healthy vertebrae (47.65, 15.06, 21.24, 16.28, 73.18, 47.42 MPa) , see Fig.1D-E. PMMA treatment reduced stress at the implant site but increased high-

stress volumes in adjacent vertebrae. In contrast, the stiffest hydrogel increased stress locally at the implant site while reducing stress transmission to adjacent levels, lowering the proportion of bone in higher stress bands, see Fig.1E. Although this suggests improved stress mitigation, the hydrogel may lack sufficient structural strength for fracture stabilization. Notably, the stiffest hydrogel did carry measurable internal stresses, indicating active participation in load transfer.

Discussion

Osteoporotic bone exhibits elevated stress levels, PMMA further increases loading in adjacent vertebrae, while the stiff, high-volume hydrogel formulation effectively participates in load transfer under biomechanically relevant loading. The findings demonstrate that treatment choice significantly alters lumbar stress distributions and offer a strong foundation for developing improved, patient-specific devices and biologically informed therapies that preserve spinal biomechanics, reduce secondary fracture risk, and enhance long-term clinical outcomes.

Multiscale Investigation of Spinal Fixation Failure Risk: The Interplay Between Global Alignment and Local Bone Properties

PhD Student Sara Panero[1,2], Dr. Simone Borrelli[1,2], Dr. Giovanni Putame[1,2], Prof. Alberto Audenino[1,2], Prof. Mara Terzini[1,2], Dr. Alessandra Aldieri[1,2,3]

[1]PolitoBIOMed, Politecnico di Torino, Turin, Piedmont, Italy. [2]Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Turin, Piedmont, Italy. [3]Department of Industrial Engineering, Alma Mater Studiorum - University of Bologna, Bologna, Emilia Romania, Italy

Introduction

At present, the interplay between biomechanical factors across spatial scales remains poorly investigated when assessing implant failure risk [1]. This study proposes an integrated multibody-finite element pipeline connecting global spinal alignment and local bone quality to improve implant loosening prediction.

Methods

Subject-specific multiscale models of the T12-S1 segment were generated from CT scans of six female subjects,with different lumbar lordosis (LL: [38.7°,67.6°]) and bone quality (T-score: [-3.6,1.1]). Assuming an L3 fracture, three titanium implant fixations were modelled for each subject (long-segment, Lf: L1-L2-L4-L5 and short-segment, Sf4: L2-L4, Sf6: L2-L3-L4).

For MB simulations, rigid vertebrae were connected via nonlinear bushings [2]. Rods deformability was described through modal analysis and screw stiffness derived from cantilever beam theory (Figure 1a). Follower loads accounted for muscle contribution. The sacrum was fully constrained, and pure moments were applied on T12 within Cone of Economy range of motions.

FE analyses were performed on L4 applying MB outputs as boundary conditions. Material properties were mapped element-wise from CT-derived HU [3]. A bonded contact at the screw-bone interface was implemented, and principal stress values at the bone were considered to investigate the regions at greater risk.

Results

At this stage, simulations were performed on the three spine models. Long and short fixations were compared, showing the outer instrumented vertebrae experiencing higher pull-out and shear forces, whereas the central vertebrae were comparatively shielded (~24% less). No clear dependence between spinal alignment and maximum shear forces at the pedicle screws emerged (Figura1b). Small deviations were observed on the L4 screws during axial rotation (~4%), whereas a linear trend was observed under lateral bending, the resulting worst-case scenario. Stress distribution (Figure 1c) appeared to be influenced by T-score, with the highest peaks occurring at the screw-bone interface and along the pedicles of osteoporotic vertebrae.

Discussion

Further analyses will be conducted on the entire cohort to refine preliminary results and achieve a multiscale understanding of how microscale and joint-level parameters contribute to implant stability and failure risk.

Two-Photon Subtractive Manufacturing of Mesoscale Porosity for Structure-Function Optimization of Electrospun Vascular Grafts

Ms. Tiffany Moreno[1], Ms. Colleen OMalley[1], Mr. Brock Pemberton[1], Mr. Markus Boettcher[2], Dr. William Wagner PhD[1,3,4], Dr. Jonathan Vande Geest PhD[1,5]

[1]Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States. [2]Miltenyi Biotec B.V. and Co. KG, Bielefeld, NRW, Germany. [3]Department of Surgery, University of Pittsburgh, Pittsburgh, PA, United States. [4]Department of Chemical Engineering, University of Pittsburgh, Pittsburgh, PA, United States. [5]Vascular Medicine Institute, University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Small diameter tissue engineered vascular grafts (TEVGs) often fail from early thrombosis and late intimal hyperplasia, due to limited vascular smooth muscle cell (VSMC) infiltration and inadequate tissue remodeling. Introducing mesoscale porosity (50–250 μm) has been proposed to facilitate cell migration, however, existing fabrication approaches, including salt-leaching and thermally induced phase separation, often lack geometric precision, limited control over pore size, spacing, and distribution. The objective of this study was to develop and characterize a two-photon (2P) laser subtractive manufacturing approach to introduce tunable pore architectures into electrospun scaffolds for TEVG applications.

Methods

Electrospun PCL/PLCL sheets were fabricated from a 10% (w/v) solution in HFP using a high-voltage system (15 kV, 10 μL/min) on a 9 cm rotating mandrel (300 rpm), producing 90 μm sheets. Four binary templates (Gradient I, Gradient II, Stent Mesh, Dodecagon Mesh) were generated in MATLAB to test cutting precision across varying complexities and applied via two-photon subtractive manufacturing (Miltenyi Biotec) with an Olympus XL Fluor 4× objective, creating 10–260 μm pores. Images were analyzed using thresholding, artifact filtering, and DICE coefficient calculation.

Results

Two-photon manufacturing generated pores 10–260 μm with high geometric fidelity (DICE 0.74–0.95). As shown in Figure 1, overlays of design masks (magenta) and 2P cuts (green) illustrated alignment quality, with higher DICE indicating stronger overlap. Welch's ANOVA ($n = 4$/group) revealed significant differences in DICE values ($p < 0.05$), with Gradient I

showing highest accuracy and Gradient II lowest. Coefficient of variation indicated repeatability, with Gradient II most variable and Gradient I least variable. These results demonstrate reliable patterning performance for evaluating structure function relationships.

Discussion

Two-photon subtractive manufacturing reliably produces mesoscale pore architectures with high fidelity and reproducibility across varying pattern complexities, enabling controlled investigation of how geometry influences cell infiltration. Variability between templates highlights the importance of pattern selection in TEVG design. This method supports engineering pore architectures tailored to biological and mechanical needs. Current work with these two-photon cut sheets focuses on forming tubular graft-like constructs and matching their compliance to native arteries, as compliance mismatch influences hemodynamic stress and contributes to small-diameter graft failure.

Digital Light Processing (DLP) 3D Printing of β-TCP/PDLLA-co-TMC Nanocomposite Scaffolds for Bone Tissue Engineering

Miss Yujie Zhang, Dr. Xiaodie Chen, Prof. Min Wang

The University of Hong Kong, Hong Kong, Hong Kong, Hong Kong

Miss Yujie Zhang

Dr. Xiaodie Chen

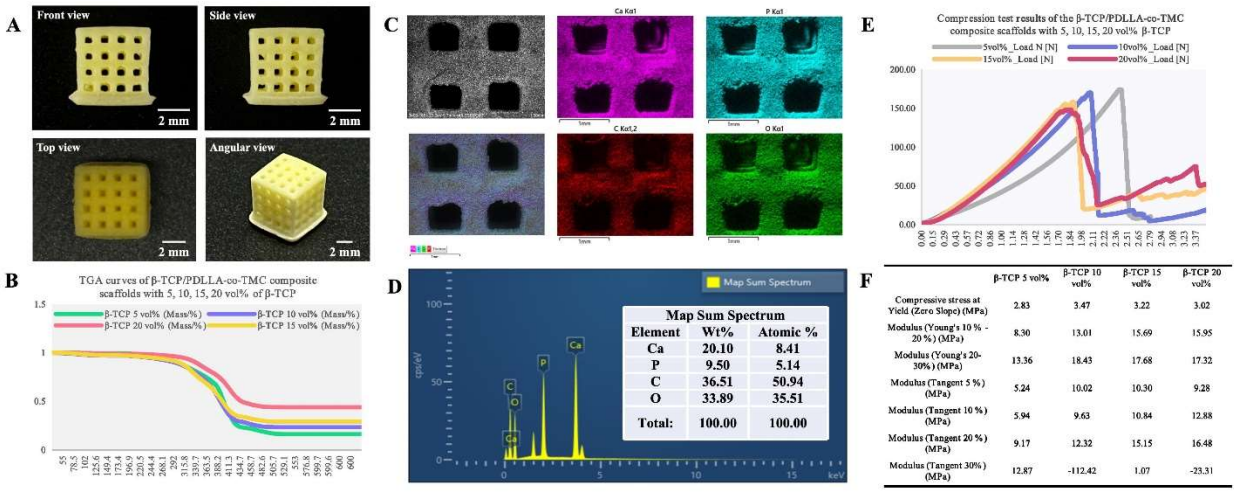
Introduction

Bone tissue engineering (BTE) scaffolds, which combine mechanical integrity, bioactivity and controlled biodegradation, promote new bone formation in human bodies. Digital light processing (DLP) 3D printing can produce complex BTE scaffolds. β-tricalcium phosphate (β-TCP) is a biodegradable bioceramic with good osteoconductivity and hence often used in BTE. Combining β-TCP with biodegradable poly(D,L-lactide-co-trimethylene carbonate) (PDLLA-co-TMC) polymer can balance biological and mechanical properties and produce shape-morphing scaffolds for BTE. In this study, a β-TCP/PDLLA-co-TMC composite printing ink system was established and inks were optimized for DLP 3D printing. DLP 3D printed composite scaffolds were subsequently assessed.

Methods

Printing inks were made by dissolving PDLLA-co-TMC in acetone, followed by adding PEGDA-600 as crosslinker. β-TCP nanoparticles were dispersed in PDLLA-co-TMC solutions at 5, 10, 15, 20 vol% loading. LAP and curcumin were photoinitiator and photoabsorber, respectively. Curcumin-Na served as a free radical inhibitor. BTE scaffolds were 3D printed on a DLP printer. Printed composite scaffolds were characterized using various techniques. Cytocompatibility was assessed using MC3T3-E1 cells through live/dead staining and CCK-8 assay.

Results



Optimized printing inks containing 5, 10, 15, and 20 vol% β-TCP exhibited viscosities, which increased with increasing β-TCP loading, suitable for layer-by-layer printing in DLP

processes. Take the 10 vol% β-TCP formulation for example. DLP successfully produced scaffolds with high dimensional fidelity and uniform pore morphology (pore sizes of 800, 600 and 400 μm, with porosities of 55.4%, 41.7% and 27.9%, respectively). The compressive strength of β-TCP/PDLLA-co-TMC scaffolds with 5, 10, 15 and 20 vol% β-TCP reached 2.83, 3.47, 3.22 and 3.02 MPa, which are within the range for human cancellous bone (2–12 MPa), indicating their suitability for BTE. MC3T3-E1 cells cultured on composite scaffolds exhibited well-spread morphology and good biocompatibility. They showed increased proliferation over the 7-day culture period.

Discussion

This study showed feasibility of formulating suitable inks for DLP 3D printing of β-TCP/PDLLA-co-TMC scaffolds and also their high-fidelity printing via DLP. Like other composite scaffolds for BTE, the bioceramic content affected mechanical and biological properties of β-TCP/PDLLA-co-TMC scaffolds.

Biosourced Molecules as Photoinitiators for Light-Based 3D Printing of Tunable Biomaterials

Ms. Hailey McCoy-Munger, Dr. Kristan Worthington

University of Iowa, Iowa City, Iowa, United States

Introduction

Two-photon polymerization (TPP) is a high-resolution additive manufacturing technique uniquely suited for biomaterial fabrication due to its inherent spatial and temporal control. Unfortunately, many common TPP resins are cytotoxic and key material properties such as stiffness are difficult to predict and control. However, using bio-sourced molecules and exploiting TPP printing parameters may address these challenges. Here, we present a cytocompatible TPP resin that employs curcumin as a photoinitiator for polyethylene glycol dimethacrylate (PEGDMA) to fabricate biomaterials with tunable stiffnesses.

Methods

Prepolymer solutions comprising curcumin (18 mM) in 550 Mn PEGDMA were used for TPP using a Nanoscribe Photonic Professional GT. Cuboid (25 x 25 x 5 μm) arrays were created using three laser powers (LP; 80, 90, 100%) and scanning speeds (SS; 70, 85, 100 mm/sec). A complex structure with void features <20 μm was also printed to demonstrate scale-up feasibility. Cuboid arrays were sterilized in 70% ethanol, laminin coated, and seeded with primary human dermal fibroblasts (HDFs). Cell viability was assessed after 24 hours using a live/dead assay (n=3). Stiffnesses (DMT modulus) of cuboids printed at select parameters were measured using atomic force microscopy. Differences in moduli (n=3) were determined using a one-way ANOVA with subsequent Tukey's test.

Results

Cuboids printed effectively at all combinations of LP and SS (Fig. 1A). HDFs seeded on the TPP structures maintained high viability (> 80%) across all printing conditions (Fig. 1B-C). The PEGDMA-curcumin resin could also form more complex, high-resolution TPP structures (Fig. 1D). At 80% LP, DMT modulus varied significantly with SS (Fig. 1E). However, changing SS did not significantly change the stiffness of structures printed at 70 mm/sec (Fig. 1F).

Discussion

Our results demonstrate the feasibility of using PEGDMA-curcumin as a biocompatible, readily tunable TPP resin. Printed structures support high cell viability and the resin can be

used to create intricate microstructures. Furthermore, the stiffness of cuboids was modulated by simply changing scanning speed, which may enable creating stiffness gradients within a single structure. In our ongoing work, we are expanding to other monomer and cellular systems, with long-term goals of creating cytocompatible, stiffness-tunable tissue-mimicking structures with encapsulated cells.

Images (Optional)

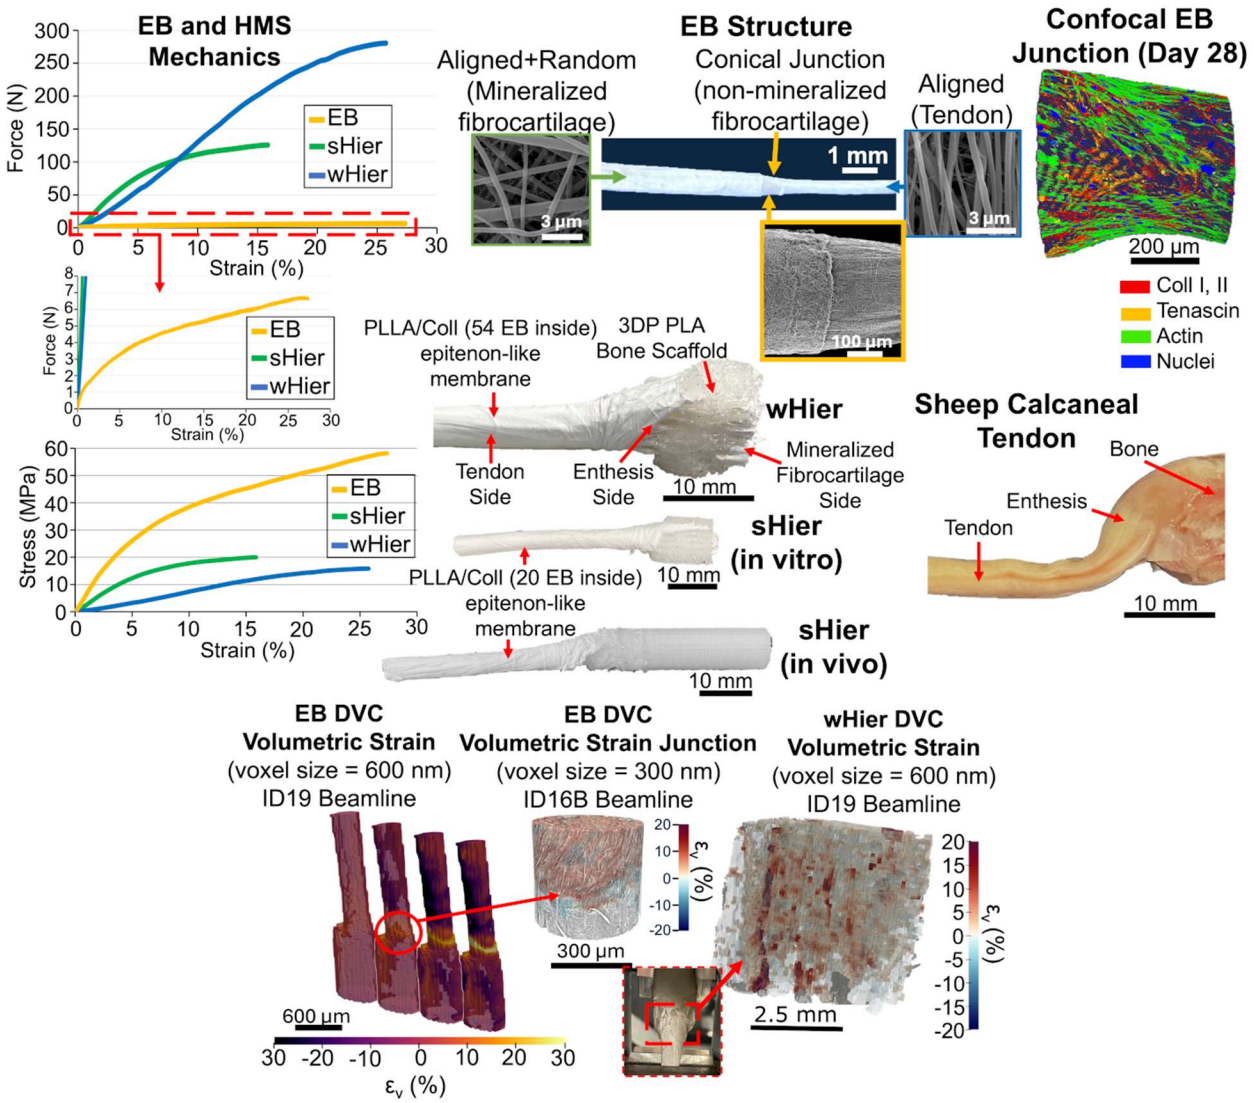
Introduction

Enthesis injuries are critical for extracellular-matrix organization-composition and auxetic mechanics [1]. Merge hierarchical electrospinning (HE) with 3D-printing (3DP) is suitable for replicate bone–enthesis–tendon chain. Enthesis fascicle-inspired auxetic electrospun bundles (EB) and hierarchical multi-material scaffolds (HMS) were fabricated mimicking structure-mechanics of sheep calcaneal tendon–enthesis–bone complex. Scaffolds' in-vitro-in-vivo performances were investigated, while in-situ Synchrotron X-ray tomography (SXCT) stepwise-tensile tests with digital volume correlation (DVC) elucidated their auxetic strain behaviour.

Methods

PLLA-Collagen-I blend EB were electrospun on a drum collector obtaining regions with controlled nanofiber orientations: mineralized fibrocartilage (random+aligned), non-mineralized fibrocartilage (conical junction, aligned), and tendon (aligned). EB morphology was examined via SEM-SXCT. EBs were seeded with human mesenchymal stromal cell (hMSC) spheroids (28days) and evaluated by qPCR, ELISA, and confocal microscopy. EB mechanics were assessed with tensile tests (strain-rate:0.4, 10, 100%/s), and full-field

strain distribution was analysed through in-situ SXCT stepwise-tensile tests with DVC. HMSs were produced grouping EBs with HE epitenon-inspired electrospun membranes resembling native tendon–enthesis tissue. STL models were generated segmenting a sheep calcaneal bone SXCT scan and used to 3DP PLA scaffolds on HMS mineralized fibrocartilage region, reproducing the whole bone–enthesis–tendon chain. HMSs with different numbers of internal EB were prepared (sHier, wHier). HMS morphology was examined via SEM/microCT, and mechanics was assessed with tensile tests at 100%/s. wHier auxetic expansion was evaluated through stepwise-tensile tests with DVC adapting the EB protocol. Custom sHier scaffolds were implanted in-vivo in sheep calcaneal bone–tendon defects, with follow-up x-rays, echography for six months.



Results

SEM-SXCT confirmed biomimetic EB-nanofibers morphology [1]. EB mechanical tests revealed tendon fascicles-like mechanics. Confocal imaging verified EB colonization by hMSCs with enthesis-specific extracellular-matrix production. EB qPCR highlighted bone/enthesis/tendon markers expression. ELISA showed Collagen-II-Tenomodulin production. DVC revealed EB junction volumetric expansion verifying auxetic behavior. Volumetric auxetic strains were confirmed with HMSs' DVC. SEM-microCT HMS investigations revealed natural tissue biomimicry while mechanical tests showed HMSs mechanical reductions complexity-dependent like natural tissues. X-rays and echography showed in-vivo bone-enthesis-tendon regeneration.

Discussion

Multi-metamaterial scaffolds for bone-enthesis-tendon regeneration were realized. SXCT-DVC confirmed electrospun scaffolds' metamaterial nature.

[2]Interuniversity Center for the Promotion of the 3Rs Principles in Teaching and Research, Torino, Piemonte, Italy. [3]Dept of Applied Science and Technology, Politecnico di Torino, Torino, Piemonte, Italy

Introduction

Epithelial tissues (ET) are naturally exposed to external environment [1], a condition reproduced *in vitro* through the air–liquid interface (ALI) approach [2]. Conventional ALI systems employ transwell inserts to separate air and liquid compartments [3]; however, their static configuration does not adequately replicate the dynamic exchange of nutrients and gases occurring *in vivo*, often resulting in uneven tissue development. In this context, we present a biomimetic bioreactor, designed to support ALI culture with continuous medium recirculation (CMR) to enhance physiological relevance for skin tissue engineering.

Methods

The bioreactor culture chamber is composed of two screwable parts, 3D-printed with biocompatible autoclavable resins, housing transwells for ensuring effective separation between air and liquid phases. The chamber is integrated in a hydraulic circuit for guaranteeing CMR under the construct (working volume = 5mL). Air bubble accumulation is prevented by specific design. Preliminary biological validation was performed culturing 3D skin-like constructs. Human fibroblasts were embedded in a GelMa hydrogel, then poured on the transwell and coated with keratinocytes. The constructs were cultured in bioreactor for 14 days (flow rate = 0.5mL/min, n=4) (Fig.1A).

Results

Performances tests confirmed the bioreactor operational suitability and proper flow circulation under continuous operation. Biological tests demonstrated that constructs subjected to dynamic culture conditions displayed markedly improved epidermal

stratification, achieving epidermal layers exceeding 100 µm in thickness (Fig.1B), together with a significant upregulation of dermis-associated genes (Fig.1C). These findings indicate a more advanced level of tissue maturation relative to static controls.

Discussion

Overall, the bioreactor provides a controlled culture environment enabling both air exposure and CMR, improving nutrient and oxygen transport, while maintaining sterility and operational ease of use. Moreover, its modularity allows parallel culture of multiple samples, supporting reproducibility and scalability. By reproducing the ET microenvironment, the bioreactor overcomes the inherent limitations of static approaches, representing a versatile tool for advanced ET engineering studies.

Cyclic Hypoxia Modulates Endothelial Permeability in a Microvascular Network Formed in an Oxygen-Controllable Microfluidic Device

Mr. Shohei Yanagita, Dr. Kenichi Funamoto

Tohoku University, Sendai, Miyagi, Japan

Introduction

Ischemia–reperfusion injury arises when hypoxic tissues are reoxygenated, triggering abrupt increases in reactive oxygen species (ROS), endothelial barrier dysfunction, and inflammation. Conversely, controlled cycles of hypoxia and reoxygenation can induce ischemic conditioning, a protective phenomenon that enhances vascular resilience. Despite extensive research, the cellular mechanisms that distinguish injury-inducing from protective oxygen fluctuations remain incompletely understood, partly due to limitations of conventional in vitro models that cannot impose dynamic oxygen changes within a 3D microvascular network. Here, we used an oxygen-controllable microfluidic device containing a self-assembled microvascular network to investigate how cyclic hypoxia regulates redox dynamics and endothelial integrity.

Methods

A 3D microvascular network was formed by co-culturing human umbilical vein endothelial cells and fibroblasts in fibrin for 7–10 days. The formed microvascular networks were then subjected to one of three oxygen conditions for 180 min: normoxia (N, 21% O_2), steady hypoxia (H0, 0.3% O_2), or cyclic hypoxia (CyH0, alternating between 0.3% and 21% O_2 every 30 min). ROS generation was quantified using a CellROX fluorescence reagent. Endothelial permeability was assessed by quantifying diffusion of FITC-labeled dextran through the vascular network. Intracellular proteins Nrf2 and VE-cadherin were observed by immunofluorescence microscopy to assess antioxidant response and cell–cell junction integrity.

Results

ROS levels decreased and reached a low steady state under the H0 condition, whereas the CyH0 condition produced oscillatory ROS fluctuations synchronized with oxygen cycling. Endothelial permeability slightly increased under the H0 condition compared with the N condition, but was reduced under the CyH0 condition, indicating endothelial barrier reinforcement. Nuclear localization of Nrf2 increased under both hypoxic conditions (H0

and CyH0), suggesting activation of antioxidant defenses. In addition, VE-cadherin junctional area increased under the CyH0 condition, indicating enhanced endothelial adhesion.

Discussion

Cyclic hypoxia elicits coordinated redox and structural adaptations in a microvascular network. The combination of oscillatory ROS dynamics, Nrf2 activation, and VE-cadherin–mediated junctional reinforcement suggests that the CyH0 condition promotes a protective endothelial state resembling ischemic conditioning, whereas steady hypoxia lacks these adaptive features. Our microfluidic platform provides a powerful tool for dissecting oxygen-pattern–dependent vascular responses and for informing strategies to mitigate ischemia-reperfusion injury or harness conditioning-based protection.

Cancer Associated Fibroblasts and Leader Cells Drive Collective Migration of Breast Cancer Metastasis Through Chemo-Mechanical Signaling

Mrs. Jessica Williamson B.S., Mr. Jesee Rolston B.S., Mr. Musaddiq Lodi, Dr. Jessanne Lichtenberg PhD, Dr. Preetam Ghosh PhD, Dr. Priscilla Hwang PhD

Virginia Commonwealth University, Richmond, Virginia, United States

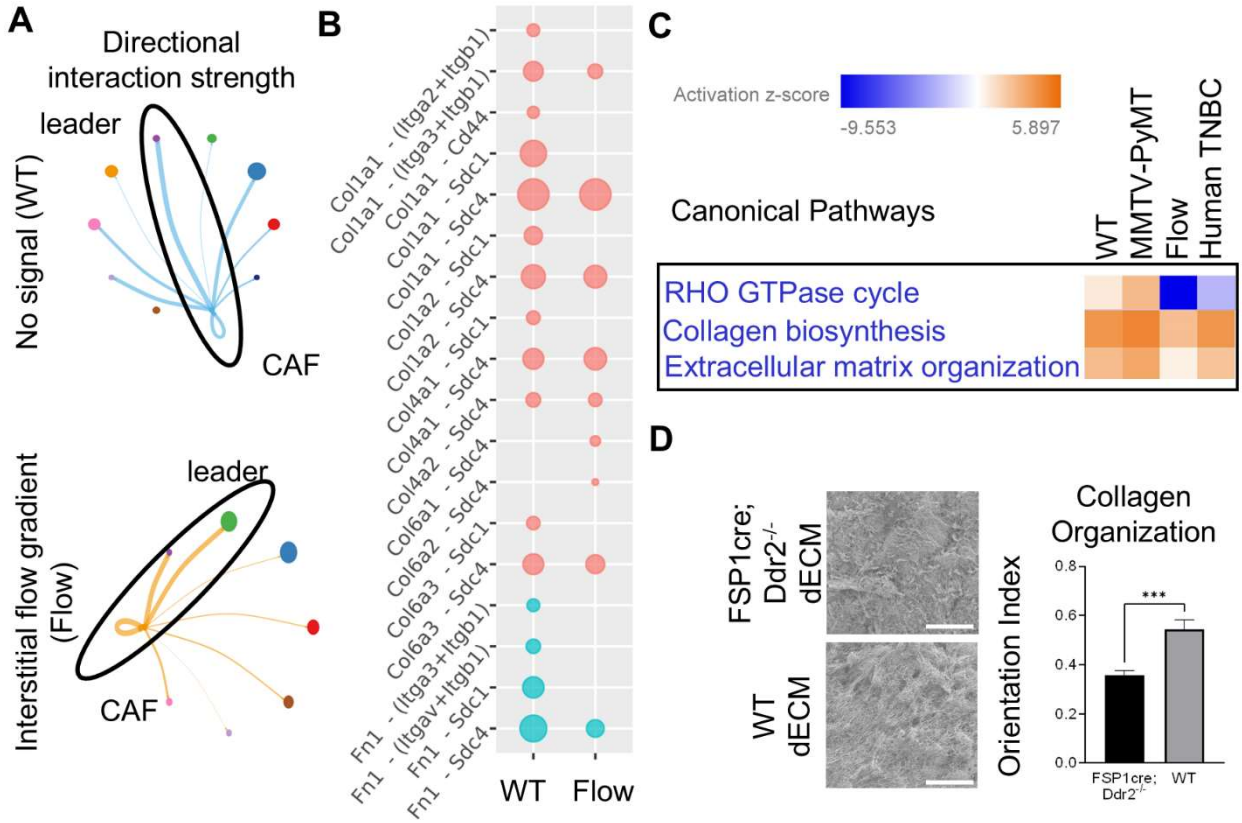
Introduction

Heterogeneous tumor clusters can detach from primary tumors and travel to distant organs via collective cell migration (CCM), where cells move as a coordinated unit. *In vivo*, tumor clusters include various tumor phenotypes, immune, and stromal cancer associated fibroblasts (CAFs) [1]. Using 3D microfluidic models we designed, we demonstrated that leader cells at the front drive directional migration and CAFs physically associate with leaders [2-4]. This project investigates how CAFs and leaders communicate to coordinate migration using our microfluidic models and single-cell RNA sequencing (scRNA-seq) assays. We hypothesize that chemo-mechanical feedback between CAFs, leaders, and mechanical matrix cues directs CCM.

Methods

Primary mouse tumor (MMTV-PyMT) organoids were cultured in 3D microfluidic devices under biomechanical gradient (interstitial flow, 12 μm/s) to induce CCM [3,4]. A non-migratory control was included. After 16 hours, organoids were isolated for scRNA-seq. Data was analyzed after principal component analysis (PCA), using Seurat's default parameters, and CAF to leader ligand-receptor interactions were assessed using CellChat. Ingenuity Pathway Analysis was used to reveal signaling pathways and to validate scRNA-seq results against *in vivo* datasets.

Results



scRNA-seq revealed 10 cell clusters without flow and 8 under flow. CAFs and leaders had the greatest number and strength of interactions (Fig1A). CAFs send signals to leaders through matrix ligands such as collagen and fibronectin interacting with syndecan (Sdc) receptors (Fig1B). Pathway analysis identified "RHO GTPase", "Collagen Biosynthesis," and "Matrix organization" as significant pathways (Fig1C). We validated our analysis with metastatic human and primary MMTV-PyMT data, finding similar pathway activation (Fig1C). Scanning electron microscopy (SEM) imaging of tumors with and without CAFs

ablated revealed differences in matrix organization, validating our scRNA-seq analysis (Fig1D).

Discussion

We demonstrate CAF ligands communicate with leader cell receptors within organoids, and our model correlates with *in vivo* conditions. This work contributes to the mechanistic understanding of how biomechanics regulate CCM in breast cancer metastasis. In the future we will perform loss/gain-of-function experiments to validate genes identified as potential therapeutic targets.

Using Biomechanical Simulation for Generalizing and Personalizing Assistance From a Supernumerary Robotic Limb for Diverse Single-Shot Activities

Mr. Haedo Cho, Ms. Zoe Kutulakos, Dr. Patrick Slade

Harvard University, Cambridge, MA, United States

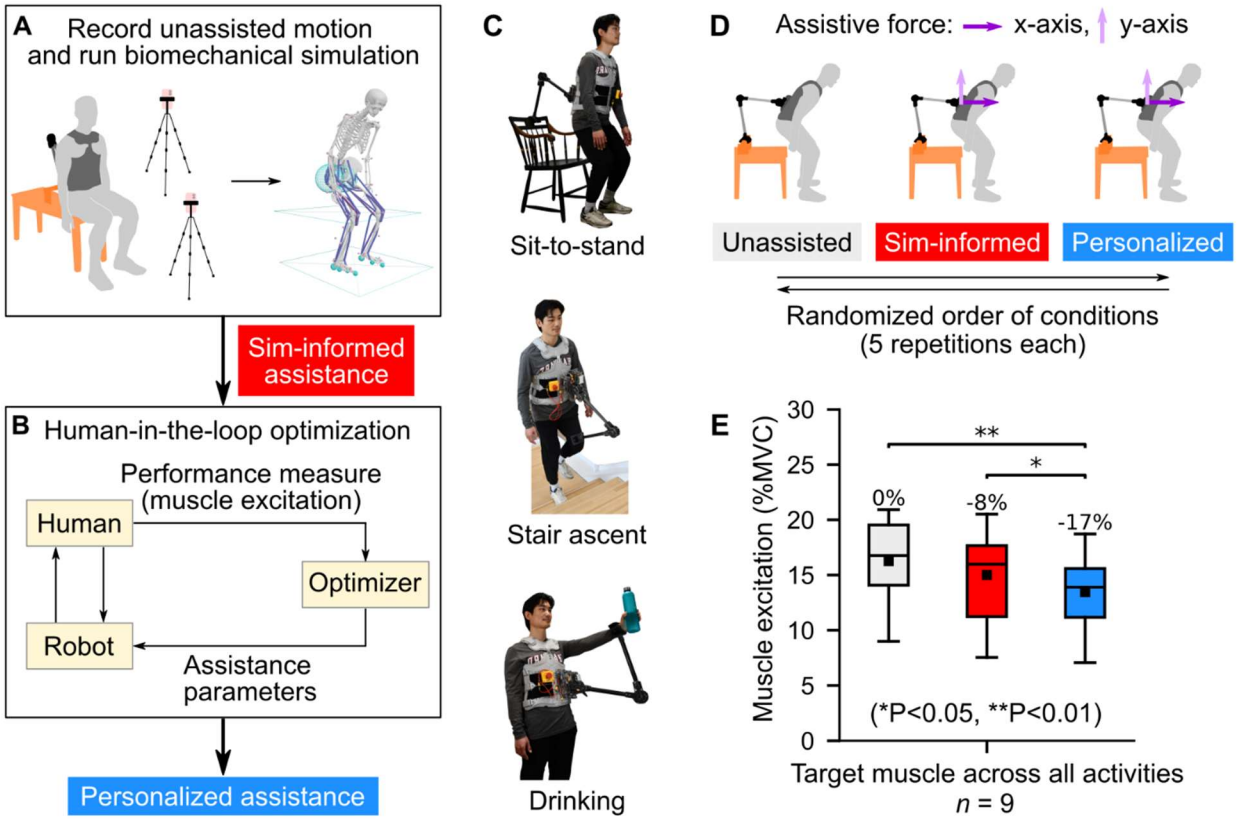
Introduction

Assistive robotic devices aim to improve mobility, but providing assistance that improves biomechanical outcomes across many different activities is challenging. State-of-the-art devices use either generalizable controllers that provide modest mobility improvements for all activities, or task-specific controllers that achieve field-leading mobility improvements for a single activity by personalizing assistance to the user. This personalization requires researchers to carefully define many settings, like assistance parameterization, informed by prior experiments. We present a framework that uses biomechanical simulation to generalize assistance to diverse single-shot activities and automatically set up assistance personalization.

Methods

Our framework (Fig 1A-B): 1) records the user's unassisted motion with OpenCap smartphone motion capture, 2) determines an idealized assistive force profile in simulation using OpenSim Moco [1], 3) personalizes the simulation-informed assistance using human-in-the-loop optimization [2]. We evaluated this approach on three single-shot activities of daily living (Fig 1C) using a wearable supernumerary robotic limb with two revolute joints, a passive end effector interfacing with the user's body or environment, and an adjustable base attached to a chest brace. Nine healthy participants (5 male and 4 female; age, 27 ± 4 yr) completed the study. During human-in-the-loop optimization, a Bayesian optimizer minimized muscle excitation for a target muscle (vastus medialis or biceps brachii), measured using surface electromyography, as participants performed 100 repetitions of each activity. Sim-informed and personalized assistance were compared to an unassisted condition for each participant and activity in a validation experiment (Fig 1D).

Results



Personalized and sim-informed assistance reduced participants' target muscle excitation by 17% and 8% compared to unassisted, respectively (Fig 1E). The simulations met best

practice benchmarks [3]. Human-in-the-loop optimization converged and identified unique assistance parameters for each participant, providing significant benefits beyond sim-informed assistance.

Discussion

These results support the feasibility of using biomechanical simulation to systematically generalize and personalize assistance. Populations like older adults or workers with physically demanding jobs could benefit from personalized assistance across many diverse upper- and lower-limb tasks.

Stair Walking-Mode Classification Using Minimal Biomechanically Relevant Features Optimized for Powered Prosthetic Knees

Mr. Ryan Busch A.S., A.A., Dr. Stephen Cain PhD

West Virginia University, Morgantown, West Virginia, United States

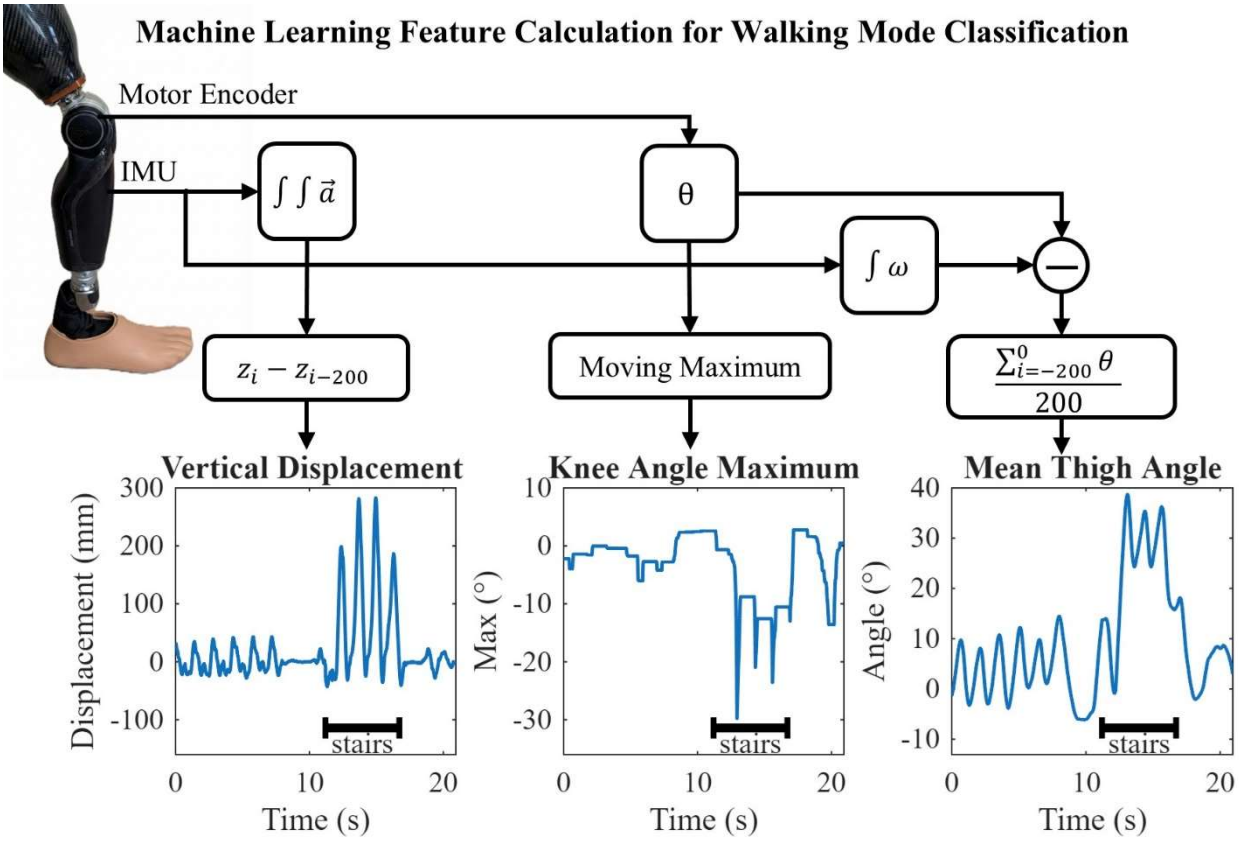
Mr. Ryan Busch

Introduction

Current powered prosthetic knees lack the ability to seamlessly switch modes when a user begins to ascend or descend stairs, making ambulation more difficult. The aim of our work was to develop a stair classification model using only data from sensors commonly integrated into powered knees that could inform the controller when to change the mode of the prosthetic knee.

Methods

Our model was developed based on a powered prosthetic knee with a motor encoder and shank IMU, which provides the angular position of the knee as well as the acceleration and angular velocity of the shank. The vertical position can be calculated using inertial navigation principles, knee angle is the direct output of the encoder, and thigh angle is the difference between knee angle and the integral of shank angular velocity. Using visual inspection, vertical position range, knee angle maximum, mean thigh angle, and thigh angle variance, calculated using a one-second reverse sliding window, were the features selected for classification. Classification was performed by a KNN model using 15 neighbors. Motion capture and goniometer data from an open dataset created by the EPIC lab at Georgia Tech was used to test our model; we used walking and stair-climbing data from the legs of 20 subjects [1]. The training group consisted of 15 randomly selected subjects, and the testing group consisted of the remaining five subjects. The best model was selected using leave-one-subject-out cross-validation and evaluated on the testing dataset. A 0.5-second debounce filter was applied to the classification output before statistics were calculated.



Results

The final model had an accuracy of 92.8%, an F1 score of 88.8%, and an AUROC of 88.6% when tested on the five held-out subjects.

Discussion

This model utilized only four features and a simple KNN model, achieving high accuracy and never confusing stair ascent with stair descent. Given these promising initial results from testing on a dataset with a wide range of subjects, we believe this system could be further refined and developed to build a robust mode detector for powered prostheses.

Efficacy of a Frugal Inertial Sensor-based Motion Capture System to Quantify Upper Limb Kinematics for Remote Monitoring Rehabilitation

Mr. Apoorv Shrivastava PhD Student[1], Ms. Aliki Statiri[2], Dr. Samrat Sagar[1], Dr. Angela E. Kedgley[2], Dr. Darshan S. Shah[1]

[1]BiOME Lab, Department of Mechanical Engineering, Indian Institute of Technology Bombay, Mumbai, Maharashtra, India. [2]Department of Bioengineering, Faculty of Engineering, Imperial College London, London, London, United Kingdom

Introduction

The need for portable home-based training systems for monitoring rehabilitation for neuromuscular disorders, such as stroke, is growing. Although inertial measurement unit (IMU) based sensors are a viable tool for remotely assessing joint kinematics, their application for monitoring upper limb kinematics is minimal, perhaps due to varying accuracies for different joints, motions and IMU-related protocols [1]. Hence, a frugal IMU-based motion capture system, developed for more accessible and customizable biomechanical analyses, was used to quantify upper limb motions, and compared to values from a commercial IMU system and a benchmark 10-camera optical motion capture system (OMC; Qualisys, Sweden).

Methods

IMUs from the frugal system – MPU9250 (InvenSense, USA) with custom signal processing, drift compensation and Madgwick filter-based sensor fusion algorithm – and the commercial system (Blue Trident, Vicon, UK) were rigidly affixed to each other, and manually aligned to the upper arm, forearm and hand segments of 9 participants (6F, 27±7yrs), following institutional ethics approval. Elbow and wrist kinematics were captured for three trials of elbow flexion-extension (E_{FE}), pronation-supination (E_{PS}), wrist flexion-extension (W_{FE}) and radioulnar deviation (W_{RUD}) following ISB recommendations [2, 3]. Root mean square error (RMSE) was used to compare the accuracy of the two sets of IMU-derived elbow and wrist kinematics to those from OMC.

Results

RMSE in joint kinematics between IMUs and OMC was lower than clinically acceptable threshold (5°) for E_{FE}, but higher for E_{PS}, W_{FE} and W_{RUD} (Fig. 1). RMSE for the custom and commercial IMU systems were within 2.65˚ of each other for all motions.

Discussion

Both IMU systems displayed lower accuracy for smaller ranges of motion and secondary degrees of freedom. Larger errors during E_{PS} could be attributed to the more proximal placement of the two IMUs, leading to an inherent difference from OMC. Higher errors observed for W_{FE} could be improved with more robust sensor-to-segment alignment protocols. Following kinematic quantification during activities of daily living, the use of custom IMUs for remote monitoring and tele-rehabilitation applications will be explored by embedding them in orthotic devices.

Designing a Lower-Limb Exoskeleton Controller to Alter the Energetics of Gait Symmetry

Dr. Anthony Chen, Ms. Tiana A. Wertelecky, Dr. Jessica C. Selinger

Queen's University, Kingston, Ontario, Canada

Dr. Anthony Chen

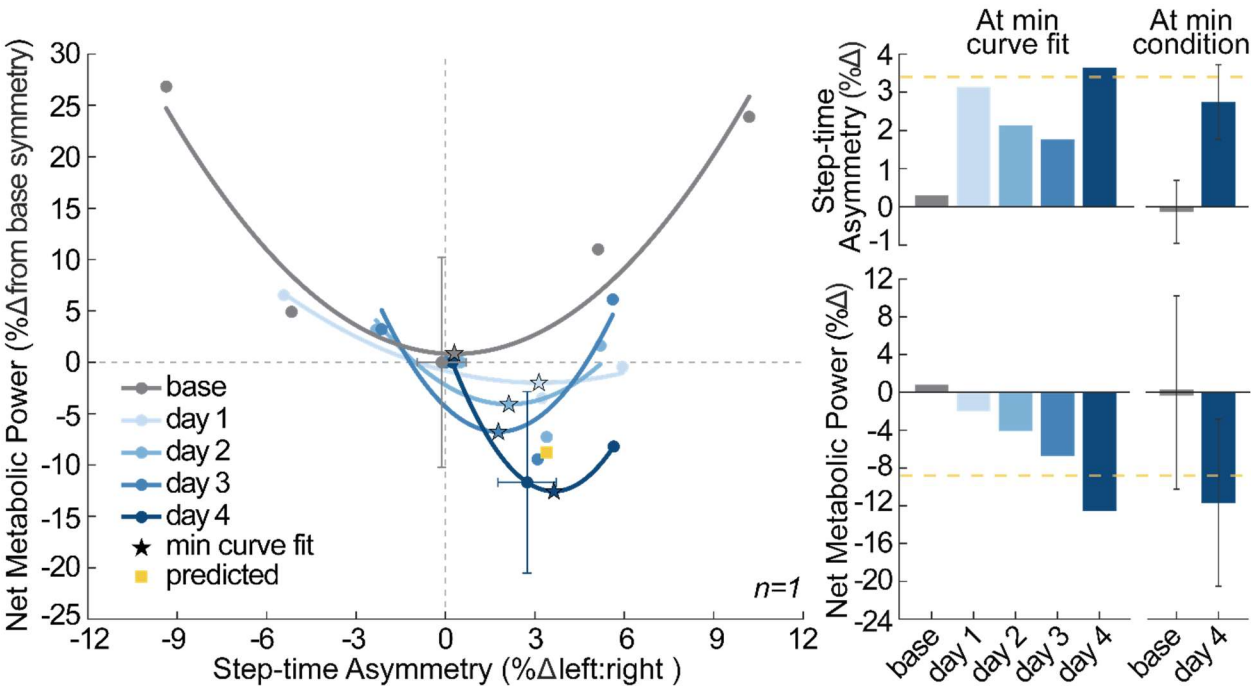
Ms. Tiana A. Wertelecky

Introduction

Persistent gait asymmetries affect over half of persons post-stroke, and often the level of asymmetry exceeds what can be explained by muscle weakness or spasticity alone [1]. Many persons post-stroke can transiently reduce asymmetries through conscious effort, but more implicit and permanent changes often remain elusive [2]. Exoskeletons that alter gait energetics have been used to change preferred step length, rate, and width in healthy individuals, but never symmetry, which may be less modifiable [3]. Here, our aim was to develop an exoskeleton controller that manipulates the relationship between step-time asymmetry and metabolic cost—incentivizing asymmetry in healthy individuals. We view this as an important proof of concept that supports our longer-term goal of incentivizing symmetric gait post-stroke.

Methods

We developed a custom controller for ankle exoskeletons (Humotech, USA) that scaled assistive plantarflexion torque in real-time based on step-time symmetry measured from an instrumented treadmill (Bertec, USA). To do so, we first modeled the interactions between step asymmetries, natural costs, assistive torque profiles, and cost reductions using literature data. We arrived at a controller that we predicted would reduce cost by approximately 9% at a +3.5% asymmetry (**Fig. 1**). To test our controller, we then had one participant walk in the exoskeleton at various step-time asymmetries, commanded with visual feedback, on four separate days while instrumented with indirect calorimetry (COSMED, Italy).



Results

Our controller accurately scaled peak assistive plantarflexion torque in real-time based on step-time symmetry and altered the energy-optimal step-time (**Fig. 1**). By day four, the participant reduced metabolic cost by 12.6% at +2.7% asymmetry, well matching model predictions.

Discussion

Our controller reliably altered the energy-optimal step-time to an asymmetric gait. We will next test if healthy naïve participants adopt energy-optimal asymmetries and adapt our controller to incentivize symmetry in persons post-stroke. Our approach—of leveraging energy optimization to incentivize clinically desirable gait adaptations—could have broad applications in assistive robotics and rehabilitation.

[3]Department of Occupational Therapy and the Healthy Aging Research Center, Chang Gung University, Taoyuan, Taiwan, Taiwan

Dr. Tsai-Yu Shih

Introduction

Mirror therapy (MT) is a prominent intervention to enhance upper extremity (UE) motor function [1]. Performing MT tasks may enhance bimanual coordination through bilateral movement practice, and mirror visual feedback may further enhance attention to the covered UE [1]. Applying anodal tDCS may further restore interhemispheric balance, potentially strengthening these effects. Therefore, this study compared MT combined with tDCS applied over the premotor cortex (PMC) or primary motor cortex (M1) to evaluate their efficacy on bimanual coordination.

Methods

Thirty-six patients with stroke were recruited and randomly allocated to the PMC, M1 or Sham group to receive MT combined with tDCS on different regions. UE kinematics were recorded using a 7-camera motion analysis system. Participants were instructed to perform bilateral reaching as rapidly as possible, and bimanual coordination was assessed before and after the intervention. Temporal synchronization was assessed using differences in movement onset ($Diff_{onset}$), movement offset ($Diff_{offset}$) and peak velocity onset ($Diff_{PV}$) between the two UEs. Total movement time (TMT) and movement overlap time (MOT) were calculated to indicate bimanual efficiency. Generalized estimating equations were applied with group (PMC, M1, and Sham) and time (baseline and post-intervention) as factors. The level of significance was set at 0.05.

Results

$Diff_{offset}$ and MOT showed significant Group×Time interactions (Waldχ2 = 9.625, p = .008; Waldχ2 = 4.063, p = .046). Post hoc analysis indicated participants in the M1 group exhibit significantly smaller $Diff_{offset}$ and greater MOT at post-intervention compared to baseline (p < .001). TMT exhibited a significant main effect of time (Waldχ2 = 4.220, p = .040), with participants across all groups showed shorter TMT at post-intervention compared to baseline. No significant interaction or main effect was found for $Diff_{onset}$ or $Diff_{PV.}$

Discussion

Applying ipsilesional M1 stimulation in combination with MT improved bimanual coordination. Participants demonstrated more synchronous bimanual reaching movements after the intervention, suggesting that their UEs operated in a more coordinated manner similar to healthy adults [2]. combining MT with M1 stimulation appears to produce beneficial effects on bimanual motor performance in patients with stroke.

Individual Baseline Factors May Predict Increased Paretic Propulsion On an Adaptive Split-belt Treadmill in People with Chronic Stroke

Ms. Rucha Kulkarni, Dr. Jill S. Higginson

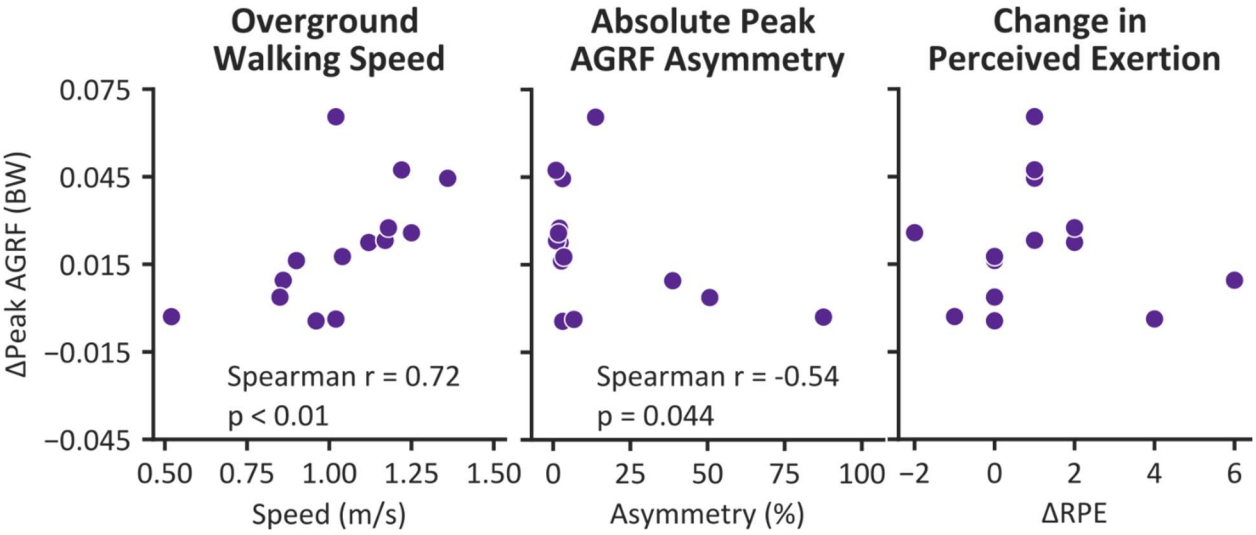
University of Delaware, Newark, DE, United States

Introduction

Stroke affects over 100 million people worldwide. However, motor impairments in stroke survivors present heterogeneously. There are often differences in baseline walking function and ability, and training paradigms often lead to mixed responses and improvements. Prior work has shown that individual baseline factors can predict changes in step length asymmetry and cost of transport. The purpose of this study was to determine the baseline factors that might predict the capacity to volitionally increase paretic propulsion (push-off) on an adaptive (user-driven) treadmill.

Methods

We developed an adaptive split-belt treadmill (sATM) that changes the speed of each belt independently based on the user's gait mechanics and can be modified to increase propulsion demand (higher propulsion to maintain belt speed) unilaterally. Fourteen stroke survivors walked on a tied-belt adaptive treadmill (Baseline) and the sATM with increased propulsion demand on the paretic side. We calculated Spearman correlations to determine the baseline factors correlated with change in paretic propulsion (peak AGRF). To determine their contribution, we modelled the baseline factors (overground walking speed, baseline peak AGRF asymmetry, and Borg's Rating of Perceived Exertion (RPE)) to the change in paretic propulsion using multiple linear regression.



Results

We observed significant correlations between baseline factors (overground walking speed and baseline propulsion asymmetry) and change in paretic propulsion compared to Baseline (Δ). We also observed a binomial distribution of ΔRPE. The best linear regression contained only a factor of overground walking speed and was determined using the lowest AIC score, highest observed R^2 (0.60) and predictive R^2 (0.26).

Discussion

Our results suggest that overground walking speed may be the best predictor of the change in peak paretic AGRF on an sATM. While the best model did not contain baseline propulsion asymmetry, it is possible that this asymmetry is minimized due to the equal speeds on both belts on the tied-belt treadmill, and we may see an association with overground asymmetry. The binomial distribution of ΔRPE suggests that increased propulsion demand may be most effective when the perceived exertion is roughly increased by 1 in comparison to baseline. This study represents a step towards developing personalized treatments to individual impairments for maximal improvement.

Stroke Survivors Retain the Ability to Harness Mediolateral Assistance to Improve Weight Transfer During Walking

Mr. Jason Tsai, Dr. Hao-Yuan Hsiao Ph.D.

University of Texas at Austin, Austin, Texas, United States

Introduction

Post-stroke gait is characterized by impaired frontal-plane control and inefficient weight transfer [1]. Walking on a lateral oscillating treadmill provides a unique means to deliver mediolateral forces that may help restore more efficient body transfer mechanics. Understanding whether stroke survivors can harness external energy to enhance weight transfer performance has implications for gait rehabilitation and designing assistive devices.

Methods

Five stroke survivors and five elderly controls walked on a mediolateral sinusoidally oscillating treadmill (1-cm amplitude; oscillation frequency = stride frequency). Participants completed non-oscillation and oscillation trials at self-selected comfortable speeds after familiarization. Kinematics and kinetics were collected using motion capture and an instrumented treadmill. We quantified synchronization between weight transfer and treadmill motion, treadmill mediolateral mechanical energy input, vertical ground reaction force (vGRF), and weight-transfer time (WTT) toward the leading limb (paretic in stroke; nondominant in controls).

Results

Both groups synchronized to similar oscillation phases during mid–weight transfer (stroke: 0.74–0.85π; controls: 0.71–0.86π), indicating comparable weight transfer timing strategies. All participants received similar amounts of net positive treadmill energy during weight transfer (stroke: 0.004–0.009 J/kg; controls: 0.005–0.013 J/kg). Stroke survivors showed larger increases in paretic vGRF (≈ +0.02–0.04 N/kg) and greater reductions in WTT (≈ –0.02s to –0.05 s) than controls (vGRF ≈ –0.02–0.03 N/kg; WTT ≈ 0.00 to –0.02 s), indicating a more pronounced effect of oscillation on weight-transfer mechanics.

Discussion

Across groups, participants synchronized weight transfer with the oscillation that delivered net positive mechanical energy, demonstrating a shared strategy that accepts external

assistance. This conserved behavior indicates that stroke survivors retain the capacity to exploit predictable mediolateral assistance.

However, healthy controls showed only minor changes in vGRF and WTT, reflecting their minimal need to alter baseline efficient weight-transfer and limb-loading strategies. In contrast, stroke survivors displayed larger increases in vGRF and greater reductions in WTT, indicating that the mechanical energy was redirected toward supporting limb loading and weight-transfer demands. These findings suggest that oscillatory assistance may preferentially benefit individuals with impaired frontal-plane control, highlighting its potential to enhance weight transfer after stroke.

Effect of Stroke on Limb Contributions to the Lateral Center of Mass Trajectory During Walking

Ms. Grace Kellaher[1], Ms. Sarah Overby[1], Dr. Elisa Arch[1], Dr. Jason Franz[2,3], Dr. Darcy Reisman[1], Dr. Jeremy Crenshaw[1]

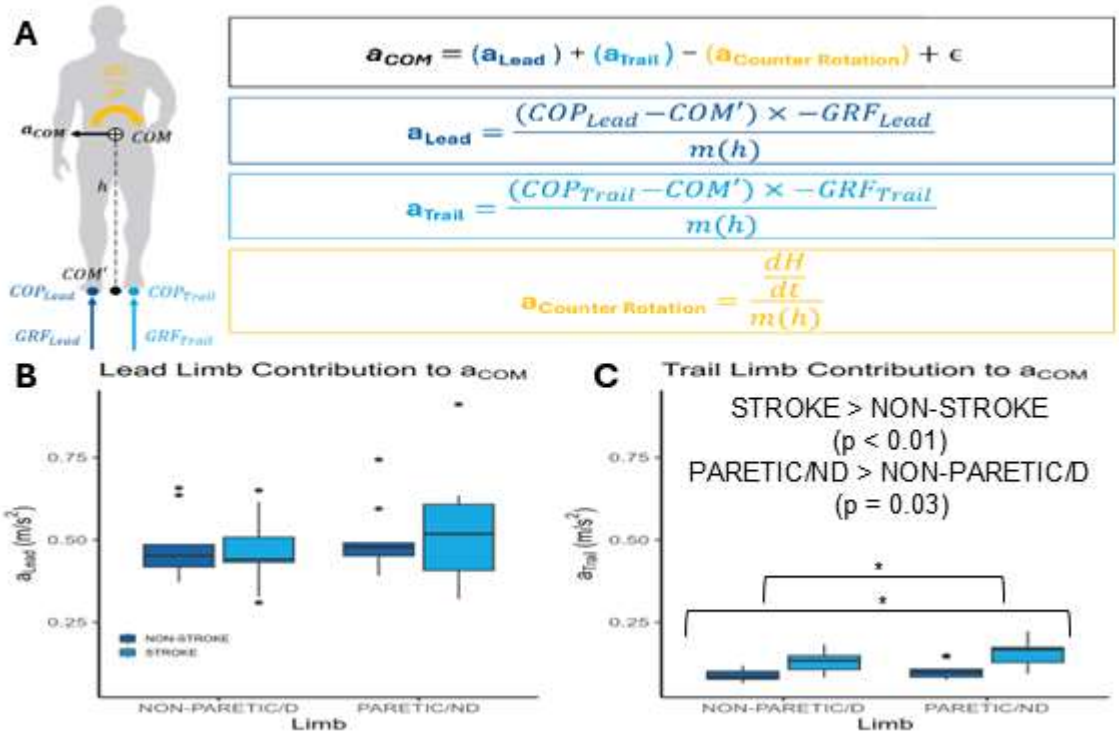
[1]University of Delaware, Newark, Delaware, United States. [2]University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States. [3]North Carolina State University, Raleigh, North Carolina, United States

Introduction

Individuals with chronic stroke have known balance impairments that contribute to their higher risk of falling. A large percentage of falls occur during walking, and the frontal-plane is the primary direction where instability while walking occurs, but the biomechanical contributors to frontal-plane balance during walking are unclear. Therefore, the purpose of this study was to characterize the contributions of the leading (a_{Lead}) and trailing (a_{Trail}) limbs to the lateral center of mass acceleration (a_{COM})– an aspect directly influencing frontal-plane balance during walking– in those with and without chronic stroke.

Methods

Nine adults with chronic stroke (4M/5F;65.4±4.0yrs;30.4±4.6kg/m^2;76.1±47.8 months post-stroke) and nine adults without chronic stroke (5M/4F;63.3±6.2yrs;25.1±3.9kg/m^2) have thus far participated. Kinematic and force data were recorded while participants walked on an instrumented, split-belt treadmill for 60 seconds at a self-selected speed (Stroke:0.85±0.26m/s;Non-Stroke:1.35±0.18m/s). We calculated a_{Lead} and a_{Trail} according to methods described in Figure 1 (Panel A). Two-way ANOVAs assessed the effects of Group (Stroke, Non-Stroke) and Limb (Paretic/Non-Dominant, Non-Paretic/Dominant) on contributions to a_{COM}.



Results

We found no significant main effects or interactions containing Group or Limb ($p>0.05$, $\eta_p^2<0.04$) for a_{Lead} (Figure 1, Panel B). For a_{Trail}, we found significant main effects of Group ($p<0.01$, $\eta_p^2=0.39$) and Limb ($p=0.03$, $\eta_p^2=0.13$) (Figure 1, Panel C). Individuals with chronic stroke demonstrated significantly larger a_{Trail} compared to non-stroke individuals, regardless of limb ($p<0.01$, Cohen's $d=1.15$). Across all participants, the paretic/non-dominant limb demonstrated significantly larger a_{Trail} contributions compared to the non-paretic/dominant limb ($p=0.03$, Cohen's $d=0.74$).

Discussion

These findings suggest that chronic stroke is associated with an increase in a_{Trail} contributions affecting both limbs. Since individuals with chronic stroke exhibit wider step widths and a more laterally placed paretic limb, this result may be driven by larger COM-COP separation. It remains to be seen how a_{Trail} of those with chronic stroke changes when step widths are constrained. Despite demonstrating increases in a_{Trail}, individuals with chronic stroke did not appear to compensate with smaller a_{Lead} contributions compared to non-stroke individuals. Overall, these findings help identify a new, specific aspect of frontal-plane balance while walking that is altered after a stroke.

Introduction

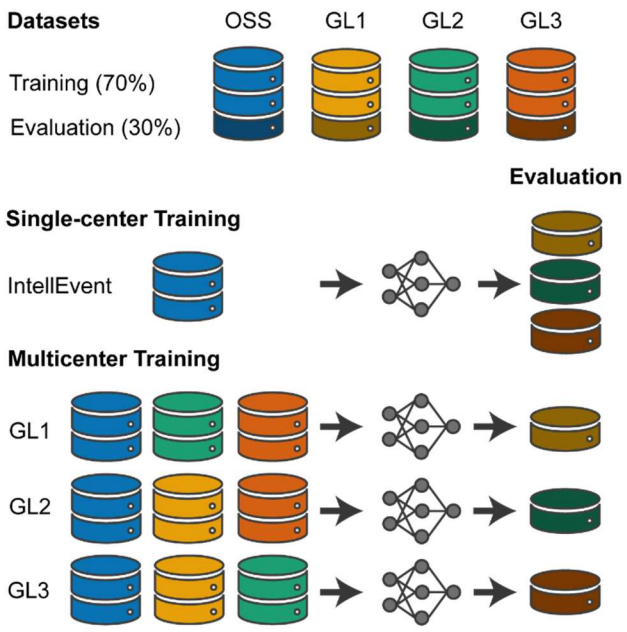
Accurate gait event detection is essential for clinical gait analysis (CGA) [1]. However, commonly used heuristic approaches are sensitive to pathology and laboratory-specific differences [2]. Deep learning-based models demonstrate improved performance but are typically trained on single-center datasets [3]. Consequently, their generalizability remains uncertain due to variability in acquisition protocols, including capture frequency, walkway lengths, and marker placement. This study investigates the performance of *IntellEvent* [3] on three large-scale CGA datasets from different laboratories and examines whether multicenter training can mitigate laboratory-specific differences.

Methods

CGA data from gait laboratories in Vienna (OSS, 150Hz), St. Gallen (GL1, 200Hz), Geneva (GL2, 100Hz), and Zurich (GL3, 200Hz) were included, comprising 4,300 patients, totaling

over 26,000 trials. 70% of each laboratory's data was used for training, while the remaining 30% was used for evaluation. Data comprised pathologies like orthopaedic disorders (OD), neurological disorders (ND) and cerebral palsy (CP). Two approaches were compared: (1) *IntellEvent*, the original single-center model trained only on OSS data [3], and (2) *IntellEvent-Multicenter,* evaluated using a leave-one-lab-out cross-validation (Figure 1A). Performance was evaluated using mean absolute error (MAE) and detection rate (DR) within ±20ms [1] for initial contact (IC) and foot off (FO), based on force plate ground truth events.

Results



IntellEvent performed accurately across diverse laboratory-specific settings. IC was detected with MAEs of 2.3-7.0ms and DRs of 96.4-99.9%. FO showed higher variability with MAEs of 7.9-21.0ms and DRs of 77.4-96.0%. *IntellEvent-Multicenter* demonstrated small improvements for IC in GL2 and GL3, and consistently improved FO detection, reducing MAE to 6.4-17.4ms and increasing DRs to 80.7–98.8% (Figure 1B).

Discussion

These results underline that *IntellEvent* generalizes strongly across laboratories despite single-center training, yet multicenter training offers additional improvements, particularly for FO. This highlights that laboratory-specific differences can influence ML methods. Multicenter training is one approach to mitigate these effects by exposing the model to diverse data distributions, strengthening its suitability as a standardized tool for CGA. Future work could investigate fine-tuning as another alternative strategy.

Evaluation of Fall Risk of Elderly by Convolutional-Transformer Neural Network Using Time-Series Gait Data

PHD Student Jie Mao, Prof. Toshiaki Oda, Prof. Shigeho Noda, Prof. Zhe Sun, Prof. Ryutaro Himeno

Juntendo University, Graduate School of Health Data Science, Urayasu, Chiba, Japan

Introduction

Early identification and prevention of falls are pivotal for maintaining the health span of an aging global population. Traditional fall risk assessment relies on manual evaluation. Wearable IMU sensors offer a scalable solution for community screening, but most existing analysis methods rely on calculated biomechanical features, such as average stride length. This approach discards critical time-series information inherent in the signals. To address this limitation, we propose a Transformer-based model that learns directly from raw IMU sequences. This method achieves accurate assessment of fall risk, balance, and muscle strength, demonstrating superior performance and robustness compared to traditional feature engineering.

Methods

We collected data from 145 elderly individuals to assess Fall Risk and Physical Performance. Standardized scores from the CDC 4-Stage Balance Test and CS-30 test were used to categorize balance and strength into 5 levels. Combined with fall history, Fall Risk was categorized as high, medium, or low. Subsequently, subjects performed a 10m walk test while wearing IMUs on the lower back and toe tips.

To establish a baseline, we first evaluated traditional classifiers (SVM and Random Forest) using extracted gait features. Subsequently, we proposed our Convolutional-Transformer neural network. By leveraging attention mechanisms, this model captures complex long-range dependencies directly from raw IMU signals, thereby enhancing representation capability.

Results

The results demonstrated that traditional biomechanical features failed to generalize effectively when applied to a large-scale population. K-means clustering based on gait features failed to correspond effectively with risk categories (accuracy: 58.62%). The accuracy of SVM for binary classification was 65.38%, and the Random Forest model reached only 69.23%.

In contrast, the Transformer model, learning directly from raw IMU data, exhibited superior robustness and accuracy. For the 5-level balance ability classification, the model achieved an average accuracy of 75.25%; for the 5-level strength classification, accuracy reached 73.30%; and for the 3-level fall risk classification, the model achieved an accuracy of 70.4%, effectively identifying high-risk individuals.

Discussion

Deep learning on raw IMU data overcomes the generalization limitations of traditional averaged features. By leveraging attention mechanisms to identify complex non-linear gait dependencies, the Transformer offers a superior and more robust representation of physical performance.

Dr. Jinsung Jung

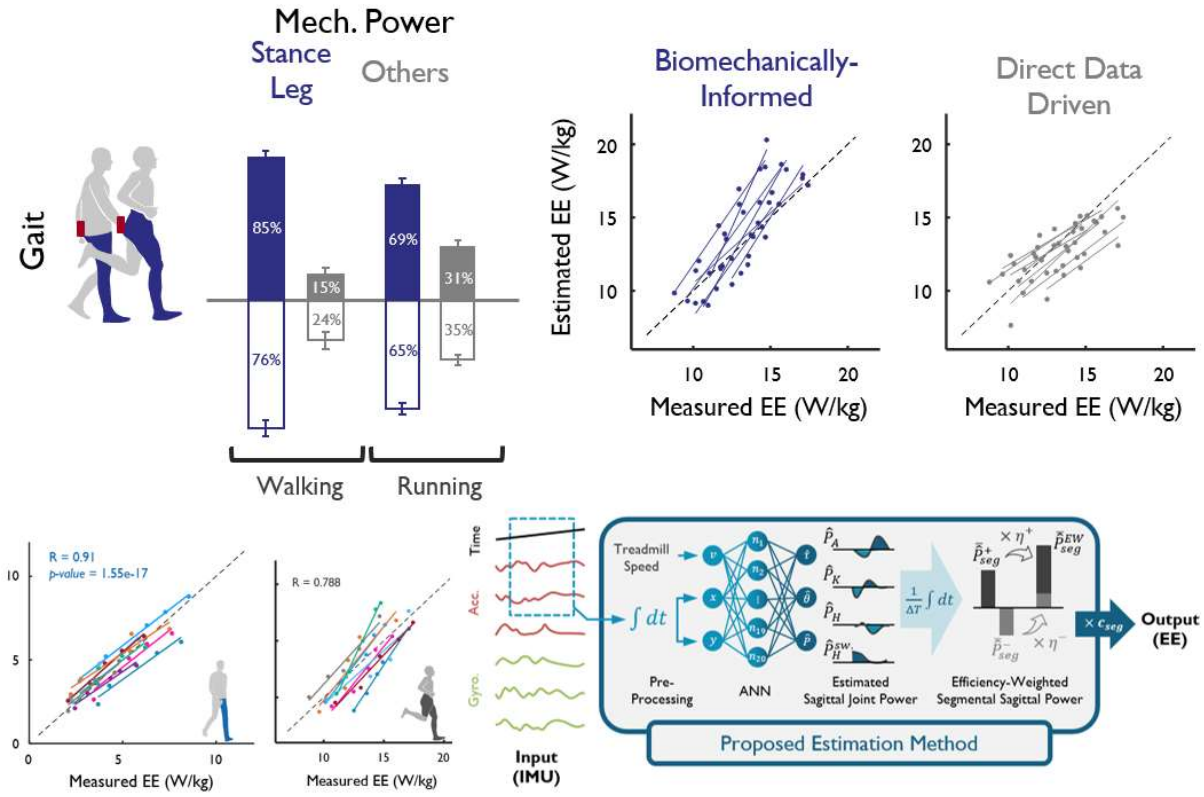
Prof. Hyerim Lim

Introduction

Energy expenditure (EE) is a key indicator of metabolic cost and is widely used in fields such as sports science, daily activity monitoring, and wearable robotics. However, indirect calorimetry, the gold standard for EE measurement, suffers from limited wearability and practicality. Recent approaches using wearable sensors often require multiple sensors or rely on purely data-driven models with high data demands and low interpretability. Since prior studies have shown that mechanical joint power explains most EE [1], reducing the required biomechanical information is essential for practical single-sensor use. In this study, we propose a single-IMU EE estimation framework grounded in biomechanical domain knowledge for both walking and running. By analyzing joint-level mechanical contributions, we identify dominant segments and use them to construct an accurate yet lightweight EE estimation method.

Methods

We collected walking data from 13 participants and running data from 8 participants at five treadmill speeds each. Whole-body motion capture, GRF, and indirect calorimetry were recorded. Joint powers were computed using inverse dynamics, and dominant segments were selected based on their contributions. A sacrum-mounted IMU was used to estimate lower-limb dynamics, given its proximity to the COM [2]. Weighted joint power—using efficiency-based weights for positive and negative work—was computed for the dominant segment, and a scale factor mapping this to EE was derived and tested using leave-one-subject-out evaluation.



Results

Stance-leg joint power accounted for ~80% of whole-body power during walking and ~70% during running, confirming its dominant biomechanical role. IMU-estimated stance-leg dynamics enabled accurate EE prediction: walking RMSE was 0.69 W/kg, outperforming a prior deep-learning model (0.95 W/kg). In running, our method showed comparable RMSE (1.40 vs. 1.32 W/kg) but higher linearity (R=0.838 vs. 0.717) and no EE-dependent residual trends.

Discussion

Overall, incorporating biomechanical structure enabled a practical, interpretable, and high-performance single-sensor EE estimation framework suitable for daily monitoring applications.

Detecting Slips on Ice Using Wearable Inertial Sensors: *Identifying Kinematic Features for Classifying Slip Events*

Mr. Davood Dadkhah[1,2], Dr. Hamed Ghomashchi[2], Dr. Hosna Movahhedinia[1], Dr. Tilak Dutta[1,2]

[1]University of Toronto, Toronto, Ontario, Canada. [2]University Health Network, Toronto, Ontario, Canada

Introduction

Falls due to slips on icy surfaces remain a persistent public health challenge, causing injuries and placing significant burdens on healthcare systems in cold-weather regions. The ability to identify slip events from data collected using wearable sensors would allow for comparing the potential for reducing the risk of slipping across different interventions, including different types of winter footwear or slip-prevention training. The objective of this project was to identify the best feature set from our wearable sensor data that could be used to identify slip events during gait.

Methods

Data was collected from 27 healthy adults walking on a 5m by 5m ice surface in WinterLab at the KITE Research Institute using inertial measurement units (IMU) that were attached to each foot, as well as a Vicon motion capture system that provided ground-truth labels. Each participant wore three different commercially available winter boots and walked on a range of slopes from level to 13 degrees. Over 400 features were engineered from the IMU measurements using a combination of time, frequency, and nonlinear domains. A leave-one-participant-out cross-validation was performed to evaluate the created features using XGBoost classifiers, and feature importance was ranked for discriminating slip events.

Results

Results revealed three biomechanical signatures that robustly distinguished slips from non-slips on the anterior-posterior (AP) axis: (1) dominant spectral amplitude of acceleration, (2) positive Hilbert envelope area, and (3) number of rotational peaks in AP-axis angular velocity. Slip steps consistently demonstrated stronger, more energetic AP acceleration frequency components and greater cumulative movement intensity, alongside markedly increased oscillations. For the most important feature, dominant spectral

amplitude on the AP axis, the median value was approximately 50% higher for slip steps compared to non-slip steps.

Discussion

These findings establish, for the first time, the specific kinematic features that best discriminate naturally occurring slips on ice during controlled ice walking. By identifying the signal characteristics of slips, this work enables more targeted design and development of wearable systems for real-time slip detection, as well as objective methods for measuring the slip resistance performance of winter footwear, advancing both fundamental understanding and practical solutions for injury prevention in icy environments.

OA55-01

Lower Extremity Kinematics During Ice Hockey Goaltender Stances

Ms. Margaret Harrington BKin, Dr. Timothy Burkhart PhD

University of Toronto, Toronto, Ontario, Canada

Introduction

Goaltending techniques have evolved to include goaltenders dropping to their knees to cover the lower part of the net, utilizing stances such as the butterfly and reverse vertical horizontal (RVH). These stances are suggested to place considerable stress on the hip, knee, and ankle joints compared to traditional stances (e.g., standing, vertical horizontal (VH)) [1,2]. However, the kinematic differences between these techniques and potential injury risk implications have not been fully explored. Therefore, this study aimed to quantify three-dimensional lower extremity joint kinematics during key goaltending stances.

Methods

Twenty-six goaltenders (mean (SD) age = 19.5 (2.3) years, six females) performed four key goaltending stances: butterfly, standing ready, RVH post-play, and VH post-play. For the post-plays, the post-side and net-side limbs were analyzed separately. Eight synchronized Sony 2D video cameras and Theia3D were used to quantify 3D hip, knee, and ankle angles. One-way repeated-measures ANOVAs or Friedman tests assessed differences in joint angles across tasks, along with effect sizes and Bonferroni-corrected post hoc comparisons.

Results

There were statistically significant differences ($p < 0.001$) between the tasks for all joint angles. Large effect sizes were shown for all hip angles, knee flexion and internal rotation, and ankle dorsiflexion. Medium effect sizes were shown for knee adduction, ankle external rotation and inversion. The butterfly and RVH, compared with the standing ready and VH, demonstrated higher mean hip internal rotation (16.6-22.2° vs. 5.2-11.4°) and ankle external rotation (11.7-15.9° vs. -1.6-10.8°) (Figure 1). Compared to the standing ready, the kneeling stances involved higher knee abduction (12.4-15.1° vs. 5.6°) and external rotation (13.0-21.3° vs. 0.7°) (Figure 1).

Discussion

The butterfly and RVH showed riskier kinematics for common hip, knee, and ankle injuries in goaltenders. Such injuries may result from the high hip internal rotation (e.g., femoroacetabular impingement syndrome and labral tears), knee abduction and external rotation (e.g., medial collateral ligament injuries and meniscal tears), and ankle external rotation (e.g., high ankle sprains). These findings provide new insights into the biomechanical demands of goaltending and how they may correspond to injury risk.

Ground Reaction Force Characteristics During Salcow and Loop Jumps in a Novice and a Junior Figure Skater: A Case Study

Ms Ami Koga, Dr Jingmin Liu

Tsinghua University, Beijing, Beijing, China

Introduction

Youth figure skaters are often exposed to substantial overuse injury risks due to repetitive and high-impact jump practices. Previous figure skating biomechanical studies have mostly focused on jump kinematics, and there are limited studies on examining on-ice force generation patterns and impact on the lower limbs across different skill-level skaters. Therefore, this study aims to compare the ground reaction force characteristics between jumps of two different skill-level skaters.

Methods

One novice level skater and one junior level skater performed single salcow, double salcow, single loop and double loop jumps. Two high speed cameras (Sony FDR-AX700, 100Hz) were used to record skaters' kinematics. W-INSHOE system from Medicapteur (8 sensors per foot, 100 Hz) was used for plantar pressure measurements at jump's take-off and landing. Ground reaction force (GRF) data obtained using plantar pressure insole were normalized using body weight (BW). Peak GRF and loading rate between skaters were compared. Due to limited data, only descriptive analysis was conducted.

Results

Detailed results of GRF variables of two skaters can be seen in Table 1. Junior skater's GRF variables including peak GRF and loading rate at jump take-off and landing are generally greater than novice skater. While junior skater's take-off force-time curves during salcow jumps followed monomodal patterns, novice skater's curves followed bimodal patterns. Landing force-time curves of all jumps showed similar patterns, which the landing leg's GRF spikes upon initial contact at the landing, then slightly decreases as lower limbs flex to stabilize the body and to absorb impact force.

Discussion

The differences in salcow jump take-off force-time curve patterns between two skaters potentially indicate technical differences between them. Moreover, junior skater

demonstrated higher peak GRF and loading rate at take-off, which indicate that junior skater applies more explosive and faster force generation to achieve greater take-off vertical velocity and jump height. However, higher impact forces especially at the landing also indicate higher risks of lower limb injuries. Novice skaters are in earlier stage of their technical development and focused more on controlled force distribution rather than explosiveness. Therefore, novice skater may benefit from more strength training.

Images (Optional)

Table 1. Ground reaction force variables during figure skating salcow jump and loop jump

	Novice	Junior	Differences (%)
Single Salcow			
Take-off 1st peak GRF (BW)	1.25	-	-
Take-off 2nd peak GRF (BW)	0.73	2.01	93.4
Landing peak GRF (BW)	2.86	2.52	12.6
Take-off 1st loading rate (BW/s)	3.95	-	-
Take-off 2nd loading rate (BW/s)	0.85	5.58	147.9
Landing loading rate (BW/s)	10.5	23.3	76.1
Double Salcow			
Take-off 1st peak GRF (BW)	0.99	-	-
Take-off 2nd peak GRF (BW)	0.78	2.07	90.6
Landing peak GRF (BW)	3.36	3.85	13.6
Take-off 1st loading rate (BW/s)	4.17	-	-
Take-off 2nd loading rate (BW/s)	1.11	5.58	66.3
Landing loading rate (BW/s)	11.5	23.6	69.0
Single Loop			
Take-off peak GRF (BW)	3.07	3.68	18.1
Landing peak GRF (BW)	2.74	4.19	41.8
Take-off loading rate (BW/s)	2.21	8.99	121.4
Landing loading rate (BW/s)	13.2	21.8	48.9
Double Loop			
Take-off peak GRF (BW)	2.94	3.81	25.8
Landing peak GRF (BW)	2.74	4.31	44.5
Take-off loading rate (BW/s)	1.99	8.49	124
Landing loading rate (BW/s)	9.75	20.8	72.3

Kinematic Differences Across Development Levels in Elite Biathletes

Mr Ethan Livingood, Mr Isaac Burgess MS, Dr. James Becker PhD

Montana State University, Bozeman, MT, United States

Introduction

Numerous studies have described differences in physiological parameters between junior (JN), national (NC), and world class (WC) biathletes. However, how global movement patterns while skiing differ between these groups is unknown and addressing this gap might highlight important technique points which coaches can target when working with athletes progressing from junior to world class ranks. Thus, the purpose of this study was to compare full-body kinematics during V2 skate skiing between JN, NC, and WC biathletes.

Methods

Thirteen WC (sex: 8M/5F, age: 27 ± 3.8 years) eight NT (sex: 6M/3F, age: 25 ± 3.9 years), and nine JN (sex: 4M/5F, age: 18 ± 1.1 years) biathletes skied on a ski treadmill at race intensity while whole body 3D kinematics were recorded using markerless motion capture. Joint angles at the shoulder, elbow, trunk, hip, knee, and ankle were calculated using a 12-segment biomechanical model. Cycles were normalized to 100% of cycle and Statistical Parametric Mapping (SPM1D) was used to assess temporal differences in joint kinematics between the groups.

Results

SPM revealed JN demonstrated greater sagittal and lateral trunk flexion than both NC and WC athletes before pole plant ($p < 0.05$), more elbow flexion during the poling phase ($p < 0.05$), less hip flexion during the transition from one ski to the other ($p < 0.05$), and, reduced hip abduction during the return phase of the cycle ($p < 0.05$).

Discussion

The differences between JN and NC and WC athletes reveal deficits in ski technique in younger athletes. Increased elbow flexion during the poling phase suggests JN athletes are allowing greater collapse of the arms while poling which reduces the force transmitted through the poles. Reduced hip abduction during the leg recovery might indicate decreased lateral balance, requiring JN athletes to bring the leg closer to their center of

mass after the push. Overall, the differences observed here highlight specific phases of a V2 skate skiing cycle where JN level athletes show different movement patterns than NC or WC athletes which could be targeted for technique interventions to help these athletes progress to NC or WC levels.

Images (Optional)

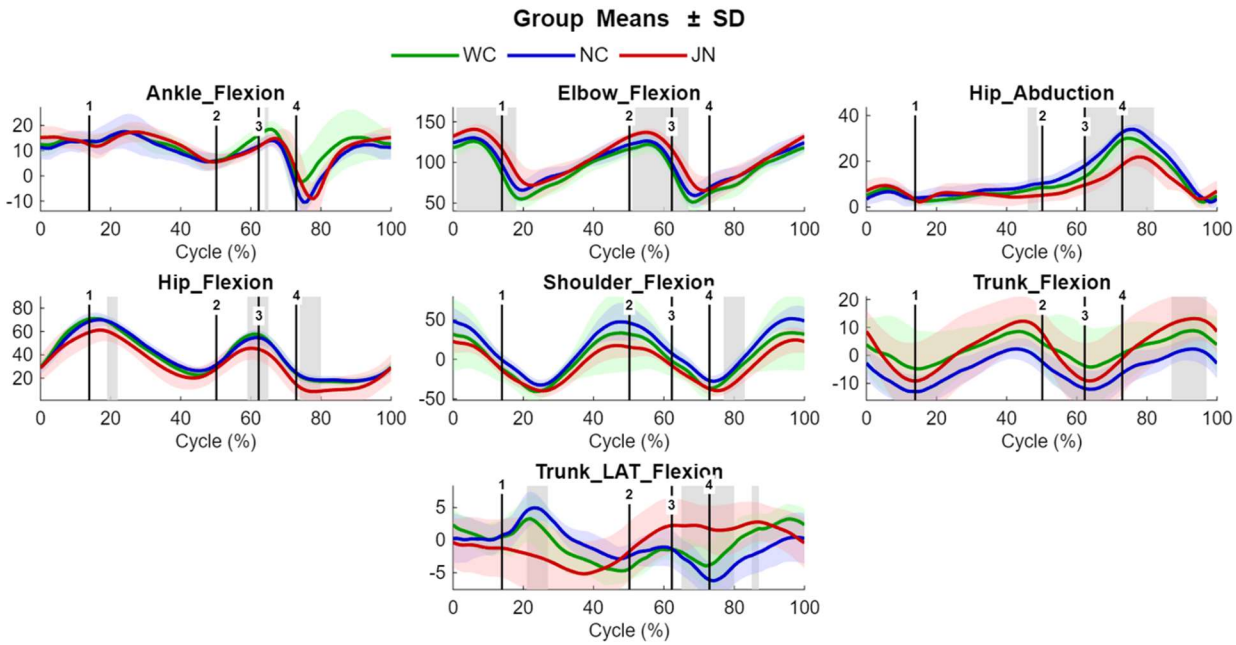

Figure 1. Group mean right leg joint angles (± SD) normalized to 100% V2 skate skiing cycle, defined from pole plant on the right ski to the subsequent plant. Vertical markers indicated events in the ski cycle: 1) right pole off; 2) right leg peak force; 3) left ski contact; 4) left ski peak force. Gray shaded bands show regions in the cycle with significant differences between groups as identified by SPM with an $\propto$ of 0.05.

Comparison of Fully-Rotated and Under-Rotated Figure Skating Jumps by Key Performance Metrics

Dr. Mia Caminita PhD[1], Dr. Dustin Bruening PhD[2], Ms. Elizabeth Klemm MS[3], Dr. Michael Jones PhD[2], Dr. Sarah Trager Ridge PhD[4]

[1]Children's National Hospital, Silver Spring, MD, United States. [2]Brigham Young University, Provo, UT, United States. [3]East Carolina University, Greenville, NC, United States. [4]University of Hartford, West Hartford, CT, United States

Introduction

In competition, figure skating jumps are evaluated by technical specialists who determine if the jump was fully-rotated. According to the International Judging System (IJS), up to 90° rotation after landing is permitted for a jump to still be considered fully-rotated. Jumps under-rotated by >90° are assigned a downgraded score. However, no studies have identified key performance metrics (KPMs) that quantitatively distinguish fully-rotated ("good") from under-rotated jumps. Therefore, the purpose of this study was to compare KPMs between fully rotated and under-rotated jumps using a waist mounted IMU to support technique optimization and training decisions.

Methods

Fifty-nine competitive skaters performed double (DJ) and triple (TJ) jumps (n=157) wearing a waist-mounted IMU synchronized with video to identify take-off and landing events and full rotation status according to IJS standards. TJ were performed by high and elite skaters (U.S. Figure Skating (USFS) levels Novice and above), while DJ were performed by lower-level skaters (USFS Preliminary-Intermediate). KPMs calculated were: air time (t_{air}), peak angular velocity (ω_p), % of expected rotations completed ($R_{\%}$), and angular velocity at landing as a percent of peak angular velocity ($\omega_{Land\%\omega p}$). One-way ANOVAs were performed with Tukey pairwise post-hoc tests (a=0.05).

Results

All KPMs showed significant main effects ($p<0.001$). Under-rotated triple jumps (URTJ) demonstrated significantly decreased t_{air} ($p=0.019$) and $R_{\%}$ ($p=0.003$) compared with good triple jumps (GTJ) (Figure 1). Similarly, under-rotated double jumps (URDJ) demonstrated significantly decreased $R_{\%}$ ($p<0.001$) compared with good double jumps (GDJ). ω_p was not significantly different between GTJ and URTJ ($p=0.182$), however, ω_p decreased significantly

in URDJ compared to GDJ (p=0.04). $\omega_{Land\%\omega p}$ of URTJ was significantly increased as compared to GTJ (p=0.039), while no difference was observed between URDJ and GDJ (p=0.343).

Discussion

Both URDJ and URTJ had significantly decreased t_{air} demonstrating this as a KPM. Further, our findings demonstrate that even fully-rotated figure skating jumps judged under IJS standards achieve only 73% of the nominal three rotations for triples and 64% of the two rotations for doubles. This is likely due to on-ice pre-rotation during take-off. Awareness of this discrepancy is important for interpreting wearable-sensor data. Monitoring these KPMs may guide technique adjustments, training-load, and competition-readiness decisions.

Images (Optional)

Jump Type	t_{air} (s)	$R_{\%}$	ω_p (deg/s)	$\omega_{Land\%\omega p}$
Good Triples (High/Elite)	0.54 ± 0.05	72.9 ± 5.5	1747 ± 122.2	90.8 ± 10.9
Under-rotated Triples (High/Elite)	0.50 ± 0.04	65.6 ± 4.3	1681 ± 116.9	95.9 ± 5.3
Good Doubles (Low)	0.38 ± 0.06	64.3 ± 3.4	1410 ± 127.1	79.3 ± 13.2
Under-rotated Doubles (Low)	0.31 ± 0.06	49.8 ± 9.3	1318 ± 129.1	88.1 ± 12.9

OA56-02

Biventricular Heart Model with Novel Pseudo-Fluid Domains and Thermodynamically-Motivated Growth & Remodeling

Mr. Darshan Senthil, Dr. Jamie Concannon, Dr. Ryan Coleman, Prof. Patrick McGarry

University of Galway, Galway, Galway, Ireland

Introduction

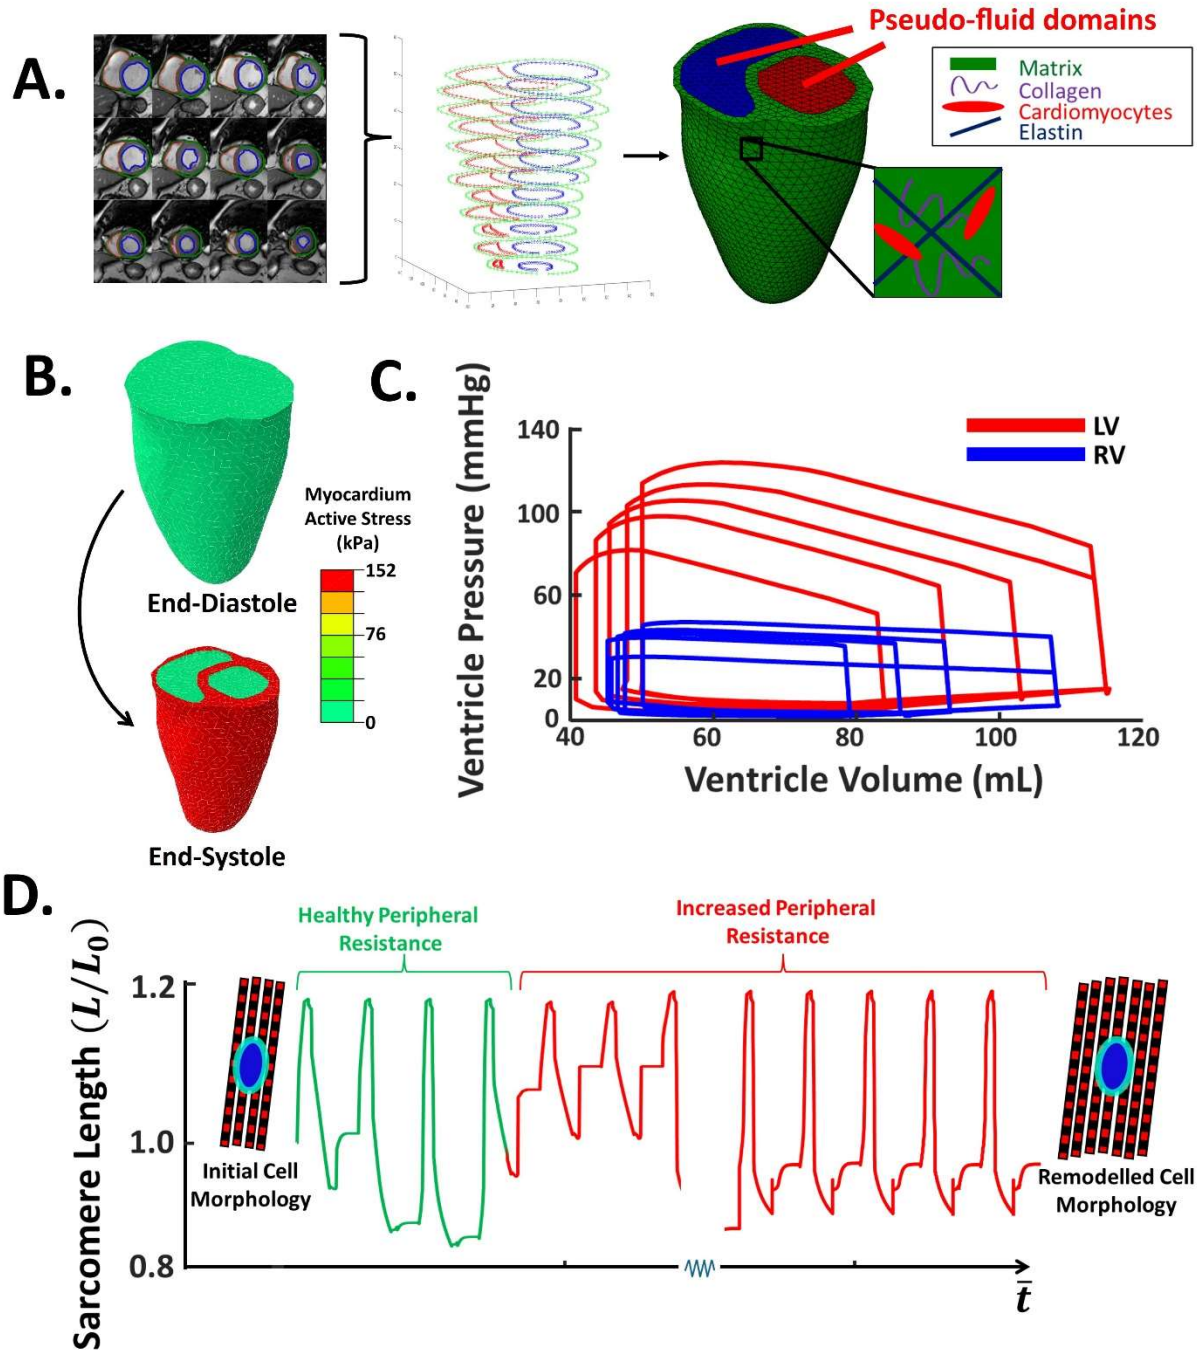
A common flaw in finite element (FE) heart models is the unphysical specification of predetermined ventricle pressure or volume. We propose a novel "pseudo-fluid" framework in which active myocardium contractility drives changes in ventricular volume and pressure, both of which are computed model outputs. We also develop a novel thermodynamically-based model for cardiomyocyte and myocardium growth and remodelling.

Methods

We process MRI images of healthy human hearts to create 3D patient-specific biventricular meshes with distinct myocardium and "pseudo-fluid" domains representing blood in each ventricular cavity (Fig.1A). Our constitutive law for myocardial tissue includes active contractility of cardiac myocytes [1] and passive anisotropic collagen in the ECM [2]. The "pseudo-fluid" material model incorporates bespoke windkessel-type constitutive laws based on aortic and pulmonary compliance and peripheral resistance.

Our novel thermodynamic model entails the computation of the myocardium free energy, which consists of active free energy due to cardiomyocyte contractility, and passive strain energy due to deformation of inter-cellular collagen. Deviation of the total free energy from a healthy homeostatic free energy acts a driver for evolution of cell morphology and sarcomere/myofibril remodelling.

Results



The deformation and active stress distribution in a patient-specific heart is shown in Fig.1B. Physiologically accurate levels of deformation and twist are computed during systole. Fig.1C shows predicted changes in PV loops following inferior vena cava occlusion (IVCO). Physiological accurate reductions in pressure, stroke volume and end-diastole volume are computed. Predictions of sarcomere remodelling in response to increased peripheral resistance are shown in Fig.1D. Initially, sarcomeres are unable to shorten sufficiently during systole, increasing the myocardium free energy over the course of a

cardiac-cycle. This results in the addition of sarcomeres in parallel, leading to enhanced contractility and a restoration of homeostatic free energy. The increase in cell thickness results in concentric hypertrophy.

Discussion

At a run time of approximately 20 minutes per cardiac cycle, our framework can potentially be used as a real-time clinical diagnostic tool. We accurately predict the short-term response to IVCO[3]. Furthermore, we uncover a thermodynamic cell-level mechanism for concentric hypertrophy[4].

Patient-Specific Investigation of Septal Repositioning Effects on Intraventricular Hemodynamics in Pediatric Dilated Cardiomyopathy

Ms. Weiru Luo PhD Candidate

Waseda University, Shinjuku, Tokyo, Japan

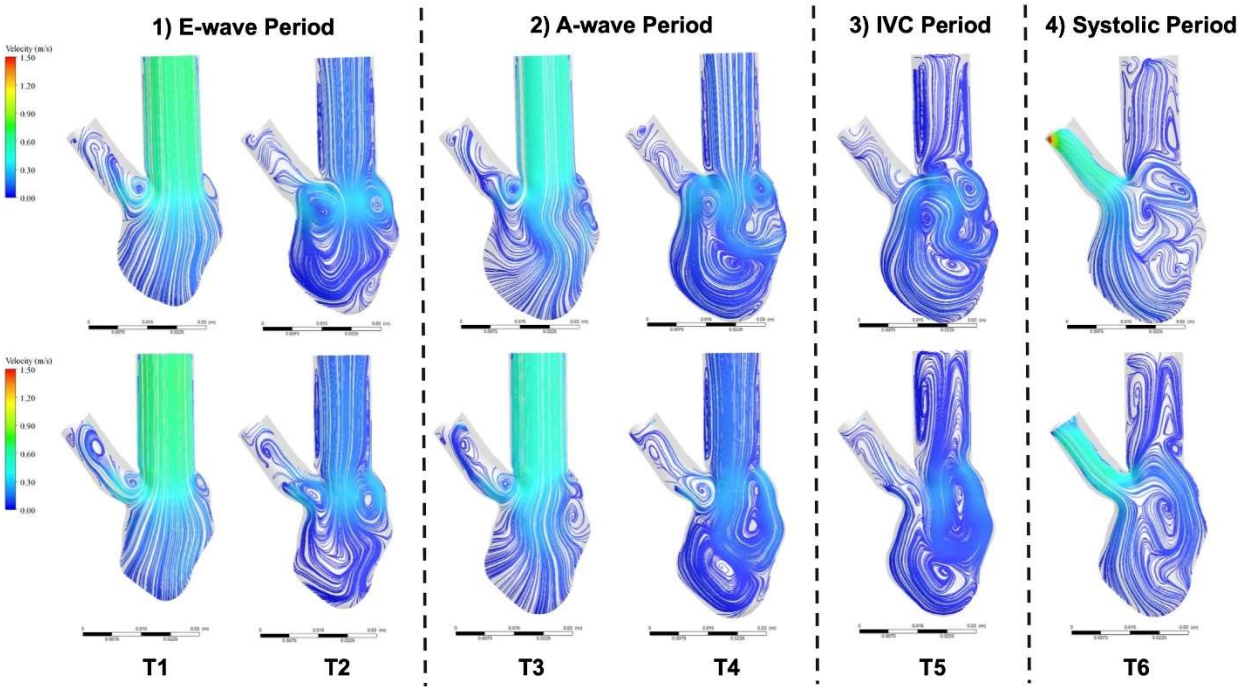
Introduction

Pulmonary artery banding (PAB) has emerged as a promising therapy for pediatric dilated cardiomyopathy (DCM), yet the mechanism by which PAB-induced interventricular septal (IVS) repositioning improves left ventricular (LV) function remains unclear. Clinical observations consistently report an acute leftward septal shift after PAB. However, its impact on intraventricular flow organization, vortex dynamics, and energetic efficiency has not been quantitatively characterized. This study aimed to elucidate the fluid-mechanical consequences of PAB-induced septal repositioning using a patient-specific computational hemodynamics framework.

Methods

Pre- and post-PAB LV geometries were reconstructed from cine MRI, with septal repositioning characterized by echocardiography and incorporated into the patient-specific post-PAB model. Transient blood flow was simulated in ANSYS Fluent using an Arbitrary Lagrangian–Eulerian (ALE) formulation with dynamic-mesh ventricular wall motion. Hemodynamic indices including flow patterns, vortex structures (Q-criterion), kinetic energy (KE), and volume-normalized viscous dissipation were quantified across the cardia cycle and compared.

Results



Echocardiography revealed a spatially heterogeneous leftward septal shift, most pronounced in the basal region, resulting in substantial LV geometric reconfiguration. As illustrated in Fig.1, this displacement compressed diastolic vortex rings (E-wave and A-wave) and redirected their propagation toward the aortic outflow tract. The apical vortex was repositioned closer to the apex, suggesting enhanced apical washout. During systole, the pre-PAB ventricle exhibited multiple dissipative vortices, whereas the post-PAB model was dominated by a single coherent jet-oriented vortex. Energetically, the post-PAB model demonstrated lower mean systolic KE, indicating a reduction in inefficient fluid recirculation. Conversely, viscous dissipation increased following PAB, reflecting the

shear cost associated with accelerating blood through the narrowed septal-outflow channel.

Discussion

PAB-induced septal repositioning reorganizes intraventricular flow, suppressing disordered vortices and promoting a more coherent ejection jet. The associated energetic trade-off, lower recirculatory KE but higher viscous dissipation, suggests a physiologically meaningful redistribution of mechanical energy that enhances systolic efficiency. However, this sustained elevation in viscous dissipation may impose a long-term energetic burden on the myocardium. Furthermore, the altered flow near the mitral annulus suggests a potential risk for valvular dysfunction, highlighting the importance of longitudinal patient monitoring. These findings provide fluid mechanistic insight into the therapeutic effects of PAB on pediatric DCM.

OA56-04

Modeling Cardiac Growth and Fiber Remodeling in a Finite Element model of Left Ventricular Mechanics

Ir. Britt van Kerkhof, Ir. Kelly Keulen, Dr. Ir. Peter Bovendeerd

Eindhoven University of Technology, Eindhoven, North Brabant, Netherlands

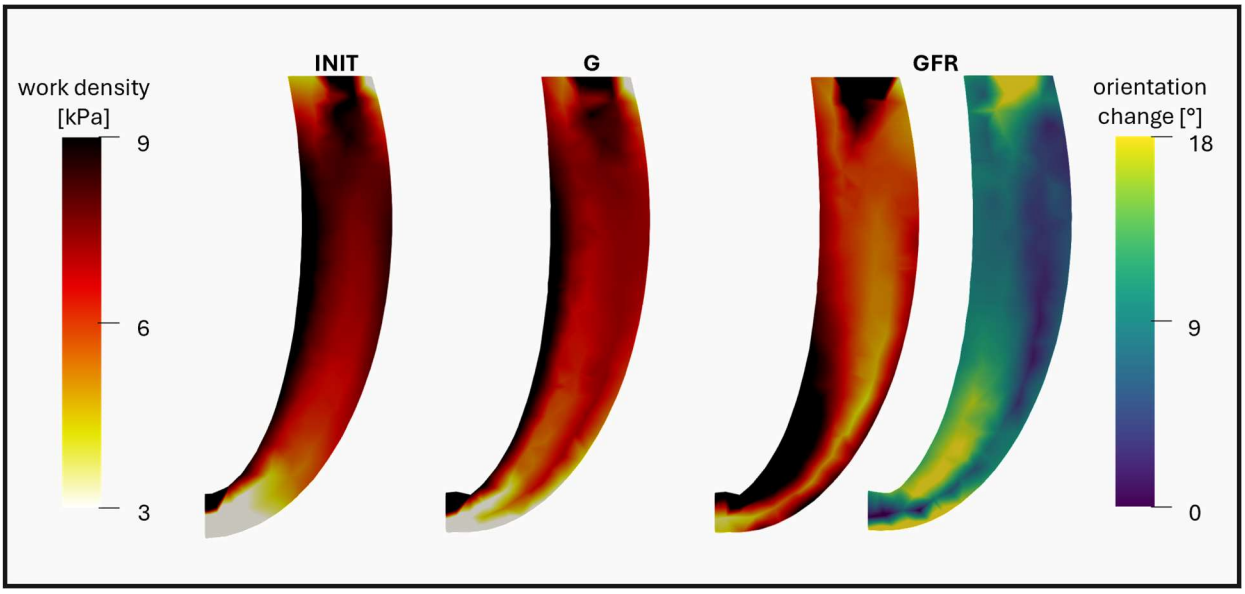
Introduction

The heart adapts via changes in mass (growth) and tissue properties (remodeling). Computational models of cardiac growth and remodeling (G&R) can be used to describe G&R in response to disease or treatment. However, published computational G&R models focus on growth alone [1]. In reality, G&R occur concurrently, with fiber orientation likely to be subject to remodeling. We combined the growth model of [1] with fiber remodeling of [2] in a Finite Element (FE) model of cardiac mechanics to simulate cardiac G&R under physiological loading conditions, where a stable end configuration is to be expected.

Methods

This study builds on the FE model in [3]. Remodeling of fiber orientation is assumed to minimize mechanics-induced reorientation during the cardiac cycle [2]. Local tissue growth is driven by the deviation of tissue work density from a homeostatic set point [1]. After each G&R step the grown state is adopted as the new stress-free state for the subsequent mechanics step. Three simulations were performed: no G&R (INIT), growth only (G), and both processes (GFR), each covering 6 cycles.

Results



In both G and GFR, the left ventricular (LV) geometry shows apical thinning and midwall thickening. Spatially averaged work density evolves towards the homeostatic value of 6.7 kPa, from 7.4±1.8 kPa in INIT, to 6.9±1.9 kPa in G, and in 6.9±2.2 kPa in GFR (Fig. 1). Wall and cavity volume rise from 136 ml and 44 ml in INIT to 145 ml and 52 ml in both G and GFR. Fiber orientation changes by 8.3° on average in GFR (Fig. 1).

Discussion

We investigated whether a combined G&R model could reproduce a stable healthy LV configuration, based on a local stimulus-effect relation. Preliminary results show that the LV geometry grows from ellipsoidal to more spherical. FR affects work density, and slightly

affects growth. Additional cycles are needed to evaluate whether the combined G&R model evolves to a steady state.

An Integrated Experimental-Computational Approach to Modeling the Mechano-Energetic Cost of Cardiac Contractility

Mr. Tanmay Mukherjee MS, Mr. Emilio Mendiola BS, Dr. Sunil Venkategowda PhD, Dr. Carl Tong MD, PhD, Dr. Mahua Choudhury PhD, Dr. Reza Avazmohammadi PhD

Texas A&M University, College Station, TX, United States

Introduction

Cardiac remodeling in cardiometabolic disease is increasingly linked to reduced ATP availability needed to support normal myofiber contraction. When energy supply becomes insufficient, the mechanical processes that enable force generation are affected. While separate endeavors have been devoted to studying the mechanical and metabolic mechanisms of cardiac structure-function, the mechanistic link across mechano-metabolic cues governing contractility remains understudied. In this study, we present an experimental-computational model devoted to delineating the mechano-energetic cost of cardiac contractility.

Methods

The left ventricular free wall (LVFW) was harvested from 8-10-week-old wild-type mice and immediately placed in PBS at 1°C. Mechanical testing was performed to measure passive stiffness at 30% equibiaxial stretch (M and F; n = 4 each). Energetics were quantified by homogenizing 10 mg of LVFW tissue using buffer A and analyzing the supernatant ATP concentration (M and F; n = 4 each, Fig. 1A). A constitutive model of mechano-energetics was implemented to recapitulate myofiber shortening using experimentally obtained ATP concentration (Fig. 1B).

Results

Bias in passive stresses towards the circumferential axis, in comparison to the longitudinal direction was evidenced, indicating the inherent anisotropy in the cardiac tissue (Fig. 1C). Sex-specific changes were also confirmed via LVFW stiffness (Fig. 1D). Baseline ATP concentration was measured in the supernatant LVFW tissue with significant sex-specific changes (Fig. 1E). The model represented metabolite production (*ATP, NADH,* and *ADP*) using simple ordinary differential equations of respective mass fractions ( ), and incorporated a hyperelastic formulation of the passive LV tissue to compute total stresses consistent with experimentally measured values.

Discussion

The alterations in stiffness and ATP levels suggest that sex-specific disruptions in mechano-metabolic coupling may be vital in examining early disease progression. Importantly, the mechano-metabolic measures presented herein may provide insight into fiber-level remodeling even before measurable cardiac dysfunction appears. For example, impaired relaxation in diastolic dysfunction has been linked to metabolic or “active” deficits at the protein level, as well as increased “passive” stiffness of the myocardial tissue, while preserving the heart’s ejection fraction. Our results indicate the ability to model the complex mechano-metabolism within the heart by establishing the mechano-energetic cost of cardiac contractility.

Images (Optional)

Frame Alignment Improves Agreement between Marker-Based and Markerless Knee Kinematics in Children with Cerebral Palsy

Dr. Eric Dugan PhD[1,2], Dr. Ariana Ortigas-Vásquez PhD[3], Dr. Adrian Sauer PhD[4], Ms Katelyn Campbell MS[1]

[1]Texas Children's Hospital, The Woodlands, TX, United States. [2]Baylor College of Medicine, Houston, TX, United States. [3]ETH Zürich, Zürich, Zürich, Switzerland. [4]Aesculap AG, Tuttlingen, Baden-Württemberg, Germany

Introduction

Markerless motion capture offers a promising alternative for clinical gait analysis, but notable differences from marker-based data have been reported in children with cerebral palsy (CP) [1]. These discrepancies may arise from differences in segment coordinate frame definitions. Ortigas-Vásquez et al. introduced the REFRAME method, which reconciles coordinate frames across modalities using a constrained optimization [2], and Antognini et al. showed that this alignment substantially reduced apparent knee kinematic differences [3]. In children with CP, we hypothesized that 1) REFRAME would markedly reduce systematic differences between marker-based and markerless knee kinematics and 2) markerless data would capture both the magnitude of stride-to-stride variability and, after alignment, the same trial-specific deviation patterns observed in marker-based measurements.

Methods

Fifty-one children with CP (GMFCS I–III) participated in simultaneous marker-based and markerless three-dimensional gait analysis during barefoot walking. Markerless segment orientations were optimized to marker-based orientations using REFRAME. Knee joint angles from both systems were compared before and after alignment. The primary outcome was root-mean-square error (RMSE) across the gait cycle. Secondary outcomes evaluated stride-to-stride variability using within-subject standard deviation (wSD) and directional agreement based on correlations of trial-specific deviation vectors.

Results

Before alignment, sizable between-system differences were present, particularly in frontal and transverse motions. REFRAME reduced RMSE by approximately 50 to 75 percent across planes, yielding post-alignment values below a conservative 3-degree clinical threshold (Figure 1). Within-subject variability was similar between marker-based and markerless measurements even before alignment, and equivalence testing confirmed that

wSD differences were biomechanically trivial. Directional agreement increased significantly after frame harmonization, indicating that both systems detected trial-to-trial deviations more consistently once coordinate-frame differences were removed.

Discussion

REFRAME improved agreement between marker-based and markerless knee kinematics in children with CP while preserving natural stride-to-stride variability. These findings indicate that most pre-alignment discrepancies likely reflected coordinate-frame inconsistencies rather than differences in how each system tracked the underlying movement. Incorporating frame harmonization may enable markerless motion capture to serve as a reliable and scalable tool for pediatric gait assessment.

Development and Validation of a Multi-Camera Dynamic 3D Foot Scanning System for Kinematic Analysis in Flexible Flatfoot

Mr. LEI LI, Dr. Hok Sum MAN, Dr. Ming ZHANG

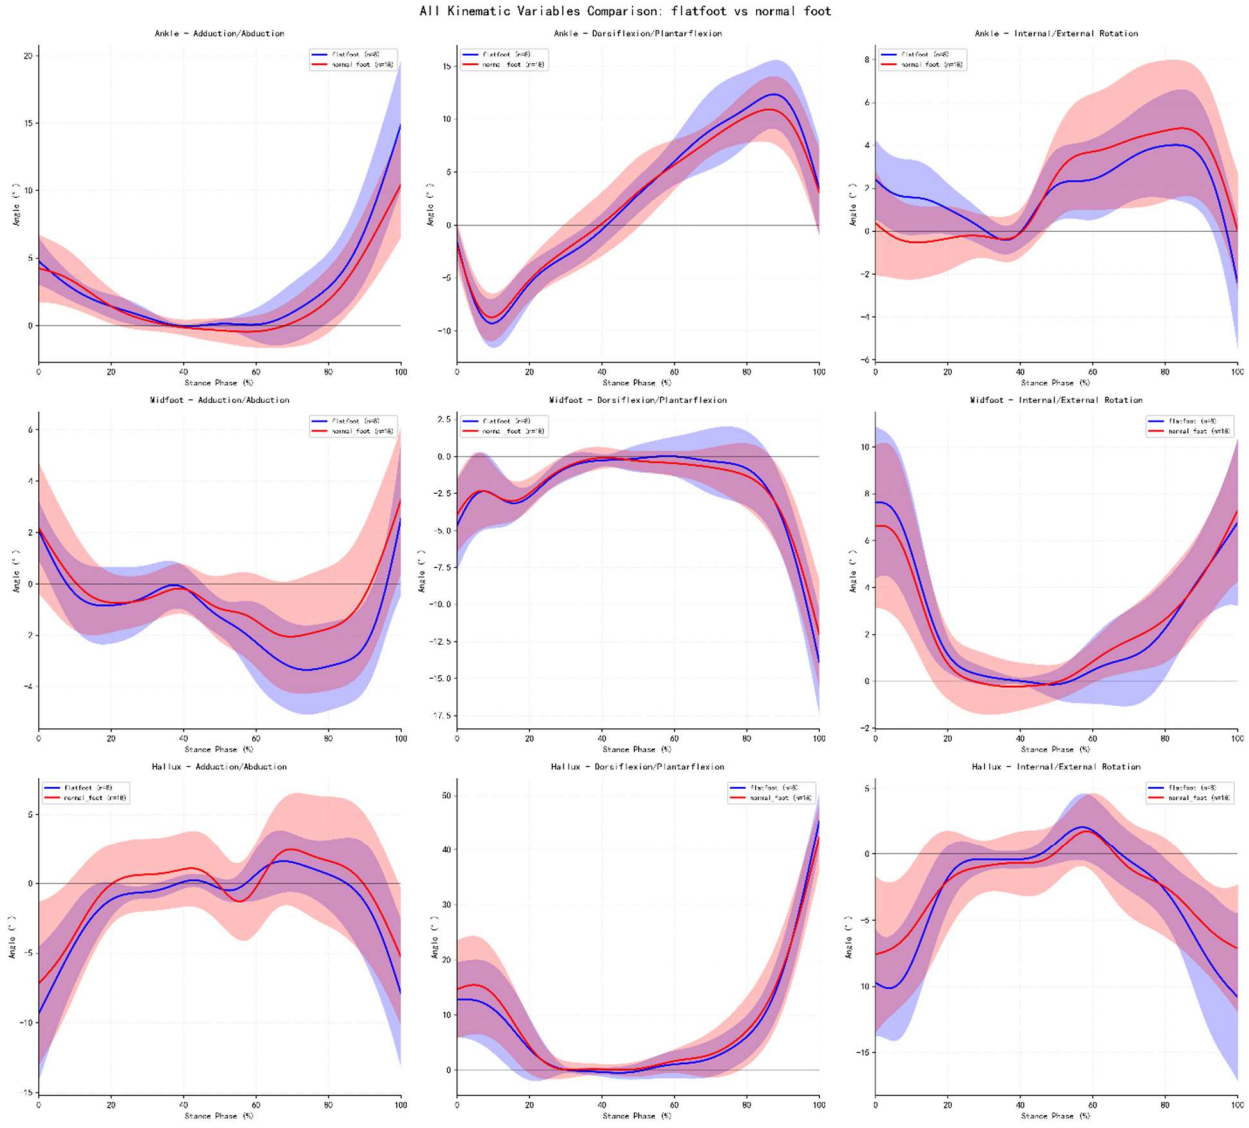
the Hong Kong Polytechnic University, Hong Kong, Hong Kong, Hong Kong

Introduction

Flatfoot is a common deformity characterized by medial longitudinal arch collapse, often leading to pain and impaired gait. Current orthotic design relies heavily on static assessments, which fail to capture dynamic foot morphology during walking. This study aims to develop and validate a novel dynamic 3D foot scanning system to capture high-frame-rate foot shapes during gait, enabling markerless multi-segment foot tracking and kinematic analysis in individuals with flexible flatfoot.

Methods

A dynamic 3D foot scanning system was constructed using eight synchronized Intel RealSense D455 cameras, capturing both geometric and texture data at 60 Hz. System repeatability and accuracy were validated using a rigid foot model compared against a commercial laser scanner (XPOD-S). Four foot segments (shank, rearfoot, forefoot, hallux) were defined using anatomical landmarks, and a two-step point-to-plane iterative closest point (PL-ICP) algorithm was implemented for segment tracking. Kinematic parameters were derived from segment transformations and compared between flatfoot (FPI ≥ 6, n=8) and normal foot (n=18) groups during walking.



Results

The system demonstrated good repeatability, with 94.3% of static scan overlap area within ±0.5 mm deviation, and 90% of dynamic scans within 1.34 mm of the reference model. Segment tracking achieved high fitness scores (≥0.90) and sub-millimeter RMSE across all segments. Kinematic analysis revealed that individuals with flatfoot exhibited significantly greater rearfoot abduction ($p=0.0256$) and coronal-plane range of motion ($p=0.0289$) compared to normal feet, while other spatiotemporal and kinematic parameters were comparable.

Discussion

The developed system provides a cost-effective, accurate, and repeatable method for dynamic 3D foot assessment. The proposed tracking algorithm outperforms existing methods in stability and accuracy, particularly during high-velocity gait phases. The observed kinematic differences highlight specific compensatory patterns in flatfoot gait, supporting the potential for dynamic morphology to inform orthotic design. Future work will include validation against gold-standard motion capture and application of principal component analysis to quantify foot deformation modes for personalized orthotic development.

Estimating Lower Limb Joint Moments, Muscle Forces, and Joint Contact Forces from Video

Dr Amir Esrafilian[1,2], Dr Tian Tan[1], Dr Nicholas Bianco[1], Dr Anthony Gatti[1], Asst Professor Akshay Chaudhari[1], Dr Jennifer Hicks[1], Professor Scott Delp[1]

[1]Stanford University, Stanford, California, United States. [2]University of Eastern Finland, Kuopio, North Savo, Finland

Introduction

Quantifying joint moments, muscle forces, and joint contact forces (JCFs) is valuable for understanding musculoskeletal conditions. While video-based motion analysis can estimate body kinematics accurately, estimating internal forces remains limited to resource-demanding marker-based motion capture (Mocap) and computational modeling. Here, we adapted a machine learning (ML) model to estimate lower-limb joint moments, muscle forces, and JCFs from video-based kinematics.

Methods

We used an OpenSim musculoskeletal model [1] and Mocap and ground reaction force data from the AddBiomechanics Dataset [2] (273 individuals, 6-84 years) to obtain gold-standard kinematics, joint moments, muscle forces (static optimization), and JCFs. Ten individuals had videos synced with Mocap data. We adopted GaitDynamics ML model [3], and trained it using 70% of Mocap and 30% of video-based data. ML model inputs were lower-limb joint coordinates, velocities, and accelerations. We used pelvis-ground and bilateral hip, knee, and ankle joints, totaling 15 degrees of freedom (Fig. 1-A). The ML model outputs were joint moments (3 components per joint), muscle forces (40 muscles per leg), and JCFs (3 components per joint) time series. Here, we reported results for seven unseen individuals, with kinematics obtained from (i) single and (ii) dual video camera [4,5].

Results

Compared to musculoskeletal model, the ML model had an overall normalized root mean square error (NRMSE) of 9.2±3.1% for dual and 10.3±3.8% for single camera systems in estimating joint moments, muscle forces, and JCFs. Demonstrated for a selected subject (Fig. 1-B, dashed lines), ML model estimated magnitudes and temporal patterns of kinetics consistent with musculoskeletal modeling.

Discussion

The ML model estimated subject-specific and task-specific lower-limb kinetics from kinematics, surpassing the accuracy of previous studies and predicting a larger set of outputs (e.g., our JCF-NRMSE: 4.8-12.7% vs. literature: 4.5-32.5%). Our ML model enables fast (few minutes from camera setup to results) and low-cost movement analysis, offering the potential to assist in personalized musculoskeletal disorder management and performance optimization.

Images (Optional)

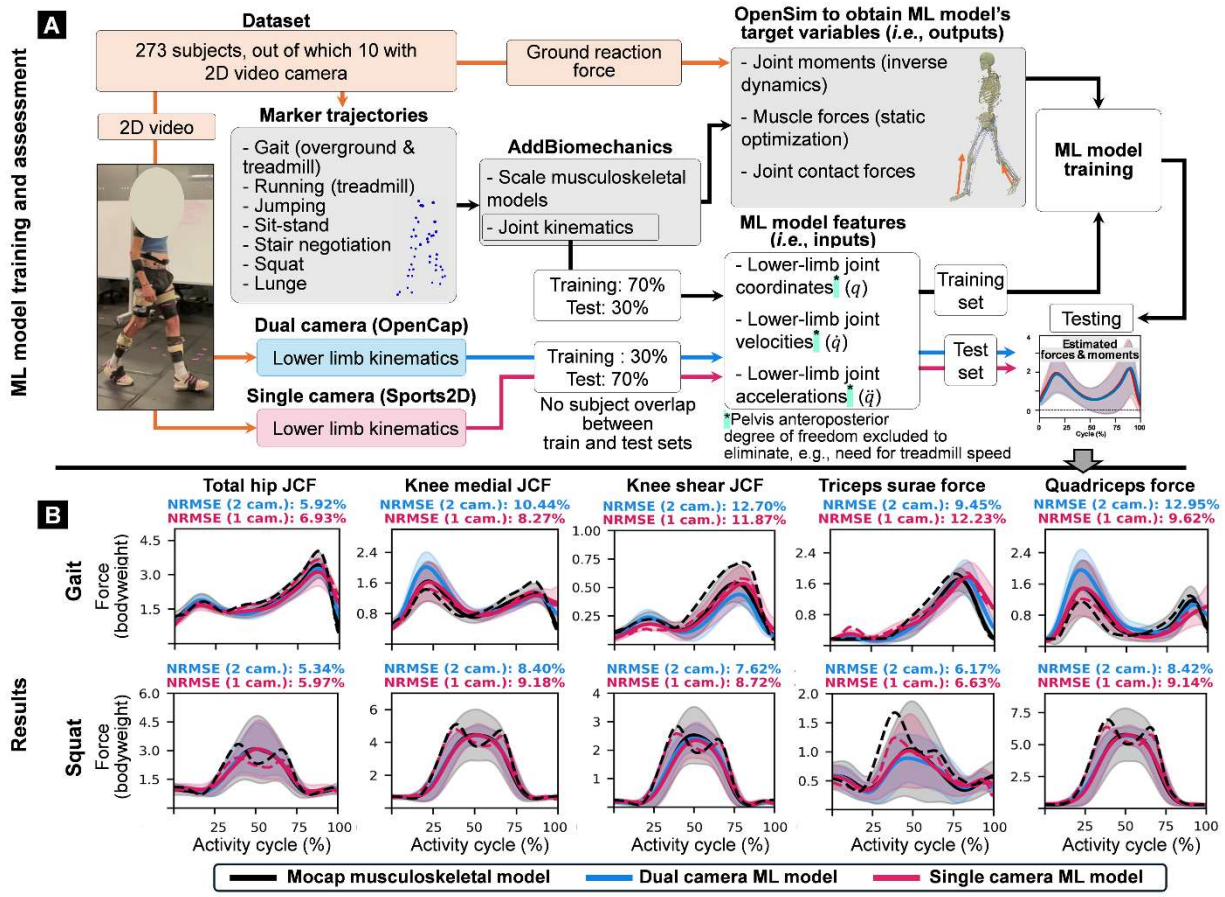

Fig. 1: A) Study workflow; ML model training using the AddBiomechanics dataset. **B)** A subset of ML outputs based on kinematics from dual (in blue) and single (in red) video camera, along with musculoskeletal analysis of Mocap data (in black). The mean NRMSE of all trials is reported, comparing the corresponding ML model with musculoskeletal analysis. Solid lines in plots illustrate mean ± one standard deviation, and dashed lines illustrate results from one representative subject.

Quantifying Marker-Wise Kinematic Sensitivity in the Shriner Children's Gait Model Using Individual Marker Error Analysis

Grant Schwiebert[1,2], Matthew Parrett M.Ed.[1], Mallory Rowan M.S.[1], Jessica Lewis PT, DPT[1], Dr. Sean Tabaie MD[1], Dr. Kirsten Tulchin-Francis PhD[1]

[1]Nationwide Children's Hospital, Columbus, Ohio, United States. [2]The Ohio State University, Columbus, Ohio, United States

Introduction

Marker placement error (MPE) and soft tissue artifact (STA) produce well-documented deviations in gait kinematics. Most clinical models, including the Shriner Children's Gait Model (SCGM), provide qualitative guidance on which markers most strongly influence joint angles. However, no
quantitative placement sensitivity or tolerances accompany these qualitative statements. This study used an Individual Marker Error Analysis (IMEA) pipeline to map marker-specific perturbations to resulting kinematic deviations for the SCGM.

Methods

A walking trial from a healthy adult was processed using a vectorized Python re-implementation of SCGM. Each marker was perturbed individually representing 3-D MPE. Perturbations were applied in segmental anatomical coordinate systems and mapped into global space to emulate bone-fixed offsets. For each perturbation, the SCGM static calibration and dynamic kinematics were recomputed. A finite-difference gradient-descent search identified the perturbation directions that maximized angle error for each axis, while linear interpolation estimated mean sensitivities (deg/mm). For each marker–axis pair, an allowable placement tolerance was computed based on preserved angle errors of ≤2% of gait cycle range of motion.

Results

IMEA quantitatively confirmed most SCGM-designated critical alignment axes. Markers identified by SCGM as essential for segment-axis definition, particularly the ASIS and medial/lateral knees and malleoli, showed the highest sensitivity to marker placement upwards of 3.0 to 6.6°/mm (Table 1) and represented errors seen across all planes.

Similarly, most markers which SCGM classified as having minimal critical alignment (e.g. PSIS) displayed correspondingly low sensitivities, often <0.01°/mm confirming negligible influence on lower-limb joint angles.

Discussion

IMEA provides the first numerical placement tolerances for SCGM, quantitatively validating the model's most influential alignment axes while identifying several markers whose true kinematic impact is far lower than implied by their qualitative labels. While IMEA characterizes marker-wise kinematic sensitivity, it does not model soft-tissue artifacts. Incorporating probabilistic STA distributions and marker-placement variability would allow for fully probabilistic IMEA weighting. Integrating these distributions with fuzzy-logic or Bayesian frameworks could enable real-time, uncertainty-aware estimation of true joint kinematics across gait cycles, enhancing clinical interpretation, surgical planning, and treatment evaluation. Future work will expand to multi-participant, multi-session datasets to establish population-level sensitivity ranges and subject-specific placement tolerances.

Accuracy of Markerless Motion Capture Tibiofemoral Rotations Benchmarked Against Biplane Videoradiography

Miss Lauren Swain, Miss Janine Flohr, Prof Cathy Holt, Dr David Williams

Cardiff University, Cardiff, Wales, United Kingdom

Introduction

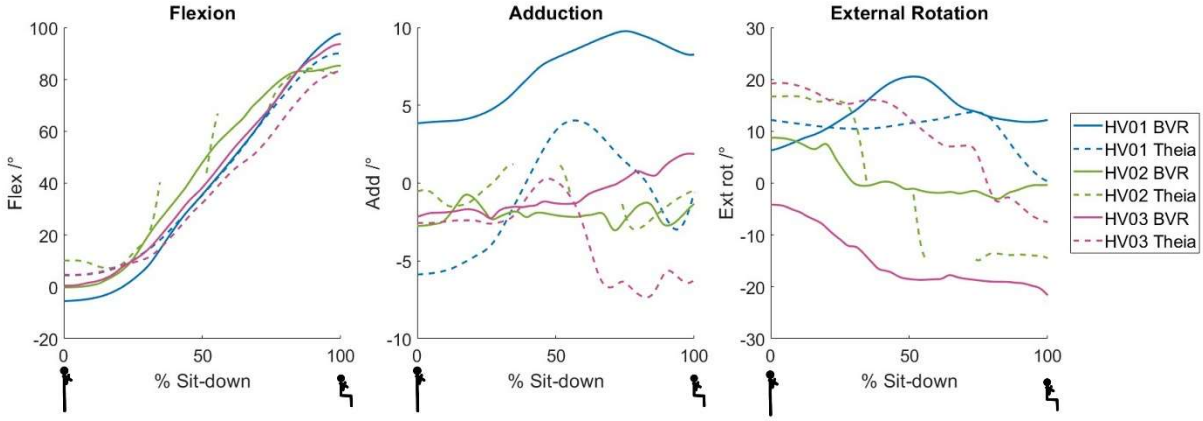
Markerless motion capture is an emerging technology for human motion analysis, with the potential to replace marker-based motion capture as it removes the need for marker placement, a time-consuming process requiring skilled personnel. Markerless motion capture has been shown to produce average joint angle differences of 2.6-13.2° compared to marker-based equivalents [1]. However, the true accuracy of markerless motion capture can only be determined by comparison to a gold standard, such as biplane videoradiography (BVR) [2].

Methods

Video footage from 10 Miqus cameras was captured simultaneously with BVR whilst 3 healthy volunteers (2M/1F) carried out a sit-down activity. Theia3D (Theia) was used to calculate whole-body kinematics from the video footage, including 3 degrees-of-freedom at the knee. Bone models segmented from MRI (Simpleware, ScanIP) were registered to pairs of X-rays (SlicerAutoscoperM [3]) for each frame of the activity. Anatomical coordinate systems were applied to the bone models [4] and 3 DOF BVR knee rotations were calculated from the bone poses (MATLAB, Mathworks) using the joint coordinate system approach [5]. An adaptive lowpass Butterworth filter was applied to all rotations.

Results

Figure 1 shows the 3 rotations for both methods, normalised to percentage activity. Flexion was generally well predicted (RMSE±SD: 6.21±1.22°); however, the total range of motion was underestimated by Theia3D. Adduction had the smallest RMSE of the three rotations (4.79±3.37°), whereas external rotation had the largest differences between the two methods (13.86±9.98°). Theia3D struggled to track the knee for HV02 due to occlusion by the X-ray equipment, leading to drop out and worse agreement when filtering was applied.



Discussion

These pilot results show the importance of comparing markerless motion capture kinematics to gold-standard BVR to understand its true accuracy. Future work will expand the comparison to more activities and participants, including pathological cohorts, as well

as comparison with marker-based motion capture to gauge markerless performance against the current clinical gold-standard.

Pelvic Tracking During Gait in Overweight and Obese Individuals

Mr. Niels Dur MSc, MD[1], Ms. Lianne Damink MSc[2], Ms. Erin Macri PhD[1], Ms. Mariska Wesseling PhD[1,3], Mr. Jaap Harlaar Professor, PhD[1,3], Mr. Wouter Schallig PhD[1]

[1]Erasmus MC University Medical Center, Rotterdam, Zuid-Holland, Netherlands. [2]Haaglanden Medical Center, The Hague, Zuid-Holland, Netherlands. [3]TU Delft Technical University, Delft, Zuid-Holland, Netherlands

Introduction

Given the global rise of obesity, accurate 3D motion analysis methods tailored to this population is needed. Pelvic kinematics measured with conventional marker models using skin-mounted anterior superior iliac spine (ASIS) markers, such as CGM 2.4, may be inaccurate due to substantial soft tissue artifacts [1]. An alternative approach uses a sacral marker cluster combined with pointer-based calibration of virtual ASIS markers. This method showed promise in individuals with a normal body mass index (BMI) [2], but has not yet been evaluated in an overweight population. This study aimed to compare pelvic kinematics and hip joint center (HJC) locations derived from these two models in a healthy-weight group and an overweight group.

Methods

Ten healthy-weight (mean BMI 23.0±1.7) kg/m^2) and ten overweight/obese (mean BMI 33.7±5.2 kg/m^2) adults were included. Gait analysis was conducted on a treadmill using CGM 2.4 and an additional sacral marker cluster to track the pelvis. A probe was used to calibrate the virtual ASIS in the sacral cluster. Pelvic kinematics and HJC locations were calculated for three consecutive steps with and without the cluster. Statistical parametrical mapping paired t-tests were performed to test for significant differences over the gait cycle in pelvic kinematics and HJC.

Results

No differences were observed in pelvic kinematics between methods for the healthy-weight group. In the overweight group, significant mean differences up to 10° were observed for pelvic obliquity throughout most of the gait cycle (see Figure 1). For HJC trajectories, statistically significant differences were observed in the anteroposterior direction in healthy-weight (mean 15mm) and overweight groups (mean 28mm) and in the superoinferior direction in the overweight group (mean 22mm).

Discussion

The use of a sacral cluster with pointed virtual ASIS markers provided different, and potentially more accurate, estimates of pelvic orientation and HJC in overweight individuals compared to a conventional model. It does, however, affect HJC estimates in healthy-weight individuals. While confirmation in a larger sample is required, this method may be more accurate than conventional models when performing gait analysis in overweight or obese individuals.

Images (Optional)

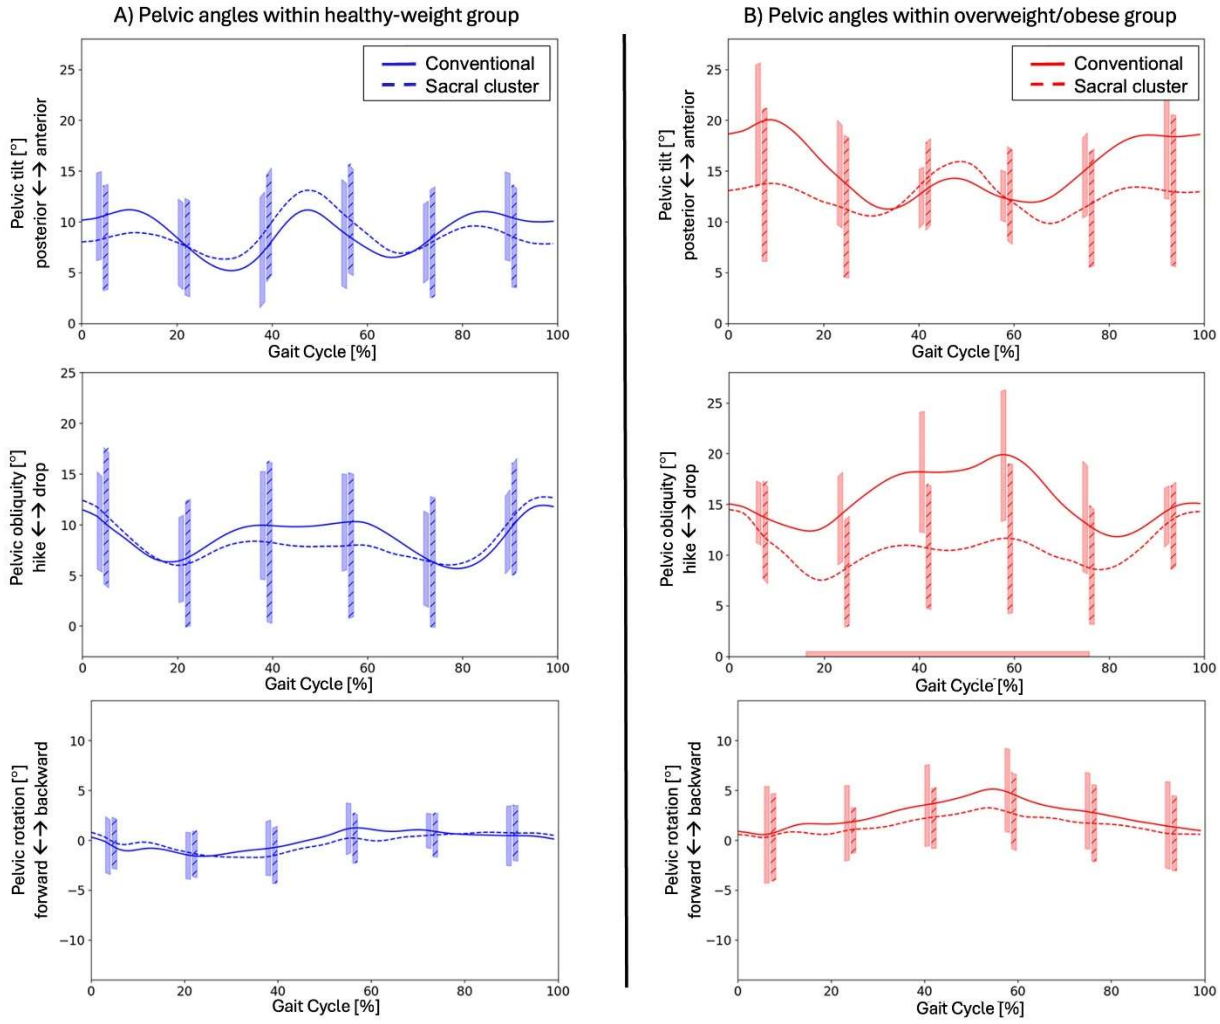

Figure 1: Pelvic angles (mean [degrees] ± SD) within (A) the healthy-weight and (B) overweight/obese group. Angles are shown in: sagittal plane (pelvic tilt), frontal plane (pelvic obliquity), the transverse plane (pelvic rotation) for conventional (continuous line) and sacral cluster (dashed line) models. Trajectories with statistically significant differences between methods are indicated with horizontal boxes.

Representative Sampling Using Realisation-Dependent Stopping Algorithm to Quantify the Relationship Between Brain Volume, Impact Severity, and Brain Strain

Ms Emily Yik Kwan Chan[1], Mr Vahid Darvishi[1], Dr Thomas Parker[2], Dr Anthony Quinn[1,3], Dr Mazdak Ghajari[1]

[1]Dyson School of Design Engineering, Imperial College London, London, London, United Kingdom. [2]Department of Brain Sciences, Imperial College London, London, London, United Kingdom. [3]School of Engineering, Trinity College Dublin, Dublin, Dublin, Ireland

Introduction

Subject-specific neuroanatomy influences finite-element(FE)-predicted brain strain. Larger brain volume yields higher strain under identical impact kinematics, and the volume–strain relationship varies with impact severity (Figure-1A) [1]. Exhaustive simulation across subjects and impacts to determine this relationship is computationally infeasible. Meanwhile, naïve down-sampling risks bias. This study uses a realisation-dependent, statistical stopping algorithm to select representative subjects and impacts to enable unbiased characterisation of volume–severity–strain relationship [2]. The aim is to determine whether using this algorithm will lead to representative samples, which are small enough to make FE runs feasible.

Methods

We used 211 MRI-scans of a large range of subjects, and 3,687 head impacts from boxing, mixed-martial-arts and rugby, captured by instrumented mouthguards (Figure-1C) [3]. Impact severity was defined as 90th-percentile maximum principal strain at corpus callosum estimated by Imperial College FE model developed from a 50th-percentile anatomy (Figure-1B) [4].

The stopping algorithm was applied separately to the two variables, volume and severity. The algorithm iteratively draws random samples of size n from the full N-sample distribution and evaluates the change in the sub-sampled distribution caused by the latest sample via the n-dependent Kullback–Leibler divergence (KLD). Sampling stops when KLD falls below a predefined tolerance, returning a stopping size n (typically $n<<N$). The tolerance was validated using 500 Monte-Carlo repeats. Representativeness was assessed by comparing the summary statistics of the n-sample to the N-sample, reporting error in standardised error (σ) unit of N. The KLD at stopping also quantifies the closeness between the n- and N-sample distributions.

Results

The algorithm independently selected 25 subjects and 75 impacts.Errors relative to full distributions were 0.33σ (volume) and 0.18σ (severity), indicating that selected samples accurately represent the full distributions (Figure1-D).

Discussion

Exhaustive simulations require 211×3,687=777,957 FE runs.The algorithm reduced this to 25×75=1,875, reducing the number of simulations by ~415times.This ensures computational feasibility while providing a KLD-based guarantee of distributional accuracy at stopping.The resulting dataset supports robust estimation of volume–severity–strain relationship and facilitates subject-specific strain prediction.

Images (Optional)

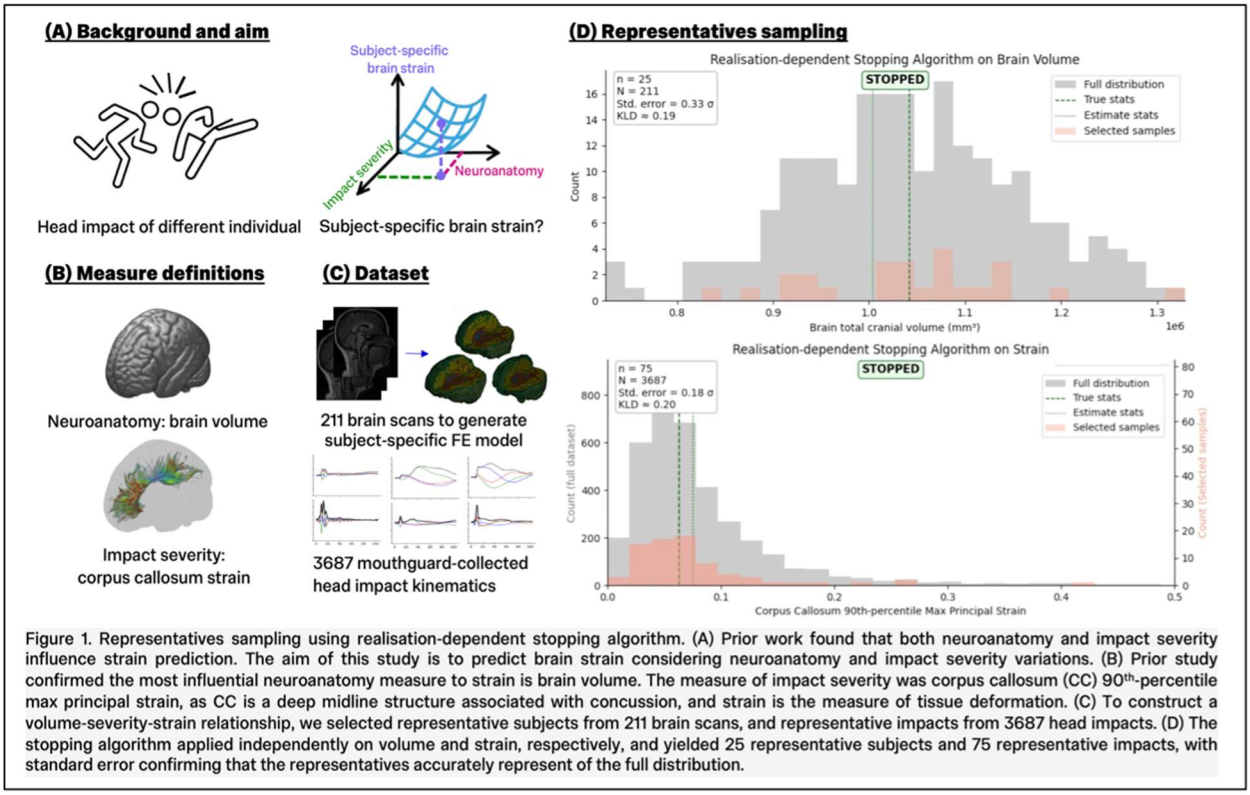

Figure 1. Representatives sampling using realisation-dependent stopping algorithm. (A) Prior work found that both neuroanatomy and impact severity influence strain prediction. The aim of this study is to predict brain strain considering neuroanatomy and impact severity variations. (B) Prior study confirmed the most influential neuroanatomy measure to strain is brain volume. The measure of impact severity was corpus callosum (CC) 90th-percentile max principal strain, as CC is a deep midline structure associated with concussion, and strain is the measure of tissue deformation. (C) To construct a volume-severity-strain relationship, we selected representative subjects from 211 brain scans, and representative impacts from 3687 head impacts. (D) The stopping algorithm applied independently on volume and strain, respectively, and yielded 25 representative subjects and 75 representative impacts, with standard error confirming that the representatives accurately represent of the full distribution.

Subject-Specific In Silico Modeling of Brain Interstitial Fluid Transport Under Traumatic Loading

Dr. Ge He[1], Mr. Chenghan Cai[2], Dr. Lei Fan[2]

[1]Lawrence Technological University, Southfield, Michigan, United States. [2]Michigan State University, East Lansing, Michigan, United States

Introduction

Interstitial fluid (ISF) transport within brain tissue is essential for nutrient delivery, waste clearance, and intracranial pressure regulation. Traumatic brain injury (TBI) disrupts ISF flow through rapid mechanical loading, tissue swelling, and microstructural damage, contributing to edema, impaired clearance, and long-term neurodegeneration. However, capturing real-time dynamic ISF flow during and after TBI is highly challenging because brain's intricate porous architecture and millisecond-scale loading response prevent direct in vivo measurement. Computational modeling provides a controlled framework to quantify ISF dynamics and investigate mechanisms of impact-induced and post-traumatic fluid transport impairment.

Methods

In this work, we extend our previously developed hyper-poroelastic constitutive model of brain tissue to characterize ISF transport at the tissue scale by implementing the constitutive model into subject-specific whole-brain geometries to computationally investigate how head impact forces affect ISF flow across anatomically realistic structures and, ultimately, to enable simulations over large cohorts of human subjects. Brain parenchyma was modeled as a deformable porous medium saturated with ISF, governed by mass continuity, Darcy flow, and a hyperelastic constitutive relation, and implemented using a finite element formulation in FEniCSx.

(1) Tissue-Level Model: A one-dimensional consolidation test was reproduced to calibrate permeability, porosity, solid stiffness, fluid viscosity, and bulk modulus. A parametric study evaluated how these parameters influence the consolidation ratio.

(2) Whole-Brain Model: A patient-specific 3D brain geometry was used to simulate transient ISF pressure and flow rate following rapid loading. Spatial distributions of ISF pressure, flow rate, parenchymal strain, and stress were quantified, and simulations across different subjects will evaluate inter-subject variability.

Results

The parametric study showed that higher permeability and fluid bulk modulus increased the consolidation ratio, whereas higher fluid viscosity delayed fluid transport. Increased porosity produced a weaker effect. Whole-brain simulations revealed a transient, spatially heterogeneous ISF response, with peak flow rates near the impact site ($\approx 10^{-5}$–10^{-4} mm/s) at 5 ms, followed by rapid dissipation. Wave-like propagation and poroelastic lag behavior were observed, reflecting tight fluid–solid coupling.

Discussion

This modeling framework reveals how TBI-like loading perturbs ISF pressure and flow rate during and after impact, providing insight into post-traumatic fluid redistribution and potential mechanisms underlying edema and neurodegeneration.

AI-based Positioning of Finite Element Human Body Models *Co-corresponding authors: Henrik Abrahamsson and Xiaogai Li

Mr. Giorgio Diena[1], Ms. Yuju Son[2], Mr. Siyuan Chen[1], Dr. Henrik Abrahamsson[2], Dr. Xiaogai Li[1]

[1]KTH - Royal Institute of Technology (KTH), Stockholm, Stockholm, Sweden. [2]RISE - Research Institutes of Sweden, Stockholm, Stockholm, Sweden

Introduction

Finite element human body models (HBMs) are essential for biomechanical injury analysis. Since most HBMs are developed in specific postures (e.g., seated or standing), they need to be repositioned for real-world applications. While existing simulation-based, lightweight physics or interpolation-based methods exist (e.g., [1-4]), they remain computationally intensive and sometimes time-consuming. This study evaluates the potential of several machine-learning approaches for HBM positioning, aiming at near-real-time generation of quality HBM meshes.

Methods

A dataset of 149 manually positioned six-year-old PIPER HBM was generated using the PIPER framework [5] and expanded to more than 1300 postures using controlled augmentation. Three AI models were trained to predict FE nodal coordinates from joint-angle inputs: (1) a Multi-Layer Perceptron (MLP) with noise injection and relative nodal coordinates; (2) a Generative Adversarial Network (GAN); and (3) a Random Forest (100 trees) included for comparison. Training used five-fold random splits (80%/20%). Performance was evaluated using mean squared error (MSE), coefficient of determination (R^2), and mesh quality via Jacobian metrics. Statistical analysis was used to compare and evaluate model performance.

Results

All models showed substantial improvements when increasing the training dataset from 149 to 1300+ poses. The MLP with noise injection and relative node achieved best-case MSE≈ 0.3 mm^2, significantly outperforming its non-noise counterparts. GAN models exhibited preliminary behavior consistent with trends observed for the MLP. Random Forest demonstrated stable performance with $R^2 = 0.86 \pm 0.02$ and MSE = 107.28 ± 13.56 across five independent splits.

Discussion

Noise injection and relative node representation markedly enhanced MLP performance, making it a promising option for HBM positioning. Some positioned HBMs exhibited localized mesh distortion, highlighting the need for future architectural refinement or post-processing to improve local element quality. Overall, this work demonstrates the potential of AI-based methods for near-real-time HBM positioning.

Investigating the Effects of Cerebral Atrophy and Tissue Softening on Brain Deformation Response in Older Adults

Mr. Bashar L. Elkhatib[1], Dr. Aaron Carass[2], Dr. Jerry L. Prince[2], Dr. Ahmed Alshareef[1]

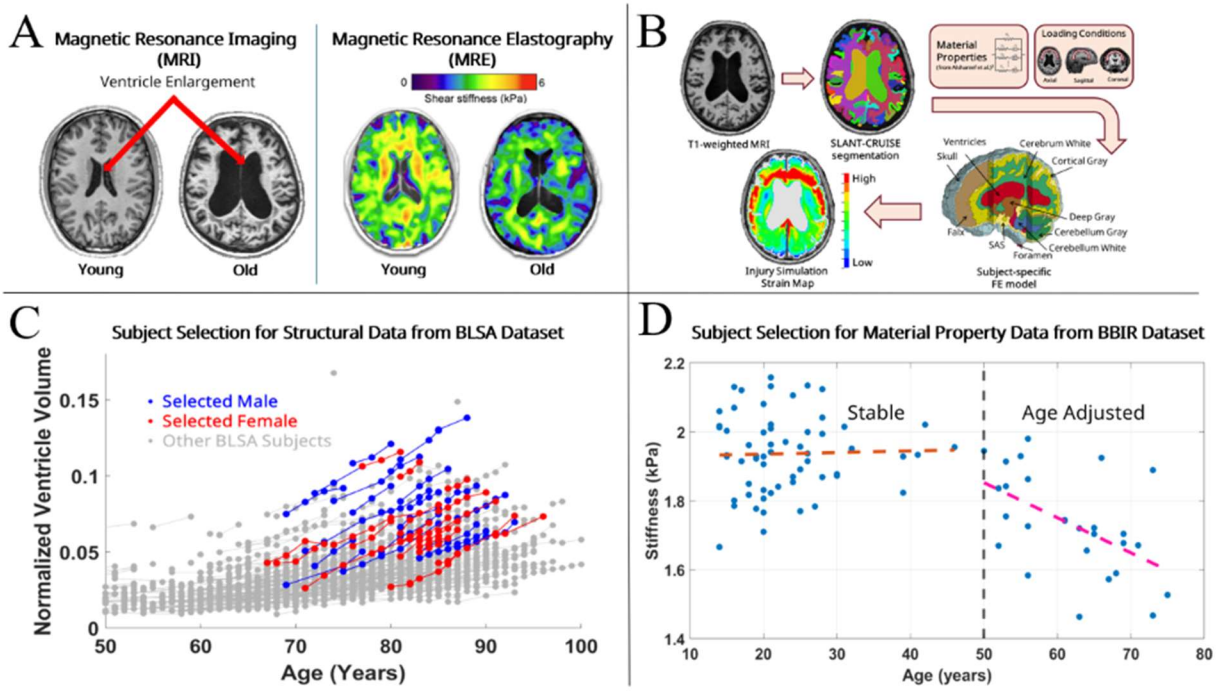
[1]University of South Carolina, Columbia, SC, United States. [2]Johns Hopkins University, Baltimore, MD, United States

Introduction

Traumatic brain injury (TBI) disproportionately affects older adults, who account for most TBI-related hospitalizations and deaths in the United States, mainly due to falls. With healthy aging, the brain undergoes pronounced structural and mechanical changes, including cerebral atrophy, ventricular enlargement, and reduced tissue stiffness (Figure 1A). These alterations can potentially change the vulnerability of the brain to tissue deformations from head impact, yet their influence on biomechanical response remains unclear. This study examines how age-related cerebral atrophy and tissue softening affect brain deformation under rotational loading using subject-specific models.

Methods

Longitudinal T1-weighted magnetic resonance imaging (MRI) data from 40 older adults (68–96 years, 3-5 scans per subject) were used to create subject-specific finite element (FE) models (Figure 1C). Age-dependent material properties were derived from MR elastography (MRE) data of 89 participants from the Brain Biomechanics Imaging Resource (BBIR) (Figure 1D). For each subject, two FE models were generated: a stable model incorporating structural changes alone with middle-age material properties and an age-adjusted model that also incorporated softening of the brain tissue. All models were simulated with a half-sine rotational pulse (peak velocity 40 rad/s, acceleration 5000 rad/s^2) similar to high severity falls onto hard surfaces from a standing height, applied across axial, sagittal, and coronal directions, totaling 960 simulations.



Results

Maximum principal strain (MPS) decreased with increasing normalized ventricle volume, indicating lower global brain deformation with greater atrophy. When material softening was incorporated, MPS values increased significantly relative to the stable models ($p < 0.05$), with softening increasing the deformation and vulnerability of the older adult brain. Models with higher degrees of atrophy showed greater sensitivity to softening, suggesting that geometric and material aging processes interact to shape overall deformation behavior and brain vulnerability.

Discussion

The results demonstrate that structural and mechanical aging exert competing influences on brain deformation during impact. While atrophy appears to reduce strain magnitude, concurrent softening amplifies deformation, leading to greater variability in biomechanical response among older adults. Integrating MRI- and MRE-derived datasets enables a data-driven modeling framework that captures these coupled effects and provides a more accurate representation of the aging brain.

Tract Morphing: A Novel Integration of Finite Element Modelling With Diffusion MRI for White Matter Tract Analysis in Mild Traumatic Brain Injury With Multimodal Fusion

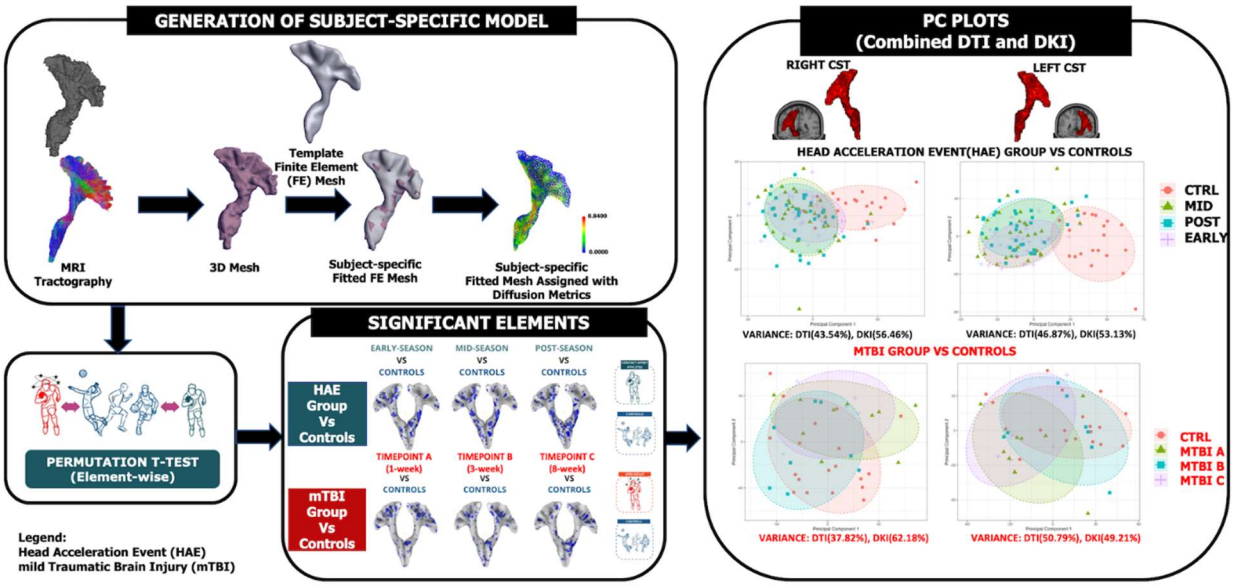
Introduction

Diffusion MRI (dMRI) enables in-vivo investigation of brain's microstructural organisation, but conventional analysis aggregates complex microstructural information, discarding significant spatial variation. To overcome this, a novel framework is introduced that projects the full voxel-wise dMRI metrics onto a subject-morphed finite element (FE) model, conforming to the subject-specific tract geometry and fibre orientation to preserve microstructural detail and enable fine-grained analysis. We applied this method to investigate effects of head acceleration events (HAE) and mild traumatic brain injury (mTBI) in rugby players on the corticospinal tract (CST) which is mostly implicated in sports-related head injuries.

Methods

Thirty-three male high school rugby players (HAE group) underwent multi-shell dMRI brain scan (3.0T GE Scanner) at early, mid-, and post-season. Ten rugby players with in-season mTBI were scanned at 1, 3, and 8 weeks post-injury. Twenty age and sex-matched non-contact-sport athlete controls were scanned once. dMRI were preprocessed, and diffusion tensor (DTI) and kurtosis (DKI) metrics were extracted. Fibre orientation distributions were estimated, and bilateral CST was segmented using TractSeg. A tetrahedral FE CST template (TetGen) was free-form deformed to each CST's mask, and nearest-neighbour mapping assigned all DTI and DKI metrics to each FE node. Permutation t-tests identified elements

showing significant group differences, and principal component analysis (PCA) was used to visualise clustering across groups and timepoints.



Results

Permutation testing revealed bilateral CST regions with significant and temporally increasing differences between controls and the HAE group across the season. In controls vs. mTBI, significant regions increased along the spine but decreased in the crown from Timepoints A to C. PCA (PC1–PC2) demonstrated separable clusters for both comparisons, with DTI and DKI contributing similarly to variance. HAE clusters overlapped across timepoints, whereas mTBI clusters showed partial separation from 1 week to 8 weeks, indicating evolving post-injury microstructural changes.

Discussion

This framework preserves maximum dMRI data within subject-specific FE models, enabling sensitive, localized detection of HAE/mTBI alterations. Morphing a common FE model increases inter-subject comparability priming outputs for machine-learning integration. In addition, this model can be extended to multimodal data fusion (e.g., strain) for inclusion in analysis, making it a powerful tool for comprehensive analysis.

Multi-Site Wearable Ultrasound for Tracking Neuromuscular Adaptation in ACL Rehabilitation: A Pilot Study

Dr. Erica L. King Ph.D., Ms. Morgan Lamarre M.S., Mr. Connor Delaney M.S., Dr. Qi Wei Ph.D., Dr. Siddhartha Sikdar Ph.D., Dr. Margaret T. Jones Ph.D., Dr. Parag V. Chitnis Ph.D.

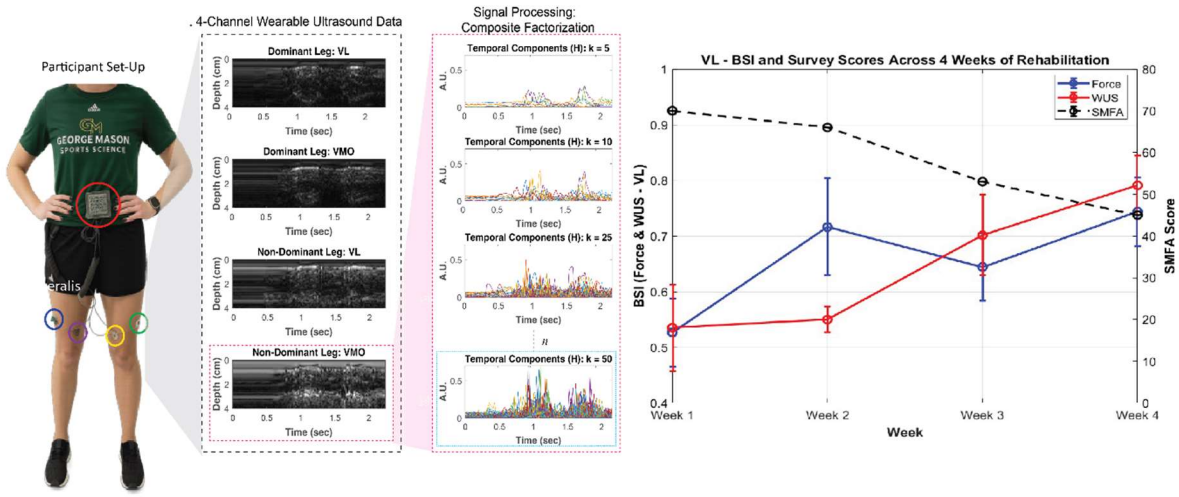
George Mason University, Fairfax, VA, United States

Introduction

Anterior cruciate ligament (ACL) injuries often lead to significant quadriceps weakness and asymmetry, which can impair knee stability and delay functional recovery. Musculoskeletal ultrasound (MSK-US) can provide real-time assessment of muscle activity during rehabilitation. However, conventional MSK-US relies on handheld, single-site probes that are bulky, operator-dependent, and unsuitable for dynamic tasks. To address these limitations, this study introduces a wearable ultrasound (WUS) system designed for hands-free monitoring of muscle function during movement. The system employs multiple transducers positioned over key muscles, enabling simultaneous acquisition of quantitative biofeedback signals for bilateral assessment.

Methods

A custom four-channel Time Delay Spectrometry Ultrasound (TDS-WUS) system was developed to capture M-mode data during rehabilitation exercises. The system transmitted 20-ms frequency sweeps (3–5 MHz) and recorded echo signals at 50 lines/s from transducers placed bilaterally over the vastus lateralis (VL) and vastus medialis oblique (VMO). Automated processing using Composite Factorization Principal Component Analysis (CF-PCA) extracted contraction dynamics and computed a muscle-specific bilateral symmetry index (BSI). One subject with a left ACL-III tear was monitored weekly for four weeks during three trials of bilateral bodyweight squats. Instrumented insoles measured plantar force, and a modified SMFA survey assessed functional status. Data were analyzed using repeated-measures ANOVA ($p = 0.05$).



Results

Results showed a significant main effect of day on plantar force ($F(3,15) = 24.35$, $p < 0.001$), with Week 1 values significantly lower than Week 2 and 4. VL-BSI also improved significantly across sessions ($F(3,6) = 16.22$, $p = 0.003$) with Week 1 lower than Week 3 and Week 3 lower than Week 4, while VMO-BSI changes were not significant. SMFA scores improved from 70 to 45, paralleling objective measures of force and symmetry.

Discussion

This pilot study demonstrates the feasibility of WUS for tracking muscle function symmetry during ACL rehabilitation. Unlike traditional MSK-US, WUS enables simultaneous, hands-free monitoring of multiple muscles during dynamic tasks, providing richer insights into neuromuscular adaptation. While limited by a single-subject design and short duration, these findings support further validation in larger cohorts and expansion to additional muscle groups. WUS offers a scalable, real-time solution for personalized rehabilitation and remote monitoring.

Objective Free-Living Metrics Challenge Traditional Prosthetic Classification Standards

Mrs Sydney Lundell M.S., Dr. Kenton Kaufman PhD, P.E.

Mayo Clinic, Rochester, MN, United States

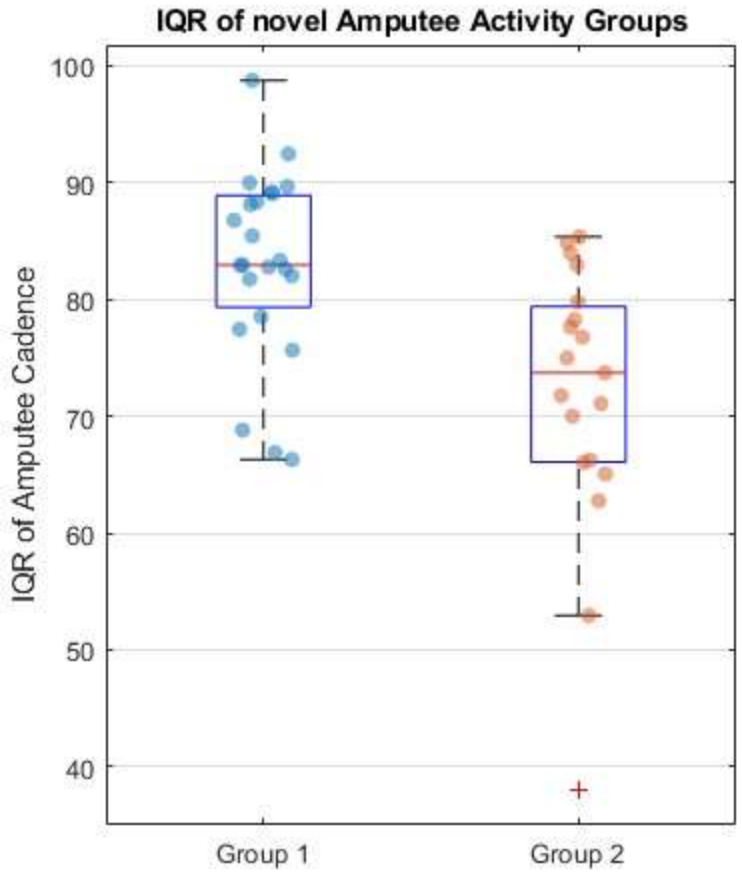
Introduction

In the United States, the Medicare Functional Classification Level (K-Level) scale, (K0-K4) reflects a patient's functional mobility potential and ability to safely ambulate using a prosthesis. K-levels guide insurance coverage for prosthetic components, but no gold standard exists, making classification subjective and reliant on clinician judgment. K1/2 individuals typically receive mechanical components with fixed resistance, while K3/4 individuals are provided advanced devices that adapt joint resistance in response to changes in walking speed. The primary distinction between K2 and K3 is the ability to ambulate with variable cadence. Falls in K2 users decrease significantly with microprocessor-controlled knees, yet clinical walking tests fail to capture real-world function. The goal of this study was to determine whether objective free-living data can classify functional mobility in this population.

Methods

The cohort included 51 amputees rated K2–K4 (male 27; 54±15.6 years). They wore tri-axial accelerometers on the ankles and waist for three days. Metrics for activity [1] and cadence [2] were calculated and averages for each metric was calculated for a total of 60 unique metrics. These metrics were then fed into an unsupervised Self-Organizing Map over a 5×5 neuronal grid for 500 epochs. Subjects were grouped according to resulting topological clusters.

Results



Two distinct clusters were identified across the 51 amputees. The strongest differentiator was the average interquartile range of cadence ($p = 0.001$; Figure 1), followed by percentage of the day spent static ($p = 0.027$). Cluster grouping did not correspond to K-levels.

Discussion

Our results indicate that real-world activity patterns among amputees differ from traditional K-level classifications and instead consist of two groups. Both groups ambulate

with a variable cadence; with the range of variability across three days having no direct relationship to K-level. K-levels had no significance in amputee cadence variability. These findings raise important questions about the adequacy of K-levels as the sole determinant for prosthetic prescription coverage, suggesting a new clinical direction that leverages wearable sensors to improve prescription and subsequently reduce fall-related healthcare costs.

Wearable Sensor Calibration for Sports Knee Injury Rehabilitation

Ms. Rosalind Bendell B.S., Mr. Joey Scilla, Dr. Sagar Doshi Ph.D., Dr. Erik Thostenson Ph.D., Dr. Jill Higginson Ph.D.

University of Delaware, Newark, Delaware, United States

Introduction

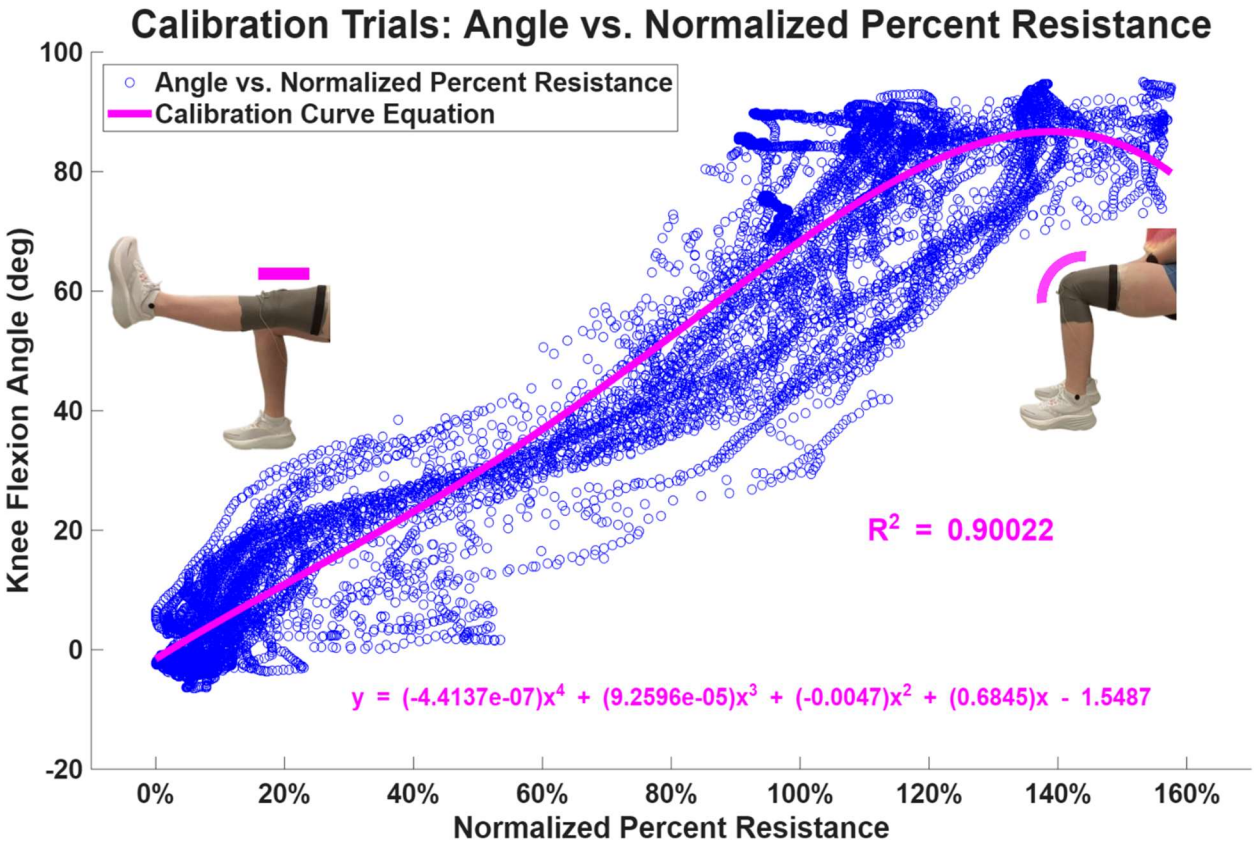
Wearable sensors have the potential to help prevent injury and monitor rehabilitation progress beyond laboratory settings. Our collaborators have developed carbon nanocomposite sensors that change electrical resistance when elongated[1]. These sensors are integrated into a compressive knee sleeve - the Smart Sleeve - to measure knee flexion angle (KFA). Our objectives are to calibrate the Smart Sleeve to measure knee angles during movement and validate the Smart Sleeve accuracy.

Methods

In this IRB approved study, participants (n=4, 1F, 3M) were outfitted with the Smart Sleeve (centered over the right knee) and retroreflective motion capture markers. Participants performed a sensor calibration trial of five seated leg extensions with KFA from 0° at full extension to approximately 90° and holds at 0° and 90°. Next, participants performed four validation trials, three consisting of 20 seated leg extensions and one 30 second walking trial at 1.0 m/s between the second and third validation trials. Motion capture data (Qualisys, 100 Hz) and sensor resistances (ohms, 20 Hz) were collected.

The percent change in resistance was normalized to recorded resistance values at 0° (baseline). For seated leg extension validation trials, a 4^{th} order polynomial equation was used to fit knee angles to sensor resistance measurements from the calibration trial. The calculated knee angles were compared to the experimental knee angles from the validation trial. A linear regression between experimental and calculated angles was applied to evaluate Smart Sleeve accuracy.

Results



The calibration equation (normalized percent resistance in ohms to degrees) for each participant had an R^2= 0.932±0.067 and RMSE=7.396±3.247°. When the calibration equation was applied to a seated leg extension validation for each participant, the linear

regression had R^2 = 0.942±0.029 and RMSE=7.865±1.901°. The calibration equation for all participants (Fig.1) had R^2=0.90022 and RMSE=10.885°.

Discussion

Linear regression R^2 values indicate a high angle detection accuracy. This work shows calibration of the Smart Sleeve to measure KFA during seated leg extensions. Future work will continue collecting data for this protocol. Then, we will calibrate and validate the Smart Sleeve for walking, running, and jumping for sports motion tracking during knee injury rehabilitation.

Capturing Individual Recovery Trajectories After ACL Injury Using Principal Component-Derived Countermovement Jump Data

Ms. Tamar D. Kritzer, Dr. Dylan Kobsar

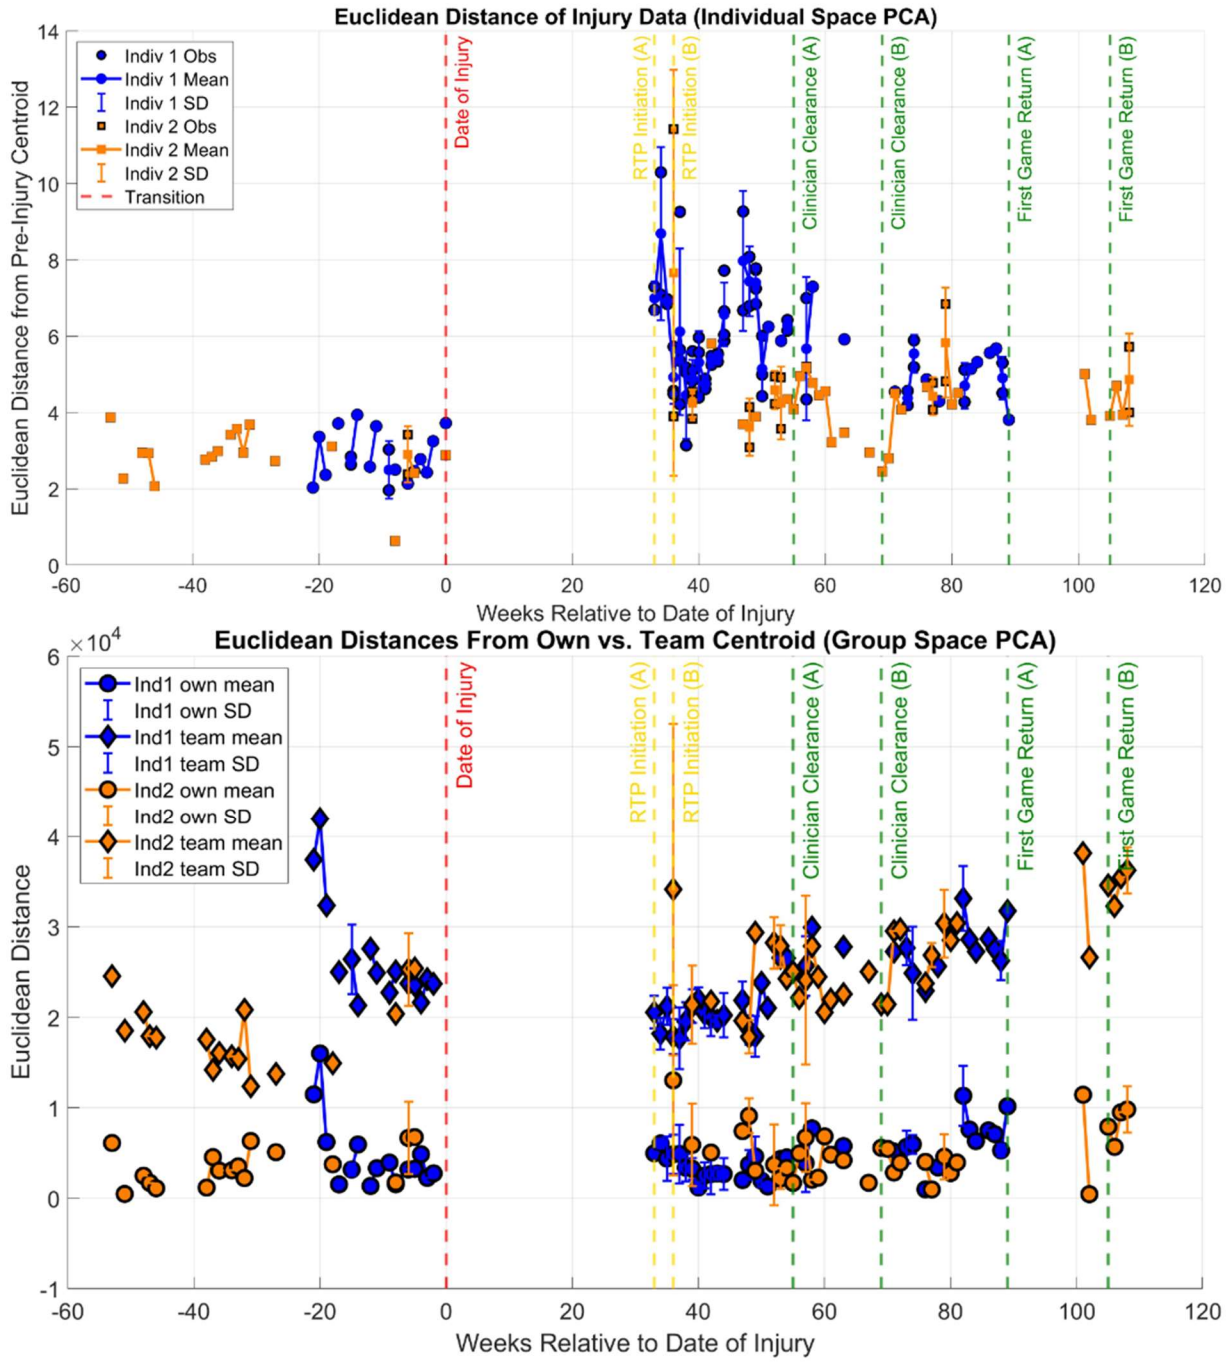
McMaster University, Hamilton, Ontario, Canada

Introduction

Anterior cruciate ligament (ACL) tears are among the most common and severe knee injuries in sports, leading to more than 400,000 reconstructions and costing approximately $3 billion annually across North America [2,4]. Despite surgical intervention, only 50–65% of athletes return to their previous level of competition, often at reduced performance and elevated risk of re-injury [1,3]. Current return-to-play (RTP) protocols remain largely generalized and emphasize subjective performance benchmarks, while overlooking continuous biomechanical and neuromuscular factors [1,3]. This study presents an approach that captures individualized, sex-specific recovery patterns to inform more evidence-based RTP decision-making.

Methods

Varsity women's basketball athletes (n = 14) completed weekly countermovement jumps (CMJs) throughout a full season. Two athletes sustained ACL injuries and were tracked through recovery. CMJs were recorded using a dual force plate system (Hawkin Dynamics, ME, USA) following a 5-minute warm-up. Weekly averages were computed for jump height and biomechanical force-time metrics. Recovery trajectories were quantified using principal component analyses of nine primary CMJ metrics (e.g., Jump Height, Time-To-Takeoff, mRSI, Left/Right Peak Braking and Propulsive Force, and Left/Right Average Braking RFD) applied at both the individual and team levels. Euclidean distances from each athlete's postoperative observations to their pre-injury or team-based centroids served as change metrics and were modeled over time to characterize recovery patterns.



Results

Distances between postoperative observations and each athlete's individual centroid showed deviation from pre-injury patterns and heightened day-to-day variability during return-to-play, with a progressive trajectory toward pre-injury values. In contrast, trajectories referenced to team-based centroids masked these deviations and recovery patterns, illustrating how generalized benchmarks can overlook meaningful individual differences, thereby emphasizing the need for personalized assessment (Figure 1).

Discussion

Individualized monitoring of ACL recovery using holistic PCA-derived CMJ patterns reveals athlete-specific deficits that may serve as an overarching indicator of return to pre-injury form. This approach has the potential to improve evidence-based decision-making, reduce re-injury risk, and optimize performance outcomes.

Task-Independent Continuous Prediction of Whole-Body and Segmental Balance during Multi-Terrain Ambulation Circuits

Ms. Marissa Pirritano, Ms. Juliana Iverson, Dr. Nicholas Fey

University of Texas at Austin, Austin, TX, United States

Introduction

Accurately quantifying whole-body angular momentum (H) and its segmental contributions offer biomechanical insight into balance control during ambulation. Current methods to evaluate H typically rely on expensive motion capture systems that are restricted to a confined tracking space. Previously, linear acceleration and angular velocity data derived from motion capture have been used to represent *signals* from a sparse set of inertial measurement units (IMUs) and when combined with machine learning, segmental contributions to H were accurately predicted [1]. This suggests that a sparse set of IMUs could enable accessible and quantitative assessment of balance in real-world settings. To validate this approach, we apply temporal convolutional networks (TCNs) to predict segment-level contributions to H using data collected from wearable IMU *sensors*.

Methods

Six able-bodied participants were instrumented with five 9-axis IMUs: one placed on the dorsal aspect of each wrist, one superior to each lateral malleolus, and one over the sternum. Each participant traversed a multi-terrain circuit comprised of a five-step staircase, raised level platforms, and a 2.5 m ramp. Each participant completed the circuit a total of 140 times over 7 trials. Kinematics were obtained using a markerless motion capture system. Ground truth segmental contributions to H were computed about the body center of mass and expressed in the pelvis reference frame. A TCN was trained on the IMU data to predict the 3D contributions to H from five body segments (each leg, each arm, and the trunk) for each participant. Performance was evaluated using RMSE between the sum of the segmental predictions and ground truth H per axis (X-sagittal, Y-frontal, and Z-transverse) on held out circuit laps.

Results

Across participants, the mean RMSE (m/s) was 0.0273 ± 0.0030 for the X-axis, 0.0275 ± 0.0058 for the Y-axis, and 0.0121 ± 0.0018 for the Z-axis.

Discussion

These results further demonstrate that a small set of wearable IMUs can reliably predict H across tasks. This approach provides a practical method for “real-world” assessment of dynamic balance which could additionally be leveraged to provide real-time feedback for human-in-the-loop control of exoskeletons and prostheses.

Images (Optional)

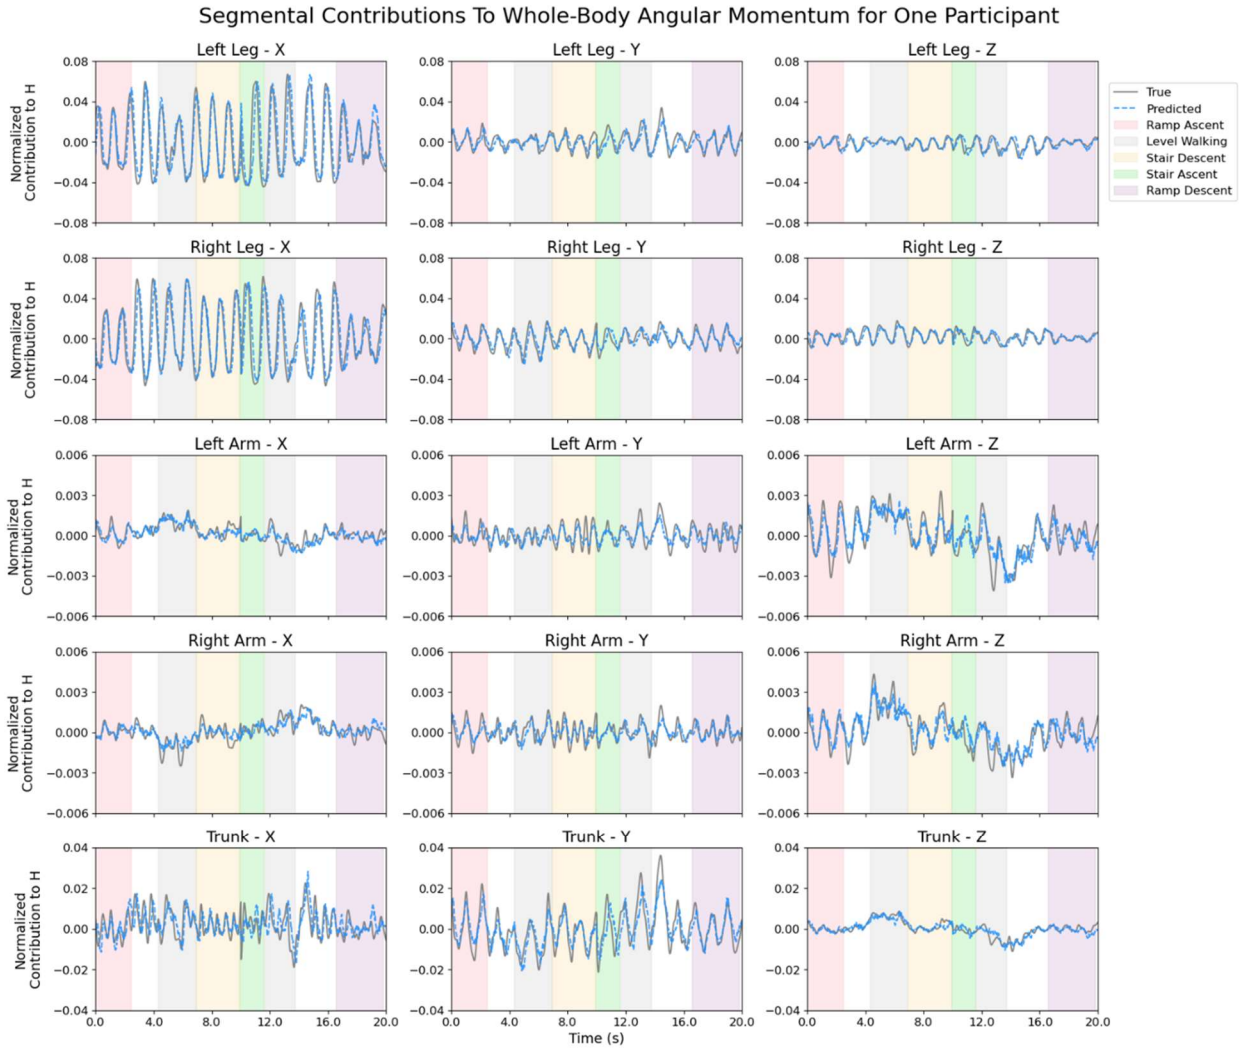

Figure 1: Comparison of ground-truth (gray) and predicted (blue) segmental contributions to whole-body angular momentum (H) during various locomotor tasks (shaded regions). The segmental contributions to H have been normalized by subject mass and height. Please note different scales across segments.

An AO Classification-Based Virtual Testing Framework for Mechanobiological Evaluation of Tibial Shaft Fracture Healing and Fixation Strategies

M.Sc Felix Scherf, M.Sc Robin Reinardt, B.Sc. Yana Böhr, Dr. rer. nat. Michael Roland, Prof. Dr.-Ing. Stefan Diebels

Applied Mechanics, Saarland University, Saarbrücken, Saarland, Germany

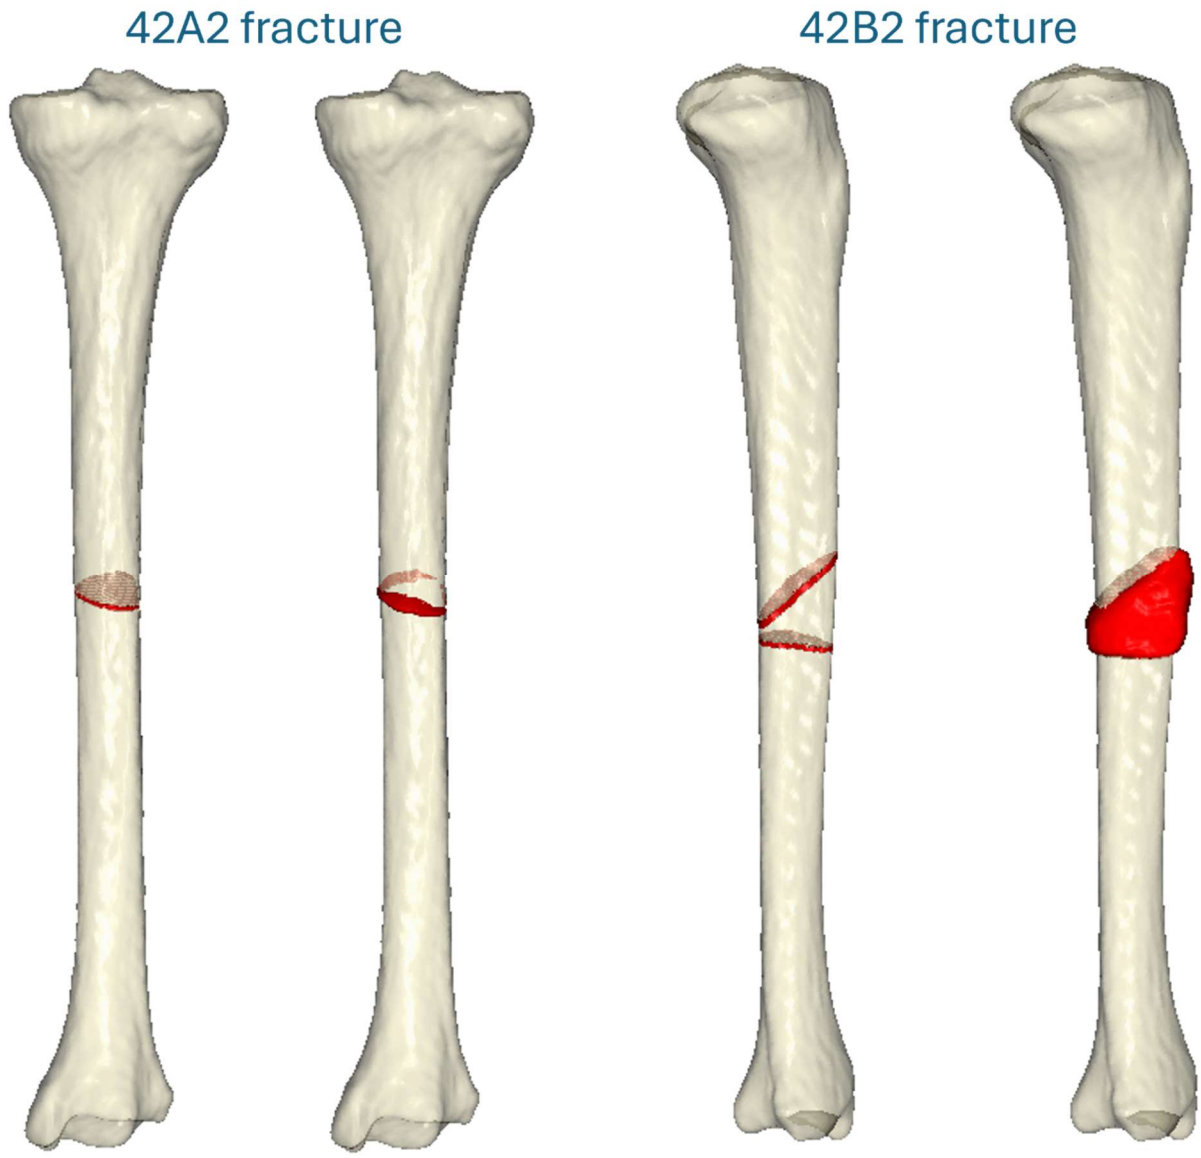
Introduction

Fracture healing is driven by coupled mechanical and biological processes and is sensitive to the local mechanical environment [1,2]. To systematically study how implants and fixation strategies influence this process, standardized tibial fracture configurations based on AO/OTA patterns are required [3]. We present a virtual testing framework that uses artificially created, AO-classified tibial shaft fractures to analyse the mechanobiological impact of different implants and fixation constructs.

Methods

A finite element–based mechanobiological model was implemented in COMSOL® Multiphysics with LiveLink™ for MATLAB®, building on our own developed established mechanoregulation concepts for tissue differentiation [1,2]. As shown in figure 1, based on a statistical shape model of the tibia, three-dimensional bone geometries were generated and assigned AO/OTA tibial fracture patterns and callus geometries according to the current classification system [3]. For each virtual fracture, multiple fixation concepts (e.g. plate configurations, screw layouts, working lengths) were created, yielding a library of implant–fracture combinations. Quasi-static structural analyses provided the local mechanical environment for each construct under physiological loading [1–3]. These mechanical stimuli were coupled to partial differential equations describing tissue differentiation and key biological regulators. Temporal changes in tissue properties updated the structural analyses, capturing the evolving fracture stiffness. MATLAB® scripts automated model generation, parameter variation, and post-processing, enabling systematic comparison of implants across tibial fracture types.

Results



The framework produced consistent, anatomically plausible tibial AO-fracture geometries and fixation constructs. Mechanical indicators relevant for healing, such as interfragmentary motion and strain, varied systematically between implant designs,

fracture classes, and loading conditions. Simulated tissue differentiation patterns reflected these differences, revealing construct-specific trends in predicted tissue matrix formation, cortical bridging, and risk of delayed or asymmetric healing.

Discussion

The proposed virtual fracture workflow enables standardized, AO-based in silico testing of implants and fixation strategies for tibial fractures without relying on patient-specific imaging. Future work will expand the catalogue of tibial fracture types and implants, refine biological submodels, and investigate how virtual trial results can support preclinical implant assessment, design optimization, and clinical fixation planning.

[3]Chair of Artificial Intelligence in Healthcare and Medicine, TUM School of Computation, Munich, Bavarian, Germany. [4]AQ Solutions GmbH, Cologne, North Rhine–Westphalia, Germany

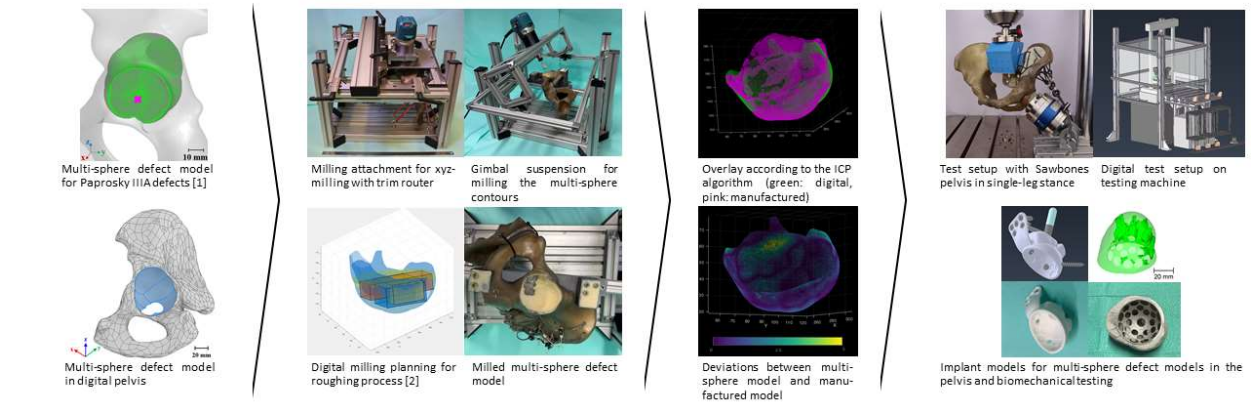
Introduction

Acetabular defects that arise during hip revision surgery are highly patient-specific, which makes it challenging to establish reproducible experimental conditions for evaluating revision implants and treatment strategies. This study addresses this limitation by presenting a computational–experimental framework that generates geometrically standardised acetabular defect models and transfers them to pelvic specimens. This enables controlled and comparable biomechanical testing.

Methods

From a dataset of 18 female revision cases, a geometrically defined multi-sphere model representative of Paprosky IIIA defects was generated (Fig.(a)) using a previously developed computational workflow for 3D reconstruction after revision arthroplasty [1]. A milling setup was designed to implement this digital defect model into pelvis specimens (Fig.(b)), supported by positioning aids and stop geometries to ensure accurate execution. The setup comprises a tilting xyz-milling attachment for linear toolpaths and a gimbal suspension for producing the multi-sphere contours. To validate the accuracy of the manufacturing process (Fig.(c)), three 3D-optical scans (Miraco, Revopoint) were performed after milling and evaluated using a custom MATLAB-based ICP deviation analysis tool [2]. Additionally, a biomechanical test setup was developed on a hydraulic tensile–compression testing machine (Zwick) to enable standardised evaluation of revision implants (Fig.(d)).

Results



Analysis of the patient dataset yielded a geometrically standardised, multi-sphere defect model that is representative of Paprosky IIIA morphology (Fig.(a)). The defect model

consists of six spheres with an equal diameter of 23.64 mm, and provides a reproducible and scalable representation of bone loss patterns. The deviation analysis between the digitally defined multi-sphere model and the manufactured defect model demonstrated a mean geometric deviation of 0.88 ± 0.21 mm. This confirms that the geometry of a multi-sphere acetabular defect can be reproduced with high accuracy.

Discussion

The results show that the proposed multi-sphere defect model is robust, scalable and experimentally manufacturable, providing a standardised geometric basis for biomechanical investigation of acetabular revision cases. This approach establishes reproducible conditions for systematic implant testing and paves the way for future comparative studies involving artificial pelvises and human specimens in hip revision arthroplasty.

Implant Design Affects Knee Kinematics During Chair Rise After Total Knee Arthroplasty

Mr. Tom Gale[1], Ms. Lauren Gross[1], Dr. Kenneth Urish[2], Dr. William Anderst[1]

[1]University of Pittsbugh, Pittsburgh, PA, United States. [2]UPMC, Pittsburgh, PA, United States

Introduction

Total knee arthroplasty (TKA) surgery has a reported dissatisfaction rate of up to 20%. One unexplored possible cause of dissatisfaction is knee kinematics asymmetry post-TKA. TKA implant designs, such as posterior stabilized (PS), medially congruent (MC), and cruciate retaining (CR), are believed to affect post-TKA kinematics. However, the association between outcomes and bilateral symmetry in kinematics after receiving these prostheses remains unknown. This study compared the kinematics asymmetry post-TKA for CR, PS, and MC designs and explored relationships between patient-reported outcomes and asymmetry. We hypothesized that CR-TKA, which retains the native cruciate ligaments, would lead to better symmetry than PS- or MC-TKA.

Methods

Participants undergoing TKA using the same robotic system were recruited for this IRB approved study. Both knees were imaged using dynamic biplane radiography at 100Hz during a chair rise activity 12 months post-surgery. A validated tracking method was used to track bone and implant motion with accuracy better than one millimeter in translation and one degree in rotation. Six degree-of-freedom kinematics were calculated and expressed relative to tibiofemoral flexion. The side-to-side difference (SSD) in kinematics waveforms post-TKA were compared among implant designs using SPM 1-way ANOVA with a post-hoc t-test, and the association between average SSD and patient-reported KOOS scores were tested using Spearman's correlation.

Results

7 CR, 13 PS, and 9 MC participants were included. The anterior-posterior (AP) translation SSD after CR was significantly greater than after MC during deep flexion ($p<0.001$)(Figure 1). No other differences in SSD were detected. No correlation between average SSD and KOOS scores were detected (mean scores 74.5+/-8.0 vs 63.3+/-11.7, CR and MC respectively).

Discussion

The differences found in AP translation SSDs between the MC and CR designs suggest that the MC design replicates native knee kinematics most closely while the CR design was the least similar. This may indicate that geometrically constrained implant designs are more capable of restoring native knee-like kinematics rather than relying on partial and possibly degenerated soft tissues surrounding the joint. Although no correlation between post-TKA KOOS scores and AP SSD were detected, other activities of daily living with differing loads and flexion angles need to be investigated.

Images (Optional)

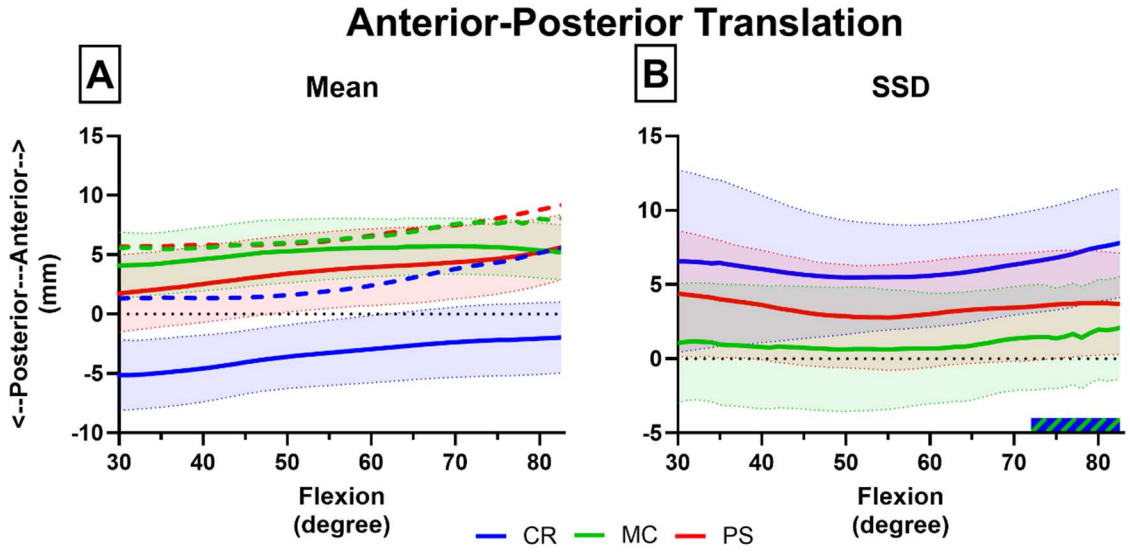

Figure 1: A) Mean tibial anterior-posterior translation relative to femur is shown, with solid lines indicating post-TKA kinematics with the shaded regions for standard deviation and dashed lines indicating native contralateral kinematics. B) The SSD for each group, with the two-toned dashed lines indicating angles of significant differences between CR and MC.

[7]Department of Engineering, Faculty of Science, Technology and Medicine, University of Luxembourg, Luxembourg, Luxembourg, Luxembourg. [8]School of Sport, Rehabilitation and Exercise Sciences, University of Essex, Colchester, Essex, United Kingdom

Introduction

The accurate assessment of wear rates in total hip arthroplasty is essential for estimating implant longevity [1]. Current implants are predominantly tested under pure walking conditions, although other high-impact activities may impose additional wear [2]. Incorporating activities such as running into preclinical evaluation could yield predictions that align more closely with clinical outcomes. This study aimed to characterise the effect of running compared to walking on wear in total hip replacements (THRs).

Methods

Wear rates for CoCr-on-XLPE THRs under walking and running were analysed for 11 participants (55.9[9.8] years) with a THR using explicit finite element analysis in LS-DYNA. Each simulation ran for 5 million cycles (Mc) [3]. Archard wear law was employed to predict sliding wear, with worn geometry updated after each simulation using a 250,000-cycle scaling factor. Joint loadings were estimated from motion data using musculoskeletal simulations in AnyBody for each participant.

Results

Across subjects, cumulative linear wear over 5 Mc ranged from 0.236–0.421 mm during walking and 0.382–1.036 mm during running. Mean linear wear rates were 0.064 ± 0.012 mm/Mc (walking) and 0.115 ± 0.037 mm/Mc (running), an ~1.8-fold increase during running. Cumulative volumetric wear was 143.90–276.80 mm^3 for walking and 258.86-777.82 mm^3 for running, with the mean rising from 207.76 ± 41.37 to 412.15 ± 146.95 mm^3 (1.98× higher). Mean contact area increased from 645 ± 39 mm^2 (walking) to 714 ± 51 mm^2 (running), indicating greater loading and variability during running.

Discussion

Relative to the commonly cited critical wear threshold of 0.1 mm/Mc for polyethylene cups [3], mean linear wear during walking was 35–40% below the limit, whereas running exceeded it by ~15%. This shows that high-impact activities substantially elevate wear risk and may contribute to aseptic loosening through periprosthetic osteolysis. Wear predictions based solely on walking therefore underestimate true loading exposure. Comprehensive assessments should incorporate multiple daily activities, including running. Ongoing work in our group is examining how realistic activity combinations influence long-term implant wear.

Images (Optional)

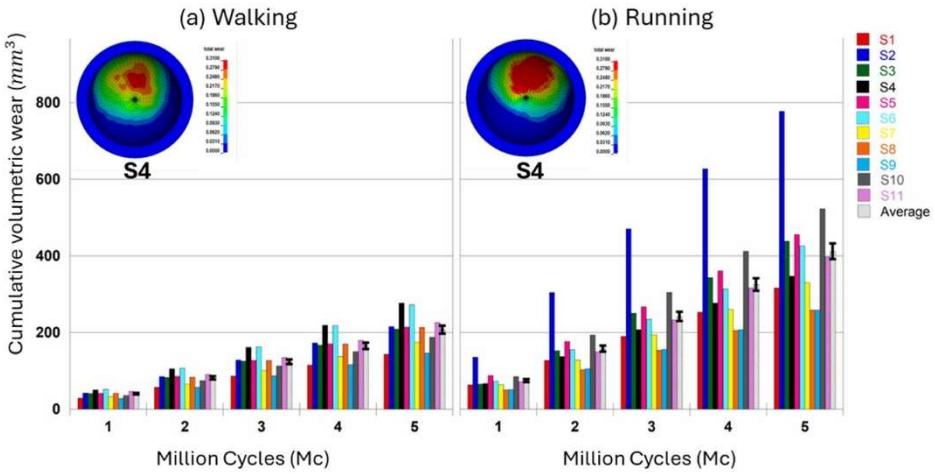

Figure1. Cumulative volumetric wear under five million cycles of walking (a) and running (b) for all subjects. The distribution of the volumetric wear is also illustrated for a representative case (S4)

Video-Based Hip Kinematic Analysis and Machine Learning for Screening of Sarcopenia During the Five Times Sit-to-Stand Test

Ms Hejin Cai[1], Mr Jialiang Xu[1], Dr Guoxin Zhang[2], Dr Tony Lin-Wei Chen[1], Ms Linjuan Wei[1], Dr Qitao Tan[1], Prof Ming Zhang[1]

[1]The Hong Kong Polytechnic University, Hong Kong, Kowloon, Hong Kong. [2]Beihang University, Hangzhou, Zhejiang, China

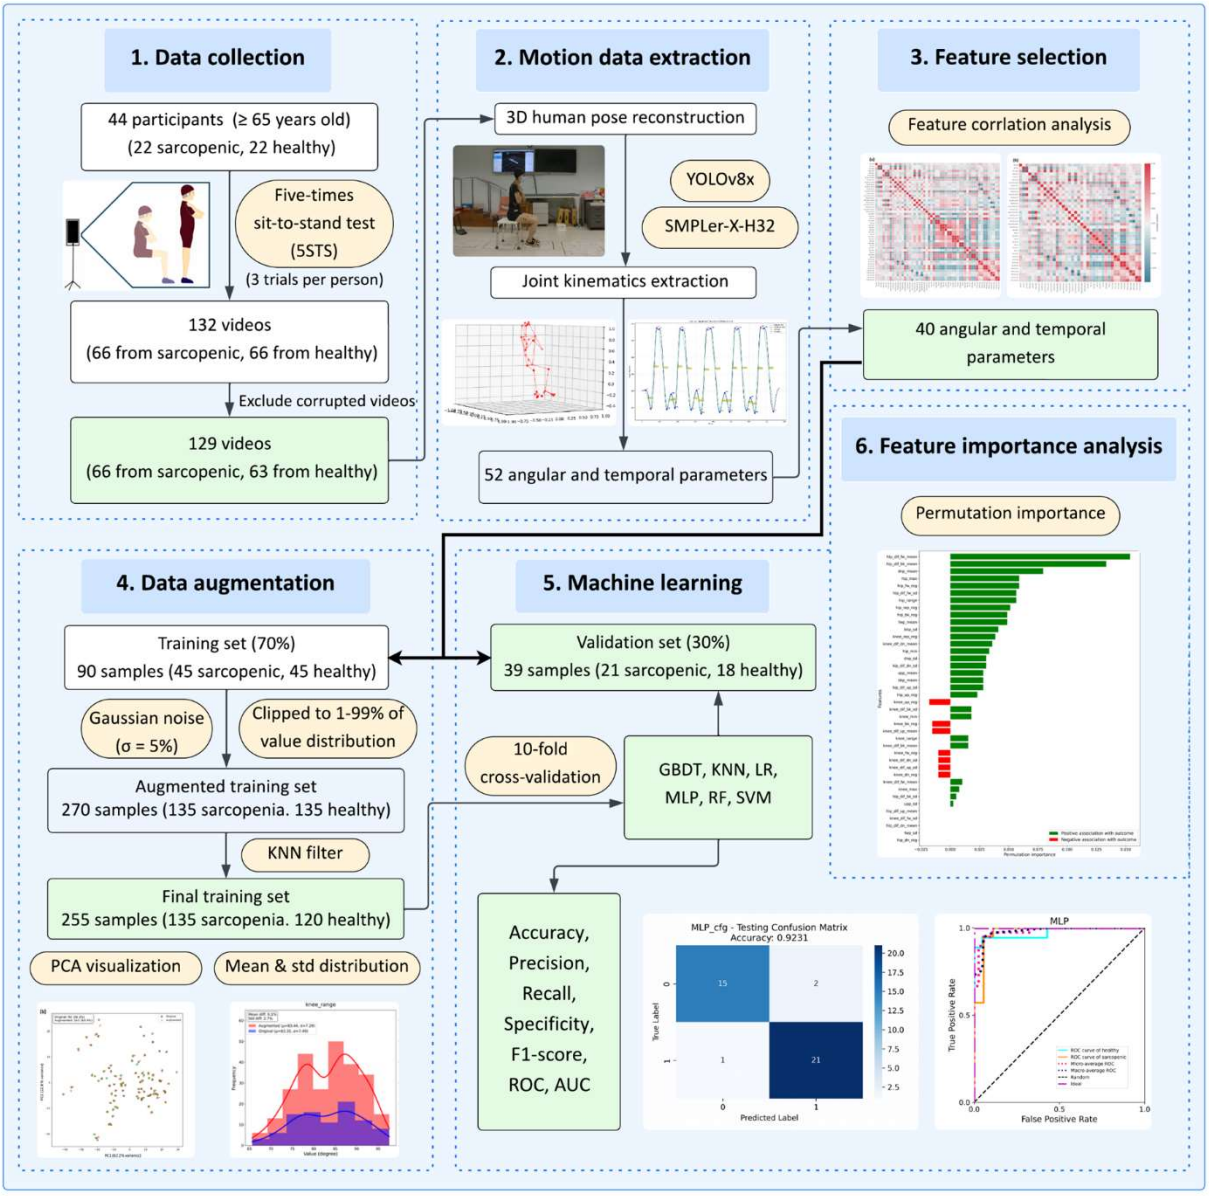
Introduction

Sarcopenia leads to marked impairments in lower-limb strength and movement control in the aging population. The five-times sit-to-stand (5STS) test is widely used in clinical assessment of sarcopenia, but stopwatch-based timing of the test often lacks the sensitivity to detect subtle, joint-level functional deficits indicative of early-stage disease. This study aimed to examine whether smartphone video-derived kinematics combined with interpretable machine learning can accurately distinguish sarcopenia from healthy older adults and identify key movement predictors of the condition.

Methods

Forty-four adults aged ≥65 years (22 sarcopenic, 22 healthy) each performed three standardized 5STS trials recorded by a smartphone. Object detection and pose estimation algorithms (YOLOv8 and SMPLer-X) provided 3D hip and knee kinematics. Each sit-stand-sit cycle was segmented into forward, upward, downward, and backward phases, from which 40 biomechanically interpretable angular and temporal features were extracted. Training and validation sets were split at the participant level (7:3). A physiologically constrained augmentation strategy with Gaussian noise and KNN-based label filtering expanded the training dataset to 255 samples. Six classifiers (GBDT, KNN, LR, MLP, RF, and SVM) were trained using 10-fold cross-validation. Performance metrics included accuracy, recall, specificity, F1-score, and AUC. Feature importance was quantified using permutation analysis. The top 10 features were further statistically compared between groups.

Results



Augmented samples preserved the distribution of original features without forming artificial clusters. The multilayer perceptron (MLP) achieved the strongest performance (validation accuracy: 0.95; recall: 1.00; specificity: 0.89; AUC: 0.98). Hip-related variables

were the most discriminative biomarkers. Greater hip range of motion in the forward (12.48° vs. 8.05°, p=0.010) and backward phases (11.48° vs. 6.78°, p=0.019) showed the strongest predictive value.

Discussion

Smartphone video-based 3D motion analysis offers a feasible, low-cost method for capturing joint-level biomechanics relevant to sarcopenia. The proposed augmentation strategy preserved physiological plausibility and improved classifier performance. The findings emphasize the central role of altered hip motion, particularly enlarged forward- and backward-phase hip range of motion, as a compensatory strategy in sarcopenia. This pipeline demonstrates the potential of accessible motion analysis and machine learning to offer a scalable, precise, and objective tool for early sarcopenia screening in both clinical and community settings.

World-Grounded 3D Pose Estimation for Marker-Less Motion Analysis in Children

Ms. Josephine Wang, Mr. Daniel Seong, Dr. Nidhi Seethapathi

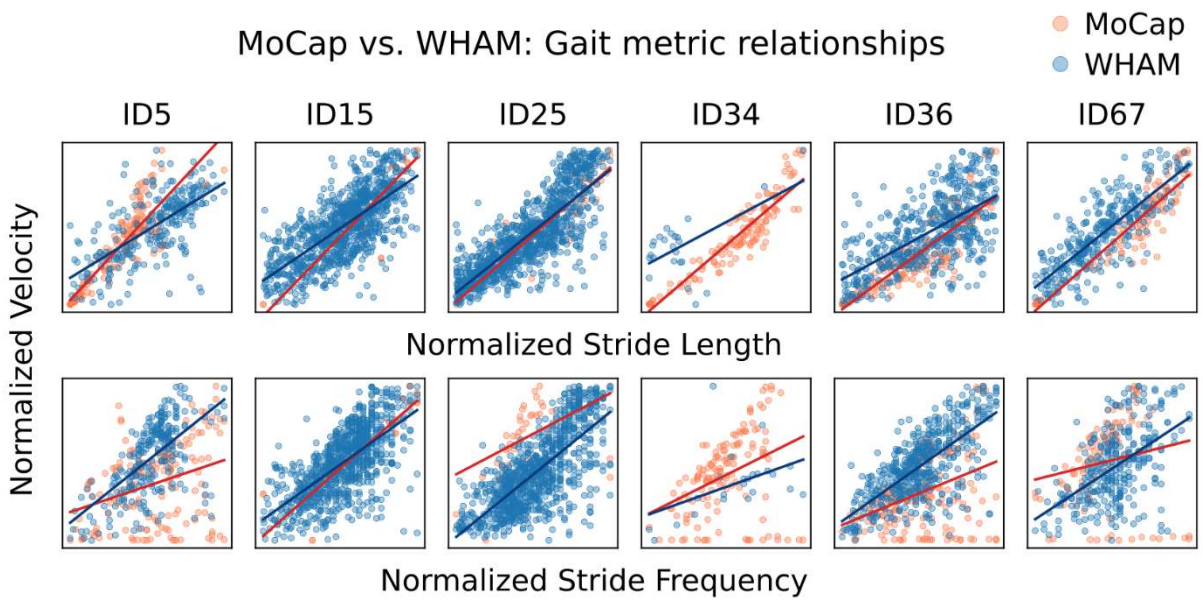
Massachusetts Institute of Technology, Cambridge, MA, United States

Introduction

Motor development research is limited by the cost and practical challenges of using motion capture with young children. Recent work shows that marker-less video-based approaches recover clinically acceptable lower limb kinematics, but assume stationary cameras [1], while at-home videos of children tend to have a moving frame. Here, we develop and validate a computer vision (CV) pipeline that extracts world-grounded 3D pose estimation from videos of children, including ones with moving cameras.

Methods

Videos of 6 children were processed with WHAM to extract 3D keypoints in a world frame [2]. For comparison, we ran AlphaPose and MotionBERT to characterize movements in the camera frame [3, 4]. The child was identified in each clip via manual bounding boxes labeled in CVAT, and adult individuals were masked with opaque overlays. From the tracked heel trajectories, we applied Savitzky-Golay filtering and peak detection to identify heel strikes, then computed stride length, stride frequency, and walking speed to compare their relationships with those obtained from ground truth motion capture (MoCap). To validate the CV-inferred heel strikes, we manually labeled left and right step events.



Results

Across all CV methods (WHAM, AlphaPose, and MotionBERT), we found that stride length was more strongly correlated with walking speed than stride frequency, consistent with MoCap (MoCap: $r = 0.896$ vs $r = 0.434$; AlphaPose: $r = 0.457$ vs 0.015; MotionBERT: $r = 0.689$ vs -0.098; WHAM: $r = 0.708$ vs 0.616). For step-detection precision, defined as the fraction of CV-identified heelstrikes that aligned with manually labeled steps, WHAM achieved the highest precision (89.7%), compared to MotionBERT (48.9%) and AlphaPose (45.0%). Across CV methods, WHAM showed the strongest agreement with MoCap.

Discussion

Comparing different CV methods, we demonstrate that world-grounded CV is more accurate than camera-fixed CV tools with the same constraints. Easy-to-use and accurate CV from video has the potential to transform the scope and scale of biomechanics through improved gait analysis from naturalistic, at-home recordings.

Markerless Motion Tracking Powered by Synthetic Data Outperforms Alternatives in Estimation of Lower-Extremity Joint Moments

Mr. Soyong Shin[1], Ms. Chaeeun Lee[1], Ms. Sijia Li[1], Mr. Zhixiong Li[1], Mr. Kunwoo Lee[1], Dr. Hanz Cuevas Velasquez[2], Mr. Anastasios Yiannakidis[2], Dr. Michael J. Black[2], Eni Halilaj[3]

[1]Carnegie Mellon University, Pittsburgh, PA, United States. [2]Max Planck Institute for Intelligent System, Tübingen, Germany, Germany. [3]Carnegie Mellon University (Department of Mechanical Engineering), Pittsburgh, Pennsylvania, United States

Introduction

Markerless motion tracking is expanding opportunities for scalable biomechanics by reducing reliance on expensive and cumbersome marker-based systems. While recent studies have assessed kinematics accuracy, it remains unclear how reliably existing markerless tools estimate joint moment and how performance depends on the number of cameras. We compared the performance of OpenCap [1], Theia3D [2], and DeepGaitLab [3] in lower-extremity joint-moment estimation. OpenCap is a two-camera open-source solution, Theia3D is a commercial tool requiring at least six cameras, and DeepGaitLab is a flexible open-source tool that operates with any number of cameras and has shown superior kinematics tracking capabilities [3].

Methods

Twelve healthy participants performed overground walking, single-leg squat, and lateral step-down while recorded with 20 infrared cameras, 10 RGB cameras, and force plates. Marker-based inverse dynamics served as the reference. We evaluated the agreement (relative root mean square difference) between Theia3D (10 cameras), OpenCap (2 cameras), and DeepGaitLab (both 10-camera and 2-camera configurations) with marker-based analysis. Head-to-head comparisons assessed DeepGaitLab against OpenCap (both using 2 cameras), DeepGaitLab against Theia3D (both using 10 cameras), and DeepGaitLab (2 cameras) against Theia3D (10 cameras). A linear mixed-effects model assessed the effect of tracking method, activity, and joint degrees of freedom, with Wilcoxon signed-rank tests and Bonferroni correction for pairwise comparisons.

Results

DeepGaitLab yielded the highest accuracy across configurations. With two cameras, DeepGaitLab outperformed OpenCap (0.27±0.07 vs. 0.42±0.17, $p<0.0001$), with the largest difference observed during single-leg squat (0.30±0.12 vs. 0.54±0.26, $p<0.0001$), hip abduction/adduction (0.41±0.14 vs. 0.69±0.27, $p<0.0001$) and internal/external rotation

(0.17±0.05 vs. 0.33±0.15, p<0.0001) moments. With ten cameras, DeepGaitLab and Theia3D performed comparably (0.26±0.08 vs. 0.29±0.09, p=0.6797). However, DeepGaitLab reached comparable accuracies even with two cameras (0.27±0.07 vs. 0.29±0.09, p=0.0991).

Discussion

These findings demonstrate that DeepGaitLab, built using synthetic data and designed for flexible hardware, is more powerful than other existing tools in estimation of lower-extremity joint moments. These results help contextualize accuracy–accessibility trade-offs among emerging markerless tracking solutions and underscore the potential of scalable biomechanics tools.

Images (Optional)

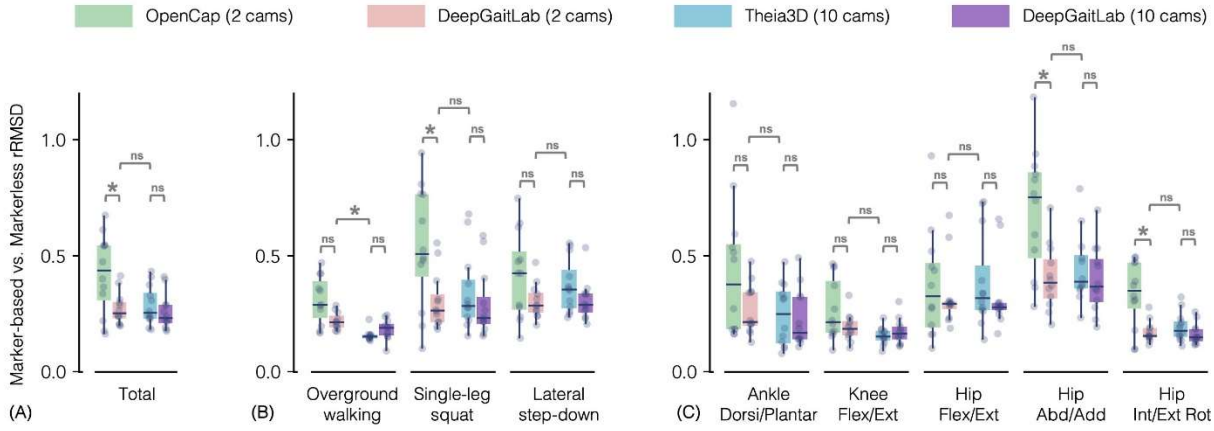

Figure 1. Performance Evaluation. (A) Overall, DeepGaitLab (2 cams) surpassed the performance of OpenCap (2 cams) and matched that of Theai3D (10 cams). (B) DeepGaitLab (2 cams) particularly outperformed OpenCap on single-leg squat and it matched Theia3D (10 cams) during single-leg squat and lateral step down. In overground walking, DeepGaitLab and Theia3D performed comparably only when using the same camera density, given the spatial coverage requirements of this type of activity. (C) DeepGaitLab (2 cams) shows greater accuracy than OpenCap (2 cams) particularly in non-sagittal degrees of freedom.

OA61-05

Influence of Camera Orientation on Joint-Angle Estimation Using Single-Camera 2D and 3D Markerless Motion Capture

Ms. Ishi Arora, Ms. Sarah Dumont, Dr. Calvin Kuo PhD

University of British Columbia, Vancouver, BC, Canada

Introduction

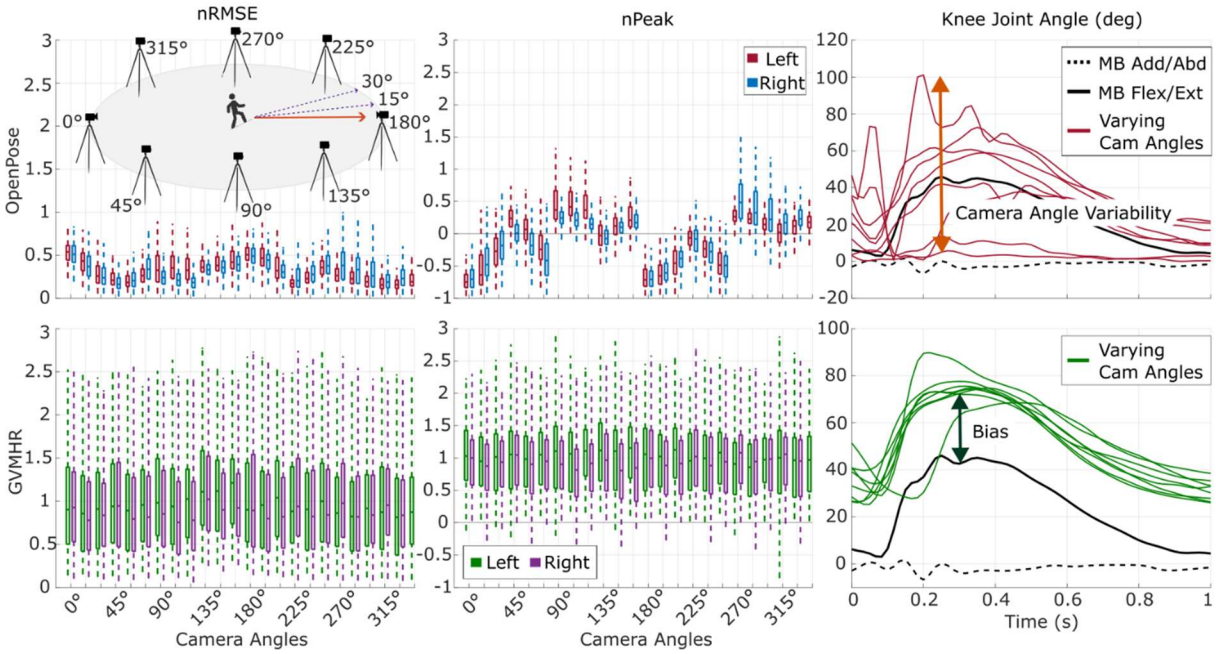
Markerless motion capture has strong potential for large-scale movement analysis in real-world settings, but accuracy and applicability in out-of-laboratory conditions remain limited. In single-camera systems, changes in camera angle can reduce joint visibility, increase occlusion, and lead to issues with observing multi-axial movements, which can affect the accuracy of joint-angle estimates in 2D (OpenPose) and 3D (GVMHR) reconstructions [1,2]. This study examines how camera angle influences joint-angle estimation in single-camera markerless systems to guide optimal camera placement for higher-quality data collection.

Methods

29 participants (24±4.1yo; 15F) performed dynamic movements while wearing 50 active LED markers. Marker trajectories were captured using an 8-camera PhaseSpace system (960 Hz), then interpolated, filtered, and downsampled to match video data. 3D knee joint angles were computed using inverse kinematics.

Simultaneously, eight Sony RX0II cameras (60Hz) were placed 2m from participants at 45° intervals. Movements were performed facing the front camera (180°) and at 15° and 30° deviations. Videos were processed with OpenPose and GVMHR to extract 2D and 3D joint centers of the knee, hip, and ankle. Data was interpolated and filtered to compute knee joint-angles (cosine law).

We then computed knee joint-angle normalized root mean square error (RMSE) and peak error relative to the marker-based system.



Results

OpenPose provides 2D pose estimation, which shows high variability in joint-angle calculations between camera angles. Oblique views, particularly rear oblique views (45°, 315°), yielded the most accurate knee joint-angle estimates. GVMHR reconstructs a 3D pose, which produced similar results across varying camera angles. However, there is a bias in knee joint-angle leading to high error bars within the plots.

Discussion

Using 2D pose estimation (OpenPose) for joint-angle measurement requires careful camera placement, while adding a 3D mesh model (GVMHR) helps generalize estimates across orientations. However, joint centers in these mesh models are not anatomically defined, introducing bias in the results that must be calibrated. By quantifying how joint-angle outputs vary with camera angle across systems, this study offers practical guidance for system setup and clarifies the limitations and capabilities of single-view markerless motion capture for kinematic assessment.

Establishing the 3D Asymmetry of the Intervertebral Disc in Adolescent Idiopathic Scoliosis

Miss Anna Iacocca[1], Mr. Jacob Jordan[2], Mr. Thomas Coleman[2], Dr. Patrick Cahill MD[2], Dr. Axel Moore PhD[1]

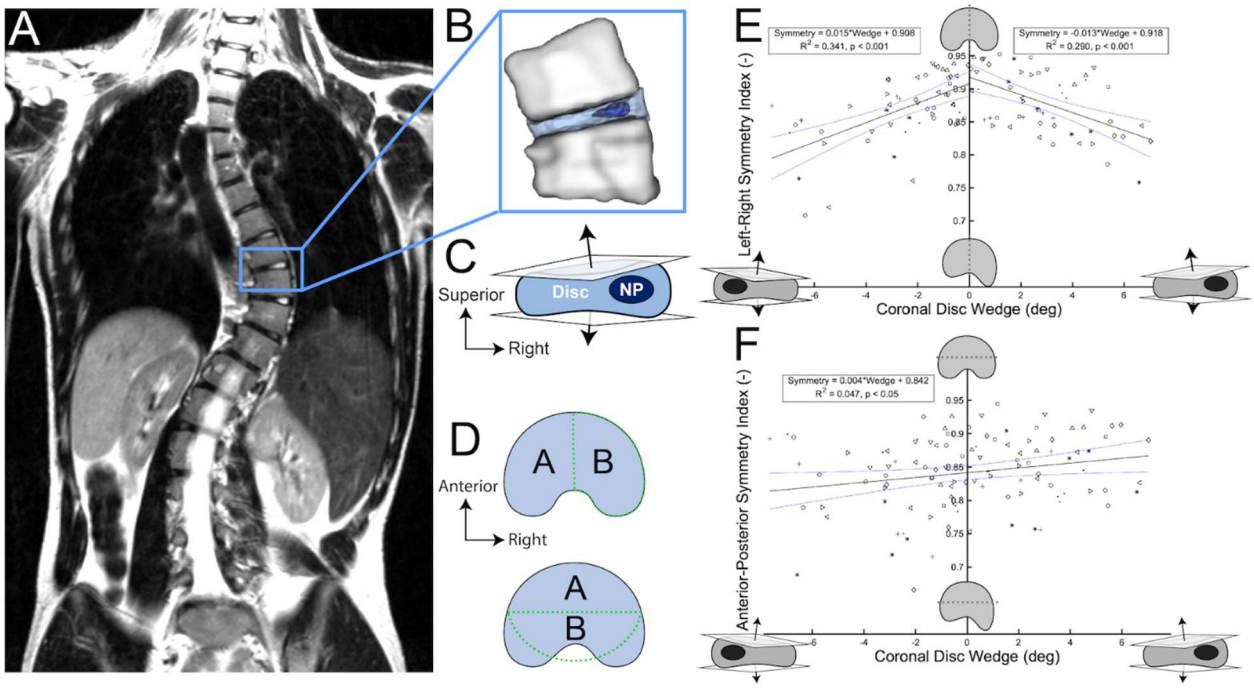
[1]Carnegie Mellon University, Pittsburgh, PA, United States. [2]Children's Hospital of Philadelphia, Philadelphia, PA, United States

Introduction

Adolescent idiopathic scoliosis (AIS) is an abnormal lateral curvature of the spine that develops prior to skeletal maturity. Though primarily defined by the coronal deformity, AIS is realistically a 3-dimensional disease that afflicts the spine in all three planes. While differential growth of the vertebrae is well-established, the effect of AIS on the 3-dimensional structure of the intervertebral disc (disc) has yet to be established. Given the tenet that structure follows function, and the function (kinematics and kinetics) of the AIS spine is inherently asymmetric, we hypothesized that AIS discs would be structurally asymmetric.

Methods

Following IRB approval, we retrospectively analyzed magnetic resonance (MR) images from 10 pre-surgical AIS patients (7 F) with Cobb angles ranging from 45 to 71 deg (**Fig 1A**). The disc and nucleus pulposus (NP) were manually segmented from the MR image stacks (**Fig 1B)**. Following segmentation, we quantified disc wedging in the coronal plane as well as anterior-posterior and left-right symmetry in the transverse plane. Disc wedge was quantified from planar fits to the superior and inferior surfaces of the disc (**Fig 1C**). Symmetry was quantified using the dice similarity coefficient, defined as the normalized area of overlap of a mirrored disc (**Fig 1D**).



Results

Our results demonstrate that the AIS disc is coronally wedged, and this wedging opens toward the convexity of the curve and follows vertebral wedging. In the transverse plane, the AIS disc is asymmetric about the anterior-posterior and left-right axes (**Fig 1E&F**). The symmetry about the anterior-posterior axis was correlated with disc wedging—more wedge = less symmetry. The symmetry about the left-right axis was not correlated with disc wedging; however, even non-scoliotic discs lack symmetry about this axis.

Discussion

In this work we demonstrate that the AIS disc is structurally asymmetric in all 3 dimensions. Currently, it is unknown whether these results stem from structural remodeling, damage, or poro-visco-elastic deformations of the disc. The observed structural asymmetry suggests that AIS discs will also display asymmetric mechanics. This work takes a critical first step towards establishing the structural, compositional, and functional state of the AIS disc.

[3]Department of Diagnostic, Interventional and Pediatric Radiology, University Hospital Bernof Diagnostic, Interventional and Pediatric Radiology, Bern, Bern, Switzerland. [4]Faculty of Medicine, University of Basel, Basel, Basel, Switzerland

Introduction

MRI is the preferred modality for soft tissue imaging, yet its capacity to visualize bone remains limited. In contrast, CT provides superior bone imaging but the associated ionizing radiation makes it unsuitable for repeated imaging in pediatric populations. High-resolution imaging is crucial for detecting subtle morphological changes and for assessing growth at the level of individual vertebral bodies. This study evaluates the feasibility of using Ultrashort Echo Time (UTE) MRI sequences to visualize vertebral bone anatomy and to enable reliable morphometric assessments over time.

Methods

Ten volunteers adolescent (16 ± 1 years) underwent two MRI examinations using UTE sequences of the thoracic and lumbar spine, acquired within a 30 minutes time interval. The vertebrae were automatically segmented using a deep learning algorithm. Vertebral morphology between the two acquisitions was then compared using surface distance metrics such as the Hausdorff distance. In addition, several anatomical measurements were evaluated, including, whole vertebra height (WVh) and width (WVw), endplate width (EPW) and depth (EPD), vertebral body height (VBH), and processus spinosus length (SPl).

Results

The segmentation achieved high repeatability with the mean difference between time points of 0.46 ± 0.05 mm. Region-specific results showed slightly better agreement in the lumbar region with a mean difference of 0.44 ± 0.04 compared to the thoracic spine where the difference between repeated acquistions was 0.47 ± 0.06. All anatomical

measurements were within 0 and 0.5 mm between the two acquisitions, except for WVw and SPl, which showed a difference between 1.5 to 2 mm (Figure 1).

Discussion

UTE MRI provides enhanced bone contrast and allows accurate, repeatable vertebral segmentation. Vertebral surface can be reconstructed with an accuracy below 0.5mm, which is smaller than the expected yearly vertebral growth in healthy children (0.8–1.2 mm/year). This level of precision supports longitudinal monitoring without radiation exposure, particularly in multi-year follow-up studies. Segmentation quality appears adequate for modeling and quantifying bone growth over one to two years, with the potential to reveal spatial patterns of bone growth, that may improve our understanding of scoliosis progression and the evaluation of conservative treatments such as bracing and physiotherapy. Future work will include comparisons vertebral morphology with CT.

Images (Optional)

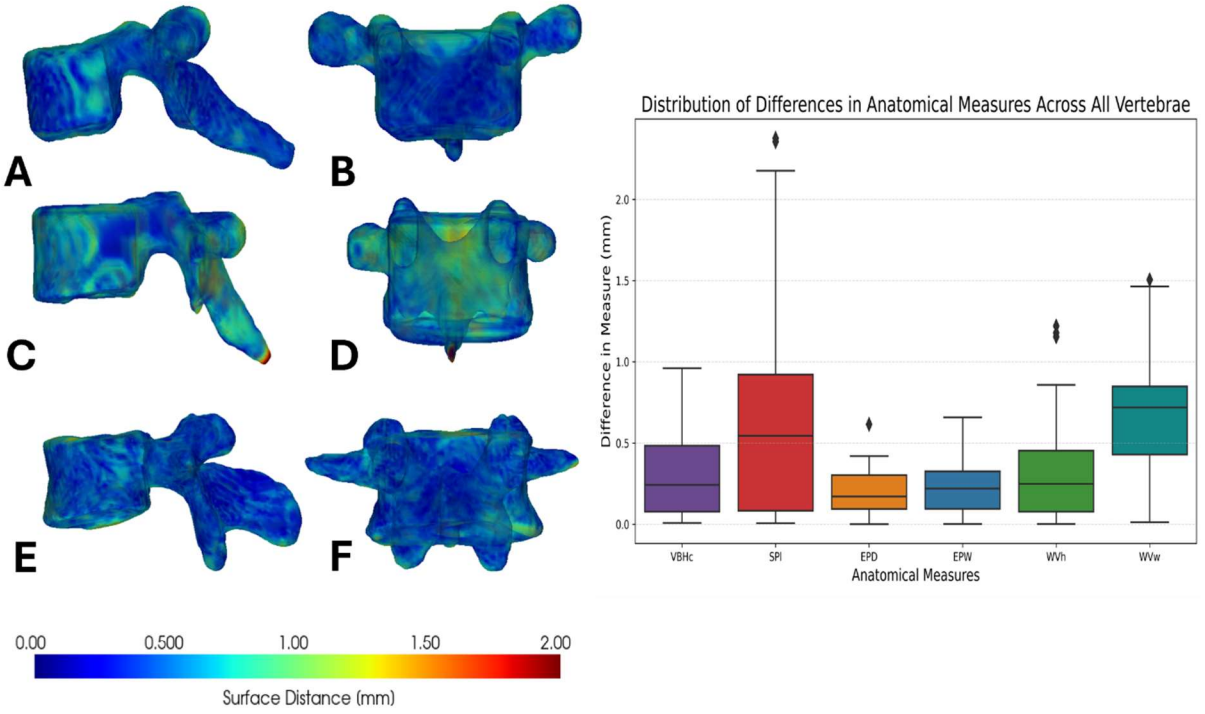

Figure 1 3D vertebrae reconstructed from UTE MRI with a heat map illustrating the Hausdorff distance. A–B) Sagittal and coronal view of the T1 vertebra, C–D) sagittal and coronal view of the T8 vertebra, and E–F) sagittal and coronal view of the L2 vertebra.
The accompanying plot shows the distribution of differences in anatomical measurements across all vertebrae, including whole vertebra height (WVh) and width (WVw), endplate width (EPW) and depth (EPD), vertebral body height (VBH), and spinous process length (SPl).

Generating Standing Posture Finite Element Models of the Spine Based on Radiation-Free Imaging

MsC Federica Incatasciato[1], Mr. Peter P.G. Lafranca[2], Prof Dr. Tom P.C Schlosser[2], Dr. Bert van Rietbergen[1], Prof Dr. Keita Ito[1,2], Dr. Joeri Kok[1]

[1]Eindhoven University of Technology, Eindhoven, N/A, Netherlands. [2]University Medical Center Utrecht, the Netherlands, Utrecht, N/A, Netherlands

Introduction

Patient-specific Finite Element (FE) spine models are typically created from CT scans acquired in supine position. To obtain the clinically relevant standing posture, these models can be morphed to standing radiographs. However, the radiation exposure limits this approach in children. Synthetic CT (sCT) generated from MRI, combined with emerging ultrasound (US) techniques that estimate 3D spinal curvature in standing position, offers a radiation-free alternative [1]. This study aims to integrate sCT and US imaging to develop a radiation-free method for generating patient-specific FE spine models in standing posture.

Methods

A cohort of 8 subjects (8-13 years old) at risk for scoliosis development undergoing upright US and supine MRI as part of a study, were included (informed consent by patients and parents/legal guardians; IRB approval MedNed 22-999). Subject-specific T3–L5 FE models were created from MRI and sCT, including vertebrae, intervertebral discs, and ligaments [2]. US scans acquired in standing position visualized posterior vertebral elements. Supine FE models were converted to standing posture by aligning T12 laminae and applying a rigid rotation that minimized the distance between the model and a curve fitted through US-measured laminae. Remaining distances were used as displacements in FE analysis to enforce the standing curvature. For validation, spinal curvature was prescribed using radiograph-derived laminae measurements, and common clinical curvature measures were calculated and compared to direct radiographic measurements (Fig.1).

Results

The procedure successfully transformed each supine model to standing position, with deviations from prescribed curvature <1 mm. Validation against radiographs showed mean within-subject differences of 7.1 ± 6.1° for thoracic kyphosis, 5.6 ± 2.5° for lumbar lordosis,

1.5 ± 0.8° for thoracic tilt, and 1.8 ± 1.3° for lumbar tilt. Non-parametric Wilcoxon signed-rank test showed no significant differences between the two modalities ($p>0.05$).

Discussion

The proposed radiation-free method accurately represented the prescribed spinal curvature at the laminae, while keeping vertebrae undeformed. Validation revealed differences in vertebral inclination between model and radiographs. These differences were small, suggesting that the morphed model will be an accurate representation of the standing spinal alignment and morphology.

Mechanics-Informed Stability and Morphological Descriptors for Predicting Adolescent Idiopathic Scoliosis Progression

Mr David Landinez Leon[1], Mr Javier Bayod[2], Mr Christian Cifuentes-De La Portilla[1]

[1]Universidad de los Andes, Bogotá, Cundinamarca, Colombia. [2]Universidad de Zaragoza, Zaragoza, Aragon, Spain

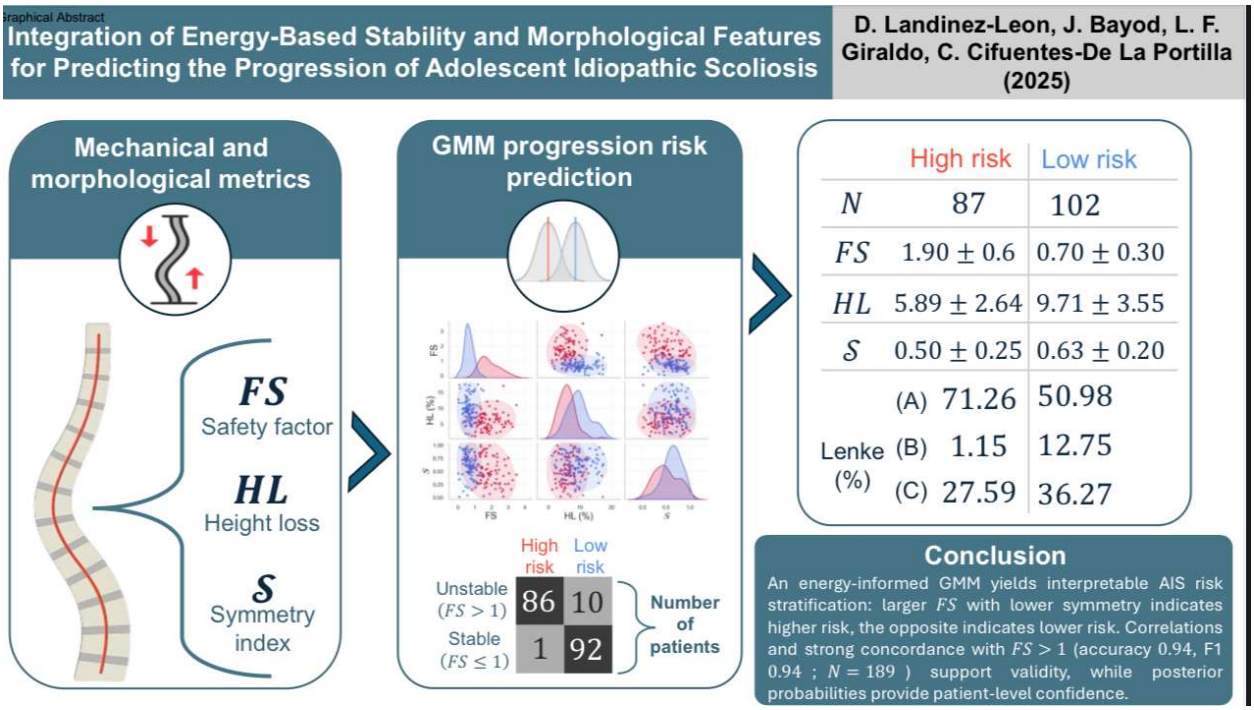
Introduction

Adolescent idiopathic scoliosis (AIS) burdens young recruits in Latin-American militaries, where access to 3D imaging is scarce and fitness-for-duty decisions rely almost exclusively on Cobb angle from plain radiographs [1]. Angle cut-offs do not capture three-dimensional mechanical stability, cumulative disc compression or morphological balance, despite their relevance for curve progression and duty limitations. There is a need for objective, interpretable biomechanical indices computable from routine standing X-rays and compatible with existing accession and follow-up workflowS.

Methods

We retrospectively analysed 209 standing posteroanterior radiographs of AIS in young members of the Colombian military health system. A convolutional neural network segmented the spine and extracted a smooth midline. A parametric finite-element digital twin was fitted by matching the radiographic curve to a precomputed simulation library under axial load. From the fitted model we derived an energy-based stability index (Rayleigh quotient), disc-height loss as a magnitude proxy, and a symmetry index describing morphological balance. After standardisation, a Gaussian mixture model identified unsupervised risk clusters in this three-dimensional energetic–morphological space.

Results



Two well-separated phenotypes emerged. The low-risk cluster showed higher mechanical stability, lower disc-height loss and higher symmetry index, indicating mechanically safer, more balanced curves. The high-risk cluster concentrated cases with reduced stability, greater cumulative compression and more asymmetric morphology. Cluster membership

probabilities were sharply peaked, suggesting limited ambiguity and good internal separability of phenotypes.

Discussion

This mechanics-informed, radiography-first pipeline enriches conventional AIS assessment without changing imaging infrastructure. Combining patient-specific digital twins with energetic and morphological descriptors yields interpretable risk phenotypes aligned with curve-type labels and intuitive notions of mechanical vulnerability. Because it operates on plain radiographs and commodity computing, the approach can support Latin-American military screening and follow-up, standardising documentation, guiding referral and potentially reducing attrition related to spinal deformity.

In-Vivo Identification of Adolescent Idiopathic Spine Properties through Intraoperative Measurement and FE Modelling

Mr. Till van der Reijden Msc.[1], Prof. Dr. Philippe Büchler[1], Prof. Dr. med. Carol Hasler[2], PD Dr. med. Daniel Studer[2], Associate Prof. Dr. sc. Georg Rauter[3]

[1]ARTORG Center for Biomedical Engineering Research, Bern, Bern, Switzerland. [2]Universitäts-Kinderspital beider Basel, Basel, Basel, Switzerland. [3]Bio-Inspired RObots for MEDicine-Lab (BIROMED-Lab), Basel, Basel, Switzerland

Introduction

Adolescent Idiopathic Scoliosis (AIS) is a complex three-dimensional spinal deformity that often requires surgical intervention to prevent progression. Although spinal fusion provides reliable correction, it limits spinal mobility and can cause serious adverse effects. Developing new treatment strategies is challenging due to limited access to *in-vivo* spinal mechanics. Cadaveric specimens are rare and cannot mimic physiological conditions. To address these limitations, this study combines intraoperative measurements collected during AIS correction surgery with patient-specific finite-element (FE) simulations to identify the biomechanical properties of the scoliotic spine.

Methods

Patient-specific FE models of three functional spinal units of a single patient were automatically generated from MRI images, capturing bone and soft-tissue anatomy (e.g., intervertebral disc, annulus, and ligaments). The annulus was modelled using the Holzapfel–Gasser–Ogden formulation, and the nucleus as a fluid-filled cavity. The vertebrae were represented as rigid bodies, and ligaments were modelled as truss elements with a user-defined stretch-dependent, tension-only response. The lateral bending moment was derived from *in-vivo* measurements [1] and applied to the cranial vertebra, while caudal vertebra displacements were constrained. Material parameters were identified using a Bayesian optimisation, which minimised the difference between model-predicted and measured *in-vivo* rotation.

Results

Simulated moment–angle curves closely matched experimental measurements, indicating reliable model performance. Material parameters converged within each analysed segment, suggesting a robust optimisation process, and the overall combined RMSE

ranged from 0.08 to 0.2 degrees. The calibrated models successfully reproduced the characteristic asymmetry observed in *in-vivo* measurements (Figure 1), showing that the calibrated models can capture the biomechanical behaviour of the scoliotic spine.

Discussion

These initial results showed that integrating intraoperative measurements with patient-specific FE modelling enables reliable estimation of *in-vivo* spinal mechanics in AIS patients. This is a major step forward, given the scarcity of representative cadaveric material and the challenges of directly measuring spinal behaviour. This integrated approach can predict subject-specific mechanical properties, supporting improved surgical decision-making and the development of personalised, mobility-preserving interventions.

Images (Optional)

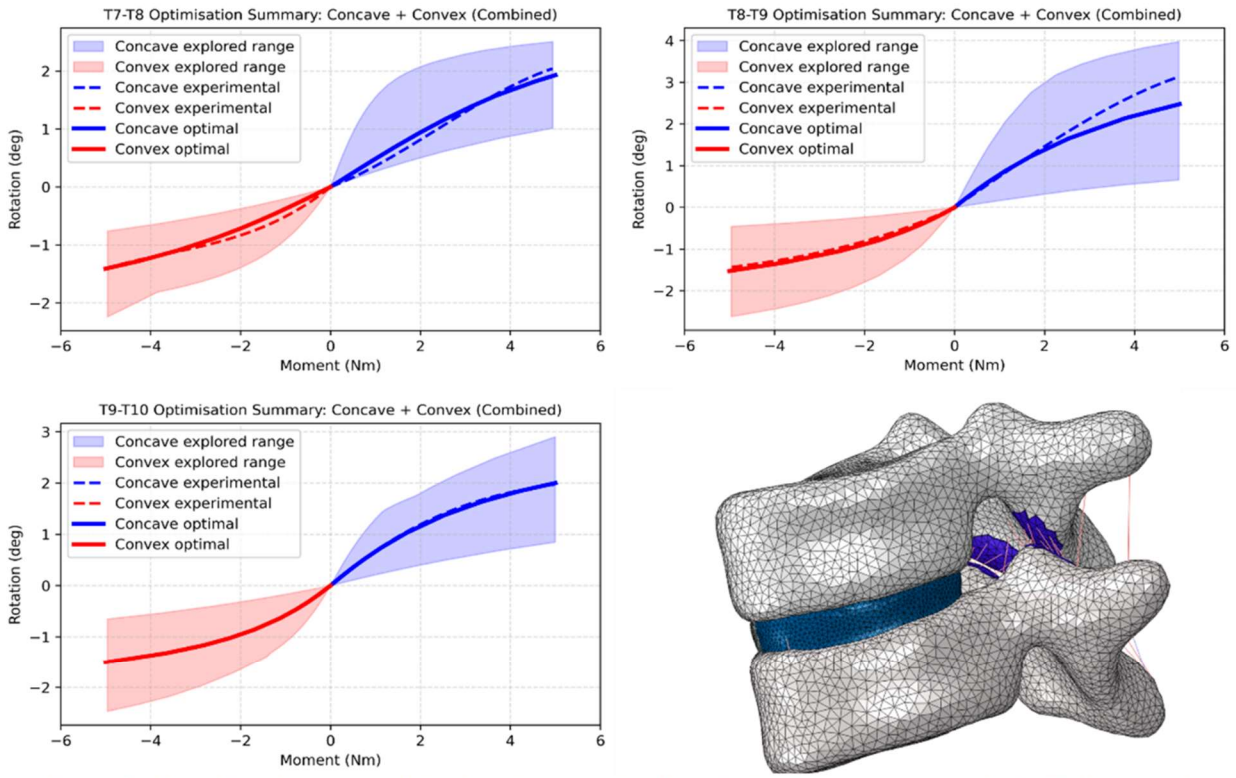

Figure 1: Combined concave (blue) and convex (red) optimisation summaries for initially tested segments (top left: T7-T8, top right middle: T-8-T9, lower right: T9-T10) of the same patient. The shaded regions show the range of moment-angle responses explored during the Bayesian optimisation process. Experimental curves are represented as dashed lines, while solid lines represent the simulations using the respective set of optimal parameters. An example of the reconstructed Abaqus model including all soft tissue structures is shown in the lower left.

[6]Department of Immunology, University of Texas Southwestern Medical Center, Dallas, TX, United States

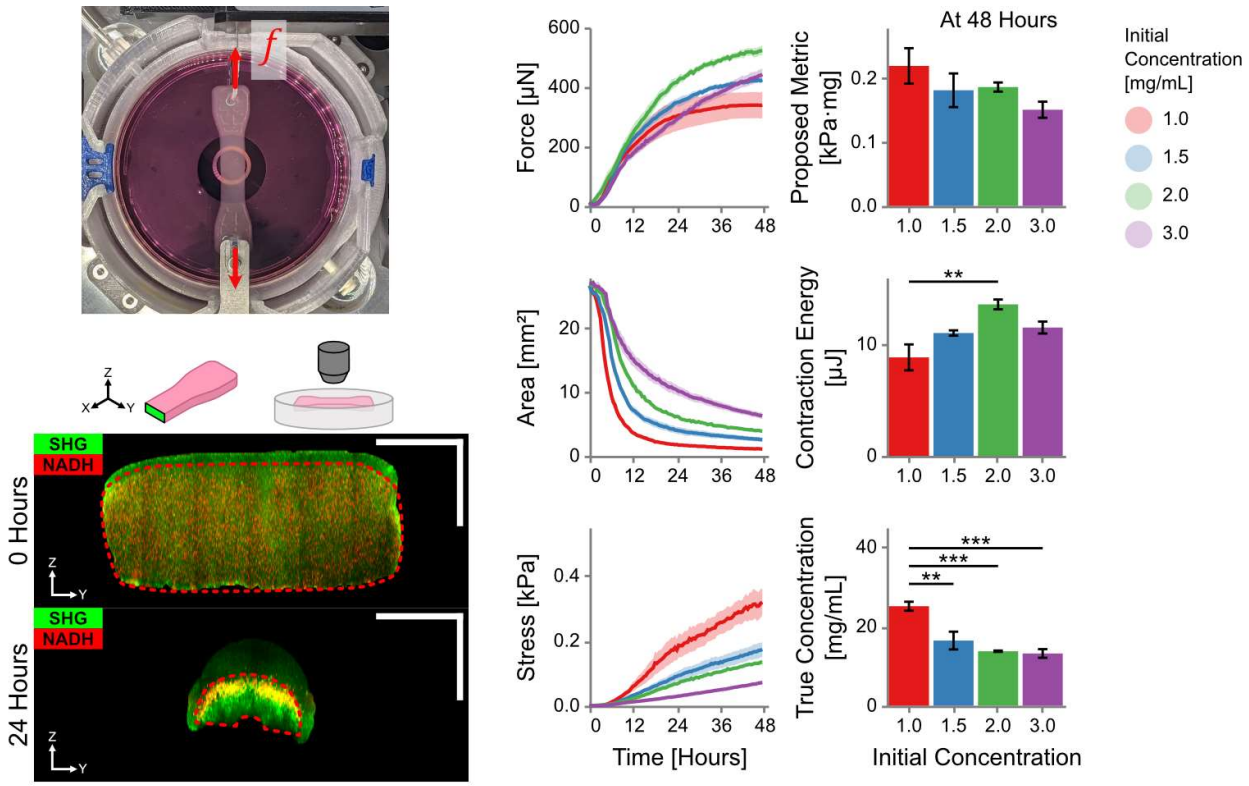
Introduction

To ensure optimal physiological function, cells maintain tensional homeostasis around a tissue-specific set-point. With fibrosis, the biomechanical function of tissues is lost due to a breakdown of this set-point, as well as excessive production of a collagen-rich extracellular matrix (ECM) by resident fibroblasts. However, it remains unclear how interactions between fibroblasts and the ECM give rise to a mechanically homeostatic state compatible with normal tissue function. Common models to study tensional homeostasis are fibroblast-populated collagen gels. Such tissue equivalents develop tensile forces in presence of a physical constraint, suggesting the existence of a homeostatic setpoint. However, the steady-state force varies in different collagen concentrations, suggesting the existence of a complex homeostatic target.

Methods

We developed the first biomechanical bioreactor fully integrated with a confocal microscope. Our platform was designed to be capable of dynamic measurements of force, structural remodeling of collagen, and tissue cross-sectional area, thereby allowing for the estimation of the Cauchy stress generated by tissue equivalents.

Results



By culturing NIH/3T3 fibroblasts in increasing concentrations of collagen, we observe that cell-generated forces reach a plateau after 24 hours[JF1] . At steady-state, force (f) increases with higher initial collagen concentrations while the cross-sectional area (a) decreases. Surprisingly, we found that stress (σ=f/a) is not conserved. Rather, tissues with

the lowest initial collagen density develop the highest stresses due to higher densification and earlier alignment of collagen fibers. We found that the product between the contraction energy W and the true collagen density ρ is maintained. We validated the trend in W by quantifying the intensity of α-smooth muscle actin via immunofluorescence and the trend in ρ by measuring the densification of collagen via confocal reflection microscopy. Bulk RNA sequencing indicates that the homeostatic state is maintained at the protein level and is disrupted by culturing fibroblasts in high collagen concentrations.

Discussion

In this work we developed a new biomechanical bioreactor and used it as a tissue engineering platform to show that the homeostatic state in tissues may not be driven by a single factor (such as the stress) but rather arises from a balance between fibroblast contractility and ECM compaction.

Tissue Maturation In Engineered Ligaments is Synergistically Improved Via Combined Slow Elongation and Rapid Intermittent Cyclic Stretch

Mx. Leia Troop, Dr. Jenny Puetzer

Virginia Commonwealth University, Richmond, VA, United States

Introduction

Hierarchical collagen fibers are the primary source of strength in ligaments; however, these fibers don't regenerate after injury.[1] Engineered replacements are promising, but it remains challenging to regenerate hierarchical fibers. Mechanical cues, including slow-growth elongation and rapid-cyclic muscle activity are critical for fiber formation *in vivo,*[1] but occur at strain rates orders-of-magnitude apart, likely effecting cells differently.[1,2] Previously, we developed a system which guides anterior cruciate ligament (ACL) fibroblasts in high-density collagen gels to form hierarchical fibers over 6 weeks,[1] and have shown slow-growth elongation and intermittent cyclic stretch individually and differentially improve fiber maturation. However, further maturation is needed to be clinically relevant. Here we evaluated whether combined slow-elongation and rapid-intermittent cyclic stretch results in synergistic fiber maturation. We hypothesize this combined loading regime will drive cells to produce significantly stronger replacements than either load alone.

Methods

Neonatal bovine ACL fibroblasts were mixed with collagen to form constructs (20mg/mL collagen, $5x10^6$cells/mL), and cultured up to 6 weeks.[1] Controls were statically clamped or stimulated with slow stretch(0.1 mm/day)[2] or intermittent cyclic stretch(1 Hz, 5% strain, 1 mm/sec)[1] every other day (Fig.1**A-B**). Combined-stretch constructs were loaded with alternating days slow and cyclic stretch. Post-culture, collagen organization, composition, and tensile properties were evaluated.

Results

Mechanical stimulation drove increased maturation, with combined load producing larger fibers with larger, more regularly spaced crimps by 6 weeks (Fig.1**C-D**). Loading drove increased fibril level alignment with combined load appearing to have increased, native-like fibril bundling (Fig.1C-SEM). Loading accelerated DNA and GAG accumulation (not shown), and combined load increased collagen accumulation over other groups by 6 weeks (Fig.1**D**). Individual loads improved LOX activity at different timepoints, while

combined had increases at both. All constructs significantly improved tensile properties, with combined load having the strongest elastic and toe moduli by 6 weeks.

Discussion

Here the combination of slow and rapid-cyclic stretch synergistically improved fiber organization, composition, and tissue strength. This study demonstrates differential strain rates drive variable cellular responses, which when combined results in synergistic improvements. Understanding how mechanical cues regulate fiber formation will help engineer replacements and develop better rehabilitation protocols.

Cyclic Mechanical Stimulation of TDPCs Improves Tendon Tissue Maturation in Vitro by Enhanced Collagen Fibril Formation

MSc Ekaterina Oleinik[1,2], MSc Felix Gross[1], MSc Magdalena Fuchs[1], MSc Lune Teplitchi-Menou[1], MSc George Gourgi[2], PhD Andreas H. Teuschl-Woller[2], PhD Philipp J. Thurner[1]

[1]TU Wien, Vienna, Vienna, Austria. [2]UAS Technikum Wien, Vienna, Vienna, Austria

Introduction

Mechanical loading is key regulator of tendon development, maintenance, and repair, and thus an essential parameter in tendon tissue engineering (TTE). Despite progress in in vitro TTE, standardized tendon model is lacking. Existing approaches either use static or cyclic mechanical loading, and it is debated in the TTE community, which approach is advantageous. This study compared the effects of static (SL) and cyclic loading (CL) on tendon-derived progenitor cells (TDPCs) to identify optimal conditions for maintaining tenocyte function in TTE.

Methods

Rat TDPCs ($4x10^6$ cells/mL) were embedded in fibrin scaffolds (10 mg/mL fibrinogen, 0.625 KIU thrombin) and subjected to mechanical stimulation in a custom-made bioreactor (MagneTissue). We applied 10% uniaxial tensile strain for 6 hours daily, followed by an 18-hour resting period at 3 % strain, over 7 consecutive days. CL was applied with 0.5Hz frequency to replicate physiological conditions. Cell proliferation (EdU), survival (TUNEL), and morphology (Actin/DAPI) were evaluated. Gene expression was analysed by RNAseq and RT-qPCR for extracellular matrix (ECM) and tendon-specific markers. Construct functionality was assessed by uniaxial tensile testing (Zwickiline, Zwick), collagen deposition by MSB staining, and fibril formation by atomic force microscopy (AFM) (Nanowizard Ultraspeed A, Bruker-JPK).

Results

CL induced pronounced cell alignment, along with higher cell proliferation and survival compared to SL. RNAseq identified two distinct transcriptomic clusters: CL upregulated tendon-specific and ECM-related genes (Scx, Tnc, Tnmd, Sparc, Col1a1, MMP3), indicating enhanced ECM remodelling and mature tendon phenotype, while SL upregulated inflammatory markers (Il6, Ccl2, Cxcl1/3). Histological and AFM analyses confirmed enhanced collagen deposition and fibril formation upon CL (Fig. 1A,B). Mechanical testing

revealed a threefold higher tensile modulus in CL constructs, indicating superior remodeling upon CL (Fig. 1C).

Discussion

This study demonstrates that CL provides markedly superior microenvironment for TTE compared to SL conditions. Enhanced cell viability, proliferation, alignment, and upregulated tendon-specific markers reflect improved tenocyte functionality. CL enhanced ECM remodeling and mechanical performance without eliciting inflammatory responses, thereby more closely mimicking physiological conditions of tissue growth and adaptation. These findings highlight the necessity of incorporating controlled cyclic mechanical stimulation in in vitro tendon modelling to achieve more functional and biomimetic tissue constructs

Dr. Tianmian Liu

Dr. Xuran Li

Prof. Mengning Yan

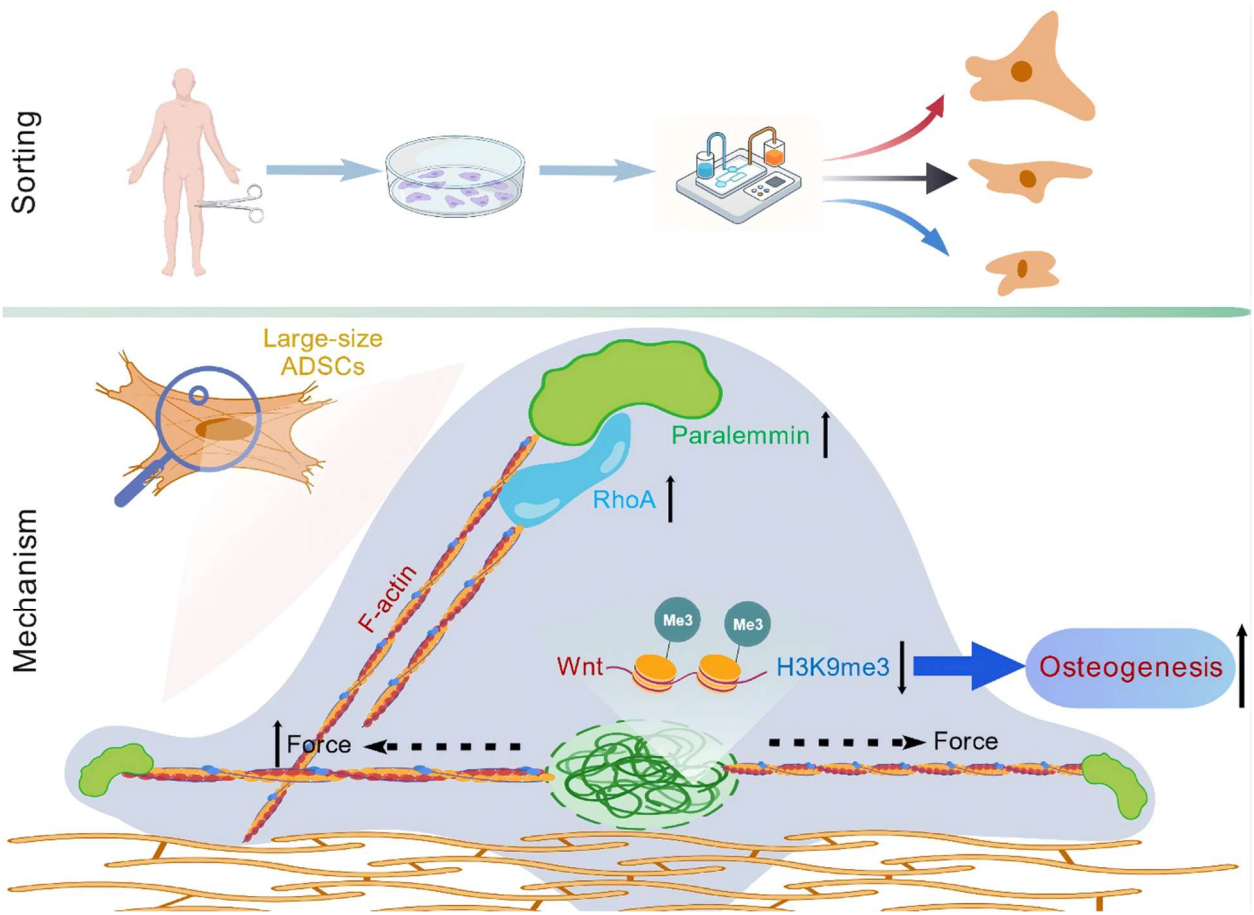
Prof. Xiaobo Gong

Introduction

Adipose-derived stem cells (ADSCs) exhibit size heterogeneity, yet whether cell size functions as an endogenous regulatory cue has not been mechanistically defined. Using a spiral microfluidic chip to isolate size-specific subpopulations, we identified large-size ADSCs in the upper ~30th percentile as displaying markedly enhanced osteogenic potential. This suggests that size acts not merely as a morphological descriptor but as a deterministic biophysical signal encoding lineage predisposition. Building on this observation, we investigated how cell size integrates cytoskeletal architecture, nuclear mechanics, and epigenetic regulation to direct osteogenic fate.

Methods

Human ADSCs were isolated from subcutaneous adipose tissue and size-fractionated using a microfluidic device to obtain large-, medium-, and small-size subpopulations. Osteogenic differentiation was assessed through alkaline phosphatase and Alizarin Red staining, qPCR, and Western blot. Cell and nuclear morphology were quantified via immunofluorescence. Mechanical properties were analyzed using atomic force microscopy. RNA-seq and CUT&Tag profiling for H3K9me3 were performed to identify transcriptional and epigenetic differences. Functional assays were conducted following PALM knockdown or inhibition of RhoA/ROCK signaling.



Results

We used microfluidic sorting to isolate ADSCs of distinct diameters. Large-size cells exhibited stronger osteogenic differentiation, greater spreading, and increased fiber formation. RNA-seq revealed enrichment of osteogenic Wnt signaling, with PALM (Paralemmin) prominently upregulated. PALM knockdown disrupted cytoskeletal organization, reduced cell and nuclear spreading, and impaired osteogenesis. Paralemmin interacted with RhoA, and large-size cells showed elevated RhoA/ROCK levels; inhibiting this pathway similarly suppressed osteogenesis. CUT&Tag profiling showed reduced H3K9me3 at WNT1 and WNT5A promoters in large cells, consistent with their higher expression. Cytoskeleton disruption increased nuclear H3K9me3 and diminished osteogenesis.

Discussion

Through precise sorting of ADSC subpopulations, we quantitatively elucidated how intrinsic cell size regulates stem cell state and lineage selection. Large ADSCs exhibit superior osteogenic potential through a Paralemmin–RhoA/ROCK cytoskeletal axis that shapes nuclear architecture, redistributes heterochromatin, and reduces H3K9me3 repression of WNT genes. The biophysical–epigenetic coupling reveals how intrinsic physical states instruct cell fate, offering a practical strategy to isolate high-potential MSC subsets and enhance bone regeneration for skeletal tissue engineering.

Introduction

Cartilage mechanoadaptation can be driven by dynamic microenvironmental cues induced by various mechanical loading modalities in bioreactor systems. This influences both extracellular matrix composition and functional properties. While dynamic mechanical cues have been shown to possess chondrogenic potential in diverse cartilage tissue engineering studies [1], the lack of standardisation has long hindered quantitative comparison and consensus on a gold-standard stimulation protocol [2]. This study systematically evaluates how different loading modalities influence matrix development in tissue-engineered cartilage constructs.

Methods

Following a PRISMA-guided systematic approach, published *in vitro* studies were included if dynamic mechanical stimulation was implemented to culture engineered hyaline articular cartilage tissue constructs. Studies using cartilage explants and qualitative assessment methods were excluded. A total of 95 studies were analysed under six conventional loading modalities: compression, tension, shear, hydrostatic pressure, fluid-induced shear, and combined stimuli. Meta-analysis using standardised effect measures (Hedges' *g*) was conducted for conventionally assessed chondrogenic outcomes, including

aggrecan and collagen-II gene expression, glycosaminoglycan and collagen deposition, and compressive equilibrium modulus.

Results

The overall chondrogenic response to dynamic mechanical stimulation across all six loading modalities showed that combined stimulation of compression and shear was particularly effective in promoting matrix production (Figure 1). This suggests that heterogeneous mechanical cues more effectively promote cartilage mechanoadaptation compared to single-modality stimulation. Meta-regression revealed a parameter-dependent relationship between fluid-induced shear showing decreasing benefits at higher intensities, suggesting that mechanical stimulation must be tuned for optimal matrix development.

Discussion

This systematic approach highlights the value of using standardised effect measures to enable cross-study comparison in cartilage tissue engineering, despite methodological heterogeneity. To identify optimal mechanobiological environments for cartilage matrix development, loading parameters must be optimised at the microstructural scale under standardised culture conditions. Addressing gaps identified in this work, such as inconsistent reporting, variation in outcome assessment, and the lack of sub-tissue mechanical histories, will be critical for improving reproducibility, guiding the development of future bioreactor systems, and advancing mechanically stimulated chondrogenesis for cartilage regeneration.

Mechanobiological Regulation of Transport and Shear in Hierarchical Bio-Inspired Scaffolds for Bone Repair

Dr. Federica Buccino[1], Dr. Sara Sebastiani[1], Prof. Giuseppe Banfi[2], Prof. Laura Vergani[1]

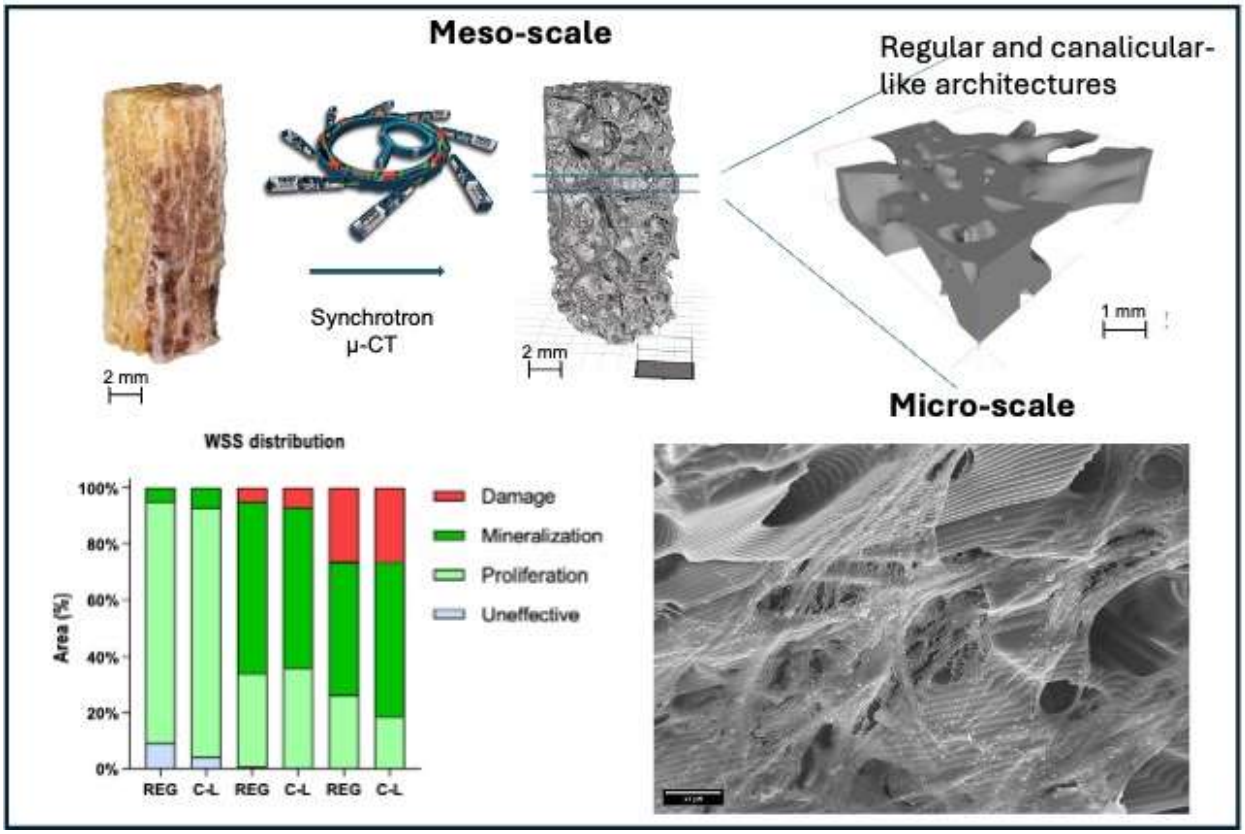
[1]Politecnico di Milano, Milano, Lombardy, Italy. [2]IRCCS Galeazzi Orthopaedic Institute, Milano, Lombardy, Italy

Introduction

Mechanical cues such as fluid-induced WSS regulate osteogenic differentiation [1–2], yet achieving uniform stimulation in complex 3D scaffolds remains challenging [3]. Native bone accomplishes this through its hierarchical trabecular and lacuno–canalicular architecture, which shapes flow and local mechanical signals [4]. However, how such features interact with perfusion to generate meaningful WSS is poorly understood [4]. This study compares two hierarchical scaffold designs—one regular, the other canalicular-like—to assess how topology influences early cellular responses.

Methods

Hierarchical scaffolds were generated from a high-resolution STL of human trabecular bone and enriched with a biomimetic lacuno–canalicular layer of ellipsoidal lacunae and microchannels. Two variants were produced: a regular scaffold with ordered features and a canalicular-like scaffold with randomly distributed lacunae and Delaunay-derived interconnections. Both were fabricated with submicron fidelity via two-photon polymerization (Nanoscribe Quantum X). Representative subvolumes underwent CFD analysis in COMSOL Multiphysics under free-flow conditions using Newtonian DMEM at 10^{-5}–10^{-4} m/s, with mesh convergence and mass-balance error <0.1%. Human hBMSCs were statically cultured for 28 days, and endpoint evaluation by SEM and synchrotron micro-CT (SYRMEP beamline) provided high-resolution, non-destructive assessment of cellular organization and mineral-like matrix deposition across the architecture.



Results

Under free-flow, bypass reduced Δp (<1 Pa) and intrapore shear, with >85% of surfaces below 5 mPa and minimal osteogenic-range stimulation, leading to rim-localized matrix deposition. The regular scaffold showed long high-WSS corridors, whereas the canalicular-like design produced shorter, more diffuse hotspots. Forced-flow shifted WSS into the osteogenic window. Cell studies reflected these trends: hBMSCs penetrated more deeply and formed more internal ECM in the canalicular-like network, confirming its enhanced support for early osteogenic activity.

Discussion

The canalicular-like scaffold distributed shear more uniformly and exposed more internal surfaces to osteogenic WSS, while the regular design created high-shear corridors and under-stimulated regions. Forced-flow, especially at low velocity, improved interior perfusion and maintained WSS within the osteogenic window.

Activation of Mechanotransduction in Redifferentiating Human Articular Chondrocytes in response to Short-Term Mechanical Stimulation

Ms. Sriranjani Seshadri[1], Ms. Ruxin Yang[1], Dr. Weiping Li[2], Ms. Kiera Downey[1], Dr. Cheri Deng[2], Dr. Rhima Coleman[1]

[1]University of Michigan, Ann Arbor, Michigan, United States. [2]Michigan State University, East Lansing, Michigan, United States

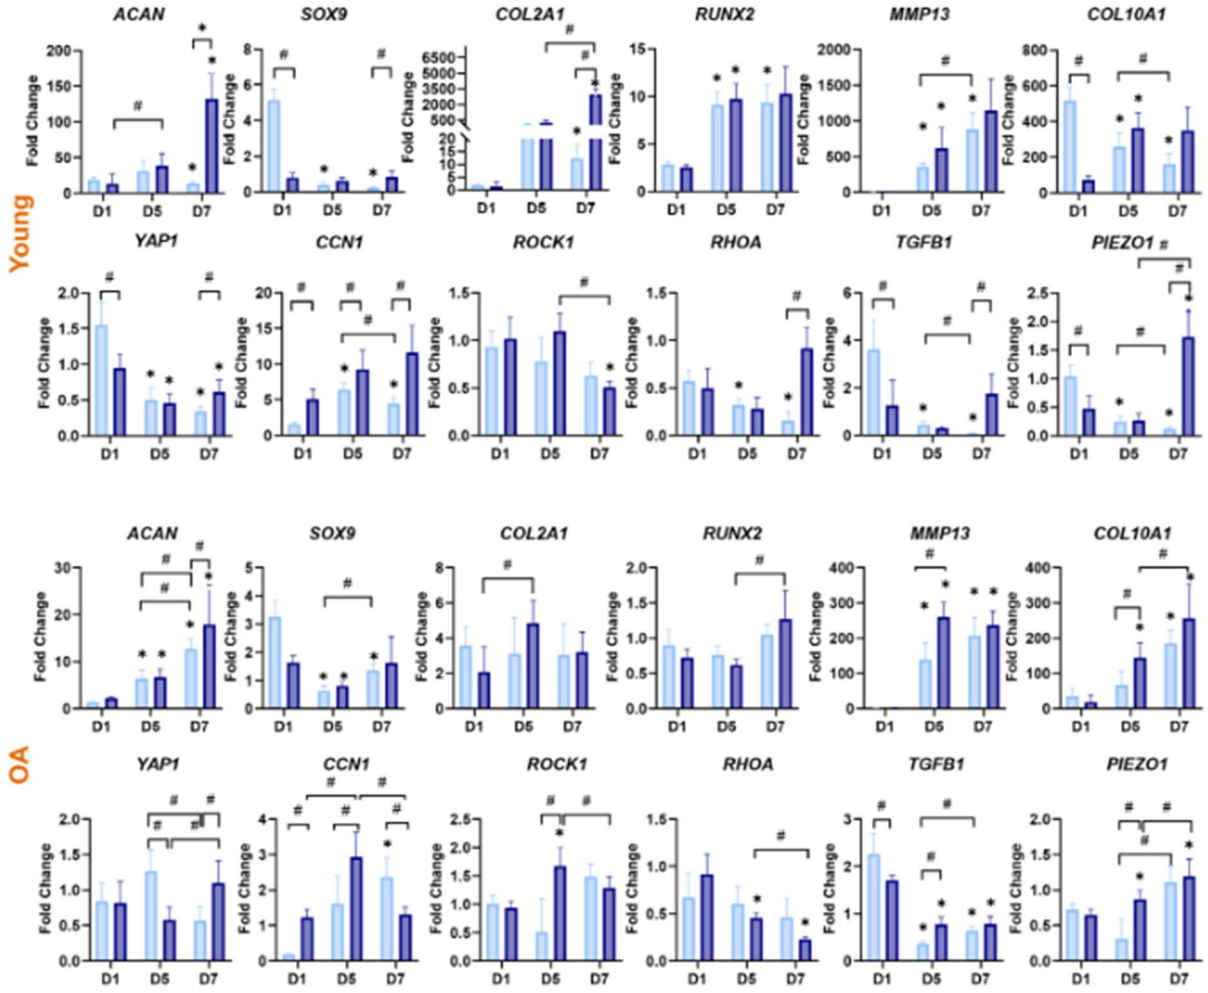
Introduction

Autologous chondrocyte implantation (ACI) is less effective in patients over 45 because expanded cells dedifferentiate and lose redifferentiation capacity. Mechanical loading may help restore chondrocyte function, but the response of early OA cells remains to be elucidated. The objective of this study was to compare the early response of early OA human articular chondrocytes (HACs) to young HACs.

Methods

HACs from young or OA donors were encapsulated (20 million cells/mL) in hydrogels composed of 5% polyethylene glycol (PEG), type I collagen, and hyaluronic acid. Cyclic mechanical loading was applied using tensile acoustic rheometry (TAR) at 10% strain and 1 Hz for 30 minutes per session, repeated over five days with a two-day rest period. Free-swelling hydrogels served as controls. Mechanotransduction and chondrocyte-specific gene expression was evaluated using RT-qPCR, protein levels were assessed by immunofluorescence (not shown).

Results



Mechanical loading enhanced ACAN, COL2A1, and hypertrophic gene expression in young HACs, (Figure 1), consistent with increased matrix synthesis and chondrocyte maturation. In OA HACs, loading did not increase chondrogenic gene expression; however, aggrecan and collagen protein levels were higher than young HACs as confirmed by immunofluorescence, suggesting that post-transcriptional mechanisms contribute to matrix deposition; protein expression in young HACs remained largely unchanged. TGF-β signaling was generally similar between cell types, though OA HACs exhibited slightly reduced SMAD1/5/9 activation and increased SMAD2/3 activation compared to young HACs, consistent with a phenotype favoring tissue remodeling processes. Hypertrophic protein markers decreased in OA HACs after loading but remained unchanged in young HACs, indicating that loading may selectively suppress pathological hypertrophy in OA HACs. Loading induced variable YAP1 and increased CCN1 expression in OA HACs, similar

to young HACs but to a lesser extent, suggesting that mechanotransduction pathways remain partially responsive in disease-altered cells.

Discussion

Short-term mechanical stimulation modulated behavior in both young and early OA HACs, but with different magnitudes. Overall, brief loading benefited OA HACs by enhancing matrix deposition and reducing hypertrophy.

OA65-02

Exoskeleton Reduces Knee Contact Force Through Consistent Decreases in Intersegmental Forces and Varied Changes in Muscle Forces Across People

Ms. Ashley Brown, Mr. Dominic Locurto, Dr. Patrick Slade

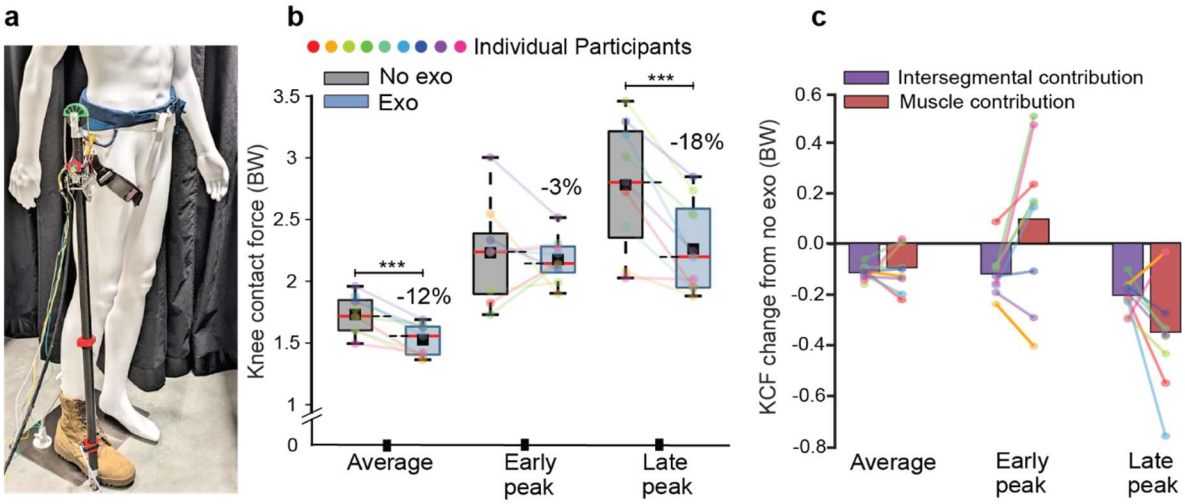
Harvard University, Cambridge, MA, United States

Introduction

Knee osteoarthritis (OA) is the most common cause of adult musculoskeletal pain, affecting over 14 million people in the US. High peak mechanical loading in the knee during walking is strongly correlated with knee OA progression. Knee contact force (KCF) is the measure of total loading at the knee joint and is comprised of intersegmental and muscle forces. There is a need for new interventions that target a key mechanism of knee OA progression by reducing loading and subsequent pain. We developed a bilateral exoskeleton capable of offloading muscle forces and intersegmental loads by providing whole-leg assistance proportional to the individual's ground reaction force (GRF).

Methods

Healthy young adults (N=9) were recruited for a two day protocol. On day 1, participants walked in the exoskeleton for 40 minutes at progressively higher assistance levels proportional to their GRF. On day 2, participants walked in the exoskeleton at four proportional GRF magnitudes linearly spaced between 10% and the comfortable maximum value that the participant identified on day 1. GRF, motion capture, and electromyography (EMG) from 7 knee spanning muscles were collected. EMG-informed musculoskeletal simulation in OpenSim Moco was used to estimate KCF as described in [1].



Results

For each participant, we identified the assistance condition that minimized the RMS of the early and late stance KCF peaks. This selected condition was then compared to normal shoes walking to evaluate device efficacy. Across 9 participants, average KCF over stance decreased by 12%, early peak KCF decreased by 3%, and late peak KCF decreased by 18%. Five subjects showed meaningful increases in muscle contribution to KCF during early stance, while four subjects decreased their early peak KCF.

Discussion

The results suggest the device is capable of providing assistance to reduce early peak KCF, but individuals' natural coordination patterns may affect its benefits. Some participants naturally adopted an effective coordination strategy indicating that such patterns are feasible, and targeted retraining may promote more consistent and larger benefits. Combining this novel exoskeleton assistance and additional user training could represent a breakthrough in knee OA treatment.

Tuning Twisted and Coiled Artificial Muscles (TCAMs) for a Combined Passive-Active Ankle-Foot Orthosis

Mr George Elias[1], Ms. Katherine Vaiciulis[1], Mr. Braeden Harrell[1], Dr. Kirsten M. Anderson PhD[1], Ms. Xandra McGlasson[2], Prof. Jason Wilken PT, PhD[1], Prof. Caterina Lamuta PhD[1], Prof. Deema Totah PhD[1]

[1]University of iowa, Iowa City, IA, United States. [2]University of Iowa, Iowa City, IA, United States

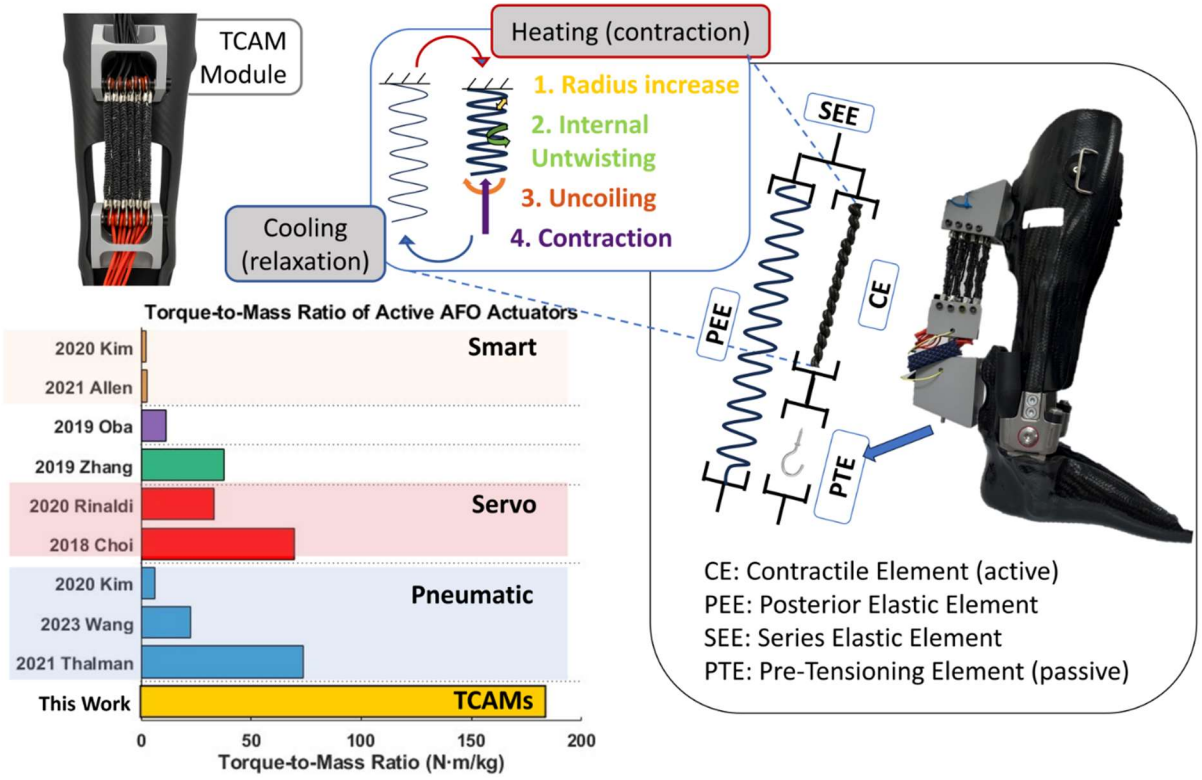
Introduction

Passive ankle-foot orthoses (AFOs) typically use mechanical components like leaf springs and/or dampers to store and release user energy, providing limited gait support. Active AFOs can supplement ankle power through actuators but are often bulky leading to metabolically inefficient systems. Twisted and coiled artificial muscles (TCAMs), a new smart material actuator, can provide both *passive and active support in a single component* with high force output and low mass on the distal limb [1]. This work presents an experimental characterization of a TCAMs-actuation module, within a powered AFO, undergoing flexion through a gait cycle's range of motion. The unique contribution lies in the TCAM's significantly higher torque-to-mass ratio compared to existing active exoskeletons.

Methods

Manufacturing TCAMs involves twisting a carbon fiber/silicone rubber yarn and forming a helical coil after a curing process. The coiled structure has *passive* elastic properties. Further, applying voltage across the TCAMs produces thermal expansion, resulting in uncoiling and shortening of the artificial muscle, producing *active* contractile force. This passive-active TCAM actuation module was incorporated into a custom carbon-fiber AFO with a metal ankle joint. Four passive and three active support levels were tested by pre-tensioning the TCAMs and varying voltage, respectively. An encoder and in-line loadcell measured ankle angle and torque while the AFO was flexed through a normative gait cycle in a custom apparatus.

Results



The TCAMs produced peak torque ranging from 10 to 50 Nm over the gait cycle demonstrating the ability to provide meaningful assistance during the stance phase. By strategically configuring both passive and active components of the actuator system, the

device was able to reproduce up to 40% of peak healthy ankle moment, augmenting the plantarflexor muscles.

Discussion

These results suggest that TCAM-based actuators can supplement lost ankle function in individuals with neuromuscular impairments and represent a clinically significant step toward adaptable, low-profile orthotic devices with broad applicability. Future work will test this technology with a clinical population and validate its use for creating adaptable, user-optimal, low-weight, and flexible robotics customized to increase mobility and improve gait performance for its specific user.

Mechano-Luminescence-Optoelectronic Health Monitoring Wearables for Physical Health Digital Twin

Dr. Donghyeon Ryu[1,2], Mr. Alexander Watts[1], Mr. Joseph Gallegos[1,2], Mr. Aaron Madrid[1], Dr. Peter Anselmo[2]

[1]New Mexico Tech, Socorro, NM, United States. [2]RD Health Sensing Inc., Socorro, NM, United States

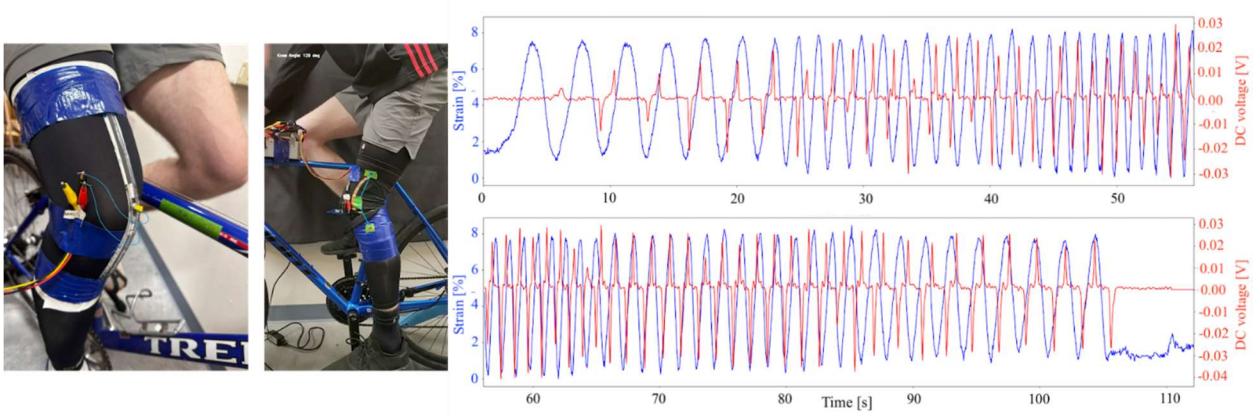
Introduction

This study aims to propose a novel physical sensing technology-based health monitoring wearable platform to help improve our knowledge base about a human neuromuscular system. A model mimicking physical phenomena (namely, physical health digital twin) is created in a digital environment using long-term in-plane strain sensor data from the wearable platform. The physical health digital twin (PHDT) keeps improving the similarity in physical behaviors of the actual human body as it keeps being updated with continuous inflow of strain data. This PHDT serves as a baseline to detect anomalies through data processing of the strain data during daily activities. It is hypothesized that the data anomalies are attributed to neuromuscular health disorders because physical behaviors are outputs of the neuromuscular system with numerous known/unknown inputs. Throughout this study, we plan to verify the hypothesis using the novel strain sensor technology.

Methods

A highly stretchable and self-powering strain sensing fiber (HSF) is designed using the patented design platform of multifunctional mechano-luminescence-optoelectronic (MLO) composites and manufactured using two functional mechano-luminescent (ML) and mechano-optoelectronic (MO) constituents. The MLO-based HSF produces direct current (DC) when subjected to mechanical strain and the DC varies with the strain and strain rate. The HSF at major joints can produce DC and sense in-plane strain by tracking change in DC on a human body. As a validation test, we perform a fitness bike riding with a single HSF instrumented at a knee cap on a human body subject.

Results



DC from HSF was shown to vary with a leg movement during a bike riding. We train long short-term method (LSTM) model using the DC sensor data as well as reference in-plane strain data that were produced after processing video footages recording leg movement.

The trained LSTM model is used for quantifying the in-plane strain and strain rate with the DC sensor data.

Discussion

The DC responds well to the in-plane strain and strain rate on the knee cap under a large strain up to 15% strain. We are in process of building one-leg PHDT using strain and strain rate from the trained LSTM model with the DC sensor data.

Second Harmonic Generation-Derived Collagen Fraction as a Biomarker for Early Osteoarthritis Detection in Human Tibial Cartilage

Ms Benafsha Tughra[1,2], Dr. Ziad Abusara PhD[1,2], Mr. Azim Jinha MSc[1,2], Mrs. Sue Miller MSc[2,3,4], Dr. Scott Timmermann MD[2,3], Dr. Walter Herzog PhD[1,2]

[1]Human Performance Laboratory, Faculty of Kinesiology, University of Calgary, Calgary, AB, Canada. [2]McCaig Institute for Bone and Joint Health, Cumming School of Medicine, University of Calgary, Calgary, AB, Canada. [3]Section of Orthopedic Surgery, Department of Surgery, University of Calgary, Calgary, AB, Canada. [4]Taylor Institute for Teaching and Learning, University of Calgary, Calgary, AB, Canada

Introduction

Early osteoarthritis (OA) involves subtle disruptions in the collagen network that appear before clinical detection. Because collagen architecture governs cartilage mechanical behavior, methods to detect early microstructural change are needed to improve OA diagnosis and monitoring. Second Harmonic Generation (SHG) imaging provides a label-free measure of collagen volumetric fraction (Φ_{col}), while indentation stiffness (E_{inst}) reflects mechanical function. Our previous work across the OA range (regions 0–2, where 0 is healthy and 2 represents severe degeneration) showed a strong linear relationship between Φ_{col} and E_{inst} ($\Phi_{col} = 0.081\ E_{inst} + 0.007$, $R^2 = 0.92$) [1]. This study evaluated whether this association persists in healthy or minimally degenerated knees (regions 0–1) and SHG can detect early tissue deviations indicative of incipient OA.

Methods

Following institutional approval, tibial plateaus were obtained from the Alberta Tissue Bank (three donors, 68 regions). Each region was tested for the instantaneous indentation modulus (E_{inst}) and then imaged to compute Φ_{col}, and regions were graded as 0 or 1 using streaming-potential–based criteria [1, 2]. Linear regressions relating Φ_{col} to E_{inst} were compared with our previously published region 0–2 OA dataset.

Results

In the current cohort of healthy knees (regions 0–1), $\Phi_{col} = 0.026\ E_{inst} + 0.15$, $R^2 = 0.54$ (Fig. 1). The OA slope was approximately 3.05× steeper, and the two regression models for healthy and replaced knee joints intersected at $E_{inst} \approx 2.6$ MPa, $\Phi_{col} \approx 22\%$, marking the point at which their structure–function profiles began to diverge.

Discussion

SHG imaging detected measurable reductions in Φ_{col} from region 0 to 1 despite minimal gross degeneration, demonstrating sensitivity to early matrix disruption. The steep and high correlation between Φ_{col} and E_{inst} in the otherwise healthy knees reflects a tight coupling between collagen loss and mechanics, whereas the lower R^2 relative to replaced knees indicates greater baseline heterogeneity in the replaced joints. The intersection highlights stimulus-dependent inversion of contrast that may refine diagnostic protocols. SHG-derived Φ_{col} shows strong promise as a non-destructive biomarker for early OA detection, progression monitoring, and future clinical translation.

OA66-01

Replicating Physiological Stance Knee Flexion Reduces Residual Hip Torque in Above-Knee Amputees

Ms. Karen Walker, Dr. Grace Hunt PhD, Dr. Lukas Gabbert PhD, Dr. Tommaso Lenzi PhD

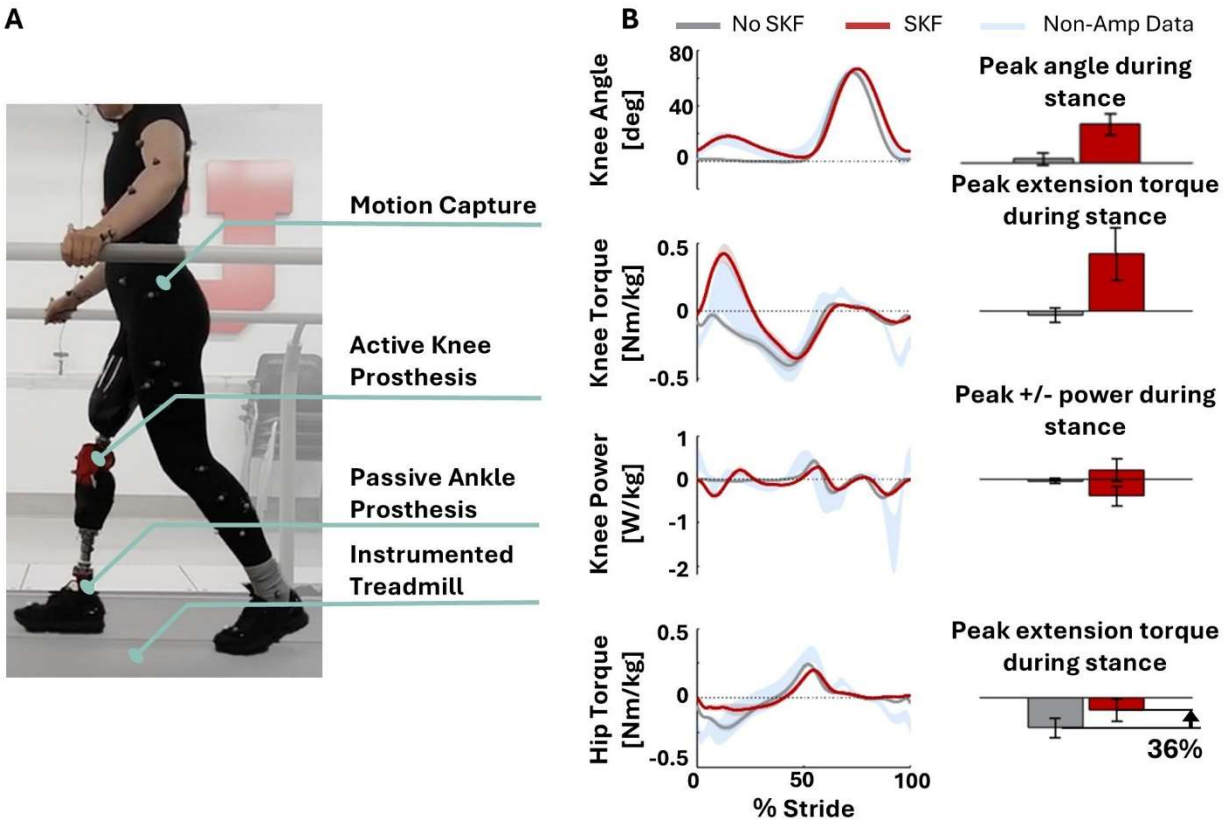
University of Utah, Salt Lake City, Utah, United States

Introduction

The biological knee functions as a shock absorber during stance, absorbing energy to soften impacts with the ground and returning energy to assist forward momentum, a process known as "Stance Knee Flexion" (SKF) [1]. Unfortunately, above-knee amputees typically lack SKF, as conventional passive prostheses cannot generate the positive power required for physiological energy return [2]. Active prostheses can theoretically address this limitation, as their motors can produce both positive and negative power needed for physiological SKF. However, previous studies have not fully replicated physiological SKF kinetics [3]. This study aimed to evaluate gait biomechanics with an active knee prosthesis controlled to deliver physiological SKF. We hypothesized that replicating physiological knee energy absorption/return would reduce compensatory strategies by decreasing residual hip extension torque. The rationale is the energy stored and returned during SKF will supplement forward propulsion, reducing the need for the user to pivot over a fully extended leg.

Methods

Eight unilateral above-knee amputees walked on an instrumented treadmill at a self-selected speed using an active knee prosthesis (Fig.1A) first controlled in a high-impedance mode to prevent SKF, and then with the same device controlled to enable physiological SKF. Lower-limb joint kinetics and kinematics were calculated using ViconNexus and Visual3D.



Results

Without SKF, the prosthetic knee remained fully extended in early stance. In contrast, with SKF, the knee prosthesis successfully matched biological knee behavior, flexing to 18.9+/-5.0°and generating up to 0.46+/-0.19 Nm/kg of extension torque, while absorbing/returning up to -0.25+/-0.26/0.44+/-0.22 W/kg of power (Fig.1B). Crucially, residual hip extension torque decreased by 36% when walking with SKF (0.14+/-0.06 Nm/kg) compared to walking without SKF (0.22+/-0.07 Nm/kg).

Discussion

To our knowledge, this is the first demonstration of an active prosthesis fully replicating the kinematics and kinetics of physiological SKF. Our results suggest that properly replicating SKF facilitates forward movement and reduces the effort required from the residual joint. This reduction in compensatory hip loading could improve mobility and reduce fatigue in above-knee amputees.

Isometric Hip Extensor Torque-Angle Relationships Differ Between the Residual and Intact Limb of Transfemoral Prosthesis Users.

Mrs. Ashlyn Wormsley BS, Dr. Hannah D. Carey PhD, Mrs. Julie Ferrell-Olson MSc, Dr. Andrew Sawers CPO PhD

University of Illinois Chicago, Chicago, Illinois, United States

Introduction

Hip muscle strength is critical to walking speed, balance, and endurance in transfemoral prosthesis users (TFPU) [1]. How amputation and/or subsequent inactivity and disuse alters muscle physiology – particularly the force-length relationship - remains unclear, this limits mechanistic insight and intervention development. The objective of this study was to compare hip extensor torque-angle (force-length) relationships between the residual and intact limbs of TFPUs. We hypothesized that the residual limb would have a flatter torque-angle slope and a more extended peak torque angle due to amputation and/or inactivity.

Methods

Sixteen TFPUs (8 females; 50.3±17.3 years) performed bilateral maximum voluntary isometric hip extension contractions on a motor-driven dynamometer. Each participant completed three trials at nine randomized hip flexion angles between 85° and 165° in 10° increments. Torque-angle relationships were plotted as trial-averaged torque against hip angle (Figure 1). Peak torque angle, linear-fit slope, and R^2 values from torque-angle curves were compared between residual and intact limbs using paired t-tests.

Results

Isometric hip extension torque decreased as hip flexion decreased (Figure 1). Linear models fit the data similarly in both limbs (residual R^2=0.45±0.35; intact R^2=0.54±0.26; p=0.18). Peak torque angle did not differ significantly between limbs (residual=101±17°; intact=106±21°; p=0.48). Residual limb torque-angle slopes were significantly flatter (-0.16±0.17) than intact limb slopes (-0.29±0.22), p=0.03.

Discussion

Consistent with unimpaired adults [2], residual and intact limbs exhibited descending hip extension torque-angle relationships with moderate linear fits. Because peak torque angle was similar between limbs, isometric hip extension strength testing could be standardized at a single, evidence-based hip angle (e.g., 100°-105°). These findings also suggest TFPUs' hip extension strength is underestimated, since many studies use more extended hip

angles during testing [1,3]. Flatter residual limb torque-angle slopes suggest reduced hip extensor torque-generating capacity across muscle lengths, especially at more flexed angles where hip extensors are longest. Between-leg asymmetry in slope suggests that amputation -rather than inactivity or disuse - disrupts the torque-angle (force-length) relationship, since inactivity would likely affect both hips similarly. Direct comparisons to unimpaired adults are ongoing.

Introduction

Anatomical and functional asymmetries from unilateral transtibial limb loss may make asymmetric walking more energy-efficient than symmetric patterns. While preferred stance time asymmetries minimise metabolic cost [1], it remains unclear whether other biomechanical variables demonstrate symmetry or asymmetry during the user's preferred, and likely energetically optimal, gait condition. We aimed to determine whether the preferred walking speed (PWS) of unilateral below-knee prosthesis users reflects the speed that minimises metabolic cost of transport (COT) and/or yields the greatest symmetry in spatiotemporal, vertical ground reaction force (vGRF) and limb work metrics.

Methods

Nine unilateral below-knee prosthesis users (age: 46.3±13.2 years; body mass: 83.0±14.2kg; mean±SD) provided informed consent. The protocol was approved by the University of New South Wales Human Research Ethics Committee. Despite an inclusive, extended recruitment period, a male-only convenience sample was sourced. Markers on the malleoli/prosthesis were tracked (200Hz; Bonita, Vicon) as participants walked on an instrumented split-belt treadmill (1000Hz; M-Gait, Motek Medical) at their PWS and 0.8, 1.0, 1.2, 1.4 and 1.6m/s. Each five-minute trial included metabolic gas collection. Generalised linear mixed models identified speed effects for all variables; optimal values were predicted from fitted functions and compared to PWS.

Results

PWS (1.26 m/s) COT (3.98 J/kg/m [3.50, 4.46]; mean [95%CI]) did not differ from the optimal predicted value (4.04 J/kg/m [3.87, 4.22]; $p=0.21$). The Robinson Symmetry Index [2] was not different between measured values at the PWS and predicted optima for step time ($p=0.889$), step length ($p=0.35$), negative limb work ($p=0.329$) and first peak vGRF ($p=0.692$). Positive limb work ($p<0.001$) and second peak vGRF ($p=0.007$) differed.

Discussion

This study contextualises metabolic cost and key symmetry variables across walking speeds, showing prosthesis users favour speeds that optimise energy cost and, at least in some measures, symmetry. Greater overall symmetry was achievable at slower-than-preferred speeds (5/6 variables could have been simultaneously optimised), but these speeds were likely avoided due to higher metabolic cost. Despite the clinical emphasis on symmetry, asymmetry may serve a functional role, possibly minimising energy expenditure.

Introduction

Falls are common among lower limb prosthesis (LLP) users. Prosthetic foot stiffness is believed to affect LLP users' stability. Previous research on foot stiffness used experimental feet or provided limited accommodation time, limiting the clinical relevance of these findings. This study aimed to determine whether the stiffness of commercially-available prosthetic feet influenced unilateral transtibial LLP users' stability after a week-long accommodation period.

Methods

Using mechanical testing (ISO 10328), we characterized the sagittal-plane stiffness of commonly-prescribed prosthetic feet. Subsequently, unilateral transtibial LLP users wore three different feet of varying stiffnesses for one week, in a randomized order and while masked to foot type. Following each foot accommodation period, participants walked at self-selected walking speeds (controlled within-participant across feet) on level (LVL) and uneven terrain treadmills (UNV) for at least 30 seconds. Using kinematics recorded with optical motion capture during walking, we calculated minimum mediolateral margin of stability (MoS) during each step. [1] Participants rated their balance confidence with each foot on a 0-10 scale. We used linear mixed-effects regression to test for within-participant associations between foot stiffness (N/mm) and gait outcomes (MoS, step width, and balance confidence), controlling for foot type.

Results

Nine male LLP users [mean(SD) age=61.7(9.9)years] have completed the study. Participants selected slower walking speeds for UNV [0.58(0.12)m/s] compared to LVL [0.93(0.22)m/s]. For every 10N/mm increase in prosthetic foot stiffness: 1) prosthesis-side MoS decreased by -0.64±0.10cm on LVL ($p<0.001$) and -0.56±0.12cm on UNV ($p<0.001$); 2) step width decreased on LVL (-0.48±0.17cm, $p<0.05$), but did not change on UNV; and 3) participants' balance confidence decreased (-0.3±0.1, $p<0.001$).

Discussion

Reduced prosthesis-side MoS suggests poorer lateral gait stability with stiffer commercially-available prosthetic feet, especially on UNV where step width was unchanged. Reduced participant-reported balance confidence with stiffer feet corroborates the MoS findings. These results agree with those of previous studies which showed that increased stiffness in experimental prosthetic feet was associated with reduced participant-reported balance confidence. These findings could be useful to clinicians when selecting feet for transtibial LLP users to reduce fall risk.

OA66-05

Hip Muscle Co-Contraction in Transfemoral Prosthesis Users May Not Be an Inherent Consequence of Amputation

Dr Hannah Carey, Mrs. Ashlyn Wormsley, Mrs. Julie Ferrell-Olson, Dr. Andrew Sawers

University of Illinois Chicago, Chicago, IL, United States

Introduction

Walking with a transfemoral prosthesis is believed to involve pronounced co-contraction, potentially due to compensations for missing knee/ankle function, muscle weakness, user experience, or task context (e.g. effort). However, these assumptions have rarely been tested [1]. As a first step towards understanding how amputation affects co-contraction in transfemoral prosthesis users (TFPU), we compared hip co-contraction between residual and intact limbs across effort levels. We used a seated isometric task to remove walking-specific mechanical demands that could mask amputation-related differences in co-contraction. We hypothesized greater co-contraction in the residual than intact limb.

Methods

Thirteen TFPUs (6 females; 50±16 years old) performed isometric hip extension and abduction contractions with their residual and intact limbs on a motor-driven dynamometer at three effort levels: 30%, 60% and 100% MVC. Submaximal efforts were obtained using a visual torque-matching task. Surface EMG was collected from rectus femoris, biceps femoris, gluteus medius, and adductor magnus. Co-contraction values were calculated as the ratio of the less active to more active muscle multiplied by the sum of both muscles [2]. Values were compared using separate two-way repeated measures ANOVAs for extension and abduction.

Results

There was a main effect of effort ($p=0.009$) but not leg ($p=0.454$) for co-contraction during hip extension. However, post-hoc tests revealed no significant pairwise differences between effort levels. For hip abduction there was a main effect of effort ($p<0.001$) but not leg ($p=0.247$). Post-hoc tests revealed higher co-contraction at 100% versus 30% ($p=0.01$) and 60% effort ($p=0.016$).

Discussion

Because hip co-contraction did not differ between limbs during the isometric task, elevated co-contraction during walking in TFPUs likely reflects compensations for lost knee and ankle function or muscle weakness, not amputation per se. Consistent with

unimpaired adults [3], hip abduction co-contraction increased with effort. This trend may reflect greater demands for joint stability and torque accuracy as effort increases, or a common descending command to agonist-antagonist muscle pairs [4] that scales with effort. Direct comparisons to age- and sex-matched controls are ongoing.

Images (Optional)

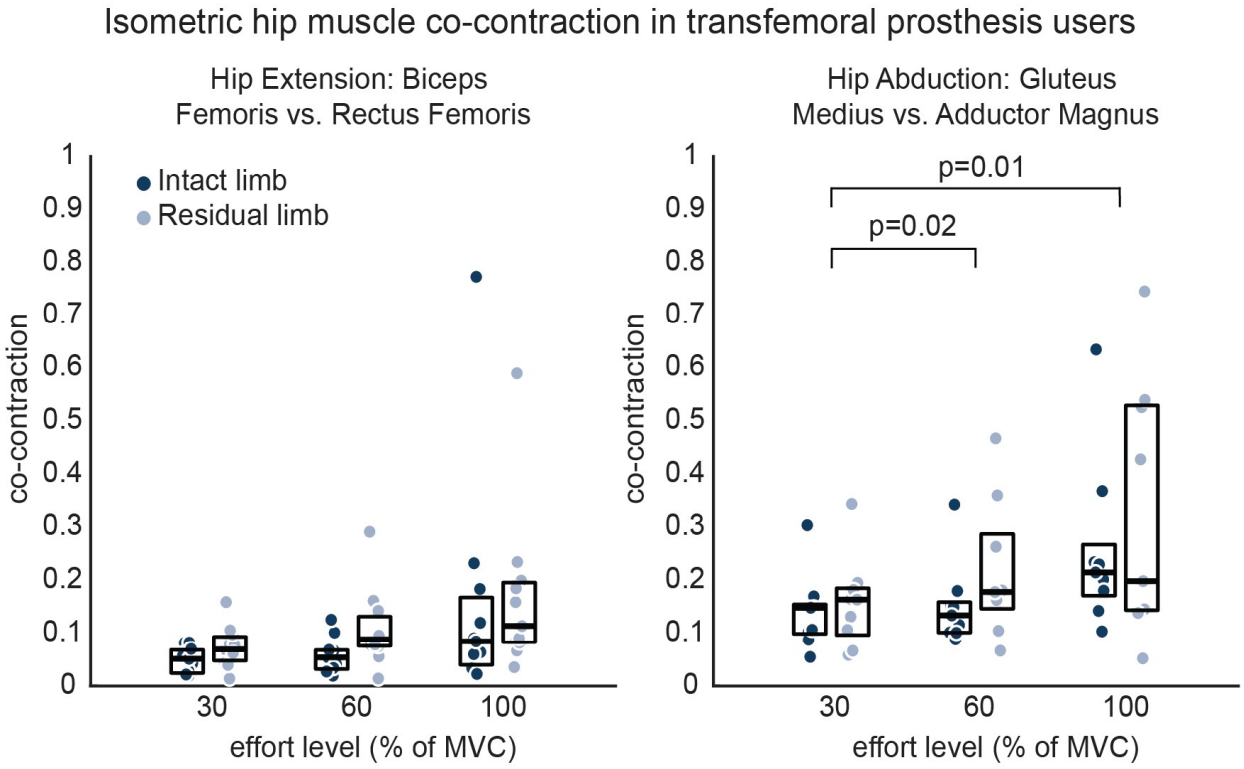

Figure 1. Agonist-antagonist co-contraction during isometric maximum voluntary contractions (MVC, i.e., 100%) and submaximal contractions (30% and 60% of MVC) for hip extension (left panel) and hip abduction (right panel). A Comparison of Gait Adaptations During Two Types of Dual-Task Walking in Individuals With Unilateral Lower Limb Amputation: Part 1- Gait Spatiotemporal Outcomes

Ms. Emily Parsowith M.S., CSCS[1], Dr. Lisa Zukowski Ph.D[2], Dr. Paul Kline PT, DPT, Ph.D[1]

[1]Virginia Commonwealth University, Richmond, VA, United States. [2]High Point University, High Point, NC, United States

Introduction

Following lower limb amputation (LLA), spatiotemporal gait asymmetries are common with prosthesis use and adversely affect gait efficiency and functional performance [1]. Cognitive-motor dual-task assessments have been utilized in people with LLA to assess readiness for real-world walking, but there is large variation in the type of cognitive task used [2]. The purpose of this study is to compare gait spatiotemporal parameters between single-task walking, vision-based cognitive-motor dual-task walking, and non-vision-based cognitive-motor dual-task walking in people with unilateral LLA.

Methods

16 participants were enrolled; 14 (11 males, 3 females; age=55.3±13.4 yrs, BMI=29.7±4.0 kg/m2, 10 transtibial, 4 transfemoral) had complete data for analysis. Three walking tasks were performed, each two minutes in duration: single-task (ST), serial subtraction dual-task (SS; non-vision-based), and visual puzzles dual task (VP; vision-based). The two cognitive tasks were evaluated to compare between types of cognitive-motor dual-tasking. APDM Opal 3-sensor wireless inertial sensors, attached to the dorsal aspect of the left and right feet and the posterior of the lower back at the L4/L5 lumbar spine, were used to measure gait speed, cadence, stance time, step duration, and stride length. Normalized symmetry index (NSI) was calculated to compare the effect of task on stance, step duration, and stride length. A NSI value of 0% is considered perfect symmetry.

Results

A repeated measures ANOVA revealed a significant main effect of task condition on gait speed ($F=17.313$, $p<0.001$), cadence ($F=17.332$, $p<0.001$), stride length in the amputated limb ($F=16.633$, $p<0.001$) and stride length in the non-amputated limb ($F=15.869$, $p<0.001$). Post-hoc paired-samples t-tests indicated that gait speed, cadence, and stride length in the amputated and non-amputated limb were greater for ST compared to SS and VP.

Notably, VP had a higher cadence than SS (p=0.007, d=-0.845). Complete results from the statistical analysis can be found in Table 1.

Discussion

These findings suggest type of cognitive task during cognitive-motor dual-tasking influences cadence in people with LLA. Additional research on dual-task performance based on types of cognitive task and real-world walking are needed.

Wearable Ankle Resistance Training to Enhance Gait Function in Older Adults: A Proof-of-Concept Feasibility Study Using a Smart Passive Device

Mr. Ethan Simaitis[1,2], Mr. Benit Namahoro[1,2], Mr. Max Trnonja[1,2], Mr. Roshan Ragu[1], Dr. John Batsis MD, PhD[1], Dr. Michael Lewek PT, PhD[1,2], Dr. Zachary Lerner PhD[3], Dr. Jason Franz PhD[1,2]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States. [2]North Carolina State University, Raleigh, NC, United States. [3]Northern Arizona University, Flagstaff, AZ, United States

Introduction

Preventing walking disability in our rapidly aging population is a significant public health challenge. Reduced strength and functional output from muscle-tendon units spanning the ankle (i.e., plantarflexors) during push-off represent known determinants of walking disability due to the aging process and a potential target for intervention [1]. To overcome the poor compliance of conventional interventions, we theorized that targeted and context-specific ankle resistance holds potential to revolutionize therapeutics to restore plantarflexor function and gait biomechanics for older adults. We conducted a proof-of-concept test to determine the feasibility and early efficacy of wearable ankle resistance training to enhance plantarflexor and gait function older adults.

Methods

A pilot cohort of n=3 slow-walking (1.01±0.14 m/s) and physically inactive older adults (aged 65-74) completed a 6-week training study. In each of 12, 20-min sessions, participants walked while using a novel wearable ankle resistance system designed with a carbon fiber leaf spring and embedded sensors on the foot and ankle. The device provided real-time audio-visual ankle power biofeedback to promote plantarflexor muscle engagement during push-off. Walking speed and ankle resistance increased progressively based on 70% success in exceeding a target ankle power of 110% of habitual walking. Primary outcome measures included feasibility (compliance and retention), gait performance (comfortable/fast walking speeds), and plantarflexor function (maximum voluntary isometric contraction [MVIC] strength via dynamometry and medial gastrocnemius thickness via *in vivo* ultrasound).

Results

Participants reported no safety or comfort concerns, completed 100% of their 12 training sessions, and averaged 70% success in plantarflexor engagement. Compared to pre-

training, 6 weeks of wearable ankle resistance training elicited on average a 27% increase in calf muscle strength and a 13% increase in calf muscle thickness. Functionally, local muscle improvements were accompanied by up to 20% (0.18 m/s) and 6% (0.10 m/s) increases in preferred and fastest possible walking speeds, respectively.

Discussion

Preliminary safety and feasibility data, as well as early gait and muscle-level efficacy data, support moving to more rigorous evaluations of wearable ankle resistance training with on-board ankle power biofeedback as an effective therapeutic strategy to enhance gait function for older adults.

Images (Optional)

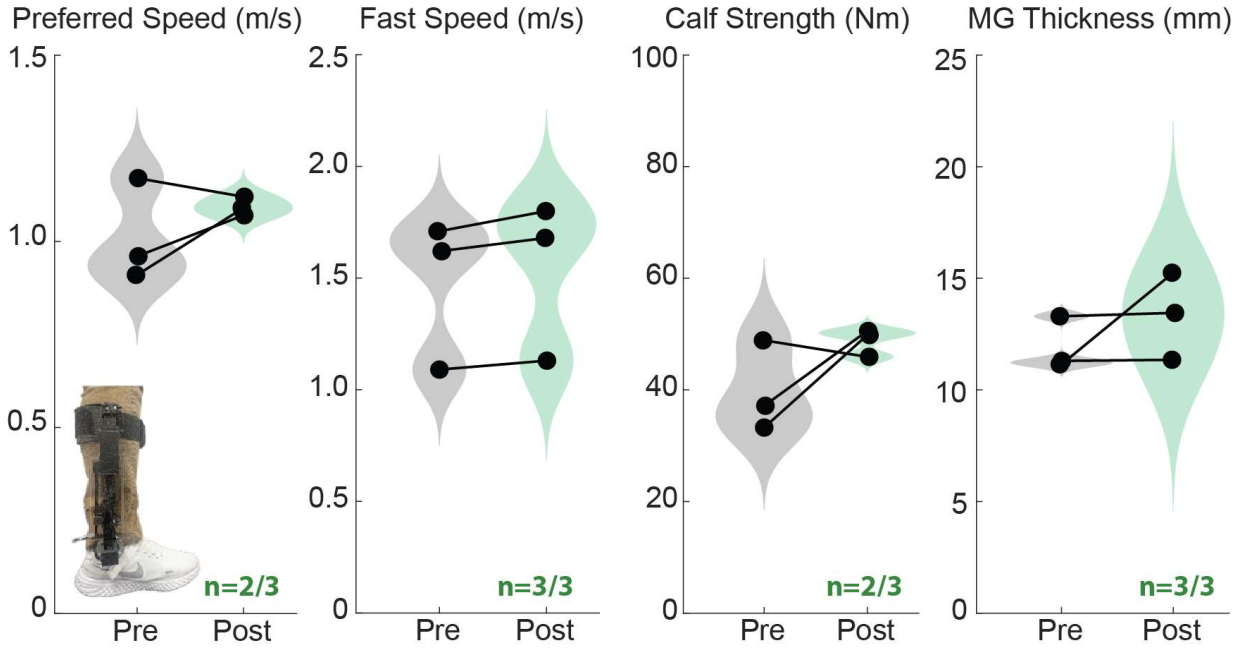

Figure 1. Pre-post comparisons for a pilot cohort of n=3 older adults who participated in a 6-week wearable ankle resistance training program. The passive device (shown) was worn bilaterally and provided plantarflexor resistance via carbon fiber leaf springs and ankle power biofeedback via embedded sensors to encourage plantarflexor engagement in walking.

Bottom-Up and Top-Down: Learning Physiologically Plausible Exoskeleton Control via Physics-Informed Musculoskeletal Simulation

Dr. Inseung Kang, Mr. Itak Choi, Mr. Ilseung Park

Carnegie Mellon University, Pittsburgh, PA, United States

Dr. Inseung Kang

Mr. Itak Choi

Introduction

Wearable exoskeletons have advanced rapidly, yet real-world deployment remains limited by the difficulty of creating control policies that generalize across users, tasks, and environments. Current controllers often require hardware-in-the-loop tuning under narrow conditions, restricting scalability. Advances in musculoskeletal simulation and AI now enable digital twins capable of physiologically plausible motion, providing a scalable platform for exploring user variability without exhaustive physical experiments. Here, we compare two complementary strategies, bottom-up reinforcement learning (RL) and top-down imitation learning (IL), to assess their potential for exoskeleton control.

Methods

We evaluated RL and IL using a 21-DOF, 90-muscle musculoskeletal model. The RL agent learned locomotion through reward shaping (reduced muscle activation) combined with domain randomization to promote robustness across walking conditions. The top-down agent tracked reference kinematics, receiving future target states and generating muscle excitation commands. The IL reward emphasized kinematic tracking while penalizing excessive kinetics. Biomechanical fidelity was assessed by comparing simulated joint moments to physiological profiles. As a proof of concept, the learned digital twin was integrated with a hip-exoskeleton model to train an assistance controller.

Results

The RL agent produced biomechanics profiles bounded within human-like motion while maintaining stable locomotion across settings (Moment R^2=0.79, RMSE=0.25~Nm/kg;

Angle R^2=0.919, RMSE=4.30°). Deploying the RL-trained controller on a physical hip exoskeleton yielded torque profiles with R2=0.60 and RMSE=0.048 Nm/kg, indicating a manageable sim-to-real gap. The IL agent reproduced highly human-like gait patterns, with hip and knee angle errors of 4.82° and 2.46°, and moment estimation errors of 0.13 and 0.09 Nm/kg.

Discussion

The two strategies provide complementary strengths rooted in how they learn. RL acquires locomotion directly from physics, producing behaviors that remain stable across settings. Its independence from motion references enables broad exploration and strong robustness to out-of-distribution conditions. In contrast, IL generates physiologically realistic biomechanics for personalization. However, this reliance on reference data also makes it sensitive to conditions not represented in the demonstrations, limiting its generalizability. These trade-offs motivate a hybrid framework that anchors motion within physiological norms through IL while leveraging RL for stability, enabling exoskeleton controllers that are personalized for real-world use.

Images (Optional)

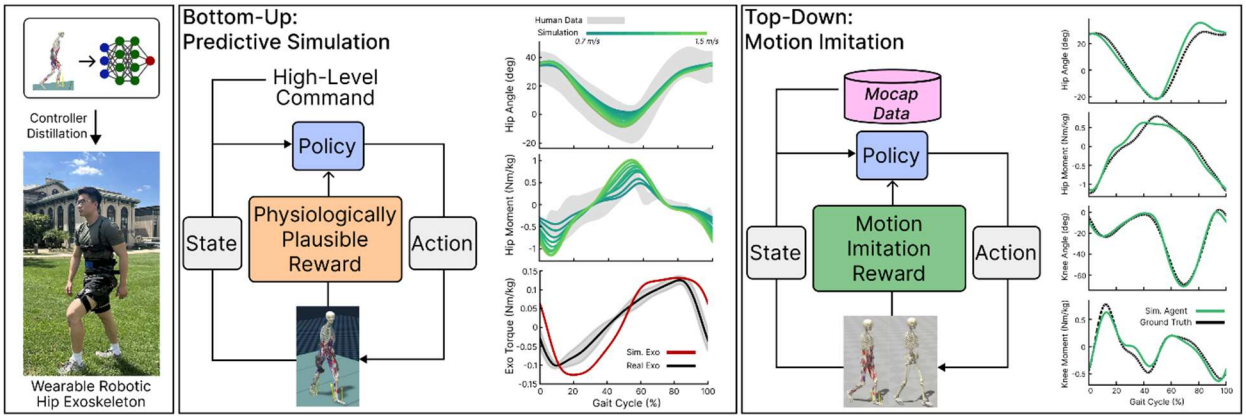

Figure 1: Bottom-up and top-down motion generation strategies used for developing exoskeleton control policies through simulation-to-real distillation. The bottom-up agent optimizes biomechanical objectives, yielding broad generalization across tasks and enabling the training of a viable hip exoskeleton assistance controller directly from the learned policy. The top-down agent imitates human motion trajectories, producing physiologically plausible biomechanics. Together, these complementary approaches highlight the need for a hybrid framework that integrates human-likeness with robustness for reliable real-world exoskeleton control.

Powered Footwear System Designs Must Account for Athlete Kinematic Changes in Response to Ankle Assistance and System Compliance

Dr. Julia Butterfield, Ms. Kristin Quah, Ms. Kristin DeHart, Ms. Hannah Frame, Dr. Alison Sheets-Singer

Nike, Inc., Beaverton, Oregon, United States

Introduction

Nike is designing powered footwear systems (PFS) to provide metabolic benefits during walking and running. The systems aim to provide large torques in late stance as literature [1,2] suggests are important for large metabolic reductions. They include compliance at the device-body interfaces for comfort and wearability, even though torque-induced deformations of compliant interfaces may negatively impact device function. Nike's first PFS prototype (Fig.1) did not produce the expected metabolic benefits, and participants felt assistance stopped too early; therefore, this study aims to investigate potential causes including: ankle plantarflexion changes with assistance, electro-mechanical limitations impacting the system's on-body performance, and interactions between these factors.

Methods

Six athletes gave informed consent and completed two 90-second, 6-mph running trials on a Bertec treadmill: shoes-only, and wearing the PFS. Motion capture (Vicon) of the athlete and PFS were collected during the final 20-seconds, and stance-phase metrics were calculated: difference in peak biological ankle plantarflexion angle with and without the PFS; and difference between biological ankle and mechanical PFS ankle range of motion (ROM), peak plantarflexion angle, and peak and average angular velocity.

Results

Wearing the PFS increased all athletes' peak stance-phase biological plantarflexion angle (mean difference from shoes: 6.0±3.1°). The biological and mechanical PFS ankle angle in the powered trials also differed due to system compliance: the PFS moved through a larger ROM than the athlete's biological ankle (difference: 12.0±2.5°), reached larger peak plantarflexion angles (difference: 8.4±3.2°), larger maximum angular velocities (difference: 125.5±73.1°/sec), and had larger average angular velocity between maximum dorsiflexion and toe-off (difference: 34.9±16.8°/sec).

Discussion

The PFS torque increased biological plantarflexion, and system compliance allowed increased mechanical ROM, meaning the PFS had larger-than-expected mechanical plantarflexion which shifted it into a region with limited torque-production capability. Additionally, the larger-than-biological PFS angular velocity suggests the system must be able to generate higher electro-mechanical power since power is a function of torque and angular velocity. Recent Nike PFS iterations that include these updated specifications are more capable of delivering metabolic and perception benefits when optimally controlled.

Images (Optional)

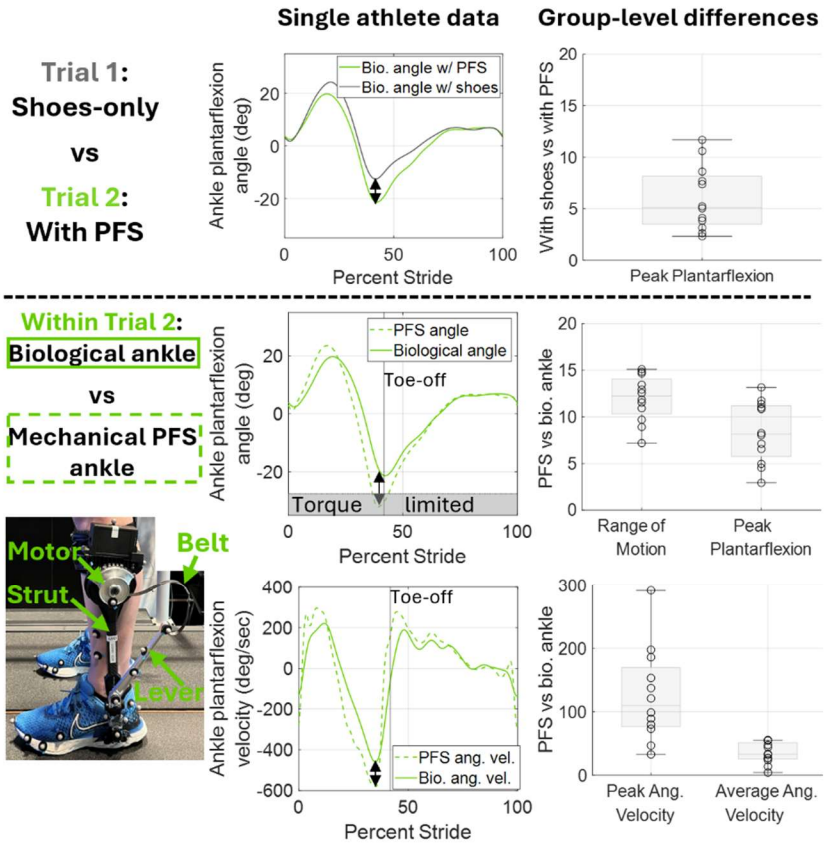

Figure 1. Athletes completed motion capture trials with shoes-only and with a powered footwear system (PFS). The PFS produces torque about the ankle by spinning the motor to shorten the belt, causing the lever to rotate relative to the strut. As the lever nears alignment with the strut, the PFS's ability to apply torque decreases as the moment arm approaches zero. The biological ankle angle is defined using markers on the shoe and the shank. The mechanical PFS ankle angle is defined using markers on the PFS lever and strut. **(Top)** Athletes reached larger biological plantarflexion angles during stance when running in the PFS compared to running in shoes. **(Middle)** The mechanical PFS ankle joint moved through a larger sagittal range of motion than the biological ankle and reached a higher peak plantarflexion angle in stance. For some athletes, the PFS plantarflexed enough that the system's ability to produce torque was severely limited due to strut-lever alignment. **(Bottom)** The mechanical PFS ankle also had larger peak plantarflexion angular velocity during stance and larger average plantarflexion angular velocity between maximum dorsiflexion angle and toe-off than the biological ankle. Data are shown for the right leg of a representative athlete (left column, lines represent the average across all strides within a trial) and for the group (right column, circles represent individual athlete data with separate circles for the left and right sides). Positive values in the group-level data indicate that the mechanical PFS ankle had a larger range of motion and more plantarflexed peak position than the biological ankle, and that athletes have a larger peak stance-phase biological plantarflexion angle when wearing the PFS compared to running in shoes.

Control of a Modular Hip-Knee Exoskeleton via Reinforcement Learning for Sit-to-Stand and Squatting Assistance

Dr Neethan Ratnakumar, Ms. Mariya Tohfafarosh, Dr. Xianlian Zhou

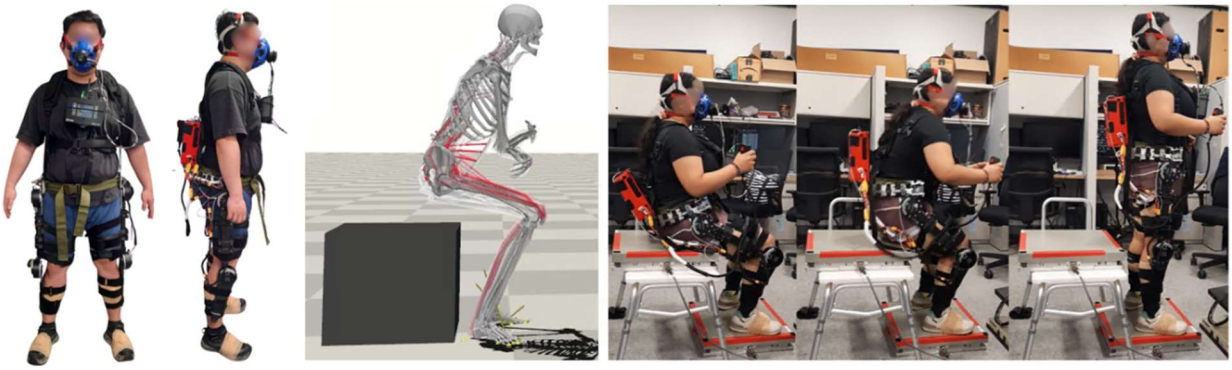
New Jersey Institute of Technology, Newark, New Jersey, United States

Introduction

As the global population ages, the demand for wearable assistive technologies that can enhance mobility, independence, and quality of life continues to rise. Sit-to-stand(STS) transitions and squatting are two of the most biomechanically demanding daily movements, requiring substantial lower-limb strength, joint coordination, and balance control. Developing adaptive and intuitive control strategies for lower-limb exoskeletons is therefore essential to provide safe, timely, and personalized assistance for these tasks.

Methods

We developed a new hip–knee exoskeleton by augmenting an existing hip exoskeleton[1] with powered knee joints. The 8.5-kg system was engineered for high backdrivability, easy adjustability across users, and compatibility with multiple sensing and control frameworks. The device incorporates an IMU-based kinematic measurement system that streams data wirelessly to an onboard Raspberry Pi for real-time processing and control. To design task-specific assistance profiles, we employed a reinforcement learning (RL) framework that generated muscle-driven human motion simulations and jointly optimized hip and knee torque assistance for STS and squatting. A human-subject evaluation involving five healthy adults assessed the feasibility, safety, and physiological impact of the RL-driven controller using indirect calorimetry, heart rate, electromyography (EMG), and full-body kinematics.



Results

In simulation, the RL-trained controller produced torque assistance patterns that closely matched the timing and shape of muscle-generated joint moments, substantially reducing predicted muscle activation and joint loading. When implemented on hardware, the controller demonstrated robust user adaptation, generating personalized torque profiles (kept below 10 Nm for safety) that aligned with each participant’s natural motion. During repetitive squatting, active assistance reduced net metabolic rate by approximately 10%. STS assistance yielded smaller metabolic reductions, likely due to suboptimal control near the seat-contact phase. Ongoing EMG analysis will further quantify changes in muscle recruitment and fatigue across assistance conditions.

Discussion

These preliminary findings demonstrate that RL-based control is a promising strategy for adaptive, task-specific exoskeleton assistance and can reduce physiological effort during high-demand movements. Observed performance sensitivities, such as fit, user acclimation, comfort, and latency, highlight opportunities for hardware refinement and improved sensing integration. This work establishes a streamlined framework for rapid development, simulation-based optimization, and real-world deployment of advanced exoskeleton controllers.

Same Jump Height, Different Movement Strategy: Five Force Production Phenotypes in Elite Athletes

Dr. Bahman Adlou M.Sc., Ph.D.[1,2], Mr. John Grace MS[1], Dr. Christopher Wilburn Ph.D.[1], Dr. Wendi Weimar Ph.D.[1]

[1]Auburn University, Auburn, Alabama, United States. [2]US Soccer Federation, Fayetteville, Georgia, United States

Introduction

Jump height remains the predominant metric for countermovement jump (CMJ) assessment in high-performance athletes, yet this single value cannot distinguish how athletes achieve their performance. If multiple coordination strategies produce equivalent outcomes, practitioners may fail to detect meaningful neuromuscular changes even with consistent monitoring. This study applied functional data analysis [1] to determine whether distinct force production strategies exist in elite athletes and whether different strategies can yield similar jump heights.

Methods

Force-time data from 17,767 verified CMJ trials across 448 NCAA Division I athletes (323 male, 125 female; 9 varsity sports; 6,200 testing sessions; 2022-2025) were sampled at 500 Hz and underwent phase-linked temporal normalization and functional principal component analysis (fPCA). K-means clustering identified movement strategies, validated through gap statistic, silhouette coefficient (0.31), and bootstrap resampling (1,000 iterations; Jaccard similarity=0.82). Statistical parametric mapping (SPM) quantified temporal force differences. Within-athlete consistency was evaluated using intraclass correlation coefficients.

Results

Four principal components captured 95.50% of force-time variance. Five stable strategies emerged (Figure 1) with jump heights ranging from 31.6±6.9 cm (Strategy 4) to 48.4±5.6 cm (Strategy 3). Within-athlete consistency was high (ICC=0.66) while sport-specific clustering was weak (Cramér's V=0.066), indicating stable individual phenotypes. Critically, two high-performing strategies achieved comparable jump heights (Strategy 2: 45.7±7.7 cm; Strategy 3: 48.4±5.6 cm) through different coordination: Strategy 3 produced 4.7% greater peak force (2.92 vs. 2.79 BW; $p<0.001$, $d=0.47$) with distinct temporal force application during

braking and propulsive phases (18-92% vs. 14-92% of movement cycle). These two strategies represented 41% of all testing sessions.

Discussion

Elite athletes employ multiple distinct strategies to accomplish the CMJ task, though individuals remain consistent, and equivalent jump heights do not guarantee equivalent neuromuscular function. An athlete transitioning between strategies while maintaining jump height would appear stable under conventional assessment, potentially masking fatigue, compensation, or early-stage injury. Force-time waveform analysis detects coordination changes invisible to discrete metrics and should be integrated into performance monitoring and return-to-play decision-making. Limitations include absence of prospective injury data. Future work should examine whether strategy-matched training interventions produce superior individualized adaptations.

Joint Loading and Performance Implications of an Isolated Reduction in Footwear Rotational Traction

Lead Biomechanics Researcher Marlon Rainville, Senior Biomechanics Researcher Amanda Cann, Lead Biomechanics Researcher Nick Frank, Director of Footwear Biomechanics Elysia Davis

Nike Sport Research Lab, Beaverton, Oregon, United States

Introduction

Mechanically available traction between footwear and playing surface describes the resistance to relative motion and can be measured in translational and rotational components [1]. Footwear traction is critical for athletic performance [2], but high rotational traction is linked to lower extremity non-contact injuries [1] and high joint loading [3] in field sports. NIKE Inc. designed a novel forefoot cleated traction pattern that reduces rotational but maintains translation traction compared to traditional patterns. The purpose of this study was to measure the effects of reduced rotational traction footwear on agility performance and knee joint loading during cutting.

Methods

Twenty athletes (6F, 14M) completed seven maximal effort 180° shuttle cuts in two footwear conditions on artificial turf with embedded force platforms. Mechanical testing measured the NIKE Phantom Luna (“LowRT”) cleat reduced rotational traction by 47% and maintained translational traction compared to the NIKE Phantom GT2 (“Control”) cleat (**Table 1a**).

Kinematic and kinetic data were collected to quantify agility performance, ground reaction forces, and stance leg kinematics and kinetics. A two-way mixed ANOVA was used to test for interaction effects between footwear and gender. For variables without an interaction effect, gender was collapsed to identify significant main effects ($\alpha < 0.05$) of footwear using paired t-tests.

Results

A significant interaction exists between gender and footwear for agility performance time, with female athletes performing faster in the LowRT cleat (-2.6% Female x LowRT, $p = 0.04$) and male athletes showing no performance difference (0% Male x LowRT, $p > 0.05$).

Footwear did not affect utilized translational traction. The LowRT cleat significantly reduced peak free moment in early stance. The LowRT cleat significantly reduced peak knee abduction moment and peak knee transverse external rotation moment in late stance. Athletes exhibited greater transverse-plane internal foot rotation during stance, starting from a more externally oriented foot position at ground contact in the LowRT cleat (**Table 1b**).

Discussion

Footwear that maintains sufficient available translational traction but reduced rotational traction reduces knee joint loading without compromising agility performance.

Height or Hops: Why Do Female Hoopsters Rarely Dunk?

Dr. Emily Haag PhD, CSCS, Dr. Peter Weyand PhD

Texas Christian University, Fort Worth, Texas, United States

Introduction

Since dunking data has been available for both men's and women's professional basketball (2002), there have been over 200,000 regular-season dunks recorded for men and 34 total for women. Indicating that the men's hoopsters dunk 6,000 times more often than the women.

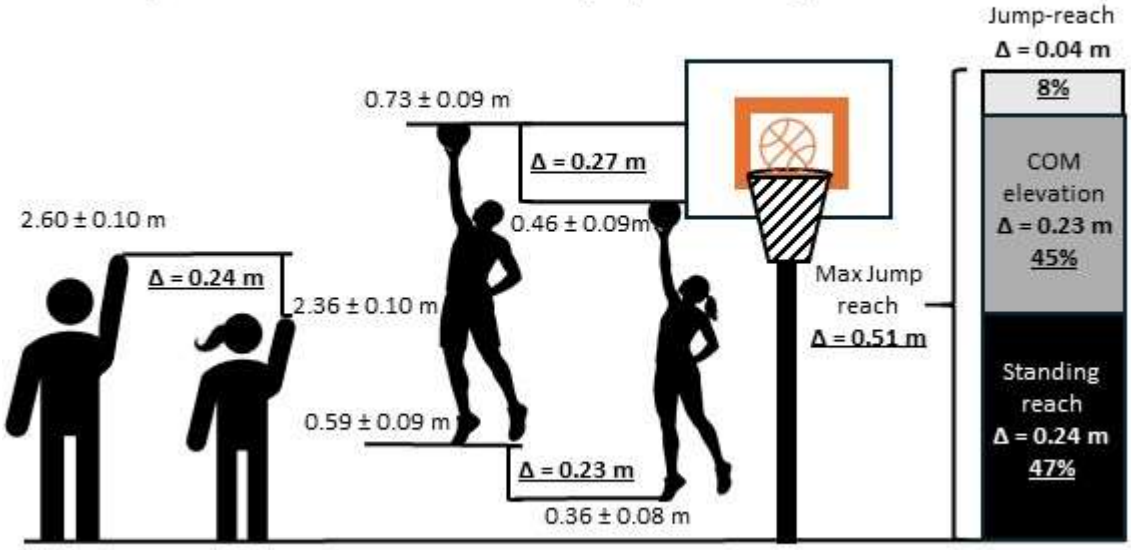
The 10-foot rim is the same for both sexes; therefore, the deficit could be attributable to either (1) women being shorter than men, and therefore having to jump higher to attain the same jump and reach height, or (2) women being less able to elevate the body to attain the height needed, or both.

We hypothesize that the basis for the sex difference in dunking frequency is equally attributable to stature and jumping ability.

Methods

To determine the relative contributions of stature and jumping ability to maximal projected jump and reach height of professional men and women basketball players, mean reported heights of NBA and WNBA players were acquired (2.00 ± 0.08 m, 1.85 ± 0.07 m, respectively). Standing reach heights of professional players were determined using reported arm length/ height ratios. The sex difference in jumping ability was assessed by measuring kinetics and maximal vertical countermovement jump and reach height for 20 athletic men and 20 athletic women subjects, jumping off laboratory force platforms.

Results



As seen in Figure 1, the mean sex difference in the maximal projected jump and reach height was Δ=0.51 m. The relative contributions of stature and jumping ability to this overall differential were broken down into standing reach (Δ=0.24 m; 47%), center of mass (COM) jumping elevation (Δ=0.23 m, 45%), and jump and reach height difference from COM elevation (Δ=0.04 m, 8%).

Discussion

In contrast to our initial hypothesis of equally attributable factors, stature and reaching ability account for relatively more (55%) of the differential than jumping ability (45%). In conclusion, the sex difference in dunking frequency is primarily attributable to sex differences in stature and secondarily to vertical jumping ability/heights. We also identified a small additional contribution from differences in jump and reach height that were greater than standing reach height differences.

Images (Optional)

Quantifying Execution Variability in the CMJ: Phase-Specific Responses to Practice-Induced Fatigue

Mr. Anil Palanisamy, Mr. Aniakh Randhawa, Dr. Dylan Kobsar

McMaster, Hamilton, ON, Canada

Introduction

Fatigue can disrupt motor control, leading to changes in movement variability, defined as the trial-to-trial fluctuations in repeated skill execution. Execution variability captures the subtle adjustments performers use to maintain a stable coordination strategy in well-learned, multi degrees-of-freedom (DOF) movements(2). Because execution variability is sensitive to coordination shifts, complex goal-directed tasks offer an effective model for studying how fatigue influences movement control (6). The countermovement jump (CMJ), a coordination-intensive task used in athlete monitoring, is well suited for this purpose. When paired with force-plate analysis, the CMJ allows phase-specific analysis of jump execution, making it a practical tool for detecting fatigue-related changes in execution (3). However, how fatigue affects the magnitude of execution variability remains unclear (4).This study tested whether basketball practice alters the magnitude of execution variability, quantified using the coefficient of variation (CV) (5). We hypothesized increased post-practice variability, particularly in eccentric-phase metrics sensitive to fatigue(7).

Methods

This repeated-measures study assessed pre- to post-practice changes in CMJ execution variability in thirty basketball athletes (14 males, 16 females). CMJs were performed on dual uniaxial force plates (ForceDecks FDLite, VALD Performance), which recorded vertical ground reaction forces at 1,000 Hz (1). Force–time data were processed using ForceDecks software to derive phase-specific CMJ metrics with established accuracy and reliability relative to laboratory force plates (1). Within-subject CV was calculated to quantify the magnitude of changes in execution variability(4).

Results

Eccentric-phase variability increased in Braking RFD ($\beta = 20.6\%$, $p = 0.050$) and Deceleration RFD ($\beta = 23.3\%$, $p = 0.014$). Concentric variability increased: Concentric Impulse Phase 1 (first 50% of concentric; $\beta = 36.1\%$, $p = 0.001$) and Concentric Impulse–100 ms ($\beta = 33.6\%$, $p = 0.001$) both increased. Jump-height variability also increased ($\beta = 24.5\%$, $p = 0.014$).

Discussion

Despite reductions in mean force and jump performance, most CMJ variability metrics remained stable, indicating preserved coordination under typical training loads. Larger changes emerged in the concentric phase, where variability in early (Phase 1) and rapid (100-ms) impulse production increased. In contrast, increases in Braking and Deceleration RFD variability suggest diminished tolerance to eccentric loading under fatigue (2).

ACL Injury Resilience Score Distinguishes Risky and Protective Biomechanics with In-Lab and Out-of-Lab Measurement Tools

Dr. Kirsten Seagers MS, PhD[1], Dr. Krithika Swaminathan MS, PhD[1], Dr. Julie Kolesar MS, PhD[1], Dr. Sam Hamner MS, PhD[1], Ms. Julie Muccini MS, OTR/L[1], Dr. Gregory Myer PhD, FACSM, CSCS*D[2], Dr. Jennifer Hicks MS, PhD[1], Dr. Scott Delp MS, PhD[1]

[1]Stanford University, Stanford, CA, United States. [2]Emory University School of Medicine, Atlanta, GA, United States

Introduction

ACL injuries are among the most debilitating in sports, but many occur during non-contact incidents and are preventable through targeted training [1]. A metric is needed to assess injury risk across multiple sport-related movements and target neuromuscular training to individualized risk factors. In this study, we aimed to develop a score that reflects an athlete's overall biomechanical performance during movements that differentiate injury risk. We compared this score between in-lab (motion-capture) and out-of-lab (OpenCap) measurement tools.

Methods

We collected concurrent 3D motion-capture and OpenCap video data for 26 uninjured female athletes (15.7±1.2 yrs) during five common injury-risk screening activities (Figure 1A)[2, 3]. We calculated activity-specific biomechanical risk factors and compared these factors to existing literature on injured groups to establish an injury resilience distribution (high resilience = low injury-risk). By defining a sample-adjusted injury threshold, we calculated resilience factor-specific z-scores (Figure 1B). The ACL Injury Resilience (AIR) Score was derived by averaging z-scores, with higher scores indicating greater resilience. We compared musculoskeletal model visualizations from athletes with low and high AIR scores to literature-derived profiles of injury-prone versus injury-resilient movements. AIR scores computed with kinematics from motion-capture and OpenCap were compared with a Pearson correlation.

Results

Musculoskeletal visualizations showed the athlete with the lowest AIR Score (red) exhibited riskier mechanics, while the athlete with a high AIR Score (green) displayed protective movements (Figure 1C). AIR Scores calculated from motion-capture and OpenCap kinematics were strongly correlated ($r=0.73$, $p<0.005$; Figure 1D)[4].

Discussion

The AIR Score assesses injury resilience during multiple movements using literature-derived thresholds linking biomechanical factors to ACL injuries. Musculoskeletal visualizations highlight vulnerable and injury-resilient movements, suggesting the AIR Score can guide targeted neuromuscular training programs to reduce injury risk. Moreover, the AIR Score can be reliably captured with smartphone-video data. Larger datasets collected out-of-lab with injury incidence outcomes are required to validate and refine the AIR Score framework.

Images (Optional)

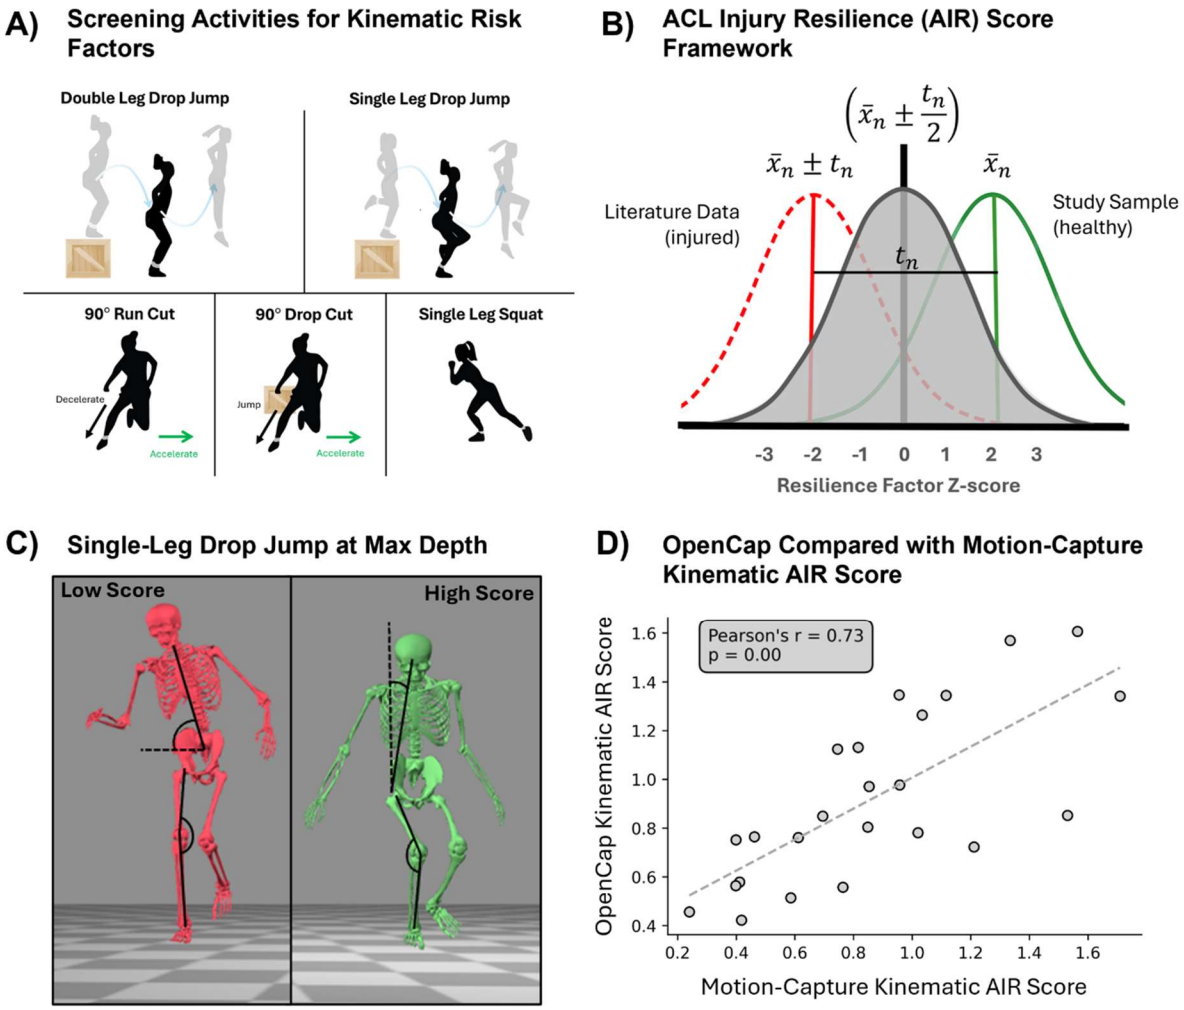

Figure 1: A) Kinematic risk factors from five screening activities are used in the B) ACL Injury Resilience (AIR) Score framework. The AIR Score identifies athletes with risky (red) and protective (green) biomechanics. C) Musculoskeletal models of representative participants with low (red) and high (green) AIR Scores at the maximum depth of a single-leg drop jump's landing phase. D) There is strong agreement between AIR Scores calculated from 3D motion-capture (in-lab gold standard measurement) and OpenCap, a video-based out-of-lab measurement.

Upward Movement Velocity and Acceleration Strategies That Enable the Minimum-Velocity Advantage in Basketball Free Throws

Ms Kaitlin Jackson[1], Dr. Kirk Goldsberry[2], Dr. Owen Beck[1]

[1]University of Texas, Austin, TX, United States. [2]University of Texas, Austin, Texas, United States

Introduction

Free-throw success depends on ball-release parameters. Prior research indicates that skilled shooters release the ball near the minimum velocity required for a made shot, reducing the sensitivity of ball in-ring position to small execution errors in release parameters (e.g. release angle) (1). We examined the kinematics of how free-throw shooters produce their individualized minimum release speed.

Methods

Basketball shooters (12 NCAA D1 females, 16 NBA males, 12 novice females, and 12 novice males; novices highest level = high school) completed 50 free throws. Three-dimensional ball-trajectory and full body kinematic data were collected using 3D motion capture. Each player's probability of a made free throw based on ball release speed and angle was calculated using projectile motion equations, including release height and distance from the hoop. We used Pearson correlations and multivariate regressions.

Results

Actual and minimum-required ball release speeds were strongly related ($r=0.96$, $p<0.001$), and release speed was less variability than release angle ($p<0.001$) indicating that shooters may prioritize their consistency in release speed versus angle. Shooters who shot nearest to their model-predicted minimum speed were more consistently (std of release speed, $r=0.66$, $p<0.001$) and had better shooting accuracy ($r=0.74$. $p<0.001$). Higher release height was associated with slower release speed ($r=0.87$, $p<0.001$), suggesting taller shooters require a lower minimum release speed. Lower elbow upward velocity at release predicted better accuracy ($p<0.001$). Peak acceleration timing: earlier pelvis and elbow peak upward accelerations were associated with slower release speed ($p<0.001$and $p=0.0024$, respectively) and better accuracy ($p<0.001$and $p = 0.045$, respectively), whereas earlier wrist peak acceleration was associated with higher release speed ($p<0.001$) and reduced accuracy ($p=0.029$).

Discussion

Shooters with superior shot accuracy better prioritized and demonstrated more consistent minimum release speed. While NBA data require further analyses, our current findings imply that free throw shooters should release the ball with a relatively slow release speed while focusing on earlier acceleration of the pelvis and elbow and delaying wrist acceleration closer to release.

Images (Optional)

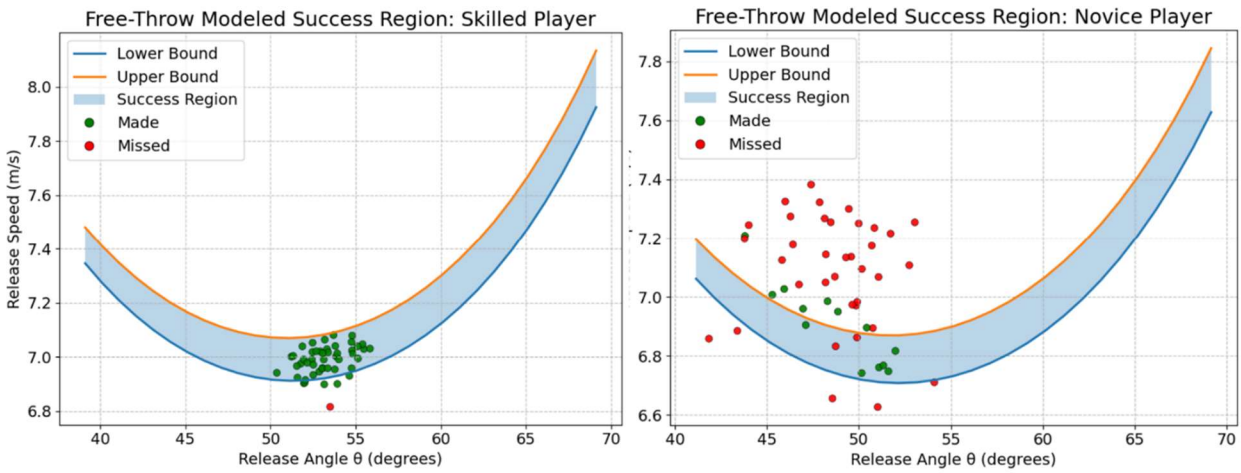

Figure 1. **Skilled shooters release the ball near their minimum possible speed.** Model-based estimation of each player's optimal success region represented by upper and lower bounds of the angle–speed combinations of a successful free throw with actual shot data of made (green) and missed (red) shots. Skilled shooters (left) exhibit the minimum-velocity strategy, demonstrating high accuracy, low variability, and repeated selection of their individualized minimal release speed. Novice shooters (right) exhibit poor minimum-velocity strategy (reduced accuracy, greater variability, and higher-than-necessary release speeds).

Integrating In-Silico and In-Vitro Approaches to Elucidate the Role of Flow-Induced Vascular Wall Vibrations in Arteriovenous Fistula Failure

Dr. Luca Soliveri[1], Ms. Elena Carrara[2], Ms. Sofia Poloni[1], Dr. Kristian Valen-Sendstad[3], Dr. Anna Caroli[2], Prof. Andrea Remuzzi[1], Dr. Chiara Emma Campiglio[1], Dr. Michela Bozzetto[2]

[1]University of Bergamo, Dalmine, Bergamo, Italy. [2]Mario Negri Institute for Pharmacological Research IRCCS, Bergamo, Bergamo, Italy. [3]Simula Research Laboratory, Oslo, Oslo, Norway

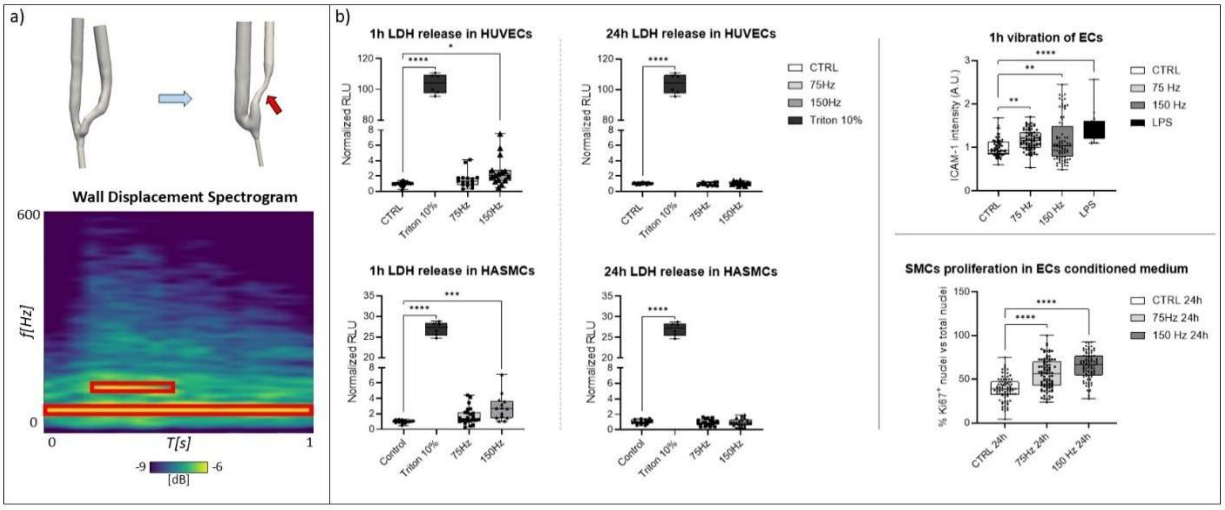
Introduction

The arteriovenous fistula (AVF) is the preferred vascular access for hemodialysis, but 40% fail within 1 year due to stenosis. We have recently shown that turbulent-like flow induces AVF wall vibrations, and we observed in a case study that elevated vibration amplitude localized in the venous segment where stenosis subsequently manifested [1]. The aim of this investigation was to computationally identify relevant vibration frequencies and amplitudes associated with vascular remodeling and then experimentally investigate how such mechanical stimuli affect human umbilical vein endothelial cells (HUVECs) and aortic smooth muscle cells (HASMCs) behavior.

Methods

We monitored with magnetic resonance images and Doppler ultrasound 6 patients within 1 year after AVF creation. We performed high-fidelity fluid-structure interaction (FSI) simulations [2] in patient-specific AVF models and analyzed the frequency content of the vascular wall vibrations to identify relevant frequency bands related to AVF failure. Then, we exposed HUVECs and HASMCs to vertical vibrations at frequencies computationally determined from patients who developed stenosis, for 1 and 24 hours, with static cultures serving as controls. Cell viability was assessed by LDH assay. Proliferation, adhesion, mechanotransduction, and endothelial activation were evaluated by immunofluorescence, quantifying Ki67-positive cells, VE-cadherin and paxillin distribution, YAP localization and ICAM-1 expression. The effect of conditioned medium from vibration-exposed HUVECs on HASMC proliferation was examined through Ki67 quantification.

Results



FSI results revealed the presence of relevant frequency bands around 75-150 Hz in the patients who later developed stenosis (Figure 1a). Mechanical vibrations at these

frequencies induced transient membrane perturbations without long-term cytotoxicity and promoted HASMC proliferation. VE-cadherin (HUVECs) and paxillin (HASMCs) distribution shifted toward patterns associated with greater cell motility. HUVECs showed mild YAP activation and increased ICAM-1, indicating mechanotransduction pathways and endothelial activation. Conditioned medium from vibration-exposed HUVECs enhanced HASMC proliferation, revealing a paracrine endothelial contribution to smooth muscle cell responses (Figure 1b).

Discussion

These findings suggest that flow-induced vibrations modulate vascular cell behavior through multiple mechanobiological mechanisms that may contribute to vascular remodeling. Integrating in-silico and in-vitro approaches can elucidate these mechanisms and allow the identification of new therapeutic targets.

Relationship Between Wall Shear Stress and Coronary Computed Tomography Angiography-Derived Features in Diseased Coronary Arteries

Dr. Maurizio Lodi Rizzini PhD[1], Dr. Marco Stefanati PhD[2], Prof. Diego Gallo PhD[1], Prof. Claudio Chiastra PhD[1], Mr. Marco Stimolo MSc[1], Prof. Fabrizio D'Ascenzo MD, PhD[3], Prof. Stefano Salizzoni MD, Phd[3], Prof. José Félix Rodríguez Matas PhD[2], Prof. Umberto Morbiducci PhD[1]

[1]Politecnico di Torino, Torino, Piemonte, Italy. [2]Politecnico di Milano, Milano, Lombardia, Italy. [3]Città della Salute e della Scienza di Torino, Torino, Piemonte, Italy

Introduction

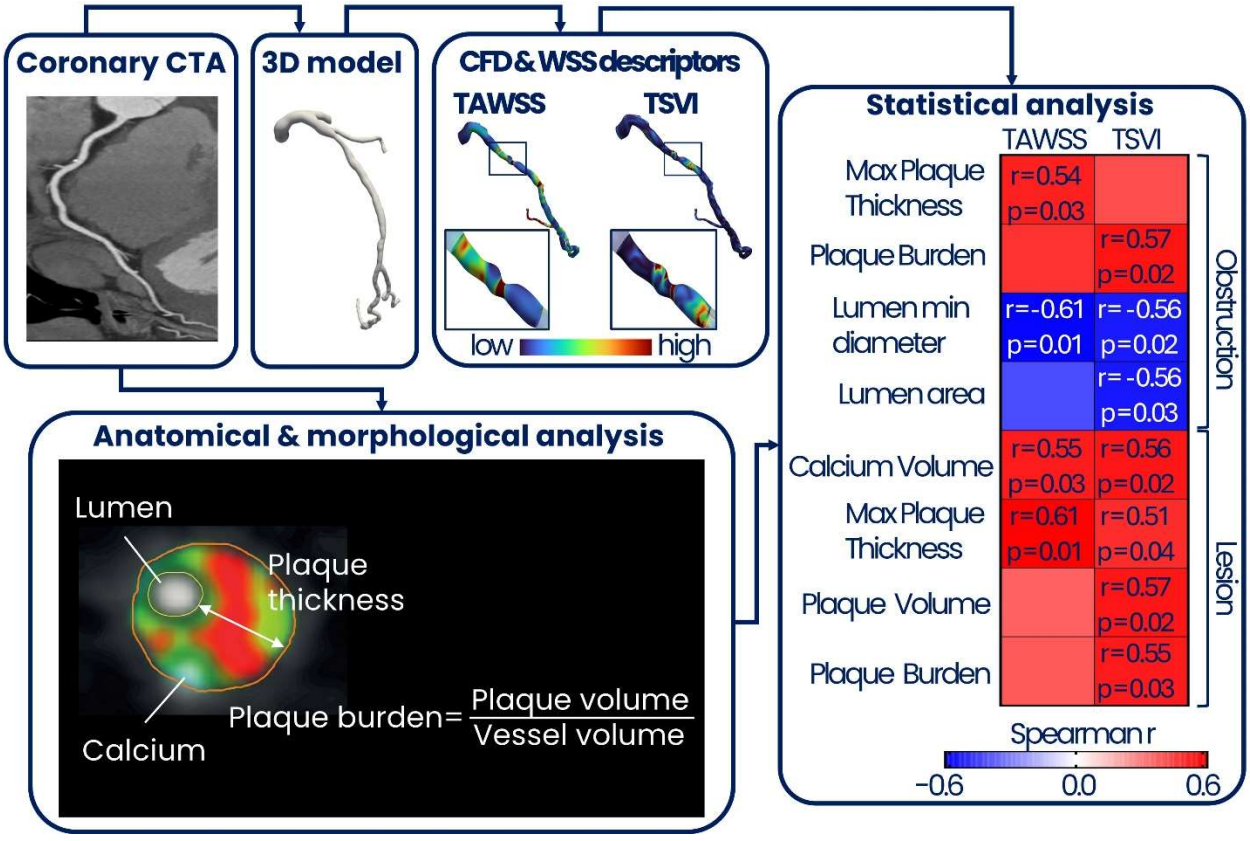
Coronary computed tomography angiography (CCTA) allows non-invasive evaluation of both anatomical stenosis severity and plaque morphology, including features of plaque vulnerability [1]. Additionally, CCTA enables accurate 3D reconstruction of the coronary lumen, facilitating quantification of wall shear stress (WSS) via computational fluid dynamics (CFD). WSS is a key mediator of hemodynamic stimuli on endothelial biopathways and has been associated with adverse clinical events [2].

This study investigated the relationship between CCTA-derived morphological features and WSS in coronary atherosclerotic plaques, with the aim of refining plaque vulnerability assessment.

Methods

The study included 14 patients (16 coronary arteries) who underwent CCTA. Lumen reconstruction and plaque characterization were performed using the QAngioCT Research Edition software (Medis Medical Imaging). Morphological metrics were extracted at (i) lesion volumetric level, and (ii) cross-sectional site of maximal obstruction. Transient CFD simulations were performed using the finite volume method [2]. Hemodynamics were characterized by Time-Averaged WSS (TAWSS) and the Topological Shear Variation Index (TSVI) [2]. Hemodynamic quantities were spatially averaged over each lesion surface, and associations with morphological features were evaluated.

Results



At the lesion level, both TAWSS and TSVI were positively correlated with calcium volume (TAWSS: $r=0.55$, $p=0.03$; TSVI: $r=0.56$, $p=0.02$) and maximum plaque thickness (TAWSS: $r=0.61$, $p=0.01$; TSVI: $r=0.51$, $p=0.04$). Only TSVI showed significant correlations with

plaque volume (r=0.57, p=0.02) and plaque burden (r=0.55, p=0.03). At the site of maximal obstruction, both TAWSS and TSVI were inversely correlated with lumen minimum diameter (TAWSS: r=-0.61, p=0.01; TSVI: r=-0.56, p=0.02). TAWSS alone was correlated with maximum plaque thickness (r=0.54, p=0.03), whereas TSVI alone was correlated with lumen area (r=-0.56, p=0.03) and plaque burden (r=0.57, p=0.02).

Discussion

These findings suggest a mechanistic link between plaque morphology and local hemodynamics. While TAWSS predominantly reflects stenosis severity, TSVI demonstrates additional sensitivity to overall plaque burden, suggesting that WSS topological dynamics reflect global plaque characteristics more comprehensively than WSS magnitude alone. The integration of CCTA-derived morphological features with advanced hemodynamic descriptors may provide a more comprehensive plaque vulnerability profile and ultimately enhance risk stratification.

Introduction

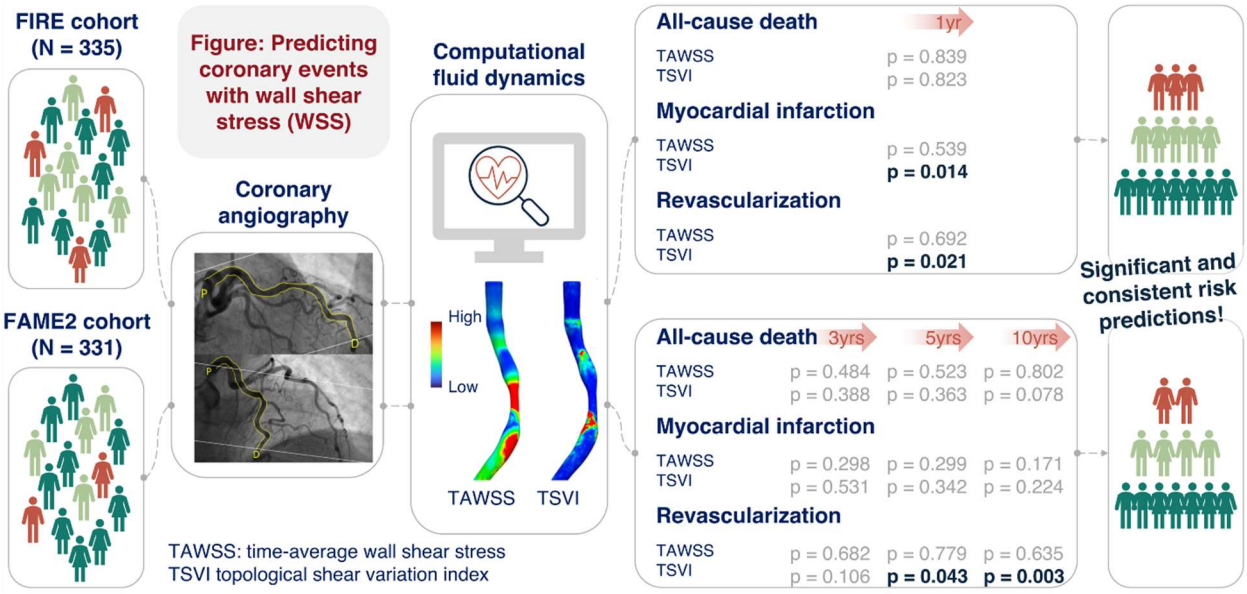
Recent trials have demonstrated the prognostic value of hemodynamics-based assessment of coronary atherosclerosis to determine the risk of future adverse events. However, such assessment is mostly limited to the evaluation of the pressure drop across luminal narrowing [1]. Here, we tested whether wall shear stress (WSS)-based quantities obtained from personalized in silico hemodynamic models provide additional prognostic information in the largest patient cohorts to date.

Methods

Two patient populations from recent randomized clinical trials were analyzed. From the FIRE trial [2], 335 patients who experienced myocardial infarction (MI) and had one lesion non-culprit for MI were included. A second cohort of 331 patients from the FAME2 trial [1] consisted of patients with stable coronary artery disease treated with medical therapy. FIRE patients had 1-year follow-up, whereas FAME2 patients had follow-up at 3, 5, and 10-years.

Personalized computational fluid dynamics (CFD) simulations were performed in angiography-reconstructed geometries. Lesion-level descriptors included the time-average WSS magnitude (TAWSS) and the topological shear variation index (TSVI), which quantifies the variability of the contraction/expansion action exerted by WSS on the endothelium along the cardiac cycle [2].

Outcome events included MI, death, or revascularization. For each cohort, Cox proportional-hazard models were fitted to estimate hazard ratios (HRs).



Results

In the FIRE cohort, higher lesion TSVI was associated with a higher risk of future MI (HR 1.01, p=0.014), and revascularization (HR 1.06, p=0.021). In the FAME2 cohort, TSVI predicted revascularization at 5 and 10 years (HR 1.03, p=0.043; HR 1.02, p=0.003, respectively), but not at 3 years (HR 1.02, p=0.106). TAWSS did not predict events in either cohort (Figure).

Discussion

The results confirm and expand the utility of WSS characteristics captured by TSVI for assessing the propensity of coronary lesions to cause acute events. The observed associations in acute (FIRE) versus stable (FAME2) patients suggest distinct mechanisms of action of hostile WSS conditions, with short-term effects in acute MI settings and longer-term effects in stable coronary artery disease.

Computational Analysis of Posture-Dependent Cerebrovascular Hemodynamics Using a Multiscale Model with Vascular Autoregulation

Mr. Youngjae Choi[1], Prof. Hyun Jin Kim[1], Mr. Chang Min Lee[1], Prof. Hyeyeon Chang[2], Prof. Keun-Hwa Jung[3]

[1]Korea Advanced Institute of Science and Technology, Daejeon, Daejeon, Korea, Republic of. [2]Konyang University Hospital, Daejeon, Daejeon, Korea, Republic of. [3]Seoul National University Hospital, Seoul, Seoul, Korea, Republic of

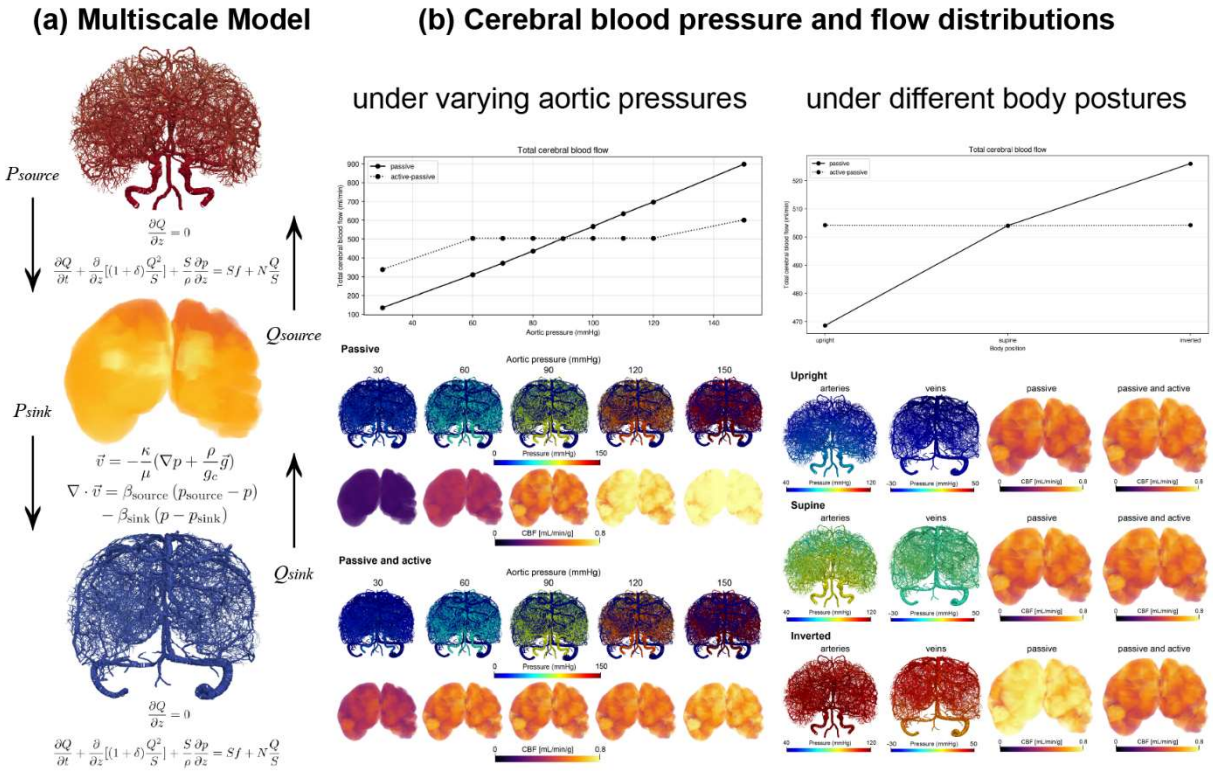
Introduction

Cerebral blood flow (CBF) is tightly regulated through autoregulatory mechanisms that counteract changes in arterial pressure and gravitational loading. Although several modeling studies have examined cerebrovascular responses to pressure or posture changes, most have focused on localized vascular regions rather than the integrated system. This study quantifies the effects of aortic pressure and posture on cerebrovascular hemodynamics using a multiscale blood flow model comprising arterial, venous, and microvascular domains with embedded autoregulation.

Methods

Arterial, venous, and tissue domains were segmented from brain imaging, and the microvasculature was extended to precapillary and postcapillary levels via a synthetic vascular tree generation algorithm. One-dimensional blood flow equations were solved in the extended vasculature, while capillary flow was modeled as Darcy flow by treating brain tissue as a porous medium. Explicit coupling ensured mass conservation across domains. Vessel wall mechanics was represented using a hyperelastic tube law, and active autoregulation was implemented by modulating arteriolar radius in response to local metabolic demand. Simulations were conducted for aortic pressures ranging from 30 to 150 mmHg and under supine, upright, and inverted postures, with wall stiffness varied to assess the impact of vascular compliance.

Results



Without active regulation, total CBF increased nearly linearly with aortic pressure, while the inclusion of autoregulation maintained CBF within a physiological pressure range. Posture changes produced CBF differences in the passive model due to hydrostatic effects; however, the full autoregulatory model preserved near-constant perfusion across

postures. Arterial volume increased with aortic pressure, whereas venous volume was relatively insensitive to pressure but varied with posture. Increased vessel compliance amplified posture-induced variations in venous volume and arteriolar radius, while stiffer vessels dampened these responses.

Discussion

The proposed multiscale cerebrovascular model, integrating passive mechanics and arteriolar autoregulation, demonstrates how cerebral perfusion is maintained across a wide range of arterial pressures and postures. Arteries deform passively in response to pressure, while arterioles serve as the primary regulators of CBF. The venous system functions as a reservoir containing a substantial fraction of intracranial vascular volume. This framework provides a physiologically grounded tool for studying how altered vessel compliance or impaired autoregulation may impact cerebrovascular hemodynamics in health and disease.

Muscle Contributions to the Hip and Knee Articular Contact Forces in Highly Functional Unilateral Transtibial Amputees During Gait

Mr Bryan Rivera Calagua[1], Dr. Anthony M. J. Bull[2], Dr. Pouya Amiri[1]

[1]Queen's University, Kingston, Ontario, Canada. [2]Imperial College London, London, London, United Kingdom

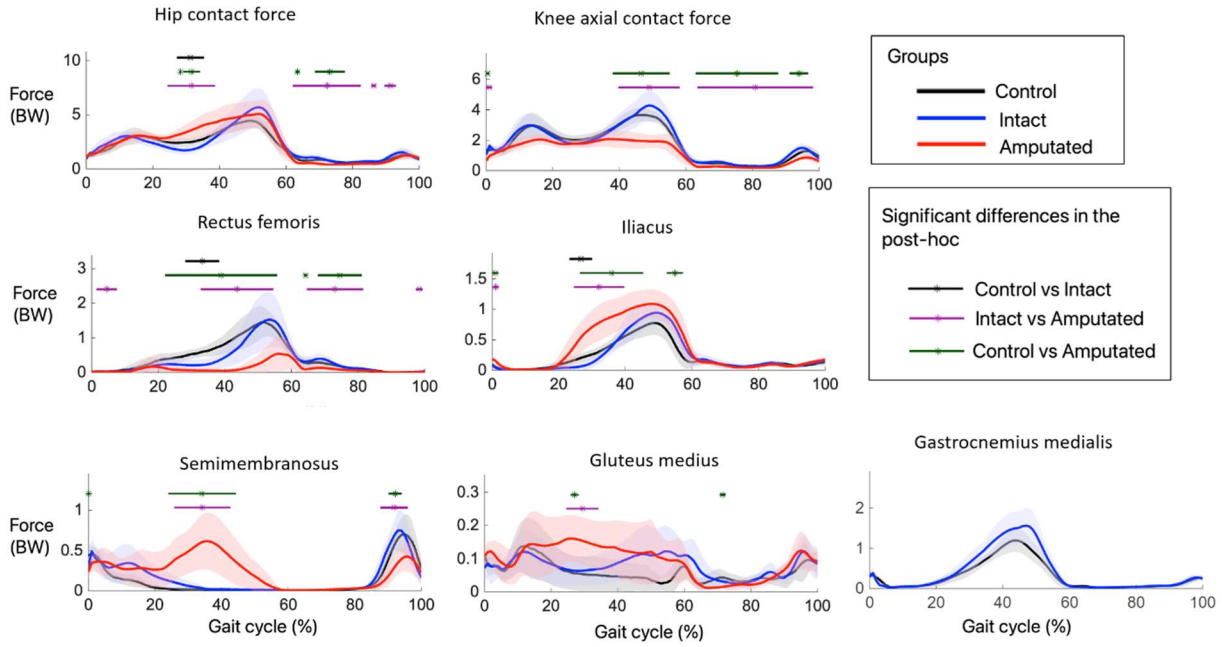
Introduction

Unilateral transtibial amputees (UTAs) adopt compensatory strategies in the intact limb, increasing joint loading and the risk of knee and hip osteoarthritis [1]. Since muscles are the primary contributors to joint loading [2], understanding how muscle forces influence joint contact forces may support improved prosthetic designs. This study investigated muscle contributions to hip and knee joint contact forces in highly functional UTAs compared to non-amputees using musculoskeletal modeling.

Methods

Gait data were collected from 12 UTAs (32.9 ± 3.2 years; BMI 26.6 ± 2.6 kg/m^2) and 10 controls (32.1 ± 4.6 years; BMI 25.3 ± 3.8 kg/m^2) using 10 optical cameras and force plates. Musculoskeletal simulations were performed in OpenSim 4.4 using the Rajagopal model for controls and a modified version for UTAs [3]. Static optimization estimated muscle forces and hip and knee joint contact forces. Statistical parametric mapping (SPM1D) compared the control, intact, and amputated limbs using parametric or non-parametric ANOVA with post-hoc tests.

Results



The figure shows the joint contact forces, muscle forces, and significant differences. Hip contact forces differed during mid-stance: the intact limb showed the lowest forces, the control limb intermediate forces, and the amputated limb the highest. Increased iliopsoas, gluteus medius, and hamstring forces in the amputated limb may contribute to this higher loading. For knee contact forces, the amputated limb exhibited the lowest forces during late stance, likely due to the absence of gastrocnemius force generation.

Discussion

Amputees walked with higher mid-stance hip contact forces on the amputated side, associated with increased hip flexor and abductor forces. However, unlike previous work [4], we did not observe elevated intact-limb knee contact forces, potentially because gastrocnemius forces did not differ from controls. Hip contact forces appeared elevated

overall, consistent with known overestimation of muscle forces in the Rajagopal model [5]. Future work will focus on modifying the model to bring hip contact forces within physiological bounds.

Modeling the Infant Head-Neck Complex to Investigate Positional Asphyxia Risk in Inclined Environments

Graduate Assistant Andrew Bossert BS, Mechanical Engineering[1], Associate Professor of Orthopedic Surgery Dennis Anderson PhD, Engineering Mechanics[2], Associate Professor Clare Fitzpatrick PhD, Mechanical Engineering[1], Associate Professor Erin Manned PhD, Mechanical Engineering[1]

[1]Boise State University, Boise, ID, United States. [2]Beth Israel Deaconess Medical Center, Boston, MA, United States

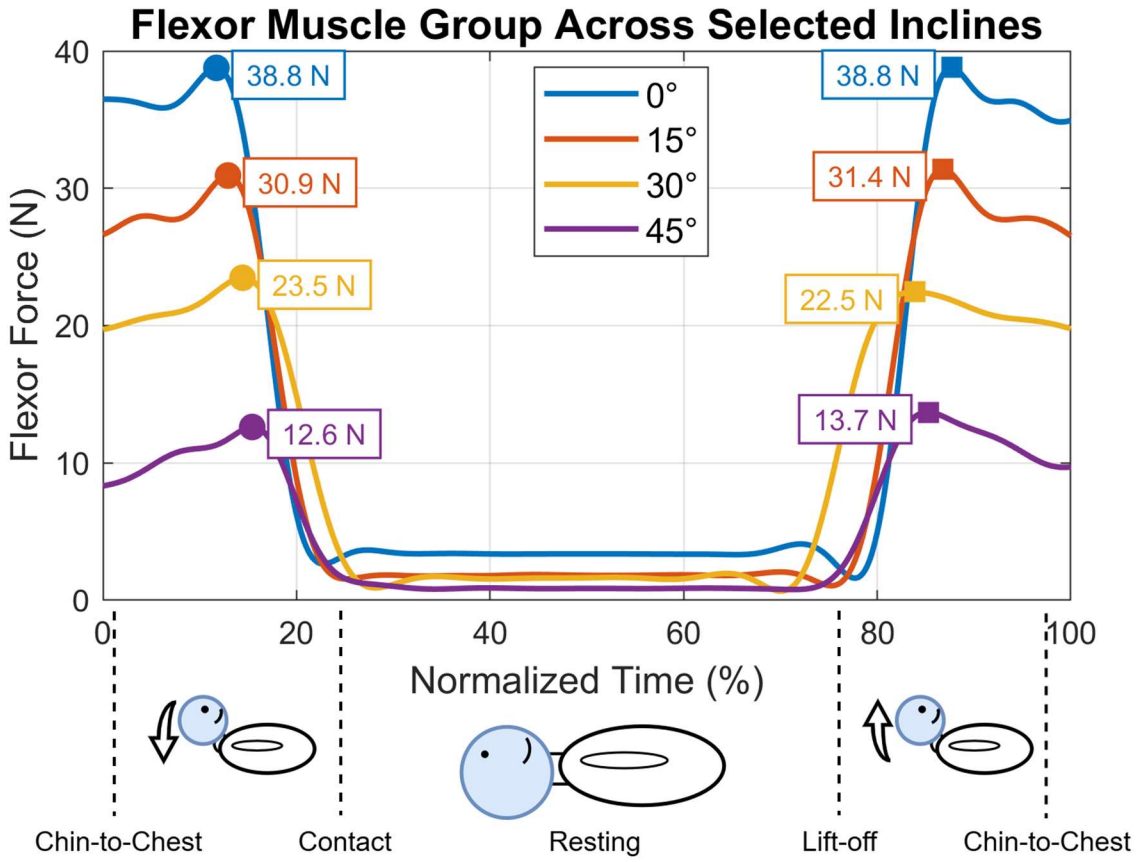
Introduction

Of the 3600 sudden infant death cases in the United States each year, nearly 1/3 are from asphyxia [1]. Chin-to-chest positioning increases risk of asphyxia, and an infant's ability to achieve and self-correct from this posture in common inclined environments is poorly understood. It's unethical to expose living infants to dangerous experiments; thus, robust computational models are critical to elucidate mechanics of positional asphyxia. This study created a novel infant model to understand risks of chin-to-chest postures.

Methods

Experimental data (neck kinematics, head ground reaction force) were generated using a physical surrogate of an infant allowing neck flexion-extension. At body incline angles of 0°, 15°, 30°, and 45°-representing incline angles of common infant products- starting from a chin-to-chest position, the neck was extended to contact the force plate, and then flexed to return to the chin-to-chest position. An OpenSim cervical-musculoskeletal model [2] was adapted into a novel infant model to simulate the experimental setup. Muscle forces to flex and extend the neck at each inclination angle were predicted from static optimization. Grouped neck flexor and extensor muscle forces were analyzed.

Results



As incline angle increased, peak force necessary to lift the head decreased in sinusoidal proportion. Figure 1 shows peak forces prior to the head contacting the platform, coming to rest, and peak forces to lift the head from the platform. At 45° body incline, 65.7% less force was required to lift the head off the platform compared to 0°.

Discussion

The lower force required to achieve chin-to-chest posture at greater body inclines demonstrates an inherent vulnerability for infants to assume positions associated with

elevated asphyxia risk. Notably, many infant products currently on the market feature back-rest incline angles between 15-45°, placing infants in situations where chin-to-chest postures are more easily achieved. Our computational model provides a framework for comparing how positional changes contribute to asphyxia risk across product designs. Future work incorporating EMG measurements to validate muscle activation patterns may further clarify the relative muscle forces involved in chin-to-chest motion, ultimately informing design features that prioritize infant safety.

The Development and Implementation of a Computational Framework to Simulate Patellofemoral Joint Mechanics: Direct Comparisons Between Musculoskeletal Modeling and Finite Element Analysis

Mr. Mahmood Rashedi[1], Dr. Mark Seeley[2], Dr. Brecca Gaffney[3], Dr. Benjamin Wheatley[1]

[1]Bucknell University, Lewisburg, Pennsylvania, United States. [2]Geisinger, Danville, Pennsylvania, United States. [3]University of Colorado Denver, Denver, Colorado, United States

Introduction

Anterior knee pain occurs in nearly 25% of adults and is linked to altered patellofemoral joint (PFJ) mechanics. PFJ modeling varies widely, with no clear gold standard. Simplified muscle-driven musculoskeletal models estimate joint kinetics but lack relevant tissue-level mechanics. Finite Element (FE) models overcome this limitation by solving for cartilage contact mechanics, but at a higher computational cost. This project establishes a workflow to test the correlation between musculoskeletal-predicted joint loads and FE-predicted cartilage contact pressure in a healthy individual.

Methods

Marker-based motion capture was performed during squatting on one adult male using a 12-camera VICON system and AMTI force plates (Figure 1A). Optimal control and a Rajagopal Opensim model with polynomial-based patellar kinematics were used to generate kinetics and patellofemoral joint reaction force (PFJRF) (Figure 1B). A left PFJ FE model was built in Abaqus using OpenKnee (OKS009), with rigid bones, neo-Hookean cartilage, and ligament/tendon springs. Tibiofemoral kinematics were applied via cylindrical joints in addition to muscle forces computed from musculoskeletal simulations (Figure 1C).

Results

Musculoskeletal-predicted PFJRF reached 6.47×BW at 100° flexion (Figure 1E). FE model results, reported as the mean of the top 5% patellar cartilage contact hydrostatic pressure, reached 12.90 MPa at 100° flexion. PFJRF and FE-predicted patellar cartilage pressure increased with knee flexion (R^2=0.92, Figure 1F), and deeper squats produced larger contact areas, with greater loading on the lateral facet (Figure 1D).

Discussion

This study developed a workflow integrating musculoskeletal and FE modeling to compare PFJ mechanics. Results supported our hypothesis: higher musculoskeletal-predicted PFJRF corresponded to greater FE cartilage contact pressure. Muscle activation profiles, PFJRF values, and patellofemoral contact area distributions matched prior reports, providing key model validation. Ongoing work will increase sample size from n=1. This framework can be applied to pathological conditions such as muscle weakness, morphological abnormalities, and soft tissue laxity to better understand how different modeling approaches simulate patellofemoral mechanics.

Impact of Personalized Model Using the Opensim-Torsion Tool on Muscle Contribution for CG Acceleration Estimation in CP Children

Prof. António Veloso[1], Dr. Basílio Gonçalves[2], Dr. Filipa João[1], MSc Rodrigo Mateus[1], MSc Carolina Silva[1]

[1]Faculdade de Motricidade Humana, Cruz-Quebrada, Lisboa, Portugal. [2]University of Viena, Viena, Viena, Austria

Introduction

Children with cerebral palsy CP frequently present pathological gait patterns, with crouch gait CG being one of the most prevalent and severe. Musculoskeletal MSK modelling is commonly used to study CG, but generic models based on healthy adults overlook subject specific anatomy [1]. This limits their applicability to pathological gait. To address this, personalized MSK models have been developed, the OpenSims torsion tool offers a way to incorporate femoral and tibial torsions and improve personalization [1]. This study examined the impact of this tool on CG biomechanics and on induced acceleration (IAA) estimations of body center of mass (CM) in a child with spastic diplegic CP.

Methods

The participant was a 13 year old height 169.7 cm 60.6 kg GMFCS III who underwent clinical gait analysis one month before SEMLS. Kinematic and kinetic data were collected. Four OpenSim scaled MSK models were created a generic Gait2392 model, a personalized model based on clinical and radiographic torsion values, and two additional models incorporating upper and lower limits of agreement for femoral anteversion tibial torsion and femoral neck shaft angle. Muscle forces were estimated during single support and normalized to each muscles maximum isometric force. IAA analysis quantified muscle contributions to CM dynamics.

Results

Pre surgery antero-posterior center of mass contributions showed pronounced differences in the right leg. The generic model predicted higher soleus propulsion while models including torsional deformities showed reduced contribution. This shows that excessive tibial torsion diminishes the soleus ability to support and propel the body. After surgery differences between models decreased and by one and ten years post surgery model

outputs became similar indicating reduced influence of torsional deformities after correction.

Discussion

Torsion personalization strongly influenced muscle force predictions and center of mass accelerations particularly before surgery. Only the personalized model captured the expected improvement in soleus function after SEMLS. These findings support the need for subject specific MSK modelling for accurate assessment of crouch gait and surgical outcomes.

Images (Optional)

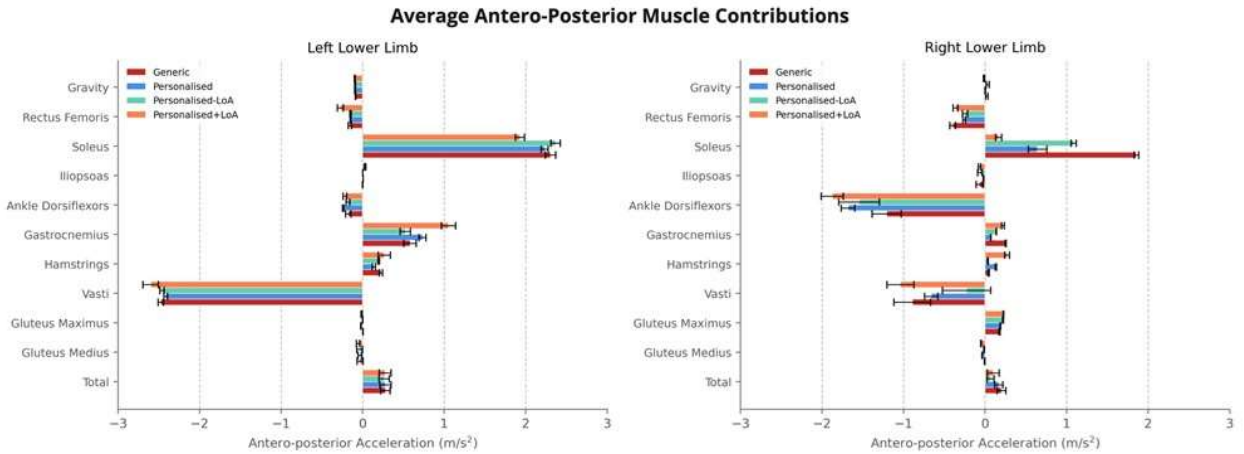

Figure 1 Pre-surgery avg muscle contributions to A-P CM acceleration for all four models. The total acceleration and contributions from gravity are also shown. Positive values indicate anterior acceleration, while negative values posterior acceleration.

Automated Subject-Specific Modeling of 6 DoF Glenohumeral Kinematics

Dr. Eva C. Herbst[1,2], Dr. John E. Lloyd[3], Dr. Heath B. Henninger[4], Prof. Dr. med. Philipp Moroder[2], Professor Stephen J. Ferguson[1]

[1]ETH Zurich, Zurich, ZH, Switzerland. [2]Schulthess Klinik, Zurich, ZH, Switzerland. [3]University of British Columbia, Vancouver, Vancouver, Canada. [4]University of Utah, Salt Lake City, UT, United States

Introduction

Semi-constrained joints are typically used to reduce kinematic tracking error in inverse dynamic musculoskeletal simulations. However, the sub-mm accuracy of biplanar fluoroscopy data, coupled with subject-specific bone models from CT, can be used to kinematically validate subject-specific models that achieve joint constraint solely through realistic contact conditions and muscle activation. Our goal was to develop an automated method to generate subject-specific musculoskeletal models of the glenohumeral joint capable of replicating subject-specific kinematics.

Methods

Our pipeline automatically generates 6 DoF glenohumeral joint models in Artisynth, using a 3 DoF OpenSim template model [1]. Subject-specific bones directly replace template bones. The glenohumeral joint is modeled as contact between elastic bodies, with cartilage geometry automatically generated from glenoid and humeral anatomic neck boundaries, incorporating cartilage thickness variation (Fig. 1A). Large passive glenohumeral bounds were defined to test whether glenohumeral translations can be stabilized with muscular activity. Muscle parameters were based on per-muscle scaling without optimization algorithms and wrap objects and landmarks were deformed and transferred using affine and deformable transforms representing anatomical changes between template and target bones. Nineteen models were tested, with inverse simulation input tracking biplanar fluoroscopy kinematics during coronal abduction (Fig. 1B).

Results

Our method enables incorporation of subject-specific anatomy and kinematics, is entirely automated except for the selection of the glenoid and humeral anatomic neck boundaries, and solves common wrap object issues (e.g., muscle via points ending up inside wrap object, muscle wrapping around wrong side of wrap object). Thirteen of nineteen subjects achieved glenohumeral translations within a few mm of target values, i.e., not approaching the bounds of the glenoid (Fig. 1C).

Discussion

The majority of models were able to stabilize glenohumeral joint translations through muscular activity alone, mimicking the *in vivo* condition. The main advantage of our model is that the capacity for dislocation requires active recruitment of the rotator cuff for realistic muscle stabilization; dislocations (6/19 cases) indicate insufficiency of the template model or subject modeling pipeline. Future work will aim to resolve dislocations by testing the effect of the template model and muscle parameters and wrapping on kinematic tracking accuracy.

OA70-06

Design of Patient-specific High Tibial Osteotomy Surgery using Predictive Simulations of Walking

Prof. Benjamin Fregly Ph.D., Mr. Spencer Williams B.S.

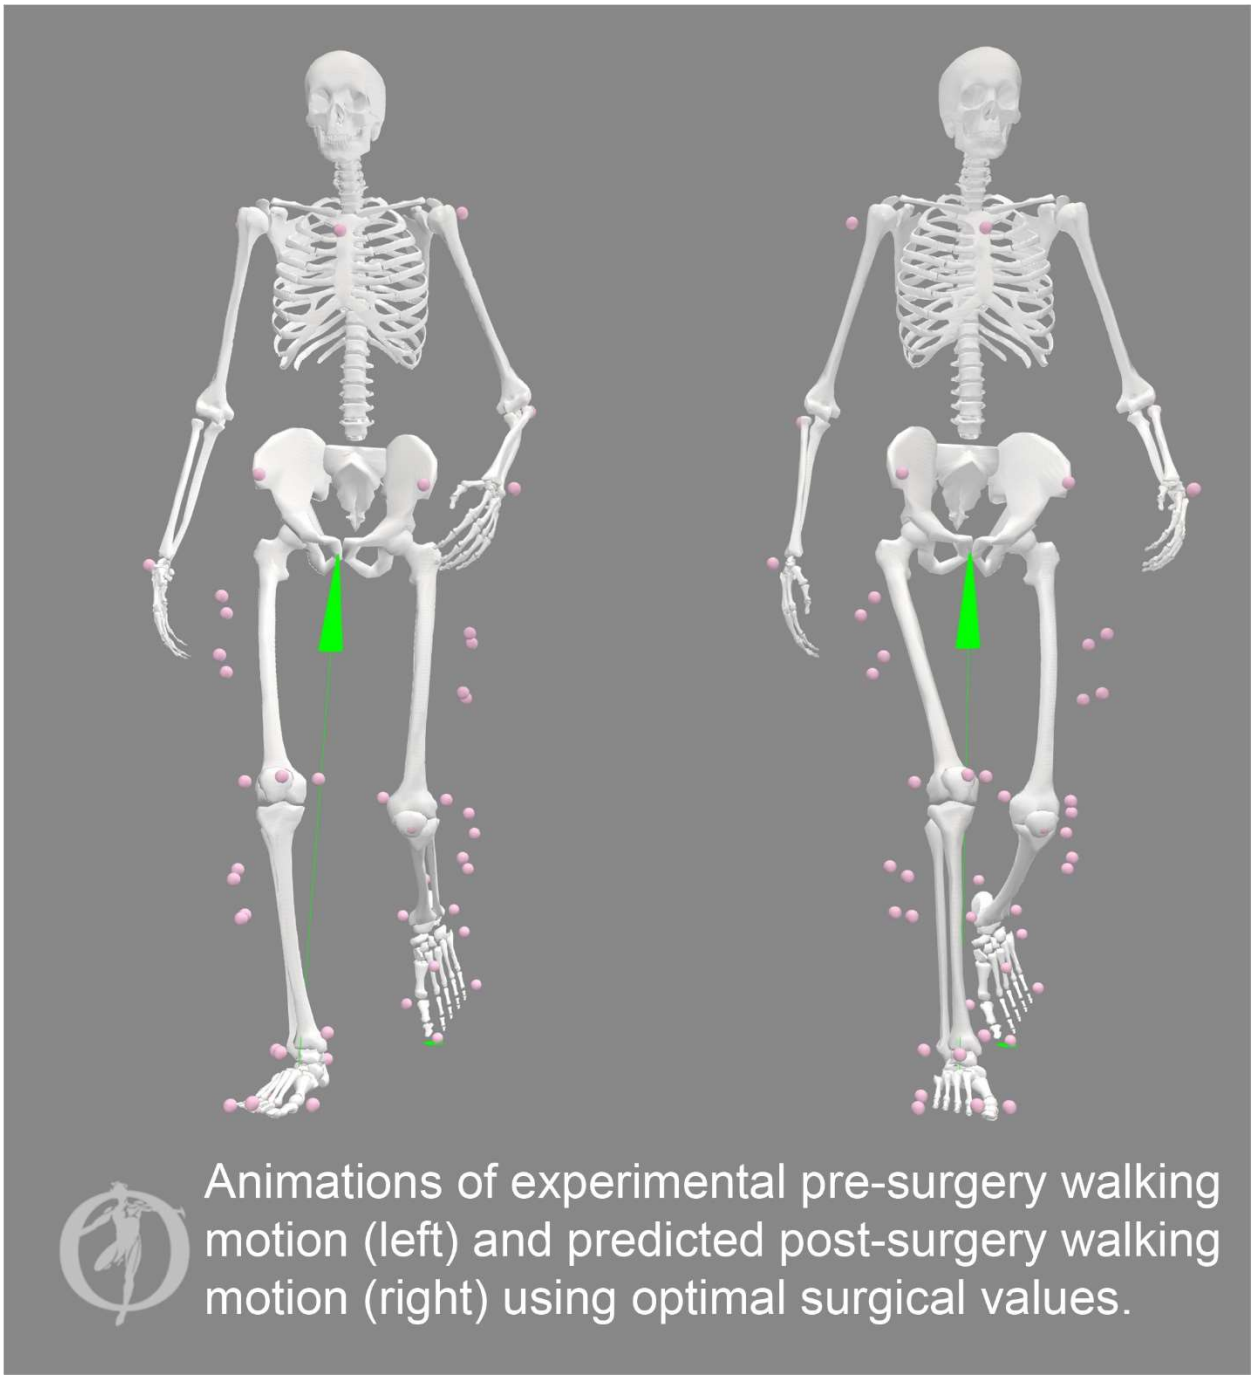
Rice University, Houston, TX, United States

Introduction

High tibial osteotomy (HTO) is a useful yet oftentimes unreliable surgery for medial knee osteoarthritis. By cutting the tibia and angling it outward, surgeons make a bow-legged (varus) individual knock-kneed (valgus), thereby shifting some tibiofemoral contact force from the diseased medial to the healthy lateral side of the knee. Reducing the peak knee adduction moment to approximately 2.5% BWxHt during post-surgery walking produces the best long-term clinical outcome. However, for any patient, surgeons currently have no way of predicting the amount of tibial valgus correction needed to achieve this post-surgery functional target. The objective of this study was to investigate whether patient-specific predictive simulations of post-surgery walking can be used to perform such predictions.

Methods

Experimental walking data collected from a subject with bilateral medial knee osteoarthritis were used in the Neuromusculoskeletal Modeling Pipeline [1] with OpenSim [2] to 1) create a personalized full-body skeletal model of the subject, 2) generate a dynamically consistent walking simulation that closely tracked experimental data, 3) perform virtual HTO surgeries on both tibias of the model using valgus corrections of 3, 6, and 9°, 4) perform predictive walking simulations to determine corresponding values of post-surgery peak knee adduction moments, 5) estimate optimal amount of valgus correction for each tibia via quadratic fit, and 6) perform a final predictive walking simulation using optimal valgus correction values to verify final post-surgery peak knee adduction moments of 2.5% BWxHt.



Results

Patient-specific predictive simulations of post-surgery walking yielded a near-linear relationship between amount of tibial valgus correction and value of post-surgery peak knee adduction moment. Using the optimal amounts of correction (5.5 and 6.5° for the right and left tibia, respectively), a final predictive simulation produced a peak adduction moment of 2.5% BWxHt for each knee as desired.

Discussion

HTO surgeries are currently planned using a target value of post-surgery *static knee alignment*. In contrast, this study demonstrates that patient-specific predictive simulations of post-surgery walking could potentially be used to plan HTO surgeries using a target value of post-surgery *dynamic knee loading*.

[3]Montanuniversität Leoben, Leoben, Styria, Austria. [4]European Synchrotron Radiation Facility, Grenoble, Auvergne-Rhône-Alpes, France. [5]Aix-Marseille Univ, AP-HM, Marseille, Provence-Alpes-Côte d'Azur, France

Introduction

The enthesis is the insertion site of tendon into bone. Its high durability stems from gradients in its collagen and mineral content, organization and structure on multiple hierarchical length scales [1]. However, its regeneration after injury is poor and surgical repair often fails. Despite extensive research into its structure and mechanics, the local deformation mechanisms are poorly understood. This study aims to characterize the spatially resolved multiscale mechanical response of the enthesis by combining *in situ* mechanical testing with scanning small- and wide-angle X-ray scattering.

Methods

Hindlimbs were dissected from 12 mice. Scattering measurements were performed at the European Synchrotron Radiation Facility. Samples were loaded *in situ* in steps of 200µm using a custom-built tensile loading device (Fig.1A). 2D maps including the calcaneal bone and Achilles tendon were collected at preload and displacement steps after relaxation (Fig1.B). Collagen fibril and molecule as well as mineral particle and crystal strains were extracted [2,3].

Results

At the tissue scale, displacement steps resulted in ~10% strain each. Nanoscale and molecular differences were observed between regions (Fig.1B-D). While mineral particles remained unchanged, collagen fibrils strained ~2%, with the region close to the enthesis exhibiting a stronger axial response than the Achilles tendon (Fig1.B-C). The tendon exhibited ~0.5% molecular strain but the region close to the enthesis remained unstrained

(Fig1.D). Minerals exhibited ~0.05% strain along their c-axis, with a stronger response close to the enthesis compared to the calcaneal bone.

Discussion

Decreasing strain was observed across the hierarchical structure with 10%, 2%, 0.5% and 0.05% strain in the tissue, nanoscale fibrils, collagen molecules and mineral crystals respectively, indicating a strong strain partitioning across length scales. Differences in both structure at preload as well as their mechanical response were observed depending on the proximity to the enthesis, indicating a regional heterogeneity in the activation of deformation mechanisms of different components. These findings support the notion of a tissue adopted to a complex and changing mechanical environment with an outstanding ability to dissipate energy through its hierarchical structure and tissue organization.

Image-to-Mechanics Mapping of Bone via DECT-Quantified Composition: A Numerical Study

Professor Yunhua Luo Y.

University of Manitoba, Winnipeg, Manitoba, Canada

Introduction

Accurate characterization of bone mechanical behavior using imaging is critical for assessing bone quality, screening osteoporosis, and evaluating fracture risk. Clinical methods relying solely on bone mineral density are limited because bone is a composite of inorganic minerals (primarily hydroxyapatite), organic proteins (mainly type I collagen), and water, each influencing stiffness, strength, and toughness. We are developing a dual-energy CT (DECT)–based framework to quantify these three components and predict mechanical properties from their spatial distribution. This study presents preliminary numerical results demonstrating the feasibility of linking DECT images with mechanical performance.

Methods

A representative bone volume (RBV) with prescribed fractions of mineral, protein, and water was generated. Virtual DECT scanning was performed using MATLAB implementations of the Radon transform and filtered back-projection to simulate low- and high-energy CT acquisitions. Image noise, beam-hardening artefacts, and partial-volume effects were included to approximate realistic DECT conditions. Constitutive behavior for hydroxyapatite, collagen, and water was assigned using stress–strain data extracted from the literature. A finite element model of the RBV was then constructed, and uniaxial compression was simulated to obtain its apparent elastic modulus, strength, and toughness as functions of the underlying composition.

Results

The simulated DECT images captured distinct attenuation differences corresponding to variations in mineral, protein, and water fractions. Preliminary finite element results showed a monotonic increase in elasticity modulus with increasing mineral fraction and a pronounced reduction in strength when protein or water fractions were elevated, accompanied by a substantial improvement in toughness—a key parameter for mitigating fall-induced hip fractures. The mapping between DECT-derived voxel intensities and

mechanical outputs exhibited strong monotonic trends, demonstrating that variations in composition captured by DECT can be used to predict key mechanical properties within the generated dataset.

Discussion

These initial findings support the feasibility of predicting bone mechanical behavior directly from DECT-quantified composition. Ongoing work includes characterizing stress–strain data, particularly for collagen in human bone, validating the computational framework using experimental measurements, and developing regression and machine-learning models to generalize the image–mechanics relationship. The long-term goal is to establish a clinically viable DECT-based tool for voxel-wise assessment of bone strength.

[9]Department of Mechanical and Aerospace Engineering, University of California, San Diego,, San Diego, CA, United States

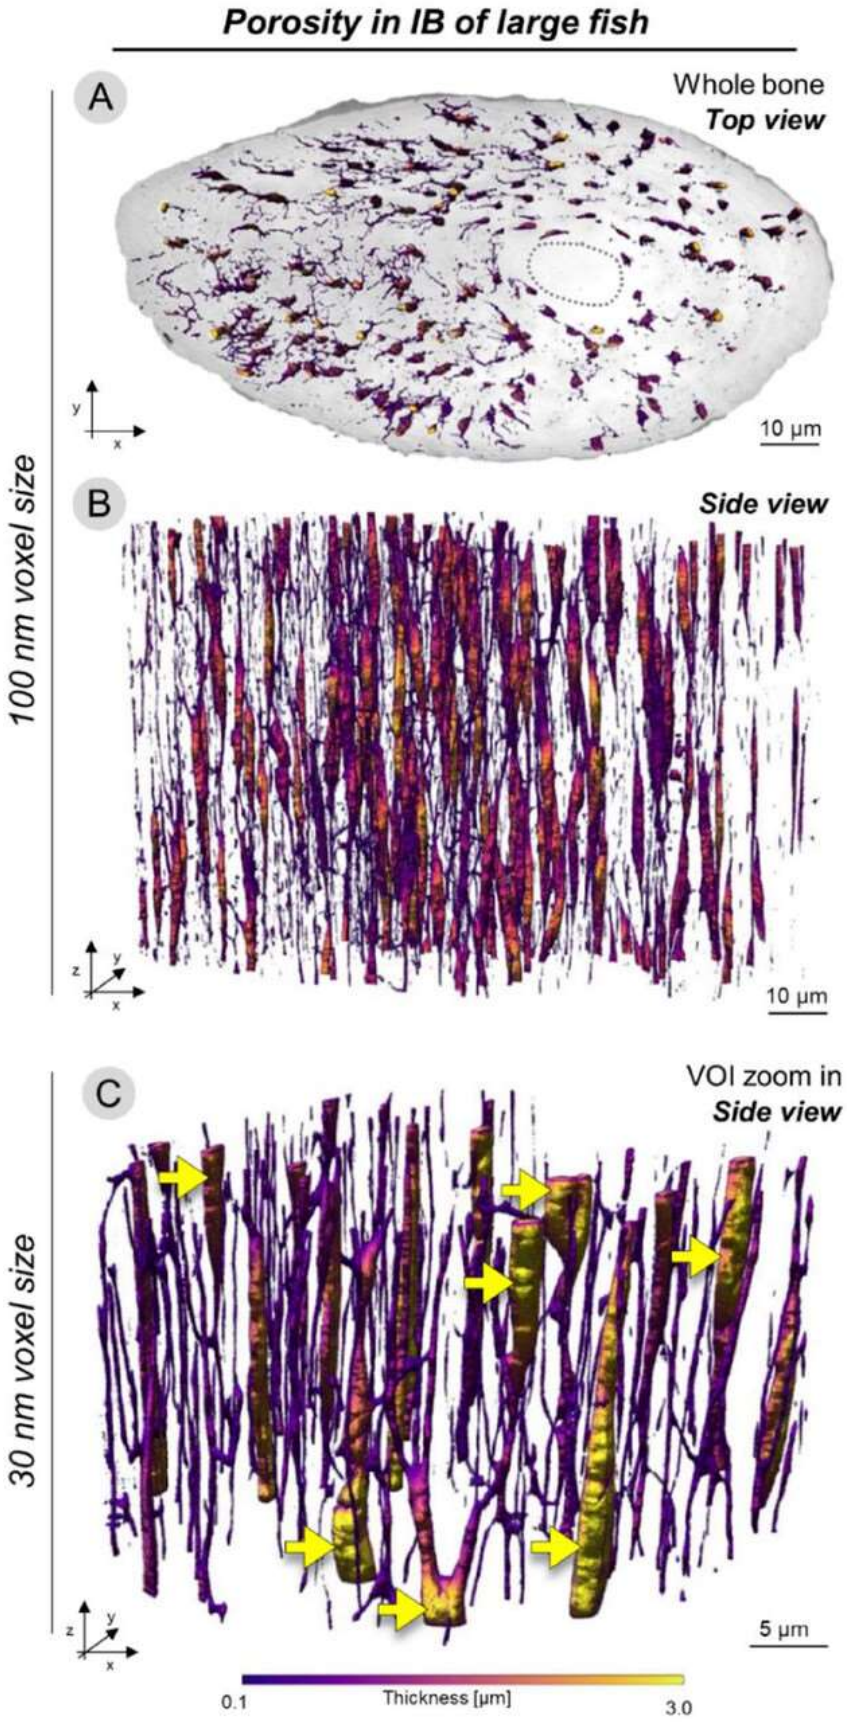
Introduction

Intermuscular bones (IB) are exclusively found in the skeleton of bony fish. This specialized mineralized tissue, derived from ossified tendon, exhibits a unique combination of mechanical properties: strength comparable to mammalian bone and the capacity for large deformation typically associated with mammalian tendons. This unusual pairing of stiffness and extensibility challenges conventional assumptions about mineralized tissue behavior. To identify the factors underpinning the unique whole-bone mechanical behavior of IB, we extended our investigation to smaller length scales than previously examined. We hypothesized that their ability for large deformation is reflected at the level of mineralized collagen fibrils and associated with structural features at microscopic and sub-microscopic length scales.

Methods

To test our hypothesis, we analyzed mineral composition using thermogravimetric analysis (TGA), assessed tissue- and fibril-level mechanics using synchrotron small-angle X-ray scattering (SAXS) combined with in situ uniaxial tensile testing, and characterized micro- and sub-microstructural organization using synchrotron phase-contrast nano-computed

tomography (nanoCT). In total, 293 IB were collected from twenty freshly obtained Atlantic herring.



Results

IB from large fish exhibited a 50% higher strain-to-failure—reaching up to 4.5%—compared with IB from small fish ($p = 0.015$). The applied macroscopic strain was almost entirely transmitted to the collagen fibrils, indicating highly efficient fibrillar load transfer. Although IB from larger fish showed greater mineral maturity, their overall mass density did not differ substantially from that of smaller fish. NanoCT imaging revealed concentric patterns of hypo- and hyper-mineralized regions in both groups, with these features being more pronounced in larger IB. Furthermore, larger IB displayed an extensive porous network, with tissue porosity increased by 180% relative to smaller IB ($p = 0.036$).

Discussion

Extending previous findings, our results indicate that the pronounced deformation capacity of IB arises from a combination of factors: marked tissue heterogeneity with concentric layers of differing mineral density, high strain transmission and stretching at the collagen fibril level, and potential cellular (re-)modeling processes that shape local microstructure. This unusual integration of stiffness, extensibility, microstructural heterogeneity, and distinct mineralization patterns positions intermuscular bones as a compelling biological template for the design of composite biomaterials with tailored structure–function relationships.

Modeling Immuno-Mechanics in Vascular Adaptation

Professor Jay Humphrey PhD[1], Professor Ana Estrada PhD[2]

[1]Yale University, New Haven, CT, United States. [2]Fairfield University, Fairfield, CT, United States

Introduction

Accumulating data for arteries reveal that mechanobiological responses tend to contribute to homeostasis whereas immunobiolological responses tend to compromise homeostasis. There is, therefore, a pressing need for a theoretical framework that can account simultaneously for these often-competing drivers of vascular (mal)adaptation.

Methods

In response to this critical need, we developed two complementary modeling frameworks: a constrained mixture-based growth and remodeling model that can be coupled easily to fluid-solid-interaction models to achieve tissue-to-circulation level understanding and a logic-based cell signaling model that can be coupled easily to the constrained mixture model to achieve transcript-to-tissue level understanding. Fundamental to both models is constitutive relations for constituent-specific rates of mass production, mass removal, and material behavior.

To parameterize and test these computational models, we collected data from 20 adult mice (with IACUC approval) that were rendered hypertensive for 4 weeks via chronic infusion of the potent vasoconstrictor angiotensin II. Data were collected at 2 or 4 weeks and included bulk RNA-sequencing, histological, immunohistochemical, and biomechanical.

Results

We found that we could capture time-course changes in key geometric and mechanical metrics by augmenting our traditional constrained mixture model with a stress-threshold based immunobiological function that alters rates of cell and matrix turnover. We also found that we could parameterize a three-cell (smooth muscle, fibroblast, and macrophage) logic-based cell signaling model that was capable of capturing phenotypic modulation of the cells (e.g., M1-type to M2-type macrophage expression). In particular,

both models were capable of capturing differential thickening of the medial and adventitial layers and both models successfully captured the loss of homeostatic control of wall stress in the presence of strong inflammation, with homeostatic responses recovered when neglecting inflammation.

Discussion

Notwithstanding accumulating multiscale data on vascular (mal)adaptations under many different conditions, the complexity of in vivo behaviors demand multiscale computational models to increase understanding. We submit that the present modeling approaches can contribute in this regard. Indeed, given that both models include a tissue-level constrained mixture module, we submit that transcript-to-tissue-to-circulation models should soon be possible, hence enabling basic biological data to predict (patho)physiological outcomes, with further promise for identifying new pharmacotherapies.

Community-Based RoboGym Circuit Training Improves Gross Motor Function, Independence, and Quality of Life in Children With Cerebral Palsy

Mr. Chaesu Kim M.Sc., Mr. Joshua Sung You Ph.D.

Yonsei university, Wonju, Gangwondo, Korea, Republic of

Introduction

Children with cerebral palsy (CP) frequently experience lifelong deficits in gross motor function, balance, and independence, and many are unable to maintain regular self-directed exercise without external support. Conventional hospital- or community-based rehabilitation (CBR) often provides insufficient intensity, task specificity, and long-term continuity, leading to regression of gains after discharge. To address these limitations, we developed a community-based RoboGym (CRG) program that integrates multiple task-specific robotic modalities into a circuit-style intervention for long-term CP management.

Methods

Thirty-one children with CP (mean age 12.8 ± 4.1 years, GMFCS II–III) were randomly allocated to CRG or conventional CBR. Both groups received 90-minute sessions, twice weekly, for 6 months (48 sessions). CBR emphasized activity-based, neurodevelopmental treatment approaches. CRG delivered a structured robotic circuit including therapeutic robotic horse-riding (TRH), automated motorized cycling (AMC), robotic-assisted reciprocal upper- and lower-limb gait trainer (RGT), robot-assisted gait training (RAGT), and overground suspension gait (OSG). Outcomes were assessed pre- and post-intervention using the Gross Motor Function Measure-66 (GMFM-66), Pediatric Balance Scale (PBS), Functional Independence Measure (FIM), and Pediatric Quality of Life Inventory (PedsQL). Group differences over time were analyzed using ANOVA/ANCOVA with Bonferroni correction.

Results

CRG produced significantly greater improvements than CBR in multiple domains. GMFM-66 total and key subdomains (lying/rolling, crawling/kneeling, standing) improved more in CRG, with medium-to-large effect sizes, indicating meaningful gains in gross motor capacity. PBS scores increased by ~38% in CRG versus ~7% in CBR, reflecting superior enhancements in static and dynamic balance. FIM scores improved by ~50% in CRG compared with modest gains in CBR, demonstrating clinically relevant increases in self-

care, transfer, and locomotion independence. PedsQL physical, emotional, social, and school functioning improved by approximately 20–30% in CRG versus 8–10% in CBR, indicating better translation of motor gains into participation and quality of life.

Discussion

A multi-modal, community-based RoboGym circuit produced larger and more comprehensive improvements in gross motor function, balance, functional independence, and quality of life than conventional CBR in children with CP. These findings support CRG as a feasible, intensive, and sustainable community model that leverages complementary robotic modalities to deliver long-term, task-specific rehabilitation across ICF domains.

Device / Training Type	Purpose / Functional Domain	Volumetric Intensity (Frequency × Duration × Program Length)	Parametric Intensity(Device-Specific Adjustable Parameters)	Clinical Decision-Making Rationale
TRH – Therapeutic Robotic Horse 	Stability: Improve dynamic postural control, head–trunk alignment, and proximal stability.	30 min/session, 1 session/week, for 6 months.	Frequency: 10–80 HzSpeed: 0.1–2.0 km/hAmplitude: adjustable oscillation up to 5–10 cm vertical displacement.Mode: forward/reverse astride, side-sit, kneel, quadruped.	Clinicians increase frequency and amplitude progressively to stimulate vestibular and proprioceptive inputs without inducing spastic responses. For GMFCS III–IV, lower frequency and greater postural support are maintained early. For GMFCS II, dynamic transitions and higher oscillation enhance trunk control and adaptive equilibrium responses.
AMC – Automatic Motorized Cycling 	Mobility: Enhance reciprocal lower-limb coordination and endurance within functional range.	30 min/session, 1–2 sessions/week, for 6 months.	Speed: 10–15 km/hResistance: 5–25 N·m torque, auto-adjusted to cadence and muscle tone.Mode: passive → active-assist → resistive.Pedal symmetry feedback integrated.	Clinicians titrate cycling speed and resistance based on lower-limb selective motor control and endurance. Passive or active-assist modes are used initially for GMFCS IV, progressing to resistive loads as coordination improves. Higher torque promotes muscle activation symmetry and cardiopulmonary endurance.
RGT – Robotic Gait Trainer (Upper–Lower Coupled Trainer) 	Transitional Mobility: Re-educate interlimb coordination for walking and postural transfer.	30 min/session, 1–2 sessions/week, for 6 months.	Speed: 0.4–1.0 km/hResistance: graded 0–30 N·mSupport mode: 30–60% body weight assist.Arm–leg reciprocal control module synchronized with trunk sensor feedback.	Parametric control of resistance and speed allows individualized motor learning. Clinicians reduce body-weight support as trunk control stabilizes, and increase step frequency for rhythm entrainment via central pattern generators (CPG). Target progression: slow repetitive walking → dynamic reciprocal stepping → dual-task control.
RAGT – Walkbot Robotic-Assisted Gait Training 	Skilled Mobility: Optimize functional gait symmetry, endurance, and selective control.	40 min/session, 1–2 sessions/week, for 6 months.	Speed: 1.0–2.0 km/hSuspension: 50% → 30% body weight unloadingResistance: 10–50 N·m torque modulationMode: passive → active → interactive assist-as-needed (AAN).	Clinicians adjust speed and unloading according to gait stability, spasticity, and energy efficiency. Lower speeds and higher support promote postural safety; progressive load and speed enhance task-specific neuroplasticity. Resistance promotes eccentric control and interlimb coordination via spinal CPG activation. Target: symmetrical gait with improved hip–knee–ankle phasing.
OSG – Overground Suspension Gait Trainer 	Transitional / Dynamic Mobility: Promote balance and independent stepping in a partial weight-bearing environment.	20 min/session, 1 session/week, for 6 months.	Suspension: adjustable 10–40% body weightSpeed: clinician-determined overground cadence (0.4–1.2 km/h)Tasks: forward, backward, lateral, and obstacle walking.Support harness with multi-directional pelvic control.	Used after sufficient trunk and hip control from TRH/AMC/RGT. Clinicians reduce suspension gradually to challenge balance and anticipatory control. Progressive reduction of support encourages autonomous dynamic balance, weight-shifting, and gait adaptability under task-specific contexts.

Relative Demand on the Knee Extensors During Running Following an Anterior Cruciate Ligament Reconstruction

Dr. Meredith Owen PhD, Dr. Darren Johnson MD, Dr. Brian Noehren PT, PhD

University of Kentucky, Lexington, KY, United States

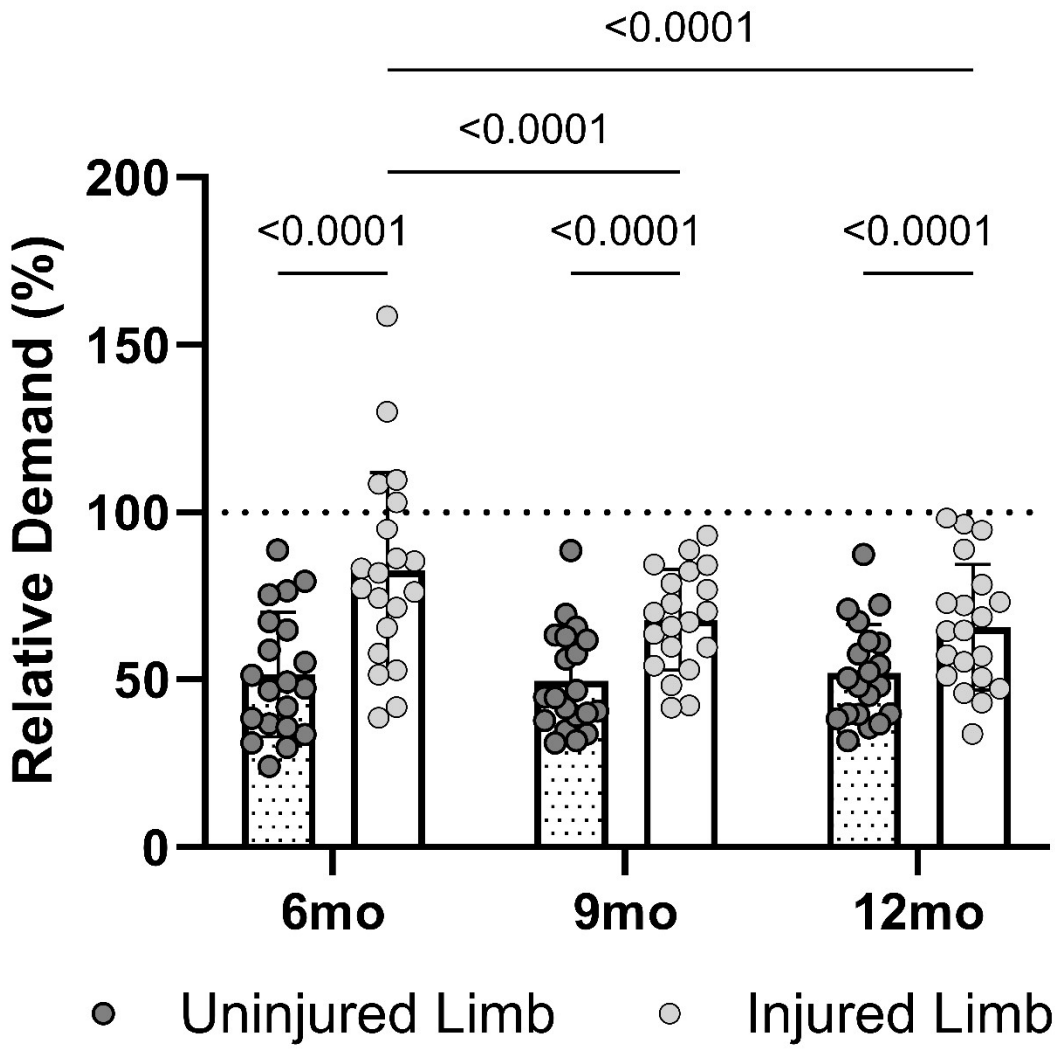
Introduction

Return-to-running following anterior cruciate ligament reconstruction (ACLR) is an essential milestone of recovery. Adequate quadriceps strength is critical to successful return-to-running to control knee loading. When task demands exceed the maximal force-producing capacity of the quadriceps, compensatory movement strategies may emerge to ensure task completion, potentially increasing the risk of future injury. However, the relative demand on the quadriceps during running across the first year of recovery is unknown. The purpose of this work was to determine relative demand on the knee extensors during running across late-stage ACLR rehabilitation.

Methods

20 individuals (13 F/7 M, 20.1 years, 1.7 m, 70.1 kg) were assessed at 6, 9, and 12 months post-ACLR. Participants completed an instrumented running assessment with marker (200 Hz) and ground reaction force (2000 Hz) data sampled synchronously. Peak knee extension moment (KEM) was determined and averaged across 5 steps. Peak knee extensor strength was taken as the peak of four maximum voluntary quadriceps contractions. Relative demand on the extensors was estimated as the ratio of peak KEM of the uninjured limb (e.g. the goal needed for symmetrical running) to peak isometric torque of the injured and noninjured limbs. Differences between limbs and timepoints were assessed using a two-way repeated-measures ANOVA with Tukey's post-hoc tests.

Results



Peak PKEM was significantly lower in the ACLR limb than the healthy limb across all timepoints (6mo: -58.9 Nm; 9mo: -53.9 Nm, 12mo: -45.9 Nm difference between limbs; all $p<.01$). Relative demand on the ACLR limb was significantly higher than for the uninjured limb for all time points and decreased significantly over time (Figure 1).

Discussion

We show that the relative demand on the quadriceps required to achieve symmetric joint moments is significantly higher for the injured limb across all timepoints. Further, even though individuals possess the strength to run symmetrically at 12 months, with relative

demand reduced below suggested normative values (~60% relative demand during running), asymmetries in the peak KEM still exist. Persistent asymmetries could be due to learned disuse or fear of reloading, suggesting the potential need for gait retraining throughout the return-to-run phase of rehabilitation after ACLR.

OA72-03

Assessing the Posteriorly Directed Forces Applied to Pediatric Knees by ACL Orthoses

Dr Alexandria Mallinos PhD, Dr Kerwyn Jones MD, Ms Kristen Smith RN

Akron Children's Hospital, Akron, Ohio, United States

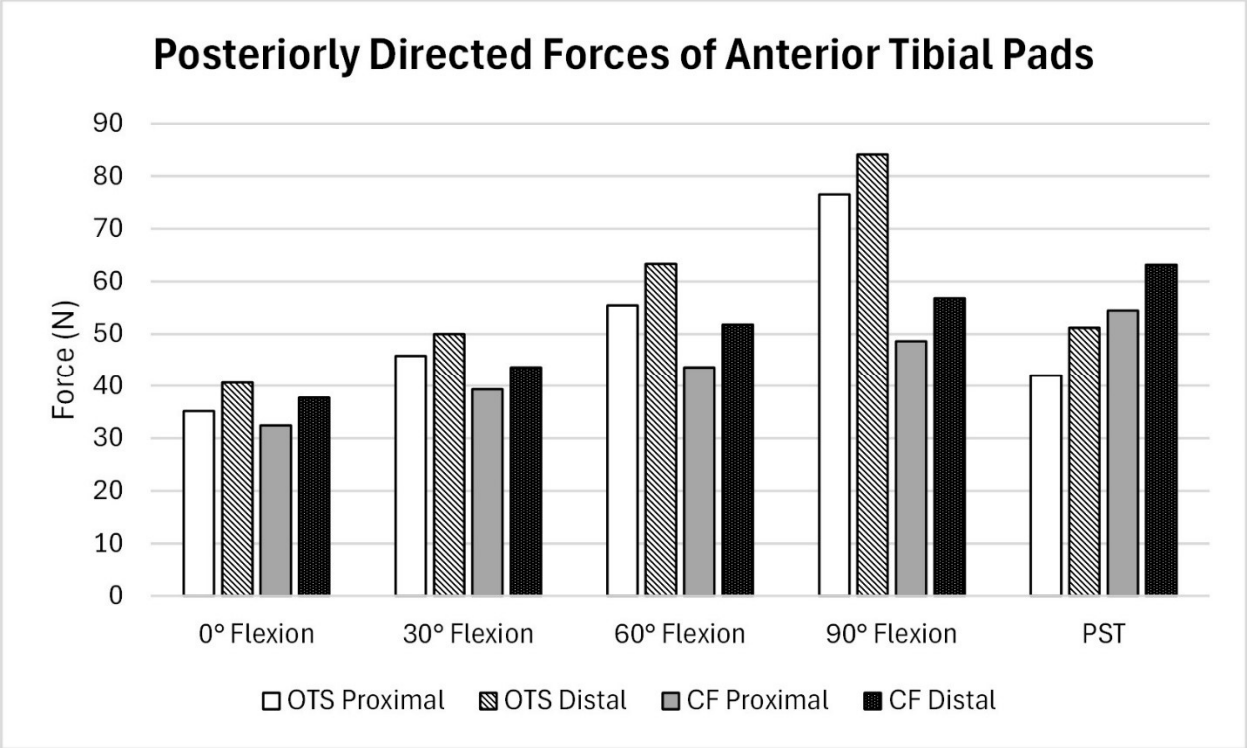
Introduction

Functional anterior cruciate ligament (ACL) orthoses are used to limit anterior tibial translation and valgus loading, providing external stabilization during healing and return-to-sport. These devices apply posteriorly directed forces (PDF) through anterior tibial pads, yet the magnitude of these forces across brace designs in pediatric populations is not well defined. This study quantified PDF generated by custom-fit (CF) and off-the-shelf (OTS) ACL orthoses in pediatric patients.

Methods

Thirty patients within one year of ACL reconstruction (17 females, 13 males; mean age 16.3 years; mean weight 71.6 kg) were enrolled. Inclusion criteria required unilateral ACL reconstruction. Patients with additional ligament injury or neuromuscular impairments were excluded. Participants brought their prescribed CF DonJoy Defiance orthosis and were fitted with an OTS DonJoy Playmaker II. LoadPad sensors (Novel Electronics) were placed under the proximal and distal anterior tibial pads to measure PDF.

Static testing was performed at 0°, 30°, 60°, and 90° of knee flexion, with each angle held for 5 seconds and repeated three times. Dynamic testing consisted of three pivot shift tests (PST) following standard clinical protocols. LoadPad data were processed in MATLAB to compute average PDF for each condition. Descriptive statistics and independent t-tests compared forces between orthosis types.



Results

PDF measurements showed that both orthosis types produce increasing loads with greater knee flexion (Figure 1). The OTS orthosis consistently generated higher forces during static flexion, whereas the CF orthosis experienced greater PDF during the PST. Although the OTS orthosis demonstrated significantly higher proximal pad forces at 90° of flexion ($p = 0.043$), no other differences between orthosis types reached statistical significance.

Discussion

Both orthoses demonstrated increasing PDF with flexion, consistent with prior studies. The higher static forces observed in the OTS brace may reflect its total-contact design, whereas the CF brace's superior performance during dynamic loading suggests improved conformity and contact maintenance. Although most differences were not significant, these trends indicate that brace design may influence load transfer and dynamic knee stabilization. Limitations include a single postoperative cohort and two brace models. Future work should incorporate broader brace designs, full-surface pressure mapping, and links between PDF, knee stability, and patient outcomes.

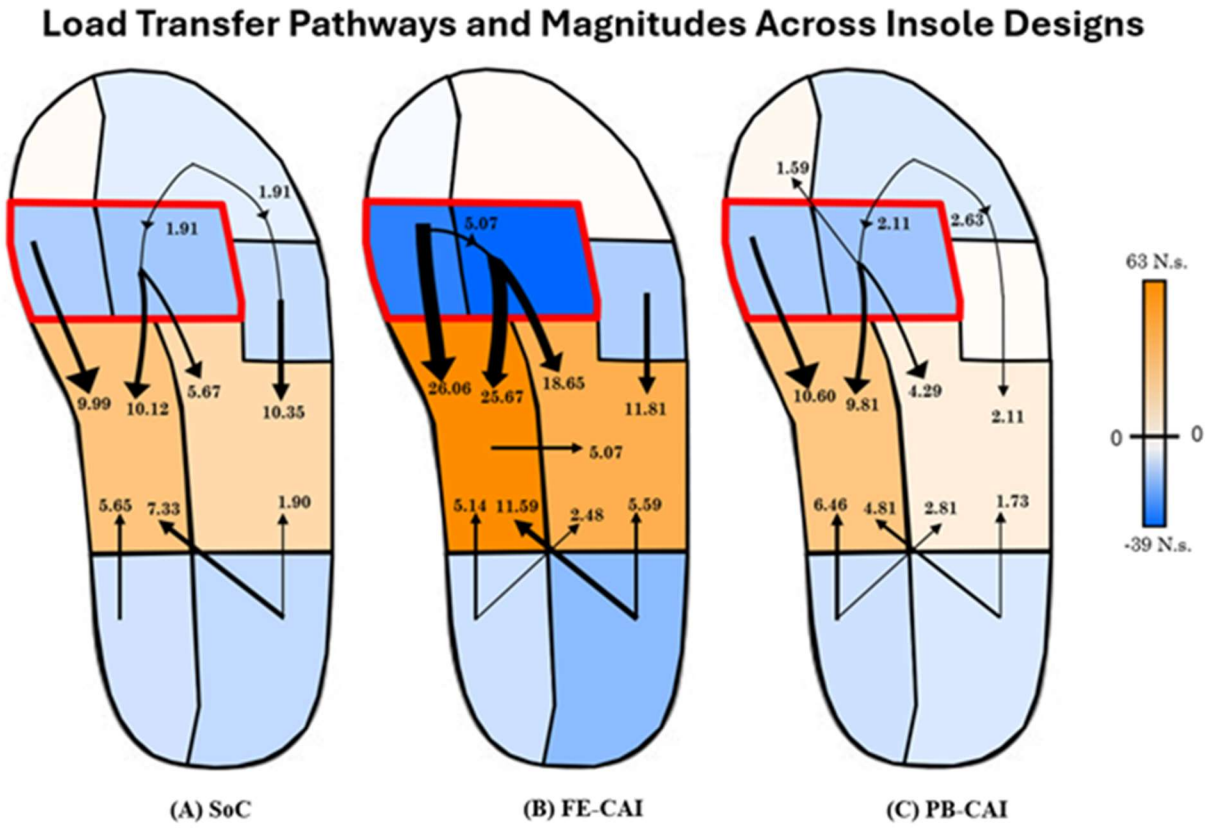
[1]VA RR&D Center for Limb Loss and MoBility (CLiMB), Seattle, WA, United States. [2]Department of Mechanical Engineering, University of Washington, Seattle, WA, United States. [3]Department of Orthopaedic Surgery and Sports Medicine, University of Washington, Seattle, WA, United States

Introduction

Custom accommodative insoles are commonly prescribed to reduce plantar pressures in people with diabetes who are at elevated risk for foot ulceration. We have developed 3D-printed custom accommodative insoles that incorporate patient-specific geometry and tunable material properties, resulting in improved offloading performance compared with standard-of-care designs. Although these insoles effectively reduce forefoot pressures, the mechanisms by which they redistribute load throughout the entire plantar surface are not fully understood. The objective of this study was to characterize and compare load redistribution pathways across nine anatomical plantar regions for standard of care and 3D-printed insoles using a quantitative load-transfer algorithm.

Methods

Twenty-six feet from 17 adults with diabetes and elevated forefoot plantar pressures in the first-to-third metatarsals were analyzed. Each participant was provided with three types of custom accommodative insoles: a standard of care clinical insole, a finite-element–optimized 3D-printed insole, and a pressure-based 3D-printed insole. Plantar pressures were collected during walking using an in-shoe pressure measurement system (pedar-X), and peak plantar pressure and force-time integral were computed for each anatomical region. A load transfer algorithm was then applied to quantify how reductions in loading in one region corresponded to increases in another, enabling identification of redistribution pathways unique to each insole design.



Results

Across all insole conditions, the dominant load-transfer pathway occurred from the metatarsal heads to the midfoot, with the strongest redistribution observed from the first metatarsal head to the medial midfoot. The finite-element–optimized 3D-printed insoles produced the largest reductions in metatarsal loading and the largest corresponding increases in midfoot loading, indicating more effective and targeted redistribution compared with the standard-of-care and pressure-based designs.

Discussion

Design features such as arch height, metatarsal bar geometry, and targeted offloading zones strongly influenced the redistribution pathways identified. These results highlight the capacity of advanced custom insole designs to offload high-risk plantar regions while more effectively engaging the midfoot as a load-bearing structure. The load-transfer framework provides an additional metric for evaluating insole performance and may help guide future patient-specific design strategies, although individual variability in loading patterns remains a critical consideration.

[3]Integrative Neuromuscular Sport Performance Lab, University of Calgary, Calgary, Alberta, Canada. [4]McCaig Institute of Bone and Joint Health, University of Calgary, Calgary, Alberta, Canada. [5]Alberta Children's Hospital Research Institute, University of Calgary, Calgary, Alberta, Canada

Introduction

Lower-limb eccentric and concentric strength are important for performance and injury prevention in **youth female athletes**, who **experience disproportionately high ACL injury rates**. However, most assessments rely on single-joint dynamometers that do not reflect the multijoint, high-velocity actions of real-world ACL injury mechanisms (i.e., rapid braking/deceleration) [1]. Eccentric strength deficits after ACL reconstruction (ACLR) may impair movement and increase reinjury risk [2]. Social factors, including strength-training attitudes, may influence force production, supporting a biomechanical–social view of ACL injury risk [3]. This abstract **(i)** quantifies multijoint maximal eccentric (MEF) and concentric (MCF) leg extensor force in female athletes with ACLR and healthy controls, and **(ii)** examines associations between strength-training attitudes and force production.

Methods

Healthy female athletes (n=177) and female athletes with **ACLR** who returned to sport (n=13) performed **MEF and MCF leg extensions on a robotic servomotor leg press**. Body mass–normalized force outputs were obtained for the ACLR limbs, contralateral limbs, and healthy control limbs. Participants rated their agreement with the statement, "**I prefer strength training with light/bodyweight versus heavy weights**," on a 7-point Likert scale. Linear mixed-effects models accounted for repeated limb measurements, and Holm-adjusted estimated marginal means assessed group differences.

Results

ACLR limbs demonstrated significantly lower MCF than contralateral (β:–2.17 N/kg, p=0.006) and **healthy limbs** (β:–2.27 N/kg, p=0.008). Contralateral and healthy limbs did not differ (β:–0.10 N/kg, p=0.90). MEF did not differ by limb condition (ACLR vs healthy: β:–0.89 N/kg, p=0.51), though contralateral limbs showed a non-significant trend toward

higher MEF than healthy limbs (β:2.17 N/kg, p=0.108) (**Figure1**). **Athletes preferring light/bodyweight training produced lower maximal force** (β:–1.12 N/kg, p=0.05), with no differences between healthy and contralateral limb conditions (β:0.43 N/kg, p=0.72) or contraction type (MEF versus MCF) (p=0.46).

Discussion

ACLR limbs showed significant MCF deficits relative to contralateral and healthy limbs, while MEF was preserved. Preference for light/bodyweight training was linked to lower strength, **supporting a biomechanical–social approach to evaluating ACLR and healthy female athletes.**

Biomechanical Correlates of Positive Hip Joint Work and Symmetry in Post-Stroke Gait

Mr. Dongwon Jeong[1,2], Mr. Dongho Park[3,4], Dr. Aaron Young[3,4]

[1]School of Computing, Georgia Institute of Technology, Atlanta, Georgia, United States. [2]Bio-Convergence, Integrated Science and Engineering Division, Yonsei University, Seoul, Seoul, Korea, Republic of. [3]George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States. [4]Institute for Robotics and Intelligent Machines, Georgia Institute of Technology, Atlanta, Georgia, United States

Mr. Dongwon Jeong

Mr. Dongho Park

Introduction

A vast majority of stroke survivors exhibit asymmetric gait, leading to metabolic inefficiency and long-term musculoskeletal consequences. Driven by hemiparetic deficits, individuals commonly compensate by shifting joint work from the paretic to the non-paretic limb. This reliance on the non-paretic side reinforces inefficient gait strategies. Although real-time gait biofeedback is widely used, target selection has often relied on theoretical assumptions rather than on quantitative analyses on metrics directly tied to hip joint mechanics. Given the hip joint's substantial capacity to generate positive work, understanding the specific biomechanical correlates of positive hip joint work (PHJW) is essential. This study aimed to quantify the correlations between commonly used biomechanical variables and PHJW magnitude and symmetry in post-stroke gait.

Methods

Treadmill walking data were analyzed from 20 post-stroke subjects across multiple speeds. We computed PHJW and 15 biomechanical variables for both limbs, including: peak hip/knee/angle moments and angles, trailing limb angle (TLA), stride length, step length, step width, cadence, stance time, swing time, single limb stance time, and peak anterior-posterior ground reaction force (AP-GRF). Pearson correlation coefficients (R^2) were calculated to determine linear relationships between: (1) each variable and paretic limb PHJW, and (2) the symmetry index of each variable and the PHJW symmetry index.

Results

A subset of variables showed meaningful correlations with paretic PHJW: paretic hip flexion moment (R^2=0.35±0.29), non-paretic hip extension moment (R^2=0.42±0.53), paretic knee extension moment (R^2=0.25±0.27), paretic hip extension angle (R^2=0.25±0.23), TLA (R^2=0.26±0.30), and stride length (R^2=0.28±0.28). Across nearly all metrics, non-paretic limb variables were more strongly correlated with PHJW than paretic limb variables. However, the symmetry index showed that only hip flexion angle (R^2=0.23), knee flexion angle (R^2=0.33), ankle dorsiflexion moment (R^2=0.26), and step width (R^2=0.21) were associated with PHJW symmetry (all p<0.05).

Discussion

These findings demonstrate that despite high inter-subject variability, several clinically actionable feedback variables do recur across subjects and that even if a variable is correlated with PHJW, it may not be a suitable biofeedback target to meet PHJW symmetry. Furthermore, this study provides data-driven insights for designing future biofeedback strategies aimed at post-stroke gait rehabilitation.

Images (Optional)

Simulated Medial Knee Contact Force is More Predictive of Cartilage Thinning Than Static Alignment: An Analysis of 3,301 OAI Subjects

Dr. Anthony Gatti, Dr. McKenzie S. White, Dr. Nicos Haralabidis, Ms. Anoosha Pai, Dr. Constance Chu, Dr. Seth Sherman, Dr. Gatti E. Gold, Dr. Scott Delp, Dr. Feliks Kogan, Dr. Akshay Chaudhari

Stanford University, Stanford, CA, United States

Introduction

Systematic reviews confirm knee adduction moment predicts osteoarthritis (OA) progression. While High Tibial Osteotomy (HTO) slows progression by surgically redistributing knee load, surgical planning relies solely on static alignment, ignoring mechanical load. Predictive simulations could bridge this gap by estimating joint loads under varying surgical plans. Purpose: To demonstrate feasibility of using predictive simulations for surgical planning, we tested whether predictive simulations personalized to Osteoarthritis Initiative (OAI) subjects predicted longitudinal cartilage thinning.

Methods

We generated personalized predictive gait simulations for 3,301 Osteoarthritis Initiative participants (6,602 knees). Subject-specific musculoskeletal models were created by scaling a generic model[1] using femoral/tibial lengths, Hip-Knee-Ankle (HKA) alignment extracted from full lower limb radiographs, and body mass. We simulated a full gait cycle, normalizing the walking speed to a Froude number of 0.25 to account for subject size. We used the OpenSim AD pipeline minimizing the cost function as previously described[2] with an additional cost term tracking generic reference kinematics. Medial knee contact force (MCF) was estimated using a frontal plane static equilibrium model.

To test predictive power, we auto-segmented medial femoral cartilage of each subject from all available OAI MRI timepoints and computed the annual rate of thinning per knee. We compared the correlation of static clinical metrics (Body Mass, BMI, HKA) and simulation-derived MCF metrics (Peak 1, Peak 2, Impulse) against the rate of cartilage thinning.

Results

Simulation-derived MCF was moderately correlated with HKA alignment (**corr**: peak 1=-0.61, peak 2=-0.57, impulse=-0.58). HKA alignment was the strongest clinical predictor of cartilage thinning (corr: HKA=0.20, body mass=-0.13, BMI=-0.14). MCF peak 1 and impulse had a significantly stronger correlation (**corr**: peak 1=-0.22, peak 2=-0.19, impulse=-0.21) with cartilage thinning ($p<0.001$ vs HKA).

Discussion

The data show that predictive simulations can be deployed at epidemiological scale to estimate joint loads. Predictive simulation-based MCF better predicted disease progression than clinical metrics. Integrating pre-operative kinematics into the physics-based simulations could further improve simulations for surgical planning.

Images (Optional)

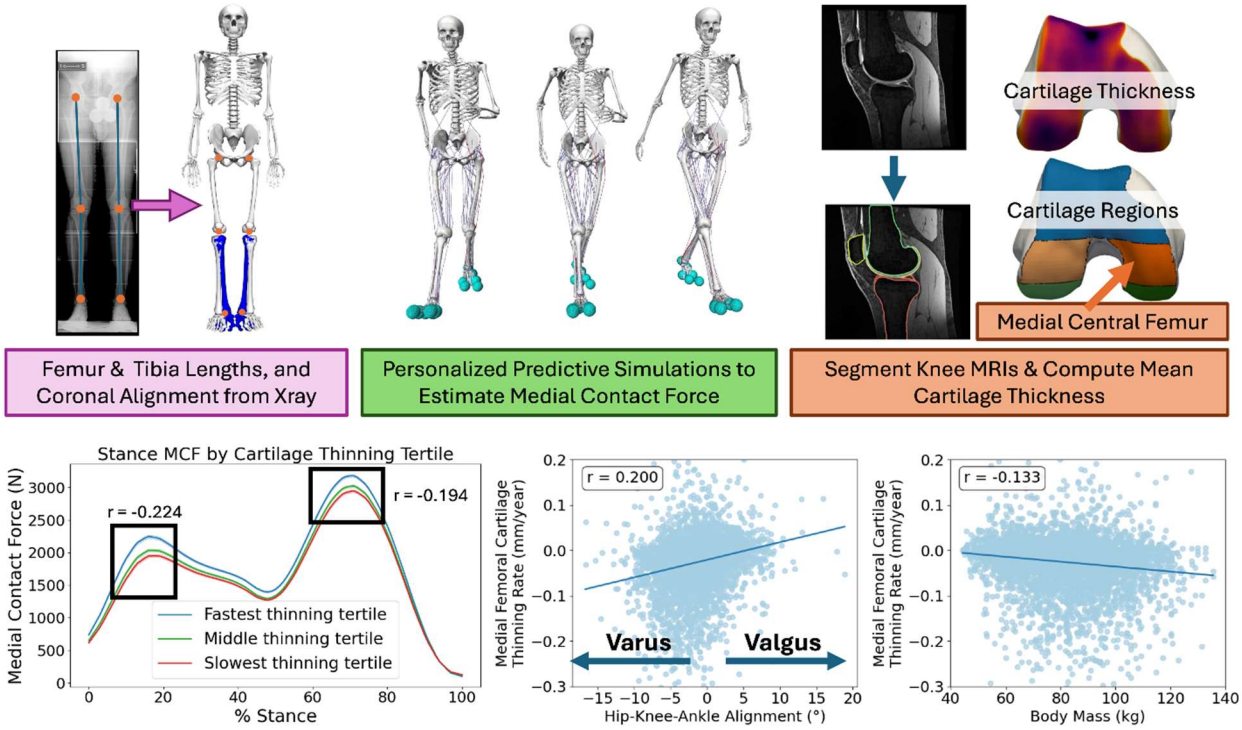

Figure 1. Personalized musculoskeletal models were scaled using radiographic HKA and limb lengths to drive predictive simulations for estimating MCF. Longitudinally, medial femoral cartilage thinning rates were quantified via automated MRI segmentation. The left lower plot shows mean +/- 95% confidence intervals for MCF over stance for the lowest, middle, and highest tertiles of cartilage thinning; black boxes annotate correlations per peak with thinning rate. Scatter plots show association of thinning rate with Body Mass, and HKA.

Cartilage Biomechanical Responses Are Reduced by Valgus Bracing in Varus Malaligned Knees With Medial Osteoarthritis

Mr. Joose Peitola MSc[1], Dr. Amir Esrafilian PhD[1], Dr. Atte Eskelinen PhD[1], Dr. Scott Starkey PhD[2], Assoc. Prof. David Saxby PhD[3], Assoc. Prof. Laura Diamond PhD[3], Assoc. Prof. Michelle Hall PhD[4], Prof. Rami Korhonen PhD[1,3]

[1]University of Eastern Finland, Kuopio, Northern Savo, Finland. [2]The University of Melbourne, Melbourne, Victoria, Australia. [3]Griffith University, Gold Coast, Queensland, Australia. [4]The University of Sydney, Sydney, New South Wales, Australia

Introduction

Valgus bracing is a common intervention method to reduce medial knee compartment loading. However, its effects on cartilage tissue-level biomechanics have not been examined using advanced fibril-reinforced material models. Such models consider how the collagen fibril network provides tensile stiffness and structural integrity, and how its interaction with fluid pressure governs tissue deformation and stress [1]. We investigated how valgus bracing affects cartilage biomechanics in individuals with knee varus malalignment and medial knee osteoarthritis (KOA) using fibril-reinforced poroviscoelastic (FRPVE) and -poroelastic (FRPE) materials for cartilage and menisci, respectively.

Methods

Twenty-five participants (aged ≥50 years) with varus-malaligned medial KOA (Kellgren–Lawrence grade ≥ 2) completed unbraced and braced (Unloader One©, Össur) walking trials. Personalized knee geometries from magnetic resonance imaging were implemented into a validated 12-degree-of-freedom knee model and combined with electromyography-informed neuromusculoskeletal simulations [2] (Figure 1A) to estimate tibiofemoral kinematics and kinetics as inputs for the finite element (FE) analysis (Figure 1B). Next, the cartilage and meniscus geometries were imported into an FE model [3] with FRPVE and FRPE material models and meshed using hexahedral elements. A soils consolidation analysis (Abaqus 2023) was performed. We report maximum principal stress (MPa), maximum shear strain (%), and collagen fibril strain (%) (Figure 1C) as indicators of cartilage damage.

Results

Bracing reduced medial tibial cartilage stress and strain at the second peak in contact loading during stance (i.e., 70–90% of stance). The maximum principal stress, maxium shear shear strain, and collagen fibril strain within medial tibial cartilage decreased from

9.5±3.9 MPa to 8.5±3.6 MPa (p=0.01), 31.0±5.1% to 29.5±5.2% (p=0.025), and 4.4±0.7% to 4.2±0.7% (p=0.014), respectively.

Discussion

Valgus bracing applies an external abduction moment to the knee, and our analysis indicates this reduces biomechanical stresses and strains in the medial tibial knee cartilage. This may help limit collagen fibril network damage in individuals with varus malalignment, potentially slowing medial KOA progression.

The Impact of Estrogen on Stress Relaxation Properties and Collagen Content in Chondrocyte-Seeded Alginate Gels

Ms. Emma Stevens, Mr. Marcus Torres-Negron, Dr. Jill Middendorf Ph.D.

Johns Hopkins University, Baltimore, MD, United States

Introduction

Women make up a disproportionate share of osteoarthritis cases [1], yet mechanisms linking sex hormones to cartilage biomechanics remain poorly defined. Estrogen, a key sex specific hormone, has been shown to upregulate collagen II and downregulate matrix metalloproteinases gene expressions [2]. However, changes in mechanical properties and measures of matrix production due to estrogen is unknown. Therefore, the goal of this study was to identify how estrogen alters matrix production and the mechanical properties of chondrocyte seeded alginate gels.

Methods

Chondrocytes were isolated from porcine femoral condyles and embedded in alginate at 10^7 cells/ml. Hydrogel samples were placed in control (complete) or estrogen media (+1pM 17*b* estradiol) and incubated for 1, 2, or 3 weeks. After culture, stress relaxation tests, comprised of 6 steps of 5% strain, was performed ($N \geq 6$). Stress-time plots were fit to a biphasic model to find instantaneous and equilibrium moduli and tissue permeability [3,4]. Hydroxyproline assay assessed collagen content (N=3).

Results

No significant changes in instantaneous modulus, equilibrium modulus, or permeability based on media condition were observed (Fig 1A). Trends suggest that estrogen produces a slightly weaker, more permeable construct than control media. Time dependent decreases in construct mechanics may be due to alginate degeneration [5]. A significant decrease in collagen content between estrogen and control conditions occurred at week 2 ($p = 0.014$, Fig 1B).

Discussion

Since compressive properties often correlate strongest with aggrecan content, insignificant mechanical changes due to estrogen likely indicates no significant changes in proteoglycan concentrations. However, contrary to prior data on chondrocyte gene

expression [2], this study showed decreased collagen production and trends towards decreasing compressive mechanics due to estrogen. Since estrogen's impact changes with chondrocyte age and sex [6,7], these contradictions may stem from these factors. Nevertheless, our results demonstrate that estrogen may predispose the joint to degeneration in women as estrogen concentrations fluctuate.

Images (Optional)

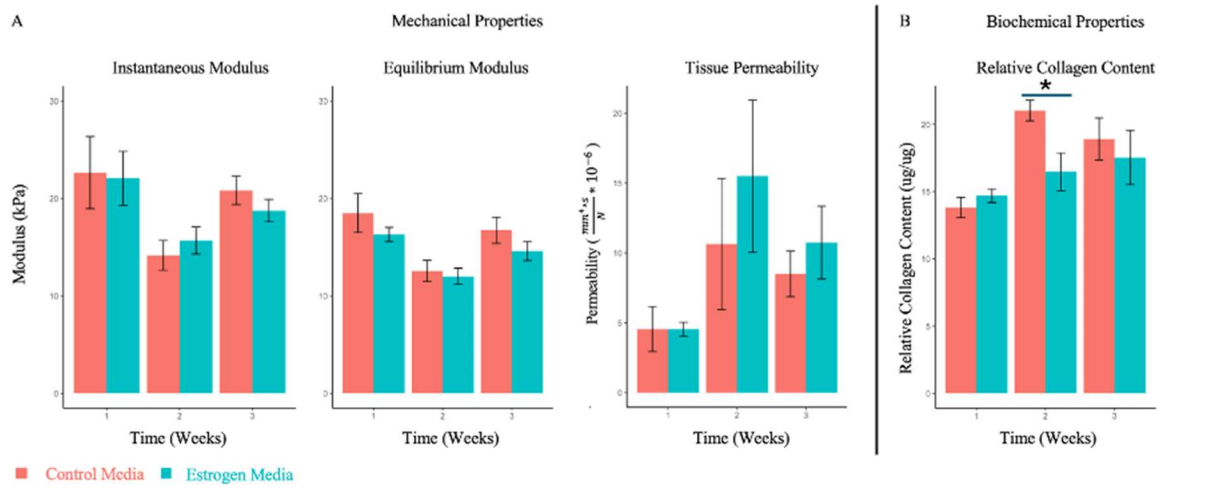

Figure 1: A) Stress relaxation properties demonstrate changes over time supersede changes by media condition. Trends show samples treated with estrogen generally have lower equilibrium and instantaneous moduli and higher permeability compared to samples treated with control media (n≥6/condition). B) Hydroxyproline assay demonstrates lower moduli correspond with lower relative collagen content when normalized by wet weight (n=3/condition). (* p<.05)

Cartilage Thickness not Pain Variability is Associated with Higher Stride Length Variability in Knee Osteoarthritis

Dr. Skylar Holmes[1], Dr. Garry Gold[1], Dr. Anthony Gatti[1], Dr. Katherine Boyer[2]

[1]Stanford University, Stanford, CA, United States. [2]University of Massachusetts Amherst, Amherst, MA, United States

Introduction

Knee osteoarthritis (KOA) has been linked to movement adaptations, specifically greater spatiotemporal gait variability than age-matched controls[1]. However, it is unclear whether increases in variability are driven by pain, a primary symptom of OA, or structural differences. Therefore, the purpose of this work was to determine whether pain variability or structural severity would predict spatiotemporal gait variability in KOA. It was hypothesized that greater pain variability and structural severity would predict greater spatiotemporal gait variability in KOA.

Methods

Seventeen adults with KOA (9F, age: 70±4y, BMI: 25.9±3, KOOS Pain: 69.3±12) participated in this study. Participants completed a 30-minute treadmill walk (30MTW) at preferred speed. The standard deviation of stride length and step width (spatiotemporal variability) were calculated with 7 – 30 strides of data collected at min 2 of the 30MTW. Knee pain was reported on an 11-point verbal numeric rating scale (NRS) every 6 minutes during the 30MTW. Change in pain (Δpain) was the difference between NRS at minutes 30 and 0 of the 30MTW. The standard deviation of the 1st derivative of pain scores (Δpain/Δtime) and Δpain were used to quantify pain variability. Affected knee MR images were obtained using a 3-dimensional Double Echo Steady State sequence. The medial-to-lateral (M/L) cartilage thickness ratio was defined as mean medial femoral weight-bearing thickness divided by mean lateral femoral weight-bearing thickness. Separate linear regression models were used to assess the relationships between change in pain, pain variability, M/L cartilage thickness ratio with measures of gait variability ($\alpha = 0.05$).

Results

Pain variability was not associated with stride length nor step width variability. There was a positive association between M/L thickness ratio and stride length ($p=0.03$, Table 1). KOA

individuals who have a larger M/L thickness ratio or thicker medial relative to lateral cartilage (less severe medial OA) have greater stride length variability.

Discussion

M/L ratio not pain predicted gait variability suggesting structural severity may independently impact movement adaptations in KOA. These findings suggest that while pain is an important clinical symptom it may not underly movement variability in KOA.

Images (Optional)

Table 1. Regression Models

Outcome Variable	ΔPain Beta (95% CI)	Pain Derivative	M/L Ratio
Stride Length Variability	0.01(-0.01 0.03)	-0.02(-0.09,0.06)	0.06(0.07,0.04)*

Longitudinal Bone and Joint Changes After High Tibial Osteotomy for Medial Knee Osteoarthritis

Mr. Tadiwa Waungana MSc.[1], Miss Elisa Moretta[2], Dr. Giacomo Dal Fabbro MD[2], Prof. Stefano Zaffagnini MD[2], Mr. Enrico Schileo PhD[2], Mr. W. Brent Edwards PhD[1], Mrs. Sarah Manske PhD[1], Mrs. Fulvia Taddei PhD[2]

[1]University of Calgary, Calgary, Alberta, Canada. [2]Istituto Ortopedico Rizzoli, Bologna, Emilia-Romagna, Italy

Introduction

Varus joint alignment is common and contributes to knee osteoarthritis (OA) progression through cartilage degeneration, typically observed as joint space narrowing, and bone sclerosis in the medial compartment[1]. Medial opening wedge high tibial osteotomy (MOWHTO) is a surgical procedure that corrects varus malalignment and redistributes compartmental loads, whilst preserving the native joint surfaces, to alleviate pain and restore joint function[2]. However, we have limited understanding of its effects on articular structures and whether it slows load-mediated joint degeneration. This clinical trial investigated the efficacy of MOWHTO on restoring bone and joint structure.

Methods

51 patients (9 female, mean age 53 ± 8.6 yrs) with medial knee OA (KLG ≤ 3, varus knee alignment > 4°) were assigned to non-surgical or surgical MOWHTO groups. All patients underwent baseline and one-year knee imaging using weight bearing computed tomography (Onsight 3D, Carestream). We quantified changes in three-dimensional tibiofemoral joint space width (ΔJSW) and subchondral bone plate thickness (ΔSbp.Th) to determine the effects of MOWHTO.

Results

We observed consistent trends of decreasing femoral Sbp.Th, with moderate ($0.53 < d < 0.96$) and small to moderate ($0.27 < d < 0.75$) effect sizes in lateral and medial ΔSbp.Th, respectively. Compared to non-surgical patients, we observed a significant decrease in Sbp.Th in the lateral trochlea ($p = 0.015$) of surgical patients. Overall, Sbp.Th increased in the lateral tibia of surgical patients ($-0.64 < d < -0.53$), whilst changes in the medial tibia varied by region. Trends towards increased medial JSW were accompanied by decreased lateral JSW in surgical patients ($d_{Medial} = -0.60$, $d_{Lateral} = 0.54$), but these changes were not significant compared to non-surgical patients.

Discussion

Whilst the decrease in Sbp.Th and increase in JSW in the medial compartment was consistent with unloading due to MOWHTO, we were surprised to find decreased Sbp.Th in the lateral femur, suggesting that load redistribution may affect the femur and tibia differently. Our results suggest that load redistribution may lead to bone adaptations that may underpin extended joint survivorship in MOWHTO patients[2] and have important implications for OA treatment strategies.

Craniofacial CBCT: Addressing Volume-Resolution Dilemma using Generative Artificial Intelligence

Dr. Seyedmahdi Hosseinitabatabaei[1], Dr. Andrew Nelson[2], Dr. Nicolas Piché[3], Dr. Didem Dagdeviren[4], Dr. Natalie Reznikov[1,4,5]

[1]Department of Bioengineering, McGill University, Montreal, Quebec, Canada. [2]Department of Anthropology, University of Western Ontario, London, Ontario, Canada. [3]Comet Technologies Canada Inc., Montreal, Quebec, Canada. [4]Faculty of Dental Medicine and Oral Health Sciences, McGill University, Montreal, Quebec, Canada. [5]Department of Anatomy and Cell Biology, McGill University, Montreal, Quebec, Canada

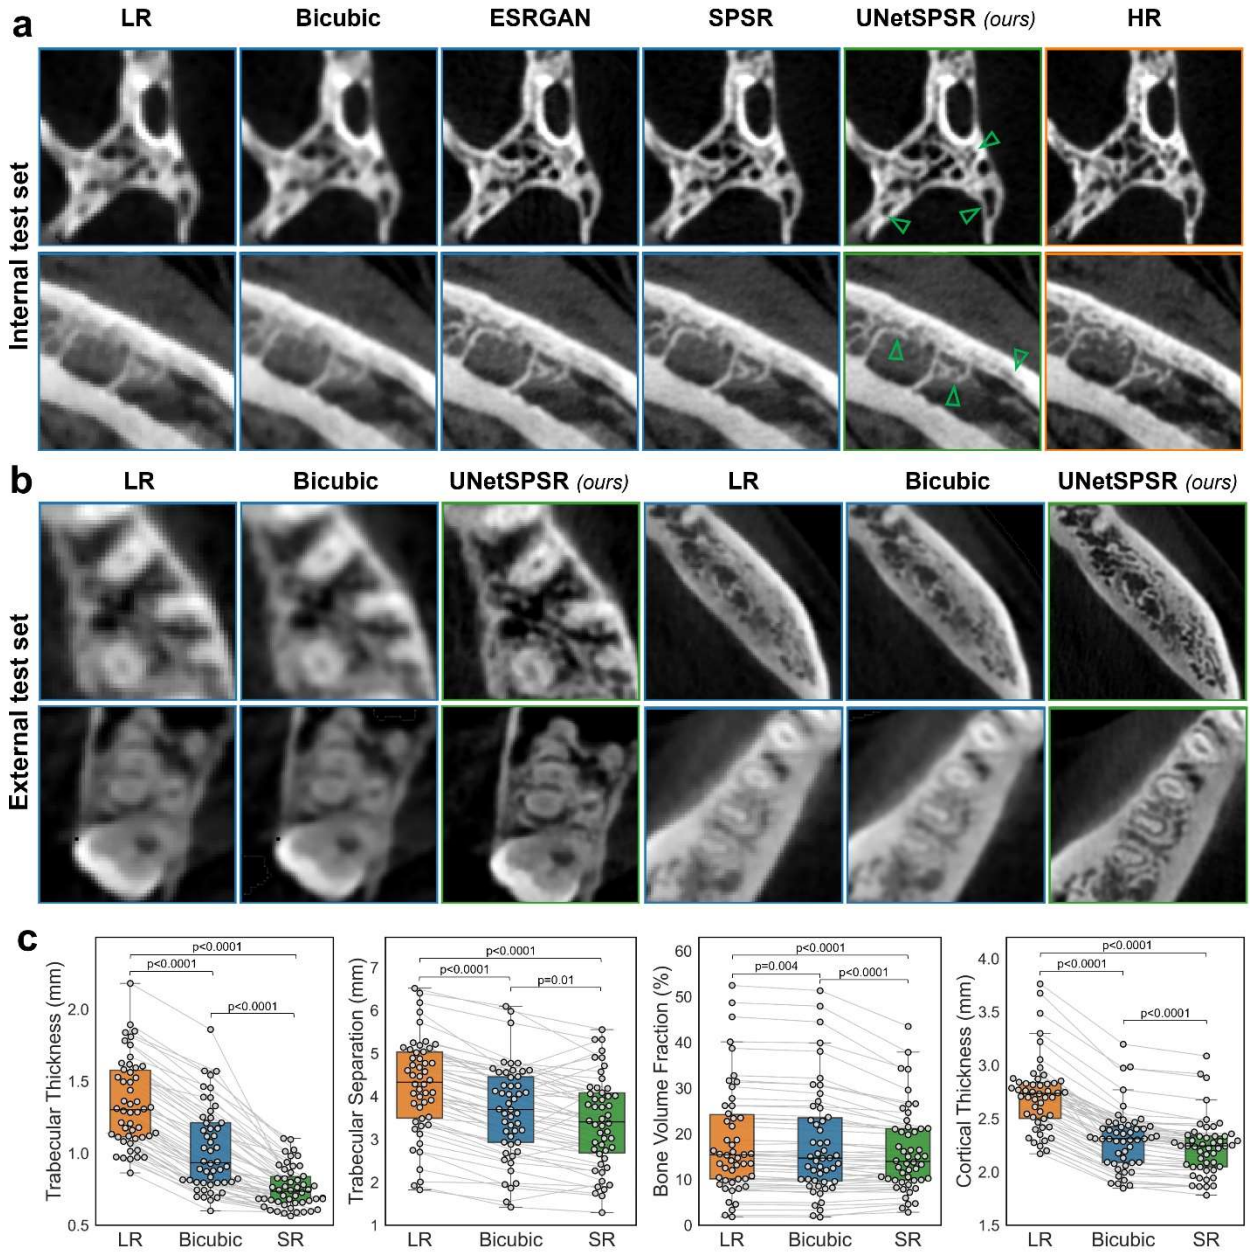
Introduction

A dilemma in cone-beam computed-tomography (CBCT) is resolution vs field-of-view: one can get either a large volume or high resolution. In low resolution CBCT, fuzzy and diffuse edges result in poor segmentation that affect biomechanical analysis of bone. Super-resolution can recover sharp details, but most such AI-based algorithms rely on artificially downgraded images, phantoms, or excised specimens, limiting real-world applicability. Using real low- and high-resolution image pairs, we developed a Generative-Adversarial-Networks (GAN)-based super-resolution method for clinical CBCT that recovers sharp edges while avoiding hallucinations.

Methods

CBCT scans of 1 human skull, 4 cadaveric human heads, and 6 sheep heads were acquired at 270µm and 135µm voxel, and a GAN (Unet-Structure-Preserving Super-Resolution [UNetSPSR]) was designed to recover fine image details in low-resolution images. The low- and high-resolution pairs were registered and used for training and testing using pixel-, edge-, and perceptual-accuracy loss terms. Performance was benchmarked against state-of-the-art methods using peak signal-to-noise ratio (PSNR) and learned perceptual image patch similarity (LPIPS), and further evaluated through downstream segmentation of trabecular bone using paired t-tests. Independent clinical CBCT scans from five patients with osteogenesis imperfecta and an external public dataset (n=50) were used for generalization testing.

Results



UNetSPSR achieved the highest PSNR (+0.66 seen, +0.11 unseen compared to the runner-up method) and lowest LPIPS (−0.01), indicating improved detail recovery (Figure 1a). Its similar performance on seen and unseen sets demonstrates generalization, effectively

recovering sharp gradients from diffuse patterns instead of ‘memorization’. It further recovered fine details without introducing artifacts in independent clinical low-resolution scans of individuals with osteogenesis imperfecta, despite varying imaging parameters, as well as external data, supporting its generalizability (Figure 1b). UNetSPSR reduced overestimation of trabecular bone morphology, notably lowering trabecular thickness overestimation from 61% to 11%. The network generalized well to external data, significantly improving microarchitectural measures ($p < 0.05$) with patterns similar to the internal dataset (Figure 1c).

Discussion

Our proposed network, UNetSPSR, accurately recovered sharp features in CBCT without introducing artifacts and generalized across cadaveric, clinical, and external datasets. With further validation, UNetSPSR holds promise as a practical tool for both retrospective data enhancement and prospective clinical imaging.

4D Reconstruction of Fetal Left Ventricles from Echocardiography via Geometric-Aware Radial Segmentation and Graph-Fourier Reconstruction

Mr. Haziq Shahard[1], Mr. Kamrul Hasan[1], Mr. Qifeng Wang[2], Mr. Lucas Iljima[1], Ms. Nida Ruseckaite[1], Mr. Yihao Luo[1], Dr. Iris Scharnreitner[3], Dr. Andreas Tulzer[3], Prof. Bin Liu[2], Dr. Guang Yang[1], Dr. Choon Hwai Yap[1]

[1]Imperial College London, London, England, United Kingdom. [2]Dalian University of Technology, Dalian, Liaoning, China. [3]Medical Faculty, Johannes Kepler Uni- versity Linz, Linz, Upper Austria, Austria

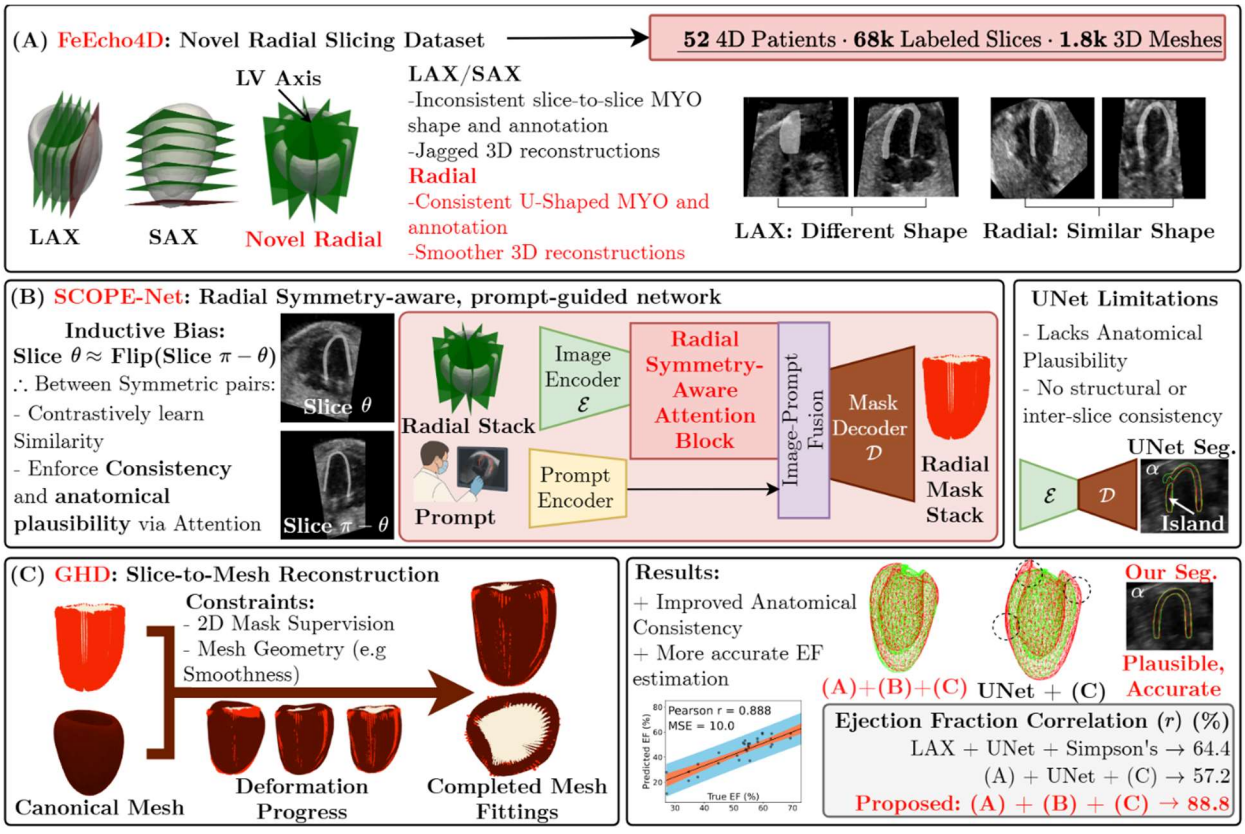
Introduction

Deep learning (DL) 3D fetal left ventricle (LV) reconstruction from echocardiogaphy images is useful for congenital malformation detection and biomechanics modelling. Here, we developed the first public 3D+time fetal echo dataset to enable training such a network. Further, we developed a novel 2.5D reconstruction approach, utilizing 2D segmentation via SCOPE-Net (Symmetry-COnsistent, Prompt-Enhanced Network), followed by 3D mesh reconstruction. Rather than planar Cartesian slicing, radial slices revolving around the LV longitudinal axis are extracted to enhance performance.

Methods

Image dataset: 3D+time fetal echocardiograms of 52 patients from the Kepler University Hospital (ethics approval 1009/2017), complete with 2D segmentations and 3D mesh reconstructions over the cardiac cycle, are publicly shared at https://feecho4d.github.io/Website/. DL 3D Reconstruction: SCOPE-Net performs 2D segmentation on all radial image slices, followed by 3D mesh reconstruction via the Graph Harmonic Deformation (GHD) approach [1] (shape modelling with Fourier surfaces). SCOPE-Net's 2D segmentation employs a self-supervised novel geometric inductive bias, which aligns the latent features of symmetrically opposed radial slices with attention and contrastive learning.

Results



Experiments with UNet and SAM showed that radial slicing of the 3D image enabled more accurate 2D DL segmentation and 3D mesh reconstruction compared to planar Cartesian slicing. SCOPE-Net achieves superior Dice (0.893 ± 0.044) compared to the UNet (0.838±0.140) and SAM (0.881±0.040), and lowers the percentage of erroneous

segmentation islands: 0.0036% vs SAM's 0.025% and UNet's 1.39%. The reconstructed 3D mesh was used to quantify ejection fraction. SCOPE-NET achieved Pearson's r=0.888 compared to ground truths, exceeding performance of 2DUNet+GHD (r=0.572), and 3DUNet(r=0.731). Similar enhanced accuracy is observed for global longitudinal strain quantifications.

Discussion

Results show that our LV radial sampling outperformed standard slicing in segmentation due to the more consistent myocardium "U" shape, allowing for more natural 3D shape reconstructions. Our 2.5D approach outperformed other methods, with less computational expense. Further testing may be performed with other modalities, and finite element modelling with our meshes. Anatomically asymmetric cases, such as severe congenital deformations, may cause our inductive bias to fail; future work is necessary with broader sample sizes and asymmetry-aware network modifications.

oNLI: Operator Nonlinear Inversion of Magnetic Resonance Elastography Data for Real-Time Viscoelasticity Reconstruction

Mr. Juampablo Heras Rivera MS, Ms. Caitlin Neher MS, Dr. Mehmet Kurt PhD

University of Washington, Seattle, WA, United States

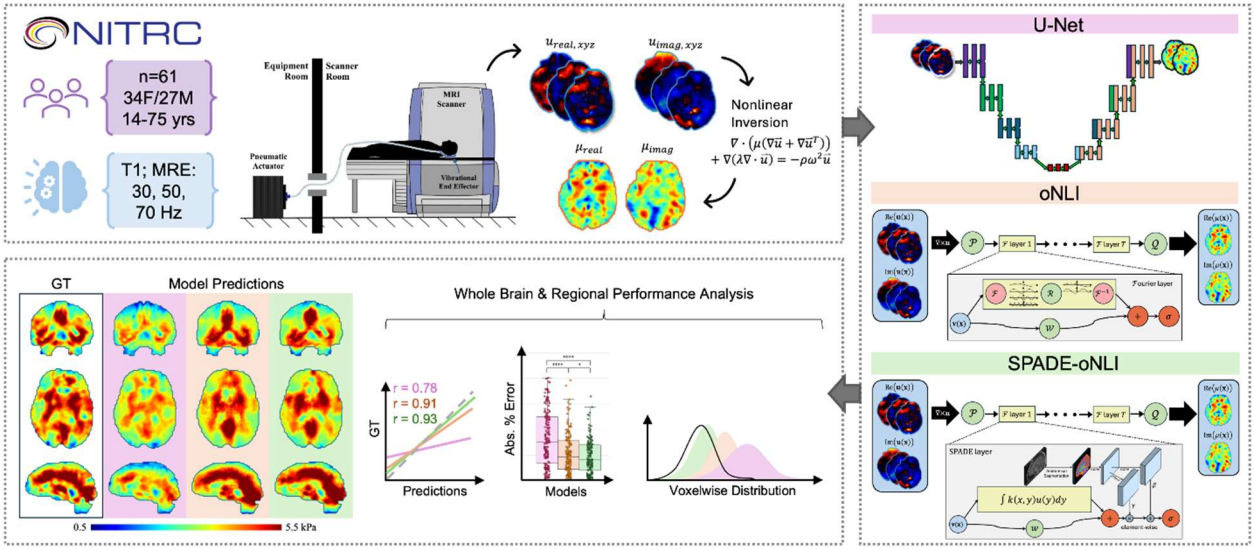
Introduction

Magnetic resonance elastography (MRE) is a quantitative method for noninvasively obtaining the mechanical properties of tissues, such as the liver, brain, and kidneys. MRE involves three steps: 1) mechanical actuation of the tissue, 2) a specialized phase-contrast MRI sequence to capture spatiotemporal displacement fields, and 3) an inversion algorithm to reconstruct material properties. Time-efficient inversion methods typically approximate tissue as a linear, incompressible and locally homogeneous material. Alternatively, nonlinear inversion (NLI) relaxes these assumptions at a high computational cost. Here, we frame inversion as done in NLI as a neural operator learning problem (oNLI), where the goal is to learn a mapping between displacement fields and complex shear stiffness in the infinite-dimensional function space, effectively learning a general operator that maps any subject's MRE displacement data to their respective shear moduli in one sub-second forward pass.

Methods

This retrospective study used publicly available data from 61 subjects (34F/27M, 14-75 years old), including anatomical T1 and multifrequency MRE at 30, 50, and 70 Hz with pneumatic anterior-posterior actuation. Elastograms were calculated using NLI and served as training targets. Three models were trained on the multifrequency displacement inputs: a baseline U-Net, a Fourier neural operator (oNLI), and a SPADE-oNLI variant incorporating a spatially-adaptive normalization block at each layer. Ten-fold cross-validation with held-out data was used for evaluation. Whole-brain and regional analyses quantified reconstruction accuracy relative to NLI.

Results



The oNLI framework enabled real-time inversion (30,000x speedup) while preserving the fine-grained spatial accuracy of NLI. Across evaluation metrics, the operator-learning approach consistently outperformed the U-Net, yielding improved correlation (r = 0.934 vs.

0.782), reduced absolute percent error (8.4% vs. 15.8%), and lower Wasserstein distance (0.035 vs. 0.063).

Discussion

This study introduces a data-driven operator-learning framework for real-time MRE inversion and demonstrates its extension with anatomical priors (SPADE-oNLI). The approach rapidly predicts heterogeneous tissue mechanical properties, representing progress towards real-time high-fidelity MRE for complex organs such as the brain.

Sex-Specific Morphological Determinants of Cardiac Ageing in a Healthy Population

ir. Beatrice Moscoloni[1,2,3], Mr. Cameron A. Beeche[3], Prof. Dr. Julio A. Chirinos[3], Prof. Ir. Patrick Segers[1], Dr. ir. Mathias Peirlinck[2]

[1]Institute of Biomedical Technology - BioMMedA, Ghent University, Ghent, East Flanders, Belgium. [2]Department of BioMechanical Engineering, TU Delft, Delft, South Holland, Netherlands. [3]Division of Cardiovascular Medicine, UPenn, Philadelphia, PA, United States

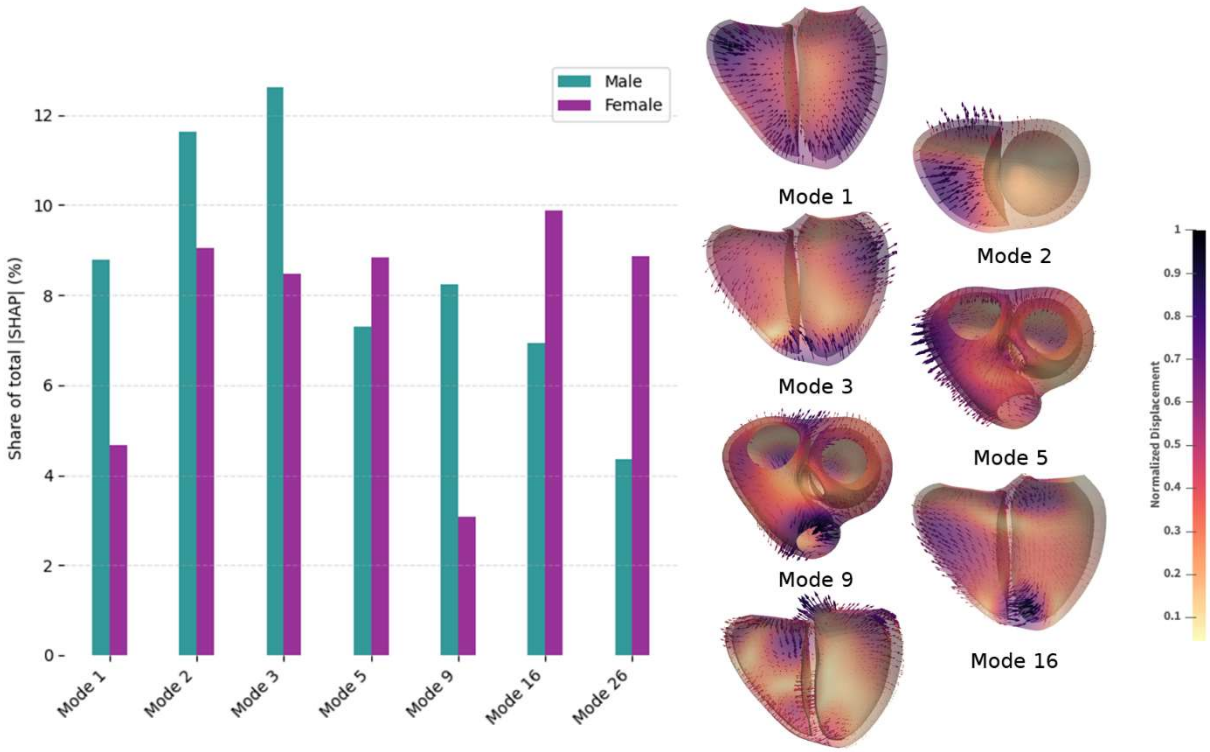
Introduction

Despite growing awareness of sex differences in cardiovascular disease, the mechanisms underlying sex dimorphism in cardiac remodelling remain poorly understood. Recent analyses leveraging statistical shape modelling have revealed intrinsic sex differences in cardiac anatomy, even after accounting for body size, blood pressure and age [1]. Ageing is one of the most important unmodifiable risk factors for heart disease, and understanding its sex-specific effects on cardiac morphology is fundamental to uncover sex-specific pathways of structural remodelling.

Methods

In this study, we developed sex-specific models to investigate the morphological determinants of cardiac ageing in 2064 healthy participants from the UK Biobank, aged 46 to 83. Specifically, we employ an open-source image-to-mesh pipeline to reconstruct biventricular meshes from cardiac magnetic resonance images [2]. Then, we apply a previously developed shape modelling pipeline to derive a set of 3D morphological descriptors (principal modes) characterizing cardiac anatomy [1]. Then, we use automatic relevance determination regression to predict chronological age from the first 28 normalized modes as model inputs. Finally, we perform SHapley Additive exPlanations (SHAP)-based feature importance analysis stratified by sex, by combining the five most predictive features for each sex and quantifying each feature's percentage contribution to age prediction [3].

Results



Modes 2 (increased anterior–posterior chamber width), 3 (eccentric structural remodelling), 5 (right ventricle -RV - lateral-septal width) and 16 (apical septal bulging) emerged as shared predictors of cardiac age, with mode 3 being 1.5× more important in males and mode 16 being 1.4× more important in females. Male-dominant features

included mode 1 (overall chamber size reduction) and mode 9 (tilting of the RV outflow tract), whereas mode 26 (basal septal bulging) was a female-specific determinant, contributing approximately four times more to cardiac age estimation in females than in males (Figure).

Discussion

Our findings reveal sex-specific patterns in the morphological determinants of cardiac ageing and identify shape features that differentially associate with heart ageing in males and females. These results provide important new insights into sex-specific patterns in structural cardiac remodelling.

Surface Topography-Based Analysis for Automated Classification of Adolescent Idiopathic Scoliosis (AIS)

Grad Research Assistant Mahmoud Hashim, Grad Research Assistant Mariam Ezzat, Postdoctoral Scholars Bruna da Rosa, Assistant Lecturer Behzad Vafaeian, Assistant Professor Qipei Mei, Professor Samer Adeeb, Associate Professor Lindsey Westover

University of Alberta, Edmonton, Alberta, Canada

Introduction

Adolescent Idiopathic Scoliosis (AIS) is the most common spinal deformity in youth, affecting 1–3% of children aged 10–16 years [1]. Diagnosis is based on a Cobb angle ≥10° on X-ray [1, 2], and while AIS occurs in both sexes, it is more progressive in females [3]. Posterior-anterior radiographs are the gold standard for monitoring [2]. Key limitations include the Cobb angle's poor representation of 3D deformity [3] and the radiation burden from repeated imaging and subjective screening referrals. This study aims to leverage machine learning methods for scoliosis screening, with the goal of reducing unnecessary radiographic referrals.

Methods

Torso scans from healthy volunteers (n = 482) and AIS participants (n = 602), aged 10–18, were collected using an infrared 3D structure sensor. AIS cases were confirmed through radiographic exams with Cobb angles of 10°–60°. Deviation maps were obtained using surface topography analysis. Each scan was mirrored, aligned to the sagittal symmetry plane, and mapped to a 102×102 grid. A corresponding 102×102 depth map was generated for the model's second pathway. A two-pathway CNN was trained for 100 epochs with early stopping. The dataset was split 70% training, 20% validation, and 10% testing, with severity levels balanced. Performance was evaluated using sensitivity and specificity.

Results

The model showed excellent training performance and strong validation generalization, with a sensitivity of 0.87 and a specificity of 0.98. On the independent test set, it achieved a sensitivity of 0.96 and a specificity of 0.94, indicating reliable performance with only minor specificity reduction.

Discussion

This model maintained high sensitivity and specificity across training, validation, and testing, indicating strong generalization and effective feature learning from depth and deviation features. Minor sensitivity reduction on the validation set did not affect overall stability, and test results confirmed reliable detection of AIS while limiting unnecessary referrals. These outcomes highlight the potential of 3D surface-based AI screening as a radiation-free complement to standard radiographic assessment.

Super-Resolution and Denoising of Left Ventricle 4D Flow Images

Mr. Yusuf Ozturk[1], Dr. Jie Zheng[2], Dr. Fanwei Kong[1]

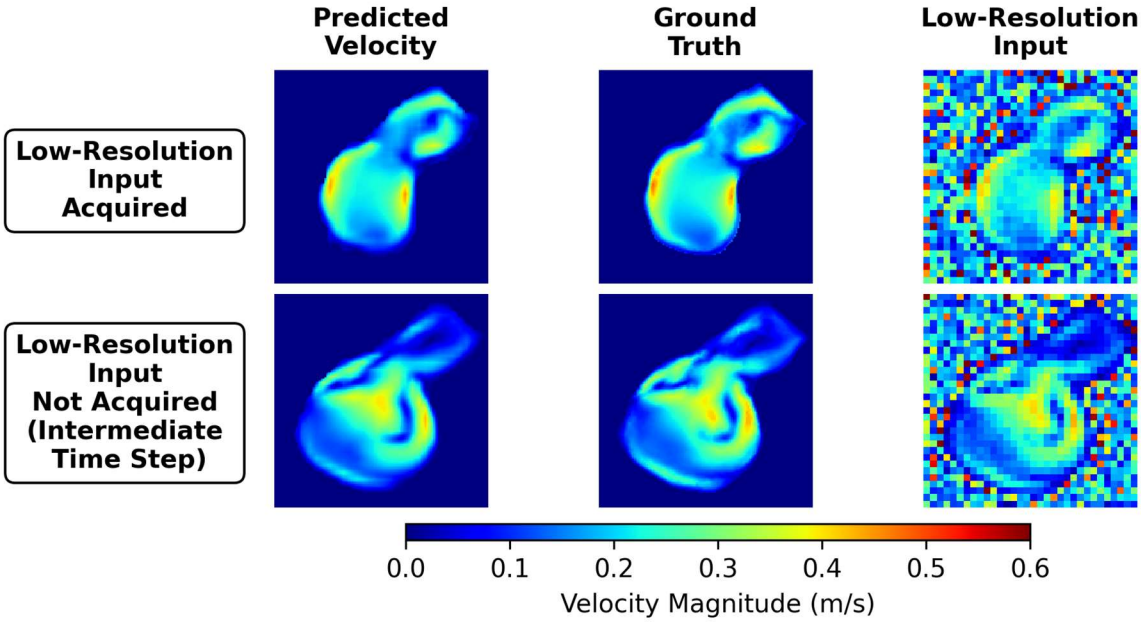
[1]Washington University in Saint Louis, St. Louis, Missouri, United States. [2]Washington University in Saint Louis Medicine, St. Louis, Missouri, United States

Introduction

4D Flow Magnetic Resonance Imaging (MRI) is a non-invasive imaging technique that quantifies 3D blood velocity fields throughout the cardiac cycle. However, its clinical applications have been limited by substantial image noise, low temporal(40ms<) and spatial resolutions(2.5mm<), and prolonged acquisition time. Although recent work has applied deep learning (DL) methods to super-resolve and denoise 4D Flow MRI, prior approaches [1, 2, 3] focused primarily on vascular applications and assumed rigid blood vessels. We propose a strategy that integrates physics-informed DL with CFD simulations of the cardiac flow to denoise and super-resolve cardiac 4D flow MRI.

Methods

Our model leverages a Convolutional Neural Net to extract latent representations of the low-resolution velocity fields. We then sample this latent volume at arbitrary coordinates for an Multilayered Perceptron to predict velocity-pressure values. The network generates highly resolved velocity-pressure fields through physics-informed loss function. The physics loss is formulated using the Arbitrary Lagrangian–Eulerian form of the incompressible Navier–Stokes equations due to deforming left-ventricle. The datasets are generated using CFD simulations of six left-ventricle geometries with prescribed motions. The simulations for synthetic data are performed in svFSI[4]. Error measurements are used to assess model accuracy on validation dataset.



Results

Our model successfully predicts high-resolution velocity fields (up to a four-times increase in both spatial-temporal resolution) from low-resolution noisy images. Figure 1 shows the predicted fields from a low-resolution time step, along with predictions at an intermediate step that demonstrates the model's temporal super-resolution capability. However, the predictions at time steps where low-resolution input was acquired were more accurate. The difficulties in generalizing to real 4D Flow MRI after training solely on synthetic datasets are noted.

Discussion

Our study demonstrates a framework that successfully predicts high-resolution, denoised flow fields from low-resolution ventricular flow with moving boundaries. Future work includes validation on real 4D flow MRI and improving the temporal super-resolution capability.

Hydrostatic Pressure Reconfigures Nuclear Mechanics to Activate Proliferative Signaling in Cancer Cells

Ms. Norino Uenaka M.E., Prof. Daisuke Yoshino Ph.D.

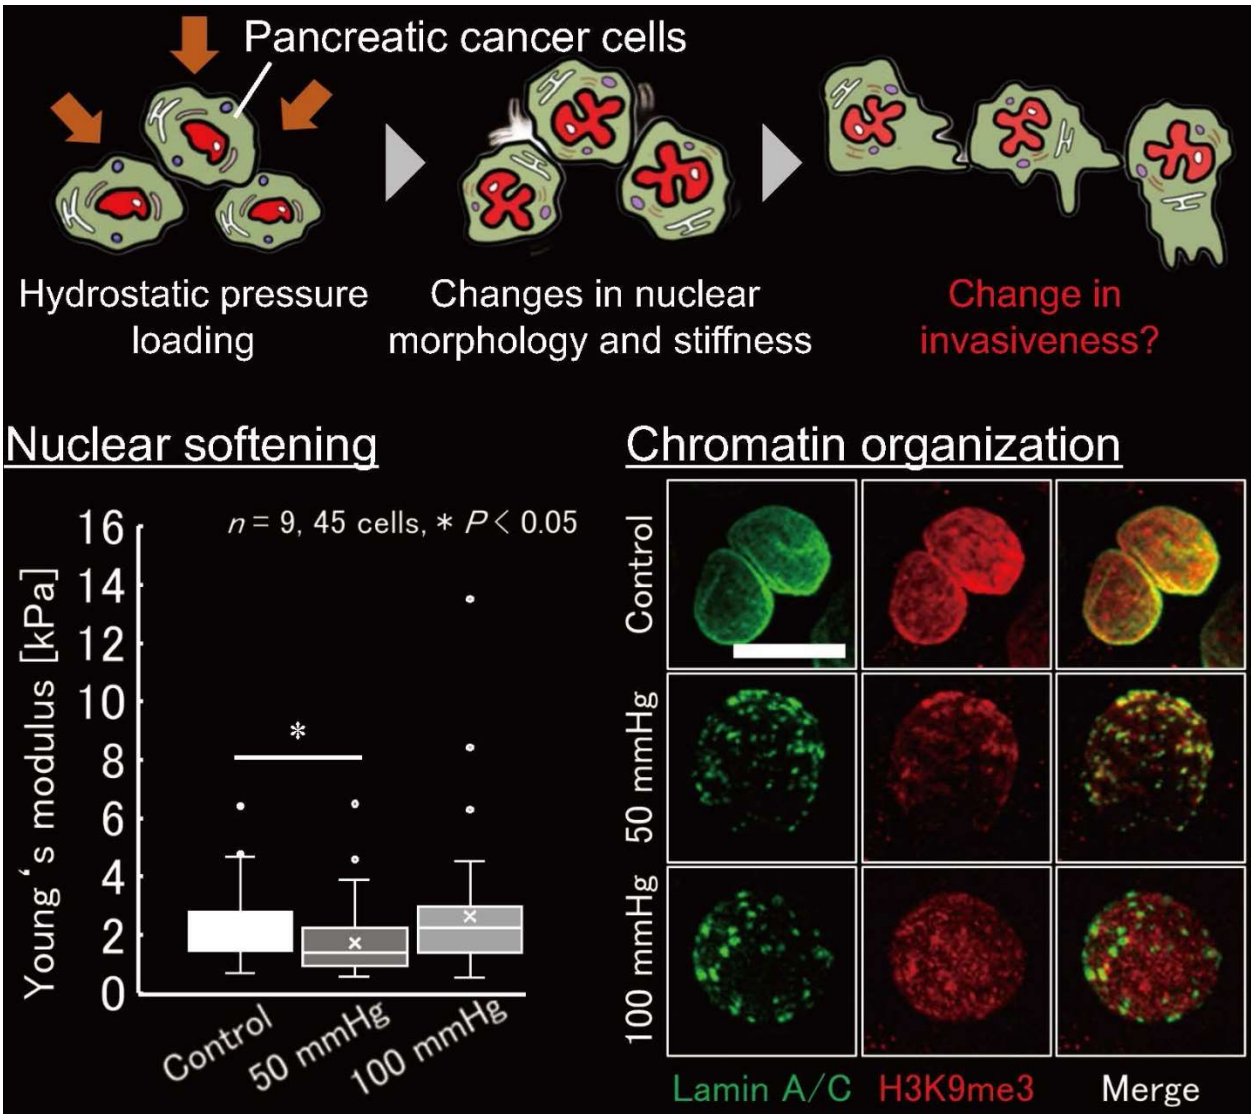
Tokyo University of Agriculture and Technology, Koganei, Tokyo, Japan

Introduction

Cancer cells proliferate rapidly within confined tissue environments, where they experience elevated hydrostatic pressure generated by surrounding tumor masses. While mechanical forces are increasingly recognized as regulators of tumor progression, the mechanism by which hydrostatic pressure influences nuclear mechanics and cell behavior remains unclear. This study aims to elucidate how sustained hydrostatic pressure affects nuclear structure, chromatin organization, and cell-cycle regulation in pancreatic cancer cells.

Methods

MIA Paca-2 pancreatic cancer cells were exposed to controlled hydrostatic pressure (0, 50, or 100 mmHg for 24 hours) by subjecting the culture medium to compression. The nuclear stiffness was evaluated using atomic force microscopy (AFM). Immunofluorescence imaging was performed to visualize Lamin A/C, F-actin, and heterochromatin marker H3K9me3. The role of histone H3 methylation in Lamin A/C localization was assessed through pharmacological inhibition. The expression levels of the methyltransferase SUV39H1 and various cell-cycle regulators (Cyclin D1/E2, CDK4, phosphorylated Rb) were analyzed through the use of immunoblotting and immunostaining techniques.



Results

Hydrostatic pressure induced a significant decrease in nuclear stiffness, indicating nuclear softening. Lamin A/C displayed pressure-dependent reorganization, characterized by a dotted distribution at the nuclear periphery. H3K9me3 exhibited altered nuclear localization under pressure, and inhibition of histone H3 methylation suppressed Lamin A/C redistribution, suggesting that chromatin modification is required for nuclear mechanoadaptation. SUV39H1 expression increased under elevated pressure, supporting an epigenetic regulatory mechanism. Pressure also enhanced cell proliferation, as evidenced by increased Ki-67 positivity and upregulation of G1–S transition proteins, including Cyclin D1/E2, CDK4, and phosphorylated Rb.

Discussion

These findings indicate that hydrostatic pressure acts as a potent mechanical cue that remodels chromatin, repositions Lamin A/C, and softens the nucleus through epigenetically regulated pathways. The concurrent activation of cell-cycle signaling suggests that nuclear mechanical adaptation facilitates tumor cell proliferation in confined environments. This mechanobiological mechanism potentially contributes to enhanced invasiveness and metastatic competence. Targeting nuclear stiffness regulation or histone modification pathways may represent a promising strategy to suppress pressure-driven malignant progression.

Bioenergetic Pathways Regulate Distinct Patterns of Invasion and Matrix Remodeling in Breast Cancer Cells Upon YAP/TAZ Activation

Mr. Adil Khan[1,2], Mr. Haider Ali[1], Mr. Bishant Karki[1], Dr. Xaralabos Varelas[3], Dr. Jacopo Ferruzzi[1,2]

[1]University of Texas at Dallas, Richardson, TX, United States. [2]University of Texas Southwestern Medical Center, Dallas, TX, United States. [3]Boston University, Boston, MA, United States

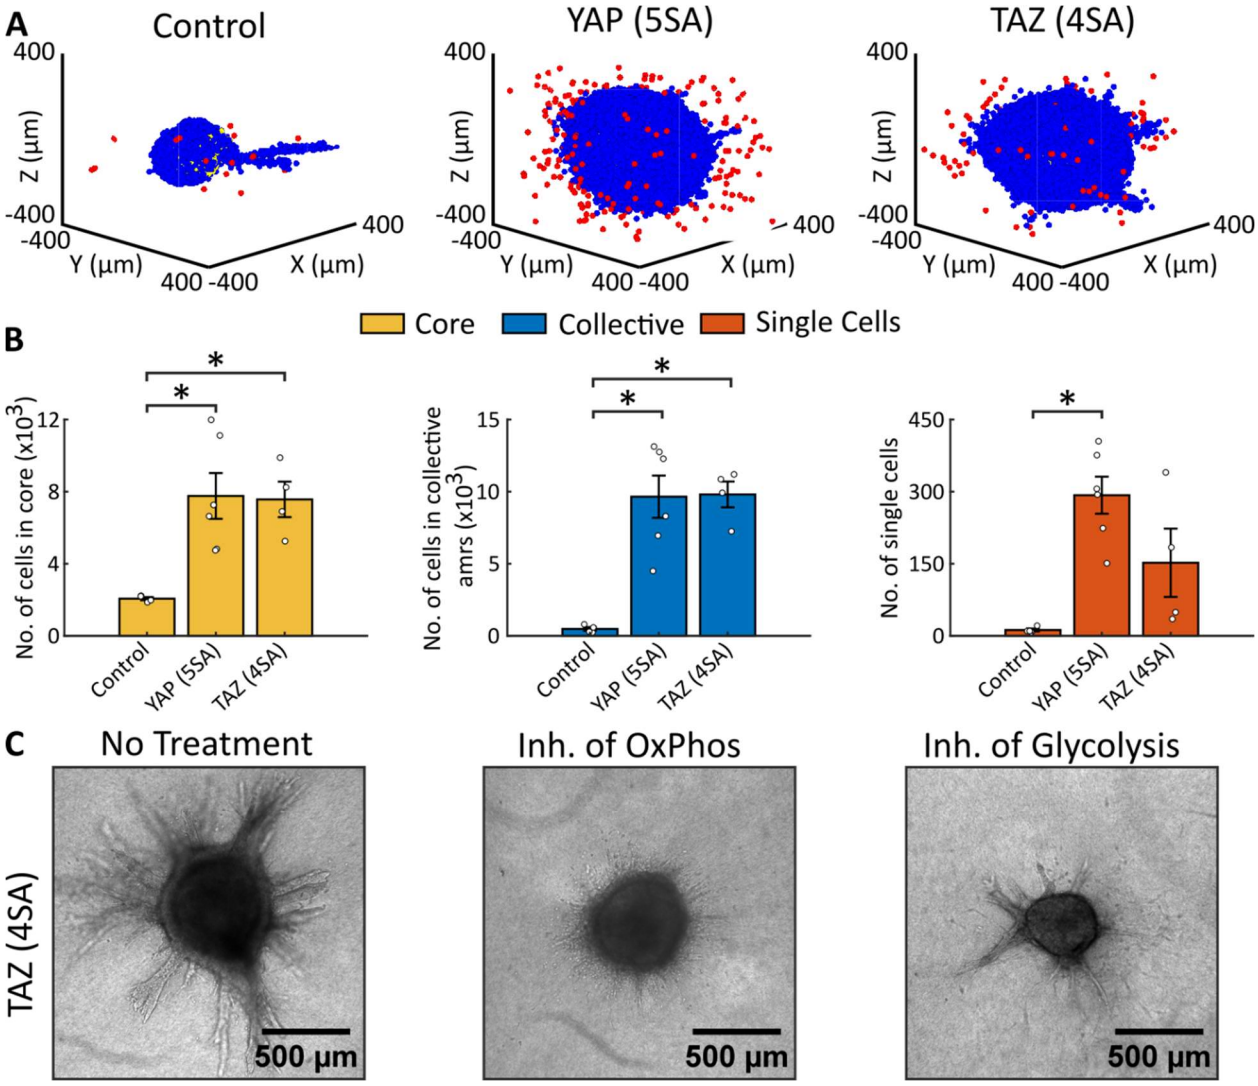
Introduction

Breast cancer invasion depends on intracellular signaling and microenvironmental factors. Central to this process are the transcriptional coactivators YAP and TAZ, two regulators of the Hippo pathway [1]. YAP/TAZ are known to respond to biomechanical and metabolic cues by translocating to the nucleus, where they regulate genetic programs that promote tumor progression. In the tumor microenvironment, extracellular matrix (ECM) remodeling and altered cell metabolism modulate invasion. However, how YAP/TAZ coordinate ECM mechanics and cancer cell metabolism during invasion remains unclear.

Methods

MCF-10A cells and doxycycline-inducible MCF-10A YAP(5SA) and TAZ(4SA) mutants [2] were used to generate spheroids and conduct invasion assays in collagen. Micro-mechanical changes in collagen during invasion were monitored using 3D Magnetic Twisting Rheometry (3D-MTR), a technique developed in our lab to assess heterogeneous mechanical properties [3]. Metabolic changes in invading cells were monitored using Fluorescence Lifetime Imaging Microscopy (FLIM) of NAD(P)H [4]. To probe the role of metabolic pathways in YAP/TAZ-driven invasion, we inhibited oxidative phosphorylation (OxPhos) using rotenone/antimycin A (50nM each), and glycolysis using 2-deoxyglucose (5 mM).

Results



Control MCF-10A spheroids exhibited limited ECM remodeling and invaded collectively while YAP/TAZ-activated spheroids displayed increased proliferation and invaded aggressively through both collective protrusions and single-cell migration (Fig. 1A-B). 3D-MTR showed that YAP/TAZ-activated spheroids stiffened peritumoral collagen by increasing collagen alignment. FLIM showed that, upon YAP/TAZ activation, the spheroid core

exhibited an optical signature consistent with glycolysis, while the periphery adopted a mix of glycolysis and OxPhos. In YAP/TAZ-activated spheroids, inhibition of OxPhos shifted invasion from collective to single-cell modality (Fig. 1C). Conversely, inhibition of glycolysis reduced single-cell migration, shifting invasion towards collective migration (Fig. 1C).

Discussion

We found that YAP/TAZ activation couples ECM stiffening with metabolic plasticity to regulate invasion modality. Inhibiting oxidative metabolism shifted invasion from collective to single-cell migration, while inhibiting glycolysis had the opposite effect, suggesting that the metabolic state controls both cancer cell contractility and invasion modality.

Hyper-Selective Neurectomy Shifts Sarcomere Length in Spastic Human Biceps Toward Normal Values

Dr. Zheng Wang[1], Dr. Rajeswari Pichika2[2,3], Dr. Peter Rhee[1], Dr. Kenton Kaufman[1], Dr. Richard Lieber[2,3]

[1]Mayo Clinic, Rochester, MN, United States. [2]Northwestern University, Chicago, IL, United States. [3]Hines V.A. Hospital, Mayowood, IL, United States

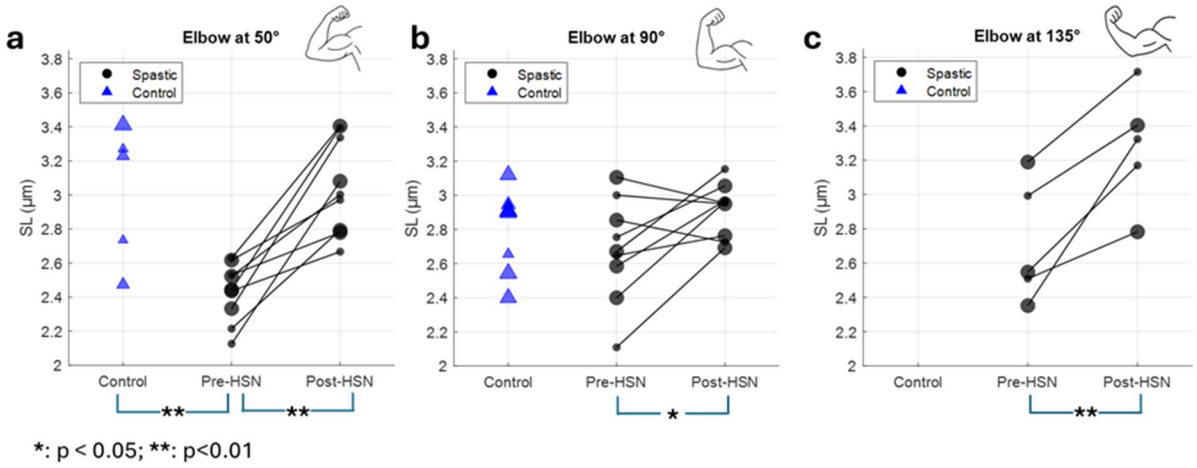
Introduction

Spasticity after upper motor neuron injury causes muscle overactivity and structural remodeling. Neurectomy is known to reduce spasticity, and hyper-selective neurectomy (HSN) is emerging as a targeted technique with advances in anatomy and intraoperative mapping. Although HSN's clinical benefits are established, its structural impact on human muscle remains unclear. To address this knowledge gap, this study quantified sarcomere length (SL) before and after HSN.

Methods

Individuals with elbow flexor spasticity undergoing planned two-stage HSN were prospectively enrolled (n = 10). Stage 1 released the elbow flexors and provided a pre-HSN biceps brachii biopsy. Stage 2 performed three months later to treat forearm flexors, provided a post-HSN bicep brachii biopsy. All biopsies were obtained with customized clamps at predefined elbow angles (50°, 90°, 135°), fixed, and analyzed for SL. Clinical spasticity was assessed before Stage 1 and again before Stage 2 using the Modified Ashworth Scale (MAS). Control samples were obtained from biceps brachii in individuals undergoing cubital tunnel release at 50° and 90° due to limited exposure. A mixed-effects model tested within-subject pre-to-post differences and comparisons with controls.

Results



MAS scores decreased significantly, from 1.89 ± 0.93 to 0.35 ± 0.53 ($p < 0.05$) after HSN. At 50° of elbow flexion, spastic biceps exhibited significant shorter sarcomeres preoperatively (2.45 ± 0.18 μm), compared to control values (3.02 ± 0.40 μm, $p < 0.01$). After HSN, SL (3.05 ± 0.28 μm) increased significantly ($p<0.01$), no longer different from controls (Fig. 1a.). At 90°, neither pre-HSN (2.70 ± 0.29 μm) nor post-HSN SL (2.91 ± 0.16 μm) differed significantly from controls (2.81 ± 0.23 μm) ($p >0.05$). However, paired analysis showed a

significant increase in SL from pre- to post-HSN ($p<0.05$, Fig. 1b). At 135°, SL significantly increased ($p<0.05$, Fig. 1c) from pre-HSN (2.72 ± 0.36 μm) to post-HSN (3.24 ± 0.32 μm).

Discussion

Spastic muscles showed measurable increases in sarcomere length (SL) toward normal values when excessive neural input was reduced with a HSN. These changes highlight the muscle fiber capacity to undergo rapid structural remodeling, with sarcomere organization in response to altered activation patterns.

Accelerated Rotator Cuff Degeneration in Manual Wheelchair Users with Spinal Cord Injury: Longitudinal MRI and 5-Year Transition Modeling

Dr. Omid Jahanian[1], Ms. Meegan Van Straaten[1], Dr. Jiefei Wang[2], Dr. Hannah Houde[2], Ms. Kathylee Pinnock Branford[3], Dr. Stephen Cain[3], Dr. Naveen Murthy[1], Dr. Melissa Morrow[2]

[1]Mayo Clinic, Rochester, Minnesota, United States. [2]The University of Texas Medical Branch, Galveston, Texas, United States. [3]West Virginia University, Morgantown, West Virginia, United States

Introduction

Manual wheelchair (MWC) use places high biomechanical demand on the shoulder, potentially accelerating rotator cuff tendon degeneration. This study compares 2-year progression of rotator cuff tendon tears between MWC users with spinal cord injury (SCI) and age- and sex-matched able-bodied (AB) individuals, and estimates 5-year probabilities of tendon pathology progression.

Methods

In this longitudinal cohort study, 37 MWC users with SCI and 44 AB individuals completed baseline and 2-year follow-up shoulder MRI. Rotator cuff tendon health was graded using a novel scoring system from normal tendon to full-thickness tear, and progression was defined as an increase in tear score from baseline to follow-up [1]. Presence of shoulder pain was recorded at both visits. Logistic regression examined factors associated with tear progression. 5-year transition probabilities among tendon states (normal, tendinopathy, tear) were estimated using multi-state Markov transition models using all available longitudinal data.

Results

Over two years, MWC users showed significant increases in tendon tear scores in both dominant ($p=0.001$) and non-dominant shoulders ($p=0.016$), whereas AB individuals showed no significant progression. After adjusting for age, sex, and baseline tendon scores, MWC users had 2.26 times higher odds of tear progression (95% CI:1.05–5.00; $p=0.04$). Older age was associated with progression in both cohorts. Shoulder pain remained more common in MWC users but did not consistently correspond with rotator cuff tendon pathology progression.

Five-year transition estimates showed markedly faster progression in MWC users (Figure 1). The probability of progressing from normal to tear in the dominant supraspinatus was

37.3% in MWC users versus 3.1% in AB individuals, and the probability of progressing from tendinopathy to tear was 70.8% versus 10.0%, respectively.

Discussion

MWC users with SCI showed greater 2-year progression of rotator cuff pathology than AB individuals and higher 5-year probabilities of transitioning from normal or tendinopathy to tear states. Age contributed to progression, while shoulder pain did not reliably reflect changes in tendon health. These findings highlight the need for early detection and targeted strategies to preserve shoulder integrity in individuals with SCI.

Images (Optional)

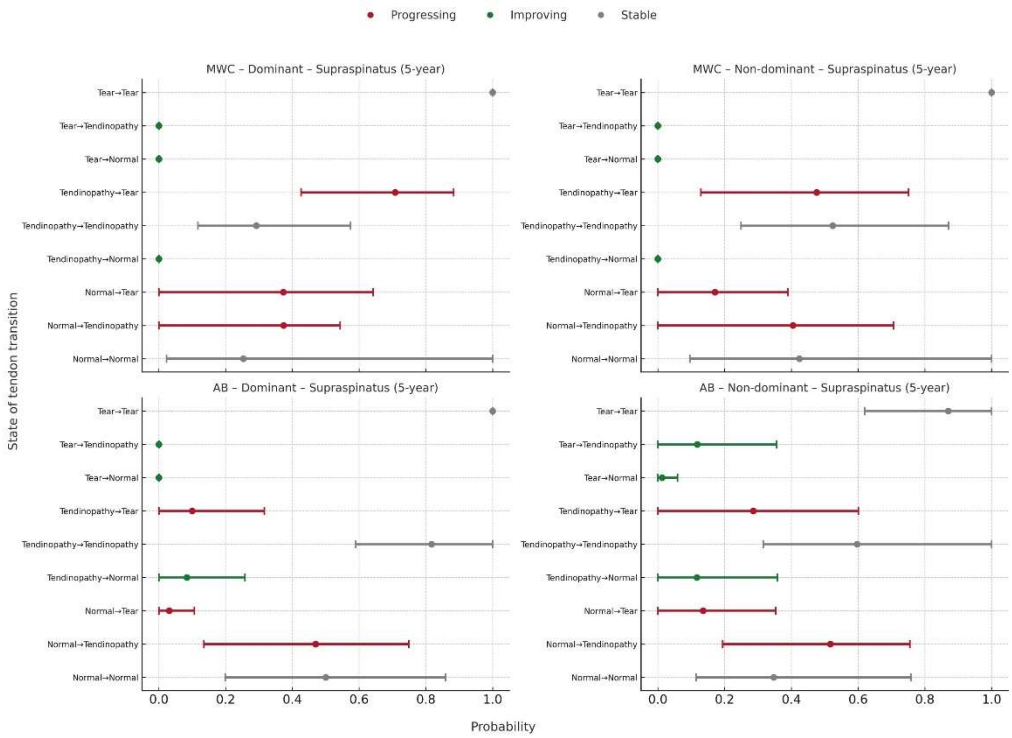

Figure 1. Five-year transition probabilities for supraspinatus tendon health in manual wheelchair (MWC) users and able-bodied (AB) individuals with 95% confidence intervals. Forest plots display the probability of transitioning between tendon states (normal, tendinopathy, tear) for dominant and non-dominant shoulders.

Dr. Renato Miyadahira

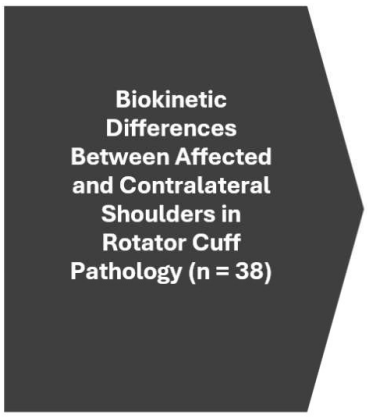
Introduction

Rotator cuff pathology often presents along a spectrum of functional limitations. These disorders affect shoulder strength, range of motion (ROM), and scapulohumeral rhythm, yet few studies have evaluated these biokinetic factors simultaneously. This study aimed to compare shoulder kinematics during arm elevation, as well as measures of strength and passive ROM, between affected shoulders and their contralateral healthy shoulders in individuals with rotator cuff pathology.

Methods

This cross-sectional observational study evaluated 38 adults who presented with unilateral rotator cuff pathology and a healthy contralateral shoulder (mean age 47 ± 12.8 years; 31.6% female) across five motion analysis laboratories. Bilateral 3D scapulothoracic and glenohumeral kinematics during scapular-plane elevation, passive ROM testing, and isometric strength testing (normalized to body weight) were obtained. Kinematic data were collected using a four-camera high-speed motion capture system using International Society of Biomechanics standards. Variables included glenohumeral elevation, scapular upward rotation, tilt, internal/external rotation, vertical displacement, maximum humeral elevation, and scapulohumeral rhythm. Passive shoulder ROM was measured using a digital inclinometer, and isometric strength was assessed using a hand-held dynamometer.

Paired t-tests ($p < 0.05$) compared affected and contralateral shoulders and effect sizes were reported using Cohen's d.



Results

Kinematic differences emerged only above 90° of elevation (Table 1). Compared with the contralateral shoulder, the affected side showed reduced glenohumeral elevation (61.5° ± 8.8° vs. 64.3° ± 6.8°; $p = 0.011$), reduced maximum humeral elevation (153.6° ± 15.2° vs. 158.7° ± 14.9°; $p = 0.003$), greater scapular upward rotation (29.9° ± 6.7° vs. 27.3° ± 5.4°; $p = 0.011$), and increased scapulohumeral rhythm (0.50 vs. 0.43; $p = 0.002$). No significant differences were observed below 90°. Passive ROM did not differ between sides. Strength deficits were limited to external rotation in the neutral position ($p < 0.05$). Effect sizes ranged from 0.23–0.35.

Discussion

Individuals with rotator cuff pathology demonstrated increased scapular upward rotation and decreased glenohumeral elevation during higher-range arm elevation, consistent with compensatory mechanisms reported in prior studies. These adaptations may increase joint reaction forces, potentially contributing to long-term dysfunction. Integrating strength, ROM, and kinematic assessments can identify impairments and compensatory strategies to address clinically.

Images (Optional)

Domain	Variable	Affected Shoulder	Contralateral Shoulder	P Value	Effect Size (d)
Kinematics > 90°	Glenohumeral elevation (°)	61.5 ± 8.8	64.3 ± 6.8	0.011	0.23
	Maximum humeral elevation (°)	153.6 ± 15.2	158.7 ± 14.9	0.003	0.35
	Scapular upward rotation (°)	29.9 ± 6.7	27.3 ± 5.4	0.011	0.31
	Scapulohumeral rhythm	0.50	0.43	0.002	0.35
Kinematics < 90°	All variables	No significant differences	—	> 0.05	—
Passive ROM	All measures	No significant differences	—	> 0.05	—
Strength	External rotation (neutral)	Decreased	—	< 0.05	—

Table 1: Comparison of scapulothoracic and glenohumeral kinematics, passive range of motion, and isometric strength between affected and contralateral shoulders in individuals with unilateral rotator cuff pathology (n=38). Significant differences were observed only above 90° of humeral elevation, including reduced glenohumeral elevation and maximum humeral elevation, and increased scapular upward rotation and scapulohumeral rhythm on the affected side. No significant differences were identified below 90° or in passive range of motion. Values are reported as mean ± standard deviation where applicable. Effect sizes are reported as Cohen's d.

It is Worth the RASL: Scapholunate Ligament Reconstructive Surgery Aids Restoration of Healthy Kinematic Patterns

Mr. Justen Saini[1,2], Dr. Brodie Ritchie[3,4], Dr. Neil White[2,3,4], Dr. Koren Roach[1,2,5,6], Dr. Sarah Manske[2,5]

[1]University of Calgary, Department of Biomedical Engineering, Calgary, Alberta, Canada. [2]University of Calgary, McCaig Institute, Calgary, Alberta, Canada. [3]University of Calgary, Department of Surgery, Calgary, Alberta, Canada. [4]South Campus Research Unit for Bone and Soft Tissue, Calgary, Alberta, Canada. [5]University of Calgary, Department of Radiology, Calgary, Alberta, Canada. [6]University of Calgary, Faculty of Kinesiology, Calgary, Alberta, Canada

Introduction

Scapholunate interosseous ligament (SLIL) injuries are the most common wrist ligament injury, often resulting from a fall on an outstretched hand. These injuries disrupt normal carpal biomechanics, including altered load transmission and carpal kinematics. A hallmark symptom of these injuries is pain in load-bearing positions. SLIL surgical reconstructions, such as the Reduction and Association of the Scaphoid and Lunate (RASL) procedure, can be employed in an attempt to restore normal biomechanics. However, the efficacy of these procedures in restoring wrist function and stability in functionally load-bearing positions remains unclear, due to limitations with current unloaded imaging modalities.

Objective: Evaluate the efficacy of the RASL procedure to restore healthy carpal kinematics and arthrokinematics in functionally load-bearing positions using weight-bearing computed tomography (WBCT).

Methods

Healthy controls, SLIL-injury participants, and minimum 1-year post-RASL participants (n = 10/group) underwent WBCT scans in a non-weightbearing position (NWB), a weight-bearing pushup bar grip position (WBPUB), and a weight-bearing extension position (WBEXT). Participants with advanced osteoarthritis were excluded. Helical axis orientations, bone rotations, contact area between neighbouring bones, and contact centroid shifts were compared between groups using a repeated measures ANOVA.

Results

SLIL-injured wrists demonstrated altered carpal bone rotations compared to controls when loaded, including significantly greater scaphoid rotation (WBPUB: p=0.027, WBEXT: p=0.012) and significantly decreased lunate rotation (WBPUB: p=0.037, WBEXT: p=0.012). Radioscaphoid contact area increases from the NWB position to WBEXT were significantly greater for injured wrists compared to controls (p=0.002) and RASL-reconstructed wrists (p=0.001). Contact centroid shifts were similar in the controls and RASL-reconstructed wrists, indicating healthy load distribution is restored following surgery (Figure 1).

Discussion

SLIL-injured wrists had altered kinematics and contact behaviour under load, particularly in the extended position, which may contribute to accelerated degenerative changes. In contrast, RASL-reconstructed wrists demonstrated rotational coupling and load distribution comparable to healthy wrists under load, indicated by centroid shifts consistent with healthy wrists and significantly reduced radioscaphoid contact area compared to injured wrists. These findings support RASL reconstruction as an option to restore functional biomechanics under physiologic loading. WBCT provides a clinically relevant tool to assess post-surgery biomechanics under load, supporting future improvements in surgical planning and outcome assessments.

Images (Optional)

Developing a Collagen Fiber-Mimetic Strain Model of the Meniscus Cell Mechanoresponse After Injury

Ms. Janie Johnson, Dr. Katherine Meinhold Ph.D., Dr. Jennifer Robinson Ph.D.

University of Washington, Seattle, Washington, United States

Ms. Janie Johnson

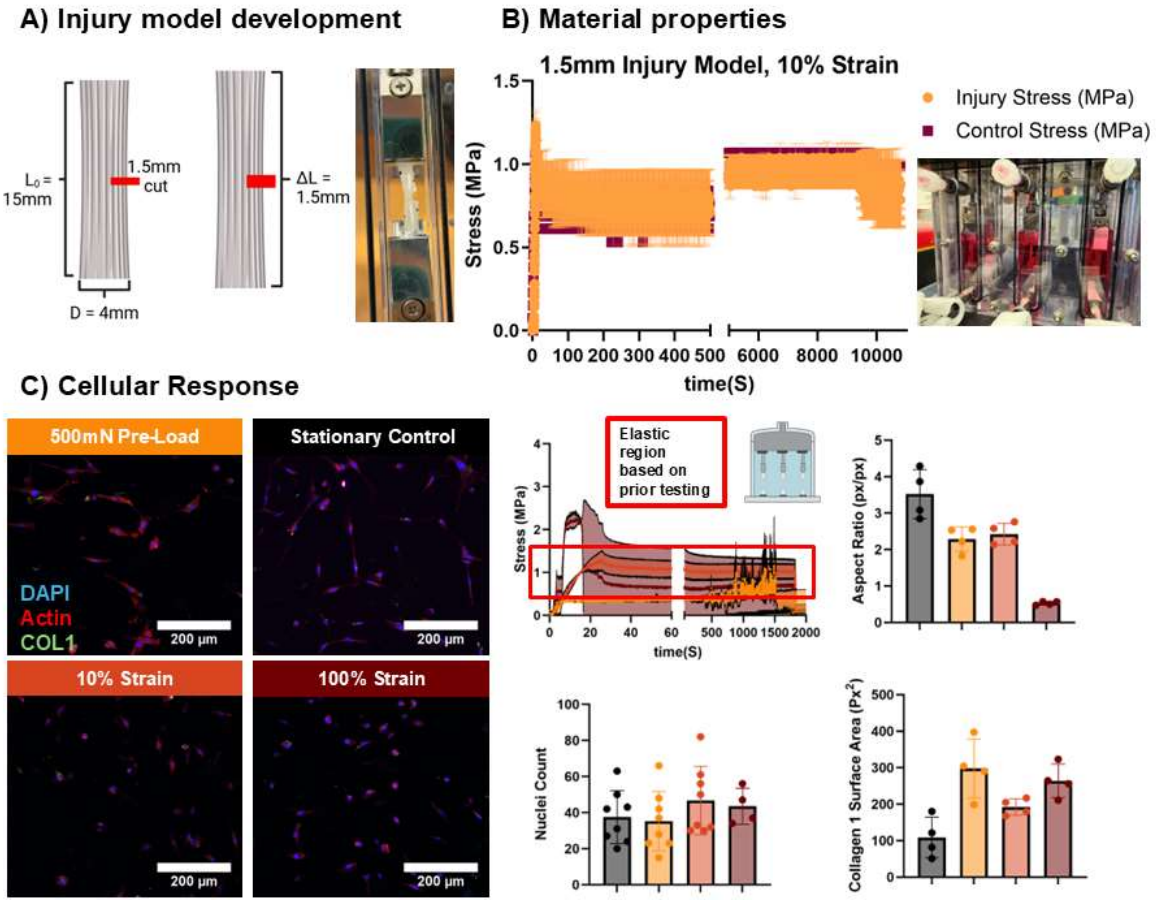
Dr. Katherine Meinhold

Introduction

Meniscal injuries are the most common intraarticular knee injury, with radial meniscus tears exhibiting the poorest healing potential partly due to collagen fiber structure and anisotropy. We hypothesize that the loss of residual strain occurring when collagen fibers are torn leads to increased apoptosis and fibrosis, similar to prior results in intervertebral disc fibrocartilage [1]. Our poly(caprolactone) (PCL) electrospun fibrous meshes recapitulate the structure and material properties of native meniscus collagen fibers, but there remains a need to develop an *in vitro* injury model using these meshes to incorporate fiber mechanical properties. Thus, the objective herein is to establish an *in vitro* injury model and examine the human meniscal cell (hMC) response to physiological strain after a partial tear.

Methods

Material Properties: Two approaches were tested to develop a model that captures residual strain loss and resultant hMC behavior. First, plastic deformation of aligned and non-aligned samples was characterized at 100% strain in a CellScale Mechanoculture J. Second, a 1.5mm cut (37.5% total width) was created in aligned fibrous meshes, mimicking a tissue-level radial tear (***Figure 1A***). Physiological 10% strain was applied to aligned meshes (2-3 technical replicates, per condition) for 3 hours and resultant stress determined. Cell Response: Morphology, apoptosis, collagen production and fibrotic marker αSMA were assessed from MCs subjected to 500mN pre-load, 10% strain, and 100% strain for 48 hours.



Results

Both tear models achieve mechanical properties in the range of native menisci without substantial stress relaxation (***Figure 1B:*** *1.5mm cut,* ***1C:*** *100% strain*). The evaluated stress of 1.5mm-tear (0.91±0.1MPa) and control (1.3±0.3MPa) samples at 10% strain matches the elastic region of 100% strain samples. Quantification of MC alignment on non-aligned fibers showed a modest decrease in aspect ratio after 10% strain (***Figure 1C***, 2.4 vs. 3.5 control) whereas 100%, injurious strained cells displayed dramatic rounded morphology (aspect ratio 0.5), indicating aberrant behavior. Current studies are focused on 10% strain in the1.5mm-tear injury model to characterize YAP/TAZ response in hMCs.

Discussion

By establishing an *in vitro* mechanobiology system we can investigate regenerative strategies to combat aberrant mechanosignaling.

Introduction

Mesenchymal stromal/stem cell (MSC) therapies offer potent immunomodulatory and anti-inflammatory benefits, making them attractive for regenerative medicine [1]. However, translation is limited by low expandability ex vivo and a risk of differentiation with loss of stemness during standard 2D cell expansion. Preserving MSC phenotype requires recapitulating mechanotransduction pathways in vivo-like. Therefore, we present an architected 3D microscaffold to evaluate stemness maintenance without biochemical inducers, which are often undesirable prior to clinical re-implantation.

Methods

The 3D microscaffold, the Niche, consists of a lattice of cubic pores (15×15×15 μm^3) fabricated by two-photon polymerisation of the biocompatible resin SZ2080 directly onto glass coverslips [2]. Rat bone-marrow–derived MSCs were cultured either on flat glass (2D) or within the Niche. F-actin organisation and nuclear morphology were quantified from confocal immunofluorescence images. Fluorescence-lifetime imaging microscopy (FLIM) inferred cell metabolism, while Brillouin microscopy quantified cell stiffness. Bulk RNA sequencing was performed to assess differential gene expression and pathway enrichment between 2D and 3D conditions.

Results

Cells cultured in the Niche showed fewer actin stress fibres than in 2D, with F-actin redistributed into a cortical rim (Fig. 1a,b). Nuclear shape modelling showed rounder nuclei

in 3D compared with 2D (Fig. 1c,d). Brillouin microscopy revealed a difference in cell stiffness between 2D and 3D conditions (Fig. 1e,f). FLIM indicated a shift towards a more glycolytic metabolic state in 3D culture. Pathway enrichment analysis identified significantly overexpressed mechanotransduction and stemness-related programmes in 3D versus 2D.

Discussion

These results indicate that the architected 3D scaffold provides defined structural cues that reorganise actin towards a cortical pattern, reshape nuclear geometry and shift cell mechanical properties, with a coherent move towards a glycolytic state. The enrichment analysis supports the view that this environment helps preserve a mesenchymal, non differentiated phenotype compared with 2D. This makes the scaffold a robust, reagent free platform for standardised MSC expansion and biomechanics informed screening.

Images (Optional)

Wavy Topography Enhances Contractile Phenotype and YAP Nuclear Localization in Primary Vascular Smooth Muscle Cell

Mr. Wei-Chen Leo Lin, Dr. Pen-hsiu Grace Chao

National Taiwan University, Taipei, Taiwan, Taiwan

Introduction

Vascular smooth muscle cells (VSMCs), located in the medial layer of blood vessels, regulate vascular tone and maintain vessel function. Pathological stimuli and aging can drive VSMCs from a contractile to a synthetic phenotype [1]. We previously demonstrated that wavy fibrous scaffolds, which mimic the native arterial structure, enhance contractile marker expression and suppress proliferation [2]. Yes-associated protein (YAP), a mechanosensitive regulator has been implicated in VSMC phenotype regulation [3-5]. In this study, we hypothesize that wavy structures modulate VSMC phenotype through YAP-dependent mechanotransduction.

Methods

Polylactic fibrous scaffolds were manufactured based on previously reported protocols [6]. Primary VSMCs isolated from murine thoracic aortas via explant culture were cultured on straight or wavy electrospun scaffolds for 3 weeks. VSMC phenotype was assessed via fluorescent staining and gene expression analysis for contractile markers.

Results

VSMCs on wavy fibers followed the fiber structure with curved actin cytoskeletal organization, reduced alignment, and significantly increased expression of contractile markers SM22 and calponin (Fig A-C). The immunocytochemistry findings were consistent with increased transgelin expression, which encodes SM22 (Fig. D). At the same time, VSMCs on wavy fibers exhibited higher YAP nuclear localization (Fig. E), supporting the involvement of morphology-dependent mechanotransduction.

Discussion

Mechanical cues such as substrate stiffness, dimensionality, and fiber alignment are known to control VSMC phenotype [7]. Our results indicate that wavy and straight fibers create distinct structural cues that regulate VSMC phenotype and YAP signaling. Part of the Hippo pathway, YAP plays complex roles in VSMC regulation, associating with both contractile maintenance and synthetic transition [4,5]. Our findings suggest that YAP may contribute to preserving the contractile phenotype in native structure. Future studies will

investigate the role of YAP in topography-mediated phenotypic regulation and evaluate VSMC responses under physiologic and pathologic mechanical stimulation.

TGF-β2 and Matrix Stiffening Elicit Mesenchymal Transition of Choroidal Endothelial Cells In Vitro

Mr. Richard Cliver, Dr. Kristan Worthington

The University of Iowa, Iowa City, Iowa, United States

Introduction

Age-related macular degeneration (AMD) is a prevalent cause or irreversible blindness. Although its underlying pathophysiology is complex, endo- and epithelial-to-mesenchymal transition (EMT) is implicated in AMD. EMT involves aberrant de-differentiation, proliferation, and matrix production. In other tissue systems, EMT can be caused by biochemical signaling factors and by increases in tissue stiffness. Given that retinal and vascular tissues stiffen with age, our goal is to characterize the extent to which these biomechanical changes contribute to retinal cell EMT compared to classical biochemical instigators.

Methods

Due to their involvement in early AMD pathology, we focused our initial efforts on choroidal endothelial cells using an immortalized ChEC line (imChECs) for our preliminary studies. We characterized the extent to which three canonical drivers of EMT (TGF-b1, TGF-b2, and TNF-a) impact cell proliferation, morphology, endothelial phenotype (e.g., expression of VE-Cadherin and PECAM-1), and EMT (a-SMA, N-Cadherin, SNAI1, and Vimentin) for one week. Age-related biomechanical tissue changes were simulated using an accelerated *in situ* matrix stiffening model: imChECs were seeded and allowed to attach to a GelMA hydrogel, followed by a secondary photocrosslinking to increase the matrix compressive modulus. We validated imChEC viability before and after secondary photocrosslinking and characterized cell response as described above.

Results

Exposure to TGF-b1 caused moderate upregulation of EMT markers in imChECs within 7 days while TGF-b2 elicited a substantial EMT response (**Fig.1A**). Secondary photocrosslinking of GelMA hydrogels produced a change in compressive modulus from

approximately 5 kPa to more than 10 kPa (**Fig.1B**), which mimics age-related biomechanical changes. ChECs readily attached to GelMA substrates and remained viable (>95%) after being subjected to secondary photocrosslinking (**Fig.1C**). Within two days of matrix stiffening, imChECs demonstrated transcriptomic downregulation of VE-cadherin and upregulation of α-SMA (**Fig.1D**).

Discussion

Our results demonstrate the feasibility of using secondary photocrosslinking to increase matrix stiffness without disrupting existing cell attachments or causing cell death. We also show that imChECs are susceptible to EMT, as instigated by either canonical biochemical signal or biomechanical cues. Our ongoing studies that utilize human iPSC-derived ChEC and RPE cells and additional timepoints and assays will further elucidate the mechanisms driving EMT in AMD pathophysiology.

Prof. David Fletcher

Introduction

Chiari malformation is a disorder where the cerebellar tonsils herniate into the spinal canal. This is assumed to obstruct normal cerebrospinal fluid (CSF) flow and cause cough-associated headache. Recent real-time phase contrast (PC) MRI [1] showed that the CSF velocities were two times greater in patients with Chiari than healthy controls. Additionally, the CSF space around the vertebrobasilar arteries anterior to the pons were more restricted. These findings suggested that high velocity CSF flow during coughs may stress the vertebrobasilar and contribute to headaches.
In this study, machine learning was used to construct subject-specific computational models from anatomical and PC-MRI data. These models were used to evaluate whether cough induced CSF flow increased the stresses acting on the vertebrobasilar arteries in patients with cough associated headache.

Methods

Previously trained U-Net segmentation models [1] were used to extract the CSF regions from the T1-weigthed anatomical images, and real-time PC-MRI taken at mid-C3 and the foramen magnum. Models were generated for 27 Chiari patients (7 without cough headache), and 12 matched controls. The fluid domain was meshed using Simpleware. The outlet at the suprasellar cistern was given a 7mmHg [2] static pressure. A CSF flow waveform measured at mid-C3 that included both cardiac and cough pulses was applied to the inlet. Simulated flow was validated against PC-MRI measurements taken at the foramen magnum, and peak shear stress on the vertebrobasilar artery was collected.

Results

Simulated CSF velocities were similar to those measured at the foramen magnum during the cardiac cycle (-0.6±1.7cm.s^{-1}) and the cough (-0.11±3.5cm.s^{-1}), in pilot models of a control and patients with and without cough headache (N=3). The peak shear stresses on the vertebrobasilar arteries were greater in Chiari patients than controls at all time points (Fig.1). During the coughs shear stress was twice as great in patients with coughing headache than those without.

Discussion

These results suggest that differences in cranial anatomy and greater arterial stresses could contribute to cough headaches. Additional models are required to determine if this is consistent within the larger cohort.

Process-Specific Numerical Simulations as an Optimization Tool of Microfluidic Nanoparticles Synthesis

Doctor Marco Bellotti[1], Doctor Enrica Chiesa[1], Doctor Elia Bari[2], Professor Michele Conti[1,3], Professor Ferdinando Auricchio[1], Doctor Alessandro Caimi[1]

[1]Università degli studi di Pavia, Pavia, Pavia, Italy. [2]Università del Piemonte Orientale, Novara, Novara, Italy. [3]IRCCS Policlinico San Donato, San Donato Milanese, Milano, Italy

Introduction

Conventional nanoparticles (NPs) synthesis methods offer limited control over size, polydispersity, and reproducibility. Microfluidic technologies overcome these limitations by enabling precise control of flow, mixing, and residence times [1]. However, optimization still relies largely on Design of Experiment (DoE) strategies, which are time-consuming, expensive, and focus on outcomes rather than underlying physicochemical mechanisms. Integrating numerical simulations with knowledge of NPs formation mechanisms can streamline formulation optimization, improve reproducibility, and facilitate translation across different microfluidic devices. This approach could reduce experimental workload and supports the rational design of new microfluidic geometries tailored to specific NPs synthesis requirements [2].

Methods

CFD simulations were employed to examine mixing patterns of various binary mixtures and NPs (i.e. liposomes, Eudragit L100, PLGA, fibroin) precursors in microfluidic chips with different geometries. Both transient and steady-state species transport simulations were performed depending on domain complexity. Formation-specific mechanisms were integrated during post-processing to derive new variables linked to NPs properties. Complementary experimental data were obtained by synthesizing model-drug-loaded NPs and characterizing their morphology using Dynamic Light Scattering , Nanoparticle Tracking Analysis , and Transmission Electron Microscopy, enabling correlation between simulations and experimental outcomes.

Results

Numerical results highlighted that fluid physical properties, such as viscosity, strongly influence mixing patterns within microfluidic chips. Incorporating NPs-specific precipitation curves for polymeric NPs and self-assembly curves for liposomes revealed that formation zones are highly dependent on the binary mixtures used. Key fluid dynamics parameters, including total flow rate and flow rate ratio , impact internal velocities,

residence times, and the speed at which optimal dilution occurs, directly influencing NPs morphology. Microfluidic chip geometry further modulates these effects by shaping internal flow and mixing (Figure 1A,C,E). Experimental data validated these findings, linking specific numerical and experimental boundary conditions to observed NP morphological features (Figure 1B,D,F).

Discussion

CFD simulations combined with mechanistic insight into NPs formation can reveal new morphology-linked variables, simplifying DoE approaches and reducing time and cost. These insights also ease the transfer of optimized formulations across microfluidic chips and guide the design of chips tailored to specific processes for more efficient synthesis.

Artificial Microswimmer Propulsion in Blood: Surface-Active Designs Reduce Resistance and Improve Trajectory Stability

Dr. Chenjun Wu[1], Associate Prof. Toshihiro Omori[2], Prof. Takuji Ishikawa[2,3]

[1]School of Advanced Studies Sant'Anna, Pontedera, Pisa, Italy. [2]Graduate School of Engineering, Sendai, Miyagi, Japan. [3]Graduate School of Biomedical Engineering, Sendai, Miyagi, Japan

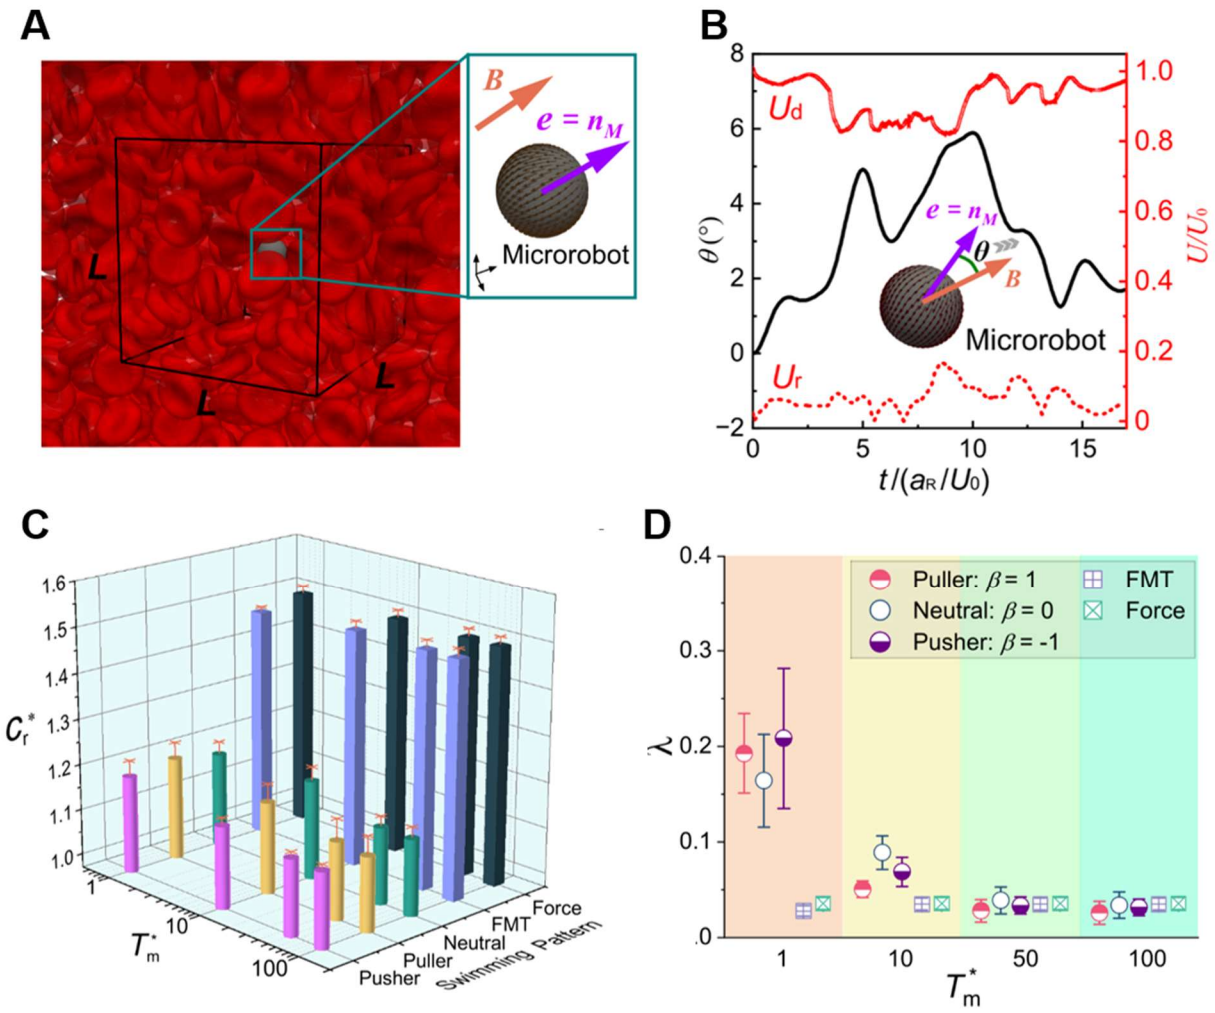
Associate Prof. Toshihiro Omori

Introduction

Blood is a dense suspension of deformable red blood cells (RBCs) that generates strong hydrodynamic resistance and destabilizing interactions for artificial microswimmers (1). Although such microswimmers have shown promise for biomedical applications, the influence of RBC mechanics on their propulsion efficiency and trajectory stability remains poorly quantified (2). In particular, how surface-active propulsion fundamentally differs from inert designs remains unclear, especially when swimmers are controlled by external magnetic actuation in crowded RBC environments (3). This study addresses these gaps using an RBC-resolved computational framework to evaluate locomotion performance across propulsion modes.

Methods

We simulated microswimmer–RBC interactions using a fluid–structure interaction framework that couples boundary-element hydrodynamics with finite-element modeling of deformable RBC membranes, while treating the microswimmer as a rigid body (Fig. A and B). Surface-active swimmers were implemented using a squirmer formulation with prescribed slip velocities representing puller, pusher, and neutral modes. Inert designs were modeled as non-slip swimmers actuated solely by externally applied magnetic forces. Simulations were performed under varying magnetic actuation strengths to assess propulsion behavior in crowded RBC environments.



Results

Surface-active microswimmers exhibited consistently lower hydrodynamic resistance than inert designs across all magnetic actuation levels (Fig. C). For inert microswimmers, the force-magnetic-torque-driven (FMT) microswimmer differs from purely force-driven motion and it only induces slight orientational perturbations, leading to minor variations in the relative resistance coefficient (C^*_r). In contrast, C^*_r or squirmer microswimmers decreased more notably with increasing magnetic torque, with an slightly drop when dimentionless magnetic torque (T^*_m) is greater than 10. Besides, surface-active microswimmers showed markedly reduced lateral drift (λ) and suppressed angular fluctuations (Fig. D).

Discussion

Our findings show that surface-active propulsion fundamentally alters microrobot–RBC interactions, generating slip flows that redirect nearby RBCs and reduce both hydrodynamic resistance and destabilizing collisions. These results suggest that integrating slip-based actuation with magnetic control is a promising strategy for reliable navigation in dense blood environments and motivate future validation in microvascular-scale experiments.

Early Biomechanical Insights into the Association between Offloading Adherence and Gait Mechanics in Diabetic Foot Ulcer Patients Offloaded with Removable Cast Walkers

Mr. Nahir Negron-Fernandez MS, Dr. Ryan Crews PhD, Mr. Sanam Jhaveri BS, Dr. Noah Rosenblatt PhD

Rosalind Franklin University, North Chicago, IL, United States

Introduction

While removable cast walkers (RCWs) are commonly prescribed to offload diabetic foot ulcers (DFUs), adherence with RCWs is low. To optimize offloading adherence (OA), this ongoing, multi-site trial aims to evaluate the impact of existing RCW designs on OA and to collect preliminary data to quantify the effect of RCW design biomechanical correlates of usability and their ability to predict OA.

Methods

Data was analyzed from an initial set of eight participants in an ongoing clinical trial focused on offloading DFU. Participants in the trial were randomized to receive one of two RCW offloading interventions. OA with the RCW was monitored via dual accelerometers over four weeks, after which participants visited the motion capture lab for a single session to assess 10 biomechanical correlates of usability related to energetics, joint loading, and stability. Principal component analysis (PCA) was performed on the set of biomechanical variables, and Spearman correlations were used to evaluate the strength of association between PCA component scores and OA.

Results

PCA resulted in three components explaining 81.7% of the variance in the data. Component 1 loaded heavily on vertical ground reaction forces, non-boot external knee adduction moments (EKAM), overground walking velocity, and posterior perturbation thresholds; component 2 on pelvic tilt measures, cost of transport, and anterior perturbation thresholds; and component 3 on boot-condition EKAM and pelvic tilt range of motion. OA was indexed separately by walking (steps) and standing time (minutes). Correlations between OA and the principal component scores were of weak to moderate strength ($0.2< \rho<0.5$; all $p \geq 0.29$).

Discussion

These preliminary findings demonstrate the feasibility of capturing OA and rich gait mechanics data in DFU patients following a one-month acclimation period to an assigned RCW. While underpowered to vet the PCA approach, small-to-moderate effects are encouraging for a behavioral outcome like OA, which is influenced by biomechanics and psychological factors captured in the larger trial. Biomechanical data clustered into three components (loading, pelvic mechanics, stability), and additional measures such as trunk dynamic stability, which have been collected but not yet analyzed, may further clarify OA, highlighting the value of biomechanical methods for addressing clinically important questions.

Postural Instability in Diabetes Mellitus: Insights from Rambling-Trembling and Non-linear Approach

Dr. Kai Cheng PhD[1], Dr. Carl Luchies PhD[2], Dr. John Miles MD[1], Dr. Jianghua He PhD[1], Dr. Hannes Devos PhD, PT[1], Dr. Chun-Kai Huang[1]

[1]University of Kansas Medical Center, Kansas City, KS, United States. [2]University of Kansas, Lawrence, KS, United States

Introduction

Diabetes mellitus (DM) is a chronic condition that causes microvascular damage and impairments in sensory processing, leading to postural instability and an increased risk of falls. Both peripheral and central sensory processing are crucial for balance maintenance, but the relative contributions of each to postural instability in DM are not well understood. Previous research suggests that DM-related neuropathy, retinopathy, and vestibular dysfunction all contribute to poor balance, but how these systems interact in postural control remains unclear. The objective of this study is to investigate sensory system contribution to postural control using center-of-pressure decomposition and nonlinear approaches.

Methods

A VR-based Sensory Organization Test that simulated sensory conflicts among somatosensory, visual, and vestibular inputs were adopted. The center-of-pressure data were decomposed into Rambling (RM) and Trembling (TR) components, representing central and peripheral postural control, respectively. Variables such as root mean square, velocity, acceleration, and jerk were calculated for both RM and TR in anteroposterior (AP) and mediolateral (ML) directions. Sample Entropy was used to assess the predictability and regularity of postural control dynamics.

Results

DM showed significantly greater sensory ratios in RM jerk (ML), particularly when relying on visual input, indicating reduced central processing. Additionally, DM exhibited increased velocity and acceleration in TR (AP), especially under visual and vestibular reliance conditions, suggesting inefficient peripheral reflex adjustments. SampEn analysis revealed decreased predictability and regularity in central processing (RM) and peripheral responses (TR), particularly when relying on the vestibular system.

Discussion

The findings suggest that DM leads to altered postural control, characterized by impaired central processing and inefficient peripheral compensation when relying on visual or vestibular systems. These results align with the hypothesis that DM affects both the central and peripheral processing contributing to balance impairment. The increased jerk in RM components and excessive velocity and acceleration in TR components indicate that DM participants engage in maladaptive strategies, possibly due to impaired sensory integration. Future interventions targeting both central and peripheral mechanisms, such as multisensory integration exercises and gaze stabilization, may improve postural control in individuals with DM.

Comparing Upper Limb Muscle Activation Following Unilateral and Prophylactic Contralateral Mastectomy for Unilateral Breast Cancer

Ms. Sarah Fitzgerald MHSc, Dr. Kenzie Friesen PhD, Dr. Angelica Lang PhD

University of Saskatchewan, Saskatoon, Saskatchewan, Canada

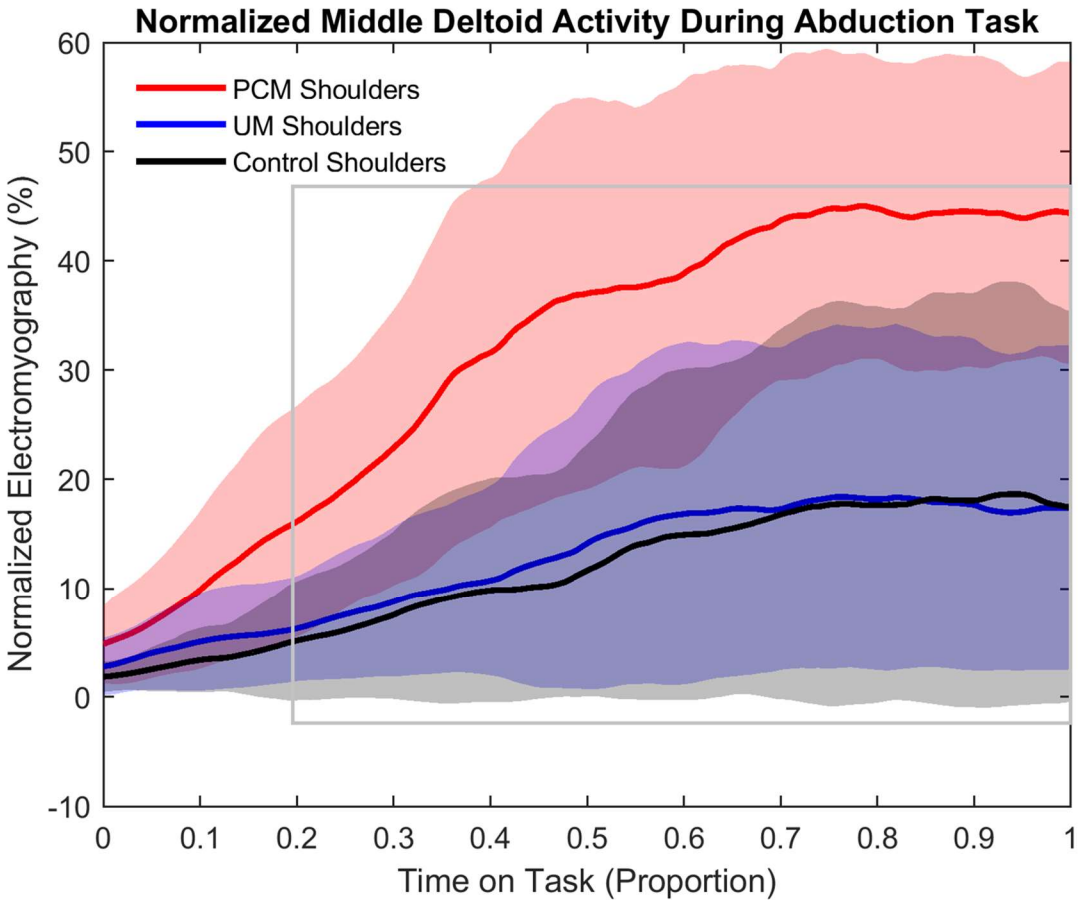
Introduction

Breast cancer (BC) is the most commonly diagnosed cancer among women in Canada[1]. Unfortunately, treatment often results in upper limb morbidities[2]. Commonly performed surgical treatments for unilateral breast cancer include unilateral mastectomies (UM) with or without prophylactic contralateral mastectomy (PCM). However, the merits of both these options are debated. To the best of our knowledge, no previous literature has examined the relative impact of UM alone or with PCM on upper limb biomechanics and function. As such, the objective of this study is to examine the impact of PCM and UM alone on shoulder biomechanics.

Methods

Sixteen participants (N = 10 PCM | N = 3 right-sided UM | N = 3 left-sided UM) are included in this abstract, with data collection ongoing. Activity of the bilateral upper trapezius, lower trapezius, serratus anterior, infraspinatus, pectoralis clavicular, and middle deltoid was measured during a range of functional and range of motion tasks. EMG activity was normalized to maximum voluntary contractions and smoothed with a second order Butterworth bandpass filter. Data was then compared between PCM shoulders (n=20), UM affected shoulders (n=6), and UM unaffected shoulders (n=6) using one-way SPM ANOVAs ($p < .05$).

Results



Preliminary analyses demonstrated elevated middle deltoid activity among PCM shoulders as compared to both groups of UM shoulders during arm elevation tasks (Figure 1; $p < 0.001$).

Discussion

Preliminary results demonstrate interesting trends of elevated middle deltoid activity among PCM shoulders as compared to UM and control shoulders. This may reflect reduced middle deltoid strength among these participants. Data from this work are expected to contribute to improving resources available to support BC survivorship. Improved

understanding of these biomechanical effects of PCM and UM will supplement shared decision-making with patients and surgeons.

Gait Variability and Velocity Improve With Partnered Dance Intervention Among Individuals With Breast Cancer and Chemotherapy-Induced Neuropathy: A Pilot Study

Dr. Aya Alwan[1], Ms. Kristen Lantis[2], Dr. Ashley Hawke[3], Dr. Madeleine Hackney[4,5], Dr. Maryam Lustberg[3], Dr. Lise Worthen-Chaudhari[6]

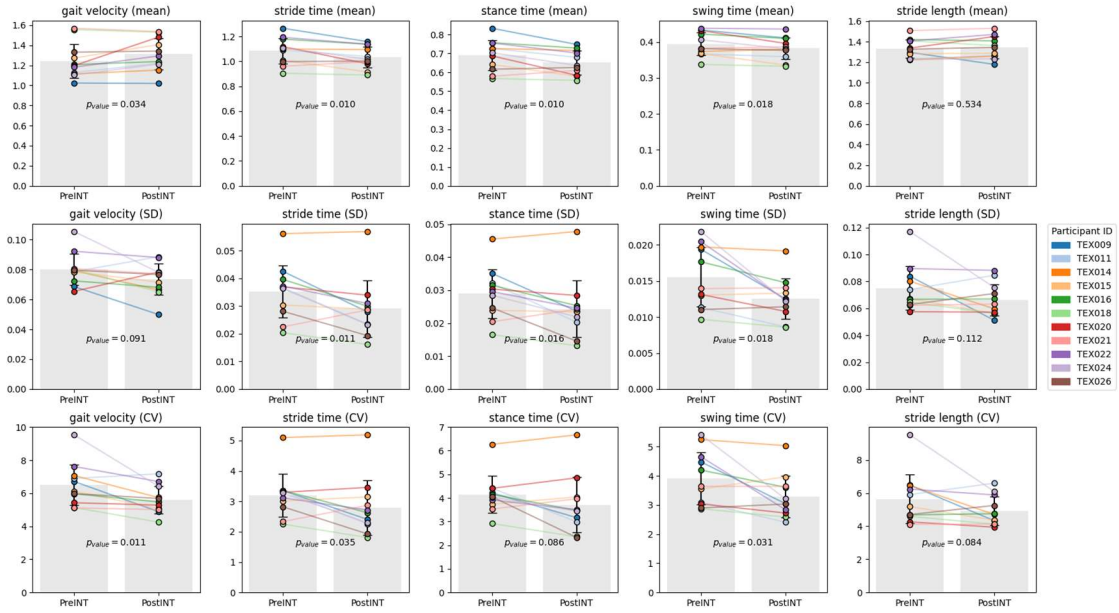
[5]Atlanta VA Health Care System, Birmingham/Atlanta, Virginia, United States. [6]The Ohio State University College of Medicine, Columbus, OH, United States

Introduction

Breast cancer (BC) survivors with chemotherapy-induced neuropathy (CIN) experience sensorimotor deficits, altered gait patterns, and increased fall risk. We evaluated partnered, adapted, Argentine Tango dance training (Tango) as nonpharmacologic treatment for these deficits. Here, we report intervention effects on gait function, specifically. The intervention was designed to decrease gait variability through step and support motor learning techniques unique to Tango. Because gait variability is believed to represent a trainable mechanism underlying fall risk, improvements in this metric are clinically relevant. We hypothesized that Tango intervention would reduce gait variability as measured by coefficient of variation in stride-to-stride speed (CV_{speed}).

Methods

Eleven female BC survivors with CIN and demonstrated balance deficits were randomized to receive the Tango intervention (TEX, 2x/week for 8-weeks, ~30-minute dose/session). Effects were measured during an instrumented 6-minute walk test (6mwt) performed pre- and post-intervention. From inertial measurement units (IMUs) placed on the sacrum and feet, we computed spatiotemporal gait metrics during straightaway bouts of walking using *gaitmap* library. Across all strides per participant and timepoint, we calculated CV_{speed} as the primary outcome and additional measures as exploratory outcomes (e.g., mean, standard deviation (SD), and coefficient of variation (CV) of stride time and length). We used paired t-tests to assess change with intervention (significance level $p < 0.05$).



Results

The primary outcome (CV_{speed}) decreased with intervention (p = 0.011). Exploratory analysis identified additional functional gains associated with the intervention such as increased gait speed (p = 0.034; mean(SD) improvement = ~5.6(8.1)%) and decreased CV stride time (p = 0.035) and swing time (p = 0.031). Stride length did not change with intervention.

Discussion

Tango training improved stride-to-stride variability and other aspects of gait variability among BC survivors with CIN. The intervention improved gait speed, although we did not target this outcome. While the small sample limits clinical generalizability, the dataset is sufficient for biomechanical inferences. Future work will examine turning-specific gait metrics, foot placement control (step-to-step error correction), dynamic stability (resilience to small perturbations), and post-intervention falls incidence to explore the potential for nonpharmacologic treatment through Tango among BC survivors with CIN.

A Personalised Intervention Integrating Pressure-Optimized Footwear, Self-Management and Education Reduces the Incidence of Foot Ulcer Recurrence in Diabetes: The DIASSIST Multicenter Randomised Controlled Trial

Prof. dr. Sicco Bus[1], MSc Lisa Vossen[1], Dr. Chantal Hulshof[1], MD Heleen Berendsen[2], Dr. Chantal Bakker MD[3], Dr. Louise Sabelis MD[1], Prof. dr. Marcel Dijkgraaf[1], Dr. Jaap van Netten[1]

[1]Amsterdam UMC, University of Amsterdam, Amsterdam, NH, Netherlands. [2]Reinier de Graaf Gasthuis, Delft, ZH, Netherlands. [3]Maxima Medisch Centrum, Veldhoven, Brabant, Netherlands

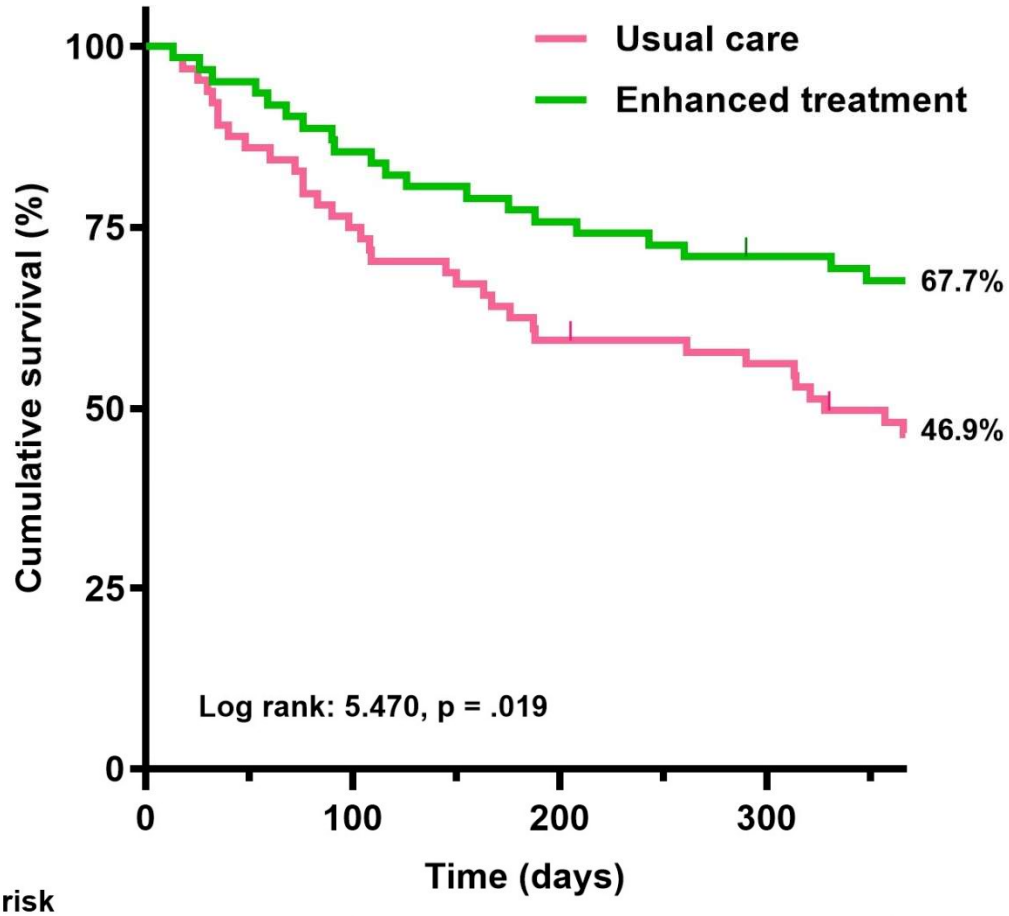
Introduction

The prevention of foot ulcers in diabetes helps reduce the large patient and healthcare burden of diabetic foot disease. To prevent foot ulcers, guidelines recommend patient education, self-management, appropriate foot care and pressure-optimized footwear [1]. For the latter, protocol-based footwear design and modifications guided by in-shoe plantar pressure analysis is used [2]. We assessed the effect of an integrated multimodal and personalized intervention on the incidence of diabetes-related foot ulcer recurrence.

Methods

In a parallel-group multicentre superiority randomized controlled trial in 5 hospitals in the Netherlands, 126 participants with diabetes, peripheral neuropathy, ulcer history, and custom-made footwear, were randomly assigned to usual care or enhanced treatment. Enhanced treatment consisted of pressure-optimized custom-made footwear, pressure-optimized indoor footwear; at-home foot temperature monitoring; and structured education, including motivational interviewing. Participants were followed for 12 months, with incident foot ulcer recurrence as primary outcome, which was assessed masked to group allocation and with all participants included. Trial registration: clinicaltrials.gov, ID: NCT05236660.

Results



Participants were assigned between 2/3/2022 and 25/9/2024: 64 to usual care (54 male; 10 female), 62 to enhanced treatment (52 male; 10 female). On the basis of intention-to-treat, 20 (32.1%) participants in enhanced treatment and 34 (53.1%) in usual care had a recurrent foot ulcer (RR 0.607 [95%CI 0.396-0.931], p=0.018). There were significantly more ulcer-free days for enhanced treatment (mean ± SD 320±87) than for usual care (298 ± 94, p=0.039). Of the 10 participants in enhanced treatment who wore their pressure-optimized

footwear >10h/day and adhered to foot temperature-monitoring recommendations, 1 (10%) had an ulcer, significantly fewer than the 53.1% in usual care (RR 0.188 [95%CI 0.029-1.226], p=0.015).

Discussion

Integrated multimodal and personalized treatment including pressure-optimized custom-made footwear and pressure-optimized indoor footwear, significantly reduces incidence of foot ulcer recurrence in people with diabetes, and this effect can be further improved when patients adhere to self-management recommendations and prescribed footwear use. These outcomes help reduce the burden of diabetic foot disease in high-risk persons.

Myofascial Massage Reduces Pain in Breast Cancer Survivors but Does Not Induce Acute Changes in Tissue Stiffness- a Pilot Study.

Ms. Layla Lynch MS, CSCS[1], Ms. Margit Fried[1], Mrs. Diane Mastnardo BS, LMT[2], Dr. Suzi Wolfram PhD[3], Dr. David Lipps PhD[1]

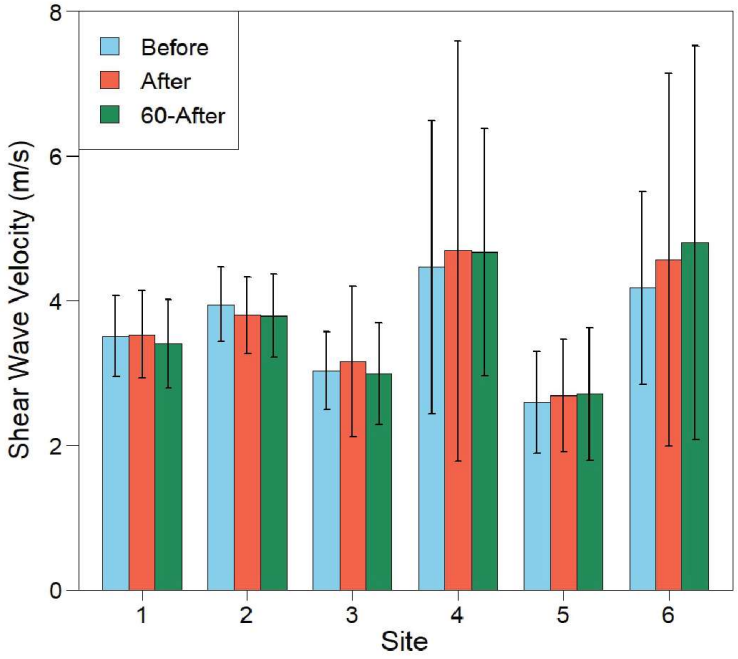
[1]University of Michigan, Ann Arbor, Michigan, United States. [2]Mastnardo Massage Therapies, Westlake, Ohio, United States. [3]Northumbria University, Newcastle, Northeast England, United Kingdom

Introduction

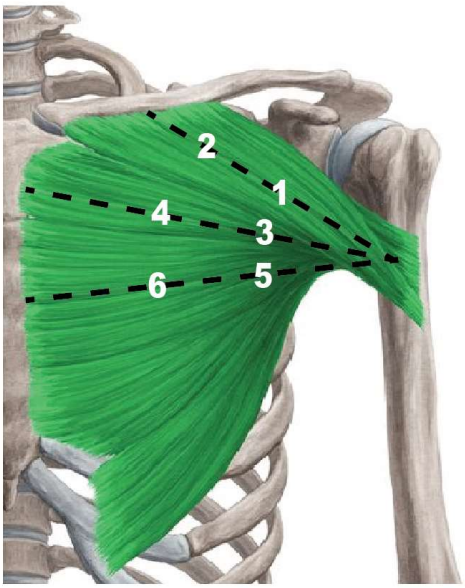
Up to 50% of breast cancer survivors (BCS) experience persistent upper quadrant myofascial pain[1], which impairs their quality of life. Myofascial massage reduces pain and increases shoulder mobility in BCS[2], but its underlying mechanisms are poorly understood. Surgery and radiation therapy can cause fibrosis and stiffness, leading to thickening and tightening of connective tissue. Myofascial massage may counter these changes and break down fibrotic tissue. This study examined how myofascial massage affects pectoralis major stiffness and pain in BCS. We hypothesized that a single session of myofascial massage would reduce tissue stiffness and pain.

Methods

Twenty breast cancer survivors with upper quadrant myofascial pain (mean ± SD, age: 53.5 ± 11.3) participated after providing written consent. Each participant received a 30-minute individualized myofascial massage to the chest wall and axilla. Ultrasound shear wave elastography (SWE) assessed tissue stiffness before, immediately after, and 60 minutes after the intervention at six distinct sites on the pectoralis major. A linear mixed-effects model tested the effect of myofascial massage on shear wave velocity (SWV) with site, time, radiation exposure, and their interaction (time x radiation) as fixed effects. Patient-reported outcomes at enrollment assessed average pain in the past week (PEG), and one week post-intervention, PEG and change in condition (PGIC) were evaluated.



Results



Following treatment, most participants (17/20) reported improvement and reduced pain (PEG: $p = 0.001$). SWV significantly differed between site locations ($p = 0.039$) (Fig. 1), with greater stiffness in the medial portion of the sternocostal region. Time, radiation, and their interaction did not exhibit statistically significant relationships with SWV (all $p > 0.51$).

Discussion

Myofascial massage improved patient condition and reduced pain, but did not change SWV within 60 minutes of the intervention. SWV varied significantly across sites, suggesting regional differences in general tissue properties. Limitations included a small sample size, variable massage histories, and the possibility of multiple sessions needed to alter tissue biomechanics. Following this pilot study, future research should consider extended intervention periods and larger, more controlled samples to better assess the effects of myofascial massage.

Optimizing Prosthesis Knee Damping Minimizes Intact-Knee Contact Forces During Ramp Descent in Transfemoral Amputees

Ms. Elise Nielsen, Ms. Marissa Cowan, Dr. Lukas Gabert, Dr. Scott Uhlrich, Dr. Tommaso Lenzi

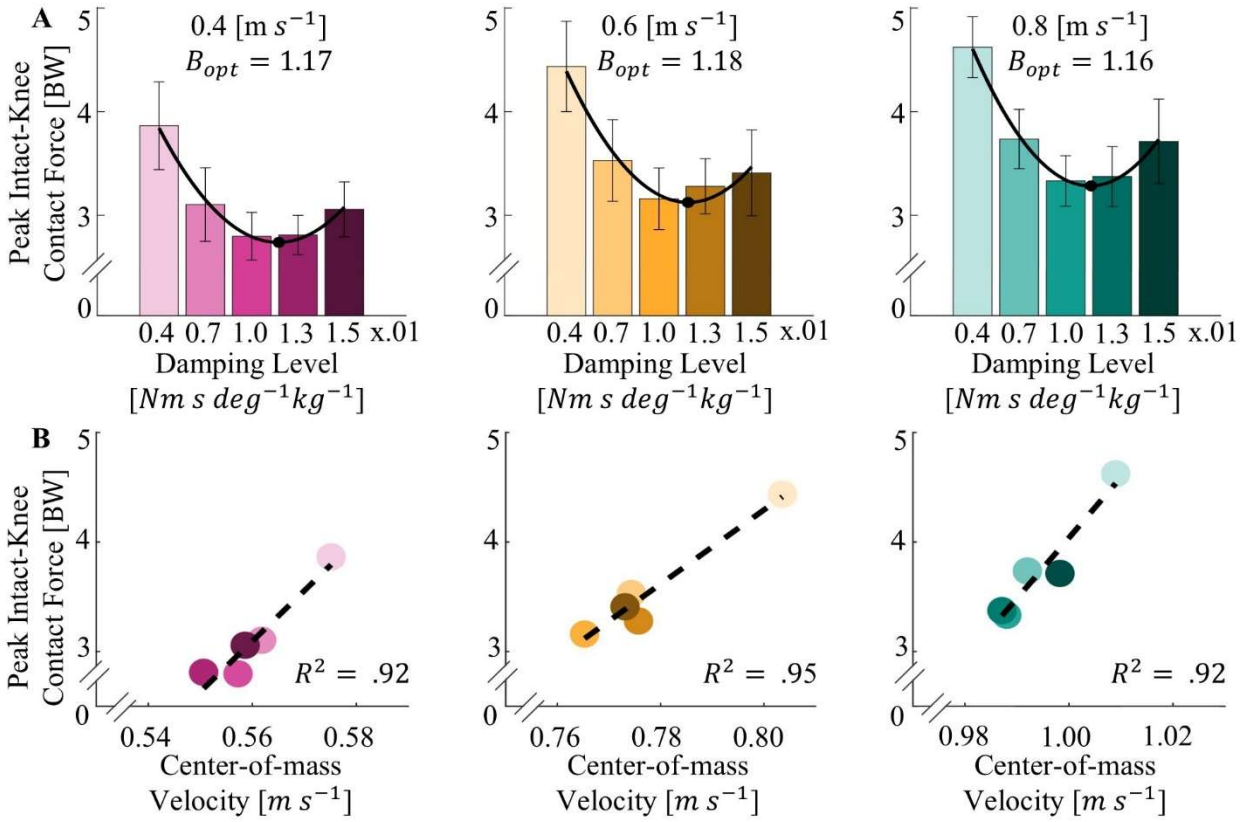
Univeristy of Utah, Salt Lake City, UT, United States

Introduction

Individuals with transfemoral amputations are 40% more likely to develop knee osteoarthritis than non-amputees [1], a risk linked to elevated knee contact forces on the intact limb [2]. These forces are particularly high during activities that require lowering the center of mass, like ramp descent [3]. Knee prostheses use damping to resist knee flexion and control the descent. However, the influence of this damping on intact-knee contact forces remains unknown. Our objective was to assess the effect of damping on transfemoral amputees' intact-knee contact forces during ramp descent. We hypothesize that intermediate levels of damping will minimize intact-knee contact forces. The rationale is that high damping prevents the necessary knee flexion for a smooth center-of-mass descent, while low damping results in excessive knee velocity. Both extremes force users to abruptly transfer weight to the intact limb for stabilization, increasing knee loading.

Methods

Eight transfemoral amputees walked on a declined (7.5º) instrumented treadmill with an active knee prosthesis. After training, we recorded kinematics and ground contact forces at three speeds (0.4, 0.6, and 0.8 $m \cdot s^{-1}$) across five randomized damping levels (0.004-0.016 $Nm \cdot s \cdot deg^{-1} \cdot kg^{-1}$). We estimated intact-knee contact forces using static optimization in OpenSim and fitted quadratic curves to identify the optimal damping level.



Results

We found a quadratic relationship between damping and intact-knee contact force, with a theoretical minimum (B_{opt}) occurring at an intermediate damping level (0.012 $Nm \cdot s \cdot deg^{-1} \cdot kg^{-1}$) across all speeds (*Figure 1A*). At B_{opt}, peak contact forces were reduced by 30% and 10% compared to the lowest and highest damping, respectively. Additionally, peak contact forces correlated strongly with center-of-mass velocity (R^2 0.92-0.95, *Figure 1B*), indicating that B_{opt} facilitates controlled lowering of the body.

Discussion

Our findings indicate that prosthesis damping directly influences intact-knee contact forces. Notably, B_{opt} remained constant across walking speeds, simplifying future controller implementation. Tuning prosthesis damping to B_{opt} limits the center-of-mass velocity, reducing the mechanical stress on the intact joint and potentially lowering the risk of osteoarthritis.

Current Clinical Practice for Prosthesis Alignment Does Not Yield Lowest Interlimb Asymmetry in People With Unilateral Transtibial Amputation during Walking

Ms. Kelsie Heffernan[1], Dr. Alena Grabowski[2,3], Dr. Janet Zhang-Lea[1]

[1]University of Oregon, Eugene, Oregon, United States. [2]University of Colorado Boulder, Boulder, Colorado, United States. [3]Department of Veterans Affairs Eastern Colorado Healthcare System, Denver, Colorado, United States

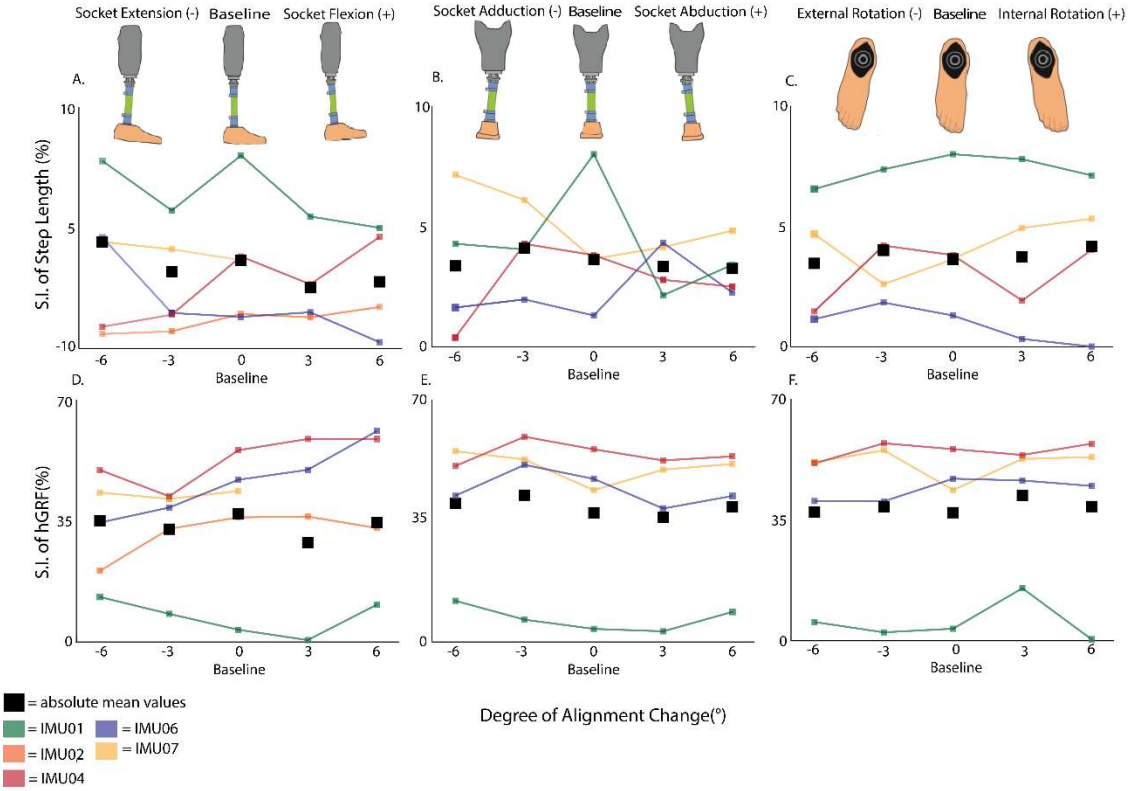
Introduction

Proper alignment of prostheses is critical for reducing interlimb asymmetry and secondary injury risk for people with unilateral transtibial amputation (UTTA). Currently, aligning a prosthesis is done by a prosthetist based on their subjective evaluation. In this study, we modified prosthesis alignment by systematically changing 3D angular rotations from a neutral alignment. We aimed to investigate whether prosthetic alignment based on current clinical practice (baseline) yields the lowest interlimb asymmetry during walking compared to the modified alignment. We hypothesized that the baseline alignment will yield the smallest symmetry index (SI) for both step length and peak horizontal ground reaction force (hGRF) compared to 3° and 6° alignment changes.

Methods

Five participants with UTTA walked on an instrumented treadmill at 1.25 m/s for 3 minutes with 13 alignment conditions for the same low-profile passive-elastic prosthesis. We started with a baseline trial, with the prosthesis set to a neutral alignment by a prosthetist. The prosthetic alignment between the socket and pylon was then changed by ±3° and ±6° in the three planes (sagittal, coronal, and transverse), 6 directions total (plantarflexion/dorsiflexion, abduction/adduction, internal/external rotation; Figure 1). We assessed the SI of step length and hGRF at baseline, and all alignment conditions. SI=0 means perfect symmetry.

Results



None of the 5 participants presented the lowest SI for step length or hGRF at baseline (Figure 1). SI at baseline was averaged at 3.64±4.89% (step length) and 37.06±20.09% (hGRF). Modifying alignment with +3° change in sagittal plane yielded the lowest SI for step length (2.53±3.46%) and hGRF (28.37±30.04%) SI of step length was the highest (4.43±5.46%) with -6° change on the sagittal

plane alignment. SI of hGRF was the highest (42.16±30.33%) with -3° change on the coronal plane.

Discussion

The baseline alignment did not yield the lowest interlimb asymmetry compared to the 3° and 6° alignment changes in 3 directions. Our results suggest that subjective evaluation may not be the most effective tool to reduce interlimb asymmetry during walking in people with UTTA. We suggest the need for a more objective tool to quantify prosthesis alignment in the future.

A Comparison of Gait Adaptations During Two Types of Dual-Task Walking in Individuals With Unilateral Lower Limb Amputation: Part 2- Limb Loading Symmetry

Ms. Emily Parsowith M.S., CSCS[1], Dr. Lisa Zukowski Ph.D[2], Dr. Paul Kline PT, DPT, Ph.D[1]

[1]Virginia Commonwealth University, Richmond, VA, United States. [2]High Point University, High Point, NC, United States

Introduction

Individuals with unilateral lower limb amputation (LLA) exhibit limb-loading asymmetry that impairs function and may increase risk of knee osteoarthritis [1]. Cognitive-motor dual-task assessments reveal altered joint loading in response to additional cognitive demands, but this response may vary by the type of cognitive task utilized. The purpose of this study was to compare kinetic parameters between single-task walking, vision-based cognitive-motor dual-task walking, and non-vision-based cognitive-motor dual-task walking in people with unilateral LLA.

Methods

16 participants were enrolled, 14 with complete data for analysis (9 males, 5 females; age = 56.9±11.1 yrs, BMI = 29.1±4.5 kg/m^2, 10 transtibial, 4 transfemoral). Three walking tasks were performed, each two minutes in duration: single-task (ST), serial subtraction dual-task (SS; non-vision-based), and visual puzzles dual task (VP; vision-based). The two cognitive tasks were evaluated to compare between types of cognitive-motor dual-tasking. Loadsol® wireless force-sensing insoles were placed in the shoes of the amputated and non-amputated limb to measure peak loading, impulse, and loading rate. Normalized symmetry index (NSI) was calculated to compare the effect of task condition (ST, SS, and VP) on peak loading, impulse, and loading rate normalized to body weight. An NSI value of 0% is considered perfect symmetry between amputated and non-amputated limbs.

Results

A repeated measures ANOVA revealed a significant main effect of task condition on peak loading NSI ($F=3.547$, $p=0.043$). Post-hoc paired-samples t-tests indicated that peak loading NSI was significantly improved during VP compared to ST ($p=0.022$, $d= -0.697$). Differences between ST and SS ($p=0.344$, $d= -0.263$) and SS and VP ($p=0.06$, $d= -0.55$) were not significant. There were no significant main effects of task condition on impulse

(F=0.361, *p*=0.700) or loading rate (F=0.827, *p*=0.449) Additional results from the statistical analysis can be found in Table 1.

Discussion

These findings suggest that the VP task resulted in greater between-limb peak loading symmetry, primarily through increased loading of the amputated limb. These findings suggest unique adaptations based on cognitive task during cognitive-motor dual-task walking, including potential deviations from the individuals' preferred loading strategy, warranting further investigation.

Images (Optional)

Outcome Variable (NSI)	Task	Mean±SD	F	*p*-value	Paired Samples t-test	Mean difference±SD	*p*-value	Cohen's *d*
Peak Loading (%)	ST	-3.09±9.00	3.55	0.04*	ST-SS	-0.85±3.25	0.34	-0.26
	SS	-2.24±8.36			ST-VP	-1.92±2.75	0.02*	-0.70
	VP	-1.17±9.39			SS-VP	-1.07±1.94	0.06*	-0.55
Impulse (%)	ST	-6.50±8.03	0.36	0.70				
	SS	-6.74±8.77						
	VP	-6.34±8.82						
Loading Rate (%)	ST	-12.35±13.40	0.83	0.45				
	SS	-14.02±16.13						
	VP	-11.58±16.00						

Table 1. Within-subjects analysis of task condition effect on kinetic variables. Statistical significance is designated by an *. Negative mean NSI % indicates a greater non-amputated limb peak loading, impulse, and loading rate, respectively. Negative mean difference values indicate improved symmetry in the second task compared to the first.

Amputee Motor Control During Steady-State Overground Walking with Non-Prescribed Feet

Mr. Satria Ardianuari M.S.[1,2], Dr. Richard Neptune Ph.D.[3], Dr. Glenn Klute Ph.D.[1,2]

[1]Center for Limb Loss and MoBility (CLiMB), VA Puget Sound Health Care System, Seattle, WA, United States. [2]Department of Mechanical Engineering, University of Washington, Seattle, WA, United States. [3]Walker Department of Mechanical Engineering, The University of Texas at Austin, Austin, TX, United States

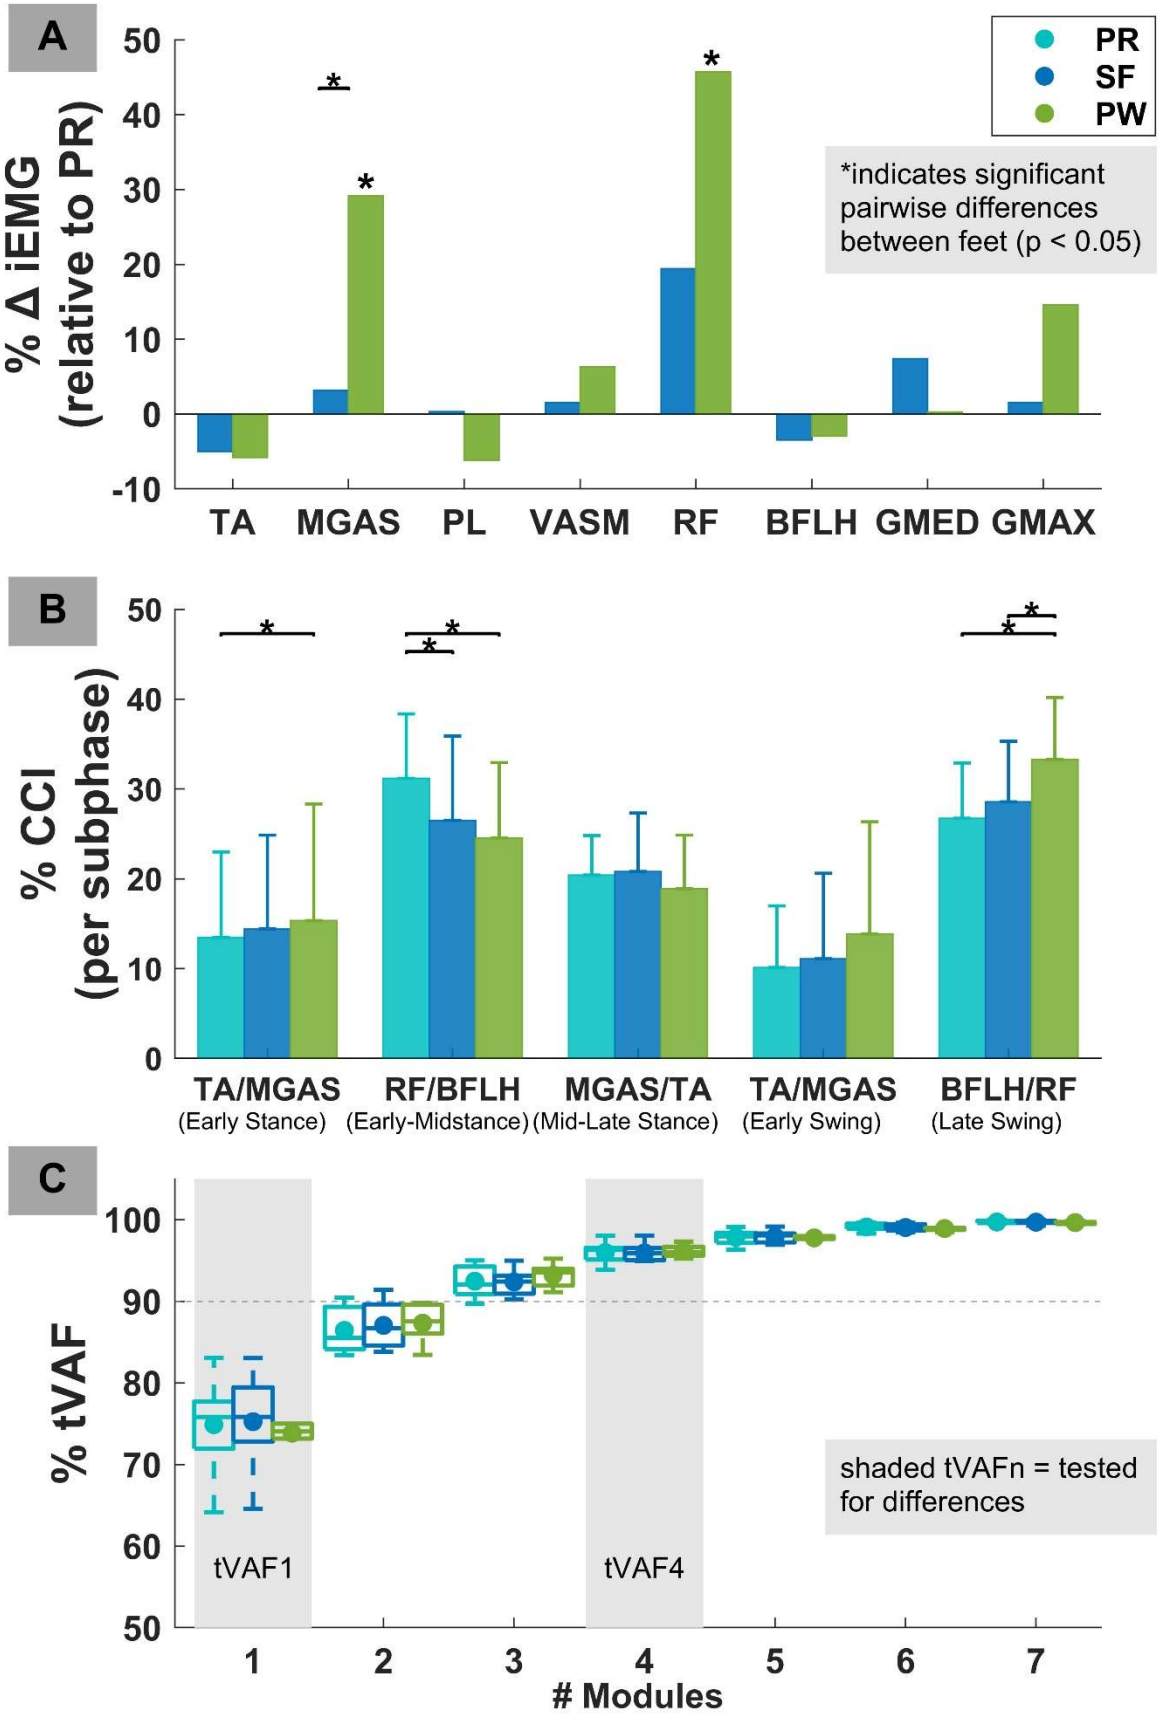
Introduction

Transtibial amputees (TTA) demonstrate altered muscle activations with increased co-contraction but preserved motor modules (co-excited muscles) during level and non-level ground walking [1-3]. How changing foot prescription (i.e., stiffer foot (SF) or powered foot (PW)) affects their overall motor control is unknown. Thus, this study investigated how foot prescription influences muscle activations and motor complexity (i.e., the number of independent modules).

Methods

Twelve unilateral TTA (46 ± 15 y; 10 M) completed motion analysis at preferred speed using their prescribed foot (PR) and SF. Seven subjects also walked with a PW. EMG data from eight intact-limb muscles: tibialis anterior (TA), medial gastrocnemius (MGAS), peroneus longus (PL), vastus medialis (VASM), rectus femoris (RF), biceps femoris (BFLH), gluteus medius (GMED), and gluteus maximus (GMAX) were filtered, rectified, and normalized to peak activation. Integrated EMG (iEMG) was calculated to quantify muscle excitations, and an index $(CCI) = iEMG_{min} / \Sigma iEMG_{ago_antago}$ was used to compute co-contraction [4]. Non-negative matrix factorization (NNMF) extracted modules (W) and their activations (C) such that $muscle\ activations = W \times C + error$ [5]. Total variance accounted for by n modules ($tVAF_n$) assessed motor complexity. Linear-mixed effects regression tested for differences between feet.

Results



MGAS and RF activations increased with the PW foot (Fig. A). Ankle co-contraction increased with the PW foot (early stance) while knee co-contraction decreased (early-

midstance) but then increased (late swing) with SF and PW feet (Fig. B). No differences were observed in complexity (n=4) across feet for the selected $tVAF_n$ (Fig. C).

Discussion

In early swing, the heavier, higher-inertia PW foot may require increased MGAS activation for forward propulsion [6] and increased ankle and knee co-contractions for limb stability [4]. Despite changes in key support muscles like MGAS, similar modules across feet suggest preserved overall motor complexity. Thus, the influence of prosthetic feet on motor control may be insignificant.

Using Stereoradiography to Investigate Ankle Motion with a Powered Footwear System

Mr. Destan Norman[1], Dr. Peter Laz[1], Dr. Alison Sheets-Singer[2], Dr. Kris Quah[2], Dr. Casey Myers[1]

[1]University of Denver, Denver, CO, United States. [2]Nike, Beaverton, OR, United States

Introduction

Powered footwear and exoskeletons can enhance human performance. Despite load-reduction benefits [1,2], ankle motion under exoskeleton use is not well understood. Marker-based motion capture (MOCAP) may lack accuracy in describing ankle joint movement. Stereoradiography offers an accurate description of bone motion [3], but has limited field of view and metal components may obscure bones. The objective of this study was to investigate the feasibility of using stereoradiography to measure ankle motion during walking and running with a powered footwear system (PFS).

Methods

Following IRB approval, MOCAP and stereoradiography data were collected on four adult subjects (3 female, 1 male) wearing a PFS during walking and running. A scaled OpenSim model was used to compute dorsiflexion from marker data. Models of the tibia/fibula, talus, and calcaneus were segmented from CT and assigned coordinate systems per [4,5]. Components of the FPS were also assigned anatomical coordinate systems. Models of the bone and device were registered to each stereoradiographic frame to generate a 3D pose throughout the activity. Ankle dorsiflexion from stereoradiography was represented as relative bone rotation (tibia-talus and tibia-calcaneus) and device rotation (shin strut-heel strut) where each was calculated about the mediolateral axis.

Results

Stereoradiography visualization of bony anatomy and device components was clearly defined for model registration using calibrated imaging settings (Figure 1). The bones and mechanical structures were tracked during stance phase of walking and running (Figure 1).

While kinematics from MOCAP and stereoradiography were strongly correlated (R= 0.961-0.984) throughout stance, notably less tibia-talus and tibia-calcaneus dorsiflexion was observed between mid-stance and toe-off compared to MOCAP.

Discussion

Stereoradiography was effective at dynamically visualizing ankle bone kinematics during exoskeleton use. This study identified distinct movement patterns of the ankle compared to those derived from motion capture, including the relative contributions at multiple bony joints. Understanding the true bone motion patterns can support the design (e.g. sizing, alignment, control) of powered footwear systems.

Experience Led Biomechanics: Multivariate Links Between Foot and Ankle Kinematics and Transition Perception with a New Footwear FlexZone Technology

Ms. Megan Saftich MEng, Dr. Evan Day PhD, MS, Mr. Eddie Martinez MSc, Dr. Jennifer Sumner PhD, MS

Brooks Sports, Seattle, Washington, United States

Introduction

Foot torsion, defined as frontal-plane motion of the forefoot relative to the rearfoot [1], is often overlooked in running footwear design, where flexibility typically targets sagittal-plane metatarsophalangeal (MTP) motion. This study investigated how a shoe built for enabling more foot torsion influences biomechanical and perception metrics.

Methods

Biomechanical and perception data (n=10; 3.35 m/s treadmill running) were collected in the Brooks Glycerin Flex ("Flex", with "FlexZone" technology, Figure1) and Brooks Glycerin 23 (neutral counterpart). Kinematics (sagittal and frontal-plane MTP and ankle joint) and center of pressure (COP) trajectories were analyzed alongside Likert-scale ratings for transition (fluidity, speed, flexibility, energy return, and overall satisfaction). Paired t-tests compared biomechanics between shoes. Relative differences (Glycerin – Flex) were calculated to control for inter-subject variability. Principal component analysis (PCA) was used to reduce dimensionality and identify meaningful biomechanical change patterns between shoes. Pearson's correlations were used to relate biomechanical PCs to perception data.

Results

Frontal-plane MTP range of motion (ROM), ankle ROM, and medial-lateral COP excursion (late stance) were significantly higher in the Flex ($p<0.05, <0.001, <0.04$). PC2 (22.6% variance) showed a strong-negative correlation with fluidity ($r= –0.72, p= 0.02$). PC2 was characterized by high positive loading for the average medial-lateral COP velocity in the midfoot (+0.56) and moderate negative loadings for frontal and sagittal-plane landing angles (-0.48, -0.34), as well as frontal-plane MTP ROM and ankle ROM in the late stance (-0.31, -0.36).

Discussion

This study demonstrated that footwear with FlexZone technology influences kinematics and perception. FlexZone, designed to enable foot torsion in push-off, led to an expected higher medial-lateral COP excursion and frontal-plane ROM (MTP, ankle) in late-stance. In a shoe, if runners demonstrated greater late-stance frontal-plane ROM, combined with slower medial-lateral COP velocity in the midfoot; and landed more dorsiflexed and everted (PC2) they tended to perceive that shoe as more fluid. The landing angle influence suggests that in a shoe with midfoot-focused technology, such as the FlexZone, heel strikers may feel a more fluid transition.

Analysis of Backpedal Mechanics and Achilles Tendon Loading in Elite American Football Athletes

Dr. Rachel H. Teater PhD[1], Ms. Anna C. Workman BS[1], Mr. W. Brody Hicks MS[1], Mr. Cody M. O'Cain MS[1], Dr. Evan A. Dooley PhD[1], Dr. Kristy B. Arbogast PhD[2], Dr. Laura C. Schmitt PT, PhD, FAPTA[3], Dr. E. Meade Spratley PhD[1]

[1]Biomechanics Consulting and Research (Biocore), LLC, Charlottesville, Virginia, United States. [2]Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, United States. [3]The Ohio State University, Columbus, Ohio, United States

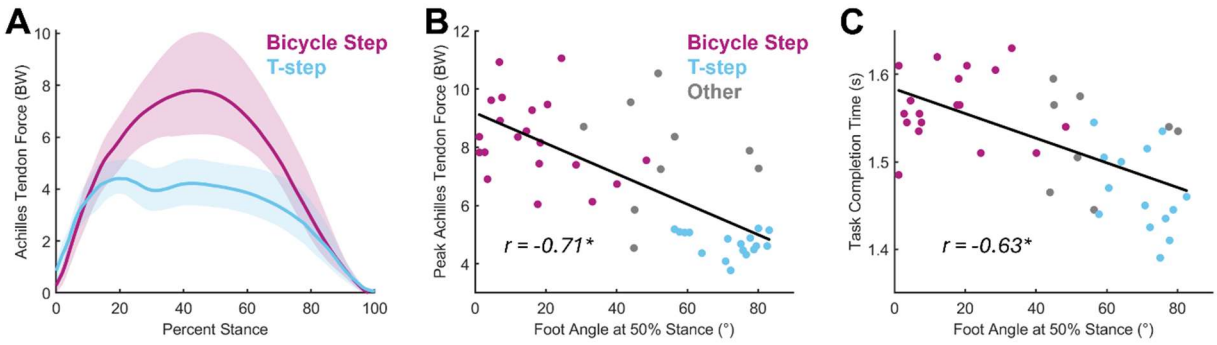
Introduction

In the National Football League, Achilles tendon (AT) ruptures often occur when players attempt to accelerate forward by pushing off their back limb extended behind their center-of-mass. "Breaking out of a backpedal" is a common defensive maneuver in which the final back step requires a powerful eccentric-concentric plantarflexor action. Understanding AT loading during this movement and whether trainable movement patterns might reduce load without compromising performance could inform injury prevention strategies. This study examined how backpedal technique, specifically foot orientation during the final back step, influences AT load and performance in American football athletes.

Methods

Fifteen elite American football athletes (male, 27 ± 5 yrs; 1.93 ± 0.26 m; 100.9 ± 14.2 kg) performed a standardized backpedal-to-sprint task on an outdoor synthetic turf field. Athletes were retrospectively classified as using a "Bicycle step" (in-line foot), "T-step" (out-turned foot), or "Other strategy" based on visual inspection of their final back step. Data were collected using marker-based motion capture and embedded force plates. AT force was estimated by dividing the ankle plantarflexion moment by a 5 cm moment arm and normalized to body weight (BW). Transverse plane foot angle relative to the direction of travel was computed at 50% stance, and task completion time quantified performance. A two-sample t-test compared peak AT force between Bicycle step and T-step groups, and linear correlations were computed between key variables (α=0.05).

Results



Seven athletes used a Bicycle step, five used a T-step, and three used other strategies. Average peak AT force across all trials was 6.8 ± 2.1 BW, with 8.3 ± 1.4 BW for Bicycle step

and 4.7± 0.4 BW for T-step ($p<0.001$). A more out-turned foot angle correlated with lower peak AT forces (Fig. 1B) and slightly improved performance (Fig. 1C) ($p<0.001$).

Discussion

Elite American football athletes who used a more out-turned foot during the final back step experienced lower peak AT forces without compromising performance. These findings suggest that adopting a T-step may be one strategy to mitigate AT loading when initiating forward acceleration. Understanding how these athlete movement variations distribute load across lower-limb joints could inform coaching and training strategies to reduce AT rupture risk while optimizing on-field performance.

OA81-04

Fifth Metatarsal Cumulative Loading Across Rugby-Specific Movements in Elite Athletes Assessed via Plantar Pressure Measurement

Dr. Zixiang Gao Postdoctoral Researcher, Dr. Robin Trama Postdoctoral Researcher, Mr. David McNish Master's Student, Prof. Darren Stefanyshyn Professor, Dr. John Wannop Assistant Professor

Human Performance Laboratory, Faculty of Kinesiology, University of Calgary, Calgary, Alberta, Canada

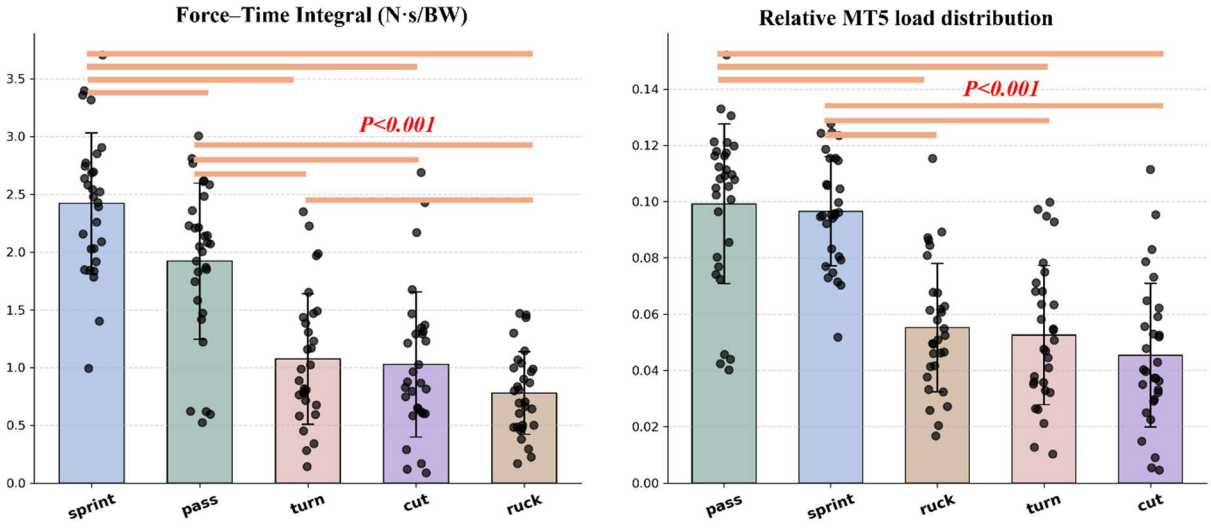
Introduction

Fifth metatarsal (MT5) fractures (Jones fracture) are common in turf-based sports involving rapid acceleration and direction changes such as rugby, with 4.1% of foot injuries consisting of metatarsal fractures [1]. These injuries are associated with prolonged recovery and high recurrence rates despite surgical intervention [2]. However, it remains unclear which specific movements impose the greatest cumulative loads on the MT5, limiting the development of targeted injury-prevention strategies. Plantar pressure analysis provides a practical means to estimate MT5 loading and infer potential pathways relevant to MT5 injury risk.

Methods

Thirty elite North American rugby players (8 males, 22 females) performed five rugby-specific movements: sprinting, running pass, 90° V-cut, 180° turn, and ruck. All tasks were executed on an infilled artificial turf (FieldTurf) laid over the laboratory floor (3 trials per movement). Plantar pressure data were recorded using an Xsensor system (235 sensors) during stance. The MT5 region was manually defined using the sensor-coordinate grid by selecting sensors corresponding to the anatomical location of the MT5, and its force–time integral (FTI) and relative load ratio (MT5 FTI \total-foot FTI) were computed to assess cumulative 5th-metatarsal loading. Repeated-measures ANOVA with Bonferroni-adjusted pairwise comparisons were used for statistical analysis (a=0.05) to compare the different movements.

Results



Significant effects of movement were present for both the MT5 FTI ($F(4,112)=113.94$, $p<0.001$) and relative load ratio ($F(4,112)=70.35$, $p<0.001$). Post-hoc comparisons indicated that sprinting produced the highest MT5 FTI and running pass had the highest load ratio,

which were both significantly greater than the cutting, turning, and ruck movements ($p<0.001$).

Discussion

This pattern indicates that MT5 loading is strongly influenced by lateral–medial pressure distribution. Sprinting showed the greatest MT5 cumulative load, reflecting the higher overall mechanical demand of straight-line sprinting, while the running pass produced the highest MT5 load ratio due to its more lateral pressure during trunk rotation. Cutting, turning and ruck actions demonstrated more medial pressure tendencies, reducing MT5 loading. Future work should incorporate finite element modeling to determine the MT5 internal loading.

Acute Effect of Incremental Exhaustive Treadmill Running on Running Biomechanics in Well-Trained Runners

Prof. Dr. Steffen Mueller[1], B.Eng. Leah Reiter[2], M.Sc. Marco Rahner[1], Prof. Dr. Jörg Lohscheller[3], Dr. Juliane Mueller[1]

[1]Trier University of Applied Sciences; Department of Computer Science – Therapeutic Sciences, Trier, RLP, Germany. [2]Trier University of Applied Sciences; Department of Engineering, Trier, RLP, Germany. [3]Trier University of Applied Sciences; Department of Computer Science, Trier, RLP, Germany

Introduction

Understanding the biomechanical responses of runners to increasing metabolic load and exhaustion is essential for optimizing running performance and minimizing fatigue-related injury risk. This study aimed to quantify acute changes in running biomechanics including vertical peak force, contact time, and vertical stiffness during progressive incremental treadmill running.

Methods

Eight well-trained male runners (31±6y; 178±2cm; 70±4kg; 65±24.5km in 6.5±1.8h training/week) performed an incremental treadmill test to exhaustion. The test started with 8km·h^{-1} (MIN) up to termination (3minutes steps, 2km/h per step increase). Capillary blood samples were taken to determine lactate thresholds (LT1: aerobic 2mmol·L^{-1}; LT2: anaerobic 4mmol·L^{-1}). Ground reaction force (GRF) data were recorded on each increment after 30s(A) and 150s(B) for 20s using an instrumented treadmill (h/p/cosmos 3D/Gaitway). The parameters peak vertical GRF (Fz: normalized/bodyweight [%BW]), contact time (CT: percent/stride time [%ST]) and vertical stiffness (k_v [a.u.]) were analysed at initial START (8km), LT1 (14.7±1.2 km/h), LT2 (17.0±1.4 km/h) and FINAL (20.3±1.6 km/h) running increment. Differences for acute fatigue (B-A [%]) were calculated. Descriptive analysis was followed by repeated-measures ANOVA using post hoc Tukey-Kramer ($\alpha = 0.05$).

Results

Fundamentally, with increasing running speed, Fz [%BW] increased from START 228.4±25.8 to FINAL 296.6±32.3 ($p<0.001$). CT [%ST] decreased from START 40.2±3.0 to FINAL 27.2±2.7 ($p<0.001$). Stiffness increased from START 4754±437 to FINAL 6766±999 ($p<0.001$). Acute fatigue during an increment (difference B-A [%]) showed for Fz [%] no differences at START 1.1±4.3, LT1 -0.3±2.6 and LT2 -1.0±1.2 ($p>0.05$), but a significant reduction

at FINAL -3.1±3.4 ($p<0.05$). For CT [%ST] no difference at any increment (START -0.5±1.2, LT1 0.1±3.0, LT2 -0.6±1.8 to FINAL 1.9±4.2 ($p>0.05$)) appeared and for stiffness no differences at START 0.1±1.2, LT1 0.0±2.0, LT2 0.1±2.8 ($p>0.05$) and a small reduction at FINAL -3.5±4.5 ($p=0.07$) was present (Fig. 1).

Discussion

Acute fatigue affects biomechanics only near exhaustion, suggesting relatively stable running patterns until maximal load. These findings highlight important implications for performance optimization and fatigue-related injury prevention.

Images (Optional)

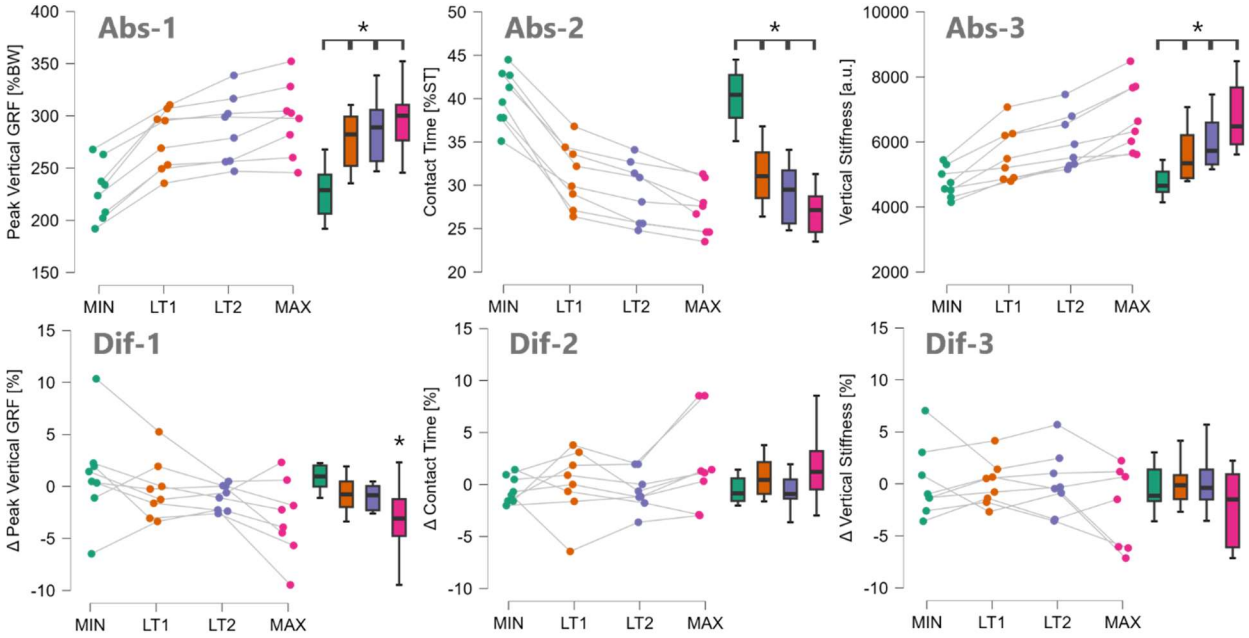

Fig. 1: Absolute between-increment changes in peak vertical GRF (Abs-1), contact time (Abs-2), and vertical stiffness (Abs-3) for the measurement A, and relative within-increment changes (Dif-1, Dif-2, Dif-3) for the increments (MIN, LT1, LT2, MAX) in well-trained runners. Significant differences are indicated: $p<.05$*

Assessment of Achilles Tendon Loading During Outdoor Running Using a Novel Wearable System

Mr. Fisher Adkisson[1], Ms. Lindsay Rehme[1], Ms. Megan Thompson[1], Mr. Brady Huggins[1], Dr. Patrick Corrigan[2], Dr. Alex Reiter[1], Mr Charlie Minard[3], Mr Charlie Minard[4]

[1]Saint Louis University, St. Louis, MO, United States. [2]Cleveland Clinic, Cleveland, Ohio, United States. [3]Saint Louis University, St. Louis, Missouri, United States. [4]St Louis University, St. Louis, missouri, United States

Introduction

Achilles tendon injuries are highly prevalent in athletes. Because clinicians lack the ability to measure tendon loading, they often rely on symptomatology to guide rehabilitation decisions, including running volume and intensity. Shear wave tensiometry has emerged as a noninvasive tool that directly assesses *in vivo* muscle-tendon loading [1]. Recent work has deployed the technology for assessing Achilles tendon loads during real-world walking with favorable results. However, it remains unknown if this technology can characterize loading during running in real-world settings [2]. This preliminary study investigated the capacity of an updated wearable tensiometer system to track changes in Achilles tendon loading during outdoor running.

Methods

Healthy, physically active adults completed 100-meter outdoor walking (1.34 m/s) and running (2.68, 3.35, and 4.47 m/s) trials. Participants donned a custom wearable data acquisition system that measured Achilles tendon loading via tensiometers (Fig 1A) [2]. Using a previously established calibration technique, tendon force was derived from wave speed [2-3]. Data were processed in MATLAB to normalize time for each gait cycle. Preliminary wave speed results were compared with descriptive statistics.

Results

To date, four adults have participated in this study (3/1 males/females, age: 21.8±2.3 years, height: 1.82 ± 0.12 m, mass: 75.6±14.0 kg). Preliminary results for outdoor locomotion show peak wave speed increased with increasing locomotion speed from 36.9±3.6 m/s during walking to 46.8±12.6 m/s during the fastest running speed (Fig 1B). Furthermore, stance phase decreased from ~60% of the gait cycle during walking to ~40% during running (Fig 1B). Recruitment of additional participants and calibration of wave speed to force are ongoing.

Discussion

The wearable system successfully captured expected time series trends and changes in wave speed magnitude, which were also similar to previous work using tensiometry during indoor running [3]. Advances in wearable sensors such as these present an exciting opportunity to track tendon loading during high-dynamic, unobstructed movement in real-world environments, with the goal of improving patient outcomes by providing clinicians with objective ways of progressing rehabilitation.

[3]Section of Vascular Surgery, Cardio Thoracic Vascular Department, Fondazione I.R.C.C.S. Ca’ Granda Ospedale Maggiore Policlinico, Milan, Lombardia, Italy

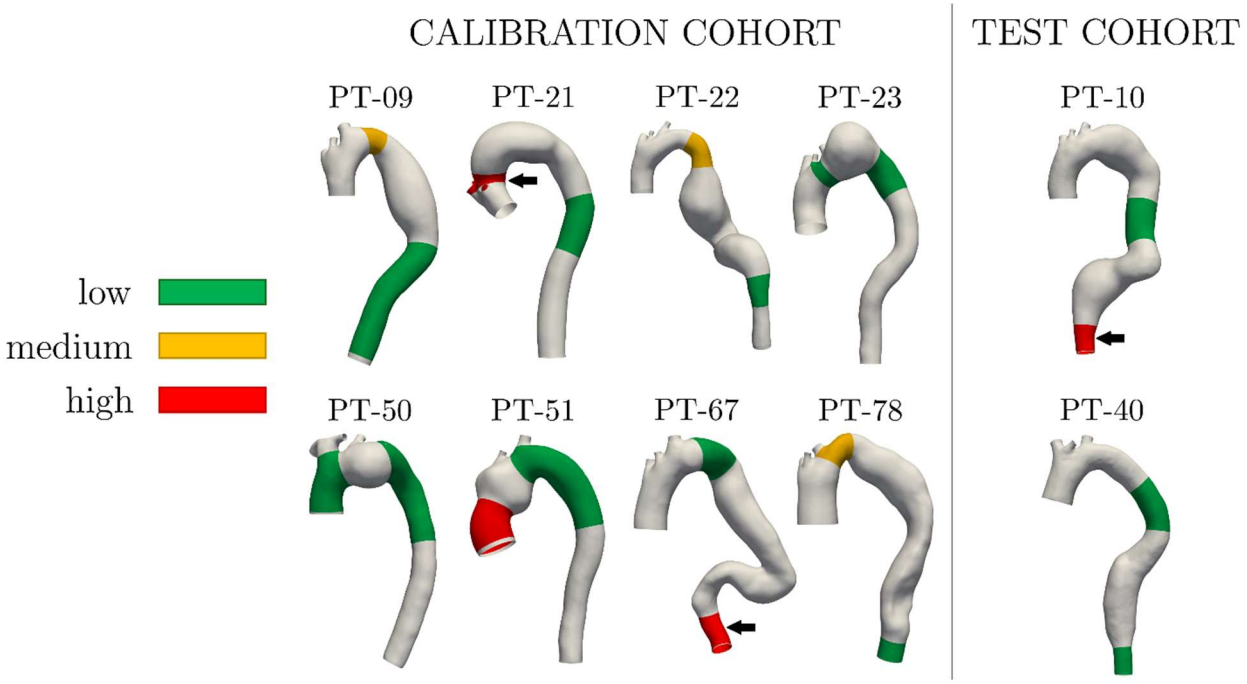
Introduction

To avoid endoleak formation after Thoracic Endovascular Aortic Repair (TEVAR), adequate stent-graft stability must be ensured at the device fixation sites (i.e., landing zones, LZs). In this work, we apply a Fluid-Structure Interaction (FSI) computational framework to ten pre-operative patient-specific Thoracic Aortic Aneurysms (TAA) cases, for which post-TEVAR outcomes are known, to propose a hemodynamic risk factor useful to predict the formation of type I and III endoleaks.

Methods

A cohort of ten patients, who underwent TEVAR for a diagnosis of TAA, was selected for this study and, at the time of the last follow-up, five patients showed an endoleak. Following the pipeline already presented in [1] and using the finite element library life^X [2], we performed an FSI simulation in each pre-operative scenario to compute the Drag Forces (DFs). These were then used to calculate the risk factor R in each LZ: $R = (DF_{\perp}^2 * DF_{||} * p_{tortuosity})/10^6$, where $DF_{\perp}$ and $DF_{||}$ are the DFs’ perpendicular and parallel components to the vessel centerline, and $p_{tortuosity}$ is the endoleak formation probability based on the LZ tortuosity. R was then scaled between 0 and 1 in each LZ. The patients’ cohort was divided into two groups: an eight-patient calibration set, used to associate specific R values with different risk levels, and a two-patient test set, employed to validate the predictive capability of R.

Results



In the calibration set, all the type I endoleak cases occurred in landing zones with $R \geq 0.95$. Black arrows in Figure highlight the LZs where the type I endoleak occurred. For type

III endoleak, LZs with R ≤ 0.30 had no endoleak, those with 0.31 ≤ R ≤ 0.75 showed endoleaks in some cases, and all the LZs with R ≥ 0.76 presented an endoleak.

Discussion

Based on the results obtained (Figure), LZs with R ≤ 0.30 could be considered at low risk, those with 0.31 ≤ R ≤ 0.75 at medium risk, and those with R ≥ 0.76 at high risk. When we applied this classification to the test cohort, the patients follow-up outcomes were correctly predicted.

Onset and Nature of Flow Instabilities in Cerebral Venous Diseases

Ms. Rojin Anbarafshan[1], Dr. David A. Steinman[1,2]

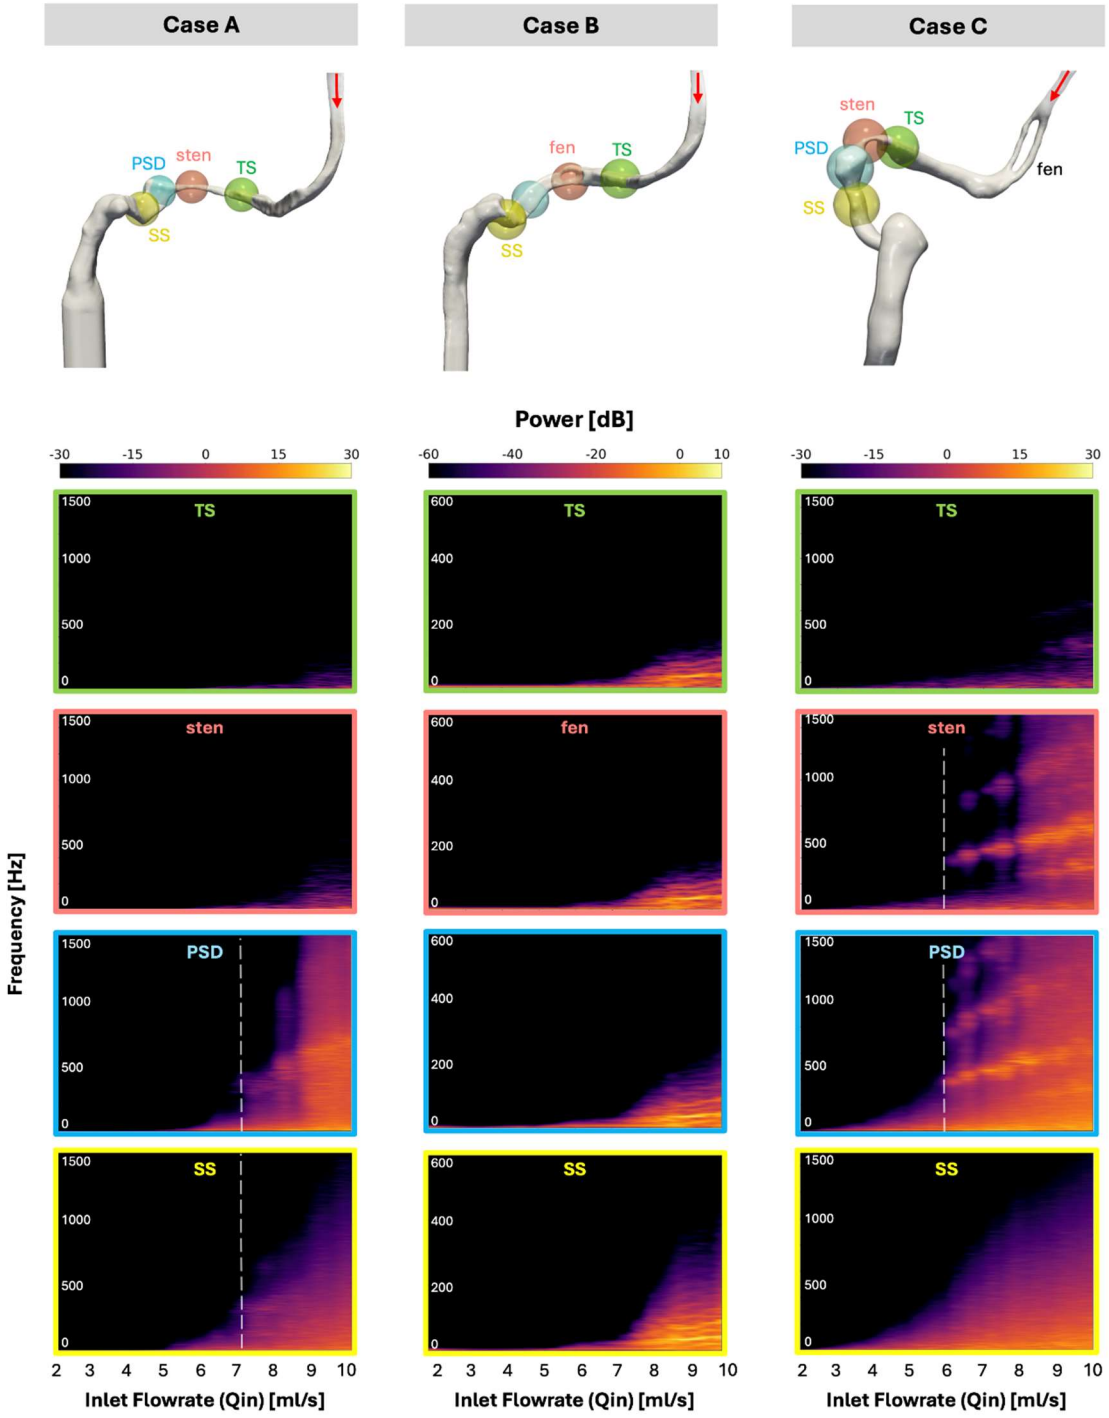
[1]Department of Mechanical Engineering, University of Toronto, Toronto, Ontario, Canada. [2]Institute of Biomedical Engineering, University of Toronto, Toronto, Ontario, Canada

Introduction

Morphological abnormalities in cerebral venous sinuses are strongly implicated in disorders like pulsatile tinnitus (PT). Recent CFD studies have demonstrated presence of high-frequency, turbulent-like flow instabilities plausibly linked to PT sounds; however, their onset mechanisms and fluid mechanical nature remain poorly characterized, and hampered by a lack of patient-specific flowrates. Here we aimed to systematically investigate the emergence and evolution of these flow instabilities and associated sounds as a function of inlet flowrate.

Methods

Three patient-specific PT anatomies with transverse sinus (TS) stenosis, previously studied under pulsatile conditions, were simulated under linearly increasing inlet flowrate (Qin) ramped up through a physiologically plausible range of 2-10 ml/s. Fluid mechanics were inspected using velocity isosurfaces, streamlines, and Q-criterion to identify vortical structures and instabilities. Time-resolved spectral power index (SPI) and spectrograms of wall pressure fluctuations were used as first-order proxies of flow-induced sound.



Results

In cases A and C, high-frequency vortical flow instabilities emerged at or distal to the stenosis at roughly 5 and 3 ml/s respectively. Spectrograms revealed onset of pseudo-acoustic activity at roughly 7 and 6 ml/s (dashed lines in figure), with discrete harmonic bands at the post-stenotic dilatation (PSD) indicative of periodic vortex–wall interactions, and more broadband, turbulent-like flow downstream in the sigmoid sinus (SS). Case B, which has a fenestration (fen) instead of a true stenosis, generated only weak, low-frequency spectral content even at highest Qin (note different frequency range and dB scales in figure).

Discussion

Strong flow instabilities near auditory structures can manifest as either or both narrowband and broadband characteristics, consistent with the disparate nature of PT sounds that have been recorded. The relationship between Qin and both flow instability and sound generation is strongly nonlinear, where modest changes (~10%) in inflow in the physiological range can shift the system to different flow and acoustic signatures. This is consistent with postural and diurnal variations in PT sounds reported by patients, and highlights the need for patient-specific vs. generic inflow information—potentially via reduced-order modeling of the cerebral venous network—to pinpoint the fluid dynamic sources of sound production, especially when multiple anomalies might be present.

Ultrasound-Based Fluid Structure Interaction Modelling of Diseased Carotid Arteries

Ir. Lotte Piek[1,2], Ir. Joerik de Ruijter[1], Prof. Dr. Marc van Sambeek[2], Prof. Dr. Ir. Richard Lopata[1]

[1]Eindhoven University of Technology, Eindhoven, Noord-Brabant, Netherlands. [2]Catharina Hospital, Eindhoven, Noord-Brabant, Netherlands

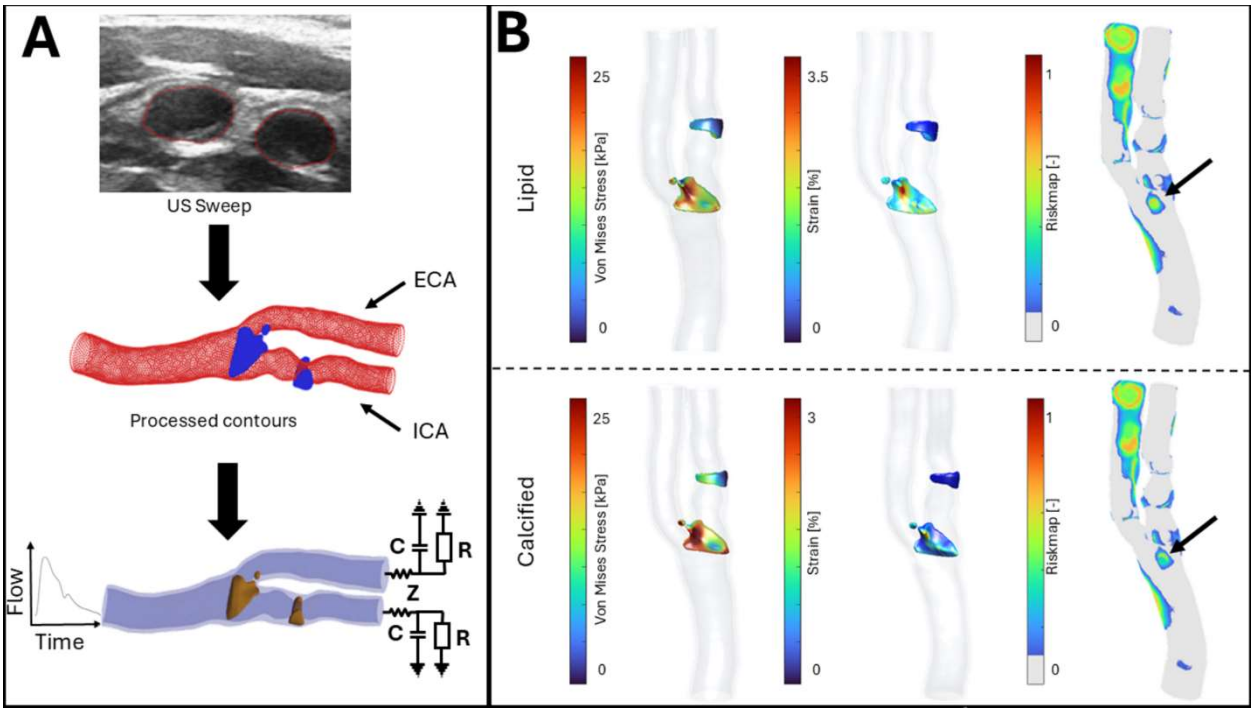
Introduction

Carotid artery disease poses significant risks such as stroke and transient ischemic attacks. Current interventions are primarily based on diameter measurements. There is a need for patient-specific computational models to support clinical decision-making. Ultrasound (US) offers a cost-effective, rapid, and safe solution for geometry assessment as basis for such biomechanical models. This study presents a framework to aid personalized treatment strategies through the use of US-informed fluid structure interaction models for patient-specific geometries, making it suitable for diagnostic and monitoring in subsequent patient studies.

Methods

To obtain the geometries with sufficient resolution, ultrasound scans were acquired using manual sweeps (N=5). Data were segmented automatically using our in-house method. The resulting contours were smoothed (Fig A).Inlet conditions were set using a clinically measured velocity profile, while distal vasculature was represented by Windkessel models.The wall was modeled as a Neo-Hookean material (shear modulus: 250 kPa), chosen for its suitability for the pressure range given. Plaques were also modeled as Neo-Hookean solids, with shear moduli of 50 kPa for lipid-rich regions and 1.3 MPa for calcified regions.

Results



Fluid-structure interaction (FSI) simulations revealed distinct structural and hemodynamic behaviors for lipid- and calcified plaques (Fig B). Lipid plaques exhibited lower von Mises stress but higher strain, indicating greater compliance and deformation under pulsatile loading. Calcified plaques showed markedly higher stress and minimal strain, confirming their rigidity. The fluid-derived risk map highlighted disturbed flow near plaque shoulders

for both cases, with the largest local differences occurring at the most prominent plaque (arrows in Figure B). Overall risk map differences between plaque types were minor.

Discussion

The minor differences in risk maps suggest that flow-based metrics alone, even when derived from FSI, may not fully capture plaque vulnerability. Structural metrics such as stress and strain provide critical complementary information, underscoring the value of combining fluid and structural analysis.By integrating patient-specific ultrasound-based geometries with FSI, this approach enables simultaneous evaluation of wall mechanics and flow-derived risk factors in a clinically feasible workflow. Such combined insights could improve stratification beyond diameter or flow-based criteria, supporting personalized treatment planning

A Proper Orthogonal Decomposition-Based Approach to Expedite Transient Clinical-Use CFD in Coronary Arteries

Mr. Girolamo Mastronuzzi MSc[1], Dr. Maurizio Lodi Rizzini PhD[1], Prof. Diego Gallo PhD[1], Dr. Valentina Mazzi PhD[1], Mrs. Bianca Griffo MSc[1], Prof. Claudio Chiastra PhD[1], MD. Alessandro Candreva PhD[2], MD. Carlos Collet PhD[3,4,5], Prof. Umberto Morbiducci PhD[1]

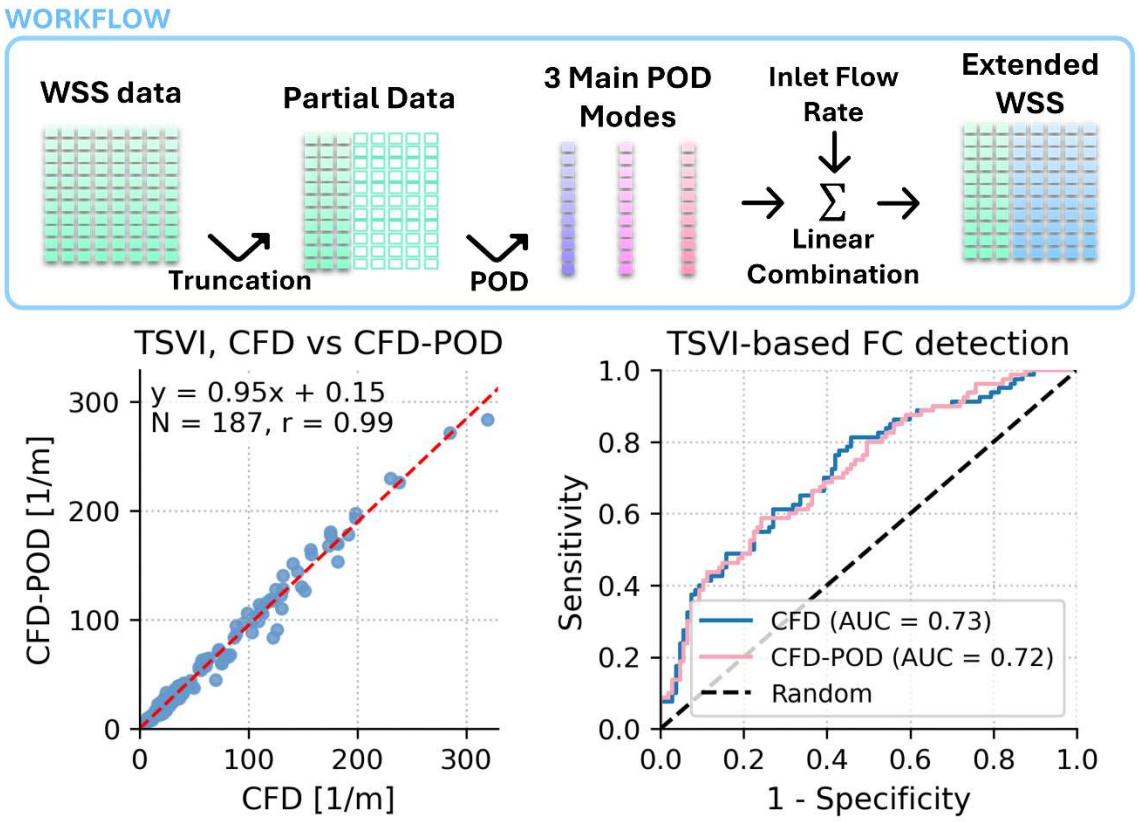
[5]Clinical Trial Center, Cardiovascular Research Foundation, New York, NY, United States

Introduction

Emerging evidence shows that wall shear stress (WSS)–derived quantities can help identify/predict coronary disease [1] and outcome [2]. As WSS cannot be measured directly, personalized in silico models are required, but transient Computational Fluid Dynamics (CFD) simulations remain computationally expensive within a clinical framework. This study introduces an approach based on Proper Orthogonal Decomposition (POD) that reconstructs full transient hemodynamics from partial CFD data, markedly reducing computational cost and supporting clinical translation.

Methods

Three-dimensional geometries of mildly stenosed coronary arteries were reconstructed from coronary angiography. The dataset originated from a clinically adjudicated cohort of 80 patients and comprised 80 lesions culprit of future myocardial infarction (MI) and 107 non-culprit lesions [2]. Transient CFD simulations were carried out on the reconstructed geometries. For each case, instantaneous WSS data over a hemodynamically representative window (22%) of the cardiac cycle were extracted and decomposed using POD. The three main POD modes (capturing >99% of variability) were linearly combined using the inlet flow rate waveform and its first and second derivatives, enabling WSS reconstruction over the entire cardiac cycle. Accuracy was assessed through lesion-averaged, clinically relevant WSS quantities, including time-averaged WSS (TAWSS) and the Topological Shear Variation Index (TSVI), the latter capturing topology-aware WSS features [1]. The prediction capability for future MI of TSVI from CFD and CFD-POD was then evaluated in terms of area under the curve (AUC) and compared.



Results

CFD-POD reconstruction of cycle-averaged WSS-based quantities required ~1s, yielding a computational cost reduction of ~78% with respect to traditional CFD. The reconstructed TAWSS and TSVI showed a remarkable proportional relationship with quantities calculated from CFD ($r > 0.99$). When predicting future MI, TSVI from CFD-POD achieved identical performance as traditional CFD (AUC=0.72, $p<0.0001$ vs. 0.73, $p<0.0001$), confirming preservation of prediction power.

Discussion

The proposed POD-based framework accurately reconstructs WSS fields while markedly reducing computational cost. Its agreement with CFD demonstrates robustness and suitability for efficient characterization of coronary hemodynamics. These findings support integration of accelerated WSS-based risk assessment into routine practice, enabling broader adoption of personalized, simulation-driven diagnostics.

OA83-01

Biofidelic Foot Models for *In Vitro* Gait Simulation Must Include a Compliant Plantar Surface

Dr Antony Crossman, Dr Angela Kedgley

Imperial College London, London, Greater London, United Kingdom

Introduction

In vitro gait simulation is used in the development of surgical methods and implant designs. Although the research field is almost thirty years old [1], control methods have remained broadly the same. Previous systems have applied pre-calculated average muscle forces to specimens, leaving kinematics unconstrained. One reason for the lack of progression may be the cost and ethical considerations of testing new methods on cadaveric specimens. Therefore, a multi-segment foot and ankle model that replicates joint kinematics and enables the application of muscle forces, with anatomically accurate moment arms, would benefit the gait simulation community. The hypothesis was that such a model must include compliance on the plantar surface for accurate vertical ground reaction force (vGRF) control.

Methods

A five-segment, nine-tendon, multi-articulated foot and ankle model was designed and manufactured (Figure 1a). Segments were 3D printed with PLA plastic (80% infill), totalling a weight approximately that of an average 75kg male's foot [2]. Tendons were represented by steel wires running through nylon-coated brake cable sheaths. A second model incorporated a 10mm TPU compressible heel (30% infill).

Both models were tested by simulating 10 repetitions of the stance phase of gait (vGRF scaled to one eighth of in vivo). Accuracy and repeatability were defined as mean kinetic and kinematic errors, and mean standard deviations between trials, respectively.

Results

The rigid heel model achieved vGRF accuracy of 37.5N ± 20.7N, with a repeatability of 14.0N ± 7.1N (Figure 1b). The soft heel improved the kinetic accuracy to 7.7N ± 4.8N, with a repeatability of 3.7N ± 1.5N. The soft heel also improved kinematic accuracy by 36% across all controlled joints.

Discussion

Introducing compliance into a foot and ankle model, to test in vitro simulation methods, improved load acceptance at the beginning of stance. Without this, contact of the foot with the ground resulted in a sharp increase in vGRF, which caused instability within the control system. The instability propagated throughout the remainder of the simulation as the controller was never able to recover the accuracy.

Construct Validity of a Novel Arthrometer-Based First Ray Relative Mobility Index: A Cadaveric Biomechanical Study

PD Dr Florent Moissenet[1,2], Dr Mickaël Chollet[2], Mr Quentin Praz[2], Mr Spyridon Schoinas[2], Dr Alberto Bailez[3], Dr Antoine Acker[4], PD Dr Mathieu Assal[4], Pr Stéphane Armand[2,1]

[1]Geneva University Hospitals, Geneva, Geneva, Switzerland. [2]University of Geneva, Geneva, Geneva, Switzerland. [3]Clínica Corachan, Barcelona, Catalonia, Spain. [4]Foot and Ankle Surgery Centre, Centre Assal, Geneva, Geneva, Switzerland

Introduction

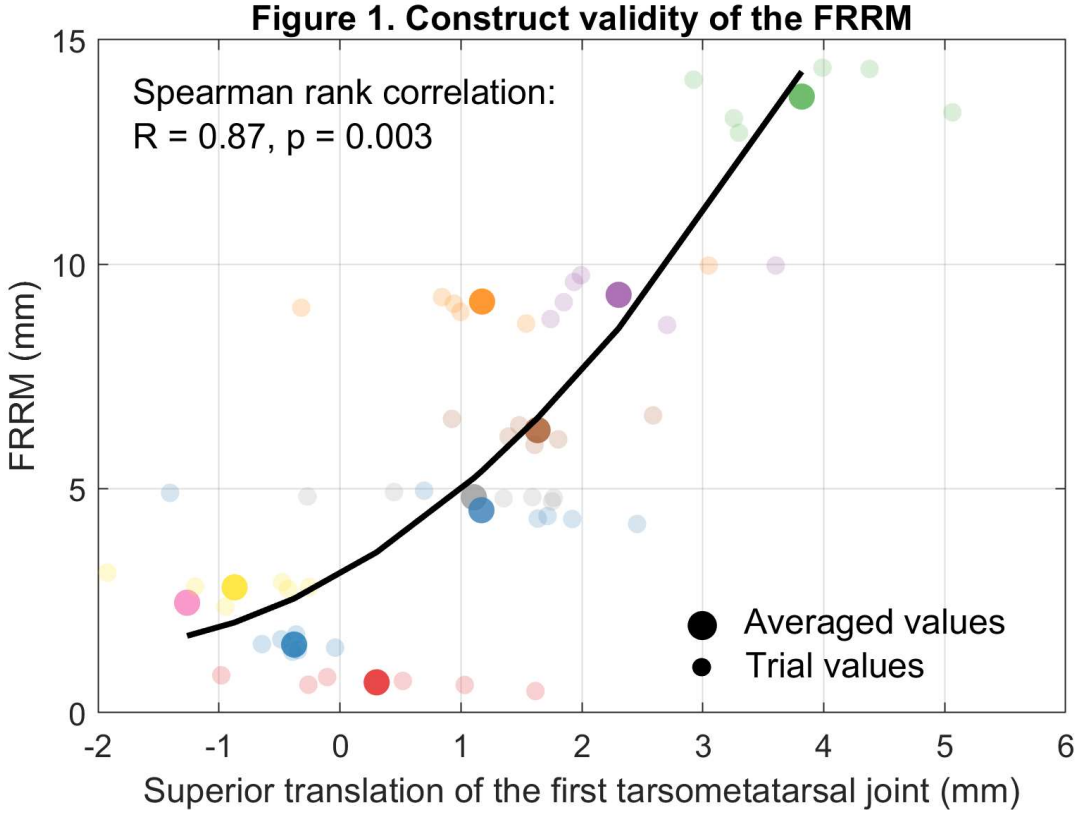
First ray hypermobility contributes to several forefoot disorders and is a key mechanical factor in hallux valgus development. Clinical assessment remains largely subjective, relying on manual tests of absolute first ray mobility that poorly capture the functional loading behaviour. A new automated arthrometer quantifies an alternative metric, the first ray relative mobility (FRRM), by comparing the first ray displacement to that of the lesser metatarsals under equal loads [1]. This study evaluated its construct validity against the superior translation of the first tarsometatarsal joint, the principal biomechanical marker of the first ray instability [2].

Methods

Ten fresh-frozen lower limbs without major degeneration or prior surgery were instrumented for controlled loading. The Achilles, tibialis anterior, tibialis posterior, and peroneus longus tendons were attached to a loading system applying physiologic forces, with additional tibial loading to maintain heel contact. The arthrometer applied equal loads (10-50 N, 5 N increments) to the first and lesser metatarsal columns. The FRRM was defined as the change in vertical displacement difference between these columns from 10 to 50 N. The superior translation of the first tarsometatarsal joint was measured using 3D motion capture with intracortical pins. After preconditioning, averaged data from six trials were analysed using Spearman correlations with bootstrap intervals (10,000 resamples) and leave-one-out robustness testing.

Results

Construct validity was very strong, with a significant correlation between the FRRM and the superior translation of the first tarsometatarsal joint (Spearman r = 0.87, 95% CI [0.40-



1.00], p = 0.003; Fig. 1). The association was non-linear and remained highly stable across specimens in leave-one-out testing, with variations in r below 0.10 (range 0.82-0.92).

Discussion

The FRRM showed a very strong construct validity, indicating that the relative first ray excursion closely reflects the superior translation of the first tarsometatarsal joint under physiological loading. These results support FRRM as a meaningful biomechanical measure of forefoot instability and a potential alternative to absolute displacement metrics. Confirmation in larger in vivo cohorts is warranted.

A Combined MRI and Inverse Finite Element Analysis (iFEA) Workflow for Subject-Specific Characterisation of Meniscus Material Properties *In Situ*

Dr Sherif Zantiba, Dr Nagitha V.N.Wijayathunga@leeds.ac.uk, Dr Marlène Mengoni, Prof. Ruth Wilcox

University of Leeds, Leeds, England, United Kingdom

Introduction

Over 375 million people worldwide are afflicted by knee OA. The meniscus is a critical load-bearing structure, and its damage can cause or accelerate knee OA. Understanding its mechanical behaviour is essential for developing effective treatments. Traditional mechanical testing is destructive and fails to capture the tissue's functional behaviour while computational models are limited by a lack of subject-specific, *in-situ* material properties. This study aimed to develop and validate a novel workflow combining MR-imaging of *in-vitro* loaded joints with iFEA to characterise the *in-situ* meniscus material properties.

Methods

A novel, calibrated MRI-compatible loading rig was developed (*Figure-1*) to apply physiological compressive loads to in-vitro knee joints, uniquely permitting tibial axial rotation to accommodate the screw-home mechanism.

Three porcine knee joints were imaged (Siemens 3T Vida) under stepped compressive loads (to 1500N) in the neutral position. A new kinematic measurement technique was developed to quantify meniscus radial distance from the MR images, using the tibial eminence as a stable reference point to account for tibial rotation.

Subject-specific FE models were generated from specimen MR and CT images. A preliminary sensitivity study was performed to identify which transverse isotropic material parameters most influenced meniscus radial movement. An iFEA workflow, driven by a particle swarm optimiser, then calibrated these candidate parameters by minimising the error between FE-predicted and MRI-measured radial distances in the neutral configuration.

Results

The sensitivity study confirmed fibre, in-plane, and shear stiffness values as the dominant parameters influencing radial movement. The subsequent iFEA calibration successfully identified these properties for all samples. The in-plane stiffness was consistently found to be 20 MPa, while fibre stiffness ranged from 161–250 MPa and shear from 13–30 MPa. The optimised models achieved a good fit, with a normalised root mean squared error between 7% and 11%.

Discussion

A novel, *in-vitro* methodology for characterising subject-specific, *in-situ* meniscus material properties was successfully developed and applied to derive meniscus properties from axially-loaded experiments. This workflow provides a robust foundation for future patient-specific stratification and the pre-clinical assessment of meniscal replacement devices.

In Vitro Biomechanical Assessment of Nucleus Augmentation for the Treatment of Degenerated Intervertebral Discs

Dr Andrew Dixon PhD, Dr James Warren PhD, Dr Nagitha Wijayathunga PhD, Dr Marlene Mengoni PhD, Prof Ruth Wilcox PhD

University of Leeds, Leeds, West Yorkshire, United Kingdom

Introduction

Nucleus augmentation is an emerging intervention for intervertebral disc (IVD) degeneration. Previous nucleus replacement procedures have shown poor outcomes clinically due to device expulsion or fragmentation. One challenge in the development of successful interventions is the lack of effective *in-vitro* biomechanical models. The aim of this study was to develop and apply cyclic loading testing methods to evaluate a nucleus augmentation biomaterial.

Methods

A peptide-glycosaminoglycan hybrid hydrogel was developed previously [1]; it self-assembles *in*-situ, allowing delivery down a fine needle to prevent annulus damage. The hydrogel was tested in bovine and human IVDs. The IVDs were imaged and cyclically loaded (loading range dependent on specimen size) in their native state, following artificial degeneration (bovine specimens) and following augmentation with the hydrogel. Specimens were held under load in a fluid bath for 24 hours between each stage to allow hydration equilibrium. Bovine IVDs were first tested to 1000 cycles to optimise the procedure [2]. Tests were then extended to 20000 cycles at either the native, degenerated or treated stage to examine the longer-term performance, using a mathematical model based on the first 1000 cycles to compare between states. Human IVDs were tested in both the native (naturally degenerated) and augmented state to 5000 cycles.

Results

In the bovine specimens tested to 1000 cycles, nucleus augmentation restored bovine IVD height and stiffness to the native levels, which were significantly different to the degenerated levels (Figure-1A inset). After 20,000 cycles, there was no observed hydrogel expulsion in treated IVDs and the stiffness restoration was generally maintained (Figure-1B). In human IVDs, the augmentation increased height and reduced stiffness although the change was more variable, with limited effect on specimens exhibiting calcification (Figure-1C).

Discussion

This in-vitro biomechanical assessment allows early optimisation of nucleus augmentation procedures prior to costly animal or clinical studies. The hydrogel provided sustained stiffness restoration in the bovine model and promising results in the human model, which will help guide patient selection for future clinical studies.

Images (Optional)

Tendon Injury Mechanism and Severity Alter Musculotendon Mechanics in an *ex-Vivo* Rabbit Model

Ms. Kathryn Rex[1], Dr. Joshua Pataky PhD[1], Dr. Meghan Vidt PhD[1,2]

[1]Pennsylvania State University, University Park, Pennsylvania, United States. [2]Penn State College of Medicine, Hershey, Pennsylvania, United States

Introduction

Achilles tendon injuries vary in severity, from partial- to full-thickness tears, and in mechanism, either traumatic or chronic [1]. Musculoskeletal models help quantify how injury variation affects biomechanics, which is unclear *in vivo*. Previous work assumed musculotendon force decreased linearly as injury severity increased [2]. The validity of this assumption is unconfirmed, therefore, this study experimentally defined how injury severity and mechanism influence musculotendon mechanics.

Methods

New Zealand White rabbit Achilles tendons (N=46) were grouped by injury mechanism: uninjured (0%), traumatic, or chronic. Partial tendon transection simulated traumatic injury and mechanical overload simulated chronic injury at 3 severity levels (25%, 50%, 75%). Mechanical testing (MTS 858 Bionix, MTS Systems, MN, USA) occurred immediately post-injury and musculotendon mechanics were calculated [3]. The impact of severity and mechanism were assessed using 1-way ANCOVAs with sex as a covariate and Pearson correlation tests (Kruskal Wallis and Spearman tests for non-parametric data) with $p<0.05$ ($\chi^2<0.05$) considered significant (SAS Institute, NC, USA).

Results

Traumatic yield stress ($\chi^2=0.0014$), maximum force (Fig. 1A), maximum stress ($\chi^2=0.0007$), and cross-sectional area (CSA) ($p=<0.0001$) decreased with increased severity. Stiffness increased ($p=0.0395$), percent relaxation ($p<0.0001$) and yield stress ($p=0.0013$) decreased, and CSA did not change with increased chronic severity. Chronic injuries had greater stiffnesses (25%: $\chi^2=0.025$, 50%: $\chi^2=0.0104$, 75%: $p=0.0237$), lower yield stress (25%: $p=0.0009$, 50%: $\chi^2=0.0039$, 75%: $p=0.0237$), and lower maximum stress (25%: $p=0.0023$, 50%: $p=0.002$, 75%: $\chi^2=0.0062$) than traumatic injuries at those same severities. Maximum force was positively correlated with traumatic CSA but had no correlation to chronic CSA (Fig. 1B).

Discussion

Results revealed that maximum force decreases linearly with increased traumatic injury severity. Chronic injuries impact musculotendon elasticity but not force transmission. Traumatic CSA decreases while chronic CSA is not altered with increased severity. This suggests that structural damage from chronic injury does not impede force transmission like traumatic injury. Findings suggest that tendon compliance and maximum force should be considered when modeling chronic injury. Continued work will evaluate ways to implement injury severity and mechanism into computational models.

Images (Optional)

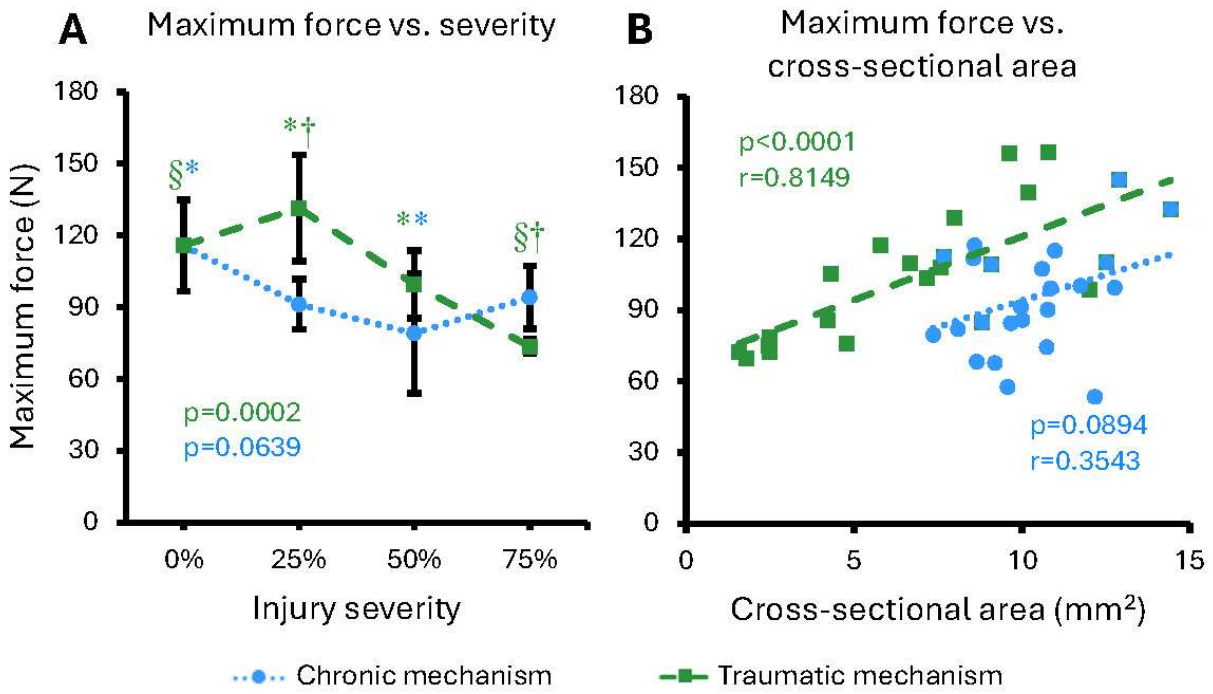

Figure 1: A) Mean maximum force for each severity group. B) Maximum force of each sample by the cross-sectional area measured after injury. Samples that underwent traumatic injury are shown by green squares and samples that underwent chronic injury are shown in blue circles.

Digital Image Correlation for Measuring Strain in the Achilles Tendon During Cyclic Loading

Mr Nisal Jayaneththi, Dr Hans Gray, Prof Peter Lee

The University of Melbourne, Melbourne, Victoria, Australia

Introduction

We aimed to develop a novel method for measuring strains using digital image correlation (DIC) in cadaveric Achilles tendon specimens during a prolonged physiologically representative cyclic loading experiment.

Methods

A specimen comprising the distal half of the calf muscles, the Achilles tendon, and the calcaneus was obtained (Age 85, female). The calcaneus was potted and mounted to the base of a tensile testing machine, and the proximal end of the specimen was held in a custom cryogenic clamp (Fig. 1A).

The specimen was subjected to published loads occurring in daily activities scaled to account for age - jogging (490N at 1.35Hz for 2656 cycles), running (690N at 1.43Hz for 3040 cycles), sprinting (1300N at 2.33Hz for 3536 cycles) and unilateral jumping and landing (640N and 600N at 0.658Hz for 208 cycles).

Two synchronised cameras imaged the tendon, on which a speckle pattern had been applied. A purpose-built programmable module synchronised the cameras with the testing machine and enabled recording predetermined cycles. Every 15th cycle for jogging, 9th cycle for running, 5th cycle for sprinting, and 5th cycle for jumping were recorded (50Hz).

Surface displacements, strains and projection errors were calculated using a DIC software (VIC-3D, correlated solutions, SC, USA). The correlation coefficient was calculated between the displacement of the proximal end of the specimen calculated using DIC, and the displacement of the actuator.

Results

The projection error (0.0291 ± 0.004px) was below the recommended threshold (0.100px) for accurate measurement (Fig. 1B). A total of 424.8GB of data was generated during the experiment. Correlation coefficients between the DIC displacement and the testing

machine displacement for jogging, running, sprinting and jumping were 0.978, 0.986, 0.982 and 0.963, respectively.

Discussion

The developed method could measure tendon displacements using DIC during all loading conditions. The low projection errors and the high correlation for displacements are indicative of acceptable measurement accuracy. The capability to capture data for a sample set of cycles reduced the required storage capacity by 87% compared to capturing every loading cycle. This is of significant importance as it greatly increases the capacity for continuous experimentation.

Images (Optional)

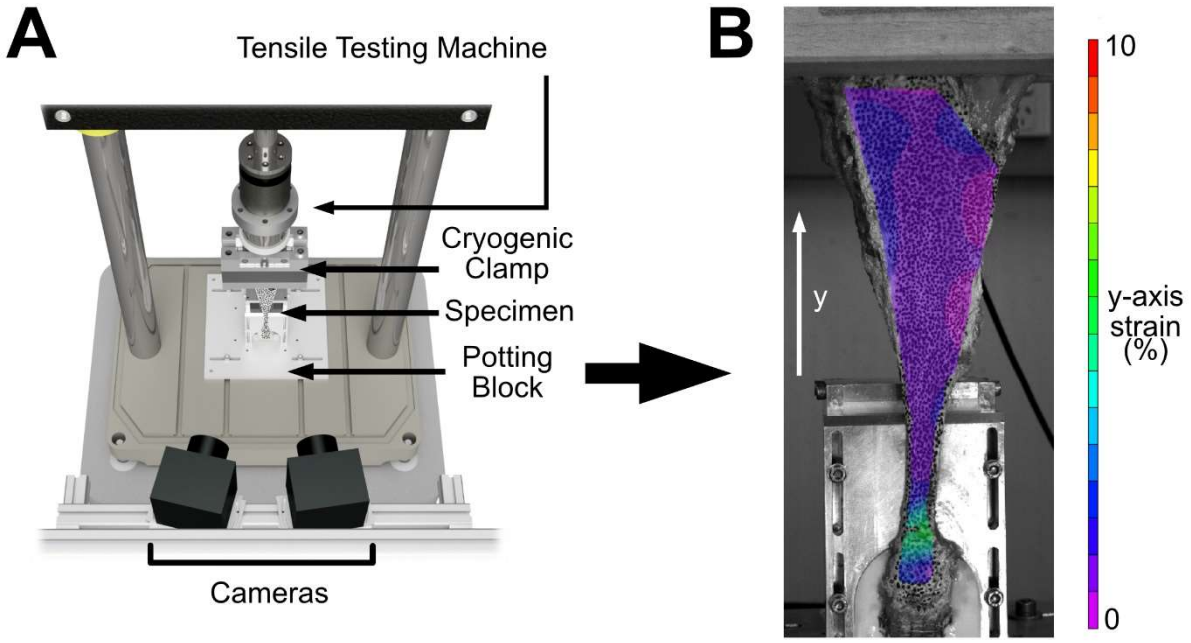

Figure 1 - A) Mechanical testing setup with two cameras mounted on a frame, recording the specimen. The distal end of the specimen is potted and mounted to the base of the testing machine and the proximal end is clamped cryogenically. A black speckle pattern has been applied to the surface of the tendon. B) A strain map along the y axis for the 422nd sprinting cycle generated by the DIC software.

JAX-based High-Speed Simulations of Mitral Valve Transcatheter Edge to Edge Repair

Mr. Kenneth Meyer[1,2], Dr. Michael Sacks[1,2]

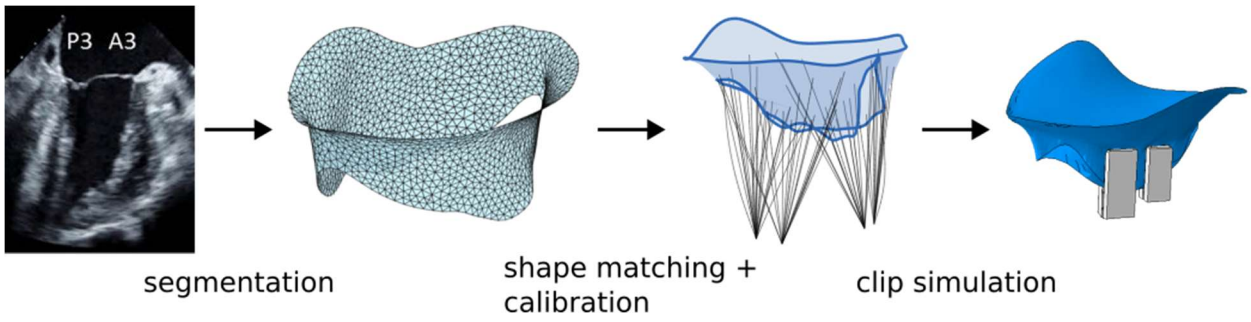
[1]The University of Texas at Austin, Austin, Texas, United States. [2]The Oden Institute for Computational Engineering and Sciences, Austin, Texas, United States

Introduction

Mitral Valve (MV) regurgitation (MR) is a deadly disease affecting 2% of the world. Various MV repair techniques such as transcatheter edge-to-edge repair (TEER) provide minimally-invasive treatments. However, long-term clinical outcomes remain poorly understood. To better understand the post-treatment state and to guide clinicians for optimal methods for MR repair, we have developed a Google JAX-based Finite Element package, CARDIAX-MV, to simulate patient specific TEER procedures. This new platform greatly accelerates simulations through GPU-based parallelization and provides a differentiable framework for determining patient-specific MV mechanical states. Coupled with time-dependent modeling of MV leaflets, we aim to predict patient-specific long-term outcomes to TEER.

Methods

Patient-specific reconstructions of the MV are required for TEER procedure predictions; 3D spline-based discretizations are used to represent MVs. Isogeometric Analysis (IGA) is integrated into CARDIAX-MV via an extraction-based approach. Another major feature of CARDIAX-MV is contact; Incremental Potential Contact provides a robust and high-speed approach for MV closure simulations. To determine patient-specific mechanical states, we compute MV leaflet and chordae tendinae (CT) pre-strains. The adjoint method is used to determine these pre-strains. Lastly, to characterize MV leaflet remodeling caused by medical devices used in TEER procedures, structural and Neural-Network based material models will be tested to elucidate MV leaflet remodeling mechanisms.



Results

Current results have shown that CARDIAX-MV can dramatically accelerate inverse modeling of organ-level function when compared to pipelines that use commercial FE codes (ABAQUS). Speedups of 24x, using 5x more data, were observed [1]. Similar speedups are also being evaluated when applying the same CARDIAX inverse modeling pipelines to MV pre-strain calculations.

Discussion

In this work, we developed a high-speed pipeline that determines patient-specific 3D MV mechanical states with higher fidelity than existing MV modeling pipelines. This will be useful to cardiologists to understand the mechanisms behind in-silico predictions of surgical repair outcomes, and time-dependent MV remodeling will be used to help explain this.

Mechanical Vulnerability of the Hypertensive Marfan Aorta

Mr Gavin Mays BS, MS, Professor Jay Humphrey PhD

Yale University, New Haven, CT, United States

Introduction

Marfan syndrome (MFS) is a hereditary connective tissue disorder that affects multiple tissue systems, notably the proximal thoracic aorta which becomes susceptible to dilatation (aneurysm) and dissection (intramural failure). Mouse models having different induced genetic mutations yield a spectrum of aortic phenotypes from mild to severe. Uncontrolled hypertension is a strong risk factor in patients but has not been studied in detail in the mouse. We report detailed biomechanical and histological evidence of a hypertension-induced increase in disease severity in an otherwise mild MFS phenotype in mice.

Methods

To mimic human risk factors, with IACUC approval we combined a high salt diet (8% NaCl in the chow) with endothelial dysfunction (blocking nitric oxide synthase with L-NAME) to render adult wild-type (WT) and *Fbn1*(*C1041G/+*) MFS mice hypertensive, with systolic blood pressures ~160 mmHg. To assess potential aortic vulnerability, we further exposed sub-sets of mice to BAPN, an inhibitor of the extracellular matrix cross-linker lysyl oxidase. After four weeks, the ascending aorta was excised and subjected to biaxial mechanical testing and histological examination.

Results

The aorta of both the WT and MFS mice evidenced what appeared to be mild hypertensive remodeling, including increases in wall thickness and homeostatic control of wall stress. When further exposed to BAPN, the WT aortas showed modest differences from hypertensive alone whereas ~60% of the MFS mice exhibited aortic dissection with ~50% mortality. Biaxial data revealed a marked decrease in in vivo axial stretch and storage of elastic energy in the dual-treated MFS, but not WT, mice which suggests marked vulnerability of the elastic laminae in the medial layer of the Marfan aorta, which was confirmed histologically. Data similarly revealed a marked structural stiffening in the dual-

treated MFS, but not WT, mice which histology revealed was due in large part to an increased accumulation of adventitial collagen that was likely not functional.

Discussion

The healthy aorta exhibits a remarkable resilience to a hypertensive-challenge whereas the Marfan aorta contains an underlying vulnerability within the medial layer that is exacerbated in hypertension. Compensatory collagen deposition and cross-linking can offset this vulnerability in part and should be a target for adjuvant therapies.

Evaluation of the Role of Macrostructure in the Anisotropy of the Atrial Appendage Tissue

PhD student Kundry Reibel[1], PhD Baptiste Pierrat[1], Prof Stéphane Avril[1], Mrs Claudia Cino[2], M Nicolas Curt[1], PhD Fanette Chassagne[1]

[1]Mines Saint-Etienne, INSERM, U1059 Sainbiose, Saint-Etienne, Auvergne-Rhône-Alpes, France. [2]Università degli Studi di Palermo, Palermo, Sicilia, Italy

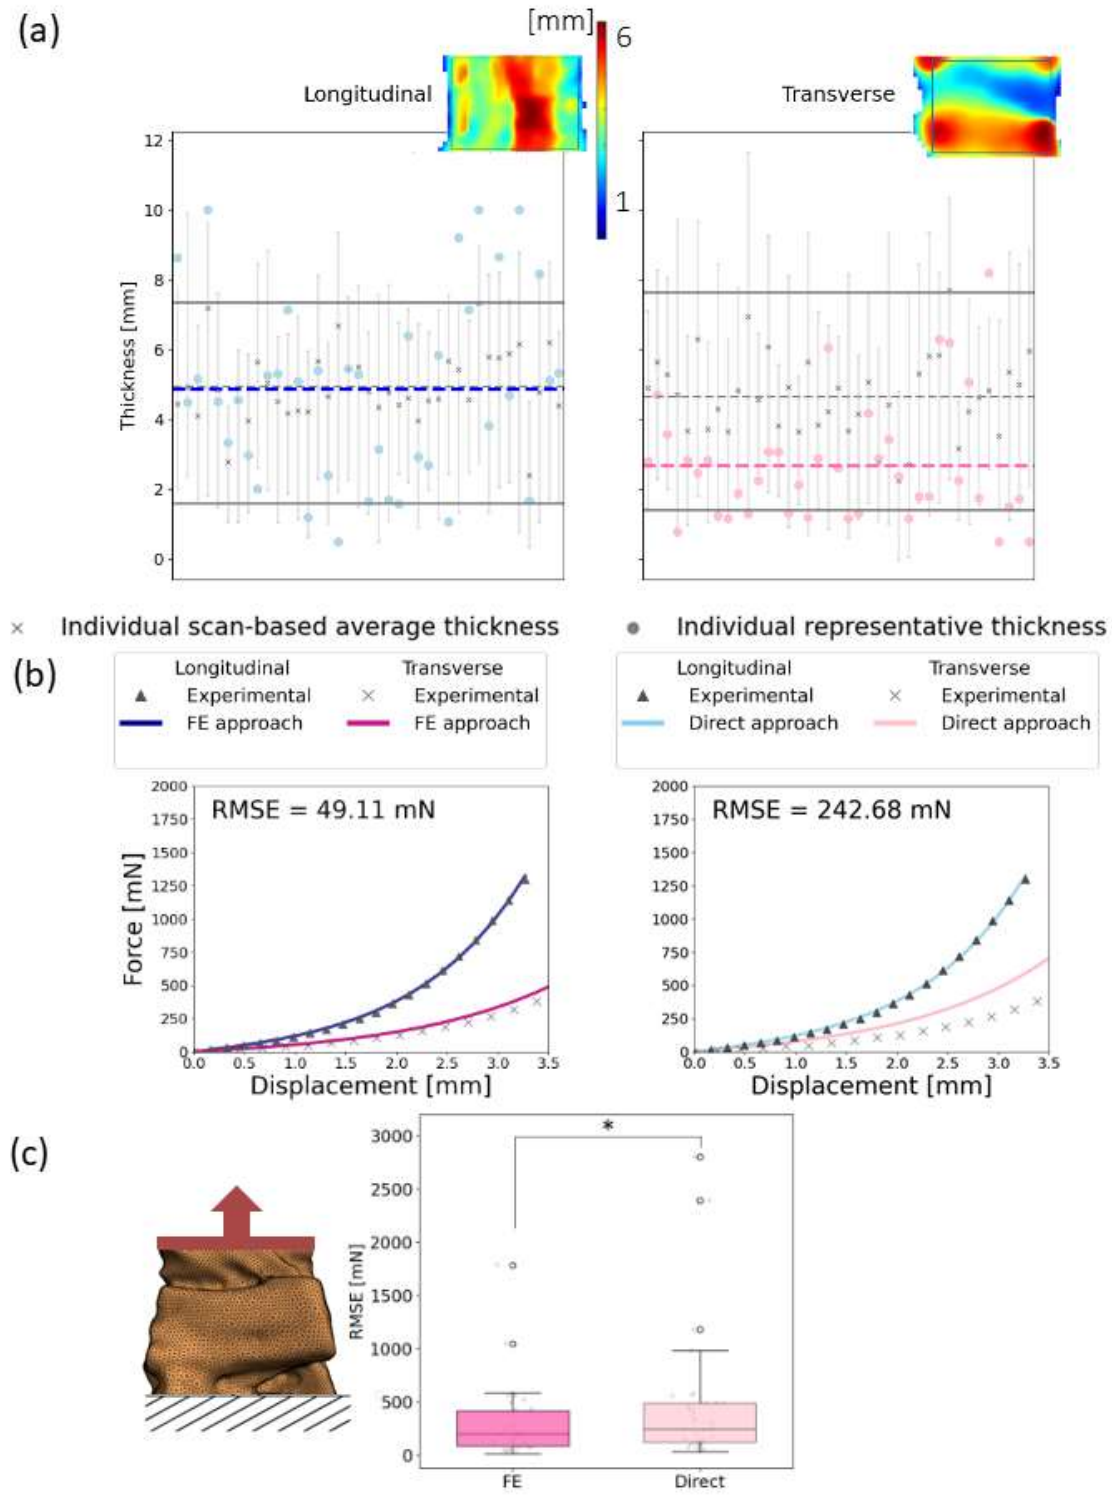
Introduction

Atrial appendage mechanics remains poorly understood, and its highly trabeculated macro-structure produces strong and spatially variable thickness. To clarify the role of macro-structure in the mechanical response, this study combines full-field 3D thickness mapping, uniaxial testing, and modeling to evaluate how structural variability influences apparent anisotropy in atrial appendage tissue.

Methods

Porcine atrial appendages (n=40) were dissected to obtain paired longitudinal and transverse rectangular specimens, tested under uniaxial loading. Dimensions were first measured with a caliper, and samples were then scanned using high-resolution 3D imaging. The scans were processed in MATLAB to generate full-field thickness maps. Mechanical behavior was modeled using an isotropic Veronda–Westmann law through two approaches: (1) a direct analytical model using the scan-derived mean thickness, and (2) an inverse finite element (FE) model incorporating each specimen's full 3D geometry. First, material parameters were identified individually. Secondly, longitudinal parameters were transferred without re-fitting to predict the transverse response. Finally, effective thicknesses were determined by fixing these parameters and optimizing thickness to best match the experimental data.

Results



Thickness maps revealed pronounced intra- and inter-sample heterogeneity, with calipers underestimating scan-based average thickness by ~25%. All specimens showed nonlinear behavior with substantial variability. Identified C1 values were consistently higher in the longitudinal direction. When longitudinal parameters were used to predict the transverse response, FE models yielded lower error than the direct analytical approach ($p<0.03$), demonstrating that geometry improves predictive accuracy. However, errors in prediction

were non-null, indicating that geometry alone cannot fully account for the mechanical response. Effective thicknesses in transverse specimens often approached the minimal local thickness, whereas effective thicknesses for longitudinal samples were larger and more variable, reflecting different engagement of trabecular structures under loading.

Discussion

These results show that geometric heterogeneity strongly influences atrial appendage mechanics and contributes to apparent anisotropy. Nonetheless, residual discrepancies between FE predictions and experiments indicate additional contributions from meso- and microstructural organization, such as fiber orientation and layered composition. Preliminary micro-CT imaging supports this interpretation by revealing abrupt structural transitions. Overall, the study highlights the need for geometry-informed constitutive modeling to accurately describe the mechanics of these highly heterogeneous cardiac tissues.

Images (Optional)

(a) Example thickness maps for longitudinal (left) and transverse (right). For each direction, scan-based average thickness values (gray crosses) are compared with the representative thicknesses (blue and pink markers). Gray lines show mean minimum and maximum scan-based thicknesses. Blue and pink dashed lines denote the representative longitudinal and transverse model thicknesses. **(b)** Representative transverse prediction curves for scan-based (left) and direct (right) approaches corresponding to the lowest FE RMSE. **(c)** RMSE distributions for both approaches.

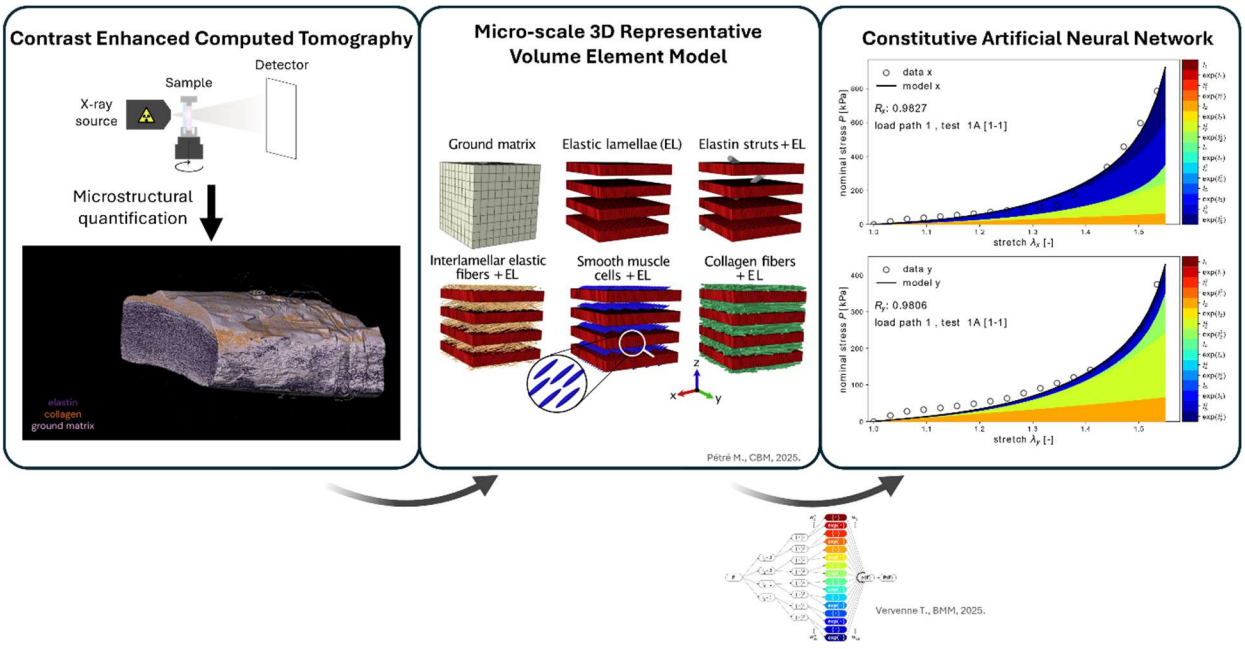
[5]Prometheus, Division of Skeletal Tissue Engineering, KU Leuven, Leuven, Belgium. [6]FIBEr, KU Leuven Core Facility for Biomechanical Experimentation, Leuven, Belgium

Introduction

Accurate modeling of arterial mechanics is critical for understanding cardiovascular pathologies. Traditional phenomenological constitutive models, such as the Gasser-Ogden-Holzapfel model, rely on fitting parameters to macroscopic mechanical data. While effective for fitting, these models often impose a fixed functional form that may not capture the complex behavior of heterogeneous tissues. We propose a workflow that derives governing constitutive behavior from microstructural data obtained via contrast-enhanced microfocus computed tomography (CECT), using Constitutive Artificial Neural Networks (CANNs) [1] to learn the specific mechanical response generated by microstructural simulations.

Methods

We present a framework integrating CECT-informed Representative Volume Elements (RVEs) [2] and CANNs. Microstructural features of the medial porcine descending thoracic aorta, such as collagen and elastic lamellae volume fractions, are quantified using CECT. These metrics guide the generation of 3D finite element RVEs that incorporate elastic lamellae, elastin fibers, collagen fibers, and smooth muscle cells. The RVEs undergo virtual biaxial tensile testing to generate stress-stretch datasets. These datasets are subsequently used to train a CANN. In this framework, the CANN acts as a surrogate, learning the complex stress-stretch behavior outputted by the RVE without relying on phenomenological formulas.



Results

RVE simulations revealed that microstructural variations significantly modulated the macroscopic mechanical response. The trained CANNs successfully captured these complex anisotropic behaviors, reproducing the RVE-derived stress-stretch curves with high fidelity where traditional fixed-form models struggle. Furthermore, the application to RVEs adapted to infrarenal arteries highlighted distinct mechanical phenotypes. Therefore, the framework can be generalized for RVEs that are adapted to varying microstructural environments, such as with different species or arteries.

Discussion

This study establishes a direct link between microstructure and computational mechanics. By training CANNs on RVE-derived data, we create constitutive models that are inherently faithful to the underlying microstructure. This approach allows us to easily vary the microstructural composition of the arterial wall in the RVE stage and observe changes on the tissue-scale via the trained CANN, offering a scalable method to generate high-fidelity material models for finite element simulations of diverse arterial diseases.

Effects of Proactive and Reactive Perturbations on Foot Placement Modulation in People With Chronic Stroke

Dr. Jesse Dean PhD

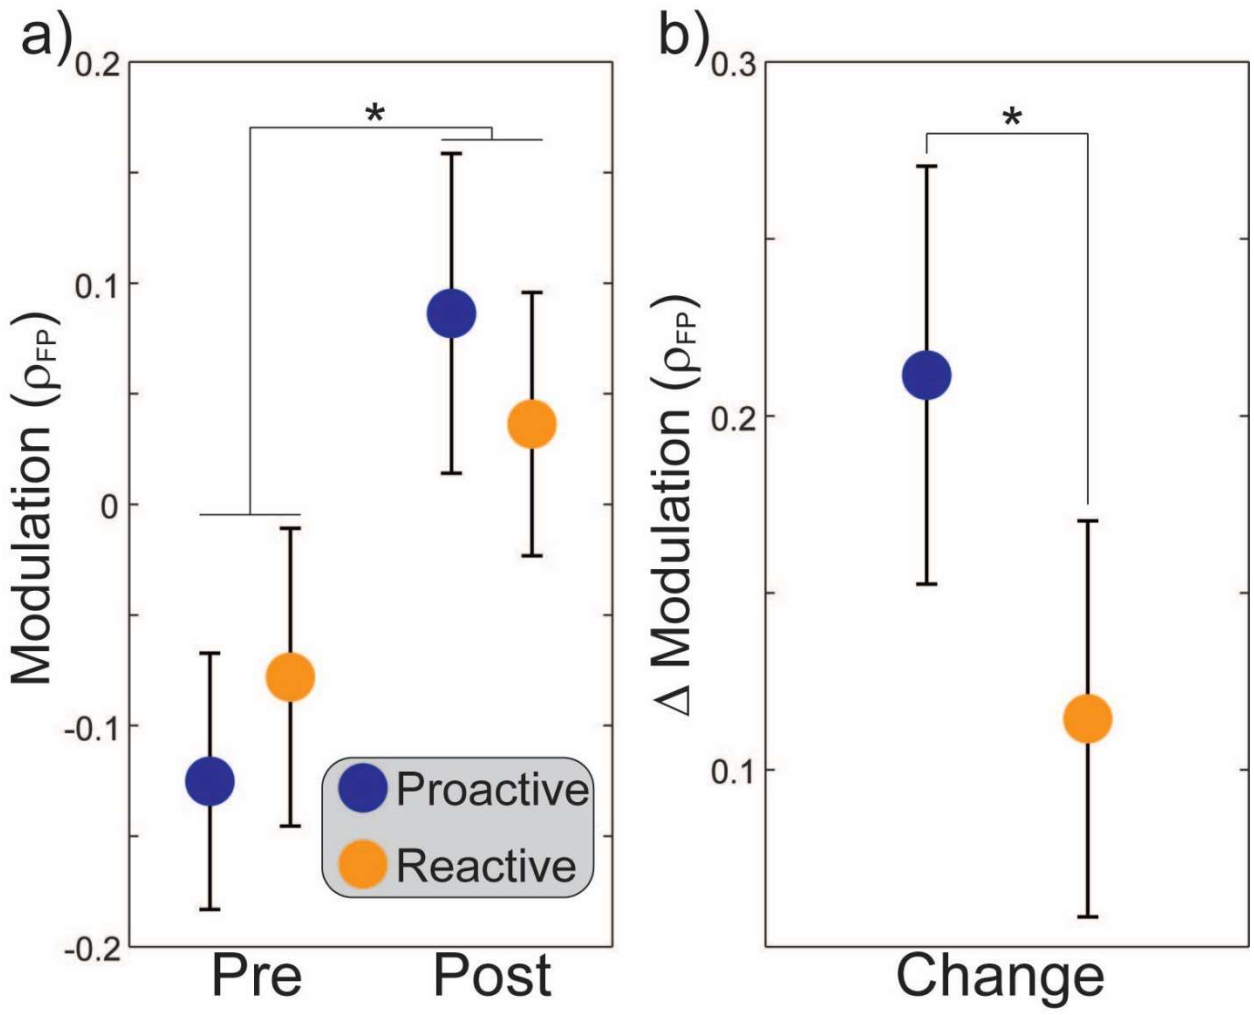
Medical University of South Carolina, Charleston, SC, United States

Introduction

Mediolateral foot placement modulation is an important strategy for ensuring walking balance [1], but is disrupted in many people with chronic stroke (PwCS). Such foot placement modulation deficits are associated with poorer clinical balance performance and increased falls [2]. Foot placement modulation can be strengthened using appropriately applied swing leg perturbations, with sustained effects following repeated exposure [3]. By pushing the swing leg medially when lateral foot placement is warranted (and vice-versa), individuals appear able to relearn this proactive balance strategy. The objective of this randomized controlled trial was to compare the effects of Proactive perturbations with simpler Reactive perturbations, in terms of post-stroke foot placement modulation.

Methods

PwCS were randomly assigned to a Proactive perturbation group (n=43) or a Reactive perturbation group (n=43). Both interventions lasted 8-weeks, with 2 training sessions per week, and up to 30-minutes per session of perturbed walking. As before, the Proactive group experienced mechanics-dependent weak mediolateral pushes to their legs. The Reactive perturbation group experienced mediolateral trunk forces every ~15 seconds, with timing and direction randomized. These forces progressively increased from 3% to 15% of body weight. Our primary analyses focused on the partial correlation between mediolateral pelvis displacement and foot placement, a measure of foot placement modulation [2]. We used a linear mixed model to assess the effects on foot placement modulation of Time (pre- vs. post- intervention), Group (Proactive vs. Reactive) and Stepping Leg (Paretic vs. Non-paretic), as well as their interactions.



Results

From before to after the intervention, foot placement modulation increased significantly (Fig. 1a; Time, $p<0.001$). However, this increase was significantly larger in the Proactive than the Reactive group (Fig. 1b; Time X group, $p=0.01$).

Discussion

The present results demonstrate that traditional Reactive perturbation methods – while useful – are not as effective as a more specifically targeted Proactive approach in terms of strengthening foot placement modulation. Future analyses will investigate whether similar unique benefits of Proactive perturbations are present in other balance strategies, as well as real-world falls.

OA85-02

Neuromuscular Fatigue-Integrated Balance Training Does Not Improve Fatigue Resilience of Dynamic Postural Control in Individuals With Chronic Ankle Instability: Double-Blinded Randomized Controlled Trials

PhD Student Suji Yoon[1], Professor Hyunsoo Kim[2], PhD Student Kyungeon Kim[1], PhD Student Eun Ji Hong[1], PhD Student Kyoung Uk Oh[1], Postdoctoral Researcher Hyung Gyu Jeon[3], Professor Sae Yong Lee[1,4]

[1]Department of Physical Education, Yonsei University, Seoul, N/A, Korea, Republic of. [2]Department of Kinesiology, West Chester University, West Chester, Pennsylvania (PA), United States. [3]Department of Sports Culture, Dongguk university, Seoul, N/A, Korea, Republic of. [4]International Olympic Committee Research Centre Korea, Seoul, N/A, Korea, Republic of

Introduction

Chronic ankle instability (CAI) is characterized by recurrent giving way, proprioceptive deficits, and neuromuscular control impairments that compromise postural stability and elevate re-injury risk. Although balance training (BT) is central to CAI rehabilitation, it is rarely performed under fatigued conditions despite evidence that most ankle sprains occur during neuromuscular fatigue. Fatigue disrupts sensory reweighting, force production, and cortical–spinal motor control, potentially exacerbating postural deficits. Training under fatigue may promote performance-relevant neuromuscular adaptation. However, previous studies relied on localized or isokinetic fatigue that do not reflect functional, multi-joint fatigue. Therefore, this study investigated whether four weeks of fatigue-integrated BT improves dynamic balance and fatigue resilience in individuals with chronic ankle instability.

Methods

Sixteen CAI meeting International Ankle Consortium criteria were randomized to traditional BT (BAL; n = 8) or fatigue-based BT (F-BAL; n = 8). Both completed a four-week hop-to-stabilization program. In the F-BAL group, BT were performed immediately after a fatigue protocol combining sprinting, directional changes, hopping, and jumps. Fatigue was confirmed by: <80% MVJH, ≥90% HRmax, and RPE ≥17. Dynamic balance (SEBT reach; normalized to leg length) was assessed pre-/post-intervention under non-fatigued/fatigued conditions. Fatigue resilience was calculated as Δ(NF–F). A 2×2 mixed ANOVA tested Time (PreΔ, PostΔ) × Group (BAL vs. F-BAL). Secondary analysis compared absolute performance under fatigue (Pre-F vs. Post-F).

Results

No significant Time or Time × Group interaction effects were found for Δ(NF–F) in any SEBT direction (all $p > .69$). No significant improvements occurred in absolute balance performance under fatigue across groups.

Discussion

Four weeks of BT performed under neuromuscular fatigue did not improve fatigue resilience of dynamic balance in individuals with CAI. This suggests that fatigue sensitivity may represent a stable neuromechanical characteristic not readily altered through short-term balance interventions. Fatigue-integrated BT may also stimulate a different adaptation pathway, reflecting the demands of dynamic sport tasks rather than postural stabilization. Moreover, unchanged SEBT performance does not rule out adaptation; dynamic balance represents task success, but underlying kinematic and kinetic strategies may still differ. Future research should incorporate biomechanical analyses and longer, higher-demand interventions to determine whether fatigue-specific neuromuscular adaptation occurs.

OA85-03

A Minimally Invasive Implant Acts as a Digital Nervous System for Manipulating Limb Mechanics

Dr. Jennifer Leestma Ph.D.[1], Mr. Alexander Madinger M.S.[2], Dr. Shriya Srinivasan Ph.D.[1]

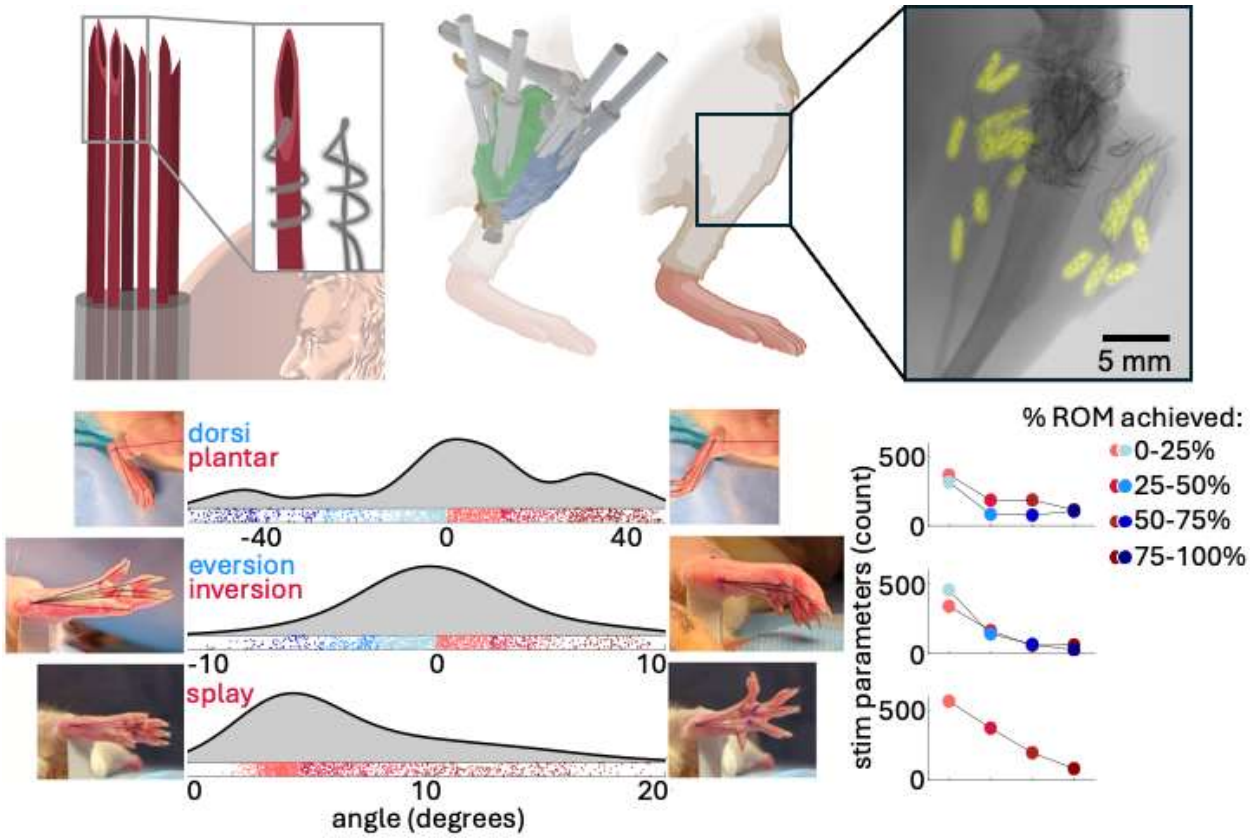
[1]Harvard University, Cambridge, MA, United States. [2]Massachusetts Institute of Technology, Cambridge, MA, United States

Introduction

Various conditions and diseases influence the function of the peripheral nervous system and inhibit everyday movement, despite biological actuators remaining intact. Our goal was to design a minimally-invasive muscle implant to act as a 'digital nervous system', capable of both reading muscle activity and inducing muscle activation via stimulation, to restore and manipulate biomechanics [1,2]. We hypothesized that we could continuously modulate ankle and toe joint motion, avoiding discrete 'bang-bang' behavior that is common in non-invasive stimulation.

Methods

We surgically implanted the shank segment of seven rats with a custom 36-lead muscle implant via a 1cm incision in this study approved by the Harvard University Institutional Animal Care and Use Committee. We targeted the anterior and posterior superficial and deep compartments of the shank musculature (see Figure). We stimulated all possible pairs of leads at 1000, 3000, and 5000 microamperes. We collected video data from the sagittal, frontal, and transverse planes at 240 Hz. We attained kinematics using custom-trained DeepLabCut models [3,4].



Results

We implanted all rats without any perforation or adverse consequences. With stimulation, we induced a maximum of 48° plantarflexion, 57° dorsiflexion, 9° inversion, and 10° eversion at the ankle. We induced a maximum of 20° of mean finger splay. Stimulation conditions were able to reliably access and hold small position changes relative to the overall achievable range of motion (ROM), while also achieving large overall joint position changes (see Figure).

Discussion

The implant produced a wide range of joint motions while demonstrating smoothly graded responses at lower stimulation levels, supporting its potential to restore naturalistic muscle-driven motion characterized by varying magnitudes of desired joint excursions. A current limitation is the pending direct comparison to standard surface stimulation, which we are in the process of evaluating. Our related ongoing work includes how muscle stimulation can be used to induce proprioceptive sensation and maintain accurate forces in the presence of stimulation-induced fatigue.

Relating Mechanical Stiffness to Quasi-Stiffness at the Knee During Walking Using an Adjustable Stiffness Leg Brace

Ms. Sierra Foley, Mr. Jack Wallace, Dr. Edward Washabaugh

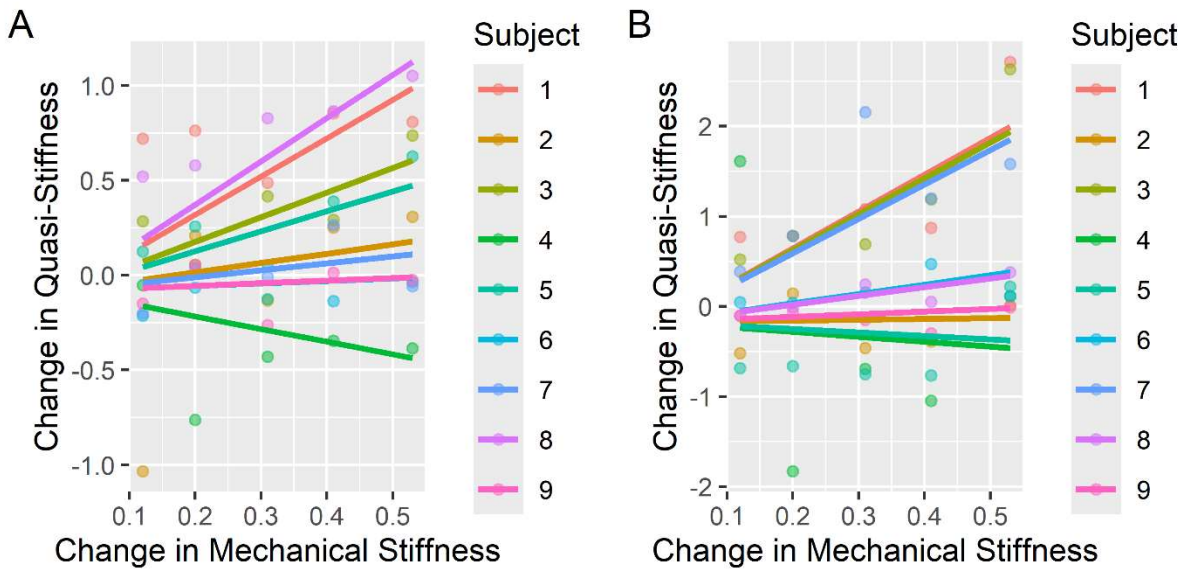
Wayne State University, Detroit, MI, United States

Introduction

Neuromusculoskeletal injuries can alter joint stiffness and lead to gait impairments. Having a metric to measure stiffness during functional tasks (e.g., walking) would improve clinicians' ability to treat altered joint stiffness (e.g., using nerve blocks or braces); however, measuring mechanical stiffness requires equipment that is not currently clinically feasible. Quasi-stiffness is a more clinically feasible metric that estimates stiffness behavior, but it is unclear how quasi-stiffness relates to mechanical stiffness; hence, the purpose of this study was to determine how alterations in mechanical stiffness during walking relate to changes in quasi-stiffness.

Methods

We developed a leg brace with interchangeable leaf springs to introduce mechanical stiffness to the knee during walking. We conducted a human subjects experiment on uninjured individuals (n = 9) to measure quasi-stiffness as participants walked with varying levels of mechanical stiffness (k = 0.12, 0.20, 0.31, 0.41, and 0.53 Nm/deg). Participants first performed a 1-minute baseline where they walked without stiffness, then the stiffness levels were introduced in a randomized order. Quasi-stiffness during stance was estimated using linear regression on the moment-angle curve. A linear mixed-effects regression (random slope) was performed to compare the change in mechanical stiffness to the measured change in quasi-stiffness from baseline while the knee was flexing and extending.



Results

Mixed effects regression showed that quasi-stiffness and mechanical stiffness were moderately correlated when accounting for random subject effects during knee flexion (Slope = 0.79, R^2 = 0.64; Figure 1A) and extension (Slope = 1.48, R^2 = 0.63; Figure 1B). When removing random subject effects, mechanical stiffness had a poor correlation with quasi-stiffness (R^2 < 0.06).

Discussion

These results suggest that quasi-stiffness is correlated with mechanical stiffness on an individual subject level. Increasing mechanical stiffness tended to increase quasi-stiffness; however, individuals showed large variance in the extent to which these increases occurred. One reason for this variation could be differences in how subjects adapted to walking with increased stiffness. Notably, quasi-stiffness alone is a poor predictor of mechanical stiffness on a population level. However, this study supports the idea that quasi-stiffness could be used as a surrogate to track changes in stiffness for individual patients.

Influence Of Delayed Onset Muscle Soreness On Joint Stiffness In Different Jumps Landing Tasks

PhD Andressa Lemos[1], PhD Karine Stoelben[2], MSc Inaê de Oliveira[1], PhD Felipe Carpes[1]

[1]Federal University of Pampa, Uruguaiana, RS, Brazil. [2]Children Hospital of Eastern, Ottawa, ON, Canada

Introduction

Delayed onset muscle soreness (DOMS) may reduce joint range of motion and transiently impair strength, potentially altering joint moments, stiffness, and support torque in landing biomechanics. However, DOMS symptoms do not always translate into biomechanical changes. Understanding its effects on landing tasks is essential for managing injury risk and ensuring proper movement technique. Here we aimed to determine whether exercise-induced DOMS changes joint stiffness during landings from different jumps.

Methods

Twenty-six physically active adults (15 women and 11 men) underwent a lower-limb DOMS induction protocol using squatting exercises. Before and 48 hours after this protocol, DOMS was assessed using a numerical pain scale, and a 3D motion analysis system was used to collect kinetic and kinematic data of forward jump, vertical jump, and drop jump. Joint stiffness was determined during the landing phase of each jump.

Results

The protocol effectively induced DOMS, with pain ratings increasing from baseline to 48 hours. Across vertical, forward, and drop jumps, DOMS did not alter hip, knee, or ankle joint stiffness. In all tasks, joint stiffness differed consistently between joints: hip stiffness was highest, knee was intermediate, and ankle was lowest. No joint-by-day interactions were observed. A small overall time effect appeared only for ankle stiffness, which was slightly higher under DOMS, independent of jump type.

Discussion

Our findings do not support the hypothesis that DOMS alters joint stiffness or landing technique in drop jumps. Hip and knee control during landing remained stable, which is favorable given the importance of hip strength in these tasks. Knee stiffness exceeded ankle stiffness during vertical jump landings, suggesting a more dominant role of the knee

in lower-limb stiffness organization. Although joint stiffness patterns were similar across tasks, forward jumps were less affected by DOMS, likely because this movement relies more on hamstrings, whereas soreness was induced mainly in the quadriceps. Despite moderate pain, participants maintained stiffness and impact control, adopting protective strategies.

Interim Report on Foot Structure and Function after Minimally Invasive Distal Chevron Osteotomy vs Lapidus Bunion Corrections

Ms Minah Waraich BS[1], Ms Silvia Zanini MS[1], Dr Howard Hillstrom PhD[1], Dr Holly Johnson MD[1], Dr Matthew Conti MD[1], Dr Rajshree Hillstrom PhD[2], Dr Constantine Demetracopoulos MD[1], Dr Mark Drakos MD[1], Ms Isabella Voellmicke BS[1], Mr Lance Ward BS[1], Dr Scott Ellis MD[1]

[1]Hospital for Special Surgery, New York, New York, United States. [2]Biomed Consulting, New York, New York, United States

Introduction

Hallux valgus (HV) is a common forefoot deformity associated with first ray hypermobility and pes planus foot type which can have substantial impact on physical function. Surgical intervention is common and includes the selection of a wide variety of treatments. The modified Lapidus procedure addressed the bunion through fusion of the 1st metatarsal-cuneiform joint, however it requires a longer postoperative healing time. The minimally invasive (MIS) distal chevron osteotomy is performed with a smaller incision yielding a faster recovery yet its ability to correct foot structure and function is unknown. The objective of this study is to evaluate changes in foot structure and function pre- and post-operatively between Lapidus and MIS chevron procedures.

Methods

In this prospective IRB approved study, 27 participants with HV (2M, 25F; 47.69 ± 17.49 years; 163.22 ± 8.09 cm; 63.59 ± 15.22 kg) who underwent surgical treatment were recruited: 15 received Lapidus and 12 received MIS chevron bunionectomies. Structural foot measurements while sitting (Arch Height Index (AHI), First ray mobility (FRM)) and functional foot parameters (peak plantar pressures (PP) at the hallux, 1st metatarsophalangeal (MTP) joint, and 2nd MTP joint) at self-selected walking speed while barefoot were collected from each subject preop and at 6 months post-op. Radiographically, hallux valgus angle (HVA) and intermetatarsal angle (IMA) was acquired at preop and 6 months post-op. Repeated-measures ANCOVA across visits and surgical procedure was examined with significance at $p<0.05$.

Results

The Lapidus procedure significantly increased AHI, improved IMA and HVA, decreased PP under MH2 and hallux, while the MIS procedure only significantly improved IMA and HVA. As a pooled cohort of 27 patients, CPEI was significantly different pre vs post-op (p =

0.031). When comparing the two surgeries, Lapidus significantly decreased PP under MH2 compared to MIS, but there was no difference in IMA, HVA, and CPEI improvement.

Discussion

Both surgeries are successful at realigning the 1st ray. However, the more involved Lapidus procedure also improves arch height and pressures under the foot during ambulation. Other trends in the data may become significant as our full cohort (40 people) returns for follow-up in the next few months.

OA86-02

Joint Space Distance Measurements of Controls and Individuals With Asymptomatic Flatfoot Across the Stance Phase of Walking

Ms. Elizabeth Bowman BS[1], Mr. Andrew Peterson MS[1], Mr. Tradd Rector[1], Dr. Kassidy Knutson PhD[1], Dr. Karen Kruger PhD[2], Dr. Amy Lenz PhD[1]

[1]University of Utah, Salt Lake City, UT, United States. [2]University of Wisconsin-Milwaukee, Milwaukee, WI, United States

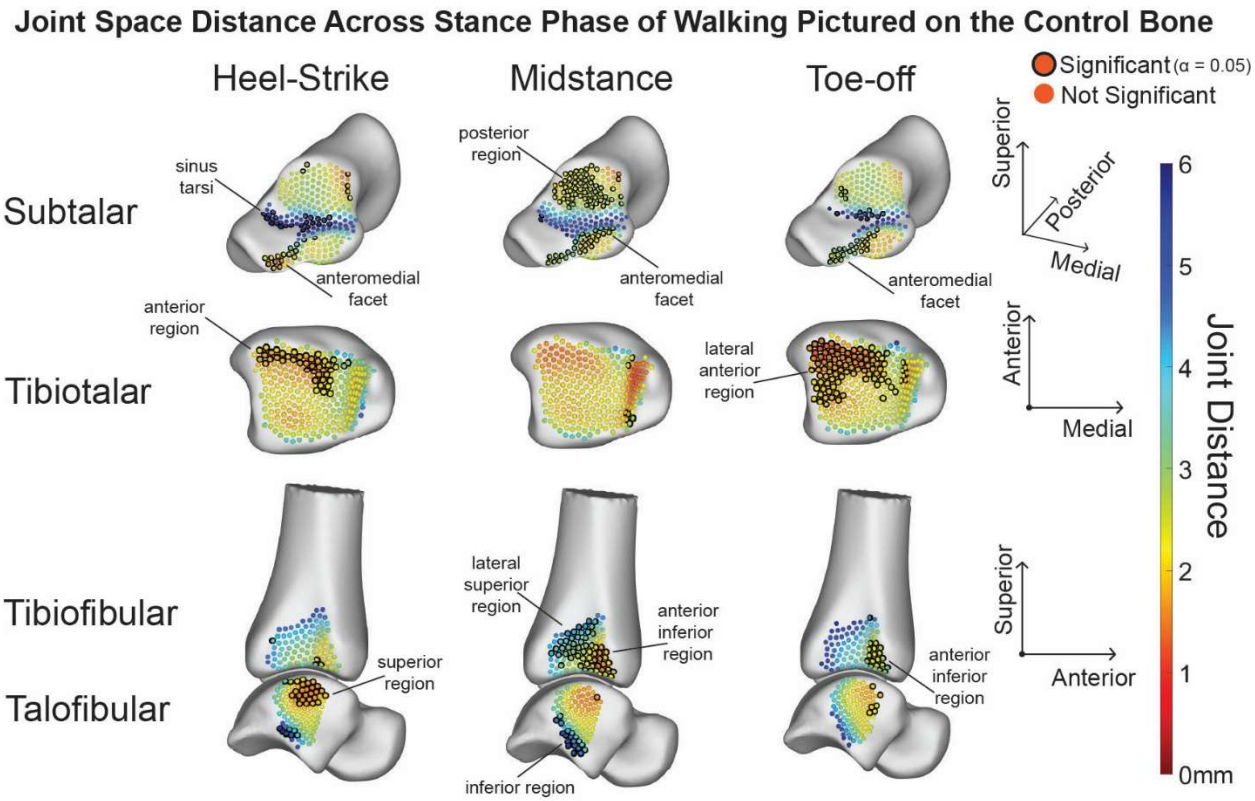
Introduction

Individuals with asymptomatic flatfoot (AFF) exhibit altered hindfoot alignment, specifically increased subtalar eversion and external rotation, as well as increased tibiotalar inversion. By analyzing changes in joint space distance from heel strike to toe-off, we aim to characterize how altered kinematics affect the motion of the subtalar, tibiotalar, tibiofibular, and talofibular joints between individuals with AFF and healthy controls (CNO).

Methods

Weight-bearing CT and biplane fluoroscopy gait data from twenty-three participants (10 AFF, 13 CNO) were used to generate group-specific statistical shape models to drive the joint measurement analysis (JMA). Joint space distances for the subtalar, tibiotalar, tibiofibular, and talofibular joints were computed using the JMA toolbox during both static and dynamic movements. This toolbox utilizes a correspondence-based approach to register shape models with dynamic biplane fluoroscopy data, computing point-to-surface distances between articulating surfaces at each frame. A two-sample Student's T-test (α=0.05) compared AFF and CNO joint space distances for both static and dynamic trials.

Results



Differences in static joint space distance between AFF and CNO were observed in the subtalar, tibiotalar, and tibiofibular with minor differences in the talofibular joint. Dynamic analyses revealed significant differences in each joint across the stance phase of gait, as seen in Figure 1.

Discussion

In the subtalar joint, individuals with AFF demonstrated significantly increased sinus tarsi spacing and reduced anteromedial facet spacing, indicating greater eversion and talar

medial rotation throughout stance. In the tibiotalar joint, the AFF group showed significantly reduced anterior-lateral joint space at heel strike and toe-off, implying altered ankle alignment during high-loading phases when stability demands are greater. This also suggests that the AFF talus sits more plantarflexed and drives increased forefoot abduction. In the tibiofibular and talofibular joints, the fibula rotates and translates, likely compensating for medial collapse at the subtalar and tibiotalar complex. These joint redistributions may elevate localized stress and alter how the joints articulate, supporting AFF as a dynamic, multi-joint alteration in hindfoot function. Even without symptoms, these deviations may predispose individuals to pain or progressive conditions, highlighting the value of joint-level quantification for early risk identification and intervention.

OA86-03

SSM-Guided Segmentation of the Bones of the Foot in CT Data with Extremely Narrow Inter-Bone Joint Spaces

Mr. Kuan-Hsien Wu[1], Ms. Han-Chieh Hsieh[1], Dr. Tung-Wu Lu[2,3,4]

[1]Department of Biomedical Engineering, National Taiwan University, Taipei, Daan, Taiwan. [2]Department of Biomedical Engineering, National Taiwan University, Taipei, Daan District, Taiwan. [3]Department of Orthopedic Surgery, School of Medicine, National Taiwan University, Taipei, Zhongzheng District, Taiwan. [4]Health Science and Wellness Research Centre, National Taiwan University, Taipei, Daan District, Taiwan

Introduction

Segmentation of individual foot bones from CT is challenging because the joint spaces are extremely narrow, causing conventional automatic or semi-automatic methods to merge adjacent bones into a single structure. This limitation prevents accurate biomechanical modeling and subject-specific analysis. To address this unmet need, we developed an SSM-guided multi-bone segmentation framework that can separate all 28 foot bones even when only a single fused CT segmentation is available. The objective was to create a robust, anatomically constrained method capable of restoring physiologically valid bone boundaries from imperfect surface data.

Methods

Ten manually segmented feet were decomposed into 28 bones to construct a multi-part SSM, with ICP/CPD establishing point correspondence and each vertex labeled by bone identity and articular surface. For new CT data where segmentation produced a single fused foot surface, decomposition was performed in two stages. First, the SSM mean model was aligned to the target and its shape parameters optimized using a cost function combining weighted surface fitting and a constraint separation across joint surfaces. Second, each bone underwent localized refinement, and non-articular vertices were snapped back to the CT surface to restore geometric detail while preserving bone separation.

Results

The proposed SSM-guided decomposition framework was tested on 29 CT-derived foot models that initially failed to yield separate bones using standard segmentation approaches. The method successfully decomposed 28 of the 29 datasets into clean, anatomically plausible 28-bone models. Bones were fully separated without topological overlap, and joint surfaces were preserved with physiologically consistent spacing. The

final refinement step restored detailed cortical geometry from the original CT data while maintaining separation enforced by the SSM constraints.

Discussion

Conventional CT segmentation methods struggle to distinguish individual foot bones due to extremely narrow joint spaces. By incorporating anatomical priors and joint-surface constraints within a multi-stage SSM-guided optimization, the proposed approach reliably segments a fused CT-derived foot surface into 28 anatomically separate bones. The high success rate (28/29 cases) highlights its robustness and utility for downstream biomechanical analyses. The primary limitation is the dependence on reasonable initial CT surface quality. Future work will expand the SSM training set and improve pre-processing to enhance generalizability.

[5]University of Utah, Dept. of Mechanical Engineering, Salt Lake City, UT, United States

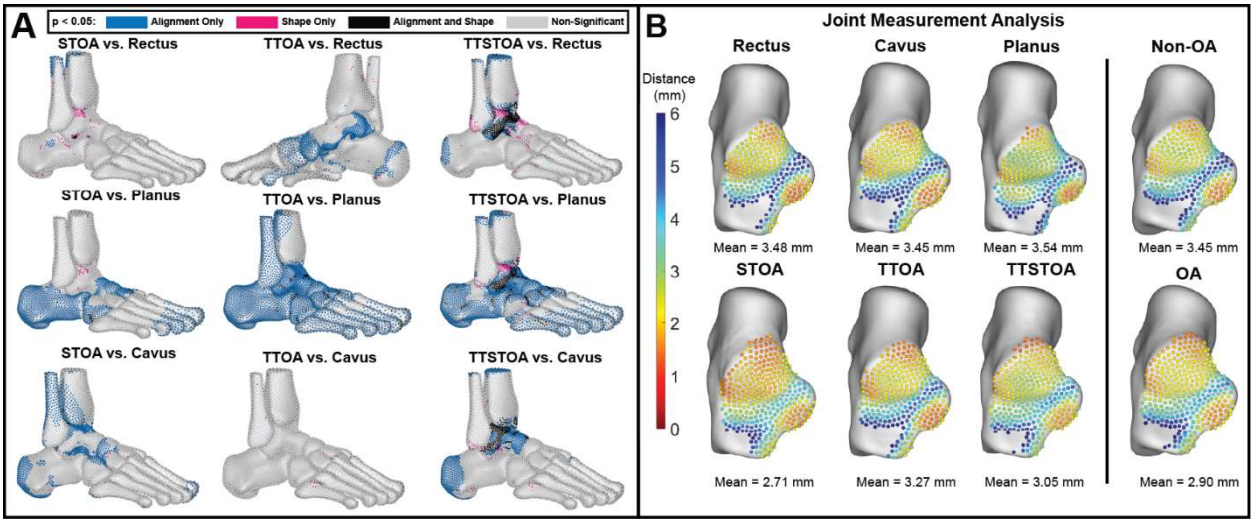
Introduction

Foot and ankle osteoarthritis (OA) can affect the subtalar, tibiotalar, or both joints, and it remains unclear whether inherent foot types (high/low arch) predispose individuals to specific OA presentations. Identifying morphological risks could improve early detection and surgical planning. Radiographs lack the dimensionality necessary to capture complex anatomy or subtle variations associated with OA. Statistical shape modeling (SSM) offers a 3D framework for comparing joint anatomy across populations, potentially revealing patterns underlying different OA manifestations. This study aimed to identify morphological and alignment similarities between foot types and OA presentations using SSM, joint measurement analysis (JMA), and radiographic measurements.

Methods

204 weightbearing computed tomography scans from 138 OA patients (50 subtalar OA (STOA), 44 tibiotalar OA (TTOA), 44 combined subtalar/tibiotalar OA (TTSTOA)) and 66 asymptomatic individuals (19 cavus, 26 planus, 21 rectus/neutral) were used to make a 14-bone SSM. Principal component analysis (PCA) evaluated shape and alignment variations between groups, and Hotelling's T^2 test identified localized discrepancies. Radiographic measurements, describing arch height and hindfoot alignment, were automatically calculated using anatomic coordinate systems. JMA assessed joint space distance and variations along articulating surfaces.

Results



PCA mode 1 revealed statistical differences between foot types and between the STOA and TTOA groups. No statistical differences were observed between STOA and rectus

alignment, nor between TTOA and cavus alignment. PCA mode 3 distinguished OA from non-OA, highlighting joint space narrowing. Hotelling's T^2 results confirmed these variation patterns, and JMA demonstrated joint space narrowing in all OA groups relative to non-OA data. Radiographic measurements reinforced similarities between STOA and rectus groups, and between TTOA and cavus alignment.

Discussion

This study identified morphological similarities between rectus and STOA groups, and cavus and TTOA groups. Rectus alignment may predispose individuals to subtalar joint degeneration, whereas cavus alignment may increase the risk of TTOA. Load distribution and joint kinematics likely drive these patterns, but further investigation is needed to confirm these mechanisms. Recognizing alignment-specific patterns enhances our understanding of the biomechanical OA risk factors and may support earlier identification of at-risk individuals. These findings emphasize the importance of considering inherent foot type during OA assessment and surgical planning.

Pediatric Flatfoot Tarsal Morphology Variation via Statistical Shape Modeling

Mr. Nick Slavik[1,2], Ms. Renae Lapins[3], Dr. Amanda Whitaker MD[4], Dr. Amy Lenz PhD[3], Dr. Karen Kruger PhD[1,2,5]

[1]Medical College of Wisconsin, Milwaukee, WI, United States. [2]Marquette University, Milwaukee, WI, United States. [3]University of Utah, Salt Lake City, UT, United States. [4]Shriners Children's - Northern California, Sacramento, CA, United States. [5]Shriners Children's - Chicago, Chicago, IL, United States

Introduction

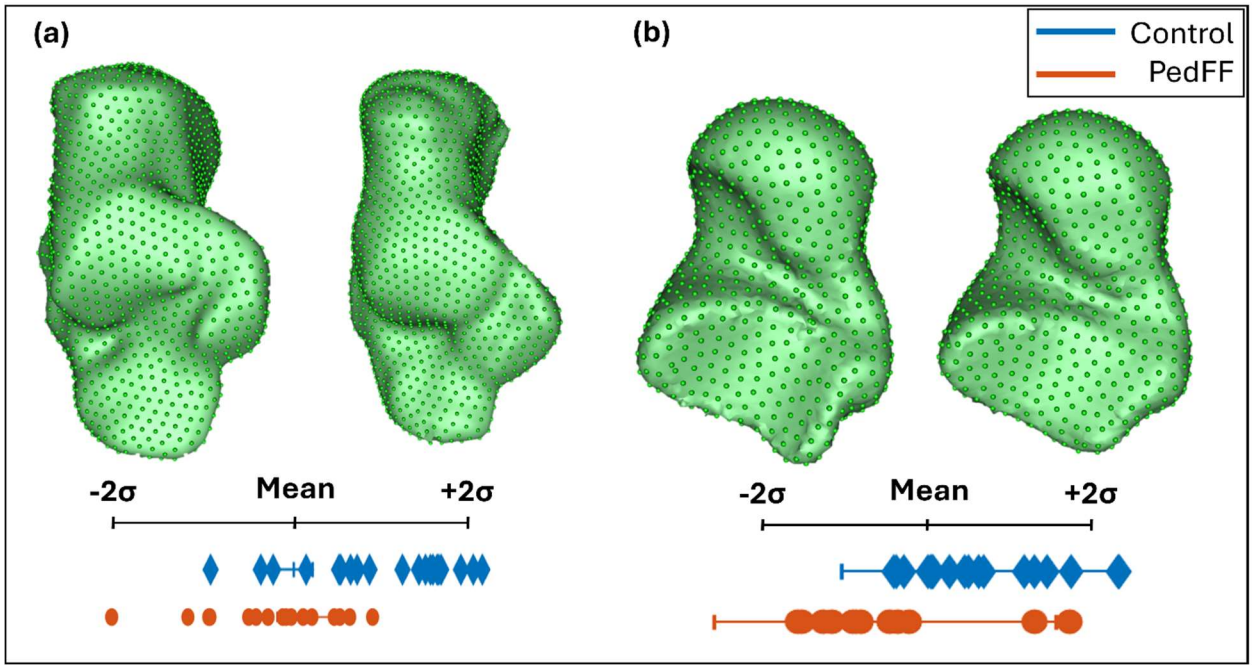
Pediatric flatfoot is among the most prevalent disorders affecting children and adolescents. The growing availability of weightbearing computed tomography (WBCT) has the potential to identify early abnormal bone development. This exploratory pilot study aimed to compare bone morphology in children with flatfoot to asymptomatic controls using statistical shape modeling (SSM).

Methods

This IRB approved study included a control group of typically developing children (n=20 feet, age=11±2.4 yrs) and a flatfoot group of children who underwent clinical WBCT for assessment of flatfoot deformity (n=16 feet, age=13±2.5 yrs). Segments were aligned and Procrustes analysis was used to remove orientation and size as variation modes. Single-domain SSMs were generated to assess bone geometry and alignment [1]. Principal component analysis (PCA) with Holm-Sidak corrected parallel analysis was conducted to identify significant modes of shape variation statistically separating our sample cohorts.

Results

PCA identified significant shape variation modes for all assessed bones; cumulative explained variance 63.9%, 74.4%, 62.1%, 68.9% for calcaneus, talus, navicular, and cuboid SSMs, respectively.



Discussion

Significant group differentiating PCA modes revealed morphology variation in pediatric flatfeet, relative to control cohort. **Calcaneus SSM:** Reduction in medial and posterior facet bone volume, and a larger, more pronounced anterior facet (Figure 1a). **Talus SSM:** Complimentary to calcaneus SSM, talus bone volume increased for the posterior and

medial facet articulations and anterior facet volume reduction (Figure 1b). **Navicular SSM:** Increased bone thickness of superior-medial aspect and reduced volume of the inferior-medial aspect. **Cuboid SSM:** Reduced bone volume between calcaneal-cuboid and navicular-cuboid articulations that results in less defined and smaller articular surfaces.

These findings support our hypothesis that children with flatfoot deformity will have different morphologic development than a typically developing child. For each of the hindfoot bones analyzed, we identified at least one significant shape variation mode statistically separating the flatfoot cohort from the typically developing. Our future work will focus on greatly increasing our sample sizes for all cohorts, with the aim of better understanding the clinical significance and relevance of these morphological differences.

Fracture and Non-Fracture Tibiotalar Osteoarthritis Present Distinct Morphologies in the Midfoot and Ankle Joint

Mr. Jordan Langford[1], Ms. Elana Lapins[1], Mr. Andrew Peterson[1], Mr Jacob Benna[1], Dr. Curran Reddy[1], Dr. Maryam Soltanolkotabi[1], Dr. Donald Anderson[2], Ms. Julie Agel[3], Dr. Conor Kleweno[3], Dr. Justin Haller[1], Dr. Amy Lenz[1]

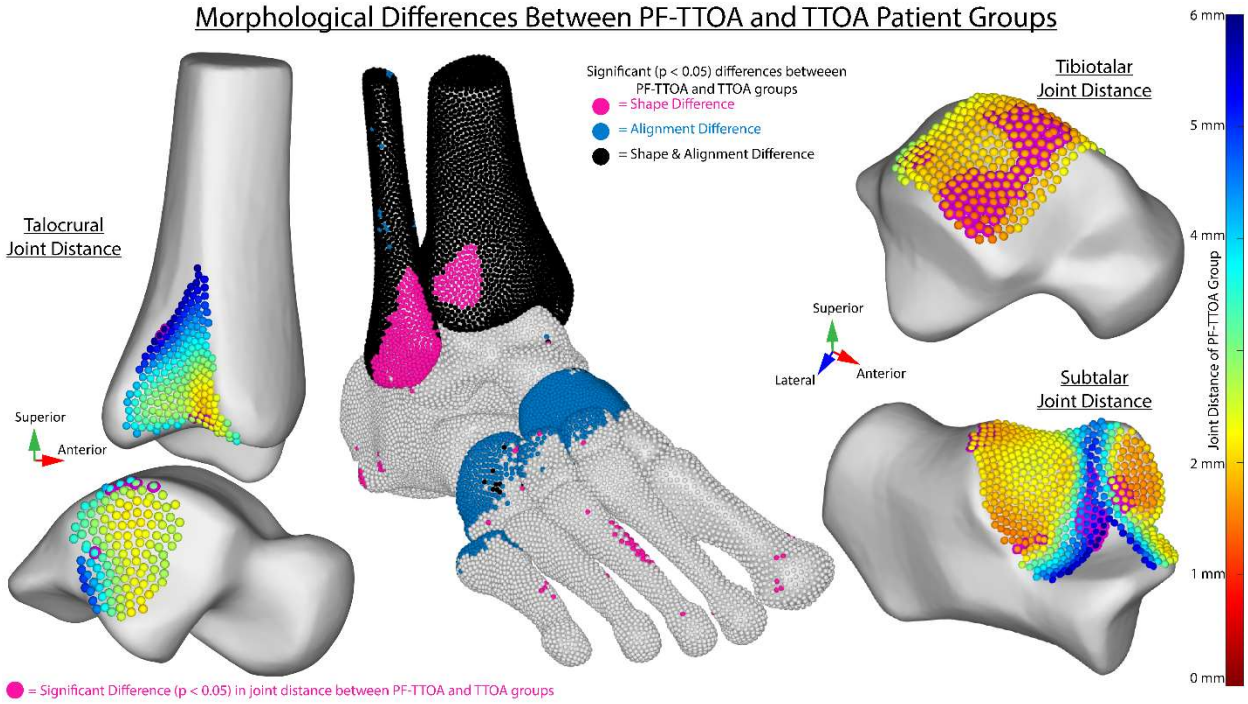
[1]University of Utah, Salt Lake City, UT, United States. [2]University of Iowa, Iowa City, IA, United States. [3]Harborview Medical Center, Seattle, WA, United States

Introduction

Ankle osteoarthritis (OA) is an understudied OA type affecting an estimated 1% of the global population. Unlike in other joints, ankle OA is predominantly trauma-induced. Trauma-induced OA includes both OA subsequent to fracture and OA subsequent to non-fracture trauma, such as sprains or strains. However, fracture and non-fracture ankle OA are often considered *en banc*, with little distinction being made between the fracture and non-fracture OA. Here, we hypothesize that fracture and non-fracture ankle OA present with distinct morphological typologies.

Methods

Weight-bearing computed tomography scans of 31 pilon fracture patients with post-fracture tibiotalar osteoarthritis (PF-TTOA) and 44 non-fracture tibiotalar osteoarthritis (TTOA) patients were collected at the University of Utah, Harborview Medical Center, and the University of Iowa. The scans were processed into 3D models for analysis, and fourteen-bone statistical shape models were generated for each patient cohort. The shape models were analyzed for shape and alignment differences using a Hotelling's T^2 test, and the joint distances were analyzed using the joint measurement analysis toolbox.



Results

Statistically significant differences in alignment were observed in the navicular and cuboid (Fig 1). Differences in both alignment and shape are visible throughout the tibia and fibula (Fig 1). Joint distances significantly differed between PF-TTOA and TTOA groups in several regions, including the talar dome (PF-TTOA narrower than TTOA), facies articularis talaris posterior (TTOA narrower), sulcus calcanei (TTOA narrower), and talocrural joint (TTOA narrower) (Fig 1).

Discussion

Significant differences in midfoot and ankle joint alignment indicate that PF-TTOA and TTOA present differently morphologically. These differences can be summarized as PF-TTOA patients having a more collapsed tibiotalar joint space, while TTOA patients tend to have reduced joint distances in other joints. Additionally, PF-TTOA midfeet are generally more everted. Differences in alignment, shape, and joint distance may indicate distinct mechanisms of compensation and different regions of joint space narrowing that contribute to OA. These differences in morphology necessitate further investigation and may suggest that PF-TTOA and TTOA are distinct phenotypes that may follow divergent mechanobiologic pathways, which could justify separate consideration in clinical decision-making and future OA classification systems.

Full-Field Strains of the Anterior Cruciate Ligament under Physiologic Loading Configurations

Ms. Charlotte Andreasen, Ms. Chloe Stacey, Dr. Ulrich Scheven, Dr. Ellen Arruda

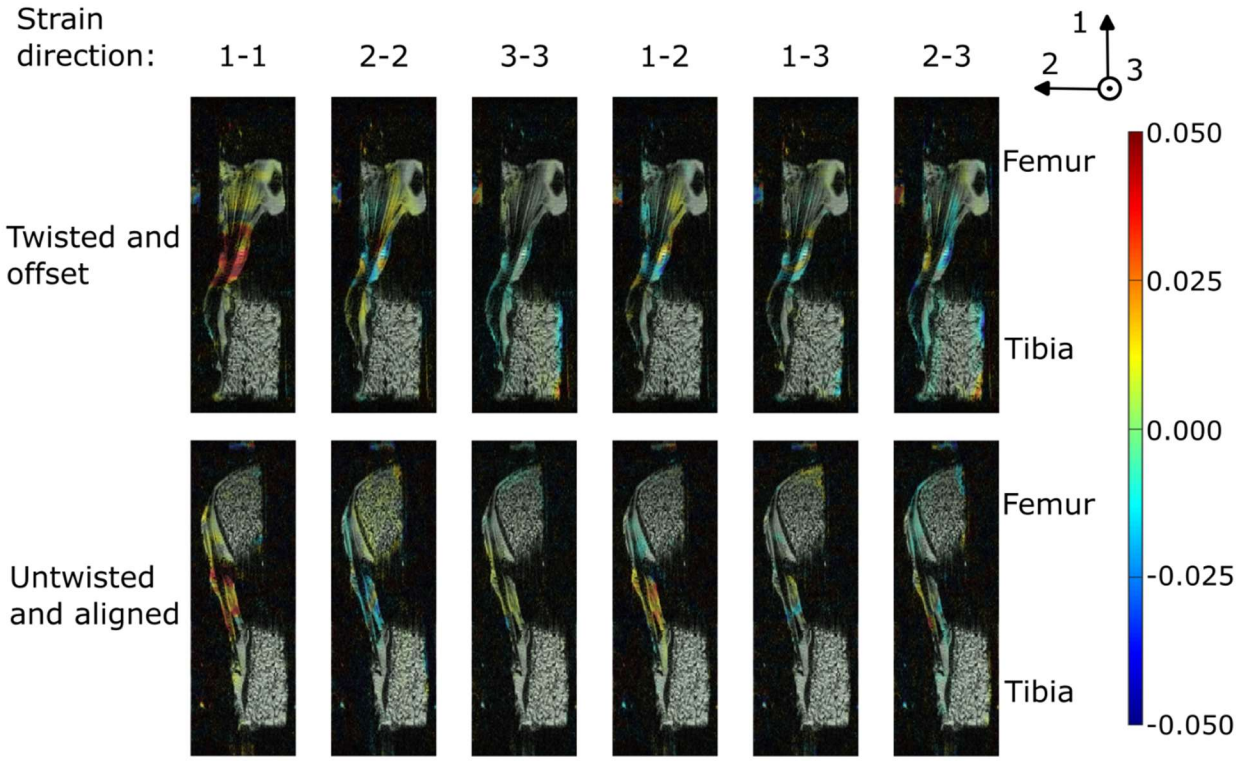
University of Michigan, Ann Arbor, MI, United States

Introduction

Anterior cruciate ligament (ACL) tears are a common, traumatic injury among athletes that are often non-contact, so understanding the failure mechanics is vital to prevention. Mechanically characterizing biological materials like ligaments can be challenging because of the geometric irregularity, non-linearity, heterogeneity, and visco-elasticity. To simplify mechanical characterization of the ACL, it is generally untwisted, straightened, and the anteriomedial (AM) and posterolateral (PL) bundles are separated during uniaxial loading. However, macroscale geometry, including factors like splay, is known to impact the mechanical behavior. Therefore, we believe that the bone insertion angle, twist, and offset between the axis of loading and main axis of fiber direction in the ACL will impact the mechanical response of the ACL under tension.

Methods

In this study, we designed a fixture that accommodates the entire ACL with femoral and tibial attachments for loading in the MRI to collect full-field strain data throughout the entire volume of the ACL. Our new design allows for controlled twist angles at 45° increments of the tibial insertion relative to the femoral insertion. It also gives us control of the medial-lateral and proximal-distal offsets between the two bones of up to 4mm in both directions. This allows us to replicate the twist and insertion offsets that the ACL experiences during anterior tibial translation (ATT), a motion of the knee that primarily loads the ACL.



Results

Preliminary data indicate that we can identify differences in the full-field strain with different offsets and twist angles. As shown in figure 1, when the ACL is twisted and insertions offset, we see shifts in strain magnitudes and locations. Specifically, we see strains closer to zero in the 3-3 direction in the untwisted configuration; as well as higher 1-1 strains through the entire mid-tendon in the twisted, offset configuration.

Discussion

This novel testing method allows us to determine the strains the ACL AM and PL bundles undergo from being in their twisted configuration *in vivo*. We are beginning to characterize the response of the ACL to more complex loading conditions, which will eventually be used to identify individuals at a higher injury risk and lead to injury prevention.

Effects of Wrist Posture and Pinch Force on Median Nerve Flattening in the Carpal Tunnel

Mr. Trevour Greene MS, Dr. David Jordan PhD, Dr. Zong-Ming Li PhD

The University of Arizona, Tucson, Arizona, United States

Introduction

The median nerve (MN) and flexor tendons pass through the carpal tunnel. Wrist flexion-extension (FE), radioulnar deviation (RUD), and pinch force may increase MN compression by changing contact with surrounding tissues and carpal tunnel pressure. This study investigated the independent and combined effects of wrist posture and pinch force on MN flattening.

Methods

Eleven healthy young adults were immobilized in a hand splint set to one of nine wrist postures combining FE at 30° flexion, 0°, and 30° extension with RUD at 15° radial, 0°, and 30° ulnar. Ultrasound at the distal carpal tunnel captured cross-sectional videos. Participants performed a thumb-index pinch that increased from 0 to 20 N. MN perimeter was manually traced and MN flattening ratio was calculated. A three-way repeated-measures ANOVA examined effects of FE, RUD, Force, and interactions. Tukey post-hoc tests were used for pairwise comparisons ($\alpha=0.05$).

Results

MN flattening ratio was affected by the main factors FE and RUD ($p<0.05$) but not Force ($p=0.20$). All the two- and three-way interactions were significant ($p<0.05$). At 0 N, flattening ratio was most influenced across RUD postures and increased from ulnar to radial deviation. For example, flattening ratio increased 57% from 30° ulnar to 15° radial deviation when FE was fixed at 30° flexion ($p<0.05$, Figure 1a). At 20 N, flattening ratio was most influenced across FE postures and increased from extension to flexion. For example, flattening ratio increased 184% from 30° extension to 30° flexion when RUD was fixed at neutral ($p<0.01$, Figure 1b). Flattening ratio was influenced by factor interactions and increased with radial deviation, flexion, and 20 N force. For example, flattening ratio increased 84% from 0° FE with 30° ulnar deviation at 0 N to 30° flexion with 0° RUD at 20 N ($p<0.001$, Figure 1a and 1b).

Discussion

In this study, we found MN deformation is driven primarily by wrist posture and interactive effects of pinch force. RUD had the strongest influence on MN shape without pinch force, and FE became the most influential when pinch force was applied. Our study suggests everyday tasks involving flexion and radial deviation under load may increase MN compression risk.

Abrocitinib Induces Hypertrophy in an Engineered Human Ligament Model

Dr. Adam Kositsky PhD[1], Dr. Alec Avey PhD[2], Mr. Jared Ong[2], Assoc. Prof. Lauri Stenroth PhD[1], Prof. Rami Korhonen PhD[1], Prof. Keith Baar PhD[2]

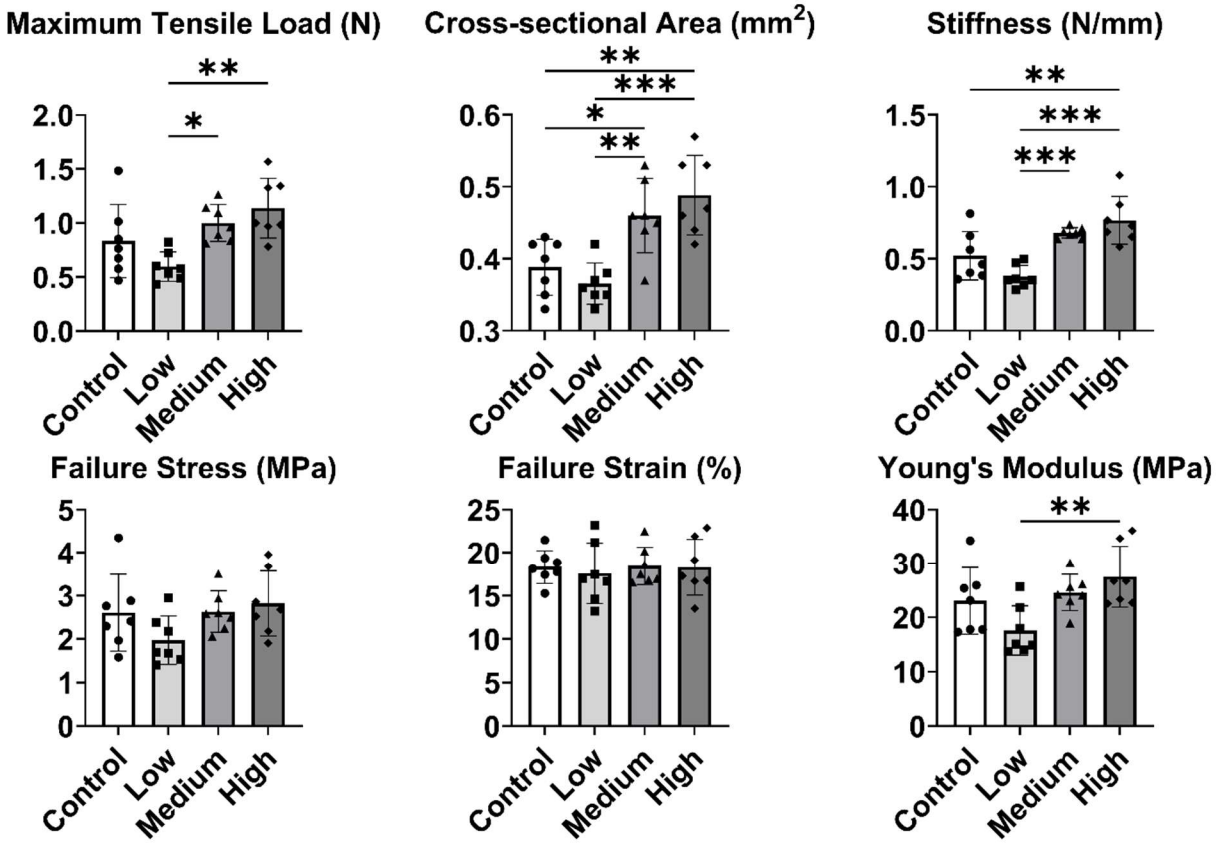
[1]University of Eastern Finland, Kuopio, North Savo, Finland. [2]University of California, Davis, CA, United States

Introduction

Abrocitinib is an FDA-approved prescription medicine used to treat patients with atopic dermatitis through systemic inhibition of janus kinase 1 (JAK1), reducing inflammation. A different JAK1 inhibitor, itacitinib, has been shown to alter engineered human ligament (EHL) function [1]. Therefore, use of this class of drug may have secondary effects on connective tissues. Accordingly, we used an EHL model to investigate the potential effects of abrocitinib on ligament development.

Methods

Twenty-eight EHLs were constructed using standardized protocols [1,2] from human fibroblasts of anterior cruciate ligament remnants obtained during reconstructive surgery (IRB #779755). Every second day, EHLs were fed a standardized growth media supplemented with ascorbic acid, proline, and transforming growth factor beta-1. From day 8, EHLs were fed this growth media supplemented with either 0 (control), 0.1 (low), 1.0 (medium), or 10 (high) μM doses of abrocitinib (n = 7 per group). On Day 14, cross-sectional area was determined by measuring width and thickness using optical coherence tomography (OQ LabScope, Lumedica) and assuming an elliptical shape. For mechanical tensile testing (68SC-1, Instron), EHLs were housed in a saline solution maintained at 37°C. After applying a tare load (0.05 MPa), EHLs underwent 10 preconditioning cycles (0.10 MPa at 1%/s) followed by a ramp to failure (0.5%/s). Data were low-pass filtered at 10 Hz and analyzed as true stresses and strains using MATLAB (R2023b). One-way ANOVAs ($p < 0.05$) were performed using GraphPad Prism (v10.6.1).



Results

At medium and high abrocitinib doses, EHLs were generally stronger, stiffer, and bigger than those of control and/or low dose groups (Figure 1). There were no significant differences between the control and low dose groups or between medium and high doses.

Discussion

Here, we show that an FDA-approved drug (abrocitinib) alters the morphology and mechanical properties of EHLs. Clinical examination of ligament and tendon properties in patients taking this medicine may thus be warranted. Investigation of the mechanistic pathway of JAK1 on ligament and tendon mechanics is ongoing.

OA87-04

A New Mechanical Clamping System for Bone-Ligament-Bone Tensile Testing

MSc. Minoo Tehrani[1,2], Dr Adam Kositsky Ph.D.[1], Dr. Aapo Ristaniemi[1,2], Dr. Rami Korhonen[1]

[1]University of Eastern Finland, Kuopio, North Savo, Finland. [2]Kuopio University Hospital, Kuopio, North Savo, Finland

Introduction

Accurate mechanical testing of bone-ligament-bone specimens requires stable boundary conditions, yet reliable gripping in knee ligament tensile tests is difficult due to limited bone contact and variable geometry. Existing solutions, such as roughened flat grips, cryogenic clamps, PMMA potting [1], and mechanical bone-locking, often suffer from slippage, uneven load transfer [2], thermal effects, or long sample preparation time. Therefore, we aimed to design a new mechanism that overcomes these limitations.

Methods

We developed a novel mechanical clamping system with several integrated features (Fig. 1A-B). The gripping mechanism relies on downward-oriented grooves that create a self-locking effect as load increases. To enhance the fixation, sharp screws are used to tighten the specimen to the jaws. The clamp is easy to assemble onto the machine, and the jaw components can be detached and replaced when needed.
To experimentally test the new design, one bovine lateral collateral ligament (LCL) was mounted (Fig. 1C) and subjected to an incremental stress-relaxation and ultimate tensile testing protocol (Instron 8874). For comparison, a second bovine LCL was tested in the same manner using a conventional clamping system with flat pyramid-serrated jaws. (4-mm serration depth).

Results

No slipping at the grips was evident throughout stress relaxation or ultimate tensile tests. The ultimate force reached 1289 N compared to 216 N with conventional clamping.

Discussion

The designed clamping system eliminated slippage, which helps to achieve repeatability and accuracy in estimating mechanical parameters of bone-ligament-bone samples. The ultimate force of 1289 N is higher than reported for human LCLs (up to 629 N [1]), demonstrating good applicability of the new clamps to bone-ligament-bone testing. Repeatability tests are being performed.

OA87-05

Sarcomere Length and Force Behavior in Skeletal Muscle Myofibrils

Mr. Taiki Ino

University of Calgary, Calgary, Alberta, Canada

Introduction

Muscles can produce two types of force: active and passive. Active and passive forces are dependent on the length of the sarcomere [1]. Active force is generated through cross-bridge cycling, while passive force in myofibrils depends virtually exclusively on the protein titin [2]. Within a myofibril, sarcomeres are arranged in-series, thus they transmit identical forces at any instant in time. When active force production in sarcomeres differs, passive forces should compensate for the lack of active force by elongating until passive force reaches the required magnitude. This adjustment of sarcomere length has been thought to lead to so-called sarcomere "popping", which has been proposed as a mechanism of muscle injury, residual force enhancement, and force depression [3]. We developed a novel technique to locally deactivate one sarcomere in an otherwise fully activated myofibril with the purpose to test if deactivated sarcomeres will "pop" when active force is eliminated.

Methods

We used single myofibrils from rabbit psoas muscle. A single myofibril is suspended between a needle (for length control) and a cantilever pair (for force measurement). A large and a small-bore pipette are used for activation and deactivation of the myofibril and single sarcomeres, respectively.

Results

We found that locally deactivated sarcomeres did not overstretch in an otherwise fully activated myofibril as predicted by the popping sarcomere theory. Deactivated sarcomeres lengthened by about 0.6μm from about 2.6 to 3.2μm (Fig. 1). At 3.2μm, rabbit psoas sarcomeres have a small passive force (about 127nN/μm^2), thereby questioning how these deactivated sarcomeres can sustain the active stresses exceeding 370nN/μm^2.

Discussion

We propose that activated sarcomeres form a linked framework between actin and titin, which enhances passive force and thereby protects against "popping" and sarcomere damage under these experimental conditions. Activation induces a titin–actin linkage that stabilizes sarcomeres, and this linkage is not immediately broken upon deactivation. Our

findings reveal a novel built-in safety mechanism in previously activated sarcomeres that prevents them from being overstretched and damaged when deactivated.

Images (Optional)

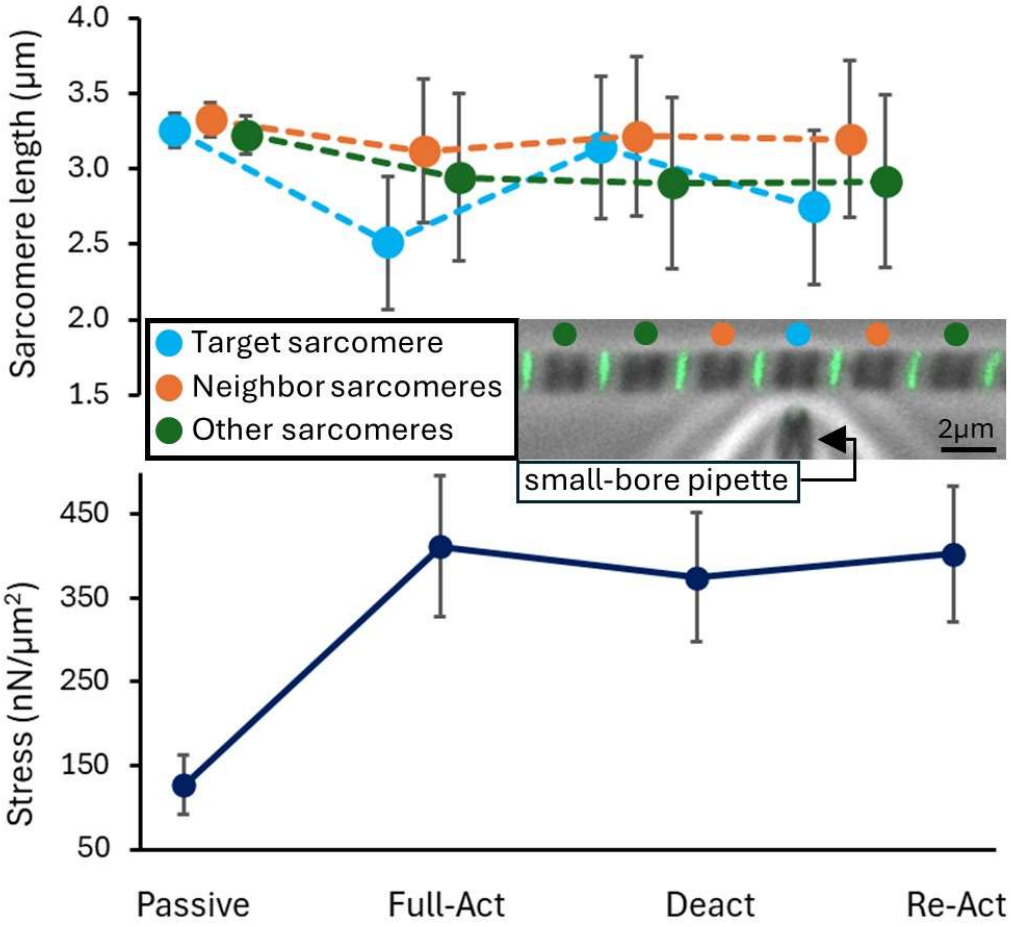

Figure 1: Sarcomere length and stress changes as a function of experimental conditions. The target sarcomere is the one being deactivated. The neighbor sarcomeres are the sarcomeres on either side of the target sarcomere. The other sarcomeres are sarcomeres not immediately neighboring the target sarcomere.

Resilient Biomechanical Phenotype of Memory CD4⁺ T Cells in Long-Lived Mice

PhD Aldo Abarca-Ortega[1], PhD Blanca González-Bermúdez[2,3,4], PhD Gustavo R. Plaza[2,3,4]

[1]Universidad de Santiago de Chile, Santiago de Chile, Región Metropolitana, Chile. [2]Center for Biomedical Technology, Universidad Politécnica de Madrid, Madrid, Madrid, Spain. [3]Departamento de Ciencia de Materiales, ETSI Caminos, Canales y Puertos, Madrid, Madrid, Spain. [4]Instituto de Investigación Sanitaria Hospital Clínico San Carlos, Madrid, Madrid, Spain

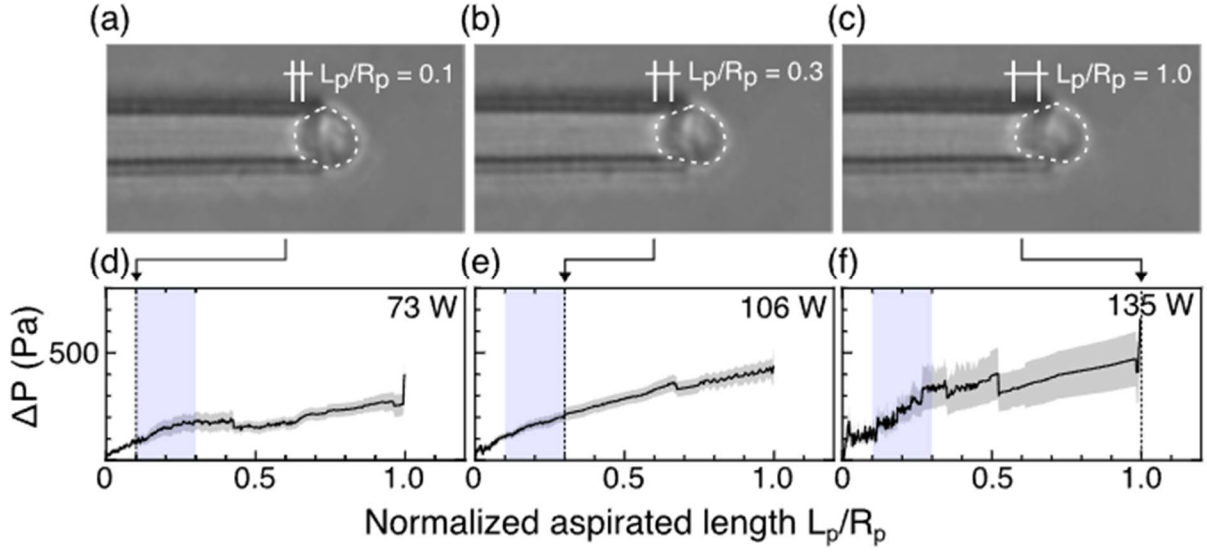
Introduction

Immunosenescence drives functional alterations in T cells, often correlated with increased cellular stiffness as previously reported in longitudinal studies [1]. However, the biophysical evolution of these cells in individuals achieving exceptional longevity remains unexplored. While aging typically correlates with progressive mechanical deterioration [1], we hypothesized that survivors reaching extreme age might exhibit a distinct phenotype. This study investigates the mechanical and structural properties of memory CD4⁺ T cells in a murine model of extreme longevity to identify signatures of mechanical resilience.

Methods

We performed a cross-sectional analysis on memory CD4⁺ T cells isolated from female ICR-CD1 mice across three distinct age groups: Old (72 weeks), Very Old (96 weeks), and Long-lived (>120 weeks), following established longevity criteria [2]. Cellular stiffness (apparent Young's modulus) was quantified via micropipette aspiration (Fig. 1) utilizing a linearized elastic model [3]. Functional motility was assessed through spontaneous migration assays in Boyden chambers. To correlate mechanics with intracellular architecture, we employed 3D confocal microscopy to analyze the relative nuclear size (R_n/R_c) and cytoskeletal anisotropy, alongside flow cytometry for protein expression.

Results



As expected, T cells from the Very Old group exhibited significant stiffening and reduced migration compared to the Old group, consistent with standard aging trajectories. However, this trend did not persist in the Long-lived group. Remarkably, cells from long-lived individuals displayed a mechanical phenotype comparable to the younger Old cohort, with stabilized stiffness values and significantly recovered migratory capacity compared to the "Very Old" group. Conversely, flow cytometry showed no significant differences in

cytoskeletal protein abundance (actin, myosin, vimentin) or senescence markers (p16) across groups.

Discussion

These findings demonstrate a decoupling between chronological age and cellular biomechanical decline in extreme longevity. The preservation of deformability and motility challenges the assumption of continuous stiffening in the immune system. We propose that this distinct biophysical phenotype in long-lived survivors allows for sustained immune surveillance, identifying cell mechanics as a potential biomarker for successful aging distinct from traditional biochemical markers.

Integrated mRNA–miRNA Profiling Reveals Dysregulation of Mechanotransduction Pathways in Osteoporotic Bone

Dr. Syeda Masooma Naqvi BSc, MSc, PhD[1], Mr. Munam Bukhari[1], Mr. Colin Murphy[2], Prof. Laoise McNamara[1]

[1]University of Galway, Galway, Connacht, Ireland. [2]University Hospitals Galway, Galway, Connacht, Ireland

Introduction

Osteoporosis is not solely a disease of bone loss; it involves disruption of cell–matrix signalling, mechanotransduction, and ECM homeostasis, diminishing bone quality. The mechanobiological basis of impaired osteocyte mechanosensing in osteoporotic bone remains unclear. Although circulating microRNAs (miRNAs) implicated in osteoporotic remodelling have been identified, transcriptional and post-transcriptional regulation within human bone tissue remains insufficiently characterised. To address this, we present the first integrated mRNA–miRNA mechanobiological profile of human osteoporotic femoral head bone to identify regulatory signatures linked to disrupted osteocyte mechanosensation.

Methods

Femoral head samples were collected from female patients undergoing total hip replacement and categorised as Non-OP (n = 8; age 55.6 ± 11.6 years) or OP (n = 4; age 80.7 ± 9.0 years). Total RNA was analysed using custom RT^2 Profiler arrays targeting anabolic, catabolic, and mechanosensitive genes. For miRNA profiling, cDNA was synthesised using the miRCURY LNA RT Kit and amplified via customised miRCURY PCR panels. Relative expression was determined using the comparative Cq ($2^{-}\Delta\Delta$Cq) method. Data dimensionality reduction and differential expression analysis identified clusters.

Results

mRNA profiling revealed transcriptional separation between groups, with PCA distinguishing OP from Non-OP samples (Fig. 1A). OP bone exhibited significant upregulation of anabolic and ECM-related genes (FN1 ↑22.7-fold, DMP1 ↑10.92-fold, BMP2 ↑8.8-fold, OPN ↑8.1-fold), osteocyte- regulation of osteoclasts (SOST) (Fig. 1B-D) and mechanosensitive genes encoding Axin-1, β-catenin, connexin-43, and integrin-β1 (Fig. 1C). miRNA profiling also distinguished OP from Non-OP bone (Fig. 1A). OP samples had

higher expression of osteogenic miRNAs (miR-29 family, miR-148a ↑57.9-fold) and the resorptive regulator (miR-27a) (Fig. 1B-D), while mechanotransduction-associated miRNAs (miR-141, miR-182, miR-183) remained unchanged (Fig. 1C), suggesting a selective disruption of mechanosensitive miRNA pathways.

Discussion

Integrated mRNA–miRNA analysis reveals a mechanobiologically imbalanced, high-turnover yet dysfunctional phenotype in osteoporotic bone, where elevated anabolic transcripts coexist with miRNA-mediated repression that may constrain effective matrix production. Increased expression of mechanosensitive genes highlights dysregulated osteocyte mechanotransduction, particularly within Wnt signaling, integrin–ECM interactions, and connexin-43–mediated communication. We propose that osteoporosis represents a maladaptive, mechanosensory-impaired state driven by discordant transcriptional and post-transcriptional regulation. This research identifies potential targets for therapies aimed at restoring load-responsive bone remodeling.

Mechanotransducers Downstream of LFA-1 Control Leukocyte Upstream Migration in the KG-1a Cell Line

Dr. Ai Mochida[1], Miss Emily Valerio[1], Dr. Janis Burkhardt[1,2], Dr. Daniel Hammer[1]

[1]University of Pennsylvania, Philadelphia, PA, United States. [2]Children's Hospital of Philadelphia, Philadelphia, PA, United States

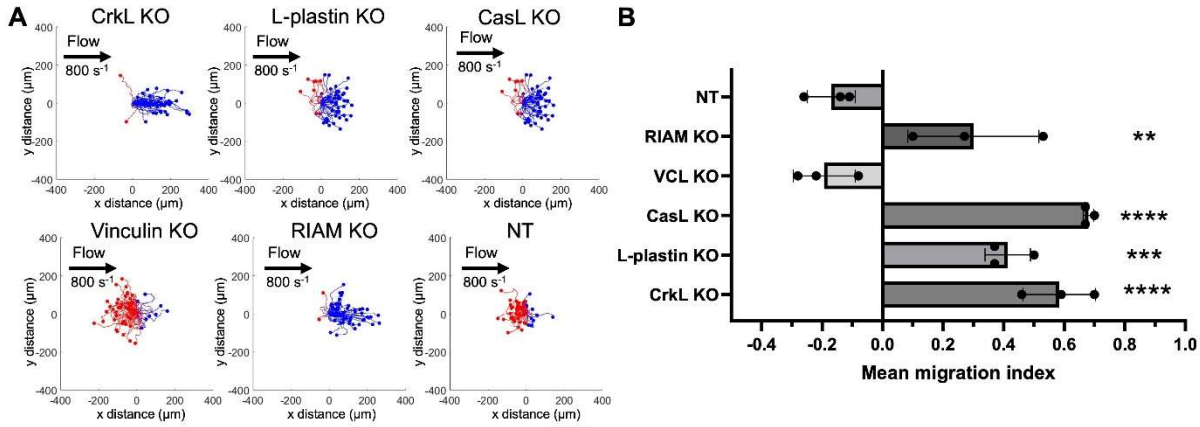
Introduction

Leukocyte migration is critical for an effective immune response. During homing, leukocytes experience high shear stresses as they crawl on the endothelium before transmigrating into tissues. On surfaces with intercellular adhesion molecule-1 (ICAM-1), which engages the integrin lymphocyte functional antigen-1 (LFA-1), lymphocytes preferentially migrate upstream, or against the direction of shear flow. Previous studies showed that signaling through LFA-1, including Crk and c-Cbl adaptor proteins but not PI3K, Arp2/3, or Cdc42 were critical for upstream migration. However, it is unclear if there are other intermediate molecules that link LFA-1 to actuating networks that modulate migration in response to shear flow. We studied the role of actin nucleation promoting factors (NPFs) WASP and Hem1; Ena/VASP-like (EVL) protein; CasL, which binds to Crk; and molecules linking the actin cytoskeleton to integrins including vinculin, L-plastin, and RIAM.

Methods

We used the human HSPC-like KG-1a cell line to generate CRISPR/Cas9-mediated knockouts. Migration on ICAM-1 under shear flow (n=3, at least 30 cells/experiment) was analyzed to calculate the mean migration index (MI), where negative MIs represent upstream migration and positive MIs represent downstream migration. Lifeact-GFP videos (at least 5 cells/KO) were analyzed for leading edge dynamics. For statistical analysis, we used one-way ANOVAs with Dunnett’s multiple comparisons.

Results



We found that L-plastin, CasL, CrkL, and RIAM-deficient cells were unable to migrate upstream. Meanwhile, Hem1, WASP, EVL, and vinculin were dispensable for upstream migration. Compared to upstream-migrating cells, knockouts that reversed direction of migration appeared to have F-actin localized to the uropod instead of the lamellipod. In

addition, the knockouts protruded continuously along the direction of shear flow and did not retract compared to upstream-migrating cells.

Discussion

We have identified 3 novel molecules that controlled the direction of cell migration under shear flow in KG-1a cells. Leukocyte upstream migration has been observed *in vivo*, with studies indicating upstream migration may enable more effective transmigration, leading to increased homing to target organs. Future work includes assessing transendothelial migration on a HUVEC monolayer to investigate the physiological relevance of upstream migration. This study provides insights into mechanotransduction and integrin signaling that regulate leukocyte migration under shear flow.

Introduction

Burkitt lymphoma (BL), an aggressive type of B-cell lymphoma, is highly overrepresented among people living with HIV. Intriguingly, the risk of developing HIV-related BL remains high even when viral load is well-controlled. In BL patients with HIV, the HIV-1 Trans-activator of Transcription (Tat) protein is internalised within tumour cells. Emerging evidence suggests that the HIV viral proteins can promote oncogenic events in bystander cells. It is unclear whether this impacts BL cell mechanics, which may have implications for BL pathogenesis and treatment. This research aimed to determine if and how Tat expression modifies the mechanical properties of BL cells, and whether such changes can be chemically adjusted by targeted treatment.

Methods

Shear-flow deformation cytometry was used to compare the mechanical properties of Tat-expressing Burkitt lymphoma cells (BL-41-Tat) with their parental line under two conditions: 2 μM cytochalasin D for actin disruption or 1% DMSO vehicle control. Cells were cultured under standard conditions, treated for 30 minutes, and suspended in 2% (w/v) sodium alginate. Cell suspensions were driven through a straight 200 μm × 200 μm square microchannel and imaged using a CMOS camera at 50 frames per second. Cell deformations were analysed with a UNet-based neural network to extract single-cell mechanical parameters, including stiffness, storage and loss moduli, and fluidity. Two independent biological repeats were performed, each comprising 10 runs with an average of 500 cells per run for each group.

Results

BL 41-Tat cells were stiffer and less fluid than BL 41 cells. With cytochalasin D treatment, the elastic (G') and viscous (G'') response of BL-41-Tat indicated a reversal to BL-41 values. Stiffness and fluidity shifted towards the parental BL-41 mechano-phenotype (Figure 1).

Discussion

Tat expression shifted BL-41 cells toward a more solid-like, less deformable mechanical state, consistent with reinforcement of the actin cytoskeleton and a potentially more aggressive lymphoma phenotype. Cytoskeletal disruption with cytochalasin D largely reversed this Tat-induced mechanical behaviour, indicating that the altered cell mechanics are predominantly actin driven, with residual differences likely reflecting additional cytoskeletal reorganisation. Further research will elucidate whether these mechano-phenotypic changes can inform strategies targeting invasiveness and chemoresistance of HIV-associated BL.

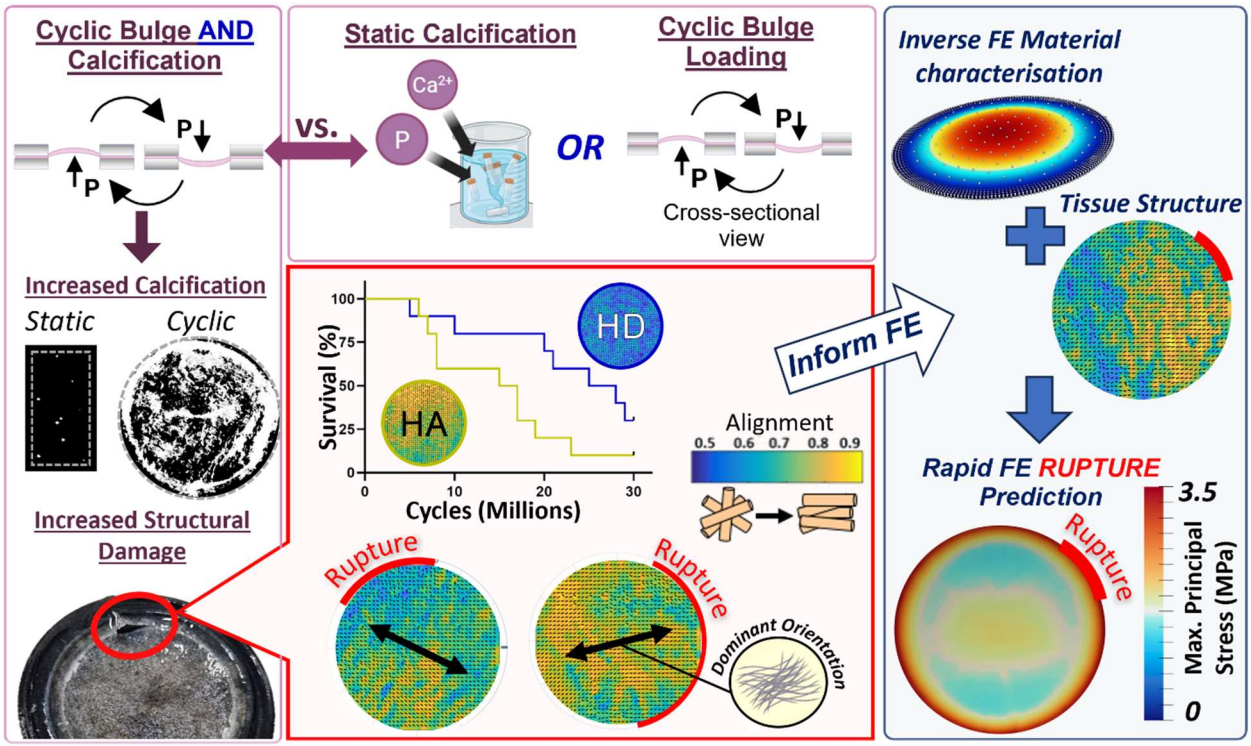
Introduction

Severe aortic stenosis (AS) is a life-threatening condition that narrows and stiffens the aortic valve, with a four-year mortality rate of 44.9% [1]. Minimally invasive bioprosthetic heart valve (BHV) implantation has transformed AS treatment. However, device durability remains limited by regurgitation or stenosis [2]. Calcification and structural damage are key contributors to device failure, yet their interaction is debated [3]. This study investigates interactions between calcification and structural damage and the influence of fibre architecture, and uses these insights to inform CARDIAX, a rapid cardiac mechanics simulation platform [4], with a view to extending pericardial tissue durability.

Methods

Porcine pericardium (PP) was screened non-destructively using a small angle light scattering (SALS) system to separate highly aligned (HA) and highly dispersed (HD) fibre groups [5]. Samples underwent in-vitro calcification in a cyclic bi-directional bulge inflation rig for 30 million cycles. Structural damage and calcification were quantified throughout using digital image correlation (DIC) and μCT imaging respectively [3]. Calcified samples were compared to uncalcified PP loaded in the same conditions. A finite element (FE) model was developed in CARDIAX using a modified fibre-ensemble constitutive equation based on Sacks et al. [6], calibrated with inverse modelling across three pressurisation levels.



Results

16 of 20 samples loaded in calcification solution ruptured; a behaviour absent in saline-loaded samples. HA tissue ruptured at approximately twice the rate of HD, with rupture sites dictated by dominant fibre direction, see Figure 1. FE simulations of HA PP reveal stress concentrations along the dominant fibre alignment, indicating a predictive link between fibre architecture and rupture.

Discussion

Calcification and structural damage act together to induce pericardium failure. The 2x increase in rupture rate observed in HA calcified tissue substantiates that fibre-mediated tissue mechanics affect leaflet durability in prosthetic valves. GPU-accelerated simulations combined with non-destructive fibre screening provide a pathway for optimising leaflet selection, improving long-term outcomes for patients treated with BHVs.

Introduction

Transcatheter aortic valve implantation (TAVI) is an established treatment for aortic stenosis, yet paravalvular leakage (PVL) remains a clinically relevant complication. Patient-specific numerical simulations offer powerful tools for predicting procedural outcomes. However, current models are limited by methodological heterogeneity and incomplete validation against clinical data[1]. Specifically, most studies rely on qualitative echocardiographic comparisons, and none incorporate cardiac MRI, limiting translational reliability.

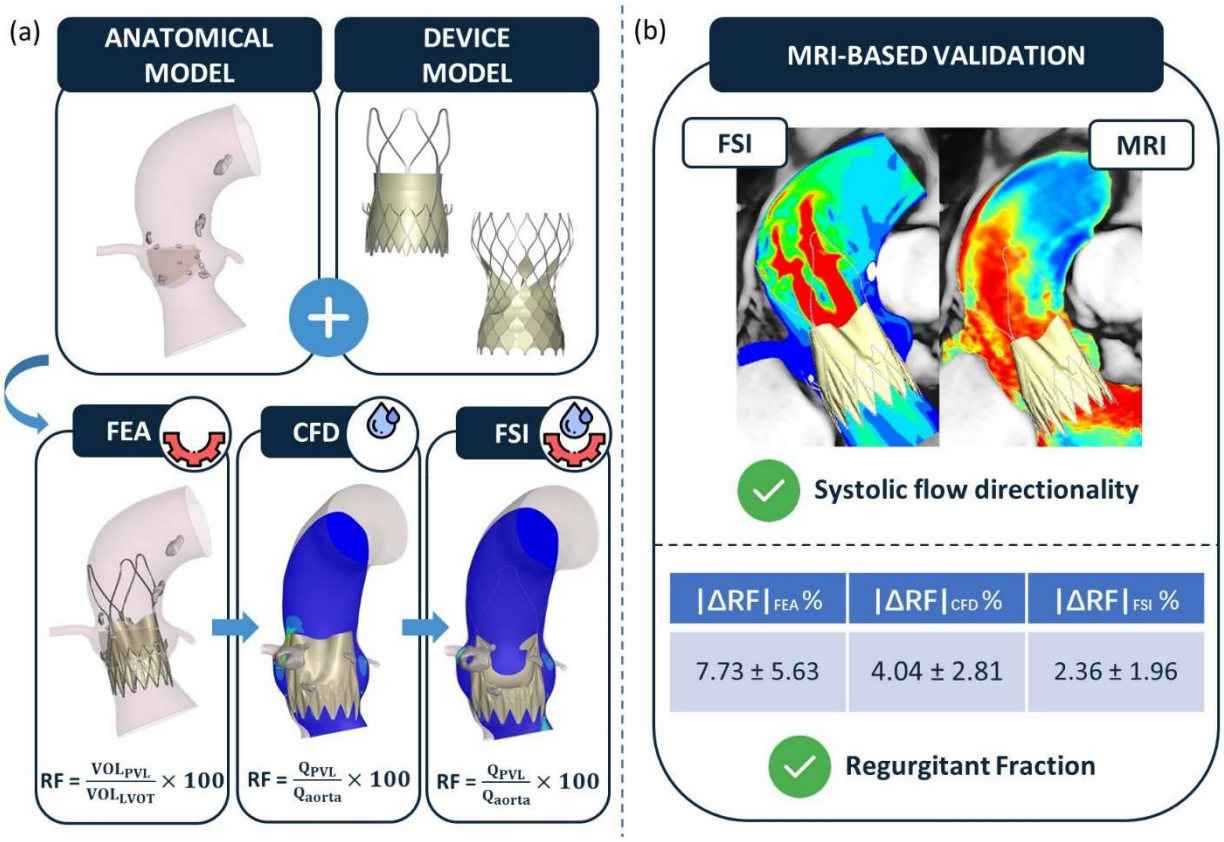
To fill this gap, this study aims to validate different numerical strategies for PVL prediction by quantitively comparing in-silico outputs with post-TAVI MRI measurements, to identify the modelling approach with the highest clinical accuracy.

Methods

Ten patients undergoing TAVI were prospectively enrolled, and dedicated post-procedural MRI images were acquired. Patient-specific anatomies were reconstructed from pre-operative CTs, and device models were calibrated using ad-hoc crimping tests[2]. FEA simulations reproduced device deployment within each native anatomy. Subsequently, diastolic CFD simulations were performed using patient-specific transvalvular pressure gradients as boundary conditions (BCs). A novel FSI framework was also implemented, setting intraoperatively acquired pressure waveforms as BCs, with calibrated Windkessel models at coronary outlets.

FSI-based systolic flow directionality was visually compared against cine MRI to confirm correct prosthesis orientation. For each strategy (FEA, CFD, FSI), the regurgitant fraction (RF) was quantified, and its absolute deviation from MRI-derived RF was computed. Figure1a depicts the workflow.

Results



Simulations were successfully completed for all patients. The directionality of systolic flow within the aortic root exhibited good qualitative agreement with MRI acquisitions(Figure1b). The average absolute RF deviation with respect to MRI-based measurements was 7.73±5.63% for FEA-based geometric assessment, 4.04±2.81% for CFD and 2.36±1.96% for FSI analysis.

Discussion

Among the investigated numerical strategies, FSI demonstrated the highest accuracy in predicting post-TAVI PVL. By integrating patient-specific, time-dependent boundary conditions within a deformable anatomical domain, FSI captures the dynamic interaction between the prosthesis and the cardiovascular system, yielding the most physiological haemodynamic representation.

These findings represent a methodological advancement over current state-of-the-art, identifying the validated FSI simulations developed in this study as an accurate in-silico strategy for assessing TAVI outcomes and guiding patient-tailored procedural planning.

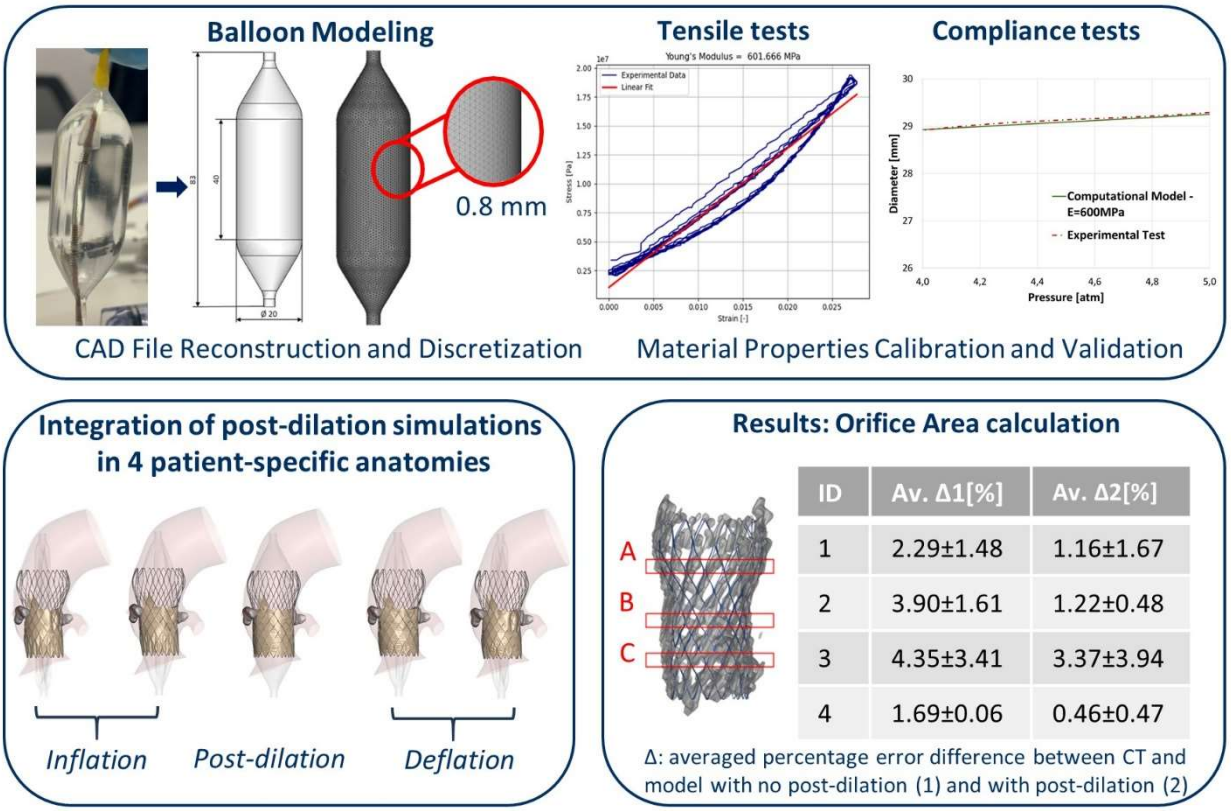
Introduction

Transcatheter Aortic Valve Implantation (TAVI) is a minimally invasive treatment for aortic stenosis. Balloon post-dilation, commonly performed to optimize device expansion and reduce paravalvular leakage (PVL), critically influences final device–tissue interaction and clinical outcomes. Despite its clinical importance, post-dilation is often omitted in computational models, limiting their ability to replicate real-world behaviour and predict procedural risks. This study develops and validates patient-specific numerical simulations of TAVI post-dilation to improve the mechanical realism and predictive power of existing models. Simulation results are validated based on post-operative CT images, and their impact is assessed by comparing them with models without post-dilation.

Methods

Four patients were included. The Edwards Lifesciences post-dilation balloon was reconstructed, discretized, and its material properties calibrated through uniaxial tensile tests. Experimental and computational compliance tests were then performed to validate the material model. Finally, the calibrated balloon was integrated into patient-specific anatomies, after simulating TAVI deployment, to carry out finite-element post-dilation simulations. The orifice area (OA), averaged across three cross-sectional stent planes, and the eccentricity were extracted from both the segmented and simulated stent configurations to quantify the predictive accuracy of the simulations as outlined in our previous work [1]. Prediction errors from simulations with and without post-dilation were then compared to evaluate its impact. Figure 1 illustrates the workflow and previous results.



Results

Post-dilation simulations were successfully performed on the previously implanted TAVI devices. The average absolute deviation of OA percentage difference error between the simulated and CT-derived stent configurations decreased from 3.06±1.27% in simulations without post-dilation to 1.55±1.26% when post-dilation was included. A similar improvement was observed for eccentricity percentage error, decreasing from 5.70±5.80% to 1.62±1.08% when post-dilation was simulated.

Discussion

A dedicated computational workflow was established to model balloon post-dilation, with material properties calibrated and validated experimentally. The effect of post-dilation on stent deformation was systematically assessed. This work is novel, as previous studies have not modelled this clinically critical step, despite its role in optimizing valve expansion and improving outcomes, especially in complex anatomies.

A Mechano-Mimetic Mitral Valve for Evaluation of Repair in Grades of Mitral Regurgitation – In Vitro and In Silico Findings

Dr Sina Javadpour[1], Prof Fergal O'Brien[1,2], Dr Claire Conway[1,2]

[1]RCSI, Dublin, Leinster, Ireland. [2]Trinity College Dublin, Dublin, Leinster, Ireland

Dr Sina Javadpour

Prof Fergal O'Brien

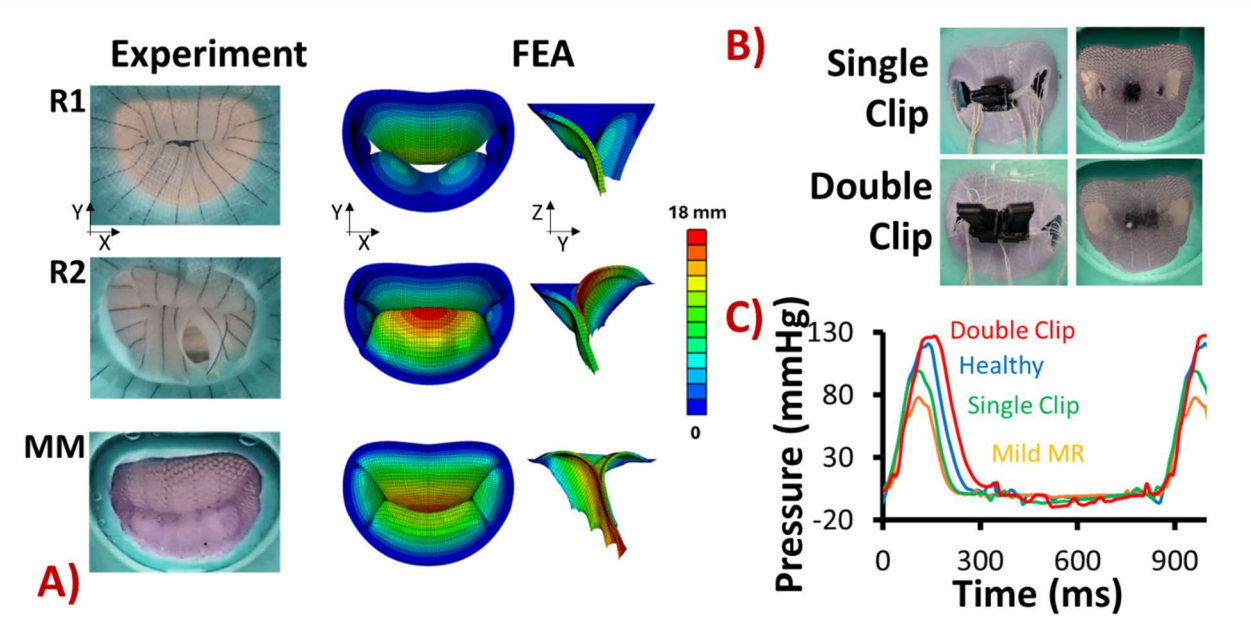
Introduction

Mitral valve mechanics play a significant role in its function and alterations in mechanics are classical indicators of valvular disease. As minimally invasive treatments emerge the modes of study of the mitral valve need to advance. In-vitro flow rigs with ex-vivo mitral valves lack pathology, have low anatomical consistency, and varied material properties. Therefore, synthetic mitral valves are being developed for flow examinations, but to-date lack anisotropy and capacity for physiological pressures.

Methods

A novel mechano-mimetic synthetic mitral valve with anisotropic leaflet mechanical properties is presented. A left heart simulator for a mechano-mimetic mitral valve loading under physiological flow conditions (70 beats per minute, cardiac output 4-6 L/min, transmitral pressure ~120 mmHg) and related computational models (FEA - finite element analysis) are presented. The mechano-mimetic valve (MM) is compared to two other polymeric valves with varying types of reinforcement (R1, R2 – Fig1A). Grades of mitral regurgitation (MR) are introduced via annular dilation, via extension in the posterior leaflet direction, and edge-to-edge repair (EER) is investigated for centrally placed single and double clips (Fig1B).

Results



The left heart simulator successfully tested the mechano-mimetic mitral valve under physiological conditions. Left atrial viewing of coaptation profiles, during systolic ventricular ejection, mimicked clinical features, in particular, with anterior mitral leaflet

dominance noted in MM. FEA predicted a similar coaptation profile, healthy range of leaflet bulge, and quantification of coaptation length in mm (Fig1A). EER for grades of MR revealed clipping repair most suited to mild levels of MR (Fig1C). There were minimal improvements with single or double clipping for moderate and severe grades of MR.

Discussion

This novel, low-cost physical model addresses the compelling need for anatomically representative, repeatable, and durable synthetic mitral valves with precise control over leaflet thickness and incorporating anisotropic material properties to advance our understanding mitral mechanics. With the capability to simulate controlled grades of MR, it represents a vital advancement for device testing, as demonstrated here for EER clipping scenarios.

Label-Free Particle Accumulation in Helical Microtubes with Secondary Flows

Mr Tianmian Liu[1], Mr Deyun Liu[1], Mr Shenghong Zhang[1], Prof Kazuyasu Sugiyama[2], Prof Xiaobo Gong[1]

[1]Shanghai Jiao Tong University, Shanghai, Shanghai, China. [2]The University of Osaka, Toyonaka, Osaka, Japan

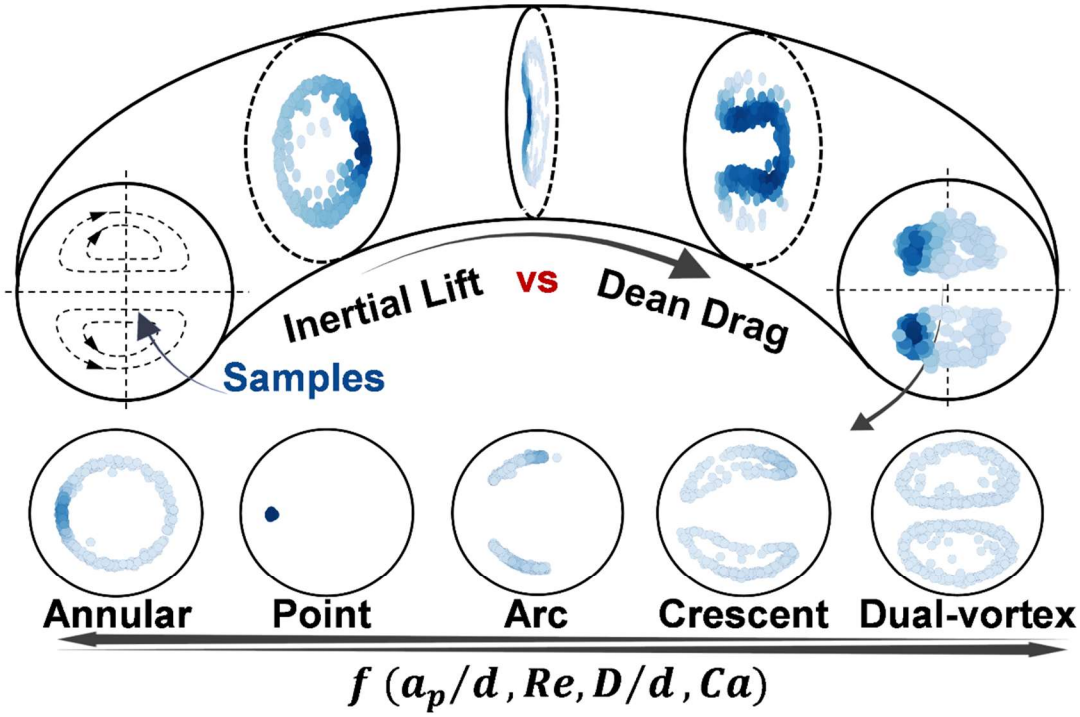
Introduction

Curved microfluidic channels utilizing secondary flows offer a label-free strategy for sorting rare and heterogeneous targets such as exosomes, T cells, and mesenchymal stem cells. However, limited understanding of particle dynamics constrains sorting efficiency and precision. This study aims to elucidate the hydrodynamic mechanisms driving the formation and transition of distribution patterns of rigid particles and deformable cells in three-dimensional helical microtubes.

Methods

We develop a three-dimensional microfluidic platform with helical microtubular channels that generates steady, tunable secondary flows across a broad range of Reynolds (Re=1–224) and Dean numbers (De=0.056–25.04) to visualize cross-sectional particle distributions using fluorescence microscopy. The force balance between inertial lift and Dean drag, together with particle trajectories, is further analyzed using semi-analytical approaches and the immersed boundary method.

Results



Within the parameter ranges of Reynolds number $1 \leq Re \leq 224$, normalized helical diameter $80 \leq D/d \leq 320$, and particle-to-channel diameter ratio $0.06 \leq ap/d \leq 0.27$, five distinct cross-sectional distribution patterns are observed. A dimensionless parameter, the characteristic inertial force ratio (γ), defined as the ratio of the maximum inertial lift to the maximum Dean drag, is introduced to elucidate the transition of distribution regimes from lift-dominated to drag-dominated states, providing a quantitative basis for predicting pattern evolution.A trade-off between focusing efficiency and size resolution is revealed, and an off-axis collection strategy is proposed to exploit non-horizontal equilibrium positions for improved sorting accuracy. Furthermore, a comparison between rigid particles and Jurkat cells show that cell deformability alters equilibrium positions and focusing patterns in the helical flow. The deformation-induced lift force, characterized by

the Capillary number (Ca), emerges as a key parameter governing the lateral migration behavior of cells.

Discussion

This work establishes a unified physical framework for understanding particle and cell migration in secondary-flow microfluidics. The combined parameters γ and Ca govern distribution transitions, offering design guidance for optimizing focusing efficiency and sorting precision in label-free microfluidic platforms.

Analysing the Effect of RBC Aggregation and Deformability in the Microhaemodynamics

Miss Gladys Diaz Armas, Dr. Joseph van Batenburg-Sherwood

Imperial College London, London, London, United Kingdom

Introduction

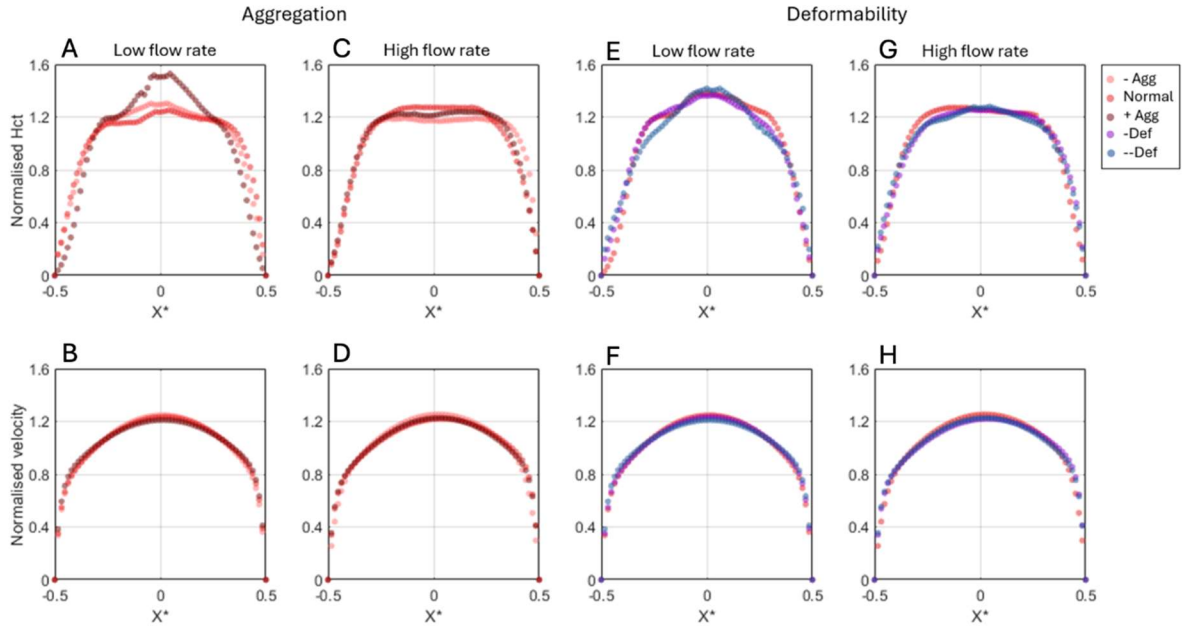
In diabetes, red blood cell (RBC) aggregation increases and deformability decreases, likely contributing to microvascular symptoms by raising blood viscosity, altering the flow dynamics, and impairing oxygen transport. Although aggregation and deformability have been studied individually, their combined effects remain unclear. Our work aims to determine how these two mechanical properties jointly shape blood flow in health and disease. We began with a simple model, a straight channel, to examine how RBC velocity and concentration change with altered aggregation and deformability.

Methods

We built an optical system that alternates blue and red illumination to capture image pairs at high-speed. Red-light images yield velocity profiles via Particle Image Velocimetry (PIV), with underestimation corrected using a flow sensor. Blue-light images provide local haematocrit based on the principles of optical densitometry and the Beer–Lambert law. Healthy RBCs were washed and suspended at 25% haematocrit in solutions of 0.5% or 1% Dextran 500 kDa to induce normal or increased aggregation. Deformability was reduced by incubating cells with 0.04% or 0.08% glutaraldehyde before resuspension in low-aggregation media. A 43x40 μm channel was used, and flow was controlled by pressure differences between the inlet and outlet.

Results

At low flow rates, RBC migration increases with aggregation (Fig. 1a). At higher flow rates, the difference is subtler but present (Fig. 1c). Velocity profiles appear blunter with increased migration, indicating a negative correlation between velocity and haematocrit bluntness (Fig. 1b,d).



A similar trend is observed with varied deformability. Consistent with [1], stiffer cells showed increased migration, contrasting with what is generally expected for rigid discs (Fig.

1e,g). Velocity profile bluntness also shows a negative correlation with haematocrit bluntness (Fig. 1f,h).

Discussion

Both increased aggregation and decreased deformability increase migration, affecting the local viscosity at the walls and therefore changing the shear stress. The different profiles will impact how RBCs are distributed at bifurcations, which could lead to some branches having low Hct, causing hypoxia in specific locations. Next steps include analysing these samples in networks that better represent the microvasculature to better understand the role of RBC mechanical properties in blood flow.

Introduction

The chick embryo is a valuable model for studying the effects of new drugs on the vascular system, a knowledge crucial to understand vascular related diseases. Intravital imaging of animal vasculature is limited by upright microscopes, invasive windows or reduced signal-to-noise ratio. We developed the "Eggs&Beacon" platform for performing longitudinal intravital imaging on avian embryos on inverted microscopes and MRI-systems. We used this platform to quantify immune reaction to implanted human breast cancer tumors and we developed a predictive model of druggability.

Methods

We created an artificial eggshell assuring a sufficient oxygen influx and transparency. Eggshell's supported by a plastic case (Form3B+, Formlabs) made of a body, a cap and an imaging window (Fig.1a). This platform fit embryos on inverted microscopes (EclipseTi-2, Nikon). We observed the same embryo at different time-points (EID 8,11,14). The imaging window is a millifluidic device imaged with a water-immersion objective (40X, NA=1.1, WD=0.8mm) where fluids were used to correct optical distortions. We performed MRI imaging (Bruker, Ettlingen) on a 7T scanner (BioSpec70/20), with a 72mm 1H-linear radiofrequency coil (T2-RARE echo-time=100ms;rep-times=8400ms;slice=1mm).

Results

The platform enabled embryo survival >33% and longitudinal imaging up-to 14days. Nonlinear microscopy showed inflammatory reaction at the tumor-implanted region with a drug controllable modulation. SHG revealed referentially oriented collagen-I in

microenvironments. The realized membranes (thickness<130µm) enabled the embryos to survive until EID14 (Fig.1a). Eggs&Beacon allowed to expose the vasculature to the microscope objective, without compromising the embryo's viability (Fig.1b-e). We quantified angiogenesis with TPEF (Z=600µm, λexc=800nm, λem<450nm, Fig.1c,e). SHG (Z=600µm, λexc=910 nm, λem=450/55nm, Fig.1e,f) showed collagen-I matrix and enabled us to measure amount and direction of fibers. By MRI, we quantified the vascular network growth and the embryo's body dimension (Fig.1d-f).

Discussion

We developed a multimodal imaging platform compatible with inverted microscopy and MRI to monitor living avian embryos up to EID14. By enabling the longitudinal quantification of fibrosis, as blood vessel density, and collagen production allows for the assessment of anti-angiogenic drugs and systemic responses. Crucially, this versatile approach offers a method to evaluate pharmaceutical efficacy and safety in-vivo while significantly reducing the reliance on mammals' models.

OA90-06

The Influence of Red Blood Cell Deformability on Endothelial Cell Nitric Oxide Signalling: A Biomicrofluidic Approach

Miss Ioana Esanu, Dr Joseph van Batenburg-Sherwood

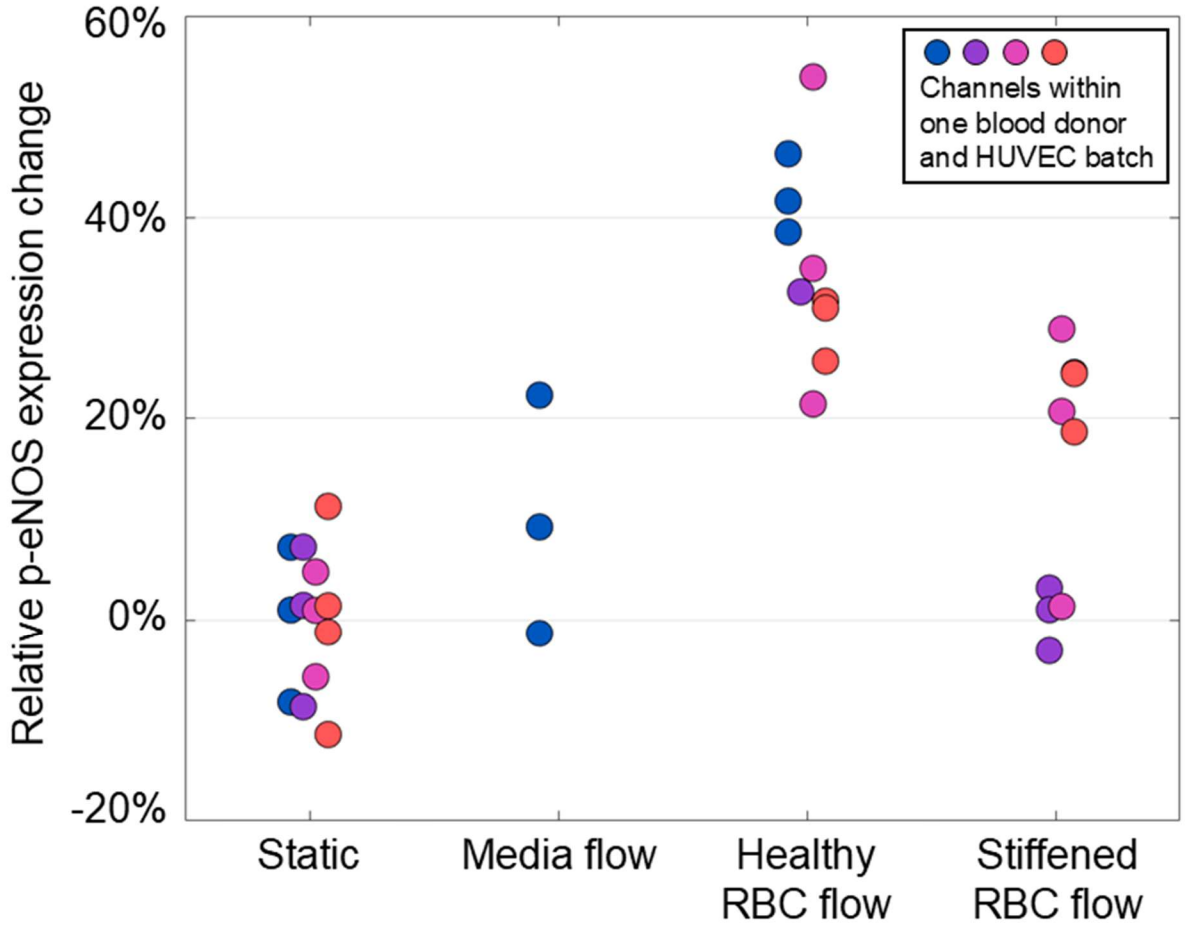
Imperial College, London, London, United Kingdom

Introduction

The endothelial cells (ECs) lining the vessels experience shear stress imposed by blood flow, which is detected by ECs and modulates behaviour like vasoregulation, permeability and inflammation. Microvascular flow and the resulting shear stress are determined by the physical properties of red blood cells (RBCs), particularly deformability, which decreases in diabetes and even more in diabetic retinopathy. We therefore hypothesise that reduced RBC deformability modifies local shear stress, contributing to microvascular dysregulation in diabetes.

Methods

Microfluidic channels (50x900µm) were fabricated from laser-cut adhesive tape, acrylic layers and a glass coverslip bottom, on which HUVECs were grown under continuous media turnover via hydrostatic pressure. A pressure controller then supplied 24mbar, generating an arteriolar-level shear stress of 30dyn/cm^2, irrespective of fluid. Channels were perfused for 1h with culture media or with 25% haematocrit RBC suspensions from human donors (healthy or glutaraldehyde-stiffened to mimic diabetes). Immunofluorescence intensity of cytosolic phosphorylated eNOS was quantified relative to a static control within each blood donor and HUVEC batch, averaged across 4 images per channel.



Results

Perfusion with healthy RBCs increased p-eNOS intensity by 23 [17, 29]% compared to media flow (mean [95% CI], p<0.002, one-way ANOVA, Tukey post-hoc). Stiffened RBC flow resulted in a change of 3 [-6,12]% compared to media (p>0.05), which was statistically different from healthy RBCs (p<0.001). As the same average shear stress was applied with all perfusates, we attribute these differences to local, transient, RBC-driven changes in blood flow. Linear mixed-model ANOVA showed no dependence on blood donor or HUVEC batch.

Discussion

RBCs enhance EC mechanical activation via the nitric oxide signalling pathway, but the response is supressed when RBCs are stiffened, despite the same average shear stress. We posit this is due to enhanced migration of stiff RBCs towards the vessel centre [1], reducing discrete EC-RBC interactions. We believe this points to a key role of RBCs in endothelial mechanotransduction, which upon disruption may contribute to microvascular dysfunction, emphasising the need to include RBCs more widely in EC flow studies. Future work will examine long-term and spatial effects of RBC flow in branching microfluidic networks.

Composition-Dependent Mechanics and Stability of Collagen Proteins

Dr. Alaa Al-Shaer, Ms. Janine Srocka, Ms. Kassandra Richard, Mr. Daniel Sloseris, Prof. Nancy Forde

Simon Fraser University, Burnaby, BC, Canada

Introduction

As the predominant proteins in our bodies, collagens are the building blocks of connective tissues and the extracellular matrix, where they perform critical structural and mechanical roles. Surprisingly, individual collagen proteins are structurally unstable at body temperature [1]. We apply atomic force microscopy (AFM) imaging to characterize the bending stiffness and structural stability of different types of collagen, thereby learning about the interplay among stability, mechanics and chemical composition in these essential proteins.

Methods

We imaged different types of collagen proteins (collagens I, III and IV) using AFM, and deposited collagen samples at different temperatures to investigate their thermal stability. Collagen I was treated with ribose as a chemical model of aging. We used our SmarTrace software [2] to analyse the conformations of hundreds of collagen proteins, determining contour lengths and bending stiffnesses. For collagen samples with a globular end, we mapped the chain flexibility as a function of position, providing a mapping between protein sequence and bending stiffness [3].

Results

We observed collagens to be unstable at 37°C [4], consistent with previous bulk measurements [1]. Our analysis of large ensembles of denaturing and renaturing collagens allowed us to map the thermally induced unfolding and refolding pathways of collagen IV, and we determined that disulfide bonds are critical for renaturation [4]. We also found that interruptions in the (Gly-X-Y)n sequence within collagen IV enhance flexibility [3], and that aging causes collagen proteins to destabilize and stiffen [5].

Discussion

Our results demonstrate the power of AFM imaging to provide insight into the mechanics and structural stability of collagen proteins. Because these proteins are not amenable to high-resolution structural study with conventional approaches, AFM can fill a valuable niche in mapping sequence and compositional changes, e.g. arising in disease, to their

effects on local mechanics and structural stability. Increasing spatial resolution will further deepen our mechanistic understanding of this key structural building block of our tissues.

Structural Determinants of Microtubule Mechanics: A Computational Analysis of Protofilament Architectures

Dr. Eric Adriano Zizzi[1], Dr. Maco Cannariato[1], Dr. Marcello Miceli[2,1], prof. Umberto Morbiducci[1,3], prof. Marco Agostino Deriu[1]

[1]PolitoBIOMed Lab, Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Turin, TO, Italy. [2]Dalle Molle Institute for Artificial Intelligence IDSIA. USI/SUPSI, Lugano-Viganello, CH, Switzerland. [3]Department of Life Sciences, Università Degli Studi di Modena e Reggio Emilia, Modena, MO, Italy

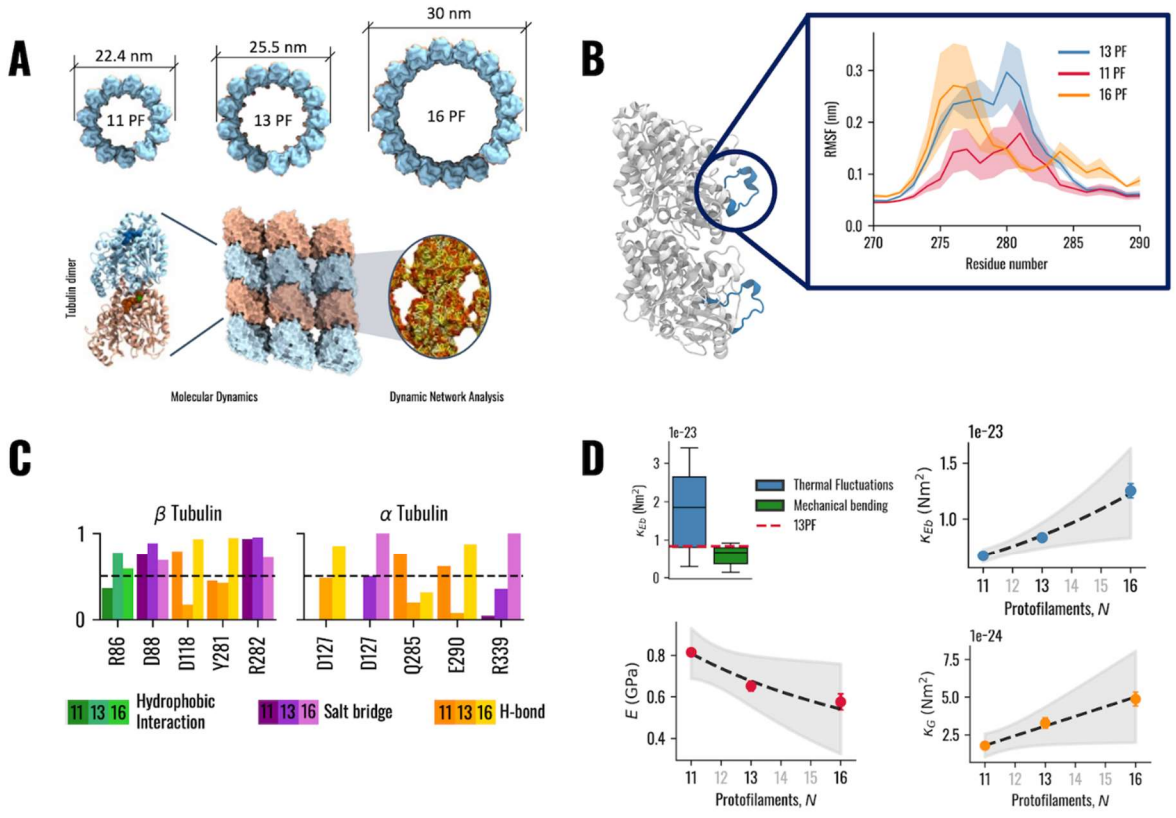
Introduction

Microtubules (MTs) are αβ-tubulin polymers that govern key cellular processes and exhibit a considerable architectural heterogeneity, with protofilament (PF) numbers varying depending on assembly conditions, cellular context and tubulin isotypes [1,2]. This heterogeneity has been shown to determine functional consequences. However, how architectural differences determine emergent mechanical properties of the MT has not been fully elucidated. Herein, we conducted an *in-silico* investigation of the structure–mechanics relationships in MTs.

Methods

We constructed human αIb-βIII tubulin patches from the 3J6F PDB template, subsequently fitted to architecture-specific cryo-EM maps [3] to generate 11, 13, 16 PF systems (Figure 1A). We performed 500-ns molecular dynamics (MD) simulations using GROMACS 2021.4 and the AMBER ff99SB-ILDN force field, and evaluated the root mean square deviation (RMSD) and fluctuation (RMSF), inter-tubulin contact probabilities, electrostatics, and performed dynamic network (DN) analysis. Conformations were extracted to reconstruct 400-nm MTs for the elastic network modelling – normal mode analysis (ENM–NMA).

Results



Architecture-dependent differences in βM-loop dynamics emerged from simulations (Figure 1B), with 16PF architecture also exhibiting C-terminal stabilization. The 16PF architecture also featured larger buried interface, the 11PF higher hydrophobic character, and each lattice showed residue-specific interactions (Figure 1C). The DN analysis revealed how mechanical communication path lengths increased with PF number, while the ENM yielded persistence lengths consistent with experimental measurements [4], and demonstrated that bending (k_{Eb}) and torsional (k_G) stiffnesses increased with PF count (Figure 1D). The Young's modulus *E*decreased from ~ 0.8 GPa to about 0.6 GPa with

increasing numbers of PFs (Figure 1D), revealing a competing effect between MT material properties and geometrical characteristics.

Discussion

PF number is a tunable architectural parameter determining MT mechanics: lower PF lattices exhibit more efficient vibrational communication, whereas higher PF architectures provide enhanced stiffness, supporting the view that MT architecture encodes function and revealing the design principles underlying cytoskeleton mechanics. Ongoing work extending this framework to different tubulin isotypes will further elucidate how molecular-level variations modulate emergent MT mechanical behavior.

High-Resolution Imaging of Untwisted and Melted DNA in a Cell Nucleus

Assoc. Prof. Koichiro Maki PhD[1], Dr Jumpei Fukute PhD[2,3], Mr Shu Kanikawa BS[1], Ms Miwa Rokudo BS[1], Mr Akira Kumano BS[1], Prof Taiji Adachi PhD[1]

[1]Kyoto University, Kyoto, Kyoto, Japan. [2]The University of Tokyo, Bunkyo, Tokyo, Japan. [3]Karolinska Institute, Stockholm, Stockholm, Sweden

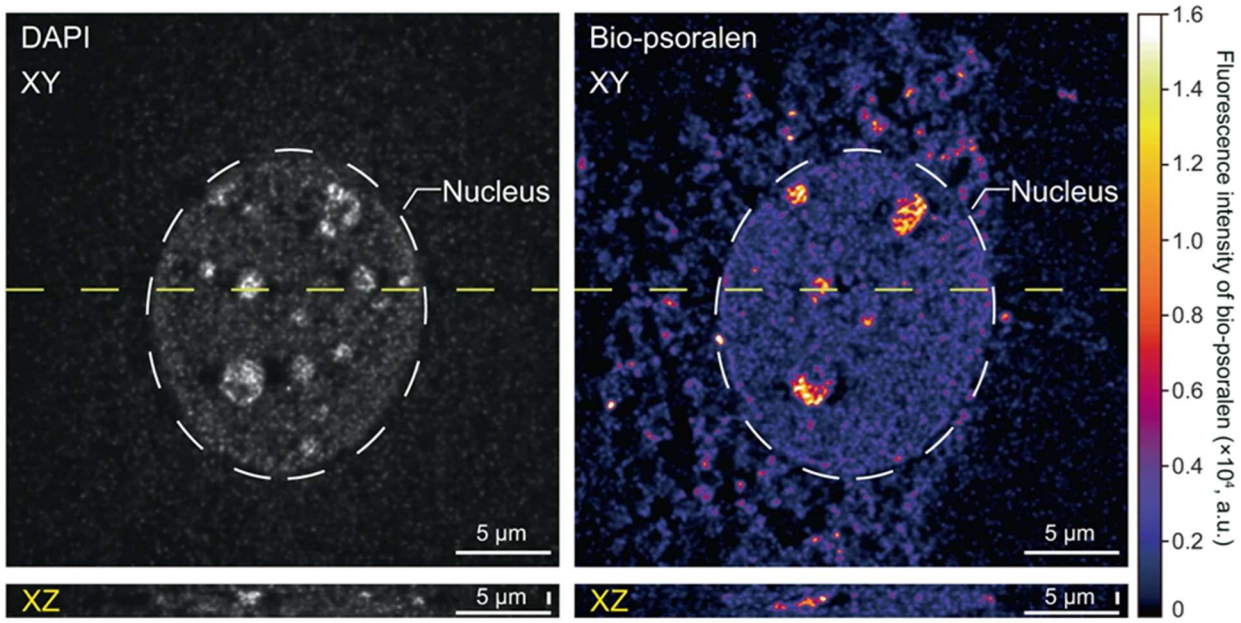
Introduction

Cellular mechanotransduction is mediated by various kinds of mechano-sensors. Recently, nuclear chromatin is reported to contribute to mechanotransduction under hydrostatic pressure, by altering the architecture for transcriptional regulation [1]. Although one of the possible mechanisms is deformation of DNA duplex (e.g. untwisting and melting) under mechanical environment, which would be critical in the regulation of chromatin architecture and transcription, there are few available techniques for detecting deformed DNA duplex. In addition, DNA deformation would be highly depending on local mechanical environment in a cell nucleus. Therefore, the development of *in situ* imaging technique is required to explore how DNA is deformed under local mechanical environment in a nucleus.

Methods

In order to fluorescently label untwisted DNA, we utilized a psoralen, which is an intercalator that preferentially binds to untwisted DNA [2]. Cells were gently permeabilized with digitonin and treated with biotinylated psoralen followed by UV irradiation for crosslinking untwisted DNA and psoralen. After fixation by paraformaldehyde and further permeabilization, incorporated biotinylated psoralen was fluorescently detected by NeutrAvidin Protein, DyLight 488. SYBR Green II was utilized to label single-stranded DNA after RNase A treatment.

Results



As a result, we observed that untwisted DNA is abundant inside nucleolus (Figure). The abundance of untwisted DNA was reduced by inhibition of RNA polymerase I (RNAPI) as well as by blocking G-quadruplex (G4) structure, implying the importance of RNAPI-based torque-generation coupled with its G4-based constraints of axial rotation by NPM1, which forms phase separated condensates. More interestingly, single-stranded DNA was found to be accumulated surrounding the nucleolar shell [3]. This suggests a positive feedback

mechanism in which untwisted DNA produced in the nucleolar core transits to single-stranded DNA toward the shell, to supply G4 structures for further DNA untwisting.

Discussion

We revealed that DNA deformation (untwisting and melting) occurs under endogenous mechanical environment. In future, we explore how endogenous mechanical forces such as hydrostatic pressure affects the deformation state of DNA for transcriptional regulation.

Mechanomic Profiling of Cytoskeletal Architecture and Intracellular Forces in Senescent Fibroblasts

Prof. Shinji Deguchi Ph.D., Ms. Yuika Ueda, Ms. Intan Chairun Nisa, Dr. Pirawan Chantachotikul, Dr. Takumi Saito Assistant Professor

The University of Osaka, Toyonaka, Osaka, Japan

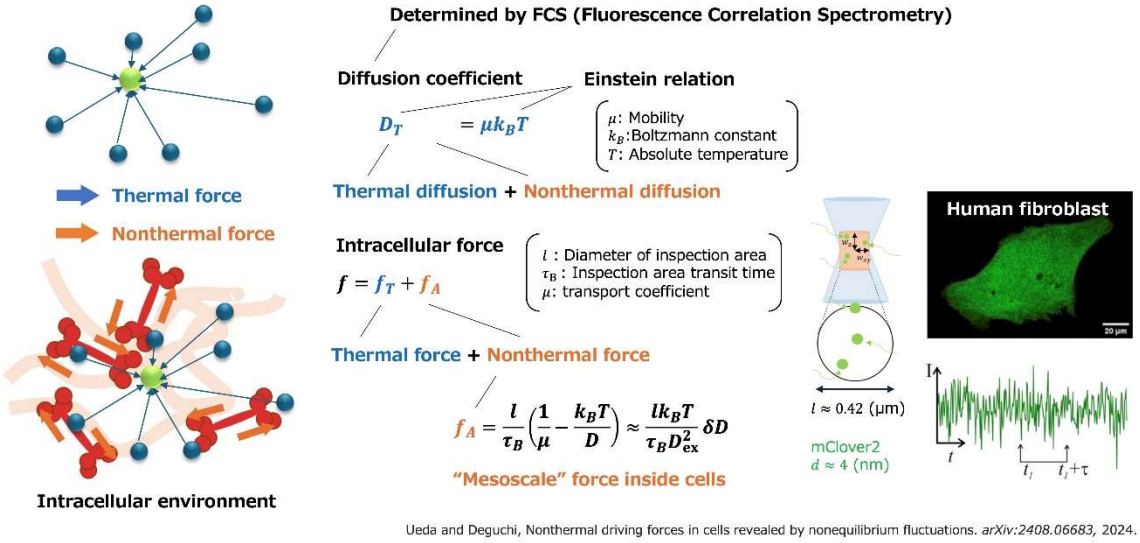
Introduction

Cellular senescence involves extensive remodeling of intracellular architecture, but the molecular and physical distinctions between senescent and young cells remain incompletely understood. Our previous work revealed systematic remodeling of stress-fiber-associated proteins and partial rejuvenation by molecular modulation [1,2]. Here, we investigate how cytoskeletal architecture and intracellular mechanics are reorganized in senescent human fibroblasts.

Methods

Primary human fibroblasts were driven into replicative senescence and verified by molecular markers. Intracellular forces were quantified using fluorescence correlation spectroscopy with tandem GFP probes (Figure). Force landscapes were reconstructed using spatial statistical modeling [3,4]. Pharmacological perturbations targeting actin and myosin were applied, and active-force magnitude and spatial heterogeneity were analyzed quantitatively.

Results



Fibroblasts exhibited nonequilibrium intracellular fluctuations driven by active forces on the order of ~100 pN. Inhibition of actin polymerization or myosin II significantly reduced force levels, while microtubule motor inhibition had minimal effect, indicating actomyosin dominance. Senescent cells generated higher forces than young cells but displayed fewer fluctuation modes, revealing simultaneous amplification and simplification of intracellular dynamics.

Discussion

Our results identify actomyosin activity as the primary intracellular force source and demonstrate that senescence is characterized by reduced dynamic complexity, suggesting that senescent cells rely on restricted mechanical pathways. Together with our previously

developed methods [5-7], this study provides a physical framework for understanding senescence as a mechanical state transition. Thus, our approach establishes a new approach for mechanistic analysis and potential intervention in cellular senescence.

Using Self-Generated Rhythmic Cues to Enhance Gait in Parkinson: Preliminary Analysis of a 12-Week Intervention

Dr. Sidney T. Baudendistel PhD, MS[1], Dr. Ryan P. Duncan PT, DPT, MSCI[1], Ms. Alison J. Cole MBA, MT-BC[2], Dr. Kerri S. Rawson PhD, MS[1], Dr. Gammon M. Earhart PT, PhD, FAPTA[1]

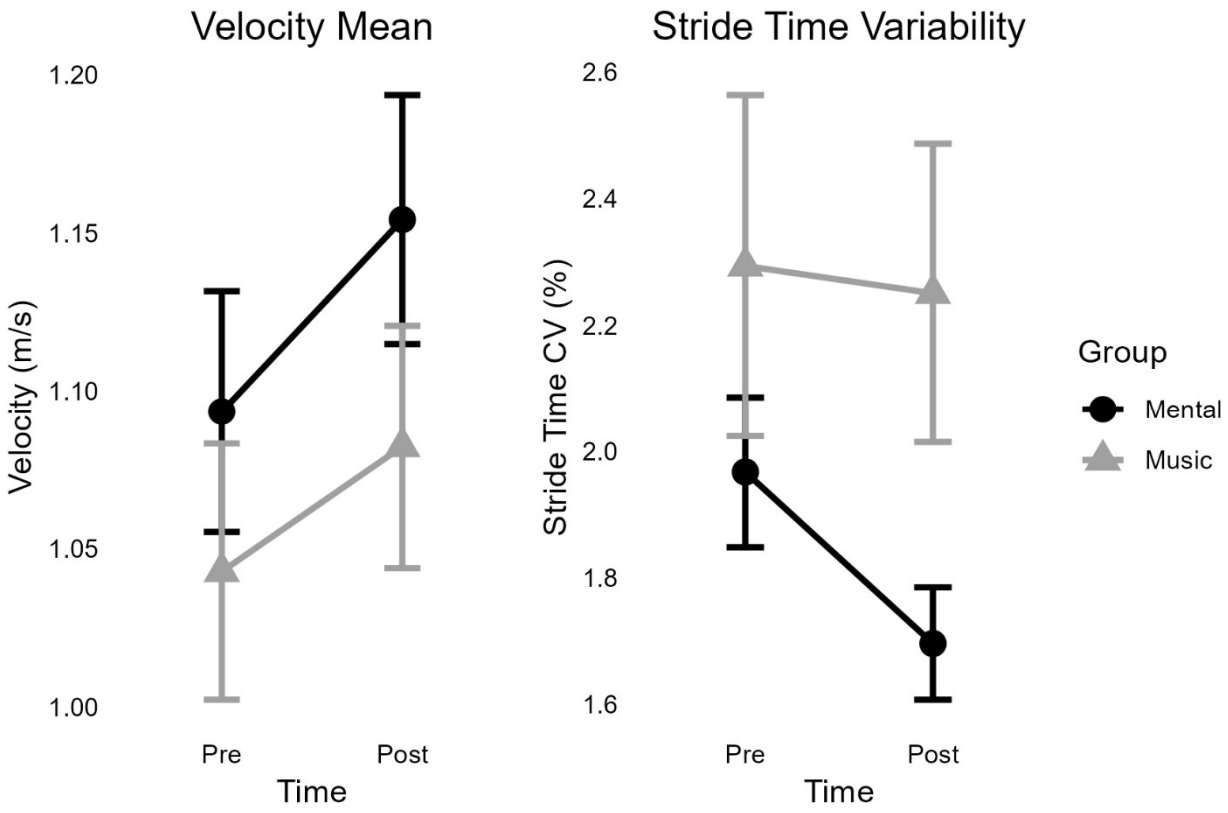
[1]Washington University in St. Louis School of Medicine, St. Louis, MO, United States. [2]Alison Cole, LLC, St. Louis, MO, United States

Introduction

People living with Parkinson disease (PD) walk with shorter, slower, and more variable steps compared to controls resulting in mobility impairment and reduced quality of life. Rhythmic auditory cueing, such as matching steps to the rhythm of an externally played song, is an accepted method to enhance gait performance. Our previous work showed that, in a single session, mentally singing a song in one's head without playing it externally may produce similar, or even greater, benefits than listening to the song. It is not known whether repeated practice of internal or external cues produce greater gains in walking ability among people with PD. This study aimed to address this gap.

Methods

Participants were included in one of two interventions led by a music therapist and physical therapist. Both interventions included 24 one-hour group classes (twice weekly). Classes focused on standard elements of training in beat perception, production, and synchronization. Individuals focused on either rhythmic movement training using external musical cues (MUSIC) or rhythmic movement training using self-generated, internal singing cues (MENTAL). Participants were asked to practice what they learned on their own for an additional 90 minutes per week. Six sensors (APDM) measured velocity and stride time variability during uncued, preferred walking before and after the intervention while participants were on anti-PD medication. We modeled the data with a RM-ANOVA (2x2, group x time).



Results

Sixty-one participants with mild-moderate PD completed the intervention (MENTAL=28, MUSIC=33). There were no significant differences in velocity or stride time variability between groups at baseline ($p \geq .301$). For both variables, there was no interaction effect ($p \geq .132$), nor an effect of group ($p \geq .124$). The effect of time was significant for velocity ($F(1,59)=17.840$, $p<.001$) and stride time variability ($F(1,59)=4.426$, $p=.040$), indicating the interventions improved these measures for both groups (Figure 1).

Discussion

This preliminary analysis suggests both internal and external- based rhythmic auditory cueing training provides significant improvement in key measures of gait in PD. As MENTAL cueing does not require a device and can be deployed covertly, this may be an alternative treatment strategy to enhance gait parameters in PD.

OA92-02

Quantifying Contributions From Individual Wrist Muscles to Hand Tremor in Persons With Essential Tremor

Mr. Nolan Howes BS[1], Prof. Dario Farina PhD[2], Prof. Steven Charles PhD[1]

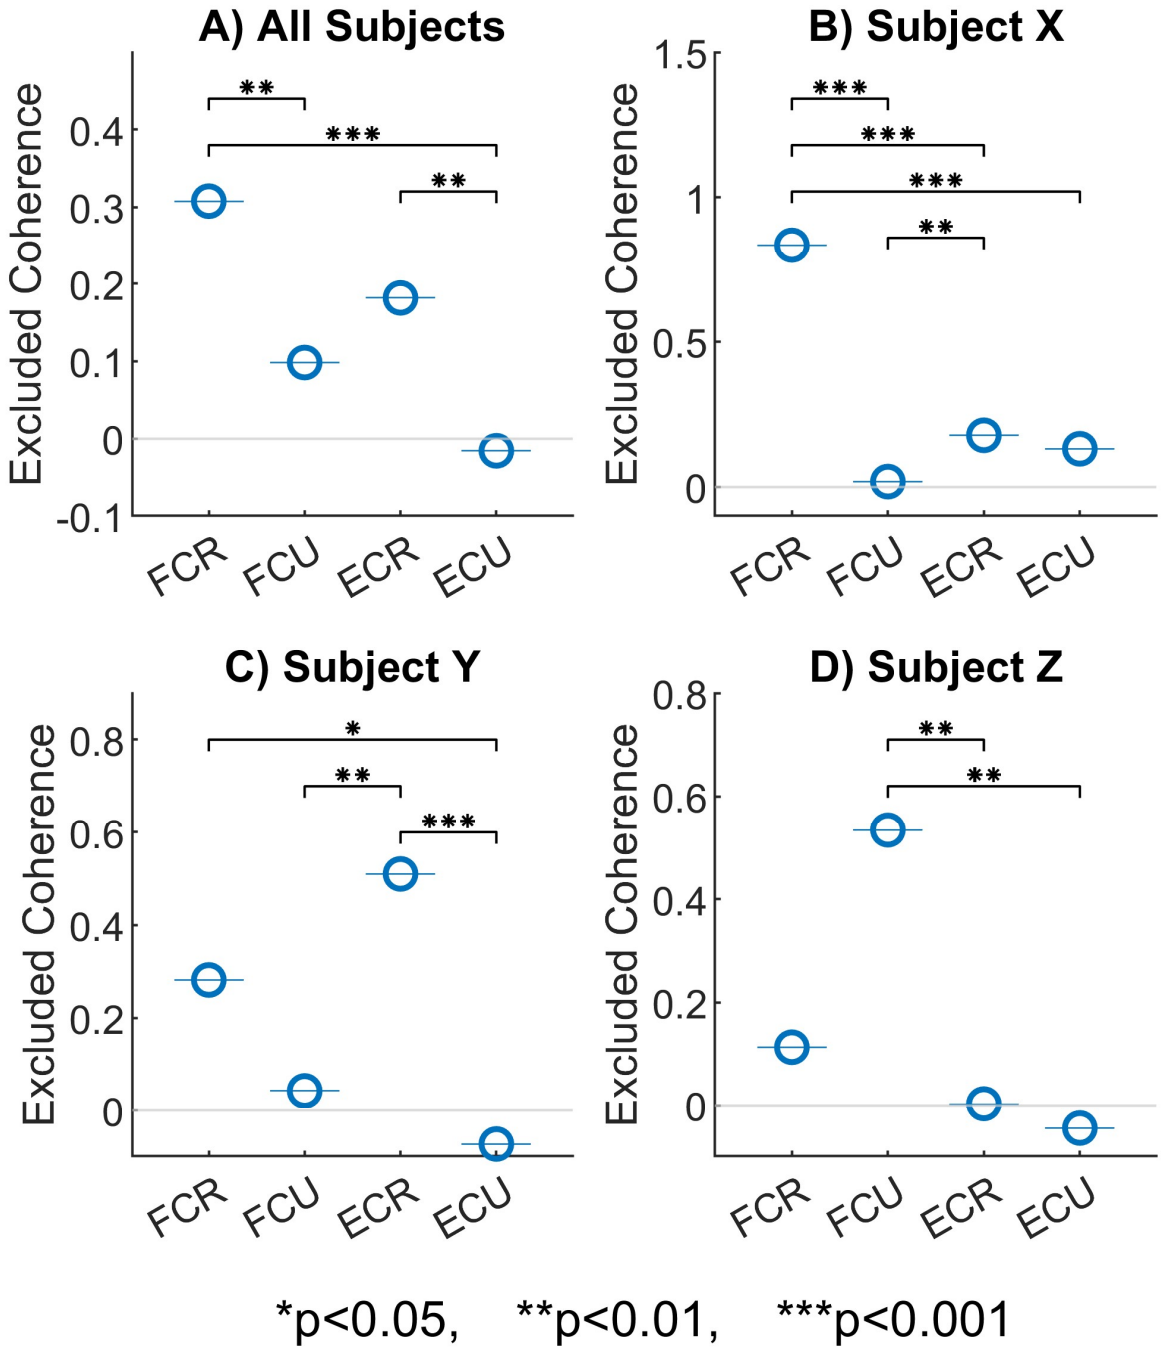
[1]Brigham Young University, Provo, UT, United States. [2]Imperial College London, London, Greater London, United Kingdom

Introduction

Tremor is the most common movement disorder, and many individuals remain unsatisfied with outcomes from standard treatments, which intervene at the level of the central nervous system. Peripheral suppression methods, including injections of botulinum toxin A, low-level electrical stimulation, or filtering orthoses/exoskeletons, show promise but could be optimized by identifying the muscles most responsible for tremor. This study aimed to quantify the contribution of individual wrist muscles to hand tremor.

Methods

Surface electromyography from the four prime wrist muscles and motion capture of hand translation were recorded in 14 individuals with Essential Tremor. Subjects attempted to maintain a neutral wrist posture while the upper limb was constrained to isolate the wrist joint. Contributions of individual muscles to hand tremor were determined using excluded coherence between muscle activity and hand motion. Excluded coherence is a novel measure capable of estimating input contributions in multi-input systems with correlated inputs [1]. It describes the portion of output power (in this case, tremulous motion of the hand) that would be removed if a given input (tremorogenic muscle activity) were excluded.



Results

We found many statistically significant differences in tremor contributions between muscles. Averaged across all subjects, the flexor carpi radialis (FCR) contributed the most to tremor, followed by the extensor carpi radialis (ECR) and flexor carpi ulnaris (FCU), with the extensor carpi ulnaris (ECU) consistently contributing very little (Figure 1A). However, the dominant contributing muscles varied between individuals (Figure 1B-D). The majority of tremor power was caused by direct contributions from individual muscles rather than constructive interference between muscles. Also, we found that although suppressing certain muscles could theoretically increase tremor (because they interfere destructively with other muscles), this is unlikely to occur.

Discussion

This is the first quantification of muscle-specific contributions to tremor in multiple subjects. The presence of significant trends across subjects suggests that a general peripheral tremor suppression plan targeting the same muscles for all subjects could be effective, but personalized treatment based on subject-specific contribution patterns would be optimal. Excluded coherence analysis provides an effective tool for calculating these contributions.

A Single Thigh-worn Accelerometer and Context-Specific Features to Predict Fall Risk in Persons with Multiple Sclerosis

Dr. Guido Mascia[1], Dr. Josh Cherian[1], Mr. Dheeraj Kairamkonda[1], Dr. Brett Meyer[2], Dr. Andrew Solomon[3], Dr. Ryan McGinnis[1]

[1]Center for Remote Health Monitoring, Wake Forest School of Medicine, Winston-Salem, NC, United States. [2]Medidata Solutions, New York, NY, United States. [3]Department of Neurological Sciences, University of Vermont College of Medicine, Burlington, VT, United States

Introduction

People with Multiple Sclerosis (PwMS) experience motor function decay that negatively impact their ability to generate lower-limb strength, increasing the probability of falling [1]. Recent advancements in wearable technology may allow for a more granular assessment of fall risk than infrequent clinical visits. The 30-second chair test (30CST) used to quantify functional capacity and lower limb strength is perfectly suited this hybrid approach. The aim of the study is to predict fall risk in PwMS performing multiple 30CST by leveraging signals extracted from a single accelerometer.

Methods

Sixty recording sessions from 36 PwMS were analyzed. For each, participants reported whether they fell at least once in the past 6 months (32/60 fallers). Participants completed the Activity-specific Balance Confidence Scale (ABC), the Modified Fatigue Index Scale (MFIS) and the Multiple Sclerosis Walking Scale (MSWS). Participants went home wearing an accelerometer on their right thigh, where they performed a series of unsupervised 30CSTs. Sit-to-stands were automatically segmented and leveraged for extracting signals used as inputs for convolutional neural networks, long-short-term memory networks, and gated-recurrent neural networks, along with the corresponding ABC, MFIS, and MSWS scores, leading to a total of 13 features. An attention layer was added to track feature importance. Models were evaluated using Leave-One-Subject-Out Cross-Validation.

Results

A total of 8870 transitions (4502/8870 fallers) were used for training, validating, and testing 45 models. Mean feature attention from the 5 best performing models (AUC = 0.80—0.83) was computed, and features for each model were sorted based on their average rank. The analysis revealed Rotational Power [2] as the most important one, whereas negligible contribution was exerted by the clinical scores (Fig. 1).

Discussion

The current study demonstrated the possibility to predict fall risk in PwMS leveraging a single, thigh-worn accelerometer outside of the clinic. This is encouraging, given the recent trends in remote monitoring and large clinical studies employing similar experimental setups. Future studies may benefit from the inclusion of a chest sensor, accounting for trunk-flexion strategies, naturally implemented by PwMS.

Biomechanical and Sensory-Cortical Interactions During Postural Control in Parkinson's Disease

Dr. Ashwini Sansare[1], Mr. Hossein Soroushi[1], Ms. Taylor Gauss[2], Dr. Jan Hondzinski[2], Dr. Deanna Kennedy[1], Dr. Yuming Lei[1]

[1]Texas A&M University, College Station, TX, United States. [2]Louisiana State University, Baton Rouge, LA, United States

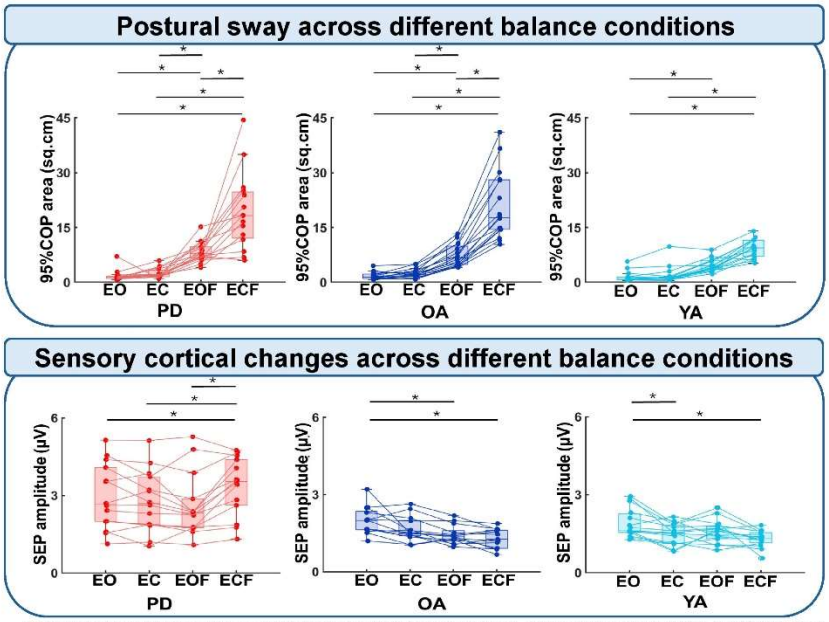
Introduction

Postural stability requires coordinated integration of sensory input with biomechanical control strategies. Individuals with Parkinson's Disease (PD) often exhibit peripheral sensory deficits and atypical cortical processing of somatosensory information, yet how these neural alterations influence standing balance remains unclear. During functional tasks, afferent nerve stimulation typically produces sensory gating, i.e. reduction of somatosensory-evoked potential (SEP) amplitude, to suppress irrelevant input and optimize neural resources for movement control. Altered SEP responses have been linked to poor upper limb function in PD, but their implications for balance are unknown. We investigated how PD affects the interplay between sensory-cortical activity and postural sway across increasingly challenging conditions. We hypothesized reduced sensory gating in PD, particularly as task difficulty increased.

Methods

Forty-eight adults participated: 16 high-functioning individuals with PD, 16 neurologically healthy older adults (OA), and 16 neurologically healthy young adults (YA). Participants completed three 60-second standing trials under four randomly ordered conditions: eyes open (EO), eyes closed (EC), eyes open on foam (EOF), and eyes closed on foam (ECF). We quantified center-of-pressure (COP) on an AMTI force plate. The primary biomechanical outcome was COP 95% confidence ellipse area; secondary metrics included mean COP velocity, RMS COP displacement, and frequency dispersion. SEPs (P38 component) were recorded via EEG during tibial nerve stimulation. Mixed-Model repeated-measures ANOVAs revealed effects of group as the between-subject factor and the condition (EO, EC, EOF, ECF) as the within-subject factor.

Results



PD and OA exhibited greater 95% COP ellipse area, COP velocity, RMS displacement, and frequency dispersion than YA, consistent with age-related changes in balance. No significant differences between PD and OA suggests similar sway characteristics in aging

and PD. In contrast, cortical responses diverged. YA and OA showed the expected decline in SEP amplitude as task difficulty increased, reflecting intact sensory gating. PD showed minimal SEP modulation across conditions, indicating reduced adaptability of sensory-cortical processing.

Discussion

Despite exhibiting sway characteristics comparable to age-matched controls, individuals with PD demonstrated markedly impaired sensory gating. These findings suggest that sensory-cortical dysfunction may precede observable declines in balance and highlight a dissociation between neural and mechanical aspects of balance control.

Images (Optional)

Box and whisker plots, with scattered dots indicating each subject, showing the trend in the 95%COP area (top panel) and SEP amplitude (bottom) as the balance conditions become increasingly challenging from eyes open (EO), eyes closed (EC), eyes open on foam (EOF) to eyes closed on foam (ECF) for the three group, PD (red), OA (dark blue) and YA (light blue).

Real-Time Amplitude-Based Haptic Feedback Enhances Arm Swing and Spatiotemporal Gait Parameters in Older Adults

Ms. Ines Khiyara M.S., Dr. Babak Hejrati PhD

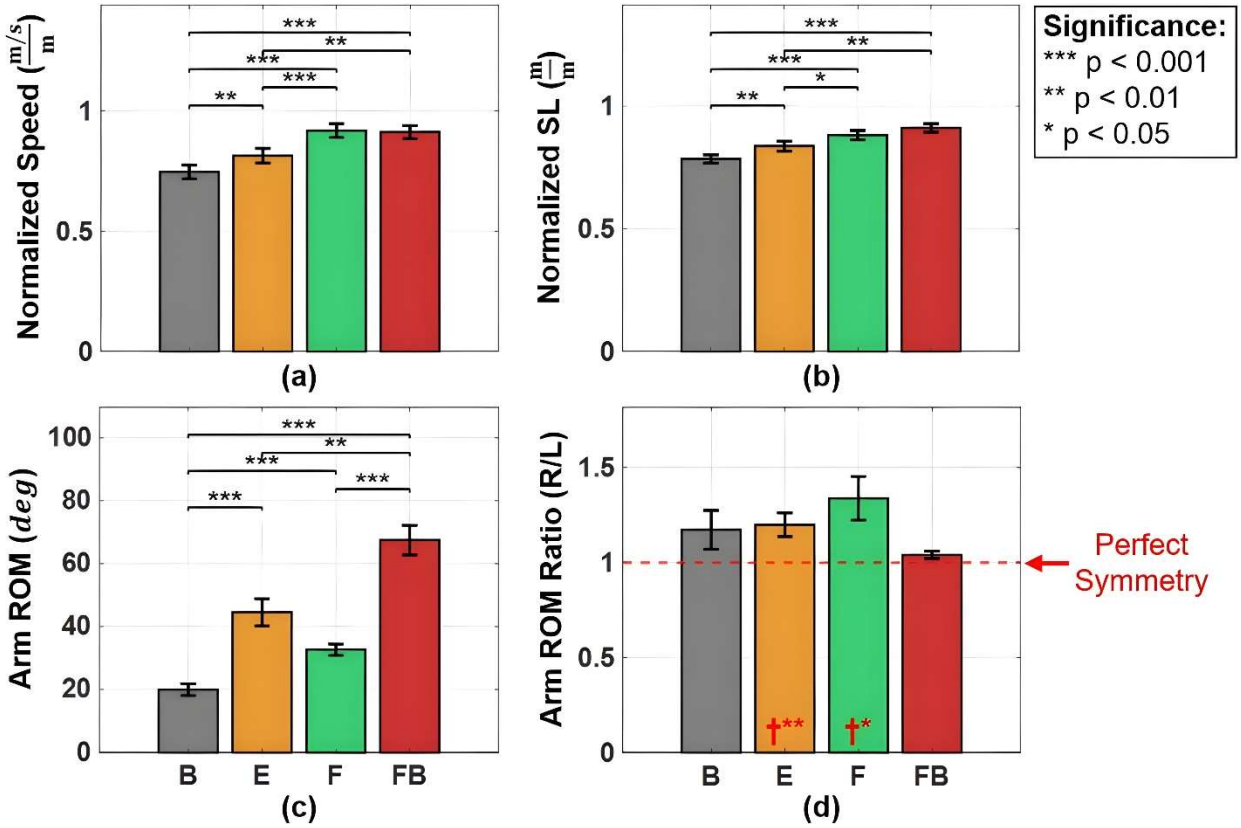
University of Maine, Orono, Maine, United States

Introduction

Arm swing supports gait stability, yet older adults show reduced motion linked to slower gait, shorter strides, and increased fall risk. While voluntary modulation and timing-based cueing can alter gait, amplitude-based feedback remains underexplored. Therefore, the study evaluated how real-time haptic feedback influences arm range of motion (ROM), arm-swing symmetry, gait speed, and stride length (SL) in older adults.

Methods

Eleven older adults (72.8±4.2 years) completed nine 200-m trials: Baseline (B), Exaggerated (E), Fast (F) and six error-feedback (FB) conditions in a 3×2 design (vibration location: flexion/extension/combined × intensity: 100%/200% of baseline amplitude). Participants were ≥65 years, walked independently, and reported no neurological or gait-affecting musculoskeletal disorders. Arm/foot kinematics were captured with Movella DOT IMUs, and a custom Android app delivered cues when amplitude fell below targets. Outcomes included gait speed, SL, and arm ROM/symmetry (Right/Left ratio). Repeated-measures one-way ANOVA compared Baseline, Exaggerated, Fast, and Feedback; symmetry was tested using one-sample t-tests; and a two-way ANOVA assessed Location×Intensity effects.



Results

Significant condition effects were found (Figure 1) for speed ($F(3,30)=35.20$, $p<0.001$, $\eta^2=0.78$), SL ($F(3,30)=35.29$, $p<0.001$, $\eta^2=0.78$), and arm ROM ($F(3,30)=55.32$, $p<0.001$, $\eta^2=0.85$). Feedback significantly increased ROM beyond Baseline ($p<0.001$), Exaggerated ($p=0.006$), and Fast ($p<0.001$). Symmetry improved under Feedback (ratio=1.041, $p=0.061$), whereas Exaggerated ($p=0.009$) and Fast ($p=0.015$) deviated significantly from 1.0. Feedback speed and SL matched Fast but exceeded Baseline ($p<0.001$) and Exaggerated ($p=0.005$). In the 3×2 ANOVA analysis, 200% intensity increased ROM, combined-location showed the highest ROM, and no Location×Intensity interaction was found ($p=0.19$).

Discussion

Amplitude-based haptic feedback substantially enhanced arm swing—238% over Baseline, 52% over Exaggerated, and 107% over Fast—while restoring symmetry. Compared to our prior timing-based cueing (18% speed, 30% ROM increases), amplitude-based feedback produced larger improvements in both speed (22% over Baseline) and ROM. The stronger 200% intensity and absence of interaction suggest independently optimizable feedback parameters. These results support wearable IMU-driven feedback as a promising rehabilitation tool, where quantitative amplitude cues outperform instructional strategies for improving gait biomechanics in older adults.

Rhythmic Cues with Different Modalities and Structures Distinctly Affect Spatial and Temporal Structure of Gait Kinematics

Mr Seung Kyeom Kim[1], Mr Vasileios Mylonas[1], Ms Marilena Kalaitzi Manifrenti[1], Dr Nick Stergiou[1,2], Dr Aaron Likens[1]

[1]University of Nebraska at Omaha, Omaha, NE, United States. [2]Aristotle University of Thessaloniki, Thessaloniki, Thessaloniki, Greece

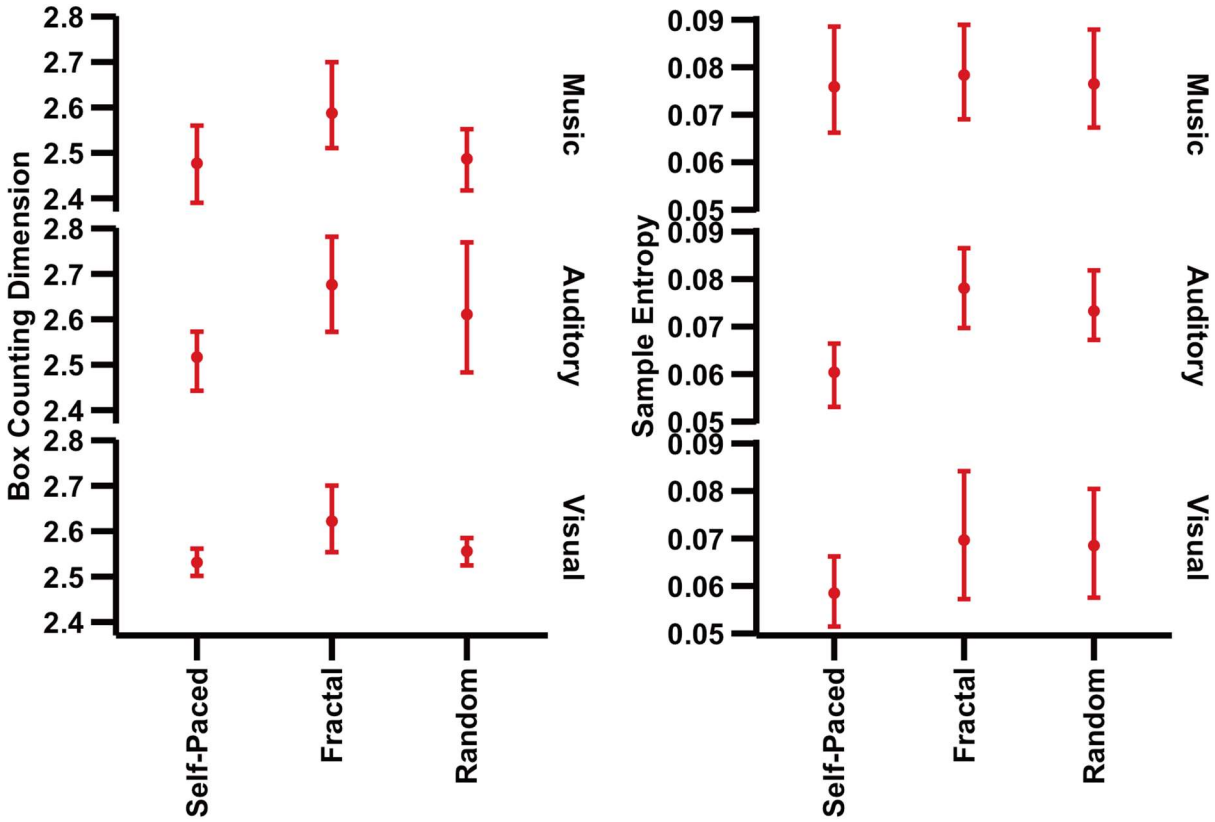
Introduction

Humans readily synchronize movements to rhythmic cues (RC) across modalities (e.g., vision, auditory). RCs also modify gait variability (GV; subtle timing and spacing changes across gait cycles) by entraining to external rhythms. Healthy GV is fractal, meaning spatiotemporal features are related over time, but becomes random with age and disease. RCs are a promising tool for restoring GV; however, most studies deliver constant auditory inter-beat intervals that may differ from natural GV. Previous work focused on basic gait measures like stride intervals or length, leaving joint or segment angles–the variables of interest–less explored. Modality and rhythm structure (e.g., fractal(FRAC), random(RAND)) influence GV, but their impact on gait kinematics (GK) is unclear. This study investigated the effect of modality and rhythm structure on gait kinematics.

Methods

Eighteen participants were assigned to one of three groups (non-musical-auditory, AUD(Age=26.286±4.096); Female=3); visual, VIS(Age=27.667±3.249); Female =1); music, MUS(Age=25.429±2.718); Female =3) and walked for 12-min, self-paced, then two 12-min walks synchronized to each of two rhythmic structures (FRAC, RAND). Spatial characteristics of thigh GK were quantified using box counting dimension (BCD); higher values reflect less constrained movement in space. Temporal characteristics of thigh GK were quantified using sample entropy (SampEn); higher values reflect less predictable movement over time. Metrics were computed on sagittal plane. Multilevel models were analyzed to examine the modality×rhythm structure interaction on BCD and SampEn.

Results



Models revealed a modality×rhythm structure interaction for both metrics. Rhythm structure induced large effects within each modality (Figure 1). In AUD, FRAC increased BCD (D=1.2845) and SampEn (D=1.2231), indicating less constrained and more irregular

coordination. In VIS, FRAC increased only SampEn (D=0.7759). In MUS, FRAC increased only BCD (D=0.8854).

Discussion

These findings demonstrate RCs affect the spatial and temporal characteristics of GK in a modality-specific manner. FRAC consistently affected both characteristics of GK in AUD, whereas only temporal and spatial characteristics were affected in VIS and MUS, respectively. This implies a distinct entrainment mechanism across cue modalities and rhythm structures. Therefore, modality and rhythm structure should be chosen based on the purpose of RC-based rehabilitation.

A Variability-Embedded Music System (VEMS) Modulates Gait Variability as Effectively as Auditory or Visual Cueing

Mr Vasileios Mylonas MSc[1], Ms Marilena Kalaitzi Manifrenti MSc[1], Dr Nick Stergiou PhD[1,2], Dr Aaron Likens PhD[1]

[1]Department of Biomechanics and Center for Research in Human Movement Variability, University of Nebraska at Omaha, Omaha, Nebraska, United States. [2]Department of Physical Education and Sport Science, Aristotle University of Thessaloniki, Thessaloniki, Thessaloniki, Greece

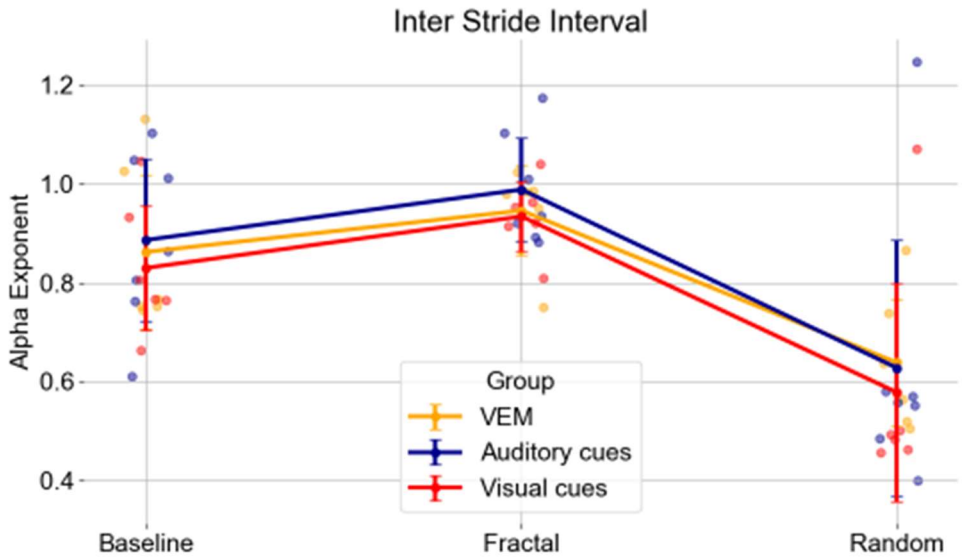
Introduction

Human gait of healthy individuals varies from one step to the next. These variations over many gait cycles create a structured (fractal-based) pattern where gait patterns are related over time. With pathology, this structure degrades, making gait overly periodic or overly random. This degradation reflects reduced adaptability of the locomotor system and has been associated with gait instability and increased fall risk. Restoring the gait variability structure requires external variable cueing. We developed Variability Embedded Music System (VEMS), a novel auditory cueing approach that embeds fractal patterns into the inter-beat intervals of commercial music, providing an alternative to traditional cueing methods. Here, we compare VEMS to auditory and visual cueing on the temporal structure of gait variability.

Methods

18 healthy adults (6 per group) were assigned to one of three cueing conditions (non-musical auditory (NMA): 3F, 27.6±3.25 years, visual (VIS): 1F, 26.3±4.1 years, VEMS: 3F, 25.3±2.72 years) and completed a 12-min baseline walk, followed by two randomly ordered 12-min cued (fractal and random). Cues were delivered via headphones or a lightweight head-mounted display. The standard deviation of the step-to-beat relative phase was computed. Detrended Fluctuation Analysis (α-exponent) was used to assess the temporal structure of gait variability in the form of the α-exponent. Cueing preference was also obtained. Statistical analysis involved a 3×3 multilevel model. Type-1 error= 0.05.

Results



A significant main effect of cue type was found ($F_{(2,36)}$=24.86, p<0.001, η^2_p=0.58; Figure 1). Random trials were associated with significantly lower α-exponents than both baseline (p<0.001, d=1.57) and fractal (p<0.001, d=2.22) trials. Step-to-beat synchronization was

similar across groups and cue types. Preference differed across groups ($F_{(2,16)}$=4.24, p=0.033, η^2_p=0.27); VEMS was preferred over NMA (p=0.032, d=0.35).

Discussion

Our results indicate that VEMS is as effective as VIS and NMA in modulating gait variability, with similar synchronization accuracy across modalities. Fractal cues preserved the temporal structure of healthy gait, whereas random cues significantly reduced the α-exponent, showing that all three modalities can alter gait dynamics. VEMS, therefore, offers an effective and more enjoyable alternative for restoring heathy, fractal patterns in gait variability.

Effects of Delay and Amplification of Auditory Feedback for Gait: Variability and Cadence Adaptation

MS. Jingxian Gu, Dr. Dobromir Dotov

University of Nebraska Omaha, Omaha, NE, United States

MS. Jingxian Gu

Introduction

Rhythmic auditory cueing of gait with exogenous stimuli is a widely studied technique for improving symptoms of gait disorders. Less is known about the effects of self-cueing, such as endogenously generated sounds of one's own footsteps. We adopted the delayed auditory feedback (DAF) paradigm which is known to improve symptoms of speech disorders in various populations such as Parkinson's disease but has not been studied in gait.

Methods

Young healthy adults (N=30, 19 to 35 years old) participated. They were instructed to walk overground at a comfortable self-selected pace on a circular track. Feedback consisted of the lateralized continuous sound of their footsteps, captured with shoe-worn microphones and relayed to closed-cup headphones (15 ms delay) via a belt-worn mini-computer. The feedback manipulations consisted of delay (zero, eighth, and quarter step), amplification (half or full self-selected amplitude), and masking pink noise (half or full self-selected amplitude). Baseline cadence was recorded in a pre-test trial without auditory manipulation. Participants wore an IMU system to record gait parameters. Additionally, we used mobile brain imaging (fNIRS) to measure the activation in prefrontal cortical areas involved in purposeful attention, reported separately.

Results

Statistical analysis with linear mixed-effects models revealed that gait variability and cadence were influenced by delay and amplification. We found that amplification without delay had the effect of reducing variability ($p<.05$), see Figure 1. Interestingly, delay had the effect of increasing cadence ($p<.05$) which is opposite to the prediction derived from DAF for speech.

Discussion

These findings confirm the hypothesis that auditory information from self-produced action is used for sensorimotor integration and gait regulation. The increase of cadence with delay contradicts traditional internal model theories of motor control but can be explained either by a Bayesian account of sensory uncertainty or by a dynamic model for anticipatory synchronization with delayed feedback that we adopted. The combination of delay and amplification, particularly the reduction in variability with amplified feedback, suggests that this simple technique may be used for daily in-community rehabilitation and re-training of gait.

Introduction

Nordic walking, that uses poles, is considered to reduce push-off ground reaction forces (GRF) and lower-limb loading compared with normal walking, which may be beneficial for older adults. However, differences in study methods (e.g., Nordic walking techniques) and limitations in previous studies have left other biomechanical characteristics unclear and led to inconsistent findings for GRF and joint biomechanics. Notably, research on the "defensive" Nordic walking style, with poles placed nearly perpendicular to the ground, remains limited despite its frequent use in rehabilitation. Therefore, the purpose of this study was to comprehensively examine GRF and lower-limb biomechanics of defensive-technique Nordic walking.

Methods

Twelve healthy adults performed normal and Nordic walking. GRF and 3-dimensional motion data were recorded using three force plates (lead-foot (right), trail-foot (left), and left-pole) and nine motion-capture cameras (Fig.A and B), respectively. Joint angles and moments were calculated through inverse kinematics and dynamics tools in OpenSim, respectively. GRF and joint moment were normalized by body weight. Statistical parametric mapping paired t-tests were compared for GRF, joint angles, and moments between normal and Nordic walking.

Results

Nordic walking exhibited smaller vertical (13–38% of stance) and braking (13–23%) GRF of lead-foot (p<0.001) (Fig.C and D). Nordic walking also showed a more flexed hip joint angle (2–57%, p<0.001) than normal walking, whereas knee and ankle angles showed no significant differences (Fig.E). In addition, Nordic walking showed a smaller knee extension moment (14–22%, p=0.009) than normal walking. Although hip extension moment was smaller in Nordic walking (1–7%, p=0.010) (Fig.F), this difference occurred before the pole-loading phase.

Discussion

Defensive-technique Nordic walking selectively reduced knee moments without altering ankle or hip moments during the pole-loading phase. This occurred together with smaller vertical and braking GRF at the lead foot and a more flexed hip posture throughout stance. Thus, the pattern reflects targeted unloading at the knee rather than a global reduction in lower-limb mechanical demand, as propulsion-related mechanics were largely preserved. Such selective unloading may be clinically meaningful for older adults or individuals with knee pain and supports defensive Nordic walking as a knee-targeted gait modification.

Effects of Body Weight Support on Temporal Features of Walking and Crawling Gait in Near-Walking Infants

Mr. Tristan McCarty[1], Ms. Melanie Barahona[1], Dr. Cole Galloway[2], Dr. Elena Kokkoni[1]

[1]University of California, Riverside, CA, United States. [2]Baylor University, Waco, TX, United States

Introduction

The development of independent locomotion in infancy, like crawling and walking, is critical for overall development [1]. Temporal gait abnormalities, such as those often seen in infants diagnosed with Down Syndrome (DS), can affect gait stability, resulting in delays to the onset of independent locomotion [2]. While exposure to dynamic body-weight support (BWS) has been shown to immediately alter the temporal features of walking gait in adults, its influence on infant gait parameters is less understood. Here, we report how immediate exposure to BWS alters temporal walking and crawling gait in near-walking infants.

Methods

Eleven typically developing (TD) infants (M=9.9±1.2 months) and five infants diagnosed with DS (M=17±3 months) participated in two experimental sessions. In each session, infants performed crawling and walking trials before BWS exposure (Pre), with BWS (IN), and after BWS exposure (Post). Multi-view video recordings were collected for digitization of limb contact and lift-off events in each gait segment. For each segment, temporal variables of interest (cycle duration, duty factor, cadence, and continuous relative phase) were calculated and assessed using non-parametric Friedman tests to examine differences between the three conditions.

Results

In a preliminary analysis of a subset of participants, we saw significant decreases in crawling gait cadence ($p=.041$) and more synchronized crawling gait as measured by the continuous relative phase ($p=.015$) when TD infants were exposed to BWS (Pre vs. IN). While not significant, a trend was observed of more asynchronous continuous relative phase for walking gait in infants with DS ($p=.097$, Pre vs. IN). However, none of these changes were retained once the infants were removed from BWS (Pre vs. Post).

Discussion

This work demonstrates infants' ability to immediately alter their temporal gait features during both crawling and walking in response to BWS exposure. While these changes were significant during immediate exposure, they were not retained after removal from BWS, suggesting that longitudinal exposure may be needed for long-term retention of these effects.

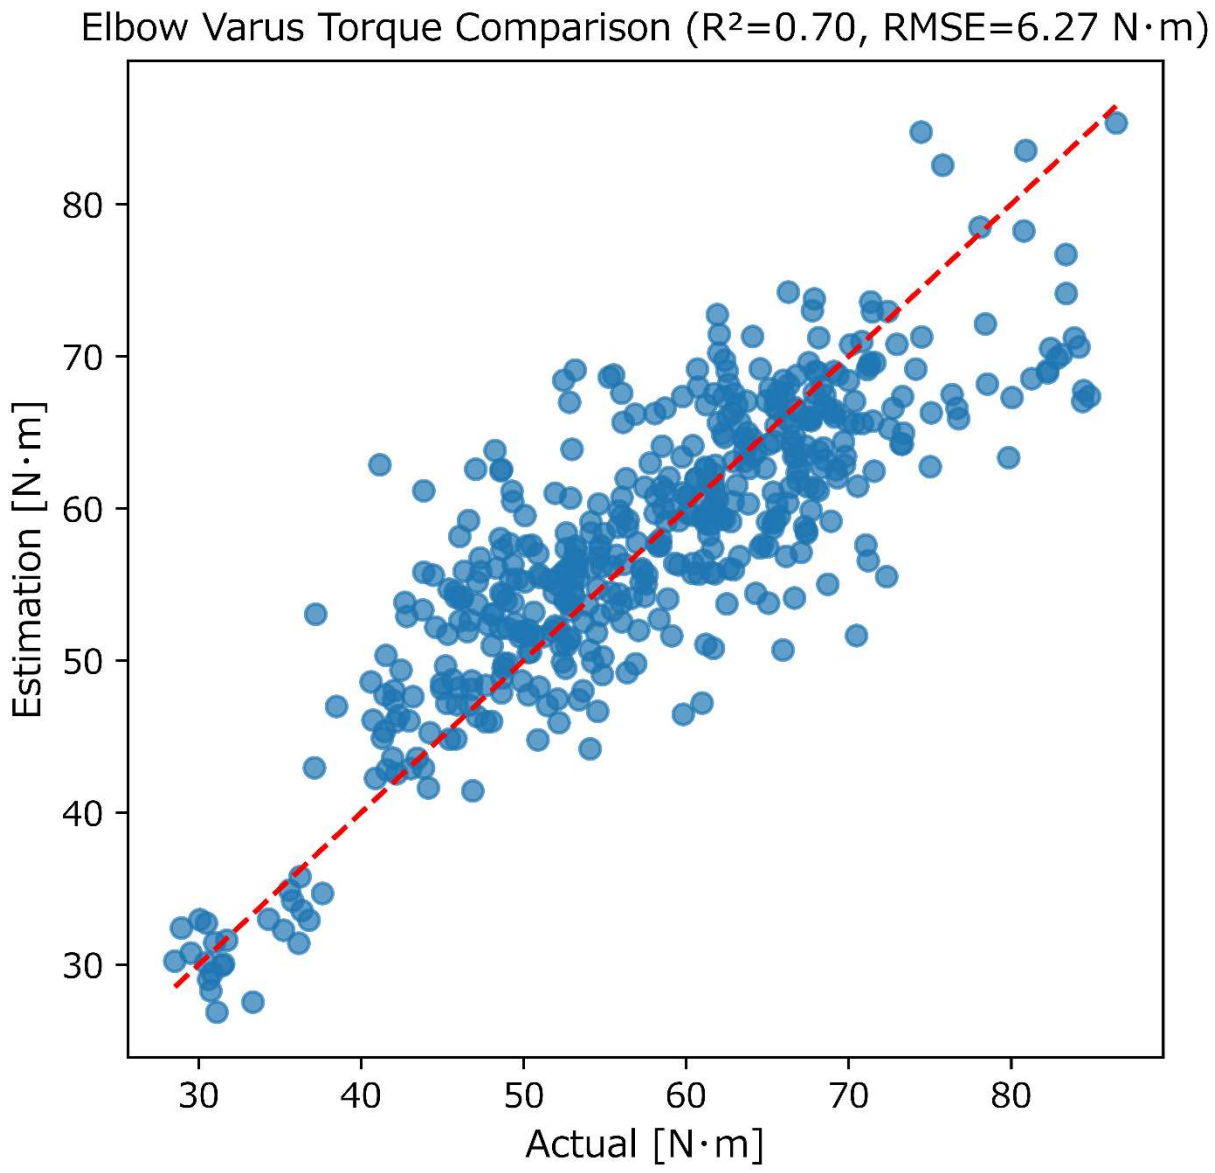
Introduction

Ulnar collateral ligament (UCL) injury in baseball pitchers requires prolonged rehabilitation before returning to play. Peak elbow varus torque during pitching has been identified as a primary risk factor for UCL injury. Although sensor-based estimation methods have been proposed, their accuracy remains insufficient. The purpose of this study was to develop a new method for estimating the peak elbow varus torque using a sensor-embedded ball.

Methods

Twenty collegiate baseball pitchers each threw twenty-four pitches (eight each of four-seam fastballs, sliders, and curveballs). Measurements were conducted using a sensor-embedded ball (500 Hz) equipped with an accelerometer (±32 G), a high-range accelerometer (±400 G), a gyroscope, and a magnetic sensor, each with three axes. The pitching motion was recorded using a three-dimensional motion capture system (500 Hz), and inverse dynamics analysis was performed with a three-link model. An elastic net machine-learning model ($\alpha = 0.01$, L1 ratio = 0.5, maximum iterations = 10,000) was used to estimate the peak elbow varus torque. Model performance was evaluated using the coefficient of determination (R^2) and root mean square error (RMSE) derived from a 10-fold cross-validation procedure that independently partitioned the training and testing datasets. Time-series data from a high-range accelerometer and a gyroscope in the sensor-embedded ball were segmented into two phases: within 0.06 s before ball release and an earlier phase. For each phase, variables showing consistent time-series trends across trials were represented by their mean, while variables with large intertrial variability were represented by their range, resulting in ten derived features. The height and body mass of

each pitcher were added to these, giving a total of twelve features used in the machine learning model. The high-range acceleration data were transformed into a fixed coordinate system aligned with the velocity vector of the ball immediately after release.



Results

The estimation model achieved an R^2 of 0.70 and an RMSE of 6.27 N·m.

Discussion

These results indicate that the new method can sufficiently estimate peak elbow varus torque using data obtained from the sensor-embedded ball. These findings suggest that this novel measurement is useful for evaluating a risk factor for UCL injury in field settings.

Dr. Felipe F. Gonzalez

Introduction

Single-leg hop landing tests are widely used in orthopedic rehabilitation and return-to-play decisions, but traditional assessments often rely on performance metrics or inter-limb symmetry, which may not capture compensatory movement strategies or neuromechanical deficits. Our objective was to establish a generalizable functional classification by identifying unique biokinetic profiles of a single-leg hop landing test across both healthy individuals and orthopedic populations, using unsupervised machine learning on a large-scale clinical dataset, and to classify these profiles based on clinical parameters.

Methods

Kinematic data from 1878 lower limbs (n=939 adults) were captured via three-dimensional motion analysis during single-leg hop landings. Twenty-four variables were processed through a previously validated five-step unsupervised machine learning pipeline (including

kernel-based normalization, self-organizing maps, and k-means clustering). Subgroups were characterized according to performance (hop distance), isometric strength, flexibility, pain, self-reported functional capacity, and diagnosis distribution. Statistical comparisons were made using ANOVA, post hoc Tukey tests, and chi-square analyses ($p<0.05$). Effect sizes were interpreted using Cohen's d.

Results

Six profiles (P1–P6) emerged (Figure 1). P1 was marked by proximal compensation and stiff landing, associated with higher pain ($p=0.0006$) and ankle/foot disorders ($p=0.005$). In contrast, P6 showed a distal compensation strategy in response to proximal mobility deficits, evidenced by reduced hip flexion and higher ankle eversion, possibly linked to its lower soleus strength ($p=0.02$). P3 showed a higher prevalence of post-anterior cruciate ligament reconstruction cases and reduced dorsiflexion, stiff landing, and knee varus thrust ($p<0.0001$). P5 demonstrated dynamic valgus and a higher prevalence of knee disorders ($p=0.005$). P4 showed globally stiff mechanics, and P2 combined optimal biomechanics with the highest asymptomatic proportion ($p<0.001$). P2 and P5 exhibited higher hop performance ($p<0.0001$), while P1, P3, and P4 performed worse. Despite some group-pathology associations, diagnoses were distributed across profiles.

Discussion

This study demonstrates that single-leg hop landing profiles, identified through unsupervised machine learning, provide a clinically meaningful functional classification that is not captured by traditional diagnostic categories. Incorporating biokinetic profiling into clinical assessment enables more precise identification of neuromechanical deficits and supports the development of patient-specific rehabilitation strategies, optimizing return-to-play decisions.

Predicting Peak Elbow Varus Torque from Ball Tracking Release Metrics with Machine Learning in Professional Baseball Pitchers

Dr. Connor Moore PhD[1,2], Ms. Brittany Dowling MS[3], Dr. Jason Avedesian PhD[4], Dr. Edward Mitchell PhD[5], Dr. Melissa Boswell PhD[6], Dr. Reed Gurchiek PhD[1]

[1]Clemson University Department of Bioengineering, Clemson, SC, United States. [2]Maven Baseball Lab, Atlanta, GA, United States. [3]Midwest Orthopaedics at Rush, Chicago, IL, United States. [4]Cleveland Cavaliers Basketball Operations, Cleveland, OH, United States. [5]Joe Gibbs Human Performance Institute, Huntersville, NC, United States. [6]Rethink Health LLC, Charlotte, NC, United States

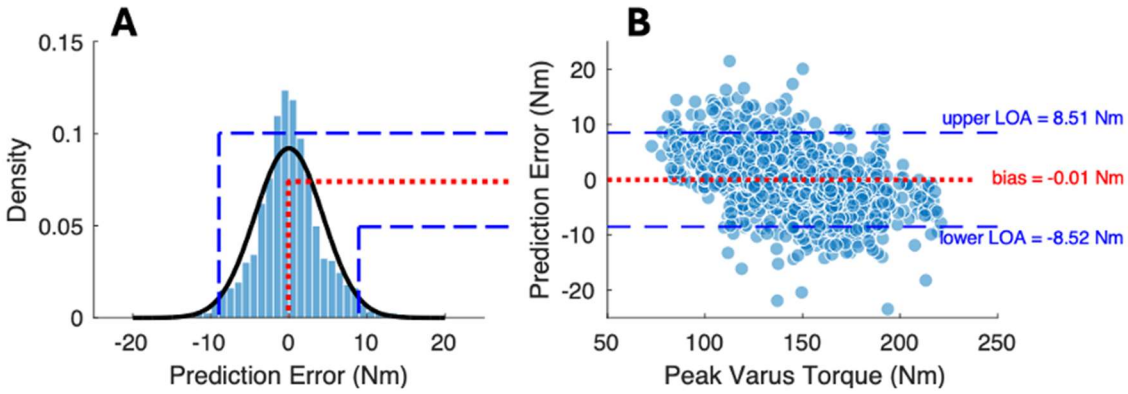
Introduction

Ball tracking and biomechanics technologies are increasingly used in baseball to optimize performance and monitor pitcher health. Current applications lack the ability to estimate injury-related joint loads on a pitch-by-pitch basis without using motion capture, restricting the potential of biomechanics-informed workload monitoring in baseball pitching. However, no attempt has been made at leveraging popular ball tracking technology for predicting clinically relevant elbow load metrics (e.g., peak elbow varus torque), which are needed as rates of major elbow injury rise across levels of play. The study at hand thus sought to address this gap by predicting peak elbow varus torque directly from ball tracking release metrics.

Methods

Two separate machine learning models were trained and compared: random forest (RF) and linear regression (LR). Both models used a historical data source consisting of marker-based motion capture and ball tracking data from 150 professional pitchers (2,901 pitches). Peak elbow varus torque was calculated with an OpenSim pipeline, and models were developed and trained in Python. The models were trained with leave-one-subject-out-cross-validation to maximize out-of-sample data available for evaluation, and both modeling approaches were compared using root mean square error (RMSE) computed across all held out pitches. The best performing model was further evaluated with a Bland-Altman analysis and permutation-based feature importances.

Results



The RF model predicted peak elbow varus torque with an RMSE of 4.61 Nm, substantially outperforming LR (21.41 Nm RMSE). Limits of agreement (−8.52 Nm to 8.51 Nm) from the Bland-Altman analysis fell within previously established ranges distinguishing injured from

non-injured pitchers. Permutation-based feature importance analysis identified release speed, release position (vertical and horizontal), and spin rate as the most important predictors of peak torque.

Discussion

Despite limitations related to sample size and the range of torque values (142 ± 24.8 Nm) compared to previous research, this study demonstrated that peak elbow varus torque can be predicted directly from ball flight metrics using machine learning. Such results demonstrate the feasibility of leveraging ball tracking technology as a scalable, non-invasive tool to monitor biomechanical workload, and in the future can support more informed decisions around performance enhancement and injury prevention in baseball.

A Machine Learning Approach for Predicting the Grade of Execution of Triple Axel Jumps in Male Figure Skaters Using Real-World Kinematic Data from the World Championships

Dr. Seiji HIROSAWA

Toin University of Yokohama, Yokohama, Kanagawa, Japan

Introduction

In figure skating competition, the Grade of Execution (GOE) of jumps as well as their difficulty is important. However, current criteria—such as “very good height and length” and “good take-off and landing”—leave interpretive flexibility even for kinematic characteristics. Previous studies on women’s double Axel jumps have shown that greater horizontal distance and landing distance are associated with higher GOE[1]. However it remains unclear whether these findings apply to the more difficult triple Axel by male skaters. To provide objective and practically applicable indicators for technical instruction, this study examined the relationship between GOE and kinematic characteristics in men’s triple Axel jumps.

Methods

The dataset comprised 49 triple Axel jumps performed at the 2019 and 2023 World Championships, limited to jumps that received non-negative GOE from all nine judges. The object variable was the trimmed-mean GOE (maximum = 5). Kinematic variables were obtained using a media-oriented tracking system based on two-dimensional DLT reconstruction and included vertical height (VH), horizontal distance (HD), landing distance (LD), and ratio-derived features: (HD+LD)/VH, LD/HD, and HD/VH. Because of strong multicollinearity, Elastic Net regression was used to select influential variables and compared with standard multiple regression.

Results

The Elastic Net model showed superior performance (adjusted R^2 = 0.266, Mean Absolute Error = 0.581, Root Mean Squared Error = 0.726) and identified VH, LD, and LD/HD as positive predictors of GOE.

Discussion

These results indicate that greater jump height as well as smoother flow after landing contributes to higher GOE. Interestingly, HD—identified as important in women's double Axel—was not selected, suggesting that the kinematic features emphasized in GOE evaluation differ by rotation level and athlete category. The model's MAE was smaller than errors previously reported for novice judges and skaters estimating GOE from video [2], indicating its usefulness as an objective reference in training. This study provides the first quantitative evidence that the kinematic features valued in subjective evaluation differ across categories and technical levels, offering data-driven insights for technique optimization and coaching strategies.

A Framework for Simulating the Geometric Evolution of Abdominal Aortic Aneurysms with Hemodynamic Validation

Prof. Tingting Fan, Dr. Jinhang Wang, Prof. Haixia Zhang

School of Bioengineering, Capital Medical University, Beijing, Beijing, China

Introduction

Abdominal aortic aneurysm (AAA) rupture is associated with high mortality. Current clinical surveillance, which relies primarily on maximum diameter measurements, fails to adequately characterize long-term three-dimensional morphological progression. We propose a region-specific spatiotemporal (RSS-AAA) modeling framework for the longitudinally fitting and prediction of AAA centerline .

Methods

Centerlines were extracted from AAA geometries at multiple follow-up time points. A modified Coherent Point Drift algorithm was employed for non-rigid registration, incorporating lesion-segment weighting, arc-length and path consistency, and segment-wise anisotropic stiffness to achieve "lesion-prioritized" alignment across time. Subsequently, a temporal global least-action model was formulated, integrating velocity/acceleration priors and bending-energy regularization. This model was used to infer unobserved morphological states and to predict future AAA geometry. Geometric accuracy was assessed using length-weighted point-wise distance, curvature error, and bending-energy error. Computational Fluid Dynamics (CFD) simulations were performed on both real and predicted geometries, and flow fields were compared.

Results

(1) In the AAA segment, the length-weighted centerline distance error was ~4.15 mm and the relative bending-energy error was 3.26%–14.62%, indicating that the algorithm can reliably infer the overall pattern of morphological change in the diseased region.

(2) For interpolated and predicted AAA shapes, maximal diameter errors were ~5.22% and 4.27%, respectively, with volume errors <0.5% and ~0.02%, demonstrating good morphologic prediction performance.

(3) CFD showed close agreement between real and predicted models in main jet path, recirculation/vortex structures, and high-/low-shear regions, supporting the hemodynamic validity of RSS-AAA reconstructions.

Discussion

The RSS-AAA framework synthesizes anatomical priors, temporal constraints, and AAA-specific bending energy to achieve temporally consistent reconstruction and short-term prediction of AAA morphology, while preserving essential hemodynamic characteristics. This work offers substantial and potential technical support for aneurysm research, serving as a tool for studying the morphological evolution of aneurysms, and also can provide quantitative support for early AAA rupture risk assessment.

Predicting Patient-Specific TEVAR Outcomes With Finite Element Models: A Proof-of-Concept Study

MEng Giulia De Campo[1], Dr. Anna Ramella[1,2], Dr. Sara Barati[1,2], Dr. Giulia Luraghi[1], Dr. Maurizio Domanin[3], Dr. Irene Fulgheri[3], Prof. Robin Heijmen[4], Prof. Santi Trimarchi[3], Prof Francesco Migliavacca[1,3]

[1]Politecnico di Milano, Milan, Italy, Italy. [2]AllStent srl, Milan, Italy, Italy. [3]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy, Italy. [4]Radboud University Medical Centre, Nijmegen, Netherlands, Netherlands

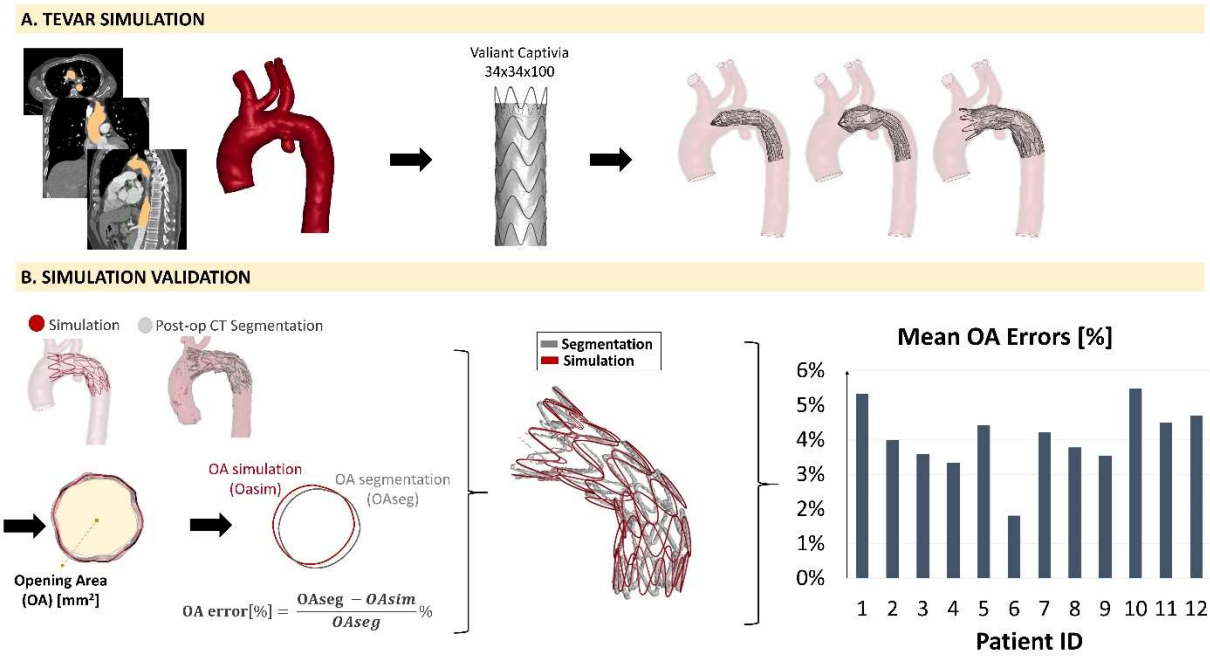
Introduction

The thoracic endovascular aortic repair (TEVAR) has become the preferred treatment option for thoracic aortic pathologies. The current procedural planning relies on manual and geometric assessment, overlooking the complex device–aorta interaction [1]. This study presents the application of a validated high-fidelity finite element methodology [2,3] to replicate the TEVAR procedure in a cohort of twelve patient-specific anatomies presenting aneurysms and acute aortic syndromes with variable curvature and tortuosity. Pre-operative and post-operative computed tomography angiography (CTA) images of patients who underwent TEVAR using a specific stent-graft were analysed. To ensure the accuracy and reliability of the TEVAR digital twin, the simulation results were validated against post-operative image-based reconstructions.

Methods

Patient-specific geometries were segmented from CTA using the level set technique (VMTK). Digital twins of the pre-operative anatomy and stent-graft models were generated. Explicit finite element numerical simulations were conducted to replicate the stent-graft deployment (Fig.1-A). Simulation validation consisted of comparing the simulated stent configuration to the stent reconstructed from post-operative CTA, using the stent ring opening area percentage errors (eOA%) as quantitative metric (Fig.1-B)[2].

Results



The simulations successfully replicated stent-graft implantation across all anatomies, with eOA% consistently remaining below 10% per stent each ring and below 6% on average (Fig.1-B). Particularly, low errors were observed in the proximal and distal stent rings, critical for ensuring sealing (<3.7% average). These findings demonstrated improved

accuracy compared to values previously reported in the literature (error range 5% - 30%) [4].

Discussion

This study establish the credibility of the TEVAR digital twin for clinical use, providing a reliable tool for pre-procedural planning. Although the patient cohort is limited, the preliminary results support the capability of numerical simulations to predict short-term post-operative outcome in anatomies with diverse pathologies, curvatures and tortuosity.

[6]Unit of Radiology, IRCCS Policlinico San Donato, San Donato Milanese, Lombardia, Italy

Introduction

Hemodynamic forces (HDFs) exchanged between blood and left ventricle (LV) wall are emerging as markers of LV dysfunction and adverse remodeling [1]. 4D Flow MRI is the gold standard for HDF assessment; a simplified approach using only long-axis bSSFP images has been proposed but it does not exploit the short-axis stack nor account for valvular regurgitation [2]. We aimed to automate short-axis data integration into simplified HDF calculation and compare the resulting HDFs with those from 4D Flow MRI.

Methods

A training set (n=150) was created by annotating LV endocardial wall on short-axis bSSFP images in Segment (Medviso). A ResNet34 was trained to predict endocardial control points, starting from upper-layer training and progressively unfreezing deeper layers. The tool, integrated into an in-house pipeline, reconstructed LV endocardial 3D surface frame-by-frame, tracking wall motion via diffeomorphic shape matching in Deformetrica. Simplified HDFs were computed according to [2] with enforced mass conservation. HDFs were also computed from 4D Flow MRI and analyzed using Medis suite. Preliminary tests were conducted in a healthy male (71y) and in a female patient (89y) with LV hypertrophy due to severe aortic stenosis (AS) and aortic regurgitation (AR), using 2D phase-contrast (PC-MRI) to correct HDFs.

Results

Network performance improved by retraining head and layers, yielding a Dice score of 0.941±0.073 and Hausdorff distance of 2.05±1.72mm., simplified HDFs captured the temporal pattern seen with 4D Flow in the healthy subject: systolic apex-base and septal-lateral components were higher with 4D Flow, while simplified HDFs showed a higher apex-base peak for diastolic E-wave. Flow rates from mass conservation well resembled PC-MRI measurements. In the patient, systolic apex-base and septal-lateral HDF magnitudes were comparable when using 4D Flow while the simplified method showed a HDF pattern with septal-lateral predominance and greater diastolic values. AR estimates agreed with 2D PC-MRI, despite 24% (aortic) and 29% (mitral) lower mean flow rates.

Discussion

The proposed approach captured the overall pattern of 4D Flow HDFs in healthy conditions. Under pathological LV conditions, extensive analysis and further testing are required to improve agreement.

A 0D Simulation-Based Framework for Fast and Accurate Boundary Condition Optimization in Coronary Arteries Steady-State and Transient CFD Simulations

Mr Luca Mariani MSc[1,2], Ms Marta Pillitteri MSc[1], Ms Giulia Frigerio MSc[1], Mr Gianluca Pontone MD[3,4], Mr Alberto Redaelli PhD[1]

[1]Department of Electronics Information and Bioengineering, Politecnico di Milano, Milano, Lombardy, Italy. [2]European Society of Biomechanics (ESB), Milano, Italy, Italy. [3]Department of Perioperative Cardiology and Cardiovascular Imaging, Centro Cardiologico Monzino IRCCS, Milano, Lombardy, Italy. [4]Department of Biomedical, Surgical and Dental Sciences, Università degli Studi di Milano, Milano, Lombardy, Italy

Introduction

Coronary artery disease represents one of the leading causes of death worldwide. Predicting plaque progression using CFD-derived indices, which have been shown to correlate strongly with plaque growth and remodelling [1], is therefore crucial in the early identification of culprit lesions. However, a spread limitation lies in the reliable estimation of patient-specific boundary conditions (BCs) from limited clinical data, and in the high computational cost of 3D transient CFD simulations. We propose a framework that leverages 0D models to optimize BCs for both steady-state (R) and transient (RCRCR) simulations, enabling patient-specific flow-rate waveforms and outlet impedances in minutes.

Methods

Coronary geometries from 20 patients were segmented from CT images using an in-house automatic segmentation tool. Initial inlet flowrates and outlet BCs were estimated from literature formulas and assigned to a baseline 3D simulation and to its equivalent 0D model. Results from the 3D simulation were used to calibrate the internal parameters of the 0D circuit through a optimization algorithm. The calibrated 0D model was then used to optimize steady and transient output BCs to match the patient's measured mean arterial pressure (MAP) at the coronary ostium (Figure 1). Wall shear stress (WSS), WSS topological skeleton, oscillatory shear index (OSI), and wall pressure gradient (WPG) were computed through 3D simulations using the optimized BCs.

Results

Following internal calibration, 0D models showed strong agreement with 3D simulations when using identical BCs, yielding a relative MAP error of 0.15%. Compared to conventional iterative frameworks, our method reduced computational time for transient

and steady BC estimation respectively by 59% and 54% using a 120-core CPU, with further gains with lower-end CPUs. The approach achieved a mean ostial pressure error, compared to MAP, of 0.13% for steady simulations and 2.31% for transient. Moreover, simulations accuracy was proved by comparing vFFR with invasive iFFR values [2], resulting in a mean error of 4.10%.

Discussion

The proposed 0D-based framework enables fast, reliable patient-specific BCs estimation while substantially reducing computational cost, facilitating more efficient CFD-based assessment of coronary hemodynamic and plaque-progression predictors.

Coupled Eulerian-Lagrangian Modelling of Orthopaedic Trauma Bone Screw Pullout

Dr. Lin Wang[1], Dr. Dana Coombs[2]

[1]DePuy Synthes, Leeds, West Yorkshire, United Kingdom. [2]DePuy Synthes, West Chester, Pennsylvania, United States

Introduction

To ensure patients' safety, evaluating mechanical fixation of bone screws is critical. However, the typically used cadaveric or standard benchtop tests (ASTM F543) are limited by the large variations of donor bone quality and costly design-prototyping-testing iterations. To address those limitations, an innovative computational method is developed to simulate pullout of six trauma screws and validated against benchtop testing.

Methods

An advanced ABAQUS/Explicit R2024 solver using Coupled Eulerian-Lagrangian (CEL) is employed to model the ultra large material deformation and highly nonlinear process. Pullout models of DePuy Synthes locking and cortex self-tapping screws, each with three sizes (1.5x20, 3.5x20 and 4.0x20mm), were built as per benchtop testing (Figure 1a). For computing efficiency, the insertion step was simplified with geometrical Boolean between screws at the full insertion depth (Figure 1b) and 20PCF polyurethane foam (Sawbone™) which was modelled as elastic-plastic material, while the much stiffer screws were assumed to be rigid bodies. Their interactions were simulated with a frictional "penalty" algorithm.

Results

Under the current assumptions, it is predicted that for both locking and cortex screws studied, a larger diameter results in a higher peak pullout force, broadly following the rank order of benchtop testing (Figure 1c). However, the computational models underpredict the experimental peak forces by 10% to 20%, which could result from a few factors such as material variations of Sawbone foam and simplification of the insertion step. When comparing the pullout force history, predicted peak force occurs slightly earlier than measured force (Figure 1d), where the experimental fixtures may take longer to "settle", while neglected numerically.

Discussion

CEL modelling has been successfully developed to simulate bone screw pullout, which would otherwise be extremely challenge for other solvers e.g. Finite Element Analysis, due to severe element distortion. In general, the CEL approach is able to capture the rank order of screws as per benchtop testing. Notably, the models solve in a few hours, which is considerably less time than prototyping and benchtop testing. Moreover, this approach offers a valuable "controlled" platform which only evaluates screw designs while keeping all other variables consistent in contrast to cadaveric tests.

Finite Element Investigation of Load-Driven Bone Density Distribution in Dysplastic and Normal Hips

Mr. Mohammad Mahmoodi[1,2], Prof. dr. Sita Bierma-Zeinstra[2], Dr. Rintje Agricola[2], Dr. ir. Nazli Tumer[1,2], Prof. dr. ir. Amir Zadpoor[1]

[1]Delft University of Technology, Delft, Zuid Holland, Netherlands. [2]Erasmus University Medical Center, Rotterdam, Zuid Holland, Netherlands

Introduction

Bone tissue adapts to its mechanical environment [1], making bone density distribution (BDD) an essential indicator of physiological and pathological loading. This study investigates how dysplastic hips (DH), a strong risk factor for hip osteoarthritis [2], differ from normal hips (NH) in BDD under representative loading conditions.

Methods

Ten dysplastic and ten normal hips were semi-automatically segmented from publicly available CT scans [2, 3] using TotalSegmentator. Acetabular regions and their corresponding coverage areas on each femur were automatically identified, and muscle attachment sites were mapped using a 3D statistical shape model of the proximal femur to ensure consistent muscle force application across all the specimens. First, joint contact forces and muscle forces, including magnitudes and directions, were obtained from individuals without any known hip pathologies [4]. These forces, referred to here as normal loading, were then applied in our simulations. A multi-phasic tissue adaptation model implemented in FEBio [5] was used to simulate BDD. All modelling steps (e.g., discretization, material assignment) were automated using a custom GUI-based pipeline that generated FEBio input files and managed the complete workflow. The adaptation model was first validated against CT-derived densities. Adaptation simulations were then conducted for all hip geometries under normal loading conditions, and statistical comparisons were performed to assess the normal loading effects on DH and NH geometries. In the next phase, dysplastic loading conditions obtained from dysplastic patients will be incorporated into the analysis.

Results

BDD revealed clear differences between NH and DH under normal loading conditions (Fig. 1). The BDD was higher in the head and neck region for NH. Overall, dysplastic cases

demonstrated a 25% lower average total density, with the femoral head density reduced by 21% compared with normal hips.

Discussion

Normal loading revealed consistent differences in adaptation between NH and DH, demonstrating the model's ability to detect geometry-dependent remodelling patterns and supporting its use for evaluating pathological loading effects.

A High-Fidelity Finite Element Model of the Lumbar Spine to Quantify Load Sharing Across Functional Tasks

Ms Linda Carpenedo, Prof. Luigi La Barbera

LaBS, Dept. of Chemistry, Materials and Chemical Engineering, Politecnico di Milano, Milan, Italy, Italy

Introduction

Spinal stability relies on the coordinated action of passive (vertebrae, ligaments), active (muscles), and neural subsystems, and any deficits in one of them require compensation by others. Because direct measurements of spinal loads are invasive or unfeasible, computational models are used. This study proposes a fully deformable musculoskeletal finite element model to examine how soft tissues contribute to load sharing across different tasks.

Methods

The geometry from a validated parametric CAD model of the lumbar spine is used, and all structures are represented as continuous deformable bodies in Abaqus [1]. Body weight is applied eccentrically at each vertebral level. Eight muscle groups are included and discretized into 28 uniaxial fascicle connectors per side, whose stiffness k=qF/l adapts to task demands (Fig.1a). Muscle activations are estimated through an energy-based-optimization informed by a Plackett–Burman screening and a surrogate-optimization based on a generalized linear model predicting the activation patterns needed to satisfy the desired kinematics at each spinal level during standing and 10°/20° flexion. Optimized muscle forces and assessed intradiscal pressures are compared to *in vivo* data [2]. Compressive and shear forces (CFs, SFs) are extracted to assess the soft tissues' load sharing.

Results

The energy-based-optimization estimates physiologically plausible muscle forces (Fig.1b) [2]. Intradiscal pressures increase from standing to 10° and 20° flexion (e.g., at L5–S1: 0.50, 0.57, 0.90 MPa). The anterior column bears the highest CFs and SFs, exceeding 140% of total CFs in flexion (Fig.1a), mainly supported by the anulus. Among posterior ligaments, facet capsules (FCLs) contribute most to load sharing (±40% CFs, ±35% SFs).

Discussion

Estimated muscle forces and spinal loads align with *in vivo* references [2]. The anterior column and FCLs are crucial in standing and flexion, matching the results of other computational strategies and supporting model credibility [3]. The FE model offers detailed insight into soft tissue contributions during daily activities. Future work includes sensitivity analyses on muscle architecture and examining additional tasks under more severe loading conditions.

OA96-04

Fabric and Density Based Determination of Habitual Bone Loading with Homogenised Finite Element Models

MSc Gabriela Gerber, Prof. Dr. Philippe Zysset

ARTORG Center for Biomedical Engineering Research, University of Bern, Bern, Bern, Switzerland

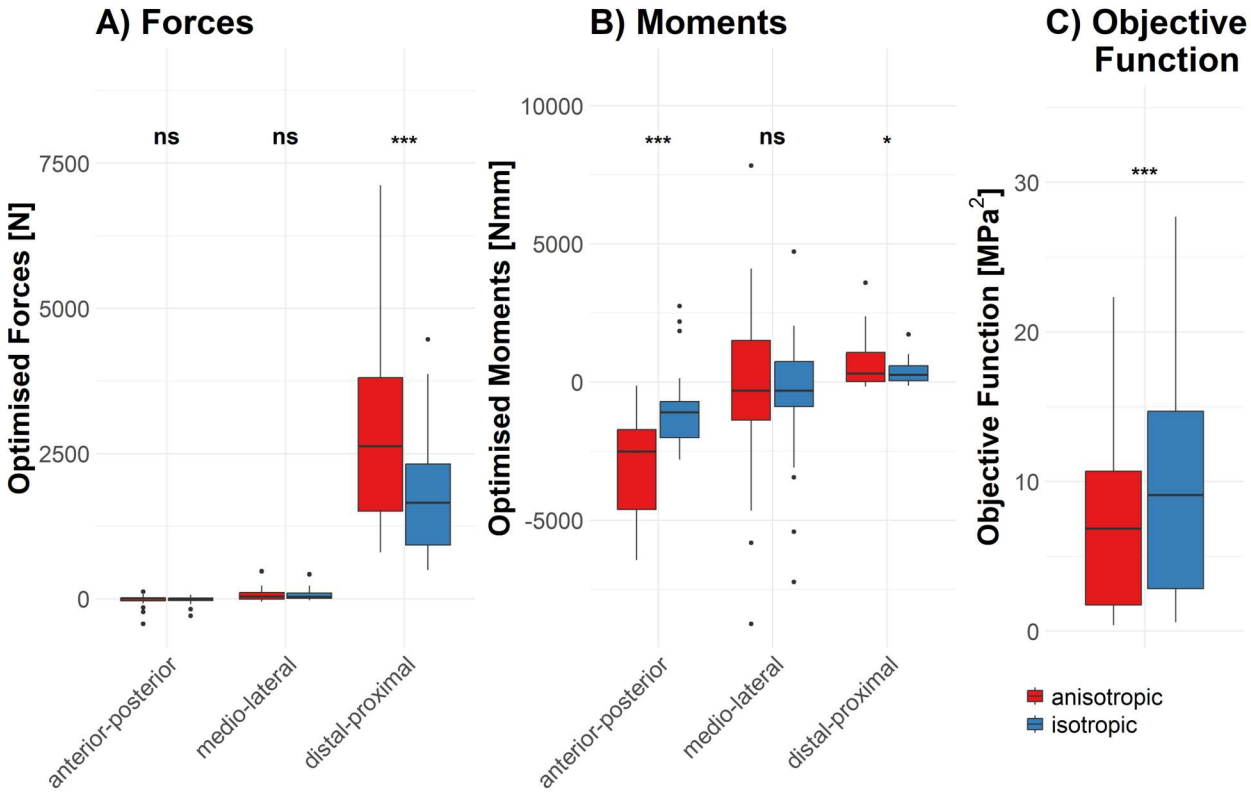
Introduction

A bone's morphology is closely tied to its mechanical function. Computational inverse remodelling allows to estimate personalised habitual load cases based on local bone density and microstructural orientation obtained from high-resolution CT images. Homogenised finite element (FE) models substantially improve computational performance compared to the traditionally used micro-FE approach but have so far only been considered for density-based remodelling [1]. This study aims to include both density and microstructural (fabric) orientation in homogenized inverse bone remodelling algorithms for the estimation of bone's habitual loading history.

Methods

Homogenised FE models of n=24 left human distal tibia sections were created following established procedures [2]. The habitual load case for each bone was defined as a linear combination of scaled unit forces and moments. Appropriate scale factors were determined by minimising the cumulative local difference between the element stress resulting from the combined habitual loading and the ideal local stress based on the element's density and fabric [3]. This optimisation was once performed with the sample's local fabric distribution, and once with an isotropic fabric. The statistical difference between the two methods was evaluated with a paired sign test.

Results



The figure presents (A) optimised forces, (B) optimised moments, and (C) the objective function for isotropic and anisotropic optimisation approaches.

Discussion

During walking, compressive axial forces acting on the distal tibia are slightly shifted laterally [4], inducing a negative moment around the anterior-posterior axis, which corresponds to the largest moment emerging from our inverse analysis. Considering the

fabric orientation in homogenized inverse remodelling leads to an increase in the dominant force and moment and reduces the objective function by 27%, indicating that the osseous structure is better adjusted to this load case than the purely density based remodelling solution. Future analysis will include quantification of St.-Venant's effect on the optimisation results and the estimation of a safety factor relating the habitual load case to the bone's compressive yield force.

Rapidly Converging, Patient-Specific Finite Element Modeling of Foot-Ground Interactions on Variable Terrains and Surface Compliances

Mr Samuel Allen, Dr Nelly Andarawis-Puri

Cornell University, Ithaca, NY, United States

Mr Samuel Allen

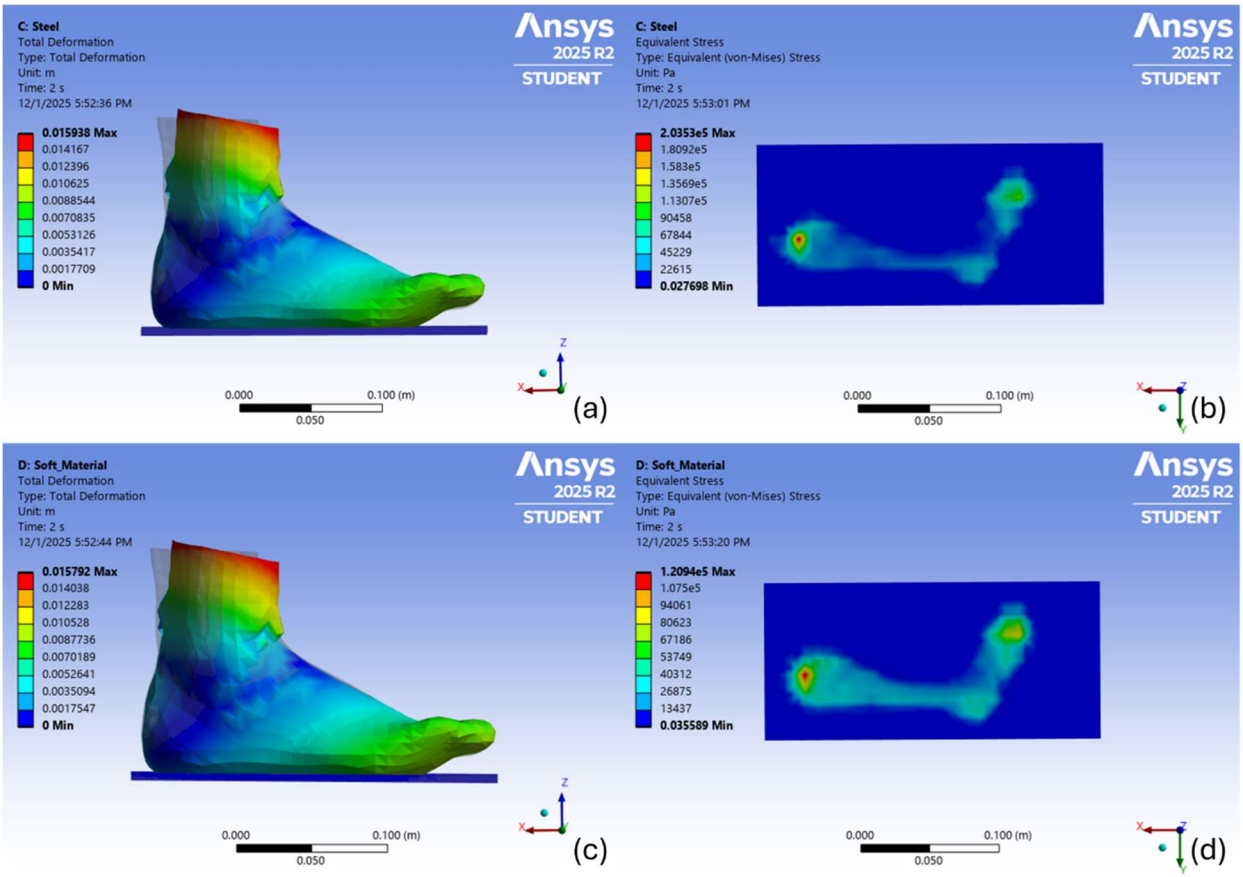
Introduction

From rigid hardwood to compliant sneakers, daily locomotion spans a wide range of terrains and surface compliances. However, existing biomechanical tools struggle to accurately capture interactions of the body with diverse surfaces. Multi-body dynamics platforms, such as OpenSim [1], are patient tailored but oversimplify the foot-ground interface. In contrast, finite element models (FEM) can offer greater fidelity [2] but are too computationally expensive to pair with inverse dynamics and patient individualization. This project bridges this gap by developing an automated, patient-specific global foot FEM in Ansys. By simplifying soft-tissue representation and joint contacts, the model predicts tendon loads and plantar pressures within 10 minutes.

Methods

Bone and skin geometries were reconstructed from T1-weighted MRI scans (5 mm slice spacing). Bones were represented as rigid bodies and skin as shell elements. Inter-bone kinematics were simplified to revolute or spherical joints based on the shape of articular surfaces. Joint passive stiffness was calibrated using clinical tests of ankle and longitudinal/lateral arch flexibility. To improve computational efficiency and stability, volumetric soft tissue was approximated with a non-linear spring network. The simulation was driven by ankle inverse-dynamics loads, with loading of tendons within the foot solved via minimization of Hill-type tendon actuators throughout the walking gait cycle.

Results



For a standing load case on rigid steel versus compliant foam (~4000x more compliant), the model converged in 8 and 7 minutes. Peak pressures were localized under the heel and metatarsophalangeal joint (Fig 1b, d). On the compliant surface, peak pressure decreased

while contact area increased. Total deformation (Fig 1a, c) shows the model's large deformation capability.

Discussion

This framework combines the patient-specificity of multibody dynamics with the high-fidelity contact mechanics of FEM. By achieving rapid convergence across a four-orders-of-magnitude compliance range, this model is a robust platform for simulating real-world locomotion. Critically, the automated generation of a patient-specific model using standard clinical MRI scans and mobility tests establishes a practical tool. This efficient process will allow isolation and prediction of the effects of specific footwear materials and insole designs on individual patients.

Changes in Biomechanical Properties of Paediatric Femora With Age Estimated by Finite Element Methods

Mr George Allison[1,2], Mr Salman Almutairi[3], Professor Amaka C Offiah[3,2], Dr Xinshan Li[1,2]

[1]School of Mechanical, Aerospace & Civil Engineering, University of Sheffield, Sheffield, England, United Kingdom. [2]Insigneo Institute, University of Sheffield, Sheffield, England, United Kingdom. [3]School of Medicine and Population Health, University of Sheffield, Sheffield, England, United Kingdom

Introduction

There is currently a lack of understanding of bone strength (failure load) in children, which is important to understand normal skeletal growth and development. One of the main challenges is the difficulty in obtaining paediatric bone samples. Therefore, finite element (FE) modelling utilizing post-mortem computed tomography (CT) images is a useful method to non-invasively investigate femoral bone strength in children through a range of loading conditions.

Methods

Seventy anonymized and retrospective post-mortem CT scans of children (0-15 years old) were obtained from the Sheffield Children's Hospital and processed through the PyPeCT2S pipeline to create 3D FE models. Personalised heterogeneous material properties were derived through CT attenuation. Three loading conditions were applied (Figure 1): (1) 4-point bending with two equidistant forces applied to the femoral shaft and partially fixed ends. (2) external rotation and (3) internal rotation torsion, where the proximal end was fixed with multi-point constraints and a moment was applied to the distal end. The region of interest for all boundary conditions was the femoral diaphysis. Values of interest were defined as critical moments where the predicted peak strain exceeded a yield strain of 0.73% for tension and 1.04% for compression (1).

Results

FE predicted critical moment increased with age and a quadratic fit was a better predictor than linear. Bending tests produced the highest values and the highest critical moment. Torsion predicted maximum critical moments of 86 Nm and 146 Nm for internal and external rotations, respectively, while 4-point bending predicted values up to 168 Nm. Both

bending and torsional results exhibited the same trend with increasing age, which were also in line with previous results from (2).

Discussion

This study presents a sizeable cohort of data with a well-spaced age range, and the largest dataset of CT-based paediatric biomechanical femoral models in infants. The results of this study reinforce age as a key predictive factor for bone strength and show good correlation with previous experimental studies. Additionally, the results offer insight regarding the rate of change of bone strength during normal growth and development in children.

Images (Optional)

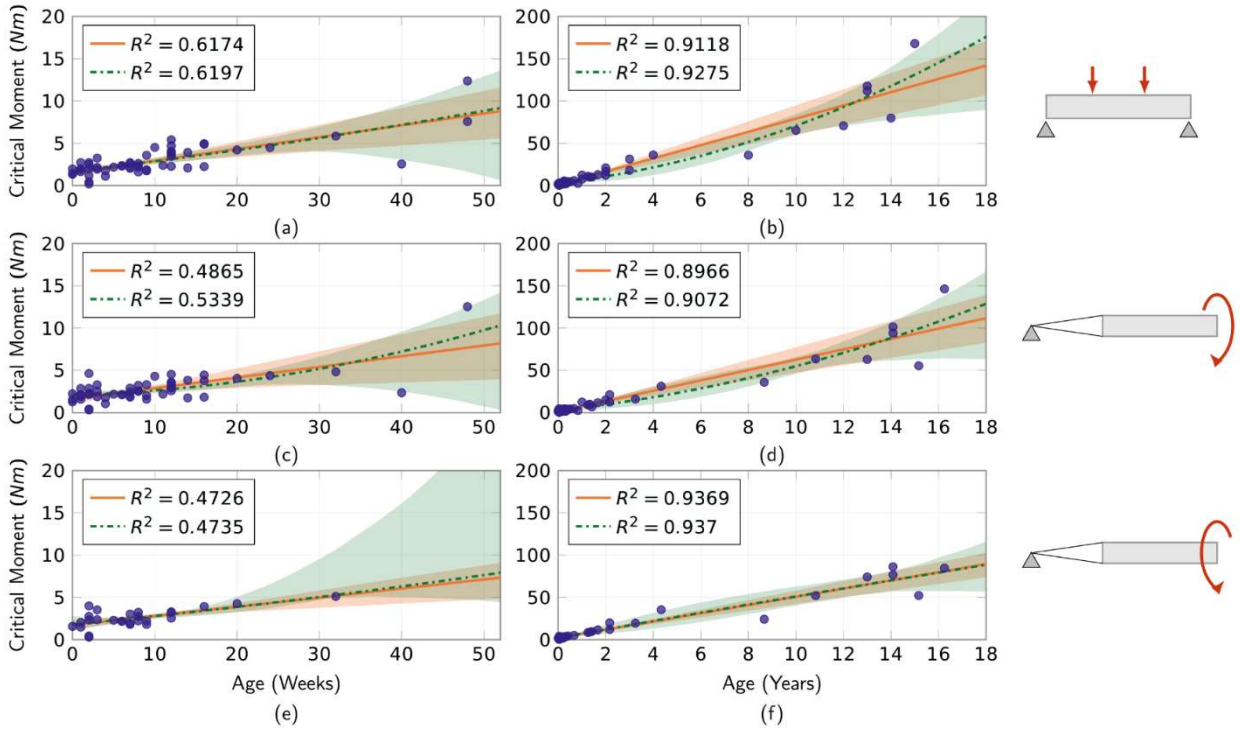

Figure 1: Figures in the left column are representative of children up to 1-year-old, while figures on the right are the entire age range of the cohort (n=70). Linear and quadratic regressions were performed on all data sets, where linear regression is shown in orange, and quadratic regression in green. (a) and (b): the 4-point bending. (c) and (d): torsion with external rotation. (e) and (f): torsion with internal rotation.

Biophysical Modeling of Human Colonic Motor Patterns in Health and Disease

Dr. Ahilan Anantha Krishnan PhD[1], Prof. Phil Dinning PhD[2], Prof. Maria Holland PhD[1]

[1]University of Notre Dame, Notre Dame, IN, United States. [2]Flinders University, Bedford Park, South Australia, Australia

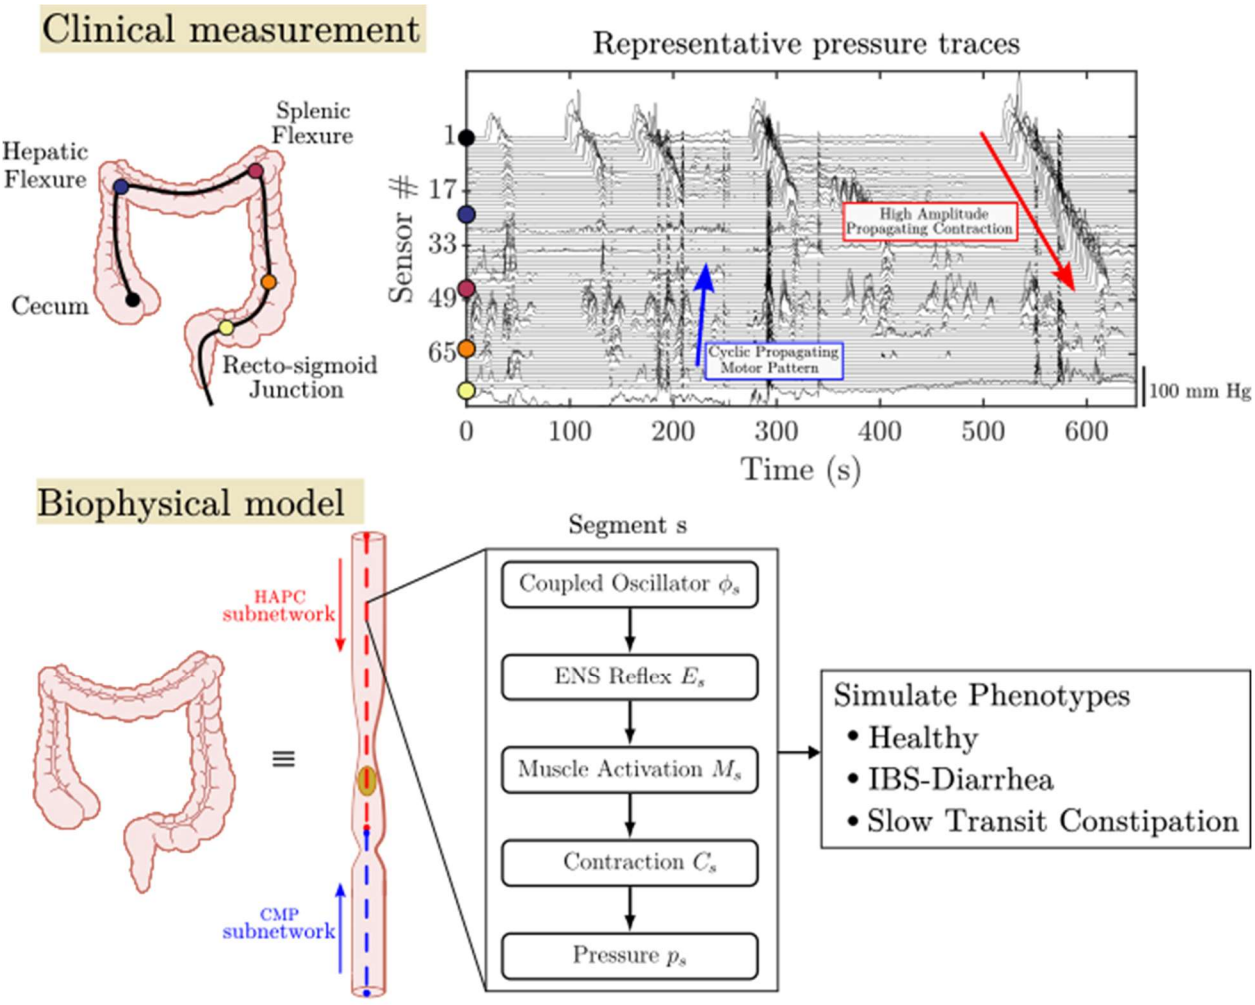
Introduction

Colonic motility disorders such as diarrhea predominant irritable bowel syndrome (IBSD) and slow transit constipation (STC) are common and can significantly impact quality of life. These conditions involve disrupted bowel function, often linked to abnormalities in colonic motility. For example, two key motor patterns observed in healthy individuals, high amplitude propagating contractions and cyclic motor patterns, are frequently reduced or absent in affected patients as shown by high resolution colonic manometry. Understanding how these patterns interact, along with the pacemaker, neural, and mechanical mechanisms that generate them, is essential for developing more effective treatments.

Methods

In this study, we developed a biophysical whole colon model that represents the colon as a chain of coupled oscillators driving smooth muscle activation. The model incorporates enteric nervous system reflexes, a pressure gated cyclic motor pattern (the rectosigmoid brake), and a nonlinear tube law describing colon wall mechanics. By adjusting a small set of physiologically grounded parameters, specifically pacemaker drive, coupling strength, directional spread, and distal gating, we reproduced three distinct motility phenotypes: healthy function, IBSD, and STC. Simulated pressure maps were compared with representative high resolution colonic manometry recordings, and local sensitivity analysis identified the parameters most strongly influencing peak pressure and motility index.

Results



The model reproduced key features observed in clinical manometry, including high amplitude propagating contractions, a retrograde cyclic motor pattern, and phenotype-specific differences in amplitude and coordination. Increased pacemaker activity and reduced distal gating generated a hypermotile pattern consistent with manometric findings in IBSD [1], while reduced coupling and added stochasticity produced fragmented, low amplitude activity characteristic of STC [2]. Sensitivity analysis identified proximal

pacemaker amplitude, coupling strength, and directional spread as dominant regulators of the global pressure response.

Discussion

This biophysical framework links measurable manometry metrics to specific physiological mechanisms controlling colonic motility. It provides a first step towards a mechanistic basis for interpreting high-resolution colonic motility, supports hypothesis-driven in silico exploration of motility disorders, and offers a platform for future patient-specific calibration to guide individualized therapeutic strategies.

The Generalized-Kelvin-Voigt-Based Visco-Hypoelastic Model Describes the Rate-Dependent Thixotropic Behavior of Individual Collagen Fibrils Under Uniaxial Tension

Msc You-Rong Chiang[1,2], Dr Orestis G. Andriotis[1], Prof Claire Morin[3], Prof Christian Hellmich[2], Prof Philipp J. Thurner[1]

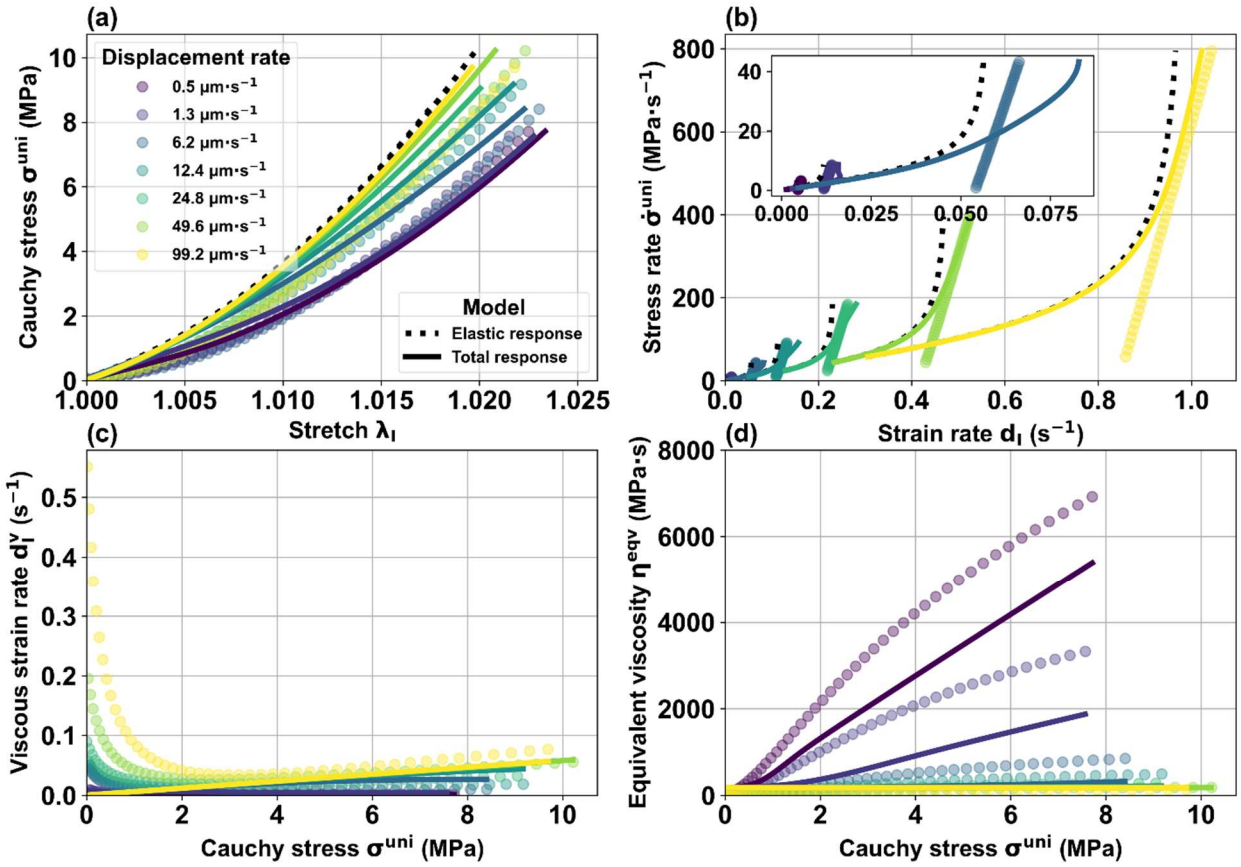
[1]Institute of Lightweight Design and Structural Biomechanics, TU Wien, Vienna, Vienna, Austria. [2]Institute for Mechanics of Materials and Structures, TU Wien, Vienna, Vienna, Austria. [3]Mines Saint-Étienne, Université Jean Monnet, Saint-Étienne, Auvergne-Rhône-Alpes, France

Introduction

Collagen fibrils provide mechanical support for most biological tissues and exhibit rate-dependent and thixotropic behavior under uniaxial tension by atomic force microscopy (AFM) [1,2]. Using the Mooney-Rivlin (MR) model in rate form within a visco-hypoelastic framework, we have previously decoupled the elastic part from the fibril total response [3]. In this process we have identified two dissipation regimes associated with molecular straightening and twisting, respectively. Here, we present an extension of our model including the dissipative behavior by implementing the generalized Kelvin-Voigt (GKV) rheological model into the visco-hypoelastic formulation.

Methods

We re-formulate the visco-hypoelastic model analogously to the GKV model. The elastic portion is governed by the MR model, while the viscous portion is represented by the Kelvin-Voigt (KV) element in series to the elastic portion. The spring in the KV element is also specified as MR type. Material parameters are determined through a two-step least-squares procedure: the first step is to identify the elastic MR properties and the latter to identify the viscous KV properties.



Results

The rate-type MR model yields an initial hypoelastic modulus of about 188 MPa, corresponding to the stiffest fibril response at the infinite strain rate (black dotted line in Figure a and b). Two dissipation regimes are found and separated at around 2 MPa , whereupon the second regime is well-described by the GKV model (Figure c). The model also captures the thixotropic behavior of collagen fibrils, as the equivalent viscosity increases with the decreasing displacement rates (Figure d).

Discussion

The GKV-based visco-hypoelastic model presented describes the rate-dependent and thixotropic behavior of individual collagen fibrils. Nevertheless, the current model is restricted to describing the second dissipation regime only (Figure c). The dissipative portion represented by the KV element alone leads to the underestimation of the equivalent viscosity at low displacement rates (figure d). The current study represents a first step toward a comprehensive visco-hypoelastic description of collagen fibrils, with further refinements needed.

[3]Department of Neurosciences, Psychology, Drug Research & Child Health, University of Florence, Florence, Tuscany, Italy. [4]Institute of Materials Science and Technology, TU Wien, Vienna, Vienna, Austria

Introduction

Hypertrophic cardiomyopathy (HCM) is strongly associated with interstitial fibrosis, a key regulator of ventricular stiffening. Cardiac fibroblasts (CFs), mediators of extracellular matrix (ECM) remodeling, are highly mechanosensitive and respond to matrix stiffening, which may drive disease progression. Three-dimensional cell spheroids (CSs) mimic the native cellular microenvironment and enable micromechanical testing via parallel-plate compression. Yet the micromechanics of HCM CFs-derived CSs remain insufficiently characterized. Here, we employed compression, stress-relaxation analysis, and confocal imaging to characterize the viscoelastic-structural properties in healthy and HCM CF-derived CSs.

Methods

Four CS groups were studied: control untreated (CU) and treated with TGF-β (CT), HCM untreated (HCMU) and treated with TGF-β (HCMT). TGF- activation in fibrosis is linked to collagen synthesis - a key response to inflammation. Parallel-plate compression (CellScale MicroSquisher) tests were performed in a quasi-static ramp at 50% strain and 0.5μm/s displacement rate. Force-displacement data analyzed using a Mooney–Rivlin hyperelastic model with nonlinear contact effects. Stress-relaxation tests (30% strain, 90s hold) were fitted with a generalized Maxwell model. Confocal imaging detected collagen (picrosirius red) and α-smooth muscle actin (α-SMA). Statistical analysis used Kruskal-Wallis or ANOVA with post hoc tests ($\alpha < 0.05$).

Results

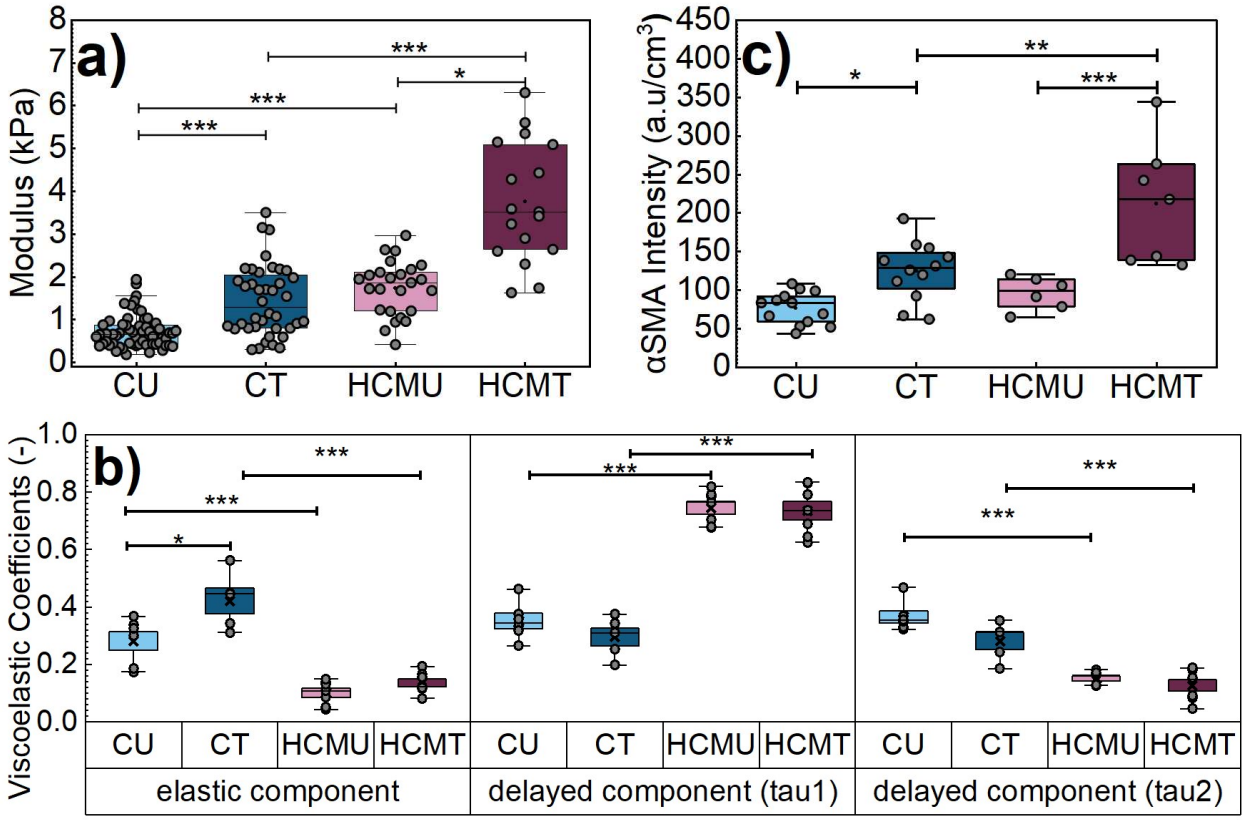

Figure1 shows results obtained from mechanical testing and confocal imaging on CSs derived from primary human CFs. Each scatter represents a measurement from one CS. HCM spheroids exhibited a nearly three-fold higher modulus than controls, with TGF-β

inducing an additional two-fold increase (Figure1a). Stress-relaxation revealed two-phase decay, successfully captured by the Wiechert model. HCM CSs showed higher viscous components. TGF-β increased elastic components, especially in controls, with slight viscous reduction (Figure1b). Confocal imaging revealed a marked induction of α-SMA by TGF-β, particularly in HCMT (Figure1c).

Discussion

In summary, the mechanical and structural analysis demonstrates that HCM CFs–derived CSs possess a distinct viscoelastic and structural phenotype consistent with fibrotic remodeling. However, further research is required to elucidate all aspects of this model, with particular emphasis on pathways such as TGF-β and HIF, which are known to contribute to other types of fibrosis, i.e. lung interstitial fibrosis.

Frequency-Dependent Changes in the Viscoelastic Properties of Porcine Brain Tissue

Ms. Laura Ruhland, Prof. Dr.-Ing. habil. Kai Willner

Institute of Applied Mechanics, Friedrich-Alexander University of Erlangen–Nuremberg, Erlangen, Bavaria, Germany

Introduction

A persistent problem in the mechanical characterization of brain tissue is the inconsistency in responses that result from different testing techniques. Particularly challenging are experiments with different time scales [1]. The aim of this study is to combine mechanical responses obtained in varying time scales and consequently characterize brain tissue over an extended time range.

Methods

To obtain the frequency-dependent material response Magnetic Resonance Elastography (MRE) was performed in three different brain areas, as well as in liver tissue. The liver tissue serves as a comparative material due to its widespread clinical and experimental use in MRE applications [2]. A tabletop MRE system, which is described in detail in [3], was used to acquire the responses for frequencies from 300 to 2100Hz. The material behavior of the brain tissue in the quasi-static time domain was examined through multi-modality rheometer experiments under cyclical loading and relaxation. From both experimental responses the frequency-dependent storage and loss moduli were calculated, with the modulus obtained from the time-domain measurements corresponding to 0Hz. A viscoelastic model was calibrated using the combined material response over the whole frequency range.

Results

Fig. 1 shows the measured storage and loss moduli as well as the calibrated model for the brain areas and the liver. The storage modulus indicates the elasticity of the material, whereas the loss modulus quantifies the viscous dissipation. All tissues exhibit a higher storage than loss modulus at low frequencies, while at high frequencies the loss modulus surpasses the storage modulus. However, the frequency point at which the loss modulus exceeds the storage modulus varies for every tissue.

Discussion

The findings indicate that the viscoelastic behavior of brain and liver undergoes a transition from an elasticity-dominated to a viscous-dominated response with increasing frequency. Furthermore, every tissue type has a unique frequency at which the material behavior transits. Therefore, we propose the crossover frequency as a model-independent material parameter to describe the viscoelastic properties of brain and liver tissue.

Images (Optional)

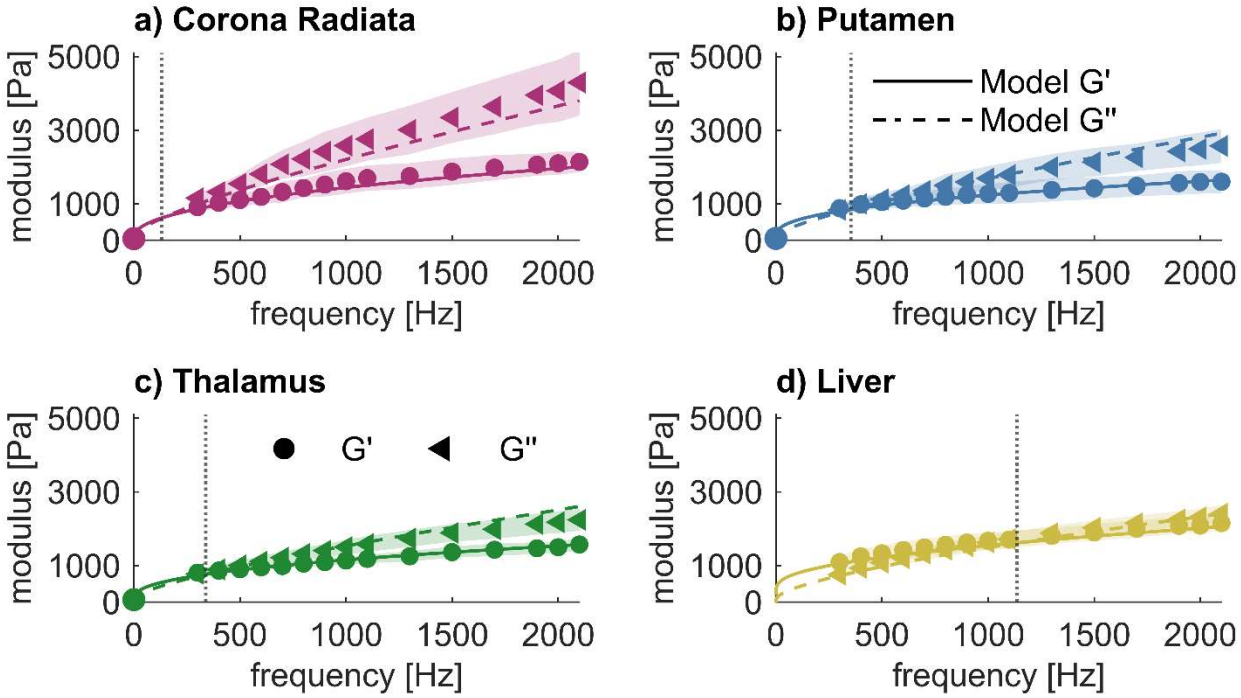

Figure 1: Measured (Mean ± Std) and modeled storage (G') and loss modulus (G"). The dotted line indicates the crossover frequency at which the loss modulus exceeds the storage modulus.

Decidualization during pregnancy alters collagen microarchitecture and mechanical response of the endometrium

Ms. Catalina Bastias, Dr. Matthew Dean, Dr. Callan Luetkemeyer

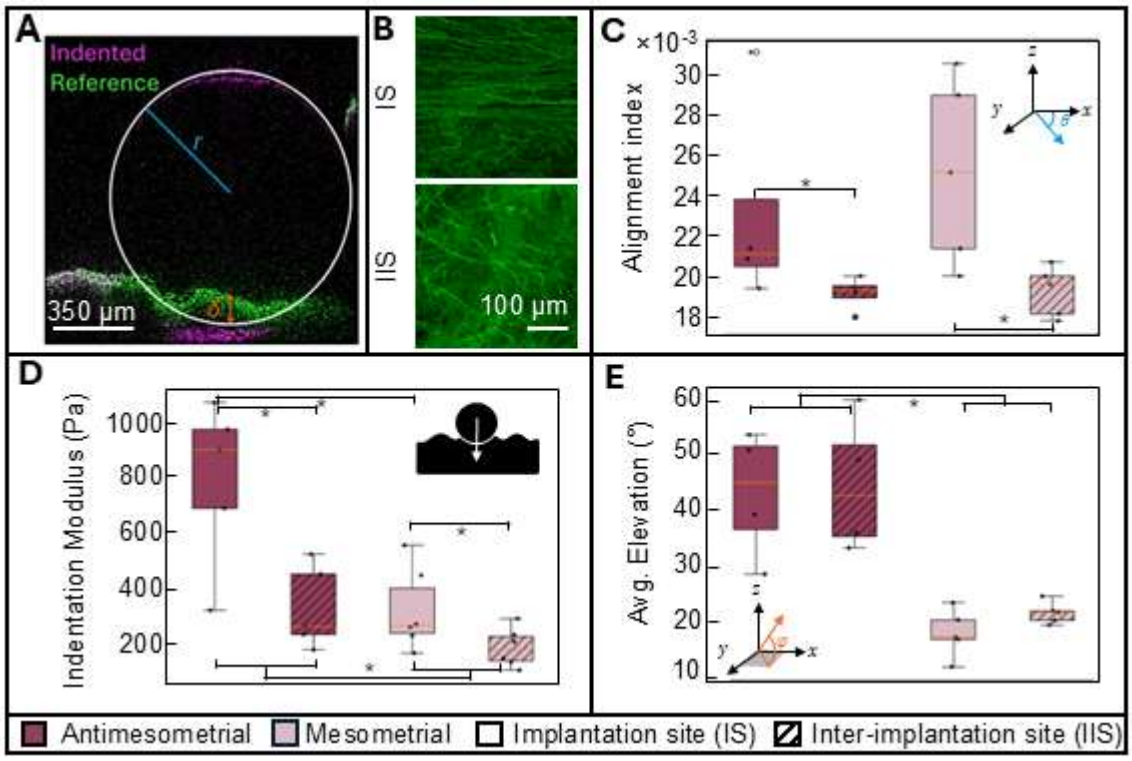
University of Illinois Urbana-Champaign, Urbana, IL, United States

Introduction

Infertility affects 8-12% of reproductive-age couples [1], and endometrial dysfunction—specifically, impaired decidualization—is believed to account for ~20% of cases. The endometrium, the uterus's innermost layer, undergoes cyclical proliferation, differentiation, and shedding with each menstrual cycle [2]. Decidualization is the process marked by dramatic cellular changes, thickening, and extensive extracellular matrix (ECM) remodeling to create a receptive environment for embryo implantation [2]. Because the ECM is heavily implicated, mechanical imaging techniques such as elastography may enable diagnosis and guide the development of treatments, which remain elusive. Thus, this study examines how decidualization influences endometrial stiffness and collagen microstructure.

Methods

8-week-old C57BL/6 female mice (n=6) were mated, then euthanized on day 8 of pregnancy. One uterine horn was cut along the antimesometrial (AM) pole (implantation pole) and the other along the mesometrial (M) pole. Samples were stained, then indented using a glass ~1 mm microsphere. 3D confocal microscopy images were captured during and after indentation at the decidualized implantation site (IS) and undecidualized inter-implantation sites (IIS). Indentation depth was estimated, from which an indentation modulus was calculated using the Hertz model (Fig.1A). Collagen microstructure was assessed via second harmonic generation imaging. Custom Python code quantified fiber orientation (azimuth and elevation); the alignment index was calculated as the inverse of the standard deviation in azimuth angle. Two-way ANOVA evaluated effects of pole (AM vs. M) and decidualization (IS vs. ISS), with significance defined as $p<0.05$.



Results

Both decidualization and pole significantly affected indentation modulus. Stiffness was higher at the AM pole and increased with decidualization, with post-hoc differences in AM-IS vs. AM-IIS and AM-IS vs. M-IS (Fig.1D). Collagen fibers were more aligned at the IS (Fig.1B-C), and elevation angle was larger at the AM pole regardless of decidualization status (Fig.1E).

Discussion

This is the first study to jointly characterize mechanical and microstructural changes during decidualization; results demonstrate that decidualization causes circumferential collagen alignment and an increase in indentation stiffness. Future work will examine mechanical anisotropy and models of impaired decidualization to inform mechanics-based diagnostics of uterine infertility.

COP Jump Metrics Reveal Bilateral Compensation and Increased Movement Variability Following ACL-Reconstruction

Dr Suzanne M Konz PhD, ATC, CSCS

Marshall University, Huntington, West Virginia, United States

Introduction

Countermovement jumps (CMVJ) are viewed as symmetrical tasks that mask neuromuscular deficits after anterior cruciate ligament reconstruction. However, the center of pressure (COP) behavior and force-time metrics may reveal compensation strategies that are not visible in traditional bilateral outputs. This study examined whether participants with ACL reconstruction (ACL-R) demonstrate altered control, loading patterns, and movement consistency during double-leg jumping compared with healthy teammates.

Methods

420 participants (323 controls particpants, 97 ACL-R (54 males, 43 females) completed force plate (Sparta Science, Sparta Plate) CMVJ testing protocol. Variables extracted included COP sway velocity, unweighting and eccentric COP displacement, landing rate of deceleration, unweighting and concentric timing, time to takeoff, time to peak acceleration, modified reactive strength index, and force expression metrics. Group differences were evaluated using Mann-Whitney U tests or independent t tests. Variance differences were assessed using Levene tests.

Results

ACL-R participants demonstrated lower COP sway velocity in the frontal plane ($p \approx 0.000002$) and greater eccentric displacement in the frontal plane ($p \approx 0.000048$). Landing rate of deceleration was lower in the ACL-R group ($p \approx 1.5 \times 10^{\wedge} -15$). Timing differences were seen in concentric duration ($p \approx 0.025$), time to takeoff ($p \approx 0.0038$), and time to peak acceleration ($p \approx 0.005$). Force expression metrics were significantly lower in the ACL reconstructed group, including modified reactive strength index ($p = 3.04 \times 10^{-14}$), relative force at zero velocity ($p = 1.72 \times 10^{-9}$), average maximum force ($p = 3.04 \times 10^{-8}$), eccentric impulse ($p = 0.00003$), and concentric impulse ($p = 7.89 \times 10^{-16}$). Variance analyses indicated greater variability in COP sway, eccentric displacement, unweighting

displacement, landing deceleration, eccentric time, and modified reactive strength index (all $p < 0.05$).

Discussion

ACL-R participants displayed differences in COP control, loading strategy, timing, and force expression during a CMVJ. They demonstrated greater variability across several control and performance measures. These findings show that ACL-R patients do not exhibit unilateral deficits but instead demonstrate bilateral compensation strategies characterized by altered COP control, prolonged timing, reduced force expression, and increased movement variability. COP-based metrics and timing variables may provide sensitive indicators for monitoring recovery and informing return-to-sport decisions.

Knee Contact Forces of TKA Patients with Asymmetrically Shortened Crankarm Lengths during Ergometer Cycling

Professor Songning Zhang PhD, FNAK, FACSM[1], Dr. Walter Menke PhD[1], Mr. Alejandro Ovispo-Martinez[1], Mr. Tsung-Lin Lu[1], Dr. Katie Stevens DPT[2], Dr. Harold Cates MD[2]

[1]University of Tennessee, Knoxville, TN, United States. [2]Tennessee Orthopaedic Alliance, Knoxville, TN, United States

Introduction

Stationary cycling is a common method used for rehabilitation of patients post total knee arthroplasty (TKA) and crankarm shorting on the replaced showed reduced knee range of motion (ROM) and unaltered knee extension moment (1). However, it is still unknown what effects of these adjustments may have on knee joint loading. The purpose of this study was to quantify the knee contact forces during cycling with asymmetrical crank arm shortening in individuals 1-2 months after TKA.

Methods

Seven participants who received a cruciate retaining implant cycled at 70 W and 70 RPM in three cycling conditions: 170mm standard crank arms on both side, and shortened 155mm and 140mm crank arms on the replaced limb and 170mm on the non-replaced limb. Kinematic (240 Hz) and pedal reaction force (PRF, 1200 Hz) data were collected simultaneously using a 12-camera motion analysis system (Vicon, Oxford, UK). The cycling tasks were conducted with a cycle ergometer (Lode). Static optimization and joint reaction analysis were conducted using a knee model in OpenSim to estimate the total knee contact force (TCF), and medial (MCF) and lateral (LCF) compartment contact forces. A one-way repeated measures ANOVA was used to assess the potential effects on MCF, LCF, and TCF as well as peak muscle forces ($p<0.05$).

Results

Decreases in crank length led to significantly reduced TCF and LCF within the replaced limb at 140mm and 155mm compared to 1700mm with $p=0.002$ and $p=0.011$, respectively (Table 1).

Discussion

Findings from this work along with the reduced knee ROM and unchanged knee extension moment previously reported, suggest that asymmetric crankarm shortening can accommodate the reduced knee ROM without overloading the knee joint. The current simulation results actually showed added benefits of reduction in knee compressive contact forces with reduced crankarms. These results suggest that stationary cycling with shorter crankarms can be implemented early in the rehabilitation process of patients with TKA to accommodate their knee stiffness while not adversely affecting estimated internal knee loading and altering knee muscle forces.

Biomechanical Performance Profiling Demonstrates a Lack of Performance Readiness Compared to Isolated Benchmarks in Athletes 14 Months Post ACL Reconstruction

Mr. Zachary McClean PhD Candidate[1], Dr. Ricardo da Silva Torres PhD[2], Dr. Walter Herzog PhD[1], Dr. Kati Pasanen PhD[1], Dr. Matthew Jordan PhD[1]

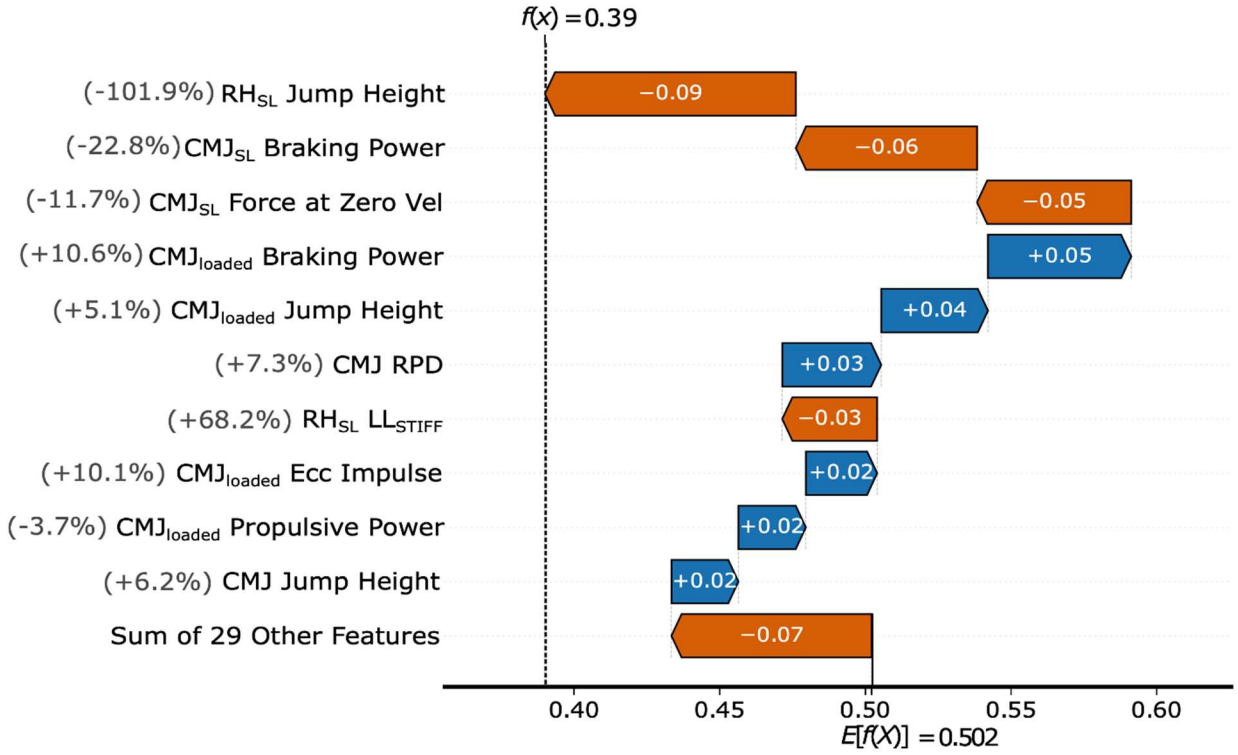
[1]University of Calgary, Calgary, AB, Canada. [2]Wageningen University & Research, Wageningen, Wageningen, Netherlands

Introduction

In addition to a high risk for subsequent anterior cruciate ligament (ACL) injury, athletes who have returned-to-sport (RTS) after ACL reconstruction (ACLR) demonstrate long-term disruptions in neuromuscular performance related to a loss of power, explosive strength and impaired biomechanics. However, the best approach to measure neuromuscular performance-readiness in this population is unclear. RTS readiness is typically determined using isolated metrics and tests (e.g., quadriceps strength, jump biomechanics) and the interlimb asymmetry index (AI). This yields numerous neuromuscular and biomechanical outcome measures. Beyond additive models based on isolated tests and outcomes, supervised machine learning (ML) has been used successfully in healthy athletes to generate performance profiles based on a weighted combination of characteristics. Additionally, ML model explainability has been used in health care settings to gain insights into the output of ML models to identify functional limitations at the individual level. Whether biomechanical performance profiling using ML and model explainability provides enhanced information on athlete performance-readiness after their RTS from ACLR compared to isolated AI measures using the contralateral limb benchmark has yet to be tested. The purpose of this study was to compare the proportion of athletes who meet an AI benchmark < 10% based off isolated metrics to the proportion of athletes classified into a target profile using BPP_{ML}.

Methods

A supervised BPP_{ML} was developed to classify healthy control athletes to sport-specific and sex-specific biomechanical profiles based on their maximal leg extensor strength, vertical jump and repeat hop testing mechanics. Competitive athletes with ACLR beyond RTS (n=19; post-op: ~14 months) performed the same biomechanical assessment. The proportion of athletes meeting a <10% AI criteria were compared to the BPP_{ML} classification.



Results

After training, the BPP_{ML} showed >93% classification accuracy in healthy controls. ACLR athletes were less likely to belong to the target profile using a BPP_{ML} (16% ACLR athletes) compared to the AI criteria (43-63%, mean=54%) (p=0.01). ML explainability identified individualized biomechanical features influencing the classification outcome (Fig 1).

Discussion

This BPP_{ML} approach should be tested in clinical and performance settings to better understand its applicability for highlighting the long-term impact of ACLR on biomechanical and neuromuscular performance after RTS.

Rotator Cuff Activation in Post-operative Rehabilitation Exercises

Ms Minah Waraich BS, Ms Silvia Zanini MS, Dr Andreas Kontaxis PhD, Dr Julia Retzky MD, Dr Michael Fu MD, Ms Bridget Assip PT, DPT, PCS, C/NDT, Dr Jennifer Jezequel PT, DPT, PCS, EdD, Ms Sophia Wang BS

Hospital For Special Surgery, New York, New York, United States

Introduction

Rotator cuff (RC) tears are a common shoulder injury, with supraspinatus repairs being the most frequent, and a high prevalence of complications and re-tears. Excessive muscle load is considered a factor contributing to repair failure. Standard rehabilitation involves 6 weeks of immobilization, with gradual progression to passive ROM and active ROM. Immobilization, however, increases risk of stiffness and muscle atrophy. The objective is to characterize RC muscle activations, with a focus on supraspinatus, during common post-operative rehabilitation exercises. This will inform clinicians to progressively increase load during rehabilitation to minimize complications.

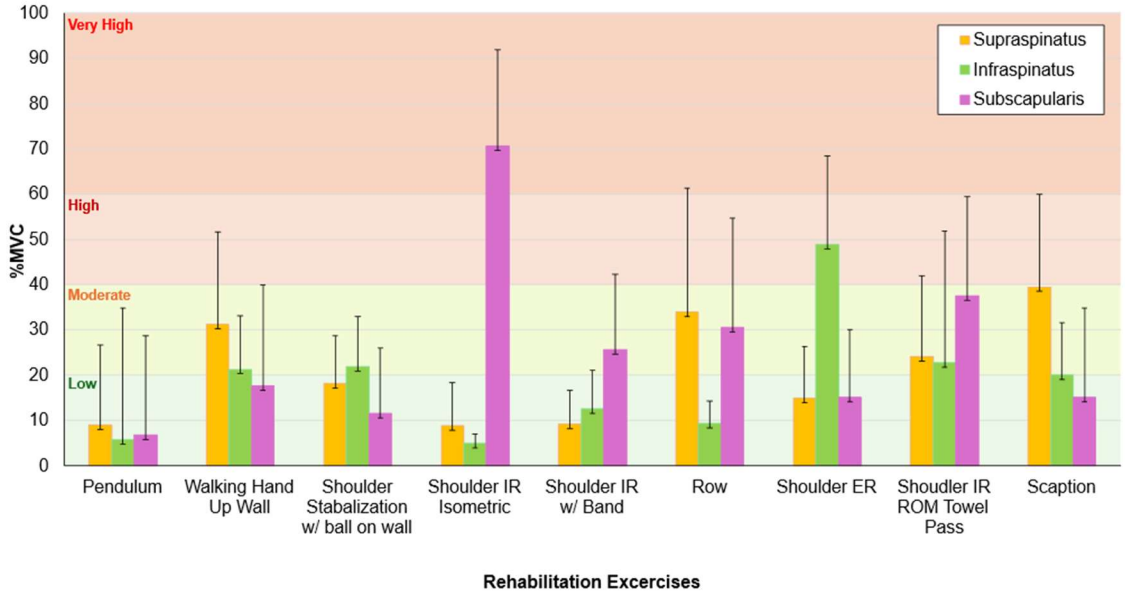
Methods

Nine healthy volunteers (9M, 28.3±5.14years; 180.7±6.23cm; 87.28±13.38kg) performed 9 commonly prescribed post-operative RC exercises (Figure 1). Participants performed maximal voluntary isometric contractions (MVICs). Muscle activity of the infraspinatus, supraspinatus, and subscapularis was recorded using fine-wire EMG.

The raw EMG data were processed using MATLAB. Raw signals were scaled, rectified, and DC offsets were removed. The linear envelope was normalized to 1000 points for time alignment. The peak linear envelopes (PLE) were defined with repetition's averaged. Average PLE was normalized by MVICs. The mean %MVIC across subjects for each muscle and exercise was categorized based on the following literature thresholds: Low (0–20%), Moderate (21–40%), High (41–60%), and Very High (>60%).

Results

The supraspinatus exhibited low activation in: pendulum (9%), shoulder stabilization with ball on wall (18%), shoulder IR Isometric (9%), shoulder IR with Band (9%), and shoulder ER (15%), and moderate activation in: walking hand up wall (31%), Row (34%), shoulder IR ROM Towel Pass (24%) and scaption (39%). High activation was shown in the infraspinatus



during shoulder ER (49%), and very high activation in the subscapularis during shoulder IR isometric (71%).

Discussion

During early-phase rehabilitation low activation exercises are appropriate for rehabilitation, while moderate activation exercises should be implemented during later phases. For supraspinatus, pendulum, shoulder stabilization, and IR/ER rotation with bands are recommended for early phase. Scaption, row, and walking hand up the wall exercises should follow later. Future work will incorporate a computational model to define muscle loading, for optimized rehabilitation.

The Relationship Between Changes in Cartilage Thickness and Knee Joint Contact Stress: A Comparison of Walking and Running

Mr Shinya Ogaya PhD, Ms Riona Kaizu BS, Ms Moko Kitahara BS, Mr Satoshi Horiguchi BS, Mr Kenta Horiuchi MS, Mr Masahiko Shimamura PhD

Saitama Preferctural University, Koshigaya, Saitama, Japan

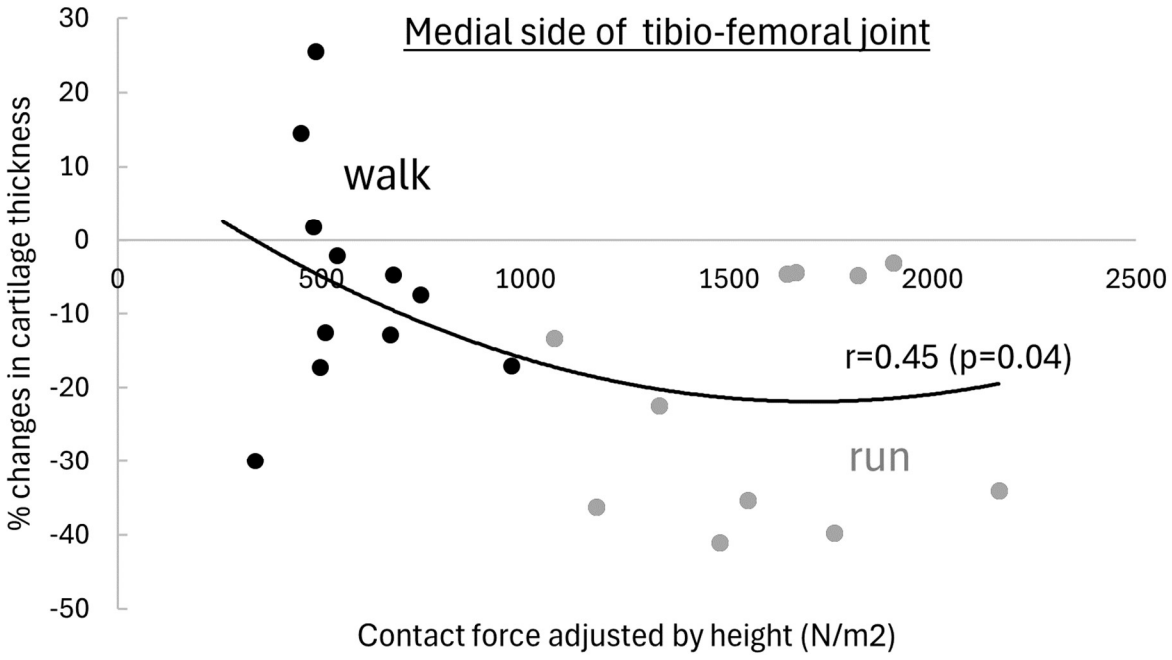
Introduction

Repetitive weight-bearing loads on the knee joint compress cartilage, reducing its water content and thickness. However, it remains unclear whether changes in cartilage thickness are correlated with the magnitude of joint contact force. In this study, we used walking and running to vary the magnitude of cartilage loading and examined the resulting changes in cartilage thickness.

Methods

We recruited 11 recreational runners aged over 45 years who reported knee pain and had no history of knee surgery. The study included measurements of cartilage thickness, motion analysis, and imaging (X-ray and MRI). Cartilage thickness was assessed using ultrasound at four sites: medial and lateral tibiofemoral (mTF, lTF) and medial and lateral patellofemoral (mPF, lPF) joints. Measurements were performed before and after 10 minutes of treadmill walking or running. Motion analysis was performed using a three-dimensional motion capture system while participants walked or ran on a treadmill. The tibio-femoral and patella-femoral joint alignment of musculoskeletal model were individually adjusted using X-ray-derived femoro-tibial angle and MRI-based patellofemoral facet orientation, respectively. Vertical contact forces normalized to squared height at mTF, lTF, mPF, and lPF were estimated during the stance phase using OpenSim. Paired t-tests compared walking and running; Pearson correlation was used to examine the force-thickness relationships.

Results



Contact forces at all joint sites were significantly higher during running compared to walking. Percentage change in cartilage thickness at the mTF joint decreased significantly more after running (-21.1%) than after walking (-5.6%). When the walking and running data were combined, the percentage change in cartilage thickness was significantly associated

with the contact force at the mTF in a quadratic manner (r=0.45, p=0.04) with higher contact forces corresponding to larger decreases in cartilage thickness shown in Figure.

Discussion

Cartilage thickness decreased more after running than after walking, suggesting that cartilage is more susceptible to deformation under higher mechanical stress. This finding indicates that the cartilage thickness response may be associated with the magnitude of joint loading.

Dr. Felipe Gonzalez

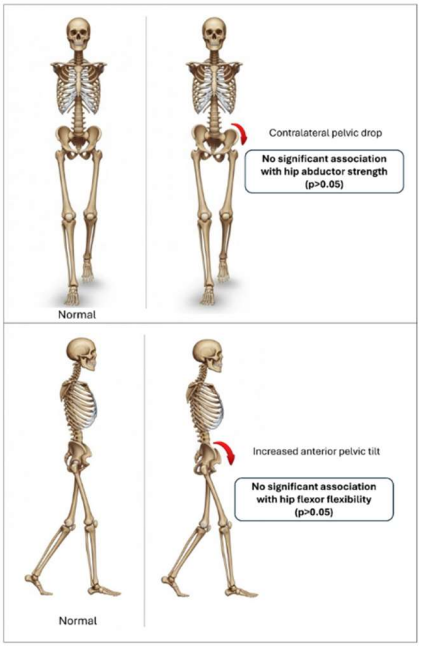
Introduction

The spine and hips are biomechanically interconnected, and disorders affecting both are often categorized under hip-spine syndrome. This study explores the link between pelvic motion impairments and hip physical characteristics in low back pain patients with increased contralateral pelvic drop and anterior tilt during gait. The hypothesis was that hip strength and flexibility would correlate with pelvic gait kinematics.

Methods

This cross-sectional retrospective study included participants with a mean age of 44.6 (Range: 21–60) years, presenting acute or chronic low back pain and independent gait. Participants had been previously categorized into distinct gait profiles (P1: Flexed trunk, P2: Lumbar rectification; P3: Pelvic impairment; P4: Trunk extension and rotation; P5: Tight axial control) based on three-dimensional gait kinematics using machine learning algorithms. The current analysis examined intra-profile correlations between pelvic motion during gait (pelvic drop and anteversion) and clinical measures of hip function (hip abductor strength and hip flexor/extensor flexibility). Spearman's rho was used to assess linear correlations and normalized mutual information was computed to explore non-linear associations. Statistical significance was set at 5%.

Results



No statistically significant correlations were found for profiles 3, 4, and 5 ($p > 0.05$) (Figure 1). Although significant correlations between hip strength/flexibility and pelvic kinematics emerged within profiles 1 and 2, as well as when considering profiles 1–5 as a single group ($p < 0.05$), these lacked clinical relevance due to low biomechanical plausibility.

Discussion

This study builds on previous literature on gait profiles in low back pain and provides new insights into the mechanisms underlying hip-spine syndrome. There was no association between hip strength or flexibility and altered pelvic kinematics during gait in individuals with low back pain. These findings suggest that the observed pelvic motion impairments are likely compensatory responses rather than primary deficits in the hip musculature. As such, interventions aiming to increase strength or flexibility are likely insufficient, and interventions that may further restrict spinal mobility could exacerbate compensatory pelvic mechanics and potentially contribute to the progression of underlying hip pathology. These findings support adding motion analysis to clinical assessment to identify compensatory patterns and refine treatment selection.

Joint Implant Contact Force During High-Impact Exercises in People With Hip and Knee Replacements

Introduction

Subjects with hip or knee joint replacement are commonly advised to avoid high-impact physical activities (PA) because of concerns about implant integrity. Yet high-impact PA can be important for mitigating age-related bone loss. However, the safety of such PA on the joint implants remains uncertain. This study quantified implant loads across a spectrum of high-impact PA in people with hip or knee joint replacement.

Methods

Eleven participants with total hip (55.9 [9.8] years), four with a total knee (63.7 [4.8] years), and three with a unicompartmental knee (65.3 [2.5] years) replacement who had successfully returned to high-impact PA participated. Optical motion capture (Vicon) with in-ground force plates (Kister) and an instrumented treadmill (Bertec) were used. Participants performed both overground and treadmill walking and running (various slopes and cadences), countermovement jumps, unilateral and bilateral hopping, drop landing, and change of direction (COD) at various intensity levels.

Results

For participants with a total hip replacement, COD, unilateral hopping, and running produced >1.5x greater hip implant loads than walking (~ >8BW; all $P < 0.001$) as shown in Figure 1a. Treadmill walking (with/slopes) and jumping produced similar loads on the hip implant compared to level walking. For participants with a total knee replacement, unilateral hopping, running, and COD produced >1.5x greater knee implant loads than walking (7-9BW, all $P < 0.001$) (Figure 1b).

Discussion

Determining optimal loads that stimulate bone adaptations without compromising implant integrity is needed. These rankings provide initial comparative data to inform training programs aimed at preventing bone loss in persons with a hip or knee joint replacement, and to guide future hip or knee implant load-testing protocols.

Images (Optional)

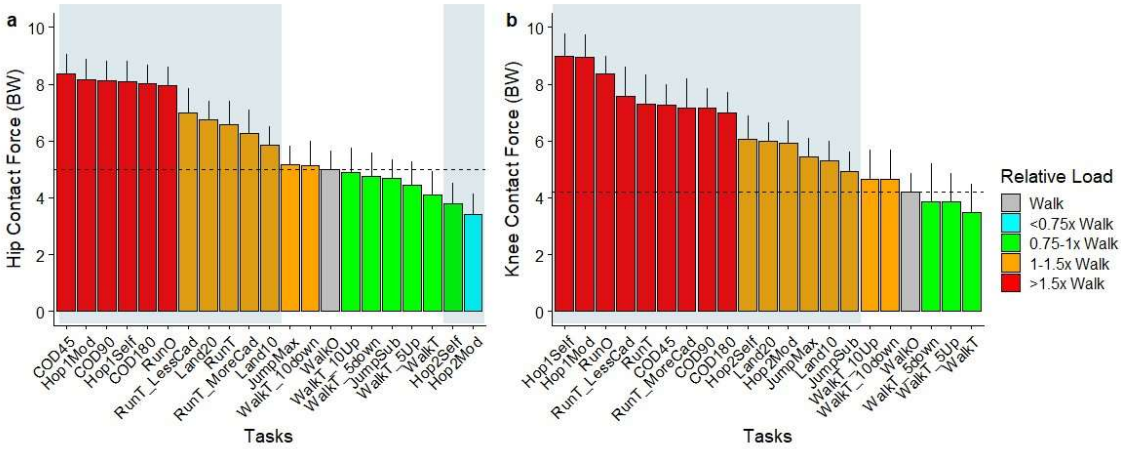

Figure 1. Predicted (with 95%CI) resultant implant contact forces at a) the hip for total hip replacement, and b) the knee for total knee replacement. The shaded regions indicate a statistically significant ($p < 0.05$) difference from overground walking (WalkO). **Abbreviations.** COD: change of direction (45°, 90°. 180°); Hop1Mod/Hop2Mod (unilateral/bilateral hopping 2.6Hz); Hop1Self/Hop2Self (unilateral/bilateral hopping self-paced); RunT/RunT_LessCad/RunT_MoreCad (running treadmill self-paced, with lesser or greater cadence); Land10/Land20 (drop land bilateral 10cm or 20cm); WalkT (walking treadmill self-paced, level surfaced); 5up/5down/10up/10down (5° or 10° upslope or downslope); JumpMax/JumpMod (maximal or moderate effort countermovement jumps).

[7]Old Dominion University, Norfolk, VA, United States

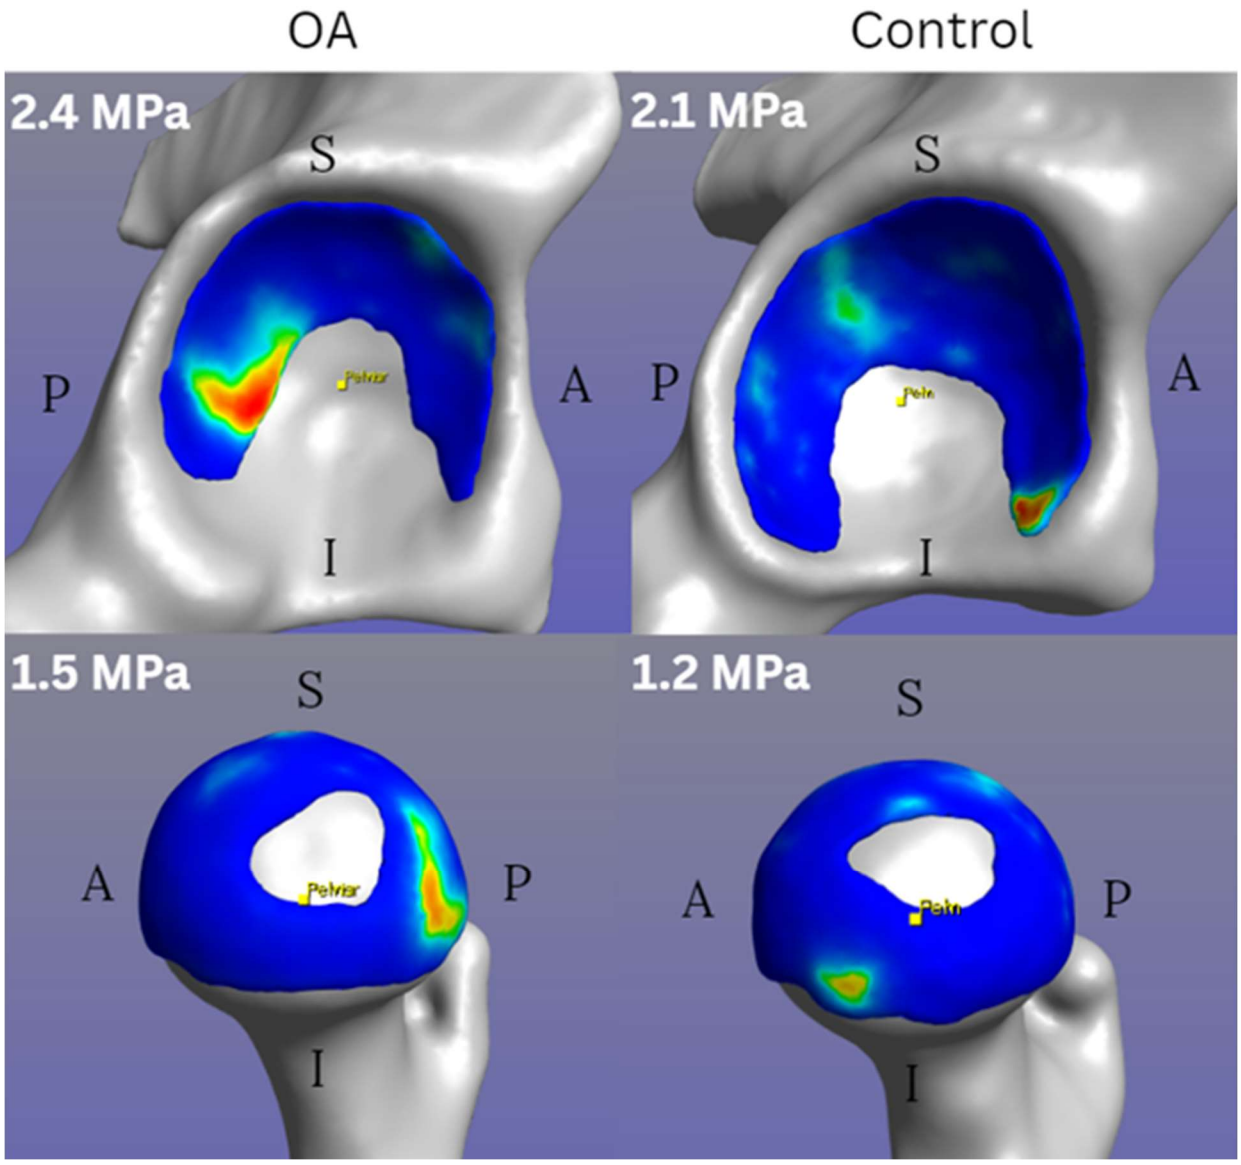
Introduction

Peak hip stress occurs within the anterior hip joint during loading response in normal gait. Individuals with hip osteoarthritis exhibit higher peak hip flexion angle during loading response. It is not well understood how these altered kinematics during loading response relate to hip cartilage mechanics resulting in severe structural abnormalities. The goal of this study was to compare hip cartilage mechanics in individuals with symptomatic hip osteoarthritis (sHOA) and asymptomatic controls without radiographic hip OA by utilizing subject-specific, magnetic resonance (MR) imaging-based finite element models (FEMs).

Methods

FEMs were developed for three individuals with sHOA (Kellgren Lawrence [KL]=2–3 and HOOS pain score of < 80) and three asymptomatic controls (KL=0-1 and HOOS pain score > 90). MR-images of the bony and cartilage morphologies were segmented for each individual to develop subject-specific mesh. Subject-specific hip kinematics and moments at the peak vertical ground reaction force during loading response were applied to each model to estimate maximum shear stresses (MSS) on the acetabular and femoral cartilage layers. Due to the small sample size, Cohen's d effect sizes were used to assess between group differences in MSS magnitudes, kinematics and hip moments.

Results



The sHOA self-reported worse hip-related pain (lower HOOS pain scores) compared to the control group (sHOA: 98.3±2.36, Control: 57.5±2.04, d=2.70). Peak MSS for the sHOA group

were located more posterior on both the acetabular (sHOA: 1.14±0.92MPa, Controls: 1.87±0.56MPa, d=0.787) and femoral (sHOA: 0.82±0.49MPa, Control: 1.10±0.37MPa, d=0.525) cartilage layers, whereas the peak MSS for the control group were located within the anterior acetabular and femoral cartilage layers. The sHOA group exhibited a smaller femur internal rotation angle (sHOA: 2.43±0.81degrees; Control: 7.25±4.78degrees, d=1.148) and larger hip extension moment (sHOA: -0.37±0.20Nm, 0.06±0.18Nm, d=1.318) compared to the control group.

Discussion

The sHOA group exhibited more posteriorly oriented peak acetabular and femoral cartilage MSS compared to the control group. Future work should assess the association between hip muscle dysfunction and proximal hip morphology with these altered cartilage contact mechanics to inform future exercise and gait retraining interventions to optimize hip contact mechanics and mitigate hip joint disease.

Retrospective Analysis of Hip Joint Morphology: Affected versus Unaffected Joints of Hip Resurfacing Arthroplasty Patients

Ms. Emily Cameron PhD Candidate, MASc, BASc[1], Mr. Utomobong Essien BASc Candidate[1], Mr. Bishoy Awad BSc Candidate[2], Ms. Ella Connop BASc Candidate[1], Dr. John Rudan MD, FRSC(C), FCAHS,[3], Dr. Heidi Ploeg Ph.D., P.Eng., FASME, FORS[1]

[1]Mechanical Engineering, Queen's University, Kingston, Ontario, Canada. [2]Health Sciences, Queen's University, Kingston, Ontario, Canada. [3]School of Medicine, Queen's University, Kingston, Ontario, Canada

Introduction

Aging and degenerative joint diseases alter pelvic and acetabular morphology, affecting joint orientation, load distribution and mechanical function. Pelvic tilt, acetabular orientation, centre-of-rotation (CoR) alignment, and depth-width geometry are clinically relevant structural markers and may be associated with joint replacement success. This retrospective study aimed to assess hip morphology in pre-operative hip resurfacing (HRA) patients from computed tomography (CT) data.

Methods

Clinical CT scans of the pelvis from HRA patients (n=158; age≈51.9 years, male = 143, female = 19) were reconstructed (Mimics v.26) (ethics # 6006471). A data pipeline (MATLAB 2025) applied ISB-standardized pelvic coordinate systems, quantified pelvic tilt, acetabular orientation, femoral/acetabular CoR, acetabular CoR-to-CoR distance, radii, femoral-acetabular radius mismatch and acetabular width, depth and depth-to-width ratios (Fig 1.A).

Morphology differences were analyzed using linear mixed-effects models (SPSS Statistics v.29.0.2), with patient identification for paired left-right hips. Fixed effects were Affected Status (affected vs. unaffected), with models adjusted for age, pelvic tilt, and acetabular CoR-to-CoR distance (α=0.05; Bonferroni-corrected).

Algorithm accuracy was validated against physical (vernier caliper) and virtual (Artec Studio 19 Professional) measurements of surface models (Artec Eva) of male and female Sawbones pelves (model # 1301, 1302). Bland-Altman analysis and ICCs (95% CI) were used for comparison.

Results

Affected Status significantly influenced morphology. Affected hips had larger femoral head radii ($p<0.001$), differences between affected and unaffected acetabular radius ($p=0.04$) and femoral-acetabular radius mismatch ($p<0.001$). Pelvic tilt was strongly associated with radius- and depth-based measures (all $p<0.001$). Age was not significant.

When normalized to acetabular CoR-to-CoR distance, femoral head radius remained significantly larger ($p<0.001$), indicating disproportionate radial enlargement independent of pelvic size (Fig 1.B). Acetabular depth also showed pelvic size-independent increase ($p<0.001$), indicating disproportionate acetabular deepening (Fig 1.C).

Validation confirmed excellent agreement across measurement modalities with minimal bias and ICC(3,1) of 0.80-0.98.

Discussion

Normalization to acetabular CoR-to-CoR distance confirmed that femoral head enlargement and acetabular deepening represent true morphological changes rather than pelvic size variation. Increased radii, femoral-acetabular radius mismatch, and pelvic-tilt effects indicate reduced joint congruency and altered load transfer, with implications for moment-arm geometry, implant sizing accuracy, and restoring hip biomechanics.

Images (Optional)

Altered Hip and Knee Between-Limb Symmetry During Sit-to-Stand in Cam-Type Femoroacetabular Impingement

Mr. Patrick Ippersiel PhD[1], Ms. Ariane Parisien MSc[2], Mr. Andrew Tucker B.Sc. (Hons)[2], Mr. Andrew Spiers PhD, P.Eng[3], Mr. Mario Lamontagne PhD[1], Dr. Paul Beaulé MD, FRCSC FAAOS CHE[2]

[1]University of Ottawa, Ottawa, Ontario, Canada. [2]The Ottawa Hospital, Ottawa, Ontario, Canada. [3]Carleton University, Ottawa, Ontario, Canada

Introduction

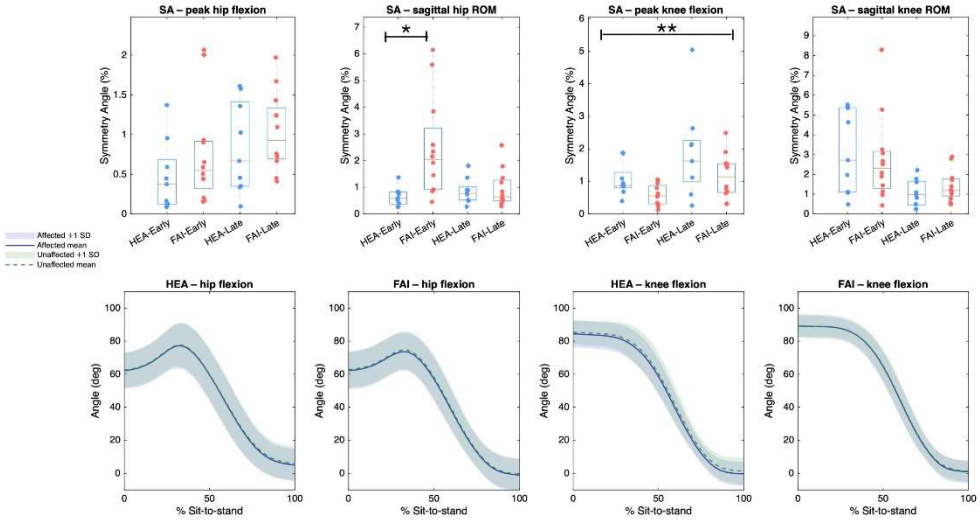
Cam-type femoroacetabular impingement (FAI) is associated with altered hip mechanics, joint loading, and early osteoarthritis, yet the extent of between-limb asymmetry during demanding functional tasks remains unclear.[1] Asymmetry provides insight into compensatory strategies and uneven loading patterns. This work compared lower-limb kinematic and kinetic symmetry between individuals with and without FAI during a sit-to-stand (STS) task. We hypothesized greater between-limb asymmetry in FAI patients, compared to controls.

Methods

FAI patients (n=12; 11 males; iHOT-33=44.3) and healthy controls (n=9; 9 males; iHOT-33=98.45) completed 5 standardized STS trials. Forty-five reflective markers tracked 3-d joint kinematics at 200Hz with a 10-camera system (Vicon MX, UK), and kinetic data were collected from a bench-mounted and two floor-embedded force plates (Kistler, 1000 Hz). Data were processed in Nexus (modified Plug-in-Gait) and MATLAB (R2023b). STS was partitioned into early (movement initiation to seat-off) and late (seat-off to upright) phases using bench-mounted force plate data. Between limb symmetry (affected vs. un-affected) was quantified using the Zifchock method for peak hip/knee flexion, sagittal hip/knee ROM, and vertical ground reaction force (vGRF).[2] Mixed ANOVAs tested the effects of group (FAI/healthy), phase (early/late) and their interaction (group*phase) on kinematic outcomes. Mann-Whitney U tests compared kinetic outcomes.

Results

A group*phase interaction was observed for hip ROM symmetry ($p=0.02$, $\eta^2_p=0.233$), with post-hoc Tukey's tests showing less between-limb symmetry in the FAI group during the early phase (mean difference=1.79, $p=0.049$, Fig.1). A group effect showed greater peak knee flexion symmetry ($p=0.043$, $\eta^2_p=0.198$), in the FAI group, independent of phase. Mann-



Whitney U tests revealed more vGRF symmetry in the FAI group during early phase (p=0.009, mean difference=13.89; cohen's d=1.043).

Discussion

Group differences in early-phase between-hip ROM symmetry may be related to reduced hip flexion in the affected limb in FAI patients. Greater symmetry in vGRF and peak knee flexion across limbs reflects more even weight bearing in FAI patients. This suggests movement adaptations that preserve external weight bearing while modifying joint mechanics in ways that might lessen mechanical demand on the symptomatic hip.

Images (Optional)

Figure 1. Sit-to-Stand Symmetry Angles and Sagittal Hip and Knee Joint Angles in Individuals With and Without FAI

Top row indicates symmetry angles in FAI (red) and Healthy (blue) group across early and late STS phases for kinematic metrics. Larger symmetry angles (SA) values indicate greater asymmetry. Bottom row indicates group means +/- 1 SD for affected (solid blue) and unaffected (dashed green) limb joint angles for the hip and knee. (*) denotes statistical significance (p<0.05) based on post-hoc Tukey's tests. (**) denotes significant group effect (p<0.05). HEA: Healthy; FAI: Femoroacetabular impingement; ROM: Range of Motion.

Head Center Restoration With the Cutting Guide Q-Ring During Total Hip Arthroplasty

Mrs. Katja Brand[1], Dr.-Ing. Gerd Huber[1], Ms. Celina Ibrahim[1], Prof. Michael Morlock[1], Prof. David Beverland[2]

[1]Institute of biomechanics, TUHH, Hamburg, Hamburg, Germany. [2]Primary Joint Unit, Musgrave Park Hospital, Belfast, North, Ireland

Introduction

Restoration of the femoral head center is a crucial aspect to achieve native biomechanics and reduce the risk of instability after total hip replacement surgery (THA) [1]. This is usually determined based on the surgeon's experience and anatomical landmarks as references. The present study evaluated the accuracy of a standardized workflow using a cutting guide for the head resection during posterior-approach for cementless stem insertion.

Methods

Eight cadaveric femoral pairs (5f/3m, Ø 77.1 years) were CT-scanned before head resection by an experienced surgeon using a cutting guide (Q-Ring, enztech, NZ, Fig. 1a). After compaction broaching (Corail, Johnson&Johnson MedTech, US), trial neck and head components were selected to reconstruct the head center. The laser scan models of assembled THAs (scan resolution 0.012 mm; HandySCAN Black+™|Elite, Creaform, CA) were aligned with the femur models derived from CT-scans (root mean square error: 0.1 mm, PolyWorks|Inspector, InnovMetric Software, CA). Differences between native and THA head center position were determined relative to the anatomical axis (Fig. 1b; MATLAB 2023b, MathWorks, US). Stem orientation in varus/valgus and the anterior-posterior offset were assessed.

Results

The reconstructed head center was on median 2.7 mm (inter quartile range [-0.2, 4.6]) higher and 3.7 mm [2.6, 4.8] more medial compared to the native head center. Stem orientation showed a varus tilt of 2.2° [3.4, 0.4], with an anterior-posterior offset of 3.8 mm [1.4, 5.6] compared to native.

Discussion

The largest reconstruction mismatch occurred in the anterior-posterior offset, likely due to the cutting guide controlling height and lateral offset but not 3D-stem orientation. Deviations are slightly larger than those reported for 3D-digital planning [1] which, however, is not widely used in clinical settings. With a similar range to typical stem migration (<2.7 mm [2]) the observed mismatch should clinically be acceptable. The Q-ring cutting guide standardizes head resection and helps to reconstruct the native head center better than a purely manual approach [3]. Results are limited by the precision of determining the native head center, particularly in patients with arthritis.

Comparative Biomechanics of Gluteus Medius Repair: A Finite Element Analysis

Mr. Matthew Allen[1], Mr. Yuan Liu[2], Mr. Brendan Rockwell[3], Dr. Stefano Bini[1]

[1]University of California, San Francisco, San Francisco, California, United States. [2]Touro University, Vallejo, California, United States. [3]University of California, Berkeley, Berkeley, California, United States

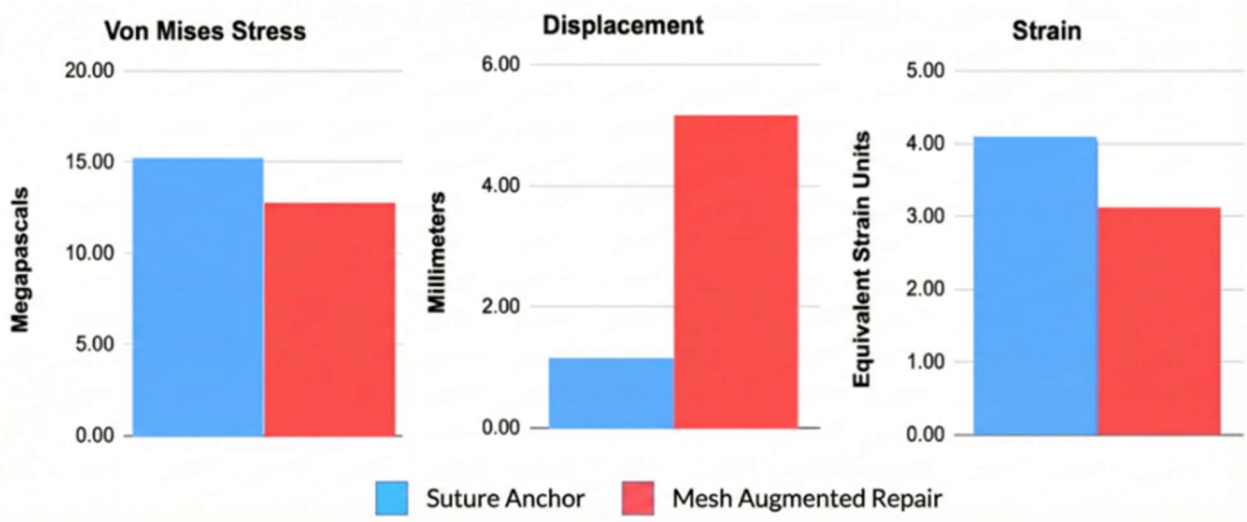
Introduction

Surgical repair of Gluteus Medius tendon (GMed) tears is complicated by constant post-operative mechanical load during ambulation. Suture Anchor (SA) repairs are standard, but suffer from a 6-7% structural failure rate, characterized by suture pull-through due to focal stress concentrations. We hypothesized that augmenting the repair with a scaffold would reduce these stress concentrations. We used Finite Element Analysis (FEA) to systematically evaluate the benefit of two simulated repair configurations on the mechanical properties of tendon-to-bone repair in a 3D volumetric mesh derived from a normal hip MRI.

Methods

High-fidelity 3D volumetric meshes were generated from patient-specific hip MRI using nnU-Net segmentation. Using SolidWorks, we simulated two repairs: SA as control and a Collagen/PLLA mesh augmentation (AR). The AR scaffold was modeled to span from the distal footprint to the proximal musculotendinous junction, permitting direct load transfer. This offers a potential solution to the 'cheese-wiring' phenomenon by converting focal suture points into a distributed area of compression.

A nonlinear FEA solver was utilized to model soft tissue hyperelasticity. The tendon was assigned hyperelastic Neo-Hookean material properties. A distributed tensile load of 200N was applied to the proximal face of the tendon-scaffold composite to simulate the clinical failure threshold of degenerative tendon during early rehabilitation.



Results

Compared to SA, AR demonstrated peak Von Mises stress decrease of 15.7% (12.80 MPa vs 15.18 MPa), and equivalent strain reduction of 24.6% (3.06 vs 4.06). Conversely, the AR exhibited a 355% increase in displacement (5.15 mm vs 1.13 mm).

Discussion

GMed repair biomechanics are poorly studied. We show that augmenting repair constructs with a mesh decouples tissue strain from construct displacement at time-zero. By acting as a compliant load-sharing element, the augmented repair reduces peak Von Mises stress, potentially mitigating the "cheese-wiring" failure mode observed in rigid standard suture anchor repairs. Limitations of this study include the use of static loading which does not replicate cyclic gait mechanics, and the assumption of idealized friction interfaces. Despite these constraints, the data supports that shifting load-bearing to a distributed surface area protects the distal tendon. Next steps will validate these analyses in vitro using cadaveric models.

Collagen Fiber Orientation in Human Achilles Tendons Affects the Mechanical Response

Dr Chiara Garavelli PhD[1], Dr Hector Dejea PhD[2], Dr Joseph Brunet PhD[2,3], Miss Renate Janssen MSc[1], Dr Maria Pierantoni PhD[1], Prof Hanna Isaksson PhD[1]

[1]Department of Biomedical Engineering, Lund University, Lund, Skåne, Sweden. [2]European Synchrotron Radiation Facility, Grenoble, Auvergne-Rhône-Alpes, France. [3]Department of Mechanical Engineering, University College London, London, Greater London, United Kingdom

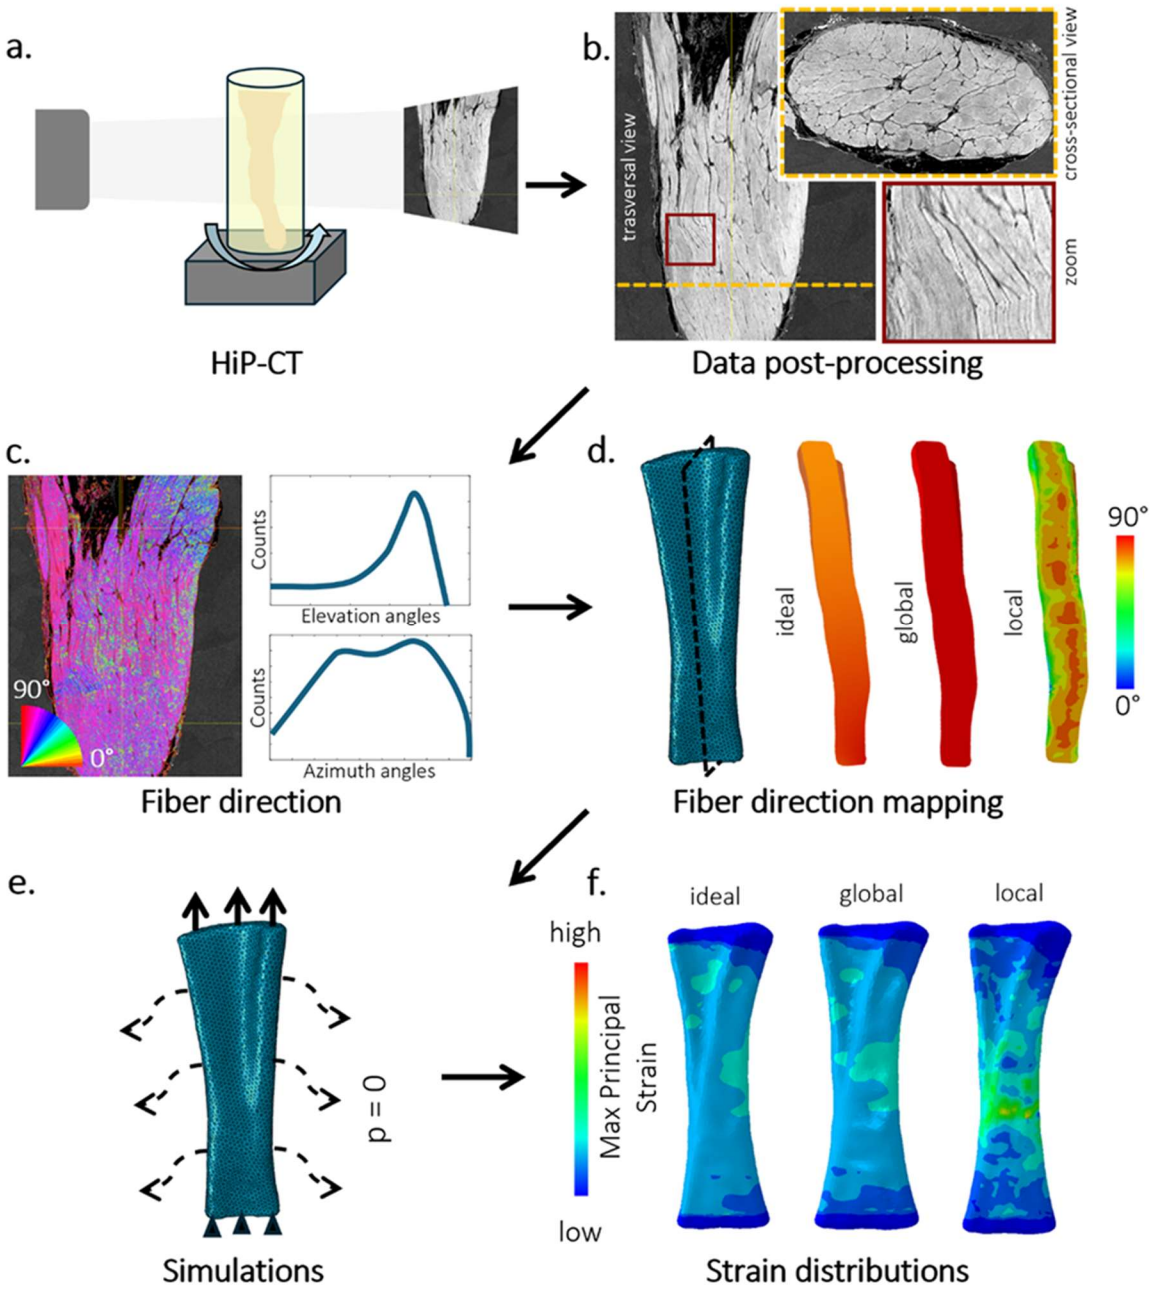
Introduction

The Achilles tendon (AT) is frequently subjected to overuse, contributing to the rise of tendinopathy. Collagen fiber distribution is important for mechanical response; however, clinical imaging modalities are unable to resolve it. This limits the possibility to mimic real tissue behavior. Therefore, this work aimed at assessing the effect of simplification in fiber modeling on the strain distributions, through the integration of synchrotron experimental data and finite element modelling.

Methods

Five entire human ATs (age: 59-73 y) were imaged at BM18 of ESRF (The European Synchrotron) within the Human Organ Atlas Hub, using Hierarchical Phase-Contrast Tomography (HiP-CT) [1] (voxel size 10.1µmx10.1µmx10.1µm). 3D orientation distribution of collagen fibers was determined through structure tensor analysis [2]. Parallelly, the ATs contours were segmented, meshed and assigned a poro-visco-hyperelastic material model. The collagen fibers were assigned as: I) following the tendon axis (idealized); II) approximated as the global average orientation from HiP-CT (global); and III) extracting the local distribution from HiP-CT within each element (local) [3]. The finite element (FE) models were subjected to stress-relaxation (10% strain at 1%/s), and the strain distributions were compared between specimens and fiber modeling approaches.

Results



HiP-CT allowed to resolve the fiber orientation, assessing variation in fiber distributions between (20% difference between donors) and within AT (wider azimuth angles in the free tendon region). The different fiber orientations (ideal, global, local) resulted in significantly different ($p<0.001$, Wilcoxon signed rank test) strain distributions. The full-width at half-

maximum of the strain distribution increased with increasing model complexity (ideal to local: +6.8%; global to local: +6.6%). Peak reaction forces differed between 19-66% between the different model approaches.

Discussion

Fiber orientations derived from HiP-CT enabled us to assess the variations in FE-based strain predictions depending on the level of donor-specific fiber information. These results highlighted the strength of the synergy between high-resolution imaging and FE modelling in understanding tendon biomechanics.

Images (Optional)

Project workflow. Tendon data acquired with HiP-CT (a, b) were used to obtain collagen fiber direction information at each point, (colormap shows elevation angles (c)), and to segment the tendon outer contour. Inside each element the collagen fibers were oriented with an ideal, global or local distribution (d), while the other components of the poro-visco-hyperelastic material model were kept constant. The models were loaded under the same boundary condition in stress-relaxation (e). The resulting strain distributions were compared (f).

Influence of Collagen Network Dispersion on Torsional Shear Loading of Articular Cartilage With Synchrotron-Based Fibril-Reinforced Finite Element Models

Mr Viktor Jönsson MSc, Assistant Professor Lorenzo Grassi PhD, Assistant Professor Anna Gustafsson PhD, Dr Maria Pierantoni PhD, Professor Hanna Isaksson PhD

Lund University, Lund, Scania, Sweden

Introduction

The collagen network plays a critical role during shear loading of articular cartilage [1], and its dispersion affects the response during axial loading [2]. The objective of this study was to determine the influence of collagen dispersion during torsional shear. To achieve this, we employed fibril-reinforced poro-visco-hyperelastic (FRPVE) FE models based on in situ torsional shear loading with synchrotron phase-contrast micro-tomography (PhC-µCT) of cartilage (Fig.1A), using three collagen orientation models with increasing complexity.

Methods

In situ PhC-µCT (TOMCAT, SLS) imaging (2.75µm isotropic voxel size, 5.54x3.85mm^2 field of view) with concurrent stress relaxation was performed on cylindrical (4mm ⌀) knee femoral cartilage samples (bovine N=1, human N=4). Mechanically, compression (10% strain, 1%s) was followed by torsional shear (10% applied strain, 1%/s), FRPVE [3] FE models were generated with both idealized and segmented geometry (Fig.1B,C). The Benninghoff arcade pattern was used as basis for the three collagen orientation models: #1 no dispersion(arcade), #2 isotropic dispersion [3] (isotropic) and #3 x-ray scattering based dispersion (SAXS) [4] (Fig.1D,E). The three orientations were implemented in the FE models and the simulated stress relaxation results were compared, using one set of material properties.

Results

The idealized geometry (Fig.1B) shows that the isotropic and SAXS collagen models are both comparable with the experimental data for compression and torsion loading (Fig.1F,G). In contrast, the arcade model shows less time dependency and does not match experimental data well for torsion (Fig.1G).

Discussion

We show that the classical Benninghoff arcade collagen pattern does not contribute to the time-dependent torsional behavior, likely due to fibrils buckling during compressive loading. The time dependency is instead attributed to fiber dispersion, seen with the isotropic and SAXS-based collagen models. Next step is to simulate the different collagen models with sample specific models (Fig.1C) to determine the influence of realistic sample geometries with collagen orientation.

OA100-04

Heterogeneous Strain Distribution in Rat Achilles Tendon From Physiological Loading: A Finite Element Study

Dr. Yeswanth Pydi PhD, Dr. Maria Pierantoni PhD, Assiatant Professor Anna Gustafsson PhD, Professor Hanna Isaksson PhD

Lund Universitry, Lund, Skåne, Sweden

Introduction

The rat Achilles tendon comprises three subtendons originating from the medial gastrocnemius (MG), lateral gastrocnemius (LG), and soleus (SOL) muscles. Knowledge of region-specific strain variations in rat tendons during physiological activities is lacking in the literature; however, it is critical for understanding their load-sharing and injury mechanisms. The goal of the current study was to evaluate the strain distribution resulting from rat subtendons under physiological loads.

Methods

FE models, including the three subtendons, were developed from three rat Achilles tendons that earlier underwent phase-contrast synchrotron-based X-ray tomography [1]. Images were segmented using 3D Slicer, and FE models were generated using ANSA (Fig. 1a). This study uses experimentally measured subtendon MG forces from literature during walking, trotting, and galloping (Fig. 1b) [2]. These experimentally derived MG loads were scaled to estimate forces in the LG and SOL based on physiological cross-sectional areas [3]. The simulations were performed in Abaqus using a fibril-reinforced poro-visco-hyperelastic material model [4]. The fiber orientations were determined from the synchrotron images, assuming the average fiber orientation in the whole tendon [1].

Results

The forces applied on the subtendon were heterogeneous (4.1 N on MG, 5.2 N on LG, and 0.6 N on the SOL) (Fig. 1c). The subtendons deformed non-uniformly, which can significantly influence the strain distribution and the energy storage (Fig. 1d) [2]. Throughout the loading phase, the maximum principal strain varied from 0.01 to 0.19 (Fig. 1e). Higher strains were observed on the medial (MG) side and minimal strain on the posterior (SOL) side, indicating uneven load transfer between subtendons.

Discussion

These findings provide insight into the mechanical interaction between subtendons under physiological loading conditions. The work will be extended by incorporating local fiber orientations per element [4], which will further elucidate the role of subtendon structure on strain heterogeneity and load transfer.

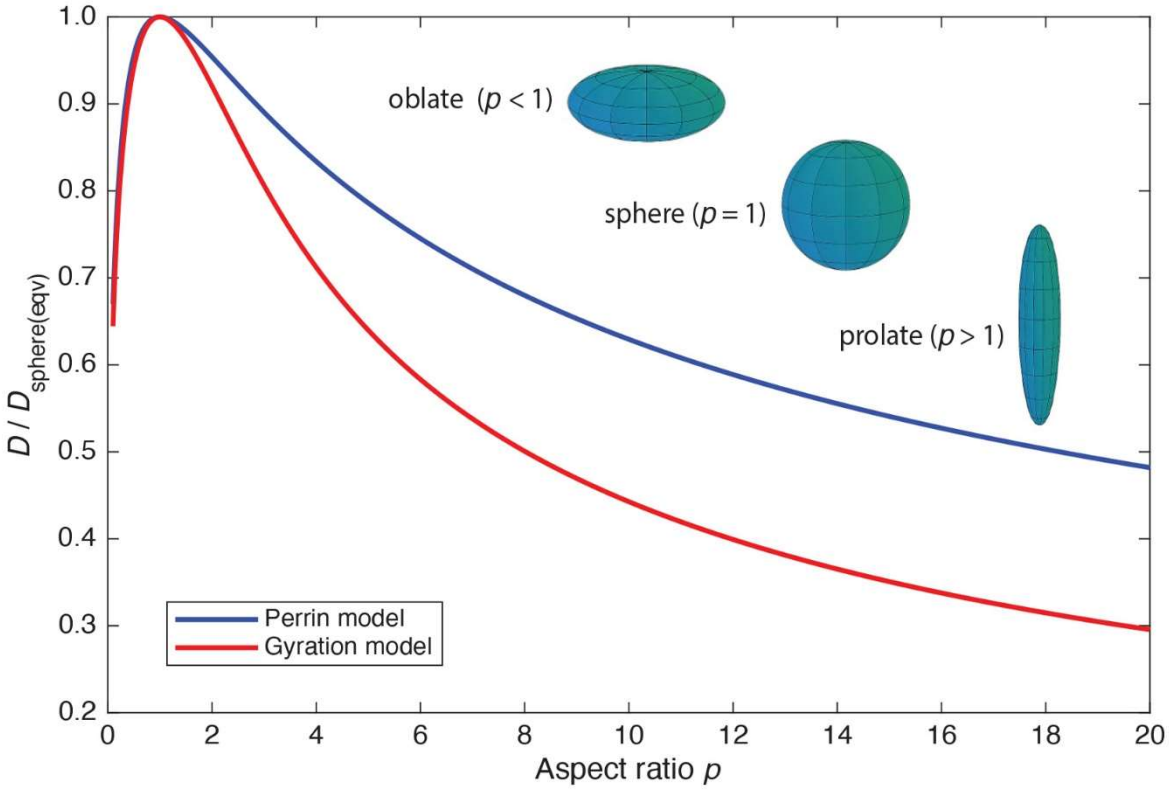
Introduction

Diffusion of macromolecules through tissues is critical for nutrient/drug transport, especially for avascular tissues, e.g., articular cartilage. Conventional diffusion models assume that the molecules are spheres or revolution ellipsoids, and miss the effect of more complex molecular conformations. The purpose of this work is a diffusion model that accounts for more general molecular conformations via the gyration tensor, a measure of how far a geometrical shape is from a sphere.

Methods

We assume that the preferred direction of diffusion for a molecule is that associated with the smallest eigenvalue of its gyration tensor: roughly speaking, the direction associated with the smallest cross-section. Since the molecules of the same species are randomly oriented in the solvent, the effective diffusion tensor is isotropic and given by a certain average of the directional diffusivities for the molecule. We choose the harmonic average, i.e., the reciprocal of the sum of the reciprocals of the diffusivities (hindrances). The model

was validated against Perrin's classical model [1] for revolution-ellipsoidal molecules, across a wide range of shape ratios.



Results

For spherical molecules, the model reproduced the classical Stokes–Einstein prediction. For elongated molecules, anisotropy significantly reduced the effective diffusion. Compared to Perrin's model, our approach predicted lower diffusion for highly anisotropic shapes. This is because of the use of the harmonic average: the smallest directional diffusion causes the highest hindrance effect. This result is especially significant for highly anisotropic molecules, for which diffusion tends to zero. Overall, for rod-like (prolate) molecules, our results showed lower diffusion compared to Perrin's model, while for disk-like (oblate) molecules, our model is close to Perrin's model.

Discussion

This work introduces a versatile analytical framework that moves beyond idealised revolution-ellipsoidal molecules, enabling the prediction of anisotropic diffusion for complex macromolecules. The model provides a mechanistic basis for quantifying nutrient transport and designing drug delivery systems [2]. Future work will incorporate the model into a framework for diffusivity in anisotropic porous media [3], such as articular cartilage.

Investigating Leader Cell Mechanics of Breast Cancer Collective Invasion Using Tumor Decellularized Matrices and Microphysiological Systems

Mrs Jessica Williamson, Dr Jessanne Lichtenberg, Dr Priscilla Hwang Associate Professor

Virginia Commonwealth University, Richmond, VA, United States

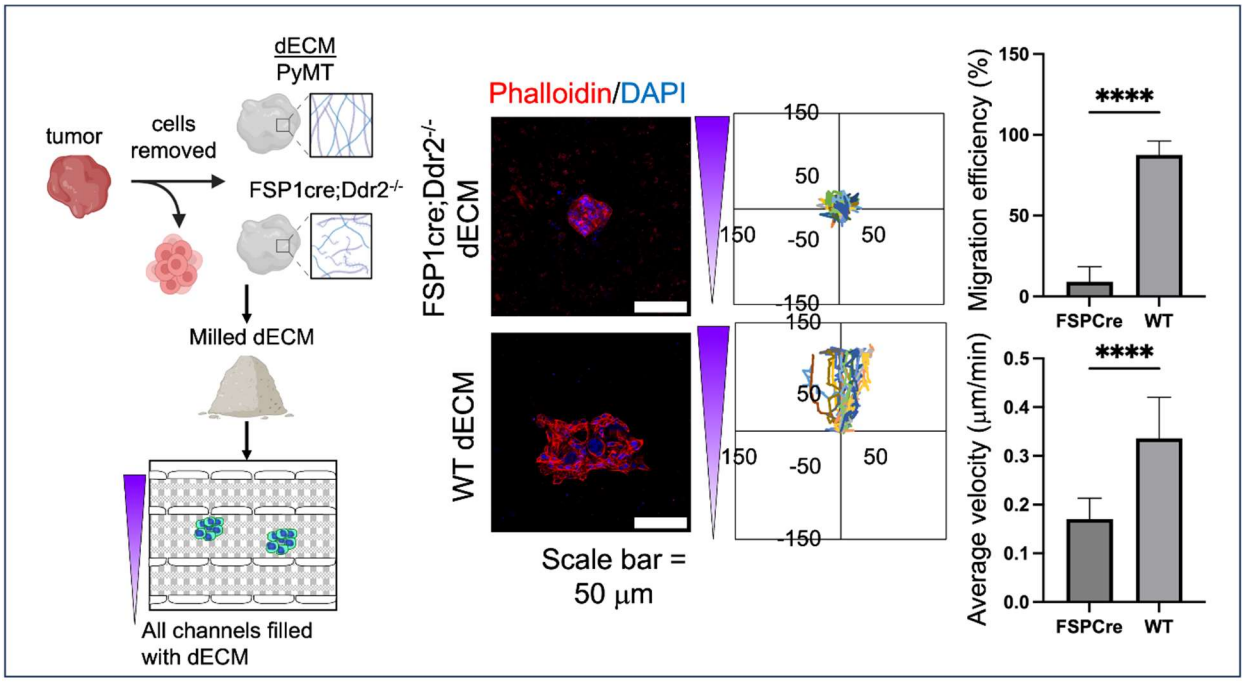
Introduction

Collective invasion, where cells move together and are connected via cell-cell adhesions, is an essential component of breast tumor invasion. During collective invasion, a few cells at the front (i.e. leaders) define the front, integrate signals from the extracellular matrix (ECM) and send signals to neighboring (follower) cells. Our work demonstrated leader cells must arrive (or polarize) at the front to begin invasion. The tumor microenvironment contains many mechanical cues including matrix architecture and fluid flow gradients, yet their impact on invasion or leader cell response is not fully understood. Here we investigated how matrix architecture and fluid flow gradients work together to drive invasion. We hypothesize leader cells biophysics are primary sensors of mechanical matrix cues, and a sub-group of followers directly reorganize the matrix to prime the environment for invasion.

Methods

We used our previously designed *ex vivo* 3D microfluidic model and primary mouse breast tumor organoids (MMTV-PyMT) to incorporate native cell heterogeneity. We generated decellularized matrix (dECM) integrated in our model to maintain inherent properties of native ECM. We identified a sub group of followers (cancer associated fibroblasts (CAFs)) that remodel the surrounding matrix via collagen receptor, discoidin domain receptor 2 (DDR2). Thus, we generated a PyMT mouse model to knockout DDR2 in CAFs only (FSPcre;DDR2$^{f/f}$), and synthesized dECM. We performed live-cell imaging, tracked invasion, and measured changes in focal adhesions.

Results



Tumor organoids migrated significantly slower and without direction when cultured in decellularized matrix where DDR2 is knocked out in CAFs (FSPcre;DDR2$^{f/f}$) (Fig 1). Further, tumor organoids had smaller and less number of vinculin focal adhesions when cultured on FSPcre;DDR2$^{f/f}$ dECM. From our single cell sequencing analysis, we also identified

ligand-receptor pairs responsible for leader-CAF communication. These ligand-receptor pairs were all associated with matrix remodeling pathways.

Discussion

We demonstrate mechanical environment cues can dictate tumor invasion, specifically via interactions between the mechanical environment, CAFs, and leader cells. Our work contributes new perspectives which can bring new approaches for therapy design. Further, our work can provide new mechanical signatures of collectively invading tumor clusters, which can add more universal biomarkers that can diagnose or predict cluster-based metastasis in patients.

Beta-Amyloid42 Oligomers Soften Neuronal Cells by Reorganization of Cytoskeleton

Prof. Yuan Feng[1], Ms. Huijing Jin[1], Ms. Qian Suo[1], Dr. Shengyuan Ma[1], Mr. Xingqun Gao[1], Mr. Peijun Zhao[1], Prof. Aili Zhang[1], Prof. Yaohui Tang[1], Prof. Yue Zhou[1], Prof. Assaf Zemel[2], Prof. Shengce Tao[1], Prof. Daniel Czajkowsky[1], Prof. Linyong Zhu[1], Prof. Zhifeng Shao[1], Prof. Guang-Zhong Yang[1]

[1]Shanghai Jiao Tong University, Shanghai, Shanghai, China. [2]Hebrew University of Jerusalem, Jerusalem, Jerusalem, Israel

Introduction

Alzheimer's disease (AD) is the leading cause of dementia and is characterized by progressive neuronal loss and cognitive decline. Central pathological features include extracellular deposition of β-amyloid (Aβ) peptides and intraneuronal accumulation of tau neurofibrillary tangles. Although amyloid plaques are mechanically rigid, multiple studies have shown that AD brains are globally softer than those of healthy individuals, raising an unresolved conflict at the interface of pathology and biomechanics.

Methods

SH-SY5Y human neuroblastoma cells were cultured and treated with Aβ42 oligomers. Live-cell mechanics were measured with AFM in fluid. Global stiffness was probed using bead-functionalized cantilevers. Elastic modulus was extracted from force–displacement curves using the Hertzian contact model (v=0.5). RNA sequencing was performed on cells treated with Aβ42. Differentially expressed genes were identified with DESeq2, and pathway enrichment was assessed using GO and KEGG databases.

Results

Quantitative analysis revealed that global Young's modulus declined significantly in a concentration-dependent manner. Both actin filaments and microtubules underwent extensive disintegration, accompanied by further increases in microtubule porosity and pronounced shortening of axons. KEGG pathway analysis revealed significant downregulation of focal adhesion and ECM–receptor interaction pathways, indicating impaired cell–cell and cell–matrix contacts as well as reduced responsiveness to extracellular stimuli. Such adhesion deficits disrupt the intracellular tension network, thereby weakening actin retrograde flow mediated by adaptor proteins and impairing actin

polymerization. This reduction in cytoskeletal tension is expected to lower cellular stiffness, reflected in decreased Young's modulus values.

Discussion

The precise molecular mechanisms underlying Aβ42-mediated neurotoxicity remain incompletely defined, and the full scope of its cellular effects is still under active investigation. Here, we show that oligomeric Aβ42 alters neuronal mechanics, highlighting a previously underappreciated mechanobiological dimension of Alzheimer's pathology. The biomechanical properties of cells offer rich diagnostic and therapeutic potential, and our findings place cytoskeletal remodeling at the center of Aβ42-driven dysfunction.

Mechanobiology of Schlemm's Canal Inner Wall Endothelial Cells in Glaucoma

Prof. C. Ross Ethier[1,2], Dr. Hiayan Li[1], Dr. Seyed Mohammad Siadat[2], Ms. Kristin Perkumas[3], Prof. W. Daniel Stamer[3], Prof. Darryl Overby[4]

[1]Emory University, Atlanta, GA, United States. [2]Georgia Tech, Atlanta, GA, United States. [3]Duke University, Durham, NC, United States. [4]Imperial College, London, England, United Kingdom

Introduction

Glaucoma, the leading cause of irreversible blindness, is treated by lowering intraocular pressure (IOP). Schlemm's canal (SC), a fluid collecting duct in the eye, is lined by specialized endothelial cells that experience significant stretch *in vivo* and whose permeability influences IOP. Here we use an *in vitro* assay to study the mechanobiology of SC cells.

Methods

Human SC cells from normal and glaucomatous donors were cultured on microspheres to induce cellular stretch, and transcellular pore formation was quantified [1]. SC cells were also cultured on substrates of different stiffness and subcortical cell stiffness was measured by AFM (10 um spherical tip). To gain insight into mechanosensing pathways in SC cells, we modulated the activity of the mechanosensitive ion channel TRPV4 [2] using the antagonist HC067047 (10 μM) or the agonist GSK1016790A (100 nM). To investigate the role of microtubule stability, known to affect IOP [3], we treated SC cells with paclitaxel (10 μM, microtubule stabilizer) or nocodazole (10 μM, microtubule destabilizer), and additionally used siRNA targeting GEF-H1, a microtubule-associated Rho guanidine exchange factor.

Results

Stiffer substrates increased SC cell stiffness and F-actin levels, and decreased microtubule stability (acetylated tubulin levels). These responses were strongly modulated by TRPV4 activity. Specifically, transcellular pore formation was potentiated by short-term (<2 mins) TRPV4 activation (1.5-fold increase, $p < 0.05$), and by long-term (2 days) TRPV4 inhibition (1.6-fold increase, $p<0.0001$). However, these effects were dampened/absent in glaucomatous SC cells. Microtubule stabilization potentiated pore formation and reduced cell stiffness. In contrast, microtubule destabilization increased cell stiffness by 1.5-fold

($p<0.001$), and enhanced F-actin levels (1.9-fold, $p<0.0001$). Knockdown of GEF-H1 attenuated the effects of microtubule destabilization. Taken together, pore forming ability showed a strong inverse correlation with cell stiffness (Figure 1).

Discussion

SC cells are mechanoresponsive to substrate stiffness (altered in glaucoma) and to stretch. This mechanosensitivity is dependent in part on TRPV4 and is altered by microtubule stability, both of which affect SC cell transcellular pore formation. These processes offer novel targets for IOP-lowering therapies in glaucoma.

P-Cadherin Regulates Collective Migration Phenotypes During Epithelial Morphogenesis via Rho Signaling

Ms. Corinne Leonard B.S.[1], Dr. Jessanne Lichtenberg Ph.D.[1], Ms. Hazel Sterling[1], Mr. Jesse Rolston B.S.[1], Dr. Priscilla Hwang Ph.D.[1,2]

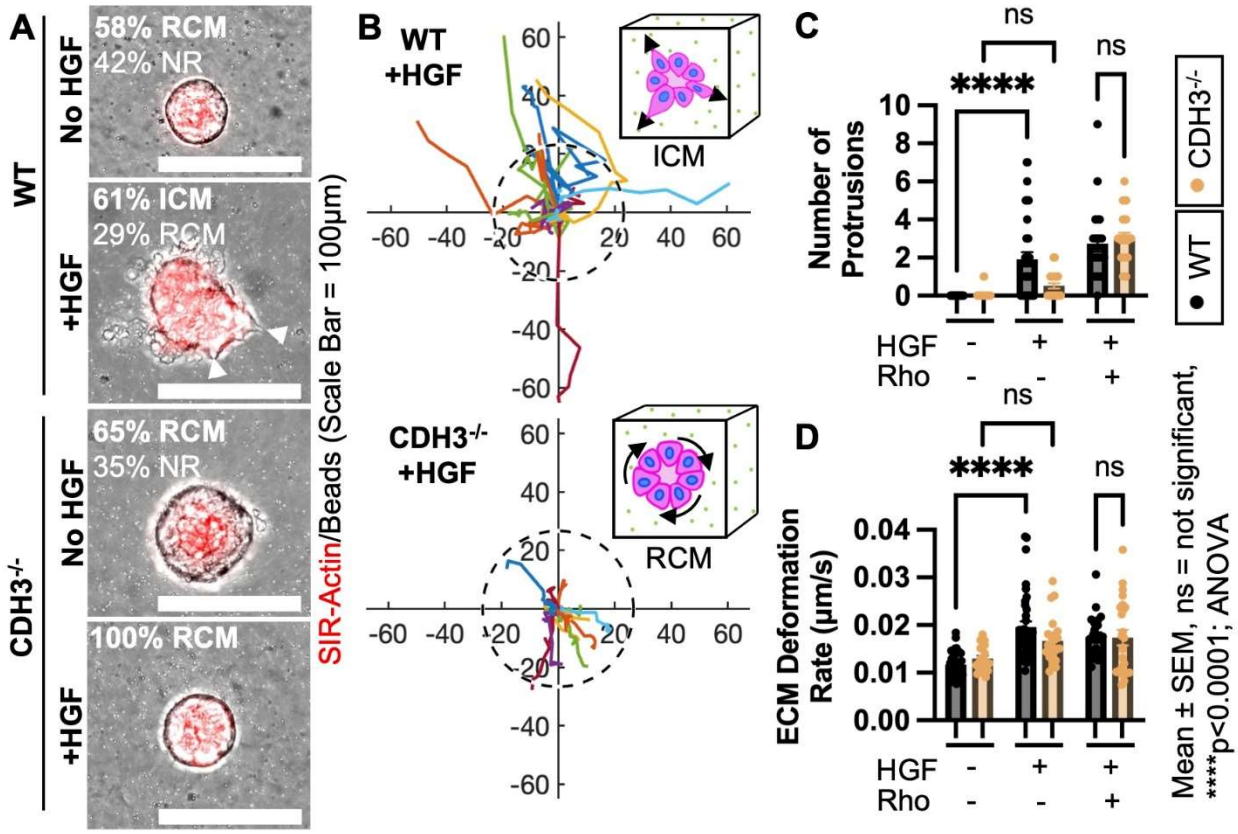
[1]Virginia Commonwealth University, Richmond, Virginia, United States. [2]Massey Comprehensive Cancer Center, Richmond, Virginia, United States

Introduction

Epithelial cells undergo different modes of collective cell migration (CCM) during morphogenesis. For example, cells spinning (rotational collective migration (RCM)) in a coordinated manner can develop acinar structures, and cells collectively invading (invasive collective migration (ICM)) can develop duct-like tissues. Cadherins are cell-cell junctions that support CCM and act as force transmitters driving tissue remodeling. Our lab demonstrated P-cadherin (CDH3) regulates CCM in breast cancer invasion and morphogenesis, but it's unclear what drives adoption of different phenotypes. In this study, we investigate how CDH3 impacts RCM or ICM phenotypes during epithelial morphogenesis, by quantifying cell-matrix interactions. We hypothesize CDH3 controls establishment of mature cell protrusions, a first step for ICM phenotype, that is regulated by extracellular matrix (ECM) deformation rates and Rho signaling.

Methods

Using our previously published epithelial morphogenesis microfluidic model [1], we integrated the ability to measure ECM deformation rates in real-time. We used epithelial clusters (wild-type (WT) or CDH3-depleted (CDH3-/-). We performed live-cell imaging before and after inducing cell protrusions (hepatocyte growth factor (HGF) treatment), and quantified changes in migration phenotypes (ICM vs RCM), morphology, and ECM deformation rates. We also treated samples with RhoA activator.



Results

Most WT epithelial cysts adopt RCM phenotype and transition to ICM phenotype upon HGF stimulation (Figure 1A,B). CDH3-/- cysts lose their ability to transition from RCM to ICM after HGF stimulation (Figure 1A,B), revealing CDH3-/- cysts are unable to generate mature cell protrusions (Figure 1C). ICM cysts have higher ECM deformation rates compared to RCM cysts (Figure 1D). Treatment of CDH3-/- cysts with RhoA activator rescues their ability to adopt an ICM mode with matrix deformation rates and protrusion formation like WT cysts (Figure 1C,D).

Discussion

Our findings demonstrate CDH3 is a mechanosensor regulating CCM modes through dictating the generation of mature cell protrusions and changing matrix deformation rates, modulated by RhoA signaling. This knowledge is essential in understanding developmental processes and can be applied to broader applications such as cancer progression. Future directions include investigation of cell-matrix adhesions regulated by CDH3 and Rho signaling, to understand their direct impact in regulating ECM deformations.

Engineering Reliable Bioabsorbable Magnesium Stents: A Pipeline From Computational Design Optimization to *In Vitro* Testing

M.Sc. Diego Blunda[1,2], M.Sc. João Cruz[2,3], M.Sc. Simon Pöstges[2], PhD Alexander Kopp[2], Prof. Claudio Chiastra[4], PhD Dario Carbonaro[4], Prof. Ted J. Vaughan[1]

[1]University of Galway, Galway, Galway, Ireland. [2]Meotec GmbH, Aachen, Nordrhein-Westfalen, Germany. [3]Chair for Laser Technology (LLT), Aachen, Nordrhein-Westfalen, Germany. [4]PoliToBIOMed Lab, Dept. Mechanical and Aerospace Engineering, Torino, Piemonte, Italy

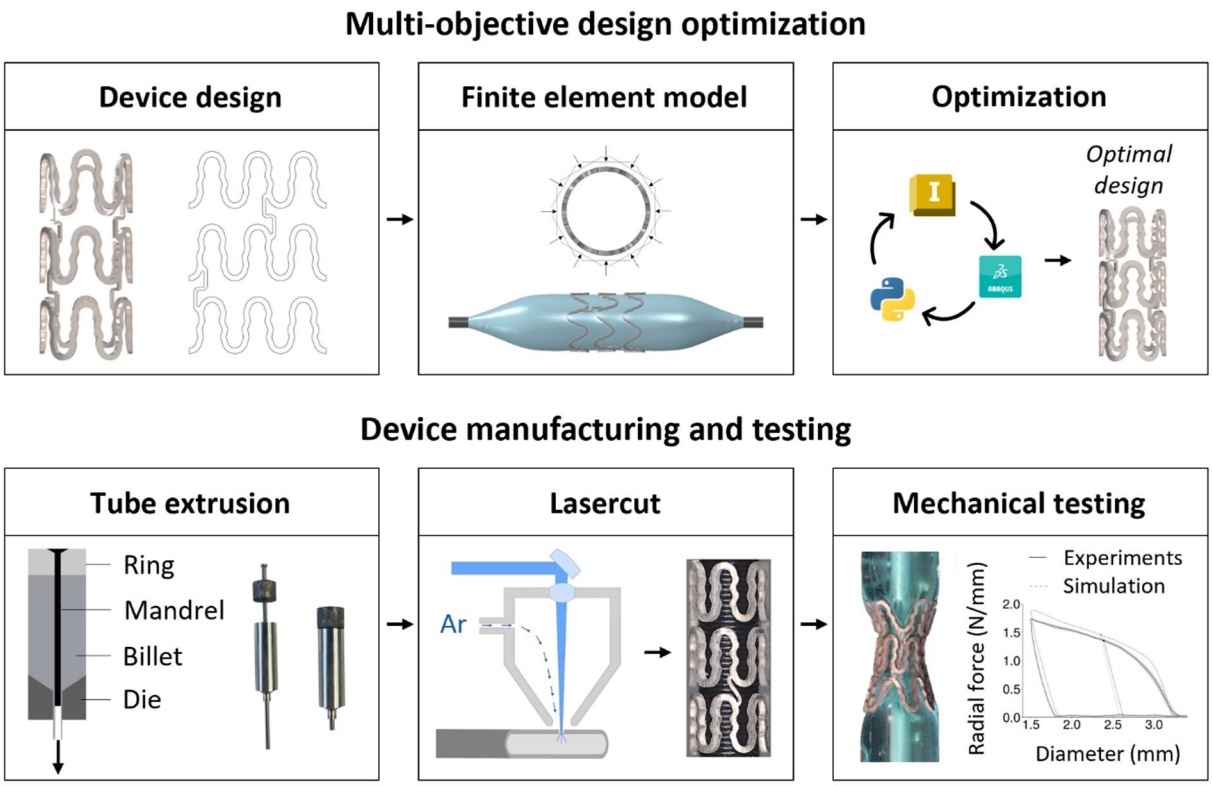
Introduction

Drug-eluting stents are effective for treating coronary artery disease, but remain associated with long-term complications due to their permanent structure. Bioabsorbable magnesium stents (BMgS) can potentially avoid these issues, providing temporary support and then degrading [1]. However, BMgS are prone to acute mechanical failure, requiring rigorous design and manufacturing control. This study presents a comprehensive workflow for BMgS design, optimization, and fabrication.

Methods

The workflow comprises design and manufacturing phases. In the design phase, a parametric stent geometry was evaluated using a finite element (FE) framework incorporating crimping on a balloon catheter, expansion, and radial compression (ASTM F3067-14). Simulations of multiple geometric variants trained surrogate models for key metrics, enabling an NSGA-III multi-objective optimization. From the resulting Pareto front, an optimal design was selected and compared with a baseline configuration. In the manufacturing phase, WE43 magnesium billets were extruded into microtubes and laser-cut using a femtosecond ultra-short-pulse system to reproduce the optimized geometry. Three stents based on the optimized geometry were fabricated and experimentally tested through crimping, deployment, and radial compression to validate the FE predictions.

Results



The surrogate models showed high predictive accuracy ($R^2_{pred} > 0.93$), and NSGA-III optimization yielded a clear Pareto front. Relative to the baseline, the identified optimized stent reduced material damage by 4.5 %, increased radial strength by 57.7 %, and lowered the surface-to-volume ratio by 17.9 %. Fabricated stents were successfully crimped,

deployed, and radially compressed. Experimental radial recoil was 8.45 ± 0.31 %, closely matching simulation (8.4 %; 0.6 % relative error). Radial strength at 20 % diameter reduction was 1.363 ± 0.020 N/mm versus 1.456 N/mm in simulation (6.8 % relative error), confirming strong agreement between FE model and experiments.

Discussion

This study demonstrates the feasibility of an integrated computational-experimental workflow for developing BMgS. The optimization framework identified a design that outperformed the baseline, and the strong agreement between simulations and *in vitro* tests confirmed the reliability of the FE model in capturing acute stent mechanics. Successful extrusion and femtosecond laser cutting further validated manufacturability. Overall, the workflow provides a solid foundation for accelerating the design and translation of next-generation BMgS.

Biomechanically Optimized Peripheral Artery Stent Remonstrates Reduced Intimal Hyperplasia and Stenosis In a Swine Model

Professor and Chair Alexey Kamenskiy Ph.D.[1], Postdoctoral Fellow Barbara Batista de Oliveira M.D.[2], Associate Professor Anastasia Desyatova Ph.D.[1], Research Scientist Frazer Heinis Ph.D.[1], Research Scientist Jordan Rosenbohm Ph.D.[1], Research Scientist Paul Deegan MSc[1], Professor Jason MacTaggart M.D.[2]

[1]University of Nebraska Omaha, Omaha, Nebraska, United States. [2]University of Nebraska Medical Center, Omaha, Nebraska, United States

Introduction

Endovascular treatment of peripheral artery disease (PAD) remains limited by high restenosis rates, particularly when stents are placed in biomechanically active regions such as the adductor hiatus or behind the knee. Commercial stents often fail to accommodate large limb-flexion-induced deformations, producing adverse stent-artery interactions that impair healing.

Methods

A computational Design-of-Experiments framework with response-surface methodology was used to optimize the geometry of a NiTi PAD stent for improved apposition, reduced wall stress, and minimized pinching under physiologic axial compression, bending, and torsion. The optimized design was manufactured, crimped into a custom delivery system, and implanted in 8-month-old Yucatan swine (n=6). Each animal received the optimized stent on one side and a commercial Zilver stent - representing average biomechanical behavior - contralaterally. Stents were deployed behind the inguinal ligament to replicate the severe deformation environment near the human adductor hiatus. Animals survived 12 weeks on a high-fat, high-sugar diet with interim CTA in straight and flexed postures. After sacrifice, μCT and histology quantified intimal hyperplasia and stenosis.

Results

All treated arteries remained patent with preserved side branches. CTA showed that the optimized stent accommodated limb-flexion deformations more effectively (Figure), exhibiting greater physiologic axial compression (13 ± 3% vs. 7 ± 2%) and smoother transitions at stent ends. In contrast, Zilver stents frequently produced distal-end kinking during flexion. μCT analysis demonstrated substantially reduced neointimal hyperplasia

with the optimized design (251 ± 86 mm^3) compared with Zilver (407 ± 90 mm^3). Correspondingly, maximum stenosis (47 ± 9% vs. 63 ± 7%) and mean stenosis (32 ± 10% vs. 47 ± 7%) were significantly lower in the optimized stents (all $p<0.001$, Figure).

Discussion

A stent engineered explicitly for lower-limb biomechanics demonstrated superior ability to accommodate limb-flexion-induced deformations and produced markedly improved vascular healing in vivo. These findings underscore that biomechanical compatibility - particularly in regions of high dynamic strain - should be a core design requirement for next-generation PAD stents.

Images (Optional)

Numerical Analysis of Knee Bending Effects on Blood Flow in a Femoral Arterial Stent Using a Centerline-Based Deformable Model

Professor Marie Oshima Ph.D, Mr. Kotaro Onoue, Dr. Katsuyuki Hoshina M.D.

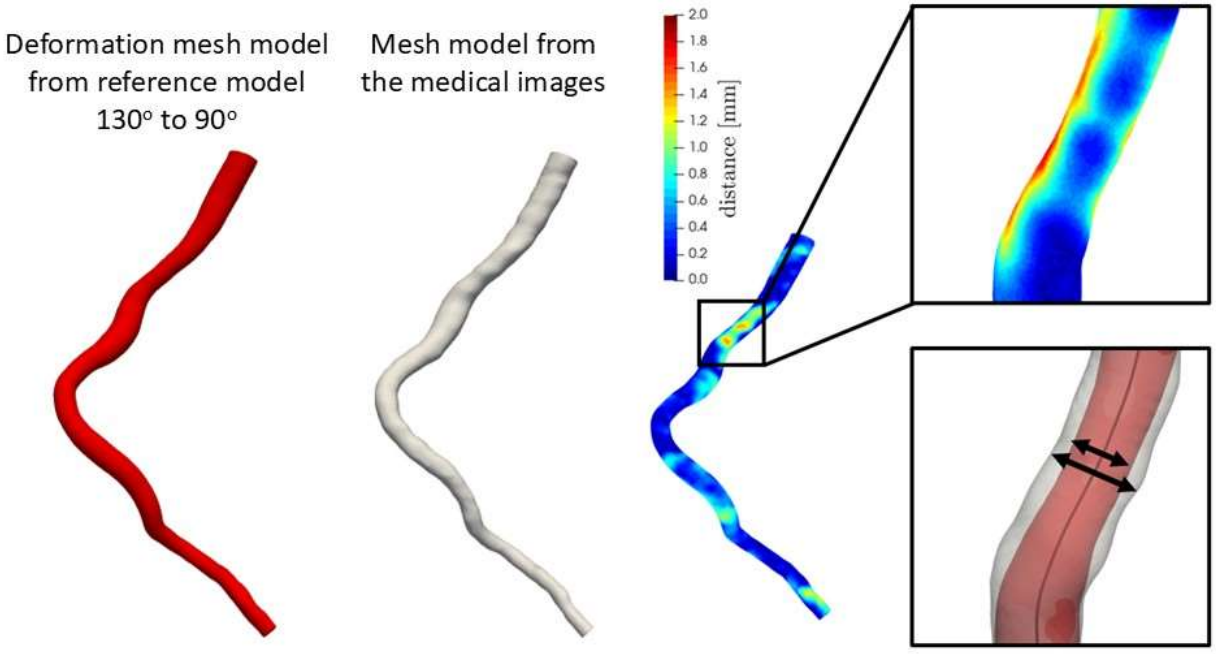
The University of TOkyo, Tokyo, Tokyo, Japan

Introduction

Revascularization procedures are routinely performed for patients with severe femoral artery stenosis caused by progressive atherosclerosis to prevent critical limb ischemia. However, some patients experience poor postoperative outcomes due to stent migration or collapse associated with knee bending motion. Regular follow-up imaging is therefore essential to detect morphological changes over time. Because medical images obtained at different time points produce different geometric models, a new mesh must be generated for each model. Therefore, it becomes difficult to conduct quantitative comparison of simulation results between analysis models in an efficient manner. To solve this issue, we developed a centerline-based deformable modeling method to investigate the effects of knee bending motion on hemodynamics in the femoral artery.

Methods

The proposed method transforms a standard analysis model into a target model using vascular centerlines. First, three-dimensional vascular geometries at multiple time points are segmented from medical images to construct both the standard and target models. After centerline extraction for each model [1], the analysis mesh of the standard model is generated using Gmsh [2]. A transformation matrix is then derived from the correspondence between the two centerlines. This matrix is used to deform the standard analysis model so that its centerline matches that of the target geometry. The surface mesh of the target model is generated using the same correspondence, and a smoothing procedure is implemented to reduce distortions in the transformed surface.



Results

The target analysis model was successfully created by transforming the centerline and surface mesh of the standard model according to the derived transformation matrix. The smoothing algorithm effectively improved mesh quality by reducing distortions in highly deformed regions.

Discussion

Verification and validation of the proposed method were performed using simplified geometries. The method was further applied to patient-specific femoral artery simulations using CT images acquired at three different knee bending angles. Geometric differences and hemodynamic outcomes were compared across the three configurations. The results demonstrated the capability of the method to enable consistent quantitative analysis across time-varying vascular geometries.

Hemodynamic Testing of a Composite Leaflet Material for Transcatheter Aortic Valve Replacement (TAVR)

Ms. Vivienne Zacher BS[1,2], Ms. Shweta Karnik MS[1,2], Dr. Sanchita Bhat Ph.D.[1,2], Ms. Mabel Prejean BS[3], Ms. Abbey Nkansah BS[3], Dr. Elizabeth Cosgriff-Hernandez Ph.D.[3], Dr. Lakshmi Prasad Dasi Ph.D.[1,2]

[1]Georgia Institute of Technology, Atlanta, GA, United States. [2]Emory University, Atlanta, GA, United States. [3]The University of Texas at Austin, Austin, Texas, United States

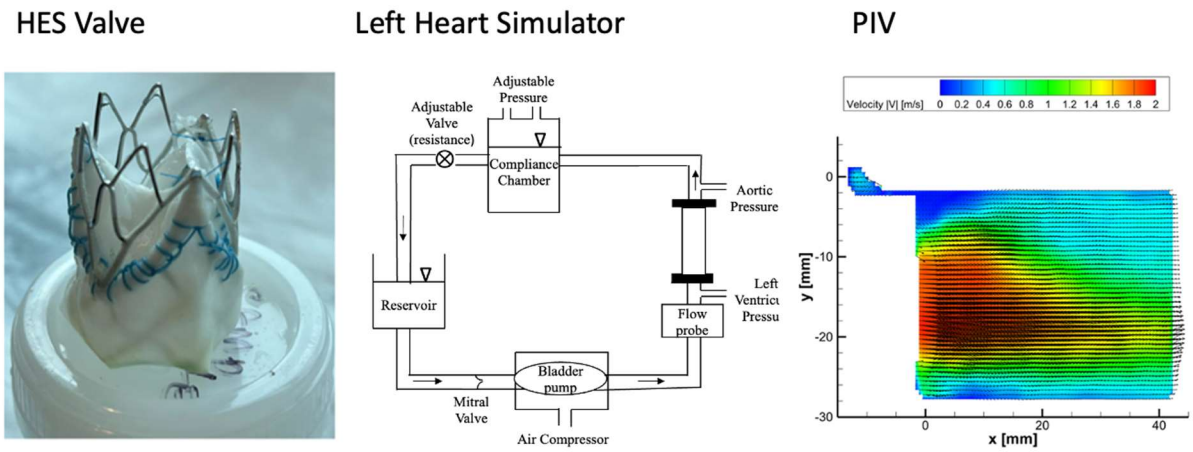
Introduction

Aortic Stenosis (AS) obstructs blood flow from the left ventricle to the aorta, often leading to the need for an aortic valve replacement. Transcatheter Aortic Valve Replacement (TAVR) is a minimally invasive option to treat severe AS where a stent with bioprosthetic leaflets is most commonly deployed via access from the femoral artery [1]. Bioprosthetic leaflets have limited long-term durability due to calcification and degeneration [2]. Therefore, there is a need for an alternative leaflet material to prolong TAVR durability. Here, we hypothesize that the use of hydrogel-coated electrospun (HES) composite leaflets will improve the hemodynamic performance and durability of TAVRs.

Methods

The leaflets were fabricated as illustrated in previous studies [3]. The polyurethane will provide enhanced mechanical properties, and the hydrogel coating provides thromboresistance.

HES leaflets were sutured on a cobalt-chromium stent (MP35N). A left heart simulator was used to test the hemodynamic performance at physiological aortic conditions. The downstream fluid velocity through the valve was analyzed using phase-locked particle image velocimetry (PIV). The left heart simulator fluid was seeded with fluorescent particles to track the fluid motion and the data was recorded using a high-speed camera. The peak velocity for an average of 100 cardiac cycles was obtained using DaVis 8.4, a software used to analyze raw PIV images.



Results

The effective orifice area and regurgitation fraction were 1.52 ± 0.34 cm^2 and 9.6 ± 1.8%, respectively. The velocity magnitude at peak systole was 1.93 m/s.

Discussion

The effective orifice area and regurgitation fraction met ISO 5840 standards. The mean transvalvular pressure gradient was also comparable to current clinical devices [3]. Future studies will include finite-element simulations of stents to improve stent design and minimize stress concentrations, therefore preventing fracture of stent frames. These simulations will illustrate the stresses on the stent while loading it into the catheter and expanding it using a balloon during the TAVR procedure. Additionally, accelerated wear testing will be completed to access mechanical durability.

Not All Hoppers Are Built for the Desert: Effects of Substrate on Hopping Kinematics of Kangaroo rats.

Ms. Sage Murthy[1], Ms. Kaylee Nguyen[2], Ms. Mary Pena[1], Dr. Craig McGowan PhD[1]

[1]University of Southern California, Los Angeles, California, United States. [2]University of California, Irvine, Irvine, California, United States

Introduction

Bipedal hopping is often associated with arid environments and it has been suggested that this mode of locomotion offers selective advantages under these conditions. In a recent study we showed that desert kangaroo rats are capable of hopping on soft sand with almost no changes in kinematics, relative to hard surfaces [1]. However, not all kangaroo rats live in sandy dunes and it remains unclear if bipedal hopping alone provides a unique ability to hop on soft substrates. In this study, we examined the kinematics of hopping on solid vs sand surfaces by California kangaroo rats, a species whose native habitat is grasslands. We hypothesized that, similar to desert kangaroo rats, there would be little difference in kinematics for California kangaroo rats hopping on sand vs solid surfaces.

Methods

To test our hypothesis, we collected high-speed sagittal plane video (300 Hz) from 9 California kangaroo rats (*D. californicus*) while hopping on a custom built rotary treadmill at 1.8 m/s on solid and sand (25 mm) surfaces. The animals' fur was shaved and the hindlimb joint centers were marked and digitized in order calculate limb and joint angles. A repeated measures ANOVA was used to test for differences between the conditions.

Results

Ours results showed several significant differences between hopping on solid and sand surfaces. Hopping frequency decreased on the sand while duty factor increased. The animals hopped with a more couched posture on sand, characterized by a shorter effective leg length, and there were significant changes in joint angles leading to increased limb extension at foot off. Joint angle changes were most pronounced at the knee and ankle.

Discussion

Our hypothesis was not supported. Unlike desert kangaroo rats, California kangaroo rats change their hopping kinematics significantly when hopping on the sandy substrate. The changes in kinematics are consistent with the animals having to do more mechanical work, presumably to replace energy lost to the movement of the sand under the foot. These

outcomes indicate that, while some bipedal hoppers are able to locomote on sand with little apparent energetic penalty, it is not a function of the hopping gait alone.

Influence of EMA and Musculoskeletal Stress Reduction on Postural Changes in Walking vs Climbing in Rats

Mrs. Cassandra Shriver, Dr. David Hu, Dr. Young-Hui Chang

Georgia Institute of Technology, Atlanta, GA, United States

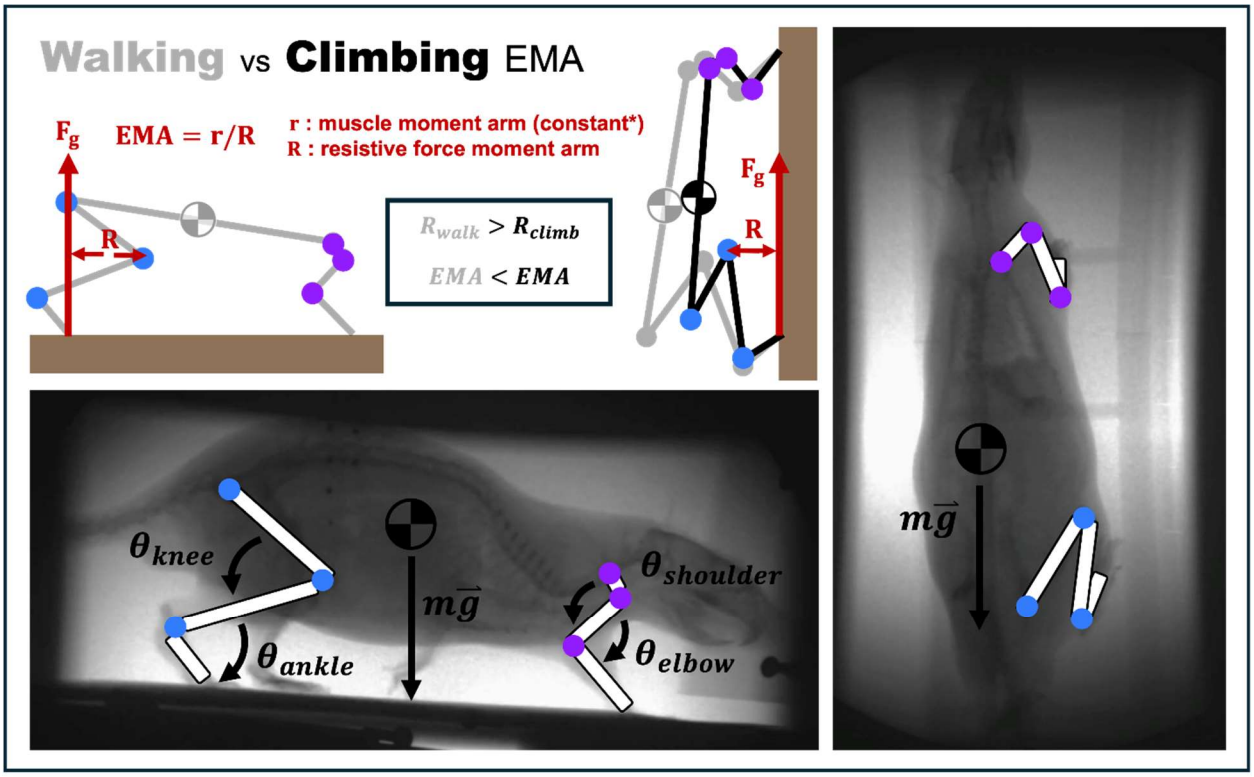
Introduction

Climbing is a challenging type of locomotion requiring constant ascent against gravity, yet there are many scansorial animals capable of both walking and climbing. How do limb positions and body posture change between horizontal and vertical locomotion? We hypothesize different locomotor constraints impacting musculoskeletal stress in walking versus climbing induce postural changes that reduce pitchback torque and improve the effective mechanical advantage (EMA) of limb muscles.

Methods

We conducted preliminary experiments with six rats (*Rattus norvegicus)* in a GT IACUC-approved protocol (#A100530). Individuals completed ten horizontal walking trials on a treadmill and ten vertical climbing trials on a ladder. Kinematics were collected using a biplanar x-ray system. We used DeepLabCut [1] to train point-tracking models for labeling limb joints. Markers were fed into XMALab [2] to obtain 3D-coordinate positions. We calculated forelimb and hindlimb effective limb lengths and joint angles to assess postural changes between the locomotor modes. Differences in musculoskeletal stress were estimated with the Effective Mechanical Advantage (EMA) of the limb using a quasi-static inverse model [3].

Results



Preliminary analyses on two rats support our hypothesis that limb posture becomes more crouched during climbing. Effective hindlimb length decreased by 1.5±0.5 cm. This was achieved by decreasing joint angles, but maintaining similar contact patterns, as opposed to a sprawled limb posture. Similar changes were observed in elbow angles, reducing effective forelimb lengths (0.5±0.3 cm).

Discussion

Bringing the hips and shoulders closer to the locomotor surface during climbing reduces musculoskeletal stresses via an increased EMA. An increased EMA reduces torques

associated with a smaller moment arm of the substrate reaction force. In contrast to larger walking animals that display a more upright posture to increase their EMA, we propose that larger climbers likely adopt more crouched postures to increase EMA, due to biomechanical differences from body orientation relative to gravity. Future work will examine how these changes are exacerbated by mass scaling in larger climbers subject to proportionally greater gravitational constraints.

Images (Optional)

Effective mechanical advantage (EMA) differences in walking vs climbing. *The muscle moment arm (r) is assumed to be constant in comparison to the magnitude of change in the resistive force moment arm (R). In horizontal locomotion, more crouched postures increase the moment arm of the gravitational resistive force about distal joints, resulting in reduced EMA compared to more upright postures. In vertical locomotion, the opposite is true. Rats crouch more during climbing than walking, improving EMA in comparison to applying the same walking posture to climbing.

Multimaterial Models Reveal Functional Principles of Armored Fish and Bioinspired Devices

Dr. Cassandra Donatelli[1], Ms. Megan Vandenberg[2], Dr. Karly Cohen[3], Mr. Lorenzo Martinez[4], Mr. Brody Anderson[5], Mr. John Racy[2], Dr. Adam Summers[2,3]

[1]University of Washington Tacoma, Tacoma, WA, United States. [2]University of Washington, Seattle, WA, United States. [3]Friday Harbor Laboratories, Friday Harbor, WA, United States. [4]Rhodes College, Memphis, TN, United States. [5]Washington State University, Pullman, WA, United States

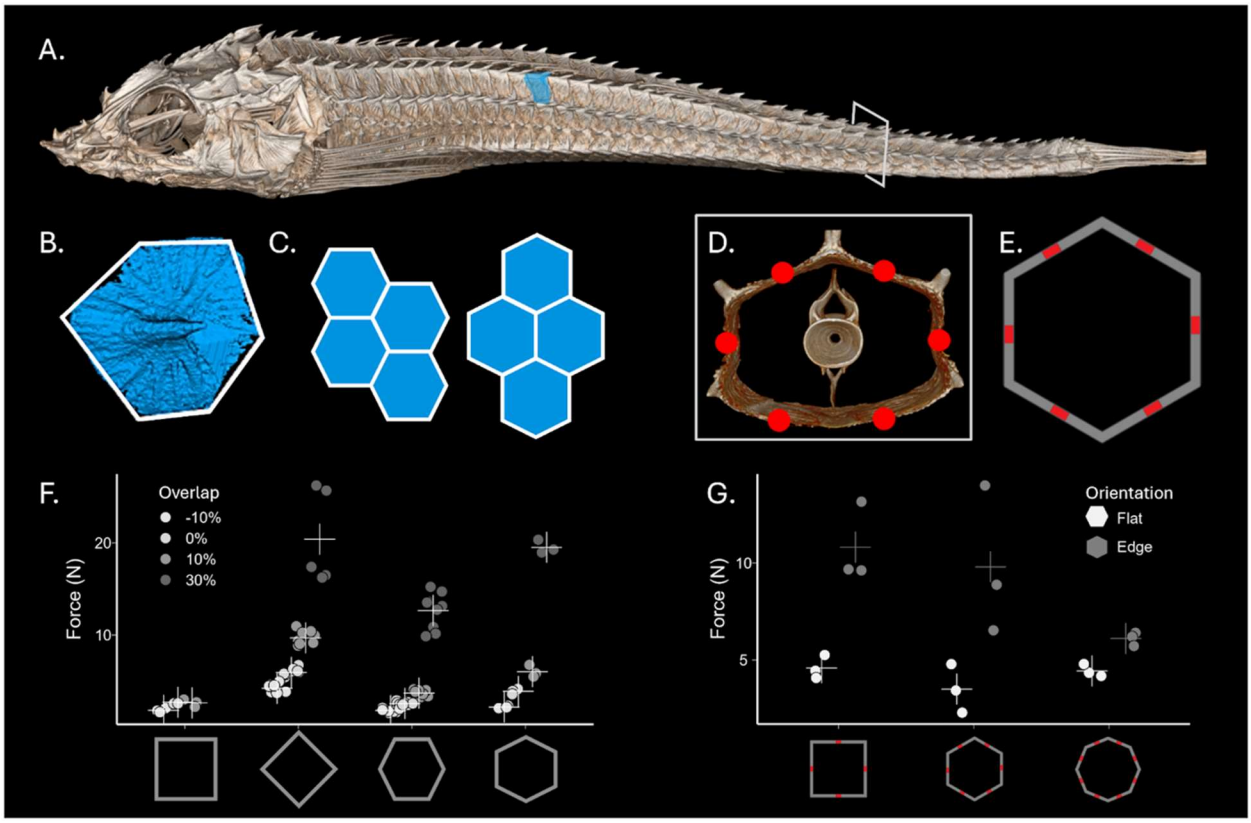
Introduction

Armored fishes are extraordinary, exhibiting morphological diversity ranging from interlocking bony plates, to fused strut systems, to flexible embedded scales. They are ideal models for understanding how rigid elements and flexible joints can be arranged to balance protection, mobility, and efficiency. These natural structures face the same constraints seen in engineered protective systems such as the need to dissipate forces, restrict harmful deformation, and maintain flexibility, which makes them useful sources of bioinspiration. Understanding how those demands are balanced requires computational and physical models that let us probe mechanics directly. Advances in multi-material 3D printing and computational fluid dynamics allow us to model biological complexity using accessible, low-cost tools, enabling rapid prototyping and testing. These models inform our biological understanding and engineered design.

Methods

We quantified the diversity of shapes and plate arrangements in one family of armored fishes, the poachers (Agonidae, Figure 1.A). Using micro-CT scanning. microscopy, and geometric morphometrics, we explored plate shape (Figure 1.B), body shape (Figure 1.D), and plate arrangement. We examined the tissues with dissection and histology to understand how plates are connected. With these data, we designed and mechanically tested multimaterial 3D-printed models that incorporated embedded fabrics (Figure 1.C, E) and flexible materials (Figure 1.E,G) to mimic the geometry and the material differences of natural armor.

Results



Our models show that the shape and arrangement of rigid components, and the integration of soft materials, influence the mechanical performance of armored systems (Figure 1. F, G). Bioinspired models that closely mimic natural morphology and tissue organization tend

to resist compression and bending more effectively than other designs. Variation in joint placement, material flexibility, and fiber reinforcement all affect system mechanics, demonstrating the importance of testing the combination of segment shape and overlap, soft–hard interfaces, and composite-material anisotropy.

Discussion

These models show how natural armor balances protection and flexibility. Our multimaterial composite additive manufacturing framework provides a systematic approach for continued evaluation of the geometric, interfacing, and material drivers of armor performance. In addition to helping us understand biological armor, we also use these approaches to inform human-focused design challenges such as bioinspired prosthetics and medical braces.

Numerical Study of Drag Influence on Magnetic Micro-Particle Aggregates in Magnetic Resonance Navigation for Tumor Embolization

Mr Mahdi Rezaei Adariani[1,2], Dr Jiří Pešek[2], Dr Cyril Tous[1], Dr Ning Li[1], Prof Gilles Soulez[1], Prof Irene Vignon-Clementel[2]

[1]CRCHUM, Montreal, QC, Canada. [2]Inria, Saclay Ile-de-France, Palaiseau, France

Introduction

Magnetic resonance navigation (MRN) of medicinal particles is an emerging technique for liver cancer treatment. MRN relies on particle clusters formed via interactions induced by the MRI scanner's magnetic field. These aggregates are injected into the blood flow and steered toward target vessels by blood drag, magnetic gradient forces, and gravity. A critical challenge is understanding aggregate motion near vessel walls, which remains inadequately addressed by existing models. This study investigates these factors using numerical simulations to provide insights into aggregate behavior and improve computational models for targeted embolization.

Methods

Magnetic micro-bead aggregates were simulated in hepatic artery geometry under physiologically relevant flow conditions and validated against in-vitro phantom experiments. Inlet conditions were derived from phase-contrast MRI, with outlet flow rates measured manually. Particle motion was modeled using a Lagrangian point-particle approach based on the Maxey-Riley equation. Drag was estimated by the bead drag model for chain-like aggregates, with near-wall corrections available in the literature. While these simplifications neglect shape effects and flow complexity, they provide a framework for analyzing aggregate behavior near vessel walls, which is key for the application. Hydrodynamic forces on individual particles were further analyzed using direct numerical simulation (DNS) to better capture aggregate dynamics close to walls.

Results

The study began with chains of spherical particles oriented parallel or perpendicular to flow. Total drag predictions were validated against experimental data and the bead-chain drag model. Near-wall corrections were further validated using DNS for a particle moving in stationary flows and a particle fixed in shear flow. Strong agreement between analytical

solutions and numerical results confirms the model's accuracy for these configurations. Moving particles in flow were also analyzed.

Discussion

The simplified model was verified and validated against phantom experiments. Preliminary results suggest that the method provides reasonable estimates of drag. However, the bead drag model is limited to rigid chains of spherical particles, and further research is needed to generalize hydrodynamic effects on aggregates of varying shapes in arterial flow. Ongoing work aims to develop a semi-empirical model to better bridge the gap between one-way coupling simulations and experiments, providing a foundation for optimizing MRN-based tumor embolization in-vivo.

A Physics-Informed Computational Model Based on Diffusion MRI for Predicting Ischaemic Stroke Evolution

PhD student Hsuan-Ju Chen[1], Dr. Stephen Payne[2,1]

[1]Institute of Applied Mechanics, National Taiwan University, Taipei city, Da'an District, Taiwan. [2]School of Engineering Mathematics and Technology, University of Bristol, Bristol, South West England, United Kingdom

PhD student Hsuan-Ju Chen

Introduction

Current clinical imaging techniques, particularly DWI and PWI, are central to stroke diagnosis but capture only a single time point in stroke evolution. Dynamic prognosis requires predicting how perfusion deficits evolve into permanent tissue damage by integrating these data into a physics-based model.

We propose a physics-informed FEM brain model, based on our previous cerebral perfusion work [1], integrating DWI-derived parameters to simulate restricted water motion, which is highly sensitive to early ischaemic changes.

Methods

The study utilized a longitudinal dataset from 3 large animals, with each scanned at three checkpoints post-intervention: immediate (post-cooling), 24-48 hours, and 30 days. A voxel-wise diffusion coefficient map, D(x,y,z), was generated from raw DWI data.

The spatio-temporal evolution of the stroke was modeled using the partial differential equation (PDE): $\partial u/\partial t = \nabla \cdot (D(x)\nabla u)$, where, u represents the evolving diffusion measurement, governed by a diffusion field. The lesion ROI was manually delineated on the DWI maps and a corresponding contralateral normal ROI was also generated by mirroring the lesion geometry across the midline.

Results

In the immediate group, the lesion ROI was found to exhibit a marked reduction in mean diffusivity (0.758 vs. 0.887 x 10^{-3} mm^2/s) compared to the contralateral normal tissue, which is consistent with restricted water motion. The 24-48 hours group demonstrated

pseudonormalization (0.862 vs. 0.838 x 10^{-3} mm^2/s), while the 30-day group showed elevated diffusivity (0.981 vs. 0.855 x 10^{-3} mm^2/s), which may reflect structural changes associated with subacute to chronic stroke evolution.

Discussion

Results from the Immediate group highlight energy failure, helping to explain the high-intensity signals in clinical DWI. The transition from acute restriction to chronic tissue liquefaction mirrors temporal dynamics previously seen in stroke models [2]. The acute slower decay serves as a robust biomarker for the severity of the ischaemic core. Persistent restricted diffusion indicates areas where metabolic suppression may not have fully prevented cellular injury. Ultimately, this helps to validate our physics-informed computational model as a framework for characterizing and predicting ischaemic stroke evolution.

Sensitivity Analysis of Ventricular Shunt Obstructions on Cerebrospinal Fluid Drainage

Dr. Bryan Good PhD, Dr. Stephanie TerMaath PhD

University of Tennessee, Knoxville, TN, United States

Introduction

Hydrocephalus is a condition where an excessive amount of cerebrospinal fluid (CSF) accumulates within the ventricles of the brain resulting in elevated intracranial pressure (ICP) that can cause permanent brain damage and impairment. The primary treatment is the implantation of a ventricular shunt to drain excess CSF. While effective in controlling ICP, ventricular shunts have extremely high failure rates, with most patients requiring a shunt replacement within two years. Approximately 85% of pediatric patients will require a shunt revision, with 5% requiring 10 or more revision procedures over their lives. Therefore, our objective is to determine the sensitivity of ventricular shunt CSF drainage to different obstruction scenarios within the proximal catheter.

Methods

OpenFOAM and its 'porousSimpleFoam' solver was used to simulate CSF flow within a simplified lateral ventricle and proximal catheter model (**Fig. 1A**). The catheter featured 2 rows of 8 drainage holes, with each designated a "porous" zone in the model. An inlet flow rate of 21 ml/hr was prescribed, representing choroid plexus CSF production, with a fixed outlet pressure. Since no data of shunt obstruction properties exists, we varied the Darcy coefficient (inverse of material permeability) from $1e^{0}$-$1e^{10}$ m^{-2} in each catheter hole to determine the sensitivity of catheter performance to obstructions.

Results

When normalized by baseline "unobstructed" flow (**Fig. 1B**), obstructions with Darcy coefficients $<1e^{7}$ had no significant effect on CSF drainage. On the other extreme, Darcy coefficients of $1e^{10}$ were sufficient to completely obstruct CSF drainage. We also found that obstruction of Hole 8 (closest to outlet) had the greatest effect on other holes' CSF flows, increasing between 42-51% over baseline. Hole 1 obstruction (closest to inlet) had the least impact, only increasing Hole 2-4 flows by 2-10%.

Discussion

These results provide baseline data for our ongoing machine-learning study to determine the combined effects of catheter hole obstructions on shunt performance. We have narrowed our range of obstruction permeabilities and also determined the effect of single hole obstructions on overall catheter drainage. Our ultimate goal is to optimize shunt performance, while minimizing the effects of catheter obstructions, to decrease the number of shunt revisions for hydrocephalus patients.

Mechanical Responses and Key Parameter Identification in a Finite Element Model of the Mouse Cervical Spinal Cord under CSF Pulsatile Loading

Doctoral student Duzhi CHEN

Laboratoire de Biomécanique Appliquée, Marseille, Provence-Alpes-Côte d'Azur, France

Introduction

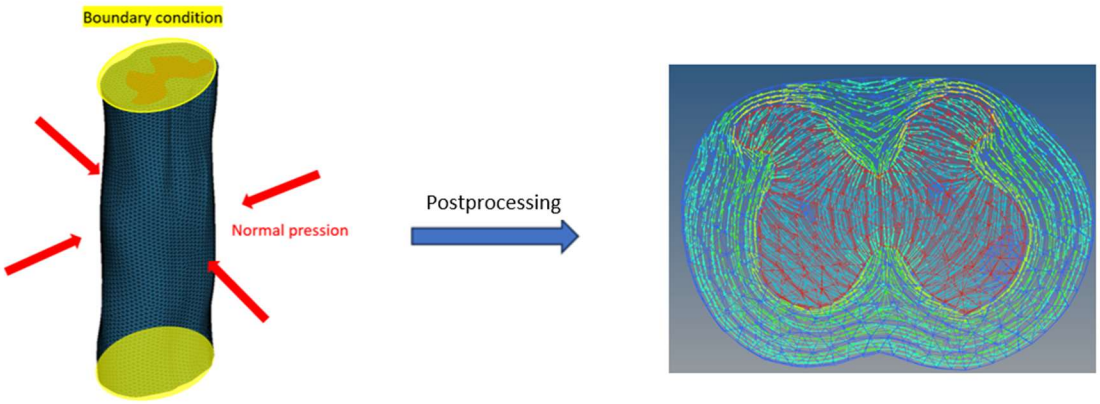
Numerous numerical spinal cord models exist, yet analyses of the mechanical loading environment due to cerebrospinal fluid (CSF) pulsation remain sparse. Reported mechanical properties vary widely across species, sample preparations, experimental protocols, and constitutive assumptions, while the dynamics of CSF pulsation are not well defined. This study aimed to clarify the spinal cord's mechanical response under pulsatile CSF loading by reviewing previous work to establish realistic parameter ranges and identify dominant factors, and then running simulations and a sensitivity analysis to evaluate the influence of those parameters.

Methods

A finite element model of the mouse cervical spinal cord was developed, modelling grey matter (GM) and white matter (WM) separately and employing a generalized Maxwell model to capture viscoelastic behavior (elastic moduli $E_{WM} \approx 0.2$ MPa for and $E_{GM} \approx 0.025$ MPa). CSF pulsation was represented as a sinusoidal pressure load acting on the lateral surface (mean pressure at 0.00267 MPa, 1Hz). The first principal strain, von Mises stress and Lode angle were extracted from a 15-cycles simulation as an output for a sensitivity analysis using the Morris method, screened the effects of material parameters and loading conditions.

Results

Stress and strain evolved over time; although steady state was not reached within 15 s, analysis focused on this point. The Lode angle indicated predominantly compressive states in GM and tensile states in WM. Stress ranged from 0.003 to 0.5 kPa, and the first principal strain from roughly 0.0005 % to 0.1 %, with higher values in WM. Maximum strains occurred in the lateral funiculus; stress concentrations appeared at the grey–white interface near the dorsal and ventral horns. The sensitivity analysis found Poisson's ratio to be the most influential parameter, followed by loading-related variables and overall stiffness.



Viscoelasticity had limited effect; the stiffness ratio between grey and WM was negligible. Base pressure amplitude and Poisson's ratio showed pronounced nonlinear interactions.

Discussion

These simulations provide quantitative ranges for stress and strain, showing deformations are sufficiently small and that linear elasticity is adequate under CSF pulsation. Strong influence of Poisson's ratio underscores the importance of incompressibility assumptions. Accurate characterisation of CSF pulsation parameters is essential for predicting spinal cord response.

Longitudinal Assessment of Sensor-Derived Gait Quality and Clinical Functional Outcomes Following Total Hip Arthroplasty.

Ms. Jiahui Wang[1], Dr. Abner Sergooris[2], Prof. Annick Timmermans[2], Prof. Benedicte Vanwanseele[1]

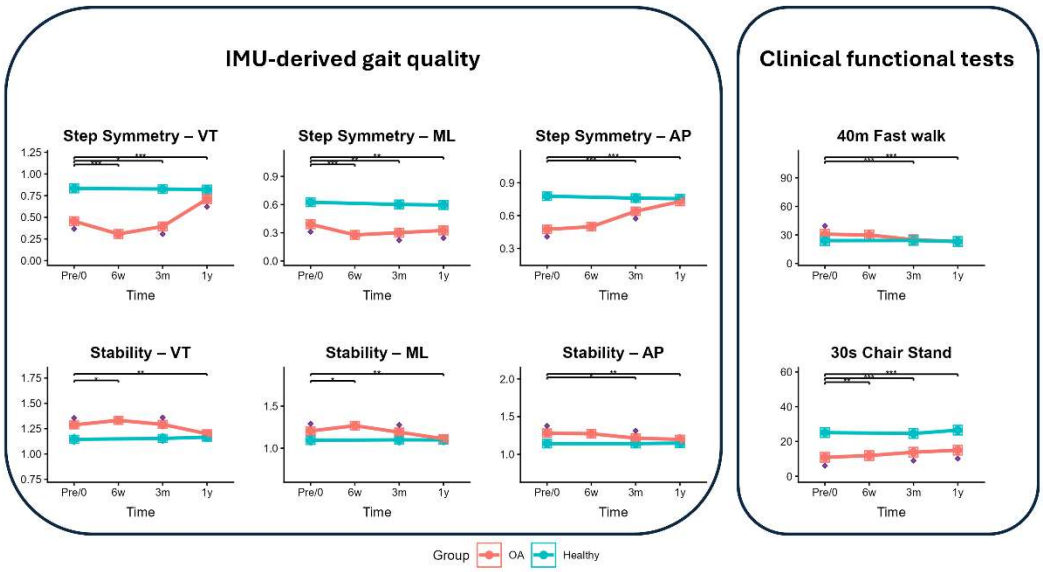
[1]KU Leuven, Leuven, Leuven, Belgium. [2]Hasselt University, Hasselt, Hasselt, Belgium

Introduction

Total hip arthroplasty (THA) is highly effective for end-stage hip osteoarthritis, yet gait biomechanics don't always fully normalize despite substantial improvements in pain and self-reported function [1]. These gait abnormalities are clinically relevant because they may influence mobility, loading, and fall risk. While functional tests often miss subtle gait abnormalities, wearable inertial measurement unit (IMU) offers a biomechanics-driven approach to quantify sensor-derived gait quality in clinics [2]. In addition, most individuals undergoing THA are middle-aged and older adults, distinguishing surgery-related recovery from age-related changes is essential. This study evaluated longitudinal changes in IMU-derived gait quality after THA and examined whether these changes were independent of aging.

Methods

Seventy-seven THA participants were assessed preoperatively and at 6 weeks, 3 months, and 1 year, while forty-five age-matched healthy individuals were assessed at baseline, 3 months, and 1 year to characterize aging effects. A trunk-mounted IMU (200 Hz) recorded habitual 25-m straight-line walking, providing step symmetry and stability in the vertical (VT), mediolateral (ML), and anteroposterior (AP) directions. Clinical assessments included the 30-s Chair Stand Test (30sCST), 40-m Fast Walk (40MFW), and hip muscle strength. Linear mixed-effects models analyzed all outcomes.



Results

IMU gait measures showed postoperative changes not explained by aging. VT and ML symmetry worsened at 6 weeks; VT improved by 1 year, while ML did not return to preoperative values. VT and ML stability decreased at 6 weeks and improved by 1 year. AP symmetry and stability improved by 3 months. Hip strength on the operated side declined until 3 months and improved by 1 year, except for external rotation. The 40MFW matched healthy performance by 3 months, whereas the 30sCST improved but remained below healthy levels at 1 year.

Discussion

ML symmetry remained impaired at 1 year, which may relate to prosthesis-altered hip rotator mechanics or residual strength asymmetry. AP measures recovered more rapidly, possibly due to preserved AP structures and earlier restoration of flexor–extensor strength. As these patterns were not explained by aging, ML gait quality represents an important target for postoperative rehabilitation.

Longitudinal Changes in Strength, Physical Activity, Mobility, and Pain Following Periacetabular Osteotomy for Hip Dysplasia

Ms. Christina Bourantas BA, Dr. Molly Shepherd PhD, Ms. Madison Wissman BS, Dr. John Clohisy MD, Dr. Michael Harris PhD

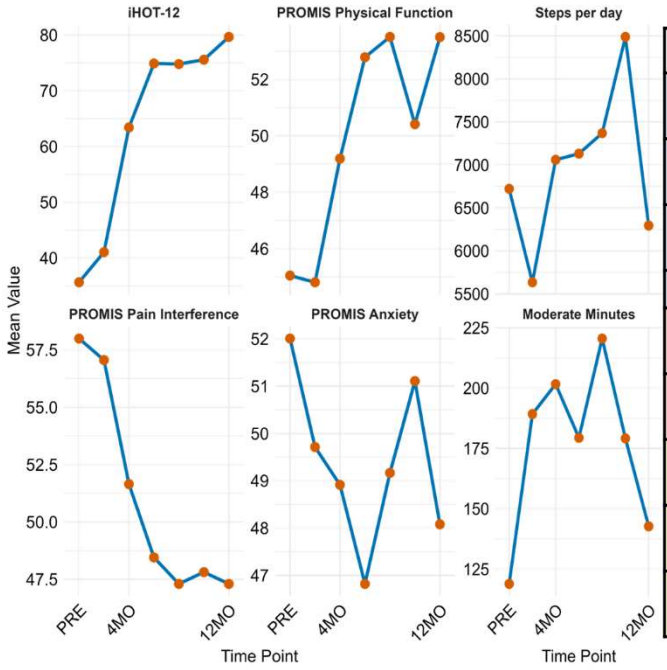
Washington University in St. Louis, St. Louis, Missouri, United States

Introduction

Developmental dysplasia of the hip (DDH) is characterized by abnormal bony geometry that reduces hip joint stability [1,2]. Many individuals with DDH are active but limit activity and seek surgery because of insidious pain. Periacetabular osteotomy (PAO) surgically reorients the acetabulum [3], yet outcomes remain variable [4]. Assessing short-term changes in activity, strength, and self-reported outcomes during the period when rehabilitation can be optimized is critical. The objective of this study was to evaluate longitudinal changes in pain, function, strength, and activity during one-year post-PAO.

Methods

Fifteen individuals with DDH completed assessments preoperatively and every 2 months post-PAO for 12 months. Participants wore a Fitbit for 7 days to measure steps and heart rate; moderate activity was defined as minutes above 50% of estimated max heart rate. Self-reported outcomes included iHOT-12 and PROMIS Pain Interference, Physical Function, and Anxiety. Isometric hip strength was assessed using a handheld dynamometer pre-PAO, 4-, and 12-months post-PAO. Paired t-tests compared outcomes across timepoints.



Results

iHOT-12, PROMIS Pain Interference, and Physical Function significantly improved at 4- and 12-months post-PAO (Figure 1). For activity, steps per day were not different pre to 12-months post-PAO, but moderate minutes changed significantly from pre to 4-months post-PAO and 4- to 12-months post-PAO. Strength significantly decreased at 4-months post-PAO but increased at 12-months post-PAO. Despite these group-level changes, variability remained high across participants, with large standard deviations in self-reports, activity, and strength measures.

Discussion

These findings demonstrate variable changes in pain, function, strength, and activity during early recovery after PAO. While self-reported outcomes improved, activity measures were inconsistent, and strength recovery decreased initially before returning to preoperative values. The variability in outcomes suggests that self-reported improvements may mask persistent functional deficits for some individuals, while others recover more rapidly. Comprehensive monitoring revealed diverse recovery patterns, reinforcing the need for individualized rehabilitation strategies. Addressing variability during this critical recovery window may help reduce long-term dissatisfaction and optimize functional outcomes.

A DXA-Based Hip 3D Finite Element Model Predicts Hip Fractures Better Than Hip aBMD Independently of FRAX Scores in a MrOS Sub-Cohort

Dr Lorenzo Grassi[1], Mr Lars Jehpsson[2,3], Dr Helena Johansson[4], Dr Magnus K Karlsson[2,3], Dr Björn E Rosengren[2,3], Dr Hanna Isaksson[1]

[1]Department of Biomedical Engineering, Lund University, Lund, Skåne, Sweden. [2]Department of Clinical Sciences, Lund University, Lund, Skåne, Sweden. [3]Department of Orthopedics, Skane University Hospital, Malmö, Skåne, Sweden. [4]Sahlgrenska Osteoporosis Centre, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Gothenburg, Sweden

Introduction

Areal bone mineral density (aBMD) measured by dual-energy x-ray absorptiometry (DXA) is a moderate predictor of bone strength, while more resource-demanding computed tomography derived 3D finite element (FE) models provide superior accuracy. We have previously presented a method to reconstruct 3D shape and BMD distribution of the femur from a single DXA image and created subject-specific FE models [1]. The aim of this pilot study was to evaluate the feasibility of using the method to predict hip fractures.

Methods

We used a sub-cohort of men from the population based MrOS Sweden study (Malmö, Uppsala). The sub-cohort (n=609) included men without previous hip fracture who had undergone evaluation by DXA and FRAX (Fracture Risk Assessment Tool) at age 75±2 years. We reconstructed 3D FE models from 2D DXA scans and predicted femoral strength for 10 different side-fall configurations using a validated technique [2,3]. We ran time-to-event analysis (hip fracture) with competing risk (death) with Fine-Gray sub-distribution hazard models 5 years after the DXA scans were performed. We predicted fractures using aBMD and FE-predicted femoral strength, with and without adding FRAX scores as covariate. Fracture risk prediction accuracy was evaluated with area under the receiver operating characteristics (AUROC) curve.

Results

Twentynine men sustained a hip fracture during the 5-year study period. FE-predicted femoral strength was useful to identify hip fracture cases (AUROC=0.72, 95% confidence interval [0.60–0.87]) and in the examined sub-cohort was superior to aBMD (AUROC=0.66

[0.46–0.86], ΔAUROC=0.06, figure 1). The differences, however, did not reach statistical significance. Similar results were seen when adjusted for FRAX (ΔAUROC=0.06, figure 1).

Discussion

FE-predicted femoral strength was useful to identify fracture cases and in the examined sub-cohort also had better discriminatory ability than aBMD (with or without FRAX). The superiority to aBMD was not statistically significant, but the observed effect size suggests potential clinical relevance. Our future work will focus on including larger sub-cohorts to the analysis to increase statistical power and verify or oppose our current inferences.

Images (Optional)

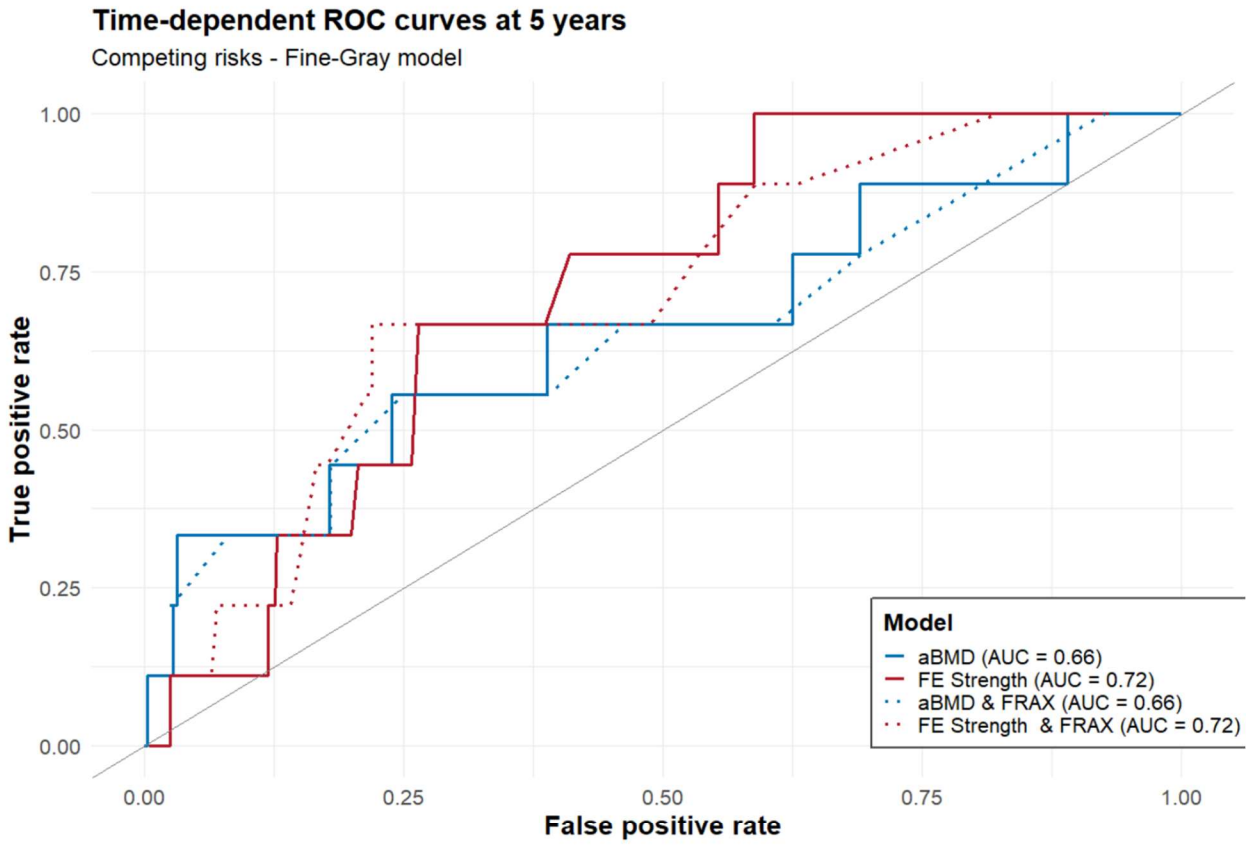

Figure 1: Receiver operating characteristics (ROC) curves for the predictions of the Fine-Gray models obtained using finite element (FE)-predicted proximal femoral strength (red) and areal bone mineral density (blue) as predictors. The dotted lines show the same predictions when FRAX scores were added as covariate to both predictons.

Phenotypic Variability in Developmental Dysplasia of the Hip: Linking Acetabular Geometry to Pain, Function, Activity, and Strength

Ms. Christina Bourantas BA, Ms. Emma Behrman, Dr. Keith Lohse PhD, PStat, Dr. John Clohisy MD, Dr. Michael Harris PhD

Washington University in St. Louis, St. Louis, Missouri, United States

Introduction

Developmental dysplasia of the hip (DDH) presents with a range of morphologic abnormalities, yet most studies consider affected individuals as a homogeneous group. This approach risks masking anatomical differences that may influence pain, function, and treatment response. Prior work showed geometric subgroups, like anterior or lateral coverage deficiencies, may be linked to patterns of intra-articular damage [1,2]. It remains unclear whether these subgroups also differ in activity or self-reported mobility and function. By classifying DDH using multiple measures of geometry rather than single radiographic thresholds, we aimed to capture phenotypic variability and examine how acetabular geometry may impact pain, function, activity, and strength.

Methods

18 individuals with DDH underwent radiographic assessment of lateral center edge angle (LCEA) and acetabular inclination (AI), along with 3D measures of anterolateral and posterolateral femoral head coverage [3]. Unsupervised K-means clustering using the elbow method [4] identified two geometric subgroups reflecting more versus less severe DDH. Participants wore a Fitbit for 7 days to record steps and heart rate; moderate activity was defined as minutes above 50% of estimated maximum heart rate. Self-reported outcomes included iHOT-12 and PROMIS Mental Health, Mobility, Pain Interference, Physical Health, and Anxiety. Isometric hip strength was assessed using a handheld dynamometer.

Results

Cluster 1 (more severe DDH), defined by decreased LCEA, lateral femoral coverage, and increased AI, demonstrated lower iHOT-12 scores and fewer daily steps than Cluster 2 (less severe DDH) (Table 1). Other self-reported outcomes were similar between clusters. Flexion strength was greater in Cluster 1, but abduction and extension were comparable.

Discussion

Geometric subgrouping captures some variability in pain, function, and activity. More severe acetabular deficiency was associated with reduced mobility and activity. However, small sample size limits generalizability and statistical power. Larger cohorts are needed to validate these preliminary cluster differences and determine whether geometric profiles consistently predict pain, mobility, and activity variation. Stratifying DDH by geometry may improve pre-operative assessment and inform personalized treatment strategies.

The Effect of Simulated Movement Training on Joint Forces in Patients with Hip Dysplasia

Ms. Madison Wissman, Dr. Molly Shepherd, Ms. Christina Bourantas, Dr. Michael Harris

Washington University in St. Louis, St. Louis, Missouri, United States

Introduction

Developmental dysplasia of the hip (DDH) is characterized by inadequate femoral head coverage, abnormal joint reaction forces (JRFs), high risk for early osteoarthritis, and functional limitations [1,2]. Patients with DDH may exhibit altered movement patterns [3]. Movement training rehabilitation aims to normalize kinematics during pain-evoking movements and has been shown to reduce pain and improve function [4]. However, its effect on joint loading is unknown, especially in DDH. Our objective was to quantify gait compensations in DDH and simulate movement training to assess its impact. We hypothesized that DDH kinematics differ from healthy gait, and that enforcing healthy kinematics would reduce hip JRFs.

Methods

We collected motion, electromyography, and ground reaction forces from 12 individuals with DDH and 15 controls without hip pathology. Patient-specific musculoskeletal models were created from magnetic resonance imaging using OpenSim. One representative gait cycle on the symptomatic limb was analyzed with OpenSim Moco to determine muscle forces and hip JRFs. Average “healthy” kinematics and ground reaction forces were computed from controls. Movement training was simulated by applying healthy kinematics to patients’ models. Joint angles and JRFs from patients’ natural motion and trained motion were compared using statistical parametric mapping.

Results

Natural kinematics revealed up to ±15° differences in flexion, adduction, and rotation from trained kinematics. Peak hip extension and abduction were larger during trained motion than natural motion. Trained JRFs were elevated in all directions during early stance; superior hip JRF was 50% greater at heel strike.

Discussion

Our hypothesis was partially supported; we observed differences between natural and trained joint angles, but JRFs increased with simulated training. Kinematic variation among patients may represent beneficial adaptations that prevent pain and reduce JRFs. Therefore, training toward one "healthy" gait pattern may not be beneficial in DDH. Movement training may be more effective for other activities (i.e. squat), with individualized target kinematics, or in conjunction with surgical intervention.

Dr. Felipe F. Gonzalez

Introduction

Rotational lower-limb deformities are associated with many conditions, including patellofemoral pain syndrome (PFP). The femoral neck version (FNV), an important rotational parameter of the lower limb, is essential in managing PFP. Traditionally, physical examinations using passive hip range of motion (ROM) have been used to estimate FNV. However, the accuracy of this method in patients with patellofemoral pain remains uncertain. This study aimed to investigate the relationship between passive hip ROM and FNV in patients with PFP.

Methods

In this retrospective cross-sectional study, 49 patients with PFP (73 symptomatic lower limbs) were evaluated. Passive hip ROM measurements, including internal and external rotation, abduction, flexion, and Ober and Thomas tests, were recorded using a digital inclinometer following validated protocols. FNV was measured on computerized tomography scans by using the posterior femoral condyle and the femoral neck as parameters. The associations between hip ROM and FNV were analyzed using Pearson

(normally distributed) and Spearman (non-normal) correlation coefficients, linear regression models, and ANOVA. Statistical significance was set at $p < 0.05$.

Results

The mean FNV was 13.2º (SD: 8.0º), ranging from 2º to 36º of anteversion. Weak but statistically significant correlations were found between FNV and hip internal ($r = 0.28$, $P = 0.015$) and external rotation ($r = -0.24$, $P = 0.036$). In the linear regression analysis, these variables remained significant predictors of FNV, with the model explaining a small portion of the variance (10.6%; $R^2 = 0.106$, adjusted $R^2 = 0.080$, $P = 0.02$). ANOVA across retroverted, normal, and anteverted groups showed a significant difference only for internal rotation ($P = 0.019$), with post-hoc analysis revealing a 7.6° greater internal rotation in the normal version group compared to the retroversion group. No other significant associations were found between FNV and the other passive ROM tests (Figure 1).

Discussion

Passive hip ROM was significantly associated with FNV in PFP patients but only explained a small part of its variance. Given the limited predictive value and multifactorial nature of PFP, these findings indicate that physical examination alone is insufficient to accurately assess femoral torsion in this population, reinforcing the need for imaging in clinical decision-making.

Understanding How People Prioritize Movement Goals During Overground Walking

Prof Patrick Slade, Ms. Jordan Feldman

Harvard University, Boston, MA, United States

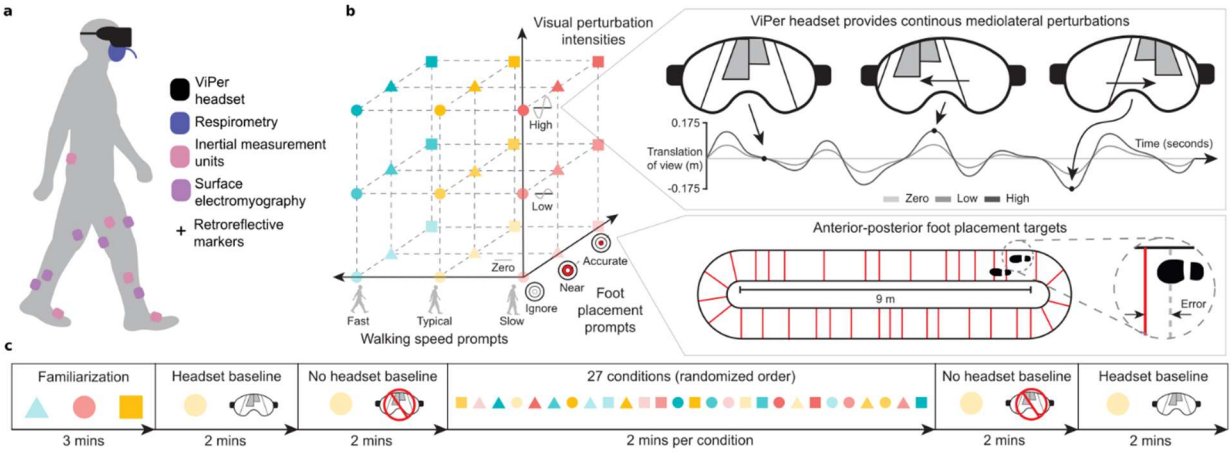
Introduction

Walking requires managing competing movement goals shaped by the demands of everyday activity. Several important goals during overground walking include maintaining a desired walking speed, achieving an intended foot placement, preserving postural and locomotor balance, and reducing energy expenditure. Biomechanical simulation and motor control-based methods use goal-related cost functions or structured models to identify people's movement priorities but are often restricted to simple movement scenarios and are currently impractical for broad deployment. Here, we systematically vary four movement goals during an overground walking experiment, characterize the resulting trade-offs in spatiotemporal gait metrics, and show that these trade-offs are sufficient to estimate participants' perceived ranking of movement goals.

Methods

Twelve healthy young adults (6 men and 6 women; age = 25.8 ± 3.7 years; body mass = 70.9 ± 10.2 kg; height = 1.75 ± 0.08 m) completed a series of walking conditions on an indoor track while wearing biomechanical measurement equipment and a visual perturbation headset (Fig. 1a). Participants performed a series of overground walking conditions guided by one of three walking speed prompts, foot placement prompts, and visual perturbation intensities, forming a three-by-three cube of 27 conditions (Fig. 1b). Baseline conditions were collected before and after the 27 conditions to determine if the unpowered visual perturbation headset altered participants' gait and evaluate if participants adapted to the headset over the course of the protocol (Fig. 1c).

Results



Gait metrics across participants became more heterogenous as combinations of movement goal prompts became more complex, suggesting person-specific movement strategies. Participants' perceived prioritization of movement goals showed systematic associations with corresponding gait metrics, with the strongest relationships observed for visually guided goals such as balance and foot placement. Subject-agnostic regression

models estimated the perceived order of importance of movement goals with 21% error, and subject-specific models reduced this error to 11%.

Discussion

Future studies could extend this framework toward more ecological and naturalistic contexts, incorporating additional goals and environmental factors to better approximate the complex prioritization processes that underlie mobility. This work establishes an approach for low-burden estimation of movement priorities and could support adaptive rehabilitation, personalized assistive devices, and an improved understanding of gait in real-world environments.

Biomechanical Factors Influencing Effort and Risk Trade-Offs in Walking

Ms Jackeline Tafur-Oviedo MS, PT, Prof James Finley PhD

University of Southern California, Los Angeles, California, United States

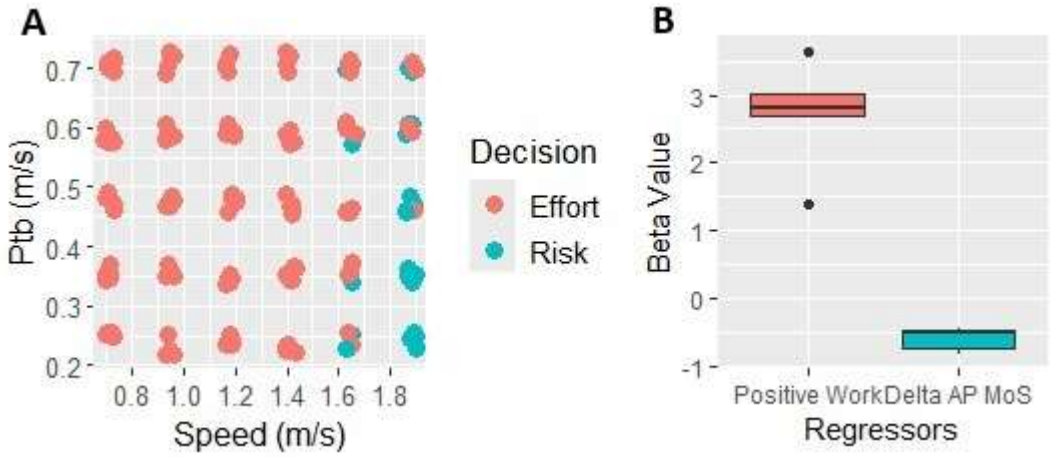
Ms Jackeline Tafur-Oviedo

Introduction

In challenging walking conditions, we may trade off physical effort to minimize the risk of falling. However, the extent to which these trade-offs guide walking remains limited. We propose that such trade-offs depend not only on walking conditions but also on the subjective value assigned to effort and risk. Here, we used a utility-based computational model to estimate how individual differences in biomechanical measures of effort and risk influence participants' walking decisions.

Methods

We asked participants to choose between pairs of experienced walking bouts that differed in physical effort and risk. In the Effort-Only Bout, the treadmill was set to one of six participant-specific walking speeds, while in the Risky Bout, participants walked while experiencing two unexpected increases in speed of 20%, 30%, 40%, 50%, or 60% of their self-selected speed. We quantified effort and risk using the total positive leg work during each bout and changes in antero-posterior margins of stability (AP MoS) in response to perturbations. We used these variables as predictors in a mixed-effect, logistic regression to estimate the probability of choosing the Risky Bout on each trial.



Results

Both effort, as measured by positive leg work, and risk, as measured by deviations in the AP MoS, were significant predictors in the logistic regression model. In general, participants were most sensitive to effort and preferred the Risky Bout when the speed associated with the Effort-Only Bout was high (Fig. 1A). In contrast, choices were less influenced by risk as the regression coefficients for effort were, on average, three times larger than those for risk (Fig. 1B). Overall, the regression model fit the decision data well with an area under the curve (AUC) of 0.83 and an accuracy of 0.76.

Discussion

When balancing trade-offs between risk and effort, young adults appear to make decisions that are largely explained by minimizing effort. Since our participants were willing to accept a greater level of risk to avoid exerting more effort, this may be attributed to their intact ability to recover successfully from balance disturbances. Ongoing studies will determine if age-related changes in balance capacity influence the trade-off between risk and effort.

Poincaré-Based Metrics Detect Cognitive–Motor Impairment During Dual-Task Gait

Ms Adeline Smith, Ms Juliana Bostock, Mr Colin Slavin, Mr Jacob Packer, Ms Cassidy Considine, Dr Kristin Morgan

University of Connecticut, Storrs, CT, United States

Introduction

When cognitive and motor tasks are performed concurrently, the increased load it places on the central nervous system can impair both cognitive performance and motor control [1]. The interference of cognitive and motor processes during dual-task conditions often manifests as changes in gait variability [1]. Quantifying changes in gait variability can be valuable for evaluating cognitive induced motor impairment. Here, we hypothesized that novel gait variability metrics would possess the sensitivity to detect cognitive-motor impairment induced disruptions in motor control.

Methods

Seventeen individuals (age: 22.0±3.1 years; height: 1.6±0.2m; mass: 65.5±13.8kg; gender: 12 females:5 males) performed a dual-ask cognitive-gait protocol. Participants walked on an instrumented treadmill for 3 minutes at a self-selected speed under single- and dual-task conditions: Auditory Stroop (AST), Visual Stroop (VST), and combined AST + VST task administered via a custom headset (Fig. 1).

Stride-time series for each limb were derived from consecutive strides collected from the treadmill. Poincaré analysis served to quantify stride time variability (Fig. 1) [2].

Differences in gait features (stride time, SD1, SD2, SD2/SD1, dual-task cost) across the single- and dual-task conditions, were assessed using Kruskal-Wallis tests with Dunnn-Šidák post hoc comparisons ($\alpha=0.05$).

Results

Poincaré-derived metrics revealed significant differences in gait variability across single- and dual-task conditions (Table 1). The combined AST+VST task produced a significant change in variability, reflected by a decreased SD2/SD1 ratio ($p<0.01$), despite note differences in mean stride time or dual-task cost. Additionally, SD2 was significantly reduced during the AST condition ($p=0.048$).

Discussion

The study demonstrated that Poincaré analysis is sensitive to cognitive-motor impairment-related alterations in motor control, by detecting changes not captured by traditional gait measures. These findings are significant and suggest that Poincaré-derived metrics could aid in the early identification of cognitive-motor dysfunction in pathological populations. Future work will investigate these metrics sensitivity to varying cognitive loads and whether it can serve as reliable biomarkers of impairment.

Effects of One Night of Sleep Deprivation on Gait: Evidence From Single- and Dual-Task Walking

Ms. Maura Seynaeve[1], Dr. Anna C. Render[2], Prof. Peter C. Fino[2], Prof. Toon de Beukelaar[1]

[1]KU Leuven, Leuven, Vlaams-Brabant, Belgium. [2]University of Utah, Salt Lake City, Utah, United States

Introduction

Sleep deprivation reduces higher-order cognitive control, potentially impacting movements that depend on these processes, like walking. To test whether gait changes after one night of sleep deprivation reflect reduced cognitive capacity, we compared its effects to those of dual-task walking, which similarly taxes cognitive resources. We hypothesize that sleep deprivation will produce gait changes similar to those under dual-task conditions.

Methods

We employed a randomized cross-over design to test eighteen healthy adults (9 female, 9 male; M=22.2 (s.d. 2.3) yrs) in two conditions: after a night of regular sleep (CON) and after a night of sleep deprivation (SDEP). The morning after each condition, participants completed two 2-min treadmill trials: single-task walking (ST) and walking with a concurrent 2-back working memory task (DT, dual-task). Using 3D marker trajectories of the lateral foot and pelvis, we calculated spatiotemporal gait variables, foot placement error (FPE) and mediolateral margin of stability (MoS_{ML}), along with variability of these measures. FPE was calculated as the difference in foot placement predicted by the center of mass (CoM) state and actual foot placement in antero-posterior (AP) and mediolateral (ML) directions [1]. Data were analyzed using linear mixed models with sleep condition and task as fixed effects and subjects as random effects.

Results

While SDEP increased average step time (CON: M=0.542 (s.d. 0.044) s; SDEP: M=0.549 (s.d. 0.046) s, $p<0.001$) and step length (CON: M=0.620 (s.d. 0.046) m; SDEP: M=0.627 (s.d. 0.048) m, $p=0.001$), DT reduced spatiotemporal variability. FPE_{AP} decreased in both SDEP (CON: M=0.010 (s.d. 0.002) m; SDEP: M=0.009 (s.d. 0.002) m, $p = 0.001$) and DT (ST: M=0.010 (s.d. 0.002) m; DT: M=0.008 (s.d. 0.001) m, $p<0.001$), while FPE_{ML} decreased in DT only (ST: M=0.010 (s.d. 0.002) m; DT: M=0.008 (s.d. 0.001) m, $p<0.001$). Additionally, mean

MoS_{ML} decreased only in SDEP (CON: M=0.093 (s.d. 0.010) m; SDEP: M=0.089 (s.d. 0.009) m, p=0.011).

Discussion

DT and SDEP influence gait through distinct mechanisms, affecting different spatiotemporal and stability metrics. Therefore, these findings suggest that the effects of sleep deprivation on gait cannot be fully explained by reduced cognitive resources alone.

Introduction

Divided attention, often induced by dual-task (DT) demands, is known to disrupt balance and increase fall risk during walking, particularly among older adults. However, its effects on the control variability of dynamic gait balance outside laboratory environments remain unclear. This study aims to identify the DT effects on gait balance control variability in older

adults using a single waist-worn inertial measurement unit (IMU) with artificial intelligence (AI) techniques in real-world community environments.

Methods

At the community centres, 102 older adults wore an IMU on the waist and completed two 10-m walking trials: a single-task (ST) walk, and a DT walk with an arithmetic task. For each trial, the IMU signals were filtered and segmented into individual gait cycles. These data were used as inputs to a validated physics-informed recurrent neural network model [1] to extract the inclination angles (IAs) between the body's centre of mass (COM) and the centre of pressure (COP) in the sagittal and frontal planes, as well as their rates of change.

For each participant, phase angles (PA) at each condition were obtained from the phase plots of the model-predicted IA. The root-mean-squared differences (RMSD) in the PA curves between conditions were calculated. The deviation phase (DP) of the PA was also calculated to quantify gait balance variability; a lower DP indicates smaller variability. A paired t-test was used to identify the DT effects on DP values during double-limb and single-limb support phases (α=0.05).

Results

The older adults exhibited similar coordination patterns of gait balance control during ST and DT walking, with RMSD values below 1°. During the double-limb support phase, they showed significantly higher DP values in the frontal plane during DT walking than during ST walking. No significant DT effects were found in any other variables.

Discussion

This study is the first to investigate the DT effects on gait balance control variability in older adults using an IMU with AI techniques in community settings. The findings revealed DT-induced alterations in gait balance control in ageing populations, potentially increasing fall risk. This approach demonstrates strong potential for real-life monitoring of gait balance.

Influence of Cognitive Dual-Task on Stride Frequency in Older Adults

Miss Haley Hentnik, Dr. Reed Gurchiek

Clemson University, Clemson, SC, United States

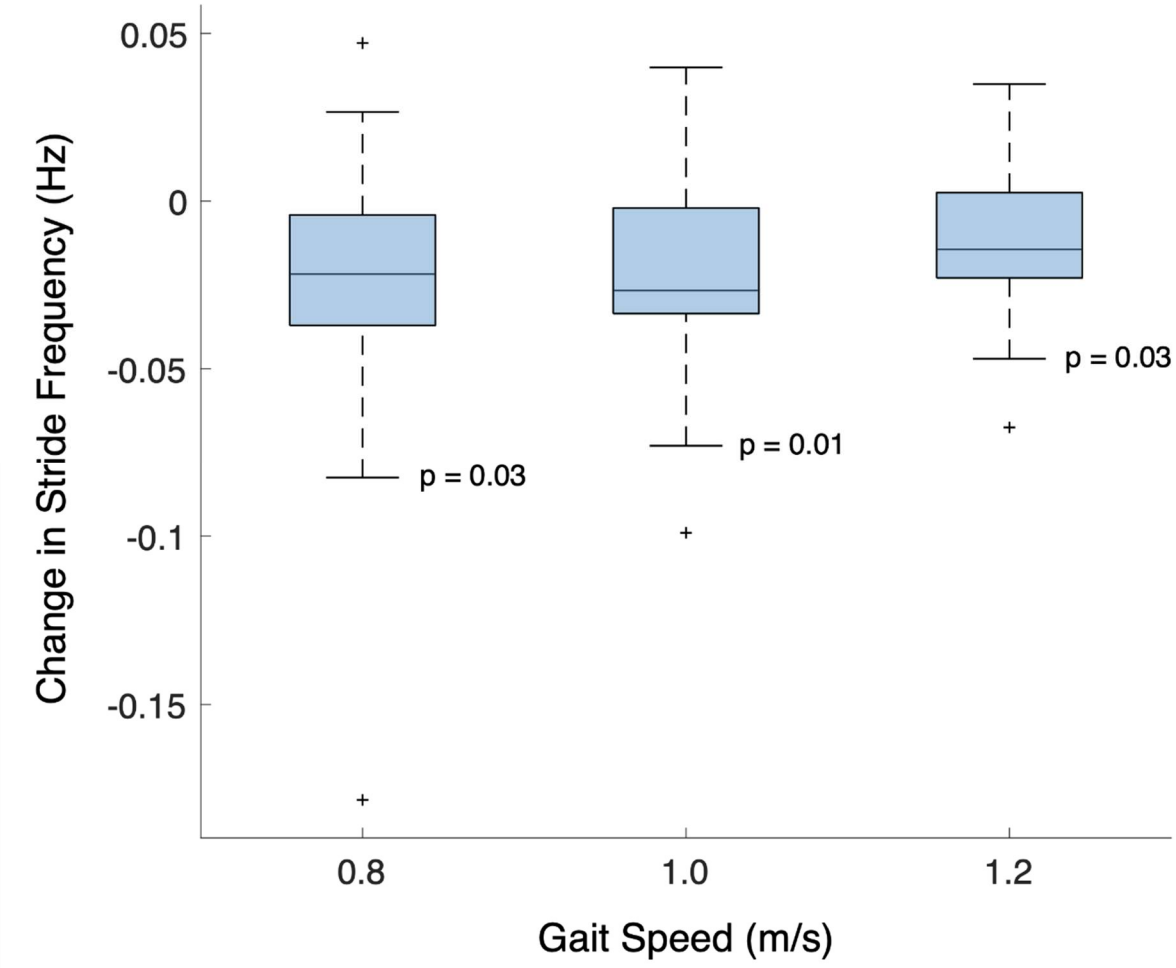
Introduction

Cognitive processes are thought to influence gait control to some extent based on observed within-person gait changes in cognitive dual-task gait. Reduced gait speed is commonly observed, a finding which contributes to initiatives that seek to leverage slow gait speed as a digital biomarker for cognitive impairment. However, a better understanding of the control principles that underlie speed changes may improve the specificity of gait-based biomarkers (since slow gait speed manifests in many clinical conditions). In our prior (unpublished) work, we observed changes in the speed-frequency relationship under dual-task conditions in healthy young adults. In this study, we conducted a similar experiment in older adults with variable cognitive abilities.

Methods

Nineteen older adults (mean age: 73 years, range: 65-92 years), ranging from high to low cognitive functioning, walked on a treadmill (0.8, 1.0, and 1.2 m/s) for 15 seconds both with a cognitive dual-task (sequential subtracting of serial 7's) and without (single-task gait). We calculated stride frequency using foot contact events identified from shank-worn gyroscope data. To determine the effect of the cognitive dual-task on the speed-frequency relationship, we performed a one-sample t-test on the person-specific differences in stride frequency observed during dual-task compared to single-task gait at each speed.

Results



Participants decreased stride frequency at each speed during the dual-task condition compared to single-task gait at all speeds (average change in stride frequency: -0.026 Hz for 0.8 m/s (p=0.03), -0.021 Hz for 1.0 m/s (p=0.01), and -0.012 Hz for 1.2 m/s (p=0.03)).

Discussion

Our findings suggest older adults adopt a lower stride frequency under cognitive dual-task conditions when compared with single-task walking at the same speed. However, while statistically significant, these changes were relatively small (the greatest average

difference, -0.026 Hz for 0.8 m/s, is only 3.12 steps per minute). In our prior (unpublished) work, we observed the opposite effect which was more pronounced during overground gait; a phenomenon we plan to explore in future work with older adults. Moreover, future work should explore potential explanations of the observed effect (e.g., based on control complexity or dynamic stability).

Why Foot Model Choice Matters: Rethinking Ankle Kinematics in Running Shoe Research

Dr. Jamie Ferris, Mr. Ben Hazelwood, Dr. Jinger Gottschall

New Balance, Boston, MA, United States

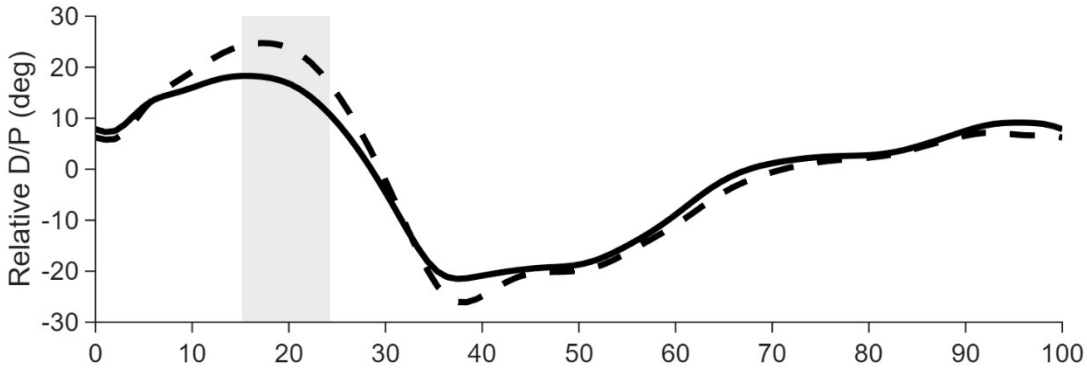
Introduction

Ankle kinematics during running are frequently estimated using a rigid mid- and rearfoot distal segment, despite midfoot deformation (Zelik & Honert, 2018). This study evaluated how this assumption influences ankle kinematic estimates and conclusions in footwear investigations.

Methods

Two cohorts of 10 experienced runners tested advanced footwear technology prototypes varying in (1) longitudinal bending stiffness (LBS) or (2) rocker geometry. LBS prototypes included: no plate, plate with medial-lateral cuts, lower-stiffness plate, and higher-stiffness plate. Rocker prototypes featured forefoot rockers with early, mid, or late onset. Ankle kinematics were computed using two different foot models: mid/rearfoot (calcaneal and metatarsophalangeal foot-mounted markers) and rearfoot (calcaneal markers only). Dorsi/plantarflexion (D/P) trajectories were compared using statistical parametric mapping RMANOVA of the angle after offset removal (angle – mean). Footwear effects under each model were analyzed with RMANOVA and Tukey's HSD ($\alpha = 0.05$).

Results



Foot model significantly altered ankle D/P trajectory, even after offset removal (Figure 1). With the rearfoot model, LBS had no effect on ankle kinematics. With the mid/rearfoot model, LBS influenced ankle kinematics including D/P ROM ($p < 0.001$; significant differences between no plate/lower stiffness and no plate/higher stiffness) and peak plantarflexion velocity ($p = 0.006$; cut/higher). Rocker geometry effects also differed between foot models. For example, stance-phase D/P ROM differed with the rearfoot model ($p < 0.001$; mid/late), while stride D/P ROM differed with the mid/rearfoot model ($p = 0.020$; early/late).

Figure 1. Average D/P angle after offset removal (angle – mean) throughout the stride cycle using mid/rearfoot (solid) and rearfoot (dashed) foot models. Shaded regions indicate significant differences.

Discussion

Assuming mid/rearfoot rigidity produced D/P trajectory differences and changed conclusions about footwear effects in both cohorts. These findings underscore the importance of anatomically valid foot models in footwear and running research.

Evaluating the Shifty Agility Drill: Repeatability and Footwear Sensitivity of a Novel Court Sport Agility Test

Lead Researcher Bryan Picco M.S., Senior Researcher Jason Hashimoto M.S., Senior Researcher Amanda Cann M.S., Director of Footwear Research Elysia Davis Ph.D.

Nike Sport Research Lab, Beaverton, OR, United States

Introduction

Athletic footwear should support sport-specific demands, yet agility drills can lack relevance, repeatability [1], and sensitivity to footwear effects. This study introduces the Shifty Agility Drill for court sports like basketball, evaluates its repeatability, and tests if drill performance varies with footwear. These insights can guide designers in creating shoes that measurably enhance agility.

Methods

The Shifty Agility Drill consists of two forward steps (left foot first), a lateral cut around a mannequin off the right foot into a left foot euro-step, and two steps toward the hoop simulating a lay-up (Figure 1). Ten athletes (93±13.1 kg; 31.6±2 yrs) performed the drill in two footwear conditions. A counterbalanced crossover design (Shoe 1–Shoe 2–Shoe 2–Shoe 1; order randomized) was used, with seven trials per condition block. Ten step-back jump shots were performed between blocks as active recovery. Motion capture (250hz), force plates (2500hz), and timing gates recorded performance.

Each shoe's mechanical properties differed. Shoe 1 was lighter (333.6 g), flexible (bending: 6.4 Nm; torsional: 348 Nmm/deg), with lower traction (DCOF: 1.06), higher impact peak (33.1 G), and lower energy efficiency (61%). Shoe 2 was heavier (355.8 g), stiffer (bending: 12.1 Nm; torsional: 472 Nmm/deg), with greater traction (DCOF: 1.14), reduced impact peak (13.2 G), and higher energy efficiency (79%).

Statistical analyses included coefficients of variation (CV1, CV2) to assess repeatability and paired t-tests to evaluate footwear sensitivity. Bland–Altman analyses assessed agreement. Two-tailed paired t-tests compared total drill and cut step times between shoes for sensitivity to footwear.

Results

The drill demonstrated strong repeatability, with mean CV1 and CV2 values ≤0.0608 and ≤0.0660. For the cut step, Shoe 1 showed lower variability (CV1: 0.0536 vs 0.0608; CV2: 0.0494 vs 0.0660). Bland–Altman analyses revealed trivial biases and symmetric variability across blocks. Shoe 2 was significantly slower than Shoe 1 ($p < 0.05$) in total drill (≈0.031 s) and cut step times (≈0.01 s)

Discussion

The Shifty Agility Drill demonstrated strong repeatability and was sensitive to footwear differences, supporting its use as a reliable, sport-relevant tool for evaluating footwear performance.

On-Field Validation of Second-Generation Female-Specific Soccer Cleats Using Wearable Sensors and Predictive Computational Modeling

Dr. Alex Denton PhD[1], Ms Danielle Page MS[2], Mr Rory Tatterton BEng[2], Ms. Laura Healey MS[2], Mr. Maximilian Grüttner MS[2], Dr. Michael Hahn PhD[1]

[1]University of Oregon, Eugene, Oregon, United States. [2]PUMA SE, Herzogenaurach, Bavaria, Germany

Introduction

Soccer cleats are historically designed based on male biomechanics, which may contribute to greater anterior cruciate ligament (ACL) injury risk in female athletes [1]. However, soccer cleat traction and lower limb mechanics of female athletes can be modified through stud parameters [2]. We identified optimal stud length, shape, and position in our initial female-specific soccer cleat prototypes 1.1 & 1.2 [3 & 4] and further optimized prototype 2.0 for evaluation in the present study. It was hypothesized that prototype 2.0 would reduce the overall mechanical demand of the knee during lateral cutting maneuvers pre- and post-fatigue.

Methods

Fifteen competitive female soccer athletes (20.3±2.1 yrs, 163.6±5.8 cm, 64.2±6.2 kg) performed unanticipated lateral cutting maneuvers targeting 120° from a running approach at 80% of perceived maximum velocity on an artificial turf field in the PUMA Future 8 and prototype 2.0 cleats on separate days. Athletes were tested pre- and post-Shuttle Fatigue Protocol, consisting of a 180 m sprint and 1440 m run with cutting steps every 30 m. Knee mechanics indicative of ACL injury risk were estimated using predictive model ensembles driven by insole pressure data (XSensor, 100 Hz). A two-way repeated measures ANOVA (cleat x fatigue) with Tukey HSD was used to evaluate knee mechanics.

Results

Peak knee flexion angle was 13.5% greater, and anterior shear force was 9.7% lower in prototype 2.0 ($p<0.001$ and $p=0.02$, respectively) (Figure 1). No significant differences were observed for valgus angle, internal knee extensor moment, or external knee valgus moment ($p>0.05$). Fatigue did not significantly affect knee mechanics ($p>0.05$).

Discussion

Prototype 2.0 demonstrated promising potential to reduce the risk of ACL injury among female soccer athletes by lowering the overall mechanical demand at the knee. However,

the absence of significant changes in frontal plane mechanics suggests future iterations may further benefit from design innovations targeting valgus loading. A refined version of prototype 2.0 will be released in anticipation of the 2027 Women's World Cup.

Wrapping Cycling Shoes Improves Cycling Performance Over Laces

Dr. Eric Honert, Ms. Milena Singletary, Ms. Bethany Kilpatrick, Mr. Adam Luftglass, Dr. Daniel Feeney, Dr. Kathryn Harrison

BOA Technology Inc., Denver, CO, United States

Introduction

Cycling shoe fit systems vary between BOA, Velcro, Lace, amongst others. BOA wrapping fit systems can improve performance over shorter durations compared to Velcro by increasing steady-state power output at a similar energy expenditure and increasing sprint power [1]. Physical exhaustion impacts cycling energy expenditure [2], and fit systems may impact energy expenditure after exhaustion. This study evaluated the differences between BOA and Lace fit systems prior to and after exhaustion.

Methods

This two-part study compared lace (Lace) and wrapping BOA (Wrap) shoes. First, nine participants completed two trials in each footwear condition. Each trial included 4 minutes at 80% of functional threshold power and a 10-second maximal sprint. Heel contact area (HCA) and peak power were extracted from the steady-state and sprint portions, respectively. Separately, participants underwent two testing sessions, using a different shoe for each session. Gas exchange was collected for five minutes before and after an exhaustion protocol (similar to [2]). Net energetic expenditure (netEE) was evaluated during the last two minutes. Bayesian linear mixed models were used to estimate differences between outcomes. The percentage of the posterior above zero (% Post.) and average difference is presented for each metric.

Results

In the first portion, the HCA was 6.6% higher in the Wrap shoe compared to the Lace (%Post: 95%). The peak sprinting power was 2.5% greater in the Wrap shoe (%Post: 96%). In the second portion, the Wrap shoe reduced netEE by 1.7% (%Post: 86%) prior to the exhaustion protocol. The difference increased to 2.2% (%Post: 88%) after the exhaustion protocol.

Discussion

This study examined how fit systems impact energy expenditure after physical exhaustion. The 2% improvement in energy expenditure in the Wrap shoe is similar in magnitude to changes observed in running shoes with supercritical foams, which are the standard in

marathon racing. The improvement in energy expenditure, as well as sprint performance, in the Wrap shoe is likely due to improved fit quantified by increased heel contact area.

Effects of Advanced Footwear Technology (AFT) on Running Biomechanics

Hyeong-Sik Kim M.S.[1], Jae-Won Kang M.S.[1], Yun-Bae Jeong M.S.[1], Jungmin Yoon M.S.[1], Dr. Sejin Kong Ph.D.[2], Prof. Sang-Kyoon Park Ph.D.[1]

[1]Korea National Sport University, Seoul, Seoul, Korea, Republic of. [2]LS Networks, Seoul, Seoul, Korea, Republic of

Introduction

Running mechanics are influenced by external factors such as surface conditions and footwear [1]. Carbon-plated shoes have recently been developed to improve mechanical efficiency by enhancing energy transfer and lowering metabolic cost. However, previous research has mainly examined the presence or stiffness of carbon plates, leaving the influence of carbon-plate curvature on joint mechanics and running efficiency unclear. This study investigated whether curvature variations improve mechanical efficiency and performance.

Methods

Participants were ten male recreational runners who ran over 20 km per week, including three trained middle and long distance athletes. They tested three shoe conditions: (1) a carbon-plated running shoe, (2) a lightweight carbon-plated shoe with enhanced cushioning, and (3) a customized shoe with modified carbon plate curvature. All runners completed trials on an instrumented treadmill at 3.3 m/s and 4.0 m/s in randomized order. For each condition, they performed a 5-minute familiarization, and the final minute was analyzed. Kinematic data were recorded at 100 Hz, and ground reaction forces at 1,000 Hz. A one-way repeated-measures ANOVA assessed biomechanical differences.

Results

Shoe 3 demonstrated greater stride and step length with a corresponding reduction in step frequency compared with Shoe 1. Furthermore, Shoe 3 exhibited increased ankle range of motion and higher ankle joint power than Shoes 1 and 2. In addition, Shoe 3 generated a larger propulsive ground reaction force during running compared with Shoe 1.

Discussion

Carbon plates enhance energy transfer and alter lower extremities mechanics during running [2]. In this study, the increased stride parameters, greater ankle motion, and higher

ankle power and propulsion in Shoe 3 indicate that modified carbon-plate curvature improves ankle mechanical efficiency, suggesting its importance as a design factor for enhancing running performance.

Tornadic Phenomena in Cerebral Aneurysms: Towards New Definitions of Hostile Hemodynamics

Dr. Valentina Mazzi PhD[1], Prof. Diego Gallo PhD[1], Dr. Thangam Natarajan PhD[2], Dr. Jonas Schollenberger PhD[3], Dr. Karol Calò PhD[1], Prof. David Saloner PhD[3], Prof. David A. Steinman PhD[4], Prof. Umberto Morbiducci PhD[1]

[1]Politecnico di Torino, Torino, Piemonte, Italy. [2]Georgia Institute of Technology, Atlanta, Georgia, United States. [3]University of California, San Francisco, San Francisco, California, United States. [4]University of Toronto, Toronto, Ontario, Canada

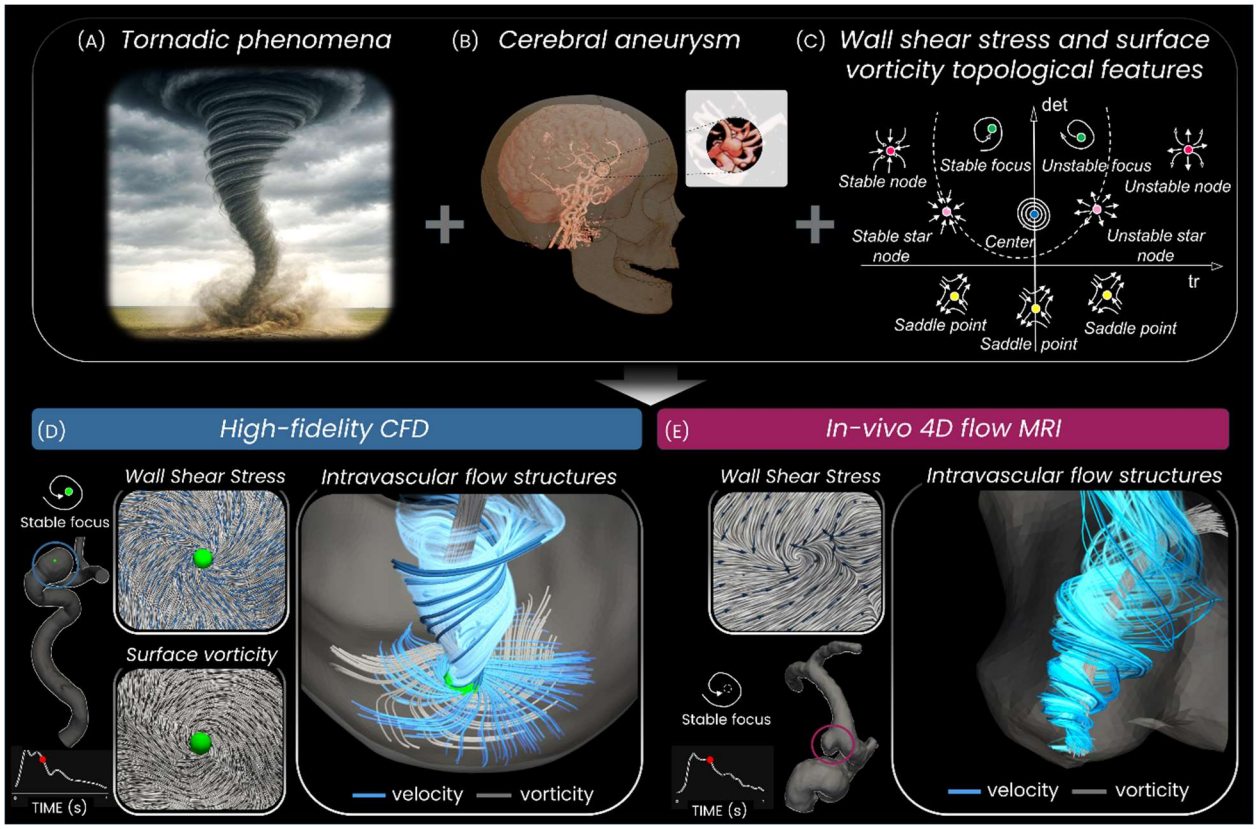
Introduction

Extreme atmospheric events arise when intense airflows, such as tornadoes, produce damaging effects upon interacting with the ground (Figure 1A). Cerebral aneurysms (CAs, Figure 1B) can also develop complex hemodynamic environments shaped by their anatomy and pulsatile inflow. Recent work linking wall shear stress (WSS) topology to near-wall vorticity has shown that specific vortical structures imprint characteristic “ground effects” on the vessel wall [1]. Despite differences in underlying physics, we demonstrate that CAs can exhibit a spectrum of previously unrecognized tornadic-like flow phenomena that can be identified through a topology-based taxonomy, providing a mechanistic alternative to elusive notions of “hostile hemodynamics”.

Methods

CA hemodynamics were analyzed using high-fidelity computational fluid dynamics (CFD) simulations [2]. WSS fixed points (Figure 1C) were extracted [3], and their dynamics were analyzed. The topology-based taxonomy, grounded in the theoretical relationship between WSS and near-wall vorticity [1], enabled unambiguous identification of tornadic phenomena in the near-wall domain. 4D flow MRI datasets were analyzed to validate *in vivo* the presence of these tornadic fluid structures.

Results



According to the adopted topology-based taxonomy, a tornado-like fluid structure in the near wall emanates from a WSS (and surface vorticity) stable focus, whose presence is revealed by the configuration of instantaneous velocity streamlines wrapping around vorticity lines (Figure 1D, CFD data). The existence of tornado-like structures and their imprints on the wall was further confirmed *in vivo* using 4D MRI (Figure 1E). Additional

atmospheric analogues, including downbursts, multiple-tornado systems, tornado-downburst combinations, and roll clouds, were likewise identified in CAs when the proposed taxonomy was applied.

Discussion

By translating concepts from atmospheric physics to vascular biomechanics, and specifically considering ground-effects analogues, this study elucidates how rotational and non-rotational fluid structures analogous to tornadic phenomena may impose distinct mechanical stimuli on the aneurysm wall. These stimuli may contribute to inflammation, remodeling, and eventual rupture. The agreement among theory, CFD simulations, and *in vivo* measurements highlights the translational potential of the topology-based framework for standardized hemodynamic phenotyping and improved risk stratification.

Effect of Estrogen on Thoracic Aortic Aneurysm Development and Progression in a Mouse Model of Marfan Syndrome

Professor Jessica Wagenseil Jessica, Dr. Krashn Dwivedi krashn, Ms. Yufan Wu Viola

Washington University in Saint Louis, Saint Louis, Missouri, United States

Introduction

Thoracic aortic aneurysm (TAA) is a life-threatening disorder involving progressive aortic dilation and rupture risk [1]. TAA is associated with Marfan syndrome (MFS) [1]. Despite similar prevalence of MFS in males and females, TAA progression and outcomes differ significantly by sex [1, 2]. This study investigates how sex hormones, specifically estrogen, contribute to sex-specific TAA growth and adverse events using a mouse model of MFS.

Methods

A severe mouse model of MFS (*Fbn1*$^{mgR/mgR}$ = MU) was used in this study. Mice exhibiting marked dilation at 30 days of age (defined as a diastolic diameter in MU mice at least ~1.2× that of their WT littermates) were included. 30 day old male MU mice had either a 17-β estradiol (bioactive estrogen) or a placebo pellet (release rate 0.25 mg/day for 60 days) subcutaneously implanted. In 30 day old female MU mice, either bilateral oophorectomy (BO) or sham surgery was performed (Fig. 1A). The ascending aortic (ASC) diameter of each mouse was then measured using ultrasound every 7 days for the entire lifespan. An autopsy was performed on each mouse after death, and the ASC was dissected. Multiphoton microscopy was performed to assess extracellular matrix (ECM) remodeling in the aortic wall.

Results

Figs. 1B–F show changes in ASC diastolic diameter with age and Figs. 1G-J show multiphoton images of the ECM after ASC dissection. Estrogen-treated male MU mice exhibited slower TAA progression and longer survival than placebo-treated male MU mice. BO-operated female MU mice displayed a marked acceleration in TAA growth and substantial ASC enlargement compared to sham-operated female MU mice. Both placebo-treated males and BO-operated females demonstrated severe elastic fiber fragmentation and increased collagen deposition in the ASC wall.

Discussion

Our preliminary results suggest that estrogen contributes to the sex-specific differences in TAA progression and outcomes in MU mice. This study is ongoing, and we are continuing to collect data to further clarify how estrogen influences vascular mechanics, ECM remodeling, and gene-regulatory pathways during TAA development and progression.

Geometry-Aware Abdominal Aortic Aneurysm Digital Twins for Patient-Specific Wall Stress Mapping

PhD Candidate Julian Carvajal Rico[1], M.D Satish C. Muluk[2], M.D Mark K. Eskandari[3], PhD Ender A. Finol[1]

[1]Department of Mechanical, Aerosp., and Ind. Engineering, UT San Antonio, San Antonio, TX, United States. [2]Department of Cardiothoracic Surgery, Allegheny Health Network, Pittsburgh, PA, United States. [3]Division of Vascular Surgery, Northwestern University School of Medicine, Chicago, IL, United States

Introduction

Abdominal aortic aneurysm (AAA) rupture risk is assessed largely by geometric surrogates (maximum diameter and growth rate), despite evidence that rupture depends on the balance between wall stress and wall strength. In the present work, we frame each image-derived reconstruction as a geometry-aware digital twin and study fast graph-based surrogates that map individual anatomy to clinically relevant wall stress endpoints.

Methods

Computed tomography angiography (CTA) scans from a multi-institution cohort were processed as geometry-aware digital twins. CTA images were segmented using a U-Net pipeline with expert refinement **(Fig.1b)**. Outer wall surfaces were standardized to nodes and enriched with node-wise descriptors, wall thickness, thrombus thickness, principal/mean/Gaussian curvature, and centered coordinates **(Fig.1c)**. Finite element analysis (FEA) simulations provided the ground truth wall stress fields, which were projected onto the outer wall surface **(Fig.1d)**. We compared two Graph Neural Network (GNN) families; GraphSAGE as a scalable inductive baseline for graph-level endpoints and a Graph Transformer (GT) with edge-aware, relative positional encodings for long-range interactions. Both yielded wall stress predictions as in **Fig.1e**. During the training process we used standardized features, AdamW, early stopping, and tail-aware readouts/losses; evaluation included graph-level RMSE-R^2, node-level errors, and spatial correlations versus FEA.

Results

For an exemplary AAA shown in **Fig.1f**, the best-performing GT model reproduced the FEA wall stress distribution with close agreement in both central tendency and tail behavior. The FEA-derived stress field had a mean of 2.54 N/cm^2 and 99th percentile of 12.19N/cm^2, whereas the GT predictions yielded a mean of 3.81 N/cm^2 and 99th percentile of 12.00

N/cm^2. Spatially, high stress regions along the sac and neck were preserved, and the corresponding histograms, PDFs, and ECDFs show near overlap across most of the distribution with mild deviations in the extreme tail.

Discussion

Treating CTA reconstructions as AAA digital twins enables patient-specific, near real-time wall stress mapping once models are trained. GraphSAGE suits rapid prediction of scalar endpoints, while GT improves full-field fidelity and tail calibration, better representing biomechanically coupled regions such as sac–neck interactions. This geometry-aware, graph-based pipeline reduces reliance on time-intensive simulations and is extensible to other vascular surfaces naturally represented as meshes.

Reversal of Dominant Loading Direction Along the Cervical Spine During Multidirectional Head Resistance: Insights From a Nonlinear 3D FE Model

Dr. Wissal Mesfar[1], Dr. Kodjo Moglo[2]

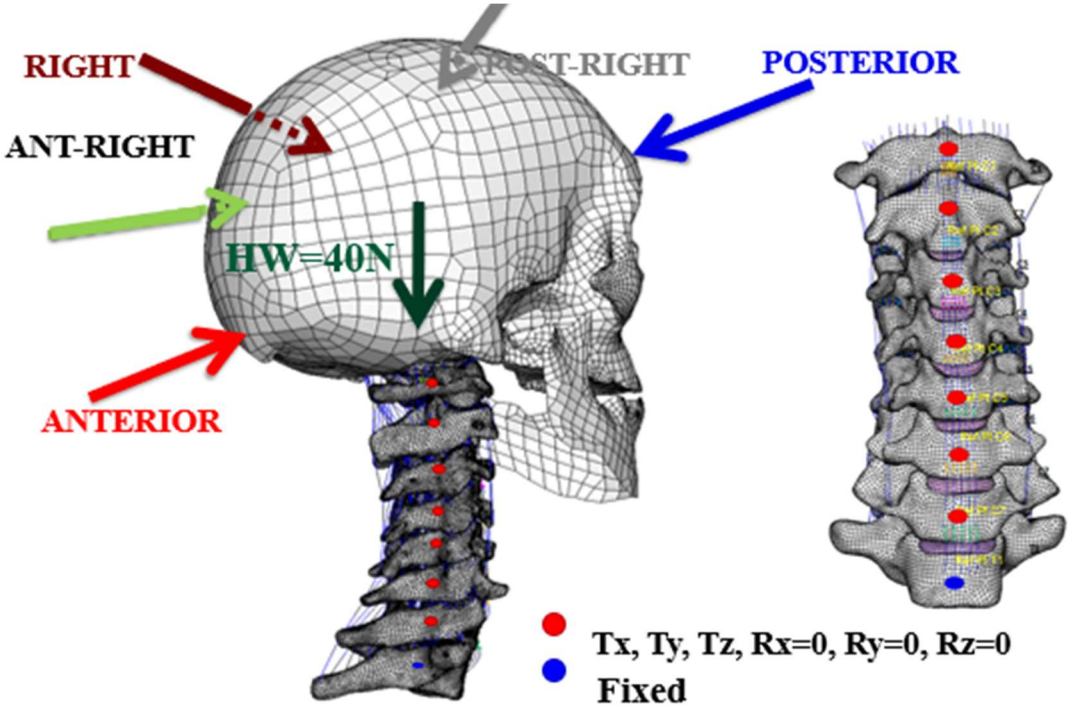
[1]King Saud University, Riyadh, Riyadh, Saudi Arabia. [2]Royal Military College of Canada, Kingston, Ontario, Canada

Introduction

Quantifying stabilizing muscle moments along the head–neck (HN) complex is essential for understanding cervical loading and predicting muscle forces. Global neck-strength measures, however, provide only overall head force and cannot detect how mechanical demands vary or shift across cervical levels. This study addresses this limitation by determining the isometric muscle moments required at each HN bony structure to resist multidirectional axial-plane loads under physiological head weight, providing the level-specific data needed for accurate cervical muscle modeling.

Methods

A validated 3D nonlinear finite element (FE) model of the HN complex was used to simulate resistance to external static loads. Forces ranging from 25–150N were applied at the head in five directions—Anterior, Posterior, Right, Anterior-Right, and Posterior-Right—while a constant 40N head weight acted at the center of mass. The T1 vertebra was fixed, while the head and cervical vertebrae were allowed translations but not rotations, reproducing the constraint normally imposed by coordinated muscle action. Reaction moments at the head and at vertebral levels C1–C7 were extracted as the net muscle moments required to maintain neutral posture. All simulations were performed using Abaqus 6.14.



Results

Stabilizing moments increased nearly linearly with load at all cervical levels. At the head, moments ranged from ≈1.7N·m (25N) to 10.1N·m (150N) under posterior loading, the highest across all directions. Right-directed loading produced the lowest head moment (≈1.1–6.4N·m). Mid-cervical levels (C3–C6) showed a directional reversal: right-directed loads generated the largest moments (≈3.5–4.2N·m at 150N) versus posterior loading (≈2.6–3.0N·m). Upper levels (C1–C2) showed minimal directional variation, while lower levels (C7) had low demands (<2N·m), highlighting strong level- and direction-specific differences.

Discussion

The head experiences the highest stabilizing moments—up to 10.1N·m—reflecting its long lever arm. Mid-cervical levels exhibit a reversal of dominant loading: right-directed moments exceed posterior by ≈30–40%, showing that moment transmission is segment-specific and shaped by vertebral geometry and soft tissues. Low C7 moments (<2N·m) indicate its supportive role. These patterns demonstrate that global neck-strength measures cannot capture the pronounced segmental and directional variations revealed by detailed FE modeling.

Late-Stage Knee Osteoarthritis Patients with Joint Pain Experience Small Variability in Knee Joint Contact Forces During Walking

Doctoral Researcher Fatemeh Jalali[1], Postdoctoral Researcher Amir Esrafilian[1], Postdoctoral Researcher Atte Eskelinen[1], Associate Professor Lauri Stenroth[1], Project Researcher Paavo Vartiainen[1], University Researcher Laura Säisänen[1,2], Professor Petro Julkunen[1,2], Professor Petteri Nieminen[3], Professor Rami K. Korhonen[1]

[1]Department of Technical Physics, University of Eastern Finland, Kuopio, North Savo, Finland. [2]Department of Clinical Neurophysiology, Kuopio University Hospital, Kuopio, North Savo, Finland. [3]Institute of Biomedicine, University of Eastern Finland, Kuopio, North Savo, Finland

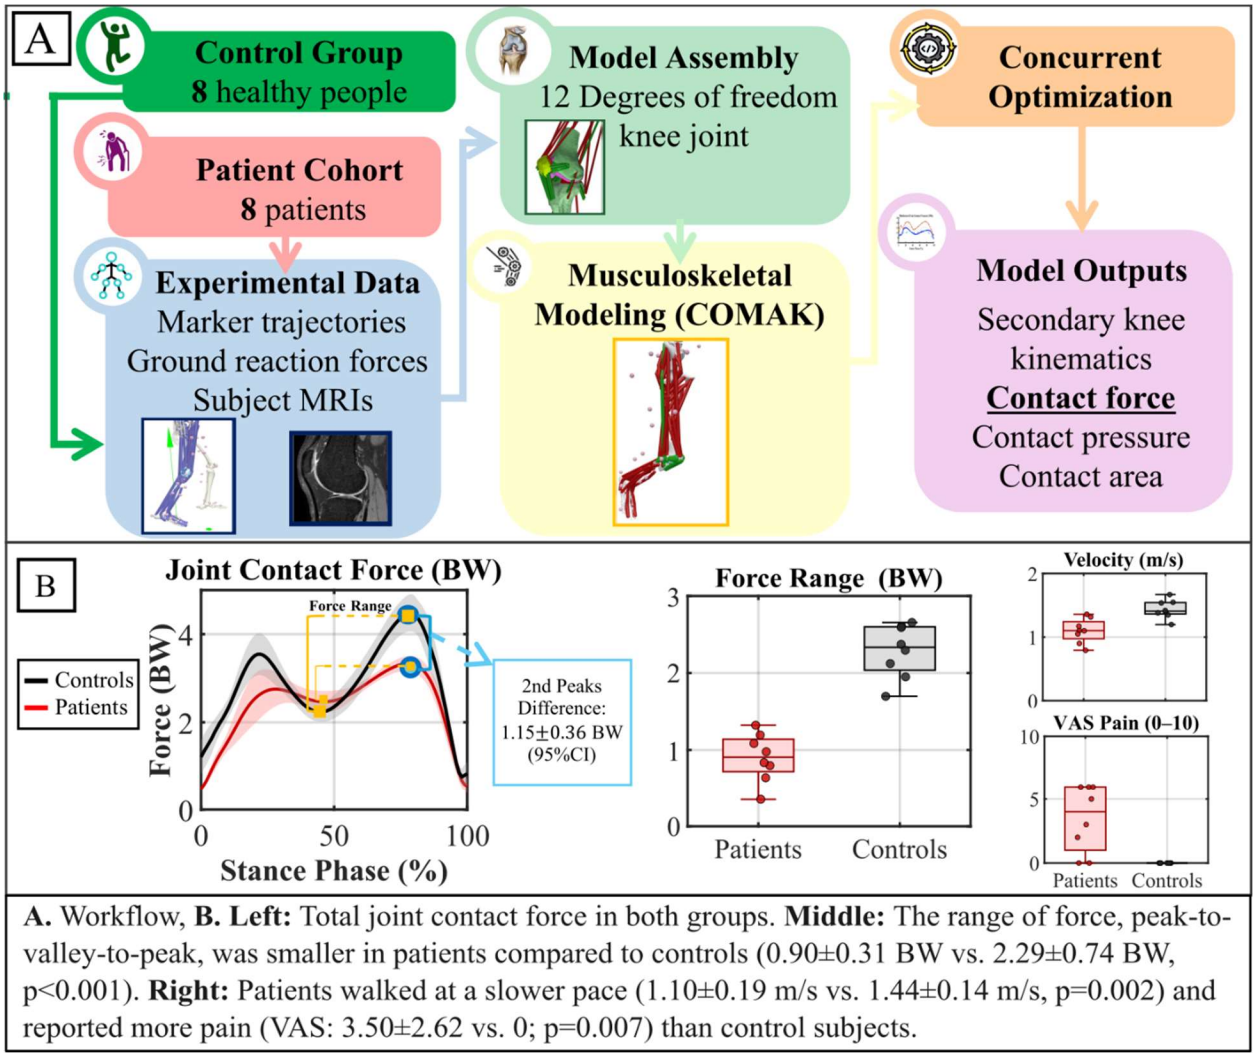
Introduction

Gait biomechanics in late-stage knee osteoarthritis (KOA) patients is poorly understood, partly because standard musculoskeletal models assume normal joint structure, which can lead to inaccurate force estimates in osteoarthritic knees. As patients often experience prolonged pain before surgery, understanding altered joint loading could support non-surgical pain relief. Using the Concurrent Optimization of Muscle Activations and Secondary Knee Kinematics (COMAK) framework, we estimated subject-specific joint contact forces (JCFs) in patients with self-reported joint pain and severe KOA.

Methods

16 participants were recruited, including 8 patients with late-stage KOA and 8 healthy controls. The patients met criteria for moderate to severe radiographic changes and joint pain [1]. Motion data, including marker trajectories and ground reaction forces, were collected during five gait trials at habitual walking speed for both groups. Additionally, Visual Analogue Scale (VAS) pain scores were obtained from patients before surgery. We utilized a musculoskeletal model with a personalized 12-degree-of-freedom knee model, based on MRI scans [2] (Fig. 1), and simulated the movements using the COMAK algorithm.

Results



Controls had higher total and compartmental JCF peaks than patients, with the second peak greater by 1.15±0.36BW ($p<0.001$) (Fig. 1). Beyond peak magnitudes, the within-stride force range between peaks (peak-to-valley-to-peak) was smaller in patients than controls, indicating a flatter mid-stance profile in late-stage KOA (0.90±0.31 vs. 2.29±0.74BW,

p<0.001). Patients walked slower (1.10±0.19 vs. 1.44±0.14m/s, p=0.002) and reported more intense pain (VAS: 3.50±2.62 vs. 0; p = 0.007) compared to controls. Within the patient cohort, pain showed no significant correlation with any biomechanical parameter (p>0.05).

Discussion

The reduced peak force and force variability in late-stage KOA patients during walking likely resulted from pain that can trigger compensatory strategies, such as reduced walking speed and altered gait. Yet, pain alone did not have a direct correlation with the JCF. It may be that more patients with larger variability in pain scores are needed, or pain is influenced by multiple factors, including biochemical and biological elements [1].

Neuromusculoskeletal Control of Foot Stabilization During Ground Contact

Dr. Michael Asmussen[1], Dr. Simon Danner PhD[2]

[1]Vancouver Island University, Nanaimo, BC, Canada. [2]Drexel University, Philadelphia, Pennsylvania, United States

Introduction

Neuromuscular control of stabilization of the foot during locomotion can involve both anticipatory muscles (co-)activation in expectation of a perturbation and feedback-driven neural responses once a perturbation occurs during the early stance phase. Relying solely on human experimentation limits our ability to sytematically probe these mechanisms (i.e., participant safety reasons). Here, we present a neuromechanical model that helps overcome these limitations and allows us to examine how the human foot adapts to ground perturbations during early stance.

Methods

The model included twelve muscles that control an ankle joint with three degrees of freedom [1]. Ligaments crossing the ankle joint were modelled as bushing torques derived from cadaveric data. We added a simulated neural network such that each muscle was controlled by a population of motoneurons activated by descending drive. Ia spindle and Ib Golgi tendon feedback of all muscles was connected to the network to simulate stretch reflex pathways, Ib disynaptic excitation and inhibition, recurrent inhibition, and phasic presynaptic inhibition of Ia afferents [2].

The neuromusculoskeletal model received simulated perturbations similar to locomotion forces. Multi-objective optimization that minimized ankle torques, ligament torque, and metabolic power was used to find weights of the synaptic connections in the neural model. The model was trained with and without neural feedback. To assess the contribution of afferent feedback to ankle stabilization, simulations with feedback connections silenced were performed.

Results

When the model was trained with feedback, but tested without it (Fig. 1A, B), the foot exhibited excessive dorsiflexion and stabilizing it required substantially increased ligament force. Models trained with and without feedback exhibited similar kinematic responses to

perturbations (Fig. 1C), but afferent feedback reduced metabolic cost by limiting muscle pre-activation (Fig. 1D).

Discussion

During locomotion, afferent feedback is important for economical and safe foot control; without it, the model either over-loads ligaments or uses excess energy to maintain stability.

Neuromuscular Modeling of the Human Eyelid

Mr Jinyoung Kim, MD Daniel Rootman, Dr Tyler Clites

University of California, Los Angeles, Los Angeles, CA, United States

Introduction

Crucial eyelid functions are driven by the *orbicularis oculi* muscle (OOM). We showed in a recent study that precise spatiotemporal control of the OOM drives different eyelid motions to perform specific functions [1]. Current eyelid models are based on statistics, and cannot recapitulate this complex relationship between OOM activation and eyelid motion [2]. Neuromuscular models (NMM) based on mechanistic dynamics offer a more complete understanding of this relationship. We present a new NMM architecture for the eyelid, built around segmental control of the OOM.

Methods

The model was built using OpenSim Creator (Fig. 1A). The OOM is designed as a series attachment of four Hill-Type muscle actuators across the eyelid. Ligaments, tendons, and levator palpebrae superioris (LPS) were modelled as passive springs to support eyelid weight and stabilize the initial condition of the eyelid-open position. The model is simulated using OpenSim Computed Muscle Control (CMC). Eyelid kinematics were derived from motion capture tracking of five markers spread across the upper eyelid margin during different blink types. Muscle excitations (U1-U4) calculated by CMC were compared to EMG data collected from bipolar fine wire electrodes (Fig. 1B) during the same behaviors.

Results

CMC results showed that input kinematics can be well tracked by the model with reserve and residual force less than 0.1 N (Fig 1C). Simulation results showed similar spatiotemporal activation patterns in the OOM to experimental data. To be specific, the medial electrodes (U1 and U2) showed a faster onset time and higher amplitude than the lateral electrodes (U3 and U4) during spontaneous blink, but not during reflex blink. This medially biased activation pattern causes eyelid movement in the medial direction during closure, which is critical to spontaneous blink function.

Discussion

A predictive mechanistic NMM would have critical implications for diagnosis and treatment of eyelid paralysis. With an accurate mechanistic model, eyelid behaviors can be simulated by changing parameters of the NMM such as reduced muscle strength and lack of OOM activation. We anticipate that this work will also serve as a starting point for model-based control of stimulation for eyelid paralysis.

The Muscle Spindle Behaves as a Tunable Feedback Controller During Perturbed Locomotion

Dr. Surabhi N. Simha[1,2], Dr. Gregory S. Sawicki[2], Dr. Timothy C. Cope[2,1], Dr. Lena H. Ting[1,2]

[1]Emory University, Atlanta, Georgia, United States. [2]Georgia Institue of Technology, Atlanta, Georgia, United States

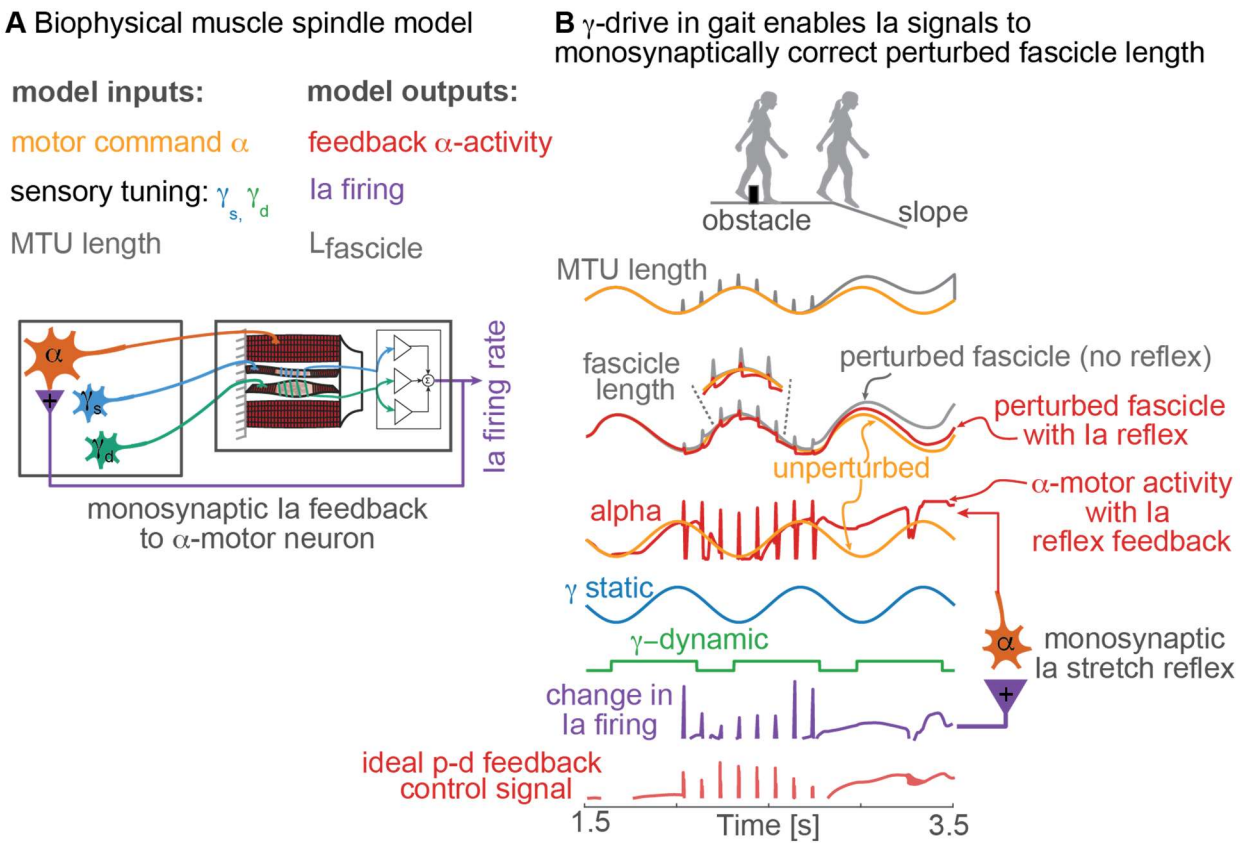
Introduction

Muscle spindles, tunable sensors in skeletal muscles, may facilitate sensing and correcting perturbations to gait. Muscle spindles receive two gamma motor drives that are modulated independent of the alpha motor drive to the parent skeletal muscle, decoupling spindle firing from joint motion. Current technology limits direct probing of how tuning of spindle firing through gamma motor drive affects voluntary behavior. Thus, we developed a biophysical computational model of muscle spindle Ia firing. We hypothesized that gamma drive serves as an efference copy, encoding intended movement, so Ia firing reflects the feedback signal that corrects for deviations from the intended movement.

Methods

We simulated modulation of Ia firing by gamma drive during sinusoidal length changes mimicking locomotion. We modelled two types of intrafusal spindle-specific muscle fibers (bag1 and chain) as half sarcomeres, whose force is determined by rate equations governing cross-bridge attachment and detachment [1,2]. Gamma dynamic drives Bag1 fiber activation, while gamma static drives chain fiber activation. Force and yank of the intrafusal fibers are linearly combined to generate a receptor potential that drives Ia firing. The parent extrafusal skeletal fiber is modelled in parallel to the intrafusal fibers, is governed by different rate equations, and receives alpha activation.

Results



Our model, tuned to relaxed stretch conditions, reproduced profound changes in muscle spindle firing seen in locomotion due to changes only in gamma motor drive. When the model received sinusoidal muscle length changes and Ia firing measured from cat locomotion, it predicted measured patterns of each gamma drive [3]. We leveraged the generalizable nature of our model to identify that the phasic gamma drive during locomotion modulates Ia firing such that when muscle length was perturbed away from

nominal movement, Ia firing encoded a position-and-velocity-error feedback control signal, correcting muscle fascicle length through the monosynaptic stretch reflex (figure).

Discussion

Our model, grounded in biophysical properties of muscle fibers, demonstrates that spindle signals, dissociated from joint motion, can be tuned to generate error signals to correct perturbations to gait.

An EMG-Informed 6DOF Knee Musculoskeletal Model for Deep Squat Tasks: Application in ACL Injury Prevention

Ms. Maria Dalle Vacche, Mr. Giulio Rigoni, Ms. Fabiola Spolaor, Prof. Zimi Sawacha

University of Padova, Padova, Veneto, Italy

Introduction

Anterior Cruciate Ligament (ACL) injuries affect 30–78/100,000 individuals annually [1], highlighting the need for prevention and deeper understanding of knee biomechanics. State of the art musculoskeletal models (MSMs) consider the knee as a 1-degree-of-freedom (DOF) joint and even when 6DOF are available either they are not suitable for deep squat movements [2] or they don't include ligaments [3].

This study introduces a 6DOF knee MSM with customizable ligament parameters [4], enabling estimation of: muscle activity (MA) and forces, ligament forces and strain, joint reaction forces. Two different EMG-informed methods (Computed Muscle Control (CMC), Moco [5]) were applied to represent individualized motor control patterns in the analysis.

Methods

Ten healthy (age 26.1 ± 1.5 yrs, BMI 22.6 ± 2.0 kg/m^2) and five ACL-injured subjects (19 ± 2.82 yrs; 26.65 ± 2.04 kg/m^2) performed three bipodalic leg drop landings and squats. Kinematics and kinetics were acquired with a stereophotogrammetric system and two force plates. An 8-channel surface-EMG (sEMG) system (1000 Hz) acquired the MA as listed in **Fig.1**.

Data were processed in OpenSim (**Fig.1**) using a 6DOF knee MSM purposely developed for deep squat movement, EMG informed through Moco or CMC. sEMG envelopes were calculated via bandpass filtering (10–450 Hz) with a fifth-order Butterworth filter. Results were compared between EMG-informed methods and Static optimization; simulated MA and experimental sEMG were also compared: root mean square error (RMSE), coefficient of multiple correlation α were computed. SPM analysis [5] was performed across all methods.

Results

The best agreement between simulated and experimental MA profiles was obtained for Moco EMG-informed approach (see **Fig.1**: $\alpha > 0.97$; RMSE < 0.05, Tibialis Anterior, controls' data))

Discussion

Results support the introduction of a 6DOF knee MSM informed by sEMG signals to investigate the knee joint biomechanics for application in ACL injury screening.

Experimental and Computational Modelling Framework for Detecting Bladder Microcontractions

Mr. James Fox[1], PD Dr. Francesco Clavica[1,2], Prof. Dr. Dominik Obrist[1], Dr. Silje Ekroll Jahren[1]

[1]ARTORG Center for Biomedical Engineering Research, University of Bern, Bern, Bern, Switzerland. [2]Department of Urology, Inselspital, Bern University Hospital, University of Bern, Bern, Bern, Switzerland

Introduction

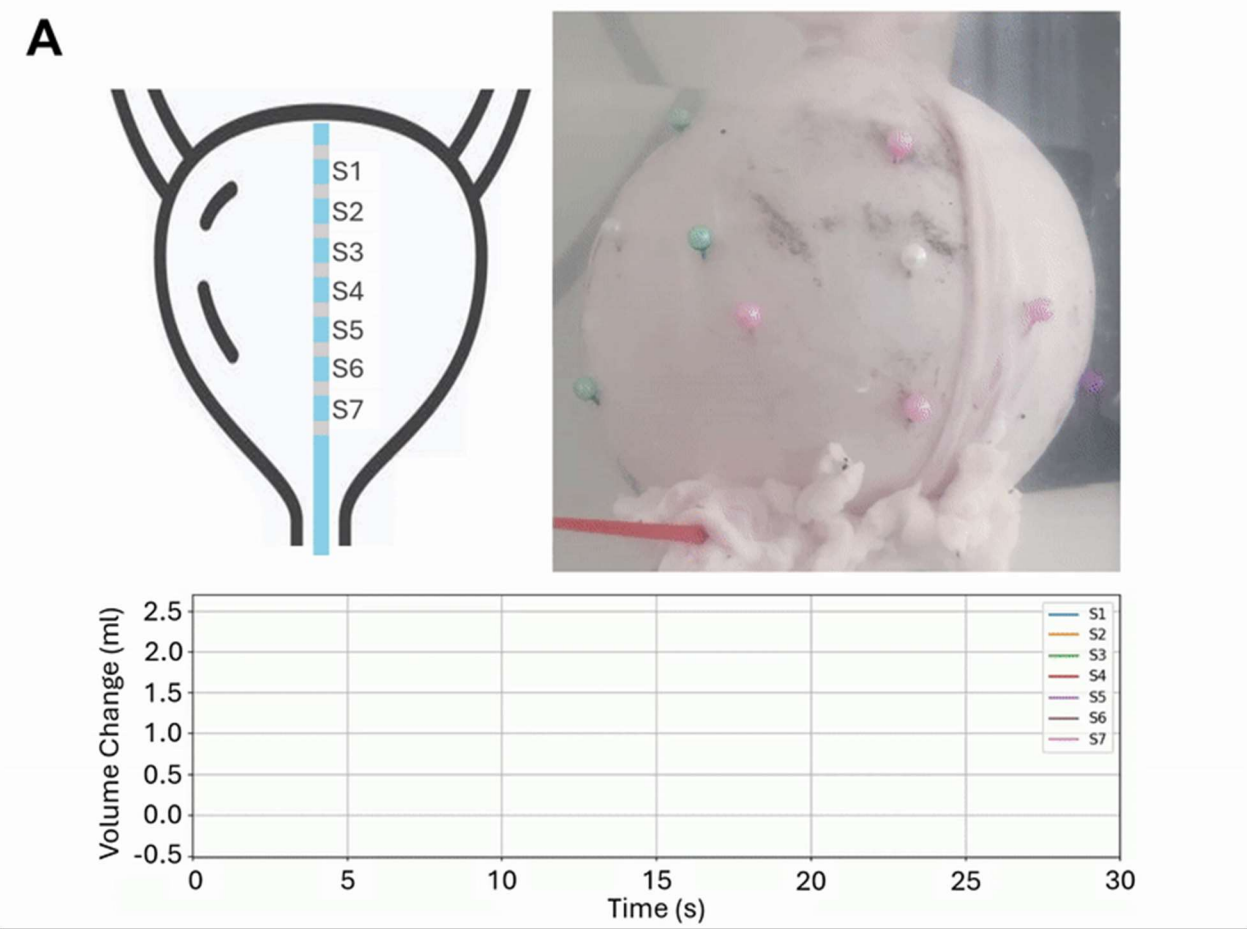
Overactive bladder is a common urological disorder. It is characterised by urgency, frequency, and nocturia. Diagnosis relies on filling and voiding cystometry; about half of symptomatic patients exhibit detrusor overactivity, detected as involuntary pressure rises during filling. However, many bladder microcontractions generate pressure changes below standard detection limits ($5 cmH_2O$) yet may contribute to symptoms. Treatment often involves intradetrusor botulinum toxin injections that suppress global bladder contractility and frequently lead to intermittent catheterisation. We hypothesised that adapting Pressure Volume (PV) catheters to the bladder would enable detection and localisation of microcontractions and support more targeted therapy. Ex-vivo and computational models of microcontractions were used to assess PV catheter performance.

Methods

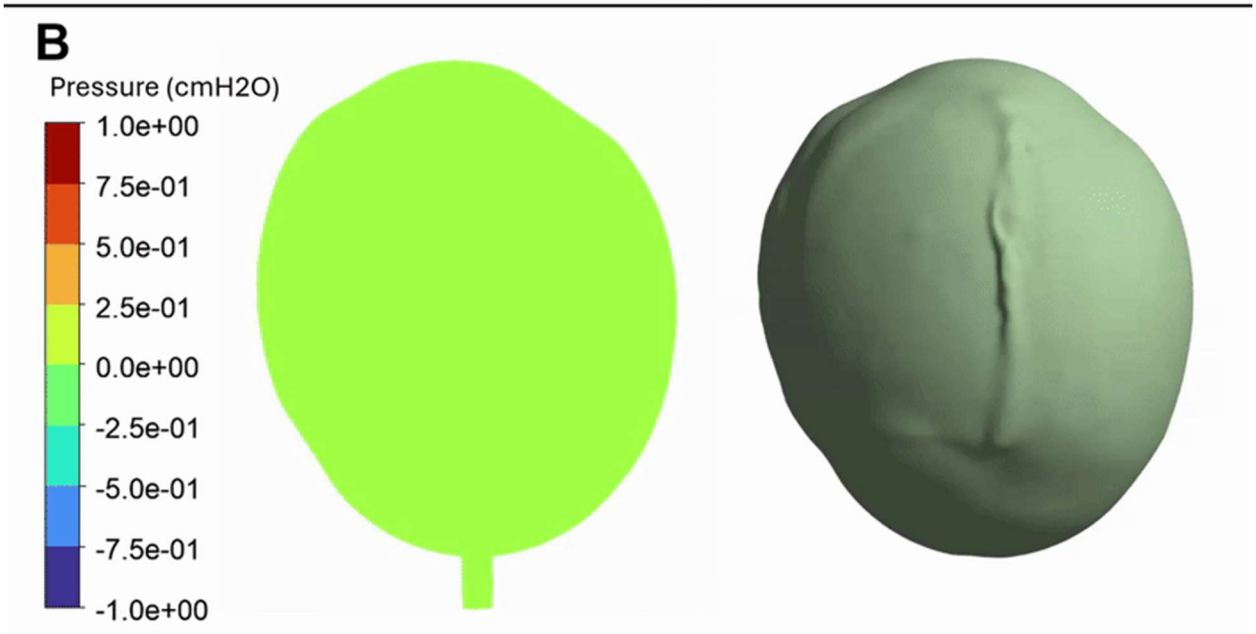
A multielectrode PV catheter (Millar, Inc.) applying a constant current along the lumen was adapted for bladder use. Voltage measurements at evenly spaced electrodes were used to infer segmental impedance and compute local volume. Viable ex-vivo porcine bladders were collected after euthanasia; removal of central neural inhibition resulted in spontaneous microcontractions. Bladder surface motion was recorded using particle tracking by applying fiducial markers to the bladder surface.

These marker trajectories were used as inputs to a computational bladder model. Bladder geometry was reconstructed by laser scanning four lateral facets, stitching surfaces into a closed topology. Fluid–structure interaction (FSI) simulations coupled an FE-model of the bladder wall with a CFD model of the contained fluid, exchanging boundary conditions until convergence.

Results



In the ex-vivo study, the PV catheter measurements reliably detected segmental volume changes associated with microcontractions. These contractions produced pressure excursions below $1 cmH_2O$ (undetectable by standard urodynamics) yet generated distinct local volume changes (Figure A).



The computational model reproduced the experimental surface kinematics, and simulations replicated the maximal-change segment and the minimal pressure response (Figure B). Both experiment and simulation localised the largest relative volume change in S1.

Discussion

Segmental volume mapping can detect microcontractions, not measurable using pressure-only urodynamics. Identifying a dominant contracting segment (S1) suggests potential for targeted intradetrusor injections, by reducing toxin use by over 85% and preserving bladder function. This represents the first combined experimental and FSI-based characterisation of bladder microcontractions. Further in-vivo validation is required.

Temporal Differential Growth Drives Sequential Midgut Protrusion, Rotation, and Retraction: A Computational Simulation Study.

Ms. Michina Saiki Ph.D student[1], Mr. Hironori Takeda[2], Mr. Yuto Kawabata Ph.D student[1], Mr. Shunichi Ishida Assistant Professor[1], Mr. Yohsuke Imai Professor[1]

[1]Kobe University, 1-1,Rokkodai,Nada,Kobe, Hyogo, Japan. [2]Kyoto University, 53 Shogoin-Kawahara-cho, Sakyo, Kyoto, Japan

Introduction

Midgut morphogenesis proceeds through a characteristic sequence of protrusion, rotation, looping, and retraction during embryonic development. However, the mechanical basis underlying these transitions remains unclear. Differential growth between the midgut and the mesentery has been proposed as a mechanism for loop formation[1], which motivates us to investigate whether this growth-based mechanism could also contribute to other stages of midgut morphogenesis, including protrusion, rotation, and retraction. In this study, we aim to determine whether temporal changes in differential growth can reproduce the sequential transitions of protrusion, rotation, and retraction observed in embryos[2].

Methods

We constructed a continuum-mechanics model representing the midgut as a compressible hyperelastic tube whose reference configuration mimics embryonic geometry. To model differential growth, we defined a mesentery region attached to the tube wall with a slower growth rate and higher stiffness than the midgut. Tissue growth was represented using multiplicative decomposition of the deformation gradient, allowing us to simulate axial elongation driven by growth. The hyperelastic response was described by a compressible Neo-Hookean model, and the governing equations were solved using isogeometric analysis with Newton–Raphson iterations. We conducted parameter studies by varying the growth stretch and stiffness to identify mechanical regimes that yield protrusion, rotation, or retraction.

Results

Uniform growth without differential properties caused the tube to deform into a U-shaped protrusion when elongated under fixed-end constraints, indicating that herniation can arise from geometric confinement alone. When differential growth was introduced, the model generated a 90° rotation. As the growth differential was further increased, the tube subsequently retracted.

Discussion

Our findings suggest that temporal differential growth is sufficient to generate major phases of midgut morphogenesis. Protrusion emerges from compression-induced buckling, rotation arises from tension redistribution caused by a stiffer, slower-growing mesentery, and retraction occurs when the growth imbalance becomes large. Although the model simplifies mesentery geometry and omits interactions with surrounding tissues, it provides a unified mechanical explanation for midgut development and offers a basis for future, more detailed simulations.

A Computational Framework for Evaluating AMS 800 Artificial Urinary Sphincter Behaviour Across Patient-Specific Urethral Anatomies

Dr Conall Quinn PhD

Trinity College, Dublin City, Dublin, Ireland

Introduction

Urinary incontinence affects up to 32% of men worldwide, severely impacting quality of life [1]. The AMS 800 artificial urinary sphincter is the gold-standard treatment for male stress urinary incontinence, yet complications remain frequent, with mechanical failure and urethral erosion common long-term issues [2]. Erosion is linked to excessive circumferential compression, but urethral stress cannot be measured clinically, limiting optimisation of pressure settings and device performance [3]. Computational modelling enables evaluation of internal stresses under realistic deployment [4]. This work presents a patient-specific framework to assess AMS 800 performance across varying urethral geometries.

Methods

AMS 800 cuff and balloon geometries (Boston Scientific) were reconstructed in Abaqus (2020). Patient-specific urethral geometries and nonlinear tissue behaviour were derived from mechanical characterisation of nine male urethras (Cunnane et al. [5]). A full preprocessing pipeline was developed to automatically generate device–tissue models, assign material behaviour, and simulate AMS 800 deployment (Fig. 1).

Device components used hyperelastic/elastic formulations based on manufacturer data whilst urethral tissues were fitted to patient-specific constitutive laws (Fig. 1C). Balloon inflation pressure, intraluminal pressure, and cuff sizing were controlled as input variables. Outputs included luminal reduction, contact pressure, and stress distribution.

Results

The pipeline successfully generated models for all urethral anatomies. Preliminary simulations demonstrated stable closure and realistic mechanical outputs, demonstrating sensitivity to cuff pressure. Increased balloon pressure raised urethral reopening thresholds and sustained continence over a wider pressure range. A complete parameter sweep assessing stress concentration and closure mechanics is ongoing.

Discussion

This framework enables quantitative evaluation of AMS 800 behaviour across varied urethral anatomies. Integrating device geometry, tissue data and automated simulation provides a scalable platform for analysing forces not measurable *in vivo*. Future work will map stress–pressure relationships, informing optimum cuff sizing and balloon inflation to reduce erosion risk.

NeuroRecoVR: Split-Belt Virtual Reality Treadmill Training for Subacute Stroke

Ms. Alexa Boyer PhD Student[1], Dr. Zaid Alsaaran MD[2], Dr. Isabelle Poitras PhD[3], Dr. John Bertram PhD[1,4], Dr. Sean Dukelow MD, PhD[2,3,4]

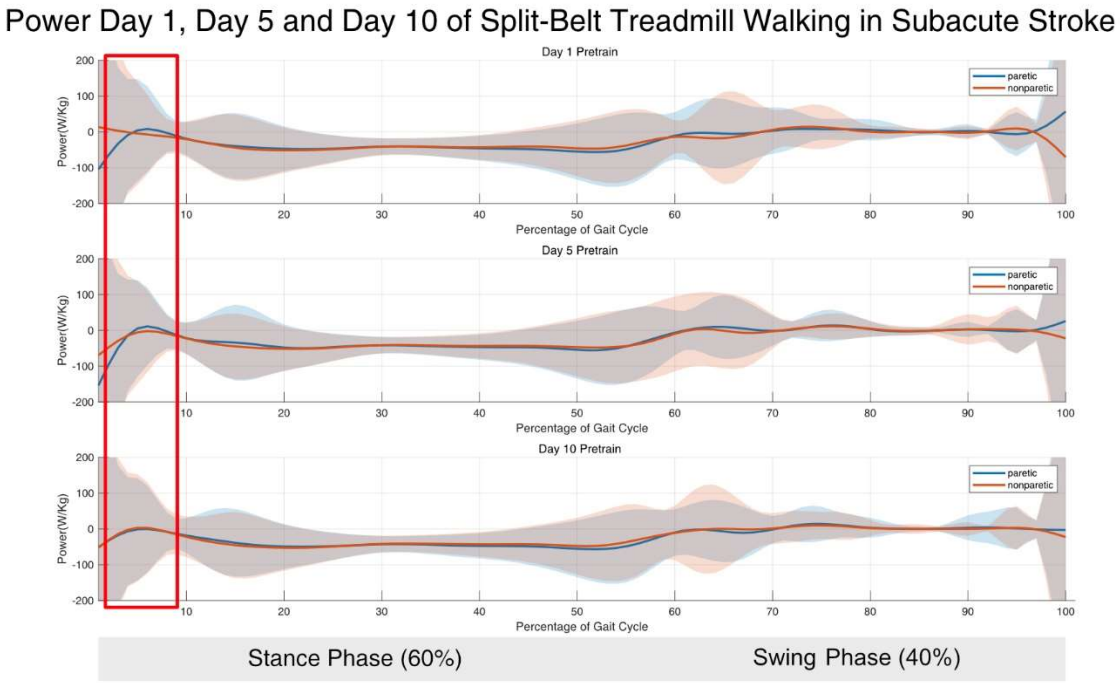
[1]Department of Biomedical Engineering, Schulich School of Engineering, Calgary, AB, Canada. [2]Division of Physical Medicine and Rehabilitation, Calgary, AB, Canada. [3]Department of Clinical Neurosciences, Calgary, AB, Canada. [4]Cumming School of Medicine, Calgary, AB, Canada

Introduction

Up to 80% of stroke survivors experience mobility challenges, including hemiparesis, which can cause difficulties with walking and balance. This hemiparesis can lead to asymmetric and functionally limited propulsive forces generated by the paretic and non-paretic limbs, potentially resulting in injury and decreased quality of life. The split-belt treadmill (SBT) assists individuals with hemiplegia and asymmetric gait to relearn symmetrical walking and may reduce propulsive asymmetry. Although the SBT has proven effective for improving walking quality in chronic stroke, its effects on those in the subacute phase remain uncertain. Traditional walking therapies often lack engagement, but incorporating virtual reality (VR) with standard care could enhance outcomes. This study aimed to evaluate the safety, feasibility and preliminary efficacy of the VR-SBT system for rehabilitation in subacute stroke patients.

Methods

Fifteen participants, 40 days post-stroke (range 18-86), completed 10 sessions of walking using the NeuroRecoVR system. The sessions involved 27 minutes of total walking, including 15 minutes of SBT walking along a virtual reality mountain pathway reminiscent of the Rocky Mountains. Baseline clinical assessments included walking speed (10-metre walk test) and endurance (6-minute walk test), which were repeated on days 5 and 10. Ground reaction forces and centre of pressure were recorded using force plates embedded in the treadmill to calculate the power of each limb, both paretic and non-paretic, over the 10-day intervention. The asymmetry in power generated by each limb was measured, with lower asymmetry values indicating greater symmetry.



Results

All participants completed the 10-day SBT training without any falls. Participants reduced their average peak heel-strike power asymmetry by 0.66 W/Kg ($p<0.93$, t-test) over 10 days (Figure 1), indicating that they were learning and maintaining a more symmetrical walking pattern. On average, participants increased their walking speed by 0.24 m/s (±0.24 SD, $p=0.002$) and their endurance by 71.1 meters (±55.7 SD, $p< 0.001$).

Discussion

The NeuroRecoVR initiative was safe and feasible, and improved post-stroke patients' walking speed and endurance, meeting the minimal clinically important difference for these clinical scores. Symmetry of heel strike power between the paretic and non-paretic limbs also improved over the 10-day intervention, with no significant adverse events.

Sit, Stand, Activate! Quantifying Muscle Activity During Mobility Aid Use in Young Children With Developmental Disabilities

Mia Hoffman PhD, Mr. Spencer Hensley, Ms. Katie Leija, Ms. Shariphine Agoalikum BS, MPhil, MPH, Ms. Allyson Clarke BS, Dr. Heather Feldner PT, PhD, PCS Emeritus, Dr. Katherine Steele PhD

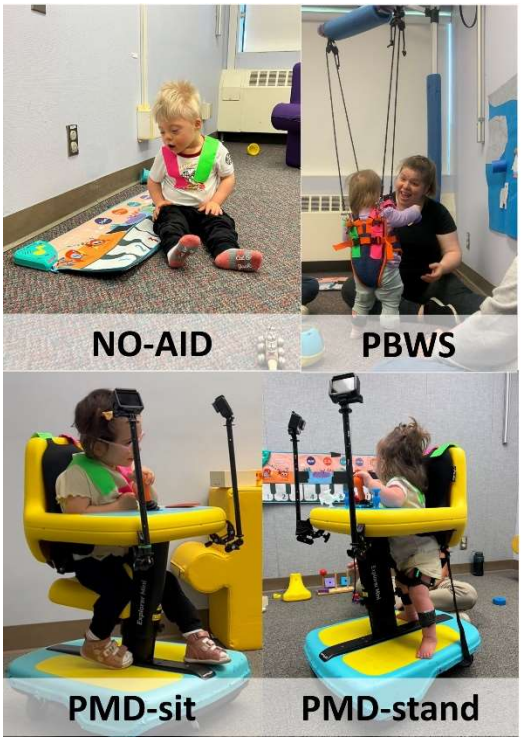
University of Washington, Seattle, WA, United States

Introduction

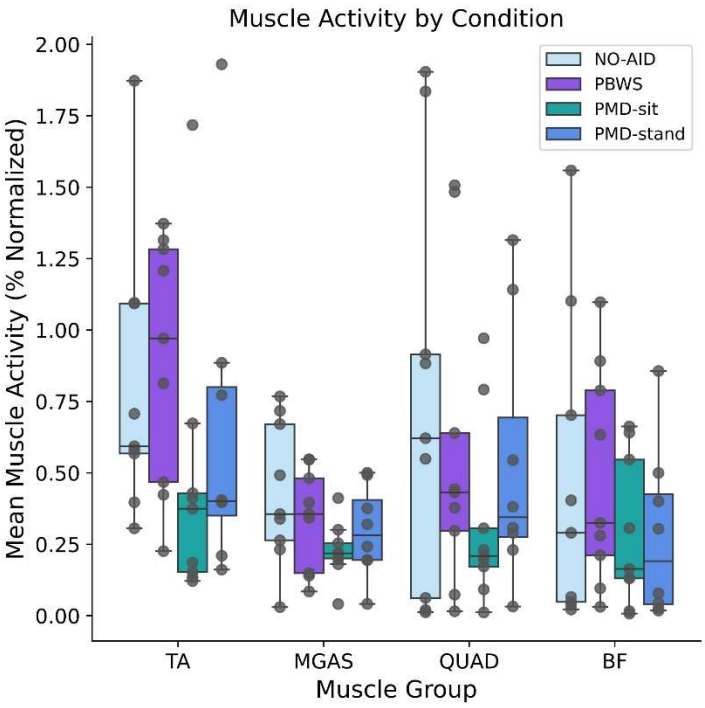
Mobility aids can support independent movement for young children with developmental disabilities [1]. While device type and positioning may affect muscle activity [2] changes in muscle activity with and without mobility aids remains largely unknown. We compared muscle activity without mobility aids (NO-AID) and with a partial bodyweight support (PBWS) system or powered mobility device (PMD) in seated (PMD-sit) or standing (PMD-stand) postures. We hypothesized that muscle activity would be greatest in PBWS and PMD-stand.

Methods

Nine children with developmental delays and atypical muscle tone (AGE: 22 ± 11 months, 3M/6F) completed four, 30-minute play sessions randomized to NO-AID, PBWS, PMD-sit, or PMD-stand. Electromyography data from the tibialis anterior (TA), medial gastrocnemius (GAS), biceps femoris (BF), and quadriceps (QUAD) were filtered, rectified, and normalized to the 95^{th}-percentile across visits. Session-level muscle activity was calculated as the mean of 15-second window averages. Differences across conditions were assessed using Friedman tests with post-hoc Wilcoxon tests and Holm-Šidák corrections. One participant's PMD-stand data was missing.



Results



BF activity differed significantly across conditions ($p = 0.047$), with higher activity in PBWS than PMD-stand ($p = 0.008$) and a trend toward higher activity in NO-AID than PMD-stand ($p = 0.04$). TA activity trended towards significance ($p = 0.0503$), with PBWS higher than PMD-sit ($p = 0.039$). MGAS and QUAD activity were similar across conditions. Rank analyses showed TA and BF were most active during PBWS, while MGAS and QUAD were most active in NO-AID. The majority of participants showed higher QUAD (6/8 participants) and TA activity (7/8 participants) in PMD-stand than PMD-sit.

Discussion

Children with developmental delay used their lower-limb muscle during all play sessions and activity was influenced by mobility aid use. Consistent with a prior case series, PMD-stand elicited higher QUAD activation than PMD-sit [2]. Increased TA and BF activation in PBWS may reflect postural stabilization in a novel environment. Muscle activity may not fully capture functional changes, as participants ranged from early sitting to cruising. These findings challenge assumptions that PMD use requires minimal effort and highlight dynamic positioning's potential to increase physical engagement.

Memory-Anchored Gestures and Visual Feedback Improve Motor Learning Efficiency and Consistency in VR

Mr. Zachary Marvin[1], Ms. Sophie Dewil[1], Mr. Yu Shi[1], Dr. Noam Harel[2,3], Dr. Raviraj Nataraj[1]

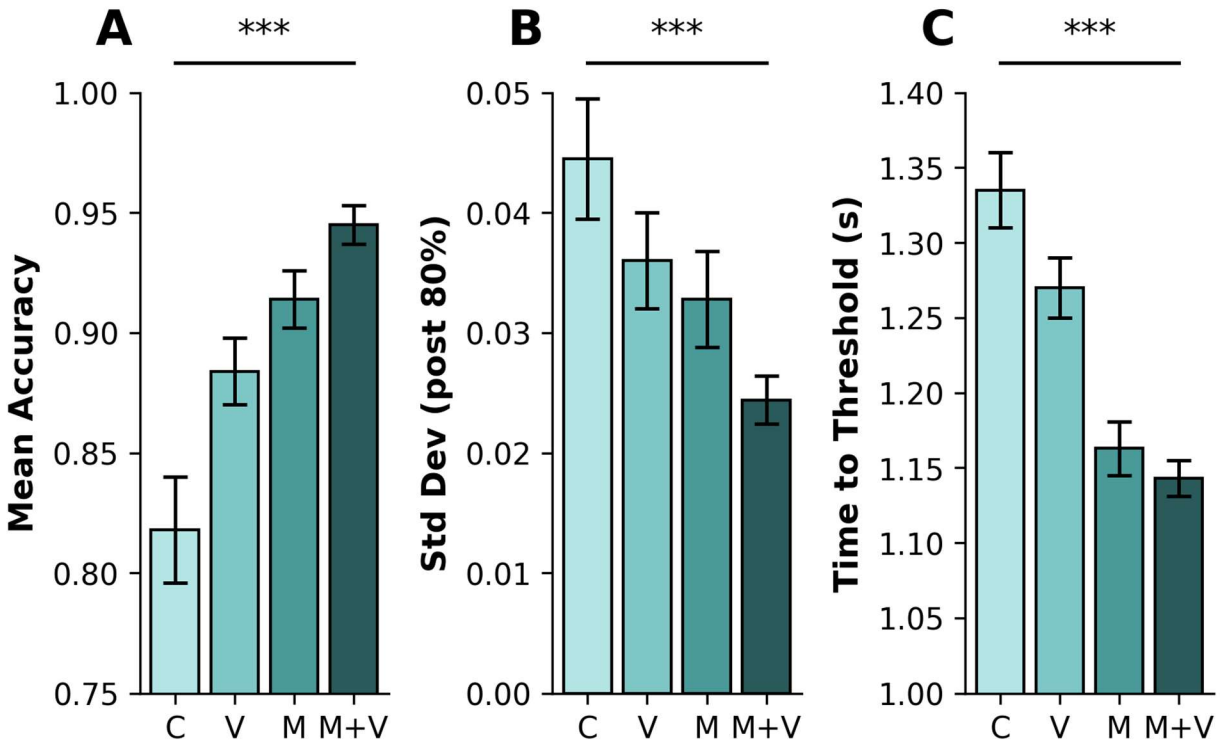
[1]Stevens Institute of Technology, Hoboken, NJ, United States. [2]James J. Peters Veterans Affairs Medical Center, Bronx, NY, United States. [3]Icahn School of Medicine at Mount Sinai, New York, NY, United States

Introduction

Neurological disorders such as spinal cord injury (SCI) and Parkinson's disease (PD) significantly impair hand dexterity and function, compromising the ability to perform important manual activities of daily living (ADLs). While practice of gestural biomechanics in physical therapy can improve dexterity, traditional methods often lack the neural engagement required to facilitate robust neuroplasticity [1]. We propose a VR-based rehabilitation approach designed to bridge this gap. In this study, we integrate augmented sensory feedback (ASF) to enhance motor awareness [2] with memory-anchored gestures inspired by American Sign Language (ASL) to leverage intuitive cognitive-motor coupling [3].

Methods

We recruited and tested 10 neurotypical adults for this pilot study. The neurotypical adults were seated in front of a webcam and were tasked to replicate target hand gestures displayed within an immersive VR environment. Participants performed gesture-matching across four conditions: 1) control, 2) visual ASF, 3) memory, and 4) memory + visual ASF. We assessed motor performance according to measures for accuracy (spatial matching to the target gesture), learning efficiency (time to reach the 80% accuracy threshold), and consistency (minimizing standard deviation past the 80% threshold).



Results

Significant main effects were observed across all conditions. The combined memory + visual ASF condition achieved the highest accuracy (94.3%), a 12.6% improvement over control. Also in this combined condition, learning efficiency improved by 15% (1.13s vs. 1.33s; $p<0.001$), and consistency increased by 51%, indicating significantly more consistent motor execution.

Discussion

The findings from this pilot study establish proof-of-concept of a framework for cognitively-enhanced sensorimotor integration for rehabilitative training. This approach could be extended by integrating multisensory activation with augmented feedback that further reinforces cognitive scaffolding during motor training. Our memory-anchored approach improved performance by converting otherwise repetitive tasks into cognitively-enriched, memory-supported training activities. Future work will translate this approach to clinical populations to assess its therapeutic efficacy in restoring manual ADL function.

Real-Time Modulation of Split-Belt Treadmill Speed Enhances Gait Propulsion and Neuromuscular Engagement in Post-Stroke Hemiparesis

Ms. Adriele Rivera[1], Mr. Hyunje Park[1], Dr. Seoung Hoon Park[1], Dr. Jooeun Ahn[2], Dr. Beom Chan Lee[1,2]

[1]University of Houston, Houston, Texas, United States. [2]Seoul National University, Seoul, N/A, Korea, Republic of

Introduction

In individuals with post-stroke hemiparesis, limited forward propulsion arising from paretic plantarflexor and knee extensor deficits impedes functional walking recovery [1, 2]. Although split-belt treadmill training ameliorates step asymmetry through error-based learning, it does not explicitly target the deficit in push-off generation. To address this limitation, this study evaluated the Adaptive Propulsion Enhancement eXperience (APEX) system [3], specifically its propulsion-facilitating mode designed to reinforce paretic-limb propulsion via real-time, phase-dependent belt speed modulation.

Methods

Ten adults ndividuals with chronic post-stroke hemiparesis completed a single-session treadmill protocol comprising baseline, training, and post-training periods. In the training period, the propulsion-facilitating mode applied a transient deceleration to the belt ipsilateral to the paretic leg during late stance, effectively extending ground contact time to augment propulsive effort (Fig. 1). Ground reaction forces were sampled at 1000 Hz using instrumented treadmill force plates, and EMG signals were acquired at 1926 Hz from the medial gastrocnemius (MG), soleus (SOL), vastus medialis (VM), and rectus femoris (RF). Outcomes included normalized peak paretic propulsive force and mean EMG amplitudes for the targeted muscles during the propulsive phase. Statistical differences across the three periods were evaluated using a one-way repeated measures ANOVA.

Results

One-way repeated measures ANOVA revealed significant period effects for all outcomes ($p < 0.0001$). Normalized peak paretic propulsive force increased from 0.78 ± 0.09 at baseline to 1.33 ± 0.14 during training and remained increased post-training (1.32 ± 0.12). MG and SOL exhibited increases from 0.97 ± 0.05 to 1.20 ± 0.10 and 1.16 ± 0.08, respectively, during and after training, demonstrating greater engagement of the plantarflexors during

push-off. Similarly, VM increased from 0.98 ± 0.07 to 1.22 ± 0.09, and RF from 0.98 ± 0.06 to 1.27 ± 0.11.

Discussion

The propulsion-facilitating mode of the APEX system significantly increased forward propulsion and neuromuscular activation of the paretic limb, demonstrating immediate and sustained improvements in push-off mechanics. These results indicate that phase-specific belt-speed modulation during late stance effectively re-engages underactive plantarflexors and knee extensors, promoting active contribution to forward propulsion.

Images (Optional)

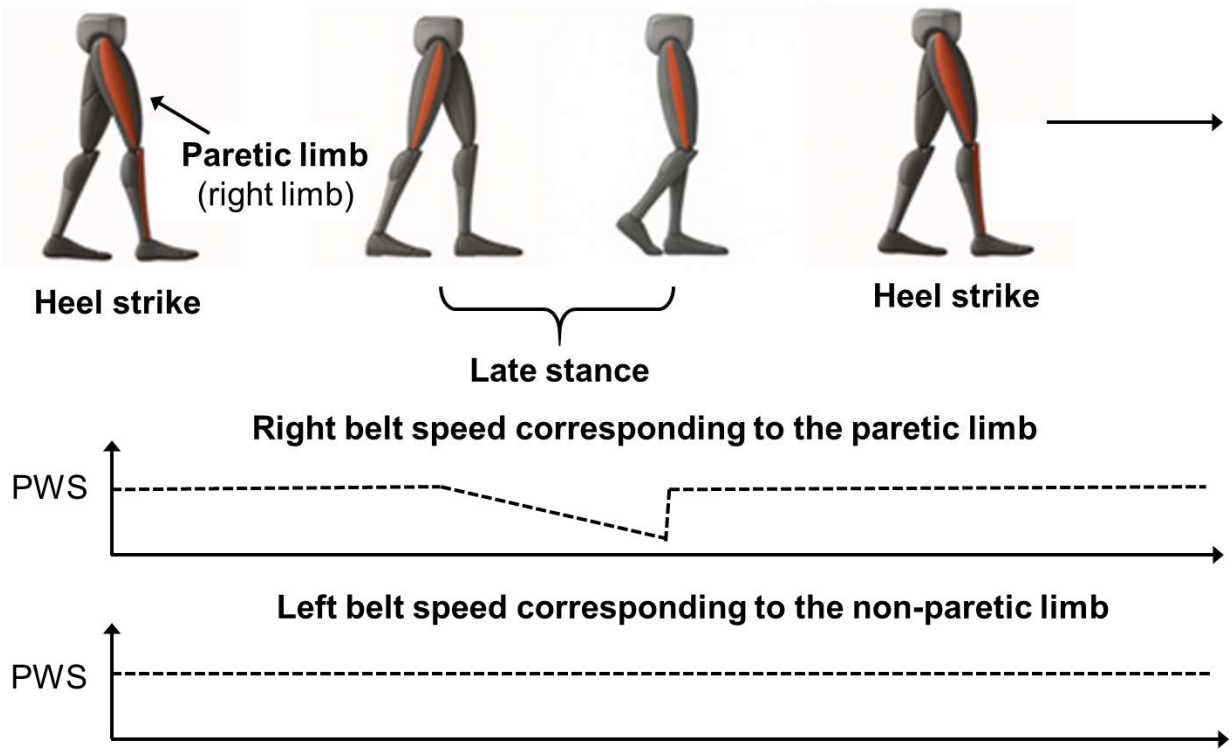

Fig. 1: Phase-specific belt-speed modulation implemented in the propulsion-facilitating mode of the APEX system. The treadmill belt under the paretic limb undergoes transient deceleration during late stance to prolong ground contact and facilitate greater propulsive engagement, followed by restoration to the preferred walking speed (PWS) after toe-off.

Introduction

Microprocessor-controlled prosthetic knees (MPKs) are prescribed to active individuals with above-knee amputations (AKA), offering advantages such as stumble recovery and adaptability to variable walking speeds. Compared with mechanical knees, MPK users often report improved mobility and quality of life, suggesting benefits that extend to both

physical and psychological well-being [1]. Yet, differences in functional mobility and satisfaction across MPK models remain unclear. Given the variability in environmental demands and individual lifestyles, evaluating multiple MPKs is essential to identify the device that best meets each patient's functional needs and expectations. This study aimed to compare functional mobility, patient-defined outcomes, and quality of life across different MPKs to inform more personalized prosthetic prescription and targeted rehabilitation.

Methods

A randomized crossover trial was conducted in five rehabilitation centers with K3–K4 participants. Each participant used two devices: their usual MPK and the QUATTRO, for at least four weeks before assessment. Objective outcomes were assessed during the 6-Minute Walk Test with Loadsol© insoles and goniometers measuring ground reaction forces (GRF) and knee angles, respectively. GRF data were used to compute impulse and step symmetry. Subjective outcomes included the Patient-Specific Functional Scale (PSFS), where participants rated 2–3 daily tasks (0–10 scale), and the SF-36 questionnaire to assess quality of life. Wilcoxon tests compared device outcomes.

Results

Seventeen AKA (15 men, 2 women) completed the trial. Usual MPKs included the C-Leg (n=11), Rheo Knee (n=5), and Orion (n=1). No significant differences were observed in step or impulse symmetry, nor in knee angles, between devices. In contrast, PSFS scores were significantly higher with QUATTRO ($p < 0.05$), as were SF-36 physical health component scores ($p < 0.05$).

Discussion

Objective gait metrics did not distinguish between MPK systems, whereas subjective outcomes revealed meaningful differences. Patient-defined goals and perceived quality of life appear more sensitive to inter-device differences than standardized gait analyses. However, it remains essential to monitor biomechanical parameters to ensure that emphasizing subjective outcomes does not compromise gait performance or safety. A patient-centered approach combining gait assessment with user-reported outcomes is recommended to guide prosthetic prescription, ensuring optimal functional performance and long-term satisfaction.

Images (Optional)

[7]Dept. of Medicine, Queen's University, Kingston, Ontario, Canada

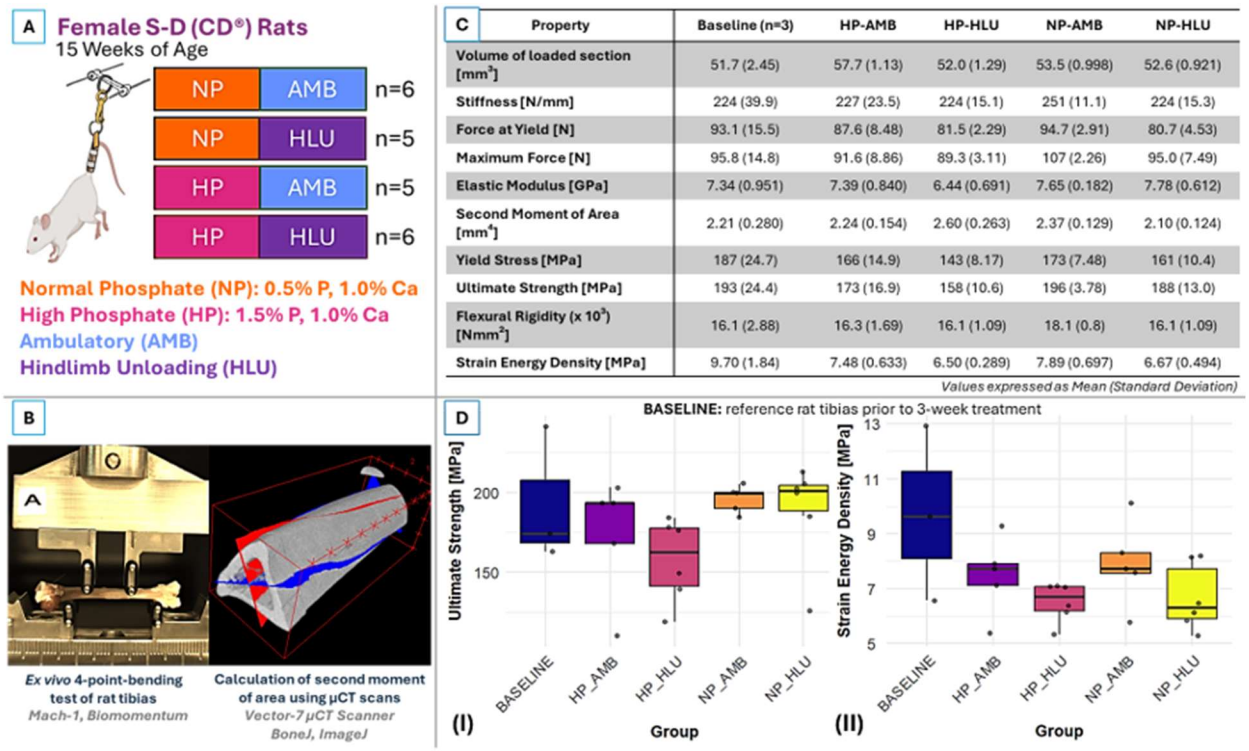
Introduction

During spaceflight, astronauts experience 1-2% bone mass loss per month, resulting in increased risks of fractures and osteoporosis. High amounts of inorganic phosphate additives are very common in processed foods (40-70% of top-selling grocery items) and may be linked to bone demineralization. As a result, astronauts consume 3-4x higher amounts of phosphate than recommended [1] and yet, the impact of this excess on microgravity-induced bone loss is unknown. The purpose of this study was to explore the impact of dietary phosphate in accelerating bone weakening using a rat model for simulating microgravity.

Methods

Twenty-five female Sprague-Dawley rats were subjected to a 3-week (n=5-6/group, n=3 baseline controls), 2×2 design combining dietary normal (NP) or high-phosphate (HP), with ambulatory (AMB) or hindlimb unloading (HLU) conditions (Figure-A). Bone volume, material, and structural properties of rat tibias were obtained *ex vivo* via 4-point-bending mechanical tests (Figure-B). Left tibias were scanned using micro-computed tomography (μCT; 50kV, 75ms with 1440 projections) prior to mechanical testing. The tibias were preconditioned and loaded 3 times within the elastic region before inducing structural failure. Bone volume and second moment of area of each specimen were measured from

reconstructed µCT images (10µm voxel-size). A 2×2 factorial Aligned-Rank-Transform, followed by post-hoc tests, were used to assess statistical significance (α=0.05).



Results

Bone volume, material, and structural properties were summarized (Figure-C). The HP diet groups showed 14.8% lower ultimate strength when compared to NP (p=0.006, Figure-D-I). HLU groups had both 11.7% and 15.4% lower force-at-yield and strain energy density (p=0.028 and 0.041), respectively, than AMB (Figure-D-II). No statistically significant interactions between diet and HLU effects were found.

Discussion

Our main findings suggest that **(1)** diet significantly impacts bone mechanical properties, confirming high dietary phosphate negatively affects bone strength and functional integrity, and **(2)** HLU negatively impacts energy-to-yield, indicating that under non-loading conditions, bone stores less energy before permanent deformation. Combined, these results highlight significant risks when considering the recommencement of normal bone loading of female astronauts returning to Earth following exposure to microgravity. Future work will include morphological analyses of bone and sex-specific responses.

Introduction

Bone adapts throughout life, but understanding of this lifelong dynamism is limited by sparse 2D measurements, small cohorts, and demographic under-representation, especially of paediatric groups [1].

This study addresses this knowledge gap by developing 3D statistical shape models of the femur based on a large, demographically stratified population, offering a comprehensive view of morphology integrated with cortical thickness.

Methods

Right femurs were segmented from CT scans of 996 individuals (460 females, aged 4 – 89 years). To achieve intersubject nodal correspondence, a template mesh was fitted to each segmented femur, and all meshes were aligned to their anatomical axes to remove positional variations. Diaphyseal endosteal surfaces were constructed using an automated cortical thickness calculation method [2].

Principal component analysis was performed on periosteal and endosteal meshes to generate a mean model for each age group (Figure 1). Moment of inertia - a metric of bending resistance, and the ratio of its minimum to maximum values - a biomechanical shape index, were computed along the diaphysis.

Results

During growth (4 – 18 years), the diaphysis showed increases in cross-sectional size and cortical thickening, with the greatest changes along the linea aspera. These growth-related changes produced a more asymmetrical shape around the mid-diaphysis and greater anterior–posterior bending rigidity.

With ageing (20 – 89 years), cross-sectional enlargement continued but mainly on the medial and lateral sides. Cortical thinning appeared, prominently along the linea aspera and anterior regions. These parallel changes led to a more symmetrical shape and shifted the direction of maximum moment of inertia towards the medial–lateral axis.

Discussion

Cortical thickness variation was more dominant near muscle attachment sites. Cross-sectional enlargement remained active into ageing on the medial and lateral sides, where higher stresses concentrate during walking or standing. Transitions between symmetrical and asymmetrical cross-sections - also seen in modern compared to pre-industrial populations [3] - was noted. Together, these findings suggest that alterations in mechanical loading could underlie lifespan-related morphological adaptations, and the model can support further numerical studies of form–function relationships.

Images (Optional)

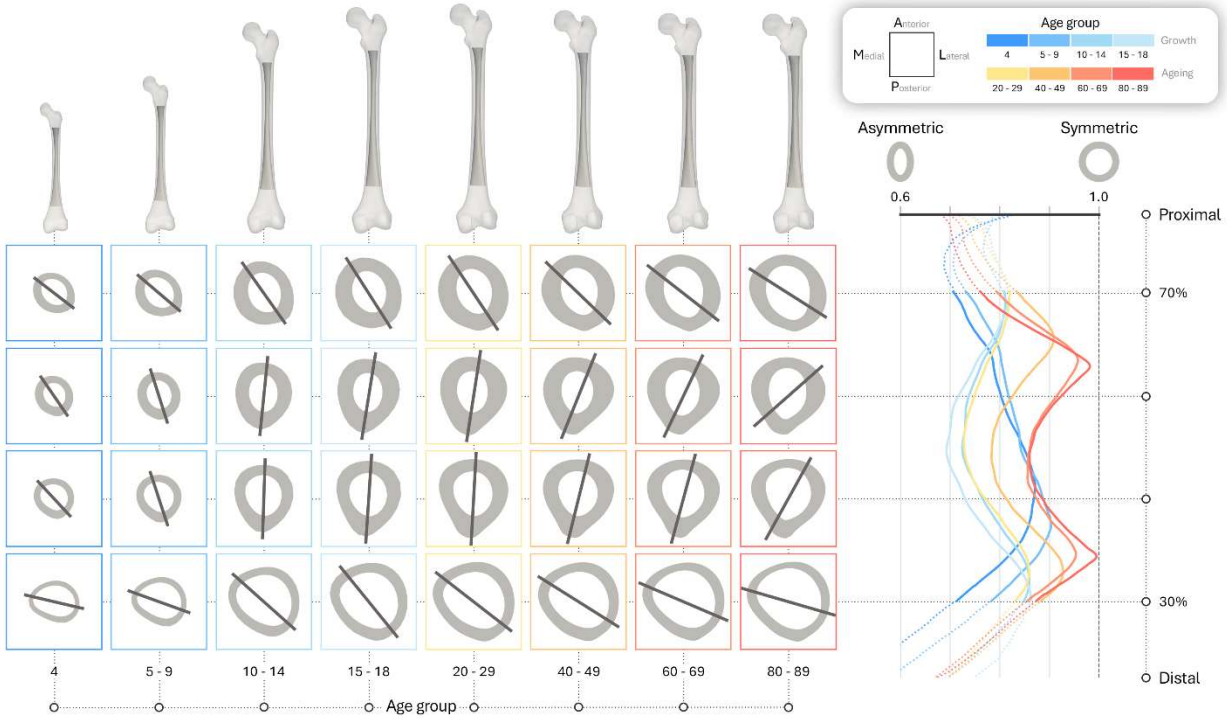

Figure 1. Top row shows 3D mean femoral models for each age group, and below are their cortical bone cross-sections (grey) with the direction of maximum moment of inertia (black line) at 30–70% of total length. Right is the shape index based on moment of inertia computed along the diaphysis (20–80% of total length), with colored curves representing age groups as shown in the legend.

Introduction

Articular cartilage is a specialised tissue maintained by chondrocytes. While early postnatal cartilage contains densely packed, disorganised cells, mature cartilage exhibits a highly ordered zonal architecture [1]. However, how this zonal structure emerges during postnatal maturation remains poorly understood, largely due to limitations in 2D histology. To address this gap, we used synchrotron-based phase-contrast tomography to visualise and quantify chondrocyte organisation and properties across multiple postnatal stages, enabling depth-resolved characterisation of cartilage maturation and providing a developmental reference to inform regenerative strategies.

Methods

Goat osteochondral cores (4 mm) were collected post-mortem from the second phalanx of Saanen goats, under approval from UCD's Animal Research Ethics Committee (AREC-21-22). Samples from seven developmental stages (neonate to adult, n = 5–6 per group) were imaged at the Diamond Light Source, beamline I139 (UK; pixel resolution = 1.625 µm). Data were reconstructed (with SAVU), followed by machine-learning-based cell segmentation and analyses (Fiji, Matlab).

Results

Neonatal and 6-week cartilage contained high cell numbers and larger chondrocytes in comparison to the more mature stage, with a layered distribution marked with two peaks in chondrocyte volumes through the depth (Fig.1a, b) and cells oriented predominantly perpendicularly to obliquely to the articular surface (Fig.1c). By 6 months, cell volume and number variation was reduced compared with the earlier organisation. A stratification emerged by 12 months, with increased mid-zone cell volume, higher cell numbers near the

surface, decreased deep-zone volume and a shift in cell orientation toward a zonal pattern, with surface-perpendicular and deep-parallel alignment to the surface (Fig. 1c, d). In the adult stage, this organisation was fully established.

Discussion

This work demonstrates the postnatal transformation of cartilage from a hypercellular, layered immature tissue into a zonally organised, mechanically specialised structure. In early development, cartilage displayed a three-layer organisation with distinct depth-dependent changes in volume and count, which diminished in 6 months. Zonal architecture became established by 12 months and fully matured in adulthood. These 3D analyses reveal organisational features not observable in 2D histology and provide a depth-resolved developmental reference essential for understanding cartilage maturation and guiding regenerative medicine approaches.

Images (Optional)

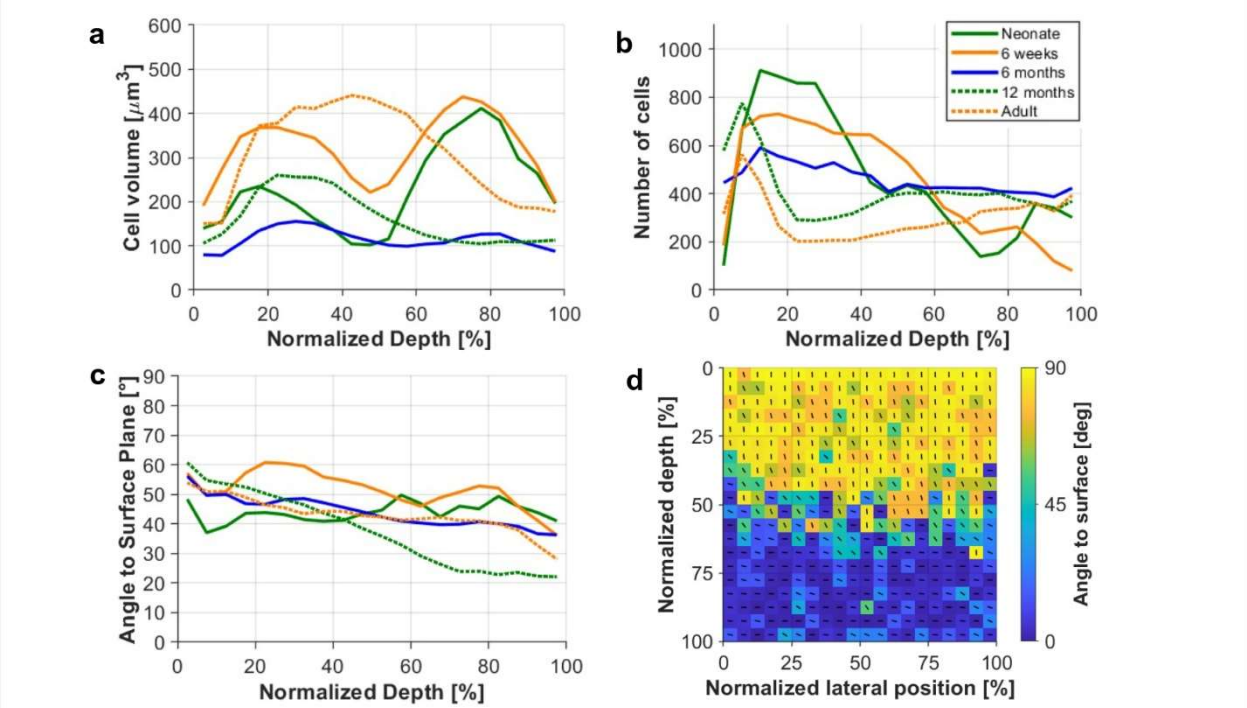

Figure 1 Chondrocyte organization transitioned from a layered, highly cellular structure in early stages to a zonally organized, orientation-aligned architecture in maturity. Shown are depth-wise profiles of cell volume (a), number (b), and orientation (c) with (d) heatmap illustrating orientation at 12 months, along normalized depth (0–100%) from the cartilage surface to the calcified front.

In Vivo Mechanical Loading Induces Site-Specific, Partially Reversible Tissue Adaptation in Vertebrae

Licensed Pharmacist Cosima Erhard PhD Student[1,2], Dipl.-Ing. Tobias Thiele[1,2], Dr. med. Lukas Schönnagel Resident Physician[1,3], PD Dr. rer. nat. Katharina Schmidt-Bleek PI[1,2], Dr. Melih Özgür Celik[4], Univ.-Prof. Dr.-Ing. Georg Duda PI[1,2,3]

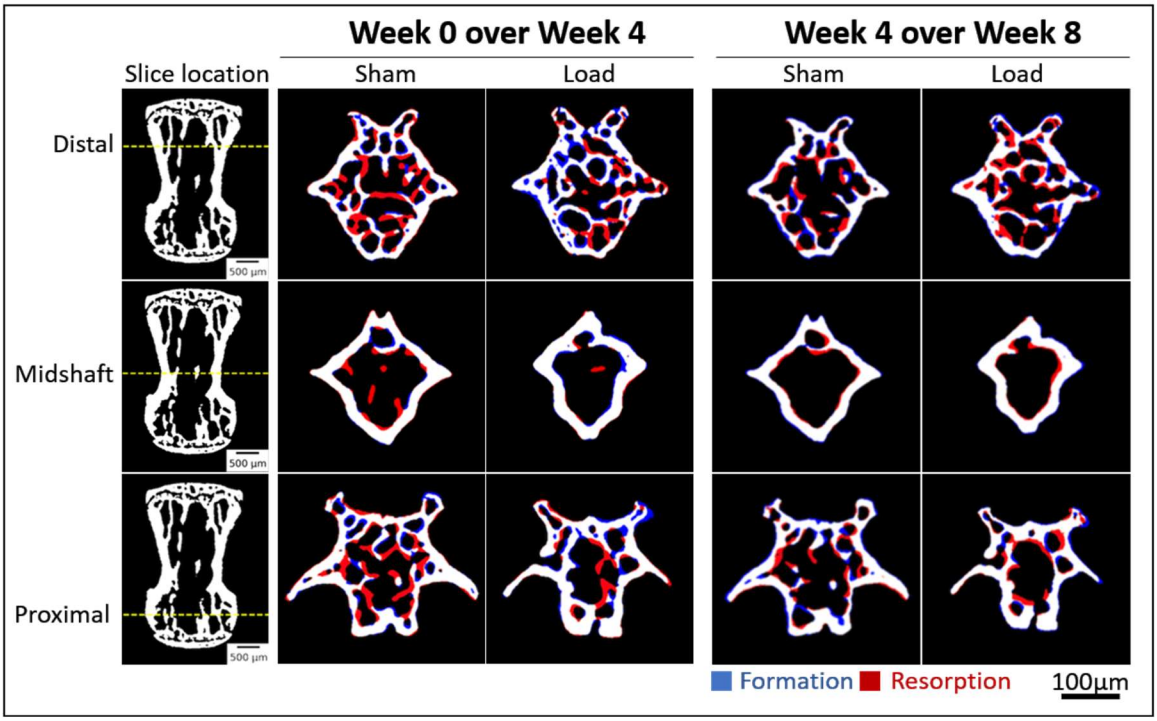
Introduction

The role of mechanical loading in spinal adaptation eventually resulting in spinal degeneration is not fully understood. Clinically, many patients associate back pain with mechanical overloading while therapeutic strategies often focus on correcting for structural changes in the spine [1]. While load-induced bone remodeling via osteoblasts and osteoclasts is well characterized in long bones, this study investigates whether mouse caudal vertebrae also respond to defined mechanical loading with structural changes, and whether these changes are reversible following load cessation [2].

Methods

Female C57BL/6 (n= 49, 11 weeks old) mice underwent mechanical loading applied via clinical grade titanium pins inserted into caudal vertebrae 5 and 7, allowing for axial cyclic compression (10 Hz, 5 min/session, 3×/week over four weeks). The sham control only underwent pinning without loading. This was followed by four weeks of non-loading. For quantification, longitudinal in vivo micro-CT (µCT; MILabs U-CT xuhr) scans were performed. Image registration and post-processing were conducted using a semi-automated workflow (Xploraytion GmbH). µCT data were compared with histological stainings, including a quantification of collagen organization and vascular structures.

Results



µCT imaging revealed distinct, region-specific bone adaptations in response to loading. Bone formation (blue) increased especially in the endplate regions, while bone resorption (red) was reduced in the loaded compared to the sham group (Fig. 1). In the midshaft area, characterized by less trabecular bone, fewer structural changes were observed. Some of

the adaptations persisted even during non-loading, suggesting only a partial reversibility of bony adaptations. Histology showed a pronounced vascular ingrowth in the endplates and the presence of osteoprogenitor cells in regions with pronounced bone formation.

Discussion

These results show that caudal vertebrae adapt to mechanical loading in a site-specific manner, with endplates being particularly responsive. These structural changes were only partially reversible after load cessation, pointing to time- and location-dependent remodeling behavior. Our future work will focus on the detailed effects at the endplates and the associated angiogenesis. Finally, our findings have to be benchmarked against patient data from clinical scenarios of vertebral overloading.

Engineering Aortic Valves via Transdifferentiating Fibroblasts Into Valvular Endothelial Cells Without Using Viruses or IPS Cells

Professor Junwei Chen, Professor Fuxiang Wei, Dr. Peng Tang, PhD Candidate Xinyu Zhang, PhD Candidate Chenyang Ji, PhD Candidate Xinman Chen, PhD Candidate Anqi Wang, PhD Candidate Wuhuang Liu

Huazhong University of Science and Technology, Wuhan, Hubei, China

Introduction

Valve replacement is the primary treatment for end-stage valvular heart disease (VHD), with hundreds of thousands of surgeries annually worldwide[1,2]. Existing bioprosthetic/mechanical valves lack growth/regeneration, challenging pediatric patients, making tissue-engineered valves an urgent need[3]. Induced pluripotent stem cells (iPSCs) offer cell replacement potential but carry tumorigenic risks and require pluripotent intermediates. The key challenge is generating valvular endothelial cells (VECs) efficiently without pluripotent states or viruses.

Methods

Mouse embryonic fibroblasts (NIH/3T3) and human primary dermal fibroblasts (HDF) were used. Transdifferentiation combined soluble factors (5-azacytidine, BMP4, VEGF, etc.) and PDMS10 (2.1 MPa, mimicking native aortic valve stiffness). Cells were seeded on PGG-crosslinked decellularized porcine valves. Assays included flow cytometry (CD31/CD144), immunofluorescence, Western blotting, DiI-Ac-LDL uptake, tube formation, teratoma formation, and ChIP-qPCR (H3K9me3, RNA polymerase Ⅱ at Flk1/CD31/CD144 promoters). In vivo validation in nude rats used Doppler ultrasonography, histology, and coagulation tests. Statistics: Student's t-test, ANOVA, Bonferroni correction.

Results

PDMS10 optimized transdifferentiation: ~70% mouse iAECs and 10% human hiVECs were $CD31^{+}CD144^{+}$ pre-sorting, reaching 95%-97% purity post-seeding. ChIP-qPCR showed lowest H3K9me3 and highest RNA polymerase Ⅱ binding at endothelial gene promoters in PDMS10 groups. iAECs/hiVECs expressed VEC markers (NFATC1, Flk1) without pluripotency markers, functionally matching native VECs. Engineered valves functioned

intact for 60 days in rats (no thrombosis/teratomas), while iPSC-derived cells had 40%-80% teratoma risk.

Discussion

This study achieved virus/iPSC-free transdifferentiation of fibroblasts into functional VECs via soluble factors and PDMS10. Core mechanism: PDMS10 reduces H3K9me3, relieving endothelial gene suppression to enhance efficiency and purity. It overcomes iPSC tumorigenic risks and viral safety concerns, offering autologous valves for pediatric patients. Limitations: non-xeno-free media, lower human cell efficiency, unclear H3K9me3 downstream mechanisms. Future work: develop xeno-free systems, optimize human transdifferentiation, and validate in large animals.differentiation, and validate clinical translational value in large animal models.

Substrate Convexity Induces Nuclear Flattening That Triggers Phenotype Marker Expression Change in Vascular Smooth Muscle Cells

Mr. Yuga Isobe PhD student[1], Mr. Takuya Nishina[1], Mr. Yudai Ishida[2], Ms. Tomoe Kamiya[2], Prof. Ryo Sudo Pfrofessor[1,2], Prof. Tadahiro Yamashita Associate Professor[1,2]

Introduction

Numerous studies in mechanobiology have revealed that the geometrical constraints in two-dimensions are transduced to biochemical signalling . Recently, the biological significance of curved surfaces at a scale equivalent to or larger than that of cells (microcurvatures) has been revealed [1]; such microcurvatures indeed change cellular protein expression and even differentiation. However, the mechanism by which the substrate curvature influences protein expression remains to be elucidated. We here hypothesise that nuclear deformation, known to mediate cellular response to geometrical inputs in two-dimentsions [2], also facilitates curvature-dependent protein expressions.

Methods

To test hypothesis, we cultured vascular smooth muscle cells (VSMCs) on substrates containing hemispherical convexes with radii spanning from 50 to 500 μm for 72h. The dependency of the expression levels of αSMA, a marker of VSMCs in the contractile phenotype, on the substrate curvature was examined by immunofluorescence and confocal microscopy. Next, we inhibited expression of nesprin1, which transmits cytoskeletal forces to the nucleus, using siRNA. Additionally, the cells were externally compressed by placing an agarose pad onto the top of the cells to test the contribution of nuclear deformation to curvature-dependent protein expression. Based on the stack of confocal images, nuclear sphericity index (NSI) representing the roundness of nuclear morphology was calculated (FigureA). The correlation between NSI and αSMA expression levels at a single cell level was examined.

Results

Elevated αSMA was observed on the convex surfaces rather than on the flat surface. αSMA expression increased as the curvature radius increased from 50 to 500 μm (FigureB).

Nesprin1 inhibition rounded the nucleus and decreased the αSMA expression, whereas the external compression flattened the nucleus and increased the αSMA expression. Overall, a moderate negative correlation between NSI and αSMA expression was observed regardless of the curvature of substrate (*R*=0.42, FigureC).

Discussion

Our results suggest that nuclear deformation is the key mediator that transduces substrate curvature to the phenotype marker expression, possibly via well-known nuclear mechanotransduction pathways [2] Our study provides fundamental knowledge on cellular geometry sensing; it may contribute to the cutting-edge biomaterials design with growing structural complexity .

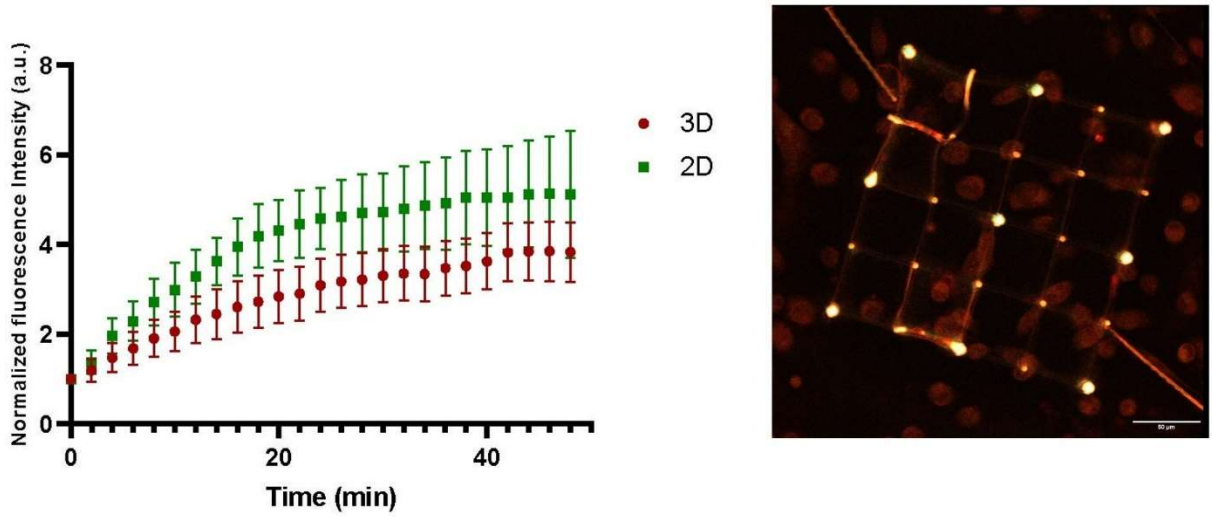
Introduction

Fibrotic remodelling alters the biomechanical properties in the tumor microenvironment, mainly due to increased collagen deposition, representing one of the main barriers to anticancer drug penetration into solid tumors [1]. To better understand and modulate these mechanisms, we developed an innovative approach combining a mechanically controlled 3D breast cancer microenvironment capable of reproducing a gradient in fibrosis, upon implantation in chick embryo chorioallantoic membrane (CAM), to provide a predictive model of chemotherapeutic drug efficacy.

Methods

Microscaffolds were fabricated by Two-Photon Polymerization (SZ2080) with different pore sizes, in which tumor cell lines MDA-MB-231, HCC1937 and BT-474 were locally seeded thanks to a 3D-printed stencil preventing surrounding substrate adhesion. In 2D, protein expression was analyzed by Western-blotting while toxicity to Doxorubicin was evaluated by metabolic assays. Fitting the acquired fluorescence data of Doxorubicin with one-phase exponential model ($F(t)=F_{max}(1 - e^{-kt})$) provided the drug release kinetic constant (k), subsequently used to estimate the Diffusion coefficient (D) in MDA-MB-231 in 2D and 3D.

Results



Tumor cell lines showed increased proliferation over time in both 2D and 3D. Preliminary protein expression results confirmed the mesenchymal phenotype of MDA-MB-231 (N-cadherin) and the epithelial phenotype in HCC1937 and BT-474 (E-cadherin). The in vitro half-maximal inhibitory concentration (IC_{50}) of Doxorubicin on controls was ~ 0.28 µM (MDA-MB-231), 0,72 µM (HCC1937), 4,95 µM (BT-474). Prior to in vivo administration,

Doxorubicin diffusion was assessed in vitro. In 2D, diffusion rate $k \approx 0.094\ min^{-1}$ yielded a diffusion coefficient of $D \approx 8 \times 10^{-14}\ m^2/s$. In 3D, the k value decreased from 0.122 to 0.062 min^{-1} inversely to scaffold height from $D \approx 1.9 \times 10^{-13}$ to $6.7 \times 10^{-13}\ m^2/s$.

Discussion

Our 3D microenvironments with optimized pore dimensions enabled cell adhesion and sustained proliferation over time, confirming their suitability for in vitro tumor cell culturing. Following implantation in the CAM chicken embryo, upon administration of antitumor drugs in combination with the antifibrotic compounds, non-linear optical microscopy combined with Raman spectroscopy will allow evaluation of collagen remodelling and correlation between drug penetration and fibrotic capsule modulation. [2]

Images (Optional)

Panel: (a) Normalized fluorescence intensity of Doxorubicin in MDA-MB-231 cells, in 2D and 3D, as a readout of drug diffusion. (b) Lifetime imaging by Confocal microscopy to monitor autofluorescence signal of Doxorubicin (λ_{em} =575 nm) in MDA-MB-231 cells embedded in the microscaffold.

The Role of Focal Adhesion Kinase in ACL Fibroblast Response to Slow Stretch Elongation Depends on Degree of Hierarchical Fiber Formation

Ms. Kelly Ott, Dr. Jennifer Puetzer

Virginia Commonwealth University, Richmond, VA, United States

Introduction

Hierarchically-organized collagen fibers strengthen tendons and ligaments but don't regenerate after injury. Previously, we developed a static system that guides cells to form hierarchical collagen fibers over 6 weeks[1] and found that addition of slow stretch at neonatal and postnatal ACL growth-rates drives further maturation.[2] However, effects of stretch changed with collagen organization, suggesting shifts in mechanotransduction.[2] Slow stretch is key in fiber maturation but difficult to replicate in adult tissue, so understanding relevant mechanotransduction pathways could help improve fiber regeneration after injury. Cells on aligned fibrils primarily sense tensile-loads via focal adhesions and focal adhesion kinase (FAK), but how they sense once larger fibers and fascicles form is unknown. This study evaluates the role of FAK in cellular sensing of slow stretch at different degrees of collagen organization.

Methods

Neonatal bovine ACL fibroblasts were mixed with collagen to form constructs at 20mg/ml collagen and $5x10^6$cells/ml[1] and cultured statically for 0, 2, or 4 weeks to obtain unorganized collagen, aligned collagen fibrils, or fibers, respectively. After, they were transferred to a tensile bioreactor and stretched at neonatal (1mm/day) or postnatal (0.1mm/day) ACL growth-rates for 1 week (Fig.1A).[2] FAK was inhibited with 10μM PF-228[3] (FAK-I) during stretch (Fig.1A). Controls were statically clamped throughout culture or dosed with DMSO during stretch. Post-culture, collagen organization, composition, and tensile strength were analyzed.[1] Data are mean±SEM.

Results

Loading increased collagen organization and mechanical properties at all timepoints (Fig.1). FAK-I reduced organization, DNA, GAG, collagen turnover, and tissue strength in unorganized collagen (Fig.1, 1wk data) but had little effect once aligned fibrils formed (Fig.1, 3wk data). FAK-I once fibers formed increased collagen organization and concentration for both stretch-rates and tensile strength with neonatal (Fig.1, 5wk data).

Discussion

FAK-I blocked stretch-driven improvements in unorganized collagen, but had little effect once fibrils had formed. Further, FAK-I improved organization and mechanics with stretch applied once fibers formed. This suggests FAK is an important mechanosensor during fibril formation, but other mechanosensors dominate cellular response to slow stretch at higher levels of collagen organization. Understanding these mechanosensors could help stimulate collagen repair after injury.

Sensitivity of Frictional Interactions During Mechanical Thrombectomy: In Silico and In Vitro Investigations

Dr. Mahesh S. Nagargoje[1], Ms. Demitria Poulos[2], Ms. Virginia Fregona[3], Dr. Giulia Luraghi[3], Prof. Francesco Migliavacca[3], Dr. Bryan Good[2], Prof. Jose Felix Rodriguez Matas[3]

[1]Politecnico di Milano, Milan, Lombardy, Italy. [2]University of Tennessee Knoxville, Knoxville, Tennessee, United States. [3]Politecnico di Milano, Milan, Lombardia, Italy

Introduction

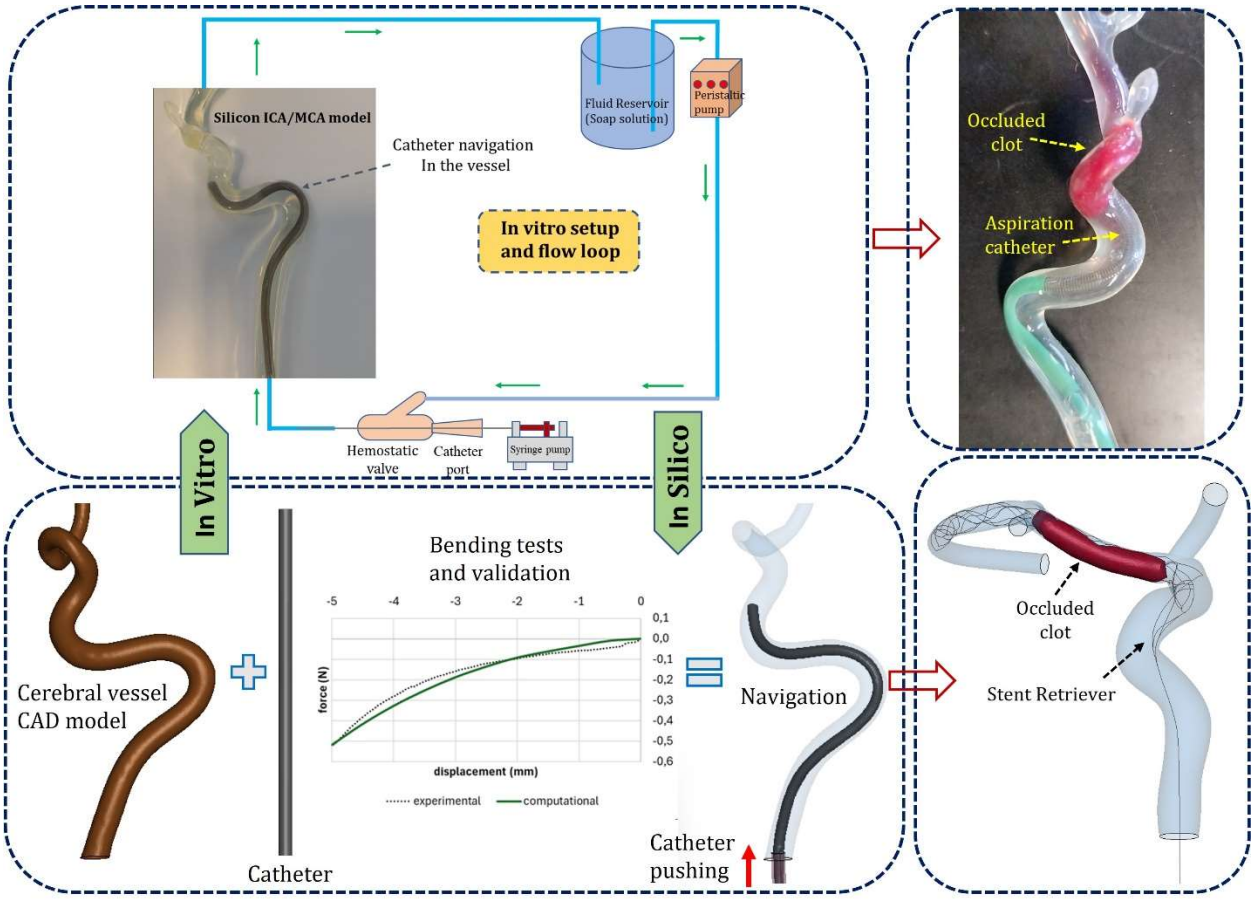
Mechanical thrombectomy (MT) has revolutionised the treatment of Acute Ischemic Stroke; however, procedural failures persist due to device–vessel friction, catheter navigation difficulties, and uncertainties in clot–device interaction mechanics [1]. Stent compression, catheter kinking, and navigation resistance are strongly influenced by vessel tortuosity and frictional forces, yet current in silico models lack validated friction coefficients and realistic catheter-tracking mechanics. This work investigates the sensitivity of frictional interactions during SR retrieval and catheter navigation, combining benchtop experiments with virtual mechanical thrombectomy (VMT) simulations in flexible vessels.

Methods

A benchtop circulatory loop was developed using a silicone ICA/MCA phantom to study SR retrieval and Aspiration thrombectomy. A Solitaire X 6×40 mm SR was deployed via a Phenom 21 microcatheter and retrieved at 2 mm/s using a programmable syringe pump. Catheter navigation tests were performed by advancing microcatheters (Plato 27B) and aspiration catheters (Sofia Plus) through tortuous pathways. Navigation resistance and catheter bending/kinking behavior were recorded.

VMT simulations were developed for the same model used for in vitro experiments. SRs were modeled with shape-memory alloy beam elements; catheters were modeled as linear orthotropic structures calibrated using experimental bending tests. Simulations reproduced crimping, deployment, retrieval, and catheter pushing in flexible vessels using finite element modeling [2]. Quantitative comparisons of stent compression, catheter path, and retrieval forces were made between experiments and simulations.

Results



High-friction conditions increased SR compression, clot fragmentation, and retrieval resistance, particularly in curved MCA regions. Lubrication reduced SR deformation and

improved clot entrapment. Catheter navigation experiments and simulations showed significantly increased resistance, kinking, and vessel traction in acutely curved vessels. Flexible-vessel MT accurately reproduced experimental catheter paths and failure modes.

Discussion

The combined analysis demonstrates that friction critically affects both SR mechanics and catheter navigability. Accurate friction modeling and flexible-vessel simulations are essential for predicting MT success, understanding failure pathways, and guiding next-generation device design. This work provides a validated framework for realistic in silico thrombectomy and catheter navigation modeling to support surgical planning and future in silico clinical trials.

Modelling Mechanical Thrombectomy in Silico: A Validation Study

MSc Virginia Fregona[1], PhD Giulia Luraghi[1], MSc Ciaran Gillespie[2], PhD Shahd Horie[2], PhD Ray McCarthy[2], PhD Jose Felix Rodriguez Matas[1], PhD Francesco Migliavacca[1,3]

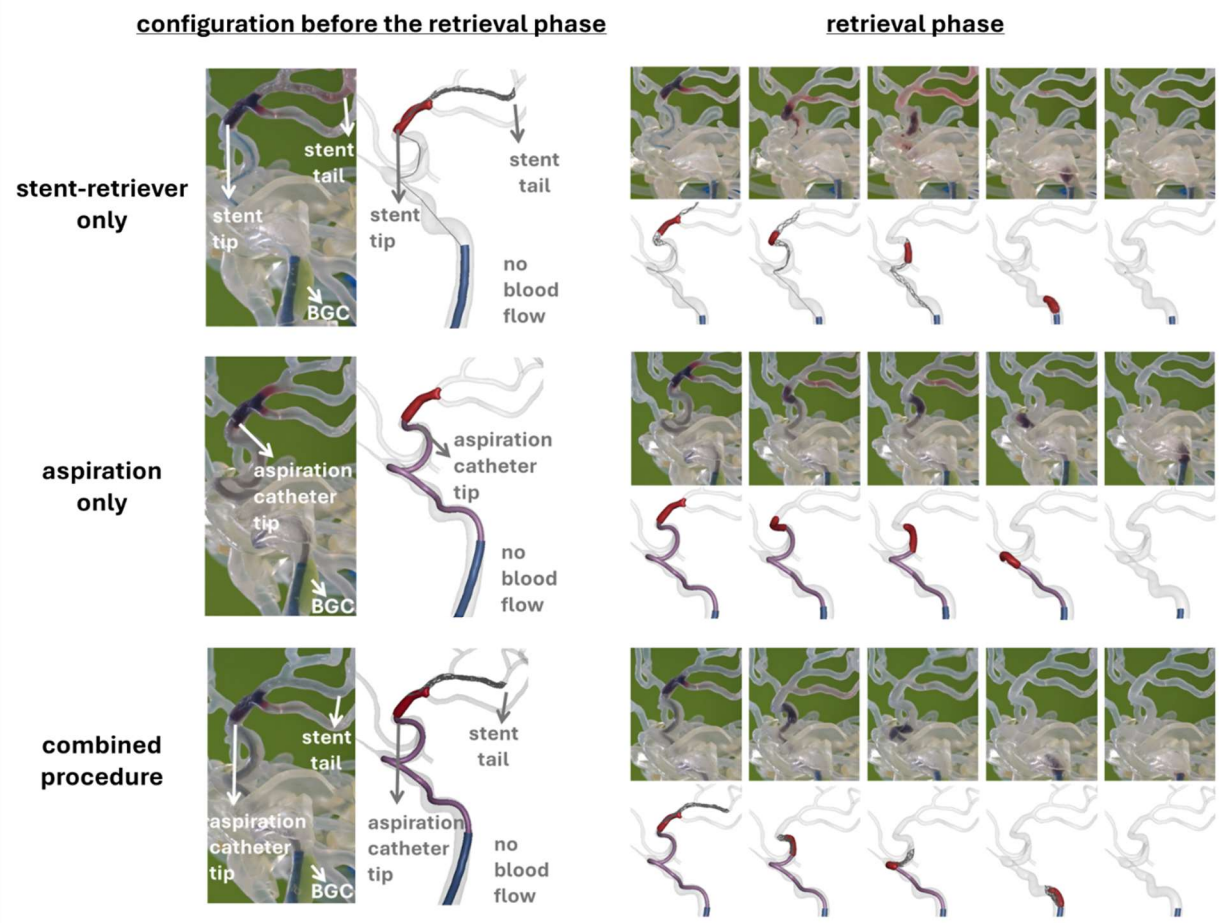
[1]Dept. of Chemistry, Materials and Chemical Engineering, Politecnico di Milano, Milan, Lombardy, Italy. [2]J&J MedTech Neurovascular, Galway, County Galway, Ireland. [3]Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Lombardy, Italy

Introduction

Mechanical Thrombectomy (MT), a minimally invasive treatment for acute ischemic stroke, aims to remove a clot from a large cerebral vessel using stent-retrievers and/or aspiration catheters. To investigate key aspects of this procedure (e.g. effect of devices, clot mechanical properties [1] or vessel morphology [2]), Finite Element Analysis (FEA) can be employed. This work aims to validate the MT FE analyses by comparing them with in vitro MTs performed using the three techniques: stent-retriever, aspiration, and combined approach.

Methods

A silicone anatomical model of the cerebral vasculature, with physiological pressures and flow rates, was used to perform the experiments with twelve different combinations of techniques (three), devices (two stent-retrievers and two aspiration catheters) and clot compositions (two: 5% and 30% RBCs, ovine clot analogues [3]). The four devices used in the tests were mechanically characterised and then modelled in silico. Finally, FE analyses were generated to reproduce each of the twelve experiments, mimicking the in vitro procedure as closely as possible. Each in vitro – in silico pair was compared in terms of success or failure of clot removal and qualitatively in terms of clot fragmentation and device-clot kinematics.



Results

Eight MTs could be reproduced with structural simulations, whereas four would require fluid-structure interaction to model aspiration and combined procedure in the presence of highly fragmentable clots (30% RBCs). All eight structural simulations reproduced the in vitro outcome, and half of them also showed a matching kinematic. One representative example per MT technique is shown in the attached figure.

Discussion

This study demonstrates that FE analyses can, in general, replicate the identified quantities of interest (namely, thrombus removal and fragmentation). However, further work is needed to model MTs in condition where purely structural simulations fail. Overall, this validation provides a foundation for an applicability analysis of MT FE analyses in clinical contexts.

Effect of Stent Retriever Behavior on Clot Removal Success During Mechanical Thrombectomy

Ms. Demitria Poulos[1], Dr. Michael Froehler[2], Dr. Bryan Good[1]

[1]University of Tennessee, Knoxville, TN, United States. [2]Vanderbilt University Medical Center, Nashville, TN, United States

Introduction

Stent retriever mechanical thrombectomy (SR MT) is an endovascular therapy to remove a thrombus from an occluded vessel causing a stroke. The first pass effect (FPE), a measure of complete revascularization with a single SR pass, is only achieved in 27% of patients. MT proves to be more complex when the occlusion occurs in tortuous anatomies, strongly influencing the rate of FPE.

Methods

A circulatory flow loop with a tortuous ICA/MCA arterial model was developed. Each curve of the model was separated into distal, center, and proximal regions to track SR deformation. Control MTs, tests without clots, were first performed to investigate SR collapse in the arterial model. Next, 50% hematocrit clots were injected into the flow loop and lodged downstream in the arterial model. Benchtop MTs were then performed (**Fig. 1A**) with both Solitaire (4x15, 4x40, 6x40 mm) and EmboTrap (5x22, 5x37 mm) commercial SRs.

Results

Control tests proved that the center and proximal regions of all SRs experienced the most collapse around a curve, while the distal segment remained generally expanded during retrieval. Overall, 30 MTs were performed with 50% hematocrit clots and SR stretching was found to negatively impact MT outcomes (i.e. failed FPE) in 13 cases. FPE was achieved in 60% of cases with the 4x40 SR and only 20% of cases with the 6x40 SR. Shorter SRs (4x15, 5x22 mm) resulted in similar FPE rates (**Fig. 1B**).

Discussion

Sufficient SR-clot integration is a key factor for successful thrombus removal with MT. Without EAs present, SR collapse was observed and varied across devices sizes, limiting the possibility for SR-clot integration. However, we suspect the expansion of the distal portion of longer SRs assists in the clot removal process despite the collapse. We hypothesize that lower rates of FPE are observed with the 6 mm SR due to SR overlap, caused by deployment of a 6 mm device within a 3 mm diameter tubing. Future studies will

continue to investigate FPE in more realistic arterial models and with clots of varying composition and mechanical properties.

Introduction

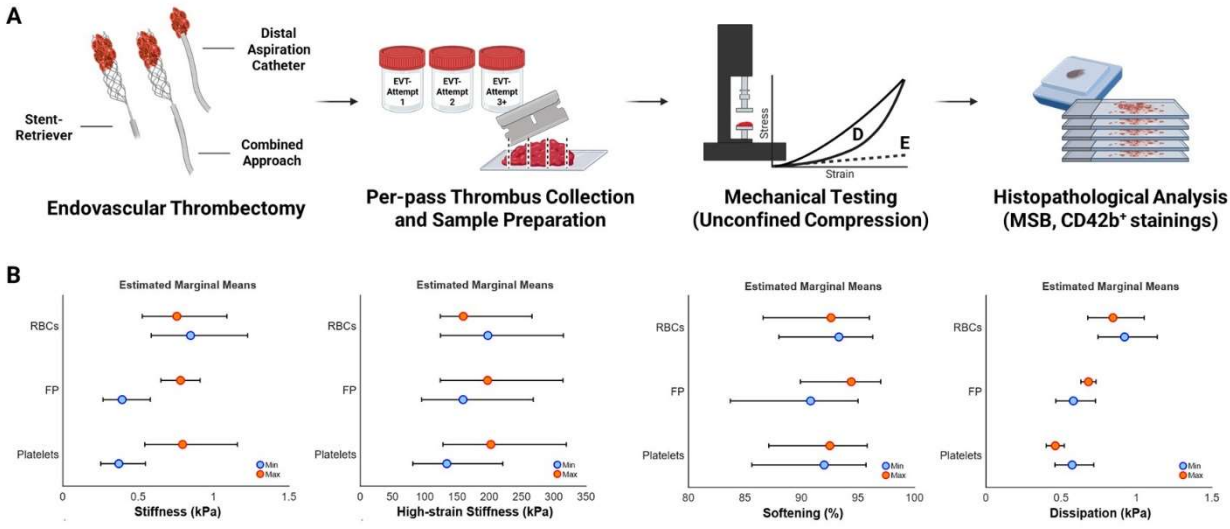
Cerebral thrombus mechanical properties influence endovascular thrombectomy (EVT) success in acute ischemic stroke (AIS). Understanding the relationship between thrombus mechanics and composition is essential to predict thrombus–device interactions. [1] While in vitro thrombus analogues are well characterized, ex vivo cerebral thrombi remain poorly described. [2] This study provides the first characterization of AIS thrombus viscoelastic mechanical properties and identifies the histopathological determinants of stiffness, softening, and energy dissipation in thrombi retrieved during EVT.

Methods

Thrombi retrieved from 73 EVT-treated patients were sectioned for mechanical testing and processed for histology within six hours (Fig.1A). Unconfined quasi-static compression tests using a custom-built device measured bulk low- and high-strain stiffness (10% and 75%-strain secant moduli), softening (stiffness variation between first and last cycle), and dissipation (strain-normalized hysteresis area). [3] A total of 346 sections (median per patient=6.5) were compressed to 80% strain for 20 cycles, at a strain rate of 10%. Histology quantified RBCs, fibrin and platelets. Linear mixed-effects regression first examined associations among mechanical properties, then assessed histological determinants.

Results

Median patient-averaged thrombus stiffness was 0.779 kPa (IQR 0.289–1.663), softening 0.897 (0.821–0.970), and dissipation 0.333 kPa (0.072–1.086). Stiffness correlated positively with dissipation (β=0.162, 95% CI 0.084; 0.240), while softening correlated negatively with dissipation (β=–0.008, 95%CI –0.013; –0.003).



Thrombus stiffness was positively associated with platelets (β=0.008, 95%CI 0.004;0.012) and negatively with RBC content (β=–0.008, 95%CI –0.012;–0.005). Fibrin showed a positive

trend with softening (β=0.021, 95%CI −0.001;0.044). Dissipation was negatively associated with RBCs content (β=–0.007, 95%CI –0.011;–0.003). Fig.1B shows the marginal effects from the regressions.

Discussion

Stiffer thrombi, enriched in platelets and fibrin and depleted in RBCs, dissipate more energy per cycle, while softer thrombi, RBC-rich, progressively lose stiffness during cyclic loading and thus might be more prone to fragment. These findings underscore the relevance of thrombus mechanical properties and composition for EVT, as mechanical variability may create distinct procedural challenges requiring tailored retrieval strategies and may inform device design and intervention planning.

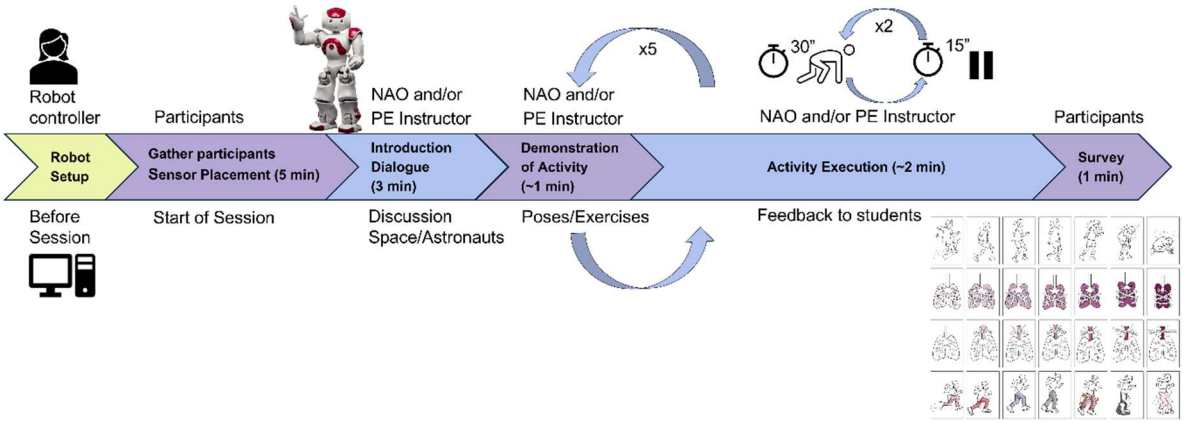
Introduction

Sedentary behavior in children, caused by factors like prolonged screen time, critically reduces opportunities and motivation for physical activity (PA) with negative effects (e.g., risk for obesity) persisting into adulthood [1]. Incorporating thematic elements in children's PA, such as NASA's "Train Like an Astronaut" (TLA) challenge, leverages children's curiosity to strengthen health knowledge and stimulate PA interest [2]. Further, socially assistive robots may capture children's attention, motivating participation in movement-based educational activities [3]. This work assesses the feasibility of a robot-assisted program that integrates motivational space-themed activities and the social appeal of a humanoid with the aim of increasing PA engagement and enjoyment, and attenuating perceived exertion compared to traditional instruction.

Methods

The cohort comprised 136 children (10–11 years old) recruited from physical education classes for a 6-week program involving two 20-minute sessions weekly. The program was integrated into an ongoing long-term STEM intervention, "Stories of Tomorrow" (focused on organizing a Mars mission and colony [4]). Participants were randomly assigned to the Human-Robot (HR) experimental group, where the robot NAO provided primary instructions supported by the instructor, or the Human-Only (HO) control group, where sessions were solely instructor-led. Both groups were engaged in high-intensity interval training exercises (e.g., plank, quadruped crawl), adapted from NASA's TLA challenge and modified to maintain participant interest. Activity was recorded via Fitbit trackers. The Physical Activity Enjoyment Scale quantified PA enjoyment every other session, while the Dalhousie Dyspnea and Perceived Exertion Scales measured perceived exertion immediately post-session. Participants' knowledge of human space exploration and health behaviors was surveyed pre- and post-study.



Results

All participants completed the sessions, attempting each exercise. Preliminary analysis supports high enjoyment scores (HO:4.4±0.90, HR:4.0±1.16), declining perceived exertion over time (HO:-38.4%, HR:-20.5%), and low baseline knowledge score (2.98±1.60).

Discussion

This study confirms the program's feasibility, with ongoing analysis assessing post-study knowledge acquisition and between-group differences.

Cardiovascular Biomechanics Workshop for High School Students

Dr. Fanette Chassagne[1], Dr. Raphaëlle Jarrige[2], Ms. Lina Abssi[2], Mr. Simon Fontaine[2], Dr. Baptiste Pierrat[1]

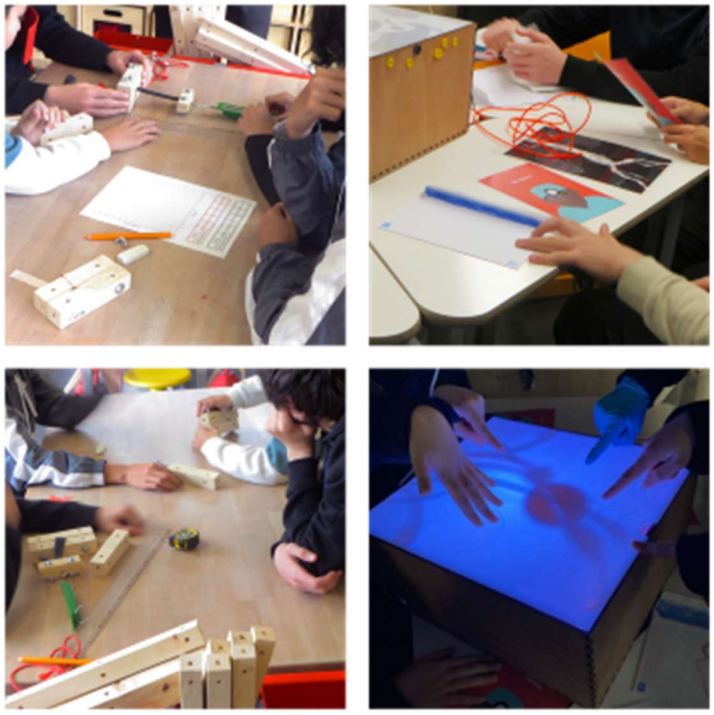
[1]Mines Saint-Etienne, Sainbiose INSERM U1059, Saint-Etienne, Loire, France. [2]Mines Saint-Etienne, Saint-Etienne, Loire, France

Introduction

Explora (https://explora.saint-etienne.fr/discover-explora/) is a dedicated center for scientific outreach located in Saint-Étienne, France. It is managed by La Rotonde, the Center for Scientific, Technical and Industrial Culture of Mines Saint-Étienne. A few years ago, Explora launched the "Research Workshop" program, specifically designed to give high school students direct exposure to the processes and realities of scientific research. Each two-hour workshop ensures maximum student engagement through active participation and includes a dedicated discussion with a professional researcher.

Methods

The workshop, defined in collaboration with scientific outreach specialists, focused on the biomechanics of abdominal aortic aneurysms and was designed to maximize student autonomy. Following a pilot test with one student group (approx. 25 students), feedback was used to refine the format. The final version was successfully implemented for nine student cohorts, engaging approximately 250 students in total.



Results

The final two-hour workshop was structured into four interactive parts. It began with an introduction using a phone-based quiz on the cardiovascular system and aneurysms. Next, during hands-on mechanical characterization, students designed improvised tensile testing devices with common tools (ruler, luggage scale, ...) to obtain force-displacement curves for materials like rubber gloves and inner tubes, comparing their results to data for human aortic tissue. The third phase focused on clinical application, where a researcher demonstrated endovascular aneurysm repair using a surgical simulator. Students then participated in a role-play, manipulating their own simulators with fake catheters and X-ray tools to experience the surgical challenges. The workshop concluded with an open Q&A with the researcher and the opportunity for students to manipulate preserved porcine aorta.

Discussion

The workshop achieved a high level of student engagement, evidenced by their demonstrated curiosity and enthusiasm for the interactive components. The design effectively integrated hands-on mechanics, clinical simulation, and direct researcher interaction. Future projects will concentrate on adapting this effective model for delivery directly within classrooms.

Stance-Phase Kinematic Biomarkers Differentiate Total Knee Replacement From Conservative Management in Women With Moderate Knee Osteoarthritis

Ms Mayra Alejandra Loayza-Saldaña[1], Dr. Simone Tassani[1], Dr. Laura Tío[2], Dr. Jordi Monfort[2,3], Dr. Gil Serrancolí[4,5], Dr. Gemma Piella[1], Dr. Jérôme Noailly[1]

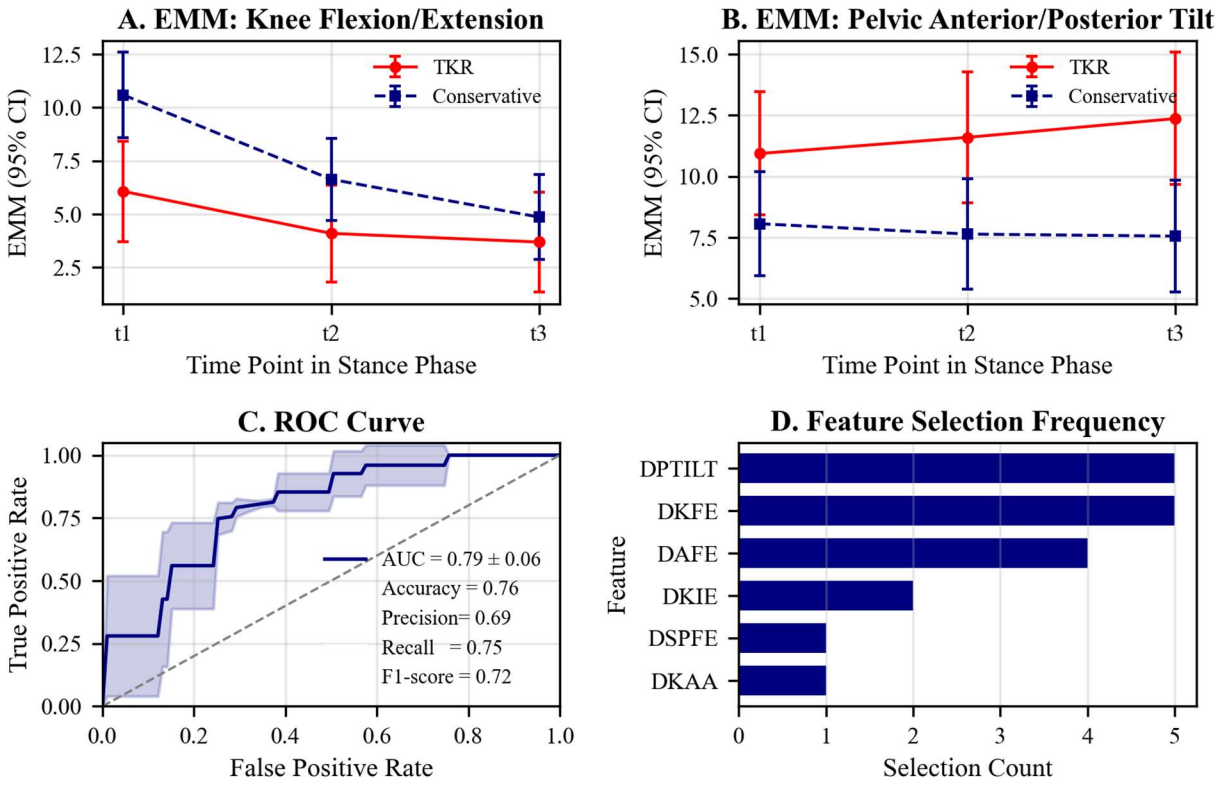
[5]Institut de Robòtica i Informàtica Industrial (CSIC-UPC), Barcelona, Barcelona, Spain

Introduction

Total knee replacement (TKR) is the primary treatment for knee osteoarthritis (KOA) with severe symptoms, yet decision-making is influenced by subjective judgment. Long-term outcomes for 10-34% of patients are unclear, prompting the need for objective patient stratification. This study aimed to identify biomechanical descriptors differentiating TKR-scheduled from conservatively managed KOA patients and to examine their association with patient-reported outcomes.

Methods

Sixty-six women (27 TKR, 39 conservative) with moderate KOA (Kellgren–Lawrence grades 2-3) underwent gait analysis. Participants were classified by age, body mass index and treatment at baseline. The effect of these factors on joint kinematics was assessed across three stance sub-phases (loading response (t1), mid-stance (t2), and terminal stance (t3)) using repeated-measures multifactorial MANOVA. Stance-phase kinematic changes (D = t3 -t1) were analyzed using Random Forest models with nested cross-validation and exhaustive feature selection, and their associations with clinical variables were examined through logistic regression. Clinical construct consistency was assessed against the Osteoarthritis Initiative dataset.



Results

MANOVA revealed significant Time × Treatment interactions (p-value = 0.001). The univariate test showed knee flexion-extension (KFE) and pelvis tilt (PTILT) associated with treatment. At initial loading (t1), patients in the conservative group exhibited greater knee flexion angles, whereas the TKR group showed stiffer joints across all three time points (Fig. A). Moreover, the TKR group demonstrated greater pelvic tilt during the stance phase compared to the conservative group (Fig. B). Machine learning achieved mean ROC-AUC of 0.79 and F1-score 0.72 (Fig. C), with DKFE, DPTILT, and DAFE as the most stable predictors (Fig. D). DPTILT predicted functional limitation (AUC 0.71), pain (0.80), and depression (0.73). Clinical construct structure was preserved between datasets, though WOMAC subscales alone yielded poor classification accuracy (<0.70).

Discussion

Stance-phase kinematics differentiate treatment pathways demonstrating that biomechanical features outperform patient-reported outcomes for treatment stratification. Strengths include comprehensive 3D gait analysis with repeated-measures multifactorial MANOVA and rigorous feature selection and hyper-parameter tuning. Limitations comprise the cross-sectional design, and the use of delta features that condense continuous trajectories. Machine learning classifiers using biomechanical sets show promise for supporting decision making, but validation in larger, sex-balanced cohorts and multimodal integration are essential.

Knee Adduction Moment Is Associated With Acute Cartilage Deformation Following Walking in Adults With Clinical Knee Osteoarthritis

Dr. Erin C.S. Lee PhD[1], Dr. Kendal A. Marriott PhD[1], Dr. Anthony A. Gatti PhD[2], Ms. Natasha K. Ivanochko MSc[1], Dr. Jacquelyn M. Maciukiewicz PhD[1,3], Dr. Lauren Straatman PhD[1], Ms. Emily Wiebenga[1], Dr. Jonathan D. Adachi[4], Dr. Michael D. Noseworthy PhD[4], Mr. Paul W. Stratford MSc[4], Dr. Monica R. Maly PhD[1]

[1]University of Waterloo, Waterloo, ON, Canada. [2]Stanford University, Palo Alto, CA, United States. [3]Waterloo Regional Health Network, Waterloo, ON, Canada. [4]McMaster University, Hamilton, ON, Canada

Introduction

The knee adduction moment (KAM) during walking predicts future cartilage loss in knee osteoarthritis (OA) [1]. However, the validity of the KAM as a proxy for medial knee load has been questioned [2] and there is a lack of data showing how KAM relates to cartilage response *in vivo*. The purpose of this study was to investigate the association between peak KAM and acute cartilage deformation following a standardized walking exposure in adults with clinical knee OA.

Methods

89 adults with clinical knee OA (females/males=59/30, age=65±7 years, BMI=28.9±5.2 kg/m^2) participated. In the first visit, 3D overground walking data were collected with optical motion capture and a synchronized force plate. Peak KAM was averaged over five trials. Approximately one week later, participants underwent magnetic resonance imaging (MRI) before and immediately after a 25-minute walk at a speed standardized to leg length [3]. We computed acute deformation as the mean difference in thickness between the pre- and post-walk scans in the medial and lateral tibia and medial and lateral weight-bearing femur. For each region, regression models determined the association between peak KAM and acute deformation after adjusting for age, sex, BMI, and pre-walk cartilage thickness.

Results

Higher peak KAM, indicating a higher medial-to-lateral load ratio, was associated with greater cartilage deformation (or thickness reduction) in the medial femur (β=-0.21 [-0.39, -0.04], p=0.02). We also observed nonsignificant trends where higher peak KAM tended to

associate with greater deformation in the medial tibia (β=-0.12 [-0.26, 0.02] p=0.08) and less deformation in the lateral tibia (β=0.11 [-0.01, 0.23], p=0.07).

Discussion

Here, we directly link KAM to *in vivo* cartilage deformation in clinical knee OA for the first time. Our findings indicate that tibiofemoral cartilage regions that experience higher loads exhibit greater deformation in adults with clinical knee OA. This deformation likely reflects increased fluid flow to dissipate loading [4]. Future work will investigate whether there is a threshold of excessive deformation that could be a mechanism contributing to cartilage degradation over time.

Images (Optional)

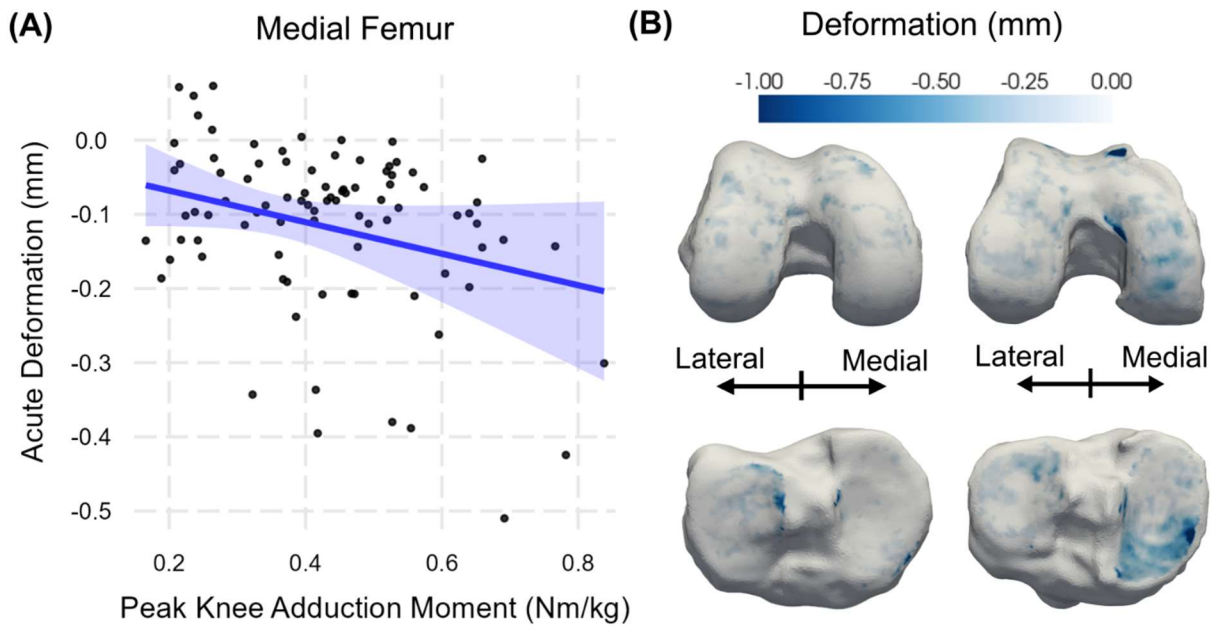

Figure 1: (A) Acute deformation associated with peak KAM in the medial femur. Negative deformation indicates a reduction in cartilage thickness after walking. **(B)** Deformation maps for a participant with low KAM and low deformation (left) and a participant with high KAM and high deformation (right) in the medial femur and tibia.

Cartilage Volume and Composition in Masters Runners With and Without Knee Osteoarthritis: Changes Immediately Following a Run and After a 12-Week Progressive Distance Running Program

Dr. Michael A. Hunt PhD, PT[1], Ms. Michaela C.M. Khan MSc[1], Ms. Natasha M. Krowchuk BSc[1], Dr. Anthony A. Gatti PhD[2], Dr. Alexander Rauscher PhD[1], Dr. Eric C. Sayre PhD[3], Dr. Jean-Francois Esculier PhD, PT[4]

[1]University of British Columbia, Vancouver, BC, Canada. [2]Stanford University, Stanford, CA, United States. [3]BC Centre on Substance Use, Vancouver, BC, Canada. [4]The Running Clinic, Lac Beauport, QC, Canada

Introduction

Recreational running provides significant physical and mental health benefits throughout the lifespan, with the number of masters runners (those aged >35 years) at an all-time high. With the increasing age of the running community comes questions about the appropriateness of running for knee joint health, especially for those with knee osteoarthritis. While there is growing evidence that running is generally not harmful to younger, healthy knees, there are still many questions regarding running with knee osteoarthritis. We aimed to address these gaps by comparing how knee cartilage in masters runners with and without knee osteoarthritis recover from a single run and react to a 12-week progressive distance running program.

Methods

47 runners with (KOA), and 27 control runners without (CON), knee osteoarthritis underwent magnetic resonance imaging of knee cartilage before (Baseline) and after (Follow-up) a 12-week progressive volume running program. We measured changes in cartilage volume and composition (T2 and T1ρ relaxation times) across 8 regions of interest in the tibia, femur, and patella immediately before and after a 30-minute treadmill run at each testing session. Within- and between-group contrasts were examined both within and between testing sessions to assess the immediate and longer-term effects of running on cartilage.

Results

Statistically significant decreases in relaxation times and volumes were observed in most regions of interest immediately following the treadmill run in both groups at both testing

sessions. Relative differences immediately following the runs were modest (T2 < 5%; T1ρ < 11%; volume < 5%). Between-group differences were observed in patellar and lateral tibial volumes at Follow-up, as well as the change in immediate responses when comparing Follow-up and Baseline (greater loss in CON in all comparisons showing a difference).

Discussion

These data indicate that osteoarthritic and non-osteoarthritic cartilage generally respond similarly to a single bout of running and to a running program focused on increasing distance. Our findings suggest that running with knee osteoarthritis does not have deleterious effects on cartilage health, thus providing important and unique information that will inform clinicians and runners in the management of knee symptoms and overall joint health.

A Markerless, Autoencoder-Derived Gait Quality Index for Knee Osteoarthritis

Ms. Julia Irvine[1], Mr. Jereme Outerleys[1], Dr. Elise Laende[1,2], Dr. Kevin Deluzio[1]

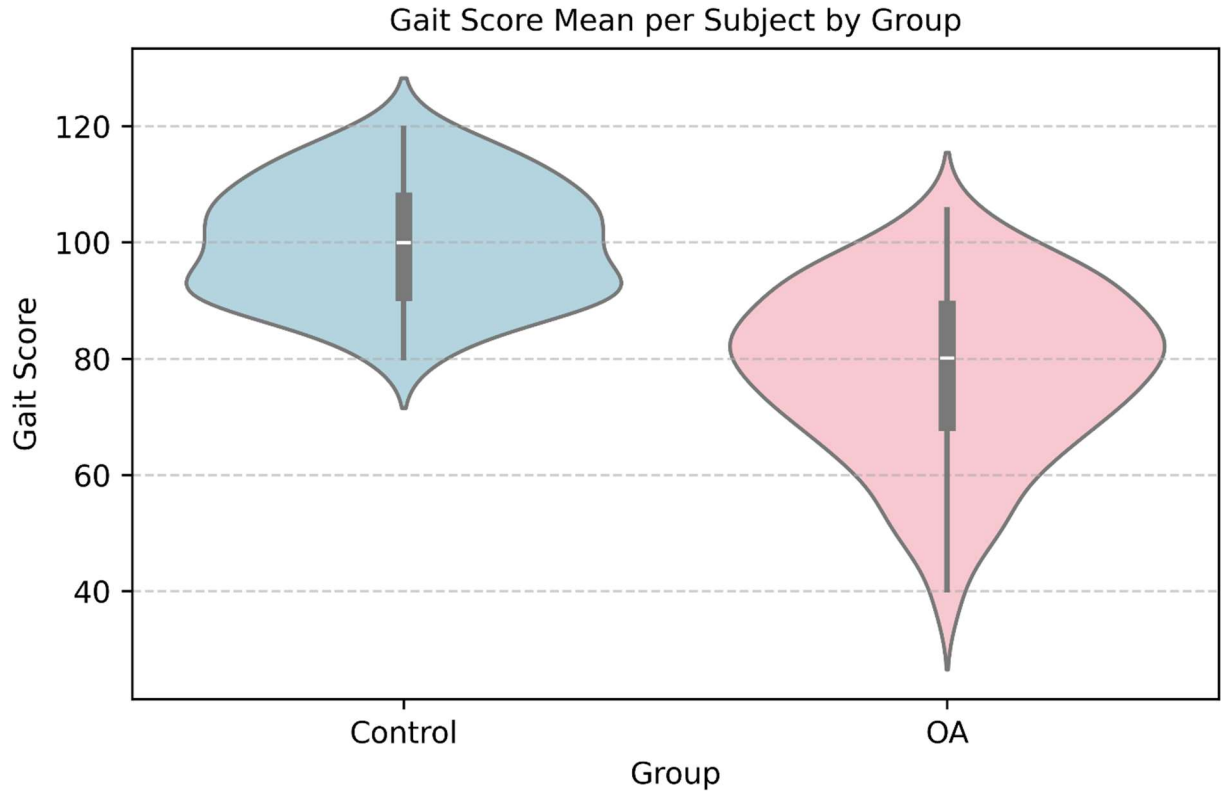
[1]Queen's University, Kingston, Ontario, Canada. [2]University of Waterloo, Waterloo, Ontario, Canada

Introduction

Radiographic severity and symptom scores in knee osteoarthritis (OA) often fail to reflect the biomechanical contributors to functional decline, despite gait impairment being a central to disability. Traditional gait summary metrics rely on linear dimensionality reduction techniques, which may overlook the nonlinear, multi-joint compensations characteristic of OA. Recent work demonstrated that autoencoders can condense high-dimensional gait data into low-dimensional representations while retaining substantially more information than linear approaches [1]. However, this methodology has not been translated to OA populations or applied with markerless motion capture, which offers a scalable pathway for routine, clinic-ready gait assessment. This study aimed to derive an autoencoder-based markerless gait index for knee OA and evaluate its discriminative ability and association with patient-reported outcomes.

Methods

The study included 294 subjects: 230 with OA (67.3 ± 8.47 years) and 64 asymptomatic controls (58.3 ± 18.6 years). Overground gait kinematics were processed using Theia3D v2023. Seventy gait variables (63 kinematic, 7 spatiotemporal) per subject were extracted and min-max normalized. A two-layer autoencoder was optimized via five-fold cross validation. Principal component analysis (PCA) was applied to the same inputs for comparison, with both methods reducing the data to a single dimension [1]. Feature importance was assessed using a tuned random forest model. The relationship between the resulting gait index and EQ-5D mobility scores were quantified using Spearman correlation.



Results

The optimized autoencoder retained 56.0±2.67% of input variance (maximum 58.4%), substantially exceeding PCA's first principal component (22.3%). OA participants exhibited significantly lower gait scores than controls with a very large effect size (Cohen's d=-1.60, $p<0.0001$). Scores correlated strongly with EQ-5D mobility (Spearman's $\rho=-0.614$; $p<0.0001$). Top contributing features included mean foot-progression angle during stance, maximum knee flexion, and hip-adduction range.

Discussion

A markerless, autoencoder-derived single-score gait index effectively distinguishes OA gait patterns and reflects mobility related quality of life. The autoencoder's superior variance retention versus PCA suggest that OA gait adaptations involve nonlinear biomechanical relationships. Limitations include cross-sectional design and single-dimension compression, which may oversimplify OA gait complexity. Future directions should validate sensitivity to change following treatment and explore whether higher-dimensional representations improve groups discrimination.

Infrapatellar Fat Pad Volume and Knee Joint Running Biomechanics in Runners With a History of Knee Surgery: Data From the TRAIL Cohort

Dr Danilo De Oliveira Silva Associate Professor[1], Dr Benjamin Mentiplay Senior Lecturer[1], Dr Kay Crossley Professor[1], Dr Prasanna Sritharan Research Fellow[1], Ms Melissa Haberfield PhD student[1], Dr Michael Girdwood Research Fellow[1], Ms Elizabeth Sylvestre[2], Mr Peter Hartley[2], Ms Yimo Wang[2], Mr Zaid Faiz[2], Ms Bhavana Billapaty[2], Mr Brody McCarthy PhD student[1], Ms Fernanda Serighelli[1], Dr Harvi Hart[3]

[1]La Trobe University, Melbourne, VIC, Australia. [2]Western University, London, Ontario, Canada. [3]Michigan State University, East Lansing, Michigan, United States

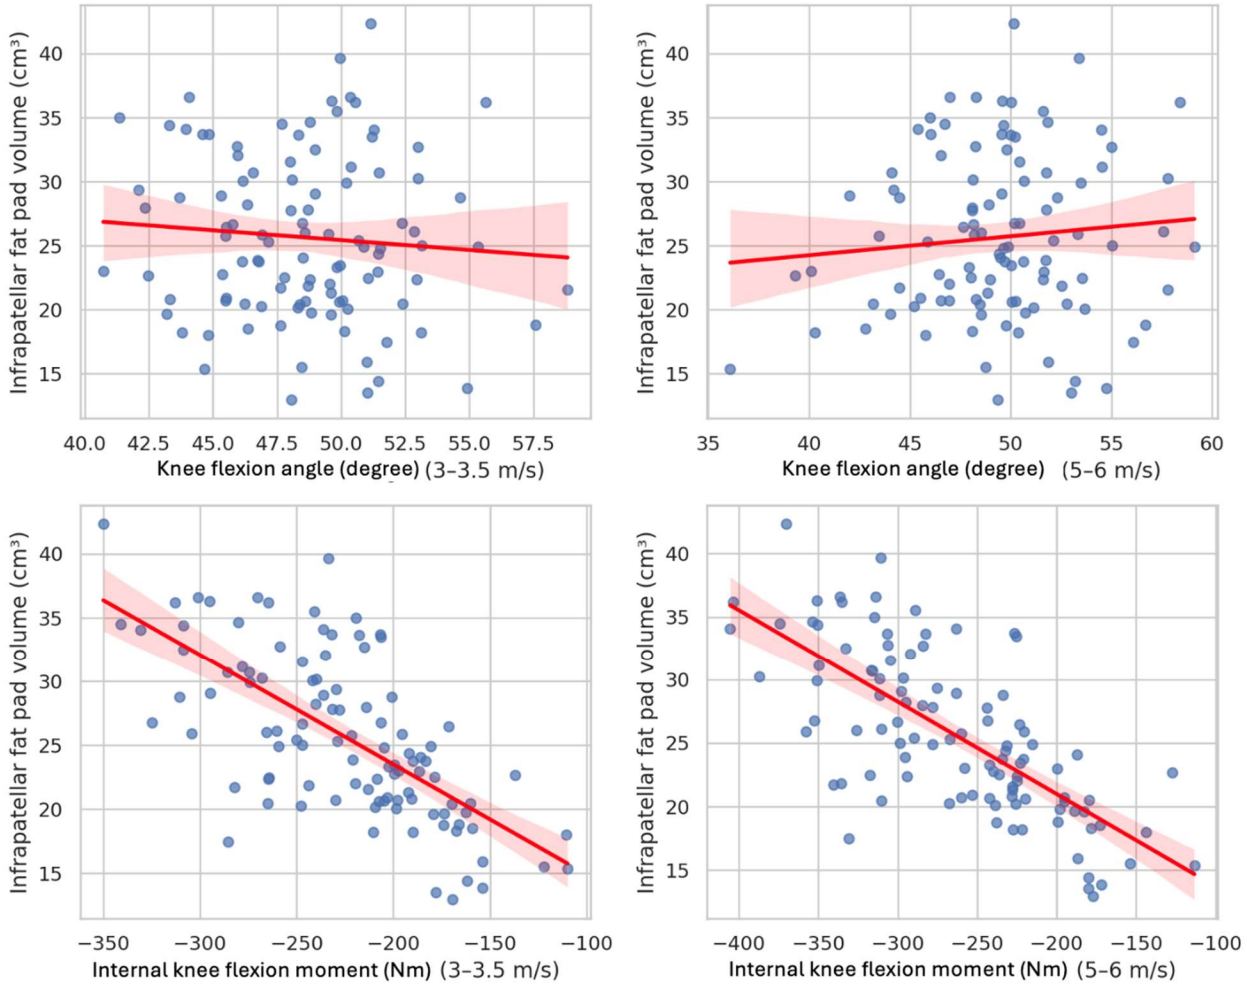
Introduction

Individuals at increased risk of post-traumatic knee osteoarthritis often show altered sagittal-plane biomechanics. The infrapatellar fat pad (IPFP) has also been linked to post-traumatic knee osteoarthritis, but the relationship between these biomechanical changes and IPFP involvement remains poorly understood. Therefore, we explored whether peak knee flexion angle and internal knee flexion moment during running are associated with IPFP volume in runners with a history of knee surgery.

Methods

Runners with a history of knee surgery who ran at least 3 times and >10km a week underwent quantitative gait analysis using a 10-camera motion capture system synchronised with force plates. Running trials were collected at 3–3.5 m/s and 5–6 m/s in participants' habitual footwear. Peak knee flexion angle and peak internal knee flexion moment for the surgical limb were calculated over the stance phase using OpenSim. IPFP volume (cm^3) was quantified from sagittal T2-mapped MRI by manually digitising the IPFP boundaries slice-by-slice. Separate linear regression models examined associations between each biomechanical variable at each speed and IPFP volume, whilst adjusting moments for body mass and sex, and angles for sex.

Results



106 runners (52 females; mean age 34±7 years, mass 77±13 kg) were included. The IPFP volume ranged from 12.9-42.3cm^3. The peak knee flexion angle was not associated with IPFP volume at 3–3.5m/s (B [95% CI]: 0.01 [−0.23 to 0.26]) or at 5–6m/s (0.08 [−0.12 to 0.28]). Lower peak internal knee flexion moment was associated with smaller IPFP volume

at both 3-3.5m/s −0.04 [−0.07 to −0.01]; R^2=0.59) and 5-6m/s (−0.04 [−0.07 to −0.02]; R^2=0.60). This indicates that a 10Nm lower peak internal knee flexion moment is associated with approximately a 0.4 cm^3 smaller IPFP volume.

Discussion

Among runners with a history of knee surgery, lower peak internal knee flexion moments, but not knee flexion angles, were associated with smaller IPFP volume. As lower moments reflect reduced quadriceps demand, these findings align with underloading frameworks in post-traumatic knee osteoarthritis, where insufficient mechanical stimulation may influence IPFP morphology. Clinically, interventions that restore knee extensor loading, if confirmed longitudinally, may help maintain IPFP health.

Time-Frequency Analysis of Muscle Activation Patterns in People With Knee Osteoarthritis During Walking

Mr. Taewoong Kong[1], Dr. Hoon Kim[1,2]

[1]Department of Software Convergence, Soonchunhyang University, Asan-si, Chungcheongnamdo, Korea, Republic of. [2]Department of Sports Medicine, Soonchunhyang University, Asan-si, Chungcheongnamdo, Korea, Republic of

Introduction

Knee osteoarthritis (KOA) is a degenerative disease that impairs neuromuscular function, including quadriceps and hamstring weakness and prolonged activation, which are reflected in altered electromyography (EMG) amplitudes. However, EMG amplitudes cannot fully explain neuromuscular alterations in KOA, given that the underlying motor unit recruitment and firing behavior can usually be captured in the frequency domain of EMG. Therefore, the purpose of this study was to investigate lower-limb muscle activation patterns in time-frequency domain in people with KOAs.

Methods

Muscle activation data of 8 lower-limb muscles from a public dataset, including ten KOA patients and ten healthy older adults, were used. Four walking trials per subject were analyzed. Wavelet transformation and principal component analysis (PCA) were applied to decompose EMG data in time-frequency domain. Two-way mixed ANOVAs and post-hoc pairwise comparisons were used to test group and muscle effects on PC scores.

Results

PCA captured contrasts between low-mid frequencies in the early/late phase and the full band in the middle phase (PC1), and low frequencies early vs. the full band in the middle-late phase (PC2). Significant group x muscle interaction was observed for PC1 ($p<0.001$) and PC2 ($p=0.001$). In addition, patients with KOA exhibited lower PC1 scores in vasti and medial hamstring, greater PC1 scores in gastrocnemius and soleus, and greater PC2 scores in hamstrings compared with healthy controls.

Discussion

People with KOA exhibited distinct deficits in muscle activations in the time-frequency domain. PC1 indicated a partial “pattern swap,” whereby vasti and hamstring activation

became more plantar-flexor-like and plantar-flexor activation more proximal knee-like, so that these muscles were not predominantly active during the phases in which they are normally most needed, consistent with a less efficient neuromuscular strategy during walking. Higher PC2 scores in hamstrings showed relatively greater low-frequency activation early in the gait cycle and reduced broadband activation during a functionally critical phase, particularly terminal swing for the hamstrings. Together, these PC1 and PC2 alterations indicate a temporally mistimed and spectrally altered knee-ankle activation strategy, reflecting a protective and inefficient strategy during early stance and compromised deceleration capability during terminal swing, which might affect gait function.

Anterior Trunk Leaning Does Not Alter Recovery Time and Sagittal Whole-Body Angular Momentum After Perturbations in Human Running

M.Sc. Luca Braun[1,2], PhD Brian R. Umberger[2], M.Sc. Carlo von Diecken[1], PhD Varun Joshi[2], M.Sc. Laila Sikeler[1], M.Sc. Sebastian Rehorst[1], M.Sc. Janina Helwig[1], M.Sc. Bastian Anedda[1], PhD Steffen Willwacher[1]

[1]Institute for Advanced Biomechanics and Motion Studies, Offenburg University of Applied Sciences, Offenburg, Baden-Württemberg, Germany. [2]School of Kinesiology, University of Michigan, Ann Arbor, Michigan, United States

Introduction

Given the substantial mass and inertia of the trunk, anterior trunk leaning (ATL) is an effective strategy to redistribute lower extremity joint moments in running, specifically reducing knee extension moments at the cost of increased hip extension and external rotation moments. By shifting the centre of mass forward relative to the base of support, ATL may influence perturbation recovery, an essential determinant for preventing falls and related injuries. However, whether ATL affects perturbation recovery - defined here as perturbation recovery time (PRT) and sagittal whole-body angular momentum (WBAM) range after slip-like anterior–posterior perturbations (SLAPPs) - remains unclear.

Methods

Sixteen recreational runners completed six treadmill runs (2.5 m/s) at one self-selected and five predefined ATL conditions spanning −4° to 28°. Each condition included five standardised SLAPPs at pseudorandomized time intervals. Kinematics and kinetics during baseline and perturbed steps were captured. Subject-specific 95% prediction bands around time-normalised baseline sagittal WBAM curves were generated. PRT was defined as the time from perturbation onset to the final time point at which WBAM re-entered this band (Fig. 1A). Linear mixed-effects models were applied to PRT (condition) and sagittal WBAM range, defined as peak-to-peak WBAM (condition, step, interaction), with subject as a random intercept.

Results

PRT did not differ across ATL conditions ($p=0.63$; Fig. 1B). WBAM range showed significant main effects of step ($p<0.001$; Fig. 1C) and condition ($p<0.001$; Fig. 1D) with no interaction

(p=0.59). WBAM range decreased with increasing ATL. Relative to baseline, WBAM range increased after the perturbation, peaked at step 3, and returned to baseline by step 5.

Discussion

ATL did not affect recovery time following SLAPPs in running. Although sagittal WBAM range was sensitive to SLAPPs and differed across ATL conditions, the sagittal plane perturbation recovery strategy on a whole-body level is unaffected by ATL, given the absence of an interaction between factors. Thus, using ATL, which reduces knee extension moments and may reduce the risk of running-related overuse injuries, does not appear to affect perturbation recovery, suggesting that fall risk after SLAPPs might be unaffected. Future work should investigate joint-level changes to determine whether recovery mechanics differ across ATL conditions.

Watch Your Step: Stepping Error Increases With Age in Response to Perturbing Visual Cues

Mr Adam Grimmitt, Mr Jonaz Moreno, Mr Paul McDonnell, Dr Douglas Martini, Dr Wouter Hoogkamer

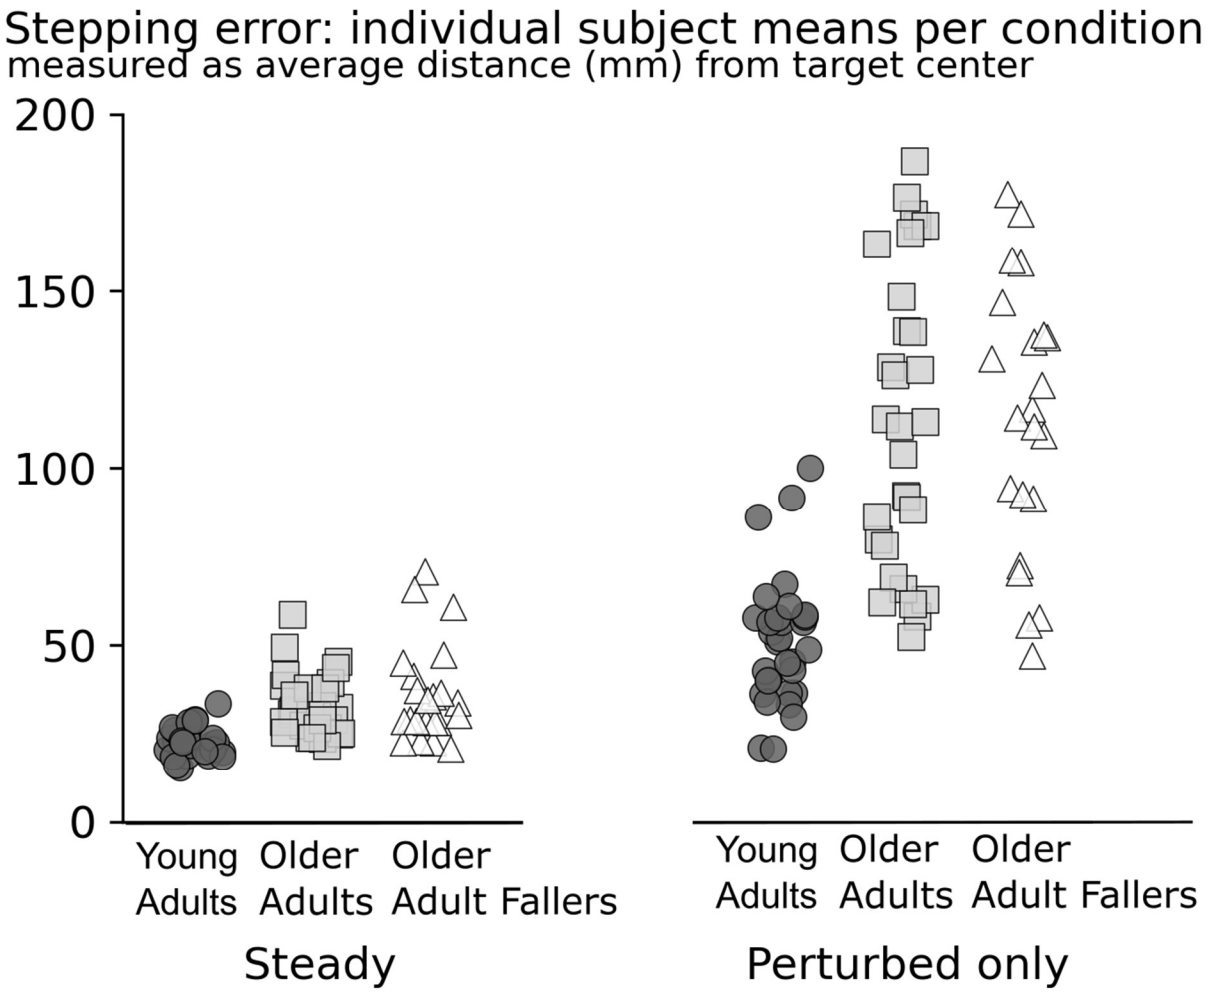
University of Massachusetts Amherst, Amherst, MA, United States

Introduction

Globally, 35% of adults over the age of 65 experience a fall annually [1]. Missteps directly increase their fall risk, and reactive step training improves their fall outcomes [2,3]. However, relationships between visual processing and missteps are largely unknown. This study compared stepping error among young adults, older adults, and older adult fallers during visually cued walking and visually cued walking with perturbations. We hypothesized that (1) stepping error would be larger in older adults, and that (2) during visually cued walking with perturbations, stepping error would be the largest in older adult fallers.

Methods

31 young adults, 30 older adults, and 22 older adult fallers walked on a treadmill for two three-minute trials at their habitual speed with visual cues (stepping targets) projected onto the surface of the treadmill at matched speeds. During visually cued walking with perturbations, random stepping targets were shifted in a forward, backward, or lateral direction. Stepping error was quantified as the average distance between the foot center at midstance and the nearest stepping target. We used a linear mixed effects model and Bonferroni corrected t-tests to compare the effects of age group across stepping target conditions: steady, perturbed lateral, perturbed backward, and perturbed forward.



Results

Our model revealed main effects of age $F_{(1,83)} = 39.17$, $p<0.001$, target condition $F_{(1,249)} = 209.24$, $p<0.001$, and an age × target condition $F_{(1,249)} = 19.29$, $p<0.001$. Specifically, stepping error was larger in older adults compared to young, $t_{(86.1)} = 8.67$, $p<0.001$. Furthermore, compared to young adults, older adult and older adult fallers were less accurate when responding to perturbed targets, $t_{(97.8)} = 10.54$, $p<0.001$, although they were not different from each other $t_{(97.8)} = 0.27$, $p=0.830$.

Discussion

Older adults exhibited larger stepping error, indicating an age-related response to virtual cues.There was no difference in perturbed target stepping error between older adults and older adult fallers. Stepping error before and after a perturbed step could elucidate differences between fallers and non-fallers, however our current findings suggest that aging, but not fall history, is associated with stepping error.

Preferred Locomotor Patterns Minimize Head Motion Variability

Mr Liam Foulger, Dr Jesse Charlton, Dr Jean-Sébastien Blouin

University of British Columbia, Vancouver, BC, Canada

Introduction

The ability to sense the world around us is crucial for movement and navigation. Given visual and vestibular sensors in the head contribute to self-motion estimates, it is important to reduce variability (i.e., noise) in head motion. Head movement variability is lowest near preferred walking speeds, similar to how our preferred locomotor patterns minimize energetic cost. This suggests that sensory demands – in addition to energetic cost – shape our movement. To determine if minimizing sensory variability is associated with other well-defined locomotor behaviours, we tested if preferred walk-run transition speeds (~2m/s) also minimize head motion variability. Secondarily, we quantified if head movement variability is lowest near our preferred running speeds.

Methods

Five participants (2F) walked and ran outdoors across a range of speeds (<0.5m/s to >5m/s). We quantified head kinematic variability by calculating the mean ratio (V_{res}) of residual variability (deviation from average stride cycle) to total magnitude of head linear accelerations and angular velocities. We fitted second-order polynomial functions to each participant's walking and running data.

Results

Participants preferred to walk at 1.39±0.20m/s and run at 3.15±0.82m/s. For the mean V_{res} calculated from net head linear acceleration, the polynomials fit well for walking (R^2=0.97±0.04, minima=1.53±0.11m/s) and running (R^2=0.95±0.05, minima=2.94±0.59m/s). The ideal walk-run transition point (intersection of the polynomials) was 1.92±0.29m/s. The mean V_{res} polynomial fits for net head angular velocity had worse fits for walking (R^2=0.74±0.31, minima=1.56±0.58m/s) and running (R^2=0.75±0.16, minima=5.85±0.57m/s). The transition point was 2.36±0.38m/s.

Discussion

We found that head kinematic variability during walking exceeded that during running around the speed (~2m/s) where humans transition from walking to running (hypothesized

to be energetically optimal). Head kinematic variability was lowest near preferred walking speeds. This relationship was less clear for running given head variability changed minimally across speeds, similar to previously reported energetic cost landscapes. Although our work presents evidence that head motion variability influences how we move, it is not clear how sensory and energetic constraints interact to shape motion. Future work should address if these are competing demands or if sensory noise is a proxy for optimizing energy expenditure.

Images (Optional)

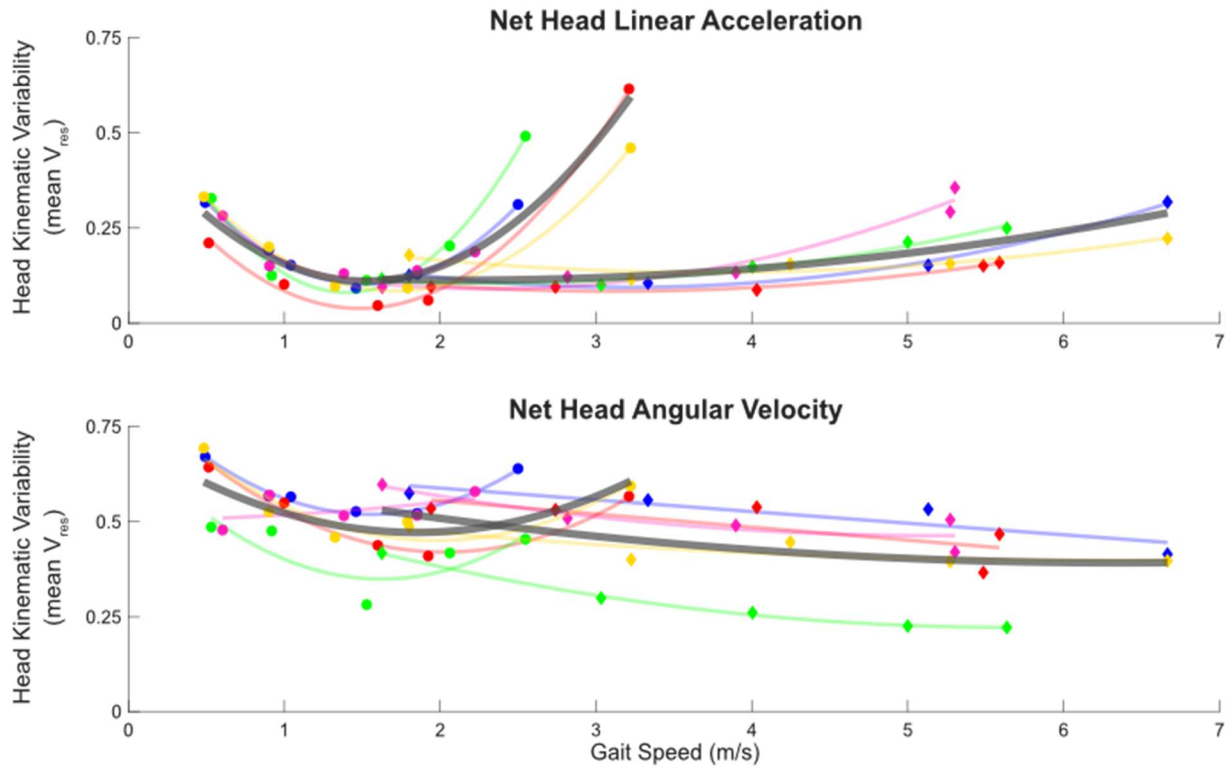

Figure 1. Head kinematic variability as quantified by the mean proportion of residual variability (V_{res}) from net head linear acceleration (top) and net head angular velocity (bottom). Participants walked (circles) and ran (diamonds) at various speeds on an outdoor track. Thin coloured lines represent fitted second-order polynomial functions for each participant's walking and running. Thick grey lines represent second-order polynomial functions fitted to the entire group data.

Does Peripheral Vision Restriction Alter Walking Function?

Ms Jasmaine Bubier-Hunter BS, Dr Frankie Wade Ph.D.

San Diego State University, San Diego, CA, United States

Introduction

As adults age, they rely more on visual feedback to maintain balance and locomotor stability; however, declines in peripheral vision can impair gait [1]. When visual information is altered, individuals adjust their gait to stay stable [2]. We isolated the effect of peripheral vision on walking function in healthy adults and hypothesized that restricted vision would lead to wider, shorter steps, reduced arm swing, stooped posture, and increased variability.

Methods

Fourteen healthy adults (28+-11 years; 70.7+-17.0 kg; preferred speed: 1.19+-0.15 m/s) walked for 2 minutes in full (VIS) and restricted-vision (LOW_VIS, 30-70°, SwivelVision Goggles) conditions on an instrumented treadmill (AMTI Tandem) at their preferred speed. 43 markers (Plug-in Gait plus greater trochanter and 5^{th} metatarsophalangeal) were sampled at 100 Hz (Vero 2.2, Vicon). Spatiotemporal gait parameters, postural measures, and sagittal plane joint kinematics were extracted. Paired t-tests compared VIS and LOW_VIS (α=.05).

Results

Restricted peripheral vision did not significantly alter spatiotemporal averages or arm swing. Trunk angle, the angle between the vector from C7 to the pelvis and the vector from the pelvis to the stance heel, did not differ between conditions. Heading, the angle between the anteroposterior axis and the vector connecting anterior and posterior superior iliac crest midpoints, showed no change. Variability in heading reduced and lower limb range of motion increased with LOW_VIS (Table 1).

Discussion

Despite reduced visual input, participants did not adopt the expected cautious gait strategy, contrary to our hypothesis and prior evidence [3]. Instead, variability reduced in heading and the only significant differences occurred at the joint level, where range of motion increased in the lower limb. This suggests healthy adults compensate for reduced peripheral vision through greater sagittal-plane joint excursions rather than altering whole-body posture. These findings align with evidence that individuals adapt to decreased sensory environments through joint-level adjustments rather than gross postural changes [4]. We continue to expand this work to incorporate aging adults in our collections.

Brachial Plexus Injury Impairs Upper Limb and Trunk Kinematics during Self-Selected Walking and Tandem Gait

MSc. Aline Dalfito Gava[1,2], PhD. Ana de David[1], MSc. Carlos Passos Goncalves[1,2], MSc. Marcio Mendonca Cardoso[2]

[1]Universidade de Brasilia, Brasilia, DF, Brazil. [2]Sarah Network of Rehabilitation Hospitals, Brasilia, DF, Brazil

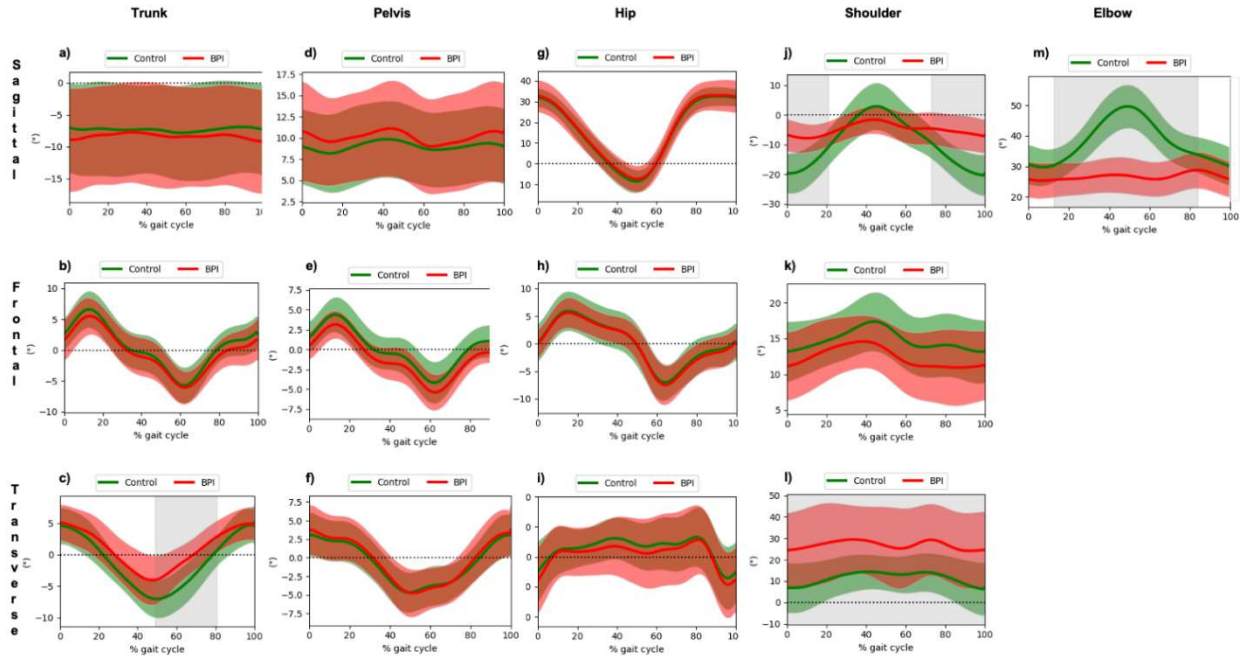
Introduction

Traumatic brachial plexus injury (BPI) reduces upper limb function and motion, which pays a crucial role in postural control and gait stability, particularly in challenging conditions. No previous studies were found investigating upper limb and trunk kinematics during gait in individuals with BPI. These comprehensions could guide future rehabilitation interventions. This study aimed to compare upper limb, trunk, and pelvis kinematics between individuals with BPI and healthy controls during self-selected walking speed (SSWS) and tandem gait (TG).

Methods

Forty adults (20 unilateral BPI; 20 controls matched for sex, age, and body mass index) performed SSWS and TG (3 meters distance). Inclusion criteria: confirmed BPI and age ≤20 years; exclusion criteria: previous surgical treatment, any musculoskeletal or neurological disorders. A motion-capture system (Vicon System, USA) with 11 cameras at 120 Hz rate was used to measure kinematics in sagittal, frontal and transverse planes using a full-body plug-in-gait marker set. Group differences were assessed by statistical parametric mapping (SPM) and t-tests ($p \leq 0.05$).

Results



Compared to controls, BPI participants walked more slowly and with shorter step lengths across both tasks ($d = -0.87$ to -1.05). The affected limb exhibited no shoulder or elbow angular motion during either task. During SSWS, the BPI group showed trunk rotation toward the affected side during terminal stance and early swing (Figure 1). Across TG, pelvic drop toward the affected side was observed during medial swing. Furthermore, the non-affected shoulder showed an add compensatory increases in internal rotation during

early and medial stance, and during medial to late swing. Participants with BPI required 36.4% more time to complete the 3-meter TG task.

Discussion

Upper limb–trunk–pelvis coupling is increased during SSWS and TG in individuals with BPI. It may reflect compensatory mechanisms linked to impaired arm swing. In TG, more challenger task than SSWS, there was a add compensatory strategy in the unaffected shoulder. These findings emphasize the importance of rehabilitation strategies that integrate upper-limb recovery in gait and postural control training. Future studies should explore whether targeted interventions can restore more symmetrical arm–trunk–pelvis coordination and improve dynamic stability.

Different Visual Scanning Strategies Are Associated With Improved Mobility in Adults With and Without Glaucoma

Dr. Michelle Harter, Dr. J. Patrick Mayo, Ms. Galen Holland, Dr. Rakié Cham

University of Pittsburgh, Pittsburgh, Pennsylvania, United States

Introduction

Glaucoma causes peripheral visual field loss and significant mobility limitations [1]. However, even those with severe glaucoma still have residual central vision, which, if leveraged appropriately, can be useful for mobility. Systematic movement of the eyes / head, called visual scanning, can help salient objects fall within an individual's preserved visual field as they walk through complex real-world environments. People with vision loss adopt different visual scanning strategies than those without vision loss [2], but it remains unclear which strategies are beneficial. This work examined how head and eye scanning patterns relate to mobility performance in individuals with glaucoma.

Methods

Seven adults with normal vision (63±8 years; 4F) and five adults with glaucoma (68±4 years; 4F; glaucoma severity ranging from mild to advanced) walked an outdoor garden path representative of real-world mobility demands while head kinematics and eye movements were tracked (Opal V2R IMUs; Tobii Pro Glasses 3). Magnitude of head scanning was quantified by peak-to-peak head pitch and yaw. Magnitude of eye scanning was quantified by the percentage of spatial area over which the participant fixated during the task. Mobility was quantified by completion time. Pearson correlation coefficients (ρ) were identified to find associations between head / eye scanning and mobility (moderate or strong correlations reported).

Results

Head and eye scanning showed different relationships with mobility in adults with glaucoma compared with those without glaucoma. In adults without glaucoma, greater head yaw and larger spatial area of fixations were associated with slower completion time (head yaw: ρ=0.85; spatial fixation area: ρ=0.60). In contrast, adults with glaucoma who showed greater head yaw and greater spatial area of fixations tended to have faster completion time (head yaw: ρ=–0.57; spatial fixation area: ρ=–0.39).

Discussion

These results highlight that head and eye scanning may be beneficial for improving mobility efficiency in people with glaucoma. These findings will be expanded in future work with the goal of developing a visual scanning training program to teach people with glaucoma effective visual scanning strategies for maintaining real-world mobility.

Cleat Engagement Patterns used by Elite American Football Athletes during Peak Utilized Translational Traction

Mr. Cody M. O'Cain[1], Mr. W. Brody Hicks[1], Dr. Evan A. Dooley[1], Dr. Kristy B. Arbogast[2], Dr. Laura C. Schmitt[3], Mr. Antonius Prader[1], Dr. Jason R. Kerrigan[1], Dr. E. Meade Spratley[1]

[1]Biomechanics Consulting and Research (Biocore), LLC, Charlottesville, Virginia, United States. [2]Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, United States. [3]The Ohio State University, Columbus, Ohio, United States

Introduction

For decades, researchers have used mechanical devices to evaluate footwear traction characteristics for investigating athlete safety and performance [1, 2]. These mechanical tests typically employ a few standardized footwear engagement patterns that often do not reflect the wide variety of footwear engagement patterns utilized by athletes during play. The goal of this study was to quantify the cleat engagement patterns utilized by elite American football athletes during peak utilized translational traction to inform more representative cleat testing.

Methods

Twenty-seven male athletes (mean ± SD: age, 27 ± 5 y; height, 1.88 ± 0.2 m; body mass, 95.6 ± 13.8 kg; shoe size, US Men’s 12 ± 1) with college or professional American football experience performed four sport-relevant motions using two commonly worn cleat models while 3D motion and ground reaction forces were captured. 3D scans were taken of the cleats, and the 3D surface mesh of each cleat was dynamically deformed based on the athlete cleat kinematics to derive the contact patch between the cleat and surface. Peak utilized traction, contact patch, center-of-force, and ground reaction force were aggregated for each motion, cleat, and loading and unloading phases. SPM1D was used to test significant differences.

Results

Contact area increased as athletes applied more vertical force during all motions and reached a maximum area between 2.5 and 3.25 bodyweight of vertical force during the loading phase. Contact area remained at this maximum until 2.5 to 1.25 bodyweight during the unloading phase. Contact area rapidly decreased below 0.25 bodyweight during the unloading phase, which corresponded with a rapid increase in utilized traction for all

motions. Significant differences were observed for utilized traction between the two cleats and the loading and unloading phases below 0.25 bodyweight.

Discussion

Prior studies have designed tests with cleat engagement patterns that mimic athletes to better evaluate the traction characteristics of cleats and surfaces [3]. This research presents a method for deriving cleat-surface engagement patterns. The applied method identified associations between peak utilized traction, applied vertical force, and cleat contact area.

Images (Optional)

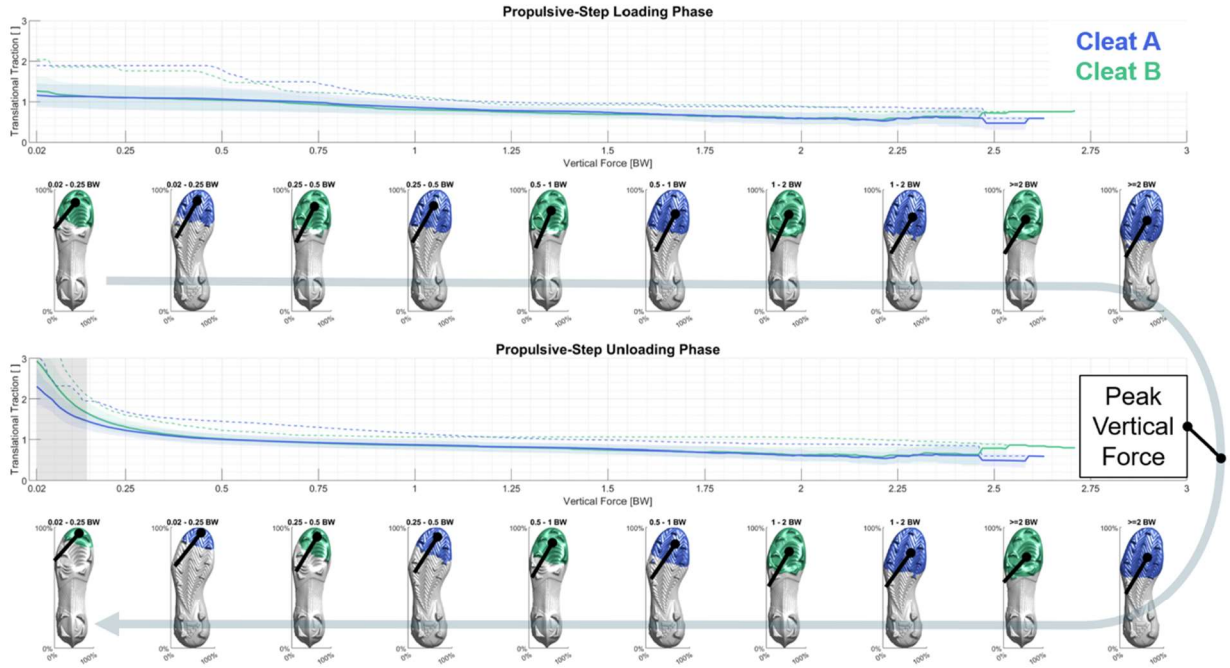

Figure 1: The cleat engagement and peak translational traction utilized for the propulsive step the population of athletes. The solid lines on the two graphs represent the average peak utilized translational traction as a function of vertical force, shade region represents +/- 1 standard deviation, and the dashed line represents the population max. The grey shaded region represents a significant difference in utilized traction between cleat A and cleat B. The blue and green shaded region on each cleat represents the average contact patch for the population during peak utilized traction, and the black dot and vector represents the center-of-pressure and cleat reaction force vector. The transparent arrow depicts time starting with touch-down in the top left, peak vertical force on the right, and ending with toe-off on the bottom left.

Absolute Energy Returned from the Forefoot of Advanced Footwear is Strongly Related to Reduced Metabolic Cost

Mr. Eddie Martinez, Mr. Jesse Frank, Mr. Daniel Shull, Dr. Bryan Conrad, Dr. Jennifer Sumner

Brooks Sports, Seattle, Washington, United States

Introduction

While greater percentage of energy return in running shoes has been associated with reduced metabolic cost (MC), recent literature suggests that energy returned from the forefoot region may be the most metabolically relevant due to the energy stored and returned from this region being later in stance [1]. Forefoot energy return can be expressed as absolute forefoot energy out (FFEO) and as the percentage of stored-to-returned energy (FFER%). The purpose of this study was to understand how FFEO and FFER% in advanced footwear technology (AFT) are associated with MC, and which may be the most relevant.

Methods

Respiratory gas exchange (Cosmed K5) was collected from 23 runners (11 male, 12 female) while running in two AFT conditions (Hyperion Elite 4, HE4; Hyperion Elite 5, HE5) at their individually estimated marathon pace. Shoe order was randomized, mirrored, and counterbalanced with five-minute bouts of running separated by five-minute rests. MC (W/kg) was averaged over the last two minutes of the two trials run in each shoe. Mechanical testing was conducted on each AFT using a biofidelic forefoot force-compression protocol with a peak force of 730N (ElectroPuls E3000, Instron). Linear mixed-effects regression models assessed the relationship between both FFEO and FFER% and MC.

Results

HE5 exhibited 38% greater FFEO (HE4: 2.1J, HE5: 2.9J) and 23% greater FFER% (HE4: 68.2%, HE5: 83.8%). Runners demonstrated 1.5% lower MC in HE5. Both FFEO and FFER% significantly predicted MC ($p < 0.001$), but FFEO demonstrated a substantially stronger negative relationship ($\beta = –0.318$) than FFER% ($\beta = –0.016$). Greater FFEO corresponded to lower MC (Fig. 1).

Discussion

A strong relationship exists between mechanically measured FFEO and runners' MC at their estimated marathon pace, exceeding that of FFER%. Given that the 25g mass difference between shoes should reduce MC by only ~0.25%, the observed 1.5% decrease indicates that HE5's greater FFEO drives metabolic savings beyond what mass alone can explain. These findings emphasize FFEO as a potentially key determinant of MC in AFT. Future work will explore this relationship and the possible application to understanding physiological performance across speeds and runner populations.

Images (Optional)

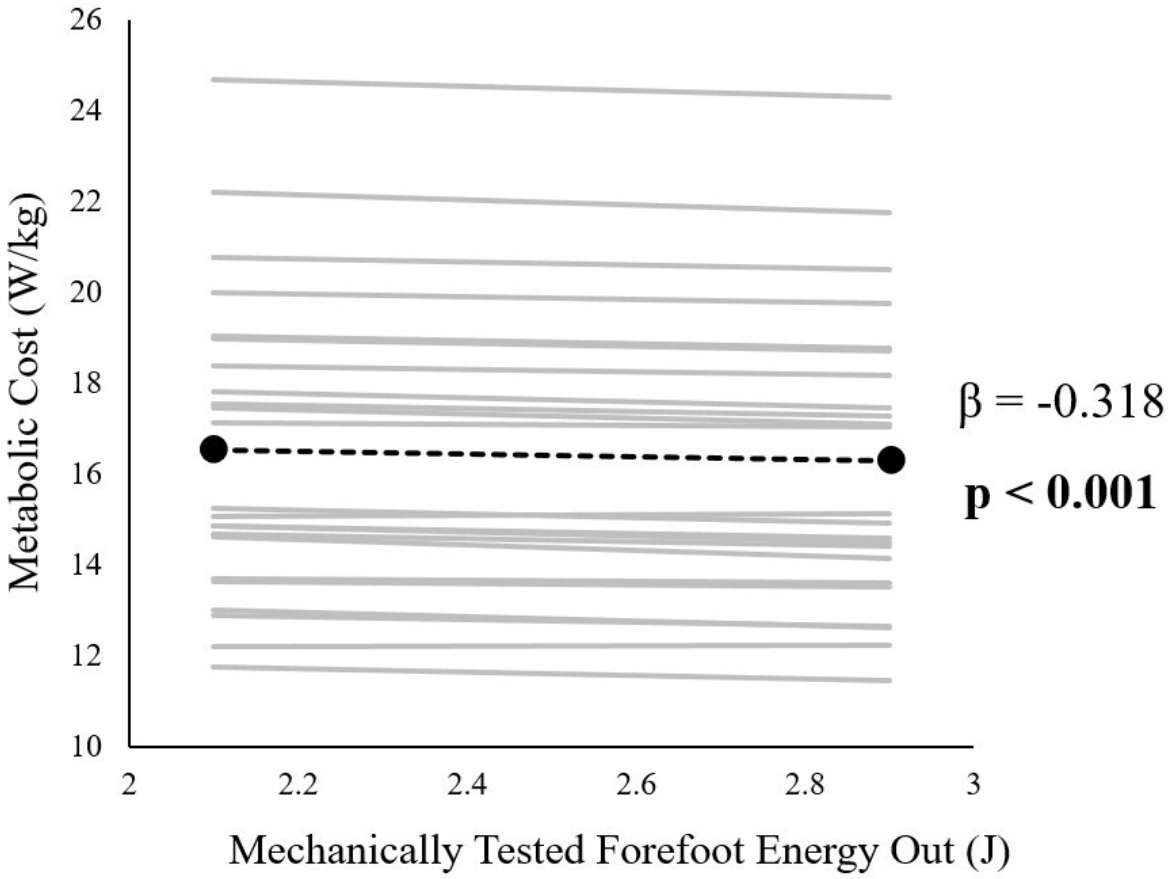

Figure 1. Metabolic cost (MC) of 23 individual runners (grey lines) plotted across the forefoot energy out (FFEO) of each shoe condition. The average MC for each condition (larger black dots connected by a dashed line) is shown to represent the overall relationship.

The Effects of Advanced Footwear Technology Shoes on Hip Joint Loading in Female Runners

Ms Maria J. Rodriguez, Dr. Colin R. Firminger PhD, Ms Chinaza Enyinnaya-Okidi, Dr. W. Brent Edwards PhD

University of Calgary, Calgary, Alberta, Canada

Introduction

Advanced footwear technology (AFT) shoes have been shown to improve running economy by 4%, resulting in performance increases of 2% [1]. However, recent evidence suggests that AFT shoes may increase injury incidence at the hip [2], which could be related to the shoes, performance increases, or both. The increased injury risk is particularly disconcerting for females, who experience higher rates of hip running-related injuries than males [3]. The primary objective of this study was to examine the effects of AFT shoes and running speed on hip joint moments in trained female runners.

Methods

To date, eight trained female runners (18-45 years; 165.46±6.1 cm; 61.63±7.2 kg) completed treadmill running trials while motion capture and force plate data were collected concurrently in three shoe conditions: the Nike Structure and Nike Infinity (both non-AFT), as well as Nike Alphafly (AFT). Each shoe condition was tested at two speeds: a 10-km race pace and a speed reflecting a hypothetical 4% improvement in running economy. Peak, mass-normalized three-dimensional hip joint moments were computed during the stance phase of running using inverse dynamics and compared using repeated-measures ANOVA.

Results

A significant effect of speed, but not shoe ($p^3$0.156), was observed for peak sagittal (p=0.029) and frontal plane (p=0.005) moments (Figure 1); however, this was driven heavily by the non-AFT shoes. A significant interaction was observed between shoe and speed for peak transverse plane moment (p=0.037), whereby hip joint moments increased with speed in the AFT shoe only.

Discussion

The significant interaction for peak transverse plane moment between shoe and speed conditions suggests that the increased speeds achieved when running in AFT shoes, but not the shoes themselves, may contribute to elevated rotational loading at the hip in female runners. Increasing sample size may help clarify and strengthen these observed statistical trends.

The Effect of Advanced Footwear Technology Spikes' Midsole Stiffness on the Biomechanics and Metabolic Cost of Running of Elite and Sub-Elite Distance Runners

Mr. Luis Morata-Moreno, Mr. Bradley Needles, Dr. Alena Grabowski

University of Colorado Boulder, Boulder, Colorado, United States

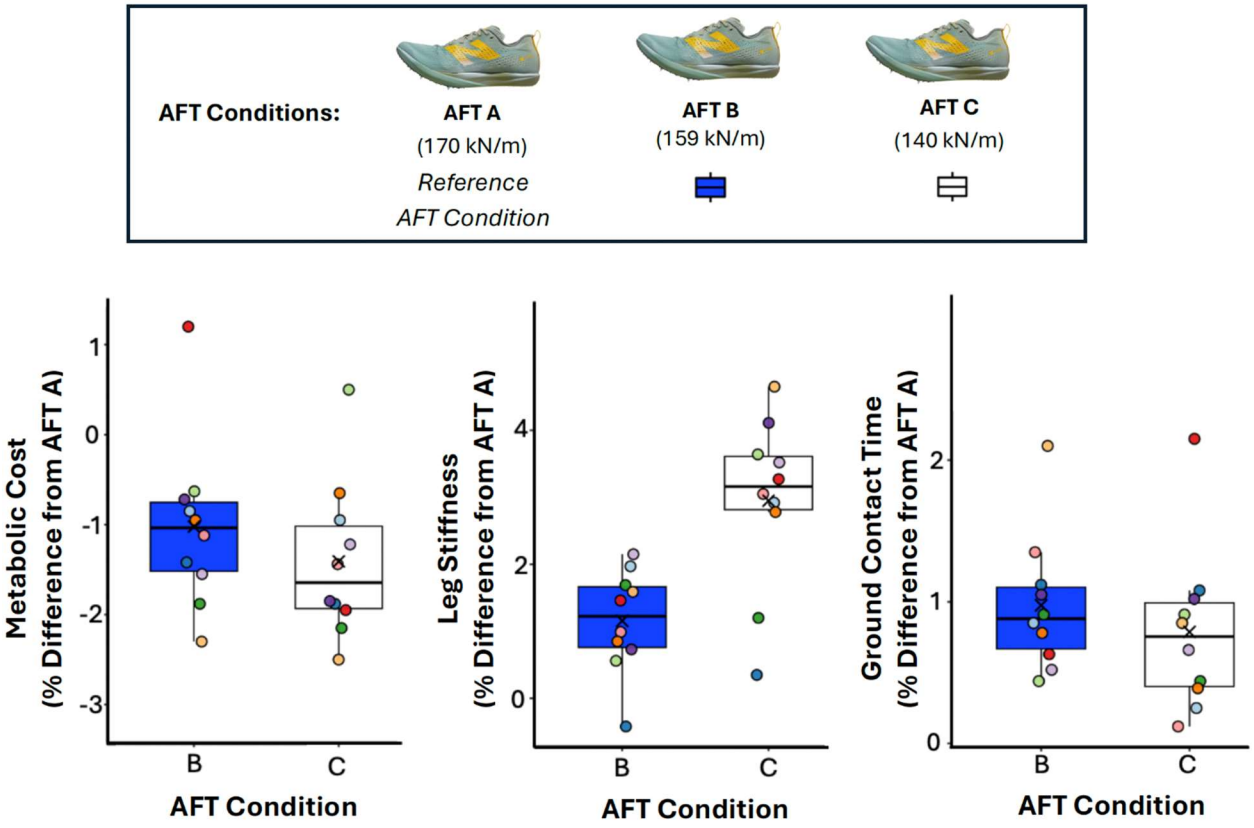
Introduction

Distance runners have experienced improved race performance and running economy when wearing compliant (low stiffness) advanced footwear technology (AFT) spikes compared to stiffer traditional spikes [1], [2], [3], which may be due to increased leg stiffness and ground contact time [1]. Thus, we evaluated the effects of elite and sub-elite distance runners wearing AFT spikes with different midsole foam stiffness on the biomechanics and metabolic cost of running. We hypothesized that when distance runners wore AFT spikes with decreased midsole foam stiffness, leg stiffness and contact time would increase and the metabolic cost of running would decrease.

Methods

10 (7 male, 3 female) elite and sub-elite distance runners (10 km race ≤37 min or equivalent within the past 6 months) completed six 5-min running trials (three shoe conditions *x* two replicates) at 4.17 m/s on a force-measuring treadmill. Participants wore three custom AFT spikes (AFT A, B, and C) that were otherwise identical but had midsole stiffness values of 170, 159 and 140 kN/m, respectively. We measured ground reaction forces (1000 Hz) and metabolic rates, and calculated and compared leg stiffness, ground contact time, and metabolic power (W/kg) across AFT spikes using linear mixed models.

Results



For elite and sub-elite distance runners wearing AFT spikes, the linear mixed models revealed that for every 1 kN/m decrease in AFT midsole stiffness, leg stiffness increased by 0.31% ($p = 0.018$) and metabolic cost decreased by 0.20% ($p = 0.041$). However, AFT midsole stiffness did not significantly influence ground contact time ($p = 0.49$) within the range of footwear tested.

Discussion

Reducing midsole stiffness in AFT spikes may decrease the metabolic cost of running, likely through increased leg stiffness. As a result, runners may experience race

performance improvements with lower midsole stiffness of AFT spikes. Consequently, further reductions in midsole stiffness within AFT spikes, relative to current commercial models, may offer a viable strategy for further enhancing distance-running performance.

The Effect of Footwear Stack Height and Outsole Traction on Ankle and Knee Kinematics during Downhill Trail Running

Ms. Kathy Reyes[1], Dr. J.J. Hannigan[2]

[1]Oregon State University, Corvallis, OR, United States. [2]Oregon State University - Cascades, Bend, OR, United States

Ms. Kathy Reyes

Introduction

Trail running is the most popular form of off-road running, often including downhill segments and uneven terrain [1]. These factors have influenced trail running footwear design, particularly midsole stack height and outsole traction. Despite these developments, trail runners continue to face high rates of running-related injuries at the ankle and knee [2]. Therefore, the purpose of this study was to examine the effect of midsole stack height and outsole traction on ankle and knee kinematics during downhill trail running.

Methods

Twenty-one trail runners averaging ≥15 miles/week participated in the study. After a 10-minute warm-up, participants ran five successful downhill trials at their comfortable pace (±10%) in three zero-drop footwear conditions in random order: maximal shoe with traction lugs (MAX; 35mm stack height), traditional shoe with traction lugs (TRAD; 25mm stack height), and traditional shoe without traction lugs (TRAD-NL; 20mm stack height).

Ten Sony RX0 II cameras captured running trials at 120 Hz along the downhill slope. Videos were processed in Theia3D, and frontal and sagittal knee and ankle kinematics (initial contact, peak, excursion, toe-off angles) were calculated in Visual3D. Differences between shoes were identified using repeated-measures ANOVAs (α=0.05) with Bonferroni-corrected pairwise comparisons, with effect sizes also calculated (η_p^2).

Results

A significant main effect of shoe was found for ankle inversion at initial contact (p=.019, η_p^2=.181) and toe-off (p=.025, η_p^2=.169), with the MAX shoe exhibiting greater inversion than the TRAD shoe (Table 1). No other significant differences were identified,

although a trending ~2-degree difference was observed in peak knee flexion with a moderate effect size (p=.073, η_p^2=.123) between the MAX shoe and the TRAD-NL shoe (Table 1).

Discussion

Inversion at initial contact and toe-off were significantly higher in the MAX shoe compared to the TRAD shoe during downhill trail running. Greater inversion at initial contact, observed in the MAX shoe, may increase the risk of sustaining a lateral ankle sprain [3]. Further research is needed to clarify how trail footwear features affect joint kinematics and injury risk.

Foot-Stiffening Socks May Improve Running Economy

Ms. Kamen Wong, Ms. Hui Tang, Dr. Owen Beck Ph.D.

University of Texas at Austin, Austin, Texas, United States

Introduction

The foot splays with each ground contact. Due to cross-axis coupling, tightly wrapping the transverse arch mitigates foot splay and stiffens the entire foot, including the medial longitudinal arch [1]. Running with wrapped transverse foot arches improves ankle gear ratio during stance and reduces the metabolic cost of barefoot running [2], similar to the function of adding carbon fiber plates to shoe soles [3]. Here, we developed socks that are stiff along the distal metatarsal region (foot-stiffening socks) and assessed whether they decrease the metabolic cost of shod running, similar to that of carbon fiber plates.

Methods

Fifteen athletes performed 9 x 5-min treadmill running trials at 3.5 m/s with 5-min rest preceding each trial. After a familiarization, participants performed two running trials in each footwear condition using a counterbalanced trial order (ABCDDCBA). The footwear conditions included each sock and shoe combination: traditional athletic socks (control), foot-stiffening socks (stiff), flexible running shoes (control), running shoes with carbon fiber plates (carbon) embedded in the midsoles.

Results

The foot-stiffening socks applied 40 ± 4 N (Avg ± SD) more compressive force to the distal transverse foot than athletic socks ($p < 0.001$). The three-point bending stiffness of shoes with carbon fiber plates was 174.5% stiffer than athletic shoes. Foot-stiffening socks reduced the net metabolic power of running across shoes by 0.82% ($p = 0.030$), whereas carbon fiber plates did not reduce the metabolic power across sock conditions ($p = 0.341$). Moreover, the change in distal foot pressure applied by foot-stiffening socks versus traditional athletic socks was associated with a greater decrease in net metabolic power during running in control shoes ($r = -0.77$, $p = 0.007$).

Discussion

Foot-stiffening socks reduced the metabolic cost of shod running. The mechanisms underlying the greater metabolic reduction using foot-stiffening socks versus carbon fiber plates requires further analysis but may relate to the difference in metatarsophalangeal

joint mobility. Here, we present the first sock design that may be able to improve running performance.

Images (Optional)

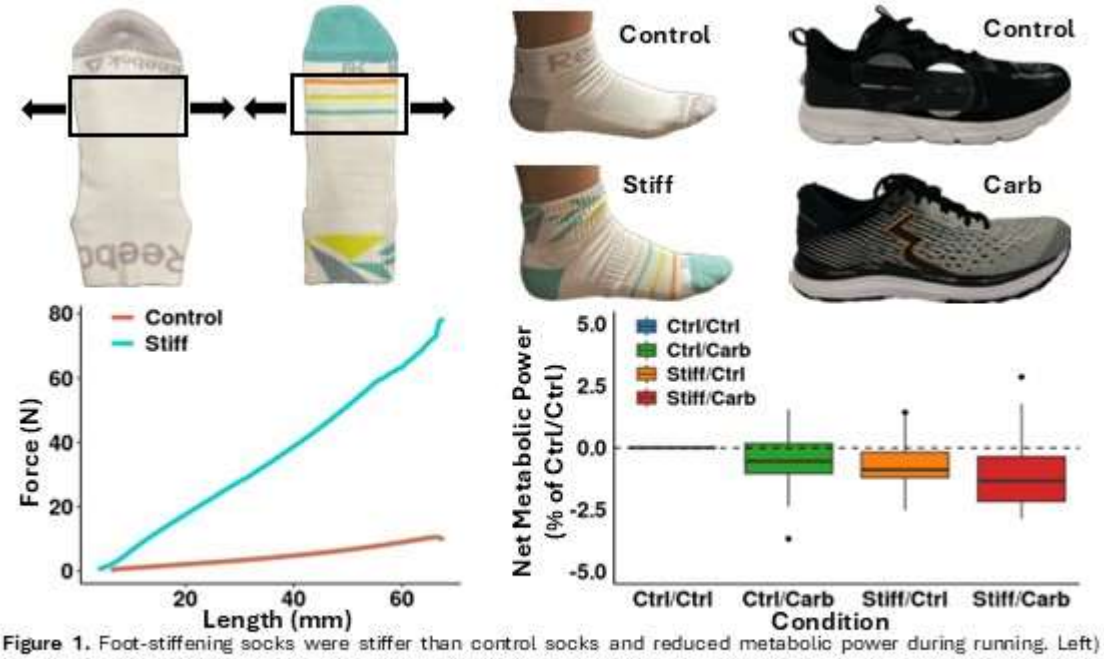

Figure 1. Foot-stiffening socks were stiffer than control socks and reduced metabolic power during running. Left) Control and foot-stiffening socks with boxed region that underwent mechanical testing as well as the corresponding force versus length results. Right) The tested socks and mass-matched shoes with and without carbon fiber midsoles. Net metabolic power during running in each footwear condition (sock/shoe) : control + control (Ctrl/Ctrl), control + carbon-fiber (Ctrl/Carb), stiff + control (Stiff/Ctrl), and stiff + carbon-fiber (Stiff/Carb).

Comparative Analysis of Resistive Immersed Surface and Immersed Boundary Methods for Aortic Valve Hemodynamics

Dr. Han Zhao[1], Dr. Alexander Kaiser[1], Dr. Fanwei Kong[2], Dr. Alison Marsden[1]

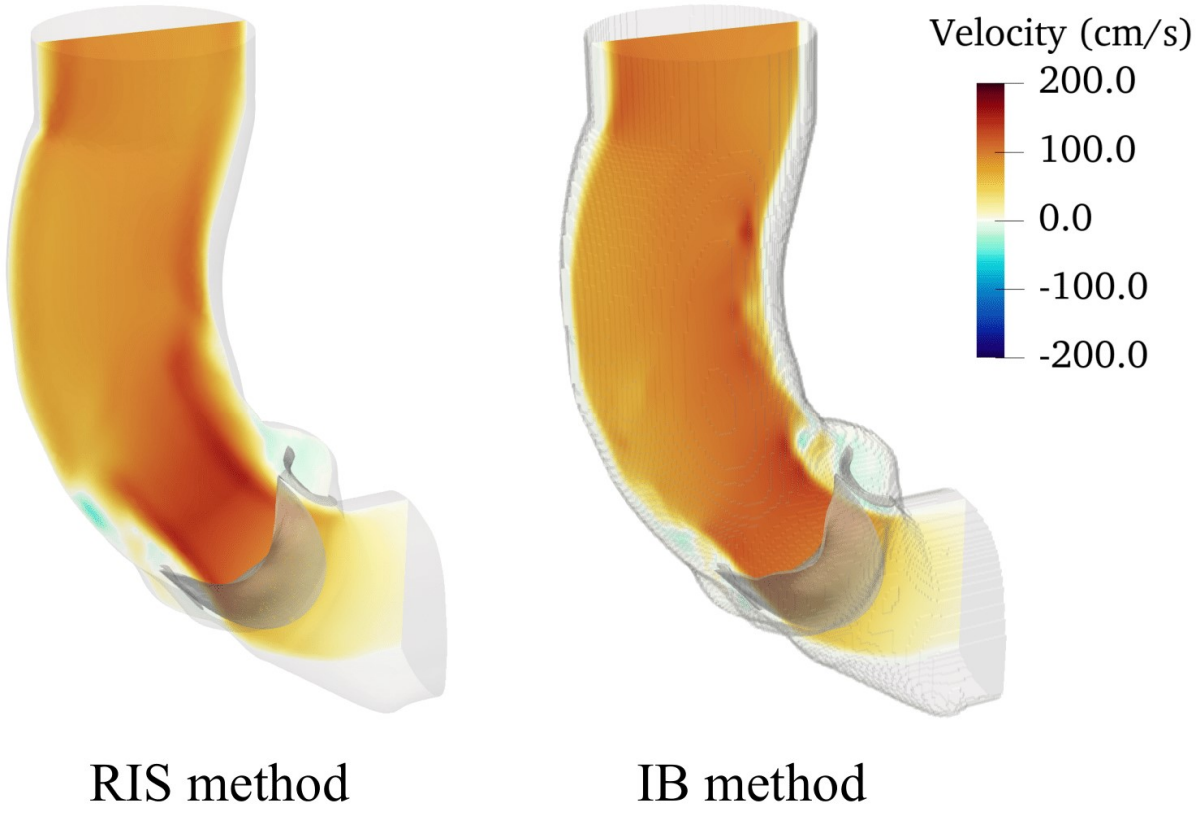
[1]Stanford University, Stanford, California, United States. [2]Washington University in St. Louis, St. Louis, Missouri, United States

Introduction

The modeling of aortic valve fluid-structure interaction (FSI) is essential for accurately predicting hemodynamics in normal and diseased valves. However, heart valve simulation remains a challenging task due to the significant motion and contact of valve leaflets. The resistive immersed surface (RIS) [1] method and the immersed boundary (IB) [2] method are two contrasting approaches for simulating heart valves. These two methods differ in coupling strategies and whether valve motion is prescribed or emergent. This study presents a comparative analysis of the RIS and IB methods for aortic valve hemodynamics and practical trade-offs.

Methods

We employ open-source implementations of the RIS and IB methods for aortic valve simulation. The RIS method is developed within the svMultiPhysics finite element solver. Valve leaflets are modeled with prescribed motion, and represented as thin resistive surfaces with a penalty force using an unfitted mesh. The framework thus uses one-way coupling, so valve motion influences hemodynamics, but hemodynamic changes do not alter valve motion. In contrast, the IB method is implemented using the IBAMR software, where valve leaflets are modeled as deformable elastic structures immersed in the fluid domain. The two-way coupled Navier–Stokes equations and structural dynamics are solved simultaneously. Both simulations use the same aorta geometry and boundary conditions, while the prescribed opening and closing leaflet motions in the RIS simulation are extracted from the IB simulation to ensure a consistent comparison.



Results

Numerical results demonstrate that both methods produce pressure gradients within 5% relative difference across the valve and comparable bulk flow motion. However, the RIS simulation does not capture the fine-scale leaflet motion or allow for potential physiologic regurgitation due to prescribed valve kinematics. Conversely, the IB method resolves the emergent leaflet kinematics and deformation and more detailed flow patterns.

Discussion

The comparison shows that the RIS method can produce comparable bulk hemodynamics in situations where valve kinematics are known prior to running simulations and prescribed. This work offers guidance for method selection depending on the objectives and known data of the application.

Introduction

Leaflet thrombosis is often detected after transcatheter aortic valve replacement (TAVR) as hypoattenuating leaflet thickening (HALT) on computed tomography (CT). In our prior work, we predicted HALT risk in a retrospective cohort of patients with tricuspid aortic valves undergoing TAVR with a balloon-expandable valve using geometric and hemodynamic features. Among the metrics included in the model (e.g., normalized circulation (NC) in the neo-sinuses), no single parameter demonstrated strong predictive power for HALT. The model also relied on actual post-deployment TAV dimensions and positioning, thus limiting its clinical translatability. In this study, we developed a computational pipeline to predict HALT risk in a retrospective cohort of patients with either tricuspid or bicuspid aortic valve anatomy, using only pre-TAVR CT.

Methods

Aortic anatomies of 151 patients who underwent balloon-expandable TAVR with a SAPIEN 3 platform were reconstructed from pre-TAVR CTs to simulate post-CT TAVR deployment at peak systole using reduced order modeling (ROM) and finite element analysis (FEA) (Figure

1A). Aortic annulus area was measured to determine TAV size based on SAPIEN 3 guidelines. For each patient, the TAV was expanded nominally and deployed at conventional and high depths depending on TAV size and rotated about its vertical axis at each depth (Figure 1B). Algorithms were developed to predict post-TAVR geometric and hemodynamic features from simulation outputs (Figure 1C), which were used to compute NCs across all deployments. NC threshold vs density plots were produced by varying NC and determining number of values that either fall below that NC (high HALT risk region) or above (low HALT risk region).

Results

Following training with a subset of 27 patients with known HALT outcomes (n=12 HALT-, n=15 HALT+), NC and density thresholds of 106-107 and 20%, respectively, resulted in highest area under ROC curve (AUC=0.78) (Figure 1D).

Discussion

This novel computational pipeline performed adequately in the initial training cohort and is now suitable for testing on the remaining 124 patients with unknown HALT outcomes. With further refinement and training and validation in a larger, distinct patient population, this tool may eventually support procedural planning. Future development may also involve adapting the pipeline for other transcatheter valve platforms.

Fluid-Structure Interaction Model of a Neonatal Quadricuspid Valve

Dr Karoline-Marie Bornemann, Dr Perry S. Choi, Mr Jay Huber, Dr Alexander K. Reed, Mr Amit Sharir, Dr Shiraz A. Maskatia, Dr Michael R. Ma, Dr Alison L. Marsden, Dr Alexander D. Kaiser

Stanford University, Stanford, CA, United States

Introduction

Quadricuspid valve morphology is a rare congenital valve anomaly in which the valve has four instead of three cusps of various size distributions. It commonly occurs in truncus arteriosus (TA), accounting for around 25% of patients. TA is a rare, severe congenital heart disease (CHD) in which blood from both ventricles enters a truncal valve through a ventricular septal defect (VSD) and exits the heart through only one great artery instead of two. In this study, we simulate the interaction between a quadricuspid valve of a neonate after TA repair in a patient-specific geometry with the surrounding blood flow.

Methods

The quadricuspid valve is constructed using an elasticity-based design approach. Based on the patient valve's gross morphology extracted from ECHO and the assumption that the valve supports a prescribed pressure, we derive its mechanical equilibrium equations. Their solution predicts a loaded configuration from which we derive a constitutive law with scaled membrane stiffnesses to achieve the predicted tensions. By solving the equilibrium equations with the derived constitutive law under zero pressure, we obtain an open valve configuration serving as initial condition. The aortic wall geometry is segmented from CT imaging using SimVascular. Fluid-structure interaction simulations are performed with the Immersed Boundary Method. Boundary conditions are derived from patient data and optimized using a 0D-model to reflect neonatal hemodynamics.

Results

During valve opening, an accelerating jet emerges which deflects toward the outer aortic curvature. An initial four-lobed starting vortex is formed which transitions into multiple elongated streamwise vortices. During systole, free edge displacement and fluttering dynamics of the thickened leaflets are highly influenced by the proximity to the surrounding vessel. During systolic deceleration, the adverse pressure gradient across the valve leads

to transient backward flow in the ascending aorta. Although the valve model is symmetric, we observe asymmetric closure kinematics and central coaptation.

Discussion

Our study provides the first fluid-structure interaction simulation of a patient-specific aortic geometry with quadricuspid valve in neonatal hemodynamic conditions. Analysis of both blood flow patterns and leaflet kinematics reveal insights into quadricuspid valve performance and can aid in predicting individual outcomes in affected patients.

3D Simulations of Electrospun Biomaterials for Replacement Heart Valves

PhD Student Ulas Akyuz[1,2], Dr. Michael Sacks[1,2,3]

[1]The University of Texas at Austin James T. Willerson Center for Cardiovascular Modeling and Simulation, Austin, Texas, United States. [2]The University of Texas at Austin Department of Mechanical Engineering, Austin, Texas, United States. [3]The University of Texas at Austin Department of Biomedical Engineering, Austin, Texas, United States

Introduction

Current replacement heart valves (RHVs) remain limited by inadequate long-term durability, thrombogenic risks, and the intrinsic variability of pericardial biomaterials. For example, despite the current success of transcatheter aortic valve replacement (TAVR), long-term durability remains unknown. Existing leaflet materials, derived from chemically treated pericardium, continue to fail from calcification and mechanical fatigue. To address these limitations, we investigate hydrogel-coated electrospun (HES) biomaterials as a new platform for RHV, leveraging their tunable mechanical behaviours and decoupled structural (mesh) and blood-contacting (gel) feature. We hypothesize that systematic, simulation-guided development of HES-based RHVs can yield designs with superior durability.

Methods

We use our novel HES constitutive model, which incorporates fiber alignment, fiber properties, and fiber–fiber interactions, along with separate gel and mesh components, to capture a broad fabrication space and support high-fidelity hyperelastic simulations.This constitutive model formed the foundation of an in-silico parametric design pipeline that utilized NURBS-based geometric representations with a neural-network finite element (NNFE) solver trained directly from the governing PDE across physiological loading states. To evaluate tri-leaflet mechanics under quasi-static peak tensile conditions, we performed all computations using CARDIAX, a JAX-based FE and isogeometric analysis (IGA) platform that leverages GPUs, providing at least a 20-fold speedup over traditional solvers and, when combined with the NNFE surrogate framework, enabling rapid predictions without experimental training data.

Results

Our results demonstrate that subtle modifications in leaflet fiber architecture can homogenize strain fields, a key determinant of durability. Eleven major design variables derived from current TAVR geometries were systematically explored to maximize strain homogenization and leaflet longevity. The HES simulations spanned the full known

fabrication space, enabling systematic optimization of fiber distributions, thickness variations, and leaflet geometry. To date, our simulations have identified leaflet shapes that substantially reduce peak tensile concentrations and promote more uniform load sharing. Several candidate designs exhibit markedly improved predicted durability compared with current pericardial-based TAVR leaflets.

Discussion

This work establishes a customizable, rationally engineered biomaterial platform coupled with a high-speed modeling pipeline for next-generation RHVs. The resulting framework supports rapid iteration, compatibility with evolving HES formulations, and direct translation toward clinical applications, including patient-specific TAVR designs.

Anti-Rotation Load-Leg in Infant Car Seats Under Misuse Conditions

Mr. Hossein Bahreinizad Ph.D. Student[1], Dr. Antonio Fernandes Human Factors Engineer[2], Dr. Suman Chowdhury Associate Professor[1]

[1]University of Florida, Gainesville, Florida, United States. [2]Uppababy, Boston, massachusetts, United States

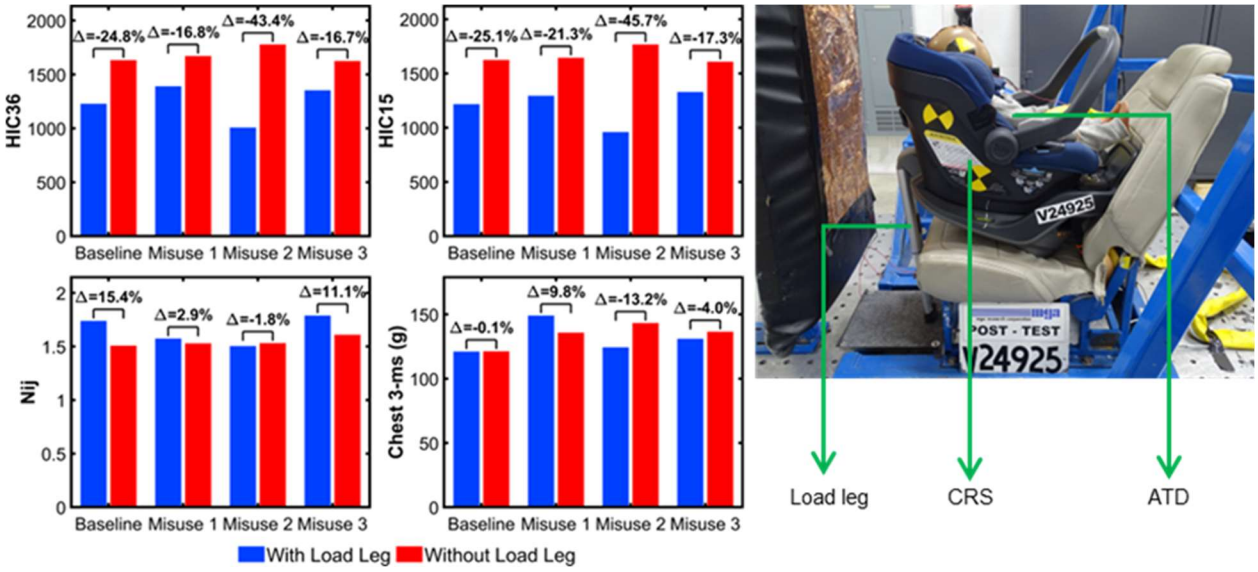
Introduction

Motor vehicle crashes (MVCs) remain a leading cause of fatal or near-fatal injuries for infants and young children. Rear-facing child restraint systems (CRS) can help reduce these injuries by limiting the head, neck, and chest movements during a crash. However, misuse of these restraints is common, despite various safety awareness programs. Issues such as loose harnesses or improper installation can significantly diminish their protective effectiveness. This study aimed to evaluate whether an anti-rotational load leg can help counteract the negative effects of CRS misuse by conducting the CR 35/35 test.

Methods

We conducted CR-35/35 sled tests using a rear-facing CRS with a CRABI 12-month infant dummy, as per standard procedures. Four installation conditions reflected proper use and common misuses: 1) proper seat with proper harness (Baseline), 2) proper seat with loose harness (Misuse 1), 3) loose seat with proper harness (Misuse 2), and 4) loose seat with loose harness (Misuse 3). We tested each condition with and without the load leg. To assess load leg performance, we estimated several commonly used injury metrics, including HIC_{36} and HIC_{15} for head injuries, Nij for neck injuries, and 3-ms chest acceleration for chest or trunk injuries.

Results



The load leg reduced head injury metrics across all conditions: HIC_{36} decreased by 24.8% in Baseline, 16.8% in Misuse 1, 43.4% in Misuse 2, and 16.7% in Misuse 3. HIC_{15} showed similar reductions of 25.1%, 21.3%, 45.7%, and 17.3%, with the highest reduction occurring in Misuse 2.

However, the load leg increased Nij in most conditions, increasing by 15.4% in Baseline, 2.9% in Misuse 1, and 11.1% in Misuse 3, and decreased by 1.8% only in Misuse 2. Chest 3-ms acceleration also showed mixed responses, slightly reduced in Baseline and Misuse 3 but increased in Misuse 1 and Misuse 2.

Discussion

Overall, the use of load legs provides improved head protection under both proper and misuse conditions, with consistent reductions in HIC_{36} and HIC_{15}. Interestingly, it showed increased Nij across most conditions and mixed chest responses, indicating the need to replicate its performance evaluation across other CRS and dummy types to understand the full spectrum of its benefits.

OA121-02

Identifying Predictors of Lap-Belt Submarining Through ROC-Based Metric Selection in Finite Element Simulations of 50th Percentile Male HBMs and ATDs

Mr. Alex Kalmar-Gonzalo B.S.[1], Mr. Bharath Koya M.S., B.E.[1], Dr. Karan Devane Ph.D, M.Tech, B.E.[1], Dr. Fang-Chi Hsu Ph.D, B.S.[1], Mr. Don Sherman M.S., B.S.[2], Dr. Cynthia Bir Ph.D, M.S., B.S.[2], Dr. Dale Bass[2], Dr. F. Scott Gayzik Ph.D, M.S., B.S.[1]

[1]Wake Forest University School of Medicine, Winston-Salem, NC, United States. [2]Wayne State University, Detroit, MI, United States

Introduction

Lap-belt submarining is associated with severe injury and has become an increased concern in the automotive safety field [1]. We present a computational study using two finite element models, intended to identify and evaluate candidate submarining metrics (CSMs) for classifying submarining outcomes in frontal impacts.

Methods

400 simulations were conducted using the Global Human Body Models Consortium (GHBMC) M50 THAN-OS v.2.3, and the THOR 50M v.1.9.2 (Farmington Hills, Michigan). Prior to simulation the M50-THAN-OS, a variant of the M50-OS model sized to match the THOR ATD, was validated against 4 studies of reclined occupant loading. Each model was run in an identical set of frontal impact simulations that varied seatback recline angle, seat pan angle, seatbelt anchor position, knee bolster presence, load limiting and pretensioning values, and delta-v. Submarining outcomes for each simulation were determined based on belt kinematics relative to the ASIS, providing a binary classification of submarining. A set of approximately 70 candidate submarining metrics including displacements, accelerations, rotational velocities, pressures, forces, moments, and strains were extracted. Receiver Operating Characteristic (ROC) analysis was completed for each CSM and the area under the ROC curve (AUC) was calculated to quantify the performance of each.

Results

ROC analysis revealed that several CSMs performed well in identifying submarining outcomes. The CSM with the greatest AUC value was pelvic rotation with an average AUC value of 0.82 across both models. A range of AUC values were observed with some candidate metrics being deemed non-predictive.

Discussion

This ROC analysis provides a systematic and quantitative method for evaluating submarining outcomes based on intrinsic model outputs and extrinsic environmental-based outputs. These findings offer insight into how HBMs and ATDs respond physically in both submarining and non-submarining scenarios and importantly show that certain outputs can be quite predictive in both types of surrogates. We provide suggested CMSs for use in large scale design of experiments studies or high throughput studies where individual analysis of simulation outcomes is impractical. This research contributes to the broader goal of mitigating abdominal and spinal injury in vehicle crash.

Computational Reconstruction of 30 Real-World Motorcycle Collisions With Facial Impact to Guide Future Helmet Standards

Dr Lucas Low[1], Dr Claire Baker[1], Dr Will Dawber[1], Dr Shiyang Meng[2], Dr Mazdak Ghajari[1]

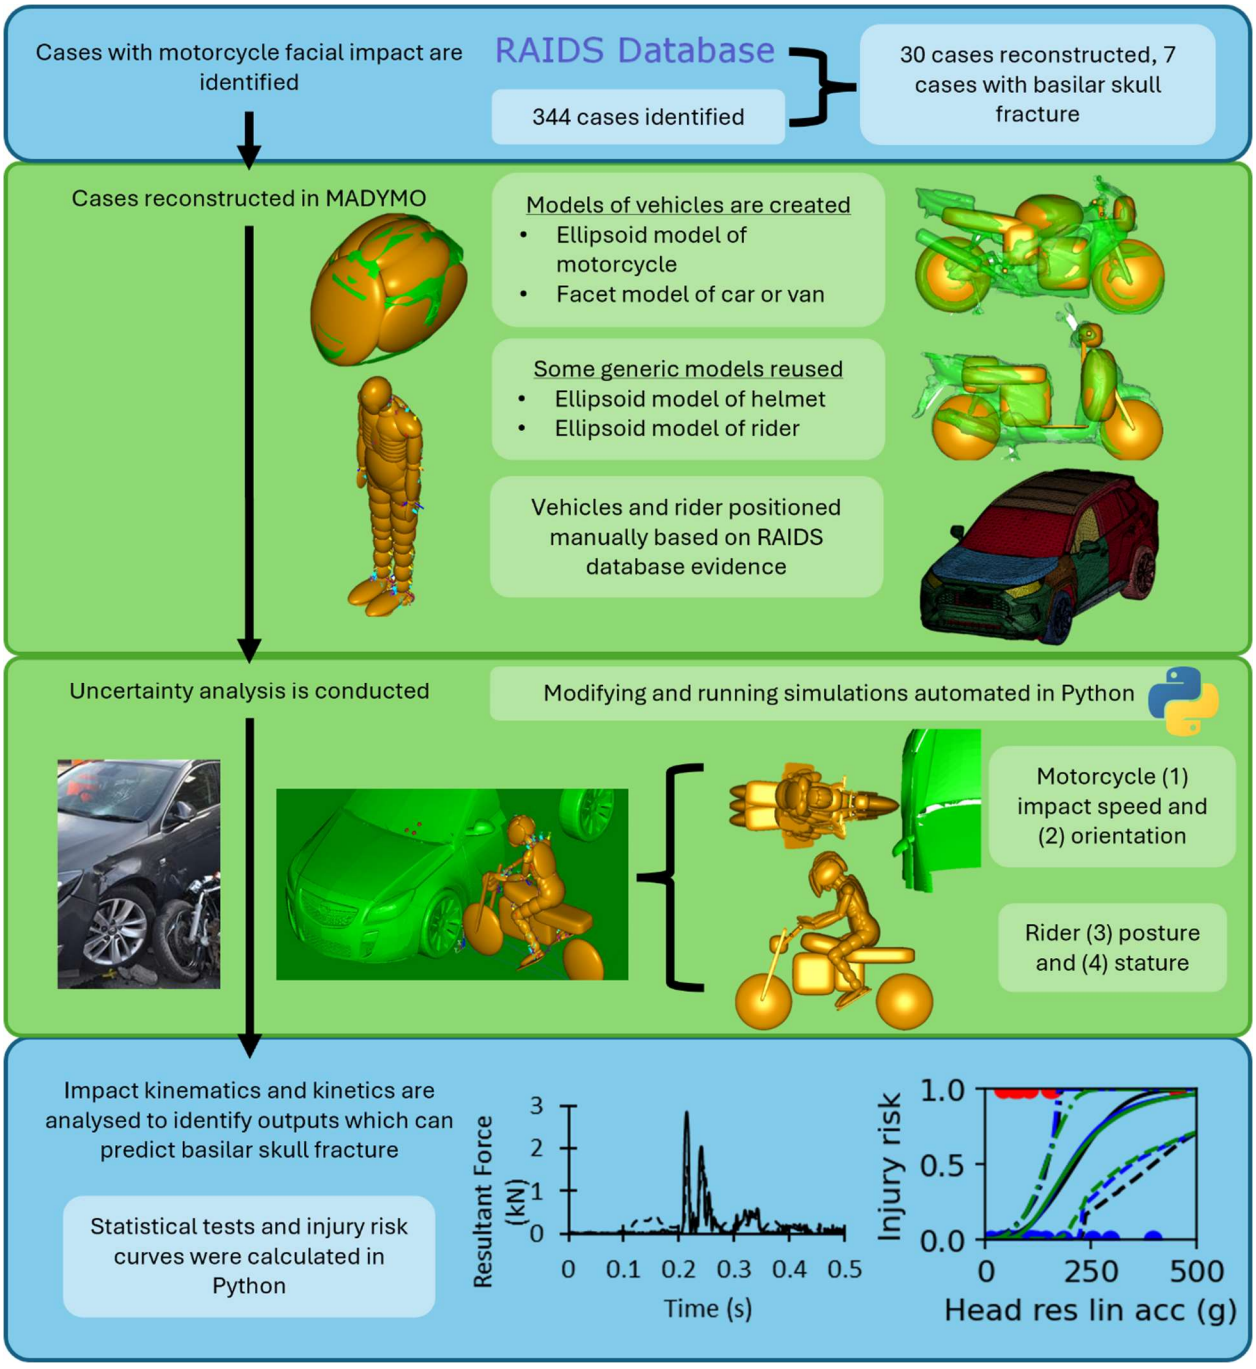
[1]Imperial College London, London, Greater London, United Kingdom. [2]Autoliv Research, Vårgårda, Vårgårda Municipality, Sweden

Introduction

Motorcycle helmets are a major focus for improving motorcyclists' safety, as they substantially reduce the rate of head injuries [1]. However, facial impacts are minimally tested in helmet safety standards internationally [2], despite accounting for over 50% of head impacts [3]. Facial impact often presents with injury remote to the location of impact, such as base of skull fracture (BSF), which is over-represented in fatal cases [3]. The aim of this study is to reconstruct real-world motorcycle collisions leading to facial impacts, to better understand the loading conditions and associated injuries, and inform future helmet standards.

Methods

The cost-free UK Road Accident In-Depth Studies (RAIDS) database was parsed for motorcycle collisions with confirmed facial impact. Reconstructions were developed in Madymo using an ellipsoid pedestrian model and helmet, as well as case-specific motorcycle and car models. Photographic evidence was used to verify the kinematics of the reconstructions, and an uncertainty analysis of motorcycle speed, orientation, rider posture, and rider stature (50th and 95th percentile male) was conducted to capture a range of possible impact configurations. Accelerations and loads significantly larger in BSF cases were used to calculate injury risk curves.



Results

30 real-world cases were reconstructed, producing 1,476 simulations from the uncertainty analysis. The head impact speeds and angles had medians of 8.7m/s and 47.5° (interquartile ranges 5.1-15.0m/s and 32.7°-60.7°). In the head and neck, cases with BSF had larger linear and rotational acceleration, and higher loads in extension, towards the posterior, and in tension. Injury risk curves were developed for the resultant accelerations and loads.

Discussion

The reconstructions provide insight into typical facial impact configurations of motorcycle collisions. The dataset may inform the head orientation, impact velocity, and angle of a future helmet facial impact test. Additionally, injury risk curves developed to predict BSF provides a biomechanical basis for the injury criterion for helmet design. Overall, this study establishes the evidence base for defining typical motorcycle facial impact conditions and helmet assessment criterion, to inform future helmet standards.

Advancing Biofidelity: Subject-Specific Validation of Whole-Body Human Models for Frontal Impacts

Dr. Sujata Khandare, Mr. Yang-Shen Lin, Mr. Kyle Boyle, Ms. Anne Bonifas, Mr. Carl Miller, Dr. Matthew Reed, Dr. Jingwen Hu

University of Michigan Transportation Research Institute, Ann Arbor, MI, United States

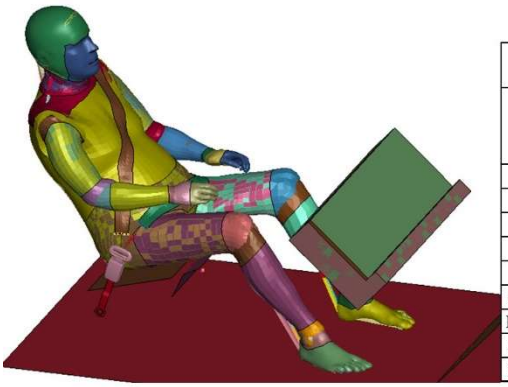
Introduction

Finite element HBMs are typically validated using population-averaged PMHS response corridors [1], but these methods rely on geometric and mass scaling and do not capture specimen-specific variation in body shape, bone morphology, or posture, factors that strongly affect belt interaction, especially in reclined seating. As virtual testing expands to diverse occupants, these limitations have become clearer. Subject-specific validation, achieved by morphing HBMs to individual PMHS geometry and posture [2], was developed and evaluated in this study.

Methods

Eight male PMHS (mean age 68.6±9.0 years, stature 172.4±4.0cm, BMI 23.8±3.1kg/m^2) were tested at 32/50 km/h and 25°/45° recline. Subject-specific HBMs were created by morphing the simplified GHBMC model using statistical posture and external shape [3,4], and ribcage/pelvis/lower-extremity geometry models [5,6], with RBF morphing [7] and joint-based positioning. Simulations matched belt, seat, and pulse conditions, and CORA with Signal Magnitude Factor weighting [8] was applied.

Results



At 32 km/h, 25°, improvements were observed at the head (0.73→0.76), T1 (0.67→0.80), T8 (0.66→0.72), T12 (0.65→0.72), and L4 (0.58→0.67). At 32 km/h, 45°, head, T1, and T8 correlations increased (0.68→0.75, 0.77→0.85, 0.69→0.75). At 50 km/h, 25°, head, T1, and T8 again improved, with T12 unchanged. At 50 km/h, 45°, head correlations increased (0.69→0.82), while thoracic and lumbar responses showed variability. Pelvic and lower-extremity changes were modest and condition-dependent.

Discussion

Subject-specific HBMs better reproduced PMHS head and upper thoracic motion, reflecting the influence of specimen-specific spinal curvature and belt interaction. Lumbar, pelvic, and leg responses were more variable due to differences in pelvis orientation and

belt fit. Results emphasize the value of individualized validation, with future work extending to small female PMHS.

Tendon Fibrils and Fascicles of the *oim* Mouse Model of Osteogenesis Imperfecta Exhibit Signs of Increased Advanced Glycation End Product (AGE) Crosslinking

Ms. Magdalena Fuchs[1], Dr. Mathis Uelner[1], Ms. Lauren Battle[2], Ms. Anxhela Docaj[2], Mr. Felix Groß[1], Dr. Orestis G. Andriotis[1], Dr. Alessandra Carriero[2], Univ.Prof. Dr. Philipp J. Thurner[1]

[1]TU Wien, Vienna, Vienna, Austria. [2]The City College of New York, New York City, NY, United States

Introduction

The *oim/oim* mouse model of Osteogenesis Imperfecta (OI) produces solely homotrimeric collagen I. In *oim/oim* bone, Advanced Glycation End Products (AGEs) are increased [1]. We hypothesize that the presence of homotrimeric collagen I and AGEs alter *oim/oim* collagen fibrils' properties and consequently collagenous tissue mechanical properties. Therefore, we quantified the mutations' effect on tail tendon (TT) fibrils' and fascicles' mechanical properties.

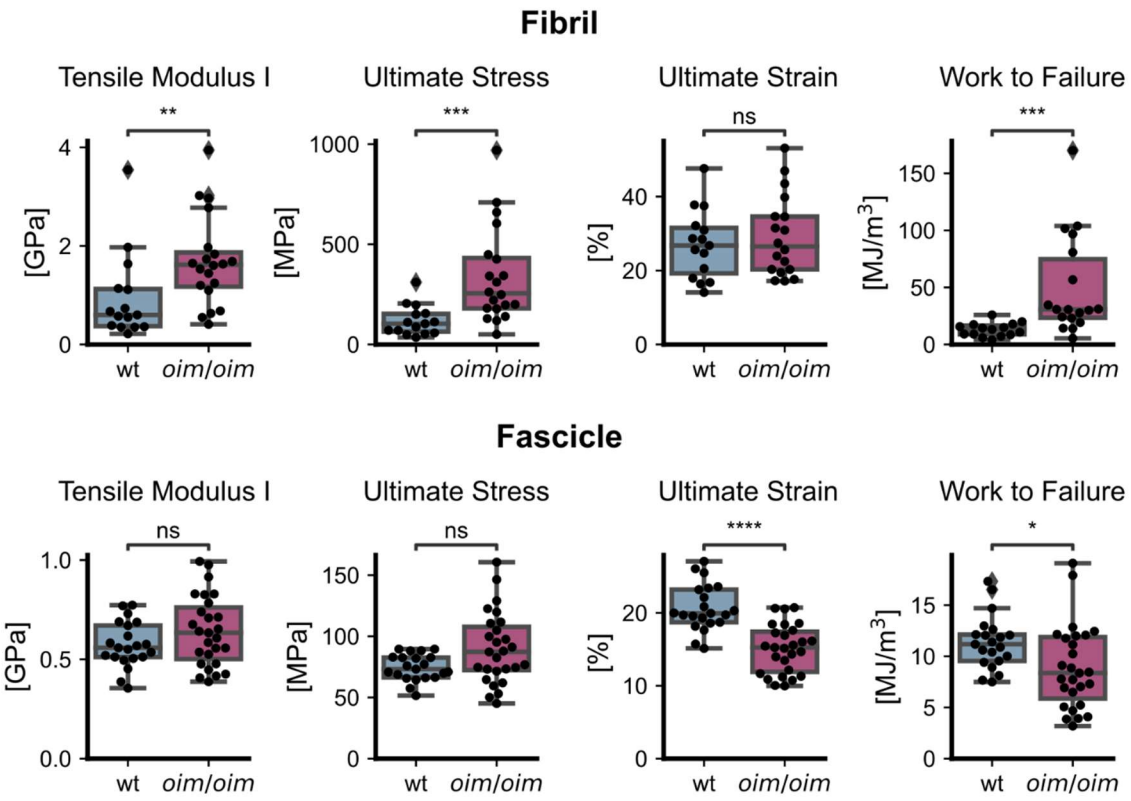
Methods

TT fibrils and TT fascicles from 14-week-old, *oim/oim* (OIM) and wild-type (WT) mice were tested in tension at $5\%s^{-1}$ and $0.1\%s^{-1}$, respectively. For fibrils, a custom-built tensile testing device [2] was used. Fibril diameters and hydration-induced swelling were assessed using Atomic Force Microscopy (AFM).

TT fascicles' cross-sectional areas were determined via Micro-CT imaging, and tensile tests were conducted using a tensile testing machine (zwickiLine z2.5, Zwick-Roell). AGEs were quantified via the fluorescence of tissue hydrolysates.

Results

While tensile moduli and ultimate stresses of WT fibrils are lower than *oim/oim* fibrils (n=21 WT, n=18 *oim/oim*), *oim/oim* fascicles (n=20 WT, n=28 *oim/oim*) did not differ in tensile modulus and ultimate stress, but showed lower ultimate strains. Despite being similar in material parameters, since *oim/oim* fascicles were thinner than WT fascicles, at the whole-organ level their mechanical competence is compromised as described in [3].



Eight of the 21 *oim/oim* fibrils tested displayed increased tensile modulus pre-rupture, not present in WT-CFs. WT fascicles exhibited decreased tensile modulus before failure, not present *oim/oim* fascicles.

Fluorescent AGEs are increased twofold in *oim/oim* TT vs. WT ones (n=5/group).

Discussion

Effects observed in *oim/oim* fibrils, and fascicle-level decreased ultimate strain, and more "brittle" failure, resemble changes due to in-vitro induced AGEs [4,5]. This highlights the importance of considering altered crosslinking for the understanding of collagen mutations. Whether AGEs potentiate or partially rescue impaired tissue mechanical properties caused by homotrimeric collagen I, remains to be elucidated.

The Hidden Influence of Osteoporosis on Bone Regeneration During Distraction Osteogenesis

Mr Juan José Toscano-Angulo[1], Dr Juan Mora-Macías[2], Dr Pablo Blázquez-Carmona[3], Dr Antonia Pajares[4], Dr Juan Morgaz[5], Dr Esther Reina-Romo[1]

[1]University of Seville, Seville, Andalucía, Spain. [2]University of Huelva, Huelva, Andalucía, Spain. [3]University of Cadiz, Cadiz, Andalucía, Spain. [4]University of Extremadura, Badajoz, Extremadura, Spain. [5]University of Cordoba, Cordoba, Andalucía, Spain

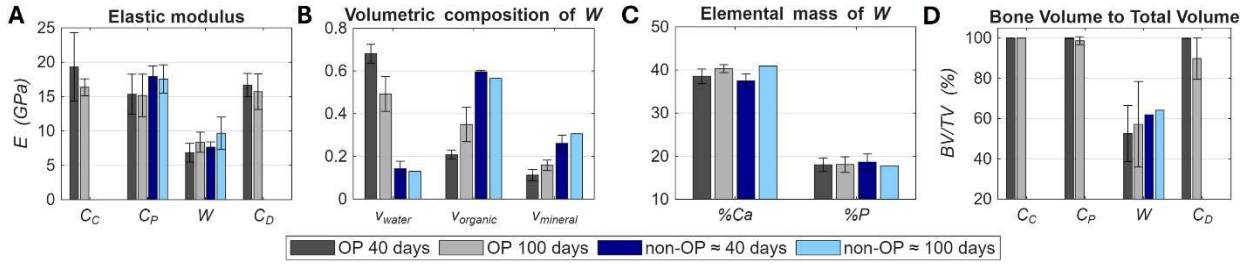
Introduction

Osteoporosis is characterized by trabecular microarchitecture deterioration, raising fracture risk. Osteoporotic post-fracture regeneration remains a clinical challenge due to the low prevalence of successful consolidation. Although the bone transport procedure is recognized for promoting bone healing, the effect of osteoporosis on its clinical efficacy has not been proven.

In this study, we conducted an *ex vivo* characterization of the regenerated woven bone and the adjacent cortical tissue to investigate the impact of osteoporosis on distraction osteogenesis.

Methods

Fifteen sheep underwent osteoporosis induction. Subsequently, distraction osteogenesis treated a 15 mm bone defect surgically created in the right hind metatarsus, stabilized by an external fixation. The subjects were randomly sacrificed at days 40 or 100 after surgery. The dorsal half of the woven tissue formed (W) and the adjacent cortical tissue (C_P, proximal, and C_D, distal) were used for μCT and nanoindentation. The plantar half of W was used for analysis of volumetric composition and elemental mineral mass. Cortical samples from the contralateral metatarsus (C_C) served as control measurements. Osteoporotic results were compared with non-osteoporotic similar studies.



Results

Figure 1A revealed similar elastic modulus of woven and adjacent cortical tissue between groups, without differences among osteoporotic cortical samples. Figure 1B reported a significantly higher specific water volume in the osteoporotic group. Consequently, specific organic and mineral volumes were significantly lower in this group. Figure 1C did not show differences in woven mass percentage of calcium and phosphorus. Figure 1D also revealed no significant differences in woven *BV/TV*. Meanwhile, *BV/TV* decreased in the adjacent cortical tissues over time compared to control data.

Discussion

These findings indicate that osteoporosis does not compromise the intrinsic bone quality of the newly formed woven tissue. However, it markedly reduces the amount of woven bone matrix produced within the distraction callus, suggesting a disease-related delay. Moreover, the mineral of adjacent cortical bone appears to be resorbed and mobilized to support woven bone ossification.

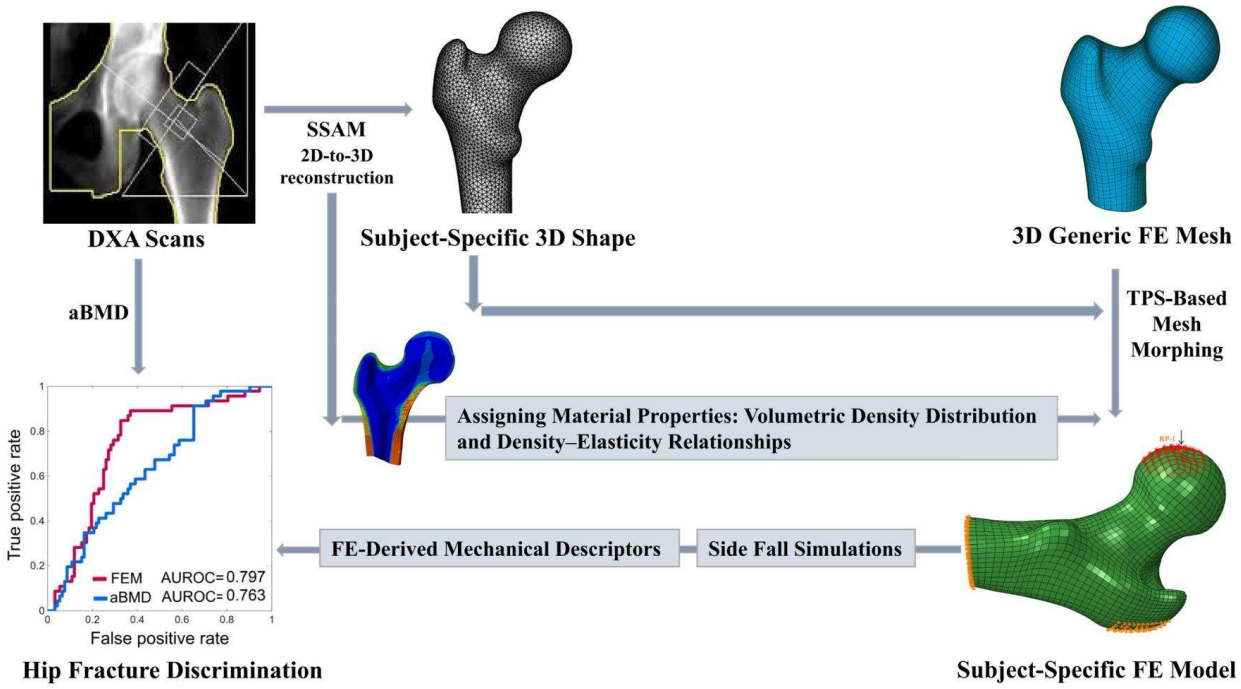
Introduction

Areal bone mineral density (aBMD) derived from dual-energy X-ray absorptiometry (DXA) is the clinical gold standard for diagnosing osteoporosis. Quantitative computed tomography (QCT)-based finite element (FE) simulations can improve hip fracture prediction compared with aBMD, but need for QCT scans limits clinical adoption. Advances in 2D–3D modelling enable the generation of patient-specific 3D-DXA models from standard DXA images, offering potential for fracture risk prediction when combined with 3D FE analyses of osteoporosis patient cohorts [1]. This study aimed to evaluate whether the exploitation of 3D-DXA-FE simulations for fracture prediction can be extended to population cohorts.

Methods

We conducted a case–control study including 1,636 women of the JPOS Study, 85 of whom suffered a hip fracture over 20-year follow-up. 3D-DXA-FE models were generated from hip DXA scans out of 3D-Shaper® (v2.14) appearance and shape modelling [2]. Side-

fall was simulated by applying displacement to the femoral head under rigid-body constraints, with the greater trochanter and shaft fixed. A perfect elastoplastic material model used bone density-dependent material properties and tension- and compression-specific yield parameters, distributed over the mesh. Failure was defined from the nonlinear force–displacement curve at the onset of force decline. Global mechanical descriptors, including strength, nonlinear deformation, and energy absorption, were quantified from FE analyses and used for fracture discrimination [1]. Figure 1 illustrates the overall methodology.



Results

The area under the receiver operating characteristic curve (AUROC) with leave-one-out cross-validation showed that combining strength and residual energy (AUROC: 0.797) improved fracture prediction compared with total hip aBMD (AUROC: 0.763). The difference between the two AUROCs was statistically significant according to the DeLong test ($p = 0.0267$).

Discussion

This is the first study demonstrating that global mechanical descriptors obtained from standard hip DXA scans outperform aBMD in predicting incident hip fractures in a population-based, prospectively followed cohort of women. These findings highlight the potential of integrating 3D-DXA and FE modelling into existing DXA-based clinical workflows to enhance fracture risk assessment.

Introduction

Mechanical loading increases bone strength, whereas postmenopausal osteoporosis compromises it. This suggests that the systemic character of pharmacological treatments could be improved by mechanical loading to focus treatment effects where mechanical competence is most needed. Because mechanical loading can stimulate both remodeling and targeted modeling-based bone formation, it remains unclear which process primarily contributes to strength gains under combined interventions. Here, we investigated how mechanical loading with three pharmacological treatments influences modeling, remodeling, and their relationship to trabecular bone strength.

Methods

Time-lapsed *in vivo* micro-computed tomography images of the 6th caudal vertebra were obtained from C57BL/6 mice ovariectomized at 15 weeks-of-age and treated from week 20 to 24 without (VEH; n=25) or with mechanical loading (ML; n=26), bisphosphonates (BIS; n=9; BIS+ML: n=9), parathyroid hormone (PTH: n=10; PTH+ML: n=9), or sclerostin antibodies (SclAB: n=9; SclAB+ML: n=8). Strain energy density (SED) was computed by micro-finite element analysis, and trabecular bone strength predicted using the Pistoia criterion [1]. Modeling and remodeling amounts per bone surface were quantified from biweekly registered images [2] and correlated with changes in bone strength.

Results

SED decreased and predicted bone strength increased in all treatment groups (Fig. 1a, $p<0.05$). Remodeling amounts were lowest in the SclAB+ML and PTH+ML group, modeling amounts were highest in these same groups (Fig. 1b). Neither modeling nor remodeling

amounts in BIS differed from BIS+ML. Modeling amounts correlated highly with predicted strength gains (R=0.928, p<0.0001; Fig. 1c). Remodeling amounts correlated moderately inversely with predicted strength gains using a power-law fit (rho=0.476, p<0.0001, Fig. 1c).

Discussion

Mechanical loading, when combined with anabolic treatments such as PTH and SclAB, enhances bone strength primarily through increased modeling rather than remodeling. The strong correlation between modeling amount and predicted strength gains identifies modeling as a key driver of mechanical adaptation, whereas only substantial suppression of remodeling yields any strength benefit. The lack of significant response in BIS-groups indicates that antiresorptives alone are insufficient to support mechanically guided adaptation. These findings suggest that incorporating controlled mechanical loading into osteoporosis therapies could selectively stimulate modeling-based bone formation thus enhancing mechanical competence.

The Effect of Short-Term Continuous Administration of Alendronate on Bone Quality and Strength of Rabbit Tibia

Dr. Tsolmonbaatar Khurelbaatar, Mr. Andrew Sawatsky, Ms. Ariunzaya Dorj, Dr. W. Brent Edwards

University of Calgary, Calgary, Alberta, Canada

Introduction

Alendronate (ALN) is a potent bisphosphonate used to treat osteoporosis and other bone diseases [1]. In preclinical studies, ALN is typically delivered several times per week via subcutaneous injection, but the efficacy of continuous drug delivery remains unknown. This study quantified the effects of four weeks of continuous ALN administration on cortical bone quality and strength in the rabbit tibia.

Methods

Thirteen female rabbits received ALN (85.7 μg/kg/day, ALN, n = 7) or injectable water (VEH, n=6) for four weeks via subcutaneous osmotic pumps (ALZET 2ML4). Fluorochrome bone labels were injected throughout drug treatment, and changes in areal bone mineral density (aBMD) were measured using dual-energy X-ray absorptiometry. The rabbit tibiae were harvested after treatment and rectangular beams (0.9 mm×1 mm×16 mm) were prepared from anterior, posterior, medial, and lateral quadrants of the cortical shaft at the distal, middle, and proximal regions of the left tibiae (Figure 1). The contralateral tibial shafts of the right tibiae were used for dynamic histomorphometry. Micro-computed tomography images (voxel size=5 μm) from the middle 3 mm of each beam were used to quantify cortical porosity (Ct.Po), vascular canal thickness (Ca.Th), and canal number per volume (Ca.N). Beams were then monotonically tested in four-point bending to compute the ultimate bending stress (σ_{bend}) and elastic modulus (E).

Results

A statistically significant increase in aBMD at the leg was observed in the ALN ($p<0.01$), but not the VEH ($p=0.46$) group. This corresponded with a significantly lower number of labeled osteons in the ALN compared to the VEH group ($p=0.03$). Linear mixed-effects models revealed that σ_{bend} and E varied by region and quadrant, but treatment did not affect σ_{bend} or E. There were also no effects of ALN on Ct.Po, Ca.Th, or Ca.N.

Discussion

Short-term, continuous administration of ALN increased aBMD and decreased remodeling activity in the rabbit tibia; however, significant effects of ALN on cortical bone microstructure and strength were not observed. Thus, improvements in aBMD with this model were likely localized to trabecular regions, and more prolonged duration therapy may be required to influence cortical microarchitecture and strength.

Introduction

3D modeling from femoral DXA scans can enhance aBMD-based fracture-risk assessment through subject-specific FE analyses [1]. This study evaluates global descriptors from 3D-DXA-based FE models to distinguish patients with incident hip fractures, comparing the open-source MoFEM with Abaqus to facilitate 3D-DXA-FE simulations in software-as-a-medical-device.

Methods

Hip DXA scans from 64 fracture and 64 control patients were retrospectively processed with 3D-Shaper® (v2.14) to obtain femur geometries [2]. Side-fall was simulated, imposing displacement on the femoral head and constraining the greater trochanter [2]. FE simulations were performed with both Abaqus and MoFEM. Each solver used a perfect elastoplastic formulation with bone density-dependent material properties with Asymmetric Compression–Tension Yield Criterion.

The initial decline of the global force-displacement response indicated the failure point. Extracted descriptors were bone strength (Fu), maximum displacement (Du), and nonlinear energy (Wu). A piecewise linear model further provided elastic quantities (FLE, DLE, WLE), nonlinear deformation (D1), and post-yield residual displacement (DR) and dissipated energy (WD) [2]. Fracture discrimination by FE-derived metrics, aBMD, and 3D-DXA trabecular vBMD was assessed using AUROC from logistic regression with leave-one-out validation.

Results

Bone strength (Fu) achieved an AUROC similar to vBMD (72%) for both solvers (Table 1). When Fu was combined with Du, Wu, or D1, discrimination with Abaqus, reached 79%. MoFEM reproduced elastic-domain results well but underperformed Abaqus with post-yield quantities. Combining FLE and WD provided MoFEM's highest AUROC (75%), compared to 77% with Abaqus.

Discussion

3D-DXA-FE-based descriptors surpassed aBMD and vBMD in fracture discrimination, particularly when post-yield behavior was captured. MoFEM matched Abaqus in the elastic range but diverged for post-yielding. This difference is mainly linked to differences in yield surface: 'Von Mises' in Abaqus, while not being the most elegant model, imposed a sudden tension-compression transition, which seemed to favor discrimination. The 'Paraboloidal' in MoFEM, with a smooth surface, probably led to more subtle differences among models, as elements entered plasticity. **Current developments target plasticity models common to MoFEM and ABAQUS with smooth yield surfaces.**

Images (Optional)

Table 1. AUROC values for fracture discrimination

Descriptors	AUROC		Difference (%)
aBMD	0.69		-
vBMD	0.72		-
	Abaqus	MoFEM

A Shoe-Integrated Soft Actuator System for Augmenting Plantarflexion During Walking

Dr. Sahel Mohammadi Ghalehney, Dr. Ahad Behboodi

University of Nebraska-Omaha, Omaha, NE, United States

Dr. Sahel Mohammadi Ghalehney

Introduction

Weak ankle plantarflexion in children with neuromuscular disorders and adults with mobility impairments reduces push-off power and leads to inefficient gait. Passive ankle–foot orthoses improve stability but cannot actively restore propulsion, and existing robotic orthoses are often bulky, noisy, and visually obtrusive—especially for pediatric users. Stacked dielectric elastomer actuators (SDEAs) offer a lightweight, compliant, and silent alternative capable of rapid longitudinal contraction, enabling compact and muscle-like actuation. The goal of this work is to embed SDEAs within a shoe midsole to provide unobtrusive push-off assistance. We call this device the Flash-Sole. **Objective**: To quantify the capability of SDEAs to power Flash-Sole.

Methods

An instrumented pediatric foot–ankle model was developed to quantify the plantarflexion moment generated by the Flash-Sole. Ankle torque was measured using a FUTEK TDD400 reaction torque sensor mounted coaxially with the joint (Fig. 1a, b). SDEAs were integrated beneath the heel region to serve as the active push-off elements (Fig. 1c). The actuators were pre-compressed to 95% of their original 40 mm length and activated using a Trek HA51U-3B high-voltage amplifier driven by a National Instruments NI-9263 module. Torque data were collected through an NI-9237 bridge module at 1 kHz. To reflect gait biomechanics, the measured ankle torque was scaled to an equivalent metatarsal-joint moment using a 137 mm heel-to-metatarsal lever arm.

Results

The Flash-Sole generated 16.87 Nm of plantarflexion moment, compensating for approximately 60–85% of the typical biological push-off demand for a 25 kg child (≈20–28 Nm).

Discussion
